
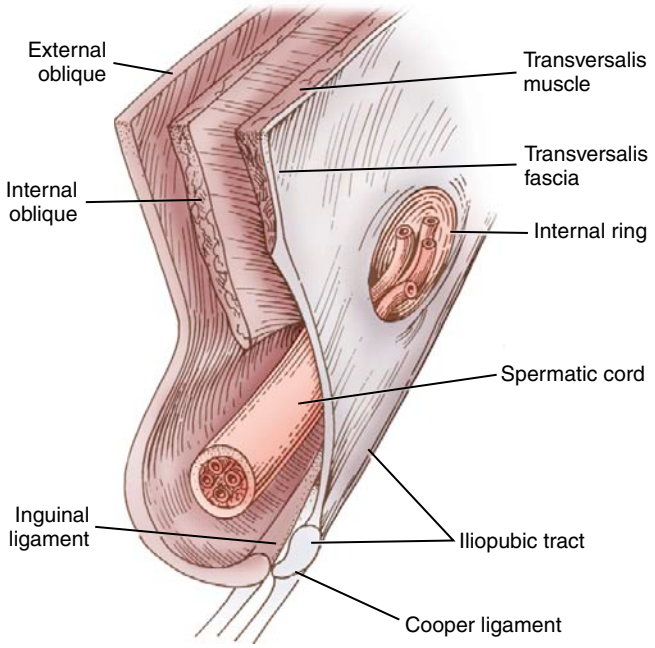

FIGURE 12-3 Right inguinal region, parasagittal section. Roof of inguinal canal is formed by external oblique aponeurosis, and floor is formed by transversalis aponeurosis and fascia.

site of the insertion of the transversalis aponeurosis along the superior ramus from the symphysis pubis laterally to the femoral sheath. The inguinal portion of the transversalis fascia arises from the iliopsoas fascia and not from the inguinal ligament.

Medially and superiorly the transversalis muscle becomes aponeurotic and fuses with the aponeurosis of the internal oblique muscle to form anterior and posterior rectus sheaths. As the symphysis pubis is approached, the contributions from the internal oblique muscle become fewer and fewer. At the pubic tubercle and behind the spermatic cord or round ligament, the internal oblique muscle makes no contribution and the posterior inguinal wall (floor of the inguinal canal) is composed solely of aponeurosis and fascia of the transversalis muscle.

None of the three groin hernias (direct and indirect inguinal hernias and femoral hernia) develops in the presence of a strong transversus abdominis layer and in the absence of persistent stress on the connective tissue layers. When a weakening or a tear in the aponeurosis of the transversus abdominis and the transversalis fascia occurs, the potential for development of a direct inguinal hernia is established.

Femoral Hernias

When the transversus abdominis aponeurosis and its fascia are only narrowly attached to the Cooper ligament, a femoral hernia may develop. This results in an enlarged femoral ring and canal, which allows for the prominence of the iliofemoral vessels, resulting in femoral herniation (Lawrence, 2006).

The walls of the femoral sheath are formed anteriorly and medially from the transversalis fascia, posteriorly from the pectineus and psoas fascia, and laterally from the iliaca fascia. The pelvis ostium consists of a relatively fixed rim of bone and connective tissue: anteriorly and medially the iliopubic tract, posteriorly the superior ramus, and laterally the iliopectineal arch.

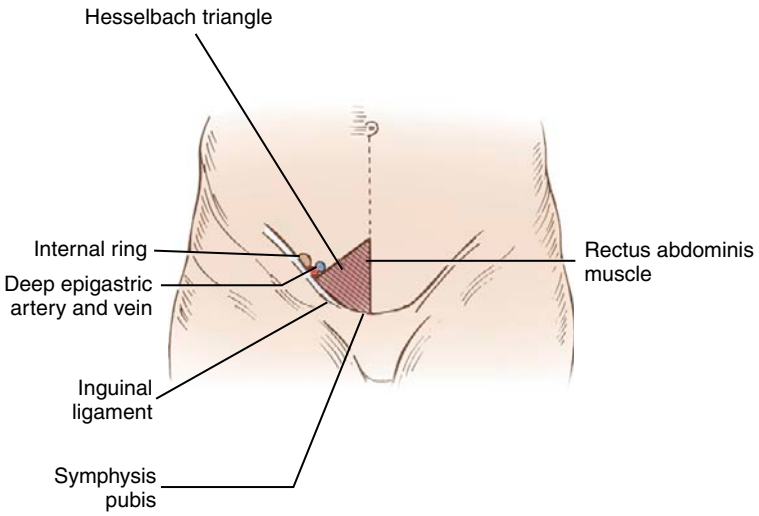

FIGURE 12-4 Schema of the Hesselbach triangle. Boundaries of the Hesselbach triangle are deep epigastric vessels laterally, inguinal ligament inferiorly, and rectus abdominis muscle medially.

The femoral sheath is subdivided into three compartments. The lateral compartment contains the femoral artery, and the intermediate compartment contains the femoral vein. The medial compartment is the smallest and constitutes the femoral canal, which is formed anteriorly and medially by the iliopubic tract. This opening is bound laterally by the iliofemoral vessels and posteriorly by the superior pubic ramus and pectineus fascia. Superiorly, laterally, and inferiorly the fossa is formed by the falciform margin of the fascia lata.

Abdominal Hernias

The anterior abdominal wall is composed of external abdominal oblique muscles attached to a thick sheath of connective tissue called the *rectus sheath*. The linea alba extends superiorly and inferiorly from above the xiphoid process to the pubis. Beneath the rectus sheath lies the rectus abdominis muscles, laterally to the right and left of the linea alba. Lateral to the rectus abdominis is the linea semilunaris. The transversus abdominis muscles originate from the seventh to the twelfth costal cartilages, lumbar fascia, iliac crest, and the inguinal ligament, and insert on the xiphoid process, the linea alba, and the pubic tubercle. The third layer of abdominal wall includes the internal abdominal oblique muscles originating from the iliac crest, inguinal ligament, and lumbar fascia, and inserting on the tenth to twelfth ribs and rectus sheath.

Direct and Indirect Inguinal Hernias

The deep epigastric vessels (inferior epigastric) arise from the external iliac vessels and enter the inguinal canal just proximal to the internal ring. The triangle formed by the deep epigastric vessels laterally, the inguinal ligament inferiorly, and the rectus abdominis muscles medially is referred to as the *Hesselbach triangle* (Figure 12-4). Hernias that occur within the Hesselbach triangle are called *direct inguinal hernias*. Indirect inguinal hernias occur laterally to the deep epigastric vessels. Both direct and indirect hernias represent attenuations or tears in the transversalis fascia (Figure 12-5).

Direct hernias protrude into the inguinal canal but not into the cord and therefore rarely into the scrotum. Direct inguinal hernias usually result from heavy lifting or other strenuous activities. Indirect hernias leave the abdominal cavity at the internal inguinal ring and pass with the cord structures down the inguinal canal. Consequently, the indirect hernia sac may be found in the scrotum. Indirect hernias may be either congenital, representing a persistence of the processus vaginalis, or acquired. In a congenital hernia, the hernia sac has a small neck, is thin-walled, and is closely bound to the cord structures. In an acquired indirect hernia, the neck is wide and the sac is both short and thick-walled. When both direct and indirect hernias are present, the defect is called a *pantaloon hernia* after the French word for "pants," which this situation suggests.

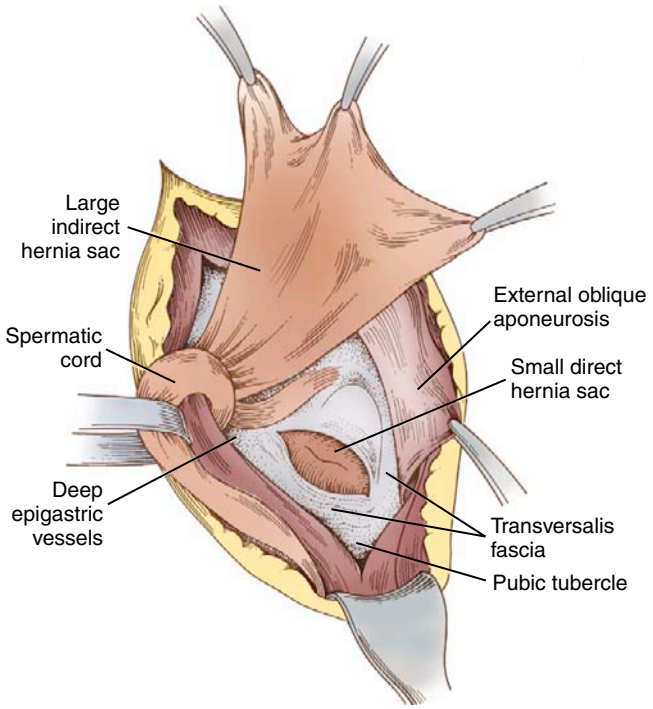

FIGURE 12-5 Defect in transversalis fascia, medial to deep epigastric vessels, results in direct hernia. Defect lateral to deep epigastric vessels results in indirect hernia.

Perioperative Nursing Considerations

Assessment

Assessment of the patient with a hernia begins with a thorough patient history. This should include the history of previous surgeries related to the herniated area. Information relating to a familial history of hernias, the patient's nutritional status, the duration of the symptoms, and a history of obesity, increased intraabdominal pressure, chronic cough, constipation, benign prostatic hypertrophy, intestinal obstruction, colon malignancy, and, for women, pregnancy should be obtained. A list of the patient's current medications should be collected, as well as a history of chronic illness and allergies, including latex allergies (because a Penrose drain may be used during the procedure). The patient's occupation and physical activities should also be determined. If it is part of institutional protocol, verification of preoperative showering should be done during assessment (Evidence for Practice).

Pain is often a notable symptom for the patient; it may be described as a burning sensation. An accurate description of the type and degree of pain is included in the assessment; obtain general information about onset, duration, severity, and quality of pain and about exacerbating and remitting factors (Barclay and Murata, 2008). Patients often describe the feeling of a foreign body, or mass, at the hernia site. This may appear on arising in the morning and disappear while sleeping.

The diagnosis of hernias should be accompanied by clinical physical examination. Palpation of the herniated area reveals the contents of the hernia sac. Fingertip palpation allows the nurse to feel the edges of the external ring or abdominal wall. Having the patient stand and cough or prolonged strain during the examination also assists in the evaluation of the herniated area. If a definitive diagnosis is not confirmed, ultrasonic scanning and imaging techniques (e.g., computerized tomography [CT], herniography, standard radiography) may be employed.

In some patients, a hernia may cause no symptoms; its only sign may be a swelling or protrusion in a restricted area of the abdominal wall. If the hernia is unilateral, the patient notes the lack of a protrusion on the other side in comparison. The area may be visible when the patient stands or coughs and may disappear on reclining. Femoral hernias can be difficult to diagnose and may resemble an enlarged lymph node.

Preoperative testing for hernia repair facilitates safe and efficient perioperative care. Baseline data are obtained by a complete blood count. Patients older than 40 years may need an electrocardiogram (ECG) and chest radiograph. Patients with a history of more complex medical problems must be fully evaluated with appropriate laboratory tests. Preoperative assessment may also involve consultation with a pulmonologist and/or cardiologist to ascertain whether or not surgical intervention is medically safe (this is referred to as "clearance" in patients with potential pulmonary or cardiac problems).

Nursing Diagnosis

Nursing diagnoses related to the care of the patient undergoing hernia surgery might include the following:

- Activity Intolerance related to pain
- Risk for Urinary Retention
- Risk for Ineffective Tissue Perfusion of the scrotal area
- Deficient Knowledge related to disease process (hernia) and convalescence

Outcome Identification

Outcome measurement and management are important parts of perioperative nursing care. Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient will return to his or her previous level of activity.
- The patient will not experience urinary retention.
- The patient will be free of or manage scrotal edema.
- The patient and family or significant others will verbalize knowledge regarding the disease process (hernia) and convalescence.

Planning

The perioperative nurse formulates a plan of care for the patient undergoing herniorrhaphy by assimilating knowledge pertaining to the anatomy involved, principles of asepsis, the

EVIDENCE FOR PRACTICE

Effectiveness of Preoperative Showers in Reducing Risk of Surgical Site Infections

First recommended by the CDC in 1999, preoperative showers have long been considered an important strategy for reducing the risk of surgical site infections. AORN's recommended practice for preoperative patient skin antisepsis states that patients undergoing open class I ("clean") surgical procedures below the level of the chin, such as inguinal hernia repair, have two preoperative showers with chlorhexidine gluconate (CHG) (AORN, 2009). This study from the Medical College of Wisconsin, Milwaukee, was conducted to validate effective skin surface concentrations of CHG using a standardized, timed protocol. It compared skin surface concentrations of CHG measured after showering with a 4% CHG liquid soap, as recommended by AORN, to those measured after cleansing the skin surface with a 2% CHG-impregnated polyester cloth. Researchers found that a timed, standardized preoperative shower was effective in achieving high skin surface levels of CHG that exceeded the concentration required to inhibit the growth of *Staphylococcus aureus,* the most common organism causing surgical site infections, and *Staphylococcus epidermidis*. Compared to use of 4% CHG soap, use of 2% CHG-impregnated polyester cloths resulted in considerably higher skin concentrations with no gaps in antiseptic coverage. CHG provides excellent activity against gram-positive organisms, and good antimicrobial activity with gram-negative bacteria and viruses, providing excellent residual activity. The researchers concluded that preoperative antiseptic showers are valuable in reducing surface skin colonization, which can play an important role in reducing the risk of surgical site infections.

Adapted from Association of periOperative Registered Nurses: Recommended practices for patient skin antisepsis. In *Perioperative standards and recommended practices,* Denver, 2009, The Association; Edmiston CE et al: Preoperative shower revisited: can high topical antiseptic levels be achieved on the skin surface before surgical admission? *J Am Coll Surg* 207:233-239, 2008.

planned surgical procedure, and requisite information provided/gained during planning specific to the surgical patient (Box 12-1). Instrumentation, draping, and positioning for the patient's surgery depend on the type of hernia and repair to be performed—for example, open versus laparoscopic.

A Sample Plan of Care for a patient having surgery for repair of a hernia is shown on p. 403.

Implementation

The patient undergoing hernia repair may receive a general anesthetic, an inguinal nerve block, a field block, a spinal or epidural block, a regional anesthetic with sedation, or a local anesthetic with sedation. Routine monitoring equipment, such as a three-lead or five-lead electrocardiogram (ECG), oxygen-saturation monitor, and blood pressure cuff, is used for a hernia repair. An intravenous (IV) line is inserted for fluid replacement and medication administration. The surgical site is marked as part of the preoperative verification process and rechecked during the time-out. In 2008 the World Health Organization (WHO) issued a surgical safety checklist as part of its "Safe Surgery Saves Lives" initiative (see Chapter 2). As part of the time-out, it recommends that all members of the surgical team identify themselves and their roles and ask simple questions such as, "Does everyone agree that this is Patient X, undergoing a right inguinal hernia repair?" The initiative also recommends an active role for the perioperative nursing team, who should review critical information such as confirming sterility of the instruments and supplies (including indicator results); discussing any equipment issues or concerns; noting whether antibiotic prophylaxis has been given within the last 60 minutes, if applicable; and verifying whether essential imaging is displayed, if applicable (WHO, 2008). Before the time-out, surgical team members may share any concerns about the planned procedure during a preoperative briefing (Research Highlight).

BOX 12-1

Planning Patient-Centered Care

Regardless of the type of planned hernia repair, discussions between the patient and their anesthesia provider, perioperative nurse, and surgeon should cover specific topics to ensure that the patient knows what to expect and what is expected of the patient. Patient-centered care emphasizes involving the patient in selecting the type of anesthesia for surgery and discussion about postoperative pain management before surgery. Educational resources, such as www.youranaesthetic.info or www.asahq.org/patientEducation.htm, can inform patients about their forthcoming anesthesia procedure and provide information about different anesthetics and pain-relief techniques. The information can be downloaded so patients and their caregivers can review it together preoperatively.

TOPICS FOR DISCUSSION

- Preoperative dietary recommendation
  - Targeted nutritional and dietary advice for obese patients in the weeks before surgery—weight loss may improve anesthetic management and postoperative rehabilitation
- Immediate preoperative preparation
  - Continuation, alteration, or cessation of normal medications
  - Need for fasting
- Choice of anesthetic technique
  - General anesthesia (with or without peripheral nerve blocks)
  - Central neuraxial anesthesia (spinal or epidural) with or without sedation
  - Inguinal nerve block/field block/local infiltration with or without sedation
  - Risks and benefits of recommended techniques on an individual patient basis
  - Possibility of converting regional techniques to general anesthesia
- Informed consent
  - Provide adequate information regarding surgical, anesthetic, and postoperative pain management, including benefits and complications
- Potential surgical complications
  - General complications such as deep vein thrombosis (DVT), pulmonary embolism, pneumonia, infection, and seroma
- Information on pain management

Patient attitudes and expectations may be influenced by preexisting pain and therefore must be assessed. In addition, if early postoperative pain is intense, rehabilitation and ambulation may be delayed unless pain is appropriately treated. Different techniques may be used to manage different levels of pain immediately following surgery, within the first postoperative day, and thereafter. Thus pain management often involves a "step-down" approach.

- For successful pain management outcomes:
  - Patients need to have a reasonable expectation of their likely postoperative stay
  - Information must be given on postoperative pain assessment, such as the use of visual analogue scale (VAS)
  - Patients require a realistic expectation of the intensity and duration of postoperative pain
  - Pain management techniques that require patient involvement (intravenous patient-controlled analgesia, patient-controlled epidural analgesia, pain pumps) need to be properly demonstrated
  - Patients will require information about all medications to be taken after discharge (medication reconciliation) as well as medications/strategies for management of pain and postoperative nausea
- After surgery patients should know what to expect with regard to:
  - Location and size of the surgical incision, dressings, and any drains
  - Intravenous fluids (as appropriate)
  - Possibility of a urinary catheter
  - Associated postoperative symptoms, such as postoperative nausea and vomiting (PONV; see Chapter 9)
  - When to return to normal oral fluids and nutrition
- Information on their recovery (see Patient and Family Education box on p. 404 for detailed information)
  - Approximate timetable for return to normal physical activities—both personal and professional
  - Advice for other postoperative care
  - Contact numbers for use after discharge and information on follow-up calls or appointments with the surgeon

Adapted from Hobbs JL: A dimensional analysis of patient-centered care, *Nurs Res* 58(1):52-60, 2009; PROSPECT (Procedure Specific Postoperative Pain Management), available at www.postoppain.org/extraPage.aspx?epid=33. Accessed April 2, 2009.

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Activity Intolerance related to pain

OUTCOME
The patient will return to his or her previous level of activity.

INTERVENTIONS
- Determine the patient's baseline activity level.
- Encourage early postoperative ambulation.
- Instruct the patient to use prescribed pain medications before physical activity and as needed.
- Advise the patient to gradually increase activity as tolerated.
- Explain anticipated postoperative activity recommendations and limitations (see Patient and Family Education).

NURSING DIAGNOSIS
Risk for Urinary Retention

OUTCOME
The patient will not experience urinary retention.

INTERVENTIONS
- Encourage patient to void before surgery.
- Monitor and record intake and output status.
- Assess bladder postoperatively for signs of urinary retention (palpable bladder or patient discomfort).
- Encourage and assist patient with early ambulation.
- Maintain adequate oral fluid intake without nausea or vomiting before discontinuing IV fluids.
- Catheterize the patient if urinary retention occurs.

NURSING DIAGNOSIS
Risk for Ineffective Tissue Perfusion of the scrotal area causing scrotal edema

OUTCOME
The patient will be free of or manage scrotal edema.

INTERVENTIONS
- Discuss the possibility of swelling and ecchymosis during preoperative assessment.
- Apply scrotal support intraoperatively.
- Assess scrotum for evidence of swelling, ecchymosis, and redness.
- Apply ice packs as prescribed.
- Elevate the scrotum on a soft pillow to prevent or control swelling.
- Reassure the patient, and instruct him on the importance of wearing the scrotal support.
- Reassure the patient that the swelling and ecchymosis will subside.

NURSING DIAGNOSIS
Deficient Knowledge related to disease process (hernia) and convalescence

OUTCOME
The patient and family or significant others will verbalize an understanding of the disease process (hernia) and convalescence.

INTERVENTIONS
- Review possible contributing factors (as individualized for type of hernia and specific patient) to hernia formation.
- Discuss postoperative pain management strategies during recovery at home.
- Describe and verify patient understanding of surgical site or incision care and reportable signs and symptoms (e.g., temperature, wound redness, tenderness at incision site, swelling, drainage). Use language such as, "Can you tell me, in your own words, how you will take care of this at home and when you should call your doctor?"
- Determine patient's dietary habits; discuss importance of fiber (fruits, vegetables, grains) to prevent constipation.
- Provide written discharge instructions. Review these with patient and family or significant others to validate understanding.
- Provide opportunity for "teach back" (Patient Safety) by the patient or family. Have them repeat discharge instructions in their own words.
- Allow time for questions; provide (or reinforce) answers and clarification.
- Verify that patient has or knows how to schedule follow-up appointment.

PATIENT SAFETY

Surgical Consent and "Teaching Back"

There is considerable evidence that many patients leave medical encounters with a poor understanding of their disease and the recommended treatment. Informed consent is a central element of safe surgical patient care. The National Quality Forum (NQF) has identified Safe Practice 5 for informed consent, recommending that each patient or legal surrogate "teach back," in his or her own words, key information about the proposed treatments or procedures for which he or she is being asked to provide informed consent. Recommended elements of this safe practice for informed consent include:

- Ask each patient or his or her legal surrogate to recount what he or she has been told during the informed consent discussion.
- Use informed consent forms written in simple sentences and in the primary language of the patient or legal surrogate.
- Engage the patient in a discussion about the nature and scope of the procedure covered by the consent form. For example, when describing hernia surgery the nurse might state the following:
  "Before surgery, you will be given a sedative to make you drowsy. A local or spinal numbing medicine (anesthesia) will be used so you do not feel pain during the procedure. In some cases, the procedure is done while you are under general anesthesia (unconscious and pain-free). The surgeon makes a cut over the area of the hernia. The bulging tissue or organ is placed back inside the muscle wall, the muscle tissue is repaired, and the skin is closed. In many inguinal hernia repairs, a small piece of plastic mesh is used to repair the defect in the muscle tissue."
- Provide an interpreter or reader to assist non–English-speaking patients or legal surrogates, vision-impaired or hearing-impaired patients, and low-literacy patients.
- Verify that the patient and/or family member/legal surrogate can state the name of the procedure and, using their own words, describe it.

Modified from Clarke ME, Degannes CN: *Cultural competency in healthcare: a clinical review and video vignettes from the National Medical Association,* available at Cme.Medscape.Com/Viewprogram/12540. Accessed August 1, 2009; Kemp EC et al: Patients prefer the method of "tell back-collaborative inquiry" to assess understanding of medical information, *J Am Board Fam Med* 21(1):24-30, 2008; National Quality Forum: *National Quality Forum Safe Practices 2009,* Washington, DC, 2009, Author, available at http://Psnet.Ahrq.Gov/Resource.Aspx?Resourceid=9757&Sourceid=1&Emailid=12706. Accessed August 1, 2009.

The patient is usually positioned supine (see Chapter 5) with basic prepping and draping procedures followed (see Chapter 3). As with any surgical procedure, the prep solution must dry before the start of the surgical procedure as part of fire safety measures. To maintain the patient's dignity and modesty, expose only the part of the patient's body necessary for antimicrobial skin preparation (Beyea, 2007). Instruments used for herniorrhaphies are those found in standard laparotomy sets, laparoscopy sets, or minor sets. Additional supplies and anticipatory preparation for other patient care needs depend both on the perioperative nurse's knowledge of the planned procedure as well as communication and teamwork. Research suggests that interventions designed to improve OR teamwork and communication may have beneficial effects both on technical performance and on patient outcome, due in part to the leadership and management skills of perioperative nurses (Catchpole et al, 2008) (Risk Reduction Strategies).

A self-retaining retractor, such as a Weitlaner, facilitates the separation of tissue layers. A moistened Penrose drain is often used to retract the spermatic cord structures for better exposure. Because the peritoneal cavity may be entered in this procedure, sponge, sharp, and instrument counts are recommended.

With a sliding hernia or an incarcerated hernia, the possibility of having to enter the peritoneal cavity must be considered. If the hernia is strangulated, necrotic bowel must be resected and instruments for performing a bowel anastomosis must be

RESEARCH HIGHLIGHT

Effect of Preoperative Briefings on OR Delays

In one study (Nundy et al, 2008), researchers at The Johns Hopkins University School of Medicine, Baltimore, sought an answer to the following question: "Do preoperative briefings reduce unexpected OR delays through improved teamwork and communication?" They implemented a preoperative briefing program in which the attending surgeon led OR personnel in a 2-minute discussion using a standardized format designed to familiarize team members with each other and with the operative plan. The researchers evaluated unexpected delays before and after the initiation of the OR briefings using an assessment tool that was distributed to OR personnel at the end of each surgical procedure. The tool was completed by 422 respondents. The use of preoperative OR briefings was associated with a 31% reduction in unexpected delays. A total of 36% of OR personnel reported delays before implementation of the briefings, and 25% reported delays after implementation. Among surgeons alone, an 82% reduction in unexpected delays was observed. Significantly, a 19% reduction in communication breakdowns leading to delays was associated with the briefings.

In another study (Lingard et al, 2008), Canadian researchers assessed whether structured team briefings that incorporated a preoperative checklist would improve communication in the OR. Over a 13-month period, surgeons, nurses, and anesthesia providers at a Canadian academic medical center completed a short team briefing guided by a checklist before 302 general surgery procedures. They found the mean number of communication failures per procedure declined from 3.95 to 1.31. A total of 34% of the briefings demonstrated utility, meaning they identified a problem, filled a critical knowledge gap, provoked a change in plan, or promoted follow-up actions.

Research shows that poor communication is the single most frequent cause of adverse events in healthcare. As in other research, these studies concluded that preoperative briefings reduce unexpected delays and decrease the frequency of communication breakdowns. Preoperative briefings have the potential to increase OR efficiency, improve quality of care, and reduce costs.

Adapted from Lingard L et al: Evaluation of a preoperative checklist and team briefing among surgeons, nurses, and anesthesiologists to reduce failures in communication, *Arch Surg* 143:12-17, 2008; Nundy S et al: Impact of preoperative briefings on operating room delays, *Arch Surg* 143:1068-1072, 2008.

RISK REDUCTION STRATEGIES

Teamwork and Communication on Surgical Teams

Despite almost universal endorsement and knowledge of The Joint Commission's *Universal Protocol for Preventing Wrong-Site, Wrong-Procedure, Wrong-Person Surgery,* avoidable surgical errors continue to occur in U.S. healthcare facilities. Research has focused on communications' failures as the underlying cause of many errors. The Medical Team Training Questionnaire was developed as part of a national program in the Department of Veterans Affairs (VA) to improve communication. It assesses organizational culture, communication, teamwork, and awareness of human factors engineering principles. The questionnaire was pilot-tested with 300 healthcare clinicians. The final version of the questionnaire was then administered to an interdisciplinary group of 384 surgical staff in 6 facilities. Analysis of questionnaire results determined that nurses and anesthesia providers tend to perceive their environment similarly, and both differ significantly from surgeons' perceptions. Surgeons perceive their environment more positively, believing there is a stronger organizational culture for patient safety—that all team members are comfortable intervening in a procedure if they have concerns about what is occurring. Surgeons also perceive better communication—that during surgical and diagnostic procedures, everyone on the team is aware of what is happening. Consistent with their positive beliefs, surgeons similarly perceive that there is good teamwork—that morale on their team is high and everyone on the team is comfortable giving feedback to other team members. Nurses and anesthesia providers did not agree with the positive perceptions of the surgeons.

According to the researchers, such disparities between team members pose a problem. If team members have disparate perceptions about how well they communicate or collaborate with each other, they do not collaborate optimally during care of their patients. Thus use of this or a similar questionnaire may prove helpful in identifying hidden problems with communication and may be useful in focusing efforts, such as team training, for improvement.

Adapted from Mills P et al: Teamwork and communication in surgical teams: implications for patient safety, *J Am Coll Surg* 206:107-112, 2008.

PATIENT AND FAMILY EDUCATION

Home Care for the Hernia Patient

HOME CARE

- Give the patient and the caregiver *verbal* and *written* instructions. Provide them with the name and telephone number of a physician or nurse to call if questions arise.
- General information
  - Review any explanation about the procedure and specific follow-up care. Verify that the patient can state the name of the procedure performed.
  - Explain and discuss the development of hernias, causes or contributing factors, care and treatment, and prevention.
- Wound/incision care
  - Discuss and demonstrate proper wound management and dressing changes: procedures, frequency, and signs to report.
- Warning signs
  - Stress the importance of seeking emergency care if bleeding from the incision or wound dehiscence with exposure of deep wound tissue occurs.
  - Review the signs and symptoms that should be reported to a physician or nurse.
    - Infection: fever, pain, edema, erythema, warmth, purulent drainage, foul odor from the incision
    - Abdominal distention, nausea, vomiting
    - Separation of wound edges
    - Hernia recurrence: firm, tender, globular, irreducible swelling in the groin or midabdomen
- Special instructions
  - Apply and demonstrate to the male patient scrotal support or ice packs to decrease scrotal edema and discomfort.
  - Assist the patient in obtaining appropriate supplies, such as sterile dressings.
  - Advise the patient with diabetes that optimal glucose level control promotes wound healing.
- Medications
  - Explain the purpose, dosage, schedule, and route of administration of any prescribed drugs, as well as side effects to report to a physician or nurse.
    - Analgesics
    - Stool softeners
    - Laxatives
- Activity
  - Encourage the patient to discuss allowances and limitations with respect to occupation, recreation, or activities.
  - Instruct the patient to avoid coughing, straining, stretching, constipation, heavy lifting (>10 lb), strenuous exercise, and sports for 6 weeks.
  - Demonstrate splinting the incision manually or with a pillow during coughing, sneezing, or hiccups.
  - Stress the importance of activity restrictions and splinting the incision for up to 6 weeks after surgery.
  - Demonstrate proper body mechanics for moving and lifting.
  - Advise returning to work in 2 weeks for desk work and 6 weeks for heavy labor.
  - Advise that sexual activity should be avoided for several weeks to avoid strain on the incision and discomfort to the scrotum, if edematous.
- Diet
  - Advise the patient to plan a high-fiber diet to help prevent constipation; provide the patient with a list of high-fiber foods.
  - Advise the patient to drink plenty of fluids, up to 2 to 3 liters per day, unless contraindicated.
  - Stress the importance of weight loss if the patient is obese.

ALTERNATIVE THERAPY

- Advise the patient to avoid yoga exercises for 6 weeks postoperatively.
- Advise the patient and family to refrain from applying lotions and creams to the incision until wound edges are completely closed and healed.
- Discuss strategies for pain management, including music therapy and guided imagery, to minimize use of narcotics, which can cause constipation.

ELDER CARE

- The older adult may be at greater risk for delayed wound healing because of preexisting cardiac disease or nutritional deficits.
- Vitamin supplements may promote wound healing, if not contraindicated.

PSYCHOSOCIAL CARE

- Encourage the verbalization of fears and concerns about altered sexual function secondary to impaired blood supply to the vas deferens.
- Encourage active participation in plan of care.

FOLLOW-UP CARE

- Stress the importance of regular follow-up visits. Make sure the patient has the necessary names and telephone numbers.
- Stress the importance of smoking cessation to eliminate the smoker's cough as a contributing factor to hernia development.

REFERRAL

- Provide information and refer the patient to community resources for weight loss and smoking cessation, if indicated.

From Canobbio MM: *Mosby's handbook of patient teaching,* ed 3, St Louis, 2006, Mosby.

available. For this procedure, antibiotics may be added to the irrigation to prevent an infection. Safe medication practices must be followed. All medications and solutions on and off the sterile field must be labeled. When the antibiotic solution is passed to the surgeon, the surgical technologist or other scrub person should announce the name and strength of the antibiotic solution to be used for irrigation.

Repair of an inguinal hernia includes approximation of the transversalis fascia with a heavy nonabsorbable type of suture; mesh may also be used. With some indirect hernias, only two or three sutures may be necessary. In other cases, however, up to 10 sutures in succession may be needed. Scarpa's fascia is approximated with absorbable sutures, and the skin is closed by one of several methods. Several types of prosthetic mesh are available and often used to support hernia repair.

A laparoscopic hernia repair is technically similar to an open laparotomy, but the instrumentation includes laparoscopic equipment. There is always a possibility that a laparoscopy may become a laparotomy, and instrumentation for this change in procedure must always be available.

Evaluation

Evaluation of the patient having repair of a hernia should include examination of all skin surfaces to assess variances with preoperative assessment data. The patient should awaken from general anesthesia, if it is used, in a reasonable amount of time without exhibiting signs of anxiety or extreme disorientation. Extubation should be timely to avoid stress on the repaired hernia site. The evaluation of the patient's status can be phrased in outcome statements such as the following:

- The patient will return to his or her previous level of activity.
- The patient will not experience urinary retention.
- The patient will remain free of or manage scrotal edema.
- The patient and family or significant others will verbalize understanding of hernia and recommendations for convalescence and will be able to describe possible complications (infection, seroma formation, hematoma, or postoperative neuralgia) that are to be reported to the physician.

When the patient's care is transferred to the postanesthesia care unit (PACU) nurse, the perioperative nurse gives a hand-off report pertaining to relevant events and patient status during the operative procedure.

Urinary retention may occur after a herniorrhaphy, and measures must be taken to prevent overdistention of the bladder. Early ambulation is encouraged to facilitate resumption of bladder and bowel functions, as well as lung expansion for patients who were intubated for induction of general anesthesia. If the bowel has been resected because of strangulation, a nasogastric (NG) tube and suction may be required to reduce the incidence of postoperative vomiting and distention with subsequent strain on the suture line.

Patient and Family Education and Discharge Planning

Greater involvement of patients in their care increases the likelihood of achieving the best outcomes and simultaneously supports a quality-improved, cost-conscious environment. For the hernia patient to assume such responsibilities, plans for patient and family education along with plans for discharge and home recovery need to be designed. Issues such as open or laparoscopic repair techniques, surgical and recovery times, analgesic requirements, complication rates, and times for return to full activity become part of informed consent (see Patient Safety). Once the patient and surgeon have decided on the surgical approach, perioperative nursing responsibilities for teaching the patient initial postoperative management strategies become crucial. Preferably, discharge planning is begun before admission. This becomes increasingly important because hernia repair is commonly performed as an ambulatory procedure. Anticipated postoperative care, including incision care, incisional splinting as appropriate to the repair approach, and the importance of early ambulation and deep breathing, is reviewed. Pain management is important as a part of discharge planning; frequently, surgical patients report inadequate pain management during their postoperative recovery and convalescence. The Patient and Family Education box presents specific home care requirements. The Ambulatory Surgery Considerations box presents information on safe use of postoperative pain pumps.

AMBULATORY SURGERY CONSIDERATIONS

Safe Use of Post-Op Pain Pumps for Surgical Analgesia

Elastomeric pumps, such as the ON-Q PainBuster, deliver local anesthetic intended to reduce pain after surgery to the tissue around the surgical site. The popular ON-Q PainBuster Post-Op Pain Relief System provides continuous infusion of a local anesthetic directly into the patient's surgical site for effective, non-narcotic postoperative pain relief for up to 5 days. Four pump models are available with this pain-relief system: one with a fixed flow rate that cannot be changed; one that delivers a basal infusion and also allows delivery of on-demand boluses; one that allows the user to adjust the flow rate within a predetermined range; and one with an adjustable rate controller and bolus device. Various sizes and types of catheters are available to deliver the medication. Pumps such as ON-Q pumps are used in many general surgical procedures. The following safe practice recommendations should be implemented to improve safety when using elastomeric pumps such as ON-Q pumps.

BEFORE USING THE PUMPS

- Establish protocols for use of ON-Q pumps, including indications; models and tubing to be used for each indication; steps for prescribing, preparing, and dispensing the pump of all associated medications; required testing of knowledge and skills; hand-off communication between providers; patient/family education; and patient monitoring.
- Have a committee, such as the Pharmacy and Therapeutics Committee, approve the drugs that can be administered through the ON-Q pump, taking into consideration the accuracy of the infusion rate (±15% to 20% of desired rate) and conditions that could influence the rate (e.g., heat and cold).
- Ensure clinical staff education before use. Include the signs of bupivacaine, ropivacaine, and lidocaine cardiotoxicity and risks associated with pump use (Rapid Response Team box).

Continued

AMBULATORY SURGERY CONSIDERATIONS

Safe Use of Post-Op Pain Pumps for Surgical Analgesia—cont'd

PRESCRIBING THE PUMPS

- Establish standard order sets for prescribing the pumps and specific medications. Specify any concomitant analgesics that are acceptable or should be avoided. Require activation of the appropriate order set before the patient is transferred from the OR.

PLACING THE CATHETERS AND SETTING UP THE PUMPS

- Ensure proper insertion of the catheter(s) in the tissue and/or adjacent nerves surrounding a wound. Do not insert the catheter directly into a joint.
- Label the pump with the name of the drug, its concentration, infusion rate (in milliliters per hour and dose per hour), and start date.
- Ensure that the adjustable rate controller (available on some models) is clicked into place under the specified rate of infusion.
- Apply an occlusive dressing over the catheter insertion site.
- Tape the flow restrictor to the patient's skin. Do not tape over the filter.

DISPENSING PUMPS AND MEDICATION

- Establish standard concentrations for the local anesthetics (and other drugs, if appropriate) used in the pumps. Also establish pharmacy compounding procedures for preparing any mixtures of drugs.
- Establish order sets in the pharmacy computer that will facilitate automated screening of the drug(s) being used for appropriate dose, drug interactions, allergies, and duplicate therapy.
- Require pharmacy preparation of the medication reservoir balls following a protocol that specifies the exact amount of solution to instill based on the duration of therapy and expected rate of infusion.

PERIOPERATIVE NURSING CONSIDERATIONS FOR PATIENTS WITH PUMPS

- Ensure that all medications administered via the pump are listed on the intraoperative nursing record.
- Ensure the occlusive dressing over the catheter site is intact.
- Check that the flow restrictor is taped to patient's skin for accurate flow rates.
- Include information about the pump in the hand-off report to PACU or other discharge unit.

EDUCATING PATIENTS ABOUT PUMPS

- Educate patients and caregivers about how the pump works and items to periodically check (e.g., flow restrictor is taped to the skin, medication ball appears to be getting smaller each day, pain is under control).
- Educate patients about the signs of cardiotoxicity, when to call the physician, and how to clamp the tubing to prevent further drug administration, if necessary (Surgical Pharmacology).
- Send the Patient Guidelines provided by the manufacturer home with patients.

Accessed August 1, 2009.

RAPID RESPONSE TEAM

Tim Johnson had an inguinal hernia repair performed in an ambulatory surgery center. At the conclusion of the surgical procedure, an ON-Q pump was inserted and the reservoir filled with a local anesthetic. He had an uncomplicated stay in PACU and was sent to the phase II recovery area for discharge preparation. Ten minutes after his arrival there, he began to complain of blurred vision, difficulty breathing, dizziness, and light-headedness. His wife activated the rapid response team (RRT), who arrived to find Tim in cardiac arrest. The RRT noticed that the medication reservoir ball of the ON-Q pump was empty. The device label indicated it had been started an hour earlier with 30 ml of bupivacaine. The surgeon arrived after the RRT activation and confirmed that the reservoir should not be empty. CPR was instituted and a lipid rescue administered. Mr. Johnson was transferred to the inpatient ICU and eventually recovered. A local anesthetic drug level was drawn and found to be markedly elevated. Fortunately, rescue efforts were successful and the patient was later discharged without any complications.

RRTs are a part of a rapid response system to intervene at the earliest possible moment in a patient's deteriorating clinical condition. In some institutions, family members as well as staff may activate the RRT call when they notice something is "not right" with the patient; numbers are listed on the walls of patient rooms so that family members may also initiate the system. The RRT is often composed of a multidisciplinary team of intensive care–trained staff who intervene in situations like Mr. Johnson's and prevent patient harm from an adverse event. Fortunately for Mr. Johnson, the ambulatory surgery center was part of an acute care hospital. In part because the OR staff followed safe medication practices, the RRT was able to determine what had been in the pump reservoir and take immediate action.

Surgical Interventions

SURGERY FOR REPAIR OF GROIN HERNIAS

Repair of Inguinal Hernias

Several operative procedures for repair of inguinal hernias are currently used. Approaches that reestablish the integrity of the transversalis fascia and simultaneously reestablish and strengthen the posterior inguinal floor are favored. A surgical repair in which transversalis fascia is sewn to the Poupart ligament accomplishes this goal.

Procedural Considerations. The patient is in the supine position for abdominal wall and inguinal or femoral hernia repairs. Arms are placed on padded armboards with the palms up and fingers extended. Armboards are maintained at less than a 90-degree angle to prevent brachial plexus stretch. If there are

SURGICAL PHARMACOLOGY

Bupivacaine, Ropivacaine, and Lidocaine Cardiotoxicity

Lidocaine (Xylocaine), bupivacaine (Marcaine), and ropivacaine (Naropin) all have similar actions. They produce analgesic effects via nerve conduction blockage. They are contraindicated in patients with hypersensitivity to amide local anesthetics (see Chapter 4). Compared to other local anesthetics, bupivacaine is markedly cardiotoxic. However, adverse drug reactions (ADRs) are rare when it is administered correctly. Most ADRs relate to systemic exposure, such as with pain pump failure.

Systemic exposure to excessive quantities of bupivacaine mainly result in central nervous system (CNS) and cardiovascular effects. CNS effects may include CNS excitation (nervousness, tingling around the mouth, tinnitus, tremor, dizziness, blurred vision, or seizures) followed by depression (drowsiness, loss of consciousness, respiratory depression, and apnea). Bupivacaine and ropivacaine are look-alike/sound-alike drugs.

Ropivacaine is found to have less cardiotoxicity than bupivacaine in animal models. Compared to bupivacaine, ropivacaine has similar CNS and cardiovascular effects.

Perioperative nurses providing discharge instructions to patients with pain pumps filled with one of these local anesthetics should be sure the medication is part of discharge medication reconciliation. An information sheet should be printed for the patient and their caregiver, and they should have one to take to their primary care physician. Be specific and direct in providing information about cardiotoxicity. Use descriptions of signs and symptoms that the patient can understand. For instance, you might tell the patient:

"The following symptoms may represent a serious medical condition. Immediately close the clamp on the pump tubing and call your doctor or 911 if you have any of the following:

- Difficulty breathing
- Dizziness, light-headedness
- Blurred vision
- Ringing, buzzing in your ears
- Metal taste in your mouth
- Numbness and/or tingling around your mouth, fingers, or toes
- Drowsiness
- Confusion"

surgical reasons to tuck the arms at the side, as may occur in laparoscopic hernia repair, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail.

The patient's skin surface area from above the umbilicus to midthigh is exposed, prepped with antimicrobial solution, and draped with sterile drapes. A sterile drape should be placed under the scrotum if it becomes necessary to enter the scrotum. Safe practices when using devices that generate surgical smoke, such as the electrosurgical unit (ESU), require the use of a smoke evacuation system and accessories in both open and laparoscopic procedures (AORN, 2009a) (see Chapter 7).

Operative Procedures

McVAY, OR COOPER, LIGAMENT REPAIR. A McVay, or Cooper, ligament repair approximates transversalis fascia superior to the inferior insertion of the transversalis fascia along the Cooper ligament. It is accompanied by a relaxing incision to reduce tension on the suture line.

1. A transverse suprainguinal skinfold incision is made; some surgeons prefer an oblique incision, made parallel to the inguinal ligament, ending two fingerbreadths lateral to the pubic tubercle (Figure 12-6).
2. The incision is carried through the superficial and deep (Scarpa) fascia to the external oblique aponeurosis. Hemostasis is maintained with fine ties or electrocoagulation.
3. The external oblique aponeurosis is opened by way of a small incision over the inguinal canal, lateral to the inguinal ring and in the direction of its fibers, to the external ring. The aponeurotic flaps are reflected back along the iliohypogastric and ilioinguinal nerves, which are identified and preserved from injury (see Figure 12-6). The ilioinguinal nerve is a sensory nerve that innervates the medial thigh and the scrotum.
4. The cremaster muscles that form an envelope around the spermatic cord and represent the continuation of the internal oblique muscles are opened, and the cord is exposed. The medial fibrous portion of the internal oblique is called the *conjoined tendon.*
5. The cord and surrounding structures are dissected and freed circumferentially from the canal, and a moistened Penrose drain is often used to gently retract the vessels and vas deferens. The cord is then examined for an indirect hernia, the sac of which is located adjacent to the cord; the sac originates from the internal ring lateral to the inferior epigastric vessels and is initially adherent to the cord.
6. If an indirect sac is identified, it is carefully dissected away from the cord until the neck of the hernia is clearly delineated (Figure 12-7).
7. The sac is opened, and any abdominal contents are returned to the peritoneal cavity.
8. A suture ligature or purse-string suture is placed high in the neck of the sac, and the excess peritoneum of the hernia is excised. The ligated stump quickly retracts into the peritoneal cavity. (If the sac is long, the distal segment may be splayed open and left in place.) The inguinal floor is then inspected for evidence of a direct hernia. If only a direct sac is present, usually no resection of the hernia is done because the sac easily returns to the abdominal cavity.

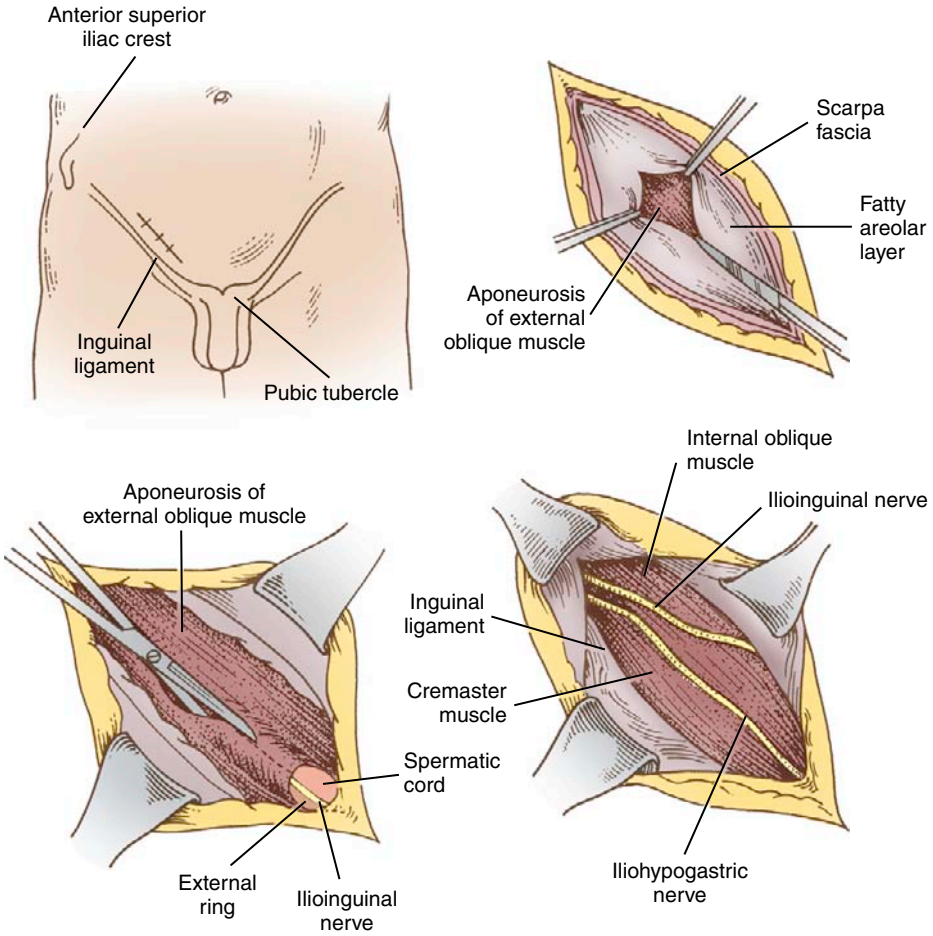

FIGURE 12-6 Skin incision with division of superficial muscle and fascial layers.

9. If transversalis fascia is present on both sides of the hernia defect, it is sutured together or a piece of mesh is interposed (Figure 12-8). Suturing begins at the pubic tubercle and continues laterally to the internal ring. If the inferior transversalis fascia is weak or not present, the superior portion is sutured to the Cooper ligament, the site of insertion of the transversalis fascia. In this case, suturing again begins at the pubic tubercle and is continued laterally along the Cooper ligament to the medial border of the femoral sheath, where a transition stitch is placed. The repair is then carried laterally, approximating transversalis fascia to inguinal ligament (Figure 12-9).
10. When the transversalis fascia is pulled down to the Cooper ligament, a relaxing incision in the rectus sheath is sometimes necessary to relieve excess tension. Essentially this incision is 5 to 7 cm long in the anterior rectus sheath. The incision begins immediately above the pubic crest, approximately 1 cm from the midline, and extends cephalad, following the line of fusion of the external oblique aponeurosis with the rectus sheath. The posterior rectus sheath and the rectus muscle itself guard against later herniation at the point where the relaxing incision is made. If too much tension makes direct approximation undesirable, a synthetic surgical mesh may be sutured in place as the new inguinal floor ("tension-free" mesh repair). The caudad edge of the mesh is sutured to the shelving edge of the inguinal ligament, the cephalad edge sutured to the conjoined tendon, and the lateral edge of the mesh split to accommodate the spermatic cord.
11. After the integrity of the posterior inguinal floor has been reestablished, the cremaster muscles are reapproximated around the cord. Repair is completed with the approximation of the external oblique aponeurosis, the Scarpa fascia, and the skin.

BASSINI REPAIR. The Bassini repair was introduced in 1887 and was formerly the standard of repair. In this procedure the conjoined tendon and the shelving edge of the inguinal ligament are sutured together up to the internal ring (Bascom, 2004). The major difference with this repair is that the superior transversalis fascia is sutured to the inguinal ligament with no attempt made to approximate it to the inferior portion of the transversalis fascia or the Cooper ligament (pectineal ligament). Critics of this procedure claim that it is not anatomic because layers that originally are not integrated (transversalis fascia and inguinal ligament) now are approximated. Nonetheless, this repair has been used successfully by many surgeons.

SHOULDICE REPAIR. More than 250,000 hernias have been repaired at the Shouldice Hospital in Ontario, Canada, with a recurrence rate of less than 1%. In the Shouldice repair a double layer of transversalis fascia is sutured to the inguinal ligament. It is reinforced by a layer of internal oblique muscle

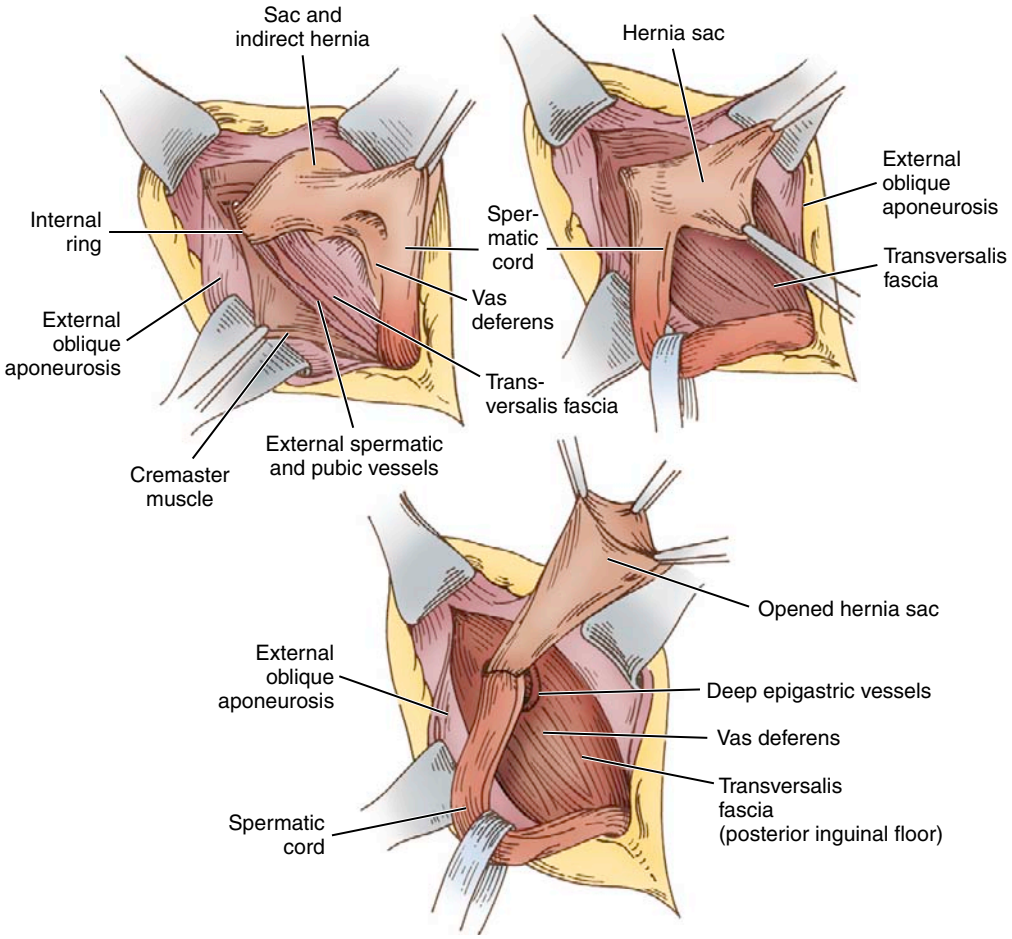

FIGURE 12-7 Indirect hernia sac is identified along with cord structures and dissected away from cord. Neck of hernia sac is clearly delineated, and sac is opened to check for abdominal contents.

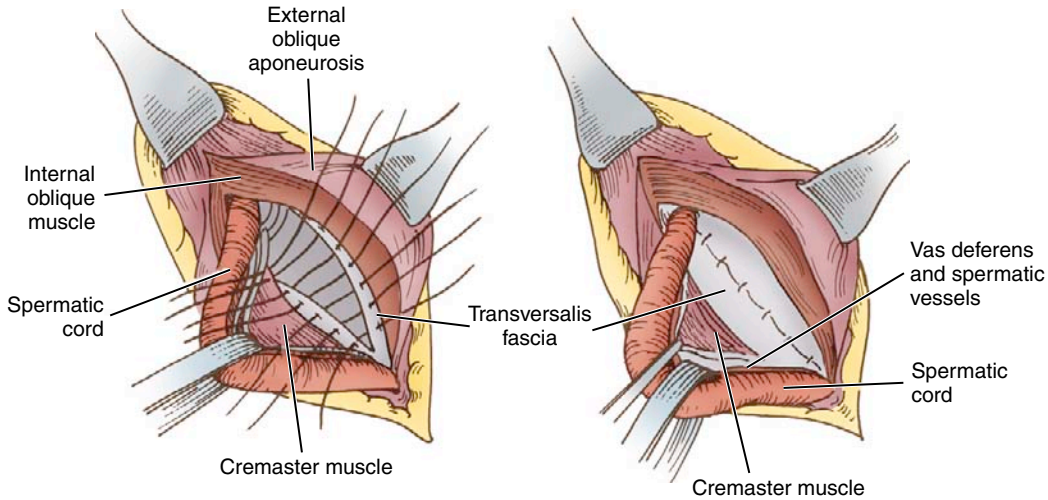

FIGURE 12-8 Transversalis fascia on either side of large hernia defect is approximated.

and conjoined tendon approximated to the undersurface of the fascia of the external oblique.

MESH-PLUG REPAIR. The mesh-plug technique has been recommended for the treatment of primary and recurrent direct and indirect inguinal hernias. The various hernia types as classified by Gilbert have a corresponding relationship to the use of mesh plugs (Gilbert et al, 2009). Types I, II, and III are indirect hernias. Type I is characterized by a tight internal ring through which any size peritoneal sac can pass. The sac, when surgically reduced, is held within the abdominal cavity by the

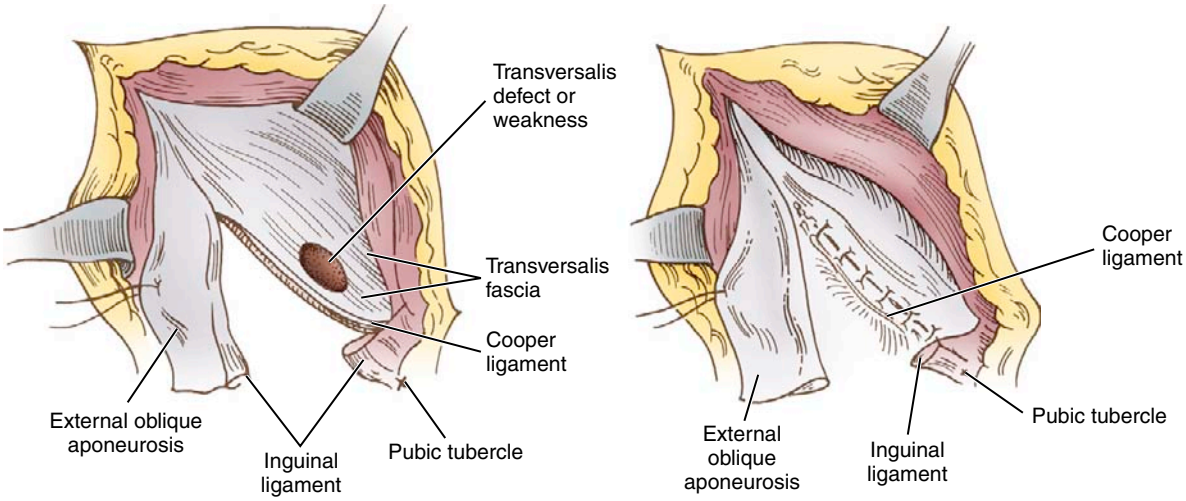

FIGURE 12-9 Defect in transversalis fascia repaired by approximation of fascia to the Cooper ligament.

intact internal ring. Type II hernias have a moderately enlarged internal ring, 4 cm or smaller. Type III hernias have a patulous internal ring larger than 4 cm. In this type, the sac can have a sliding component that impinges on the direct space. Type IV and type V hernias are direct hernias. In type IV hernias, the defect involves virtually the entire floor of the inguinal canal. Type V is a diverticular defect of the floor and is generally in a suprapubic position, resembling a punched-out recurrent hernia. Type VI includes components of both indirect and direct hernias. Femoral hernias are classified as type VII.

Regardless of the hernia type, the mesh-plug technique is performed on an ambulatory basis, through a small incision, often laparoscopically. Repair of inguinal hernias with the mesh-plug technique has provided significant advantages when compared with conventional suture technique. A plug repair requires less overall dissection, has a decreased chance of nerve injury, and ensures a tension-free hernioplasty. These factors increase patient comfort, speed rehabilitation, and contribute to a very low recurrence rate.

Surgical Technique Using the PerFix Plug

1. An oblique incision, 6 cm in length, is made, and the external oblique fascia is opened through the external ring. Exposure is obtained by use of a self-retaining retractor (e.g., a Beckman); a handheld retractor such as a Gouley may also be required. Hemostasis is usually achieved with the use of electrocoagulation.
2. The spermatic cord is mobilized, as previously described in the McVay repair. The ilioinguinal and genital femoral nerves are identified and preserved. The medial external oblique fascia is separated from the underlying transversus abdominis aponeurosis with a sweeping motion of the index finger.
3. An indirect sac and any lipoma of the cord are dissected free (Figure 12-10, *A*). The sac and lipoma are allowed to drop back through the internal ring and into the abdominal cavity. Rarely is the sac opened except for incarcerated hernias.
4. Using the Gilbert classification, the internal ring is sized and the tapered end of the mesh plug is inserted through the internal ring and positioned just beneath the crura. The plug is designed such that its fluted outer layer, combined with its inside configuration of eight mesh petals, maintains its overall contour while allowing it to conform tension-free to the configuration of the internal ring (Figure 12-10, *B*).
5. *Repair of indirect hernias.* Type I indirect hernias require one or two synthetic absorbable sutures; in type II and type III hernias, more sutures are required because of the increased size of the internal ring.
6. *Repair of direct hernias.* In direct hernias, the fusiform or saccular defect is circumscribed near its base with an electrosurgical device and the hernia is reduced, providing a surrounding margin of intact tissue for securing the plug. The plug is then inserted through the floor of the defect (Figure 12-10, *C*). With type IV and type V (direct) hernias, the mesh plug is routinely secured with up to 10 interrupted synthetic absorbable sutures. Where there are both indirect and direct hernias (type VI), two mesh plugs may be needed. Type VII defects are treated similarly with mesh plugs.
7. *Repair of femoral hernias.* In femoral hernias, a small or medium size plug is secured in position after the sac has been reduced.
8. In most types of mesh-plug hernia repairs, a second piece of flat mesh is used for reinforcement. The piece is cut to match the shape of the inguinal canal and then placed without sutures on the anterior surface of the posterior wall of the inguinal canal. The proximal portion is split to provide an opening for the spermatic cord, and the mesh tails are united with sutures to form a new internal ring (Figure 12-10, *D*).
9. With the spermatic cord structures placed on top of this flat mesh, the external oblique fascia is reapproximated over the structures with a running synthetic nonabsorbable suture.
10. An interrupted suture of a similar size is used to integrate the subcutaneous tissue, and the skin is closed with a subcuticular stitch.

LAPAROSCOPIC HERNIA REPAIRS. Ger was the first surgeon to perform a laparoscopic herniorrhaphy. In 1982 he described a laparoscopic transabdominal hernia approach. Variations in techniques for laparoscopic hernia repair continue to develop as surgeons gain experience with these procedures.

Techniques used today for laparoscopic herniorrhaphy include the transabdominal preperitoneal patch (TAPP) repair, the totally extraperitoneal patch (TEP) repair, and the intraperitoneal onlay mesh (IPOM) repair. The difference

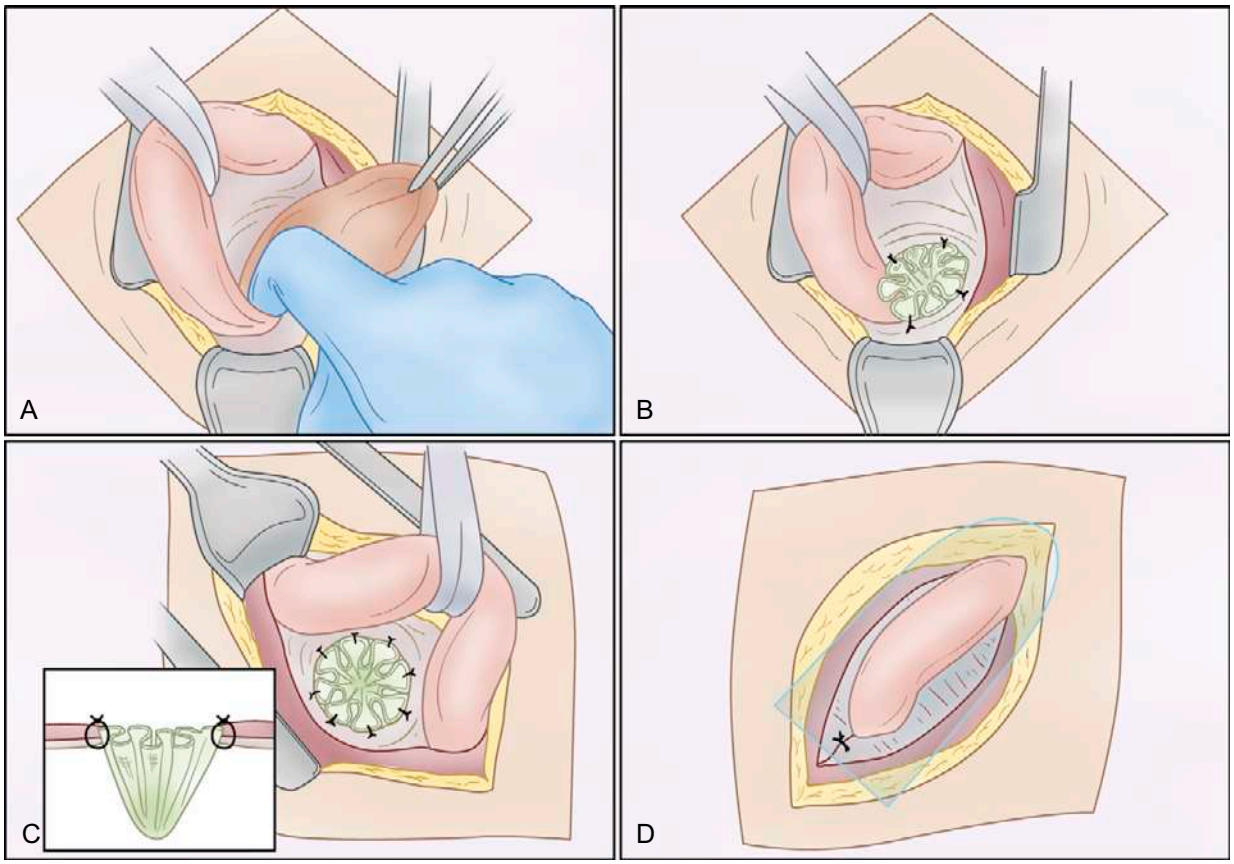

FIGURE 12-10 Mesh-plug repair using the PerFix Plug. **A**, The hernia sac is dissected free of the cord structure to the level of the internal ring. **B**, Typically, a large plug is used. Some of the internal petals may be removed if the plug is too bulky. **C**, Large or extra-large PerFix Plug is inserted. The plug should not be stretched to fill the defect. Typically, 8 to 10 sutures are used. **D**, Sutureless onlay patch. The tails of the onlay patch are taken around the cord and sutured together. The onlay patch is not sutured to the floor of the inguinal canal.

between TAPP and TEP is the manner in which access is gained to the preperitoneal space. The TAPP uses intraperitoneal trocars and the creation of a peritoneal flap over the posterior inguinal region. TEP provides access to the preperitoneal space without entering the peritoneal cavity (Research Highlight).

Studies indicating long-term postoperative hernia recurrence and complication rates with these approaches vary. The average recurrence rate for TAPP ranges from 2% to 7%; for TEP it approximates 1.8%. A laparoscopic hernia repair allegedly has the advantages of a quicker return to normal activity and some reduction of postoperative adhesions related to the minimal dissection required. Analysis of postoperative pain and paresthesia associated with laparoscopic hernia repair suggests that most patients experience minimal immediate postoperative pain and, after postoperative day 1, have minimal need for analgesics. In general, the procedure requires the placement of operative cameras and ports, identification of the inguinal floor, removal of an indirect hernia sac, insertion of mesh to fit around the spermatic cord and form a new inguinal floor, and closure of ports (Lawrence, 2006).

In 2007 the FDA granted 510(k) clearance for a hernia repair device (Rebound HRD, Minnesota Medical Development, Inc.) for the repair and/or reinforcement of hernia or other soft tissue defects where weakness exists and where the

RESEARCH HIGHLIGHT

Comparison of Different Types of Hernia Repair

This study was done to determine whether laparoscopic methods are more effective and cost-effective than open mesh methods of inguinal hernia repair. A secondary analysis was an exploration of whether laparoscopic transabdominal preperitoneal patch (TAPP) repair was more effective and cost-effective than laparoscopic totally extraperitoneal patch (TEP) repair. Laparoscopic repair was associated with a faster return to usual activities and less persisting pain and numbness. There also appeared to be fewer cases of wound or superficial infection and hematoma. However, operation times were longer, and there appears to be a higher rate of serious complications (e.g., bowel, bladder, and vascular injuries) with laparoscopic methods. Mesh infection is very uncommon, with similar rates noted among the surgical approaches. There is no apparent difference in the rate of hernia recurrence. The increased adoption of laparoscopic techniques may allow patients to return to usual activities faster. Economic savings in the form of fewer days of work missed and reduced workers' compensation have been reported.

Modified from McCormack K et al: Laparoscopic surgery for inguinal hernia repair: systematic review of effectiveness and economic evaluation, *Health Technol Assess* 9(1):218, 2005.

support of a nonabsorbable material is preferred. The device is a self-expanding framed/surgical mesh made of Nitinol, a family of intermetallic materials containing a nearly equal mixture of nickel and titanium that offers both superelasticity and shape memory. The device can be folded and inserted laparoscopically, after which it "rebounds" to its original shape for quick and easy placement over the hernia defect. Although ideally suited for laparoscopic surgery, the device also may used in an open incisional approach (Taylor, 2007).

Procedural Considerations. After induction of general anesthesia the patient is placed in supine position with the arms tucked at the sides and padded. The anesthesia screen is moved as far to the head of the bed as possible to improve surgeon ability to maneuver the laparoscope. The skin is prepped and draped to include the lower abdomen, genital area (manipulation of the scrotal sac may be necessary), and upper thighs. Following introduction of the laparoscope, the patient is placed in deep Trendelenburg's position (see Chapter 5 for positioning precautions) so that viscera fall away from the inguinal area (Feldman et al, 2007). Appropriately sized trocars and scopes, depending on the type of repair planned, ESU and appropriate smoke evacuation system, mesh, and the primary monitor and video cart are required. If the patient has voided preoperatively, urinary catheterization can be avoided.

Operative Procedure—Totally Extraperitoneal Patch (TEP) Approach (Figure 12-11)

1. An infraumbilical incision is made. The anterior rectus sheath is incised and the ipsilateral rectus abdominis muscle is retracted laterally.
2. With blunt dissection, a space is created beneath the rectus.
3. A dissecting balloon (preperitoneal distention balloon, PDB) is inserted deep to the posterior rectus sheath, tunneled and advanced to the pubic symphysis, and inflated under direct laparoscopic vision.
4. The space is opened and the PDB removed and replaced with a blunt-tip trocar. The preperitoneal space is insufflated under low pressure and additional trocars are placed.

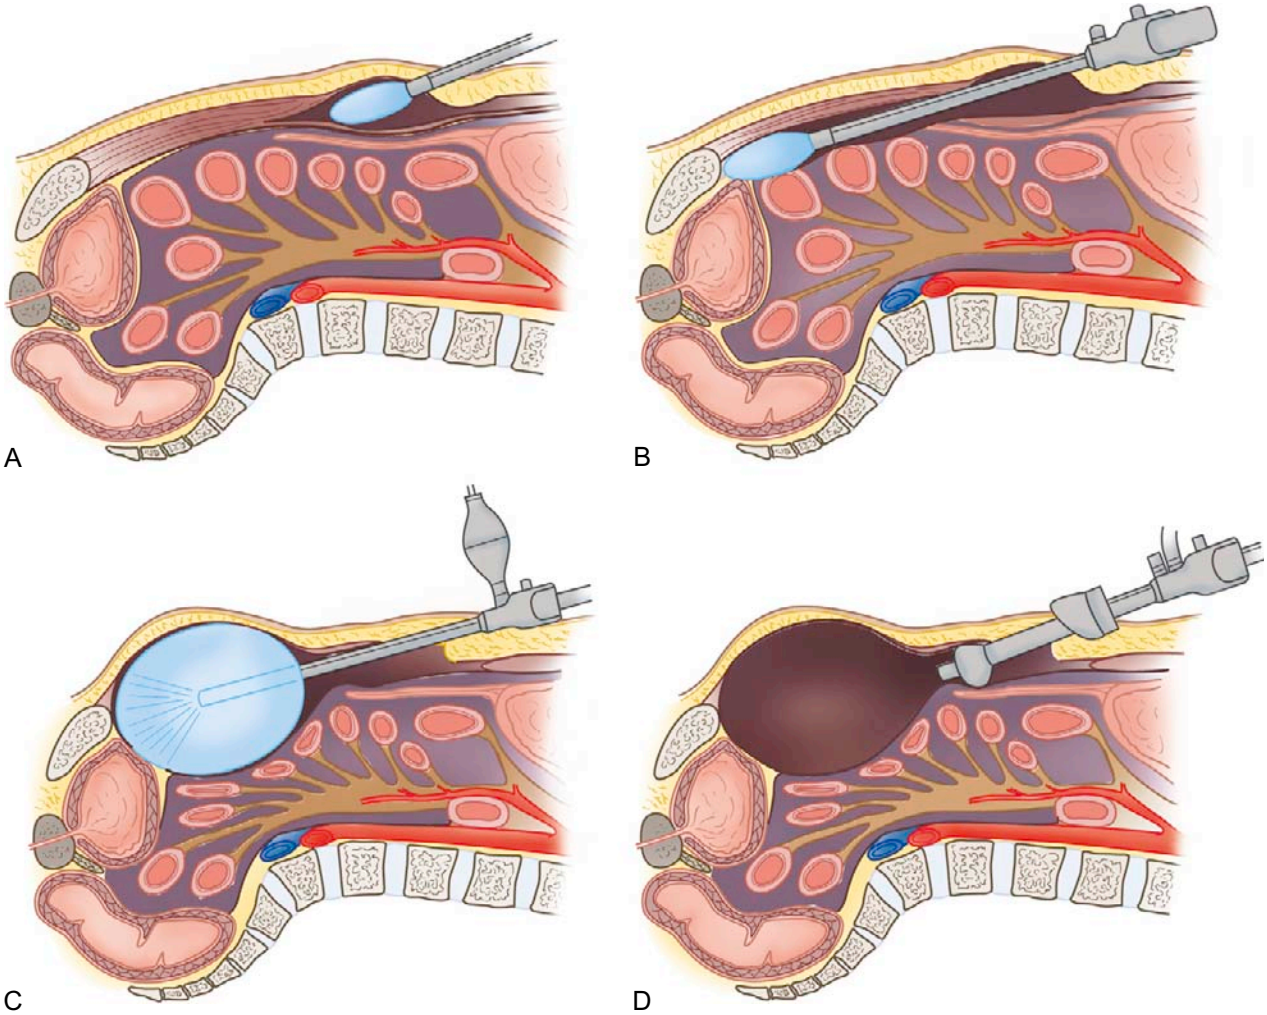

FIGURE 12-11 Totally extraperitoneal patch (TEP) laparoscopic hernia repair. **A**, The TEP approach for laparoscopic hernia repair is demonstrated. Access to the posterior rectus sheath is gained in the periumbilical region. A balloon dissector is placed on the anterior surface of the posterior rectus sheath. **B**, The balloon dissector is advanced to the posterior surface of the pubis in the preperitoneal space. **C**, The balloon is inflated, thereby creating an optical cavity. **D**, The optical cavity is insufflated by carbon dioxide, and the posterior surface of the inguinal floor is dissected.

5. Using a 30-degree telescope, the inferior epigastric vessels and lower portion of the rectus sheath are identified and retracted anteriorly.
6. The Cooper ligament is cleared from the pubic symphysis medially to the level of the external iliac vein.
7. The iliopubic tract is identified. Care is taken to avoid injury to the femoral branch of the genitofemoral nerve and the lateral femoral cutaneous nerve.
8. Lateral dissection is carried out to the anterior superior iliac.
9. The spermatic cord is skeletonized.
10. A *direct hernia sac* is gently reduced by retraction if it has not already been reduced by balloon expansion of the peritoneal space. A *small indirect sac* is mobilized from the spermatic cord and reduced into the peritoneal cavity. *A large sac* may be divided with electrocoagulation near the internal ring. The proximal peritoneal sac is closed with a loop ligature to prevent pneumoperitoneum from occurring. A piece of polypropylene mesh is inserted; unfolded to cover the direct, indirect, and femoral spaces and rest over the cord structures; and carefully secured with a tacking stapler.

REPAIR OF INGUINAL HERNIAS IN FEMALES. Regardless of the specific technique used, the initial approach to the repair of a hernia in the female is the same as that used in the male. After the cremaster muscles are opened to expose the round ligament, variations that may be encountered include the following: (1) with the sac exposed and cleared from the round ligament, the round ligament and accompanying vessels are dissected free from the inguinal floor to the labium; (2) at the labium the round ligament is clamped, ligated, and divided; (3) the sac at the internal ring is opened, checked to be sure that no abdominal contents are present, and ligated at its neck, together with the round ligament and associated vessels; or (4) the sac distal to the ligature is removed with the distal round ligament, while the ligated stump retracts promptly into the abdomen. The remainder of the repair is the same as that previously described.

REPAIR OF FEMORAL HERNIAS. A femoral hernia protrudes from the groin below the inguinal ligament into the thigh (Figure 12-12). In its most obvious form, a femoral hernia is an inflamed, tender mass below the inguinal ligament. Unfortunately, the presentation is frequently more subtle and the diagnosis is completely missed or confused with enlarged inguinal lymph nodes, a psoas muscle abscess, a saphenous varix, a lipoma, or an indirect or direct inguinal hernia. The defect is usually small and frequently nonreducible. Femoral hernias are highly likely to become incarcerated and strangulated; elective repair is clearly indicated unless serious contraindications to surgery exist.

Operative Procedure. The general approach is surgical treatment to free the tightly bound hernia, closely examine the contents of the hernia for ischemic change, and repair the hernia defect. The principles for repair of this type of hernia are the same as those described for inguinal herniorrhaphies. Ultimately, the defect must be obliterated. Repair of a femoral hernia requires approximating the aponeurotic margins of the femoral canal. The sutures are placed through the iliopubic tract superiorly and through the Cooper ligament and pectineus fascia inferiorly. Care is taken to not compromise the femoral artery and vein.

PREPERITONEAL (PROPERITONEAL) REPAIR—OPEN APPROACH. Preperitoneal (properitoneal) repair also is based on the essential role of the transversalis fascia in the cause and subsequent correction of a hernia. This repair is suitable for direct, indirect, and femoral hernias. It is particularly applicable in dealing with recurrent hernias and bilateral hernias, because exposure is obtained by operating through virgin surgical fields rather than through previous scars.

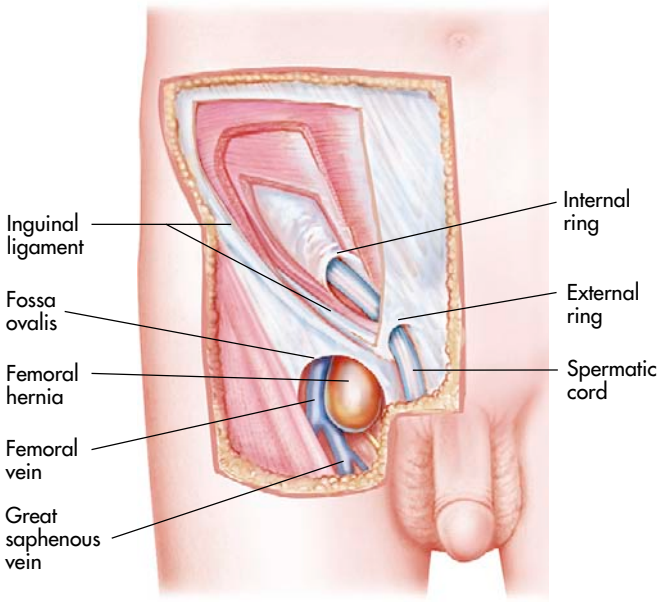

FIGURE 12-12 Bulge from femoral hernia occurring below inguinal ligament.

Operative Procedure

1. A transverse incision is made 2 cm above the symphysis pubis, through the rectus abdominis muscle on the affected side (Figure 12-13, *A*).
2. The wound is deepened by cutting the external oblique, internal oblique, and transversalis muscles.
3. The transversalis fascia is then cut, and the preperitoneal space is entered. This is the proper plane of dissection for the remainder of the operation.
4. Retraction on the lower side of the incision reveals the posterior inguinal wall and the hernia defect.

Variations in the procedure are performed for different types of hernias.

1. If the hernia is direct, it can be reduced easily and the superior edge of the hernia defect (the transversalis fascia) is sutured to the iliopubic tract (origin of the transversalis fascia) (Figure 12-13, *B*).
2. In an indirect hernia, the sac is gently retracted from the inguinal canal. A purse-string suture is placed around the peritoneal defect as the sac is excised (Figure 12-13, *C*). The lateral aspect of the internal abdominal ring is closed, and the posterior wall is reinforced as with the direct hernia.
3. In repair of a femoral hernia, the sac is again reduced by traction. After the sac is inspected for contents, a high ligation is performed. As it approaches the Cooper ligament, the defect in the posterior inguinal floor is clearly identified and is repaired by direct approximation (Figure 12-13, *D*).

After repair of any of the aforementioned hernias, the preperitoneal space is irrigated with saline solution and the appropriate layers are approximated.

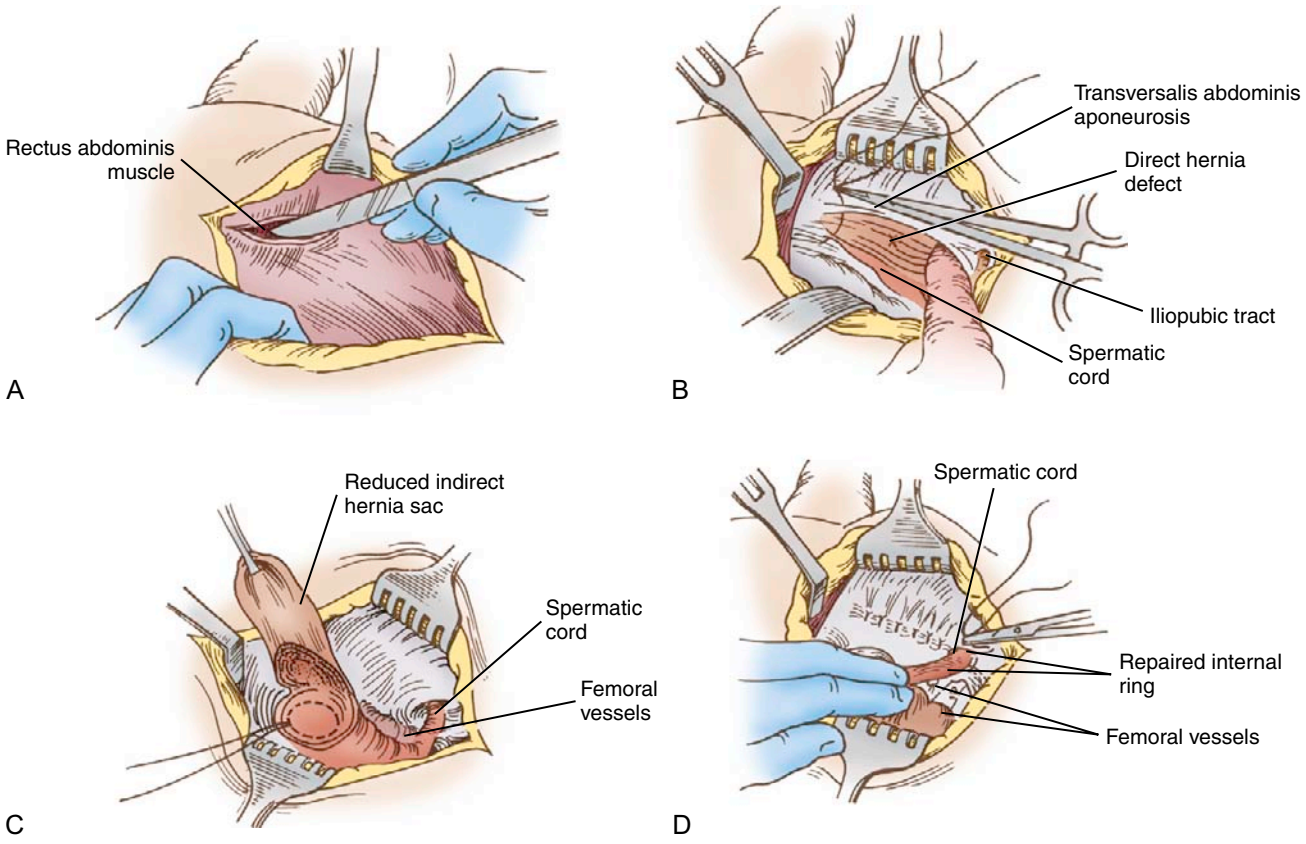

FIGURE 12-13 Preperitoneal repair. **A**, Skin incision starts 2 cm above symphysis pubis and is extended through external oblique, internal oblique, and transversalis muscles. **B**, With finger in direct hernia defect, the surgeon sutures the transversalis abdominis aponeurosis to the iliopubic tract. **C**, In case of indirect defect, the sac is reduced and then excised, with high ligation being achieved by use of a purse-string suture. **D**, Internal ring is tightened after transversus abdominis aponeurosis has been approximated to iliopubic tract.

REPAIR OF SLIDING HERNIAS. Direct or indirect hernias may occur as sliding hernias. A sliding inguinal hernia occurs when the wall of a viscus forms a portion of the wall of the hernia. The most common sliding hernias involve the bladder in direct hernias, the sigmoid colon in left indirect hernias, and the cecum in right indirect inguinal hernias (Figure 12-14). This hernia must be recognized early in the repair because attempts at surgical removal of the entire sac will injure the sliding viscus.

Operative Procedure. All operations designed to repair sliding hernias adhere to the basic principle of repairing the defect in the transversalis fascia. To free the bowel from the sac, the following steps must be taken:

1. The sac is opened in an area where no bowel is present and is excised medially and laterally to a point at which the bowel can be mobilized (Figure 12-15).
2. The lateral and medial peritoneal margins are approximated.
3. The bowel is reduced to the peritoneal cavity, and high ligation of the sac is performed.
4. Repair of the transversalis fascia is done by one of the methods previously described.

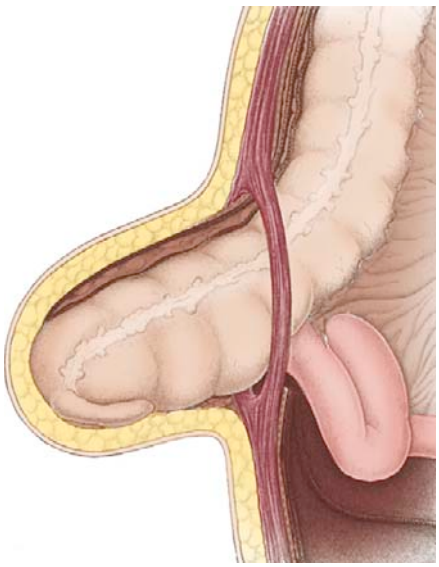

FIGURE 12-14 Sliding hernia.

LITTRE, MAYDL, AND RICHTER HERNIAS. An inguinal hernia containing a Meckel's diverticulum is called a *Littre hernia,* and one containing two loops of bowel is called a *Maydl hernia.* A special type of strangulated hernia is a *Richter hernia* (Figure 12-16). In this hernia, only a part of the circumference of the bowel is incarcerated or strangulated in the hernia. Frequently it is described as a knuckle of bowel that becomes trapped and ischemic. Because initially a very small area is necrotic, diagnosis may be delayed. A Richter hernia most frequently occurs in femoral hernias because of the small size and

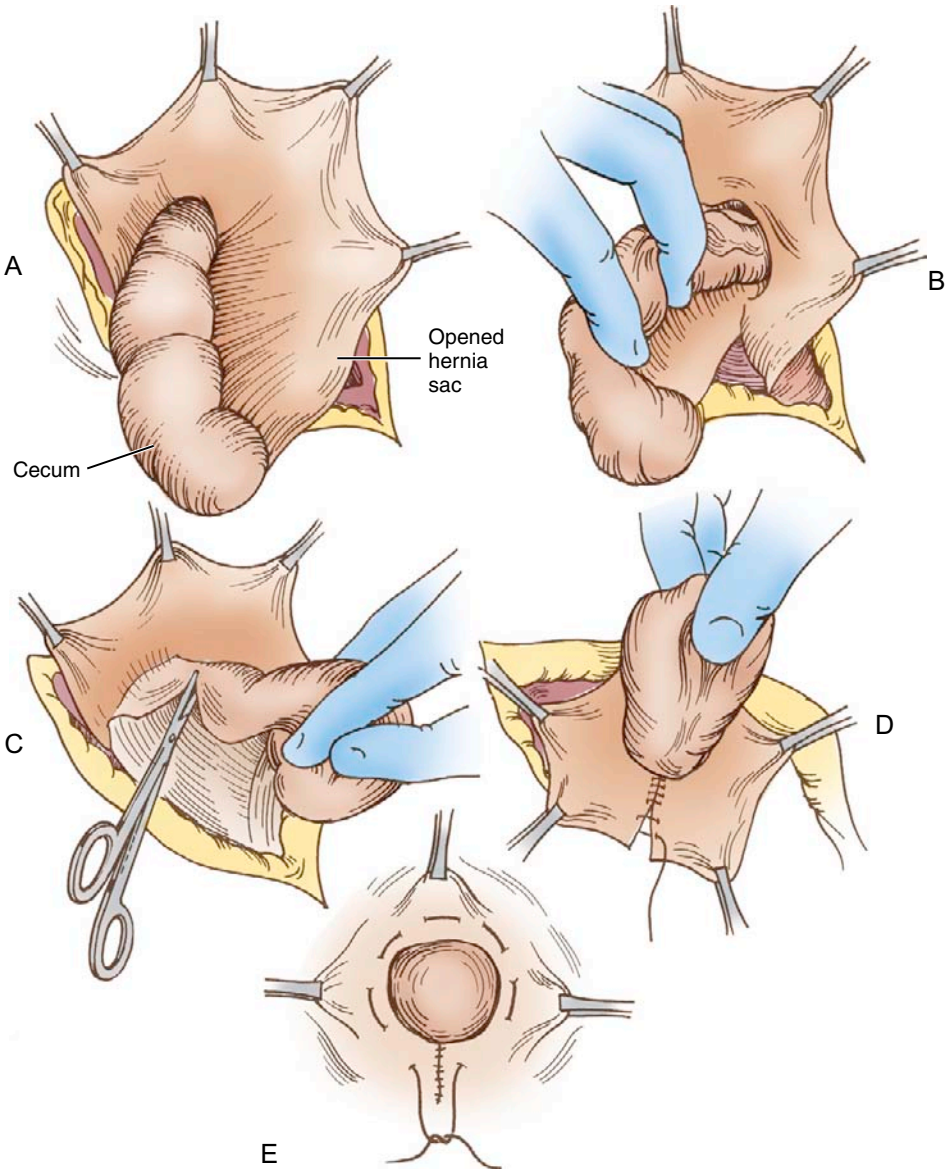

FIGURE 12-15 Right sliding hernia. **A**, Cecum forms posterior wall of hernia sac. **B**, Peritoneum is excised medially (**C**) and laterally (**D**) to allow mobilization of cecum for subsequent reduction to peritoneal cavity. Lateral and medial margins are approximated. **E**, After reduction, high ligation is accomplished using a purse-string suture.

sharp, relatively inflexible nature of the fascial ring in this area. A strangulated Richter hernia may be reduced spontaneously, and the gangrenous piece of intestine may be overlooked at the time of operation. Most commonly, the distal ileum is involved in a Richter hernia; however, omentum is frequently encountered in the sac. The favored approach for repair is through the preperitoneal space.

SURGERY FOR REPAIR OF HERNIAS OF THE ANTERIOR ABDOMINAL WALL

Ventral or Incisional Hernias

Ventral hernias can appear either spontaneously or after previous operations. Spontaneously occurring ventral hernias include epigastric and umbilical hernias. Postoperative ventral hernias, called *incisional hernias,* appear more frequently when the original incision was T shaped or a vertical midline. Operations that involve a potential for contamination, such as that for acute perforated ulcer or other perforated abdominal viscera, or wounds that become infected, are more prone to developing subsequent ventral hernias. Patients taking steroids or diagnosed with chronic obstructive pulmonary disease (COPD), as well as patients with a poor nutritional state and resulting hypoproteinemia, are predisposed to ventral hernia formation. Finally, faulty surgical technique, such as the choice of inappropriate suture materials, may result in the ultimate appearance of a ventral hernia.

Several methods have been developed for repairing ventral hernias (Research Highlight). If all layers of the abdominal wall are easily identified, anatomic layer-by-layer repair may be done.

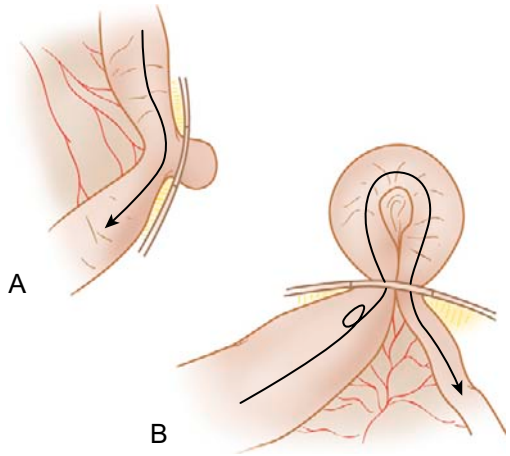

FIGURE 12-16 **A**, Richter hernia. Only a portion of bowel passes through hernial ring; arrow indicates that bowel need not be obstructed mechanically even with strangulation. **B**, Incarcerated hernia. Distended bowel in hernia cannot return to abdomen through narrow fascial defect.

Frequently a type of overlap method for repair is employed. Vertical and transverse overlap procedures are referred to as *vest-over-pants repair*. For large defects, in which approximation of tissue would result in closure with excessive tension or would cause either circulatory or respiratory compromise, synthetic materials such as surgical mesh or patches are employed.

When a very large fascial defect is present, a technique that extrapolates on the principles of tissue expansion may be used. A Tenckhoff catheter is placed percutaneously into the peritoneal cavity. Gradual expansion of the abdominal fascia is accomplished by insufflation of the abdomen with 1 to 2 liters of nitrous oxide gas, similar to the procedure for laparoscopy. The patient's vital signs are monitored during and after the insufflation procedure, which may be performed on a nursing unit or possibly in an outpatient clinical setting. The graduated expansion of the tissues sometimes allows for primary closure of the defect without the use of synthetic mesh or a patch.

Umbilical Hernias

Umbilical hernias are extraperitoneal and occur as small fascial defects under the umbilicus. They are common in children and frequently disappear spontaneously by 2 years of age. If the defect persists, a simple approximation of the overlying fascia is all that is necessary for repair (see Chapter 25 for a description of hernia repair in children). In adults, umbilical hernias represent a defect in the linea alba just above the umbilicus. These hernias tend to occur more frequently in obese people, making diagnosis more difficult. Umbilical hernias are potentially dangerous because they have small necks and frequently become incarcerated. Surgical repair is indicated for all adults with both symptomatic and asymptomatic umbilical hernias.

Epigastric Hernias

Epigastric hernias are protrusions of fat through defects in the abdominal wall between the xiphoid process and the umbilicus. Patients with epigastric hernias can have nausea, vague abdominal pain, or epigastric pain similar to that observed with cholecystitis or duodenal ulcers. Surgical repair of epigastric hernias is simple and very successful.

RESEARCH HIGHLIGHT

Comparison of Laparoscopic versus Open Incisional Hernia Repair

In the United States, approximately 4 to 5 million laparotomies are performed annually, leading to at least 400,000 to 500,000 incisional hernias. Approximately 200,000 of these incisional hernias require surgical repair. This study focused on the United Kingdom (UK), where more than 124,000 laparotomies and 7000 subsequent incisional hernia repairs were performed from 2005 to 2006 using both open and laparoscopic techniques. UK researchers undertook a meta-analysis to compare the outcomes of laparoscopic versus open incisional hernia repair, examining surgical time, duration of hospital stay, perioperative complications, postoperative surgical site pain, and recurrence rates.

The analysis included 5 randomized controlled trials that involved 366 patients—183 in the open group and 183 in the laparoscopic group. Open repair was associated with significantly higher complication rates and longer hospital stays, as well as longer surgical times than laparoscopic repair. There was no statistical difference in surgical site pain or recurrence rates. The researchers concluded that laparoscopic repair of incisional hernias is a safe, feasible, and effective alternative to open repair techniques.

Adapted from Sajid MS et al: Laparoscopic versus open repair of incisional/ventral hernia: a meta-analysis, *Am J Surg* 197:64-72, 2009.

Spigelian Hernias

The linea semilunaris, often referred to as the *Spigelius line*, marks the transition from muscle to aponeurosis in the transversus abdominis muscle. The area of aponeurosis that lies between the linea semilunaris and the lateral edge of the rectus muscle is referred to as the *spigelian zone*. Protrusion of a peritoneal sac, preperitoneal fat, or other abdominal viscera through a congenital or acquired defect in this area is called a *spigelian hernia* (Menon, 2008). It is usually located between the different muscle layers of the abdominal wall. For this reason a spigelian hernia may be referred to as an *interstitial* or *intramuscular hernia*.

Spigelian hernias are uncommon and are generally difficult to diagnose. Ultrasonic scanning has improved the diagnosis of such hernias. When ultrasonic scanning is not conclusive, CT can better visualize the hernia orifice.

Interparietal Hernias

An interparietal hernia lies between the layers of the abdominal wall. These hernias may be classified by dividing them into those that present with ventral swelling and those without ventral swelling. Diagnosis is often made during an exploratory laparotomy for symptoms of intestinal obstruction.

Repair follows the same procedure as that done for a strangulated hernia. The sac contents are closely examined for ischemia, the sac is resected, and the defect is repaired.

Synthetic Mesh and Patch Repairs

An ideal prosthetic mesh should not be physically modified by tissue fluids; be chemically inert, noncarcinogenic, and nonallergenic; resist mechanical strain; be permeable, allowing tissue ingrowth; and be pliable. Synthetic meshes, such as Mersilene,

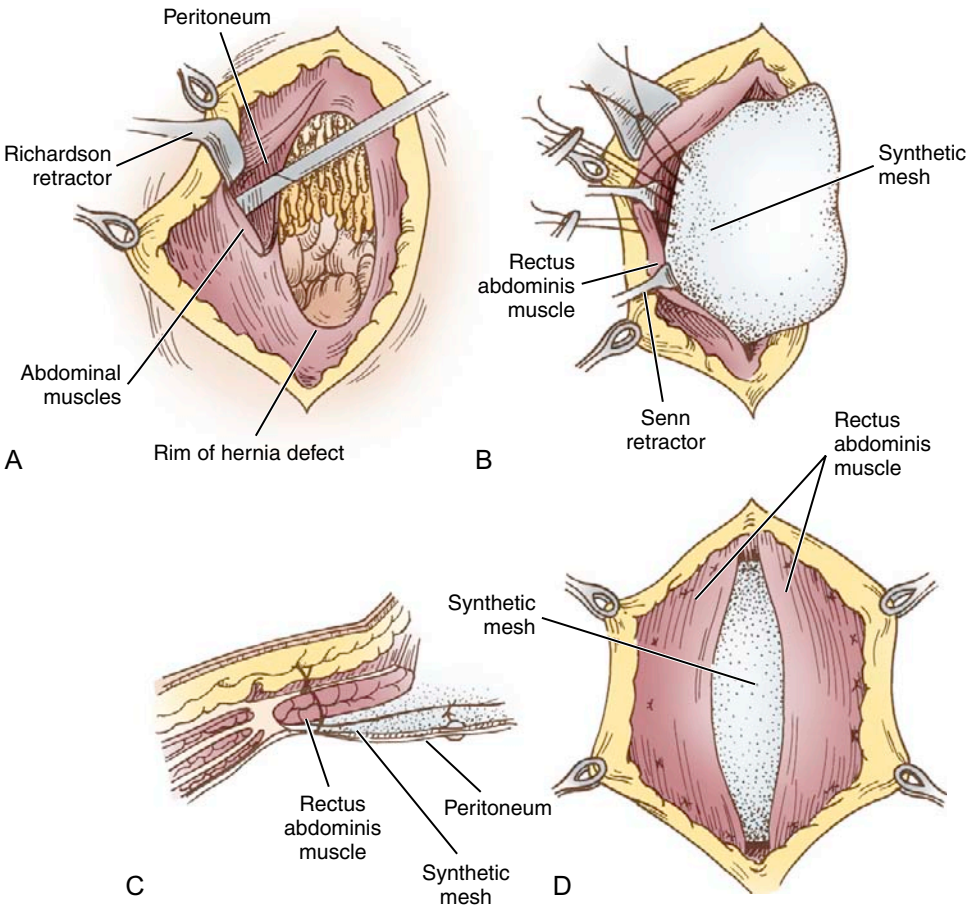

FIGURE 12-17 Use of mesh in hernia repair. After layers of abdominal wall surrounding ventral hernia are identified (**A**), mesh is inserted between rectus and peritoneum (**B**). **C**, Mesh is sutured into place on one side. **D**, With moderate tension, mesh is inserted between appropriate layers on opposite side and is sutured into place.

Marlex, Prolene, and Dacron, have been particularly helpful in repairing recurrent or large ventral hernias. Closure of the defect is obtained with minimal or no tension on the suture line. These synthetic materials are strong and durable, promoting fibrovascular growth within their pores, which lends extra strength to the repair. Single-dose antibiotic prophylaxis may be used to reduce wound infection rates with prosthetic hernia repair. Although there are studies that indicate that routine use of prophylactic antibiotics is not recommended for open non-implant herniorrhaphy, there is little direct clinical evidence on which to base recommendations when implantable mesh is used.

Another synthetic material, the Gore-Tex patch, has become popular for the reconstruction of abdominal wall defects and repair of soft tissue. Gore-Tex soft tissue patches are available in both 1-cm and 2-cm thicknesses. Impregnation of Gore-Tex patches with an antimicrobial agent has been associated with reduced incidence of infection. Gore-Tex is, however, very expensive, and surgical services departments should evaluate products such as surgical mesh with consideration to its performance, cost, effect on quality patient care, and value analysis (AORN, 2009b).

Essential to the use of mesh or patch in a hernia repair are the identification and cleaning of tissue planes to which the mesh or patch will be attached (Figure 12-17, *A*). In a ventral hernia, the peritoneum is dissected from the undersurface of the rectus abdominis muscle and the mesh or patch is placed between the peritoneum and the rectus (Figure 12-17, *B*). After the mesh or patch is positioned, it is sutured in place on one side, using the synthetic suture material compatible with the type of mesh or patch employed (Figure 12-17, *C*).

At this point the peritoneum can be closed, if possible. If the peritoneum cannot be closed, the mesh or patch can be placed directly over the omentum. The mesh or patch is then placed and sutured to the other side of the defect, with moderate tension maintained (Figure 12-17, *D*). If possible, the mesh or patch is then covered with a fascial or muscular layer before the subcutaneous fat and skin are closed. Closed-wound drainage catheters may be placed in the wound, and antibiotics are frequently used prophylactically. Using mesh or a patch to repair inguinal hernias is based on the same principles used for closing ventral hernias. With inguinal hernias, the mesh or patch is sutured to transversalis fascia on both sides of the defect.

CHAPTER 13

Gynecologic and Obstetric Surgery

DONNA R. McEWEN

Whereas changes in science and technology have impacted every area in medicine over the past century, changes in the specialty of women's health have had enormous influence over the way women live. At some point in their lives, many women face the prospect of surgery. Surgical procedures on the structures of the female reproductive system are performed for diagnostic, therapeutic, or cosmetic purposes; for conditions such as abnormal bleeding from the reproductive organs; for suspected malignant or benign neoplasms; and for infertility. Procedures are also performed to remove or repair weakened anatomic structures. Recent statistics show the majority of surgical procedures performed in the United States were performed on females (Healthcare Cost and Utilization Project [HCUPnet], 2007). A holistic approach with sensitivity to the special needs of this population is an essential component of perioperative care.

Surgical Anatomy

The female reproductive organs and their relationships are shown in Figures 13-1 and 13-2. The adult female structures associated with the process of reproduction are the external organs (vulva), the associated ligaments and muscles, the soft tissues and contents of the pelvic cavity, and the bony pelvis.

FEMALE EXTERNAL GENITAL ORGANS (VULVA)

The external organs, referred to collectively as the *vulva,* include the mons pubis, the labia majora and labia minora, the clitoris, the vestibular glands, the vaginal vestibule, the vaginal opening, and the urethral opening (Figure 13-3).

The mons pubis is a mound of adipose tissue covered by skin and, after puberty, by hair. It is situated over the anterior surface of the symphysis pubis.

The labia majora are two folds of adipose tissue covered with skin that extend downward and backward from the mons pubis. Varying in appearance according to the amount of adipose tissue, they unite below and behind the mons pubis to form the posterior commissure and in front of the mons pubis to form the anterior commissure. The labia minora are the two hairless, flat, delicate folds of skin that lie within the labia majora. Each labium splits into lateral and medial parts. The lateral part forms the prepuce of the clitoris, and the medial part forms the frenulum. The posterior folds of the labia are united by a delicate fold extending between them. This forms the fossa navicularis.

The clitoris is the homologue of the penis in the male. It hangs freely and terminates in a rounded glans (small, sensitive vascular body). Unlike the penis, the clitoris does not contain the urethra. The vaginal vestibule is a smooth area surrounded by the labia minora, with the clitoris at its apex and the fossa navicularis at its base. It contains openings for the urethra and the vagina.

The urethra, which is about 4 cm long in the premenopausal woman, is close to the anterior vaginal wall and connects the bladder with the urethral meatus. Two small paraurethral ducts, which are commonly known as *Skene's ducts,* lie on either side of the urethral meatus and drain *Skene's glands.*

The vaginal opening lies below the urethral meatus. The hymen surrounds the vaginal opening and may be circular, crescentic, or fimbriated.

Bartholin's glands and ducts are located on each side of the lower end of the vagina. These narrow ducts open into the vaginal orifice on the inner aspects of the labia minora. The glands secrete mucus and can become infected or inflamed.

PELVIC CAVITY

Uterus

The uterus is a pear-shaped organ situated in the pelvic cavity between the bladder and the rectum. It gains much of its support from its direct attachment to the vagina and from indirect attachments to nearby structures, such as the rectum and pelvic diaphragm. The uterus is supported on each side by the broad, round, cardinal, and uterosacral ligaments and levator ani muscles. The upper lateral points, the uterine cornua, receive the fallopian tubes. The fundus of the uterus is the upper, rounded portion positioned above the level of the tubal openings and just below the pelvic brim. Below, the body, or corpus, of the uterus joins the cervix. The corpus is separated from the cervix by a slight constriction (canal) called the *isthmus.* The cervix lies at the level of the ischial spines. The body of the uterus communicates with the cervical canal at the internal orifice, called the *internal os.* The constriction (canal) ends at the vaginal portion of the cervix at the external orifice, called the *external os.* The external os varies in appearance and may be oval, round, slitlike, or everted.

The uterine body has three layers: (1) the outer peritoneal, or serous, layer, which is a reflection of the pelvic peritoneum; (2) the myometrium, or muscular layer, which houses involuntary muscles, nerves, blood vessels, and lymphatics; and (3) the endometrium, or mucosal layer, which lines the cavity of the uterus.

Fallopian Tubes (Oviducts)

The Greek word *salpinx,* meaning "trumpet" or "tube," is used to refer to the fallopian tubes (Figure 13-4). The tubes are paired and consist of a musculomembranous channel about

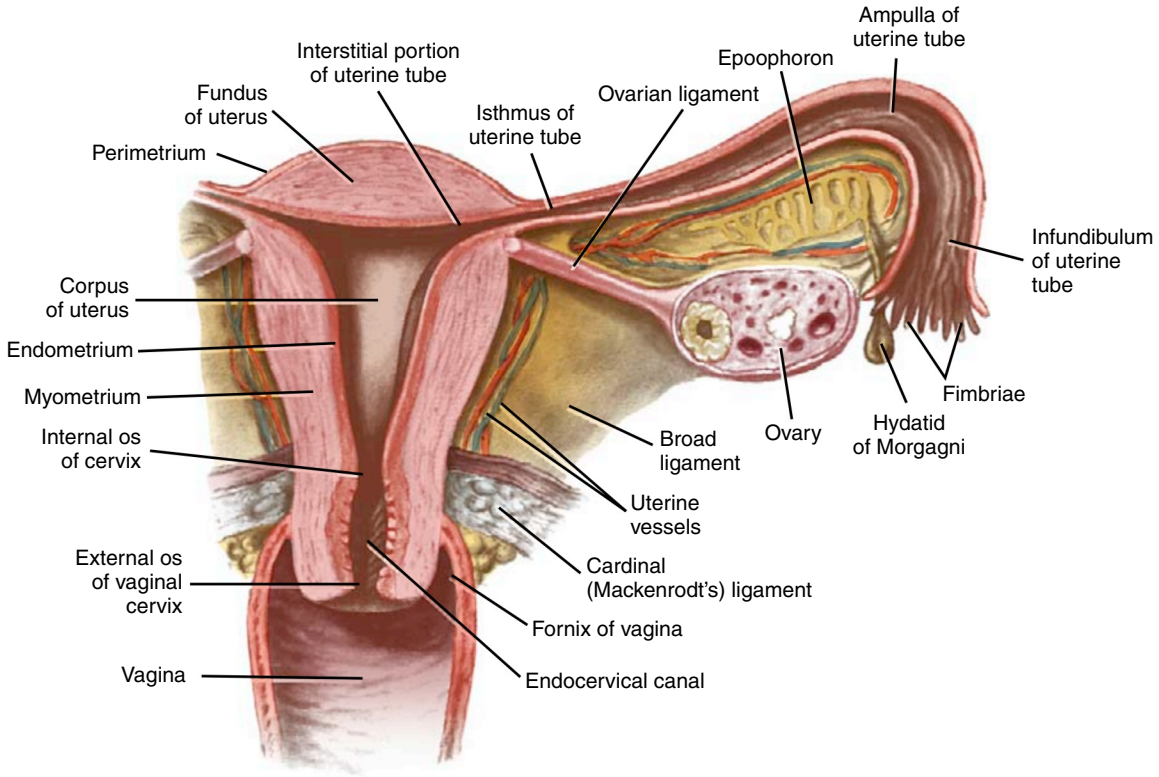

FIGURE 13-1 Female reproductive organs.

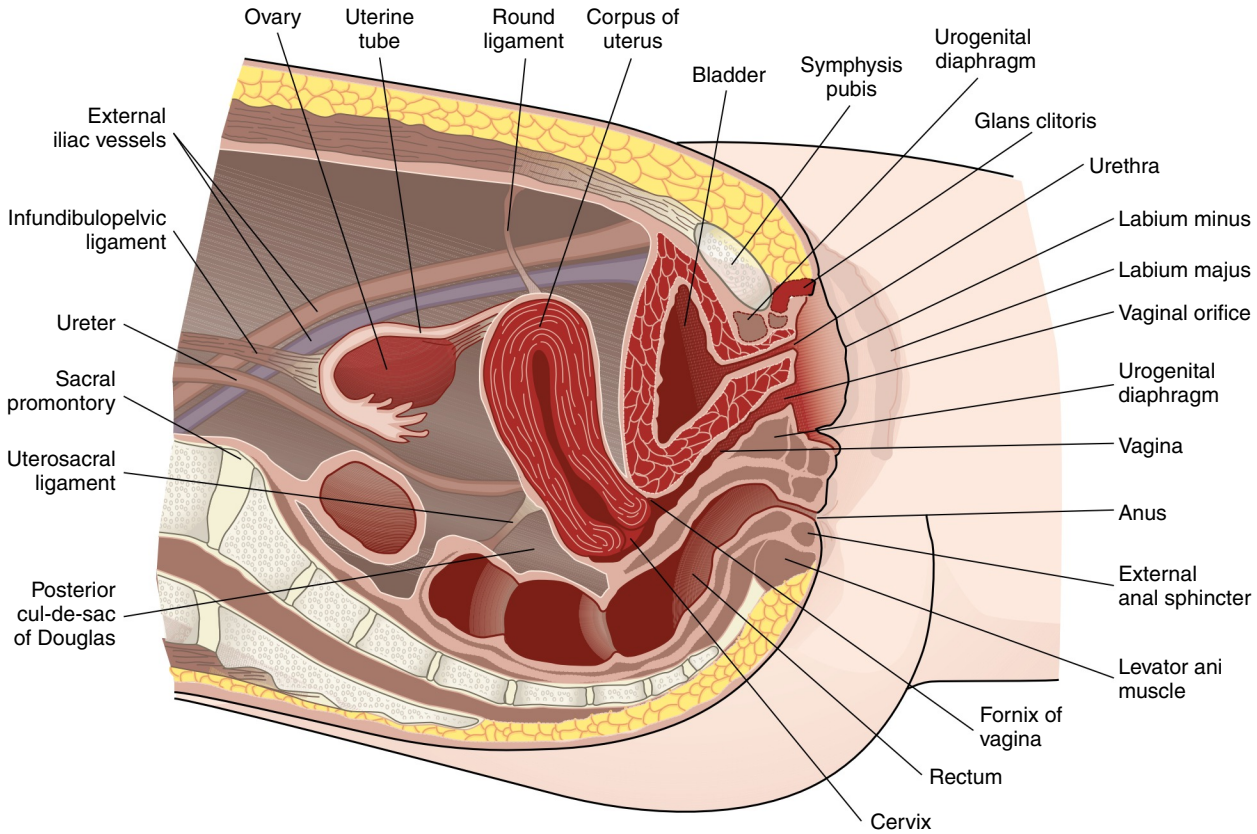

FIGURE 13-2 Female pelvic organs as viewed in midsagittal section.

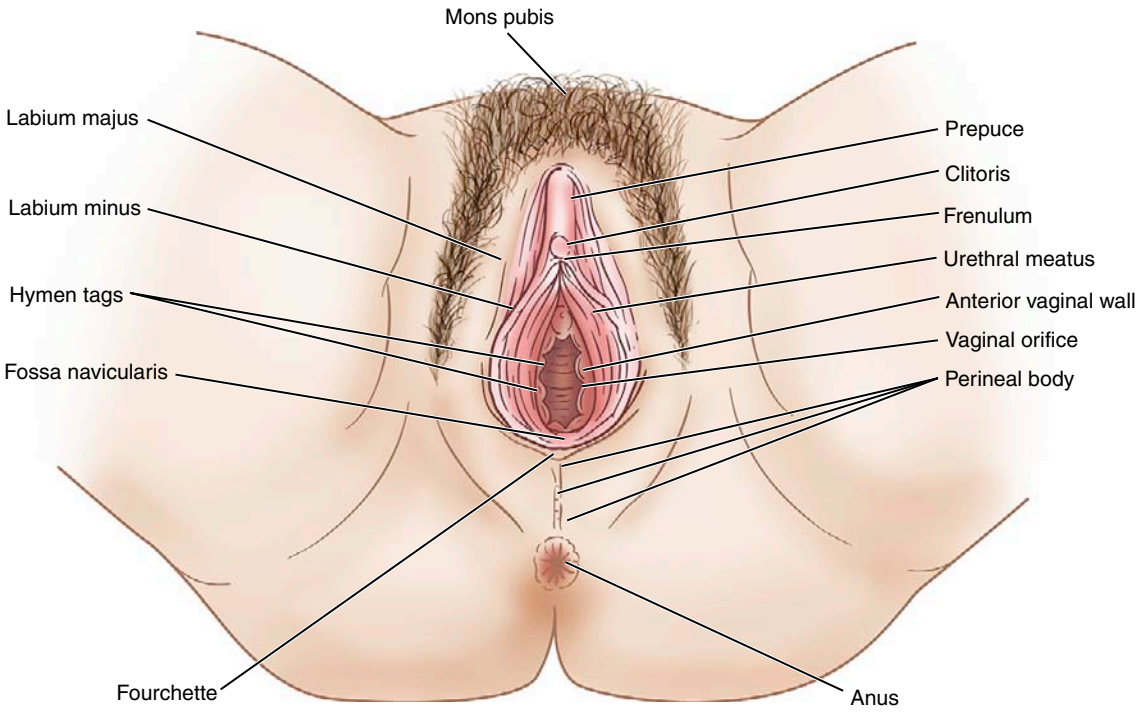

FIGURE 13-3 The structures of the external genitalia that are collectively called the *vulva.*

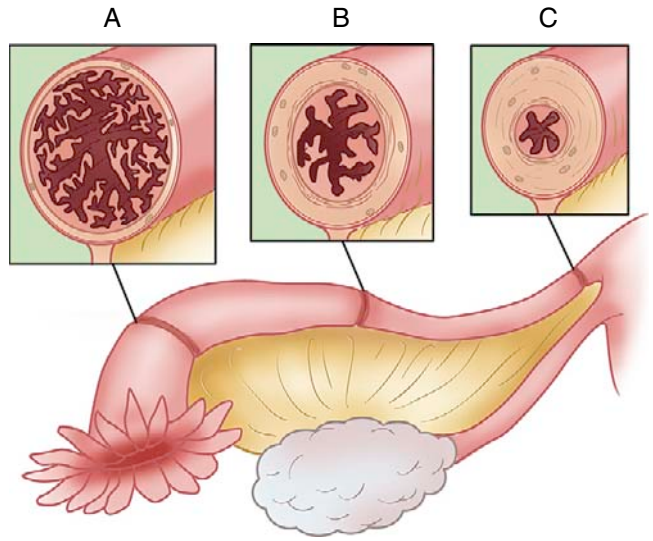

FIGURE 13-4 The longitudinal folds of the fallopian tube seen in cross section. **A**, Infundibulum. **B**, Ampulla. **C**, Isthmus.

10 to 13 cm long, forming the canals through which the ova are conveyed to the uterus from the ovaries. The outer surfaces of the tubes are covered by peritoneum. The inner layers are composed of muscular tissue lined with ciliated epithelium. Each tube receives its blood supply from the branches of the uterine and ovarian arteries and has four parts. The infundibulum is trumpet-shaped, opens into the abdominal cavity, and has fingerlike projections called *fimbriae.* The ampulla forms more than half of the tube and is thin-walled and tortuous. The isthmus is cylindric and forms approximately one third of the tube. The remainder of the tube is the uterine portion. Measuring approximately 1 cm in length, it passes through the wall of the uterus.

It has been theorized that the transfer of the ova from the ruptured follicles into the uterus is accomplished through vascular changes that occur with contraction of the smooth muscle fibers of the tube. The peristaltic action of the muscular layer and the ciliary movement propel the ova toward the uterus.

The right tube and ovary are in close relationship to the cecum and appendix; the left tube and ovary are situated near the sigmoid flexure. The fallopian tubes are also in proximity to the ureters.

Ovaries

The ovaries are located on each side of the uterus. The ovaries and tubes are collectively known as the *adnexa.* Each ovary lies within a depression (ovarian fossa) on the lateral wall of the pelvic cavity and above the broad ligament (see Figure 13-1). The anterior border of each ovary is attached to the posterior layer of the broad ligament by a peritoneal fold (mesovarium) and is suspended by the ovarian ligament.

The ovaries are small, almond-shaped organs composed of an outer layer, known as the *cortex,* and an inner vascular layer, known as the *medulla.* The medulla consists of connective tissue containing nerves, blood vessels, and lymph vessels. The ovary is covered by epithelium, not peritoneum. The cortex contains ovarian (graafian) follicles in different stages of maturity. After ovulation, the corpus luteum arises from the graafian follicle that expelled the ovum.

The ovaries are homologous with the testes of the male. They produce ova after puberty and also function as endocrine glands, producing hormones such as estrogen, secreted by the ovarian follicles. Estrogen controls the development of the secondary sexual characteristics and initiates growth of the lining of the uterus during the menstrual cycle. Progesterone, which

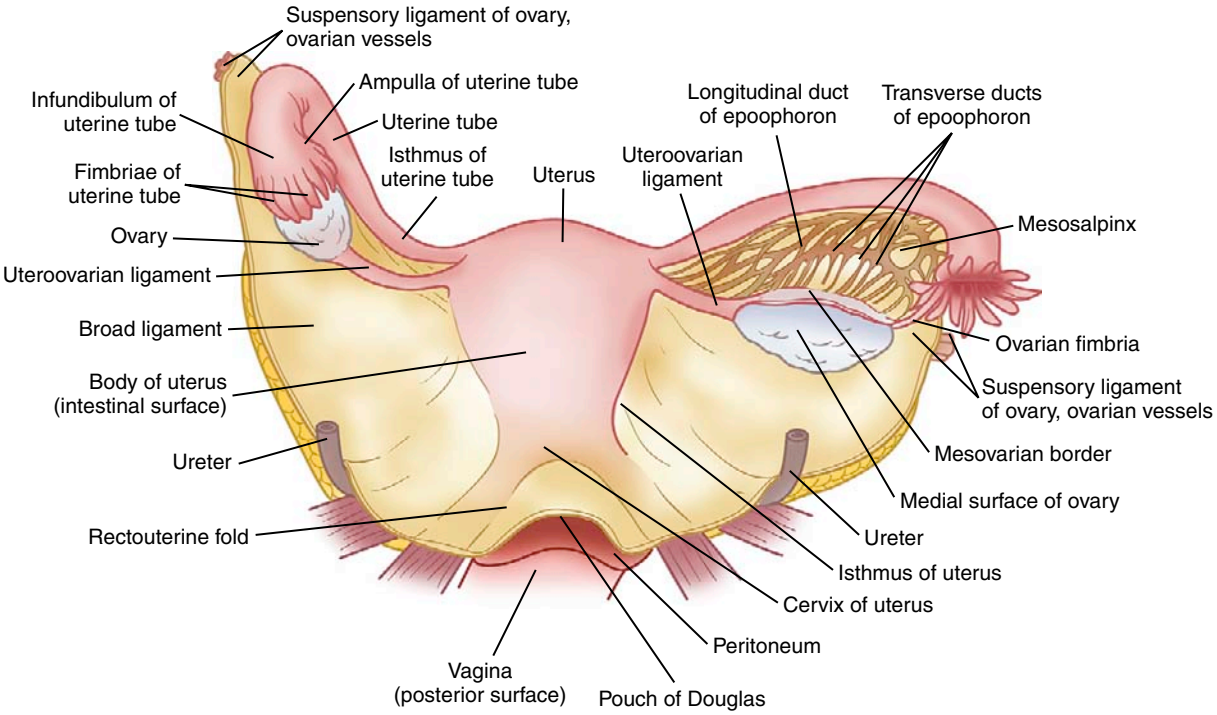

FIGURE 13-5 Schema of the broad ligament, posterior view. Note the many structures contained within the broad ligament. Note the posterior aspect of the rectouterine fold, called the *cul-de-sac*, or *pouch, of Douglas*.

is secreted by the corpus luteum, is essential for the implantation of the fertilized ovum and for the development of the embryo.

Ligaments of the Uterus

The uterine ligaments are the broad, round, cardinal, and uterosacral ligaments (Figure 13-5).

The pelvic peritoneum extends laterally, downward, and posteriorly from each side of the uterus. A double fold of pelvic peritoneum forms the layers of the broad ligament, enclosing the uterus. These layers separate to cover the floor and sides of the pelvis. The fallopian tube is situated within the free border of the broad ligament. The free margin of the upper division of the broad ligament, lying immediately below the fallopian tube, is termed the *mesosalpinx*. The ovary lies behind the broad ligament.

Round ligaments are fibromuscular bands attached to the uterus. Each round ligament passes forward and laterally between the layers of the broad ligament to enter the deep inguinal ring.

Cardinal ligaments are composed of connective tissue with smooth muscle fibers and provide strong support for the uterus.

Uterosacral ligaments are a posterior continuation of the peritoneal tissue. The ligaments pass posteriorly to the sacrum on either side of the rectum.

Vagina

The vagina is a rugated musculomembranous tube. It carries the menstrual blood from the uterus, serves as the organ for sexual intercourse, and is the terminal portion of the birth canal. The anterior wall measures 6 to 8 cm in length and the posterior wall 7 to 10 cm (see Figures 13-1 and 13-2). The anterior wall of the vagina is in proximity to the bladder and urethra. The lower posterior wall is anteriorly adjacent to the rectum. The upper portion of the vagina lies above the pelvic floor and is surrounded by visceral pelvic fascia. The lower half is surrounded by the levator ani muscles.

Cervix

The cervix consists of a supravaginal portion, which is closely associated with the bladder and the ureters, and a vaginal portion, which projects downward and backward into the vaginal vault. The projection of the cervix into the vaginal vault divides the vault into four regions, called *fornices:* anterior, posterior, right lateral, and left lateral.

The posterior fornix is in contact with the peritoneum of the pouch, or cul-de-sac, of Douglas. The rectovaginal septum lies between the vagina and rectum. The dense connective tissue separating the anterior wall of the vagina from the distal urethra is termed the *urethrovaginal septum.*

BONY PELVIS

The pelvis is that portion of the trunk below and behind the abdomen. The bony pelvis is composed of the ilium, symphysis pubis, ischium, sacrum, and coccyx. The so-called *pelvic brim* divides the abdominal false portion, located above the arcuate line, from the true portion of the pelvis, located below this line. The bony pelvis accommodates the growing fetus during pregnancy and the birth process.

The true pelvis may be considered to have three parts: inlet, cavity, and outlet. The muscles lining the pelvis facilitate movement of the thighs, give form to the pelvic cavity, and provide a firm elastic lining to the bony pelvic framework. All organs

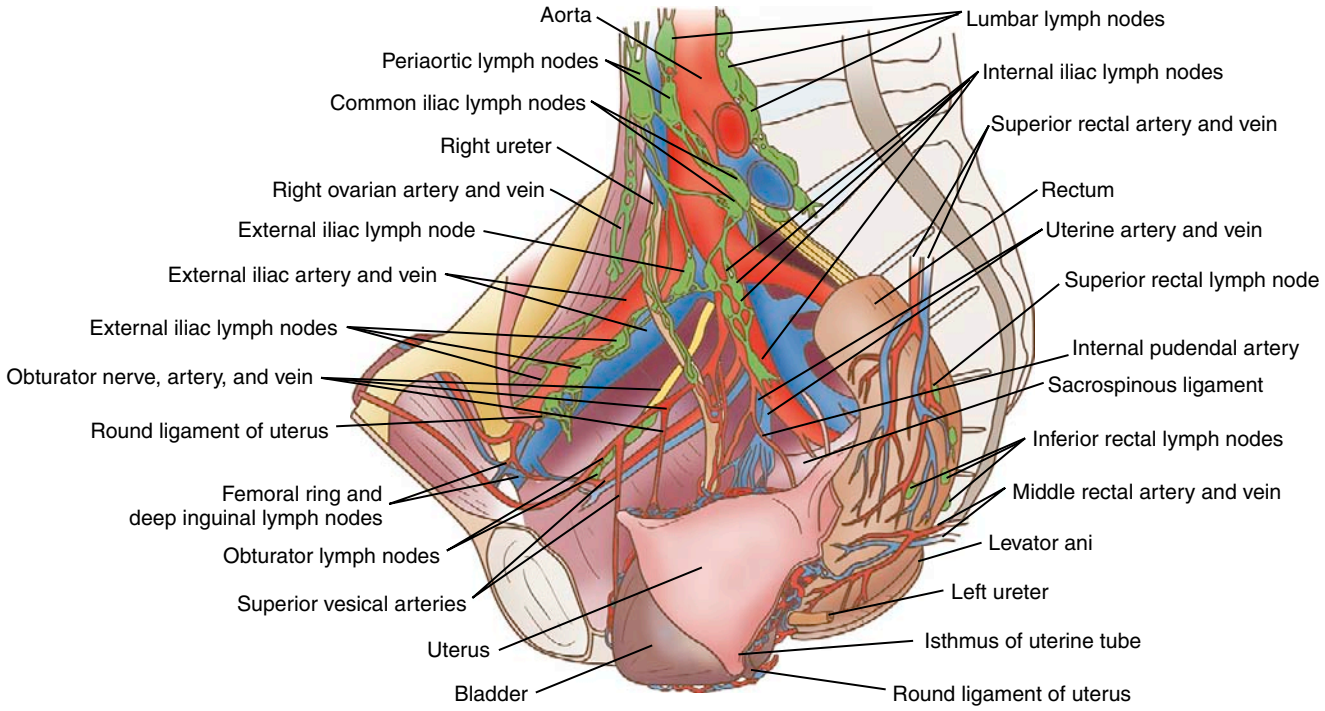

FIGURE 13-6 A lateral view of the female pelvis demonstrating the extensive lymphatic network. Note that most of the lymphatic channels follow the courses of the major vessels.

located in the pelvis are covered by pelvic fascia, which is extremely important in the maintenance of normal strength in the pelvic floor.

The fascia covering the muscles is usually dense and firm, whereas that covering organs is often thin and elastic. The nerves, blood vessels, and ureters coursing through the anatomic structures are closely associated with muscular and fascial structures.

PELVIC FLOOR

The pelvic floor acts as a supportive sling for the pelvic contents. The pelvic fascia may be divided into three general groups: parietal, diaphragmatic, and visceral. The parietal pelvic fascia covers the muscles of the true pelvic wall and perineum. The diaphragmatic fascia covers both sides of the pelvic diaphragm, which is made up of the levator ani and coccygeal muscles. The visceral fascia is thin and flexible and covers the pelvic organs. The floor of the pelvis, known as the *pelvic diaphragm,* gives support to the abdominal pelvic viscera in this region. It consists of the levator ani and coccygeal muscles with their respective fascial coverings; it separates the pelvic cavity from the perineum.

The levator ani muscles, varying in thickness and strength, may be divided into three parts: the iliococcygeal, the pubococcygeal, and the puborectal muscles. The fibers of the levator ani muscles blend with the muscle fibers of the rectum and vagina. The pubovaginal fibers of the pubococcygeal portion of the levator ani muscles, lying directly below the urinary bladder, are involved in the control of micturition. The pubococcygeal fibers of the levator ani muscles control and pull the coccyx forward and assist in the closure of the pelvic outlet. The fibers pull the rectum, vagina, and bladder neck upward toward the symphysis pubis in an effort to close the pelvic outlet and are responsible for the flexure at the anorectal junction. Relaxation of the fibers during defecation permits a straightening at this junction. During parturition, the action of the levator ani muscles directs the fetal head into the lower part of the passageway.

Vascular, Nerve, and Lymphatic Supply of the Reproductive System

The blood supply of the female pelvis is derived from the internal iliac branches of the common iliac artery and is supplemented by the ovarian, superior rectal, and median sacral arteries—branches of the aorta.

The nerve supply of the female pelvis comes from the autonomic nerves, which enter the pelvis in the superior hypogastric plexus (presacral nerve). The lymphatics of the female pelvis either follow the course of the vessels to the iliac and preaortic nodes or empty into the inguinal glands (Figure 13-6).

Perioperative Nursing Considerations

Assessment

The provision of quality perioperative nursing care depends on thorough assessment and planning. Data about the gynecologic patient are gathered through the review of systems, physical examination, nursing and medical histories, and diagnostic test results in the patient record (Table 13-1).

Application of interpersonal communication techniques is vital during nursing assessment. The interview may be conducted on the patient care unit or in the holding area of the surgical suite. Privacy must be maintained to facilitate

TABLE 13-1

Common Laboratory Studies Used in the Reproductive Assessment

Test	Normal Range for Adults	Significance of Abnormal Findings
Follicle-stimulating hormone (FSH) (follitropin)	Follicular phase, 1.37-9.9 milliinternational units/ml Midcycle, 6.17-17.2 milliinternational units/ml Luteal phase, 1.09-9.2 milliinternational units/ml Postmenopause, 19.3-100.6 milliinternational units/ml	Decreased levels indicate possible infertility, anorexia nervosa, neoplasm. Elevations indicate possible Turner's syndrome.
Luteinizing hormone (LH)	Follicular phase, 1.68-15 milliinternational units/ml Midcycle, 21.9-56.6 milliinternational units/ml Luteal phase, 0.61-16.3 milliinternational units/ml Postmenopause, 14.2-52.3 milliinternational units/ml	Decreased levels indicate possible infertility, anovulation. Increased levels indicate possible ovarian failure, Turner's syndrome.
Prolactin	0-20 ng/ml; 20-400 ng/ml in pregnancy	Increased levels indicate possible galactorrhea, pituitary tumor, disease of hypothalamus or pituitary gland, hypothyroidism.
Estradiol	Follicular phase, 20-350 pg/ml Midcycle, 150-750 pg/ml Luteal phase, 30-450 pg/ml Postmenopause, ≤20 pg/ml	Increased levels indicate normal pregnancy, precocious puberty, ovarian tumor. Decreased levels indicate failing pregnancy, Turner's syndrome, menopause, anorexia nervosa.
Progesterone	Follicular phase, <50 ng/dl Luteal phase, 300-2500 ng/dl Postmenopause, <40 ng/dl	Increased levels indicate possible ovarian luteal cysts. Decreased levels indicate possible inadequate luteal phase, amenorrhea.
Testosterone	<1 ng/dl	Increased levels indicate possible adrenal neoplasm, polycystic ovaries, ovarian tumors, trophoblastic tumors, idiopathic hirsutism.

Modified from Lowdermilk DL: Assessment of the reproductive system. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, Philadelphia, 2010, Saunders.

discussion. Questions about reproduction and gynecologic history may embarrass the patient. The perioperative nurse uses open-ended questions, progressing from general to specific, throughout the assessment interview process. For example, the nurse may initially inquire about the patient's understanding of the surgical intervention to be performed and then proceed to questions pertaining to intraoperative positioning, such as the presence of back pain and limitations in joint mobility.

The nurse will solicit the gynecologic patient's chief complaint, present problem, social history, sexual history, and relevant medical and surgical histories. A family history includes information such as maternal use of diethylstilbestrol and deaths related to gynecologic disorders, cancer, hypertension, diabetes, and heart disease. Cultural, psychologic, and religious beliefs are identified and incorporated into the plan of care. Throughout this process the perioperative nurse must remain open and supportive to help establish a trusting therapeutic relationship. Establishing a trusting relationship also facilitates the nurse's assessment for intimate partner violence (IPV). IPV is a major health concern with estimates of more than 1 million women being assaulted by an intimate partner annually (WHO, 2008). Awareness of the scope of the problem and warning signs for abuse will serve the perioperative nurse well in assessing women for IPV concerns and providing for their safety during the perioperative period and beyond (Patient Safety).

The gynecologic patient's history includes a chronologic listing of each pregnancy with length of gestation, type of delivery, complications during pregnancy, duration of labor, and fetal weight. The menstrual cycle is discussed to include age at onset, length of each cycle, amount of flow, duration of bleeding, and pain or discomfort associated with menses. The amount of flow is described in relation to the number of pads and tampons used. Additional considerations for the gynecologic assessment are noted in Box 13-1.

A medication history is taken, including use of analgesics, oral contraceptives, estrogen therapy, diuretics, antihypertensives, and cardiac medications and use of herbal medications/neutraceuticals. Medication frequency, dosage, and duration of use are noted.

Gynecologic disorders may be associated with urinary problems. The perioperative nurse should inquire about stress incontinence or loss of urine while coughing, sneezing, or laughing as well as any pain or burning sensations on urination. Gynecologic surgery is performed in proximity to the kidneys, ureters, and bladder and may warrant preoperative studies such as an intravenous pyelogram (IVP) to establish an anatomic baseline.

The nurse reviews the results of the physical examination. Baseline vital signs; height; weight; and findings from assessment of the thyroid, chest, heart, lungs, breasts, abdomen, pelvis, and rectum are analyzed for their relationship to planning intraoperative care.

The gynecologic patient may undergo numerous diagnostic studies. The studies performed depend on the gynecologic problem or disorder. A laparoscopy may be performed for

PATIENT SAFETY

Assessment Techniques for Intimate Partner Violence (IPV)

IPV can be defined as the actual or threatened physical, sexual, psychologic, or emotional abuse by a spouse, ex-spouse, boyfriend, girlfriend, ex-boyfriend, ex-girlfriend, date, or cohabitating partner. IPV may also include rape and stalking. Abuse or violence crosses all ages and segments of society; it is not limited to certain economic groups or educational level.

Nurses and other healthcare providers may represent the first and only contact that an isolated woman will seek outside of the abusive relationship and are a primary source of relief; therefore screening for IPV should be an integral part of the perioperative assessment. A variety of screening tools are available and are summarized in the CDC publication, *Intimate Partner Violence and Sexual Violence Victimization Assessment Instruments for Use in Healthcare Settings*. Characteristics common to the tools include trying to normalize the conversation with neutral opening statements, such as "The staff at our facility are concerned about your safety. We know that many things can happen in our lives that affect our mental and physical health." In addition, healthcare providers should use direct questions when violence is suspected, such as "Are you with a partner who threatens or physically harms you?"

Cues to abuse include delay in seeking medical assistance (hours or days), vague explanations of injuries, nonspecific complaints, a partner who seems reluctant to leave the woman alone with the healthcare provider, and substance abuse. Physical signs include new and old injuries to the face, breasts, abdomen, and buttocks; fractures that have a suspicious etiology; injuries at various stages of healing; and patterns that indicate injuries made by biting or fist/hand patterns. Pregnant women have an increased risk for IPV and therefore should be thoroughly assessed by the perioperative nurse.

If the nurse suspects IPV, he/she is mandated in most states to report the abuse. Domestic violence is considered a crime in all states, but the category (e.g., misdemeanor or felony) varies by state definition. Nurses must be aware of the reporting requirements for the state in which they reside. In addition to reporting the abuse or suspected abuse, the nurse must document the findings in the medical record. If appropriate to the situation, photographs can be taken and included in the record.

The nurse must assess the patient's safety before she is discharged and provide her with written information about her legal options, shelters, crisis intervention services, and counseling. The National Domestic Violence Hotline (1-800-799-SAFE) is available 24 hours a day/7 days a week. Nurses can also facilitate patient safety by providing education to women and empowering them to understand that abuse is a violation of their basic human rights; promoting assertiveness; and recommending resources that will enhance independence.

Modified from Centers for Disease Control and Prevention: *Intimate partner violence and sexual violence victimization assessment instruments for use in healthcare settings,* available at www.cdc.gov/ncipc/dvp/ipv/ipvandsv-screening.pdf. Accessed July 2, 2009; Rhynerson B: Violence against women. Accessed July 2, 2009.

diagnostic or therapeutic reasons, such as infertility, pelvic pain, pelvic inflammatory disease, ova retrieval for in vitro fertilization (IVF), lysis of adhesions, evaluation of pelvic mass, removal of ectopic pregnancy, or sterilization.

Pelvic ultrasonography helps diagnose ectopic pregnancy and adnexal and uterine disease. Uterine fibroids and blood or fluid in the pelvis may be identified by means of ultrasonography. Computerized tomography (CT) scanning and magnetic resonance imaging (MRI) may be used in evaluation of the patient with suspected malignancy in the retroperitoneal lymph nodes or bone.

The gynecologic patient may have a hysterosalpingogram preoperatively to identify abnormalities in the uterine cavity and occlusions in the tubal folds. This diagnostic tool is useful in detecting potential reasons for infertility.

A colposcopy, with colpomicroscopy, is often performed in the physician's office. This examination is indicated for the patient with an abnormal Papanicolaou (Pap) smear suggestive of dysplasia. It identifies cellular abnormalities that may involve the vulva, vagina, or cervix and helps identify areas of dysplasia and carcinoma in situ. Endocervical curette samples may be obtained during the colposcopic procedure to rule out invasive carcinoma or to detect early adenocarcinoma.

Gynecologic Carcinoma. Gynecologic cancers commonly occur in the endometrium, the cervix, the ovaries, or the vagina. Less common sites are the vulva and fallopian tubes. Risk factors associated with the development of these cancers are noted in Table 13-2.

Endometrial cancer (Figure 13-7) is the most common gynecologic cancer and is responsible for approximately 42,160 new cases of cancer each year in the United States. Patients with this type of cancer may be asymptomatic, or they may experience postmenopausal bleeding as their primary symptom (American Cancer Society [ACS], 2009).

Cervical cancer is the third most common cause of death related to gynecologic cancers. In its early, preinvasive stage, cervical cancer may be asymptomatic or associated with painless vaginal spotting or bleeding. During the early preinvasive stage, the disease may be described as dysplasia. From dysplasia, the disease progresses to carcinoma in situ (CIS). Preinvasive cancers may also be designated as cervical intraepithelial neoplasia (CIN) and classed according to severity (ACS, 2009; Lowdermilk, 2007a):

CIN 1: Mild
CIN 2: Moderate
CIN 3: Severe, to carcinoma in situ (Figure 13-8)

Ovarian cancer is often accompanied by symptoms attributable to other disease processes. It is the leading cause of death from gynecologic malignancies. These tumors are generally epithelial in nature and are associated with a poor prognosis (Figure 13-9). They spread directly to other organs in the pelvic space and distally to the lymphatics, or they seed into the peritoneum (ACS, 2009).

Vulvar cancer (Figure 13-10) represents the fourth most common gynecologic cancer and is typically slow-growing. It appears most often in women in their middle 60s to 70s. In younger women, the incidence is often linked to genital

BOX 13-1

Focused Assessment for Gynecologic Patients

GYNECOLOGIC HISTORY
- Prior Papanicolaou (Pap) smears and results
- Prior abnormal Pap smears, how treated, follow-up
- Recent gynecologic procedures
- Past gynecologic procedures or surgery (e.g., tubal ligation, hysterectomy, oophorectomy, laparoscopy, cryosurgery, conization)
- Sexually transmitted infections (STIs)
- Pelvic inflammatory disease
- Vaginal infections
- Cancer of reproductive organs

MENSTRUAL HISTORY
- Age at menarche
- Date of last normal menstrual period: first day of last cycle
- Number of days in cycle and regularity of cycle
- Character of flow: amount (number of pads/tampons used in 24 hours), duration, presence, and size of clots
- Dysmenorrhea: characteristics, duration, frequency (occurs with each cycle?), relief measures
- Intermenstrual bleeding or spotting: amount, duration, frequency, timing in relation to phase of cycle
- Intermenstrual pain: severity, duration, timing, association with ovulation

ABNORMAL BLEEDING
- Character: shortened interval between periods (<19-21 days), lengthened interval between periods (>37 days), amenorrhea, prolonged menses (>10 days), bleeding between periods
- Change in flow: nature of change, number of pads/tampons used in 24 hours (tampons/pads soaked?), presence of clots
- Associated symptoms: pain, cramping, abdominal distention, pelvic fullness, change in bowel habits, weight loss or gain
- Medications: prescription or nonprescription; oral contraceptives

PAIN
- Sequence: date and time of onset, sudden versus gradual onset, course since onset, duration, recurrence
- Character: specific location, type, and intensity of pain
- Associated symptoms: vaginal discharge or bleeding, gastrointestinal symptoms, abdominal distention or tenderness, pelvic fullness
- Association with menstrual cycle: timing, location, duration, changes
- Relationship to body functions and activities: voiding, eating, defecation, flatus, exercise, walking up stairs, bending, stretching, sexual activity
- Aggravating or relieving factors
- Previous medical care for this problem
- Efforts to treat
- Medications: prescription or nonprescription

VAGINAL DISCHARGE
- Character, amount, color, odor, consistency, changes in characteristics
- Occurrence: acute or chronic
- Douching habits
- Clothing habits: use of cotton or ventilated underwear and pantyhose, tight pants or jeans
- Presence of discharge or symptoms in sexual partner
- Use of condoms
- Associated symptoms: pruritus; tender, inflamed, or bleeding external tissues; dyspareunia; dysuria or burning on urination; abdominal pain or cramping; pelvic fullness
- Efforts to treat: antifungal vaginal cream
- Medications: prescription or nonprescription; oral contraceptives; antibiotics

SEXUAL HISTORY
- Sexual activity: number of current and previous partners; number of their partners; gender of partner or partners
- Method of contraception: current and past; satisfaction level
- Use of barrier protection for STIs
- Prior STIs

OBSTETRIC HISTORY
- G: **g**ravida: total number of pregnancies
- T: number of **t**erm pregnancies
- P: number of **p**reterm pregnancies
- A: number of **a**bortions, spontaneous or induced
- L: number of **l**iving children
- Complications of pregnancy, delivery, abortion, or with fetus or neonate
- Duration of labor, fetal weight
- Diabetes (gestational)

INFERTILITY
- Length of time attempting pregnancy, sexual activity pattern, knowledge of fertile period in menstrual cycle
- Abnormalities of vagina, cervix, uterus, fallopian tubes, ovaries
- Contributing factors: stress, nutrition, chemical substances
- Factors relating to partner's fertility
- Diagnostic evaluation to date

MENOPAUSAL HISTORY
- Age at menopause or currently experiencing
- Associated symptoms: menstrual changes, mood changes, tension, hot flashes
- Postmenopausal bleeding
- Birth control measures during menopause
- General feelings about menopause: self-image, effect on intimate relationships
- Mother's experience with menopause
- Medications: hormone replacement therapy (HRT), related side effects, breast tenderness, bloating, vaginal bleeding, other medications—prescription or nonprescription, including herbal remedies

Modified from Seidel HM et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2006, Mosby.

TABLE 13-2

Risk Factors for Cancers of the Reproductive System

Risk Factor	Endometrial Cancer	Cervical Cancer	Ovarian Cancer	Vulvar Cancer	Vaginal Cancer	Fallopian Tube Cancer
Age	50-65 yr	CIS: 30-40 yr Invasive: 40-60 yr	Infrequent before 35 yr; range usually is 40-65 yr	After 40 yr; peak is 60-70 yr	Most after 50 yr; adenocarcinoma: 14-30 yr	Most after 50 yr; range is 18-80 yr
Family history	Increased risk	—	Increased risk	—	DES exposure in utero	—
Personal history	Diabetes, hypertension	—	Breast, bowel, or endometrial cancer	Cervical cancer, diabetes, vulvar disease	Vulvar or cervical cancer	Ovarian or uterine cancer, infertility
Race	Caucasian	African American, Native American	Caucasian	—	—	—
Mother's age at delivery	—	<18 yr	>30 yr	—	—	—
Body size	Obese	—	—	Possibly obese	—	—
Parity	Nulliparity	Multiparity	Nulliparity	—	Multiparity	Nulliparity
Estrogen use	Prolonged use >3 yr after menopause	Possibly long-term birth control pill use	—	—	—	—
Smoking	Possibly increased risk	Possibly double the risk	—	—	—	—
Infection (STI)	—	Possibly STI (herpes simplex virus type 2 or papillomavirus infection)	—	Possibly STI (papillomavirus infection)	STI (herpes simplex virus type 2 or papillomavirus infection)	PID, chronic salpingitis

CIS, Carcinoma in situ; *DES,* diethylstilbestrol; *PID,* pelvic inflammatory disease; *STI,* sexually transmitted infection.
Modified from Gingrich PM: Interventions for clients with gynecologic problems. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, Philadelphia, 2010, Saunders.

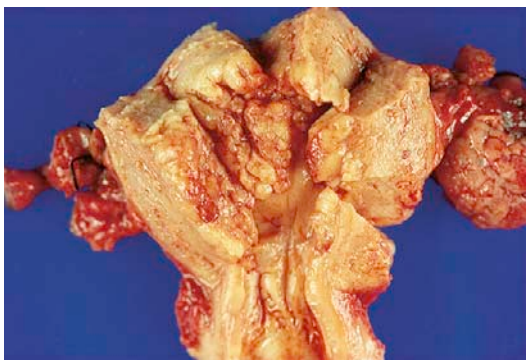

FIGURE 13-7 Endometrial cancer on posterior wall of uterus.

warts (condylomata acuminata) caused by human papillomavirus (HPV). Symptoms include irritation and pruritus in the perineal area or nonhealing lesions (ACS, 2009; Lowdermilk, 2007a).

Vaginal cancer ranks fifth of gynecologic cancers, causing fewer than 1000 deaths per year (ACS, 2009). This form of cancer is rare as a primary diagnosis and is usually an extension of cervical, endometrial, or vulvar cancers. It is generally asymptomatic in the early stages and may be accompanied by pain, foul-smelling discharge, painless bleeding, pruritus, and urinary symptoms in the later stages (Lowdermilk, 2007a).

Fallopian tube cancer is very rare, with an incidence of less than 1%. It is seen primarily as a metastasis from ovarian and endometrial cancers (Lowdermilk, 2007a).

Nursing Diagnosis

Perioperative nursing care is a planned process that is implemented to ensure safe, quality patient outcomes. Nursing diagnoses are formulated after reviewing the patient record and conducting a patient assessment. All significant data collected are reviewed and prioritized and then incorporated into the perioperative plan of care. The gynecologic patient may have multiple nursing diagnoses that warrant perioperative nursing intervention, which may include the following:

- Anxiety related to planned surgical intervention
- Risk for Urinary Retention related to edema, anesthesia, opioids, or pain
- Risk for Infection at the surgical site related to operative or other invasive procedures
- Disturbed Body Image related to surgery
- Risk for Perioperative Positioning Injury

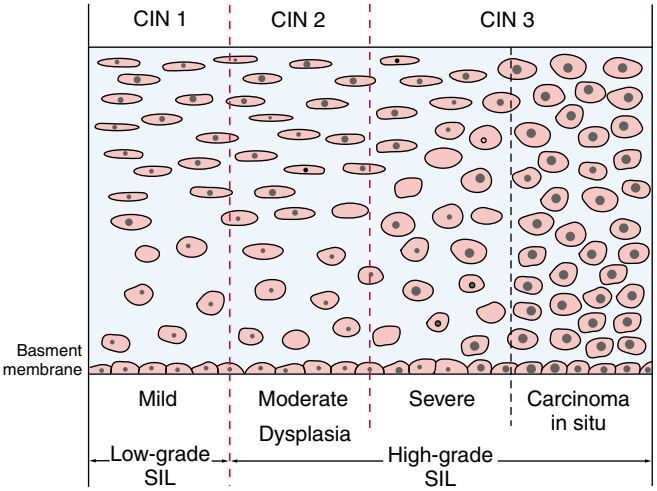

FIGURE 13-8 Diagram of cervical epithelium showing progressive changes and various terms used. *SIL,* Squamous intraepithelial lesion.

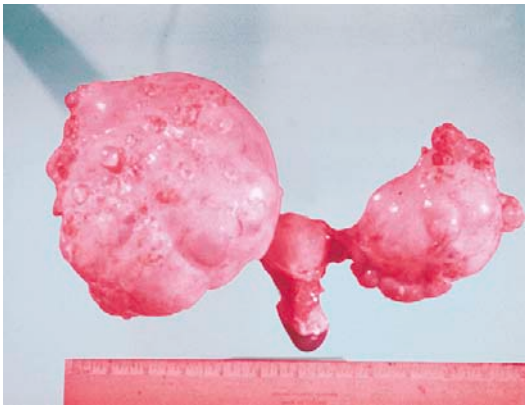

FIGURE 13-9 Bilateral ovarian carcinoma.

Outcome Identification

Outcomes identified for the selected nursing diagnoses could be stated as the following:

- The patient will verbalize reduced or controlled anxiety.
- The patient will maintain or regain normal patterns of urinary elimination.
- The patient will remain free from surgical site infection.
- The patient will acknowledge feelings regarding her body image (as applicable).
- The patient will be free from injury related to surgical positioning.

Planning

Planning enables the perioperative nurse to provide patient care in an organized and individualized manner. Planning involves preparation for both the psychosocial and physiologic needs of the gynecologic patient. Part of planning efficient and effective patient care is the gathering of the required equipment and supplies, positioning accessories, devices, and adjuncts requisite to the specific gynecologic surgical intervention. For example, if the gynecologic patient is undergoing a lengthy surgical intervention, the perioperative nurse will plan to have a forced-air warming device, pressure-reducing positioning

FIGURE 13-10 Vulvar/perineal carcinoma.

devices, antiembolic stockings, and sequential compression devices (SCDs) available. These actions will help maintain the patient's body temperature, promote skin integrity, and prevent venous stasis. Similar nursing interventions that will help the gynecologic patient reach the desired outcomes are identified for each patient. Examples of interventions for the gynecologic patient are shown in the Sample Plan of Care on p. 429.

Implementation

During implementation of the plan of care, the perioperative nurse performs the identified nursing interventions. Implementation includes gathering the appropriate instruments and patient care supplies, positioning the patient on the OR bed, performing antimicrobial skin preparation, inserting urinary catheters, draping the patient, creating and maintaining a sterile field, initiating safety measures, and monitoring the patient. Data continue to be collected, the plan of care is adjusted as required and documented, and reports are given to relief personnel, ensuring continuity of the patient's plan of care.

Instrumentation. A basic vaginal instrument set is required for vaginal and vulvar surgery. A basic abdominal gynecologic instrument set is required for abdominal gynecologic surgery. Laparoscopic, hysteroscopic, and robotic specific instrumentation may also be used. Surgeons' instrument preferences may vary, and the instrumentation described in this chapter is not meant to be all-inclusive.

For most abdominal gynecologic procedures, a dilation and curettage (D&C) set should be available.

Positioning. Principles and methods of patient positioning for different types of surgical procedures are described in Chapter 5. Stirrups for the lithotomy position may support

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Anxiety related to planned surgical intervention

OUTCOME
The patient will verbalize reduced or controlled anxiety.

INTERVENTIONS
- Determine the patient's previous experience with surgery and her level of knowledge related to the current planned surgical intervention.
- Assess the patient's level of anxiety and physical reactions to anxiety (e.g., tachycardia, tachypnea, nonverbal expressions of anxiety); classify her anxiety as low, moderate, or high.
- Use presence and touch (if welcome) to communicate comfort and caring.
- Provide time for and encourage expression of concerns or clarification of needs.
- Explore coping skills previously used by the patient to relieve anxiety (e.g., relaxation, deep breathing, imagery); reinforce these skills and facilitate their use.
- Explain the sequence of perioperative nursing activities and procedures, using nonmedical terms and clear, concise speech. Allow time for questions and concerns.
- Minimize environmental stimuli and noise.
- If conducive to anxiety reduction, provide patient with a means to listen to music in the preoperative period and intraoperatively, as applicable.

NURSING DIAGNOSIS
Risk for Urinary Retention related to edema, anesthesia, opioids, or pain

OUTCOME
The patient will maintain or regain normal patterns of urinary elimination.

INTERVENTIONS
- Before surgery, explain that an indwelling catheter will be inserted (if applicable).
- Verify the absence of any latex allergy; a latex-free catheter will be required for latex-allergic patients.
- Insert indwelling catheter using aseptic technique.
- Secure tubing to prevent inadvertent stretching or stress on catheter.
- Document size of catheter inserted.
- Keep drainage bag below the level of the bladder.
- Observe and document the color and amount of urine; report abnormalities.
- Check patency of catheter and drainage system whenever patient is repositioned.
- Discuss with the patient the importance of adequate postoperative fluid intake and early ambulation.
- Review elements of catheter care, management of drainage system, catheter removal, and signs and symptoms of urinary tract infection.
- Clarify any patient misconceptions.
- Encourage the patient to verbalize feelings and concerns regarding inability to void postoperatively, presence of indwelling catheter, and catheter removal.

NURSING DIAGNOSIS
Risk for Infection at the surgical site related to operative or other invasive procedures

OUTCOME
The patient will remain free from surgical site infection.

INTERVENTIONS
- Administer and document antibiotic prophylaxis as prescribed. Follow safe practices for all medication administered.
- Initiate measures to warm patient and maintain normothermia.
- Prepare surgical site with an antiseptic solution; document skin condition at surgical site and solution used.
- Apply dressing to surgical site before sterile drapes are removed to prevent contamination of incision.
- Follow Standard Precautions and infection prevention and control practices.
- Maintain aseptic technique, and monitor members of the surgical team for breaks in technique.
- Correctly classify surgical wound at end of procedure.
- Document the presence, location, and type of any drains inserted during surgical intervention.
- Review with patient signs and symptoms of infection at surgical site:
  - Redness
  - Swelling
  - Warmth
  - Tenderness
  - Pain
- Discuss the importance of proper handwashing techniques when changing dressings at surgical site, as applicable.

NURSING DIAGNOSIS
Disturbed Body Image related to surgery

OUTCOME
The patient will acknowledge feelings regarding her body image (as applicable).

INTERVENTIONS
- Determine the patient's expectations of her planned surgery.
- Correct unrealistic perceptions of the planned surgical intervention (as appropriate).
- Encourage the patient to express feelings about her diagnosis and surgery and how she believes it will affect her body image; clarify any misconceptions.
- Acknowledge denial, anger, or depression as normal feelings when adjusting to changes in body image or function.
- Determine the influence of cultural beliefs, norms, and values on the patient's body image.
- Maintain the patient's privacy.
- Demonstrate empathy and positive regard.
- Reinforce information provided by other healthcare team members.

NURSING DIAGNOSIS
Risk for Perioperative Positioning Injury

OUTCOME
The patient will be free from injury related to surgical positioning.

INTERVENTIONS
- Note and document any preexisting patient considerations (e.g., nutritional status, weight, preoperative chemotherapy, limitations in mobility or range of motion, neurovascular impairments) that place the patient at risk for positioning injury.
- Use adequate numbers of personnel to transfer and position the patient.
- Secure the patient to the OR bed without friction or pressure at restraining straps.
- Assess and document condition of dependent skin areas.
- Use pressure-reducing positioning devices.
- Pad and protect bony prominences and dependent pressure sites.
- Maintain proper body alignment.
- Provide support stockings or antiembolic device, such as sequential compression devices (SCDs), as indicated.
- Reassess padding and protection during any positional changes.

only the patient's feet (canvas, fabric, or gel-pad ankle straps) or may cradle and support the thighs, popliteal spaces, and lower legs. Padded cradle stirrups promote maintenance of skin integrity and assist in preventing nerve injury. The nurse may anticipate that patient positions may be modified based on the surgical procedure and surgeon's preference. The patient is placed in the lithotomy position for most vaginal and vulvar surgery. Careful attention must be focused on placing the patient in the lithotomy position to prevent injury and vascular changes. The perioperative nurse must seek assistance during positioning the patient in lithotomy to ensure the legs are raised and lowered simultaneously. For abdominal gynecologic surgery, Trendelenburg's position may be used. Some surgeons use the low lithotomy position with the Trendelenburg position for abdominal oncology procedures to facilitate access to pelvic and para-aortic nodes. Patients placed in Trendelenburg's position for prolonged gynecologic procedures are at increased cardiovascular risk because of decreased pulmonary compliance and functional residual capacity (FRC) (Faust et al, 2005). Whenever possible the nurse positions the patient's arms on padded armboards with the palms up and fingers extended. Armboards are maintained at less than a 90-degree angle to prevent stretching of the brachial plexus. If there are surgical reasons to tuck the arms at the side, the nurse pads the patient's elbows to protect the ulnar nerve, faces the palms inward, and maintains the wrists in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail. Care should be taken to protect all patients from integumentary, musculoskeletal, and nerve injury while ensuring adequate circulatory, renal, and respiratory functions.

Because pelvic and vaginal procedures involve manipulation of the ureters, bladder, and urethra, indwelling urinary drainage is frequently established before or during surgery with an indwelling urethral catheter or a suprapubic cystostomy catheter, depending on the type of procedure. The size of sutures, needles, and drains also varies, depending on the surgical procedure, surgeon preference, and patient needs.

Prepping. Skin preparation and routine draping procedures are described in Chapter 3. Care must be taken not to cross-contaminate when prepping multiple areas, such as for an abdominal hysterectomy. The nurse always preps the abdomen before beginning the vaginal prep. Two separate prep trays should be used and the prep setups should be kept separate. The perioperative nurse should take care when performing vaginal preps on patients who have been experiencing vaginal bleeding and may have clots in the vaginal vault. The clots and any gross blood on the thighs or vulva should be removed before beginning the prep to allow full contact of the prepping solution.

Examination Under Anesthesia (EUA). Many physicians will perform a pelvic examination after the patient is anesthetized and positioned. The perioperative nurse should anticipate this examination and ensure that nonsterile gloves and an appropriate lubricant are available. Culture specimens (e.g., gonococcal, chlamydial, trichomonal) and a Pap smear may be obtained during the examination. Verify with the surgeon that the prep agent and lubricant used are compatible with cytologic evaluation.

Dressings, Drains, and Packing. Various dressings are used in gynecologic surgery and may range from simple (e.g., wound closure tapes) to complex (e.g., multilayer gauze, ostomy appliances, binders). Perineal pads are used after vaginal surgery.

Closed and open drains are used. The surgeon may insert a Penrose drain through the vaginal cuff after a hysterectomy. Indwelling and suprapubic catheters are also commonly employed in gynecologic surgery. All drains and catheters should be secured for patient comfort and to avoid dislodgment. Verify that the patient has no latex allergy, as many of these drains contain latex.

Packing may be used in fistulas or other created cavities or to support and stent the vagina, absorb postoperative drainage, or aid in hemostasis. Products used for vaginal packing can include narrow fine-mesh gauze in various yardage, iodoform packing, and large-mesh gauze. Vaginal packing is usually moistened with saline or coated with antibiotic or antifungal cream before insertion. Packing must be placed with care to avoid distention of the vault and compression of its vasculature.

Evaluation

During the evaluation phase the perioperative nurse determines whether the patient met the established outcomes. Some outcomes can be reached during the preoperative and intraoperative phases of care; they are evaluated before the patient's discharge from the OR. Others require ongoing monitoring and measurement in the postoperative phase; these are denoted by the word "will" to indicate their ongoing nature. Part of the perioperative nursing report to the postanesthesia care unit (PACU) or ambulatory recovery should include the outcomes of the nursing plan of care. They can be phrased as follows:

- The patient's anxiety was reduced; she verbalized concerns and used personally effective coping strategies.
- Urinary elimination patterns were maintained; urinary output was adequate; and catheter patency was maintained.
- The patient's skin integrity was maintained; she verbalized understanding of the signs and symptoms of infection to report to her physician and acknowledged measures to prevent infection (e.g., handwashing).
- The patient will effectively cope with her disturbance in body image; questions will continue to be answered and misconceptions clarified.
- There was no evidence of injury related to surgical positioning; range of motion and neurovascular status were consistent with preoperative levels.

Patient and Family Education and Discharge Planning

Patient and family education, along with discharge planning, is a critical perioperative nursing activity. Many gynecologic surgical procedures are performed on an ambulatory basis, and for those that require an inpatient admission, length of stay continues to decrease. Thus patient education and discharge planning often begin before any admission, be it ambulatory or inpatient. Regardless of the gynecologic procedure performed, the perioperative nurse should begin patient and family education with necessary postoperative care information. The goal of this information is to restore normal body function

and may include areas such as early ambulation, prevention of respiratory complications, incision care, anticipated postoperative discomfort, managing postoperative pain, restrictions in activity, diet, and any other patient concerns. Areas such as progression of activities, emotional and physical issues, sexual activity, general nutritional needs, and health maintenance guide the education process. Gynecologic patients should also be provided specific information regarding signs and symptoms to report, especially in relation to vaginal bleeding and the surgical site, along with restrictions related to douching and vaginal penetration (tampons or sexual intercourse). With the growth in same-day surgery, many types of hysterectomies, some myomectomies, and even laparotomies are now same-day, or 23-hour–stay procedures (Ambulatory Surgery Considerations). Simple, clear information and instructions such as those presented in the Patient and Family Education box are helpful to enhance patient learning and retention.

LASERS IN GYNECOLOGIC SURGERY

Carbon dioxide (CO_2), neodymium:yttrium-aluminum-garnet (Nd:YAG), and argon lasers are used in gynecology to treat extrauterine disease such as pelvic endometriosis, cervical dysplasia, condylomata acuminata, pelvic adhesive disease, and premalignant diseases of the vulva and vagina. Lasers are generally used in conjunction with the colposcope and operating microscope, or the laparoscope. A laser plume evacuator or suction system is necessary to remove smoke and fumes from the operative field (AORN, 2009). All accessories and instrumentation used should be laser-safe and secure, and tested or examined for working order before use. Safety precautions must be implemented by the OR team when the laser is used. For example, if the argon laser is used, pressure-relief valves must be used to prevent increased intraabdominal pressure (see Chapter 7 for a full discussion of lasers and laser safety).

AMBULATORY SURGERY CONSIDERATIONS

Minimally Invasive Gynecologic Surgery

A variety of gynecologic surgical procedures can be performed using minimally invasive techniques. An advantage of minimally invasive surgery (MIS) is that patients can be discharged on the same day of surgery or within 23 hours of admission. Nurses who are involved in MIS gynecologic ambulatory surgical procedures should consider the following factors when planning and implementing care.

PREOPERATIVE CARE

Preoperative care of patients undergoing MIS should focus on patient teaching. The nurse should provide patients with written and verbal instructions to prevent misconceptions about the procedures, alleviate concerns or confusion about the robot (if used), and provide some postoperative teaching during the preoperative phone call. Teaching should focus on the following issues:

- Explaining the specifics of the particular procedure: Unfortunately, there is limited information available on robotics written for consumers, except that which is provided by the robotics' manufacturers.
- Alleviating anxiety: The nurse should make sure the patient understands that the physician is controlling the robot and that the robot is just a surgical tool that helps the surgeon be more efficient and effective.
- Explaining postoperative pain and activity limitations: It is important to remember that patients and their families will be providing postoperative care in the early days after surgery. This self-care includes recovery from anesthetic agents; return of gastrointestinal and urologic function; and management of pain, possible complications, and activity level.
- Explaining possible complications and ensuring that the patient knows when to contact her healthcare provider about problems.
- Teaching about care of the operative site: The nurse should provide written instructions to help the patient better remember what has been taught since preoperative anxiety may distract the patient. The nurse will reinforce these instructions postoperatively.

Preprocedural screening of patients is aimed at identifying risks for infection. The patient's general health is assessed to ensure that the patient can tolerate the procedure. These particular surgeries use gas (usually CO_2) to create visual space in the peritoneum—a pneumoperitoneum. The insufflation with CO_2 can cause cardiopulmonary and hemodynamic complications.

Knowing the patient's health and medication history is important. The following are complications associated with CO_2 insufflation:

- Hyperkalemia
- Pulmonary complications
- Cardiovascular and vascular complications
- Subcutaneous emphysema
- Metabolic inflammatory responses
- Gas embolism (rare)

INTRAOPERATIVE CARE

Preoperative nursing care varies little from procedure to procedure; however, intraoperative care is affected by the technologies used. Nurses assisting in robotic procedures must know how to set up, calibrate, and operate the machines. During surgery, monitoring cues and messages from the robotics' system are an important aspect of nursing care. Troubleshooting is important to promote patient safety and to avoid prolonging the procedure. Knowing emergency procedures is also important for this type or any type of surgery.

POSTOPERATIVE CARE

Postoperative care of the MIS patient is performed according to the same standards as those of traditional surgery. Care focuses on stabilizing the patient, maintaining pain control, carefully monitoring the operative site, carefully monitoring vital signs and level of consciousness, and following specific standards for the particular procedure.

Because the length of stay for these patients is generally short, keen assessment skills are important to handle issues before discharge. Teaching within the shortened timeframe may be impeded by patients and family who are not ready to learn because of postoperative pain or the effects of anesthesia. The nurse always provides verbal and written discharge instructions and, when possible, follows up with the patient and her family after discharge to ensure that complications do not arise and that patients are following instructions.

Modified from Dziedzic ME: *Mosby's Nursing Consult: clinical updates: nursing challenges in the care of patients who undergo minimally invasive surgery—are you prepared?* Available at www.nursingconsult.com/das/stat/view/146436750-2/cup?nid=198886&;sid=857030837&summaryresults=true&SEQNO=1. PATIENT AND FAMILY EDUCATION

Gynecologic Surgery

Whenever possible, provide the patient and her caregiver with *verbal* and *written* instructions. Provide them with the phone number of the physician to call if questions arise. Use visual aids to enhance instruction. Encourage the patient to verbalize any concerns she may have regarding her condition and surgery. Misconceptions about the outcome of gynecologic surgery are common. Patients may believe that undergoing a hysterectomy will cause depression, nervousness, mental instability, weight gain, wrinkles, masculinity, and hirsutism. Provide education to correct any misconceptions, and discuss any other concerns, such as fear of death, cancer, loss of femininity and childbearing ability; pain; and changes in sexuality. Education points for common gynecologic procedures are as follows.

DILATION AND CURETTAGE OF THE UTERUS

- Take your temperature once each day for the next 2 days; if your oral temperature is more than 37.7° C (100° F), call the clinic or your physician.
- Avoid sexual intercourse, tub baths, and the use of tampons for 2 weeks to allow healing and prevent infection.
- Slight bleeding is normal. However, if bleeding is as heavy as during your normal menstrual period or if it lasts longer than 2 weeks, call your physician.
- Use a heating pad or hot water bottle to relieve abdominal cramping if it occurs.
- If procedure was performed for miscarriage, add the following:
  - Mood swings and depression are common after pregnancy loss. It can be helpful to talk to friends, family, or clergy about your loss.
  - Support groups may be helpful in the recovery period.
  - Attempts at subsequent pregnancy should be postponed until indicated by your physician.

ENDOMETRIAL ABLATION

- Spotting and vaginal drainage are normal for several days (even weeks or months) after the procedure.
- Use a heating pad or hot water bottle to relieve abdominal cramping if it occurs.
- You can return to your normal activities within 2 to 3 days.
- Avoid sexual intercourse, tub baths, and the use of tampons for 2 weeks to allow healing and prevent infection.

FIBROID EMBOLIZATION

- Eat a normal diet including fluids and fiber.
- Avoid straining during a bowel movement.
- Monitor your puncture site (groin) for any excessive swelling or redness. Slight bruising may occur, but a large area of bruising or tenderness should be reported to your physician.
- Call your physician if you have any abnormal or foul-smelling vaginal discharge.
- Do not use tampons, douche, or have vaginal intercourse for at least 4 weeks or as long as directed by your physician.

VULVECTOMY

- Avoid sexual activity for 4 to 6 weeks or as long as directed by your physician.
- Rest frequently.
- Avoid crossing your legs and sitting or standing for long periods.
- Avoid tight, constricting clothing, and wear cotton underwear.
- Keep your perineal area clean and dry. Wash perineum after each elimination, and pat dry.
- Report any swelling, redness, unusual tenderness, drainage, or foul odor of the incision site to your physician.
- Eat a well-balanced diet to promote healing.
- Elevate legs periodically to prevent pelvic congestion.

HYSTERECTOMY

- You will no longer have a period, although you may have some vaginal discharge after you go home.
- Eat foods high in protein, iron, and vitamin C to aid tissue healing; include foods with high fiber content, and drink six to eight glasses of water daily.
- Rest when tired; resume activities as comfort level permits. Avoid vigorous exercise and heavy lifting for 6 weeks. Avoid sitting for long periods. Resume driving when comfort allows or on advice from your physician.
- Avoid tub baths, intercourse, and douching until after your follow-up examination.
- When vaginal intercourse is resumed, use water-based lubricants to decrease discomfort.
- Report the following symptoms to your physician: vaginal bleeding, gastrointestinal changes, persistent postoperative symptoms (e.g., cramping, distention, change in bowel habits), and signs of wound infection (e.g., redness, swelling, heat, or pain at the incision site).
- Avoid activities that increase pelvic congestion (e.g., dancing, horseback riding, sitting for long periods) until allowed to resume by your physician.
- If your ovaries were removed you may experience symptoms of menopause, including hot flashes, night sweats, and vaginal dryness.
- Estrogen replacement therapy may be prescribed.

Surgical Interventions

VULVAR SURGERY

A variety of malignant and nonmalignant conditions may affect the vulva. Nonmalignant lesions are generally excised. The treatment of early malignant disease of the vulva is accomplished by a skinning technique, by local wide excision, or, for more multicentric or extensive lesions, by simple or radical vulvectomy. Vulvar surgery may also be indicated in the treatment of vestibulitis and vestibulodynia.

Excision of Condylomata Acuminata

Vulvar/perineal condylomata are caused by the human papillomavirus (HPV) (Figure 13-11) and may be transmitted sexually. Often these warty lesions will extend into the vaginal vault and may be aggravated by hormonal changes in pregnancy. Depending on the strain of the virus, the condition may be benign or associated with dysplasia and malignancy. Surgical treatment ranges from desiccation of the lesions with electrocoagulation to sharp excision or eradication through use of the laser. Surgical intervention is based on the type and extent of the lesions.

Simple Vulvectomy

Simple vulvectomy is removal of the labia majora and labia minora, possibly but not preferably the glans clitoris, and occasionally tissue from the perianal area. A simple vulvectomy is usually done to treat carcinoma in situ of the vulva when it is multicentric. Occasionally a vulvectomy is necessary for the treatment of either leukoplakia or intractable pruritus, especially when a skinning procedure is impractical or has failed.

Procedural Considerations. The basic vaginal instrument set is required, plus an electrosurgical unit (ESU), if desired. The nurse assists with placing the patient in the lithotomy position and performs a vaginal prep.

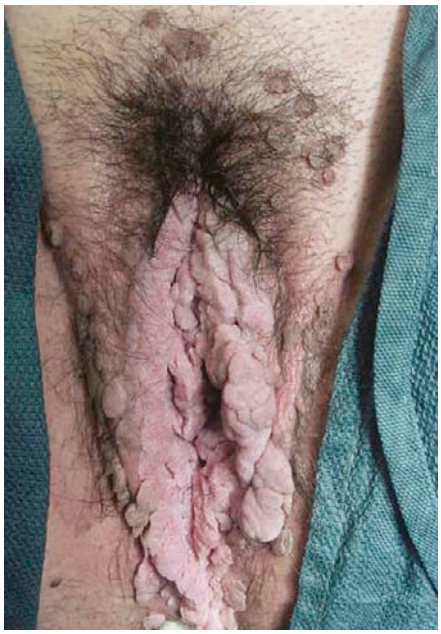

FIGURE 13-11 Condylomata acuminata.

Operative Procedure

1. The surgeon incises the affected skin, usually starting anteriorly above the clitoris. The incision is continued laterally to the labia majora, to the midline of the perineum, and around the anus, if it is involved. A knife, hemostats, gauze sponges on sponge-holding forceps, tissue forceps, and Allis forceps are needed. Bleeding vessels are clamped and electrocoagulated or ligated.
2. Periurethral and perivaginal incisions are made. Bleeding of this vascular area can be controlled by means of Kelly or Crile hemostats and the ESU. Ligation of blood vessels should be minimal. Allis-Adair forceps are used for holding diseased tissues.
3. Using curved dissecting scissors, tissue forceps, Allis forceps, and sponges on holding forceps, the surgeon undermines and mobilizes the skin and subcutaneous tissues.
4. The wound is closed, usually by simple bilateral Z-plasty. In some cases, the surgeon excises the skin around the anus to accomplish a sliding skin flap.
5. Closed-wound drainage catheters may be placed in the dependent areas, an indwelling urinary catheter is inserted, and vaginal gauze packing may be placed in the vagina. Dressings are applied.

Skinning Vulvectomy

Skinning vulvectomy is the simple removal of the external skin from the affected area, which has been previously identified with a stain such as toluidine blue. The purpose of this procedure is to preserve the underlying structures of the external genitalia. A skinning procedure may be done to treat leukoplakia, intractable pruritus, or other types of skin lesions, such as kraurosis, vitiligo, and chronic venereal granulomas.

Procedural Considerations. The instrumentation required and patient position are as described for simple vulvectomy.

Operative Procedure. The external skin is simply excised from the affected area (Figure 13-12, *A*).

Radical Vulvectomy and Groin Lymphadenectomy

Radical vulvectomy and groin lymphadenectomy are the en bloc dissection of the following structures: a large segment of skin from the abdomen and groin, the labia majora, the labia minora, the clitoris, the mons veneris, and terminal portions of the urethra, vagina, and other vulvar organs, as well as the superficial and deep inguinal nodes, portions of the round ligaments, portions of the saphenous veins, and the lesion itself. It also involves reconstruction of the vaginal walls and pelvic floor and closure of the abdominal wounds. Full-thickness pinch or split-thickness grafts may be placed if the denuded area of the vulva appears too large for normal granulation. A plastic surgeon may immediately complete skin grafts or rotation flaps to cover defects (see Chapter 21).

Radical vulvectomy and groin lymphadenectomy involve abdominoperineal dissection and groin dissection, which may be performed as a one- or two-stage operation. When performed as a one-stage operation, it is optimally done by a four-person team. The skin prep is extensive, including the abdomen and thighs; if a skin graft will be done, the donor site will also need to be prepped.

Procedural Considerations. The patient lies supine and may be placed in the Trendelenburg's and low lithotomy positions, as required for the various stages. The skin prep includes the abdomen, vulva, and thighs. An indwelling urinary catheter is often inserted to act as a urethral marker and to prevent postoperative urethral trauma. As in other radical surgery, the perioperative nurse should be prepared to measure blood loss and anticipate procedures to combat hypovolemia.

For radical vulvectomy, the basic vaginal instrument set is required, with the addition of assorted sizes of Richardson retractors, Richardson appendectomy retractors, Volkmann rake retractors, skin hooks, and closed-wound drainage systems.

For groin lymphadenectomy, the basic abdominal gynecologic instrument set is required, with the addition of Schnidt tonsil forceps, Kantrowitz thoracic clamps, ligating clips and appliers, and closed-wound drainage systems.

Operative Procedure

RADICAL VULVECTOMY

1. The skin incisions of the abdomen and thigh join with those for vulvectomy. The incisions in the vulva encircle the urethra.
2. In the vulvar dissection, the surgeon removes the terminal portions of the urethra and vagina, the mons veneris, the clitoris, the frenulum, the prepuce of the clitoris, Bartholin's and Skene's glands, and fascial coverings of the vulva with the specimen (Figure 13-12, *B*).

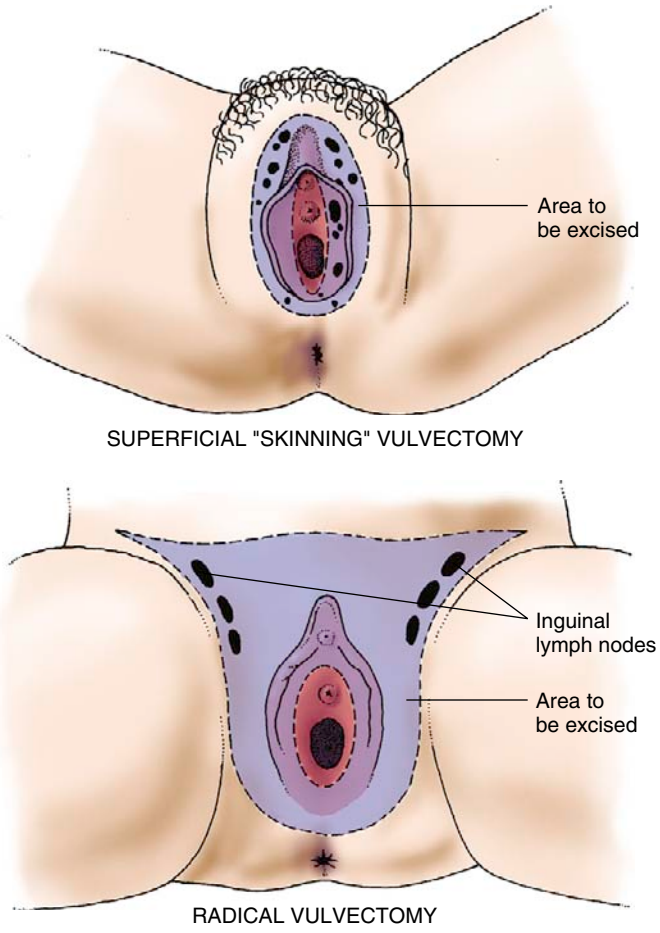

FIGURE 13-12 Outline of incisions used for (**A**) superficial skinning vulvectomy and (**B**) radical vulvectomy.

3. Reconstruction of the vaginal walls and the pelvic floor is completed.
4. An indwelling urinary catheter is inserted, closed-wound drainage catheters are placed in the denuded area, and pressure dressings are applied.

GROIN LYMPHADENECTOMY

1. The surgeon makes the first skin incision on the side opposite the primary lesion. The end of the incised skin is grasped with Allis forceps. The incision is extended to the aponeuroses of the external oblique muscle.
2. The fascia over the inguinal ligament and the fascia lata of the upper thigh are exposed, separated, and freed with retractors, knife, scissors, hemostats, and sponges.
3. Bleeding vessels, including the superficial iliac artery and vein, the epigastric artery and vein, and the superficial external pudendal artery and vein, are clamped and ligated. Smaller bleeding vessels are controlled with the ESU.
4. Using Metzenbaum scissors, tissue forceps without teeth, and long-bladed retractors the surgeon resects the fibers of the inguinal, hypogastric, and femoral nerves.
5. The lymphatic node beds may be identified with silk sutures or metal clips. Fine, long, sharp tissue dissection scissors are needed.
6. The large tissue surfaces are exposed for complete dissection by means of retractors and are protected by warm, moist laparotomy packs. High saphenous vein ligation is performed with scissors, forceps, and hemostats and then is doubly tied.
7. The surgeon cleans the femoral canal of its lymphatics; the round ligament is clamped, cut, and ligated.
8. The peritoneum is freed from the muscles; the fascia is dissected free; deep lymphatic nodes and areolar tissue are removed; and vessels and their attachments are clamped, cut, and ligated, using long curved scissors, long tissue forceps, hemostats, and ligatures.
9. The surgeon removes the lesion. In deep pelvic lymphadenectomy, the ureter may be exposed and the area drained. In some instances, ureteral stents are placed; if that is necessary, cystoscopy instrumentation is required.
10. The inguinal canal is reconstructed, the wound closed with nonabsorbable suture, and dressings applied.
11. An indwelling urethral catheter is inserted before the patient is transferred to the PACU.

Vestibulectomy and Vestibuloplasty

Vestibulodynia is defined as severe pain or burning on vestibular touch or attempted vaginal entry or tenderness localized within the vulvar vestibule. It is often associated with erythema of varying degrees (vestibulitis) (Katz, 2007). Surgical intervention is often successful in relieving the symptoms associated with the condition.

Procedural Considerations. The instrumentation required and patient position are as described for simple vulvectomy. Before the administration of the anesthetic agent, the patient identifies the painful areas of the vestibule in response to pressure from a cotton-tipped applicator. The surgeon may mark these areas with a sterile skin marker.

Operative Procedure. For vestibulectomy, the surgeon uses a #15 blade to excise the vulvar area identified by the patient,

carefully avoiding injury to the urethra. The mucosa of the hymen is removed, and the surgeon closes the mucosa and subcutaneous tissue with interrupted absorbable suture. For vestibuloplasty, the procedure is the same but closure is accomplished by advancing a vaginal flap and suturing it to the excision line.

GYNECOLOGIC SURGERY USING VAGINAL APPROACH

Plastic Reconstructive Repair of the Vagina (Anterior and Posterior Repair; Colporrhaphy)

A vaginal repair is done to correct a cystocele or a rectocele and to reestablish the support of the anterior and posterior vaginal walls, restoring the bladder and rectum to their normal positions.

A cystocele is a herniation of the bladder that causes the anterior vaginal wall to bulge downward (Figure 13-13). A defect in the anterior vaginal wall is usually caused by obstetric or surgical trauma, advanced age, or an inherent weakness. A large protrusion may cause a sensation of pressure in the vagina or present a mass at or through the introitus; it may also cause voiding difficulties.

A rectocele occurs when the anterior rectal wall (posterior vaginal wall) protrudes into the vagina. In general, the anterior rectal wall forms a bulging mass beneath the posterior vaginal mucosa (Figure 13-14). As the mass pushes downward into the lower vaginal canal, the rectum may be torn from the fascial and muscular attachments of the urogenital diaphragm and the pelvic wall. The levator ani muscles become stretched or torn. The patient may present with a mass protruding into the vagina, difficulty in evacuating the lower bowel, hemorrhoids, and a feeling of pressure.

An enterocele is a herniation of the pouch and almost always contains loops of the small intestine. An enterocele herniates into a weakened area between the anterior and posterior vaginal walls.

Procedural Considerations. The procedure is done with the patient in the lithotomy position. The basic vaginal instrument set is required. A D&C may be done in conjunction with the repair. Vaginal retractors are used for exposure. The labia may be sutured to the mons pubis if the exposure is inadequate.

Operative Procedure

CYSTOCELE REPAIR

1. The bladder may be drained, or an indwelling urinary catheter or suprapubic cystostomy catheter may be inserted (surgeon's preference). Areolar tissue between the bladder and vagina at the bladder reflection is exposed. The full thickness of the vaginal wall is separated up to the bladder neck by a knife, curved scissors, tissue forceps, Allis-Adair or Allis forceps, and gauze sponges. Bleeding vessels are clamped and tied with ligatures or electrocoagulated.
2. The surgeon mobilizes the urethra and bladder neck with a knife, gauze sponges, and curved scissors.
3. Sutures are placed adjacent to the urethra and bladder neck in such a manner that, after they have been tied, the bladder neck and the posterior urethrovesical angle are narrowed (Figure 13-15, *A*).
4. The surgeon sutures the connective tissue on the lateral aspects of the cervix into the cervix to shorten the cardinal ligaments.
5. Allis-Adair forceps are applied to the edges of the incision, and the left flap of the vaginal wall is drawn across the midline. Edges are trimmed according to the size of the cystocele. The surgeon repeats the process on the right flap of the vaginal incision.

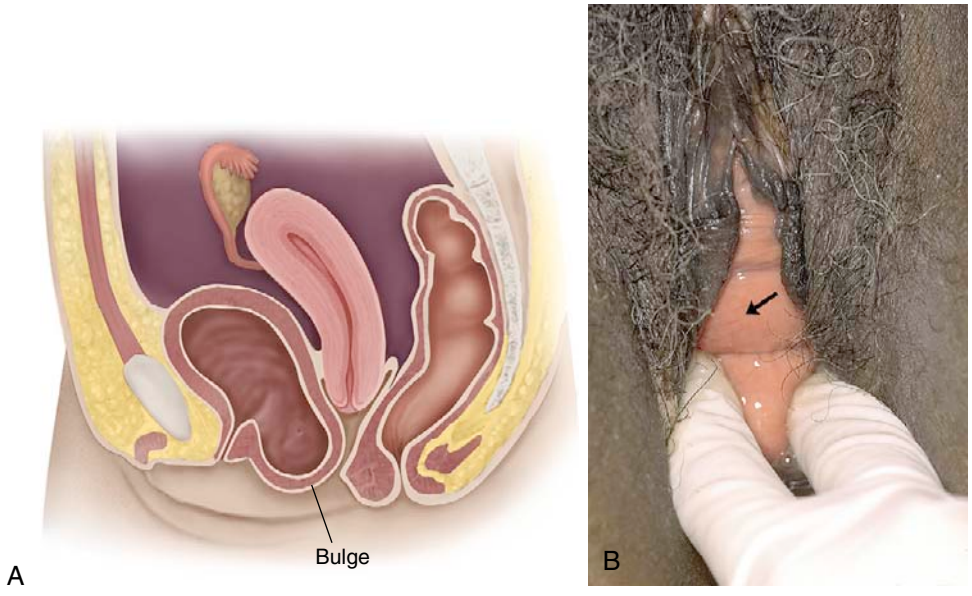

FIGURE 13-13 **A**, Cystocele resulting from unrepaired tears of muscles of pelvic floor and those under bladder, usually resulting from childbirth, surgical trauma, advanced age, or inherent weakness. **B**, Cystocele *(arrow)*.

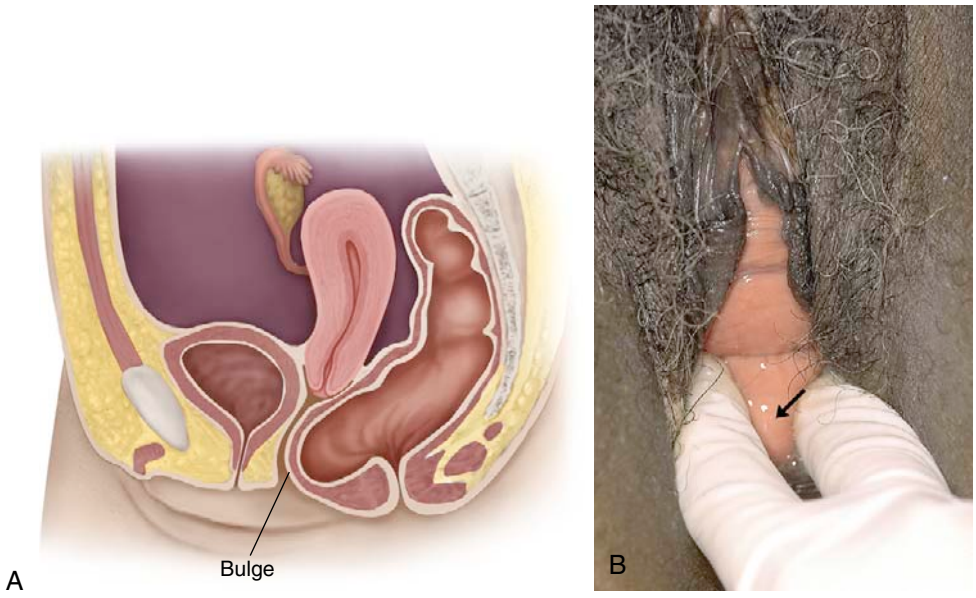

FIGURE 13-14 **A**, Rectocele resulting from unrepaired tears of muscles of pelvic floor and those under bladder, usually resulting from childbirth, surgical trauma, advanced age, or inherent weakness. **B**, Rectocele *(arrow)*.

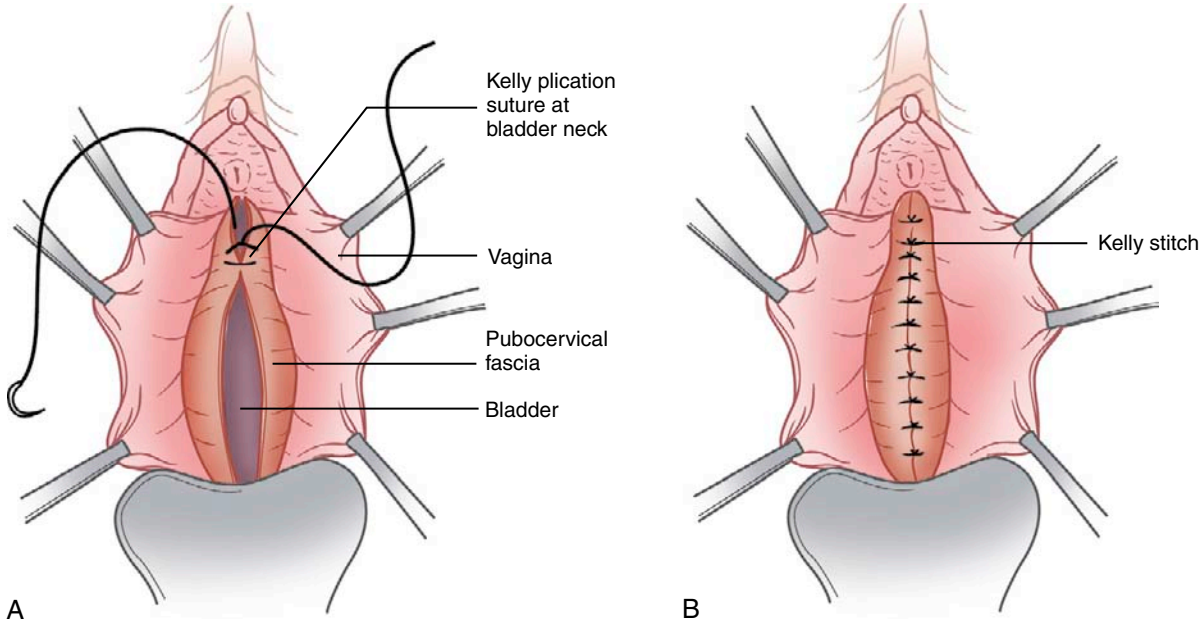

FIGURE 13-15 Cystocele repair. **A**, The placement of a Kelly stitch in the pubocervical fascia at the junction of the urethra with the bladder neck. **B**, The repair of the cystocele as the pubocervical fascia is sutured. Thus the cystocele is plicated.

6. The anterior vaginal wall is closed in a manner resulting in reconstruction of an anterior vaginal fornix (Figure 13-15, *B*). Cystoscopy instrumentation may be required to evaluate the integrity of the urethra and ureteral orifices.

RECTOCELE REPAIR

1. The surgeon places Allis forceps posteriorly at the mucocutaneous junction on each side, at the hymenal ring, and just above the anus (Figure 13-16, *A*).
2. Skin and mucosa are incised and dissected from the muscles beneath with a knife, tissue forceps, curved scissors, and gauze sponges.
3. Allis-Adair forceps are placed on the posterior vaginal wall, scar tissue (from obstetric trauma) is removed, and the surgeon continues the dissection to the posterior vaginal fornix and laterally, depending on the size of the rectocele (Figure 13-16, *A* and *B*).

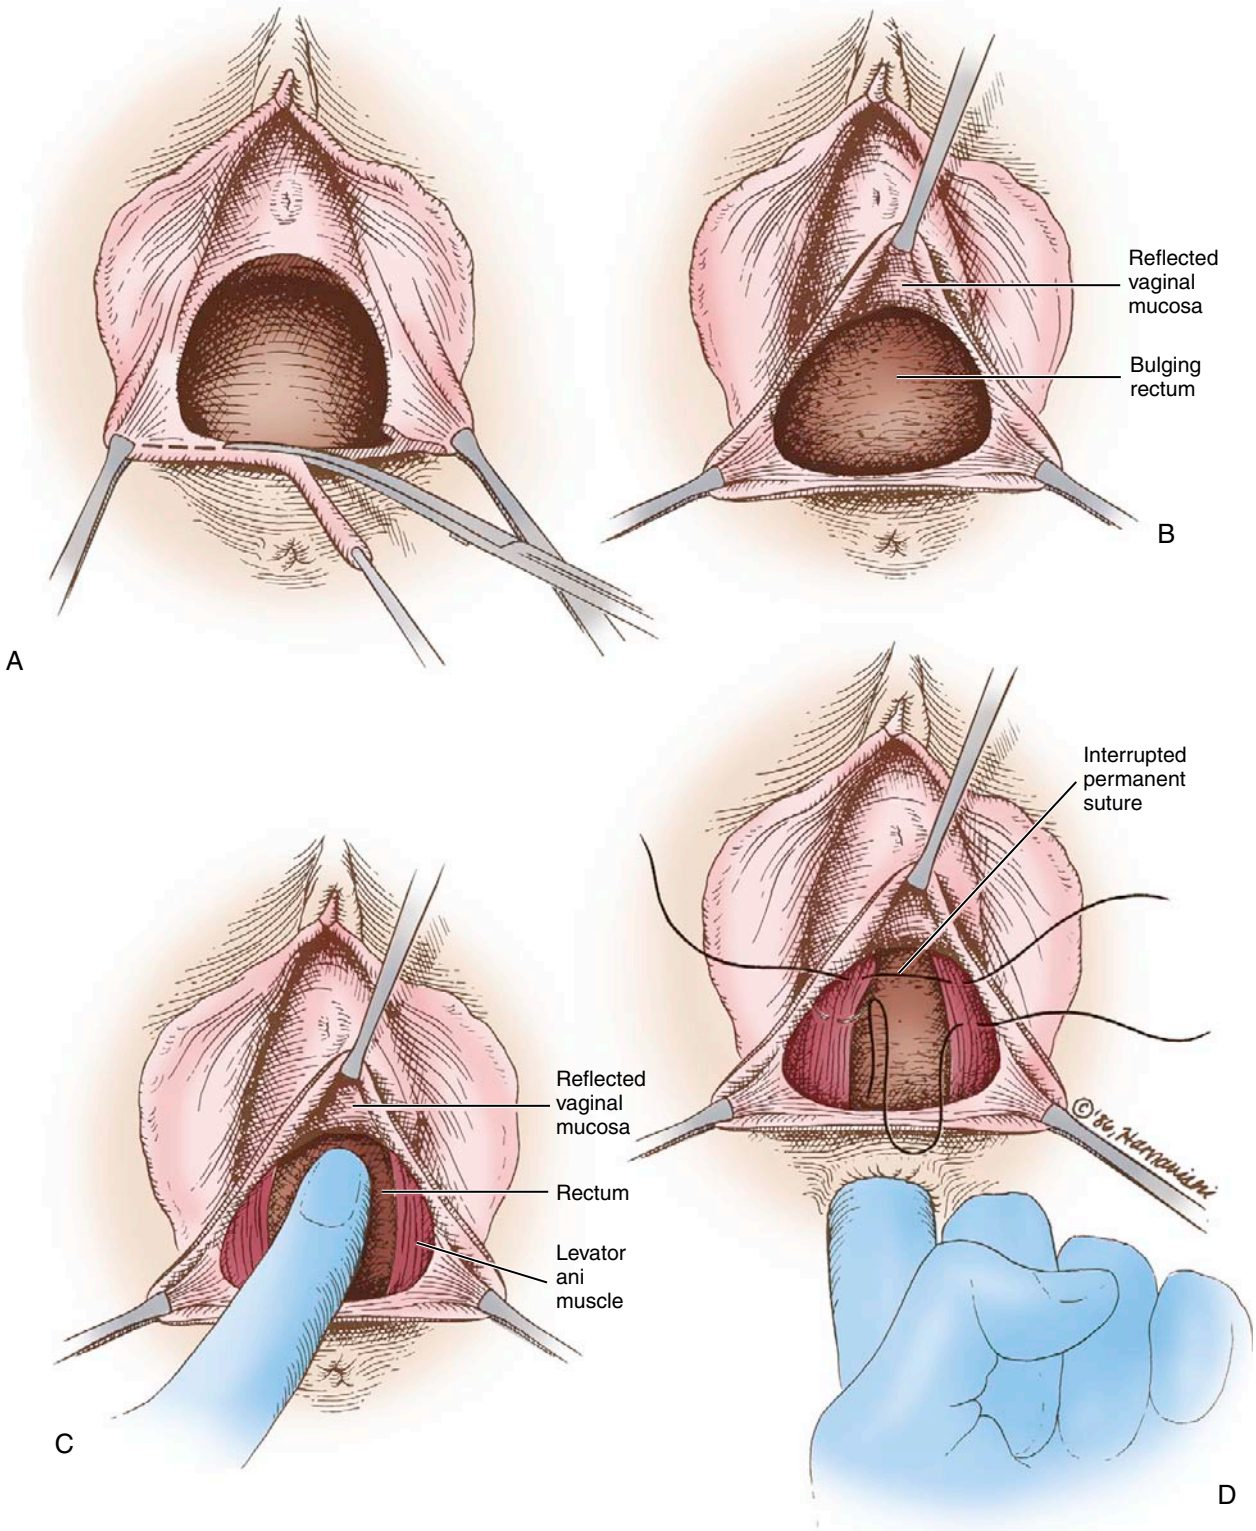

FIGURE 13-16 Rectocele repair. **A**, Placement of Allis clamps at margins of perineal incision; perineal incision is being made. **B**, Reflected vaginal mucosa with rectum bulging. **C**, Depression of rectum identifying margins of levator ani muscle. **D**, Placement of sutures in perirectal tissue and levator ani bundles.

4. The perineum is denuded by sharp dissection, and the trimming of the posterior vaginal wall is carried out with Allis forceps and curved scissors (Figure 13-16, *C*).
5. The rectal wall proximal to the puborectal muscle is strengthened by placement of sutures.
6. Bleeding is controlled, and the surgeon closes the vaginal wall from above, downward to the anterior edge of the puborectal muscle. The rectocele is repaired from the posterior fornix to the perineal body. Remains of the transverse perineal and bulbocavernosus muscles are used to augment the perineum. The anterior edge of the levator ani muscle may be approximated (Figure 13-16, *D*).
7. The mucosa and skin are trimmed, and the remaining closure is performed with interrupted sutures.
8. The vagina may be packed with 2-inch vaginal gauze packing to which antibiotic or antifungal cream may be added. An indwelling urinary catheter or suprapubic cystostomy catheter is inserted, according to the surgeon's preference.

The surgeon will require an additional pair of sterile gloves if a rectal digital exam is performed during the procedure.

ENTEROCELE REPAIR. The procedure is illustrated in Figure 13-17. The peritoneal sac must be carefully dissected from the underlying rectum, the overlying bladder, or both, so that the peritoneal tissues are completely freed from the surrounding structures. The sac is opened to establish true identification and is then closed as high as possible by permanent purse-string sutures. The portion of peritoneal tissue distal to the purse-string ties is then excised, and the area is reinforced locally by transverse suture closures using any available supportive tissues. This technique is used to prevent recurrence.

PERINEAL REPAIR. The procedure is illustrated in Figure 13-18.

VESICOVAGINAL FISTULA REPAIR. A vesicovaginal fistula (a communication between the urinary bladder and the vagina) is repaired by free dissection of the mucosal tissue of the anterior vaginal wall, closing of the fistula tract, and repair of the fascial attachments between the bladder and vagina, with establishment of urinary drainage. Fistulas vary in size from a small opening that permits only slight leakage of urine into the vagina to a large opening that permits all urine to pass into the vagina (Figure 13-19). They may result from radiation therapy, radical surgery for the management of pelvic cancer, chronic ulceration of the vaginal structures, penetrating wounds, or obstetric trauma.

Vesicovaginal Fistula Repair (Transperitoneal Approach)

Procedural Considerations. In the presence of a high vesicovaginal fistula, a suprapubic incision is used. The opening from the bladder into the vagina is closed, and the fascial attachments are repaired.

The patient is supine with a slight Trendelenburg's angle. Ureteral catheters may be inserted just before surgery (see Chapter 14). An abdominal gynecologic instrument set is required. The vagina is cleansed and may be packed with moist gauze saturated with an antibiotic or antimicrobial solution before the abdominal site is prepped.

Operative Procedure

1. The surgeon makes a midline abdominal incision, as described for laparotomy.
2. The fistulous tract is identified; the vaginal vault and the adjacent adherent bladder are separated using scissors, forceps, and sponges.
3. The vesicovaginal septum is dissected down to healthy tissue beyond the site of the fistula.
4. The fistulous tract is mobilized. The bladder site of the fistula is inverted into the interior of the bladder with two rows of inverting sutures. The muscularis and mucosa layers of the vagina are inverted into the vaginal vault by means of two rows of sutures.
5. Flaps of peritoneum are mobilized, both from the bladder and from the adjacent vaginal vault, and closed to form a new vesicovaginal reflection of peritoneum below the site of the old fistulous tract.
6. The surgeon closes the wound in layers, as for laparotomy. Abdominal dressings are applied.

URETHROVAGINAL FISTULA REPAIR (VAGINAL APPROACH). A urethrovaginal fistula (a communication between the urethra and the vagina) usually causes constant incontinence or difficulty in retaining urine. This condition occurs after damage to the anterior wall and bladder, radiation therapy, or parturition.

Procedural Considerations. The basic vaginal instrument set is required, with the addition of Kelly fistula scissors, dressing forceps, probes, skin hooks, Frazier suction tips, urethral catheters, and sterile water for irrigation. The patient is in the lithotomy position; the perioperative nurse seeks assistance during positioning to safely raise and lower the patient's legs simultaneously to prevent injury.

Operative Procedure

1. After traction sutures are placed around the fistulous tract, the surgeon grasps the tissues with Allis-Adair forceps and plain tissue forceps.
2. The surgeon excises scar tissue around the fistula, locates the cleavage between the bladder and vagina, and mobilizes the flaps using scissors, forceps, and gauze sponges.
3. The bladder mucosa is inverted toward the interior of the bladder with interrupted sutures. The sutures are passed through the muscularis of the bladder down to the mucosa.
4. A second layer of inverting sutures is placed in the bladder and tied, thereby completely inverting the bladder mucosa toward the interior.
5. The surgeon closes the vaginal wall with interrupted sutures in a direction opposite the closure of the bladder wall.
6. The bladder is distended with sterile saline to determine any leaks. An indwelling urinary catheter is inserted.

URETEROVAGINAL FISTULA. A ureterovaginal fistula (a communication between the distal ureter and the vagina) develops as a result of injury to the ureter. In some cases, reimplantation of the ureter in the bladder or ureterostomy may be done.

RECTOVAGINAL FISTULA REPAIR (VAGINAL APPROACH). Rectovaginal fistula repair by the vaginal approach includes repair of the perineum, fascia, and muscle-supporting structures between the rectum and vagina, thereby closing the fistula formed between the rectum and the vagina (Figure 13-20). In the presence of a large rectovaginal fistula, as in patients who have incurable cancer, a colostomy may be performed (see Chapter 10). The surgeon will require an additional pair of sterile gloves if a rectal digital exam is performed during the procedure.

Procedural Considerations. The basic vaginal instrument set is required for a rectovaginal fistula repair. The patient is placed in the lithotomy position.

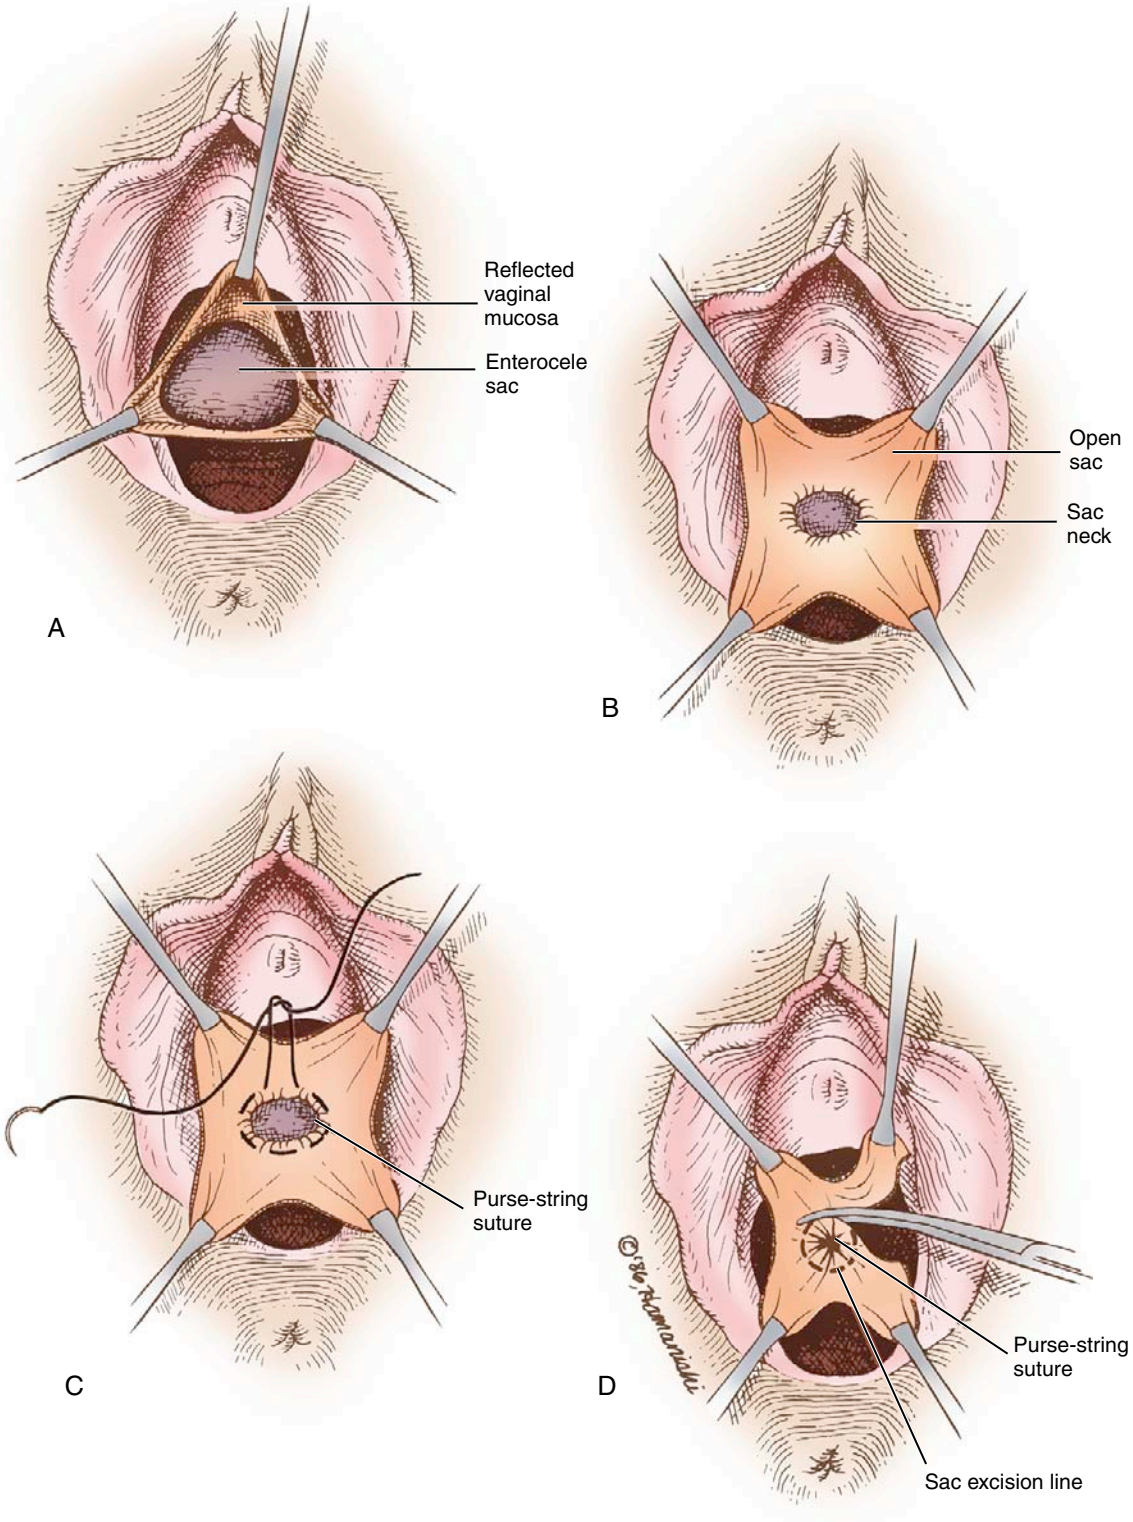

FIGURE 13-17 Enterocele repair. **A**, Appearance of enterocele sac with vaginal wall reflected. **B**, Appearance of open enterocele sac with sac neck identified. **C**, Placement of purse-string suture at neck of enterocele sac. **D**, Excision of enterocele sac.

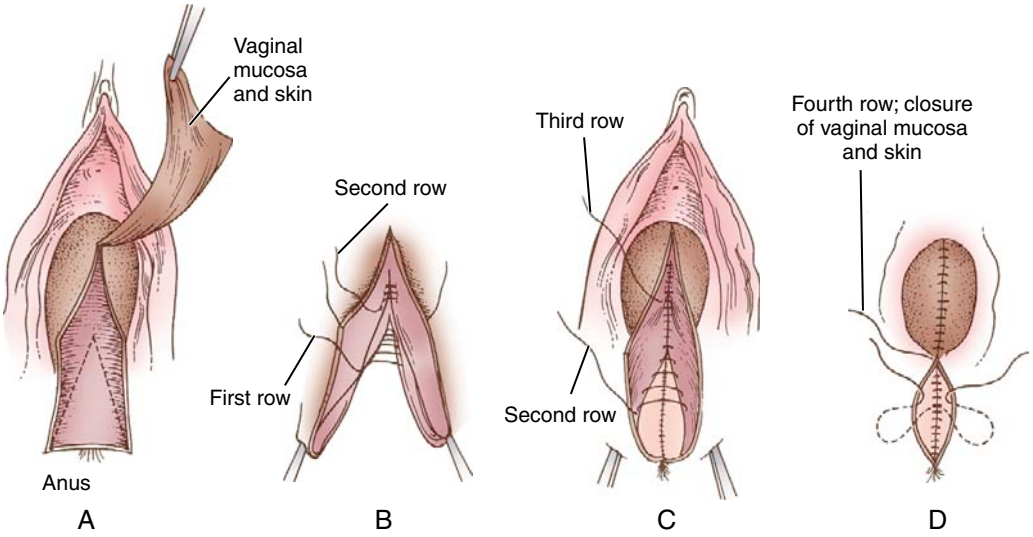

FIGURE 13-18 Repair of complete lacerations of the perineum. **A**, Lower margins of incision. **B**, Placement of first and second rows of sutures. **C**, Second and third rows of sutures. **D**, Fourth row of sutures.

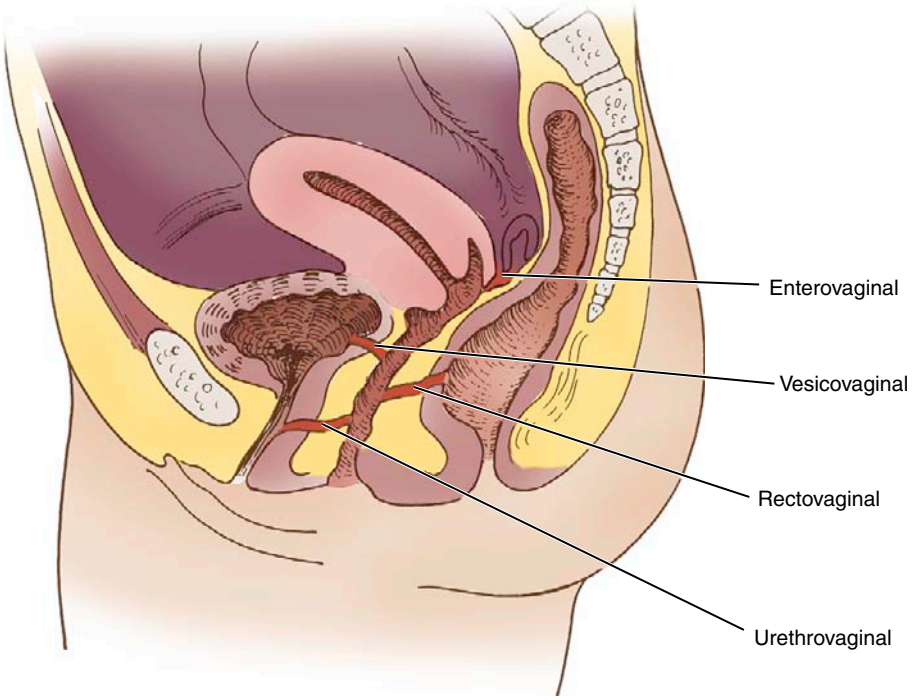

FIGURE 13-19 Genital fistulas may present as communications between the urethra, bladder, one of the ureters, or the bowel and some part of the genital tract. Two of the most common types are urethrovaginal and vesicovaginal, both of which empty into the vaginal canal.

Operative Procedure

1. The surgeon excises the scar tissue and tract between the rectum and vagina (Figure 13-21); edges of fresh tissue are approximated with absorbable sutures.
2. The rectum and vaginal walls are mobilized; the rectum is closed with inversion of the mucosa into the rectal canal.
3. The vagina is closed transversely or in a sagittal plane different from that of the rectal canal. The vaginal mucosal layer is inverted into the vaginal wall; an indwelling urinary catheter is inserted.

Operations for Urinary Stress Incontinence

Urinary incontinence describes the involuntary loss of urine. The three main types of incontinence include stress urinary incontinence (SUI), urge urinary incontinence (UUI), and mixed incontinence (MI), which describes the presence of both types of urinary incontinence simultaneously. Normal micturition depends on a finely coordinated group of voluntary and involuntary movements. As a result of volitional impulses, voiding may be inhibited or stopped by the intrinsic muscles

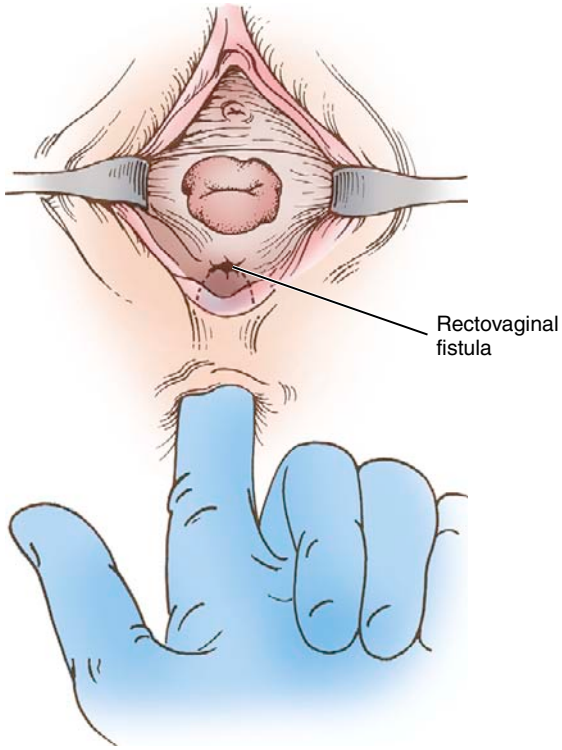

FIGURE 13-20 Rectovaginal fistula. Examiner's finger puts tension on rectovaginal septum.

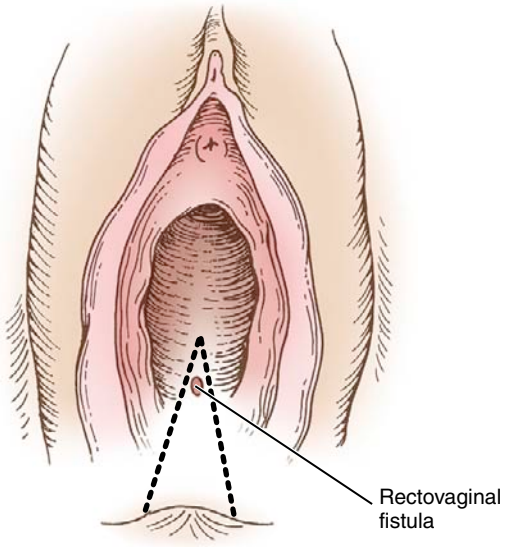

FIGURE 13-21 Repair of rectovaginal fistulas of all types is essentially the same as shown here. Portion of scar tissue to be excised is included within dotted lines; repair is as described for complete lacerations of perineum (see Figure 13-18).

of the bladder neck and proximal urethra and the puborectalis division of the levator ani muscle (see Chapter 14).

Previous pelvic procedures may have resulted in scarring and distortion, with displacement of the bladder neck. Conditions such as uterine prolapse, cystocele, urethrocele, cystourethrocele, or urogenital fistulas after radiation therapy may be associated with stress incontinence.

The type of operation selected depends on the severity of stress incontinence, the extent of the condition causing it, the patient's ability to use the anatomic mechanism for voluntary inhibition of urination, and any procedures that have previously been performed. States of stress incontinence are classified in relation to frequency and degree of incontinence, the presence of other diseases, and the function of the pubococcygeal muscle (levator ani). Surgery for urinary stress incontinence entails repair of the fascial supports and the pubococcygeal muscle surrounding the urethra and the bladder neck. This repair is performed through either a vaginal or an abdominal approach. In recent years, retropubic and transobturator suburethral tape has become important in the treatment of stress incontinence (Aschkenazi and Goldberg, 2009).

The desired outcome of any operation for urinary stress incontinence is to improve the performance of a dislodged or dysfunctional vesical neck, to restore normal urethral length, and to tighten and restore the anterior urethral vesical angle.

Operative Procedure

VAGINAL APPROACH

1. An indwelling urinary catheter or suprapubic cystostomy catheter is inserted, according to the surgeon's preference. The posterior vaginal wall is retracted, and the surgeon makes an incision through the anterior vaginal wall down to the urethra and bladder.
2. The vaginal wall is dissected from the bladder and urethra; the neck of the bladder is sutured together. The wound is closed as described for anterior vaginal wall repair.

VESICOURETHRAL SUSPENSION. The Marshall-Marchetti-Krantz procedure is fully described in Chapter 14. Basic steps of the procedure follow:

1. The surgeon enters the space of Retzius through a suprapubic abdominal incision, and frees the bladder and urethra from the underlying structures.
2. Mattress sutures are inserted through the perivaginal fascia on either side of the vesicourethral angle area and preferably at a right angle to the long axis of the urethra and bladder. These are then passed through the central portion of the undersurface of the symphysis pubis under direct vision. The application of the sutures to the perivaginal connective tissue is done with the surgeon's hand in the vagina to ensure that the suture material is not passed through the vaginal mucosa.
3. The wound is closed and may be drained if the vascularity of the area warrants. An abdominal dressing is applied.

Construction of a Vagina

Two basic approaches are used for repairing or overcoming a congenital or surgical defect of the vagina: obtaining a skin graft, which is applied to a mold and placed in the area of vaginal reconstruction; or making a simple opening in the area of vaginal reconstruction and placing a mold to permit spontaneous epithelialization of the area.

Procedural Considerations. For a skin graft, the plastic surgery instrument set (see Chapter 21) is required, with the addition of a dermatome, marking pen, and nonadherent gauze dressing. For vaginal construction, the basic vaginal instrument set is required, with the addition of iris scissors, skin hooks, a vaginal mold, Halsted mosquito hemostats, and a ruler.

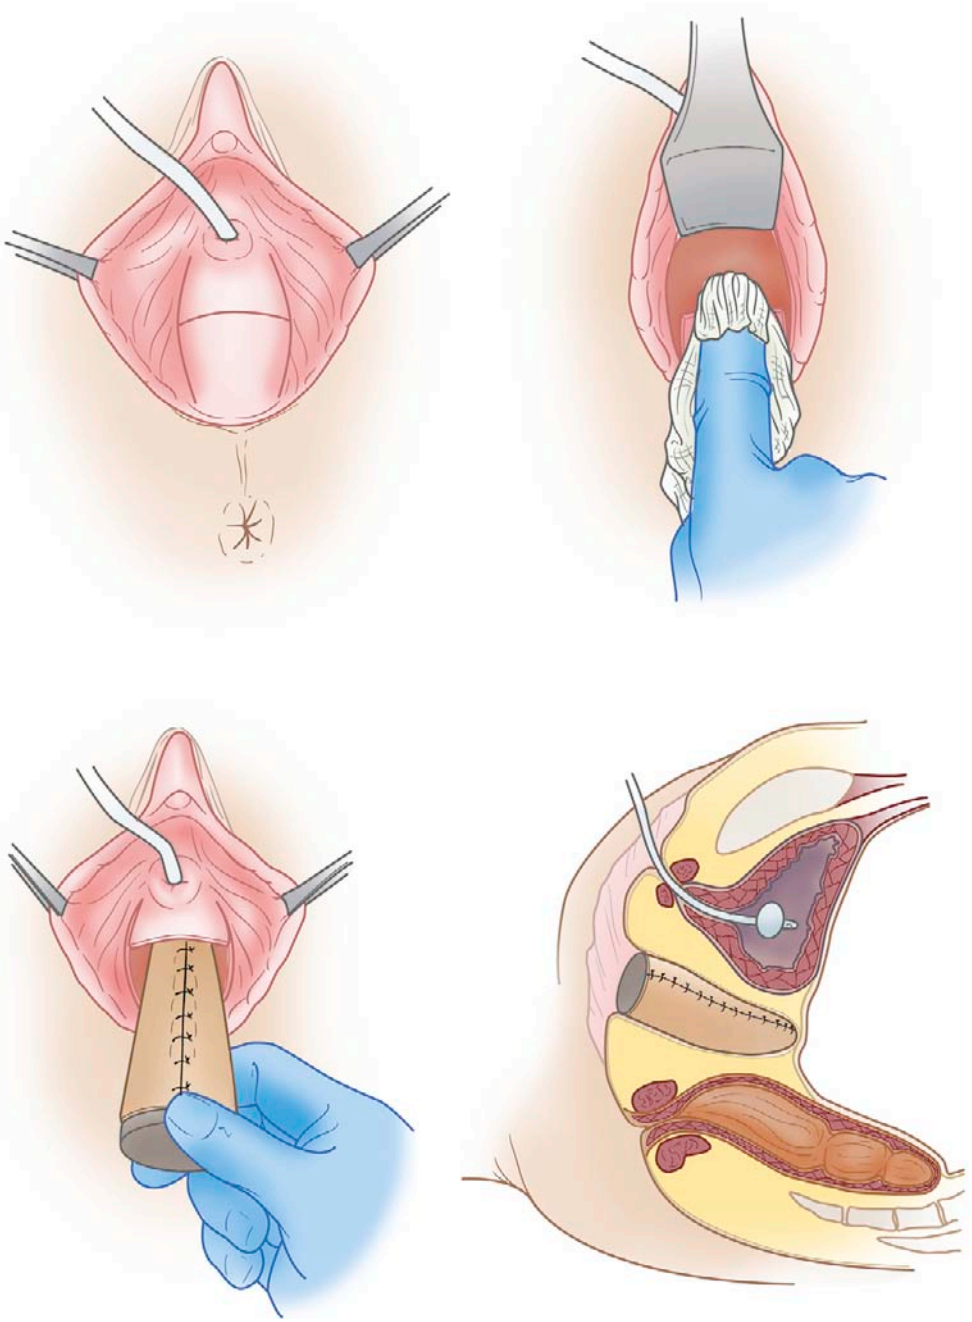

FIGURE 13-22 Vaginal reconstruction using split-thickness skin graft.

Operative Procedure

1. The skin graft is taken from the abdomen or anterior area of the thigh. The donor site is dressed in the routine manner with nonadherent gauze and a pressure dressing.
2. The skin graft is kept in a moist gauze sponge until it is ready to be used.
3. The surgeon uses sharp dissection to create a vaginal orifice, taking care to prevent damage to the rectum and bladder. A mold is used to apply the donor skin or simply to hold the dissected area open to permit spontaneous epithelialization (Figure 13-22).

Trachelorrhaphy

Trachelorrhaphy is removal of torn surfaces of the anterior and posterior cervical lips and reconstruction of the cervical canal. It is performed to treat deep lacerations of a cervix that is relatively free from infection.

Procedural Considerations. The basic vaginal instrument set is required, plus the ESU and a conization loop electrode, if desired. An indwelling urinary catheter may be inserted into the bladder, depending on the surgeon's preference. The patient is in the lithotomy position.

BOX 13-2

Supporting Patients through Miscarriage or Stillbirth

A diagnosis of pregnancy is often a joyous occasion; however, many women can experience perinatal loss, which is defined as ectopic pregnancy, miscarriage, or fetal death. Miscarriage occurs in approximately 15% of all pregnancies, and approximately 5 of every 1000 births result in stillbirth or fetal death (e.g., those occurring after 20 weeks of gestation). The primary cause of miscarriage and infant death is birth defects (127.6 per 100,000 births). Perinatal loss may occur with little or no advance warning for the mother, and unfamiliar and invasive procedures at this time can increase the woman's sense of vulnerability. The perioperative nurse can play a sensitive and supportive role when providing care for patients who present to the OR with miscarriage or cesarean section for stillbirth.

By definition, a miscarriage is a pregnancy loss that occurs before 20 weeks of gestation. In the United States, state laws often stipulate that, in addition, the weight of the fetus is less than 350 g and signs of life are absent. Abortion is the medical term used for both spontaneous and elective pregnancy termination occurring before 20 weeks of gestation. Terms used to identify the diagnosis should also be carefully chosen. Many women find the term abortion harsh and unkind when referring to spontaneous events. Some may feel insulted or misunderstood, believing that abortion refers only to an elective procedure. The term miscarriage is more neutral and should be used consistently for early loss. Products of conception are better referred to as tissue and the embryo or fetus as baby. For infant death, the nurse should use the words "dead and died" rather than "lost." The nurse should also avoid the use of clinical terminology as this may convey a lack of sincere feeling on the part of the caregiver.

When discussing perinatal loss with a woman, the nurse may want to initiate the conversation by referring to the pregnancy and listening for the patient's use of either the terms pregnancy or baby when referring to the loss. The nurse's neutrality encourages the woman to express her feelings without being encumbered by what she "should" do and what she "should" feel and eliminates the perceived expectations negatively influencing the woman. Additional tips for communicating with parents include the use of phrases and open-ended questions such as follows:

- "I am sad for you."
- "How are you coping with all of this?"
- "I am sorry for your loss."
- "I am here, and I want to listen."
- "What can I do for you?"

The following phrases should be avoided:

- "Be thankful you have another child."
- "I know how you feel."
- "You have to keep going."
- "You're young and you can have others."
- "Better for this to happen now, before you knew the baby."
- "There was something wrong with the baby anyway."

Accessed June 28, 2009.

Operative Procedure

1. The labia may be retracted with Allis-Adair tissue forceps or sutures. The surgeon grasps the cervix with a tenaculum.
2. The tissue of the exocervix is denuded with a knife. Using sharp dissection, the surgeon undermines the flaps. Bleeding vessels are clamped and ligated. The mucosa is dissected from the cervix.
3. A small distal portion of the cervical canal is coned with a knife or a loop electrode to remove tissue. Bleeding vessels are clamped and ligated.
4. The denuded and coned areas are covered by transversely suturing the mucosal flaps of the exocervix, using interrupted sutures. Tissue forceps, hemostats, and gauze sponges are needed. The sutures are placed in such a manner that the fibromuscular tissue of the cervix is included, thereby eliminating dead space where a hematoma may form, and providing a complete reconstructed cervical canal.
5. A vaginal pack may be inserted. A perineal pad is applied.

Dilation of the Cervix and Curettage (D&C)

D&C is done either for diagnostic purposes or as a form of therapy for a variety of pelvic conditions, such as abnormal uterine bleeding, or primary dysmenorrhea. D&C may also be performed when carcinoma of the endometrium is suspected, in the study of infertility, before amputation of the cervix, or before surgery for a prolapsed uterus. A common indication for D&C is incomplete abortion (e.g., miscarriage), or therapeutic abortion. The perioperative nurse should be especially sensitive to the emotional needs of a patient experiencing a miscarriage (Box 13-2).

Procedural Considerations. In D&C, instruments are introduced through the vagina for the purpose of dilating the cervix. Dilation of the cervix can also take place by inserting laminaria tents into the cervical os before surgery; these tents are removed immediately before the procedure. The patient is in the lithotomy position for this procedure; the perioperative nurse ensures assistance is available for positioning.

Operative Procedure

1. The surgeon places a Jackson or Auvard weighted speculum in the vagina. A Sims or Deaver retractor is placed anteriorly to expose the cervix. The anterior lip of the cervix is grasped with a tenaculum (Figure 13-23).
2. The direction of the cervical canal and the depth of the uterine cavity are determined by means of a blunt probe or graduated uterine sound.
3. The surgeon dilates the cervix using graduated Hegar or Hank dilators and/or a Goodell uterine dilator.
4. Exploration for pedunculated polyps or myomas may be done with a polyp forcep.
5. Using a sharp curette the surgeon scrapes the interior of the cervical canal and uterine cavity to obtain either a fractional or a routine specimen. For specific identification of the site of specimens, the endocervix is scraped with the curette first, and the specimen is separated from the curetted matter

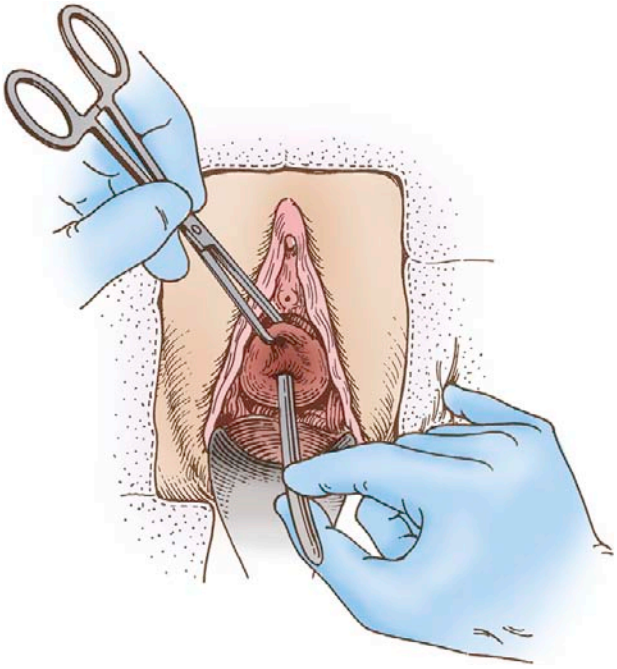

FIGURE 13-23 Dilation of cervix and curettage. Vaginal wall retracted; cervix held by tenaculum; cervix dilated with dilator. Uterine cavity curetted with sharp curettes.

of the uterine endometrium. In a routine curettage, all curetted matter is sent together for identification of tissue cells.

6. Fragments of endometrium or other dislodged tissues may be removed with warm, moist gauze sponges on sponge-holding forceps or with a teaspoon.
7. The surgeon may take multiple punch biopsies of the cervical circumference (at the 3, 6, 9, and 12 o'clock positions) with a Gaylor biopsy forceps to supplement the diagnostic studies.
8. Retractors are withdrawn; iodoform or plain gauze packing may be inserted into the uterus, using dressing forceps. The tenaculum is removed from the cervix. A vaginal pack may be inserted. A perineal pad is applied.

Suction Curettage

Suction curettage is vacuum aspiration of the uterine contents. Aspiration has proved to be a safe and effective method for early termination of pregnancy and for use in missed and incomplete spontaneous abortions. Advantages are smaller dilation of the cervix, less damage to the uterus, less blood loss, less chance of uterine perforation, and reduced danger of infection. Laminaria tents may be inserted approximately 4 to 24 hours before suction curettage to dilate the cervix; they are removed before the surgical prep begins. Suction curettage is the treatment of choice for benign gestational trophoblastic neoplasia, more commonly known as hydatidiform mole. Hydatidiform mole is a condition that arises from fertilization by the sperm in a defective egg that has no nucleus or fertilization of the egg by two sperm. This results in the synthesis of material that is termed a mole and consists of multiple fluid-filled vesicles resembling a cluster of grapes (Figure 13-24).

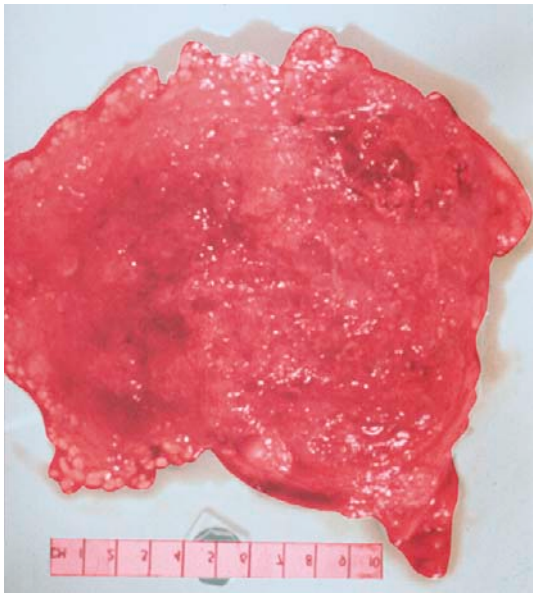

FIGURE 13-24 Hydatidiform mole. Note vesicles have appearance of grapes.

Procedural Considerations. The instrumentation required includes the D&C set, with the addition of one set of Pratt, Hawkin, or Hank uterine dilators, placenta forceps, urethral catheter, sterile cannulae, aspirator tubing, a vacuum aspirator unit, and oxytocic drugs. The patient will be in the lithotomy position.

Operative Procedure

1. The surgeon exposes the cervix with an Auvard weighted speculum and an anterior retractor, grasps it with a sharp tenaculum, and draws it toward the introitus.
2. The cervix is dilated, allowing 1 mm of cannula diameter for each week of pregnancy.
3. The appropriate-size cannula is inserted into the uterus until the sac is encountered. The suction is turned on with immediate disruption and aspiration of the contents. Continued gentle motion of the cannula removes the uterine contents (Figure 13-25). Use of uterine curettes may supplement suction in removing the entire uterine contents.
4. Retractors and tenaculum are removed.
5. A perineal pad is applied.

Removal of Pedunculated Cervical Myomas (Cervical Polyps)

Cervical polyps (small pedunculated lesions) stem from the endocervical canal and consist almost entirely of columnar epithelium with or without squamous metaplasia (Figure 13-26). They may vary in size and are soft, red, and friable. Bleeding may result from the slightest trauma. Pedunculated lesions may be removed by the snare method or by dissection from the cervical canal with a knife, cold-knife conization, or resectoscope. Usually the surgeon performs an endometrial and endocervical curettage, and a cytologic smear is taken.

Procedural Considerations. A D&C set, a tonsil snare with medium-size snare wire, glass slides, the ESU, and a blade electrode or resectoscope are required. The patient is in the lithotomy position.

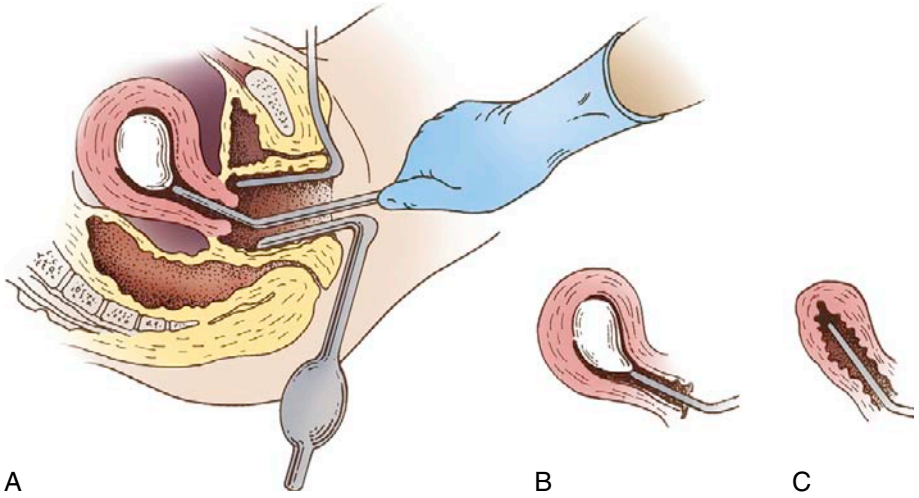

FIGURE 13-25 Suction curettage. **A**, Insertion of cannula. **B**, Gentle suction motion to aspirate contents. **C**, Uterine contents evacuated.

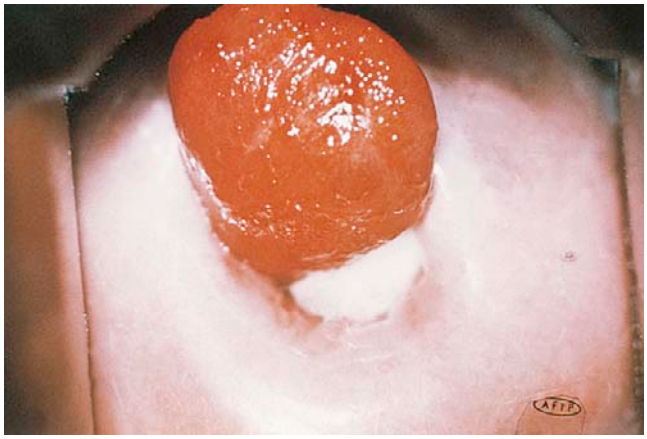

FIGURE 13-26 Cervical polyp. A large polyp protrudes from the external cervical os.

Operative Procedure

1. The surgeon grasps the anterior lip of the cervix with a Jacobs vulsellum or a tenaculum. The canal is sounded and dilated either to visualize or to palpate the base of the pedicle.
2. If the pedicle of the polyp is thin, the surgeon may place a tonsil snare over the body of the tumor, permitting the snare to crush the base of the tumor and to control bleeding. If the polyp is large, its base is dissected out with a knife. Bleeding may be controlled by the use of warm, moist gauze sponges with or without electrocoagulation. A resectoscope with the use of electrosurgery may be used to dissect the tumor.
3. Iodoform or plain gauze packing may be introduced into the cervical os. The tenaculum is removed from the cervix, and the retractors are withdrawn. A vaginal pack may be inserted for hemostasis. A perineal pad is applied.

Conization and Biopsy of the Cervix

Conization and biopsy of the cervix are generally performed for the diagnosis or treatment of cervical dysplasia. The procedure may be initiated with colposcopy and punch biopsy, followed by electrocoagulation, cryosurgery, cold-knife cone biopsy, loop electrosurgical excision cone (LEEC), or laser excisional cone.

Procedural Considerations. The instruments required include a D&C set along with an ESU or laser, conization electrical loop, and ball-tipped electrode, depending on the procedure. The patient is in the lithotomy position.

Operative Procedure

1. The surgeon retracts the posterior vaginal wall with a speculum and the anterior vaginal wall with lateral retractors. The outer portions of the cervix are grasped with a tenaculum, and the cervix is drawn toward the introitus. Cystic areas of the cervix may be treated with a needle electrode or laser. Endometrial biopsy may be done (Figure 13-27, *A*). Bleeding points are coagulated or lased.
2. The electrode is passed into the cervical canal, and the diseased tissue is treated. Ferric subsulfate (Monsel's solution) may be used for hemostasis.
3. The surgeon uses the electrical loop (Figure 13-27, *B* and *C*) or the laser to remove the diseased tissue and obtain a histologic specimen for pathologic diagnosis.
4. If a wide conization is performed, the cervix may be sutured and vaginal packing may be used. An indwelling urinary catheter may be inserted. A perineal pad is applied.

Cesium Applicator Insertion for Cervical and Endometrial Malignancy

Cesium has generally replaced radium insertions for treatment of malignancy of the cervix and endometrium.

Procedural Considerations. The patient is in the lithotomy position. The bladder is drained with an indwelling urinary catheter. The catheter balloon is inflated with a radiopaque medium for radiographic visualization after insertion of the cesium. An indwelling rectal marker is also placed by the surgeon for radiographic visualization. Various types of cesium applicators may be used according to the surgeon's preference and the area of malignancy (Figure 13-28). The cesium is

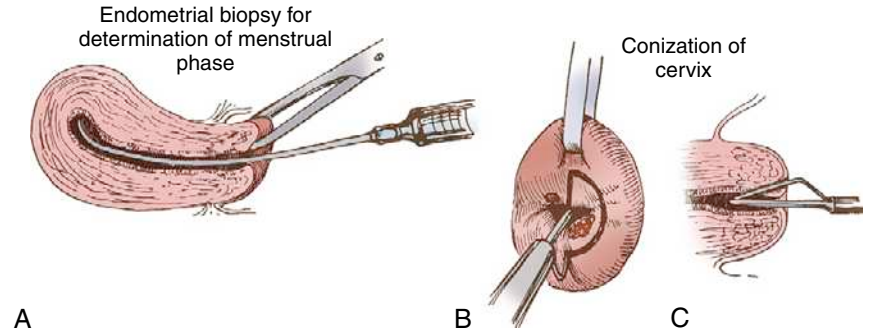

FIGURE 13-27 A, Endometrial biopsy technique. B and C, Conization loop used to treat cervical conditions or obtaining specimens for diagnostic tests.

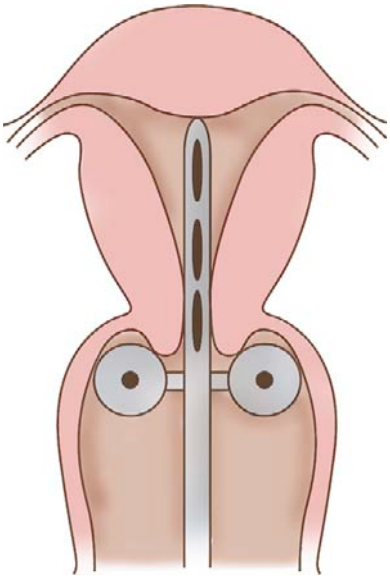

FIGURE 13-28 Intracavitary implant. Applicator in place in uterus.

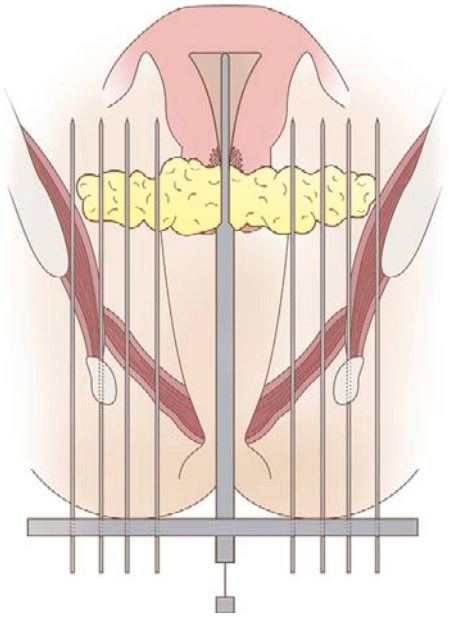

FIGURE 13-29 Interstitial intracavitary implant.

loaded into the applicators later in the radiation department or in the patient's room under controlled conditions, in which all personnel are monitored by use of a dosimeter.

Interstitial Therapy. Cesium needles are available in various lengths with small diameters for insertion into the tissue surrounding the cervix (Figure 13-29). They are inserted vaginally with a needle applicator and are used as a supplement to intravaginal or intrauterine sources. To facilitate removal, the needles have wires or threads attached to their distal ends.

Marsupialization of Bartholin Duct Cyst or Abscess

A cyst in a Bartholin gland usually follows acute infection and is treated by marsupialization. Such cysts result from retention of glandular secretions caused by blockage in the duct system (Figure 13-30). Marsupialization of a Bartholin duct cyst or abscess entails removal or incision of the cyst through the vaginal outlet and drainage of the area. In true marsupialization the cyst is surgically exteriorized by resecting the anterior wall and suturing the cut edges of the remaining cyst to the adjacent edges of the skin.

Procedural Considerations. The basic vaginal instrument set is required, with the addition of a 15-gauge needle, syringe, culture tubes (aerobic and anaerobic), iodoform or plain gauze packing, and a drain, if desired by the surgeon.

Operative Procedure

1. The labia minora may be sutured to the perineal skin on each side to expose the vaginal introitus.
2. A stellate incision is then made into the mucosa, which is distended over the cyst.
3. The surgeon dissects the cyst wall and, if indicated, removes the gland with blunt-pointed scissors. The tissue may be everted with sutures and left open. A drain or packing may be inserted, and a perineal pad is applied.

Vaginal Hysterectomy

Vaginal hysterectomy is removal of the uterus through an incision made in the vaginal wall and the pelvic cavity (History box). Contraindications to a vaginal approach are (1) a large uterine tumor, (2) a pelvic malignancy, and (3) the possibility of overlooked metastatic disease that might be present if malignancy is suspected.

HISTORY

A Historical Look at Vaginal Hysterectomy

Women undergoing vaginal hysterectomy in the 1900s did so without the benefit of technology available today. The woman was admitted to the hospital several days in advance of the planned surgical procedure. Vigorous bowel preparation and thrice-daily douches with caustic solutions were a routine preoperative preparation, as was the removal of all hair from the abdomen and genitalia.

On the day of surgery, the perioperative nurse was responsible for administering a douche before transporting the patient into the OR. After positioning the patient for the procedure, the nurse used green soap to cleanse the vulva and vaginal canal, followed by a rinse of saline and a douche of 10% creolin. The creolin was followed by an additional douche of corrosive sublimate in a 1:2000 concentration in sterile water. Using a glass catheter, the nurse ensured the patient's bladder was empty before the start of the procedure.

During the vaginal hysterectomy, the surgeon controlled the patient's bleeding with clamps or ligatures. After the uterus was removed, as many as six clamps, which were equipped with detachable handles, were left in place for hemostasis. The clamps were surrounded with a roll of iodoform gauze extending up into the vagina. A retention catheter was placed in the bladder at the end of the procedure. The catheter would be used in the postoperative period for bladder irrigations.

Before the patient returned to consciousness, the nurse tied the patient's legs together with a broad towel to prevent strain on the clamps and any ligatures that had been placed. The towel was not removed until the patient regained consciousness and was able to cooperate.

The patient was transported back to her room, with the clamps in place, experiencing considerable pain. Two days after the procedure, the perioperative nurse accompanied the surgeon to the patient's room to assist with the removal and retrieval of the clamps. The previously placed gauze packing was removed. The surgeon reattached the handles to the clamps and began removal, using a rocking motion, starting with the uppermost clamp. As the clamps were released, pieces of tissue would adhere, causing great discomfort for the patient. The nurse assisted the surgeon with repacking the patient's vagina with gauze and then returned the clamps, which were coated with rust, tissue, and secretions, to the instrument room.

The patient was allowed to sit up in bed 2 days after the clamps were removed; she was lifted to a chair on the fourth day, and began to ambulate on the fifth or sixth day.

Modified from Fowler R: *The operating room and the patient,* ed 3, St Louis, 1913, Mosby; Haubold HA: *Preparatory and after treatment in operative cases,* New York, 1910, D Appleton & Co.

FIGURE 13-30 Bartholin abscess.

Procedural Considerations. The instrumentation includes the basic vaginal instrument set with the addition of two 22-gauge needles and two 10-ml syringes. An abdominal gynecologic instrument set should be available in case laparotomy is indicated. To facilitate dissection and decrease bleeding, the vaginal walls may be infiltrated with normal saline or a local anesthetic (vasoconstrictors are optional). The patient is in the lithotomy position.

Operative Procedure

1. The labia may be retracted with sutures. The surgeon places a weighted vaginal retractor to retract the vaginal wall.
2. A Jacobs vulsellum, tenaculum, or suture ligature is placed through the cervical lips to permit traction on the cervix.
3. The surgeon incises the anterior vaginal wall with a knife through the full thickness of the wall (Figure 13-31, *A*). A circumferential saline with epinephrine injection of the submucosa may be done at this point in the procedure. The bladder is then freed from the anterior surface of the cervix by sharp and blunt dissection. The bladder is then elevated to expose the peritoneum of the anterior cul-de-sac, which is entered by sharp dissection (Figure 13-31, *B*).
4. The peritoneum of the posterior cul-de-sac is identified and incised.
5. The surgeon clamps, cuts, and ligates the uterosacral ligaments (Figure 13-31, *C* and *D*). The ends of the ligatures are left long and are tagged with a clamp.
6. The uterus is drawn downward, and the bladder is held aside with retractors and moist, small laparotomy packs.
7. The surgeon clamps, cuts, and ligates the cardinal ligaments on each side. The uterine arteries are doubly clamped, cut, and ligated.
8. The fundus is delivered with the aid of a uterine tenaculum.
9. When the ovaries are not removed, the surgeon clamps and cuts the round ligament, the utero-ovarian ligament, and the fallopian tube on each side (Figure 13-31, *E*) and removes the uterus. These pedicles are then ligated.
10. The surgeon reapproximates the peritoneum between the rectum and vagina with a continuous suture. The retroperitoneal obliteration of the cul-de-sac is accomplished by

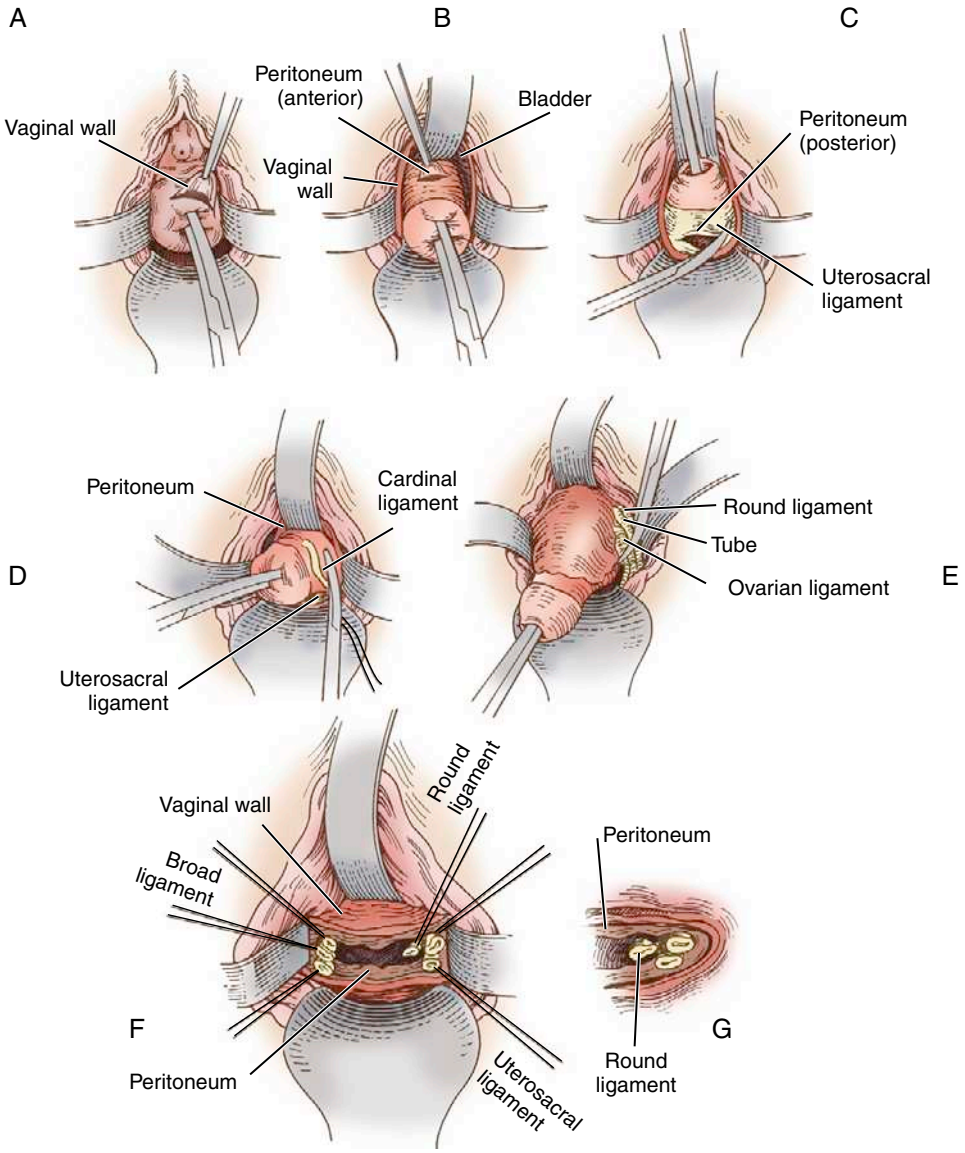

FIGURE 13-31 Vaginal hysterectomy. **A**, Incision of vaginal wall around cervix. Anterior vaginal wall slightly elevated. **B**, Deaver retractor on each side; one Deaver retractor under bladder. Peritoneum opened. **C**, Posterior cul-de-sac opened. Heaney clamp applied to left uterosacral ligament. **D**, Left uterosacral ligament cut and tied. Clamp applied to left cardinal ligament. **E**, Clamp applied to ovarian ligament, round ligament, and fallopian tube. **F**, Uterosacral ligament, broad ligament, and round ligament shown in their respective normal positions. **G**, Peritoneum closed and cardinal ligament, broad ligament, and uterosacral ligament reattached to angle of vagina. Left uterosacral and broad ligaments anchored.

passing sutures from the vaginal wall through the infundibulopelvic ligament and round ligament, through the cardinal ligament, and out the vaginal wall. The sutures are tied on the vaginal aspect of the new vault (Figure 13-31, *F* and *G*). The round, cardinal, and uterosacral ligaments may be individually approximated for additional support.

11. Any existing cystocele and rectocele and the perineum are repaired. In the presence of prolapse, reconstruction of the pelvic floor may be required.
12. An indwelling urethral or suprapubic catheter is usually inserted. The vagina may be packed, and a drain may be inserted. A perineal pad is applied.

GYNECOLOGIC SURGERY USING MINIMALLY INVASIVE TECHNIQUES

Hysteroscopy

Hysteroscopy is the endoscopic visualization of the uterine cavity and tubal orifices. The common indications for hysteroscopy include evaluation of abnormal uterine bleeding (with possible endometrial ablation), location and removal of "lost" intrauterine devices (IUDs), evaluation of infertility, diagnosis and surgical treatment of intrauterine adhesions, verification of submucous leiomyomas or endometrial polyps, resection of uterine septa or submucous leiomyomas, and tubal sterilization.

Laparoscopy may be done in association with hysteroscopy to assess the external contour of the uterus. Contraindications to either diagnostic or operative hysteroscopy include pelvic infection, cervical malignancy, and, in some instances, heavy bleeding.

A significant potential complication related to hysteroscopy is the intravasation of the fluid used to distend the uterine cavity. Intravasation can lead to hyponatremia. Signs and symptoms of hyponatremia may include bradycardia, hypertension followed by hypotension, nausea, vomiting, headache, visual disturbances, agitation, confusion, and lethargy. The perioperative nurse is responsible for accurately monitoring fluid intake and output during hysteroscopy. Monitoring may be manual (i.e., calculating the difference between inflow and outflow) or may be automatically calculated on commercially available hysteroscopy pumps, which decrease the chance of human error. Discrepancies of 500 ml or more must be communicated to the surgeon and the anesthesia provider (Cheong and Ledger, 2007).

Procedural Considerations. The instrumentation required includes a D&C set, with the addition of a hysteroscopy set, 50-ml syringes, polyethylene tubing, fiberoptic light source, the ESU or laser, hysteroscopic insufflator, pressure-infusion pump, and a video camera and monitor. The patient will be in the lithotomy position.

Operative Procedure

1. The surgeon places an Auvard weighted speculum and an anterior retractor to expose the cervix; the anterior lip of the cervix is grasped with a tenaculum and is drawn toward the introitus.
2. The direction of the cervical canal and the depth of the uterine cavity are determined by means of a graduated uterine sound.
3. The surgeon dilates the endocervical canal with graduated Hegar or Hank uterine dilators to 6, 7, or 8 mm, depending on the size of the hysteroscope.
4. A self-retaining vacuum cannula with obturator may be placed into contact with the cervix. The cannula is firmly applied to the cervix by vacuum created with a negative pressure.
5. The surgeon withdraws the obturator and introduces the hysteroscope to the level of the internal cervical os.
6. To achieve satisfactory visualization and sustained intrauterine pressure, the uterine cavity must be distended with one of the following media: 32% dextran 70 in dextrose (Hyskon), dextrose 5% in water (D_5W), sorbitol, mannitol, saline (normal saline solution [NSS]), sterile water, or by CO_2 gas insufflation. Because air or gas used for uterine insufflation may result in air or gas embolism, CO_2 pressures must be monitored closely. Injection of liquid media may be under continuous pressure from a 50-ml syringe or delivered by means of a pressure-controlled fluid-infusion (hysteroscopic) pump into the irrigating channel of the hysteroscope. When the syringe is used, care must be taken to prevent air bubbles, which distort the view or could lead to air embolism. Uterine distention with D_5W may be achieved by inserting a 500-ml plastic bag containing the medium into an intravenous pressure infusor or the infusion pump. The fluid runs freely within polyethylene tubing through the channel of the hysteroscope.
7. Exploration of the uterine cavity is begun. A video camera monitor may be used to enhance visibility for the OR team, and the procedure may be videotaped for record keeping and reevaluation.
8. The surgeon may introduce ancillary instruments, such as rigid and flexible biopsy forceps, scissors, grasping forceps, insulated coagulation electrodes, resectoscope with "rollerball" electrode, laser fiber tips, and tubal occlusive devices, for intrauterine manipulation or surgical intervention through the operating channel of the hysteroscope.
9. On completion of the procedure, the hysteroscope is withdrawn and the self-retaining vacuum cannula is removed.

If Hyskon is used for uterine distention, the instruments must be rinsed immediately and cleaned in hot water, because dextran has a tendency to harden and is difficult to remove if permitted to dry.

Endometrial Ablation

Endometrial ablation is performed to treat abnormal uterine bleeding. The overall goal of endometrial ablation is to create amenorrhea or to reduce menstrual bleeding to a normal, tolerable flow for the patient. It may be an alternative to hysterectomy in some patients with chronic menorrhagia. The procedure is performed through the hysteroscope with the use of either the laser, ESU, or microwave energy.

The Nd:YAG laser destroys the endometrium and results in scarring of the uterine lining. It is often the laser of choice for this procedure because of its ability to penetrate deep into the tissue, resulting in greater tissue destruction. The Nd:YAG, argon, and potassium titanyl phosphate (KTP) 532 lasers may be used hysteroscopically.

The two endometrial ablation techniques used with the Nd:YAG laser are *blanching* and *dragging*. In the blanching technique, the tip of the laser fiber is held away from tissue. In the dragging technique, the laser fiber tip is in direct contact with the endometrium. The endometrial lining is treated from the fundus to approximately 4 cm above the external cervical os. Air or gas is not used in cooling the laser fiber because of the risk of air or gas embolism. Because of the systemic effects of fluid absorption through open capillaries, Hyskon is not generally used as an irrigant for endometrial laser ablation.

A specially designed diode laser may also be used for endometrial ablation. The diode laser utilizes a disposable handset that emits laser beams through three separate parallel panels. The handset conforms to the shape of the uterus and delivers energy in all directions to destroy the tissue in the fundus and cornua, away from the cervical opening. A hysteroscopy may be performed at the conclusion of the therapy to evaluate the results.

Electrical energy delivered through an adapted urologic resectoscope, using continuous-flow irrigation, either coagulates or resects the endometrium. Endometrial ablation with the use of a resectoscope, with a rollerball electrode attached, is not an option for a patient who desires to remain fertile. When using the resectoscope, often Hyskon is chosen as the distending medium because it is electrolyte-free and compatible with electrosurgery.

Reported complications associated with endometrial ablation using the Nd:YAG laser and electrosurgery include hemorrhage, fluid overload, uterine perforation, recurrent bleeding, injury to bowel and bladder, cervical lacerations, and rupture of a fallopian tube.

A general anesthetic is usually administered, although endometrial ablation can be performed using a local anesthetic. If the Nd:YAG laser is to be used, the perioperative nurse ensures that all laser safety precautions for the patient and the OR team are followed (see Chapter 7). The length of the procedure is typically less than that for a hysterectomy. Therefore the patient requires less anesthetic and may be discharged the same day, provided that her condition remains stable.

Balloon Endometrial Ablation. Endometrial ablation may also be accomplished using balloon therapy. The action of balloon therapy is thermal. The uterine balloon catheter conforms to the internal uterine contour and contains a heating element. The surgeon performs suction curettage before the therapy to provide maximal balloon contact with the uterine lining. The cervix is dilated to 5 mm, and the balloon catheter is inserted in the uterus until the tip touches the fundus. The surgeon inflates the balloon with sterile D_5W to a pressure of 160 to 180 mm Hg. The solution is heated to a temperature of 86.6° C (188° F) and maintained for 8 to 10 minutes. The procedure may be performed as an ambulatory surgical procedure and does not require hysteroscopy (Practice Committee, 2008).

Laparoscopy

Laparoscopy is the endoscopic visualization of the peritoneal cavity through the anterior abdominal wall after the establishment of a pneumoperitoneum. It is used to investigate and diagnose the causes of abdominal and pelvic pain and infertility and to evaluate pelvic masses. Ancillary procedures such as adhesiolysis, fulguration of endometriotic implants (Figure 13-32), aspiration of cysts, biopsy of tissue, aspiration of peritoneal fluid for cytologic study, ovarian biopsy, ovarian cystectomy, oophorectomy, removal of ectopic pregnancy, tuboplasty, and tubal sterilization may be performed. Laparoscopy also can be used for oocyte retrieval for IVF procedures. Lasers and electrosurgery may be used with the laparoscope.

Procedural Considerations. Although laparoscopy can be performed with a local anesthetic, more often the anesthesia provider administers a general anesthetic. The nurse assists with placing the patient in the lithotomy position. The abdomen, perineum, and vagina are prepped. The abdomen and perineum are then draped for a combined procedure. Specially designed drapes with openings for the umbilical and perineal areas may be used. The bladder should be emptied with an in-and-out catheterization or through insertion of a Foley catheter.

The surgeon may perform a D&C in conjunction with laparoscopic procedures when indicated. After the cervix is exposed and the position and depth of the uterus are confirmed, the surgeon will introduce a uterine manipulator or dilator into the cervix to manipulate the uterus during the laparoscopy for better visibility. If chromotubation (e.g., injection of a dilute solution of methylene blue through the cervix to determine

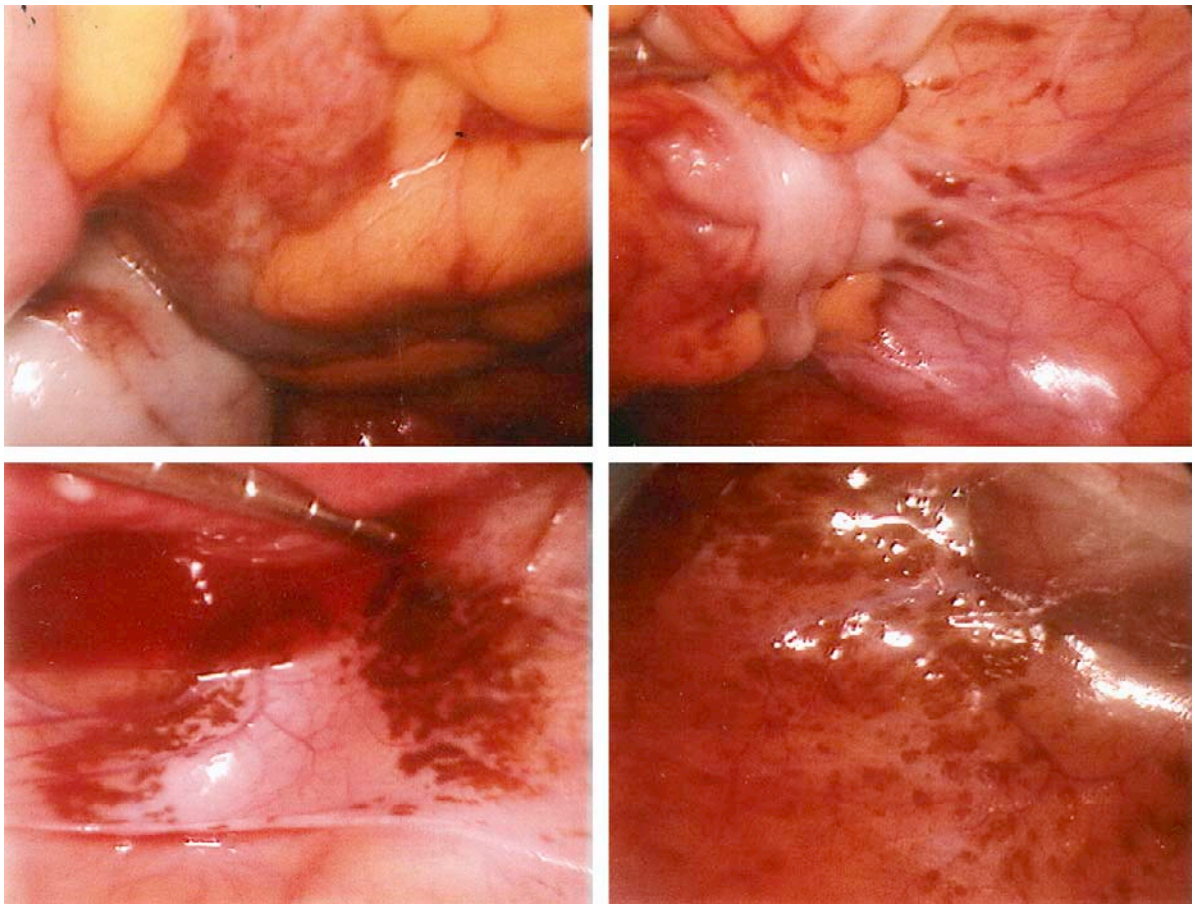

FIGURE 13-32 Laparoscopic view of endometriosis in the cul-de-sac.

fallopian tube patency) will be performed during the laparoscopy, the surgeon places an intrauterine cannula in the cervical canal at the time of D&C.

The usual instrumentation for the vaginal portion of the procedure includes a D&C set, with the addition of a uterine manipulator, intrauterine cannula, diluted methylene blue or indigo carmine solution, and a syringe.

An abdominal gynecologic instrument set should be readily available in the event that a laparotomy is indicated.

Operative Procedure

1. The surgeon makes a small incision (0.7 to 1.2 cm) at the inferior margin of the umbilicus.
2. Elevating the skin with a towel clamp on either side of the umbilicus or grasping below the umbilicus with a gauze sponge for traction, the surgeon inserts a Veress needle through the layers of the abdominal wall into the peritoneal cavity.
3. Once the Veress needle is inserted into the peritoneal cavity, a 10-ml syringe partially filled with sterile saline is attached to the needle for aspiration. If the needle has entered a blood vessel, blood is aspirated. If a loop of intestine or the stomach has been entered, bowel contents or malodorous gas is aspirated. If the needle is free in the peritoneal cavity, nothing is aspirated.
4. The surgeon attaches a plastic or Silastic tubing to the Veress needle and the gas insufflator. Approximately 2 to 3 liters of CO_2 or nitrous oxide gas is then delivered into the peritoneal cavity to achieve pneumoperitoneum. CO_2 is commonly used as the insufflation medium because it is nontoxic, highly soluble in blood, and rapidly absorbed from the peritoneal cavity. The intraabdominal pressure must be closely monitored to prevent overdistention of the abdomen and to ensure free passage of gas into the peritoneal cavity.
5. After insufflation is completed, the Veress needle is withdrawn.
6. The surgeon inserts the trocar, covered by the trocar sleeve, through the abdominal wall and into the peritoneal cavity. The angle taken by the trocar is approximately 45 degrees toward the concavity of the pelvis. The plastic or Silastic tubing is attached to the trocar sleeve, and insufflation is resumed. Some surgeons prefer a direct trocar insertion technique or the open laparoscopy technique of Hasson to establish the pneumoperitoneum through the valve of the trocar sleeve rather than through a Veress needle (see Chapter 11).
7. With the trocar sleeve in place, the surgeon withdraws the trocar and introduces the laparoscope.
8. Visualization of the pelvis and lower abdomen and the visceral contents is begun. If the lens of the laparoscope becomes foggy, application of a commercially available defogger solution may control the problem. Alternatively, the surgeon may touch the lens to a loop of intestine to clear it. Before use, warming the tip of the scope in warm saline or towels may prevent fogging of the distal lens.
9. The anesthesia provider places the patient in the Trendelenburg's position.
10. The video camera is attached to the scope to aid in the OR team's visualization, and the procedure may be recorded for future reference. If an ancillary instrument such as biopsy forceps or bipolar forceps is needed, the surgeon inserts a second trocar with sleeve under direct laparoscopic visualization through a suprapubic incision.
11. To test for tubal patency, the surgeon injects diluted methylene blue or indigo carmine solution through the intrauterine cannula into the cervical canal (i.e., chromotubation). If the fallopian tubes are patent, dye can be seen at the fimbriated ends.
12. On completion of the intraabdominal procedure, the surgeon withdraws the laparoscope and the insufflated gas is allowed to escape from the trocar sleeve or by suction. The trocar sleeve is removed and trocar sites closed.
13. Application of staples or subcuticular closure of the primary skin incision is followed by placement of a small bandage or wound closure strip.
14. The surgeon removes the uterine manipulator and checks the cervix for bleeding. If bleeding is present, pressure may be applied with a sponge stick or a suture ligature may be passed through the bleeding portion.
15. The perioperative nurse applies a perineal pad.

Salpingostomy for Ectopic Tubal Pregnancy

Ectopic pregnancy is defined as any gestation developing outside of the endometrial cavity. Risk factors for developing an ectopic pregnancy include use of intrauterine devices (IUDs) for contraception, pelvic inflammatory disease, tubal ligation, tubal dysfunction (as with endometriosis), in vitro fertilization, and previous ectopic pregnancy. Although the fallopian tube is the most common site for ectopic pregnancies (occurring in up to 95% of all cases), they can develop in the cervix or broad ligament; in a previous cesarean section scar (myotomy), they can develop in the ovary and the peritoneal cavity (Genovese, 2007). Women who experience ectopic pregnancy generally present with abdominal pain, abnormal vaginal bleeding, and a palpable adnexal mass. Diagnosis is confirmed through measurement of human chorionic gonadotropin (hCG) levels and use of ultrasound to determine the absence of a gestational sac. A serious complication of ectopic pregnancy is tubal rupture and hemorrhage (Figure 13-33). The ultrasound is also useful in identifying free fluid in the peritoneal cavity. Ruptured ectopic pregnancy is considered a surgical emergency and is associated with severe abdominal pain, tachycardia, and hypotension. The woman with a ruptured ectopic pregnancy may also experience shoulder pain because of irritation of the phrenic nerve from the hemoperitoneum. Ectopic pregnancy may be treated medically with methotrexate or surgically through salpingostomy, segmental resection, fimbrial expression, and salpingectomy

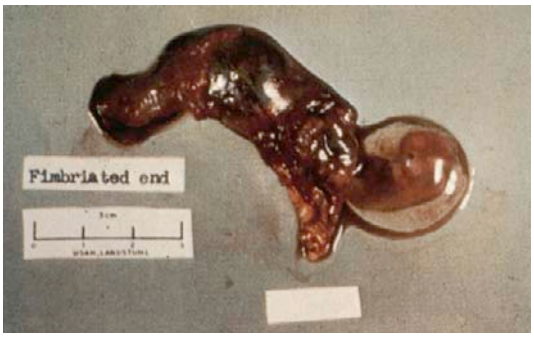

FIGURE 13-33 Ruptured ectopic pregnancy with fetus in sac.

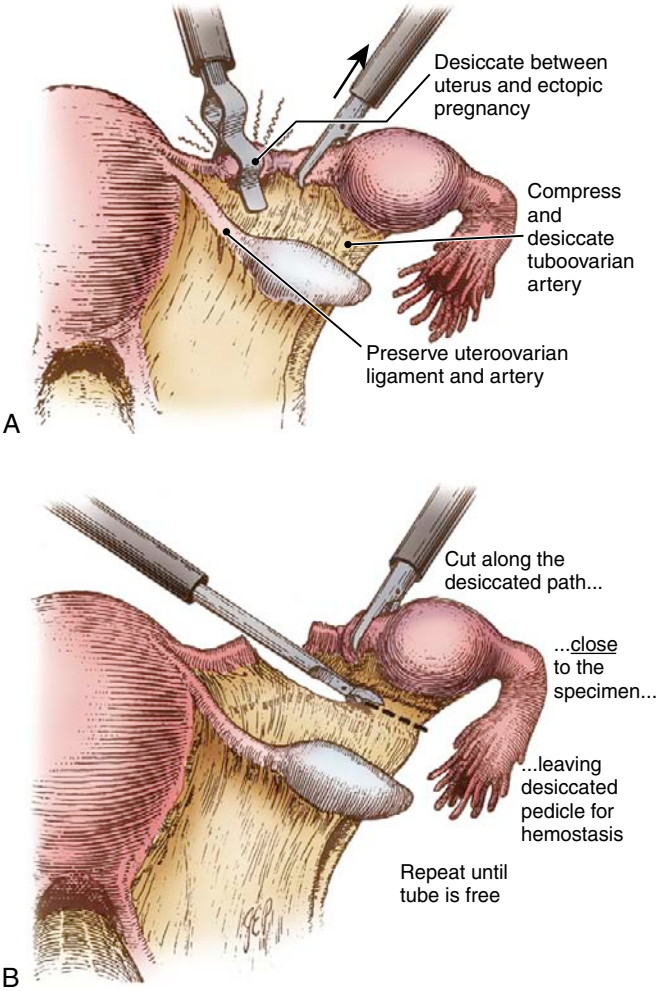

FIGURE 13-34 **A**, Electrodesiccation of the proximal fallopian tube during salpingectomy. **B**, Excision of the fallopian tube.

(Figure 13-34). Methotrexate destroys rapidly dividing cells and is often administered in conjunction with the surgical procedure to destroy any residual trophoblastic cells that might remain (Research Highlight) (Genovese, 2007). Laparoscopic and/or ultrasound-guided application of methotrexate to the extrauterine gestational sac may also be used as an alternative therapy (Lobo, 2007).

Procedural Considerations. Procedural considerations for laparoscopic salpingostomy are identical to those for any laparoscopic procedure with the addition of methotrexate.

Operative Procedure

1. The surgeon establishes a pneumoperitoneum, inserts the telescope, and mobilizes the distal end of the fallopian tube to perform an adhesiolysis. Grasping forceps are placed on either side of the fallopian tube, and gentle traction is applied.
2. Before making an incision, coagulation of the serial vessels on both sides of the anticipated incision may be performed. A dilute solution of vasopressin may also be injected into the mesenteric margin to avoid excessive bleeding (Figure 13-35).

RESEARCH HIGHLIGHT

Medical Management of Ectopic Pregnancy

Ectopic pregnancy is a devastating complication that affects up to 2% of all pregnancies. Although perioperative nurses are most familiar with the surgical treatment of ectopic pregnancy, the more cost-effective medical treatment for ectopic pregnancy is considered a front-line therapy in many major medical centers.

In this prospective study, researchers evaluated 100 women diagnosed with ectopic pregnancy who elected to have medical therapy for acceptability of the treatment and resolution of the pregnancy without surgical intervention. Participants received an intramuscular injection of methotrexate on days 0 and 4 and received additional doses on days 7 and/or 11 if their hCG levels did not decrease by 15% in the follow-up period. A total of 88 women were treated successfully with the methotrexate protocol; the others required surgery. Over half of the women (53%) treated with the protocol reported adverse effects related to the treatment, most commonly gastrointestinal complaints.

To assess satisfaction with the medical protocol, researchers mailed a questionnaire with a 5-point scale to collect data on the side effects of the treatment, missed work/school days, and the feasibility of choosing the medical protocol over surgery in the future, if necessary. A total of 64 women returned the questionnaire; 58 reported they were "satisfied" or "very satisfied" with their treatment and would also undergo the same treatment if they experienced another ectopic pregnancy in the future.

Modified from Barnhart K et al: Use of "2-dose" regimen of methotrexate to treat ectopic pregnancy, *Fertil Steril* 87(2):250-256, 2007.

3. A single incision is made with scissors from the mesenteric to the antimesenteric side of the fallopian tube, where the products of conception are exposed.
4. The tissue is removed gently with forceps while constant irrigation is maintained with an isotonic solution (Figure 13-36). Vigorous evacuation is avoided so that the highly vascular underlying interstitial layer is not disturbed.
5. Small bleeding vessels can be ligated with a fine, nonreactive suture. Simple traumatic compression of bleeding margins will also promote hemostasis. Mesosalpingeal vessel ligation may be performed.
6. The tubal incision may be allowed to close by secondary intention or, as in the instance of salpingotomy, the incision may be closed in one or two layers, with 6-0 interrupted sutures. On completion, the endoscope and instrumentation are removed. The insufflated gas is permitted to escape from the trocar sleeves. Trocar sleeves are then removed. Subcuticular closure of the primary skin incisions is followed by placement of wound closure strips or small dressings.

Ovarian Cystectomy

Ovarian cystectomy is frequently performed via the laparoscopic approach.

Operative Procedure

1. After successful laparoscopic entry, adhesiolysis is achieved.
2. On entry, peritoneal washings for cell block are obtained, if indicated.

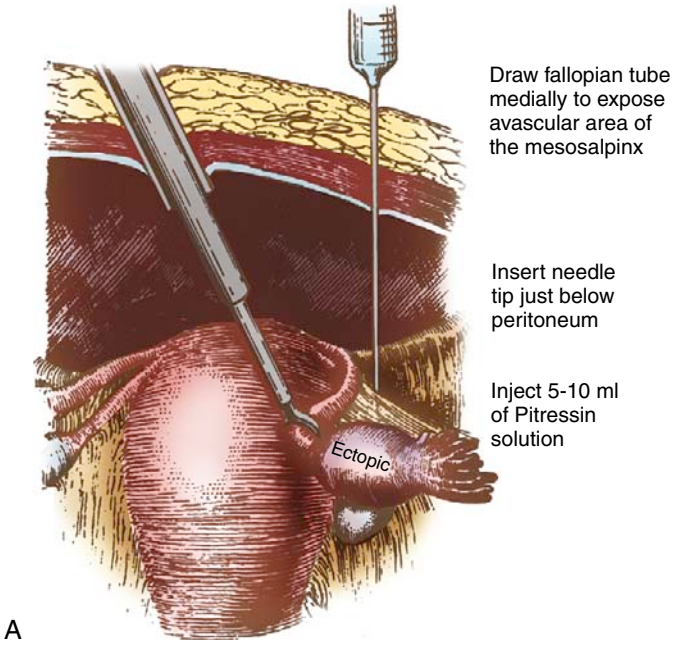

FIGURE 13-35 Salpingostomy. **A**, Injection of vasopressin into mesosalpinx. **B**, Incision made into fallopian tube.

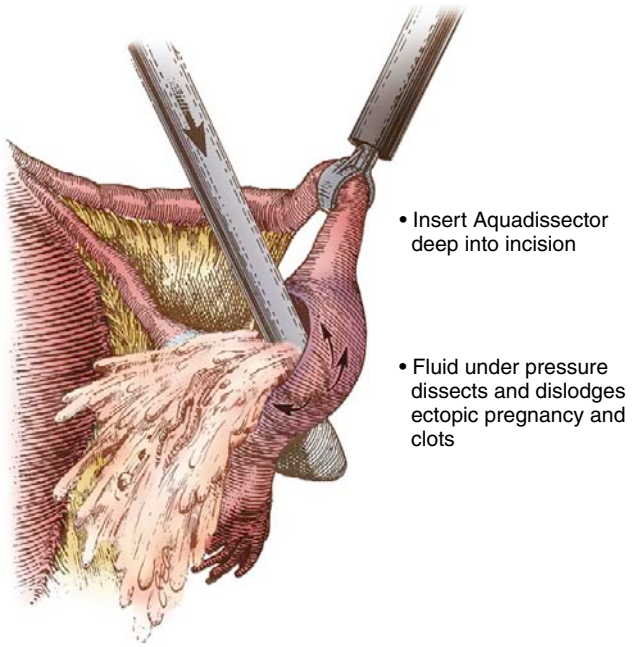

FIGURE 13-36 Hydrodissection used to separate ectopic pregnancy from fallopian tube during salpingostomy.

3. The ovarian cyst is mobilized, and the cortex is grasped with a biopsy instrument.
4. The surgeon incises the cortex with scissors or the laser, exposing the cyst wall.
5. The incision is then enlarged with scissors, and pressurized hydrodissection is used to separate the cyst from the ovarian stroma.
6. The cyst is dissected and may be removed intact by a culdotomy incision, or the cyst may be opened, evacuated, thoroughly cleaned by lavage with the hydrodissector, and then removed.
7. If the cyst is opened intraperitoneally, the patient should be placed in the supine, not Trendelenburg's, position while the fluid is removed and the pelvis is cleaned by lavage.
8. Arterial bleeders are identified and desiccated.
9. The ovary usually does not require suturing; however, if the edges gape widely, the surgeon may loosely approximate the edges with interrupted 4-0 synthetic absorbable suture.
10. On completion, the endoscope and accessory instrumentation are removed. The insufflated gas is permitted to escape from the trocar sleeves. Trocar sleeves are then removed.
11. Closure of the primary skin incisions (fascia, if necessary, followed by a subcuticular stitch) is followed by placement of wound closure strips or small dressings.

Laparoscopic-Assisted Vaginal Hysterectomy

Laparoscopic-assisted vaginal hysterectomy (LAVH) offers an alternative to total abdominal hysterectomy (TAH) and vaginal hysterectomy (VH). The patient does not have the large abdominal incision, extended hospital stay, and long recovery period that occur with a TAH. LAVH may be associated with less pain than VH or TAH. Patients who are not candidates for traditional VH may be candidates for LAVH. Although not described here, in laparoscopic-assisted supracervical hysterectomy (LASH), the body of the uterus is removed and the cervix is left intact (Goeser and Hasiak 2008).

The surgeon uses laparoscopy to visualize the pelvis and thereby determine whether disease is present. This is not possible with traditional vaginal hysterectomy. Conditions leading to LAVH include postmenopausal bleeding, pelvic pain, uterine leiomyomas, and adnexal masses. Indications for LAVH may be absence of genital prolapse, required adnexectomy, history of abdominopelvic surgery, salpingitis or endometriosis, lymphadenectomy, and endometrial cancer.

Procedural Considerations. Procedural considerations and accessory instrumentation and approach are similar to those used in other laparoscopic surgical procedures. The patient is placed in the low lithotomy position with attention to positioning interventions to protect the patient from injury.

Operative Procedure. The operative procedure may include the following:

1. Hydrodissection of the broad ligament
2. Desiccation of the round and infundibulopelvic ligaments with bipolar coagulation
3. Dissection of the broad ligaments
4. Freeing of the urinary bladder from the lower uterine segment
5. Opening of the vaginal vault with endoscopic scissors or monopolar electrode and removal of the uterus vaginally

Robotically-Assisted Procedures

Robotic-assisted surgery represents the newest available technology for minimally invasive gynecologic procedures. The robotic system has the following three components: (1) a surgeon console with a stereoscopic viewer, hand manipulators, and foot controls; (2) the vision system that provides a three-dimensional image through an endoscope equipped with stereoscopic cameras and dual optics; and (3) an ancillary cart with telerobotic arms (Reynolds, 2006). Robotic technology has been used for myomectomies, sacrocolpopexies, hysterectomies, oophorectomies, and lymphadenectomies (Fanning et al, 2008) (Research Highlight). Advantages to robotic procedures include smaller incisions (often 1 to 2 cm in length), reduced blood loss, shorter hospital stays, and greater patient satisfaction.

Procedural Considerations. General anesthesia is used for robotic procedures. Procedural considerations applicable to laparoscopic surgery are appropriate for robotic surgery including prepping and draping practices. The perioperative nurse must be familiar with the specialized equipment used for robotic surgery to minimize operative time and facilitate a smooth experience for the patient and surgical team. Instrumentation to convert the robotic procedure to an open procedure should be available.

Operative Procedure—Robotic-Assisted Hysterectomy

1. The surgeon places a uterine manipulator into the cervix and a vaginal balloon occluder into the vagina.
2. A Veress needle is placed and the surgeon establishes an adequate pneumoperitoneum. Alternately, the open Hasson technique (see Chapter 11) may be used.
3. The surgeon incises the skin at the umbilicus and places the endoscope port. Additional incisions are created and supplementary ports are inserted for instrumentation and suction.
4. The anesthesia provider positions the patient in steep Trendelenburg's position, and the perioperative nurse positions the surgical cart with the robotic arms between the patient's legs while observing the integrity of the sterile field.
5. Following the manufacturer's directions, the surgical technologist and surgical assistant dock the robotic system.
6. The surgeon moves to the console for the remainder of the procedure.
7. Using the hand and foot controls of the console, the surgeon surveys the operative field and opens the peritoneum using the ESU.

RESEARCH HIGHLIGHT

Robotic Hysterectomy for Benign and Malignant Disease

Minimally invasive approaches to gynecologic surgery have recently expanded to include robotic-assisted procedures. Robotic-assisted surgery offers several advantages over standard laparoscopy including decreased tissue trauma, enhanced precision, and stereoscopic visualization.

To evaluate the use of robotic surgery in a minimally invasive approach to hysterectomy for benign uterine disease, a group of researchers performed a retrospective chart review to examine the operative and perioperative characteristics and trends for 200 patients before and after implementation of a robotic program in a community hospital. The researchers reviewed 100 charts of patients who underwent laparoscopic hysterectomy before the implementation of the robotic program to the charts of the first 100 patients to undergo robotic hysterectomy. Indications for surgery included myomas, endometriosis, ovarian cysts, dysmenorrhea, and dyspareunia. Both groups were similar in demographics and body mass index. Their review concluded that a twofold decrease in blood loss was realized in robotic hysterectomies compared to laparoscopic hysterectomies (e.g., 61 ml in the robotic group, 113 ml in the laparoscopic group), and hospital stays were decreased in the robotic group. They also reported that the rate of conversion to an open procedure was zero for the robotic group, but 11% in the laparoscopic group.

Robotic surgery may also have a place in the treatment of malignant gynecologic conditions. Researchers in Boston sought to determine if robotic hysterectomy would improve short-term outcomes in women being treated with open radical hysterectomy for cervical cancer. Using a retrospective chart review they compared 48 radical hysterectomies. Of the 48 cases reviewed, 16 were robotic radical hysterectomies and 32 were open radical hysterectomies. All patients were similar in body mass, age, and stage of cancer. They determined that operative time for the robotic hysterectomy was significantly longer than that for the open procedures; however, mean blood loss was significantly less in robotic hysterectomy patients (e.g., 81.9 ml for the robotic group vs 665 ml for the open group). Postoperative complications were less in the robotic group, and the mean length of stay was 1.7 days in the robotic group compared to 4.9 days in the open group.

As techniques for this relatively new technology evolve, research is needed to quantify the benefits and to determine future applications in the treatment of both benign and malignant uterine conditions.

Modified from Payne TN, Dauterive FR: A comparison of total laparoscopic hysterectomy to robotically assisted hysterectomy: surgical outcomes in a community practice, *J Minim Invasive Gynecol* 15(3):286-291, 2008; Ko EM et al: Robotic versus open radical hysterectomy: a comparative study at a single institution, *Gynecol Oncol* 111:425-430, 2008.

8. The surgeon skeletonizes and ligates the uterine artery pedicles and infundibulopelvic ligament with polyglactin suture or free ties.
9. Additional dissection is performed to divide the cardinal and uterosacral ligament complex on both sides.
10. The surgical assistant provides traction on the uterus while the surgeon performs an anterior and posterior colpotomy.
11. The uterus and cervix are detached and delivered into the patient's vagina; they remain in the vagina while the surgeon closes the vaginal cuff using interrupted polyglactin suture. When the cuff is closed and hemostasis is achieved, the specimen is removed from the vagina.
12. The surgical assistant disengages the robotic arms and removes the trocars.
13. Using polyglactin suture the surgeon or surgical assistant closes the fascia. Wound closure strips are used to close the skin incisions, and small dressings and a perineal pad are applied.

Uterine Artery Embolization

Uterine artery embolization (UAE, also referred to as "uterine fibroid embolization [UFE]") is an alternate treatment for fibroids that blocks the blood vessels supplying nutrients and oxygen to the tumors. The blockage causes the fibroid muscle cells to degenerate and form scar tissue, which causes the fibroids to shrink. The greatest period of shrinkage occurs in the first 6 months following the procedure with an additional 42% to 82% shrinkage over the next 6 months (Andrews et al, 2009). This procedure appeals to many women because of its minimally invasive nature and ability to be performed in the outpatient setting. The main complication associated with the procedure is postembolization syndrome, occurring in 2% to 10% of patients. Postembolization syndrome is characterized by pelvic pain, low-grade fever, vomiting, loss of appetite, and malaise in the first 48 hours after UAE (Parker, 2007). Occasionally, the procedure is complicated by inadvertent occlusion of the ovarian blood supply. Pregnancy is not recommended following UAE.

Procedural Considerations. A hysteroscope, light source, camera, and viewing tower are required along with uterine distention system, appropriate distention fluids, and energy sources (Dooley, 2007). The patient is placed in lithotomy position with appropriate positioning safety measures (see Chapter 5). An EUA is usually performed before the start of the procedure. A perineal pad will be used at the procedure conclusion.

Operative Procedure. The procedure is performed under fluoroscopic guidance using spinal anesthesia or local anesthesia supplemented with moderate sedation. A femoral artery sheath is inserted, and arteriography of the pelvic vasculature is performed by injecting radiologic contrast through a 5-French catheter as it passes through the femoral artery to the iliac artery to the uterine artery. An embolic agent is injected through the catheter until no more proximal arterial flow or reflux of contrast material is noted. Commonly used embolic agents are gelatin sponges, nonspheric polyvinyl alcohol (PVA) particles, and trisacryl gelatin microspheres. Gelfoam pledgets are cut into strips, rolled, and loaded into a nozzle of a syringe for injection. Nonspheric PVA particles are mixed with equal parts of saline and contrast and injected through the catheter until the vessel is occluded. The PVA particle size ranges from 350 to 700 micrometers, which is comparable in size to a grain of sand. Trisacryl microspheres range in size from 700 to 900 micrometers (Scheurig et al, 2008). Collateral circulation maintains the blood supply to the myometrium. The particles remain inert in the vessel.

GYNECOLOGIC SURGERY USING ABDOMINAL APPROACH

Total Abdominal Hysterectomy (TAH)

TAH is removal of the entire uterus, including the corpus and the cervix. When TAH is combined with bilateral salpingo-oophorectomy, the procedure is commonly termed *panhysterectomy* or *complete hysterectomy.* TAH may be performed for symptomatic pelvic relaxation or prolapse, pain associated with pelvic congestion, pelvic inflammatory disease, endometriosis, recurrent ovarian cysts, fibroids (myomas), bleeding with no apparent cause in postmenopausal women, adenomyosis, or dysfunctional uterine bleeding (Evidence for Practice). TAH, usually with bilateral salpingo-oophorectomy, is also indicated in malignancy, premalignant states, and conditions of high risk for development or recurrence of malignancy. The procedure can also be used to accomplish sterilization. Approximately 516,025 hysterectomies are performed each year in the United States (HCUPnet, 2007).

Procedural Considerations. Before the abdominal skin prep, the perioperative nurse performs an internal vaginal prep using a separate prep tray, ensuring contact of the prep solution with the cervix. An indwelling urinary drainage catheter is inserted to provide constant bladder drainage during the operation. The supine position, modified during the procedure with the Trendelenburg's position, is used. Instrumentation includes the abdominal gynecologic set. Provisions are made to remove those instruments used in separating the cervix from the vagina from the surgical field, thereby avoiding vaginal contamination of the pelvis.

Operative Procedure

1. In an obese patient or for exploration of the upper abdominal cavity, a left rectus or midline incision may be made. For simple hysterectomy, a Pfannenstiel incision may be used. The surgeon opens the abdominal layers and the peritoneum as described for laparotomy (see Chapter 10).
2. As the peritoneal cavity is opened, the anesthesia provider usually places the patient in the Trendelenburg's position to provide better visualization of the pelvic organs.
3. Vasopressin may be injected into the uterus. The round ligament is grasped with forceps, clamped, and ligated with sutures on long needle holders. The surgeon cuts the pedicles with a knife or Metzenbaum scissors; sutures are tagged with a hemostat to be used as traction later. This procedure is done on both sides (Figure 13-37, *A*).
4. Using blunt dissection the surgeon separates the layer of the broad ligament close to the uterus on each side. Bleeding vessels are clamped and ligated, and a moist laparotomy pack is inserted behind the flap. The fallopian tube and the utero-ovarian ligaments are doubly clamped together, incised, and doubly tied with suture ligatures (Figure 13-37, *B*).

EVIDENCE FOR PRACTICE

Alternatives to Hysterectomy

Hysterectomy is the most common non–pregnancy-related major surgery performed on women in the United States. It is widely accepted as appropriate treatment for cancer and various noncancerous conditions, such as pain, discomfort, uterine bleeding, emotional distress, and related symptoms. Although hysterectomy can alleviate uterine problems, less-invasive treatments are available. Alternatives to hysterectomy recommended by the Agency for Healthcare Research and Quality (AHRQ) are noted in the following table.

		Pharmacologic Therapies		
Condition	**Conservative Surgery**	**Hormonal**	**Nonhormonal**	**Other Strategies**
Fibroids	Myomectomy	GnRH agonists with add-back therapy	NSAIDs	Watchful waiting
	Endometrial ablation	Oral contraceptives RU-486 (experimental) Gestrinone (experimental)		
Endometriosis	Adhesiolysis	GnRH agonists with add-back therapy	NSAIDs	Watchful waiting
	Excision or endometrial ablation	Danazol	Analgesics	Biofeedback
	Resection or cul-de-sac obliteration	Progestins	Anxiolytics	Hypnosis
	Nerve blocks	Oral contraceptives		Acupuncture
	Uterosacral nerve ablation	Tamoxifen (experimental) RU-486 (experimental)		Lifestyle modifications (nutrition/exercise)
Prolapse	Colporrhaphy Laparoscopic or vaginal suspension techniques	Estrogen		Watchful waiting Kegel exercises Pessaries Electrical stimulation Urethral beads Periurethral injections (e.g., of fat, silicone)
Dysfunctional bleeding	Dilation and curettage Endometrial ablation	Progestins Estrogens Oral contraceptives Danazol Prostaglandin inhibitors GnRH agonists Antifibrinolytic agents Luteinizing hormone agonists		Watchful waiting Antidepressants
Chronic pelvic pain	Adhesiolysis Nerve blocks Denervation procedure Uterosacral nerve ablation	Danazol GnRh agonists with add-back therapy Oral contraceptives Medroxyprogesterone acetate	NSAIDs Analgesics Nerve blocks Narcotics	Watchful waiting Counseling Biofeedback Relaxation techniques Trigger-point injections Acupuncture Psychotropics Antidepressants Physical therapy

GnRH, gonadotropin-releasing hormone; *NSAID,* nonsteroidal antiinflammatory drug.
Modified from *Common uterine conditions: options for treatment,* AHCPR Pub No. 98-0003, Rockville, Md, Dec 1997, Agency for Health Care Policy and Research, available at www.ahrq.gov/consumer/uterine1.htm. Accessed June 26, 2009.

5. The surgeon pulls the uterus forward to expose the posterior sheath of the broad ligament, and incises the ligament with a knife or Metzenbaum scissors. Ureters are identified. The uterine vessels and uterosacral ligaments are doubly clamped, divided by sharp dissection at the level of the internal os, and ligated with suture ligatures (Figure 13-37, *C*).
6. The severed uterine vessels are bluntly dissected away from the cervix on each side with the aid of sponges on sponge-holding forceps, scissors, and tissue forceps.
7. The bladder is separated from the cervix and upper vagina with sharp and blunt dissection assisted by sponges on sponge-holding forceps. The bladder may be retracted with a moist laparotomy pack and a retractor with an angular

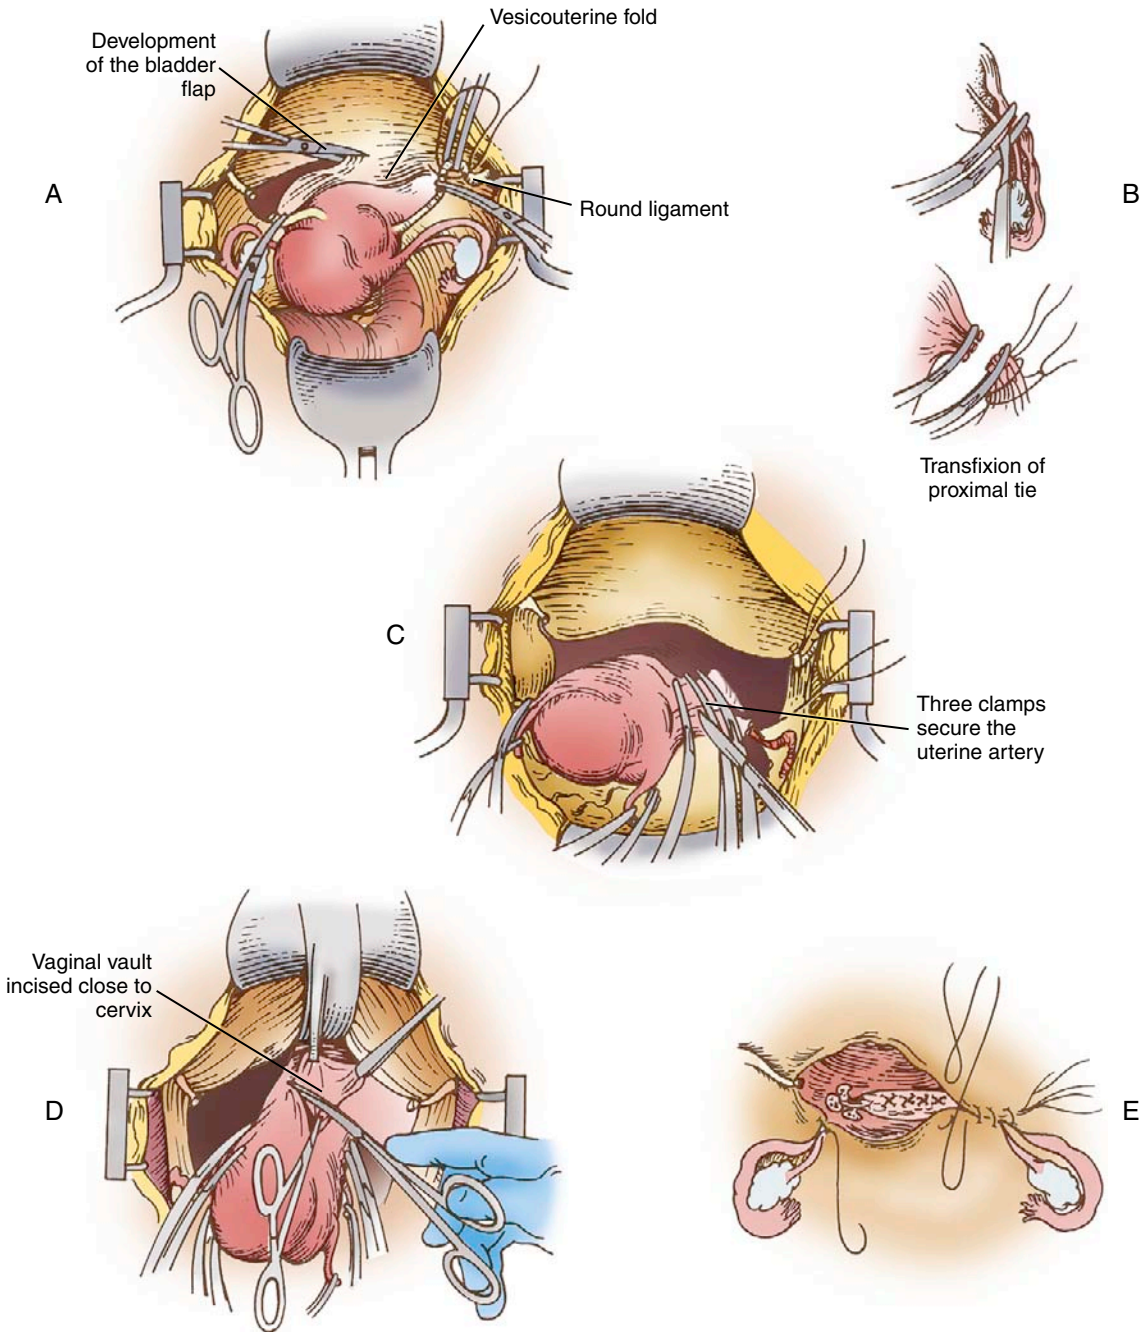

FIGURE 13-37 Abdominal hysterectomy for single fibroid uterus. **A**, Peritoneum retracted with self-retaining retractors, and organs protected with laparotomy packs saturated in warm normal saline solution. Transverse incision made through uterine peritoneum and extended to each side of uterine attachments of round ligaments. Bleeding vessels clamped and ligated. Round ligament grasped, ligated, and cut. **B**, Tube and ovarian ligaments clamped, cut, and sutured. **C**, Uterus pulled forward, posterior sheath of broad ligaments divided, and uterine artery and veins secured by three heavy curved clamps. Pedicle divided, leaving two hemostats on proximal pedicle. **D**, Bladder separated from cervix and upper vagina. Vaginal vault opened and grasped with Allis forceps. Allis forceps placed on anterior lip of cervix, and dissection of cervix carried out to complete its amputation from vagina. **E**, Three connective tissue thickenings anchored to vaginal vault, vaginal mucosa approximated, and vault closed. As shown, peritoneum closed with continuous suture.

blade. The vaginal vault is incised close to the cervix with a knife or scissors (Figure 13-37, *D*).

8. The surgeon grasps the anterior lip of the cervix with an Allis, Kocher, or tenaculum forceps. Using scissors, the surgeon dissects the cervix and amputates it from the vagina. The uterus is removed. The surgical technologist places any potentially contaminated instruments used on the cervix and vagina into a discard basin and passes them from the field (including sponge-holding forceps and suction). Bleeding is controlled with hemostats and sutures.
9. The vaginal vault is reconstructed with interrupted sutures. Angle sutures anchor all three connective tissue ligaments to the vaginal vault. The pedicles, fallopian tubes, and ovarian ligaments are left free of the vault.
10. The vaginal mucosa is approximated with a continuous suture on a long needle holder. The muscular coat of the vagina may be closed with figure-of-eight sutures to make the vault of the vagina firm and provide resistance against prolapse. A drain may be placed in the vagina.
11. The surgeon closes the peritoneum over the bladder, vaginal vault, and rectum (Figure 13-37, *E*). The laparotomy packs are removed, and the omentum is drawn over the bowel.
12. The abdominal wound is closed as described for laparotomy closure (see Chapter 10).
13. Abdominal dressings and a perineal pad are applied.

Abdominal Myomectomy

Uterine fibroids are benign tumors that arise from the muscular wall of the uterus (Figure 13-38). They may also be located in the submucosal area or the subserosal surface of the uterus. On occasion, they may become pedunculated and extend into the cervical canal. Rarely, a subserosal fibroid may pedunculate and migrate to become a parasitic fibroid attached to the omentum or mesentery. Another term for uterine fibroids is *uterine leiomyomas*. Abdominal myomectomy is removal of fibromyomas, or fibroid tumors, by carefully separating each fibroid from the uterine wall and its blood supply. Myomectomy is usually done in young women who have symptoms that indicate the presence of tumors and who wish to preserve their potential fertility. Uterine fibroids may cause pelvic pain and pressure or dysfunctional uterine bleeding, and they are a leading cause of infertility. Fibroids are more common in African-American women and become more common during the later reproductive years (Katz, 2007). Myomectomy may be performed as a prophylactic measure with other abdominopelvic surgery. Preoperative preparation may include injections of Lupron, a synthetic version of the naturally occurring gonadotropin-releasing hormone (GnRH), to reduce blood supply to the fibroid. This intervention mimics the postmenopausal state for women who receive it, as it reduces the amount of estrogen that the body synthesizes.

Procedural Considerations. The basic abdominal gynecologic instrument set and ESU are required. A laser may also be used. The patient is prepped as described for abdominal hysterectomy.

Operative Procedure

1. A midline or Pfannenstiel incision is used, and the uterus is exposed.
2. To contract the musculature of the uterine wall, a suitable drug may be injected into the fundus.
3. The surgeon grasps the fibroid tumor with a tenaculum. The broad ligament may be opened with curved hemostats and Metzenbaum scissors to determine the course of the ureter or to free the bladder.
4. Each tumor is shelled out of its bed, using blunt and sharp instruments, or the laser. Bleeding vessels are clamped and ligated or electrocoagulated.
5. The uterus is reconstructed with interrupted or continuous sutures.
6. The perimetrium is closed over the operative site, and the abdominal wound is closed.

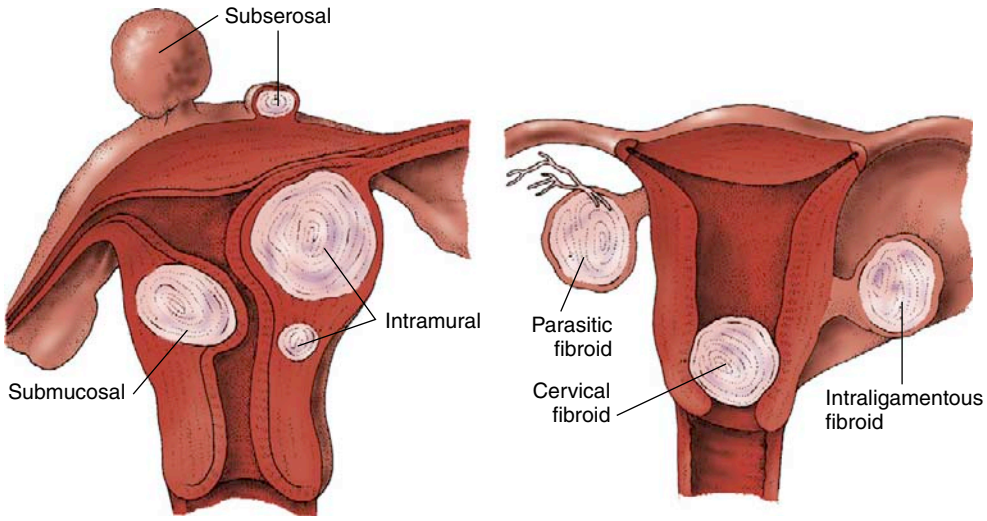

FIGURE 13-38 Classification of uterine leiomyomas.

Radical Hysterectomy (Wertheim)

Radical hysterectomy is en bloc dissection and wide removal of the uterus, tubes, ovaries, supporting ligaments, and upper vagina, together with careful removal of all recognizable lymph nodes in the pelvis (Figure 13-39). Extensive dissection of the ureters and of the bladder is also involved.

Radical hysterectomy is performed for gynecologic malignancy. Abdominal exploration determines lymph node involvement. With no lymph node involvement, a wide-cuff hysterectomy is performed. The uterus, tubes, and ovaries, together with most of the parametrial tissues and the upper portion of the vagina, are dissected en bloc. Dissection of the ureters from the paracervical structures takes place so that the ligaments supporting the uterus and vagina can be removed.

Procedural Considerations. Careful estimation of blood loss and calculation of urinary output are needed throughout the operative procedure. The patient is prepped as described for TAH. An indwelling urinary catheter is inserted. The basic abdominal gynecologic instrument set is required, with the addition of long and deep instruments and a self-retaining retractor.

Operative Procedure

1. The skin is incised, and the abdominal layers are opened, as described for laparotomy.
2. The surgeon cuts the peritoneum at its reflection on the anterior surface of the uterus between the round ligaments (Figure 13-40, *A*). Using blunt dissection, the surgeon frees the bladder surface from the cervix and vagina.
3. The right round and infundibulopelvic ligaments are clamped, cut with a knife or Metzenbaum scissors, and ligated with sutures to expose the external iliac artery. The ureter is identified and retracted with a vein retractor (Figure 13-40, *B*).
4. The lymph and areolar tissues are dissected from the iliac artery, obturator fossa, and ureter with Lahey forceps, Kitner sponges, and Metzenbaum scissors. A complete lymph gland dissection removes the tissue from the Cloquet node to the bifurcation of the iliac arteries bilaterally. The uterine artery and vein are clamped, cut, and doubly ligated.
5. The surgeon elevates the uterus and opens the cul-de-sac (Figure 13-40, *C*); the uterosacral and cardinal ligaments are clamped, cut with scissors, and doubly ligated with suture ligatures. The pararectal and paravesical areolar tissues are dissected free to skeletonize the upper vagina, and the paraurethral tissues are removed as near to the pelvic walls as possible.
6. The upper third of the vagina is cross-clamped with Heaney forceps (Figure 13-40, *D*) and divided using a long knife handle and #20 blade. The uterus and surrounding tissues are removed. Electrocoagulation is used to minimize venous oozing from small venules and capillaries. Lowering the head of the OR bed 15 degrees is also helpful in reducing the oozing of blood and serum.
7. The surgeon sutures the vagina with a running locked stitch, and inserts closed wound drains from above (Figure 13-40, *E*). The pelvis is peritonealized with a continuous suture.
8. The abdominal wound is closed (retention sutures may be used) and dressed in the usual manner. Vaginal packing and drains may be used. A suprapubic indwelling catheter may be placed to assist in preventing postoperative bladder spasm and for bladder drainage if the patient is unable to void after removal of the urethral catheter.
9. A perineal pad is applied.

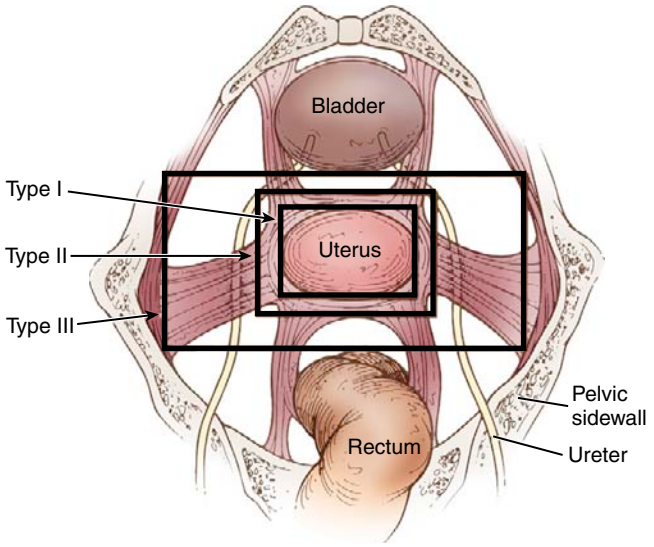

FIGURE 13-39 Different types of hysterectomy: type I—simple hysterectomy; type II—modified radical hysterectomy; type III—radical hysterectomy.

Pelvic Exenteration

Pelvic exenteration is the en bloc removal of the rectum, the distal sigmoid colon, the urinary bladder and the distal ureters, the internal iliac vessels and their lateral branches, all pelvic reproductive organs and lymph nodes, and the entire pelvic floor with the accompanying pelvic peritoneum, levator muscles, and perineum. A partial exenteration, either anterior or posterior, may be performed, depending on the origin of the carcinoma and the extent of local tissue invasion (Figure 13-41).

Pelvic exenteration is the preferred treatment for recurrent or persistent carcinoma of the cervix after radiation therapy. Advanced or recurrent vaginal, vulvar, or occasionally endometrial and rectal carcinomas are often amenable to exenteration (Jhingran and Levenback, 2007). Exenteration is considered only after a thorough investigation of the patient and disease status to determine if there is a reasonable chance of cure and of return to a productive life.

The need to create urinary and bowel diversions must also be considered, together with the patient's ability to cope with these diversions postoperatively. Plastic surgery may be required for creation of a neovagina. Psychologic preparation and support of the patient and family by the perioperative nurse and physician are prime requisites.

Procedural Considerations. Utmost care must be taken in positioning the patient because of the duration of surgery. The perioperative nurse pays strict attention to the patient's knees, hips, and lower back to prevent vascular and nerve damage. The patient is in the supine position with legs abducted in the ski position (i.e., lower extremities resting on a well-padded plantar surface rather than on the heel or popliteal area) or elevated in

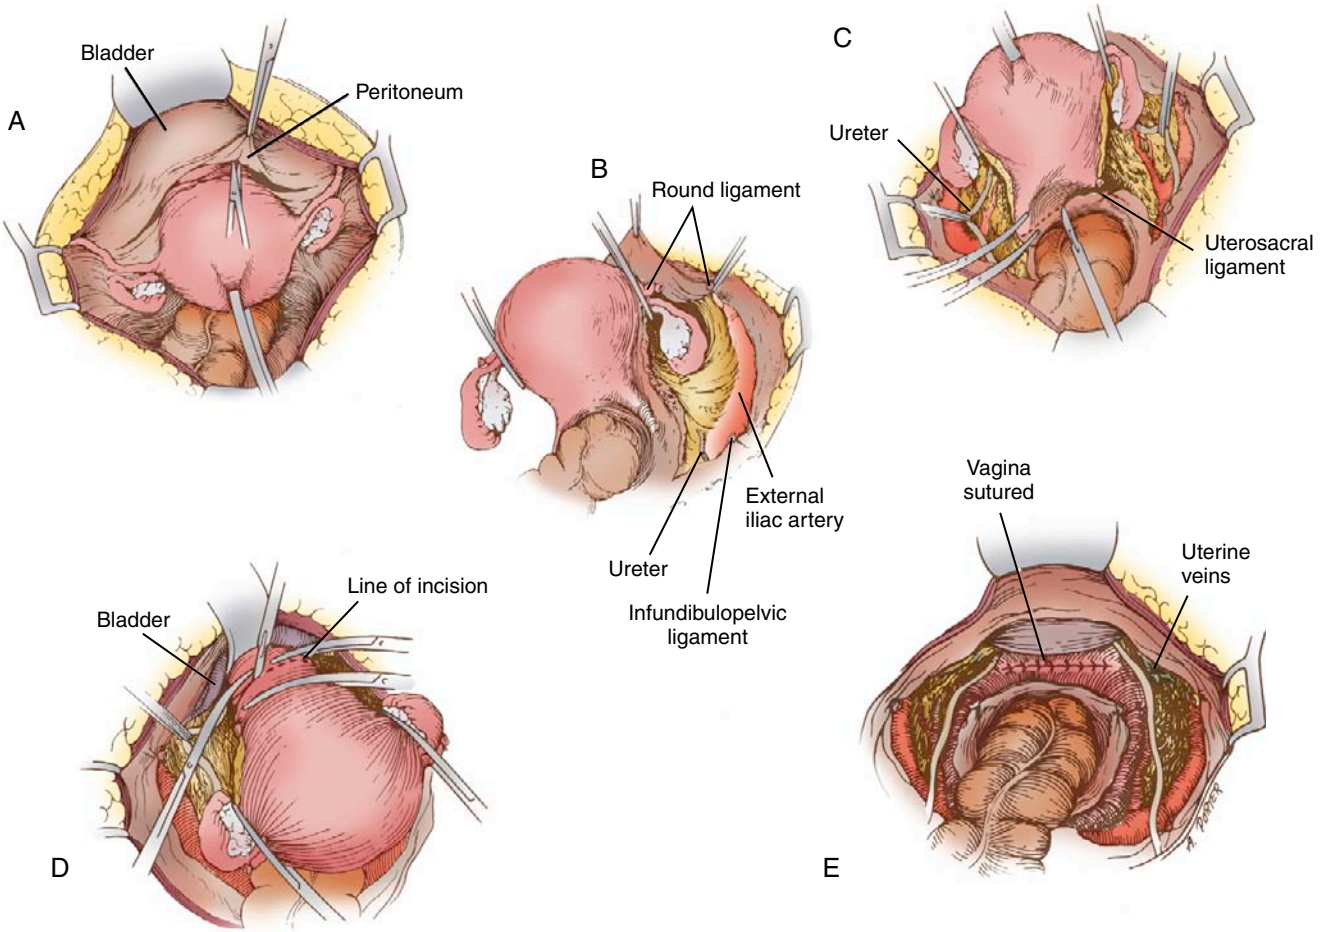

FIGURE 13-40 Wertheim radical hysterectomy. **A**, With upward traction applied on uterus, peritoneum is incised from round ligament to round ligament. **B**, Right round and infundibulopelvic ligaments are ligated and cut, thus exposing right external iliac artery. **C**, Uterus is held upward and forward, exposing cul-de-sac, which is incised as shown by dotted line. **D**, After dissection is completed, vagina is doubly clamped preparatory to transection, after which entire specimen is lifted out en bloc. **E**, Vagina is closed. Peritoneum remains to be reperitonealized.

a modified lithotomy position to allow access to the perineum without disruptive position changes. Skin prepping includes the abdomen, thighs, perineum, and internal vaginal vault.

The perioperative nurse and surgical technologist must be alert to fluid and blood loss. Irrigation solutions must be accurately measured, laparotomy packs must be weighed to assess blood volume loss, and the anesthesia provider and surgical team must be apprised of the measurements.

When the colon is transected or ureteral drainage is diverted into a segment of the ileum the gastrointestinal technique (i.e., bowel technique) as described in Chapter 10 should be followed.

Separate instrument setups are required for the abdominal and perineal approaches. Extra drapes, gowns, and gloves should be available.

For the abdominal approach, the basic abdominal gynecologic instrument set and instrumentation for abdominoperineal resection (see Chapter 10) are required.

For the perineal approach, the basic vaginal instrument set is required. To prevent contamination, the anus may be closed with a purse-string suture.

Operative Procedure

1. A long midline incision from the symphysis pubis to the umbilicus is made, and the abdomen is opened in the usual manner. A second incision within the perineum encircling the vestibule and anus is also made.
2. The surgeon explores the peritoneal cavity for metastasis to the liver, the nodes of the celiac axis, the superior mesenteric artery, and the para-aortic tissues.
3. The pelvis is explored, and the peritoneum along the brim of the pelvis is examined for lymph node involvement. Frozen sections may be indicated. The obturator fossa and the region of the uterosacral ligaments are explored. When findings at exploration are negative, retractors are placed and the small bowel is isolated with moist laparotomy packs (Figure 13-42).
4. The surgeon frees the sigmoid mesocolon and sections it by means of intestinal clamps and a scalpel or a stapling device. The proximal end is exteriorized through an opening in the left side of the abdomen; an intestinal clamp is left across the lumen until later, when the permanent colostomy will be secured to the skin.

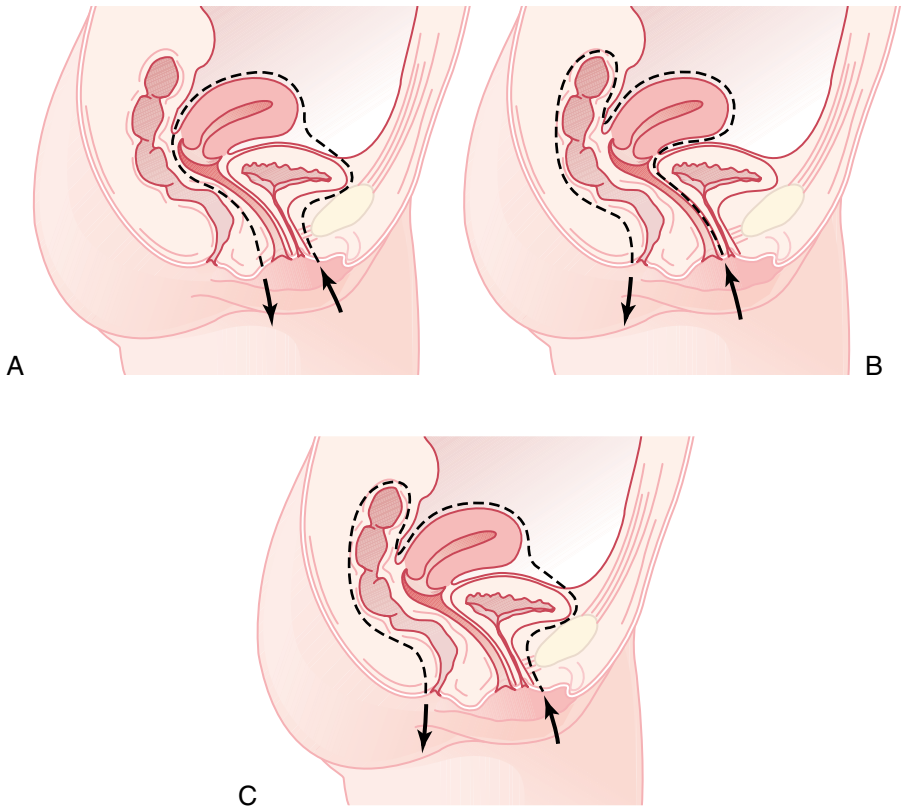

FIGURE 13-41 Organs removed in pelvic exenteration. **A**, Anterior exenteration. **B**, Posterior exenteration. **C**, Total pelvic exenteration.

5. The remaining sigmoid mesentery is clamped with Rochester-Péan forceps, cut, and ligated down to and including the superior hemorrhoidal vessels. Long instruments and sutures are used to reach the deep pelvic structures.
6. The distal sigmoid colon is closed with an inverting suture. The sigmoid colon and rectum are freed from the sacrococcygeal area by blunt and sharp dissection.
7. The lateral pelvic peritoneum is cut along the iliac vessels; the ovarian vessels and round ligaments on each side are clamped with Rochester-Péan forceps, cut, and doubly ligated.
8. The surgeon incises the peritoneum over the dome of the bladder with a long knife and Metzenbaum scissors, and separates the bladder from the symphysis pubis down to the urethra.
9. The ureters are identified and divided 2 to 3 cm below the brim of the pelvis. The proximal end is left open to allow urinary drainage, whereas the distal end is ligated.
10. The hypogastric artery, the internal iliac vein, and the superior and inferior gluteal vessels are exposed, clamped with hemostats, doubly ligated, and cut. The external iliac vein is retracted to allow evacuation of the contents of the obturator fossa, leaving the obturator nerve intact. Care must be taken in dissection not to damage the sacral plexus and sciatic nerve.
11. The surgeon isolates the internal pudendal vessels, ligates them with transfixion sutures, and cuts them. The remaining soft-tissue attachments of the pelvis are clamped and cut. Steps 10 and 11 are then performed on the opposite side.
12. The perineum is incised by an elliptic incision that includes the clitoris and anus. The ischiorectal fat is incised up to the area of the levator muscle.
13. The coccygeal attachment of the rectum is severed. The levator muscles are severed at their lateral attachments by using a long knife handle with #20 blade; hemostasis is maintained by pressure and traction.
14. The paravesical and paravaginal tissues are resected from the periosteum of the symphysis pubis and superior pubic rami by means of a knife. The specimen is completely freed and removed from the pelvis (Figure 13-43).
15. After residual bleeding vessels are identified and controlled by transfixing ligatures, the surgeon closes the subcutaneous tissue with interrupted sutures. A drain is placed in the wound, and the skin is closed.
16. Further residual bleeding vessels are controlled in the abdomen. Packs may be left in the pelvis, to be removed through the perineum after 48 hours.
17. The ileal segment is then fashioned, and the ureters are anastomosed to it. The external stoma is placed on the right side of the abdomen.
18. A jejunostomy catheter is inserted into the proximal jejunum to aid in postoperative bowel decompression. It is connected to the bowel with a purse-string suture and exteriorized to the skin, where it is sutured in place.
19. A gastrostomy tube is placed into the stomach in the same manner.
20. Hemostasis is checked. The small intestine is carefully repositioned into the pelvis. Packs and retractors are removed.

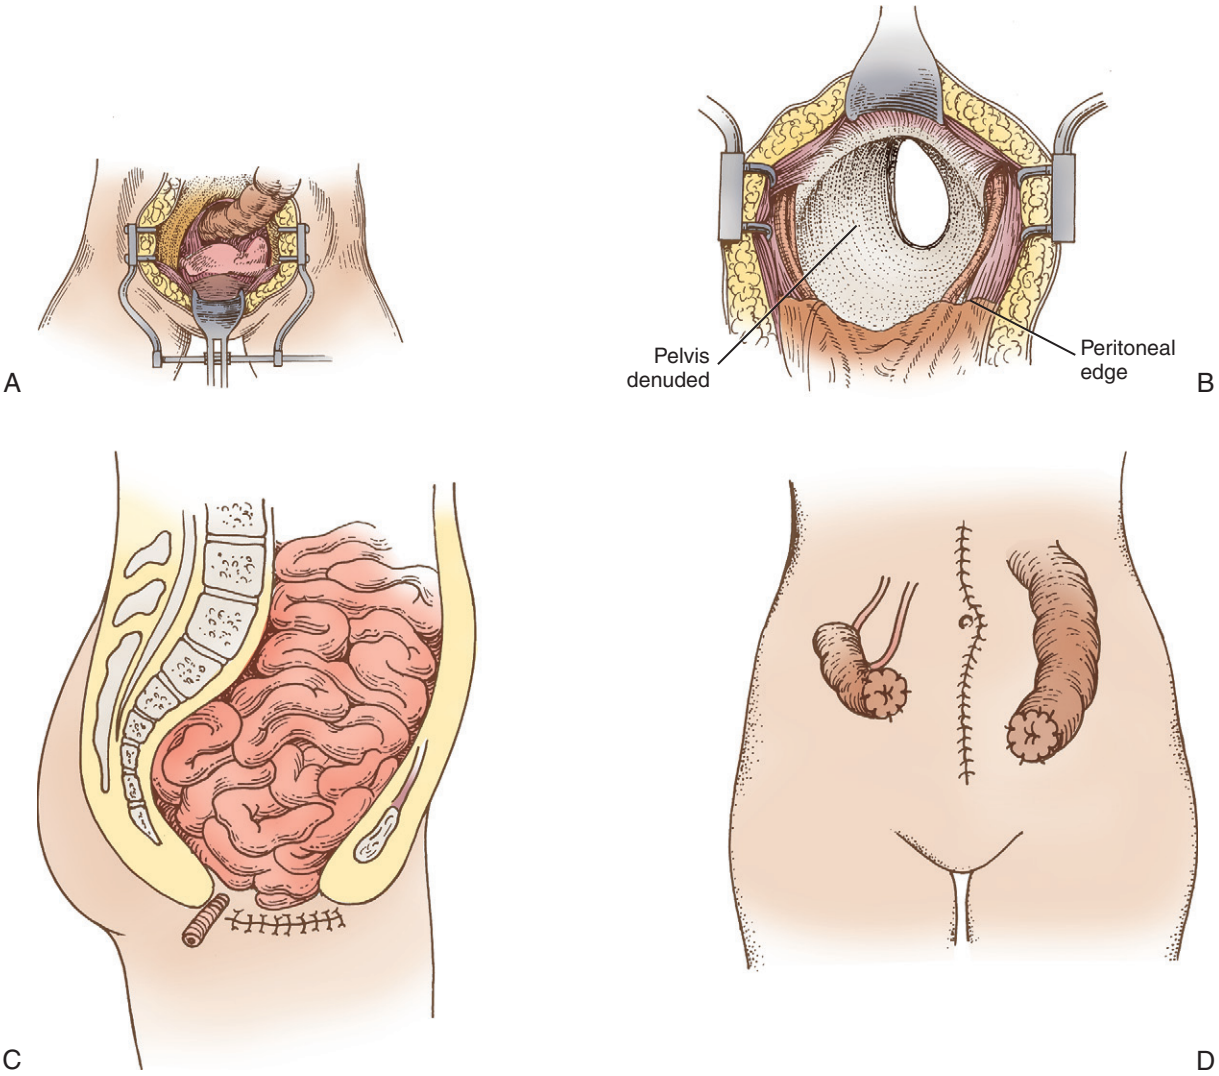

FIGURE 13-42 Pelvic exenteration. **A**, Pelvic viscera in situ as viewed from operating surgeon's vantage point after retractors are placed and small bowel is isolated with moist laparotomy packs. **B**, Empty pelvis after dissection of paravesical and paravaginal tissues and removal of specimen en bloc. **C**, Sagittal view of small bowel above pelvic defect. Perineal packing or drain may be used. **D**, After closure of abdominal wall, colostomy and urostomy stomas are sutured to skin edges.

21. The peritoneum, rectus muscles, and fascial sheaths are closed with interrupted figure-of-eight sutures. The skin is closed with interrupted sutures.
22. The colostomy stoma is prepared by removing the intestinal clamp from the sigmoid colon, opening the colon, and suturing the stoma to the skin edges.

The abdominal wound and tube sites are dressed in the usual manner. Drainage devices are applied to the colostomy and urostomy stomas.

SURGERY FOR CONDITIONS THAT AFFECT FERTILITY

Oophorectomy and Oophorocystectomy

Oophorectomy is removal of an ovary. Oophorocystectomy is removal of an ovarian cyst. Functional cysts constitute the majority of ovarian enlargements, with follicular cysts being the most common. Functional cysts develop in the corpus luteum. Benign cystic teratomas, also known as dermoid cysts, are very common and are composed of ectodermal tissues (sweat glands, hair follicles, and teeth) (Figure 13-44). Other tissues found in dermoid cysts include adult brain, bronchus, thyroid, cartilage, bone, and intestinal cells (Katz, 2007). Ovarian epithelial tumors, serous cystadenomas, and pseudomucinous cystadenomas are prone to malignant change.

The choice of operation depends on the patient's age and symptoms, findings during physical examination, and direct examination of the adnexa during exploration. If the ovarian tumor is recognized as benign, only the visibly diseased portions of the adnexa are removed. In the presence of dermoid, follicular, and corpus luteum cysts, the cyst is usually enucleated and most of the ovarian parenchyma is preserved. In tubal pregnancy, the ectopic pregnancy may be removed from the tube or the pregnant fallopian tube may be removed concomitant with, in some instances, the ovary.

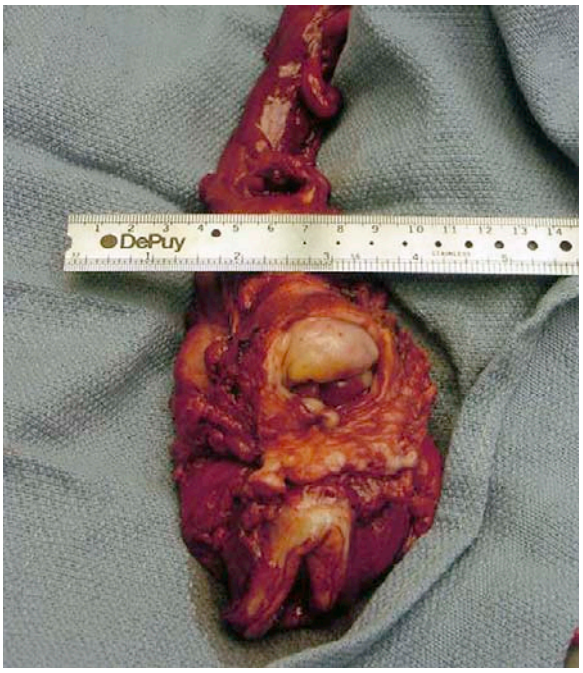

FIGURE 13-43 Pelvic exenteration specimen.

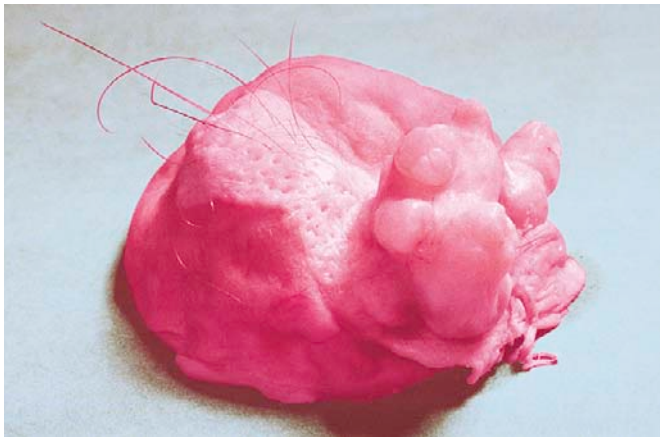

FIGURE 13-44 Dermoid cyst.

Procedural Considerations. The basic abdominal gynecologic instrument set is required, with the addition of a trocar and cannula, suction tubing, 10-ml syringe, and 21-gauge needle.

Operative Procedure

1. The surgeon opens the abdominal cavity as described for laparotomy.
2. After the abdominal cavity is opened, the surgeon has several options.
   a. For removal of a large ovarian cyst, a purse-string suture may be placed into the cyst wall and a trocar introduced in its center; the suture is tightened around the trocar as the fluid is aspirated. The trocar is removed, and the purse-string suture is tied. All normal ovarian tissue is preserved.
   b. For removal of a smaller ovarian cyst, a clamp is placed at the base of the cyst and the cyst is excised. The wound in the ovary is closed with absorbable suture (Figure 13-45).
   c. For removal of a dermoid cyst, the field is protected with laparotomy packs because the cystic contents produce irritation if they are spilled into the peritoneal cavity. An incision is made along the base of the cyst between the wall and normal ovarian tissue. The cystic wall is dissected away. The ovary is closed with interrupted or continuous sutures.
   d. For decortication of the enlarged ovary and wedge resection, a large segment of the ovarian cortex opposite the hilum is removed. The cysts are punctured with a needle point and collapsed. A wedge of ovarian stroma, extending deep into the hilum, is resected with a small knife; the cortex of the ovary is closed with interrupted or continuous sutures.
3. To prevent prolapse of the tube into the cul-de-sac, the tube may be sutured to the posterior sheath of the broad ligament.
4. The abdominal wound is closed as described for laparotomy, and dressings are applied.

Salpingo-oophorectomy

Salpingo-oophorectomy is removal of a fallopian tube and all or part of the associated ovary. Unilateral salpingo-oophorectomy may be done to cure chronic salpingo-oophoritis, for ectopic tubal gestation, or for certain disease conditions of the adnexa or large adnexal cysts. If both tubes and ovaries are diseased, they are removed with total hysterectomy.

Procedural Considerations. The basic abdominal gynecologic instrument set is required.

Operative Procedure

1. The surgeon opens the abdominal cavity as described for laparotomy.
2. The affected tube is grasped with Allis or Babcock forceps. The infundibulopelvic ligament is clamped with hemostats, cut, and ligated.
3. The mesosalpinx is grasped with hemostats and divided with the suspensory ligament of the ovary.
4. The cornual attachment of the tube is excised with a knife or curved scissors. Bleeding vessels are clamped and ligated.
5. The edges of the broad ligament are peritonealized from the uterine horn to the infundibulopelvic ligament as described for total hysterectomy.
6. The wound is closed as described for laparotomy, and dressings are applied.

Microscopic Reconstructive Surgery of the Fallopian Tube

The obstructed portion of a fallopian tube may be removed and the tube reconstructed to create patency of the remaining portion of the tube, promoting the possibility of fertilization. Reconstructive surgery of the tube, broadly called *tuboplasty,* includes reanastomosis, salpingoneostomy, fimbrioplasty, and lysis of adhesions.

The development of microsurgical techniques has advanced surgical reconstruction of fallopian tubes. Microsurgical techniques may be used with mini-laparotomy or laparoscopy, or both. Microsurgical tubal anastomosis permits atraumatic,

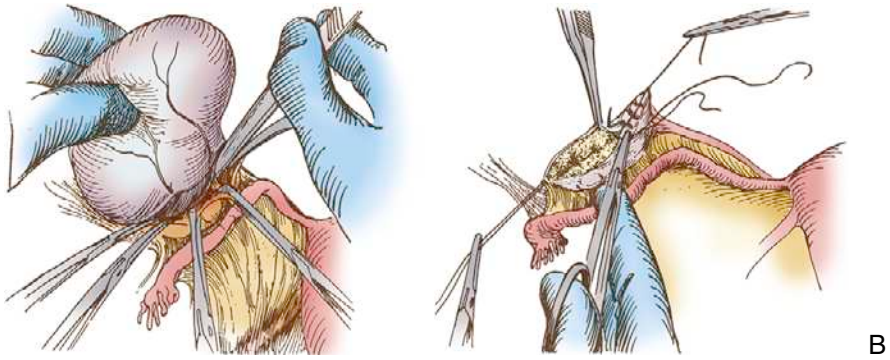

FIGURE 13-45 Resection of small cyst from ovary. **A**, Incision made around ovary near junction of cyst wall and normal ovarian tissue. Knife handle is convenient instrument for removal of cyst contents. **B**, Wound in ovary closed.

accurate alignment of fallopian tube segments. After surgery the fallopian tubes are shorter in length yet remain normal in other aspects. The laser may be adapted to the operating microscope, or the freehand approach may be used in tubal reconstructive surgery.

Procedural Considerations. The patient is in the supine position. The surgeon may place a Kahn, Calvin, Rubin, Hui, or Humi cannula or a pediatric Foley catheter into the uterine cavity for intraoperative chromotubation with diluted methylene blue or indigo carmine solution. Intraoperative chromotubation can also be achieved by applying a Buxton uterine clamp around the lower segment of the uterus and inserting an Angiocath catheter through the fundus into the cavity. A vaginal pack may be inserted to help elevate the uterus.

The basic abdominal gynecologic instrument set is required, with the addition of iris scissors (one curved and one straight), Adson forceps without teeth, Halsted mosquito hemostats, a set of Bowman lacrimal probes, Webster needle holders, Frazier suction tip, Kirschner retractor (if desired), and a Buxton uterine clamp (if desired).

Basic microsurgical instruments include microscissors (one curved and one straight), bayonet microscissors, jeweler's forceps, microforceps, fallopian tube forceps, petit-point mosquito hemostats, micro–needle holders (one curved and one straight), ball-tipped nerve hook, and glass or Teflon rods.

Accessory items include micro–needle electrodes, electrosurgical pencil, bipolar forceps with cord, irrigator, syringes and blunt needles for irrigation of the tissues, plastic or silastic tubing and connectors, diluted methylene blue or indigo carmine solution, diluted heparinized lactated Ringer's solution, microscope drape, microscope or operative loupes, ESU with monopolar and bipolar capabilities, and a video monitoring system (if desired).

Operative Procedure. Operative procedures for correction of postsurgical tubal occlusion are usually performed under the operating microscope. Other reconstructive procedures vary according to the nature of the pathologic condition of the tube and may be performed under the operating microscope or by use of operative loupes.

In microsurgery the surgeon must make sure that virtually no instruments are used in contact with the fallopian tube except those necessary to carry out the surgical technique. Microsurgery for infertility requires the use of specialized and delicate instruments. Each of these instruments is designed to permit gentle, atraumatic handling of tissues and prevent abrasions, lacerations, and vascular damage.

The tissues must be continually irrigated to prevent drying of the serosal surfaces. Lactated Ringer's solution alone or with heparin added may be used as the irrigating solution. Meticulous hemostasis is required in microsurgery. Irrigation is used to identify bleeding vessels or tissues. Hemostasis can be achieved by electrocoagulation with a micro–needle electrode or very fine bipolar forceps. When a CO_2 laser beam is used, the smoke from laser vaporization should be evacuated to prevent carbon deposits on the tissue.

Tubal Ligation

Tubal ligation is interruption of fallopian tube continuity, resulting in sterilization of the patient. In general, the indication for sterilization depends entirely on the desire of the patient. Certain medical indications and concern for the psychosocial needs of the patient are factors, and occasionally an obstetric indication exists, such as inherited fetal deformity. However, at least in the United States, sterilization is entirely a voluntary procedure. Depending on state law, a sterilization permit may have to be signed by the husband. Thorough presurgical counseling is needed for the patient and her husband or significant other because this procedure is not predictably reversible. Patients may elect to have the procedure performed on an ambulatory surgery basis at a time that is convenient for them.

Tubal ligation may be performed during or soon after delivery. This timing usually does not delay the normal discharge time for the patient. An objection to this practice is that the danger of hemorrhage still exists soon after delivery. With a vaginal delivery, tubal ligation is done on the first or second postpartum day. If a cesarean delivery is done, the tubes may be ligated at that time.

Operative Procedure. Many surgical methods and techniques are available for tubal ligation. The objective of each method is to achieve complete closure of the fallopian tube so that conception is prevented. When a segment of each fallopian tube is excised, it is preserved for pathologic examination. General surgical considerations are directed to excising a section of

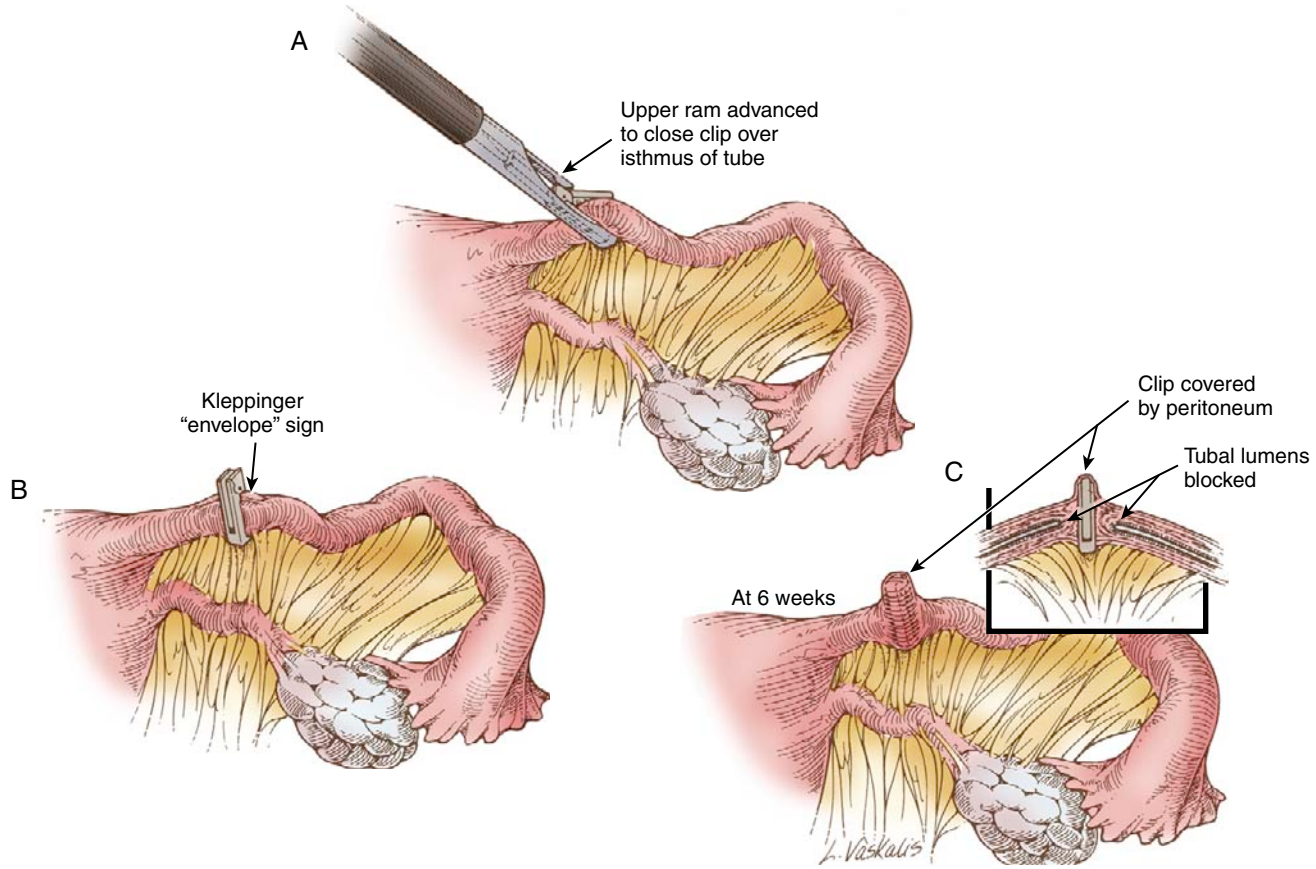

FIGURE 13-46 Spring clip. **A**, Isthmic portion (first 2 to 3 cm of tube) is maneuvered into the open jaws of the clip until it is snug against the hinge. **B**, Closing the clip will create the Kleppinger envelope sign—a fold of tubal peritoneum in the hinge of the clip. **C**, Failure to get the clip completely across the isthmus may result in pregnancy. Some surgeons routinely use two clips close together on each tube.

each fallopian tube, ligating the severed ends, achieving hemostasis, and incorporating the proximal stump within layers of the mesosalpinx. Another approach, involving insertion of an expandable spring coil into the fallopian tube to mechanically block it, is accomplished hysteroscopically via the transcervical route. The device is made from titanium, stainless steel, nickel, and Dacron fibers. Ultimately the device provides an inflammatory response and fibrosis of the intramural tubal lumen over a 3-month period (Hastings-Tolsma et al, 2006).

LAPAROSCOPIC TUBAL OCCLUSION

1. The operative approach is the same as that for laparoscopy.
2. An accessory suprapubic incision may be made for the occluding instrument.
3. Sterilization may take place by thermal coagulation or by placement of a spring clip or silastic band after the tube has been identified and isolated in the grasping forceps.
   a. Bipolar coagulation occurs when electrical current passes only through the tube from prong to prong. At least 3 cm of the tube is destroyed, which therefore prevents spontaneous recanalization. It has been recommended that the tube be grasped at least 2 to 3 cm away from the uterocornual junction at the time of this procedure so that a stump of isthmus remains to absorb the intrauterine fluid under pressure and minimize fistula formation, which could result in an ectopic pregnancy for the patient in the future.
   b. The *spring clip* occludes the isthmus of the tube by two plastic jaws (Figure 13-46, *A* and *B*). The tube is compressed by a stainless-steel spring that presses the jaws together. Spring clip application requires careful surgical technique to ensure that the clip is completely across the isthmus of the tube (Figure 13-46, *C*). Some surgeons apply two spring clips positioned close together on each tube when using this approach.
   c. With a *silastic band,* the tube is drawn 1.5 cm into a 0.5-cm diameter metal cylinder, which destroys approximately 3 cm of the tube (Figure 13-47, *A*). A silastic ring stretched on the outside of the cylinder is released to form an occlusion (Figure 13-47, *B*). Over time, about 3 cm of the constricted tube undergoes necrosis and the tubes separate (Figure 13-47, *C*).

MINI-LAPAROTOMY APPROACH

1. The surgeon creates a 2-cm transverse incision above the pubic hairline.
2. A large bivalved speculum may be placed through the incision and into the peritoneal cavity. The large Graves bivalve speculum serves as a small abdominal retractor and permits easy access to the tubes.
3. Spring clips or silastic bands can be applied, or the original Pomeroy method of ligation can be carried out. The Pomeroy technique provides a tissue specimen of each tube.

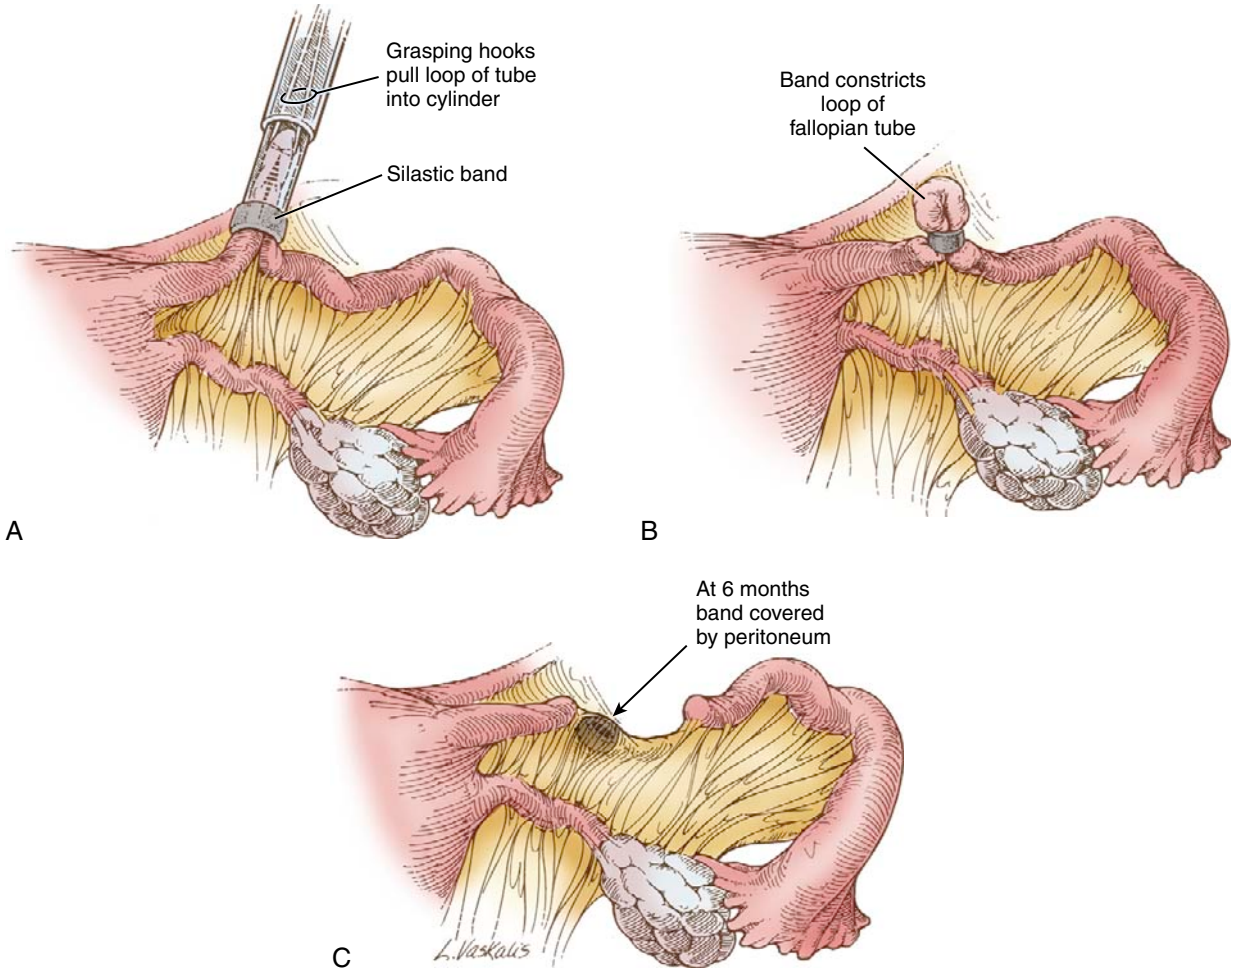

FIGURE 13-47 Silastic band. **A**, About 3 cm of tube is drawn into a 5-mm cylinder over which a silastic band has been stretched. **B**, Releasing the band constricts the knuckle of tube with eventual necrosis. **C**, As with the Pomeroy technique, 6 months later the stumps are about 3 cm apart.

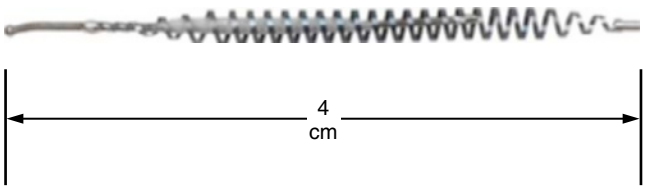

FIGURE 13-48 Essure implant.

Suture material is tied around each tube, and a section of tube is removed. Over time, the tubes separate, destroying the passage between the ovary and the uterus.

TRANSCERVICAL APPROACH (ESSURE)

1. The operative approach is the same as that for hysteroscopy.
2. The uterus is distended, and the ostia are visualized.
3. The spring device (Figure 13-48) is placed on the tip of the plastic carrier provided in the kit and inserted through the hysteroscope's channel.
4. The device is guided to the tubal ostium, and the handle for the carrying device is stabilized.
5. The device is released from the plastic carrier, and the coil is deployed as the handle is retracted (Figure 13-49).
6. The surgeon counts the number of coils trailing into the uterine cavity. There should be three to eight visible coils (Figure 13-50).
7. The sequence is repeated for the remaining fallopian tube.

ASSISTED REPRODUCTIVE THERAPIES FOR INFERTILITY

Infertility is a condition that affects approximately 10% of reproductive-age couples. Infertility implies subfertility—a prolonged time to conceive—as opposed to sterility, which means inability to conceive (Lowdermilk, 2007b). Infertility is referred to as primary when it occurs without a prior pregnancy and secondary if it occurs after a successful conception. Facing infertility is an emotionally stressful process for both partners. Treatment of infertility is multidimensional and may involve medical as well as surgical interventions. Often by the time a woman presents in the perioperative setting for a procedure related to infertility, she and her partner have undergone many months or years of testing and medical interventions. Individuals with infertility use various coping strategies, and the perioperative nurse needs to be aware of these in providing supportive care.

Eighty percent of couples that do not have fertility issues achieve conception within 1 year. A couple is considered infertile if they have not conceived after attempting for 1 year, although this landmark may be modified because of select clinical circumstances. Both partners undergo extensive testing to identify possible organic or functional causes for their infertility. Identifiable conditions contributing to infertility are attributed to the female partner in 50% of couples, the male partner in 18.5% of couples, and both partners in 18.4% of couples (Robins and Carson, 2008).

The term *assisted reproductive therapies (ARTs)* refers to the multiple options couples may select to assist them in the reproduction process. ARTs are described briefly in Table 13-3. Techniques for ART have evolved over time, with the majority of interventions conducted in the physician's office. The use of ARTs has made it possible for women to successfully conceive and have children when they are older than 40.

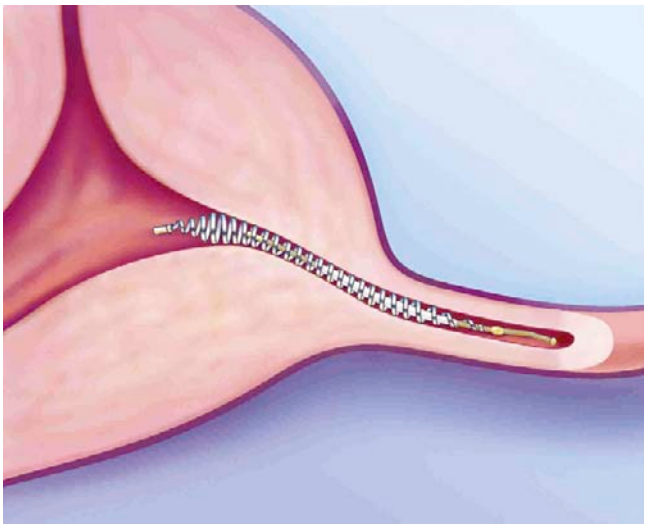

FIGURE 13-49 Essure device placed in fallopian tube.

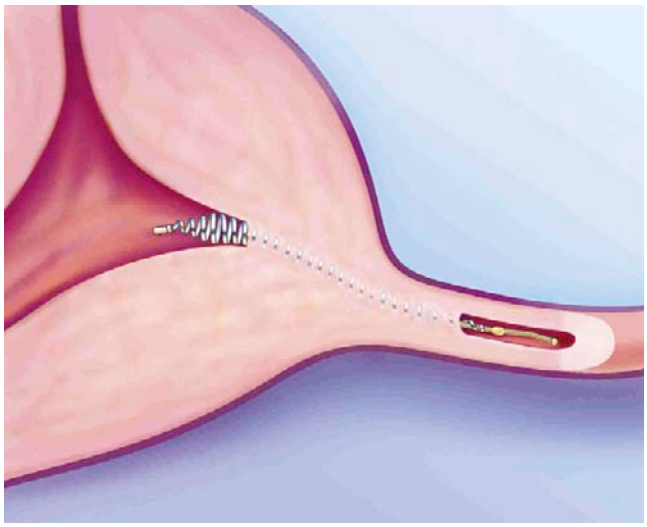

FIGURE 13-50 Essure device after carrier detached. Note coils in uterine cavity.

OBSTETRIC SURGERY

Providing safe nursing care for the perioperative patient is the goal of every registered nurse. The interventions necessary to reach that goal intensify in the pregnant woman who presents for surgery. The team is now faced with the challenge of caring for at least two patients, the mother and her child (Risk Reduction Strategies).

RISK REDUCTION STRATEGIES

Preparation for Cardiac Arrest in the Pregnant Patient

Although rare, cardiopulmonary arrest does occur in the pregnant patient. Nurses can reduce risk to the patient and her infant through familiarity with resuscitation techniques for pregnant patients. Guidelines for cardiac arrest during pregnancy include the following:

AIRWAY

- Determine unresponsiveness.
- Activate the code team and obtain the automated cardiac defibrillator.
- Position the woman supine on a firm surface with a roll or wedge placed under the right hip to displace the uterus laterally off the great vessels; or position her laterally.
- Open the airway with the head tilt-chin lift maneuver.

BREATHING

- Determine breathlessness (look, listen, and feel).
- If the woman is not breathing, give two breaths, 1 second apart.

CIRCULATION

- Determine pulselessness by checking the carotid pulse.
- If there is no pulse, begin chest compressions at a rate of 100 per minute. Chest compressions may be performed slightly higher on the sternum if the uterus is enlarged enough to displace the diaphragm into a higher position. Check the pulse after 2 minutes; if the pulse is not present, continue CPR.

DEFIBRILLATION

- If defibrillation is necessary, the nurse should ensure the paddles are placed one rib space higher than usual because the heart is displaced slightly by the uterus.

If possible the fetus should be monitored during the cardiac arrest. If the fetus is delivered within 5 minutes of the arrest, intact neurologic survival (in fetuses of viable gestational age) is likely; beyond 15 minutes, impairment or death is likely.

Successful resuscitation may be associated with complications for the woman, including laceration of the liver, rupture of the spleen or uterus, hemothorax, hemoperitoneum, or fracture of the ribs or sternum. Fetal complications may include cardiac dysrhythmia or asystole associated with maternal defibrillation and medications, CNS depression related to antidysrhythmic medications and inadequate placental perfusion, possible hypoxemia, and acidosis.

If the resuscitation is successful, ongoing intensive monitoring, including fetal surveillance, is necessary as the woman is at increased risk for recurrent cardiac arrest and dysrhythmia. Fetal status and gestational age should be considered and used in decision-making regarding delivery or continuation of the pregnancy.

Modified from McAteer J: Medical-surgical problems in pregnancy. In Lowdermilk DL, Perry SE, editors: *Maternity and women's health care,* ed 9, St Louis, 2007, Mosby.

TABLE 13-3

Assisted Reproductive Therapies

Technology	Description	Use
Assisted hatching (AH)	The zona pellucida is micromanipulated chemically or mechanically to allow the embryo to hatch and attach to the uterine wall.	Recurrent miscarriage, failed IVF, advanced maternal age
In vitro fertilization embryo transfer (IVF-ET)	Follows in vitro fertilization. The fertilized ovum is implanted in the woman's uterus. Typically three embryos are transferred.	Tubal disease or blockage, endometriosis, unexplained infertility, cervical factors, immunity issues
Donor oocyte	Eggs are donated by an IVF procedure and the donated eggs are inseminated. Embryos are transferred into the recipient's uterus, which is hormonally prepared with estrogen/progesterone.	Early menopause, surgical removal of ovaries or congenitally absent ovaries, autosomal or sex-linked disorders, lack of fertilization in repeated IVF attempts because of subtle oocyte abnormalities or defects in oocyte-spermatozoa interaction
Donor embryo	A donated embryo is transferred to the uterus of an infertile woman.	Infertility not resolved by less aggressive forms of therapy; absence of ovaries; male partner azoospermic or severely compromised
Therapeutic donor insemination (TDI)	Donor sperm are used to inseminate the female partner.	Male partner azoospermic or has very low sperm count; couple has genetic defect; male partner has antisperm antibodies
Gamete intrafallopian transfer (GIFT)	Oocytes are retrieved from the ovary and mixed in a catheter with sperm. The solution is transferred into the fimbriated end of the tube for in situ fertilization.	Unexplained infertility with normal, patent fallopian tubes
Intracervical insemination (ICI)	Performed during a natural cycle or stimulated cycle. Sperm are placed inside the neck of the cervix by means of a catheter and syringe.	Immunity issues, desire or need to use donor sperm in otherwise fertile woman, male infertility, unexplained infertility
Intracytoplasmic sperm injection (ICSI)	Selection of single sperm injected directly into the egg to achieve fertilization.	Failed IVF, oligospermia, asthenospermia, obstructive azoospermia, immunity issues, failed vasectomy reversal
Intrauterine insemination (IUI)	Similar to ICI; performed during a natural cycle or stimulated cycle. Sperm are placed inside uterus by means of a catheter and syringe.	Immunity issues, desire or need to use donor sperm in otherwise fertile woman, male infertility, unexplained infertility; failure of ICI
In vitro fertilization (IVF)	Oocytes are retrieved from the ovary and fertilized with sperm in the laboratory and allowed to develop into embryos. Embryos are then transferred to the woman using a variety of techniques.	Tubal disease or blockage, severe male infertility, endometriosis, immunity issues, unexplained infertility, cervical factors
Zygote intrafallopian transfer (ZIFT)	In vitro fertilization is accomplished and embryo is placed in the fallopian tube during the zygote stage.	Unexplained infertility with normal, patent fallopian tubes

Modified from Lowdermilk DL: Infertility. In Lowdermilk DL, Perry SE, editors: *Maternity and women's health care,* ed 9, St Louis, 2007, Mosby.

Maternal changes in pregnancy increase as the gestation progresses and include hormonal fluctuations, mechanical changes to the viscera related to the enlarging uterus, increased metabolic and oxygen demands, and hemodynamic changes. The fetus also has unique metabolic and hemodynamic needs that must be considered. Hazards of performing surgery on the pregnant patient include fetal loss, fetal asphyxia, premature labor, premature rupture of the membranes, and thromboembolic events. Many medications used in the perioperative setting cross into the placental circulation on administration to the mother (Birnbach and Browne, 2005).

Special considerations for the obstetric surgical patient include continuous monitoring of the fetal heart rate, rapid induction for general anesthesia, and preparation for the possible use of tocolytics (e.g., medications to decrease uterine activity) to prevent labor (Surgical Pharmacology). Ready access to neonatal resuscitative drugs and equipment should be established when performing surgery on pregnant women in the second trimester and beyond. If permitted by the surgical approach, the pregnant woman should be positioned with a lateral tilt or with a wedge or pillow under her right hip to provide uterine displacement and relieve pressure on the maternal vena cava. This position promotes blood flow to the placenta.

Cervical Cerclage

Incompetence of the cervix is a condition characterized by habitual midtrimester spontaneous miscarriages. The condition is characterized by shortening of the length of the cervix (observed on ultrasound) and occasional funneling of the cervix. Surgical intervention is designed to prevent cervical dilation that results in the release of uterine contents. Introduced by Shirodkar in 1951, the cervical cerclage provides a mechanical closure to the cervix. Cerclage is most commonly

SURGICAL PHARMACOLOGY

Medications Used in Gynecology and Obstetrics

Part of safe perioperative patient care focuses on safe medication practices. Strategies for safe medication administration include standardizing medication labeling both on and off the surgical field, separating sound-alike and look-alike medications, and minimizing distractions.

In addition to practicing the "seven rights" (right patient, right drug, right time, right route, right dose, right documentation and right technique) for the medications he or she administers, the perioperative nurse must be familiar with medications administered to the patient by others (e.g., anesthesia providers, surgeons). Many of the medications used in gynecologic and obstetric surgery are unique to the specialty or have unique uses within the specialty. To be able to constantly modify the patient's plan of care as needed throughout the perioperative period, the perioperative nurse must be familiar with how these medications work, dosage ranges, adverse reactions, and nursing implications.

OXYTOCICS

Medications that increase motor activity within the uterus by hormonal stimulation or direct stimulation on the smooth muscles, usually resulting in uterine contractions. Used intraoperatively and postoperatively.

Medication	Perioperative Uses	Actions	Dosage/ Administration	Adverse Reactions	Nursing Considerations
Oxytocin (Pitocin)	Postabortion bleeding, postpartum bleeding, improvement of uterine contractility after cesarean delivery	Acts on uterine myofibril activity	Given IV only, 10-40 units per liter of fluid	Hypertonicity with tearing of the uterus	Monitor BP; assess for continued bleeding; monitor fundal response to drug.
Methylergonovine maleate (Methergine)	Postabortion bleeding, postpartum bleeding	Ergot alkaline that causes vasospasm of the coronary arteries and directly stimulates uterine muscle	May be given PO, IM, or IV; most frequent route in OR is IM; IM/IV dose is 0.2 mg; may be repeated q2-4hr for no more than a total of five doses	Nausea; cramping; vomiting; dizziness; diaphoresis; bradycardia; chest pain; tachycardia; pale, cool, and blotchy skin; facial swelling; increased uterine pain	Monitor BP; assess for continued bleeding; monitor fundal response to drug. Use cautiously in patients with heart disease, hepatitis, or renal insufficiency because of vasoconstrictive effect. Assess extremities for color, warmth, movement, and pain.
Dinoprostone (Cervidil)	Postabortion bleeding, postpartum bleeding	Prostaglandin that directly acts on the myometrium, causing softening of the cervix; causes myometrial contractions in the gravid uterus	May be administered as an endocervical gel, vaginal insert, or vaginal suppository	Vomiting, nausea, bradycardia, chills/shivering, diarrhea	Keep frozen and bring to room temperature just before use. Use caution when handling to prevent skin contact. Have the patient remain supine for 15-30 min after administration. Be prepared to treat nausea. Monitor BP; assess for continued bleeding; monitor fundal response to drug.

Continued

SURGICAL PHARMACOLOGY

Medications Used in Gynecology and Obstetrics—cont'd

TOCOLYTICS

Medications that decrease uterine contractility. Most commonly used in the perioperative setting during fetal surgery or in surgical procedures on pregnant females. May also be used in the postanesthesia care unit.

Medication	Perioperative Uses	Actions	Dosage/ Administration	Adverse Reactions	Nursing Considerations
Ritodrine (Yutopar)	Prevention of preterm labor	β-Adrenergic that inhibits uterine activity by relaxing smooth uterine muscle tissue	May be given PO or IV; IV dose is 0.05-0.1 mg/min	Shortness of breath, tachypnea, tachycardia, palpitations, chest pain, fluid retention, hypotension, nausea, vomiting	Monitor vital signs closely; be prepared to treat nausea. Have propranolol available to reverse cardiovascular effects.
Terbutaline (Brethine)	Prevention of preterm labor	Adrenergic agonist that stimulates β-adrenergic receptors, resulting in relaxation of uterine smooth muscle	May be given PO, Sub-Q, or IV; usual IV dose is 2.5-10 mcg/min; may increase gradually q15-20 min up to 17.5-30 mcg/min; PO dose is 2.5-10 mg q4-6hr	Tremors, anxiety, nervousness, drowsiness, headache, nausea, heartburn, dizziness; flushing and weakness	May decrease serum potassium levels. Assess baseline maternal heart rate and fetal heart rate. Provide emotional support to help ease anxiety.
Magnesium sulfate	Prevention of preterm labor, prevention/ treatment of convulsions caused by pregnancy-induced hypertension (preeclampsia/ eclampsia)	Relaxes smooth muscle of the uterus; blocks neuromuscular transmission to produce seizure control	Loading dose of 4-6 g diluted in 100 ml of IV fluid, given over 30-60 min; maintenance dose 2-4 g/hr	Reduced respiratory rate, decreased reflexes, decreased heart rate, hypotension, sedation	Test patellar reflexes before giving drug to determine baseline. Suppressed patellar reflexes may be sign of impending respiratory arrest. Monitor vital signs. Maintain accurate I&O. Ensure calcium gluconate is available to reverse magnesium sulfate toxicity.
ANTIMETABOLITES					
Medications that interrupt cell division. May be given intraoperatively or postoperatively.					
Methotrexate	Used in ectopic pregnancy and hydatidiform mole surgery to eradicate any remaining trophoblastic cells	Inhibits RNA, DNA, and protein synthesis in rapidly dividing cells	PO, IM, IV Most commonly given IM in perioperative setting (15-30 mg)	Nausea, vomiting, stomatitis, dizziness, blurred vision, photophobia, hepatotoxicity, nephrotoxicity	Encourage patient to maintain scrupulous oral hygiene; be prepared to treat nausea and vomiting. Review good handwashing practices with patient. Discuss need for weekly repeated lab studies to monitor hCG levels 2-8 wk after procedure.

SURGICAL PHARMACOLOGY

Medications Used in Gynecology and Obstetrics—cont'd

MISCELLANEOUS AGENTS

Medication	Perioperative Uses	Actions	Dosage/ Administration	Adverse Reactions	Nursing Considerations
Misoprostol (Cytotec)	Used for cervical ripening; may be used instead of dilation and evacuation (D&E) for missed or incomplete abortion (off-label use)	Synthetic prostaglandin that acts directly on uterine muscle	Oral, rectal, or intravaginal; available in 100 and 200 mcg tablets; oral dose for missed abortion: 600 mcg; cervical ripening: intravaginal, 25 mcg (¼ of 100-mcg tablet) 2-3 hr before procedure	Diarrhea, abdominal pain; headache, nausea, uterine rupture	May increase effect of oxytocin. Do not confuse with similarly named drugs Cytoxan and metoprolol. Not approved by FDA for use in cervical ripening or missed/ incomplete abortion but endorsed by ACOG. Should not be used in patients with prior cesarean delivery.
Estradiol cream (Estrace cream)	Lubricant for vaginal packing	Increased synthesis of RNA, DNA, protein in tissues; reduces release of gonadotropin hormone from the hypothalamus; reduces FSH and LH from the pituitary gland	Topical cream, 0.1 mg/g, intravaginally	Local irritation, vaginal discharge	Assess preoperatively for any sensitivity to topical estrogens. Do not use excessive amount of cream. Cream will liquefy from patient's body heat and may soil bedding.
Miconazole nitrate cream (Monistat)	Lubricant for vaginal packing, treatment of vulvovaginal candidiasis	Inhibits synthesis of ergosterol (an important component of fungal cell formation)	2% topical cream intravaginally	Local irritation, vaginal discharge	Assess preoperatively for any sensitivity to antifungals. Do not use excessive amount of cream. Cream will liquefy from patient's body heat and may soil bedding.
Sulfathiazole/ sulfacetamide/ sulfabenzamide cream (Triple Sulfa)	Lubricant for vaginal packing, treatment of *Gardnerella* vaginitis	Exerts bacteriostatic action by competitive antagonism of PABA (a component of folic acid synthesis)	Topical cream used intravaginally; concentration: sulfathiazole 3.42%, sulfacetamide 2.86%, and sulfabenzamide 3.7%	Local irritation, vaginal discharge, Stevens-Johnson syndrome	Assess preoperatively for any sensitivity to sulfa medications or derivatives. Do not use excessive amount of cream. Cream will liquefy from patient's body heat and may soil bedding.
Vasopressin (Pitressin)	Injected directly into uterus to decrease bleeding during hysterectomy	Causes vasoconstriction through direct stimulation of smooth muscle; pituitary hormone	20 units/ml to be diluted in injectable saline as directed by surgeon	Diaphoresis, circumoral pallor, wheezing, allergic reactions	Potential for confusion related to name. Do not confuse Pitressin with Pitocin! Monitor vital signs. Verify dilution with surgeon.
Methylene blue	Indicator dye: intraoperative hysterosal-pingogram; used to test patency of ureters	Converts ferrous iron to methemoglobin	0.1-0.2% ml/kg given IV push, slowly	Hypertension, dizziness, staining of skin, discoloration of urine or stool	Warn patient about urine and stool discoloration. Methylene blue stains can be removed with mild bleach solution.

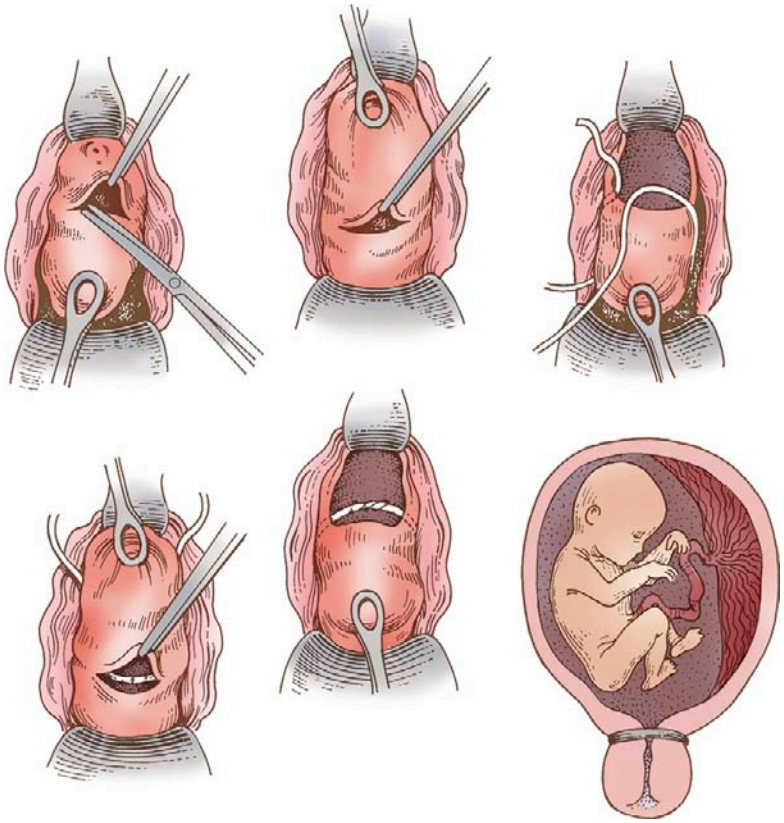

FIGURE 13-51 Principles of Shirodkar operation for treatment of incompetent internal cervical os during pregnancy.

accomplished by way of the vaginal approach (Shirodkar and McDonald approaches) or, much less commonly, the abdominal or laparoscopic approach. The Shirodkar technique involves the *submucosal* placement of a purse-string type of ligature of Mersilene, Dacron tape, heavy nylon suture, or plastic-covered braided-steel suture at the level of the internal os to close it (Genovese, 2007). The McDonald cerclage uses a secured tie or tape placed horizontally and vertically across the cervix. The vaginal cerclage is generally removed in an office procedure when the woman reaches the thirty-seventh week of gestation, or the child may be delivered by cesarean.

Procedural Considerations—Vaginal Approach. Gentle vaginal preparation is carried out. The instrumentation includes the basic vaginal instrument set, with the addition of right and left Deschamps ligature carriers, trocar needles, sutures for the internal os, and the surgeon's preference for closure of the mucosal incisions.

Operative Procedure—Shirodkar/McDonald

1. Anterior and posterior vaginal retractors are placed, and the cervix is pulled down with smooth ovum or sponge-holding forceps. With smooth tissue forceps and dissecting scissors, the mucosa over the anterior cervix is opened to permit the bladder to be pushed back (Figure 13-51).
2. The surgeon lifts the cervix and incises the posterior vaginal mucosa at the level of the peritoneal reflection. The corners of the anterior and posterior incisions are bilaterally approximated in the area of the lateral mucosa with curved tonsil or Allis forceps.
3. The prepared ligature is placed at the desired level by passage of the material through the approximated tissue and is drawn tight posteriorly to close the cervix. The suture material for the ligature is then tied. It is not necessary to suture the ligature to the underlying tissues. The suture material used for this ligation is 5-mm Dacron or Mersilene tape. The anterior and posterior mucosal incisions are usually closed with 2-0 absorbable suture to complete the procedure.
4. The McDonald cerclage is performed in a similar manner, using the same instrumentation, supplies, and preparation. The suture is not buried in the submucosa in the McDonald technique (Figure 13-52).

Procedural Considerations—Abdominal Approach. The transabdominal cerclage is reserved for select women who have a cervix that is so short or damaged that the vaginal approach is not feasible. A vaginal and abdominal prep is performed. A Foley catheter may be placed to ensure the urinary bladder remains decompressed. A basic vaginal set and an abdominal set are needed for instrumentation. Sutures used for the transabdominal cerclage are identical to those used in the vaginal approach.

Operative Procedure—Abdominal Approach

1. The abdomen is opened and the viscera retracted. The Trendelenburg's position may be used to facilitate exposure.
2. The suture material or tape is placed around the uterine isthmus medial to the uterine vessels and fixed to the anterior isthmus, to Mackenrodt's ligaments, and to the insertions of the uterosacral ligaments.

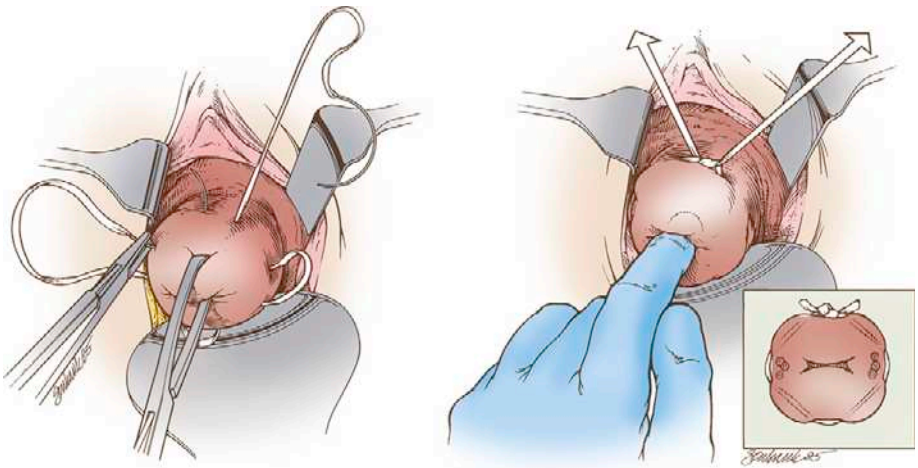

FIGURE 13-52 McDonald cerclage.

3. The abdominal wound is closed as described for laparotomy closure (see Chapter 10).
4. Abdominal dressings and a perineal pad are applied.

Procedural Considerations—Laparoscopic Approach. The laparoscopic approach may be associated with decreased postoperative pain and morbidity compared with the laparotomy approach. Standard laparoscopic equipment commonly used in gynecologic procedures is required.

Operative Procedure—Laparoscopic Approach

1. The laparoscopic camera and ports are placed for a standard laparoscopic approach, and pneumoperitoneum is established.
2. The bladder peritoneum is opened at the level of the uterine isthmus.
3. The surgeon creates a window through the broad ligament medially to the uterine vessels at the level of the internal os.
4. A strip of polypropylene mesh is placed retroperitoneally through the window circumferentially around the isthmus above the cardinal and sacrouterine ligaments.
5. The mesh is anchored with a nonabsorbable suture.
6. The laparoscopic instruments are removed, and the wounds are closed.

ABDOMINAL SURGERY DURING PREGNANCY

The incidence of the immediate need for abdominal surgery occurs as frequently among pregnant women as among nonpregnant women of childbearing ages. Diagnosis of the abdominal problems in the pregnant woman is challenging because of the enlarged uterus and displaced organs. Mild leukocytosis and increased levels of alkaline phosphatase and amylase are normal during pregnancy and may also indicate surgical intraperitoneal processes. Abnormally high or rising laboratory values should be noted. Radiographic evaluation is contraindicated in most instances during pregnancy (McAteer, 2007).

Laparotomy or laparoscopy may be required for conditions such as appendicitis and intestinal obstruction. Appendicitis is the most common nonobstetric surgical condition that complicates pregnancy and occurs with equal frequency in each of the trimesters and the postpartum period in approximately 1 in every 2000 pregnancies (McAteer, 2007).

Fetal Surgery

Developments in prenatal diagnosis have progressed to the point where clinicians may consider the fetus to be the patient. Serious congenital anomaly is diagnosable by ultrasonography, alpha-fetoprotein specimen, amniocentesis, chorionic villi sampling, or percutaneous umbilical blood sampling. When an anomaly is identified, a multidisciplinary team reviews the mother's complete medical history and prenatal ultrasonograms.

Depending on the anomaly and the immediate danger posed to the fetus, the family will be counseled on their options. If no treatment is available and the condition is fatal, the family may elect to terminate the pregnancy if it is earlier than 24 weeks of gestation or may choose to carry the fetus to term. If postnatal correction is possible, the family may consider terminating the pregnancy or may continue the pregnancy with monitoring, hoping for successful correction after delivery. Lethal and nonlethal anomalies may be treated with prenatal surgery. If a family elects this option, both the mother and the fetus are evaluated to determine if they will be acceptable surgical candidates. Fetal surgery was previously confined to treatment of anomalies that would result in fetal death before term or during the immediate postnatal period, but it now includes treatment of nonlethal conditions in selected cases. Conditions treated by fetal surgery include congenital diaphragmatic hernia (Figure 13-53), congenital cystic adenomatoid malformation, bronchopulmonary sequestration, obstructive uropathy, sacrococcygeal teratomas (Figure 13-54), twin-to-twin transfusion syndrome, thoracic lesions, twin reversed arterial perfusion syndrome, monochorionic twins, discordant twins, and myelomeningocele (Figure 13-55) (Jancelewicz and Harrison, 2009). Fetal surgery may be accomplished by way of laparotomy and hysterotomy or, in some instances, with endoscopic techniques.

Postoperatively, preterm labor is of great concern, and uterine contractions, fetal heart rate, and fetal electrocardiogram (ECG) are closely assessed. Tocolytic medications are titrated to control uterine contractions. The mother is educated in self-monitoring of uterine contractions, and tocolytic therapy

is continued on an outpatient basis. Frequent fetal ultrasonic scans are performed postoperatively to monitor fetal growth, amniotic fluid volume, and the adequacy of the surgical repair. Fetal surgery may also place the mother at risk for uterine rupture in subsequent pregnancies.

Cesarean Birth

Cesarean birth, also referred to as *cesarean section* or *C-section,* is delivery of the fetus or fetuses through abdominal (laparotomy) and uterine (hysterotomy) incisions. In general, cesarean birth is employed whenever further delay in delivery may seriously compromise the fetus, the mother, or both, and vaginal delivery cannot be safely accomplished. In recent years the use of cesarean birth has increased as a result of fetal monitoring, fetal scalp blood sampling for pH determination, and the widespread emphasis on recognition of actual or suspected impairment of fetal well-being if delivery was delayed or vaginal delivery attempted. Reasons for cesarean birth include failure to progress, malposition and malpresentation, cephalopelvic disproportion, abruptio placentae, toxemia, fetal distress, uterine dysfunction, placenta previa, prolapsed cord, previous pelvic surgery, cervical dystocia, active herpes progenitalis, and diabetes. Multiple pregnancies may also be an indication for cesarean delivery. In certain situations, and after appropriate counseling, elective cesarean delivery may be a medically acceptable option. Thus cesarean births may be classified as primary (woman's first cesarean), repeat (indicates a previous cesarean birth), elective (a scheduled procedure in either of the previous categories or at maternal request), or emergency (there is an immediate need for intervention) (Roberts and Mangan, 2009).

Cesarean delivery is ranked as the second most frequently performed major surgical operation in the United States. Approximately 1,479,646 cesarean sections were performed in 2007 (HCUPnet, 2007). Rates have decreased slightly because of increased use of labor trials and vaginal birth after cesarean birth (VBAC) in selected patients.

Cesarean delivery may take place in the obstetric labor and delivery suite or in the OR suite. Patients about to undergo cesarean birth need careful assessment and emotional support. Because cesarean birth frequently involves emergency situations, the mother may express grave concern for the infant's well-being. If the mother has participated in childbirth classes, she may believe that she has failed in some way. The perioperative nurse must be aware of the psychologic as well as physiologic needs of this patient population. Mothers may choose to remain awake after administration of a regional anesthetic; the mother's birthing partner may be permitted to accompany and support her in the OR and witness the birth (based on hospital policy). The birthing partner may need the perioperative nurse's assistance in preparing for the delivery by washing hands and donning scrub attire or a protective gown. The perioperative nurse may need to reassure and encourage the birthing partner to coach and lend support to the mother during this intensely stressful time. The birthing partner can be included in the bonding process that is initiated at birth.

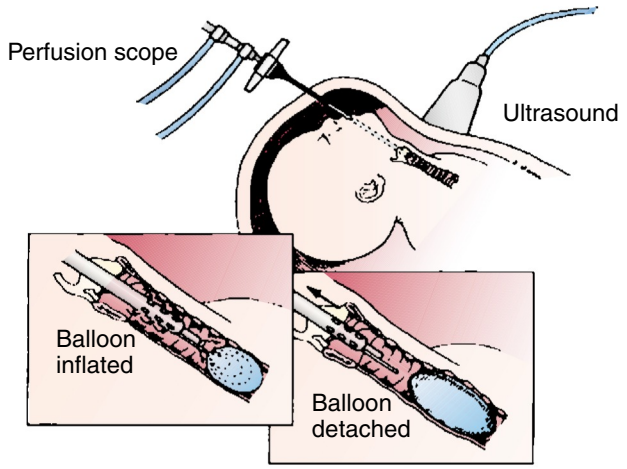

FIGURE 13-53 Fetal surgery for congenital diaphragmatic hernia. The trachea is isolated in preparation of hemoclip placement.

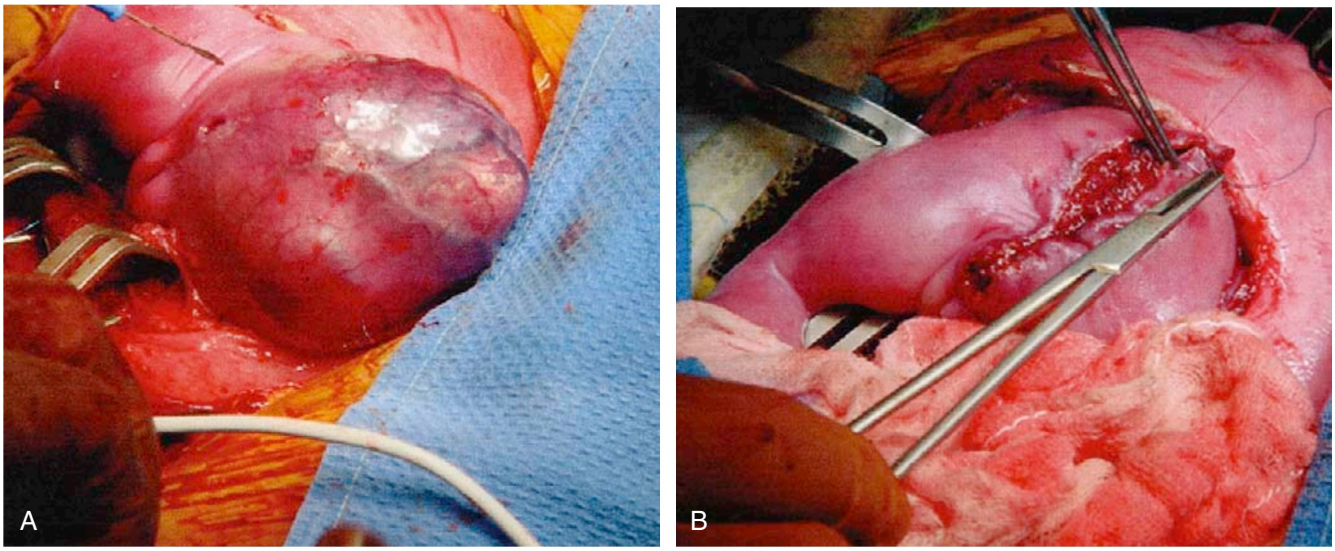

FIGURE 13-54 **A**, Start of fetal resection of a sacrococcygeal teratoma at 21 weeks of gestation. **B**, Closure of the defect.

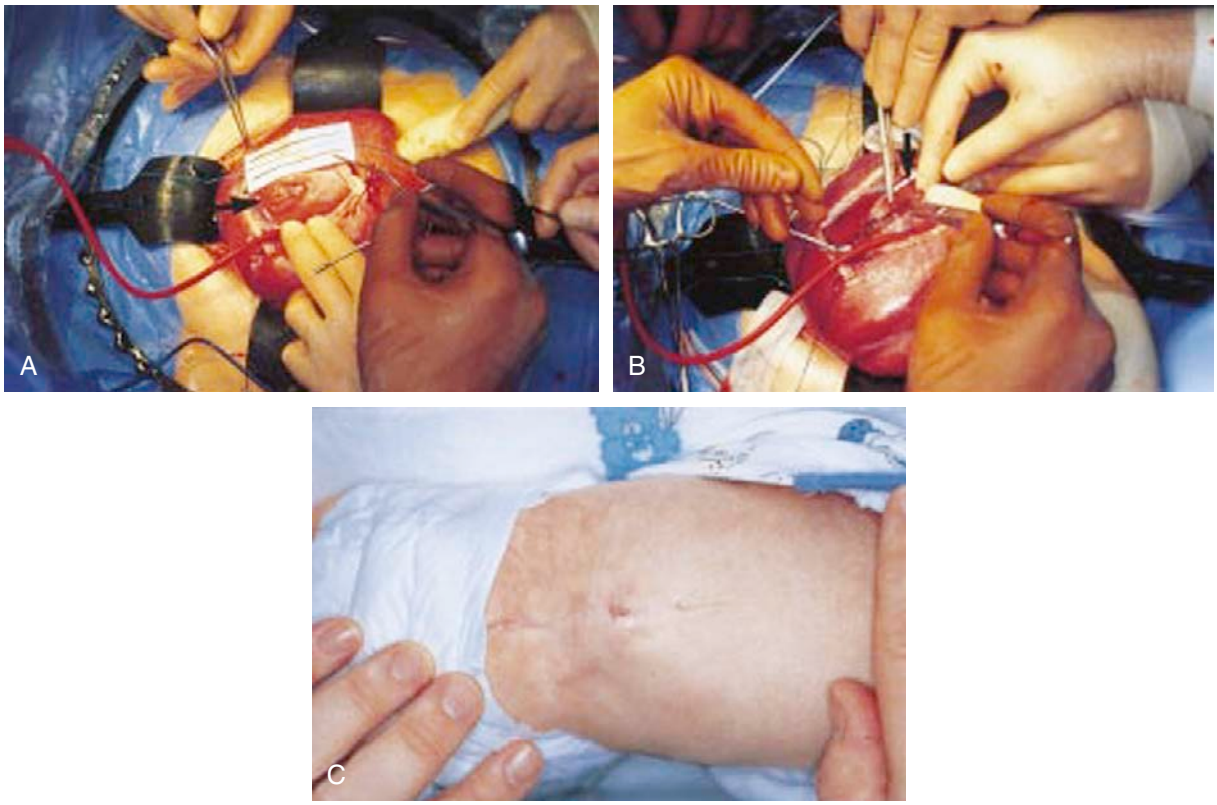

FIGURE 13-55 **A**, Myelomeningocele. **B**, Uterus is opened over defect. **C**, Myelomeningocele repair completed, appearance postdelivery.

The mother, if awake and stable, is shown and encouraged to hold the infant. The perioperative nurse promotes a positive family-oriented experience.

If the cesarean delivery is performed as an emergency, the family-oriented approach may not be feasible. In this emergency situation, the mother's support persons need to be directed to the surgical waiting area, where information will be communicated regarding the condition of the mother and infant. Support persons may then be able to accompany the infant as he or she is transferred to the nursery. In an emergency cesarean birth, certain perioperative procedures may be omitted, such as an initial surgical count. When this occurs, an abdominal x-ray is usually completed before the patient leaves the OR (Roberts and Mangan, 2009). The perioperative nurse should follow the institution's protocol for documenting the x-ray and its results, along with the reasons why the initial count was omitted.

A complication that may occur in conjunction with a cesarean delivery is amniotic fluid embolism. The perioperative nurse must be familiar with this complication and recommended treatment to resolve it (Rapid Response Team box).

Procedural Considerations. The patient should be in a supine position with elevation of the right side to displace the uterus and prevent aortocaval compression. Bony prominences are padded, and the patient is positioned in good body alignment with a safety strap above the knees. The perioperative nurse may assist the anesthesia provider with the administration of a regional anesthetic before placing the patient in the supine position. Throughout this process, maternal vital signs and fetal heart tones are monitored and recorded per institutional protocol.

If a general anesthetic is to be employed, all preparations—including skin prep, bladder drainage, draping, suction connection, counts, and gowning and gloving of all scrubbed personnel—are done before induction. In many hospitals, healthcare providers qualified to deliver newborn care and resuscitation are in attendance for the delivery. A radiant warmer and resuscitative equipment for immediate postdelivery care of the infant are available in the OR because these infants are considered to be at risk until there is evidence of physiologic stability.

The skin is prepped as for abdominal surgery. The vagina is not prepped. An indwelling urinary catheter is inserted. Instrumentation includes the basic abdominal gynecologic set, with the addition of Lister bandage scissors, Foerster sponge-holding (ring) forceps, Pennington forceps, cord clamps, a DeLee retractor, delivery forceps, a head extractor (if desired), laboratory tubes for cord blood, a drain (optional), and a bulb syringe.

Operative Procedure

1. The surgeon makes an infraumbilical vertical incision or lower transverse Pfannenstiel incision. The incision should be just long enough to allow the infant to be delivered without difficulty. Therefore the length of the incision varies with the estimated size of the fetus.
2. The abdominal wall is opened in layers. The rectus and pyramidalis muscles are separated in the midline by sharp and blunt dissection to expose the underlying transversalis fascia and peritoneum.

RAPID RESPONSE TEAM

Rapid response systems, endorsed by the American College of Obstetricians and Gynecologists, include case detection that triggers a crisis team response, and provision of a readily available response team. Within the OR setting, dedicated facility rapid response teams may or may not respond to perioperative emergencies, but in the case of obstetric emergencies, it may be necessary to summon a medical emergency team with experience in perinatal care. Perioperative nurses can positively impact outcomes by recognizing situations where early intervention is essential to prevent maternal morbidity. Amniotic fluid embolism (AFE) is an example of a situation that requires early recognition and swift action to save the mother and her child. Perioperative nurses may be responsible to summon an obstetric rapid response team for AFE if involved in cesarean section or assisting with a complicated vaginal delivery in the OR, or may be involved in assisting in the treatment of AFE in the labor and delivery department.

Although uncommon, AFE occurs when amniotic fluid containing particles of debris (e.g., hair, skin, vernix, meconium) enters the maternal circulation. The woman's pulmonary vessels become occluded and respiratory distress and circulatory collapse with coagulopathy may ensue. AFE can transpire at any point during labor and delivery and occurs in 7.7 per 100,000 births with a fatality rate between 21.6% and 37%.

The most common symptom of AFE is acute dyspnea followed by severe hypotension. Risk factors for AFE include multiparity, advanced maternal age, male fetus, cesarean section or operative vaginal delivery, abruptio placentae, placenta previa, and cervical laceration or uterine rupture. Emergency interventions are summarized below:

- Administer oxygen by face mask (8-10 L/min) or Ambu bag with 100% oxygen.
- Prepare for mechanical intubation and ventilation.
- Initiate or assist with cardiopulmonary resuscitation. Tilt the pregnant woman 30 degrees to the left to displace the uterus.
- Administer IV fluids.
- Administer blood: packed cells, fresh frozen plasma.
- Insert indwelling catheter and monitor urine output.
- Correct coagulation failure.
- Monitor fetal and maternal status.

Newer treatment modalities for AFE that may be more easily accessed in the OR include the following:

- Cardiopulmonary bypass
- Cell salvage
- Extracorporeal membrane oxygenation
- Intra-aortic balloon counterpulsation
- Invasive cardiac and hemodynamic monitoring
- Nitric oxygen therapy
- Transesophageal echocardiograpy
- Ventricular assist device

In Lowdermilk DL, Perry SE, editors: *Maternity and women's health care,* ed 9, St Louis, 2007, Mosby.

3. The peritoneum is elevated with two Crile hemostats about 2 cm apart. The peritoneum between the two clamps is palpated to rule out the inclusion of bowel, omentum, or bladder. The surgeon opens the peritoneum and enters the abdominal cavity.
4. Bleeding sites anywhere in the abdominal incision may be clamped but not ligated until later, unless the clamps obstruct exposure. When the patient has been administered a general anesthetic, speed is important to prevent an anesthetized infant. The ESU may be used for hemostasis, especially if the patient is awake and a regional anesthetic has been administered.
5. The surgeon quickly palpates the uterus to determine the size and presenting part of the fetus as well as the direction and degree of rotation of the uterus.
6. The reflection of the peritoneum (serosa) above the upper margin of the bladder and overlying the anterior lower uterine segment is gently separated by sharp and blunt dissection.
7. The developed bladder flap is held downward beneath the symphysis with a bladder retractor such as the DeLee.
8. The uterus is opened with a knife through the lower uterine segment about 2 cm above the bladder flap. Once the uterus is opened, the incision can be extended by cutting laterally with a large bandage scissors or by simply spreading the incision by means of lateral pressure applied with each index finger when the lower uterine segment is thin.
9. The presenting membranes are incised. Suction is imperative here, and many surgeons prefer no suction tip (only the large, open end of the suction tubing) during the expulsion and suctioning of amniotic fluid.

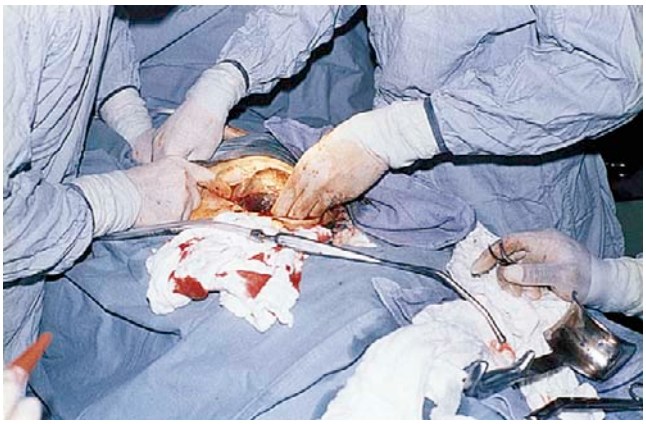

FIGURE 13-56 Fundal pressure applied. Infant's head emerging from hysterotomy.

10. All retractors are removed. The fetal head is gently elevated, either manually or by use of obstetric forceps, through the incision, aided by transabdominal fundal pressure (Figure 13-56) to help expel the fetus.
11. As soon as the head is delivered, a bulb syringe or aspirator tip is used to aspirate the exposed nares and mouth to minimize aspiration of amniotic fluid and its contents.
12. Oxytocin (20 units per liter of fluid or as directed by the surgeon) may be administered intravenously by the anesthesia provider as soon as the shoulders are delivered (or after delivery of the infant), so that the uterus contracts. This use of oxytocin minimizes blood loss.

FIGURE 13-57 Cord clamped in preparation for passing infant off field.

13. On delivery of the entire infant, the cord is clamped and cut (Figure 13-57), and the infant is given to the member of the team who is responsible for resuscitation efforts as needed. A sterile gown or sheet should be provided to the individual receiving the infant to avoid any break in aseptic technique and to maintain Standard Precautions during transfer of the infant.
14. The edges of the uterine incision are promptly clamped with Péan forceps, ring forceps, or Pennington clamps.
15. The placenta is delivered and placed in a large receptacle provided from the back table. Fundal massage or manual removal may be employed to hasten delivery of the placenta and reduce bleeding.
16. One or two separate layers of suture may be used to close the uterine incision. The perioperative nurse and surgical technologist conduct a count to verify no objects have been retained in the uterine cavity.
17. After determination that there is no further bleeding after closure of the uterine incision, the cut edges of the serosa overlying the uterus and bladder are approximated with a continuous suture.
18. Any blood, blood clots, vernix, and amniotic fluid in the pelvis and peritoneal cavity are removed. The fallopian tubes and ovaries are also inspected. Tubal ligation may be carried out at this point.
19. The peritoneum and each abdominal layer are closed.
20. After the wound is closed, the perioperative nurse massages the patient's fundus and cleans any clots that are expressed from the vagina.
21. The abdominal dressing and a perineal pad are applied.

CHAPTER 14

Genitourinary Surgery

HELENE KOREY MARLEY

Advances in genitourinary surgery, with the use of robotics, laparoscopic techniques, cryotherapy, brachytherapy, lasers, ultrasonography, lithotripters, innovative diagnostic measures, and minimally invasive surgical approaches, have expanded treatment options. As urologic surgery becomes more complex and far more precise, the perioperative nurse has challenges in maintaining up-to-date knowledge, documented competence, and new technical skills. More procedures are being done on an ambulatory or short-stay basis, allowing limited time for patient and family education and discharge planning. The success of surgical intervention and patient outcomes depends greatly on the nurse's ability and knowledge in designing, developing, and implementing a perioperative plan of care.

Surgical Anatomy

The normal genitourinary system includes one pair of kidneys, two ureters, the urinary bladder, the urethra, and the prostate gland in the male. Also considered essential to the genitourinary system are the adrenal glands, male reproductive organs, and the female urogynecologic system.

Urine is excreted by the kidneys and conveyed to the bladder through the ureters. Urine is stored in the bladder, which serves as a reservoir until its full capacity (350 to 700 ml) is reached, and is eliminated from the body by way of the urethra. Normal urinary output ranges from 0.5 to 1.0 ml/kg of body weight per hour for the average adult.

Kidneys

The kidneys are located in the retroperitoneal space along the lateral borders of the psoas muscle, one on each side of the vertebral column at the level of the twelfth thoracic to the third lumbar vertebrae. Usually the right kidney is several centimeters lower than the left because the liver rests superior and anterior to the right kidney (Figure 14-1).

Each kidney is surrounded by a mass of fatty and loose areolar tissue known as *pararenal fat*. A capsule enclosing the renal space is known as the *fascia renalis*. This is composed of *Gerota's fascia* (anterior renal fascia) and *Zuckerkandl fascia* (posterior renal fascia). These structures help keep the kidneys in their normal anatomic position. The anterior and posterior relationships of the kidneys are shown in Figure 14-2.

On the medial side of each kidney is a concave area known as the *hilum,* through which the renal artery and vein enter and exit. The renal pelvis, a funnel-shaped structure that lies within the kidney and posterior to the renal vascular pedicle, divides into several branches called *calyces* (Figure 14-3). When surgery is indicated in these structures, a posterior flank approach is preferred. When surgery for removal of a mass is anticipated, a transabdominal or thoracoabdominal incision may be chosen.

The kidneys are highly vascular organs that process approximately one fifth of the entire volume of blood at any one time. The blood supply to the kidney is conveyed through the renal artery (a large branch of the aorta) and leaves through the renal vein. On entering the kidney, the renal artery divides into anterior and posterior sections. These undergo further division into interlobular arteries from which smaller afferent branches pass to the glomeruli. Efferent arterioles in the glomeruli then pass to the tubules of the nephron.

The renal lymphatic supply originates beneath the capsule of the kidney and empties into the lumbar lymph nodes at the junction of the renal vascular pedicle and aorta. The nerves of the autonomic (involuntary) nervous system originate from the lumbar sympathetic trunk and from the vagus nerve. Removal of the nerve pathways does not impair renal function. The renal artery and vein with their accompanying nerves and lymphatics are referred to as the *pedicle* of the kidney.

Adrenal Glands

The adrenal glands lie retroperitoneally beneath the diaphragm, capping the medial aspects of the superior pole of each kidney. On the right side, the gland is triangular and adjacent to the inferior vena cava; on the left side, it is a rounded, crescent-shaped gland posterior to the stomach and pancreas. Each adrenal gland has a medulla, which secretes epinephrine (adrenaline), and a cortex, which secretes steroids and hormones. Secretions from the adrenal cortex are influenced by the activity of the pituitary gland. The adrenal glands are liberally supplied with arterial branches from the inferior phrenic and renal arteries and from the aorta. Venous drainage is accomplished on the right side by the inferior vena cava and on the left by the left renal vein. The lymphatic system accompanies the suprarenal vein and drains into the lumbar lymph nodes.

Ureters

Each ureter is a continuation of the renal pelvis. The ureter extends in a smooth S curve from the renal pelvis to the base of the bladder (Figure 14-4). It is approximately 25 to 30 cm long and 4 to 5 mm in diameter in the adult. This fibromuscular cylindric tube is lined by transitional epithelium (urothelium) and lies on the psoas muscle, passing medially to the sacroiliac joints and laterally to the ischial spines. As urine accumulates in the renal pelvis, slight distention initiates a wave of

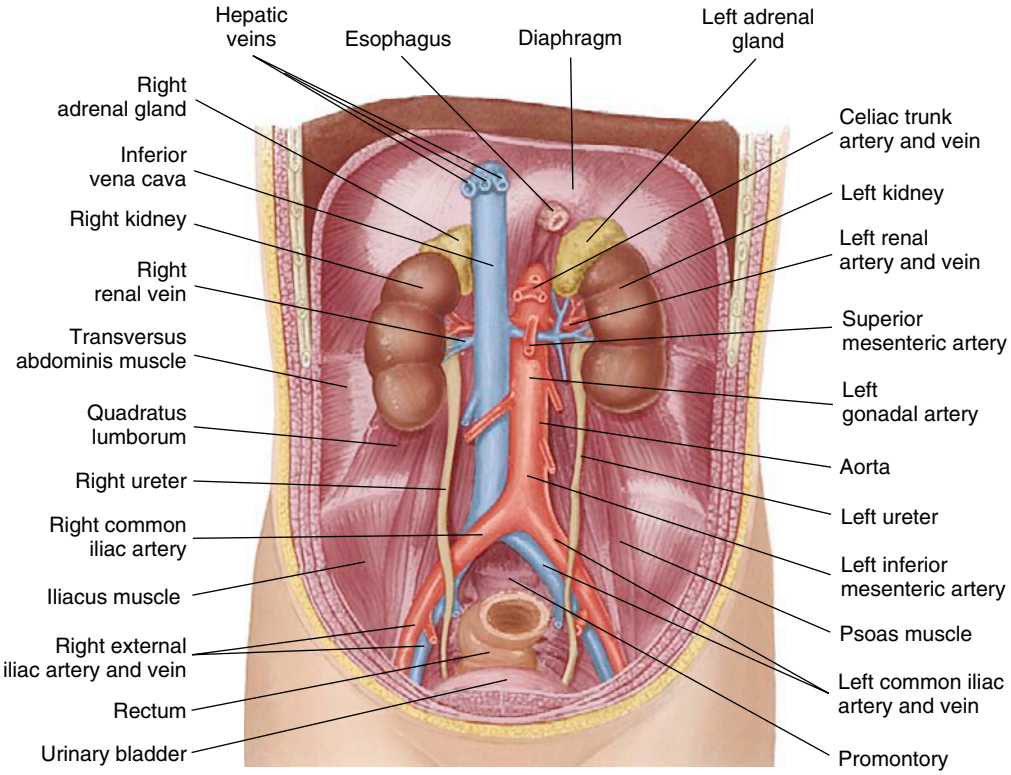

FIGURE 14-1 Location of urinary system organs.

muscular contractions. This peristaltic activity continues down the ureter, propelling urine into the bladder.

Urinary Bladder

The adult urinary bladder is a hollow, muscular viscus that acts as a reservoir for urine until micturition (voiding) occurs. It has an outer adventitial layer and inner urothelial layer. The trigone, a triangular area, forms the base of the bladder. The three corners of the trigone correspond to the orifices of the ureters and the bladder neck (opening of the urethra) (Figure 14-5). The ureteral orifices, on the proximal trigone at the interureteric ridge, are 2.5 cm apart. The bladder neck (internal sphincter) is formed from converging detrusor muscle fibers of the bladder wall that pass distally to form the smooth musculature of the urethra. Physiologically, the bladder fills with urine and expands into the abdominal cavity. The extraperitoneal location is advantageous because a suprapubic (above the pubic arch) incision may be performed without violating the peritoneum and potentially causing intraperitoneal complications.

The main arterial supply of the bladder comprises the superior, middle, and inferior vesical arteries. These vessels are derived from the internal iliac (hypogastric) artery, the obturator and inferior gluteal arteries, and in females the uterine and vaginal arteries. The bladder has a rich venous supply that drains into the internal iliac (hypogastric) vein. The lymphatic system is served by the vesical, external and internal iliac, and common iliac lymph nodes.

The bladder's size, position, and relation to the bowel, rectum, and reproductive organs vary according to the bladder's distention. In the female the vagina lies dorsal to the base of the bladder and parallel to the urethra (Figure 14-6). In the male the prostate gland is interposed between the bladder neck and the urethra (Figure 14-7). These anatomic relationships influence the symptoms that a patient experiences preoperatively and are important landmarks during pelvic surgery.

The process of bladder evacuation appears to be initiated by nerve cells from the sacral division of the autonomic nervous system. These sacral reflex centers are controlled by higher voluntary centers in the brain. Stimulation of the sacral centers results in contraction of the bladder muscles and relaxation of the bladder outlet sphincters. Muscles inside and adjacent to the urethral wall and from the pelvic floor maintain closure of the sphincters of the bladder, thus enabling continence.

Urethra

The male urethra, normally 20 to 25 cm long, extends from the bladder neck to the tip of the penis and varies in diameter from 7 to 10 mm. It is divided into two portions: the proximal (sphincteric) urethra and the distal (conduit or anterior) urethra, both of which undergo further subdivision. The proximal urethra is commonly referred to as the *posterior urethra,* where it is elevated by the verumontanum, extending from the bladder neck through the prostate and the membranous portion. Within the posterior urethra lie the prostatic and membranous portions (see Figure 14-5). As the urethra exits the prostate and crosses the pelvic (urogenital) diaphragm, it is called the *membranous urethra.* The distal urethra, commonly called the *anterior urethra,* is subdivided into the bulbar, pendulous (penile), and glandular urethras. The bulbar urethra is the area most prone to urethral strictures in the male. The prostatic urethra is approximately 3 cm long and is the widest portion of the urethra. On the floor of the prostatic urethra is the

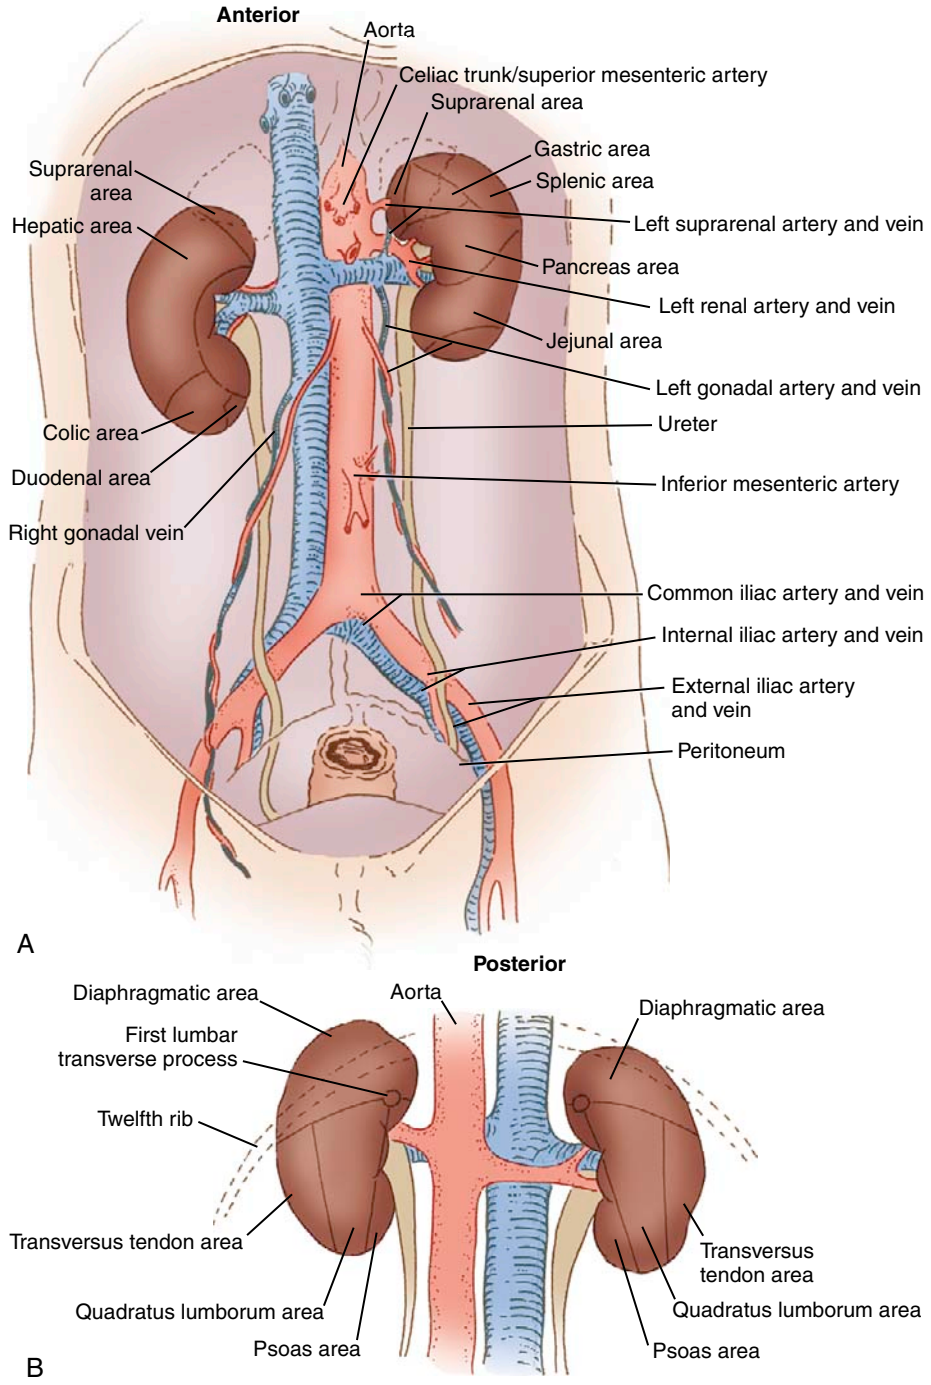

FIGURE 14-2 **A**, Blood supply of kidneys and relationship of kidneys and ureters to the main arteries and veins and the intraperitoneal organs. **B**, Relationship of the kidneys and ureters to the spinal column.

verumontanum, which contains the openings of the ejaculatory ducts. The membranous urethra is the shortest portion, measuring approximately 2.5 cm and extending from the external sphincter to the apex of the prostate. The penile, or pendulous, urethra lies within the corpus spongiosum. The urothelium of the urethra is continuous with that of the bladder.

The female urethra is a narrow, membranous tube about 3 to 5 cm in length and 6 to 8 mm in diameter. Slightly curved, it lies behind and beneath the symphysis pubis, anterior to the vagina. It passes through the internal and external sphincters and the urogenital diaphragm. The periurethral glands of Skene open on the floor of the urethra just inside the meatus. Because the female urethra is so short and in proximity to the anal and vaginal areas, microorganisms find easy access to the bladder and can cause urinary tract infections (UTIs).

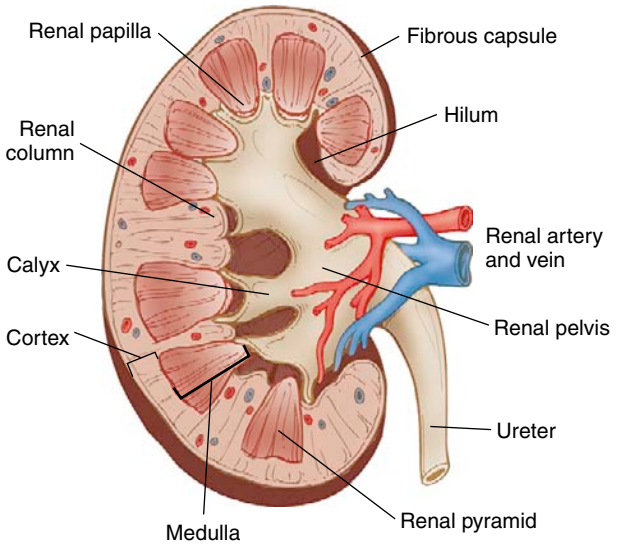

FIGURE 14-3 Normal kidney.

Prostate Gland

The prostate gland is a donut-shaped organ composed of fibromuscular and glandular components. It is located at the base of the bladder neck and completely surrounds the urethra. The gland is about 4 cm at the base, is about 2 cm in depth, and normally weighs 20 to 30 g (see Figures 14-5 and 14-7).

The four glandular regions within the prostate have two major zones (the peripheral zone and the central zone) and two minor zones (the transitional zone and the periurethral zone). Many clinicians still refer to prostate lobes as intraurethral lobes (right and left lateral) and extraurethral lobes (posterior and median). The posterior lobe is readily palpable during rectal examination and prone to cancerous degeneration. Benign prostatic hyperplasia (BPH, often referred to as hypertrophy) generally occurs in the transitional zone (intraurethral lobe).

Behind the prostatic capsule is a fibrous sheath known as the *true prostatic capsule,* which separates the prostate gland and the seminal vesicles from the rectum. This fascia is an important landmark during perineal prostatectomy.

The lobes of the prostate gland secrete highly alkaline fluid that dilutes the testicular secretion as it is excreted from the ejaculatory ducts. These secretions are believed to be essential to the passage of spermatozoa and helpful in keeping them alive. The arterial supply to the prostate is derived from the pudendal, inferior vesical, and hemorrhoidal arteries.

Male Reproductive Organs

The male reproductive organs include several paired structures: the testes, epididymides, seminal ducts (vasa deferens), seminal vesicles, ejaculatory ducts, and bulbourethral glands. Other organs of the reproductive tract are the penis, prostate gland, and urethra.

The *scrotum* is located behind and below the base of the penis and in front of the anus. Within the scrotum are two cavities, or sacs, that are lined with smooth, glistening tissue—the tunica vaginalis. Normally, a small amount of clear fluid is contained in the tunica vaginalis. Each loose sac contains and supports a testis, an epididymis, and some of the spermatic cord. The two sides of the scrotum are separated from each other by a median raphe (septum).

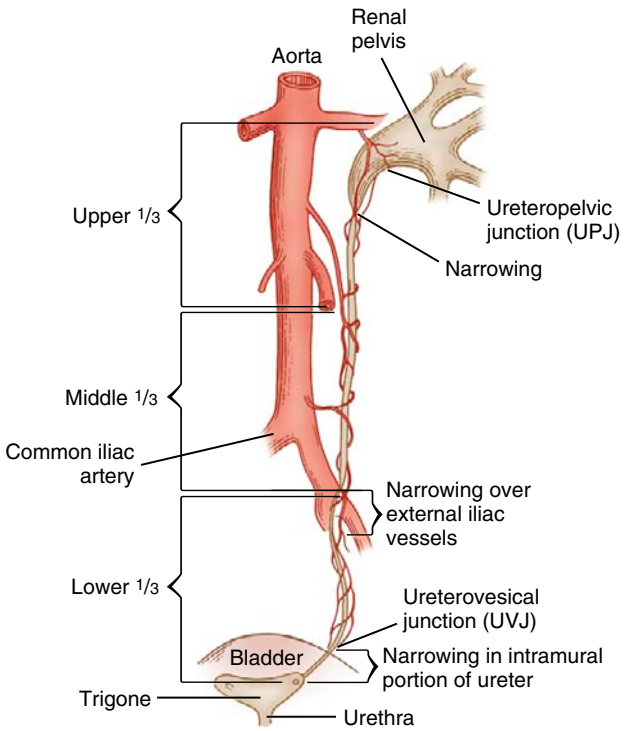

FIGURE 14-4 Anatomy of ureter.

The *testes* manufacture the spermatozoa and also contain specialized Leydig's cells that produce the male hormone *testosterone.* Each testis consists of many tubules in which the sperm are formed, surrounded by dense capsules of connective tissue. The tubules coalesce and continue into the adjacent epididymis, where the sperm mature and are stored. At the upper pole of the testis is the appendix testis, a small body that may be pedunculated (stalked) or sessile (flat).

The *epididymis* is a long, convoluted duct located along the posterolateral surface of the testis. It is closely attached to the testicle by fibrous tissue and secretes seminal fluid, which gives the sperm a liquid medium in which to migrate. The vas deferens (ductus deferens, seminal duct) is a distal continuation of the epididymis as it enters the prostate gland and conveys the sperm to the seminal vesicle.

The *vas deferens* extends from the epididymis into the abdomen and lies within the spermatic cord in the inguinal region. The spermatic cord also contains veins, arteries, lymphatics, nerves, and surrounding connective tissue (cremaster muscle), which give support to the testes. The terminal portion of each vas deferens is called the *ejaculatory duct;* it passes between the lobes of the prostate gland and opens into the posterior urethra.

The *accessory reproductive glands* include the seminal vesicles, prostate gland, and bulbourethral gland. The seminal vesicles unite with the vas deferens on either side, are situated behind the bladder, and produce protein and fructose for the nutrition of the sperm cell. Sperm and prostatic fluid are discharged at the time of ejaculation.

Cowper's glands (bulbourethral glands) are located on each side at the juncture of the membranous and bulbar urethras. Each gland, by way of its duct, empties mucous secretions into the urethra.

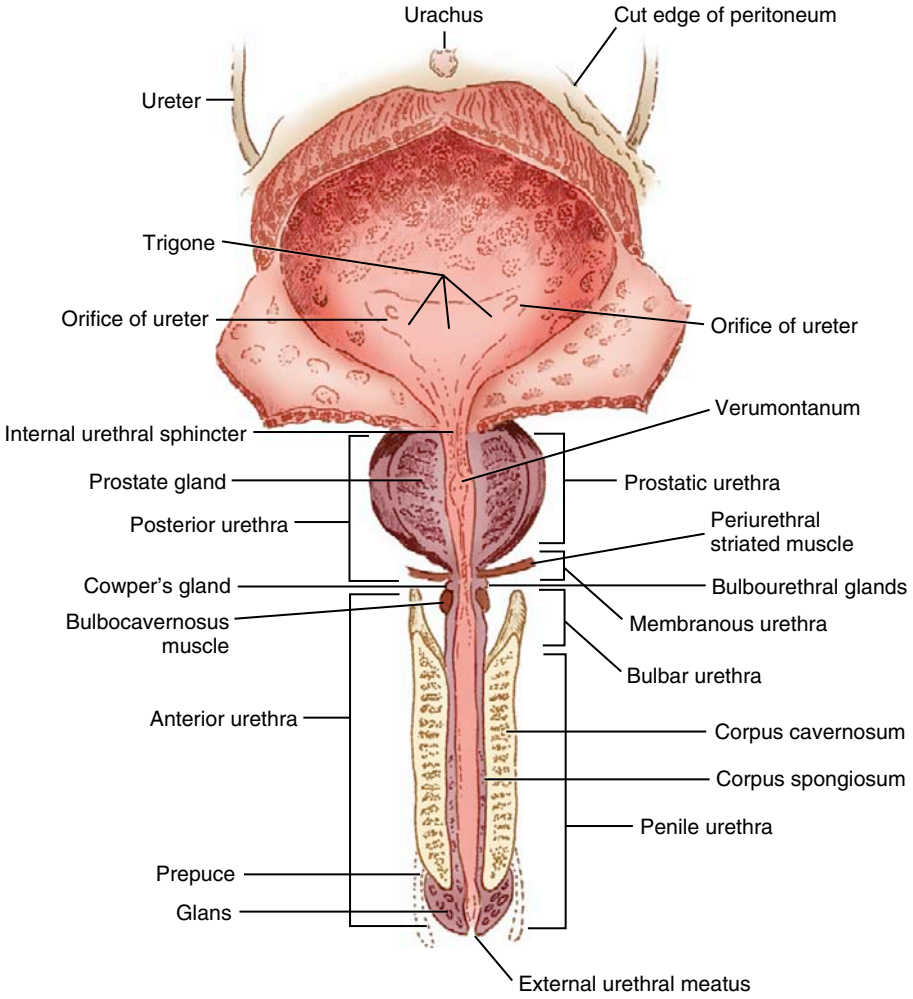

FIGURE 14-5 Anatomy of male urinary bladder, prostate gland, and urethra.

The *penis* is suspended from the pubic symphysis by the suspensory ligaments. The penis contains three distinct vascular, spongelike bodies surrounding the urethra: two outer bodies called the *right corpus cavernosum* and *left corpus cavernosum* and an inner body, the *corpus spongiosum urethrae*. These tissues contain a network of vascular channels that fill with blood during erection (see Figure 14-5). At the distal end of the penis, the skin is doubly folded to form the prepuce, or foreskin, which serves as a covering for the glans penis. The glans penis contains the urethral orifice.

Perioperative Nursing Considerations

Assessment

Patients entering a hospital or ambulatory surgery unit for genitourinary surgery exhibit many emotions and reactions, including fear, embarrassment, helplessness, hostility, anger, and grief. To most, a successful surgical outcome is of prime importance. The urology patient population varies from infants with congenital anomalies to elderly people with physiologic impairments. Because of the dramatic increase in same-day admissions and ambulatory surgeries, the nursing staff must prepare to meet patients' specific needs, from preoperative teaching to postoperative home care. The families of patients need to be involved in this preparation process. Patient education begins in the urologist's office. Communication between the office and perioperative nursing staff allows continuity of care and increases the efficiency and effectiveness of surgical procedures.

In addition to routine admission information, the perioperative nurse will obtain the patient's urologic and cardiac histories. This information includes but is not limited to vital signs, allergies (including latex), the patient's primary problem, history of the present illness, nature of symptoms, and limitations imposed by the disease condition. In some cases, patients may be seen who are not having a primary urologic procedure; instead, these patients may be scheduled for an ancillary urologic procedure, such as the insertion of ureteral catheters or stents to facilitate positive identification of the ureters and reduce the potential for severing or ligating them during pelvic or abdominal procedures. All data pertinent to the proposed operative procedure should be reviewed. Nursing observation should include the patient's general physical appearance as well as nonverbal behaviors, such as restlessness, which may indicate discomfort or anxiety. Any limitations in mobility or sensory deficits should be noted. Urologic procedures frequently require positions that create unusual stress for the patient, both

TABLE 14-1

Common Preoperative Laboratory Analyses for Patients with Genitourinary Disorders

Laboratory Studies	Normal Range (Adult Values)
COAGULATION PROFILES	
Bleeding time	<175 sec
Partial thromboplastin time (PTT)	60-70 sec
Platelet count	150,000-400,000/mm^3
Prothrombin time (PT)	11-12.5 sec
FERTILITY PROFILES (MALE)	
Follicle-stimulating hormone (FSH)	1.42-15.4 milliinternational units/ml
Luteinizing hormone (LH)	1.24-7.8 milliinternational units/ml
Testosterone (total)	280-1080 ng/dl
Sperm count	≥20 million/nl; mobility ≥50% at 1 hr
HEMATOLOGY VALUES (LOW: FEMALE; HIGH: MALE)	
Hematocrit (Hct)	37%-52%
Hemoglobin (Hgb)	12-18 g/dl
Red blood cells (RBCs)	4.2-6.1 million/mm^3
White blood cells (WBCs)	5000-10,000 million/mm^3
SERUM PROFILES (LOW: FEMALE; HIGH: MALE)	
Bicarbonate	23-30 mEq/L (HCO_3^-)
Blood urea nitrogen (BUN)	10-20 mg/dl
Calcium (Ca^{++})	9-10.5 mg/dl
Chloride (Cl^-)	98-106 mEq/L
Cholesterol	<200 mg/dl
HDL (high-density lipids)	Male >45 mg/dl; Female: >55 mg/dl
LDL (low-density lipids)	60-180 mg/dl
VLDL (triglycerides)	7-32 mg/dl
Creatinine	0.5-1.2 mg/dl
Glucose (blood sugar)	70-110 mg/dl
Osmolality	285-295 mOsm/kg H_2O
Potassium (K^+)	3.5-5 mEq/L
Phosphorus (P)	3-4.5 mg/dl
Prostate-specific antigen (PSA)	<4 ng/dl
Prostatic acid phosphatase (PAP)	0.013-0.63 unit/L
Protein	6.4-8.3 g/dl
Sodium (Na^+)	136-145 mEq/L
Uric acid	2.7-8.5 mg/dl
URINE PROFILES (VALUES NOT LISTED SHOULD BE NEGATIVE)	
Calcium (Ca^{++})	100-250 mg/day
Chloride (Cl^-)	110-250 mEq/L/day
Creatinine	88-137 ml/min
Glucose (24 hr)	50-300 mg/day (<0.5 g/day)
Osmolality (random)	50-1200 mOsm/kg H_2O
Phosphorus	0.4-1.3 g/24 hr
Potassium (K^+)	25-100 mEq/L/day
Protein	0-8 mg/dl
Red blood cells (RBCs)	≤2 cells
Sodium (Na^+)	40-220 mEq/L/day
Uric acid	250-750 mg/day
White blood cells (WBCs)	0-4 per lower field
pH	4.6-8 (average: 6)
Specific gravity	1.005-1.030

Data from Chernecky CC, Berger BJ: *Laboratory tests and diagnostic procedures,* ed 5, St Louis, 2008, Saunders; Pagana K, Pagana T: *Mosby's diagnostic and laboratory test reference,* ed 9, St Louis, 2009, Mosby.

anatomic and physiologic, such as compression of the vena cava and dependent lung during lateral positioning. Also, large amounts of irrigating fluids are frequently used intraoperatively in urologic procedures, which may impact the patient's electrolyte status. Assessment provides the perioperative nurse with data adequate to support preoperative planning, intraoperative implementation, and postoperative evaluation.

The patient may undergo several studies preoperatively, including measurement of levels of serum and urine electrolytes, blood glucose, and blood urea nitrogen (BUN); urinalysis and urine cultures; cardiac enzymes; complete blood count (CBC); prothrombin time (PT) and partial thromboplastin time (PTT); blood chemistry profiles (Table 14-1); electrocardiogram (ECG); and chest x-ray examination. The nurse reviews the patient's medical history, focusing on medication use (including the use of over-the-counter medications and herbal supplements), any infectious processes, or chronic diseases. Specific genitourinary studies can be found in the patient's medical record. They may encompass all or some of the following: computerized tomography (CT) scans, magnetic resonance imaging (MRI), bone and dual energy x-ray absorptiometry (DEXA) scans, positron emission tomography (PET), ProstaScint scans, intravenous (IV) pyelograms or urograms (IVPs or IVUs, respectively), genitourinary flat plate (KUB [kidney, ureter, bladder]), urinary flow studies, fluoroscopic examinations (angiography, cavernosography), prostate-specific antigen (PSA), and ultrasonography. After the nurse reviews the medical record, assessment information is compiled, perioperative nursing diagnoses are identified, and the perioperative plan of care is formulated.

Nursing Diagnosis

Nursing diagnoses related to the care of patients undergoing genitourinary surgery might include the following:

- Anxiety
- Risk for Perioperative Positioning Injury
- Impaired Urinary Elimination
- Risk for Deficient Fluid Volume
- Impaired Gas Exchange
- Sexual Dysfunction

Outcome Identification

Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient will verbalize an acceptable anxiety level to the perioperative nurse.
- The patient will be free from injury related to the surgical position.
- The patient will demonstrate or regain a normal pattern of urinary elimination.
- The patient will maintain adequate fluid volume and electrolyte balance.
- The patient will maintain adequate oxygen supply and alveolar ventilation.
- The patient will discuss fears and concerns regarding sexual function.

Planning

Plans of care are the organizing framework for perioperative nursing activities, wherein nursing interventions are clinical processes in a quality health outcome model. Frequently the urology patient presents a complex medical picture. Any alterations in the patient's physical, mental, or emotional status may greatly influence both the surgical and the postoperative course. A review of the patient's record; communication with the patient or family; recognition of specific psychosocial, cultural, ethnic, and spiritual needs of the patient and family; and knowledge gained from other members of the patient care team are all used to formulate the nursing database. A Sample Plan of Care for the patient undergoing genitourinary surgery is shown below.

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Anxiety

OUTCOME
The patient will verbalize an acceptable anxiety level to the perioperative nurse.

INTERVENTIONS
- Provide an accepting and supportive environment.
- Use touch (as appropriate) to convey caring and support.
- Encourage expression of feelings.
- Promote feelings of self-worth.
- Provide comfort measures (e.g., warm blankets, pillow).
- Facilitate or assist patient in using personally effective coping strategies (e.g., relaxation, deep breathing, music, imagery).
- Maintain patient privacy.
- Encourage participation of patient and family in plan of care.

NURSING DIAGNOSIS
Risk for Perioperative Positioning Injury

OUTCOME
The patient will be free from injury related to the surgical position.

INTERVENTIONS
- Maintain proper body alignment.
- Assess range of motion and musculoskeletal, peripheral vascular, and cardiovascular status preoperatively.
- Pad all bony prominences.
- Avoid compression of vulnerable nerves and neurovascular bundles.
- Secure patient to OR bed without friction or pressure.
- Provide support stockings or sequential compression devices (SCDs) as indicated.
- Initiate measures to warm patient and maintain normothermia.

NURSING DIAGNOSIS
Impaired Urinary Elimination

OUTCOME
The patient will demonstrate or regain a normal pattern of urinary elimination.

INTERVENTIONS
- Include catheter care and measures to facilitate voiding after catheter removal as part of preoperative patient and family education and discharge planning.
- Instruct patient in importance of any postoperative antibiotic or anticholinergic therapy.
- Follow aseptic technique during catheter insertion and connection to drainage device.
- Maintain closed urinary drainage system.
- Note amount, color, and character of urine; report abnormalities.
- Keep drainage tubing and collection device below the level of the patient's bladder.
- Keep urine draining freely; avoid kinks in tubing.
- Check patency of catheter after all position changes.
- Secure drainage tubing to patient to prevent pulling or retraction during transfer.
- Assess bladder for distention.
- Provide patient with information/referral on preventing recurrent urinary tract infection (UTI).

NURSING DIAGNOSIS
Risk for Deficient Fluid Volume

OUTCOME
The patient will maintain adequate fluid volume and electrolyte balance.

INTERVENTIONS
- Provide appropriate intravenous (IV) solutions, volumetric pumps, and fluid warmers.
- Monitor patency of all IV lines.
- Record volume of IV and irrigating fluids instilled.
- Monitor electrocardiogram (ECG), vital signs, and cardiopulmonary status as appropriate.
- Monitor blood loss and volume replacement.
- Monitor urinary output, and note color; report output less than 30 ml/hr and changes in color or clarity.
- Collaborate with anesthesia provider in monitoring serum electrolyte status.
- Monitor pH and specific gravity of urine as appropriate.

NURSING DIAGNOSIS
Impaired Gas Exchange

OUTCOME
Patient will maintain adequate oxygen supply and alveolar ventilation.

INTERVENTIONS
- Review breathing exercises and use of incentive spirometer with patient preoperatively.
- Position patient to provide maximum lung perfusion; have positioning devices available; check that these are clean and functioning properly.
- Assist anesthesia provider in applying cardiac monitor leads, blood pressure cuff, and pulse oximeter.
- Collaborate with anesthesia provider in monitoring ventilation or perfusion.
- Administer oxygen as required; assist with intubation and maintenance of airway during positioning.
- Assist with collection of arterial blood gases; report results promptly.

NURSING DIAGNOSIS
Sexual Dysfunction

OUTCOME
The patient will discuss fears and concerns regarding sexual function.

INTERVENTIONS
- Clarify patient's understanding of risks and benefits of surgical procedure.
- Provide an open, accepting environment for the patient to discus potentially embarrassing issues.
- Maintain patient privacy and dignity.
- Consider making a referral for patient to discuss options available to achieve sexual function postoperatively.

Implementation

The perioperative nurse begins implementation of the patient care plan during the patient interview. Information that is concise and simply presented enhances the final surgical outcome. Meeting the patient's emotional needs is a nursing priority. A calm patient retains more information and is cognitively and emotionally more receptive to perioperative teaching. The nurse provides explanations of what to expect throughout the operative period to allay the patient's fears and nurture confidence in the nursing care provided. Establishment of this relationship is key to assisting patients to minimize the effect of the surgical experience on their coping ability and to be emotionally comfortable. Perioperative nursing care requires not only the collection of pertinent patient data but also the coordination of numerous supplies and equipment to support the smooth implementation of the plan of care.

Patient Safety. The perioperative nurse considers several factors in advocating for the patient during the intraoperative period. Institutions have various protocols and processes in place to support patient safety. The rapid response team is one example of a protocol or process that focuses on safety (Rapid Response Team box). A critical safety protocol that the nurse is responsible to follow is to ensure the correct patient, correct procedure, and correct site surgery. Such a protocol includes proper patient identification, proper operative site identification, proper procedure identification, and proper medication identification. All wrong site, wrong procedure, and wrong patient surgery occurrences are considered sentinel events by The Joint Commission. In addition, the Association of periOperative Registered Nurses (AORN) has established guidelines for patient safety (AORN, 2009).

To fulfill these requirements, preoperative verification, surgical site marking, and time-out processes must occur for every surgical procedure. What the patient expresses as the intended surgical procedure is compared with what is documented on the operative permit and other items, such as the OR schedule. Patient identification is achieved by also asking the patient to state his or her full name and birth date. This information is compared with the patient identification bracelet. Documentation of the processes implemented is completed on the designated institutional form or forms.

The surgical site is marked with a permanent nontoxic marking pen. The patient should be involved in this process. A standard policy needs to be developed within the particular facility as to how marking will be accomplished for urologic, endoscopic, and abdominal procedures, particularly when they involve laterality. This mark should be clearly visible following prepping and draping.

"Time out" is a pause in the activity that occurs before the start or incision on all procedures. The entire team stops to verbally confirm the patient's identity, verify the patient's position, state and agree on the procedure and surgical site, and review that all implants and necessary equipment are available and ready (Patient Safety). The nurse documents this process according to hospital policy.

When medications are used intraoperatively the containers should always be marked with the medication and dose (refer to Chapter 2 for a full discussion of medication safety). The surgical technologist verifies the medication and dosage verbally when passing the drug in its administration device to the surgeon. Local anesthetics that contain epinephrine should be used with caution in urology. Many urologic interventions involve "end-organs," for example, the scrotum, testicles, and penis. The use of epinephrine in these areas can result in an ischemic situation and should be avoided.

Positioning. Thorough understanding of the urologic OR bed and its functions is essential for optimum patient positioning. The position in which the patient is placed for surgery is determined by the particular operation to be performed. For urologic operative procedures, the patient may be placed in the lateral, supine, prone, or lithotomy position. Any of these positions may be exaggerated to give optimum access to the organ involved, particularly in radical surgery of the prostate and bladder. When the patient is supine, his or her arms are placed on padded armboards with the palms up and fingers extended. Armboards are maintained at less than a 90-degree angle to prevent brachial plexus stretch. If there are surgical reasons to tuck the arms at the side, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained

RAPID RESPONSE TEAM

A rapid response team (RRT) is used when patients display subtle warning signs of deterioration. These teams respond to the first sign of patient decline by bringing critical care assessment skills to the bedside of the patient in order to identify and treat issues before a patient codes. When activated, the RRT, which consists of a critical care nurse, respiratory therapist, med-surg nurse, ICU resident, admitting resident, and the surgical resident, assembles at the patient's bedside to assist with treatments and help determine if transfer to a higher level of care is necessary. The team is available 24/7.

In most cases, the RRT is not utilized in the perioperative setting. Exceptions occur when PACU is used as an overflow unit and ancillary staff is unavailable. At one particular institution, the RRT was only utilized twice in this respect. In both cases, the team was called to the scene because of apnea/shortness of breath and in neither case was CPR initiated.

Health professionals are not the only persons with access to the rapid response team. At this institution, a sign is placed in all public areas of the hospital to provide notice to patients, families, and visitors about the RRT. There is also an information sheet provided to all new admissions that details patient and visitor activation of the RRT. Each patient phone is equipped with a purple and white "glow in the dark" instruction to call the emergency operator and ask for the rapid response team in case of emergency. The operator will immediately alert healthcare professionals, who will soon arrive to assess the situation. Allowing family members and visitors to access rapid response ensures patients' medical, social, and spiritual needs will be met with compassion, skill, and respect.

Modified from University of Pennsylvania Health System: *Rapid response team, 2000,* available at Uphsxnet.Uphs.Upenn.Edu/Pahhome/Nursing/Rapidresponse. Accessed April 10, 2009.

PATIENT SAFETY

Improving Teamwork to Reduce Errors

Publication of the 1999 Institute of Medicine report focused attention on medical errors and the critical importance of patient safety. Reducing errors (such as wrong person, wrong procedure, or wrong site surgery) requires, in part, human solutions, such as improving teamwork and communication in the OR team. Interdisciplinary teamwork is especially important in the so-called high-risk areas in hospitals, such as the OR. Perioperative nurses have long believed that a team approach to patient care reduces errors. Effective teamwork in perioperative patient care consists of knowledge, attitudes, and skills. Developing sustainable efforts to improve teamwork requires thoughtful application. Interventions focused on changing the behavior of team members must first take into account their attitudes. Subsequently, skills and knowledge are assessed, and a training program can be designed to improve teamwork. The benefits of improved teamwork are well exemplified in the time-out process, which aims to enhance effectiveness, increase efficiency, and lower the possibility of error. Preoperative verification processes and the time-out result in fewer errors because these processes are planned by each institution and standardized through use of the Universal Protocol of The Joint Commission. Each member of the OR team knows his or her own responsibilities as well as those of teammates; members look out for each other and note errors before they happen; and members trust one another's judgments and concerns. Teamwork during preoperative verification and the time-out allows proper integration and execution of clinical activities, gives caregivers increased control over their work environment, and provides a safety net against error.

Modified from Kaissi A et al: Measuring teamwork and patient safety attitudes of high-risk areas, *Nurs Econ* 21(5):211-218, 2003; Rajnish P et al: Fires in the operating room and intensive care unit: awareness is the key to protection, *Anesth Analg* 102:172-174, 2006.

in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail. Acting as the patient's advocate, the nurse takes considerable care to ensure that the surgical position does not interfere with respiration or circulation. It is essential to avoid displacement of the joints and undue tension on neurovascular bundles or ligaments. A patient positioned laterally (flank position) for renal surgery has the spine extended for greater access to the retroperitoneal space. Padding and stabilized support with gel pads, pillows, sandbags, and straps should be available for precise anatomic positioning and safety (see Chapter 5). When an electrosurgical unit (ESU) is to be used, care must be taken that the patient does not contact metal parts of the OR bed.

In some procedures involving stones of the kidneys or ureters, intraoperative fluoroscopy may be required. When fluoroscopy (C-arm) is to be employed, the patient must be placed on an OR bed compatible with its use. Whenever possible, the perioperative nurse takes measures to protect the patient from undue radiation exposure to the thyroid and chest areas by using small leaded shields. In urologic procedures it generally is not feasible to shield the reproductive organs.

Aseptic Techniques and Safety Measures. Prevention of infection is an important nursing goal in the care of the genitourinary patient. It is, however, seldom possible to confirm freedom from infection intraoperatively or immediately postoperatively. Aseptic techniques must be carefully maintained and monitored. Skin preparation and draping procedures (see Chapter 3) vary, depending on the surgery to be performed and institutional protocols. Special care must be taken when cleansing the perineal area to avoid contamination from the rectum to the urethra. Prepping solutions should be applied with downward strokes and the sponge discarded once it has contacted the inner vaginal or anal areas. Transurethral passage of instruments and catheters requires meticulous technique to prevent retrograde infections of the urinary tract, which account for 32% of all healthcare-associated infections (Scott, 2009).

Visualization of the bladder during transurethral procedures is often enhanced by darkening the room. Provision should be made for proper adjustments to lighting. ESUs and fiberoptic light systems are common adjuncts in urologic surgery. The nurse and surgical technologist must be familiar with the manufacturer's safety precautions and recommendations during their use.

Use of Irrigating Fluids. When the bladder is entered, sterile distilled irrigating fluid is administered to distend it for effective visualization. Commercially prepared sterile irrigation solutions with appropriate closed administration sets are highly recommended. Such closed systems prevent the inherent risks of cross-contamination. Large volumes of irrigating solutions are frequently used, particularly during more extensive endoscopic procedures. When these solutions are at the room temperature of the OR, they are cold compared with the patient's internal body temperature and can cause hypothermia. Solution-warming units are available commercially and are a useful tool to help decrease this risk. The drawback to these units may be that the warmth delays clotting, thus increasing the risk of blood loss.

Commercially prepared sterile irrigation solutions are available in collapsible bags and rigid plastic containers, both of which have the same advantages: neither depends on air, and each may be hung in series, thus providing continuous irrigation without interruption. Air bubbles, a problem that distorts visibility during the procedure, are eliminated with these systems.

For simple observation cystoscopy, retrograde pyelography, and simple bladder tumor fulgurations, sterile distilled water may be used without complication. However, during transurethral resection of the prostate (TURP), venous sinuses may be opened and varying amounts of irrigant are invariably absorbed into the bloodstream. Studies indicate that the use of distilled water during TURP may result in hemolysis of erythrocytes and possible renal failure. Other important complications include dilutional hyponatremia and cardiac decompensation (Risk Reduction Strategies).

Therefore a clear, nonelectrolytic, and iso-osmotic solution should be used. The most widely used urologic irrigating fluids are 3% sorbitol, an isomer of mannitol, and 1.5% glycine, an aminoacetic acid solution. In dilute solutions, sorbitol and glycine have many properties that make them particularly useful for irrigation during transurethral prostatectomy. At slightly hypotonic concentrations, they do not produce hemolysis.

RISK REDUCTION STRATEGIES

TURP Syndrome

Transurethral resection of the prostate (TURP) commonly is performed in older men. A variety of irrigants can be used to aid in visualization and electrosurgery during TURP. During TURP, venous sinuses within the gland may be opened and varying amounts of irrigant are invariably absorbed into the bloodstream. Depending on the type and amount of fluid used, several complications, collectively known as TURP syndrome, may occur. Patients may manifest signs and symptoms of hyponatremia and hypervolemia earlier when local and spinal anesthetics are used. Complications are more prevalent in the postoperative stage. A delay in recognizing the symptoms can be catastrophic. The perioperative nurse plays a critical role in reducing the risk of TURP syndrome and can have a positive impact through the following nursing interventions:

- **Positioning and draping.** The nurse assists with positioning the patient in the lithotomy position on the urologic table with the buttocks positioned slightly off the break in the table to provide a barrier to fluid escaping down the perineum and under the patient. The drapes should be applied in a manner that prevents pooling or loss of fluids so that losses can be monitored.
- **Maintenance of continuous irrigation.** Commercially prepared sterile irrigation solutions are available in collapsible bags and have the advantage of not depending on air, and each can be hung in series, providing continuous irrigation without interruption. The nurse retains the empty irrigation bags to assist with the fluid use calculation.
- **Volume monitoring.** The nurse monitors the amount of irrigation recovered and subtracts it from the amount of irrigation used. The total of the irrigation used minus the irrigation recovered is referred to as the volume deficit. If the cause for the deficit cannot be identified, it should be considered reabsorbed. Minimum amounts of fluids should be given and urine output carefully monitored. Irrigation fluid should be under as little pressure as possible and the bladder emptied before it reaches full capacity to prevent intravesical pressure.
- **Intraoperative observation.** Close observation during the intraoperative period is essential. Signs and symptoms such as sudden restlessness, apprehension, irritability, confusion, nausea, slow pulse rate, seizures, dysrhythmias, and rising blood pressure may be suggestive of TURP syndrome, a severe hyponatremia caused by systemic absorption of irrigating fluid used during surgery. IV diuretics such as furosemide (Lasix) may be required to prevent possible pulmonary edema associated with administration of hypertonic saline. If the patient's reaction is severe, surgery may have to be terminated.
- **Postoperative fluid management.** Immediate postoperative fluid management includes monitoring vital signs; confirming normal breath sounds in which no rales or wheezing are present; monitoring urinary output to ensure adequate volume (e.g., a minimum rate of 30 ml/hour); assessing skin color; observing blood count and electrolyte levels to confirm they are within normal limits; and maintaining IV therapy as needed.

Modified from Young E et al: Perioperative fluid management, *AORN J* 89:167-178, 2009.

However, if too much intravasation occurs with glycine, an encephalitic state can result from the ammonia produced (Surgical Pharmacology). Because the solutions are nonelectrolytic, they do not cause dispersion of high-frequency current with consequent loss of electrosurgical cutting capacity, as occurs with normal saline.

During ureteropyeloscopy, sterile normal saline is the irrigant of choice unless electrosurgery is to be employed. This solution most closely approximates a physiologic solution—an important factor if perforation and extravasation of fluid into the retroperitoneum occur. If electrosurgery is required, as with a TURP, 3% sorbitol or 1.5% glycine should be used.

Thorough knowledge of the potential hazards encountered intraoperatively during transurethral surgery is extremely important. Although complications are more prevalent in the postoperative stage, close observation during the intraoperative period is essential. Signs and symptoms such as sudden restlessness, apprehension, irritability, confusion, nausea, slow pulse rate, seizures, dysrhythmias, and rising blood pressure may be suggestive of TURP syndrome, a severe hyponatremia caused by systemic absorption of irrigating fluid used during surgery (Han and Partin, 2007). Minimum amounts of fluids should be given and urine output carefully monitored. Irrigation fluid should be under as little pressure as possible and the bladder emptied before it reaches full capacity to prevent intravesical pressure. During ureteropyeloscopy it is frequently necessary to use a pressure bag to ensure adequate visualization of the upper urinary tract. Serum electrolyte values should be obtained, and if a low serum sodium value is reported, hypertonic sodium chloride is administered by means of a slow IV drip, often on a volumetric pump. IV diuretics such as furosemide (Lasix) may be required to prevent possible pulmonary edema associated with the administration of hypertonic saline. If the patient's reaction is severe, surgery may have to be terminated.

Endoscopic and Ancillary Equipment. Cystoscopic and ancillary equipment often varies from one institution to another. Therefore it is valuable to have a reference manual or standard setup cards that illustrate and describe in detail the required instrumentation for each specific procedure.

The basic cystoscopy tray should include instruments and accessory items that are routinely used for all cystoscopy procedures. If ureteral catheterization is planned, catheterizing telescopes or an Albarrán bridge, which can be packaged and sterilized separately, may be easily added to the basic cystoscopy setup. Instruments for transurethral surgery and other special procedures may be wrapped, sterilized, and placed on separate trays so that they are available on request. This concept minimizes handling of the delicate lensed instruments and ultimately reduces costly repairs.

Cystoscopic procedures frequently require additional instrumentation. Instruments of various types and sizes, such as a visual obturator, biopsy forceps, urethral sounds, Phillips filiforms and followers, and Ellik evacuators, are available as prepackaged, sterile, disposable items. The reusable products may also be packaged separately and sterilized.

Urethral and Ureteral Catheters. A variety of urethral and ureteral catheters are designed for specific procedures. Ureteral catheters are manufactured of polyurethane material and

SURGICAL PHARMACOLOGY

Agents Used in Urologic Surgery

Category	Dose/Route	Purpose/Action	Adverse Reactions	Nursing Considerations
BULKING AGENTS				
Contigen Durasphere EXP	Transurethral, periurethral injection	Correct UH, ISD, SUI	Swelling, urinary retention Local tissue infarction/ necrosis, vascular occlusion, embolus	Avoid use of Contigen in patients sensitive to bovine products Avoid injection into blood vessels Do not use bulking agents in presences of acute cystitis, urethritis, or other genitourinary infection
IRRIGANTS				
Glycine (monocarboxylic amino acid)	1.5%, 3-5 L, intravesical	No hemolysis or dispersion of electrocurrent	Increased ammonia production Encephalitic reaction Biosynthesis of heme Blurred vision CNS disturbances TURP syndrome if absorbed	Contraindicated with clozapine usage Use with caution in diabetic patients, patients with liver disease; inhibitory neurotransmitter
Sorbitol (nonelectrolytic, iso-osmotic, hypotonic aminoacetic acid)	3%, 3-5 L, intravesical	Isomer of mannitol, no hemolysis or dispersion of electrocurrent	TURP syndrome if absorbed	Hyperglycemia may occur in patients with diabetes mellitus Use with caution in patients with renal or cardiac compromise
Water	Distilled, 3-5 L, intravesical	Irrigant, lyse cancer cells	Hyponatremia, hemolysis of erythrocytes	Avoid with TURP Intravasation can lead to dilutional hyponatremia, cardiac decompensation, and renal failure
Normal saline	0.9%, 3-5 L, intravesical	Physiologic irrigant	Hypernatremia	Not for use with electrosurgery Disperses electrocurrent
IONIC RADIOPAQUE CONTRAST AGENTS (HIGH OSMOLAR)				
Conray 60 Hypaque 50 Renografin-60	30 ml half-strength; intraurethral, intraureteral, intravesical, intrarenal	Retrograde pyelography, renal arteriography, retrograde cystourethrography	Asthmatic response, rash, lactic acidosis, anaphylaxis	Contraindicated in patients with iodine-seafood allergy, severe renal disease, dehydration Use with precaution in patients who take metformin
NONIONIC RADIOPAQUE CONTRAST AGENTS (LOW OSMOLAR)				
Omnipaque 300 Optiray 320	30 ml half-strength; intraurethral, intraureteral, intravesical, intrarenal	Retrograde pyelography, renal arteriography, retrograde cystourethrography	Back pain, dizziness, headache, diarrhea	Contraindicated in anuria, pregnancy, dehydration, severe renal and/or hepatic disease, serum creatinine >3 mg/dl Use with precaution in reduced clearance with renal disease; consider pretreatment with steroids; metformin usage

SURGICAL PHARMACOLOGY

Agents Used in Urologic Surgery—cont'd

Category	Dose/Route	Purpose/Action	Adverse Reactions	Nursing Considerations
INJECTABLES				
Indigo carmine	40 mg, IV or local	Colorize urine, vessels	Hypertension	Moderately reduces oxygen saturation
Phenylephrine (Neo-Synephrine)	0.05% (5 mg), Sub-Q	Vasoconstriction for priapism	Hypertension, reflex bradycardia	May decrease renal blood flow Contraindicated in patients with hypertension
Papaverine	30 mg/ml, 2 ml in solution, intercavernosal	Vasodilation, antispasmodic	Dizziness, dysrhythmia, hypotension, flushing, hypothermia	Contraindicated in AV block, pregnancy Depressed AV or intraventricular conduction, physiologic antagonist
Vasopressin (Pitressin)	20 units/ml: 2 ml (40 units) in solution, local	Vasoconstriction	Water intoxication, dizziness, headache, pallor	May cause tenesmus, tremors, cramps, abdominal pain, hyponatremia; retards absorption of local anesthetics Contraindicated in patients with uremia, coronary artery disease, hypertension
TOPICAL				
Methylene blue	1 ml/100 ml NS, topical	Colorize tissues, vessels	Hypertension, dizziness, headache, anemia, diaphoresis	Do not use in patients with severe renal disease, hemolytic anemia Destroys erythrocytes, may cause methemoglobinuria
OTHER				
B&O suppository (belladonna/opium)	16.2 mg/30 mg, rectal	Prevent/decrease bladder/ureteral spasm	Constipation, decreased sweating	Use with precaution in patients who take MAOIs, agents that affect GI motility, select narcotics May cause cardiovascular instability, paralytic ileus, respiratory depression, toxin-mediated diarrhea, pseudomembranous enterocolitis

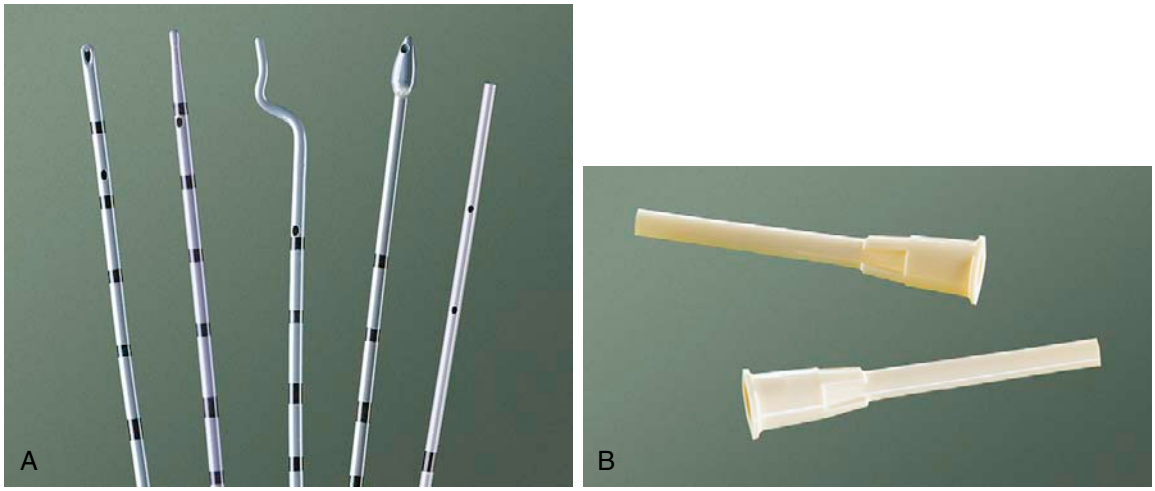

FIGURE 14-8 **A**, Ureteral catheters. **B**, Adapters.

are graduated so that the urologist may determine the exact distance the catheter has been inserted into the ureter (Figure 14-8, *A*). Most manufacturers provide sterile disposable catheters wrapped in peel-open packages to allow aseptic handling during ureteral insertion. Some indications for the use of ureteral catheters are to (1) perform retrograde pyelography, (2) identify the ureters during pelvic or intestinal surgery, and (3) bypass partial or complete obstruction that may be present as a result of ureteral tumors, calculi, or strictures. Not uncommonly, it is necessary to insert a ureteral stent in a pregnant female because of hydronephrosis or obstructing calculi.

The most commonly used catheters include the open-ended, whistle tip, cone tip, and olive tip. When a retrograde ureterogram is indicated, a cone-tipped ureteral catheter may be helpful in occluding the ureteral orifice to accomplish the x-ray study effectively. When a ureteral catheter is left indwelling, a special adapter (Figure 14-8, *B*) may be connected to the end of the ureteral catheter to facilitate connection to a closed urinary drainage system. A small slit may also be created in the Foley catheter, and the distal end of the ureteral catheter can be slipped into it and taped in place.

Indwelling double-pigtail or double-J stents are available and are passed cystoscopically to reside within the ureter (Figure 14-9). When the guidewire is removed from the core of the stent, a proximal and distal J or "pigtail" forms in the tubing to retain the stents. Many of these stents have a nonabsorbable suture attached to the distal end, which extends through the urethral meatus. A suture may be easily tied to the distal end of those that do not. The surgeon can then remove the stent in the office setting postoperatively without needing to perform a cystoscopy.

Urethral catheters have a multitude of functions as stents, as drainage tubes, and in diagnostic studies in the OR. They are generally divided into two categories—plain and indwelling (retention)—and range in different French (F) sizes, most commonly 10 through 30. The Foley catheter is the most frequently used retention catheter and is manufactured with a variety of balloon sizes, tip styles, lengths, and eye arrangements.

After transurethral prostatic surgery, a three-way Foley catheter with a 30-ml balloon capacity may be left indwelling. This type of catheter is preferred because it facilitates

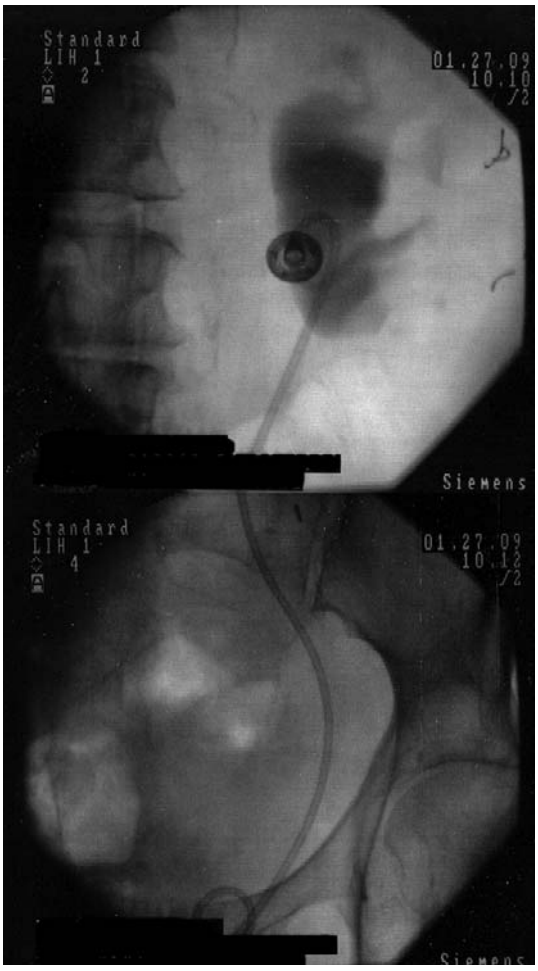

FIGURE 14-9 Double-pigtail stent set.

continuous bladder irrigation (CBI), and the large balloon aids in achieving hemostasis in the prostatic bed. The urologist may apply light traction on the Foley catheter with a leg strap, adhesive catheter anchor, tape, or a commercially available device such as the FoleyGoalie (Figure 14-10). This traction

FIGURE 14-10 FoleyGoalie.

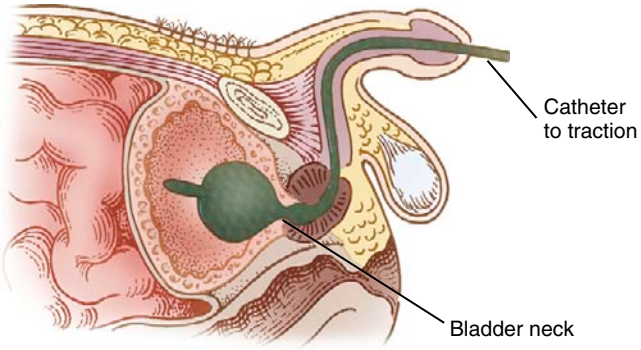

FIGURE 14-11 Balloon of Foley catheter inflated to size that prevents catheter from being pulled into prostatic fossa.

causes pressure against the bladder neck and aids in hemostasis (Figure 14-11). The FoleyGoalie is designed to prevent traumatic catheter removal in men. It is a cylindric device of helically arranged fibers that fits over the catheter and penis, secures with a Velcro strap to the base of the penis, and tapes to the catheter (Figure 14-12). If force is applied to pull out the catheter, the device tightens around the penis and catheter, holding it in position. When the force is released the FoleyGoalie loosens.

A hematuria catheter, a three-way Foley specifically for patients with excessive clot formation, is also available. This catheter is reinforced with a stretch spiral wire within the catheter lining that permits vigorous aspiration without fear of lumen collapse.

Diagnostic studies performed in the cystoscopy suite may require special catheters for specific studies. A Davis or Trattner triple-lumen double-balloon urethrographic catheter or any of a variety of urodynamic catheters may be used to diagnose

FIGURE 14-12 Attaching FoleyGoalie to catheter and penis; Velcro at base of penis, drawstring and Velcro at distal end of device to allow tightening in place.

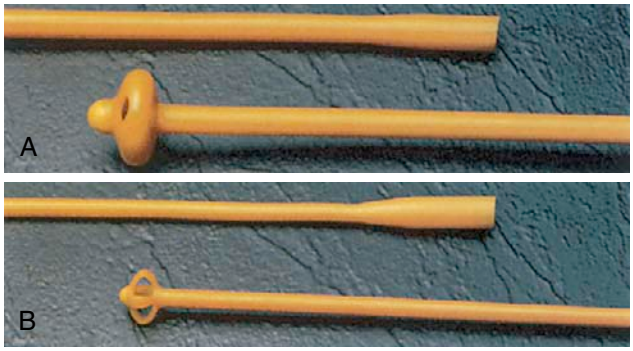

FIGURE 14-13 **A**, Pezzer (mushroom) catheter. **B**, Malecot (bat-winged) four-winged catheter.

lesions of the female urethra, such as urethral strictures, diverticula, and fistulas. To accomplish female urethrography, the catheter is inserted through the urethra into the bladder; the two balloons on the catheter are inflated, one in the bladder and one at the external urethral orifice, effectively isolating the urethra. Contrast medium is injected to visualize the entire urethra.

Another type of self-retaining catheter frequently used in the OR is Pezzer's catheter, also known as a *mushroom* catheter (Figure 14-13, *A*). It may be straight or angulated with a large single channel and a preformed tip in the shape of a mushroom. The flexible mushroom tip helps keep the catheter in place. This catheter is used primarily for suprapubic bladder drainage, often for poor-risk patients who have uremia, neurogenic bladder syndrome, or possibly long-standing urinary retention. The catheter is inserted into the bladder through a midline or small transverse abdominal wall incision and secured to the abdomen with suture or tape. The Malecot four-winged catheter, often used as a nephrostomy tube to provide temporary or permanent diversion of urine after kidney surgery and when renal tissue needs to be restored, may also be used for suprapubic drainage (Figure 14-13, *B*). A Foley catheter of preferred size is frequently chosen for either purpose. Nephrostomy tube replacement is accomplished by introducing the catheter into the surgical tract with a straight catheter guide and securing it in place with a suture or a nephrostomy retention disk that is

one size smaller than the nephrostomy tube being used. The flanges of the disk are taped or sutured to the skin. The use of other variations of urethral catheters is described throughout the chapter.

Photography in Urology. The use of photographic and video imaging equipment in urologic surgery serves to document the patient's disease, the progress of a disease process, and long-term follow-up study. It is also an important teaching resource. Video equipment adapts to endoscopic instrumentation and has the capability of projecting an enhanced image on a television monitor, permitting members of the surgical team to observe and learn during the actual surgical procedure. Other visual aids, such as slides and photographs, are used in teaching, as visual references in publication, and as documentation in patient records.

When any form of photography or video imaging is used, the patient's privacy must be ensured and an informed consent should be obtained. Special release forms should also be signed preoperatively by the patient for any videotapes or photographs to be used in teaching or publications.

Evaluation

Before the patient is taken to the postanesthesia care unit (PACU) or observation unit, the perioperative nurse evaluates the patient's general condition. The skin is assessed, and bony prominences, prepped and draped areas, and areas contacted by the attachment of ancillary equipment are observed for signs of pressure, irritation, or other changes from the preoperative status.

Many urology patients are discharged to the PACU with catheters and drains inserted, including urethral, ureteral, suprapubic, and wound drains. A local anesthetic may have been used for either primary analgesia or postoperative pain management (preemptive analgesia); preoperative or intraoperative infiltration of the surgical site blocks sensory input, resulting in postoperative analgesia. A hand-off report to the PACU nurse should include intraoperative position, problems encountered specific to the patient, and the patient's preoperative physical status as well as comprehension and anxiety levels. Documentation of medications administered from the sterile field or by the perioperative nurse intraoperatively should include time of administration, name of medication, dosage, site and route of administration, and the name of the person who performed the application or injection. Drains should be documented as to size and type, insertion site, time and date of insertion, type of collection device, name of the person who performed the insertion, and character of drainage. When several drains are in place, additional labeling on the collection devices is beneficial. Any postoperative observations before or during transport should be recorded. Evaluation should also address whether the patient met the identified outcomes related to specific nursing diagnoses in the perioperative nursing plan of care. Attainment of identified desired outcomes, included in the documentation and report to the PACU, may be phrased as follows:

- The patient verbalized an acceptable anxiety level to the perioperative nurse.
- The patient had no evidence of positional injury; neurovascular status was consistent with preoperative level, and skin integrity was intact.
- The patient maintained patency of the urinary catheter with no signs of blockage or retention. Urinary output remained within normal limits. The patient should void without difficulty after catheter removal.
- The patient had no evidence or signs of fluid volume or electrolyte imbalance; vital signs were stable, arterial blood gases were within normal limits, and urinary output was maintained at acceptable levels.
- The patient maintained adequate gas exchange; lung expansion and O_2 saturation were satisfactory.
- The patient discussed fears and concerns regarding sexual function.

Patient and Family Education and Discharge Planning

Patient and family education and preparation for discharge allow perioperative nurses to plan for the urologic surgery patient's care across a continuum. General guidelines for preoperative education are presented in Box 14-1. Information is tailored according to the procedure and the patient's status (Ambulatory Surgery Considerations). Information provided should be presented in language the patient can understand (lay terms) and clarified with the patient by having the patient repeat back in his or her own words the information provided. When possible and with the patient's approval, family members or others who will serve as caregivers should be included in the educational process at the outset. Institutions may find it helpful to inventory the patient education materials available for select surgical procedures. An example of patient education for home care after nephrectomy is presented in the Patient and Family Education box on p. 495.

Discharge instructions should be printed and include community resources and support groups as appropriate for the surgical intervention and the patient's diagnosis. These too should be presented in easily understood terms, reviewed, and confirmed by having the patient repeat back in his or her own words the information provided. Any requisite skills that the patient or family will require should be demonstrated, with return demonstrations as time permits. Perioperative nurses may find it helpful to involve institutional resource persons or departments such as the social services department in developing information related to home care services, durable medical equipment, and transfers to aftercare facilities other than home (skilled nursing center, rehabilitation facility, other long-term care facility). Patients and their families need preparation for mastering information and tasks that need to be performed. The goal of such interdisciplinary discharge planning is to provide information for the patient that is comprehensive and easy to use. This is part of perioperative nursing's ethical and professional responsibility to patients; it also meets The Joint Commission's requirements of providing consistent patient and family education.

Surgical Interventions

INTERVENTIONAL URORADIOLOGY

Many procedures that were once reserved for the OR are now being performed in the radiology department by specialists in uroradiology. As technology advances, procedures performed in the radiology department become a more common event.

BOX 14-1

Preoperative Teaching

DEFINITION

Assisting a patient to understand and mentally prepare for surgery and the postoperative recovery period

ACTIVITIES

1. Inform the patient and family/significant others of the scheduled date, time, and location of surgery, and how long the surgery is expected to last.
2. Determine the patient's previous surgical experiences and level of knowledge related to surgery.
3. Appraise the patient's level of anxiety relating to surgery; determine what the patient considers an acceptable anxiety level.
4. Provide time for the patient to ask questions and discuss concerns.
5. Describe the preoperative routines (e.g., anesthesia, diet, bowel preparation, tests/labs, voiding, skin preparation, IV therapy, clothing, family waiting area, transportation to OR), as appropriate.
6. Describe any preoperative medications, the effects these will have on the patient, the rationale for using them, and when they will be administered.
7. Inform the family/significant others of the location of the surgical waiting area.
8. Provide information on what will be heard, smelled, seen, tasted, or felt during the preoperative and intraoperative phases of care.
9. Discuss pain management strategies and the use of pain rating scales.
10. Explain the purpose of frequent postoperative assessments.
11. Describe postoperative routines/equipment (e.g., medications, respiratory treatments, tubes, machines, support hose, surgical dressings, ambulation, diet, family visitation), and explain their purpose.
12. Reinforce information provided by other healthcare members as appropriate.
13. Determine the patient's expectations of the surgery.
14. Correct unrealistic expectations of the surgery as appropriate.
15. Instruct the patient to use coping techniques directed at controlling specific aspects of the experience (e.g., relaxation, imagery) as appropriate.
16. Include the family/significant others as appropriate.

Modified from Johnson M et al: *NANDA, NOC and NIC linkages,* ed 2, St Louis, 2006, Mosby.

AMBULATORY SURGERY CONSIDERATIONS

Cystoscopy, Transrectal Guided Ultrasound of the Prostate

A commonly performed outpatient urologic procedure is a cystoscopy, transrectal ultrasound guided biopsy of the prostate (Cysto/TRUS). To minimize complications, patient selection is determined by the healthcare team. Patients classified as physical status 1 or 2, as per the American Society of Anesthesiologists, generally pose no great risk for procedures performed with general, intravenous moderate sedation (IV sedation), and local anesthetics. The majority of Cysto/TRUS patients have this procedure performed with IV sedation/local. To decrease pain during and immediately after the procedure, a viscous local anesthetic is injected into the rectum and also the urethra after IV sedation is initiated.

Preoperative and postoperative teaching of the patient and his family is most essential since the family will be the primary caregiver on discharge. Teaching begins in the surgeon's office. The office staff provides patients with a prescription for antibiotics with instructions to begin the medication 24 hours before the procedure and to continue oral antibiotics postoperatively until the prescription is completed. The office staff also advises the patient to take a cleansing enema 2 to 3 hours before the procedure. Both the antibiotics and the enema decrease the chances of postoperative infection.

Patient and family anxiety levels will be high pending the postoperative diagnosis. The patient may also be anxious because of the nature of the procedure and anesthetic used. The perioperative nurse plays a key role in supporting the patient and his family throughout the ambulatory surgical experience.

Discharge assessment following anesthesia includes the following:

- Airway patency, respiratory function, and oxygen saturation
- Stable vital signs
- Hypothermia resolved
- Level of consciousness and muscular strength
- Adequate pain control
- Mobility
- Skin color and condition
- Condition of the surgical site
- Intake and output
- Comfort
- Anxiety
- Significant other interaction
- Numeric score if used

Before discharge the nurse will instruct the patient to increase his clear liquid intake and monitor his urine output. Postoperative burning upon urination and blood in the urine as well as blood draining from the rectum are common. Patients are instructed to keep the perineum clean. The nurse ensures the patient has a prescription for pain medication, clarifies the instructions for dosage and frequency, and instructs the patient to call the surgeon for any temperature higher than 101° F. The nurse provides all instructions verbally and gives the patient and his family a written copy of the instructions. Patients call the physician as directed for results of the biopsy.

A postdischarge phone call to the patient is recommended. This phone call allows the nurse to review the patient's postoperative status, provide reassurance if necessary, and reinforce any teaching. The call also provides the patient and his family an opportunity to ask any additional questions.

PATIENT AND FAMILY EDUCATION

Home Care Education for the Nephrectomy Patient

Give the patient and the caregiver both verbal and written instructions. Provide them with the name and telephone number of a physician or nurse to call if questions arise. At the end of reviewing home care instructions, have the patient or family member repeat back, in his or her own words, information provided.

GENERAL INFORMATION

- Review the purpose and explain the type of procedure performed: partial or total nephrectomy.

WOUND/INCISION CARE

- Instruct the patient on caring for the incision and changing the dressing:
  - Wash hands.
  - Inspect the incision for signs of infection.
  - Cleanse the area with an antiseptic agent.
  - If there is no evidence of drainage, leave the site open to the air. Otherwise, cover the incision with sterile gauze squares held in place with tape.
- Teach the patient how to care for the nephrostomy tube, if present.

SPECIAL INSTRUCTIONS

- Inform the patient that showering and bathing may be resumed as recommended by the physician.
- Explain how to measure urine output as indicated.

WARNING SIGNS

- Review the signs and symptoms that should be reported to a physician or nurse:
  - Infection: incision red, warm to touch, painful, with increased or purulent drainage (define)
  - Urinary tract infection: fever, chills, hematuria ("blood in urine"), flank pain, sudden increase in urinary output

ACTIVITY

- Discuss the need to exercise to tolerance and to plan frequent rest periods. Explain that fatigue is common.
- Encourage the patient to discuss allowances and limitations with respect to occupation, recreation, and activities.
- Tell the patient to avoid heavy lifting (>10 lb) for at least 6 weeks.
- Advise the patient to avoid contact sports (e.g., wrestling, football) that could endanger the remaining kidney.

DIET

- Inform the patient that a regular diet can be followed unless there are restrictions related to the underlying reason for nephrectomy.
- Encourage the patient to drink 8 to 10 glasses of fluids per day unless restrictions of the underlying disease apply. Half of these should be fruit juices (to maintain electrolyte balance).

FOLLOW-UP CARE

- Stress the importance of regular follow-up visits. Make sure the patient has the necessary names and telephone numbers.

Modified from Canobbio MM: *Mosby's handbook of patient teaching*, ed 3, St Louis, 2006, Mosby.

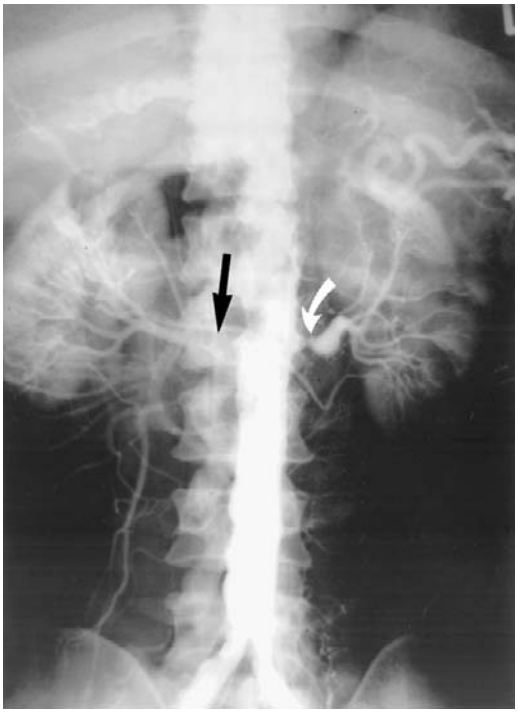

FIGURE 14-14 Bilateral renal artery stenosis. Severe stenosis of the right renal artery *(straight arrow)* is difficult to see because the artery overlies the vertebral body. The left renal artery stenosis is easier to identify *(curved arrow)*.

Those procedures include, but are not limited to, cystoscopy with stent placement, IV urogram, retrograde pyelogram, percutaneous antegrade stent placement and nephroscopic radiography, and ultrasound procedures with percutaneous access. The latter may be done to drain an abscess, to place a catheter or stent, or simply to introduce contrast material for direct fluoroscopic examination. Renal artery hypertension and stenosis may be treated successfully through new and advanced uroradiology methods, such as percutaneously placing stents in stenotic renal arteries (Novick and Fergany, 2007) (Figure 14-14).

DIAGNOSTIC AND ENDOSCOPIC PROCEDURES

Cystoscopy

Cystoscopy is an endoscopic examination of the lower urinary tract, including visual inspection of the interior of the urethra, the bladder, and the ureteral orifices. In a male patient, special attention is given to the examination of the verumontanum (which contains the ejaculatory duct), the bladder neck, and the median and lateral lobes of the prostate. In a female patient, the urethra, bladder neck, and bladder are examined.

Cystoscopy is an important diagnostic tool that provides the urologist with valuable information concerning the patient's urologic condition (History box). Indications for cystoscopy include hematuria, urinary retention, urinary tract infection, cystitis, tumors, fistulas, vesical calculus disease, and urinary incontinence. Urinary incontinence in postmenopausal women may be related to estrogen deprivation.

Procedural Considerations. Once in the preoperative area, all patients should be greeted by name and identified by their

HISTORY

How Cystoscopy Began

The blueprint for all other endoscopes is the cystoscope. In 1805 Philip Bozzini of Germany lit the way with his *Lichtleiter,* a primitive prototype of what we now know as the cystoscope. In 1872 British scientist John Tindell established the principle of internal light reflection inside glass rods. Then in 1877 Maximilian Nitze (the father of the cystoscope), in collaboration with Austrian manufacturer Joseph Leiter, turned Bozzini's prototype into the first direct-vision *kystoskop* for viewing the interior of the bladder, urethra, and larynx. This consisted of an incandescent platinum wire loop that fluoresced the bladder from the inside while magnifying the image externally through a system of lenses.

American physicians, in the meantime, worked with a German immigrant named Reinhold Wappler, who by the 1900s became known as a superior endoscope innovator. Endoscopic devices finally began to gain widespread popularity when Thomas A. Edison developed the incandescent lamp. Through miniaturization, a low-amperage mignon bulb was created from his lamp, allowing for simple, manageable, and low-cost cystoscopes to be produced.

Heinrich Lamm of Germany confirmed in 1930 that optical fibers could transmit images. But it was not until the mid-1950s that fiberoptics entered the scene, replacing these mignon bulbs with glass-fiber bundles. In 1954 fiberoptics became practical when British physicist Harold H. Hopkins produced the first usable system. A suggestion by a Dutch optics professor, Abraham van Heel, to coat the optic fibers with a transparent sheath led to unlocking the key to continuous illumination. This coating protected the fibers and prevented light from "leaking" out.

The contributions of Hopkins and van Heel became the inspirations behind the first fiberoptic gastroscope in 1957 and the first ureteroscope in 1960. Also in 1960, Hopkins introduced a refinement of his original technology, the "rod lens" rigid endoscope. This was created by combining air with long ground-up pieces of glass into an optical surface. In 1967 this method was applied to the cystoscope, thus replacing the previous prisms, mirrors, and lenses.

The 1980s brought the marriage of fibers and lenses into co-axial fiberoptic bundles through which one package of strands carried light and another returned images. These allowed increased flexibility and maneuverability without image distortion. Today endoscopy is so refined that visualization and treatment are achieved with flexible pencil-size tipped cystoscopes, ureteroscopes, and laparoscopes working through spearlike channeled sheaths and trocars.

Modified from Engel RM: Philipp Bozzini—the father of endoscopy, *J Endourol* 17(10):859-862, 2003; Wm. P. Didusch Center for Urologic History of the American Urological Association, Linthicum, Md, available at http://urologichistory.museum/content/milestones/cystoscopy/p1.cfm. Accessed May 16, 2009.

identification bracelet and number. The perioperative nurse should check the chart for operative consent and pertinent laboratory reports; IVPs and any other diagnostic x-ray studies ordered preoperatively should also be available for review. Customarily, the patient voids immediately before transport to the OR. The time of urination and the output volume should be documented for ruling out residual urine in the bladder.

After the patient is placed on the cystoscopy bed, correct positioning requires optimum relaxation of muscles of the legs and perineum. Proper positioning is a vital consideration for patient safety and comfort. Allen and Yellofin stirrups are boot-style stirrups that support the foot and calf. These have thick gel padding within the stirrup and provide optimum patient comfort and protection, relieving pressure on the popliteal space. They are especially beneficial for the patient who has limited hip mobility and altered peripheral circulatory status. The nurse should assess the patient's bilateral pedal pulses preoperatively and postoperatively when using any stirrups. Stirrups should be adjusted carefully to avoid undue pressure on the calf. If knee crutches are employed, the curve of the yoke suspension should flow outward from the perineum, in the same manner as the patient's legs. Padding the knee crutches reduces pressure on the popliteal areas. If sling stirrups that support only the feet are employed, the post should be padded and positioned to prevent pressure on the peroneal nerve. Special pads are designed for use with both of these stirrups.

After the patient is properly positioned, the anesthesia provider may tilt the OR bed so that the patient's head is slightly higher than the buttocks to allow the prep solution to drain into the collecting pan. Pooling of solutions beneath the patient may cause skin reaction and chemical irritation, as well as the potential for burns if an ESU is used. If the cystoscopic procedure requires the use of an ESU, the nurse ensures that the dispersive pad is placed on the patient in direct contact with the skin as close to the operative site as is practical. When placing the ESU pad, the nurse avoids hairy areas, bony prominences, scar tissue, and proximity to prosthetic metal implants or pacemakers.

After properly positioning the patient, the nurse or urologist dons gloves and preps the entire pubic area, including the scrotum and perineum, with an antimicrobial solution. A disposable drape sheet with a sterile screen material incorporated into it is a standard part of the cystoscopy drape pack. The surgeon and surgical technologist drape the patient in a manner that ensures aseptic technique is maintained during the urologic procedure. If a general or spinal anesthetic is required, the anesthesia provider administers it before prepping and draping. If a local anesthetic is preferred, the surgeon instills it into the urethra of the male patient after prepping and draping but before instrumentation. For a female patient, the surgeon places a cotton applicator that has been dipped into the anesthetic solution in the urethral meatus. Usually, viscous lidocaine (Xylocaine), 1% or 2%, is used. If the patient is allergic to lidocaine, instillation of 50 to 60 ml of lubricant accompanied by anesthesia-monitored sedation is often adequate to afford painless access to the urethra and bladder. The patient should be informed that a sensation of pressure is to be expected.

The basic cystoscopy setup requires a cystoscopy pack, a sterile gown or apron, sterile gloves, a fiberoptic light source, a prep cup and solution, gauze sponges, the cystourethroscope (Figure 14-15), a short bridge and fiberoptic light cord, lateral and Foroblique telescopes, a Luer-Lok stopcock, irrigation tubing and sterile water irrigant, and water-soluble lubricant. Additional items that should be sterile and available include a calibrated container to measure residual urine, test tubes with screw tops for urine specimens, an Albarrán bridge and rubber catheter nipples or adapters, a medicine glass for dye, anesthetic solution, disposable 10-ml and 20-ml syringes, medication

FIGURE 14-15 Basic instruments for cystoscopy, catheterization, electrosurgery, and retrograde ureteral pyelography (add ureteral catheter of choice). *Left to right,* Bugbee electrodes, single-horn Albarrán deflecting bridge, nipple adapters, stopcock, short double-horn bridge, 23F and 17F Foroblique cystourethroscopes and sheaths, 30-degree and 70-degree telescopes, double-horn Albarrán deflecting bridge, single-horn examining bridge, visual obturator, and fiberoptic cable.

FIGURE 14-16 Flexible cystoscope.

labels and a marking pen, a penile clamp (to occlude male urethra after local anesthetic is instilled), contrast material, an ESU and dispersive pad, and a Bugbee electrode.

The flexible cystoscope (Figure 14-16) is used for patients with obstructive symptoms resulting from prostatic hyperplasia and rigid prostatic urethra. In addition, the flexible cystoscope can be used for patients who cannot assume a lithotomy position, such as those with spinal cord injuries or severe arthritis. Flexible cystoscopy may be accomplished with the use of a local anesthetic. It affords the patient a higher degree of comfort, is less traumatic to the urethra, and can be performed in the patient's bed on the nursing unit.

Cleaning, sterilization, disinfection, and maintenance of endoscopic equipment are important procedures in the care of fiberoptic lensed instruments. Ultimately this process reduces costly repairs and ensures the availability of properly functioning instruments. See Chapter 7 for the process to correctly process endoscopic equipment.

Endoscopy of the genitourinary tract is considered a class II (clean-contaminated) procedure and, according to the Centers for Disease Control and Prevention (CDC) and the Association for Professionals in Infection Control and Epidemiology (APIC) guidelines, presently requires disinfection rather than sterilization. High-level disinfection with an agent such as activated glutaraldehyde or dialdehyde that can destroy vegetative microorganisms, most fungal spores, tubercle bacilli, and small nonlipid viruses is recommended. In most situations, the routine of meticulous cleaning of endoscopic instruments and making sure that all channels are accessed, followed by appropriate high-level disinfection, provides reasonable assurance that the items are safe to use. The level of disinfection is based on the contact time, temperature, and concentration of the active ingredients of the disinfectant, as well as the nature of microbial contamination.

Many institutions are, however, treating endoscopic interventions as sterile procedures because the sterilization of instruments provides the greatest assurance that the risk of infections transmitted by contaminated instruments has been eliminated (see Chapter 3). Some options available include glutaraldehyde solution, hydrogen peroxide solution, an automated peracetic acid unit, an ETO (ethylene oxide, "gas") sterilizer, a hydrogen peroxide and plasma sterilizing unit, and high-vacuum or gravity steam autoclaving for those components that may be sterilized in this manner. The manufacturer's recommendations should always be followed. If soaking is chosen the lid should remain on the soaking container when not in use; masks should be worn when in direct contact with the fumes. It is also imperative that the instrumentation be thoroughly rinsed in sterile distilled water after removal from soaking solution and before use. Glutaraldehyde residue remaining in the channels or on the lens can result in chemical burns for the patient and the surgeon.

Stone removal, bladder biopsy, and bladder fulguration may be accomplished by using special cystoscopic accessories, such as the Hendrickson-Bigelow lithotrite, which crushes large bladder calculi. This procedure is called a *litholapaxy.* Lowsley forceps, Wappler rigid cup forceps, and flexible foreign body forceps may also be employed. Bladder fulguration requires the use of flexible-stem electrodes available in various French sizes and tip configurations such as the ball, cone, dome, and bayonet.

Operative Procedure

1. The surgeon lubricates the cystourethroscope and introduces it into the urethra, withdraws the obturator, and drains the bladder. Residual urine may be measured at this time if the patient voided before the examination. The specimen may be saved for cultures or cytologic studies.
2. The surgeon connects the cystourethroscope to the irrigating system, and inserts and locks the telescope in place. If the patient is awake, telling the patient to try to urinate also helps facilitate passage of the scope. The surgeon controls the rate of flow and volume of fluid by adjusting the stopcock on the scope. If difficulty is encountered during insertion, the visual obturator may be used to introduce the scope under direct vision. This accessory is constructed to smooth the fenestrated edges of the cystourethroscope. It requires the use of the telescope for direct vision and permits irrigation during introduction.
3. For retrograde ureteral catheterization and pyelography, the surgeon passes ureteral catheters through the cystoscope sheath and then passes them through the ureteral orifice and into the ureter via the Albarrán bridge. A radiopaque substance (e.g., nonionic, low-osmolar agents Omnipaque 300 and Optiray 320; or ionic high-osmolar Renografin-60

and Hypaque 50) is injected (see Surgical Pharmacology, pp. 489-490). Fluoroscopic imaging is used to outline the entire upper urinary collecting system.

Periurethral-Transurethral Injection of Bulking Agents

Collagen injection is an ambulatory surgery procedure achievable with the patient administered a local anesthetic with or without sedation. Collagen (Contigen) is a live bovine dermal natural protein and is prepackaged in a sterile syringe containing the collagen material. Injection needles available are an 8-inch, 23-gauge, noncoring needle for transurethral use or a 5-inch, 22-gauge needle for periurethral insertion. Female patients with intrinsic sphincter deficiency (ISD) demonstrated by urodynamic evaluation and male patients (usually after prostatectomy) with incontinence lasting more than 1 year may benefit from this procedure. Other indications for collagen injection include urethral hypermobility (UH), stress urinary incontinence (SUI) secondary to previous stricture treatment, trauma, or myelodysplasia (Appell and Winters, 2007).

Durasphere is a bulking product consisting of pyrolytic, carbon-coated beads within a water-based viscous medium. Needles for instillation include a 1.5-inch spinal-tip subcutaneous needle and a 15-inch spinal-tip transurethral needle. It is designed to treat women with SUI secondary to documented ISD. Durasphere is not absorbed as readily as collagen and may provide a more durable effect. Durasphere is currently approved by the U.S. Food and Drug Administration (FDA) for use in women only.

Procedural Considerations. Collagen must be kept refrigerated and the FDA guidelines for its use and documentation followed. Durasphere requires no refrigeration. Patients selected for collagen injection must be skin-tested with collagen 1 month before periurethral injection. The patient receiving Durasphere does not require skin testing. A urine culture and sensitivity will be done approximately 10 days preoperatively. It is optimal to use a video system for the procedure. A basic cystoscopy set is required. The patient will usually be in the lithotomy position.

Operative Procedure

1. The surgeon instills urethral anesthetic and may supplement the anesthesia with a perineal block of 1% or 2% lidocaine. Cystoscopic examination is performed before the bulking agent is injected to rule out any associated findings. It is recommended that the irrigation be instilled by use of a pressure bag to minimize extravasation of the material by increasing the intraurethral pressure.
2. The surgeon introduces the injection needle provided by the manufacturer through the cystoscope and places the tip transurethrally, below the urethral mucosa, just distal to the bladder neck. In the female the shorter needle may also be employed for periurethral introduction. Positioning of the needle tip is accomplished when the surgeon sees the indentation of the urethra by the tip while manipulating the needle.
3. The material is injected until the urothelium enlarges and meets in the midline, approximating the appearance of lateral lobe enlargement of the prostate.

FIGURE 14-17 Grade 5 bilateral ureteral reflux.

Transurethral Ureteropyeloscopy

Transurethral ureteropyeloscopy is an endoscopic examination of the ureters and renal pelvis. The use of rigid or flexible ureteroscopes or ureteropyeloscopes provides the opportunity to diagnose filling defects in the ureter and renal pelvis, congenital anomalies (Figure 14-17), hematuria, ureteral obstruction, and damage from trauma. Manipulation, fragmentation, basketing of ureteral and renal calculi, and retrieval of foreign bodies are possible with transurethral ureteropyeloscopy. Extracorporeal shock-wave lithotripsy (ESWL), electrohydraulic lithotripsy (EHL), sonic lithotripsy, or laser lithotripsy may accompany the procedure. It may also be used to manage residual sludge after these treatments.

Ureteral strictures may be treated transurethrally, and biopsies of tumors of the ureter and renal pelvis are performed under direct visualization. Internal ureteral stents may also be inserted for ureteral patency. These range in size from 3F to 8.5F and are available in single-J, double-J, and pigtail configurations.

Procedural Considerations. The setup is similar to that for a cystoscopy with the addition of a rigid or flexible ureteroscope system (Figure 14-18). A critical factor in this procedure is allowing enough time for careful dilation of the ureter under C-arm fluoroscopy. The flexible ureteroscope has gained popularity because of its inherent tip mobility, which provides a more panoramic view of the entire circumference of the ureter. The perioperative nurse must be prepared to tilt the radiolucent operative bed at head and foot and laterally, as well as raise the bed.

In addition to the standard cystoscopy setup, the following items should be available: a rigid or flexible ureteroscope,

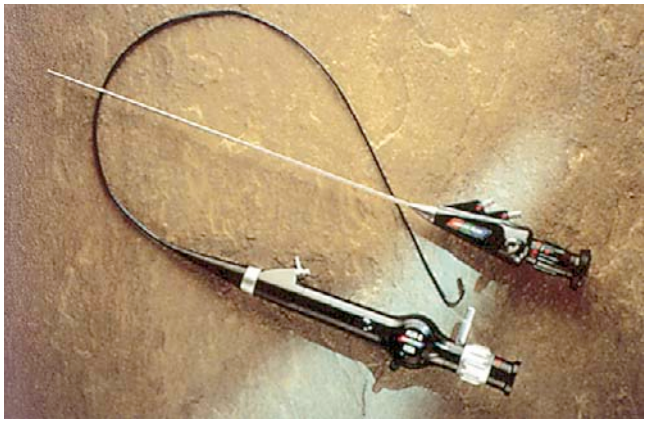

FIGURE 14-18 Flexible ureteropyeloscope and rigid ureteropyeloscope.

ureteral dilators of graduated sizes and styles, size 3-French to 5-French ureteral stone baskets of various styles, a ureteral grasping forceps, biopsy forceps, snare, scissors, catheters of various styles and sizes, stents, guidewires, balloon dilators, and radiographic contrast material. Patient allergies should be checked before the use of radiographic contrast material.

Operative Procedure

1. The surgeon inserts the ureteropyeloscope and accesses the ureter with a guidewire under fluoroscopic control. The ureter is irrigated as the guidewire is advanced. The surgical technologist assists by maintaining slight tension on the wire.
2. The ureter is dilated to 10F to 12F with a balloon dilator or co-axial dilators. If a balloon dilator is chosen, the balloon should be inflated with contrast material, using a pressure syringe to ensure that it does not exceed the maximum allowable atmospheric (ATM) pressure (burst pressure).
3. An additional working guidewire is placed by the surgeon to be used as a safety wire.
4. The surgeon passes the ureteroscope over the working guidewire, biopsies any suspicious lesions, and performs diagnostic pyeloscopy and ureteroscopy. The characteristics of calculi are observed to determine the best treatment approach. Urine may be obtained for cytologic and microbiologic examination. If a calculus is small enough to be delivered through the ureter, the surgeon engages it in a retrieval basket and removes it under visual as well as fluoroscopic control. If, after ureteral dilation, the calculus does not appear to be small enough for delivery, lithotripsy (fragmentation) is performed through the ureteroscope, or ESWL may be performed later. Lithotripsy may be performed with ultrasonic (through a rigid ureteroscope) or electrohydraulic lithotripters or with the tunable pulse-dyed or holmium:yttrium-aluminum-garnet (Ho:YAG) lasers. Appropriate laser precautions must be enforced. Chapter 7 discusses laser safety issues in more depth.
5. The surgeon assesses the ureter for integrity (perforation or laceration) with retrograde pyelography.
6. A ureteral stent is placed over the remaining safety guidewire, and the guidewire is removed.

SURGERY OF THE PENIS AND THE URETHRA

Laser Ablation of Condylomata and Penile Carcinoma

Laser ablation of condylomata or penile cancer is the eradication of diseased tissue by means of a laser beam. Laser therapy has been determined to be effective for condylomata and penile cancers that are refractory to other treatments. One of the major advantages of the laser is that heat is distributed evenly to the tissue underlying the lesion. When any laser is being used, precautions appropriate to that system must be initiated (see Chapter 7).

Procedural Considerations. Laser treatment may be performed successfully with local infiltration of an anesthetic. A U-shaped, craterlike lesion of predetermined depth with a 2-mm radius can be created. A power setting ranging from 2 to 20 watts on continuous or super-pulse mode is commonly used. With laser ablation, less edema and necrosis occur, fibrosis is minimized, and rapid healing is facilitated. The argon, CO_2, potassium-titanyl-phosphate (KTP), and neodymium (Nd):YAG lasers are all suitable for this therapeutic application.

Operative Procedure

1. The surgeon moves the beam transversely across the tissue and then in a crosshatch matrix, thereby treating all perimeters of the lesion. Throughout the procedure the surgeon wipes the area with a sponge moistened in acetic acid (5% vinegar), which results in greater visualization of the diseased tissue and allows therapy to deeper layers.
2. Postoperatively the affected areas may be coated with an antibiotic ointment. Wounds are generally left uncovered.

Circumcision

Circumcision is the excision of the foreskin (prepuce) of the glans penis. Circumcision in adult males is performed for the relief of phimosis, a condition in which the orifice of the prepuce is stenosed or too narrow to permit easy retraction behind the glans. Another condition that may require circumcision is balanoposthitis, an inflamed glans and mucous membrane with purulent discharge. Circumcision may also be done to prevent recurrent paraphimosis, a condition in which the prepuce cannot be reduced easily from a retracted position. (See Chapter 25 for pediatric considerations during circumcision.)

Procedural Considerations. The perioperative nurse assists in positioning the patient in the supine position. A plastic or minor instrument set and a local anesthetic with IV sedation are sufficient. The ESU should be available.

Operative Procedure

1. The surgeon clamps the prepuce in the dorsal midline and incises it toward the coronal margin (Figure 14-19, *A*), leaving about 5 cm of coronal mucosa intact. If the prepuce is adherent, a probe or hemostat may be used to break up adhesions.
2. A similar procedure is performed ventrally. The two incisions are then joined circumferentially. Alternatively, a superficial circumferential incision is made in the skin with a scalpel at the level of the coronal sulcus and the mucosa at the base of the glans.

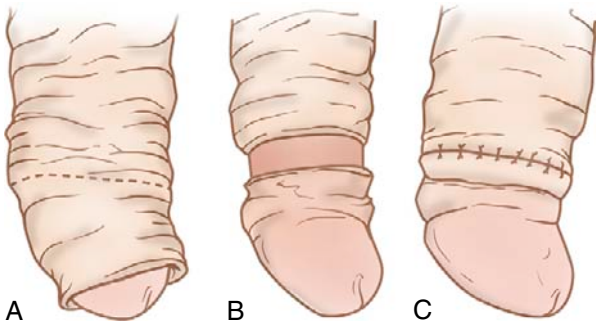

FIGURE 14-19 Circumcision.

3. The surgeon undermines redundant skin between the circumferential incisions and removes it as a complete cuff (Figure 14-19, *B*).
4. Bleeding vessels are coagulated or clamped with mosquito hemostats and ligated with fine absorbable ligatures.
5. The surgeon approximates the raw edges of the skin incision to a coronal cuff of mucosal prepuce, generally with 4-0 or 5-0 absorbable sutures on atraumatic, plastic cutting, or fine gastrointestinal (GI) needles (Figure 14-19, *C*).
6. The wound is dressed with petrolatum gauze.

Excision of Urethral Caruncle

A urethral caruncle is a benign lesion or inflammatory prolapse of the external urinary meatus in the female. Excision entails the removal of these papillary or sessile tumors from the urethra.

Procedural Considerations. The perioperative nurse assists with placing the patient in the lithotomy position. A minor or plastic set, an ESU, and a local anesthetic are used. A urethral catheter of an appropriate size may be required if the distal urethral prolapse is severe.

Operative Procedure

1. The surgeon uses a small, fine-tipped Metzenbaum or plastic scissors to expose the tumor and excise it within a wedge of ventral urethral tissue.
2. Figure-of-eight 4-0 absorbable sutures are placed at the edge of the incision to achieve hemostasis.

Urethral Meatotomy

Urethral meatotomy is an incisional enlargement of the external urethral meatus to relieve congenital or acquired stenosis or stricture at the external meatus.

Procedural Considerations. A male patient is placed in the supine position. Prepping and draping are as described for urethral catheterization. For a female patient, the lithotomy position is used. The surgeon administers local anesthesia. A plastic instrument set is required.

Operative Procedure

1. The surgeon places a straight hemostat on the ventral surface of the meatus.
2. An incision is made along the frenulum to enlarge the opening and overcome the stricture.

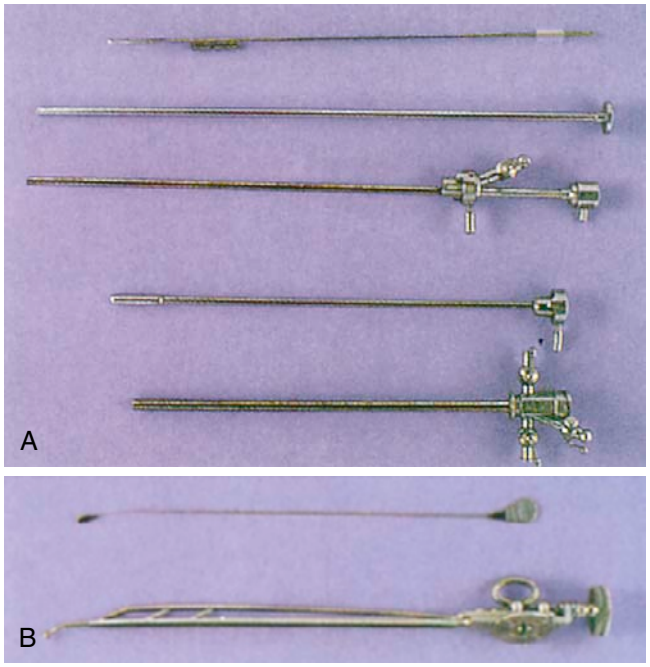

FIGURE 14-20 **A**, Optical internal urethrotome. **B**, Otis urethrotome.

3. Hemostasis is obtained by clamping the bleeding vessels and ligating them with fine absorbable sutures.
4. The surgeon sutures the mucosal layer to the skin with fine absorbable sutures.
5. A dressing of petrolatum gauze is applied.

Urethral Dilation and Internal Urethrotomy

Urethral dilation and internal urethrotomy entail the gradual dilation and lysis of a urethral stricture to provide relief of distal lower urinary tract obstruction. Urethral strictures or narrowing of the urethra may be caused by a congenital malformation that is usually found at the external urinary meatus. Infection or trauma may also contribute to stricture of the membranous and pendulous urethra. Urethral stricture disease may be treated by periodic dilation with Phillips filiforms and followers, Van Buren sounds, or balloon dilation catheters.

Procedural Considerations. The perioperative nurse assists with placing the male patient in the supine position for routine urethral dilation and in the lithotomy position for other procedures. The female patient is placed in the lithotomy position. Prepping and draping are conducted as appropriate to the patient's position and gender. The surgeon administers a local anesthetic either (1) by placing cotton-tipped applicators, which have been dipped into viscous 2% lidocaine (Xylocaine), into the urethral opening or (2) by using a urethral syringe to instill the lidocaine. Female urethral dilation is performed with short, straight metal dilators or with hollow McCarthy dilators. The latter allows a urine specimen to be obtained.

In addition to a cystoscopy setup, required instrumentation includes urethrotomes (Figure 14-20); the resectoscope working element with sheath, obturator, and cold knives; urethral dilators; Phillips filiforms and followers; Van Buren sounds; and a silicone Foley catheter. Before use, the filiforms and

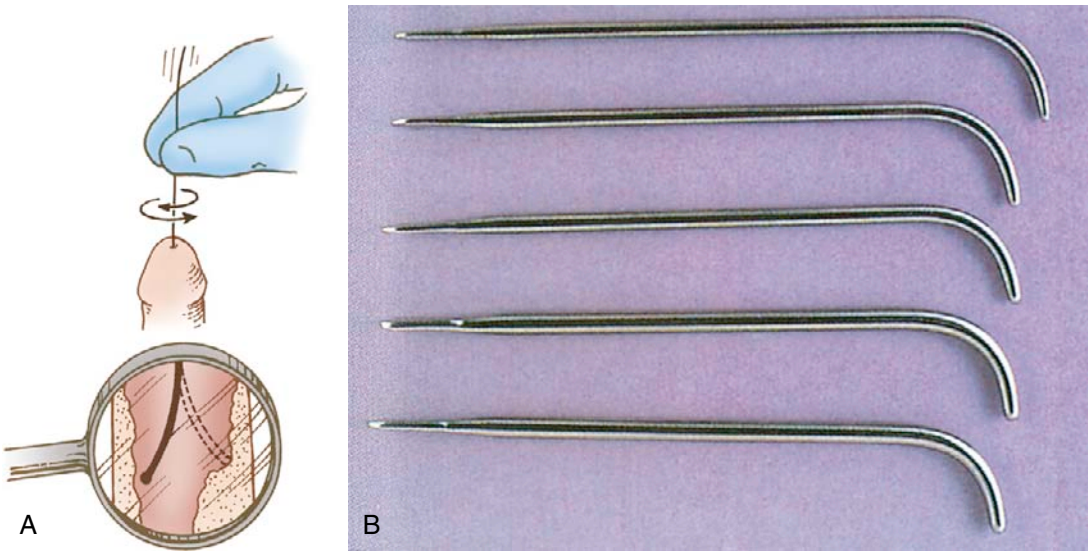

FIGURE 14-21 **A**, Method of using coudé-tipped bougie for passing stricture. **B**, Variety of urethral sounds (dilators).

followers should be carefully inspected for damaged or weak points, particularly around the scored-threaded end.

Operative Procedure

GRADUAL DILATION

1. In a male patient, the surgeon lubricates and anesthetizes the urethra with a viscous anesthetic that is instilled into the urethra with a urethral or Uro-Jet syringe. A penile clamp occludes the penile urethra at the coronal sulcus and keeps the anesthetic within the urethra.
2. Phillips filiforms of various tips and sizes are introduced first in an attempt to pass an instrument beyond the urethral stricture. Followers of increasing size are connected to the filiforms and passed through the strictured portion of the urethra, stretching the scarred area (Figure 14-21, *A*).
3. Slow dilation is also achieved with a small catheter or follower left in the urethra. It leads to softening of the stricture over the course of several days.

INTERNAL URETHROTOMY

1. The surgeon inserts the assembled visualizing urethrotome into the urethra using direct vision.
2. When necessary, the surgeon feeds a filiform or ureteral catheter into the catheterizing channel to help identify the patent portion of the urethra.
3. The surgeon advances the urethrotome to the desired position, and incises the urethral scar with the blade. The normal urethra is incised 1 cm proximally and distally beyond the stricture to achieve optimum results.
4. A silicone Foley catheter is usually left in place for 3 to 5 days after surgery.

Urethroplasty

Urethroplasty is reconstructive surgery of the urethra for strictures, urethral fractures, or narrowed segments of the urethral lumen that are congenital, inflammatory, or traumatic in origin. Urethral grafts are generally required and may include free skin grafts and mobilized vascular flaps. There are many combinations of these procedures, and in all of them some type of temporary urinary diversion may be used, depending on the location and severity of the condition.

Preoperatively, the patient usually complains of obstructive symptoms, frequently associated with a UTI. Techniques used to determine diagnosis include urodynamics (voiding pressures above and below the site of obstruction), urinary flow cytometry, IVU to rule out an upper tract lesion, cystoscopy, and urethrography. The length and density of the diseased urethra are determined to plan the appropriate reconstructive procedure. Any associated UTI must be treated and eradicated before surgical intervention. Definitive repair should not be done for 10 to 12 weeks after use of diagnostic instrumentation to allow the inflammatory reaction to subside.

Procedural Considerations. The patient is placed in the exaggerated lithotomy position by the perioperative nurse and one other person. Routine prepping and draping procedures are employed with precautions for isolating the anus (e.g., the use of an impervious plastic adherent drape). The setup includes a minor instrument set with fine plastic instruments for dissection and plastic repair. Strictures may be located deep, requiring fiberoptic lighting. An ESU may be required.

Operative Procedures

JOHANSON URETHROPLASTY. The Johanson urethroplasty is a two-stage procedure to repair and reconstruct the urethra for severe urethral stricture disease. Approximately 3 months after completion of the first stage, if the operative site is healing and the patient is voiding adequately, a second-stage procedure is performed. Vascularized flaps of preputial or penile skin may be mobilized to the ventrum by leaving them attached to the outer surface of the prepuce or as an island flap. One modification is the transverse preputial island flap neourethra with glans channel positioning for the meatus. Preputial skin is preferred because of its rich reliable blood supply and non–hair-bearing characteristics.

First Stage

1. The surgeon makes an inverted U incision in the perineum from the inner borders of the ischial tuberosities up to and including the base of the scrotum.
2. A Van Buren sound is passed into the urethra up to the stricture (Figure 14-21, *B*). The bulbocavernosus muscle is dissected and retracted laterally.
3. The surgeon makes an incision in the urethra over the strictured area and extends it in each direction at least 1 cm beyond the diseased area. The abnormal scar tissue is excised or simply incised, because scrotal skin ultimately increases the lumen.
4. A 28F sound is passed through both the proximal and the distal urethral lumens to rule out further stricture.
5. The surgeon sutures the remaining urethral mucosa to the scrotal skin with 4-0 absorbable sutures.
6. A cystotomy tube to divert the urinary stream may be left indwelling and removed in 5 to 7 days.

Second Stage (Mobilized Vascular Flap)

1. A red rubber catheter is temporarily inserted into the bladder through the proximal urethral stoma.
2. The surgeon incises the penoscrotal skin longitudinally, adjacent to the urethra.
3. A new urethra is constructed by developing the ventral preputial skin that is dissected free and fanned out. The rectangle of skin is rolled into the neourethra and measured.
4. A channel is sharply created on the ventral aspect of the glans, in a plane just above the corpora.
5. The surgeon removes the glans tissue, forming a groove approximately 14F in diameter.
6. Layers of subcutaneous tissue are dissected free from the dorsal penile skin to create an island flap that is spiraled to the ventrum. The surgeon brings the flaps together in the midline and closes with a continuous or interrupted 4-0 absorbable suture.
7. The neourethra is anastomosed proximally to the urethra and carried to the tip of the glans.
8. The dorsal penile flaps are transposed laterally to the midline, and the surgeon excises the excess skin.
9. Closure is with 4-0 absorbable interrupted mattress sutures around the glans and down the penile shaft. A bulky pressure dressing is applied.
10. Suprapubic cystostomy drainage is an option, but a urethral catheter usually suffices.

HORTON-DEVINE URETHROPLASTY (URETHRAL PATCH GRAFT). Urethral patch graft is a one-stage operative procedure that incorporates a free skin graft to correct a urethral stricture. Free skin grafts should be at full thickness. Because the free graft must be revascularized, it is important that it have a perfect skin cover of well-vascularized dorsal, preputial, penile skin.

1. The surgeon passes a 17F panendoscope into the posterior urethra, and then passes a 20F urethral dilator into the posterior urethra.
2. A perineal vertical midline incision is made into the urethral lumen. The surgeon reinserts the panendoscope and examines the incision to determine if it crosses the stricture.
3. The defect is measured, and the surgeon makes a circumferential incision on the posterior penile shaft to harvest an oval piece of skin the size of the defect.
4. The epidermal side of the graft is defatted, and 4-0 absorbable sutures are placed at the apex and base.
5. The surgeon sutures the apex into position at the proximal and distal ends of the stricture with the epidermal side toward the urethral lumen.
6. The graft is anastomosed proximally to the urethra with the suture line of the graft next to the corpus. The middle glans dart is fixed to the corpus. The graft is formed into a neourethra over a Silastic stenting catheter.
7. The surgeon reinserts the panendoscope and irrigates the urethra to check for suture-line leaks.
8. A Foley or fenestrated catheter is inserted to serve as a stent.
9. The surgeon approximates and closes the corpus spongiosum over the patched area as a separate layer with interrupted 3-0 absorbable sutures. Subcutaneous 4-0 absorbable sutures are placed.
10. The skin and the graft site are closed with interrupted 4-0 sutures.
11. A suprapubic catheter is inserted to divert urine for healing. Petrolatum gauze is wrapped around the penis and covered with gauze sponges and fluffed dressings. A scrotal support is applied to provide support and pressure.

Penectomy

Penectomy is the partial or total removal of a cancerous penis. The procedure selected depends on the extent of involvement and disease stage. Invasive penile cancer not suited for irradiation because of its size, depth, or location is best dealt with by penectomy. Excision of a 2-cm gross tumor margin is adequate for local management. Partial penectomy may afford a sufficient length for directable and upright urination. At least 3 cm of viable proximal shaft is necessary for consideration of a partial penectomy. If the residual stump is inadequate in length, detachment and mobilization of the suspensory ligaments may be an option in selected patients. A total penectomy is generally required when tumor margins are beyond a 2-cm retrievable length from the penoscrotal junction.

Options are available to limit the extent of the disfiguring surgery previously indicated for penile cancer. Chemotherapy agents, often combined with irradiation, are proving effective in shrinking penile carcinomas that would have previously mandated radical penectomy.

Reconstruction is possible after penectomy. Evaluation must take into account sexual, urinary, and cosmetic factors. Extensive or proximally invasive lesions that include the scrotum, perineum, abdominal wall, and pubis necessitate emasculation as well as expanded resection of involved tissues.

Procedural Considerations.

The setup necessary is similar to that for any inguinal surgery, with the addition of a medium Penrose drain for use as a tourniquet.

Operative Procedure

PARTIAL PENECTOMY

1. The lesion is excluded by a towel attached to the planned amputation line. The surgeon applies a penile tourniquet at the base of the penis (Figure 14-22, *A*).
2. After circumferential skin incision, the surgeon divides the cavernous bodies to the urethra with a 2-cm gross margin (Figure 14-22, *B*).

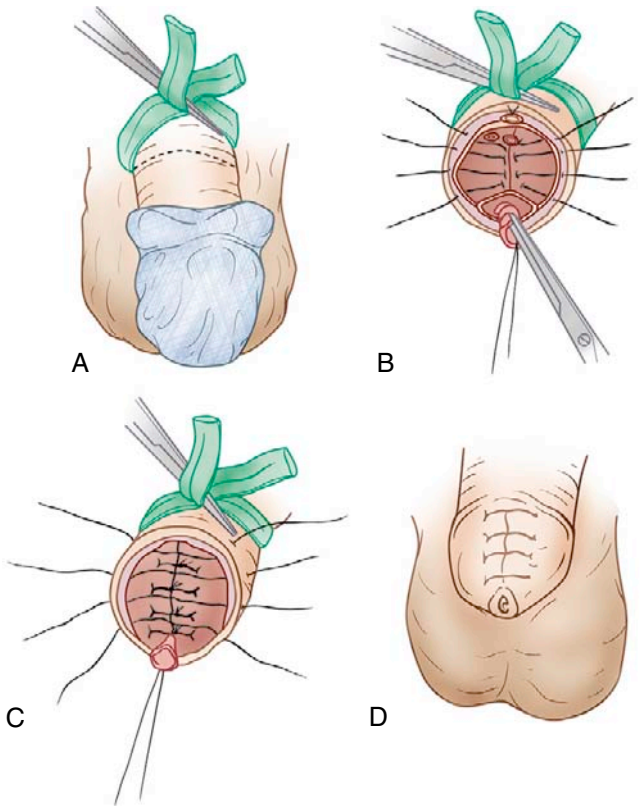

FIGURE 14-22 Partial penectomy.

3. Dorsal vessels are ligated, margins of the tunica albuginea are approximated, and the urethra is dissected proximally and distally (spatulated) to obtain a 1-cm redundant flap (Figure 14-22, *C*).
4. Without sacrificing the tumor margin, the surgeon divides the urethra. Interrupted sutures are placed on the opposite margins of the tunica albuginea to secure the corpora. The tourniquet is removed, and hemostasis is achieved.
5. After the dorsal urethrotomy, a skin-to-urethra anastomosis is performed. The redundant skin flap is then dorsally approximated (Figure 14-22, *D*).
6. A small urinary catheter is inserted, and a nonadherent dressing is applied.

TOTAL PENECTOMY

1. A vertical elliptic incision is made around the penile base (Figure 14-23, *A*).
2. The distal urethra and its ventral traction are divided through an incision in Buck's fascia, mobilizing the urethra and aiding its dissection, which extends from the corpora to the bulbar region.
3. The surgeon separates and ligates the corpora (Figure 14-23, *B*). The suspensory ligaments and dorsal vessels are divided as corporal dissection is carried out.
4. The urethra is transected from the corpora (Figure 14-23, *C*).
5. An ellipse of skin approximately 1 cm in size is taken from the perineal area. A tunnel is fashioned in the perineal subcutaneous layer of tissue. A traction suture through the tunnel, at the penile base, aids dissection for transposition of the urethra to the perineum (Figure 14-23, *D*).
6. The surgeon grasps the urethra with forceps and transfers it to the perineum. The urethra is spatulated, and a skin-to-urethra anastomosis is performed through a buttonhole incision in the perineum (Figure 14-23, *E*).
7. The primary incision is closed horizontally, elevating the scrotum away from the urethral opening (Figure 14-23, *F*).
8. An indwelling urinary catheter is inserted, and the wound is covered with a nonadherent dressing.

Penile Implant

A penile prosthesis is implanted for treatment of organic sexual impotence. Sexual impotence may be caused by (1) diabetes mellitus, (2) priapism, (3) Peyronie's disease, (4) penile trauma, (5) pelvic surgery, (6) neurologic disease (in selected cases), (7) vascular disease, (8) hypertension, and (9) idiopathic impotence. The penile implant serves as a stent to enable vaginal penetration for sexual intercourse. Penile implants are available as malleable one-piece devices, self-contained inflatable devices, and two- and three-piece devices. The procedure described for the inflatable penile implant is for the three-piece device.

Procedural Considerations. The anesthesia provider administers either a spinal or a general anesthetic. The perioperative nurse assists with positioning the patient in either the supine or the lithotomy position, as directed by the surgeon. A 5- to 10-minute skin prep is usually performed before draping is carried out. To prevent urethral injury and potential urinary retention, the surgeon may insert a 14F or 16F Foley catheter to identify the urethra intraoperatively. The ESU may be required. The surgeon may inject a local anesthetic of 0.5% plain bupivacaine (Marcaine) or 1% etidocaine (Duranest) at the beginning of the procedure into the incisional sites. Often, a penile block, composed of 0.9% saline (150 ml), 1% plain lidocaine (50 ml), and 30 mg/ml papaverine (2 ml), is instilled intraoperatively before the incision into the corpus cavernosum. This enables the surgeon to evaluate erectile size and provides some postoperative pain management.

The surgical technologist sets up a separate sterile Mayo stand or small table covered with a plastic drape for the implants. It is recommended that the implants not be in contact with paper or cloth that may shed fiber particles.

The instrument setup includes a minor set with fine instruments, plus Hegar dilators, the penile prosthesis of choice (Figure 14-24), the Furlow inserter, the closing tool, the assembly tool for clamping connectors (Figure 14-25, *A*), and the connectors of choice (Figure 14-25, *B*). Medications needed in the operative field include 50 ml of 1% lidocaine, 150 ml of injectable 0.9% normal saline, 1 ml of methylene blue (optional by surgeon preference), 2 ml of papaverine, 50 ml of 0.5% bupivacaine (Marcaine) or 1% etidocaine (Duranest), 50,000 units of bacitracin, and 80 mg of kanamycin. Medication safety practices must be implemented for all medications on the sterile field.

A serious risk with a penile implant is infection. Infection rates for first-time implantation are low at 1%, but the rate can rise to as high as 18% with reimplantation procedures. Because of the high risk of infection, models that have been irradiated and embedded with minocycline hydrochloride and rifampin (Inhibizone) are now available (American Medical Systems [AMS], 2009). The sterile team should be double-gloved

throughout the procedure. A 5-minute antimicrobial prep of the operative area is critical in reducing skin flora. The anus should be isolated in the perineal approach. Intraoperatively and before insertion of the implant components, a prophylactic antibiotic irrigant of bacitracin and kanamycin in normal saline is used on the implants without Inhibizone and in the insertion sites. Systemic antibiotics may also be required. As with any implant procedure, it is vital to maintain an environment conducive to infection prevention. The perioperative nurse ensures that traffic in and out of the OR is minimized.

It is recommended that the implants with Inhibizone not be soaked in any solution before implantation because this may

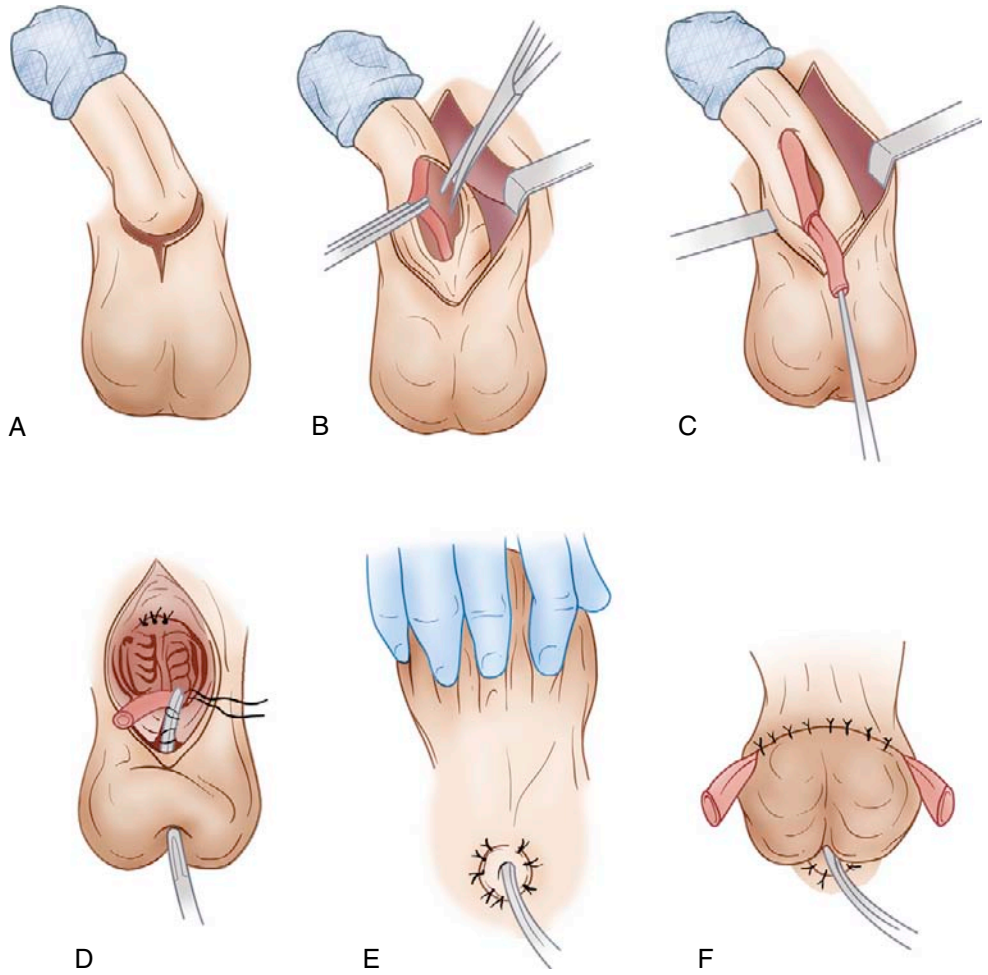

FIGURE 14-23 Total penectomy.

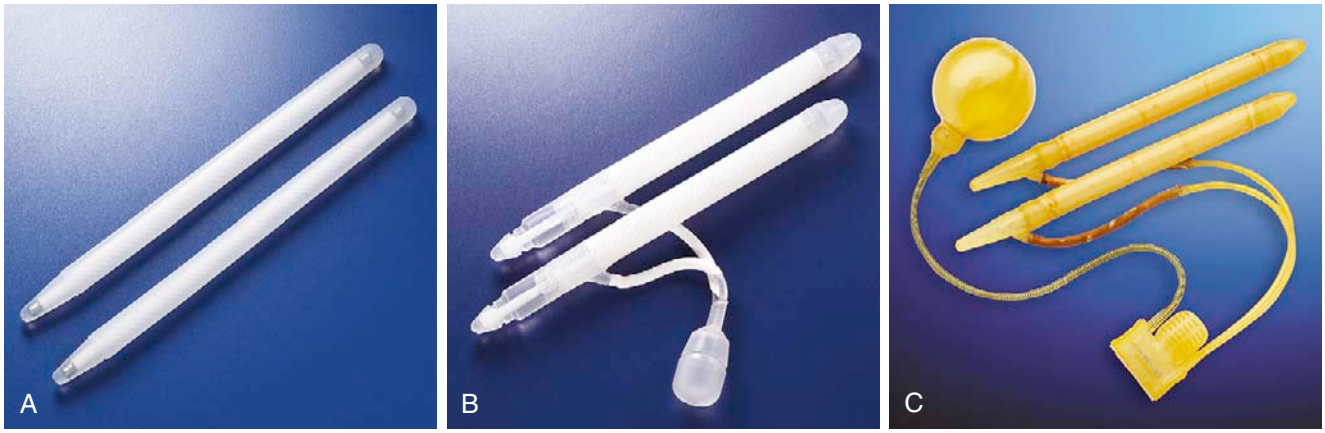

FIGURE 14-24 **A**, AMS malleable 650 penile prosthesis. **B**, AMS Ambicor inflatable two-piece penile prosthesis. **C**, AMS tactile inflatable penile prosthesis, three-piece with rifampin (Inhibizone).

cause the antibiotic component to disintegrate. The area to be implanted may be irrigated with antibiotic solution, and the implant itself may be dipped in a sterile solution of 0.9% normal saline to assist with insertion if desired. Prophylactic antibiotic protocols remain the same.

Operative Procedure

IMPLANTATION OF NONINFLATABLE (SEMIRIGID) PROSTHESIS

1. The surgeon inserts a 14F or 16F Foley catheter and attaches it to a drainage collection device to be maintained within the sterile field. The amount and color of urine are noted. The catheter is left in place intraoperatively to assist in identifying the urethra.
2. A midline incision is made from the base of the penis into the scrotum for approximately 3 cm. Some surgeons may choose a suprapubic or dorsal penile approach.

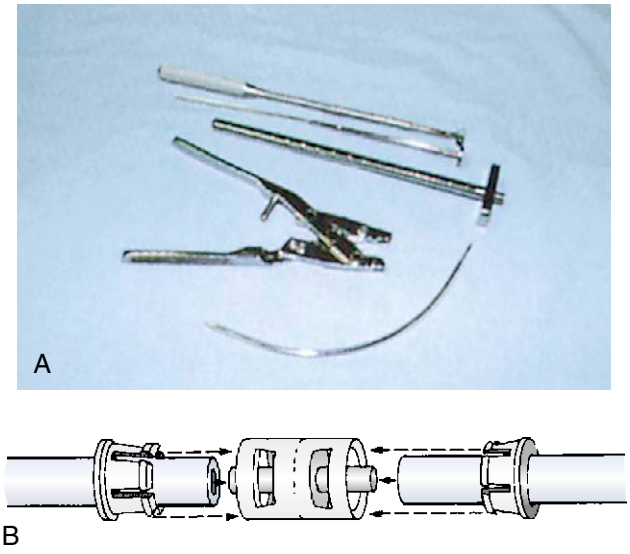

FIGURE 14-25 **A**, *Top to bottom,* Closing tool, Furlow inserter, assembly tool, tubing passer. **B**, Quik-connectors.

3. The surgeon incises the tunica albuginea over the most proximal portion of the corpora in a longitudinal manner, and places stay sutures.
4. The corpora are dilated proximally and distally with 7-mm to 14-mm Hegar dilators, depending on the diameter of the implant chosen. The corpora are dilated to 1 mm more than the implant size. Care is taken to not perforate the urethra.
5. The surgeon measures the corporal length with a Furlow inserter or sizing instrument.
6. After placement of the closure sutures, the surgeon inserts the prostheses into the corpora. Proper placement is evident immediately by a change in the configuration of the penis with no buckling of the glans.
7. The surgeon closes the tunica albuginea using the previously placed 2-0 absorbable continuous suture; 3-0 or 4-0 absorbable interrupted sutures are used for skin closure.
8. Petrolatum gauze or 2-inch Kling tube gauze may be used for the dressing.

IMPLANTATION OF INFLATABLE PROSTHESIS

1. The surgeon inserts a 14F or 16F Foley catheter and attaches it to a drainage collection device to be maintained within the sterile field. The amount and color of urine are noted. The catheter is left in place intraoperatively to assist in identifying the urethra.
2. A midline incision is made from the base of the penis into the scrotum for approximately 3 cm (Figure 14-26, *A*).
3. The surgeon incises the tunica albuginea of each corpus in the most proximal portion, and places stay sutures.
4. The corpora are dilated distally and proximally with 7-mm to 14-mm Hegar dilators. Dilation should be 1 mm more than the diameter of the chosen implant. The 700CX implant is 12 mm at its widest point. When this is used the dilation at the distal end should be 13 mm. The proximal end, however, should be 14 mm to accommodate the input tubing.
5. The surgeon measures the corporal length with the Furlow inserter.
6. Corporal sutures of 2-0 absorbable material are placed along the tunica incision and tagged. Some surgeons prefer to place these sutures last and employ the closing tool to prevent puncture of the cylinders.

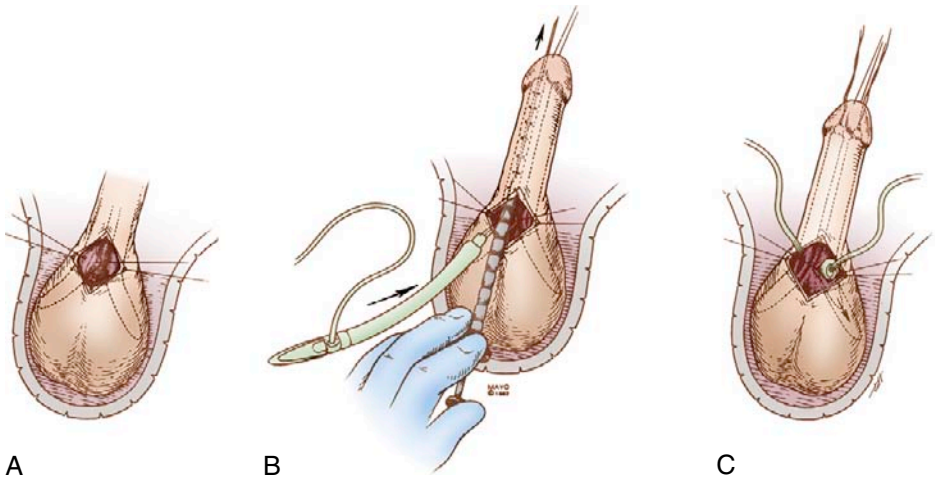

FIGURE 14-26 Penoscrotal approach for inflatable penile implant.

7. The cylinders are packaged with attached traction sutures of 4-0 braided polyester at the distal end. The surgeon places the suture through the eye of a 2½-inch Keith needle, and slides the needle into the groove of the Furlow inserter.
8. The surgeon guides the Furlow inserter along the corporal tunnel, and pushes the plunger to release the Keith needle, which punctures the glans (Figure 14-26, *B*).
9. The Keith needle is grasped with a heavy hemostat and pulled through the glans, allowing the cylinders to slide to the channel opening. The surgeon removes the Furlow inserter, inserts the cylinder, and guides it to its proper position beneath the glans penis (Figure 14-26, *C*).
10. If necessary, rear tip extenders are added to the proximal end of the cylinder. The proximal end is positioned in the crus.
11. The procedure is repeated on the other side.
12. The surgeon palpates the external inguinal ring and uses blunt dissection to create a path. Dissecting scissors are used to separate the transversalis fascia on the inguinal floor. If the Ambicor implant with self-contained reservoir is being placed, steps 12 through 14 are eliminated.
13. The perivesical space is enlarged to allow palpation of the Cooper ligament. The reservoir is then positioned into the perivesical space.
14. The surgeon fills the reservoir with 65 or 100 ml of saline solution (dependent on the reservoir size selected) and pulls it against the floor of Hesselbach's triangle.
15. The pump is then placed into the most dependent portion of the scrotum. It is generally positioned on the patient's dominant side. The space is created by blunt dissection lateral to the testicle.
16. The rods and reservoir tubings are connected to the pump with the connectors of choice, using the assembly tool to clamp them in place, and tested for inflation and deflation.
17. The surgeon closes the tunica of the scrotum over the pump with a running stitch of 3-0 absorbable suture.
18. The prosthetic device is left in a partially inflated position to reduce bleeding and promote healing for 24 hours postoperatively (Figures 14-27 and 14-28). (Following this period the implants are deflated for the remainder of the "healing phase" so the reservoir pocket heals with the reservoir in "full position" to prevent autoinflation.)
19. The surgeon closes the incision with 4-0 absorbable suture in a running subcuticular stitch, and a dressing is applied.
20. The penis is positioned flush with the lower abdomen for patient comfort. Mesh pants are useful as a nonadherent support dressing. An ice pack may be applied to reduce swelling.
21. The Foley catheter is left in place during the immediate 24-hour postoperative period and then usually removed.

Deep Dorsal and Emissary Vein Ligation

Undertaken for vascular compromise–related impotence, this procedure entails the ligation or elimination of the penile deep dorsal vein and its tributaries. Care is taken to avoid damage to the arteries and nerves lying alongside the deep dorsal vein. A common cause of erectile dysfunction in patients with organic impotence is vascular compromise. Before surgical intervention is undertaken, a definitive diagnosis of a corporal leak is made through dynamic infusion cavernosometry and cavernosography. Diagnostic results may indicate failure-to-store or failure-to-fill impotence. Patients with vascular compromise in a given anatomic region tend to be compromised elsewhere as well. Many have diabetes or hypertension. Because of this, the perioperative nurse must exercise great care in positioning the patient to prevent further damage to the patient's altered tissue perfusion. The cavernous and crural veins are suture-ligated. All circumflex and emissary branches are ligated or coagulated. The suspensory ligament is detached, and the entire deep and accessory dorsal vein is removed.

Revascularization of the Penile Arteries

The relationship of focal arterial occlusive disease to sexual dysfunction has prompted efforts to rectify the resulting impotence. Reconstructive surgery has been attempted in patients who demonstrate correctable vascular disease in the large arteries. The most widely attempted repairs are end-to-end and end-to-side microscopic anastomoses of the distal inferior epigastric artery to the proximal deep dorsal artery near the pubic level, below the rectus muscle and Buck's fascia. Paramedian and infrapubic incisions are made, and the arteries are freed and tunneled. This procedure requires both urologic and vascular surgeons.

SURGERY OF THE SCROTUM AND TESTICLES

Hydrocelectomy

A hydrocele is an abnormal accumulation of fluid within the scrotum. The fluid is contained within the tunica vaginalis. Excessive secretion or accumulation of hydrocele fluid may be the result of infection or trauma. A hydrocelectomy is the excision of the tunica vaginalis of the testis to remove the enlarged, fluid-filled sac.

Procedural Considerations. The patient is placed in the supine position. Prepping and draping of the patient include routine cleansing of the external genitalia and draping with a fenestrated sheet. A minor instrument set is required, plus a small drain, a 30-ml syringe with a 20-gauge, 2-inch aspirating needle, and a suspensory dressing.

Operative Procedure

1. The surgeon administers a local anesthetic into the cord at the base of the scrotum with 10 to 15 ml of plain lidocaine 1%.
2. An anterolateral incision is made in the stretched skin of the scrotum over the hydrocele mass with a #10 or #15 blade.
3. Bleeding is controlled with Crile hemostats, electrocoagulation, or vessel ligation with 3-0 absorbable ligatures. Stretching the skin of the scrotum compresses the scrotal vessels.
4. An incision is then made between the blood vessels. The fascial layers are incised to expose the tunica vaginalis.
5. The surgeon uses sharp and blunt dissection to free the hydrocele.
6. The sac is opened, and clamps are placed on each side incorporating the tissue adjacent to the tunica vaginalis and the skin.
7. Using Martius clamps, the surgeon everts the incised edges. The tension placed by the Martius clamp compresses the

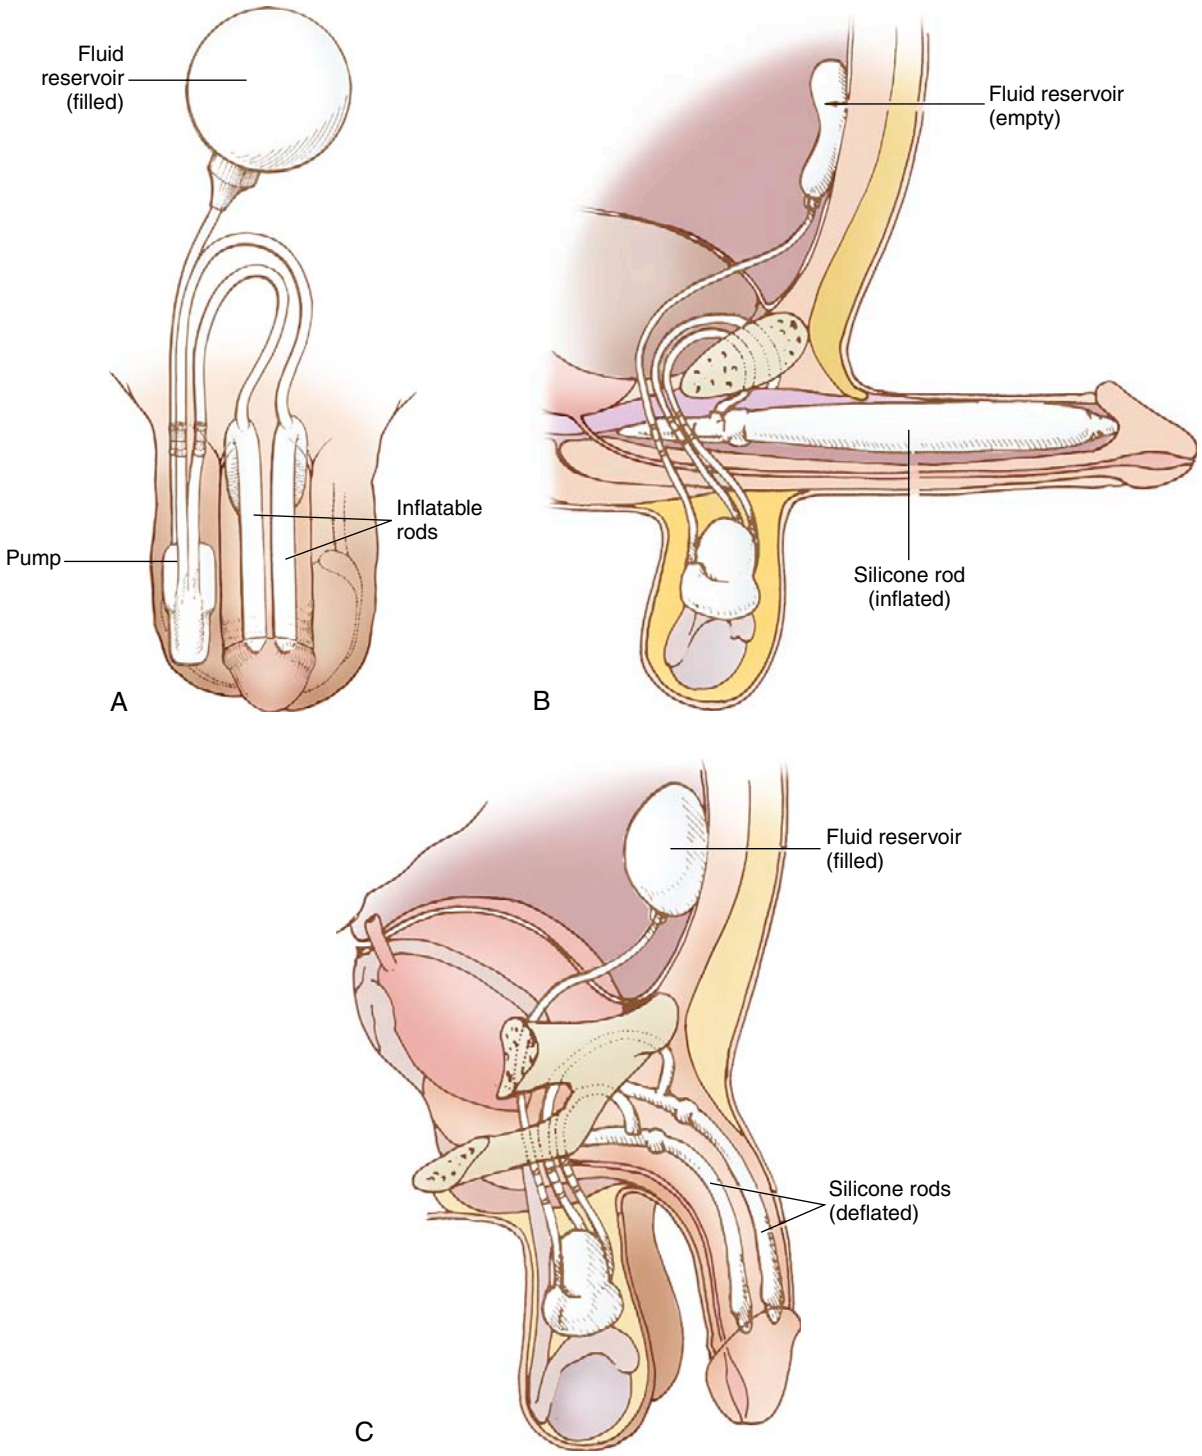

FIGURE 14-27 AMS inflatable 700CX penile prosthesis. **A**, Frontal view. **B**, Sagittal view—penis in erect position. **C**, Sagittal view—penis in flaccid position.

incised edge, controls bleeding, and prevents dissection between the tissue layers.

8. A pouch is created by dissecting between the tunica vaginalis and the dartos layer. Scrotal pressure is released. This pouch will hold the testis after the repair.
9. The surgeon opens the tunica vaginalis and evacuates the fluid contents.
10. The testis is lifted, and the sac is inverted so that it surrounds the testicular attachments and epididymis.
11. Excess tunica vaginalis may be excised. The surgeon sutures the tunica edges along the peritoneal surface with 3-0 absorbable suture in an interrupted fashion to the juncture of the testis. Six to eight sutures are placed around the circumference of the testis (Figure 14-29). Some surgeons

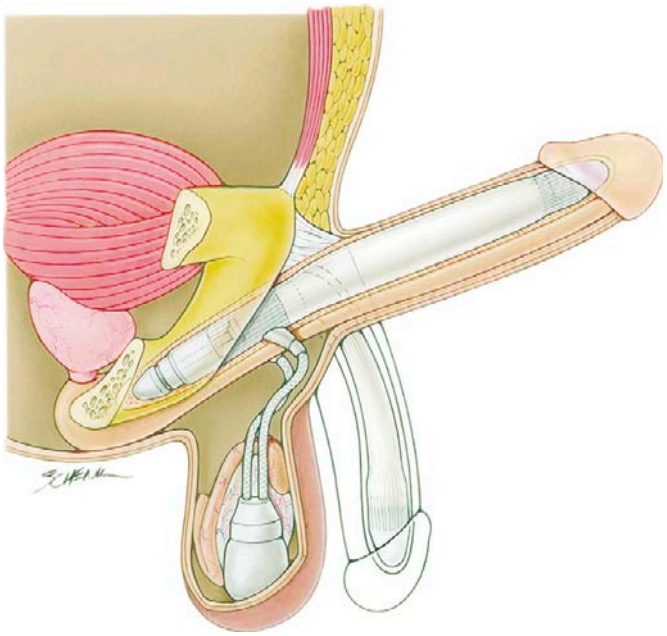

FIGURE 14-28 AMS Ambicor inflatable two-piece implant, sagittal view.

elect to sew the sac behind the spermatic cord in an interrupted fashion, and others may choose a continuous radial stitch around the posterior testis and epididymis.

12. The testis is replaced into the scrotum.
13. A drain may be placed into the scrotum and exteriorized through a stab wound in its most dependent portion. The drain is loosely sutured to the external scrotal wall to prevent migration.
14. The surgeon closes the scrotal incision with 3-0 absorbable sutures in a full-thickness continuous manner or in layers with 3-0 and 4-0 continuous absorbable sutures.
15. A fluff compression dressing contained in a scrotal support or mesh underwear aids in reducing postoperative scrotal edema.

Vasectomy

A vasectomy is the excision of a section of the vas deferens. The operation is usually performed selectively as a permanent method of sterilization. Because of the serious implications of permanent sterilization, particular attention must be paid to acquiring informed consent. Although studies have raised the question of a correlation between prostate cancer and vasectomy, a definitive causal relationship has not been established.

The patient having elective sterilization for birth control is encouraged to return to the office setting for sperm-count analysis. Generally, two successive negative counts are sufficient to indicate that sterility has been achieved. Elective vasectomies are frequently performed in the office setting.

Procedural Considerations. The patient usually lies in the supine position. A local anesthetic is used. A minor instrument set and scrotal support are needed.

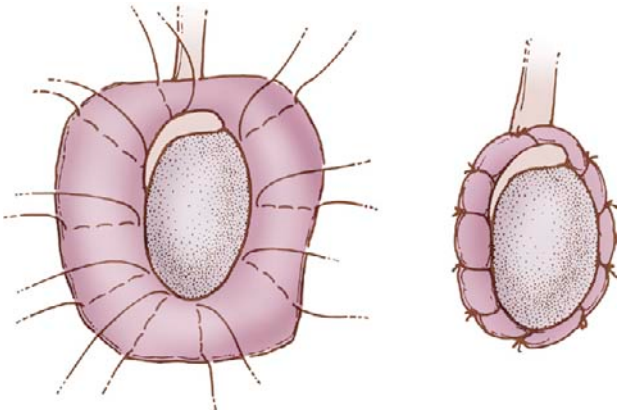

FIGURE 14-29 Hydrocelectomy.

Operative Procedure

NO-SCALPEL APPROACH

The no-scalpel technique was devised in China and has five fundamental principles:

1. Fixation of the vas deferens without entering the scrotal skin
2. Performance under direct vision to prevent damage from blind sharp scrotal penetration
3. Simplified instrumentation
4. Decreased operative time by simplification of the procedure
5. Elimination of an incision or use of a scalpel

The procedure is as follows:

1. The right vas deferens is fixed under the scrotal skin with three fingers.
2. Using a syringe with 1% or 2% plain lidocaine and a small needle, the surgeon raises a small wheal in the median raphe of the scrotum. The needle is advanced along the vas toward the external inguinal ring. Additional lidocaine is injected into the perivasal region.
3. The procedure is repeated on the left side. Pressure is applied to the wheal site to minimize edema.
4. Once adequate anesthesia is accomplished, the right vas is again fixed with three fingers.
5. The surgeon applies a vas ring clamp over the scrotal skin, encircling the vas. Lifting the clamp upward, the skin over the vas is stretched as thin as possible, leaving minimal tissue between the vas and the clamp.
6. The ring clamp is locked in place, and the scrotal skin cephalad to the clamp is stretched with an index finger.
7. The surgeon punctures the skin directly into the vas deferens with the inner prong of the pointed dissecting hemostat. Both prongs of the dissecting hemostat are placed into the puncture site and spread directly on top of the vas.
8. When the surface of the vas is visualized, one prong is used to penetrate the vas itself. The vas is brought out of the wound by twisting the hemostat 180 degrees.
9. The ring clamp is moved to directly encircle the vasal tissue. The vas may then be divided and occluded by intraluminal electrocoagulation, clips, or suture ligation. Fascia should be placed between the severed ends of the vas.

10. The surgeon repeats the procedure on the left side. It is usually possible to place the ring clamp around the left vas through the initial entry site. Sutures are not necessary.
11. After ensuring that there is no bleeding, antibiotic ointment, pressure dressings, and a scrotal support are applied.

Vasovasostomy

Vasovasostomy is the surgical reanastomosis of the vas deferens, using the operative microscope. The number of vasal reanastomosis procedures has increased dramatically. Reanastomosis may often alleviate chronic testicular pain, a not infrequent complication after vasectomy. In addition, a significant number of men who underwent a vasectomy want to regain their fertility. A precise reconnection can be performed with the use of a microscope and a modified two-layer anastomosis. Success rates vary, but in general, patency can be demonstrated by the presence of sperm in the semen within 4 weeks after vasovasostomy (Lipshultz et al, 2007). When there are no longer two viable segments of vas deferens, a similar procedure, the epididymovasostomy, may be performed. This involves anastomosis of a vas deferens to a segment of the epididymis. Postoperative precautions include no lifting or ejaculation for a minimum of 2 weeks. The sperm count and viability of sperm are rechecked at 3- and 6-month intervals. If sperm are not present by 6 months, the operation is considered a failure (Lipshultz et al, 2007).

Procedural Considerations. A minor instrument set is required, with the addition of selected microsurgical instruments and sutures. The procedure is frequently done under monitored anesthesia care with local injection of 0.5% plain bupivacaine (Marcaine) and 1% lidocaine (Xylocaine) in a 50:50 ratio.

Operative Procedure

1. After the vas deferens has been located by external manipulation, the surgeon makes a vertical scrotal incision.
2. The testicle, epididymis, and vas are displaced from the scrotum. The vasectomy site is identified, and the scarred area is excised.
3. The surgeon trims the proximal end of the vas deferens until fluid is expressed. Fluid is collected on a glass slide and examined for the presence of live sperm. Surgery continues even if results for sperm are negative unless an epididymal obstruction exists.
4. The distal end of the vas is resected until a normal lumen is visible.
5. The distal and proximal lumens are then dilated.
6. The surgeon places the two portions of the vas in an approximator clip and inserts a piece of background material underneath to provide contrast and improve visibility. Six stitches of 10-0 nonabsorbable microsuture are placed in the inner layer. The proximal end is sutured through the serosa to the mucosa, and the distal end is sutured through the mucosa to the serosa (Figure 14-30).
7. A second layer of 8 to 10 stitches of 9-0 nonabsorbable suture is placed without penetrating the lumen of the vas.
8. The surgeon closes the incision in two layers with interrupted 3-0 and 4-0 absorbable sutures.
9. Gauze sponges and a scrotal support are placed on the patient to provide a pressure dressing.

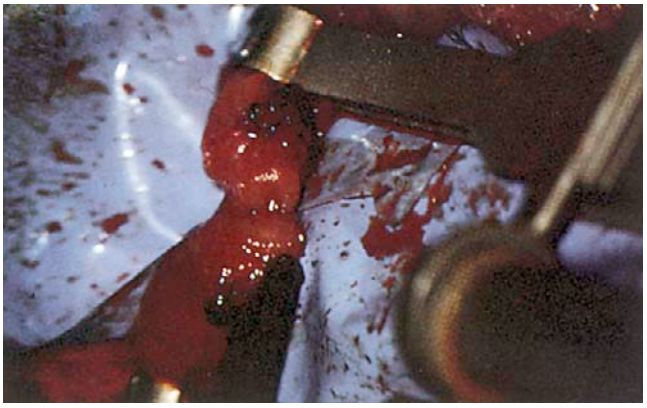

FIGURE 14-30 The two portions of the vas in approximator clip with background material as the proximal end is sutured through the serosa to the mucosa with 10-0 nylon.

Microscopic Epididymal Sperm Aspiration

Microscopic epididymal sperm aspiration (MESA) requires the availability of an in vitro fertilization team so that the aspirated sperm may be immediately processed and used for the selected in vitro technique or frozen for later use. The procedure must be timed according to the partner's cycle of ovulation. Ova are aspirated as an office procedure just before MESA is performed.

MESA should be done using the micropipette technique. The surgeon inserts the tip of a 250- to 350-micrometer (μm) pipette into an epididymal tubule to retrieve sperm cells without contamination by red blood cells. After aspiration, the fluid is given to the in vitro fertilization team to process the sperm cells. Processing involves washing debris from the cells, retrieving the most active cells from the sample, and removing any red blood cells, if possible. This is critical because red blood cells significantly interfere with sperm cell function.

After the sperm cells are aspirated, the surgeon closes the epididymal tubule using microscopic technique. If adequate numbers of sperm cells can be obtained from one testis, the other side may be aspirated to add to the sperm bank if this is desirable. It may be necessary to aspirate sperm cells from the rete testis (tubules between the testicles and the epididymal head that carry cells to the head of the epididymis) if sperm cells are not found in tubules closer to the vas deferens.

The sperm cells retrieved may be used for intracytoplasmic injection into the partner's egg (ICSI), the most successful of the in vitro techniques available. This technique is not as dependent on the quality of the sperm as earlier techniques of in vitro fertilization.

Epididymectomy

An epididymectomy is the excision of the epididymis from the testis. Epididymectomy is rarely performed, usually only as a last-choice treatment for degenerative cystic disease, chronic infection, and intractable pain of the epididymis.

Procedural Considerations. The perioperative nurse assists with positioning the patient in the supine position with his legs slightly abducted. The anesthesia provider administers

a general, spinal, or regional anesthetic. Setup is as described for hydrocelectomy, plus an ESU, if desired.

Operative Procedure

1. The surgeon makes an anterolateral incision over the testis in the scrotum to expose the tunica vaginalis. The tunica is incised to expose the testis and overlying epididymis.
2. An incision is made along the superior head of the epididymis, which is then sharply dissected from the testis. A portion of the vas deferens may also be excised.
3. Bleeding is controlled by electrocoagulation and absorbable ties.
4. The skin wound is closed with 4-0 absorbable sutures.
5. A small drain may be left intrascrotally for 24 to 48 hours.

Spermatocelectomy

Spermatocelectomy is removal of a spermatocele—a lobulated intrascrotal cystic mass attached to the superior head of the epididymis. Spermatocele is usually caused by an obstruction of the tubular system that conveys the sperm and may be a late complication after vasectomy.

Procedural Considerations. The setup for a spermatocelectomy is as described for a hydrocelectomy, plus a microscope and slides, if desired.

Operative Procedure

1. The mass is approached through a scrotal incision as described for hydrocelectomy.
2. The surgeon identifies the structures of the testis and spermatic cord and dissects the cystic structure free.
3. Bleeding is controlled with electrocoagulation.
4. The wound is closed and dressed as described for hydrocelectomy.

Varicocelectomy

A varicocelectomy is the high ligation of the gonadal veins of the testes. Varicocelectomy is done to reduce venous backflow of blood into the venous plexus around the testes and to improve spermatogenesis.

Varicoceles occur more frequently on the left side because the gonadal vein of the left testis unites retroperitoneally with the renal vein at a 90-degree angle and is consequently under greater backpressure. As a result of this unusual backpressure, the pampiniform plexus of the spermatic cord becomes tortuous and engorged, resembling a bag of worms.

Procedural Considerations. The setup for inguinal varicocelectomy is as described for an inguinal hernia repair (see Chapter 12). A microscope may be employed to better visualize the vessels involved.

Operative Procedure

The incision may be through a suprainguinal approach or an oblique inguinal approach over the external inguinal ring.

1. The surgeon identifies the structures of the spermatic cord and dissects the vessels free from the vas deferens.
2. The abnormal dilated veins in the inguinal canal are clamped and ligated. The redundant portions are excised. A drain may be placed.
3. The incision is closed in layers.

Testicular Biopsy

A biopsy of the testicle involves a wedge excision of suspicious tissue for diagnostic confirmation. Men experiencing infertility who are azoospermatic or oligospermatic with a normal or minimally elevated level of follicle-stimulating hormone may be evaluated through this means. Biopsy may also be performed to obtain sperm cells for in vitro fertilization techniques.

Procedural Considerations. The perioperative nurse assists with positioning the patient in the supine position and the anesthesia provider administers a general, regional, or spinal anesthetic. A minor instrument set is used. Special fixatives, such as Bouin's or Zenker's solution, must be available when pathologic confirmation is required. If retrieval of sperm cells is planned the perioperative nurse ensures the biopsy specimen is placed in a small amount of saline, kept warm, and taken immediately to the fertility laboratory for aspiration of cells. Formalin destroys the germinal epithelium and should not be used.

Operative Procedure

1. The scrotum is held firmly on its posterior aspect. This causes the skin on the anterior aspect to stretch tightly over the incisional site, forcing the epididymis to remain posterior and allowing the scrotal skin to part without retraction.
2. The surgeon makes a 1-cm to 2-cm vertical incision taking care to avoid injury to the epididymis.
3. The incision is continued to the tunica vaginalis. As the tunica is incised, there should be a normal efflux of clear fluid.
4. Absorbable 4-0 stay sutures are placed in the tunica vaginalis. Two more are placed in the tunica albuginea.
5. Using the scalpel in a shaving action, no-touch technique, the surgeon resects a small ellipse of tunica with its tubules. The tissue is placed in the fixative or sent to the histology department as a fresh specimen.
6. The wound is closed in three layers with 3-0 and 4-0 absorbable suture.
7. Gauze sponges and fluffed dressings are placed over and around the scrotum. A scrotal support is applied to provide pressure and support.

Orchiectomy

An orchiectomy is the removal of the testis or testes. Removal of both testes is castration and renders the patient sterile and deficient in the hormone *testosterone,* which is responsible for development of secondary sexual characteristics and potency. This operation, like vasectomy, has legal implications that require attention to acquiring informed consent for surgery. Bilateral orchiectomy is usually performed to control symptomatic metastatic carcinoma of the prostate gland. A unilateral orchiectomy is indicated because of testicular cancer, trauma, or infection. Testicular implants are available for cosmetic purposes. These must be ordered preoperatively based on preoperative measurements for size. This procedure has recently been approached through endoscopic techniques, usually in conjunction with laparoscopic herniorrhaphy.

Procedural Considerations. The perioperative nurse assists with positioning the patient supine and the anesthesia provider

administers a general, spinal, or regional anesthetic. A minor instrument setup is required.

Operative Procedure

SCROTAL APPROACH

1. For benign conditions the incision is made over the anterolateral surface of the midportion of the scrotum.
2. The surgeon carries the skin incision through the subcutaneous and fascial layers through the tunica vaginalis, exposing the testicle.
3. Retractors are placed, and bleeding vessels are clamped and ligated.
4. The spermatic cord is divided into two or three vascular bundles. Each vascular bundle is doubly clamped, cut, and ligated, first with 0 absorbable suture ligature and then with a proximal free 0 absorbable tie.
5. The vas is separately ligated with a 0 absorbable tie. The testis is removed.
6. The procedure is repeated on the opposite side if bilateral excision is planned.

INGUINAL APPROACH

1. For malignant conditions the incision is begun just above the internal ring, extending downward and inward over the inguinal canal to the external inguinal ring.
2. The surgeon exposes the inguinal canal and dissects the spermatic cord free, cross-clamps it, and divides it into vascular bundles at the internal ring.
3. Gentle forward traction is applied to the cord, which is dissected from its bed.
4. The testis is everted into the wound from the scrotum and excised.
5. The procedure is repeated on the opposite side if bilateral excision is planned.
6. Bleeding is controlled with electrocoagulation. A small drain may be placed in the empty hemiscrotum if desired.
7. The surgeon reapproximates the external oblique fascia with 2-0 absorbable interrupted sutures.
8. Subcutaneous tissue, including Scarpa's fascia, is closed with 4-0 absorbable sutures.
9. The skin is reapproximated with surgical staples or 4-0 subcuticular sutures.

Radical Lymphadenectomy (Retroperitoneal Lymph Node Dissection)

Radical lymphadenectomy is a bilateral resection of retroperitoneal lymph nodes. Dissection usually includes lymph nodes, channels, and fat around both renal pedicles; the vena cava; and the aorta, including the bifurcation of the aorta. Lymph node dissection is performed for treatment of nonseminomatous testicular tumors or in conjunction with an open prostatectomy for prostate cancer.

Procedural Considerations. The perioperative nurse assists with placing the patient in the supine position. The anesthesia provider administers a general anesthetic. If the dissection is unilateral, the patient is supine with the operative side tilted upward. Long, fine dissection instruments along with basic laparotomy instruments are required.

Although this procedure may be performed laparoscopically, this approach has not yet become the standard of practice because of its technical difficulty.

Operative Procedure

1. The surgeon makes a midline abdominal incision from the xiphoid process to the symphysis pubis.
2. The abdominal contents are explored to determine the degree of gross nodal involvement. The colon is either packed within the abdominal cavity or mobilized and kept moist outside the abdomen.
3. The surgeon opens the posterior peritoneum between the aorta and the vena cava.
4. Using blunt and sharp dissection, the surgeon removes the lymphatic structures and fat en bloc from around both renal pedicles, the vena cava, and the aorta from above the renal hilum to beyond the bifurcation of the iliac vessels on the side of the original testicular neoplasm.
5. The spermatic vessels of the affected side are removed down to and including the stump of the previous orchiectomy.
6. The inferior mesenteric artery may be sacrificed if technically necessary, but the superior mesenteric artery is not disturbed.
7. The ureter on the affected side is skeletonized to remove any perilymphatic tissue.
8. If reperitonealization is desired, the posterior peritoneum is closed with a 2-0 absorbable continuous suture.
9. The surgeon repositions the viscera into the abdominal cavity, and closes the wound in layers, usually without placement of a drain.

SURGERY OF THE PROSTATE GLAND

Glandular hyperplasia of the prostatic urethra usually manifests itself after 50 years of age. Prostatic enlargement may be benign or malignant and may occur in one or more lobes of the prostate but most frequently occurs in the lateral or median lobes. Progressive growth of the hyperplastic gland compresses the remaining normal prostatic tissue, forming what is called a *surgical capsule*. The growth of adenomatous tissue slowly encroaches on the prostatic urethral lumen, causing obstruction of urinary outflow. The surgeon must consider several factors when determining the best route for removal of the prostatic obstruction: the age and medical condition of the patient, the size of the gland and location of the pathologic condition, and the presence of associated medical disease.

Prostate cancer is the most frequently diagnosed cancer in men and is the leading cause of cancer death in men (American Cancer Society, 2008). Because of the prevalence of prostate cancer and the similarity of symptoms to benign prostatic hyperplasia (BPH), the American Urological Association (AUA) recommends that starting at age 40 the prostate-specific antigen (PSA) test and digital rectal examination (DRE) be offered to men at average risk (Evidence for Practice).

A blood sample is drawn to determine the PSA level, followed by a DRE. The blood is often drawn first, since manipulation of the gland has been known to alter the efficacy of the PSA test. The PSA test is considered a valuable tool for early detection of carcinoma of the prostate, but if used alone, it will miss 20% to 30% of all prostate cancers. If the test value is elevated, the patient is at risk for carcinoma of the prostate; a PSA value above 10 ng/ml is highly suggestive of prostatic carcinoma. Clinical evaluation and an elevated PSA usually indicate the need for a transrectal ultrasound needle biopsy to confirm the diagnosis. When the results of the biopsy are positive for

EVIDENCE FOR PRACTICE

Diagnosing and Managing Prostate Cancer

Early detection is important in the diagnosis and management of prostate cancer. Information relating to a patient's profile in initiating the algorithm (see below) includes the following:

RISK FACTORS

1. Age: After 50 years old, the risk increases rapidly; about 64% of all prostate cancer cases are diagnosed in men ages 65 and older. Although the lifetime risk for prostate cancer is 3%, prostate cancer is the most common noncutaneous cancer in men in the United States, and the second leading cause of male cancer mortality.
2. Race: African-American men and Jamaican men of African descent have the highest prostate cancer incidence rates in the world.
3. Diet: High dietary fat is associated with a greater risk for developing cancer.
4. Family history: Risk is increased for men who have first-degree relatives with prostate cancer.

CANDIDATES FOR EARLY DETECTION

1. Men 40 years old or older with a life expectancy of 10 years or longer.

DIAGNOSTIC MEASURES USED IN COMBINATION FOR EARLY DETECTION

1. DRE
2. Serum PSA
3. Biopsy if indicated (three of four men undergoing biopsy will not have cancer)

SCREENING FOR PROSTATE CANCER: CLINICAL SUMMARY OF U.S. PREVENTIVE SERVICES TASK FORCE RECOMMENDATION

Population	Men Younger than Age 75 Years	Men Age 75 Years or Older
Recommendation	**No recommendation Grade: I (Insufficient Evidence)**	**Do not screen Grade: D**
Risk assessment	Prostate cancer is more common in older men, African Americans, and men with a family history of prostate cancer. The same uncertainties about the effects of screening that apply to other men also apply to these higher-risk men.	
Screening tests	The prostate-specific antigen (PSA) test is more sensitive than the digital rectal examination (DRE). The conventional PSA test cut-point of 4.0 g/L misses some early cancer. However, lowering the cut-point would increase the rate of false-positive results. Variations of PSA screening have not yet been demonstrated to improve health outcomes.	
Screening intervals	If PSA screening reduces mortality, screening every 4 years may be as beneficial as annual screening.	
Interventions	Management strategies for localized prostate cancer include watchful waiting, active surveillance, surgery, and radiation therapy. There is no consensus regarding optimal treatment.	
Balance of harms and benefits	• The harms of screening include the discomfort of prostate biopsy and the psychological harm of false-positive test results. • Harms of treatment include erectile dysfunction, urinary incontinence, bowel dysfunction, and death. A proportion of those treated, and possibly harmed, would never have developed cancer symptoms during their lifetime.	
	For men younger than age 75 years, evidence is inadequate to determine whether screening improves health outcomes. Therefore, the balance of harms and benefits cannot be determined.	For men age 75 years or older and for those whose life expectancy is 10 years or fewer, the incremental benefit from treatment of prostate cancer detected by screening is small to none. Therefore, harms outweigh benefits.
Suggestions for practice	Clinicians should discuss the potential benefits and known harms of PSA screening with their patients younger than age 75 years. Men in this age group should be informed of the gaps in the evidence, and their personal preferences should guide the decision of whether to order the test.	
Other relevant USPSTF recommendations	A list of USPSTF recommendations on cancer screening can be found at www.preventiveservices.ahrq.gov.	

BPH, Benign prostatic hyperplasia; *DRE,* digital rectal examination; *PSA,* prostate-specific antigen.

Prostatitis, BPH, and prostate cancer can all be associated with elevated serum PSA levels. Other factors that are known to cause elevations in PSA levels include urethral or prostatic trauma, and infection.

Table from Agency for Healthcare Research and Quality: *Screening for Prostate Cancer: Clinical Summary of U.S. Preventive Services Task Force Recommendation,* AHRQ Publication No. 08-05121-EF-3, August 2008, Rockville, MD, available at www.ahrq.gov/clinic/uspstf08/prostate/prostatesum.htm. Accessed March 4, 2010.

malignancy, additional diagnostic studies are indicated including measurement of free and total serum PSA II levels, bone scans, and CT and MRI scans of the pelvis (Ignatavicius, 2010).

The most commonly used system to grade prostate cancer is the Gleason score. To calculate the Gleason score, the pathologist evaluates the prostatic tissue to determine which type of cell is the most common and which type is the second most common and gives each of the two cell types a score from 1 to 5. The two scores are combined to determine the total score. Higher numbers are an indication of more abnormal, aggressive cancer cells. Men with a Gleason score of 2 to 4 are generally cured by surgery; scores from 5 to 6 indicate mildly aggressive cancer cells; a score of 7 indicates the cancer is moderately aggressive. Scores between 8 and 10 indicate highly aggressive tumors and are associated with a poor prognosis after surgery (Epstein, 2007). Additional prostate cancer staging tools are the TNM (tumor, node, metastasis) system and the American Urological Association (AUA) system (Box 14-2).

If the prostate gland is cancerous, a radical retropubic or radical perineal prostatectomy, in conjunction with open or laparoscopic pelvic lymph node dissection, is usually performed. TURP may also be used in men who cannot have a radical prostatectomy, or to relieve symptoms caused by prostate cancer before other treatments begin. Select patients with well-differentiated or moderately differentiated lesions may be candidates for transperineal, ultrasonically guided implantation of radium seeds (brachytherapy) or cryoablation of the prostate (cryotherapy). Newer therapies for prostate cancer are being developed (Research Highlight). Many patients desire to retain sexual function. The surgeon may attempt to save the neurovascular bundles in what is termed a nerve-sparing approach. The site and size of the prostatic lesion, however, often determine if this can be achieved successfully and without undue risk to the patient.

Three open surgical approaches are possible in removing the benign hyperplastic obstructive prostate gland: retropubic prostatectomy, suprapubic prostatectomy, and perineal prostatectomy. Of these, the one most commonly employed is the suprapubic prostatectomy. All open prostatectomies hold the risk for loss of sexual potency.

TURP is the endoscopic (closed) surgical approach that has been traditionally used. Alternative modalities that have shown moderate to good success in the treatment of BPH are photoselective vaporization of the prostate (PVP), interstitial laser coagulation of the prostate (ILC), transurethral incision of the prostate (TUIP), transurethral laser incision of the prostate (TULIP), holmium laser enucleation of the prostate, and holmium laser ablation of the prostate (HoLAP). A visual laser ablation of the prostate (VLAP) was originally performed with the Nd:YAG laser but may now also be accomplished with the holmium laser (Fitzpatrick, 2007). Proper laser protocol must be followed for the type of laser being employed. The standard

RESEARCH HIGHLIGHT

High-Intensity Focused Ultrasound Prostate Cancer Treatment: A Safe Alternative to Surgery or Radiotherapy

High-intensity focused ultrasound (HIFU) is a noninvasive technique used in the treatment of prostate cancer. It is available in North America, but has not yet been approved by the FDA for use in the United States. Researchers in Europe are reporting impressive results with the technique; a multicenter trial studied 402 patients with localized cancer treated with HIFU. Although 28% of the patients required two treatment sessions, 87% of the treated patients had negative biopsy findings on follow-up; a median PSA level of 0.4 ng/ml was achieved at a minimal follow-up appointment of 6 months. These same investigators later reported a 5-year actuarial negative biopsy rate of 90%. Another group of researchers studied the long-term results in patients with low-risk disease (initial PSA level <10 ng/ml, Gleason score ≤6). In this study, 78% of the patients were considered free of disease (stable PSA level according to American Society for Therapeutic Radiology and Oncology criteria) and had negative biopsy results at 5 years. For those with intermediate-risk cancer, the disease-free rate was 53%; for those with high-risk cancer, the disease-free rate was 36%.

HIFU is highly focused into a small area, creating intense heat of 80° to 100° C, which is lethal to prostate cancer tissue. HIFU destroys tissue by heat, rather than by cavitation or mechanical shearing. Since ultrasound is nonionizing, there is no collateral tissue damage.

For the majority of patients, HIFU is indicated as a curative therapy. The best candidates are clinical/pathologic stages T1c to T3. Because of the limited focal length of HIFU, gland volume cannot be 40 ml or larger. If the gland is larger, then downsizing is required with total androgen ablation. Aside from primary therapy, HIFU can be utilized as salvage therapy, primarily after radiation. HIFU can also be repeated without any increase in risk or complications. In addition, HIFU can be used to treat cryosurgical failures. If necessary, radical prostatectomy can be performed after HIFU.

HIFU is performed as an outpatient procedure, usually after induction of anesthesia with an epidural anesthetic. The HIFU unit consists of a control console, a power generator, a cooling system, and a probe that contains a standard imaging and high-intensity treatment ultrasound head. The HIFU probe is placed into the rectum and multiple gland images are taken. The surgeon selects the treatment zones. The procedure usually lasts 2 to 4 hours. The procedure is completed without blood loss or exposure to radiation.

There will be edema secondary to the thermal effects: therefore at the end of the procedure, a urethral Foley catheter is placed into the bladder. This catheter will remain in place for 2 to 4 weeks. There may be some bladder discomfort for several days, but full activities can be resumed the day following surgery. Once the catheter is removed, the urinary stream may take several months to improve, as the urethra needs to heal, and the gland will take up to 3 months to start shrinking. During this time, some prostate tissue may slough and pass in the urine. The rest of the gland forms scar tissue.

Although HIFU is a relatively new procedure for prostate cancer treatment, it represents what may become the next generation of minimally invasive therapy for prostate cancer. The control and precision that HIFU provides truly allows the surgeon to precisely ablate the prostate gland with pinpoint accuracy and thereby preserve the adjacent structures. Furthermore, because HIFU is nonionizing, there is no collateral tissue damage.

BOX 14-2

American Urological Association Prostate Cancer Stages

STAGE A: CLINICALLY UNSUSPECTED DISEASE

A1	Focal carcinoma, well differentiated
A2	Diffuse carcinoma, usually poorly differentiated

STAGE B: TUMOR CONFINED TO PROSTATE GLAND

B1	Small, discrete nodule of one lobe of the gland
B2	Large or multiple nodules or areas of involvement

STAGE C: TUMOR LOCALIZED TO PERIPROSTATIC AREA

C1	Tumor outside prostate capsule, estimated weight ≤70 g, seminal vesicles uninvolved
C2	Tumor outside prostate capsule, estimated weight >70 g, seminal vesicles involved

STAGE D: METASTATIC PROSTATE CANCER

D1	Pelvic lymph node metastases or ureteral obstruction causing hydronephrosis, or both
D2	Bone, soft tissue, organ, or distant lymph node metastases

Modified from Nelson WG et al: Prostate cancer. In Abeloff MD et al, editors: *Abeloff's clinical oncology,* ed 4, Philadelphia, 2008, Churchill Livingstone.

TUIP procedure involves the use of electrosurgery only. Transurethral microwave therapy (TUMT) is another alternative that is performed as an office procedure.

Prostatic Core Needle Biopsy

Needle biopsy of the prostate is indicated for patients in whom prostatic cancer is clinically suspected. It may be accomplished transrectally with a needle designed for this purpose or transperineally.

Procedural Considerations.

Needle biopsy of the prostate has the risk of both intraoperative and postoperative bleeding. A cystoscopic examination may accompany a needle biopsy. Most needle biopsies are performed in the urologist's office or ultrasound department.

The most significant potential complication of a biopsy is systemic infection. This risk can be decreased with antibiotic administration before and after the procedure and bowel cleansing before the examination. The patient is given antibiotic therapy 24 hours before the procedure and is advised to use a sodium phosphate enema 2 to 3 hours before the test is performed. Before the examination, an antiseptic solution mixed with a viscous local anesthetic often is instilled into the rectum and allowed to coat the tissues for 5 to 15 minutes. The surgeon may also inject local anesthetic into the prostate and seminal vesicles transrectally with a 22-gauge, 22-cm injection needle through the needle guide on the transducer.

Operative Procedure

TRANSRECTAL, ULTRASONICALLY GUIDED BIOPSY. Transrectal, ultrasonically guided biopsy is commonly performed in the urologist's office using a high-frequency transrectal ultrasound transducer to assess the prostate gland. The technique allows the urologist to assess the size, volume, and shape of the prostate and the likelihood of the presence of a malignancy. Biopsy specimens of suspicious areas or lesions may be obtained with a needle passed across the rectal wall, with the aid of ultrasound guidance. The needle penetrates the rectal mucosa with a core biopsy system. Color-flow imaging may also be used to help identify areas that are likely invaded with prostatic carcinoma or have acute and chronic inflammation. Highly vascular areas carry a greater probability of harboring a carcinoma. A full bladder helps delineate the base of the prostate.

The urologist visualizes the prostate in three dimensions, allowing more accurate localization of abnormalities and extent of disease. For the axial view, the transrectal transducer is placed deeply into the rectum, just proximal to the seminal vesicles, to about 10 cm above the anal verge. Here the vas deferens may be distinguished. The transducer is slowly withdrawn to the level of the base of the gland, enabling visualization of the inner gland. Seminal vesicles are seen in cross section. To evaluate the prostate in the sagittal planes, the urologist rotates the probe clockwise or counterclockwise (Figure 14-31). A series of 12 biopsy specimens is generally taken with a disposable "core biopsy" needle. These are taken from the right and left medial and lateral apices, the right and left midline, and the right and left medial and lateral bases. Lesions as small as 2 to 3 mm are visible with this procedure.

TRANSPERINEAL BIOPSY. The perioperative nurse assists with placing the patient in the lithotomy or lateral position. The procedure may be performed with the patient receiving a general, regional, or local anesthetic. The surgeon performs a rectal exam to identify the induration. The needle is inserted through the perineal skin and guided ahead until the tip is against the lesion. The biopsy specimen is taken in the same fashion as described for the transrectal approach. Some surgeons may incise the site with the #11 or #15 scalpel and place a 4-0 absorbable closing suture.

The surgeon may also use the transperineal approach to perform template biopsies with ultrasound guidance, utilizing the brachytherapy (seed implant) template. The perioperative nurse assists with placing the patient in the lithotomy position, and secures his scrotum toward the abdomen with a transparent adhesive dressing. The surgeon positions the brachytherapy grid, template fixation device, and probe with cradle adjacent to the patient's perineum. Using the ultrasonic transrectal transducer the surgeon measures the prostate and calculates its total volume. Biopsies are then obtained transperineally through the template grid.

Transurethral Resection of the Prostate Gland

In transurethral resection of the prostate gland (TURP), the surgeon passes a resectoscope into the bladder through the urethra and resects successive pieces of tissue from around the bladder neck and the lobes of the prostate gland, leaving the capsule intact. The resectoscope has a stabilized cutting loop that is used to resect tissue and coagulate blood vessels by means of electric current. The electric current that powers the electrode is supplied by a high-frequency ESU. The current settings are specified by the surgeon, who activates the cutting or coagulating current with a foot pedal during the course of the procedure.

TURP is one surgical method of treating benign obstructive enlargement of the prostate gland. Several factors influence the surgical approach: size of the gland and location of the pathologic condition, age and condition of the patient, and presence of associated diseases.

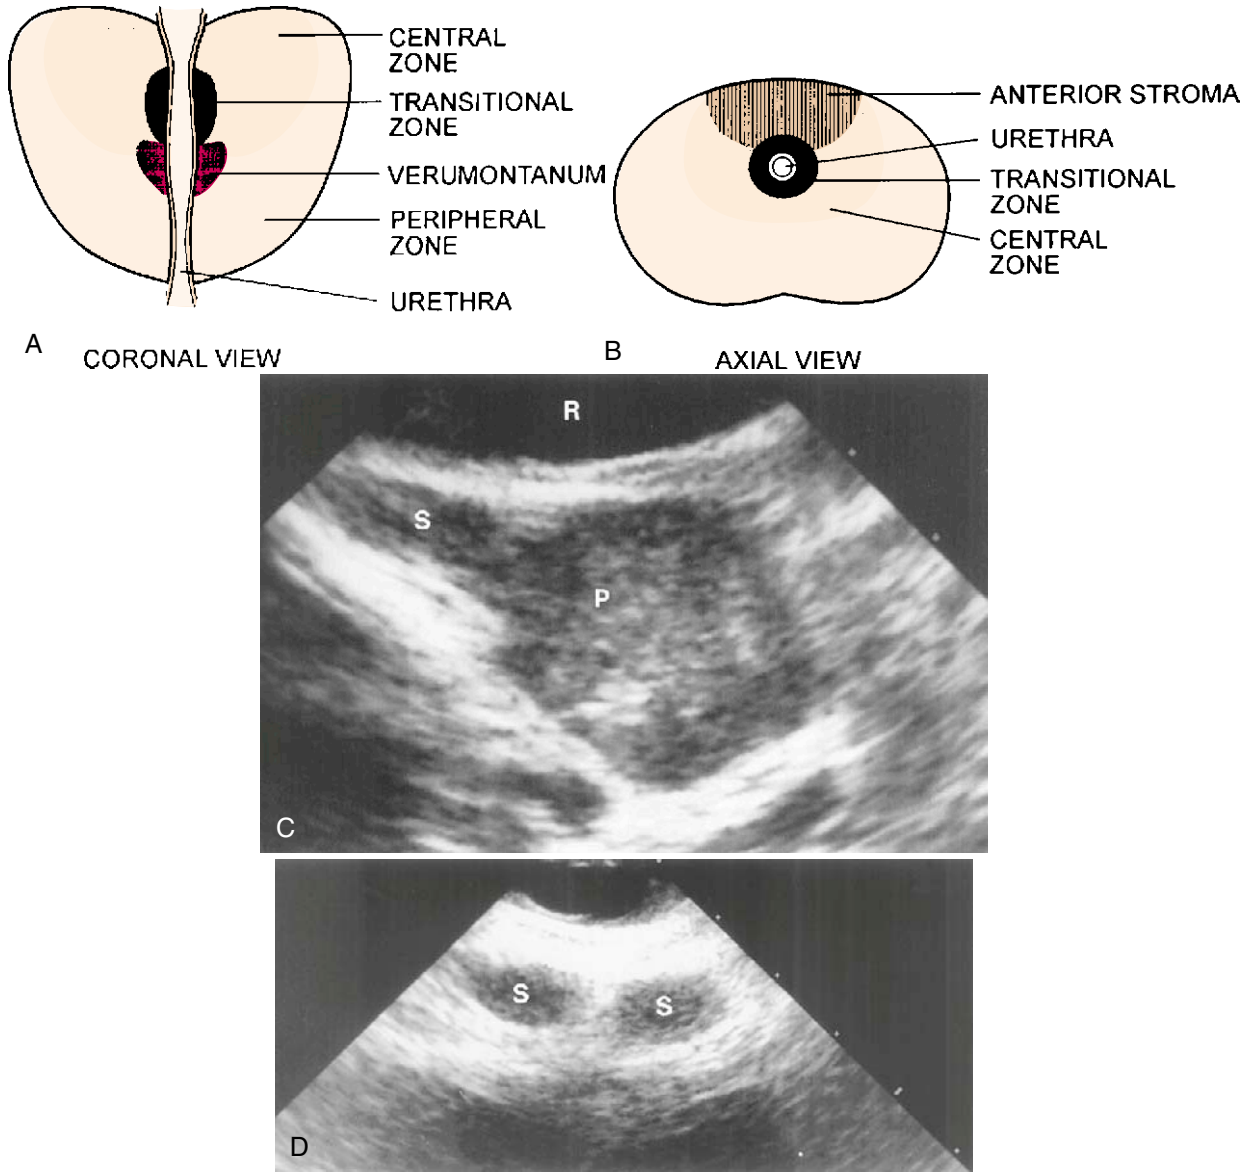

FIGURE 14-31 Schematic drawing of zonal anatomy of the prostate (*nonshaded area* is peripheral zone). **A**, Coronal view. **B**, Axial view and transrectal ultrasound views of prostate during biopsy. **C**, Sagittal image showing prostate *(P)*, seminal vesicles *(S)*, and rectum *(R)*. **D**, Transverse image of seminal vesicles *(S)*.

Procedural Considerations. The instrument setup for TURP is as described for cystoscopy with additional necessary instruments. The four principal types of resectoscopes are McCarthy, Nesbit, Iglesias, and Baumrucker. Adult resectoscopes range in size from 24F to 28F and have the following components: Foroblique telescope, operating element, cutting loops, and postresectoscope sheaths and obturators (Figure 14-32). A TURP requires a resectoscope (multiple working elements); a Foroblique telescope as well as a backup telescope; stabilized or unstabilized cutting loops; a postresectoscope sheath with its corresponding articulated obturator; a high-frequency cord; a short bridge; a Toomey syringe or the Ellik or Urovac evacuator; van Buren sounds; a 22F or 24F, 30-ml, three-way Foley catheter; a disposable urologic drape with rectal sheath; and a system for continuous bladder irrigation and urinary drainage. Supplementary instruments include a resectoscope adapter and a lateral telescope.

The continuous-flow resectoscope (CFR) (Figure 14-33) has unique components that include an outlet stopcock to which a suction tube is attached, an inflow tube on the inner sheath, and outflow holes on the outer sheath. These features enable the surgeon to resect tissue without interruption to empty the bladder, as must be done with the standard resectoscope. In addition to the CFR, which replaces the standard resectoscope, the setup includes thick-walled Silastic suction tubing and a continuous-flow pump. The continuous-flow technique decreases intravesical pressure on the bladder during the procedure, provides a clearer field of vision because of the constant inflow and outflow of irrigant, reduces the operating time because the resection process need not be interrupted

FIGURE 14-32 Resectoscope components: 24F and 26F Timberlake obturators and postresectoscope sheaths with fulgurating electrodes and Iglesias operating element, Foroblique 30-degree and 70-degree telescopes, and fiberoptic cable.

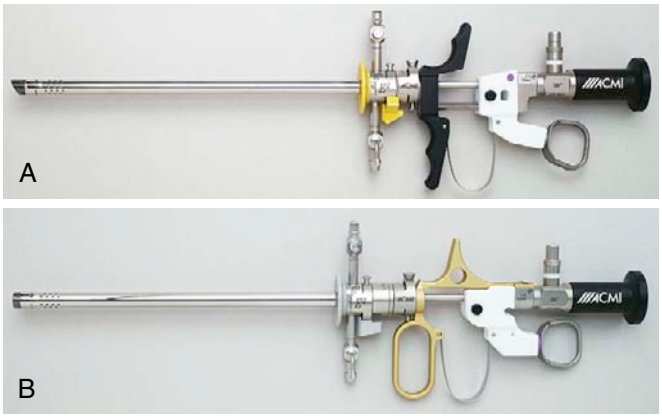

FIGURE 14-33 **A**, Continuous-flow resectoscope (CFR). **B**, Vista CFR bipolar resectoscope.

to evacuate the bladder, and provides a "still" bladder for the resection of bladder tumors.

A continuous flow of isotonic and nonelectrolytic irrigating fluid is necessary to ensure transmission of electric current and clear visualization throughout surgery. Irrigating solution such as 3% sorbitol or 1.5% glycine, 3 to 5 liters, may be connected in tandem to provide a constant flow. Warming units, available for these solutions, help to eliminate the hypothermia often experienced when large amounts of cold irrigants are employed. On the other hand, when solutions are warm, the patient may show a tendency to bleed more. The perioperative nurse must remain alert as to the status of the irrigation solution and replace it as required.

During transurethral prostatic surgery, the return of irrigation fluid must be monitored because intravasation and absorption of fluid into open prostatic venous sinuses or bladder perforation may occur. The perioperative nurse should be aware of the early signs and symptoms and measures employed to remedy these complications (Young et al, 2009). The patient usually experiences significant respiratory changes and abdominal discomfort. Continued extravasation and absorption can lead to hypovolemia and hyponatremia. Other important observations are rigidity and swelling of the lower abdomen, coupled with changes in sensorium. If extravasation of irrigating fluid is evident, the surgical procedure is discontinued and a cystogram is obtained immediately to determine if bladder perforation has occurred. Insertion of a Foley catheter is generally all that is necessary to control the situation. In the rare instance of a major perforation, surgical closure may be accomplished through a cystotomy incision.

Operative Procedure

1. The surgeon dilates the urethra with sounds sized from 20F to 30F.
2. Cystourethroscopy is performed to assess the degree of prostatic obstruction and to inspect the bladder. Some surgeons perform this diagnostic procedure several days before surgery, whereas others perform the examination in the OR immediately before surgery.
3. The surgeon passes a well-lubricated postresectoscope sheath with its fitted Timberlake obturator into the urethra.
4. The Timberlake obturator is removed, and the working element (resectoscope), assembled with the Foroblique telescope and cutting loop, is inserted through the sheath.
5. The irrigation tubing, light cord, and high-frequency cord are appropriately connected, and the surgeon opens the stopcock to allow the irrigation fluid to fill the bladder.
6. With the bladder distended, the surgeon inspects the prostatic urethra and bladder trigone.
7. After determining the location of the ureteral orifice, the surgeon begins electrodissection, alternating cutting and coagulating currents as required (Figure 14-34).
8. The bladder is drained, washing out prostatic tissue and small blood clots. At times the surgeon may use the Ellik evacuator to remove resected prostatic tissue. The Ellik is used by removing the working element of the resectoscope, fitting the nozzle of the evacuator onto the resectoscope sheath, and removing the bladder contents by manual pulsatile pressure. The surgical technologist ensures an Ellik or Urovac evacuator or a Toomey syringe is readily available for manual irrigation. Fluid may be drawn from the irrigant directly into the resectoscope sheath through the already attached tubing.
9. When the resection is completed, the surgeon inspects the prostatic fossa to ensure that all bleeding points have been coagulated.
10. The resectoscope is then removed, and a Foley catheter (22F or 24F, two-way or three-way, 30-ml balloon) is inserted into the bladder for urinary drainage. The balloon is inflated (Figure 14-35, *A*), pulled gently in traction against the bladder neck, and secured, to help control venous bleeding (Figure 14-35, *B*). The Foley balloon must not be inflated within the prostatic fossa (Figure 14-35, *C*), where it may cause excessive bleeding from the resected prostatic capsule. If desired, continuous irrigation with gravity drainage is initiated, with normal saline as the bladder irrigant instead of sorbitol or glycine. A 3-liter to 4-liter urinary drainage system is suggested to avoid frequent emptying of the drainage bag.
11. When VLAP, TUIP, or TULIP is performed, the surgeon may choose to place a standard 18F Foley with a 5-ml or 30-ml balloon connected to straight drainage. If irrigation is required postoperatively, it is then performed manually with sterile solution and a Toomey syringe.

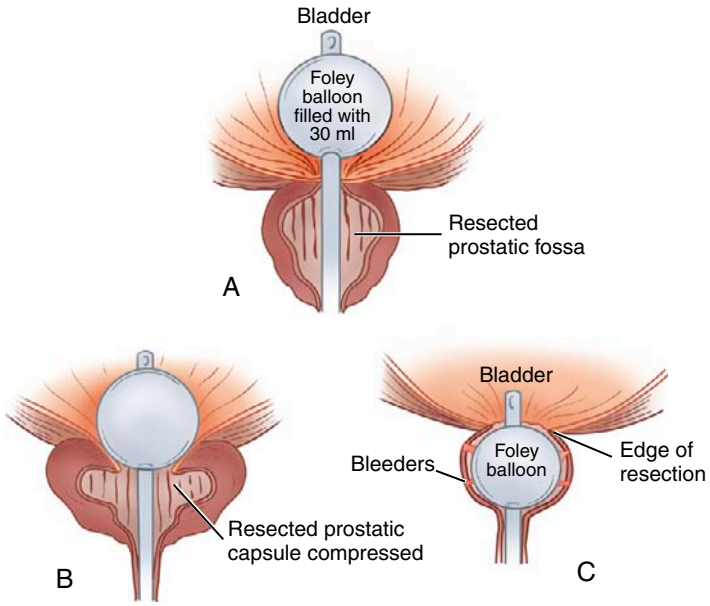

FIGURE 14-35 **A** and **B**, Proper position for Foley catheter with inflated balloon beyond prostatic capsule. **C**, Improper position.

Transurethral Incision of the Prostate (TUIP)

TUIP is a procedure in which the prostate is incised at the 5 and 7 o'clock positions to provide relief of obstruction, with results similar to those provided by a complete transurethral resection but with a lower incidence of bladder neck contracture and retrograde ejaculation. The shorter operative time inherent with the procedure minimizes fluid absorption and may decrease postoperative pulmonary and cardiovascular complications. The procedure may be performed with cold or hot knives as well as the standard resectoscope, or laser fiber (TULIP). This procedure is appropriate for sexually active patients with moderate to small obstructive prostates without a significant

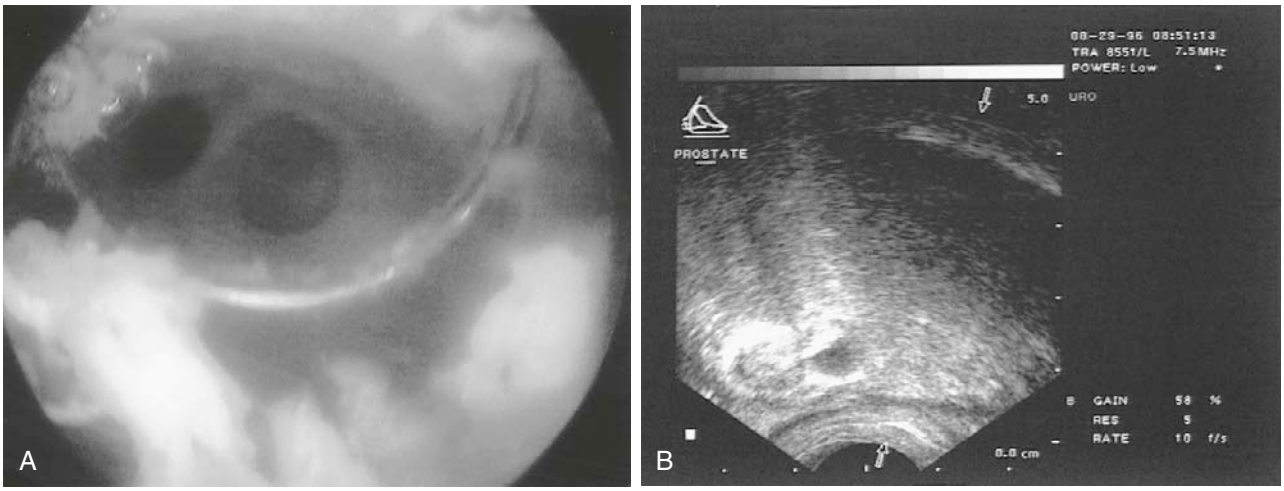

FIGURE 14-36 **A**, Dilated seminal vesicle (ejaculatory duct) with resectoscope loop approaching. **B**, Resectoscope loop entering dilated seminal vesicle (ejaculatory duct).

middle-lobe component. One major disadvantage is the potential for missing occult prostatic cancer. Despite this, some clinicians view this as an underused, feasible form of treatment.

Transurethral Incision of the Ejaculatory Ducts

Transurethral incision of the ejaculatory ducts is performed for the relief of obstructed ejaculatory ducts, a common condition in men with chronic prostatitis and prostatic calculi. Symptoms closely mimic prostatodynia and include aching in the perineal and genital areas with no lasting or significant improvement from conservative therapy (antibiotics and analgesics). The resectoscope loop is guided with transrectal ultrasound imaging to the dilated ejaculatory ducts, and the obstructed ducts are resected (Figure 14-36). Calculi may be fragmented if necessary and removed. A catheter generally is not needed.

Photoselective Vaporization of the Prostate

The KTP laser is now being used to treat BPH or prostatic enlargement. *Green-light PVP* is photoselective vaporization of the prostate and a new minimally invasive approach performed on an outpatient basis. The approach is the same as with other endoscopic techniques. A noncontact laser fiber is used to heat the prostate tissue and rapidly vaporize it to a penetration depth of 0.8 mm with minimal to no blood loss. Vaporization occurs from within the tissues where the collagen matrix eventually bursts as a result of the vapor buildup. The laser is operated in a continuous wave mode and induces a coagulation zone of only 1 to 2 mm in thickness. This prevents the excessive sloughing of necrotic tissue. The patient may not always need a Foley catheter following the procedure.

Interstitial Laser Coagulation of the Prostate

Interstitial laser coagulation (ILC) with the Indigo laser is a minimally invasive procedure for treatment of urinary outflow obstruction secondary to BPH. It is indicated for men older than 50 years with a median or lateral prostatic lobe volume of 20 to 85 ml. Designed for those men who wish to minimize the risk for incontinence and impotence found with conventional TURP, this procedure is now performed in the office setting about 80% of the time.

The procedure is contraindicated for the treatment of prostate cancer and for those patients who had previous brachytherapy with radioactive seeds. However, some physicians may elect to perform ILC before brachytherapy (or cryotherapy) in the hopes of minimizing, if not relieving, the postoperative voiding symptoms associated with these more definitive treatments.

Procedural Considerations. The patient is placed in the lithotomy position and prepped as for cystoscopy. An optional local anesthetic with oral or monitored IV sedation is generally adequate. Oral sedation is used more commonly with the office-based procedure; if the surgery takes place in the hospital or ambulatory center, monitored IV sedation may be used. An ultrasound machine with transrectal capability is often used to measure the size of the prostate gland and determine the appropriate number of laser applications (sticks). Some surgeons choose to measure by cystoscopy alone.

The setup includes a 17F or 23F panendoscope and 30-degree fiberoptic lens, ultrasound and transrectal transducer, and the Indigo laser machine with laser fiber (Figure 14-37). The fiber has graduated black depth markings used to guide placement into the prostate gland. The laser machine automatically times each "stick" for 2 minutes, 30 seconds. The perioperative nurse ensures that all laser safety precautions are observed (Chapter 7).

Operative Procedure

1. The surgeon inserts the transrectal transducer and measures the prostatic volume. (This may have been performed as an office procedure preoperatively.) Local anesthetic may be injected through the transducer guide pin with an 8-inch spinal needle or with the 8-inch collagen injection needle if ultrasound is not employed.
2. Cystoscopy is performed, and the prostatic urethra is evaluated.
3. The surgeon introduces the laser fiber through the panendoscope and passes it into the lateral lobe of the prostate gland through the urethral wall to the desired depth.
4. This is repeated one to three times on each side, depending on the measured prostatic volume.

FIGURE 14-37 Indigo Optima Laser unit with diffuser-tip fiber.

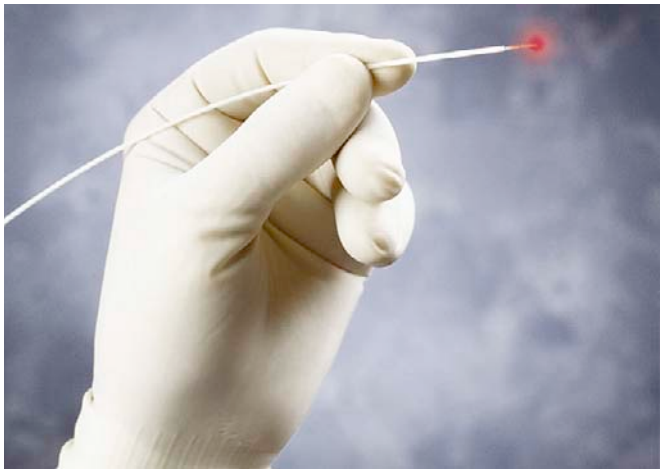

FIGURE 14-38 Indigo bare-tip laser fiber.

5. A TUIP may be performed utilizing the bare-tip fiber (Figure 14-38).
6. A 16F or 18F urethral catheter is inserted and connected to straight drainage. A 16F suprapubic Foley catheter may also be employed and attached to irrigation or drainage.

Transurethral Microwave Therapy (TUMT)/ Transurethral Needle Ablation (TUNA)

TUMT is a minimally invasive method of applying heat to the prostate gland for the relief of the symptoms associated with BPH and bladder-outlet obstruction. TUMT maintains temperatures in the urethra, sphincter, and rectum at a level that is physiologically safe while heating the tissue deep within the transitional zone of the prostate. A water-cooled catheter is combined with microwave radiation to the lobes of the prostate. This treatment is an office-based procedure.

Transurethral needle ablation (TUNA) is also a minimally invasive office procedure for the treatment of BPH of the median and lateral lobes. This technique delivers radiofrequency (RF) energy through two electrodes that are embedded in a special urethral catheter. Specific target areas of the prostate are thermally ablated by the RF energy and combined inductive heating of water molecules, leaving the urethra and the remainder of the prostate intact.

Simple Retropubic Prostatectomy

Simple retropubic prostatectomy is the enucleation of hypertrophic prostatic tissue through an incision in the anterior prostatic capsule by an extravesical approach. The retropubic approach offers excellent exposure of the prostate bed and vesical neck and readily controllable intraoperative and postoperative bleeding.

A preoperative bowel prep and antibiotic therapy are the standard of care for all open prostatectomies.

Procedural Considerations The perioperative nurse assists with positioning the patient in a slight Trendelenburg position with the pelvis elevated and the legs slightly abducted. Although the draping procedure must conform to individual OR policies, the following procedure is suggested for draping the patient:

1. The first towel, with a cuff, is placed under the scrotum.
2. The next three towels are placed around the lower abdominal incision site, followed by a sterile laparotomy sheet.
3. A fifth towel, folded in half, is placed over the penis and scrotum below the retropubic incision site and secured with two nonperforating towel clamps.

The instrument setup includes a basic laparotomy set and bladder and prostatic instruments (Figures 14-39 and 14-40). The following supplies should be readily available: Jackson-Pratt drains; water-soluble lubricant; Toomey and Asepto syringes; urinary drainage system; 20F, 5-ml Foley catheter; 22F or 24F, 30-ml Foley catheter; 10-ml and 30-ml syringes; and a self-retaining retractor such as the adjustable Omni-Tract Surgical UO400 Urology Retractor System (Figure 14-41).

Operative Procedure

1. The surgeon inserts a 20F or 22F Foley catheter with 30-ml balloon into the urethra and through the bladder neck and inflates it. This is clamped and maintained within the sterile field. Frequently, a three-way catheter is used for continuous bladder irrigation.
2. Through a Pfannenstiel or low vertical midline incision, the surgeon incises the anterior rectus sheath along with portions of the internal and external oblique muscles.
3. The rectus abdominis muscles are retracted laterally to expose the space of Retzius.
4. After placement of traction sutures, the anterior portion of the prostatic capsule is incised transversely (Figure 14-42, *A*).
5. The prostatic adenoma may be dissected or finger-enucleated from the surgical capsule (Figure 14-42, *B*).
6. The surgeon places hemostatic sutures at the 5 and 7 o'clock positions, encompassing the vesical neck and prostatic capsule, to ligate the primary blood supply to the prostate. Other bleeding points within the capsule may be suture-ligated with 2-0 absorbable sutures.
7. The prostatic capsule incision is closed with either a continuous or an interrupted 0 absorbable suture (Figure 14-42, *C*).
8. A drain is placed in the space of Retzius and exteriorized through the fascia and skin via a separate stab incision.

FIGURE 14-39 **A**, Right-angle (Mixter) clamps in various tip lengths. **B**, Scissors (*top to bottom*): Strully, curved Jorgenson, long sharp-tip Metzenbaum, standard sharp-tip Metzenbaum. **C**, Same scissor tips, *left to right*. **D**, Curved and straight Lowsley tractors in open position.

FIGURE 14-40 **A**, Urethral suture guides. **B**, Roth grip-tip urethral suture guide.

9. The abdominal incision is then closed in layers, and the wound is dressed.
10. If continuous bladder irrigation is to be used, normal saline solution irrigation is initiated through a 3-liter closed irrigation system.

Suprapubic Prostatectomy

Suprapubic prostatectomy is the removal, through a transvesical approach, of benign periurethral glandular tissue obstructing the outlet of the urinary tract. A low midline, or Pfannenstiel, incision may be used. One advantage of the suprapubic approach is that it allows access for surgical correction of any existing bladder condition such as vesical calculi or vesical diverticula. Control of bleeding is a major consideration in any prostatectomy and is one disadvantage of the suprapubic approach. Because the prostate is located beneath the symphysis pubis, ligation of bleeding capsular vessels is difficult. However, control of hemorrhage and replacement of blood loss, coupled with skilled perioperative nursing care and early mobilization of the patient, have greatly minimized complications.

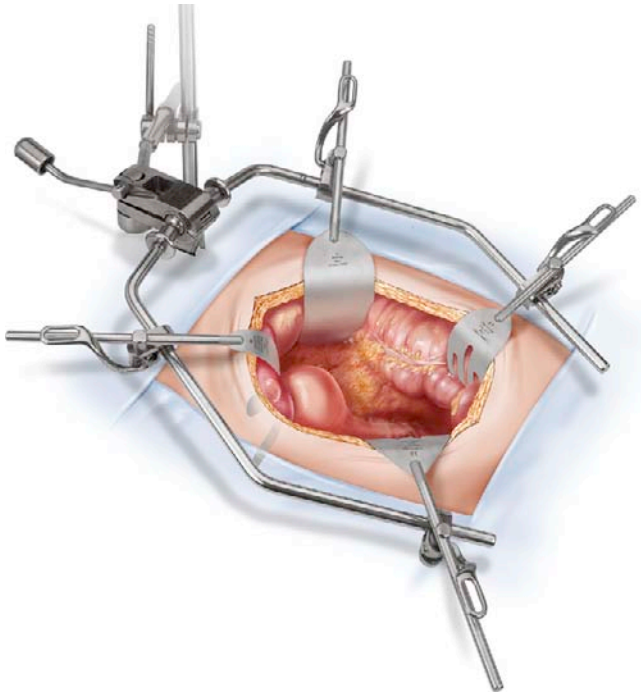

FIGURE 14-41 Adjustable Omni-Tract Surgical UO400 Urology Retractor System.

Procedural Considerations. Spinal, epidural, or general anesthesia may be selected for patients having a suprapubic prostatectomy, depending on their medical condition. The patient is placed in a slight Trendelenburg's position with the umbilicus elevated and the legs slightly abducted. Draping and instrumentation are as described for retropubic prostatectomy.

Operative Procedure

1. The surgeon inserts a 20F or 22F Foley catheter with 30-ml balloon into the urethra and through the bladder neck and inflates it. This is clamped and maintained within the sterile field. This maneuver facilitates identification of the bladder.
2. A transverse or midline lower abdominal incision is made through the skin and the two layers of superficial fascia (Figure 14-43, *A*).
3. The external and internal oblique muscles are cut along the lines of the original incision.
4. Bleeding vessels are clamped, electrocoagulated, or ligated with fine absorbable ties.
5. The rectus muscles are separated in the midline and retracted laterally.
6. After the placement of traction sutures, the surgeon opens the bladder at the dome with a scalpel. Liquid contents are aspirated, and the bladder incision is enlarged.
7. The bladder is visually and manually explored for calculi, a tumor, or diverticula.
8. The surgeon manually enucleates the adenomatous tissue using the tip of the index finger inserted through the vesical neck into the prostatic urethra (Figure 14-43, *B*). If difficulty is experienced with the enucleation, the surgical assistant may place a finger into the rectum to elevate the prostate gland. Aseptic technique is maintained during enucleation with the use of a sterile second glove on the hand used in the rectum.

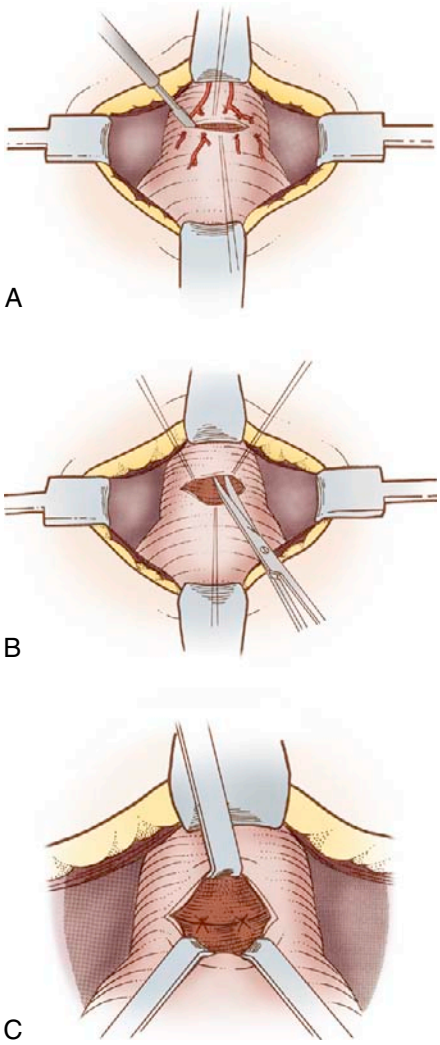

FIGURE 14-42 Retropubic prostatectomy.

9. After enucleation is completed, attention is directed to maintaining good hemostasis by suture ligation of the vesical neck at the 5 and 7 o'clock positions. Other significant bleeding points may also be ligated.
10. A suprapubic catheter is placed into the bladder lumen through a small stab incision.
11. A 22F or 24F, two-way or three-way Foley catheter with a 30-ml balloon is inserted into the urethra in place of the original one, and the balloon is inflated to a size that prevents the catheter from falling or being pulled into the prostatic fossa (Figure 14-43, *C*).
12. The surgeon closes the cystotomy incision with interrupted 2-0 absorbable sutures.
13. A drain is left along the cystotomy incision, exteriorized through a separate stab wound, and secured to the skin with a silk suture.
14. The muscles, fascia, and subcutaneous tissues are closed in layers, and a dressing is applied.
15. To reduce clot formation and maintain catheter patency, normal saline irrigation solution may be connected to the Foley catheter to provide continuous irrigation to the bladder. Continuous irrigation may be initiated during closure.

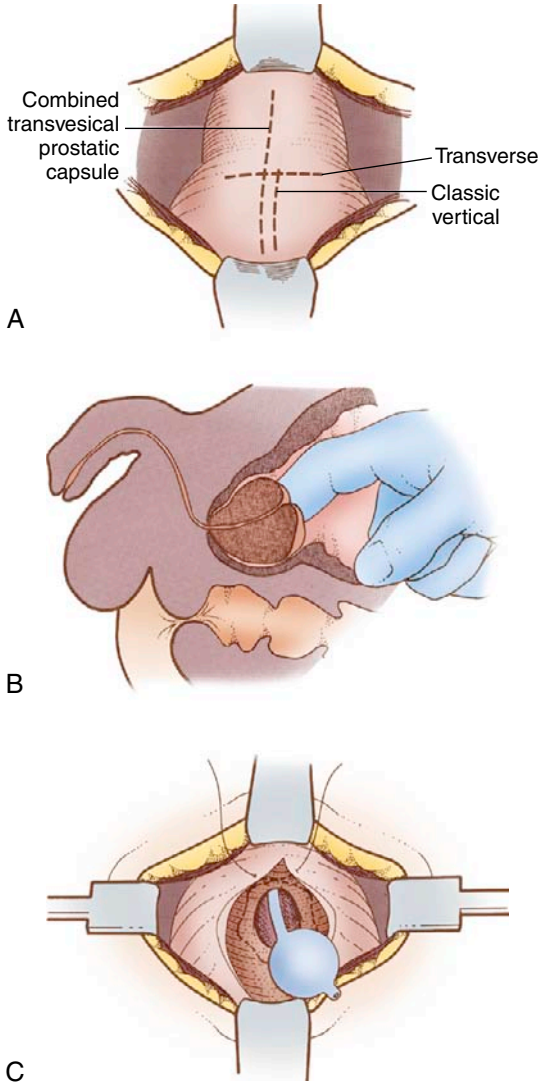

FIGURE 14-43 Suprapubic prostatectomy.

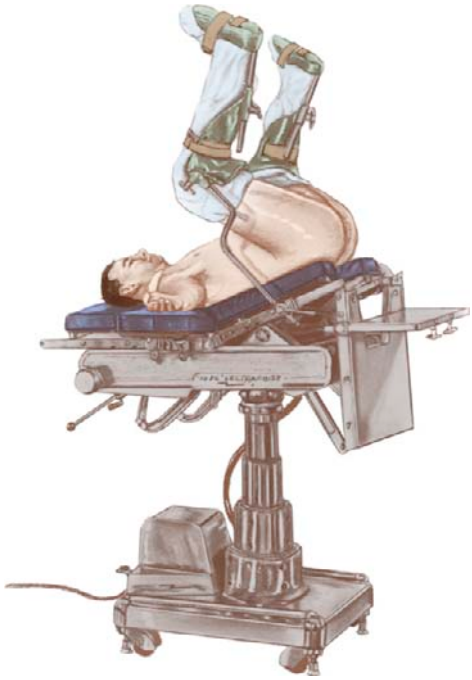

FIGURE 14-44 Exaggerated lithotomy position for perineal prostatectomy.

Simple Perineal Prostatectomy

Simple perineal prostatectomy is the removal of a prostatic adenoma through a perineal approach. A perineal approach to the prostate gland is most suitable when open prostatic biopsy is desired and, after receipt of pathologic confirmation, radical excision is to follow. Other advantages include preservation of the bladder neck, improved urethrovesical anastomosis, and easier control of bleeding. Some surgical disadvantages are (1) inability to perform biopsy of the iliac and obturator nodes for determining extension of disease and (2) possible formation of urethrorectal fistulas.

Procedural Considerations. The patient is placed in an exaggerated lithotomy position with the legs above the level of the pelvis (Figure 14-44). The perioperative nurse places a bolster beneath the sacrum to allow the perineum to be as parallel to the OR bed as possible, with the buttocks extending several inches over the bed edge. Stirrups should be well padded to protect the popliteal fossa. Sequential compression stockings are recommended to assist peripheral vascular flow. The patient is often placed in a steep Trendelenburg position. Well-padded shoulder braces, placed over the acromial processes in a manner to prevent stretch or pressure injury, may be required to prevent the patient from sliding upward on the bed. Routine skin preparation is carried out and includes an interior rectal prep. Special draping is as follows:

1. A towel folded in half is placed over the pubic area.
2. Two towels with a cuff are placed on either side of the perineum.
3. Two leggings, with points down, are placed over the legs.
4. One impervious drape is placed over the anus.
5. A large sheet fully opened with a large cuff is placed across from one stirrup to the other and secured by towel clamps.
6. A laparotomy sheet follows, with the short end to the floor.

The instrument setup is as described for suprapubic prostatectomy, omitting abdominal self-retaining retractors and adding straight and curved Lowsley tractors (Figure 14-45), Roux retractors, Jackson retractors with short and long blades, Doyen vaginal retractors, Young retractor, perineal prostatic retractors (Figure 14-46), Sauerbruch retractors, and a narrow and wide self-retaining perineal retractor, such as the Thompson retractor or the Omni-Tract Surgical UO100 Pelvic Retractor System (Figure 14-47).

Operative Procedure

1. A curved Lowsley tractor is placed through the urethra into the bladder and held back by the surgical assistant, causing the prostate to be pushed down toward the perineum.
2. An inverted U-shaped incision is made from one ischial tuberosity to another, curving just anteriorly to the anus (Figure 14-48, *A*).

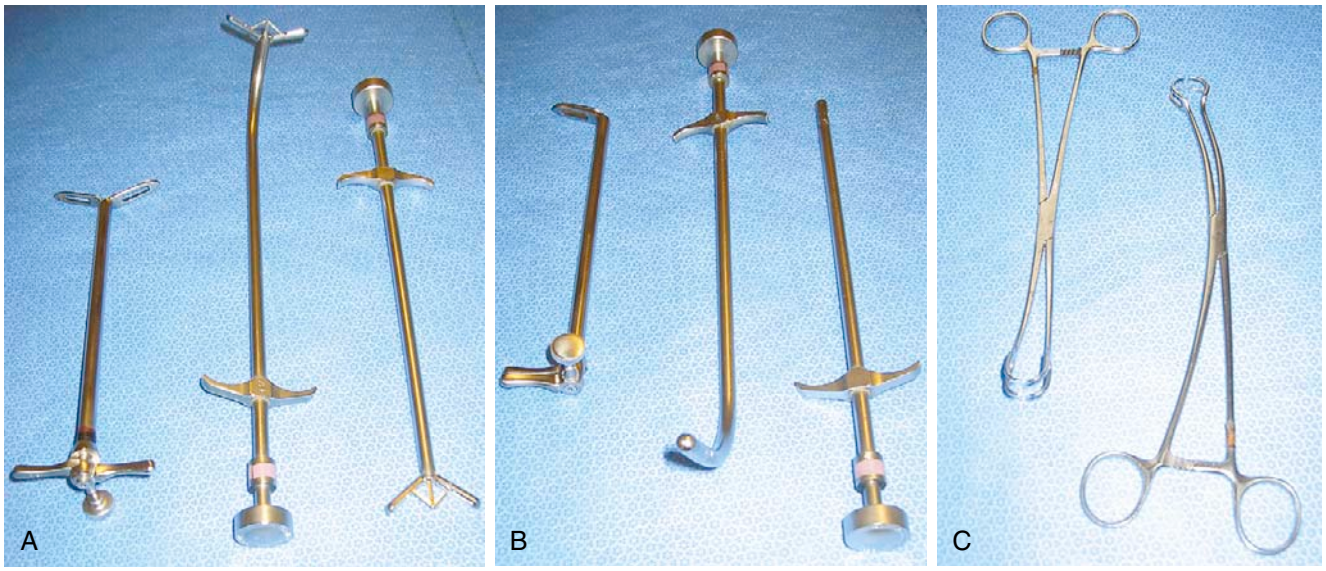

FIGURE 14-45 Young, curved Lowsley, and straight Lowsley tractors in open (**A**) and closed (**B**) positions. **C**, Curved double-prong prostate clamps.

FIGURE 14-46 Lateral, bulb, and anterior perineal prostatectomy retractors.

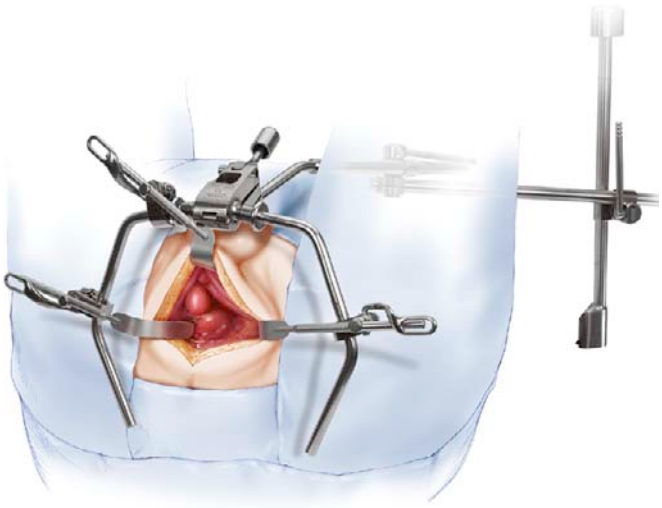

FIGURE 14-47 Adjustable Omni-Tract Surgical UO100 Pelvic Retractor System.

3. Three Martius or Allis clamps are secured to the posterior edge of the incision and retracted downward, over the anal drape.
4. The surgeon clamps any subcutaneous bleeders with straight mosquito hemostats and electrocoagulates or ties them with 3-0 absorbable ligatures.
5. The central tendon is isolated, clamped, and cut distally to the external anal sphincter (Figure 14-48, *B*).
6. The rectourethral muscle is incised and pushed downward from the central tendon.
7. The levator ani muscle is exposed and retracted laterally (Figure 14-48, *C*).
8. The prostate gland is exposed. The surgeon may send biopsies of the prostate for pathologic confirmation. If the results are negative, the prostatic adenoma is removed. If the frozen section reveals malignancy, a radical prostatectomy may be done at this time.
9. If simple enucleation is to be performed, the prostatic capsule is incised and the Lowsley tractor is removed (Figure 14-48, *D*).
10. The urethra is divided, and the Young prostatic retractor is inserted.
11. The blades are opened, drawing the prostate down, and the adenoma is manually enucleated from the surgical capsule.
12. A 22F Foley catheter with a 30-ml balloon is inserted through the urethra into the bladder.

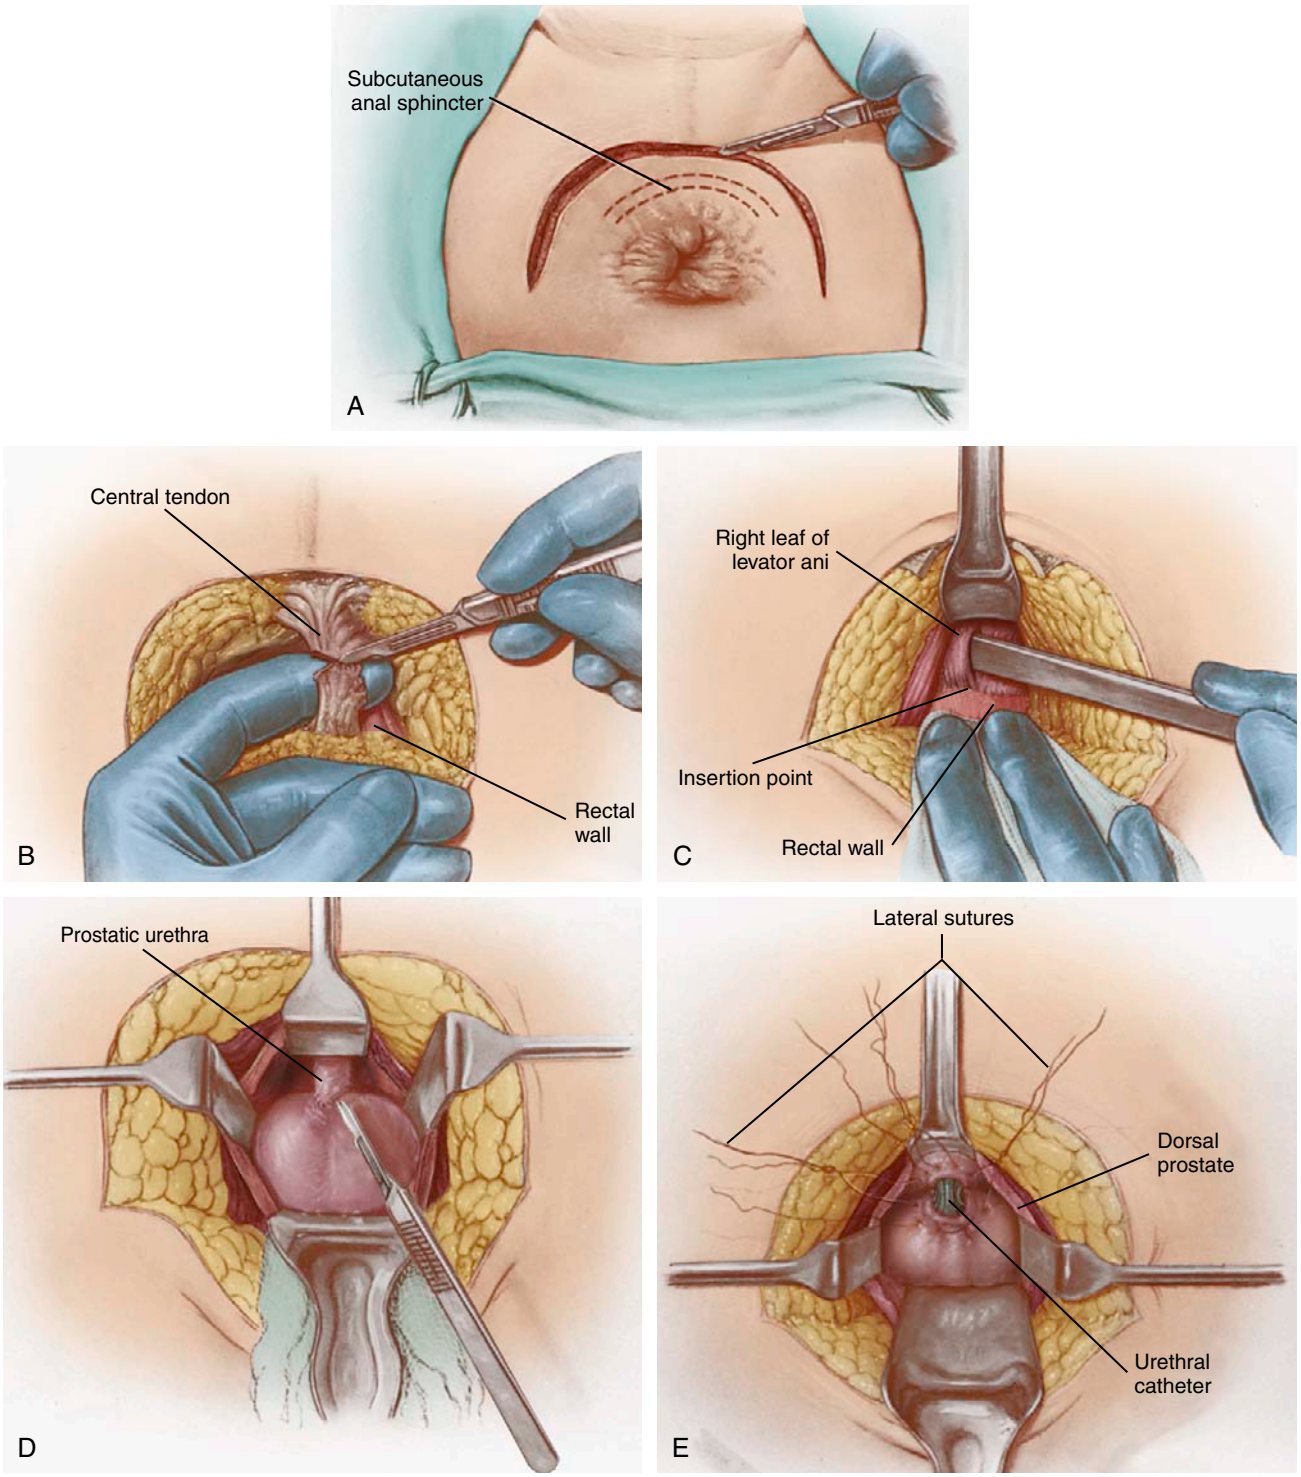

FIGURE 14-48 Simple perineal prostatectomy.

13. Bleeding is controlled at the 5 and 7 o'clock positions.
14. The capsulotomy incision is repaired with a continuous 2-0 absorbable suture (Figure 14-48, *E*).
15. A drain is left in place at the level of the capsulotomy incision.
16. The surgeon reapproximates the subcutaneous tissue with 3-0 absorbable suture.
17. The skin incision is reapproximated with 4-0 absorbable subcutaneous sutures.
18. The wound is dressed according to the surgeon's preference and taped or held with a supportive device, such as mesh pants.

Transrectal Seed Implantation (Interstitial Radiotherapy with Brachytherapy)

Brachytherapy of the prostate gland is a procedure that requires a collaborative, multidisciplinary approach to patient care. The radiation oncologist and medical physicist, in addition to the

surgeon, are vital to an optimum outcome from the initial planning stage throughout the postoperative surveillance. Preplanning is required to determine the size of the prostate, dose of each seed, the spacing necessary between each seed, and the number of seeds required. A template plan is developed preoperatively by using the ultrasound and the probe-anchoring equipment to measure and map the appropriate seed sites within the prostate. This may be accomplished in the surgeon's office, radiology department, or oncology clinic. The implant plan is finalized at the time of surgery.

The facility that offers this treatment must be licensed for "Group 6" with the radioactive materials licensing department of their respective state. If seed implantation is indicated as an adjunct to radiation therapy, it should be performed 3 to 4 weeks after the radiation treatment.

During percutaneous implantation of iodine-125 or palladium-103 seeds, the patient is positioned in the lithotomy position. The surgeon visualizes the prostate with transrectal ultrasonic imaging, and locates the midportion of the prostate on a transverse image. This location becomes an index for positioning the axial ultrasound plane at the base of the prostate. Approximately 2 to 3 hours should be allowed from start to completion. The procedure is amenable to outpatient management using a regional or general anesthetic.

Iodine seeds are commercially available in titanium-encased rods called magazines that absorb the electrons. The magazines can be sterilized in the OR at the beginning of the procedure. These seeds may also be obtained embedded in an absorbable suture that allows them to remain positioned appropriately in relation to themselves and their location within the prostate and minimizes the risk of seed migration. Palladium seeds, not presently available prethreaded, are plated onto a graphite pellet. The pellets are loaded into titanium tubes with a lead marker. The half-life of iodine-125 (60 days) is longer than that of palladium-103 (17 days) and allows the therapy to be delivered over the duration of tumor cell replication, altering the ability of the tumor cells to multiply. Compared to iodine-125, palladium-103 affords a larger dose of radiation in a shorter time interval to more rapidly growing tumors.

Procedural Considerations. Percutaneous implantation of radioactive seeds allows the delivery of significantly higher doses of radiotherapy to the prostate than provided by external beam therapy. The radius of penetration around each seed is only 5 mm, thus sparing adjacent organs. The typical radiation dose that can be delivered by external beam may be 6500 centigrays (cGy), whereas the dose that can be delivered with implantation of seeds alone is in the range of 12,000 to 16,000 cGy. Some patients may receive hormone therapy, to shrink the prostate gland, for 3 months before implantation, and some will undergo radiation therapy before implantation. Patients with stage A or stage B prostate cancer are appropriate candidates, and selection is not influenced by a rise in the PSA level, biopsy specimens indicative of further involvement, or age. Ideal patients for brachytherapy treatment as monotherapy are those with low-risk parameters (PSA ≤10, Gleason score 6 or less, low-volume disease on biopsy).

Possible complications include the risk of intraoperative seed displacement into the bladder; implantation too close to the urethra, resulting in postoperative urethral stricture or prolonged dysuria; and implantation into the perineum if the needles are withdrawn too quickly. There is also the chance of migration of seeds, placed just outside the periphery of the gland and in the periprostatic plexus, to the lung. The nurse instructs the patient to avoid extended contact with children and pregnant females and to keep a 6-foot distance from this population group for 6 to 8 weeks. The patient must strain his urine, and any seeds expelled should be retrieved and returned to the oncologist. Body wastes are not considered hazardous, however.

Bleeding from the percutaneous sites is minimal, but postoperative ecchymosis of the perineum is to be expected. Other postoperative complications that may occur in the first 12 months include acute cystitis, prostatitis, and urinary retention. Late complications may include chronic prostatitis with cystitis, urethral stricture with contracture, stress with urge or total incontinence, proctitis, and impotence. Some patients have required posttreatment TURP, bladder-neck incision, suprapubic catheter insertion, or urethral dilation to alleviate the aforementioned conditions. Much less commonly, rectovesical or rectoprostatic fistula can occur, requiring interventions such as laparotomy, colostomy, and urinary diversion. Patients are generally able to void 24 to 48 hours after implantation. The perioperative nurse positions the patient in the lithotomy position with assistance. The scrotum must be secured cephalad to allow a clear operating field. The surgeon places a traction stitch through the lateral edges of the scrotum and anchors it to the groin region.

With an experienced team, seeding is done with real-time ultrasound imaging. Throughout the procedure, random room checks with the Geiger counter will be performed to determine radiation levels. All personnel, surgical equipment, and trash (including disposable drapes) are scanned before leaving the room at the end of the procedure.

Operative Procedure

Before seeding is begun, the surgeon positions the ultrasound transducer so that the posterior margin of the prostate is parallel to the axis of the ultrasound transducer. The direction of seed insertion and the transverse images of the prostate must have a similar appearance to those on the preoperative volume study. The volume study and implant worksheet are used for continual verification of coordinates. The surgeon attaches a stabilizer bar to the OR bed. This secures the "stepping unit," which allows a 5-mm incremental forward-and-backward motion of the probe. The sled that holds the transducer is attached to the stepping unit. The probe must be securely anchored so that the position of the prostate relative to the needles used to implant the seeds remains unaltered throughout the procedure. For the needles to be positioned appropriately, the template with labeled grid is attached to the transrectal transducer so that the needles placed through the probe grid match the grid locations on the plan. The grid is labeled alphabetically *Aa, Bb, Cc,* and so on, with the center of the prostate corresponding to *D* on the grid. The plan is designed to avoid the urethra, bladder neck, and rectum to prevent urethrorectal fistula formation, irradiation of the bladder, and scarring at the bladder neck level.

1. At the beginning of the procedure the surgeon inserts a urethral catheter, drains the bladder, and then refills it with 150 ml of sterile water. The bladder then provides an "acoustic void" to better visualize the prostate. If fluoroscopy is used, contrast medium can be instilled into the bladder to delineate the position of the bladder neck.

2. The surgeon removes the urethral catheter during implantation of seeds to avoid placement of seeds close to the urethra. The catheter causes the tissue surrounding the urethra to be compressed, and if attempts are made to implant seeds into this compressed tissue, penetration of the catheter and urethra may occur. The catheter also causes an acoustic shadow that prevents visualization of the anterior prostate gland.
3. The surgical technologist covers the ultrasound probe with a sterile probe cover filled with 15 ml of sterile water to remove the artifact. Alternatively, a gel-filled probe cover can be placed on the end of the ultrasound probe. Filling with too much fluid will change the configuration of the prostate and alter the anatomic presentation. The transducer will be aimed with the tip upwards at a 10- to 20-degree angle (Figure 14-49). The posterior wall of the prostate must be far enough away from the probe so that the posterior row of seeds is placed just inside the posterior capsule. Seeds are implanted by means of loaded needles placed into the prostate according to the template plan, with the midline seeds placed slightly off center to avoid the urethra. Alternatively, individual seeds can be placed through the hollow needles using a mick applicator that utilizes a long plunger.
4. Stabilization of the prostate may be achieved with stabilization needles placed laterally to the center into the right and left lobes and then removed once the anterior seeds are in place. Another method is to use a Foley catheter as a retractor for implantation of the periphery and until implantation near the urethra occurs. The best method may be to overcompensate for the rotation of the prostate by angling or turning the needle slightly opposite to the direction desired.
5. The most anterior seeds are placed first so that imaging of the anterior portion of the gland is not obscured by the ultrasonic shadows created by seeds placed posteriorly. If strands are used, Anusol-HC (hydrocortisone) is used to seal the bevel before implantation. Strands should be cut cleanly with electrosurgery to seal the ends and avoid frayed ends, which may be split further when the stylet is inserted into the needle, adversely affecting seed placement.
6. Contrary to normal needle insertion with the bevel up, these needles are placed into the prostate with the solid, or back, side up. Every effort is extended to avoid implanting seeds into the bladder or too close to the urethra, which causes significant postoperative irritative symptoms.
7. When placing the anterior needles, passage of the needle may be prevented by the inferior arch of the pubic bone. The needle tip is visualized as a bright echo, and the angle may be altered to compensate for the bone. Alternatively, the placement of the anterior seeds may be postponed until the end when the template may be dropped down, the probe positioned parallel to the pubic arch, and the needles inserted past the anterior portion into the prostate. Rarely, the template may need to be removed from the ultrasound probe at the conclusion of the procedure to allow "free-hand" placement of anterior needles.
8. The needle is inserted beyond the desired site and then retracted. The first seed will then determine where the balance will lie because the seeds will fall into a plane that follows the first seed in a specific needle. The target volume is greater than the actual volume of the prostate so the capsular edge of the prostate and just beyond are also subjected to seed penetration (Figure 14-50). These peripherally placed seeds have a higher energy and may also have a greater tendency for migration if the tissue is not dense enough to hold the seed in place.
9. The distribution of seeds is generally 80% peripheral and 20% central.
10. The surgeon performs a cystoscopy at the end of the treatment so that seeds protruding into the urethra or left in the bladder may be removed.
11. A Foley catheter is placed and left for 24 to 48 hours.

Transrectal Cryosurgical Ablation of the Prostate Gland

Cryoablation of the prostate is a feasible, minimally invasive option for patients with localized or locally advanced prostate cancer. This method of treating the prostate gland can be used either as primary therapy or as a salvage procedure for local recurrence of prostate adenocarcinoma after previous external radiation therapy, brachytherapy, or even previous cryoablation. Cryoablation causes cell death through crystallization within the intercellular and extracellular spaces that exert mechanical shear forces on the cell membranes, osmotic changes, and cellular hypoxia. Complications related to the procedure include urinary incontinence, urethral slough,

FIGURE 14-49 Transducer on stepping unit and slide, angled upward to "get under" the pubic bone.

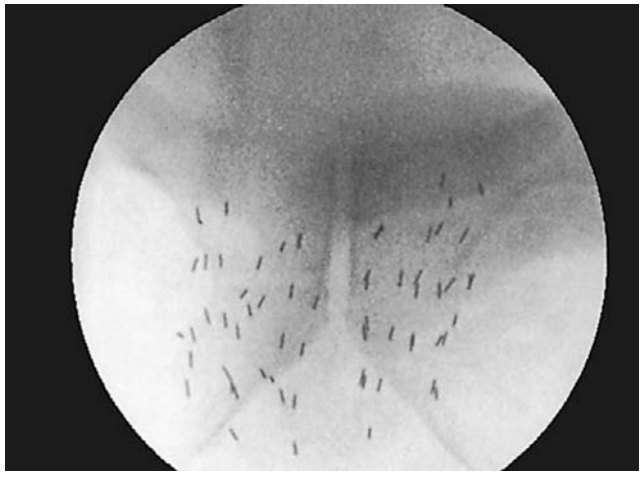

FIGURE 14-50 C-arm view of completed seed implant.

rectourethral fistula, UTI, and post-cryoablation erectile dysfunction (Langenhuijsen et al, 2009).

Procedural Considerations. The perioperative nurse assists with positioning the patient in a dorsal lithotomy position with the legs raised high enough to allow placement of a stabilizer bar that is affixed directly to the operating table. The ultrasound probe can then be placed on a sled with the use of brachytherapy. Because of the positioning required for the procedure and the length of the procedure (e.g., average 2 hours), the patient is at increased risk for developing deep vein thrombosis (DVT). The perioperative nurse initiates DVT precautions (e.g., elastic stockings, sequential compression device sleeves) as part of the plan of care. Patients treated with cryosurgery are generally admitted to the hospital after the procedure and discharged the following morning, unless bleeding, fever, or anesthetic complications prevent their discharge.

Operative Procedure

1. The surgeon performs a cystoscopy to assess the external sphincter, prosthetic urethra, bladder neck, and location of the ureteric orifices on the bladder trigone.
2. At the conclusion of the cystoscopy the surgeon fills the bladder with sterile irrigant to facilitate percutaneous insertion of a suprapubic cystotomy tube.
3. A guidewire is then introduced into the bladder upon removal of the cystoscope, to facilitate later passage of the urethral warming device.
4. The surgeon tacks the scrotum away from the perineum with suture.
5. The transrectal ultrasound probe is then affixed to the table and inserted for visualization of the prostate gland. Volume and length measurements of the prostate are made at this time.
6. The perioperative nurse attaches the needles to the cryosurgery machine to allow circulation of the argon and helium gases through the device tubing. Before insertion of the needles into the perineum, the perioperative nurse and surgical technologist test the needles in the saline to ensure production of an ice ball.
7. Once all needles are in place, the surgeon advances the urethral warming device over the guidewire previously placed in the urethra. This warming catheter remains for the duration of the procedure, and is often left in place for up to 1 hour following the cryoablation treatment. The use of the urethral warming catheter is crucial to the safety of this procedure, and cryoablation of the prostate should not be done without its use.
8. Using ultrasound guidance in the transverse and longitudinal planes, the surgeon inserts the cryosurgery treatment needles and thermocouple needles for temperature monitoring. The needles are positioned according to a template that allows for uniform freezing of the prostate gland. Alternatively, needle placement can be tailored by the surgeon to allow for focal cryoablation as clinically indicated. The needle probes are placed at least 1 cm from the location of the urethra, to minimize risk of damage to this structure and to the urinary sphincter.
9. Freezing is initiated in the anterior portion of the prostate (upper needles), and progress of the ice ball is monitored with ultrasound as the ice front progresses to the posterior aspect and apex of the prostate gland.
10. After all tissue has been frozen using a double-freeze technique, the surgeon removes the cryoprobes. Active warming of the prostate can be achieved with circulation of helium through the hollow needles, and this also facilitates removal of the needles at the conclusion of the procedure.
11. If the urethral warming catheter is to remain in place, the patient is transferred to the recovery room with the urethral warmer and circulating machine, which can be transported on an IV pole. One hour following the procedure, the warming catheter is removed and replaced with a Foley catheter, which is usually removed the morning after surgery.
12. The suprapubic catheter allows for urinary drainage for the first 1 to 2 weeks. The tube can then be clamped for a voiding trial after prostate swelling has subsided enough to allow micturition to occur.

Nerve-Sparing Radical Retropubic Prostatectomy with Pelvic Lymphadenectomy

Radical prostatectomy is the treatment preferred for patients with organ-confined carcinoma of the prostate. This procedure involves removal of the entire gland, its capsule, and the seminal vesicles. Important anatomic structures that impact erectile function are within the surgical field. Whenever possible, the surgeon attempts to spare the posterolateral neurovascular bundles, supplying the corpora cavernosa, to preserve potency. Those with tumors confined in the prostatic capsule are the best candidates for nerve-sparing procedures. In the presence of more advanced tumor extension, the surgeon attempts to spare one of the bundles, allowing the chance for potency.

Procedural Considerations. Patient preparation and basic surgical instrumentation are as for the simple retropubic approach. Additional supplies include long-tipped, right-angled clamps; urethral suture guides; a Bookwalter or Wishbone (UO400) self-retaining retractor; long Martius clamps; straight and right-angled clip appliers and clips; and right-angled scissors.

Operative Procedure

1. The surgeon creates a vertical midline lower abdominal extraperitoneal incision.
2. A bilateral pelvic lymphadenectomy is performed, removing the external iliac, obturator, and hypogastric nodes en bloc. Lymphadenectomy is done primarily for tumor staging.
3. The surgeon exposes the puboprostatic ligaments, and incises the endopelvic fascia on each side of the gland to the puboprostatic ligaments (Figure 14-51, *A*). Right-angled scissors are employed to divide the puboprostatic ligaments. The dorsal vein complex is easily subject to injury, and excessive venous bleeding may occur during this phase of the procedure. The surgical technologist and the perioperative nurse need to be alert to this potential complication.
4. A plane is developed between the lateral prostatic border and the levator ani muscles with sharp and blunt dissection. Once visualized, the muscle is dissected laterally to the urogenital diaphragm.
5. The surgeon ligates and divides the collateral veins originating from the levator ani muscle and running laterally to the puboprostatic ligaments to free the apex of the prostate.

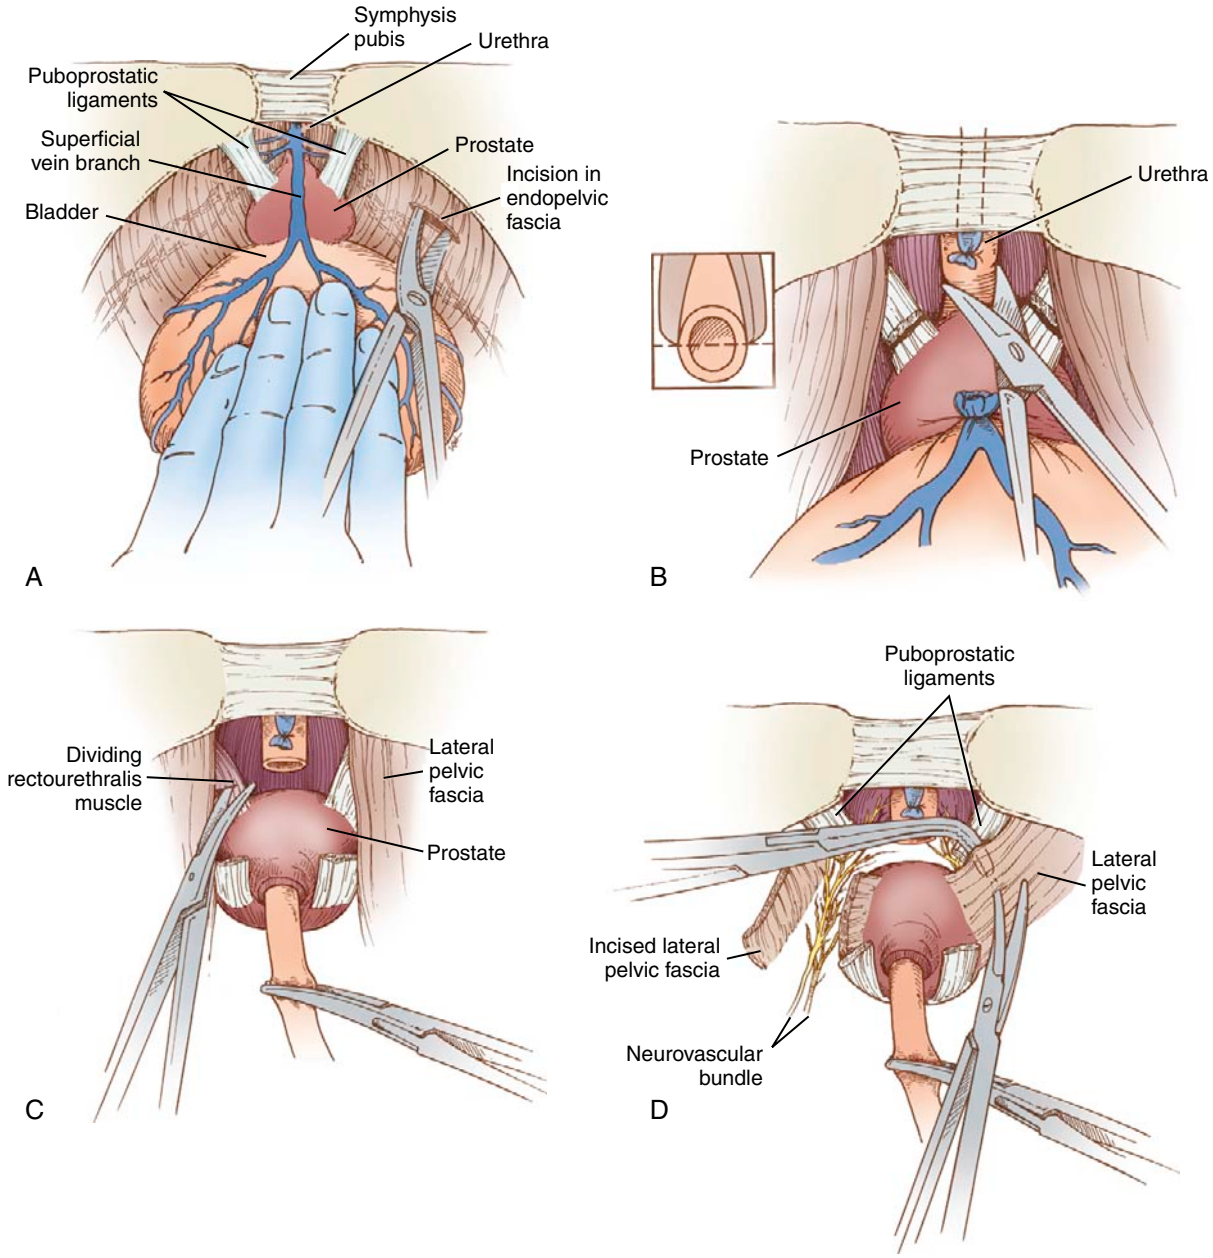

FIGURE 14-51 Radical retropubic prostatectomy.

6. The dorsal venous complex, supplying the penis, is carefully retracted medially. Once a plane is developed, the venous complex is separated from the urethra with a long-tipped, right-angled clamp. The venous complex is ligated with 0 or 2-0 absorbable ligatures. Some surgeons opt to use a stapler designed for this purpose. The complex is then transected with a #15 scalpel. Backbleeding, from the vessels onto the anterior surface of the prostate, is suture-ligated.
7. The surgeon uses a right-angled clamp to mobilize the urethra from the rectourethralis muscle between the two neurovascular bundles, avoiding damage to them.
8. A Penrose drain or vessel loop is passed around the urethra. The surgeon elevates and divides the urethra with a long-handled scissors or scalpel (Figure 14-51, *B*). The catheter is clamped proximally and pulled upward through the urethral incision, where it is cut and held cephalad.
9. The posterior urethra is transected (Figure 14-51, *B*).
10. The surgeon dissects the rectourethralis fibers free from and medial to the neurovascular bundles (Figure 14-51, *C* and *D*).
11. Next, the surgeon enucleates the prostate, divides the bladder neck, and clip-ligates the seminal vesicles (Figure 14-51, *E* and *F*).
12. Once bleeding is controlled, the urethral suture guide is inserted in place of the Foley and six 2-0 absorbable sutures on a ⅝-inch curved needle are placed inside to outside on the distal urethral segment. These are tagged and left uncut to be anastomosed to the bladder neck (Figure 14-51, *G*).

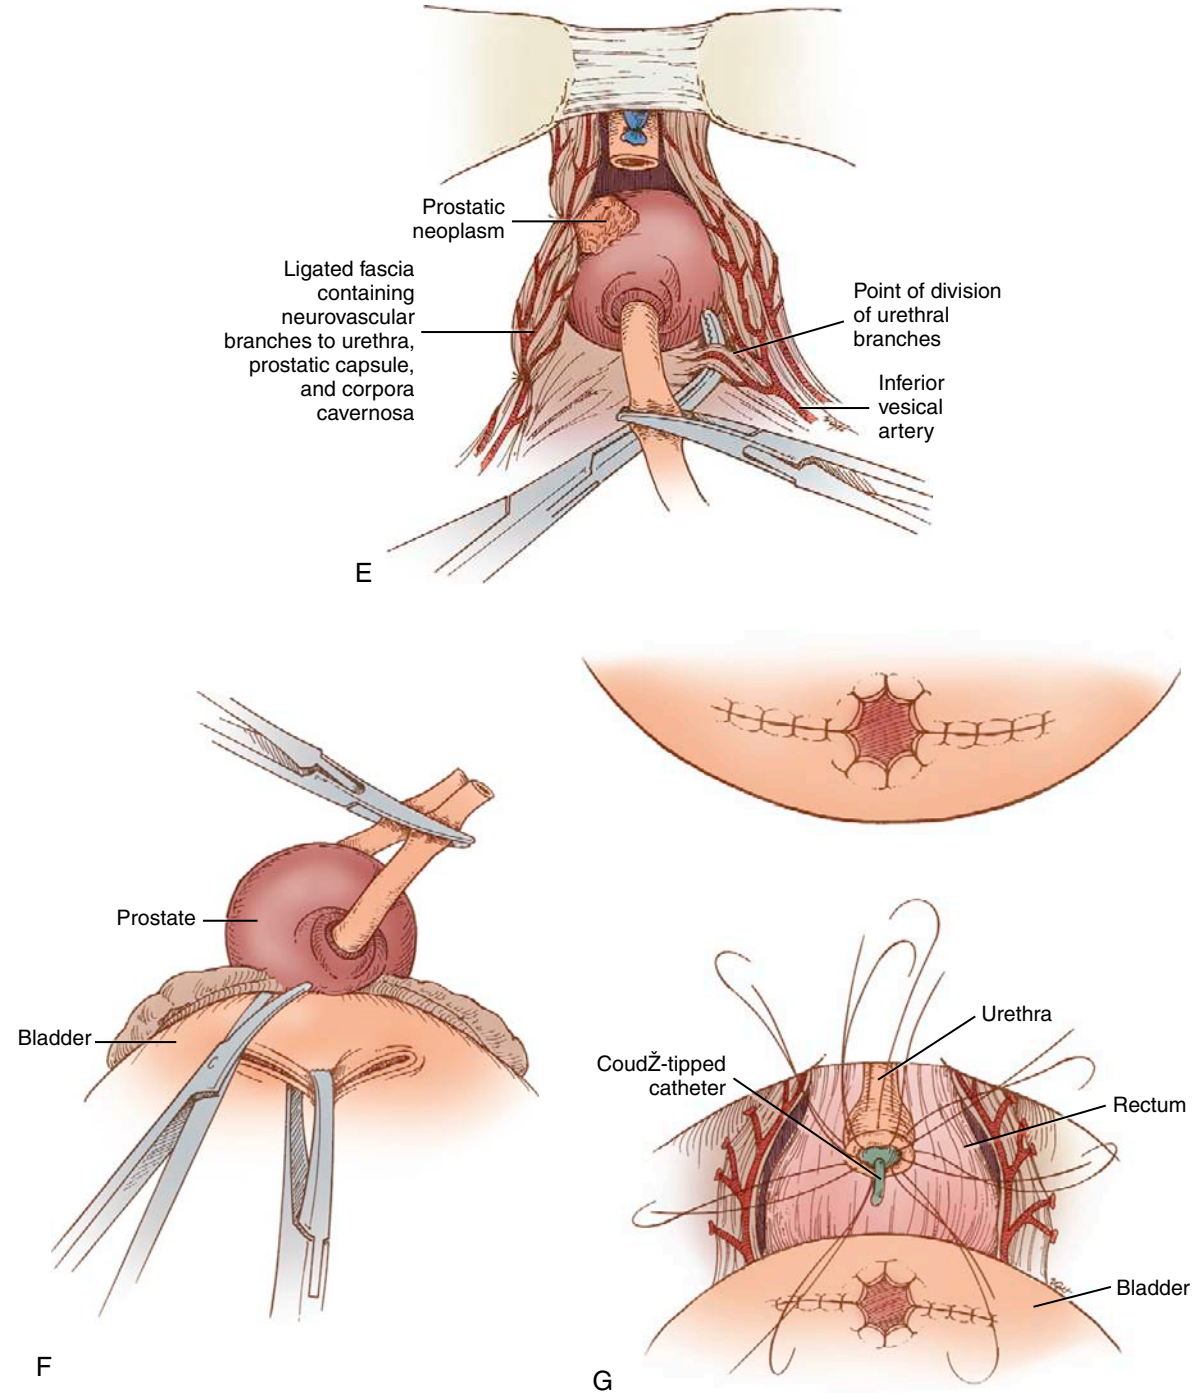

FIGURE 14-51, cont'd. Radical retropubic prostatectomy.

13. The surgeon trims and everts the bladder neck and creates a rosebud stoma. The sutures are placed from the urethra to a corresponding position on the bladder neck. When all are placed, they are brought together in single fashion and tied.
14. Closure is as for simple retropubic prostatectomy. Continuous postoperative irrigation is rarely used. A 22F, 30-ml Foley catheter is inserted and placed to gentle traction, and dressings are applied.

Radical (Total) Perineal Prostatectomy

Patient preparation and instrumentation are the same as for simple perineal prostatectomy. The radical approach is accompanied by laparoscopic or low abdominal lymph node dissection, if not previously performed as a separate procedure. Currently, laparoscopy is performed more frequently than the standard incisional approach. Supplies needed for laparoscopy include standard laparoscopic instrumentation, three 10-mm

trocars, one 5-mm trocar, an insufflation needle, a video camera unit, and CO_2 insufflation supplies.

Procedural Considerations. Two operative setups are necessary. Most commonly, laparoscopy precedes prostatectomy. The patient is in the supine position for the laparoscopy, with the area of the umbilicus slightly elevated. Sequential compressive stockings and preoperative Foley catheterization are necessary. Instruments should be available in the OR to convert to an open procedure if necessary. Lymph nodes may be sent for frozen section, primarily for tumor staging.

Operative Procedure

LAPAROSCOPIC LYMPH NODE DISSECTION

1. The surgeon inserts the Veress needle and insufflates the abdomen.
2. Trocars are placed as follows: 10-mm trocars at the 12 o'clock (umbilicus), 3 o'clock, and 9 o'clock positions; a 5-mm trocar at the 6 o'clock position.
3. The surgeon grasps the peritoneum over the vas deferens, and incises it with scissors. The vas is identified, clipped or electrocoagulated, and divided.
4. The peritoneal dissection is continued laterally and cephalad to the sigmoid colon on the left and the ascending colon on the right.
5. After identification of the spermatic cord structures, iliac vessels, ureters, and psoas muscle, the surgeon extends the incision to the pubic ramus.
6. The Cloquet node is identified and freed from under the external iliac vein.
7. Dissection continues until the obturator nerve is isolated.
8. At the level of the bifurcation of the common iliac vein, the large lymph channel is located and removed. Endoclips or scissor-coagulation may be employed. Clips offer a lower risk of postoperative lymphocele.
9. In a similar fashion, the tissue overlying the external iliac artery is removed.
10. The procedure is repeated on the opposite side.
11. Hemostasis is achieved and the trocars are removed. Each trocar is removed under direct observation with the laparoscope, to allow for identification of inner abdominal wall bleeding sites.
12. After evacuation of the gas from the abdomen, the fascia layers are closed at the 12, 3, and 9 o'clock positions.
13. The surgeon closes the skin with 4-0 absorbable subcuticular sutures and dresses the wound.
14. The patient is then repositioned and prepared for radical perineal prostatectomy.

RADICAL PERINEAL PROSTATECTOMY. Surgical approach is as for simple perineal prostatectomy (Figure 14-52).

1. The surgeon incises a layer of subcutaneous fascia and uses blunt dissection to create a space within the ischial rectal fossa (Figure 14-53, *A*).
2. The central tendon is incised, permitting dissection to be carried out beneath the triangle formed by the superficial external anal sphincter (Figure 14-53, *B*).
3. The assistant retracts the sphincter to provide visualization of the rectourethralis (Figure 14-53, *C*).
4. The true prostatic capsule is exposed by incision of the overlying fascia (Figure 14-53, *D*).
5. After dissection of the periprostatic fascia unilaterally, the surgeon passes a right-angled clamp around the membranous urethra and incises it (Figure 14-53, *E*).
6. Using a knife, the surgeon severs the posterior bladder neck and retracts the bladder superiorly (Figure 14-53, *F*).
7. Blunt dissection is used to develop a plane between the anterior bladder and the posterior prostate and seminal vesicles (Figure 14-53, *G*).
8. The surgeon identifies the vascular pedicles at the 5 and 7 o'clock positions, and incises and divides them (Figure 14-53, *H*).
9. Before closure of the bladder neck, the surgeon may place vest sutures of 0 or 2-0 absorbable material in a mattress fashion in the open bladder neck at the 2 and 10 o'clock positions and left long for later lateral perineal placement (Figure 14-53, *I*).

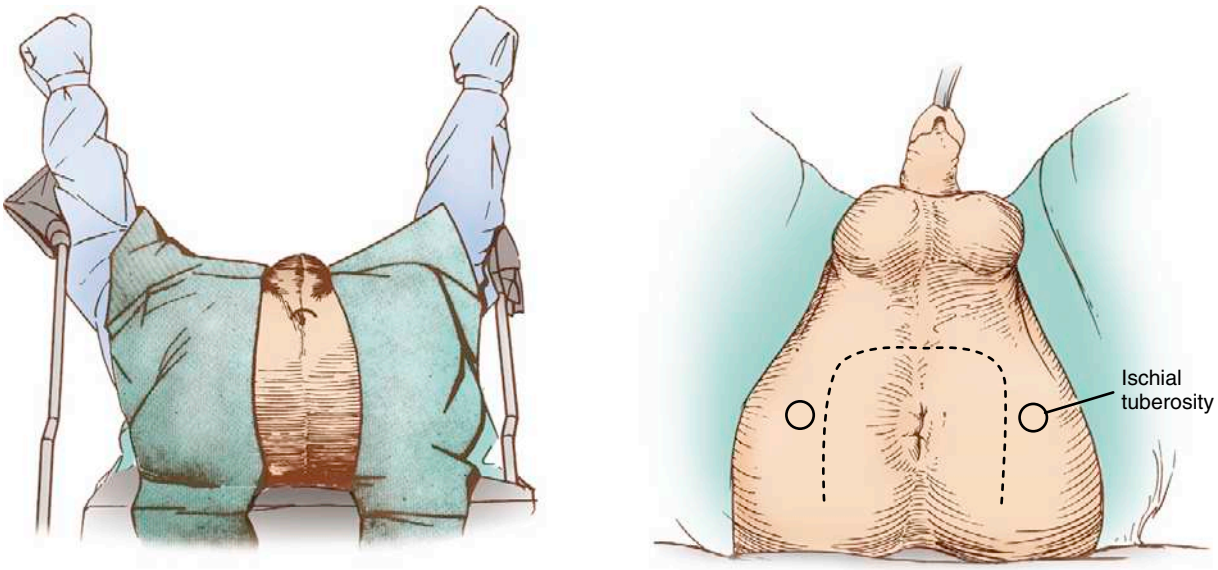

FIGURE 14-52 Radical perineal prostatectomy, draping and incision.

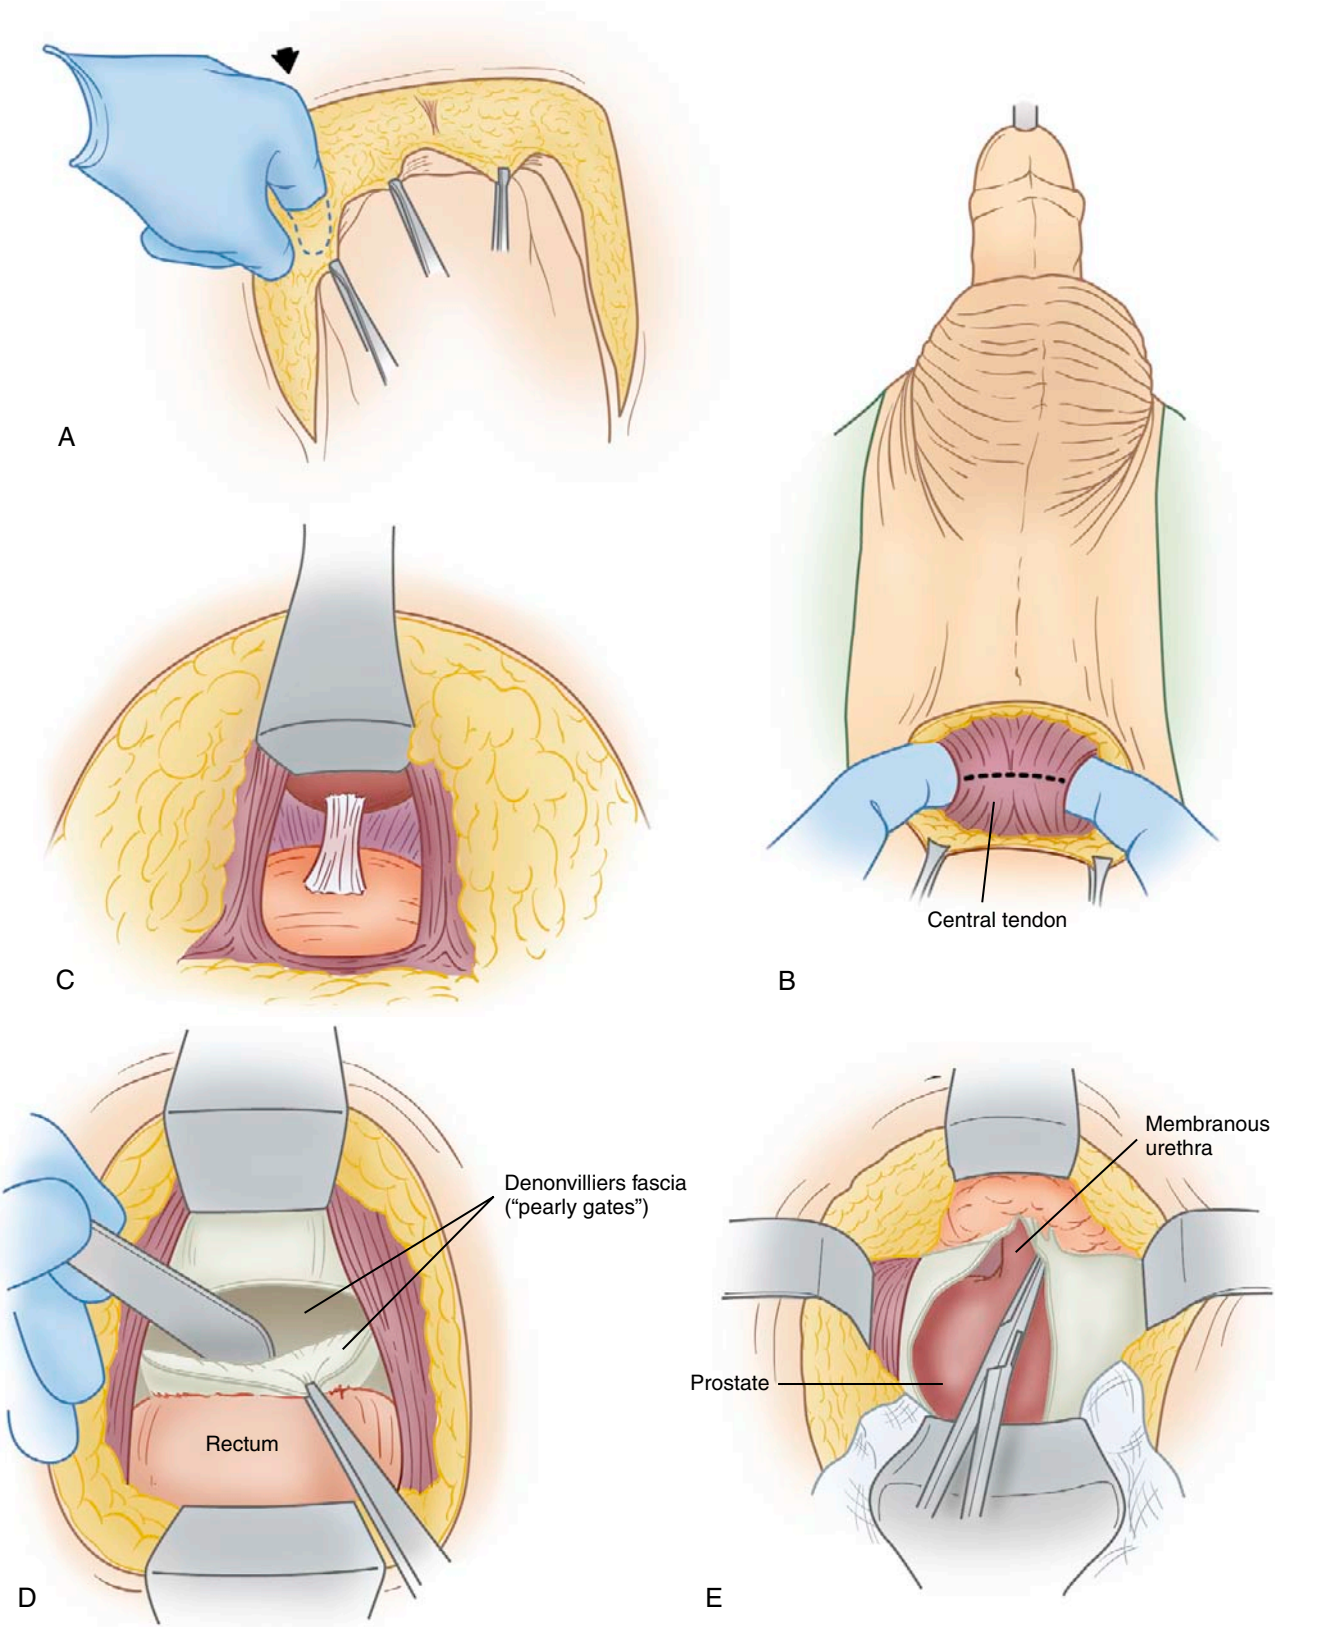

FIGURE 14-53 Radical perineal prostatectomy.

Continued

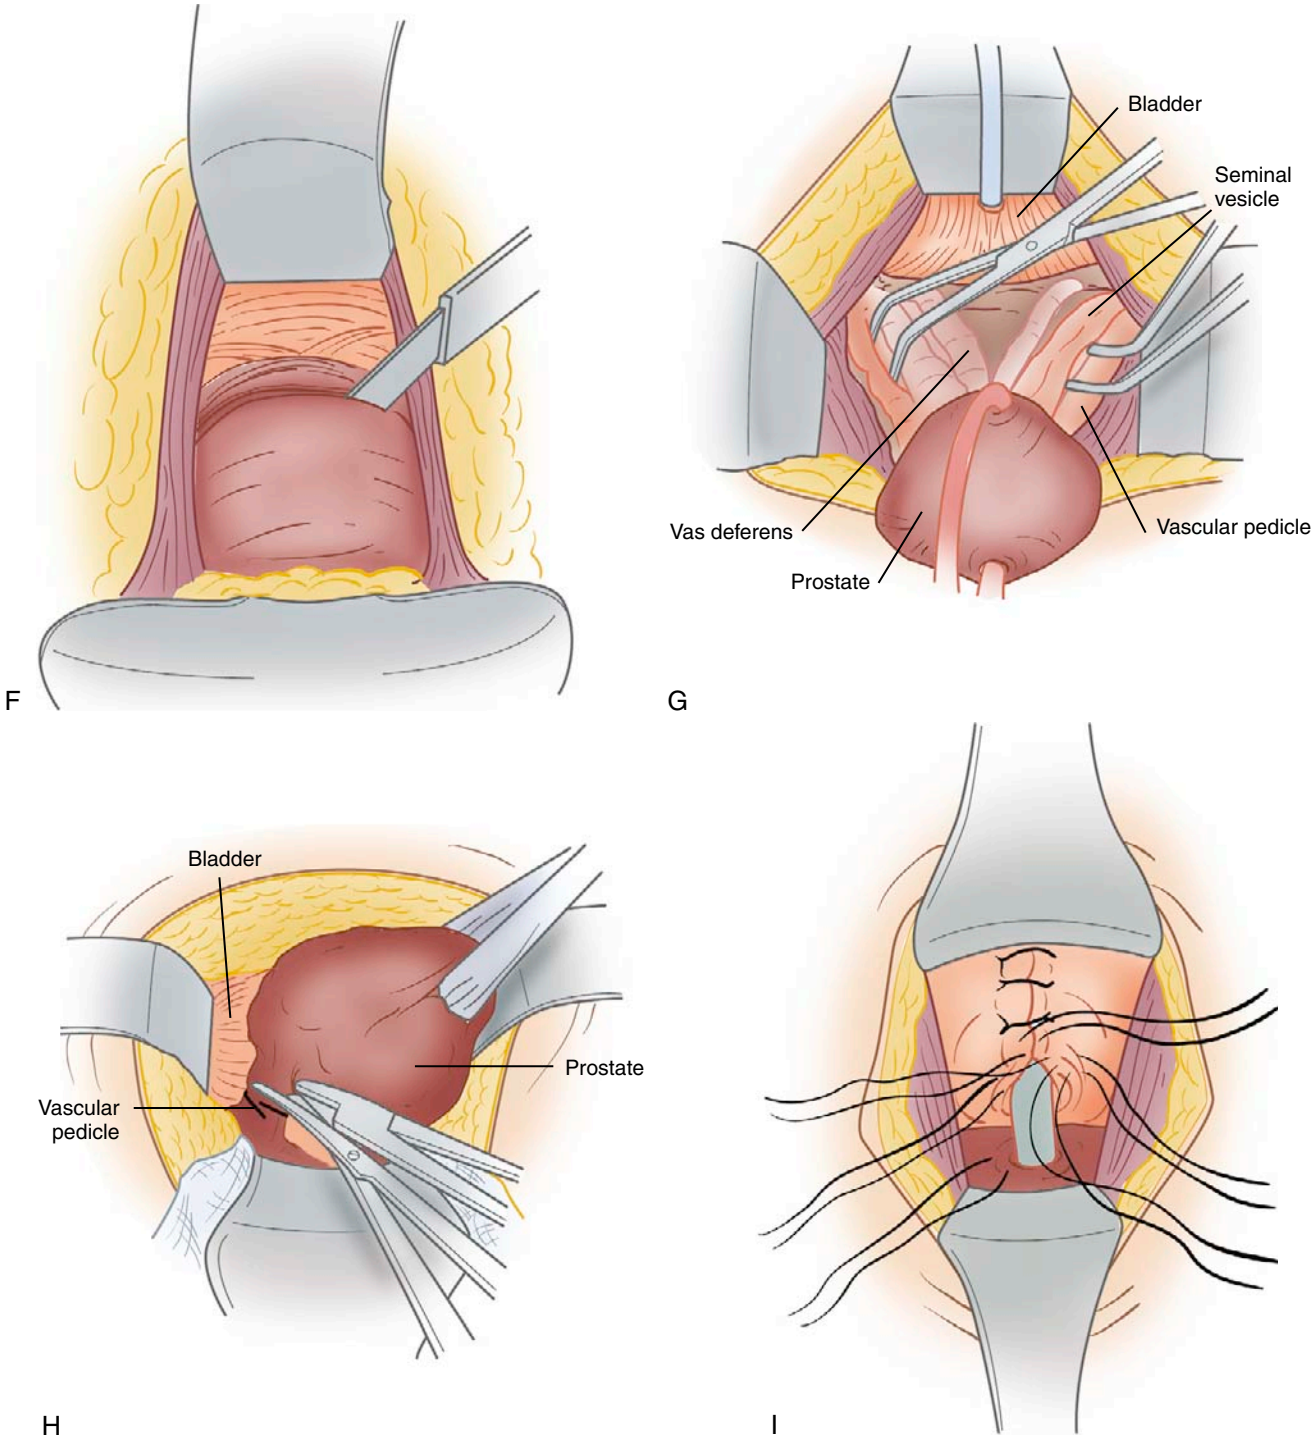

FIGURE 14-53, cont'd Radical perineal prostatectomy.

10. Once the reanastomosis is accomplished, the vest sutures are crossed, passed through the perineal body laterally and parallel to the urethra (anterior to the incision), and secured either just beneath the skin or to the skin with suture buttons.
11. After placement of the Foley catheter, the surgeon reanastomoses the urethra to the bladder neck with four to six 2-0 absorbable sutures placed at the 2, 4, 8, and 10 o'clock positions. Some surgeons opt to place sutures at the 6 and 12 o'clock positions as well.
12. A drain is placed anteriorly to the rectal surface and exteriorized through the incision line or through a separate stab wound.
13. The wound is closed as described in the simple procedure.

Laparoscopic Radical Prostatectomy

Laparoscopic radical prostatectomy (LRP) is a minimally invasive approach that may be offered to some patients in centers where practitioners are skilled in the technique. Patient

selection is the same as that for radical retropubic or perineal prostatectomy. Those patients who have undergone androgen deprivation, radiation, or perineal surgery may not be good candidates for the procedure, however. Advantages to an LRP over an open procedure are decreased intraoperative blood loss (attributable to the tamponade effect of the pneumoperitoneum on the venous sinuses, and improved access to and visualization of vascular structures), shorter hospital stays, and decreased postoperative pain. The return to continence and sexual potency is reported to be comparable with other approaches. Some practitioners suggest that retaining sexual potency is more likely because the neurovascular bundles may be visualized under magnification and therefore are more readily preserved (Gonzalgo, 2008). Because of the high cost of the numerous disposable items needed, many institutions may opt to not offer this approach to their patients.

Procedural Considerations. Generally no bowel prep is performed preoperatively. Intravenous administration of a third-generation cephalosporin and 2500 units of low–molecular weight subcutaneous heparin on the morning of surgery is standard treatment.

With the assistance of at least one additional person, the perioperative nurse positions the patient in low lithotomy position with his arms at the sides. The abdomen, entire perineal area, and the upper and inner thigh region are prepped. This entire area is draped open, and separate leggings are employed. The anesthesia provider places the patient in the Trendelenburg position. The perioperative nurse positions the video monitor between the patient's legs. A Foley catheter is inserted into the urethra and attached to drainage. After the procedure, heparin is given once daily for 2 weeks postoperatively. The drain and Foley catheter are generally removed on the third postoperative day, and the patient is discharged.

Operative Procedure

1. The surgeon inserts the Veress needle and insufflates the abdomen. Once an internal pressure of 15 mm Hg of CO_2 is achieved the needle is removed and replaced with a 10-mm trocar.
2. The laparoscope is used to inspect the interior of the abdominal wall. A second incision is then created at McBurney point, a 10-mm trocar is inserted, and the CO_2 line is moved and reattached to this port to prevent fogging of the lens.
3. Three small incisions are made for 5-mm trocar placement: one inferolateral to McBurney point, one in the left iliac fossa, and the third midline between the umbilicus and pubis.
4. If a lymph node dissection is to be performed, this is accomplished first as described in laparoscopic lymph node dissection.
5. The surgeon incises the peritoneal reflection to expose the vas deferens and seminal vesicles. The vasal artery is coagulated, and the vas is transected bilaterally. The seminal vesicles are transected bilaterally and well mobilized.
6. Denonvilliers' fascia is incised longitudinally close to the ampulla of the vas and seminal vesicles and placed on mild traction. Once the prerectal fat is visible, the surgeon begins inferior blunt dissection to the posterior surface of the prostate. Dissection is carried to the rectourethralis muscle.
7. The bladder is filled through the Foley catheter with approximately 120 ml of sterile saline to pull it posteriorly and help identify the bladder contours.
8. An incision is made medial to the medial umbilical ligament for the initiation of bladder dissection. This is carried to the vas and up the abdominal wall anteriorly and caudally until contact is made with the pubic ramus.
9. The urachus is divided in the midline and dissected to the level of the symphysis pubis, across the space of Retzius. A bipolar or monopolar dissector is often employed for this purpose.
10. After the bladder is freed anteriorly and laterally, the surgeon manually empties it with a suction or syringe device.
11. The surgeon coagulates and incises the dorsal vein. The fascia of Zuckerkandl (fat) covering the prostate is resected or pushed laterally cephalad. The periprostatic space is entered, and the endopelvic fascia is incised on its line of reflection.
12. The puboprostatic ligaments are incised to allow dissection of the dorsal venous complex. This is accomplished with a curved monopolar or bipolar scissors. The vessels surrounding the dorsal venous complex are electrocoagulated with bipolar forceps and then ligated with 2-0 absorbable ligature passed from one side to the other.
13. Using sharp and blunt dissection, the surgeon develops a plane between the bladder neck and prostate. The anterior wall of the urethra is incised, and the Foley catheter is deflated and pulled into the operative field. The lateral and posterior urethral walls are then incised.
14. The posterior bladder neck is finally incised and the retrovesical space entered. The prostatic pedicles are bilaterally electrocoagulated with bipolar forceps.
15. A lateral incision is made to expose and preserve the neurovascular bundles on each side. They are dissected free of the prostatic base to the entrance of the pelvic floor and posterolateral to the urethra.
16. The surgeon transects the dorsal vein complex and retracts it anteriorly to expose the anterior urethral wall. A knife is used to cut across the anterior urethra, and a urethral suture guide is pushed through the urethrotomy into the pelvis. The posterior wall is then transected.
17. The prostate is retracted superiorly and the remaining attachments freed.
18. The surgeon creates the urethrovesical anastomosis with interrupted 3-0 absorbable sutures using two needle holders. Once all sutures are placed and tied, the Foley is reinserted and the bladder filled to check the patency of the anastomosis.
19. A specimen collection bag is passed through the second port at McBurney point and opened. The prostate is placed in the sac, the sac is closed, and the string is cut. The port is removed and the string to the sac is placed on the abdomen outside the port, a mosquito clamp is attached to the end, and the port is reinserted.
20. Abdominal pressure is lowered to 5 mm Hg, and peritoneal incisions are left open. A drain is placed in the pelvis through the lower left port and sutured to the skin. The abdominal muscles are split, and the specimen is extracted after removal of the trocar. All trocars are then removed and the incisions closed in a routine manner.

Robotic-Assisted Laparoscopic Radical Prostatectomy

Robotic-assisted surgery uses robotic equipment to imitate the surgeon's movements, allowing for operative access through five small portal incisions rather than large incisions, which results in shorter recovery times. The robotic system enhances the surgeon's range of motion and precision and allows surgeons to preserve nerves crucial to urinary continence and erectile function. Benefits of robotic-assisted prostatectomy are similar to benefits of laparoscopic surgery. Patients have only five to six small incisions, a shorter hospital stay, decreased blood loss, and a shorter time period before the catheter is removed. Men who have undergone the procedure also have decreased incidence of postoperative urinary incontinence and improved sexual function compared to patients who undergo open prostatectomy (Gonzalgo, 2008).

The robotic surgical system consists of a surgeon console, a cart with interactive robotic arms, jointed instruments that mimic the dexterity of the human hand and wrist, and a high-resolution three-dimensional endoscope and image processing equipment. The system provides a three-dimensional stereoscopic display as the surgeon uses the master arms to make surgical movements that are translated into real-time movements of the instrument tips (Figure 14-54). The surgeon's movements are transferred to the robot 13,000 times per second (Rigdon, 2006).

The role of the perioperative nurse during robotic laparoscopic radical prostatectomy procedures begins with competency in the OR. Because use of this technology requires special skills, nurses should become familiar and proficient with all aspects of the procedure.

Procedural Considerations. Before the patient's arrival to the OR the perioperative nurse and surgical technologist collaborate to ensure all the necessary instrumentation and equipment is available for the procedure. Depending on the robotic system used, a standard laparoscopic setup is utilized with the addition of the robotic instrumentation and equipment, including the control station, the surgeon's console that provides the interface to the robot, and the robotic arms.

Patients undergoing robotic prostatectomy receive a general anesthetic. The perioperative nurse assists with positioning the patient in the supine position with his legs in Allen stirrups. Once the procedure begins, the anesthesia provider will place the patient in the Trendelenburg position to displace the viscera from the pelvis into the upper abdomen to improve visualization. Surgeons may use a transperitoneal or extraperitoneal approach to the prostatectomy. The transperitoneal approach is described in the next section.

Operative Procedure

1. The surgeon inserts a 22F Foley catheter and maintains it within the sterile field.
2. Pneumoperitoneum is established using either a Veress needle placed at the base of the umbilicus or an open trocar placement with a Hasson technique, depending on the surgeon's preference.
3. The surgeon inserts the 0-degree endoscope through the 12-mm cannula and places the remaining ports as described under direct vision: Two ports are inserted on each side of the pararectus and two additional ports are placed two to three fingerbreadths medial to the patient's right and left anterior superior iliac spine.
4. The sterile team docks the robot and the perioperative nurse transfers the cart with the robotic arms to the field and assists the surgical technologist with draping. The surgical technologist assists with connecting the robotic manipulators and other system components.
5. The surgeon moves to the console and the assistant remains in the sterile field to operate the clip applicator and suction devices.
6. From the remote location at the console, the surgeon incises the peritoneum over the vas deferens and divides them.
7. The seminal vesicles are dissected and the surgeon incises Denonvillier's fascia.
8. Using blunt dissection, the surgeon develops a plane between Denonvillier's fascia and the rectum. The surgeon identifies the endopelvic fascia, dissects it, and makes a bilateral incision.
9. The Foley catheter is removed and the assistant replaces it with a metal sound. Using a figure-of-eight 2-0 polyglactin suture, the surgeon suture-ligates the deep dorsal venous complex. The sound ensures that the urethra is not incorporated into the ligature (Figure 14-55).
10. Using ultrasonic shears or the monopolar ESU, the surgeon incises the anterior and posterior bladder neck. EndoClips are placed along the lateral pedicles as necessary for hemostasis.
11. Dissection continues along the lateral surface of the prostate and the neurovascular bundles are identified.
12. The surgeon divides the dorsal vein and divides the urethra distal to the apex of the prostate.
13. The gland is freed and placed in an entrapment bag.
14. Using a running or interrupted 2-0 polyglactin suture, the surgeon performs the urethrovesical anastomosis (Figure 14-56). The assistant fills the bladder with 100 to 150 ml of irrigant to test the anastomosis. Any visible leaks are repaired with additional suture.
15. A closed-suction drain is placed in the prevesical space.
16. The assistant extends the incision at the umbilical port site and removes the specimen.
17. The surgeon closes the port incisions.

SURGERY OF THE BLADDER

Operations on the urinary bladder may be performed through an open abdominal incision or a transurethral route. Diagnostic procedures are often undertaken via the transurethral route. Bladder tumors, diverticula, congenital defects, or trauma may necessitate an open abdominal approach. A thorough diagnostic workup and endoscopic examination help to determine the appropriate surgical approach to be employed. Radical procedures, such as total cystectomy, are performed for the treatment of invasive carcinoma of the bladder and require permanent urinary diversion.

For most open-bladder surgery the patient is placed in the supine position with a bolster under the pelvis. The Trendelenburg position may be desired because this position tilts the head down and allows the viscera to fall cephalad. This allows excellent exposure of the pelvic organs, including the bladder. The patient is draped as described for routine suprapubic prostatectomy, using a disposable impermeable drape that is placed immediately below the bladder incision. A catheter may be inserted into the urethra and the bladder distended with sterile saline at the start of surgery for easy identification. The ESU is required. The instrument setup for open-bladder operations requires a basic laparotomy set, plus Mason-Judd bladder retractors, long and short thyroid traction forceps, retropubic needle holders (or other long needle holders), one trocar, vessel loops, a catheter stylet, a closed-wound suction system, and assorted Foley, Pezzer, and Malecot catheters.

Suprapubic Cystostomy

Cystotomy is an opening made into the urinary bladder through a low abdominal incision. When a drainage tube is inserted into the bladder through an abdominal incision, the procedure is a cystostomy.

Procedural Considerations. The patient is in the supine position. Anesthesia may be general, spinal, or local with sedation. A basic laparotomy set is generally sufficient for the procedure. Foley catheters ranging from 22F to 30F should be available, as well as Malecot suprapubic catheters and a drainage bag. Frequently, a flexible cystoscopy is incorporated as part of the procedure.

Operative Procedure

1. After making a vertical or Pfannenstiel incision the surgeon divides the rectus fascia along the midline (Figure 14-57, *A*).
2. The bladder is distended with saline solution that is instilled with an Asepto syringe through a catheter.
3. The surgeon uses sharp and blunt dissection to dissect free the dome of the bladder (Figure 14-57, *B*).

4. Using a pair of Martius forceps, the surgeon grasps the walls of the bladder on either side of the midline (Figure 14-57, *C*).
5. Two traction sutures may be placed through the bladder wall and held with straight hemostats.
6. The surgeon incises the bladder downward with a scalpel. Bleeding vessels in the bladder wall are clamped and ligated.
7. The bladder contents are aspirated with a suction device.
8. The bladder opening may be extended if the bladder is to be explored for diverticula or calculi.
9. The surgeon inserts a large-size Malecot or Pezzer catheter into the bladder (Figure 14-57, *D*).
10. The incision is closed snugly about the catheter with absorbable sutures to render the closure watertight around the cystostomy tube.
11. The muscle, fascia, and subcutaneous tissue are closed with absorbable suture.
12. The surgeon closes the skin with staples or suture.
13. The cystostomy tube is secured to the skin with a 0 or 2-0 nonabsorbable suture to prevent it from being inadvertently dislodged from the bladder. A drain such as a Jackson-Pratt may be left in the prevesical space.
14. The wound is dressed, and the cystostomy tube is connected to a straight urinary drainage system.

Transurethral Resection of Bladder Tumors

Bladder lesions may be removed using a standard resectoscope, working element, loop, and a Foroblique telescope, which is passed through the urethra into the bladder. A 24F cystoscope sheath with a catheterizing bridge and biopsy forceps may be used to remove bladder tumors located at the very top or dome of the bladder (Figure 14-58). Transitional cell carcinoma of the bladder is one of the most difficult lesions to track because it can occur wherever there is transitional cell lining of the urinary tract. Bladder cancer has a tendency to recur in other areas of the bladder, even after complete resection of the original lesion.

Usually the surgeon removes not only the bladder lesion but also a portion of the bladder muscle underlying the lesion so that the pathologist can determine if any tumor has invaded the muscle. Random biopsy specimens of the normal bladder lining are also taken to ascertain if microscopic transitional cell carcinoma in situ is present. Lesions that deeply invade the muscle must be treated with an open surgical procedure, such as a partial cystectomy or total cystectomy.

The resection technique, setup, and preparation of the patient are virtually the same as those for TURP. The anesthesia provider administers a general, spinal, or regional anesthetic. A retrograde pyelogram may be done to check for lesions existing in the upper urinary tract.

Sterile water is recommended as an irrigating solution in transurethral resection of bladder tumors. Because few vessels are uncovered during this short resection procedure, water absorption with hemolysis and systemic complications such as hyponatremia do not occur. In addition, cancer cells released during the procedure tend to absorb water, causing them to rupture and lyse rather than remain viable and capable of implanting themselves into the raw surface of the bladder created by the surgery. When the procedure is completed, the

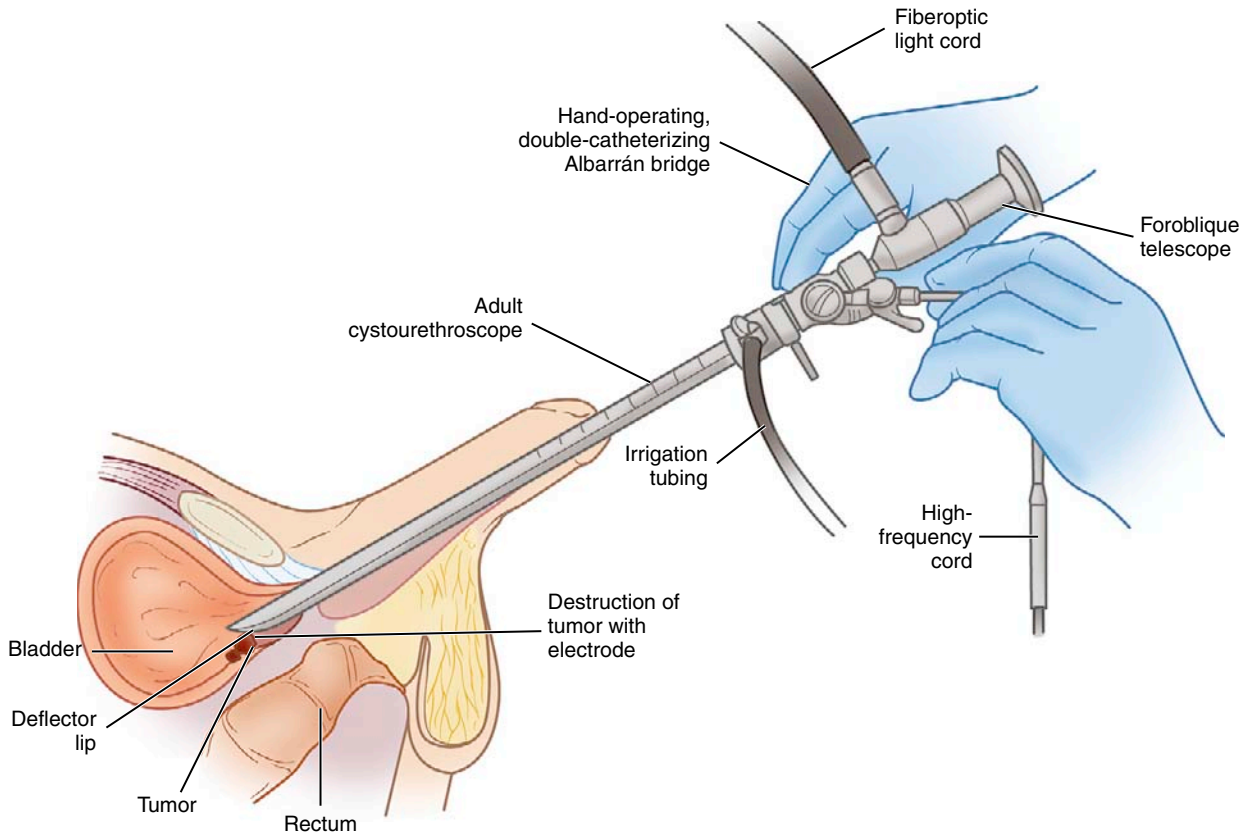

FIGURE 14-58 Laser fulguration.

surgeon passes a large catheter, usually a 24F, into the bladder and connects it to drainage.

Transurethral Laser Ablation of Bladder Tumors

The neodymium (Nd):YAG or holmium (Ho):YAG laser may be used to destroy small recurrent bladder tumors and to coagulate the tumor bed of larger bladder tumors resected with an electrosurgical loop. A powerful, highly focused beam of light in the near-infrared range is transmitted to the tumor site through a flexible glass fiber. This laser fiber is passed through the catheter channel of a cystoscope, and the fiber is directed by a deflecting laser bridge (Figure 14-59). The advantages of a laser in the eradication of bladder tumors are as follows: (1) bleeding is minimized, (2) only sedation is required, (3) the operating time is shortened, (4) there is minimal damage to healthy tissue, and (5) postoperative drainage of the bladder by a urethral catheter is not needed.

Alternatives to Surgery for Superficial Bladder Cancer

Patients with various types of cancer may be treated in the urology office setting with various therapeutic modalities including the instillation of chemotherapeutic solutions. These measures may be initiated instead of surgery or as an adjunct to surgery. Instillations are aimed at eradicating existing disease, reducing tumor recurrence and progression, and improving overall patient survival (Lamm et al, 2005).

Patients with bladder cancer that has been staged as Ta, carcinoma in situ (CIS), and T1 may be treated with intravesical, antineoplastic chemotherapy agents such as *thiotepa* (Thioplax), *mitomycin C* (Mutamycin), *doxorubicin* (Adriamycin), and *etoglucid* (Epodyl). Chemotherapy has become the treatment of choice for low-risk patients.

Immunotherapy with TheraCys or Tice *bacille Calmette-Guérin (BCG)* is used to treat patients considered to have high-risk tumors. BCG, through an unknown mechanism, strengthens the body's immune reaction to cancer and is considered the most effective therapy for recurrent and residual bladder cancer.

Combination chemotherapy and immunotherapy have become standard treatment for patients with metastatic transitional cell carcinoma. BCG has been combined with *mitomycin C* and with *interferon alfa-2b*. The latter combination has been highly effective, rescuing approximately 60% of those who failed with BCG alone (Lamm et al, 2005).

Trocar Cystostomy

Trocar cystostomy consists of draining the bladder by puncture with a needle or trocar and inserting a catheter.

Procedural Considerations. A minor instrument set along with a metal probe and grooved director, an Anthony suction tube and tubing, and trocar catheters or a prepackaged cystostomy kit is required. A local anesthetic may be used.

FIGURE 14-59 Rectoscope with bridge.

Operative Procedure

1. The surgeon nicks the skin at the site of the puncture with a scalpel and inserts the trocar into the bladder.
2. The trocar obturator is withdrawn, the bladder is drained through the trocar by suction, and a catheter is passed through the trocar cannula into the bladder.
3. The surgeon removes the cannula and sutures the catheter to the wound edges. The wound is dressed.

Suprapubic Cystolithotomy

Suprapubic cystolithotomy is the removal of calculi from the bladder. Obstructions, such as prostatic enlargement or foreign bodies, are common causes of bladder calculi and may be corrected at the time of surgery. In the past, special transurethral instruments such as the lithotrite were commonly used to crush vesical calculi manually. Bladder stones are often eradicated via the electrohydraulic lithotripter, which fragments the stone within the bladder by using an electric current to initiate shock waves (Figure 14-60, *A*), or by ultrasonic lithotripsy.

During ultrasonic lithotripsy ultrasound waves are transmitted through a hollow metal probe, which creates vibration at the tip. When applied to the surface of a calculus, the vibrating tip drills and fragments the calculus. This mechanical disintegration is continued until the stone is reduced to small fragments that are evacuated by suction through the hollow center of the probe (Figure 14-60, *B*). The holmium:YAG laser (Ho:YAG) may also be used for fragmentation of bladder calculi (Figure 14-61).

Procedural Considerations. Instruments for open-bladder operations along with Millin T-shaped stone forceps, Millin capsule forceps, and Lewkowitz lithotomy forceps are required.

Operative Procedure. The surgical approach is similar to that described for suprapubic cystotomy. When the bladder is opened, calculi are identified and extracted. If indicated, bladder outlet obstruction is repaired.

Repair of Vesical Fistulas

Vesical fistulas occurring between the bladder and the intestines or vagina may be repaired surgically. *Vesicointestinal fistulas* may be caused by ulcerative colitis, diverticulitis, or neoplasms of the colon or rectum. *Vesicovaginal fistulas* may be a complication of radiotherapy for cervical cancer, endoscopic procedures involving surgery of the trigone or vesical neck, obstetric injuries, and hysterectomies.

Procedural Considerations. The instrument setup is as described for open-bladder operations. Intestinal instruments (Chapter 10) are necessary for vesicointestinal fistulas. For vesicovaginal fistulas, vaginal preparation and a colporrhaphy set (Chapter 13) with colostomy or ileostomy instruments are used.

Vesicointestinal fistulas are more common than vesicovaginal fistulas. Of the intestinal fistulas, the sigmoid colon is most often involved (Figure 14-62). A colostomy proximal to the fistula may be performed to protect the repaired segment of bowel. The communicating area of bladder and bowel is totally resected. Generally, an end-to-end bowel resection is performed

FIGURE 14-60 **A**, Electrohydraulic lithotripter. **B**, Ultrasonic lithotripter.

FIGURE 14-61 Holmium laser unit.

after excision of the involved intestinal segment. The bladder is then repaired in three layers.

If the fistula is at the dome of the bladder, the approach will be transperitoneal, transvesical, or a combination of the two. If the fistula is in the trigone of the bladder, a vaginal approach may be employed. A suprapubic tube is usually left in the bladder.

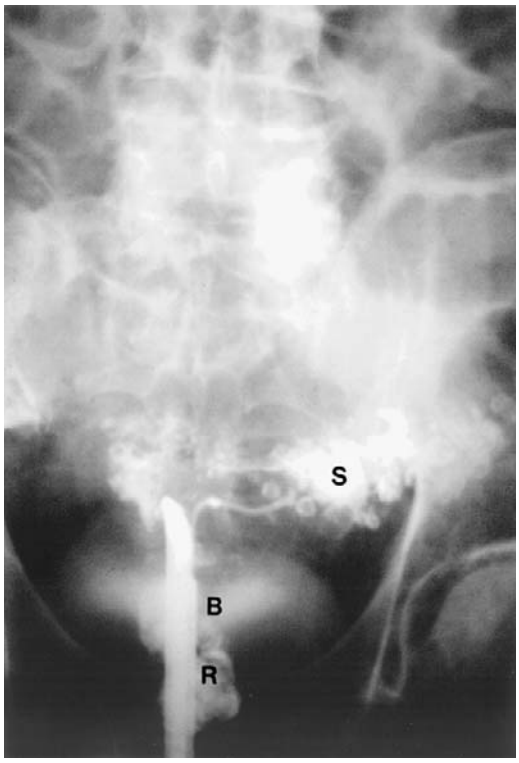

FIGURE 14-62 Vesicoenteric fistulogram (cystogram) showing contrast material in bladder *(B)*, sigmoid colon *(S)*, and rectum *(R)*.

Operative Procedure

VESICOVAGINAL FISTULA REPAIR—VAGINAL APPROACH

1. Before placing the patient in the hyperflexed lithotomy or Kraske position (jackknife), the surgeon inserts a suprapubic catheter, clamps it, and connects it to closed drainage. If the intended position is Kraske, separate draping material and instrumentation are set up for the suprapubic catheter insertion with the patient supine. The catheter is secured, and the patient is turned for the procedure.
2. The area is draped with a lithotomy or laparotomy sheet as indicated per the patient's position.
3. The surgeon sutures the labia to the outer groin or inner thigh for retraction and visualization.
4. A weighted vaginal retractor is placed posteriorly, and the defect is examined. A relaxing vaginal incision may be necessary at the 5 or 7 o'clock position.
5. The surgeon inserts a 4F ureteral catheter through the fistula, and dilates the tract to admit an 8F balloon catheter. The balloon is inflated, and the catheter is used as a retractor.
6. The area is infiltrated with vasopressin (Pitressin) solution.
7. The surgeon incises the vaginal mucosa and perivesical fascia around the defect outside of the scarred tissue.
8. Two planes are developed—one between the mucosa and fascia and one between the fascia and the bladder wall—with fine scissors, forceps, and gauze (Kittner) dissectors.
9. The bladder wall is freed from the vaginal wall.
10. The vesical defect is grasped with Martius clamps, the scarred edges are everted, and the defect is closed vertically with interrupted 3-0 absorbable sutures after removal of the catheter previously placed. In some instances,

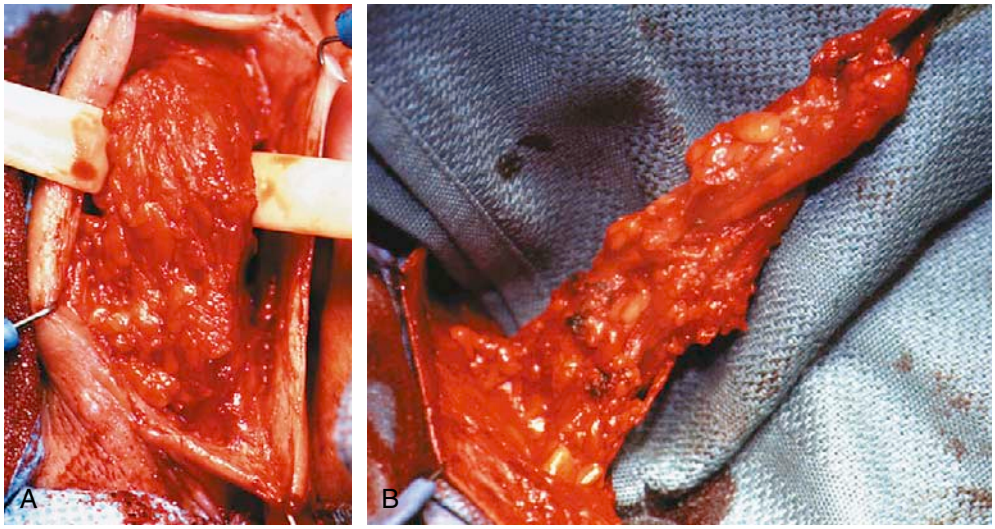

FIGURE 14-63 Creation of Martius flap.

a labial pedicle or full-thickness flap (Martius flap) may be placed between the vesical closure and the vaginal closure (Figure 14-63). This prevents suture-line stress and overlay and removes the need for a relaxing incision. Larger fistulas that do not adequately reapproximate may necessitate a vascularized muscle flap to reinforce closure.

11. The surgeon approximates the perivesical fascia and vaginal mucosa separately with transverse interrupted 3-0 absorbable sutures. A one-sided ellipse of vaginal mucosa may be excised to offset the closure.
12. Alternatively, an inverted-U incision may provide more exposure than other incisions and result in a posterior flap that completely covers the site of the defect.
13. The surgeon unclamps the suprapubic catheter, removes the labial stitches, and loosely packs the vagina.

VESICOVAGINAL FISTULA—TRANSPERITONEAL (TRANSVESICAL) APPROACH

1. The patient is placed in the low lithotomy and moderate Trendelenburg's position. Both the perineum and the abdomen are prepped and draped appropriately. A laparoscopy pack works well for this approach.
2. The surgeon inserts ureteral catheters and places a 16F Foley catheter in the bladder and clamps it.
3. A tight gauze pack or vaginal ball is placed into the vagina.
4. The surgeon makes a vertical midline or Pfannenstiel incision.
5. The peritoneum is incised and bluntly dissected from the dome of the bladder.
6. The small bowel is packed cephalad.
7. Stay sutures of 2-0 absorbable material are placed in the bladder dome, and the bladder is opened.
8. The surgeon divides the bladder wall and overlying peritoneum down to the fistula. Stay sutures are placed periodically to serve as retractors for bladder elevation.
9. The peritoneum is incised transversely at the level of the fistula, forming a pedicle flap.
10. The vagina and bladder are separated widely on each side of the fistula. An assistant places upward pressure on the vaginal ball or pack to facilitate dissection.
11. As the fistula is exposed, the surgeon excises it until it is completely removed. A probe may be used to localize it, if small, or an 8F balloon catheter may be inserted and used for traction during dissection.
12. The bladder and vagina are freed from each other until there is enough mobility for separate closures.
13. The surgeon closes the vagina, without tension, with inverting 2-0 or 3-0 interrupted sutures in two layers.
14. The peritoneal flap is swung into the defect and sutured in place for reperitonealization. A long, attached peritoneal or free peritoneal pedicle flap may be needed for reperitonealization. Alternatively, the omentum may be manipulated from behind the right side of the colon for an omental graft. A vascularized muscle flap may be placed for fistulas resulting from radiation necrosis.
15. A 22F Malecot catheter and a wound drain are inserted and pulled through separate stab wounds in the abdomen.
16. The ureteral catheters are removed, and the bladder mucosa and submucosa are closed in separate layers with 2-0 or 3-0 absorbable suture in a running fashion.
17. The muscularis and adventitia are externally approximated with interrupted 3-0 sutures.
18. The wound is closed in layers.
19. Dressings are applied, the Foley is unclamped, the vaginal ball or gauze pack is removed, and the vagina is loosely repacked.

VESICOSIGMOID FISTULA REPAIR—ABDOMINAL APPROACH

1. With the patient in the Trendelenburg position, a 20F or 22F, 5-ml Foley catheter is inserted and the bladder filled with 100 ml of sterile water. Once the patient is prepped and draped as described for laparotomy, a midline, or paramedian, and transperitoneal incisions are made.
2. The surgeon explores the abdomen.
3. The descending colon and sigmoid colon are mobilized by incising along the fascia fusion line of Toldt.
4. The involved loop of colon is identified. If a walled-off inflammatory mass is found, a transverse colostomy may be performed and a two-stage intervention considered.
5. Using blunt dissection, the surgeon separates the fistulous tract.
6. A probe is inserted to determine the extent of involvement.

7. The defects in the bladder and bowel are debrided to obtain healthy tissue. Large inflammatory masses require a colon resection.
8. The surgeon closes the bladder in two layers with a 3-0 absorbable submucosal running stitch and a 2-0 absorbable interrupted muscularis and adventitial stitch.
9. The edges of the bowel defect are trimmed to reach normal tissue, and stay sutures are placed on each side.
10. The cavity is pulled transversely, and the mucosa and submucosa are closed in one pass with a Connell stitch of 3-0 chromic catgut.
11. The surgeon approximates and closes the muscularis and serosa in one pass with 4-0 silk Lembert sutures.
12. The abdomen is irrigated with 2000 ml of sterile saline with an attempt to reach all areas.
13. A sump-style drain is placed intraperitoneally, and a Penrose or small Jackson-Pratt drain is placed suprapubically, exiting through separate stab wounds.
14. The surgeon closes the abdomen in layers in the conventional manner. If a colostomy was performed, it is opened for fecal diversion and the appropriate appliance applied.
15. Gauze and bulky absorbable dressings are applied and secured; Montgomery straps may be used.

Vesicourethral (Marshall-Marchetti-Krantz) Suspension

A Marshall-Marchetti-Krantz suspension is performed for the correction of stress incontinence caused by an abnormal urethrovesical angle. The intent of the Marshall-Marchetti-Krantz operation is to bring the bladder and urethra into the pelvis by suturing paraurethral vaginal tissue to the back of the symphysis pubis. A modification of this technique is the Burch procedure. The approach mimics the Marshall-Marchetti-Krantz until placement of the buttressing sutures. Instead of attempting difficult periosteal sutures, the surgeon places nonabsorbable size 0 sutures into the Cooper ligament from each side of the bladder neck. The Burch procedure is technically easier, and long-term results are fairly equivalent.

A large percentage of patients with stress incontinence are obese and have diabetes. It is important to evaluate for these conditions and prepare for proper patient management (i.e., positioning concerns relating to peripheral vascular circulation and pressure points, skin breakdown, risk for infection, wound healing).

Procedural Considerations. The patient is usually placed in a moderate Trendelenburg's position, frog-legged, with supports under each knee to allow for intraoperative vaginal manipulation. Abdominal and vaginal preps are required. A Foley catheter is inserted at the beginning of surgery. Both the surgeon and assistant double-glove for vaginal manipulation. Basic laparotomy and abdominal hysterectomy instruments (see Chapter 13), if needed, are used. Postoperatively, the patient commonly has a vaginal pack, a urethral catheter with or without a suprapubic catheter, and possibly a wound drain.

Operative Procedure

1. The surgeon makes a suprapubic transverse incision and exposes the prevesical space of Retzius.
2. The bladder retractor is positioned with small, moist laparotomy packs in place.
3. Using blunt dissection, the surgeon frees the bladder and urethra from the posterior surface of the rectus muscle and symphysis pubis.
4. The assistant places two fingers into the vagina, lifting the urethra upward against the symphysis pubis to facilitate ease of repair of the periurethral musculofascial structures.
5. A heavy, nonabsorbable atraumatic suture on a Heaney needle holder is placed through the supporting fascia of the vaginal wall on each side of the urethra. The suture is passed through the symphysis pubis, providing support to the urethra and bladder neck. Generally, a row of three heavy, nonabsorbable sutures is placed on each side of the urethra, the most proximal being located just at the vesical neck.
6. The surgeon closes the wound in layers.
7. The vagina may be packed with 2-inch packing, which is removed after 24 to 36 hours.

TVT Sling (Tension-Free Vaginal Tape)

A TVT sling is indicated for women diagnosed with urethral hypermobility, intrinsic sphincter deficiency, and pure stress incontinence caused by pelvic floor relaxation. It will not correct urge incontinence, although it may be used in women with combination stress and urge incontinence. This patient will need to have her urge incontinence controlled in another manner. It appears to be a viable option for the overweight and older female and for women who have had previous corrective measures that failed. It is not recommended for younger women who are pregnant or intend to become pregnant. Other contraindications include patients with intrinsic bleeding problems or who are receiving anticoagulant therapy. Risks include bladder perforation, perforation of pelvic viscera adherent to the pubis, retropubic hemorrhage and hematoma formation, infection, and urinary retention.

The tape is composed of polypropylene mesh (Figure 14-64) encased in a plastic sleeve that has a center slit and is secured to a large, curved trocar needle at each end. A T-shaped introducer is attached to these needles for passage of the sling material. The mesh is passed through the pelvic tissue and positioned under the urethra, creating a supportive sling. Unlike other corrective procedures for incontinence, no screws, anchors, or internal sutures are required.

Procedural Considerations. The procedure may be performed using a local anesthetic with monitored sedation. After the sedation is administered, the perioperative nurse places the patient in the lithotomy position.

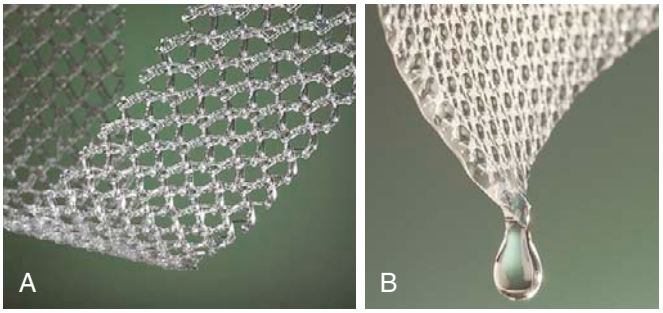

FIGURE 14-64 **A**, Uretex self-anchoring urethral support system. **B**, Pelvitex polypropylene mesh.

Operative Procedure

1. A 16F or 18F Foley catheter is inserted to drain the bladder.
2. The surgeon injects local anesthetic through the skin and into the muscle and fascia lateral to the midline and just above the symphysis pubis, bilaterally. Vasopressin (Pitressin) is commonly added to the anesthetic to help control bleeding.
3. Additional local anesthetic is injected suburethrally into the anterior vaginal mucosa to the retropubic space, bilaterally.
4. The surgeon performs a cystoscopy to confirm integrity of the bladder wall, urethral patency and length, and location of the ureters.
5. Two incisions, 0.5 to 1 cm in length, are made in the abdominal skin over each injection site.
6. The surgeon places a weighted speculum in the vagina, and grasps the anterior vaginal mucosa with two Allis clamps.
7. Using a #10 or #15 scalpel the surgeon makes a 1.5-cm incision into the anterior vaginal mucosa, 1 cm to the right of the external meatus.
8. Blunt Metzenbaum scissors are used to dissect suburethrally and periurethrally to the level of the endopelvic fascia.
9. The surgeon inserts a rigid stylet into the Foley catheter, and inserts the catheter into the bladder.
10. The bladder neck and urethra are deflected away to allow passage of the first needle by holding the Foley with its stylet against the inner ipsilateral thigh. An Allis clamp or hemostat may be placed in the center of the sling material to prevent twisting of the mesh or its sleeve.
11. After attaching the introducer, the first needle is passed 1 cm lateral to the urethra with the curve of the needle in the palm of the surgeon's hand. The needle penetrates the urogenital diaphragm behind the symphysis pubis.
12. Two fingers of the other hand are placed over the skin incision, the needle is pushed through the retropubic space, and the introducer is removed. The needle is guided up to partially protrude through the abdominal wall.
13. Before the trocar needle is extracted and removed, the surgeon removes the Foley and performs a cystoscopy. When bladder integrity has been confirmed, the first needle may be brought out through the abdominal wall and cut from the sling material, and a hemostat is attached to the mesh and sleeve.
14. The procedure is then repeated on the other side with the Foley directed toward the ipsilateral inner thigh during insertion and passage of the needle.
15. Once the tape is in place, the surgeon positions an 8F Hegar dilator between the tape and the urethra for tension testing. The patient is asked to cough, and the tape is adjusted until there is no leak or only a few drops of fluid are lost during coughing. The plastic sleeves are then removed by pulling them up through the abdominal incisions. The excess mesh that protrudes is cut at the skin surface.
16. The surgeon closes the vaginal mucosa with a running stitch of 2-0 chromic suture. Wound closure strips or skin sutures are used to close the abdominal incisions.
17. A perineal pad may be placed to absorb any vaginal bleeding. Abdominal dressings are applied at the surgeon's discretion. Vaginal packing and a postoperative Foley catheter are usually not necessary.

Transvaginal Sling with Bone Anchor

Indications and contraindications for this procedure are the same as those for the TVT sling procedure. In addition, the patient with severe osteoporosis may not be a good candidate for this technique because the bone anchors may not integrate into the pubic bone properly.

Risks with this technique include bladder perforation, inadequate fixation of the bone anchor (this generally requires abandoning the method and using a different type of sling approach), urinary retention, pain, osteitis pubis or osteomyelitis of the pubic bone, and recurrent incontinence.

Procedural Considerations. The procedure may be performed using a local anesthetic with monitored sedation. After the sedation is administered, the perioperative nurse places the patient in the lithotomy position. A formal incision may not be necessary for this procedure.

Operative Procedure

1. Before the procedure the surgical technologist loads a bone screw with preloaded #1 polypropylene suture onto the bone drill. A plastic cover fits over the screw, protecting the patient during insertion.
2. A Foley catheter is inserted, the bladder drained, and the catheter clamped.
3. The surgeon places Allis clamps on the mucosa and pulls gently upward to expose the anterior vaginal wall.
4. Tension is put on the polypropylene stitch that protrudes through the handle of the bone drill. The surgeon inserts the drill into the vagina in a line parallel to the plane of the symphysis pubis, and holds the drill head against the pubic bone (Figure 14-65).
5. Insertion is complete when the polypropylene stitch stops rotating. Fixation of the screw is tested with a gentle downward tug on the suture. The bone screws should lie lateral to the symphysis pubis in the posterior midthird of the pubic bone.
6. The Foley is opened and drained. If the urine is bloody a cystoscopy is performed. Some surgeons choose to routinely perform cystoscopy after each screw insertion to evaluate bladder patency.
7. A right-angle clamp is employed to follow the tunnel of the polypropylene suture upward. A small puncture is created in the urethropelvic ligament to allow passage of the sling material into the retropubic space. The sling material may be cadaveric fascia or polypropylene mesh.
8. The surgeon creates a 2-cm tunnel between the midurethra and bladder neck, behind the vaginal wall.
9. The sling material is perforated with a Keith needle, and the polypropylene suture is passed through the eye of the needle. The suture is then transferred to the sling material. This is done twice on each end of the material.
10. The material is passed through the tunnel (Figure 14-66).
11. Following cystoscopy, steps 4 through 6 are repeated on the contralateral vaginal wall. The polypropylene sutures are tied individually so that the material lies in close proximity to the pubic bone.
12. The vagina is sutured on each side with a single stitch of absorbable 2-0 sutures.

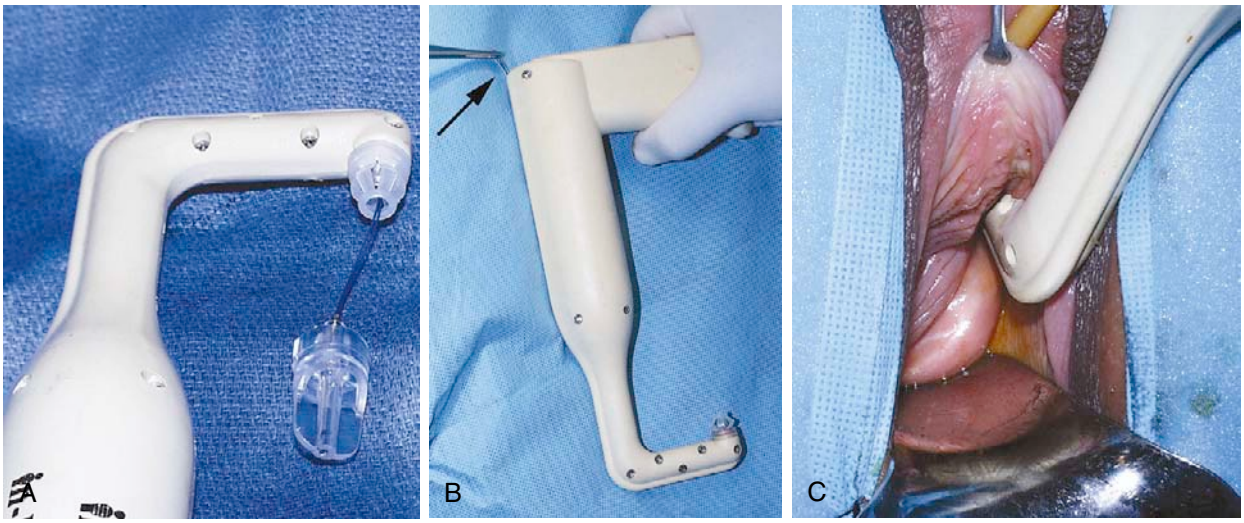

FIGURE 14-65 A, Bone anchor on bone drill with #1 polypropylene. B, Bone drill ready; polypropylene extends out handle. C, Bone drill in place.

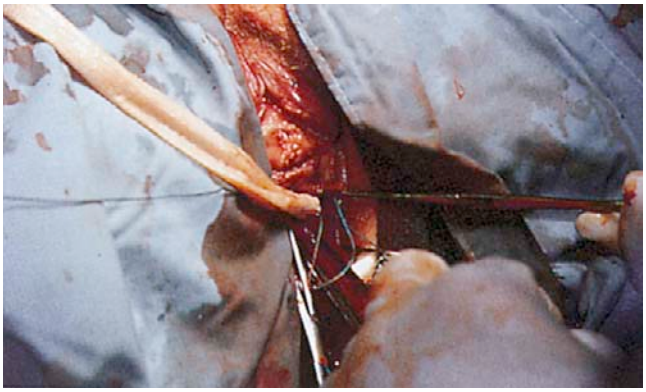

FIGURE 14-66 Fascia lata graft being placed for suburethral sling procedure.

13. A vaginal pack soaked in antibiotic or estrogen cream is inserted. The Foley catheter is drained and attached to a closed drainage system.

Implantation of InterStim Sacral Nerve Stimulator (Neuromodulator)

The InterStim System is indicated for the treatment of urinary urge incontinence, urinary retention, and significant urgency-frequency in patients who have failed or could not tolerate other measures (Sherman and Amundsen, 2007). The procedure is performed in two stages. During the first stage, a lead is implanted and connected to an external stimulator. The patient is discharged and undergoes a trial period that lasts from 2 to 4 weeks to determine if the device will be effective. During this trial period, the patient maintains a diary to track symptoms and post void residuals. If the trial is successful, the patient will return for the subcutaneous implantation of a pulse generator.

Some precautions must be taken by the patient who has had this device implanted. MRI studies are not recommended. Caution should be taken and the device turned off if electrocoagulation will be employed during any future surgery the patient might undergo. Female patients should be instructed to carry their purses on the opposite side of the implant.

Procedural Considerations. The perioperative nurse assists with positioning the patient in the prone position with a 30-degree flexion at the hips. Pillows may be placed under the patient's abdomen to support the lumbar area and decrease lordosis. Pillows are also placed under the ankles to elevate the feet and prevent pressure on the toes.

C-arm fluoroscopy is employed to visualize sacral landmarks and verify lead position intraoperatively. Although general anesthesia may be employed, monitored sedation with a local anesthetic is preferable so that the patient may verbally respond to nerve stimuli during the procedure. It is suggested that no IV muscle relaxants be administered, because this will affect the physiologic response to the stimulator. If electrocoagulation is needed, a bipolar system should be employed, because unipolar current could potentially travel into the sacral foramen. The patient is typically discharged from the hospital on the same day.

The nurse preps the patient's sacral area, buttocks, and perineum and applies the test stimulation ground pad to the patient's heel. An alternative to this placement is the calf or skin below the rib cage or iliac crest. The pad is approximately 5 to 8 cm in size. The pad will be attached by a test stimulation cable to the external stimulator. The patient is draped to expose the entire buttock area so that responses to nerve stimulation may be assessed. The feet and lower legs are also exposed to allow visualization of muscle response.

The surgeon locates and marks the sacral outline, S3 foramen, posterior iliac spine, coccygeal tip, and midline. To locate these landmarks, the surgeon palpates the upper border of the greater sciatic notch. The S3 sacral foramen is approximately one fingerbreadth from the midline whereas the S2 and S4 foramina are one fingerbreadth above and below S3. The sacral crest corresponds to S4, and the S3 foramen is 9 cm above the coccygeal tip and 2 cm from the midline.

Operative Procedure

1. The surgeon inserts the needle into the S3 foramen. The external stimulator is activated to confirm correct placement of the needle. A bellows response (flattening of the perineum) and flexion of the great toe indicate the needle is in the S3 foramen.
2. The guidewire is inserted into the foramen needle.
3. A 5-mm stab wound is created for the lead introducer.
4. The surgeon slides the lead introducer, consisting of dilator and sheath, over the guidewire and advances it into the foramen. The depth marker on the directional guide is aligned with the top of the dilator.
5. The dilator is then removed, and the sheath remains in place.
6. The surgeon inserts the tined lead, with its stylet (Figure 14-67), and passes it through the sheath until the second white marker is aligned with the back of the sheath. The four electrodes on the lead are now exposed and visible on fluoroscopy.
7. Nerve responses are again assessed at this time by connecting the mini-J hook on the patient cable to the uninsulated section of the foramen needle. The electrodes are numbered zero to three, and the connector contacts on the needle correspond to these numbers. Beginning at the distal tip of the needle, all four electrodes are tested. The lead is repositioned according to the verbalized and visualized responses of the patient. The foramen producing the best results is chosen.
8. Once the electrodes are in optimal position the lead body proximal to the sheath is held in place and the sheath is slowly backed out of the wound. This is often accomplished under live fluoroscopy.
9. As the sheath is withdrawn the tines on the lead open, anchoring it in place.
10. The surgeon creates a tunnel for the subcutaneous neurostimulator generator pocket by means of the same incision. Placement is in the upper buttock below the beltline.
11. A pocket is created with the bipolar ESU. The pocket depth should not be greater than 4 cm to avoid interference with programming and shifting of the neurostimulator. The ideal pocket is 3 to 5 cm below the superior iliac crest and lateral to the outer sacral edge.
12. The surgeon uses the tunneling tool with its metal tip and plastic tube to develop the tunnel from the lead to the intended pocket. Once tunneling is achieved the metal tip is removed and the tool is withdrawn, leaving the plastic tubing in place. The proximal lead end is then fed through the tubing to the pocket, and the tubing is removed. The protective boot is placed over the end of the lead. Leads may be placed bilaterally at the surgeon's discretion.
13. The percutaneous extension is then tunneled from the eventual generator site to the opposite posterior iliac side and exits the skin. This is then attached to the external device.
14. The incisions at all wound sites are closed. The wounds are dressed with small gauze and an occlusive dressing.

If the patient has a good response (50% or greater decrease in symptoms), then the area of generator site is extended in a second stage and the generator is connected to the lead (Figures 14-68 and 14-69). The percutaneous extension is pulled out through the other side and taken away from the field.

Male Sling

The male perineal sling is designed to improve male incontinence by increasing outlet resistance. Using cadaveric dermis, fascia lata, or pericardium, the surgeon places a triangular sling under the bulbous urethra and anchors it with six screws that are placed into the inner portion of the descending ramus just below the symphysis pubis. Other treatments for incontinence,

FIGURE 14-69 InterStim implant.

including the use of botulinum A toxin, are being investigated (Research Highlight).

RESEARCH HIGHLIGHT

Botox Treatment for Urinary Incontinence

Researchers evaluated the use of Botox in the treatment of idiopathic overactive bladder in a two-stage, randomized, double-blinded study comparing Botox to a placebo. The toxin, which is more commonly used in cosmetic treatments, works by paralyzing one of the muscles that controls the bladder, preventing it from emptying involuntarily. Stage 1 of the study consisted of a 6-week randomized, placebo-controlled trial, and stage 2 was a 9-month randomized trial of two doses of Botox without a placebo control.

A total of 22 patients participated in stage 1 of this two-stage study. Criteria for the study were overactive bladder refractory to anticholinergic medications, multiple daily incontinence episodes, and a 24-hour incontinence pad weight of 100 g or greater. Researchers injected the detrusor muscle in 8 to 10 locations above the trigone.

In analyzing the study results, the researchers reported improvements in daily incontinence episodes, number of incontinence pads used per day, and quality-of-life questionnaires in the botulinum-A toxin group with no changes in the placebo group. Complications experienced during the study were minor, and included urinary tract infection in 13% of the botulinum-A toxin group and 28% in the placebo group. One participant required intermittent catheterization.

Modified from Flynn MK et al: Outcome of a randomized, double-blind, placebo controlled trial of botulinum A toxin for refractory overactive bladder, *J Urol* 181:2608-2615, 2009.

Bladder Augmentation

Augmentation enterocystoplasty is a procedure performed to surgically enlarge the bladder capacity. A wide range of conditions that were previously treated with urinary diversion may now be successfully managed with this technique. Indications include reflex incontinence unresponsive to medical management, detrusor hyperactivity with compromised bladder function, chronically contracted bladder resulting from radiation or repeated infections, and neuropathic bladder combined with recurrent urinary tract infections or compromised renal function. A segment of bowel is used to augment the bladder. The bowel is re-formed into a semispheric shape to decrease peristaltic contractions and anastomosed to the opened bladder dome. The result is a low-pressure reservoir that provides improved bladder capacity and urinary compliance. Almost all segments of bowel as well as the stomach have been employed for bladder augmentation. Selection depends on anatomic factors, functional characteristics, and the surgeon's preference. In some cases, ureteral reimplantation or associated bladder-outlet procedures are incorporated in a one-stage procedure.

Postoperatively, intermittent catheterization and bladder irrigations may be necessary. The patient must be able and willing to learn and perform these procedures and must be accepting of this alteration in lifestyle.

Procedural Considerations. The nurse assists with positioning the patient in the supine position after the anesthesia provider administers a general or regional anesthetic. The female patient may be in a frog-leg or lithotomy position, particularly if access to the perineum is necessary. The entire abdomen and genitalia are prepped and draped. The surgeon inserts a Foley catheter after the patient has been prepped and draped so that the bladder can be filled to capacity for visualization during the procedure. Basic laparotomy and intestinal instruments are required.

Operative Procedure

1. The surgeon makes a supraumbilical to symphysis midline abdominal incision.
2. The peritoneal cavity is exposed using a Bookwalter or similar retractor.
3. The surgeon examines the intestines and stomach, and chooses the appropriate segment for reconstruction (Figure 14-70, *A*).
4. A sagittal bladder incision is made from 2 cm cephalad to the bladder neck anteriorly across the anterior bladder wall, the peritonealized dome surface, and the posterior bladder wall to 2 cm above the posterior interureteric ridge. This causes the bladder to be bivalved in a clam-shaped design.
5. The surgeon places bilateral traction sutures along the bladder incision.
6. The length of the incision is measured to correlate with the corresponding segment of bowel or stomach. Average length required is 25 cm.
7. The surgeon mobilizes the segment of bowel and closes the mesentery cephalad so that the segment is on the retroperitoneum. The segment is left attached to its mesentery to maintain blood supply (Figure 14-70, *B*).
8. The isolated segment is opened, trimmed, and detubularized. The surgeon then folds it double and sutures it to form a cup patch (Figure 14-70, *C*).
9. Anastomosis is accomplished with a running, intermittent locking, absorbable suture, beginning at the posterior apex and running up each side.

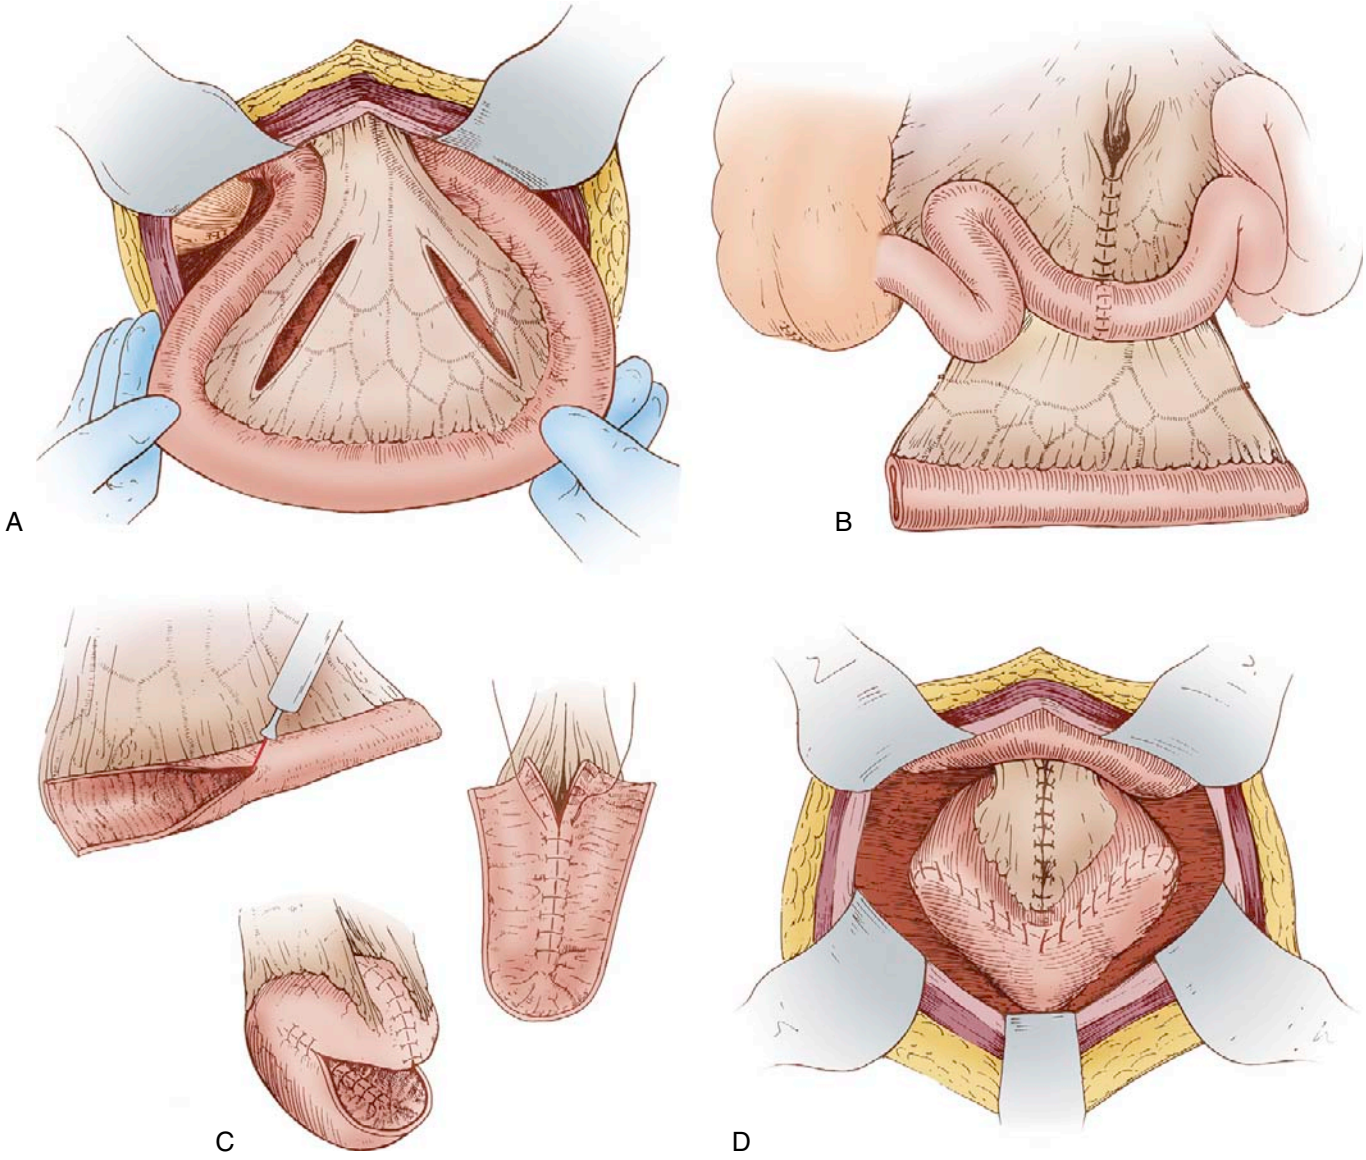

FIGURE 14-70 Ileocystoplasty for bladder augmentation.

10. With one third of the attachment complete, the surgeon places sutures at the anterior apex and runs them bilaterally to meet cephalad (Figure 14-70, *D*).
11. The surgeon fills the bladder to check the integrity of the anastomosis.
12. Abdominal closure is performed, and dressings are applied. The Foley catheter will remain for 7 to 14 days. Some surgeons may choose to place a suprapubic catheter instead of a Foley.

Implantation of Prosthetic Urethral Sphincter

Implantation of a prosthetic urethral sphincter is usually done as a last measure for patients with stress incontinence for which other modalities have failed. Problems with the device have included foreign-body reaction, persistent urethral pressure causing urethral erosion, and fluid hydraulic failure. The artificial sphincter unit has an abdominally placed, pressure-regulated reservoir that maintains a constant predetermined pressure on the periurethral cuff. Because of the connection between the reservoir and cuff, any increase in intraabdominal pressure transmits more fluid into the cuff. This connection allows for a compensatory increase in urethral resistance during coughing or straining.

The scrotal or labial pump shifts the fluid into the cuff to the reservoir to allow bladder emptying. The fluid reenters the cuff through a resistor in about 60 to 120 seconds. The locking button in the AMS Sphincter 800 artificial sphincter unit traps fluid in the reservoir to allow activation of the cuff. The sphincter is available in a single-cuff and double-cuff model.

Procedural Considerations. Standard laparotomy and lithotomy setups are required, as well as the sphincter components, contrast material diluted according to the manufacturer's recommendations, and an antibiotic solution. The patient is placed in a modified lithotomy position.

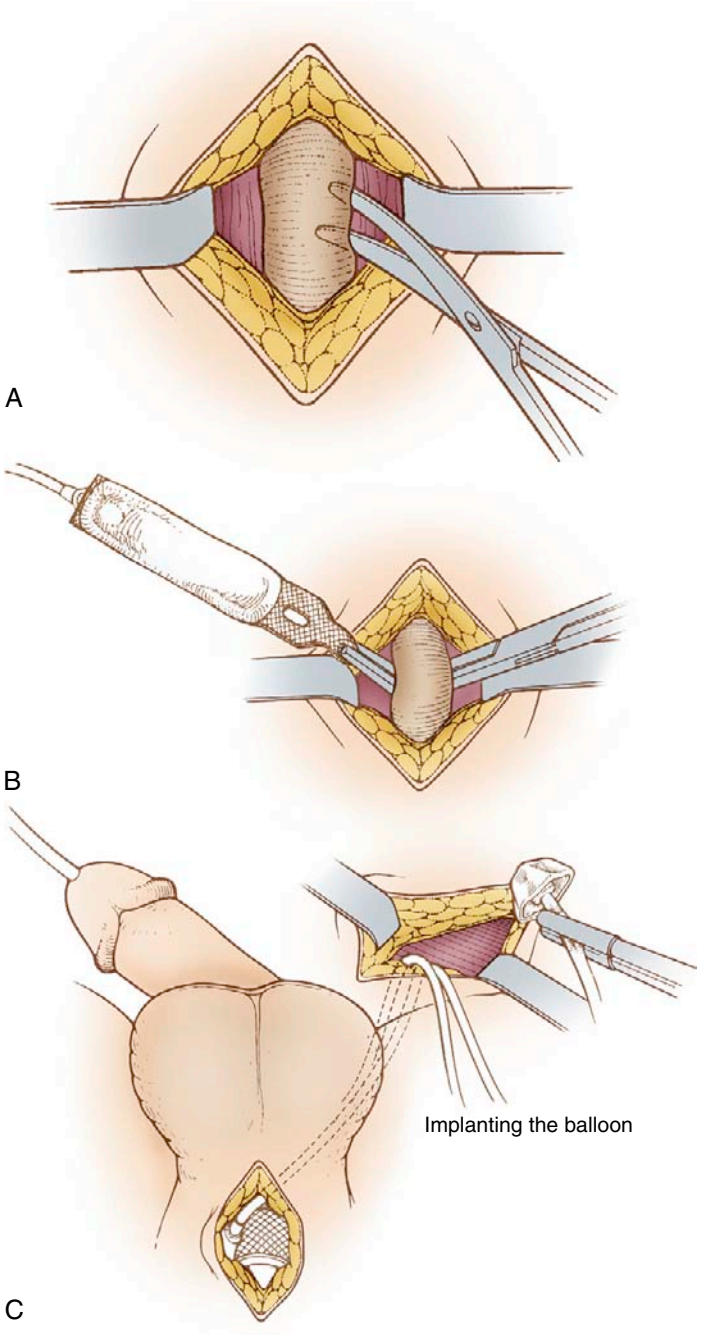

FIGURE 14-71 Implantation of artificial urinary sphincter.

Stricture disease is more commonly found in the male population, and the most common cuff placement is around the bulbous urethra. Bladder neck placement of the cuff is generally reserved only for females.

Operative Procedure

BULBOUS URETHRAL CUFF

1. Perineal and transverse suprapubic incisions are made.
2. The surgeon mobilizes the bulbous urethra through a midline perineal incision (Figure 14-71, *A*).
3. A 2-cm space is created beneath the bulbocavernous muscle and around the bulbous urethra.
4. The surgeon places the cuff, tab end first, around the bulbous urethra (Figure 14-71, *B*).
5. The reservoir is placed beneath the rectus muscle through the suprapubic incision (Figure 14-71, *C*).
6. The surgeon attaches the pump to the tubing passer, introduces it through the suprapubic incision, and transfers it to the scrotum through a subcutaneous tunnel created between the two incisions. The reservoir, cuff, and pump are connected and filled with contrast material or injectable saline to the appropriate volume (Figure 14-72).
7. The wound is closed and dressed with gauze sponges. A urethral catheter is usually not inserted.

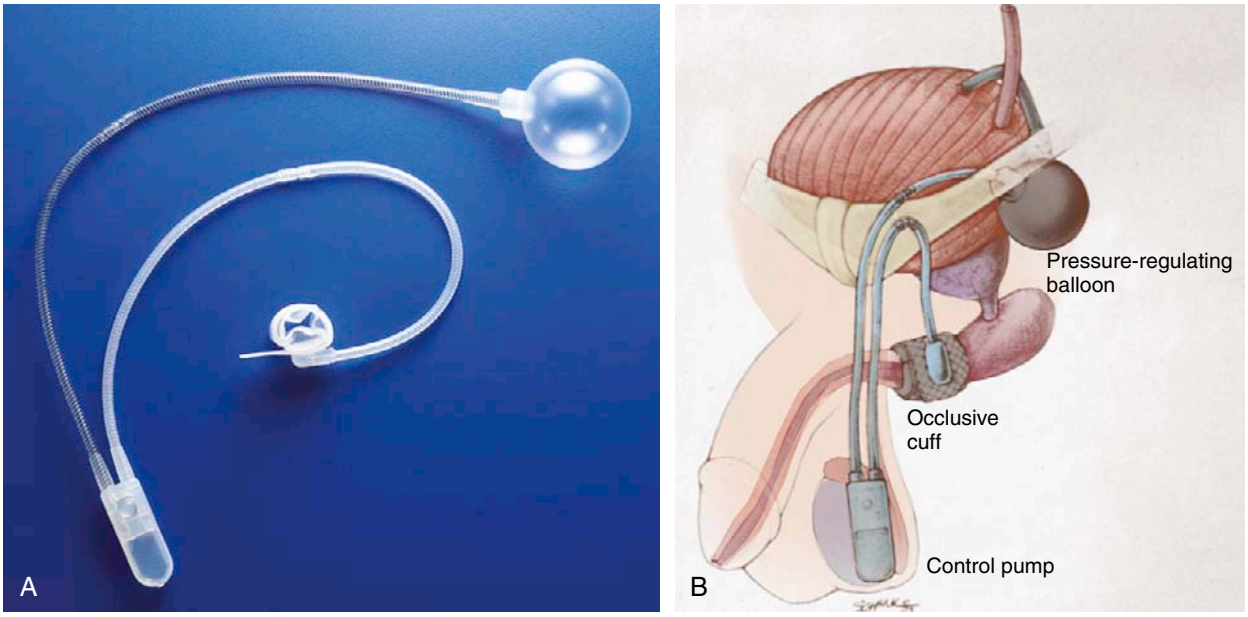

FIGURE 14-72 **A**, AMS 800 single-cuff artificial urinary sphincter. **B**, Final placement of artificial urinary sphincter.

Radical Cystectomy with Pelvic Lymphadenectomy

Cystectomy is the total excision of the urinary bladder and adjacent structures along with pelvic lymph nodes. Cystectomy is a surgical consideration when a vesical malignancy has invaded the muscular wall of the bladder or when frequent recurrences of widespread papillary tumors do not respond to endoscopic or chemotherapeutic management. The patient should be medically able to withstand surgery with the expectation of reasonable longevity. Total cystectomy necessitates permanent urinary diversion into an ileal or colonic conduit. In a male patient, the prostate gland, seminal vesicles, and distal ureters are removed with the bladder and its peritoneal surface. In a female patient, the bladder, urethra, distal ureters, uterus, cervix, and proximal third of the vagina are removed.

Procedural Considerations. The perioperative nurse places the patient in the supine position. Instruments are as described for major abdominal procedures. For a male patient, if the prostate and seminal vesicles are to be removed, prostatectomy instruments should be added. For a female patient, vaginal and abdominal hysterectomy as well as plastic surgery instruments should be added (see Chapters 13 and 21).

Operative Procedure. A midline incision from the epigastrium to the symphysis pubis, curving to the left of the umbilicus, is generally used.

1. The surgeon enters the peritoneal cavity above the umbilicus. The entire urachal remnant is clamped, divided, and ligated with heavy silk ligatures (Figure 14-73, *A*). It will be removed en bloc with the bladder.
2. The bladder dome is lifted at its peritoneal surface, and dissection proceeds laterally on either side with ligation of the major vesical arteries to the level of the vas deferens or round ligament (Figure 14-73, *B*).
3. The surgeon divides the vas deferens and cuts the urethra at the level of the pelvic diaphragm.
4. The ureters are identified and traced to the bladder. Care is taken to preserve the adventitial tissue (Figure 14-73, *C*).
5. Abdominal exploration and pelvic lymphadenectomy with frozen sections are performed to rule out metastatic disease.
6. In the male patient, the bladder is then retracted to expose the endopelvic fascia and puboprostatic ligaments. The prostate, dorsal venous complex, and seminal vesicles are dissected free, as described for a radical retropubic prostatectomy (Figure 14-73, *D*). These will be removed in continuity with the bladder.
7. In the female patient, the broad ligament is bilaterally incised posterior to the fallopian tube and ovary to the level of the posterior vagina to be removed en bloc with the bladder (Figure 14-73, *E*). The endopelvic fascia is incised at the bladder neck to expose the proximal urethra. The vagina is then incised along the lateral walls to the level of the proximal urethra and bladder neck. The anterior vaginal wall is incised in a U fashion to circumscribe the urethra (Figure 14-73, *F*). The vagina is reconstructed.
8. The surgical specimen consists of the bladder, distal ureters, prostate, seminal vesicles, and distal vas in the male and the uterus, fallopian tubes, and ovaries in the female and is removed en bloc.
9. The surgeon ligates the urethra with absorbable suture. If urethrectomy is indicated, this is done en bloc with the bladder.
10. Lap pads are placed in the denuded pelvis, and pressure is applied to reduce blood loss from oozing.
11. Urinary diversion is accomplished by means of an isolated ileal or colonic conduit, an orthotopic diversion, or a continent urinary diversion.

Bladder Substitution (Substitution Cystoplasty)

The ideal candidate for a bladder replacement after cystectomy for carcinoma is a patient with a normal urethra; a proximally located, well-differentiated bladder tumor; absence of carcinoma in situ; and proof, in the male patient, that the prostatic urethra is free of disease. High-dose radiation offers appreciable

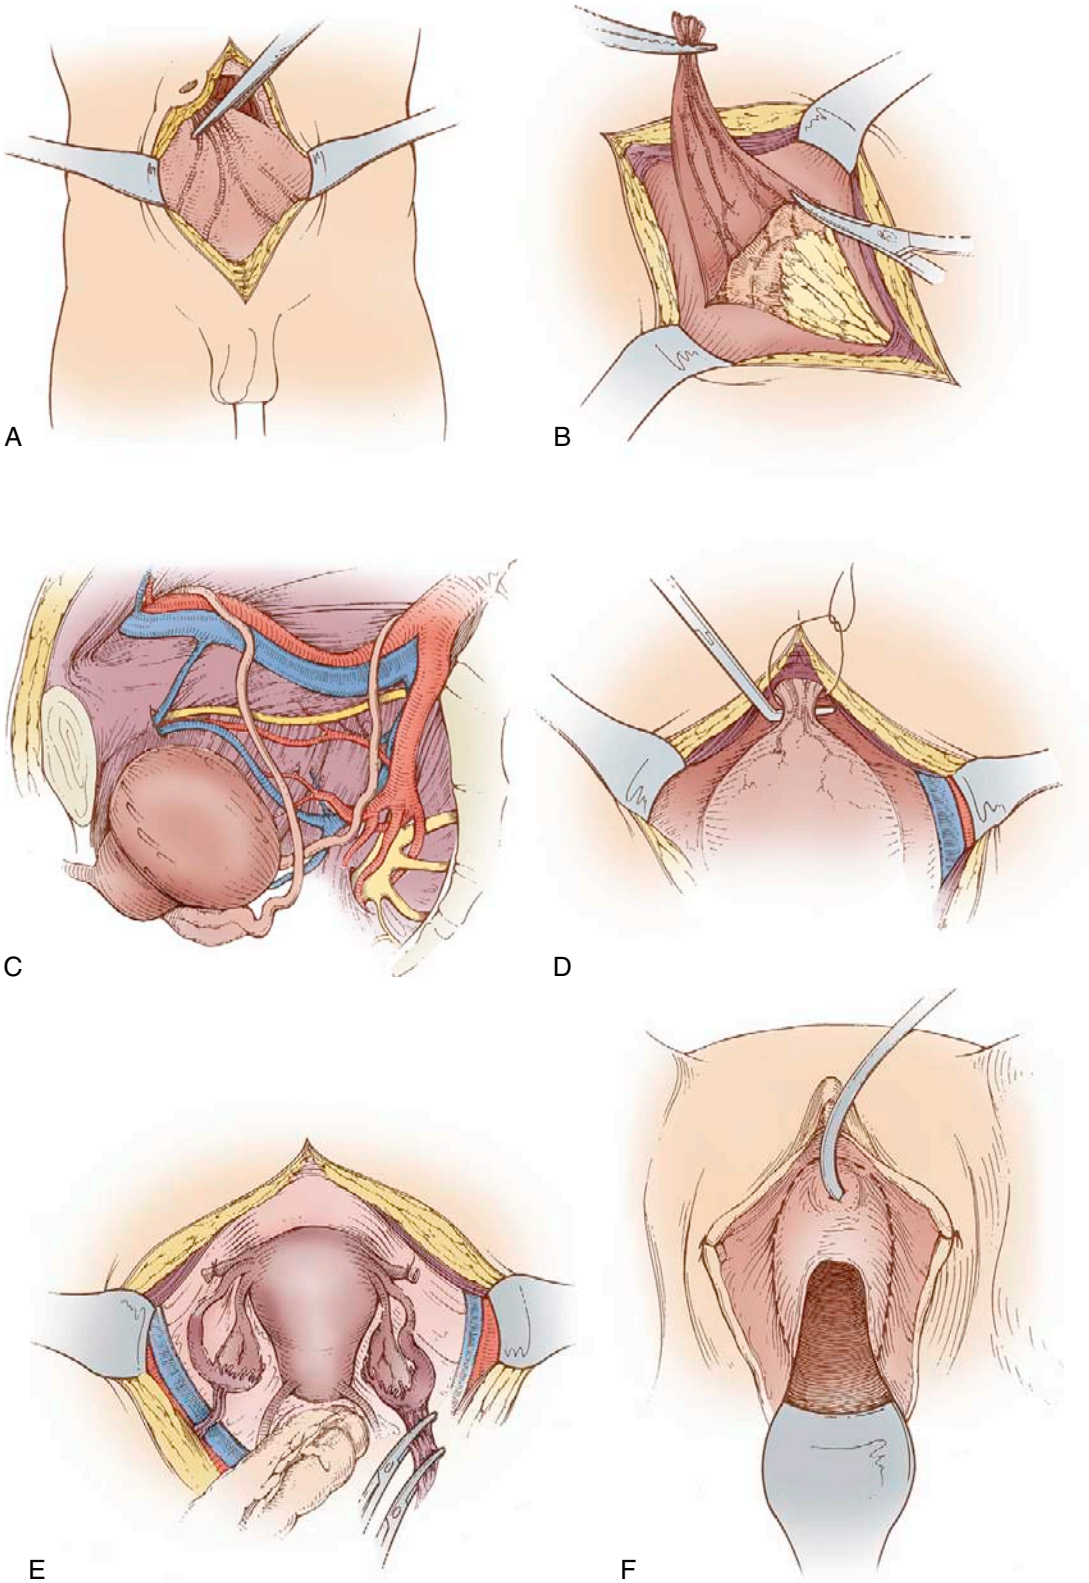

FIGURE 14-73 **A**, The urachal remnant is identified and divided just below the umbilicus. **B**, The peritoneum is divided laterally to the umbilical ligaments to the level of the vas deferens or round ligament. **C**, The ureter crossing the bifurcation of the iliac vessels is identified. **D**, Right-angled clamp is passed beneath the dorsal venous complex, anterior to the membranous urethra. **E**, In female patients the ovaries, fallopian tubes, and uterus are removed en bloc with the bladder and anterior vaginal wall. **F**, U-shaped incision is made on the anterior vagina to circumscribe the urethra.

risks for postoperative complications and is contraindicated with enterourethral anastomosis. A discussion of techniques to create a neobladder follows.

Right Colocystoplasty. Depending on the extent of involvement, the right side of the colon may be used to replace the bladder, the bladder and prostatic urethra, or the bladder and prostate with a direct enteric-to-proximal bulbar urethral anastomosis. This procedure has become more functionally effective with the use of intermittent self-catheterization and selective implantation of a prosthetic urinary sphincter.

Ileocecal Bladder Substitution. The ileum has been used as a reservoir to restore urinary continuity because it possesses a low intraluminal pressure. However, the short mesentery does not always permit the bowel to reach the urethra and results are not consistently successful. There have been significant incidences of recurrent carcinoma, renal damage, incontinence, postoperative strictures, fistula, hypokalemia, anemia, suture-line breakdown, and stone formation. Although most patients attain daytime urinary control, a small percentage still have problems with enuresis. Deterioration of the upper urinary tract as a result of infection and obstruction has historically been a significant risk with this procedure, and therefore ileocecal substitution is met with mixed reactions and recommendations.

Sigmoidocystoplasty. Because of the sigmoid colon's ease of construction, bladder proximity, decreased obstruction from mucus, and large capacity, it has been more appealing to many surgeons in their attempt to create a new bladder. More efficient emptying with a larger reservoir capacity seems to occur with a sigmoid replacement. Results yield higher intraluminal pressures, more effective urinary flow rates, and less nocturnal incontinence than with ileal segments.

Ileoascending Bladder Substitution. In an effort to improve the intestinal reservoir's capacity and antirefluxing effectiveness, the use of the ascending colon as a continent reservoir was introduced. This technique has several anatomic advantages over other methods of bladder replacement. The segment used can include the hepatic flexure and proximal transverse colon. A large-capacity reservoir is obtained, and colonic incision or tailoring is not required to achieve an appropriate shape. It easily reaches any site within the pelvis and can be anastomosed directly to the urethra without tension.

Orthotopic Ileocolic Neobladder. The Le Bag continent diversion technique utilizes the right colon and ileum as an orthotopic bladder replacement. Bladder substitution relies on meticulous dissection of the prostatic apex with preservation of the urinary sphincter and neurovascular bundles, as well as a watertight urethral anastomosis. Most patients have achieved a high degree of daytime continence and a minimum of nocturnal enuresis. Short-term complications encountered include bleeding, infection, urinary extravasation, bladder perforation, urethral stricture, fistula formation, urinoma, and small-bowel obstruction. Long-term problems include chronic constipation or diarrhea, compromised enterohepatic circulation, vitamin B_{12} deficiency, and urinary incontinence in a small percentage of patients.

Considerations influencing patient selection include age, general health, and fitness for extensive, complicated surgery. Contraindications include previous radiation therapy, bowel disease (diverticulosis, Crohn's disease, colitis), and other major medical problems. Preoperative urethral biopsy specimens are frequently taken to rule out tumor or cellular atypia in the urethra, which would prevent this particular intervention.

PROCEDURAL CONSIDERATIONS. The patient is placed in the supine position. SCDs are applied before the induction of anesthesia. A cystectomy and prostatectomy or hysterectomy are performed. Major deep intestinal, bladder, and prostate or hysterectomy instruments, as well as a large self-retaining retractor, are needed.

OPERATIVE PROCEDURE

1. After cystoprostatectomy, the right side of the colon is reflected medially along the mesentery to the hepatic flexure. The distal ileum that is to be used in the neobladder is inspected.
2. The surgeon divides the small bowel, positions it in an S shape, and places stay sutures of 2-0 or 3-0 absorbable material.
3. The posterior walls are sewn from inside to outside with running 3-0 absorbable suture.
4. A seromuscular wedge of the dependent cecum is excised, and the mucosa is everted with 4-0 absorbable sutures to form a bladder neck.
5. The left ureter is brought retroperitoneally under the sigmoid mesentery, a submucosal tunnel is created, and the ureters are reimplanted through the colonic wall. Anastomosis is done from the interior of the pouch.
6. The surgeon places anchor sutures of 3-0 or 4-0 silk at the outer entry point. The wall of the colon is anchored to the psoas muscle with 3-0 or 4-0 silk to prevent migration of the neobladder.
7. Ureteral stents are placed and exteriorized through the colonic segment and a separate abdominal stab wound, along with a catheter, to serve as a suprapubic tube.
8. Sutures of 2-0 absorbable material are placed around the urethral stump and tagged.
9. The surgeon inserts a Foley catheter into the urethra in a retrograde manner, and the urethra is anastomosed to the neobladder at the point of the new bladder neck.
10. The neobladder is closed in an intestinal fashion or with a GI stapler in a side-to-side anastomosis. Wound drains are placed, the bladder filled to test for leaks, and the wound closed.

Cutaneous Urinary Diversions

Ileal Conduit. The ileal conduit is the classic method by which the urine flow is diverted to an isolated loop of bowel. One end of the isolated loop is exteriorized through the skin so that the urine can be collected in a drainage bag, which is intermittently emptied. The surgeon consults with the enterostomal therapist preoperatively to determine the stoma site. The selected site, usually in the right lower quadrant of the abdomen, above the beltline, is marked with a fine needle dipped in methylene blue to prevent erasure during skin preparation. The goal is to create a round, protruding stoma without wrinkles in the skin, to prevent urine leakage under the collecting device. The candidate for ileal diversion must have a retrievable ureter at least 1 cm in diameter with a thick, well-vascularized wall. The patient must

be able to care for the appliance. Conditions amenable to diversion include neurogenic bladder, interstitial cystitis, and bladder carcinoma. Cystectomy may be performed before or after this procedure, depending on the patient's diagnosis. In cases that do not involve bladder cancer, the surgeon may choose to leave the bladder in situ rather than subject a debilitated patient to further surgery. In certain cases of extensive bladder carcinoma, the surgeon may elect to treat the patient with radiation in an attempt to decrease the size of the tumor and neutralize the regional lymph nodes before performing cystectomy.

PROCEDURAL CONSIDERATIONS. The perioperative nurse assists with positioning the patient in the supine position. Abdominal and GI instruments are required. A cystectomy, prostatectomy, or hysterectomy may also be done at the time of the surgery. Endostapling devices, with absorbable staples, should be available.

OPERATIVE PROCEDURE

1. The bladder is decompressed with a catheter.
2. The surgeon enters the abdomen through a midline abdominal incision and places a self-retaining abdominal retractor to exclude the viscera from the region of dissection.
3. The ureters are identified and severed approximately 2.5 cm from the bladder.
4. The surgeon creates a retroperitoneal tunnel so that the left ureter lies close to the right ureter.
5. The distal ileum and mesentery are inspected to identify the bowel's blood supply.
6. A drain is passed through the mesentery, midway between the two main arterial arcades adjacent to the ileum at the proximal and distal ends of the selected segment. This segment usually makes up 15 to 20 cm of the terminal ileum, a few centimeters from the ileocecal valve. The ileocecal artery is preserved to maintain adequate circulation to the isolated ileal segment.
7. The surgeon incises the peritoneum over the proposed line of division of the mesentery.
8. Intestinal clamps are placed across the ileum, and the bowel is divided flush with the clamps.
9. Using GI technique (also referred to as bowel technique; see Chapter 10), the surgeon closes the proximal end of the isolated ileal segment first with a layer of absorbable sutures and then with a second layer of interrupted 2-0 nonabsorbable sutures.
10. The proximal and distal segments of ileum are reanastomosed end-to-end in two layers.
11. The surgeon closes the mesenteric incision with interrupted nonabsorbable sutures.
12. The closed proximal end of the conduit segment is fixed to the posterior peritoneum.
13. The ureters are implanted in the ileal segment, using fine instruments and 4-0 absorbable ureteral sutures on atraumatic needles.
14. The surgeon separates the peritoneum and muscle of the abdominal wall lateral to the original incision with blunt dissection.
15. The abdominal opening for the stoma is made, and the distal opening of the ileal conduit is then drawn through a fenestration in the muscle, fascia, and skin.
16. The ileum is fixed to the fascia with 2-0 sutures. A rosebud stoma is constructed as the ileum is sutured to the skin using subcuticular stitches (Figure 14-74).
17. Ureteral stents are usually left in the stoma, and a urinary collecting pouch is placed over the rosebud stoma to collect urine.
18. The surgeon inserts closed-suction wound drains and closes the abdominal incision. The skin is reapproximated.

Continent Urinary Diversions

The Kock pouch, the right colocystoplasty, and the Camey version of the ileocystoplasty have been modified for anastomosis to a urethral stump or the prostatic capsule, resulting in effective continent bladder replacement. All continent urinary diversions create an easily catheterized stoma and a nonrefluxing ureteral anastomosis. Different parts of the bowel and the stomach have been used as continent reservoirs. The choice of the antireflux mechanism depends on the implantation site. The stoma does not require an appliance; therefore the site may be placed below the beltline or bikini line, permitting it to be catheterized when the patient is sitting. It may be anastomosed to the proximal urethra, thus forming an orthotopic bladder.

Ileal Reservoir (Kock Pouch)

PROCEDURAL CONSIDERATIONS. A continent reservoir formed into a U configuration is constructed from a section of ileum proximal to the ileocecal valve. The legs of the U are sewn together at the antimesenteric border. The intestine is opened adjacent to the antimesenteric border, and the back wall of the pouch is reinforced with absorbable suture.

Continence is achieved by the valve mechanism with the nipple valve attached to the skin. Nipple valves are created proximally and distally by intussusception of the bowel into the reservoir cavity. Once the nipples are fixed to the sidewall of the reservoir with absorbable suture or polyglycolic staples, the anterior wall is closed. The ureters are anastomosed to the afferent limb of the pouch, preventing reflux. The efferent limb is drawn through the stoma site and anchored to the abdominal wall fascia.

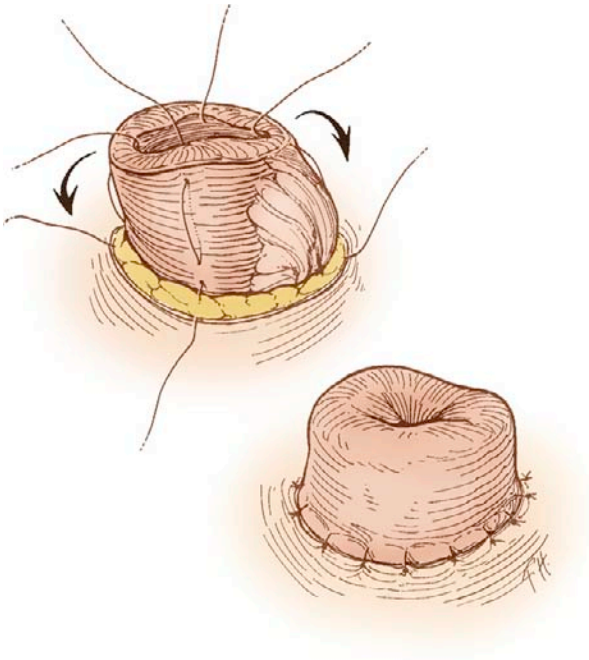

FIGURE 14-74 Rosebud suture technique for stoma.

OPERATIVE PROCEDURE

1. The mesentery is divided and suture-ligated or staple-ligated along the avascular plane between the superior mesenteric artery and the ileocolic artery.
2. The surgeon divides the bowel, and four segments are measured and marked with silk suture tags. These segments will serve as the efferent conduit, the pouch, and the afferent limb.
3. A portion of the proximal ileum is resected and discarded along with a wedge of mesentery. Suction is passed down the lumen to clear any fecal material or mucus.
4. The surgeon closes the proximal end of the bowel with suture or staples.
5. The segment to be employed is spread out in a U-shaped fashion. The sides are sewn together with 3-0 absorbable suture in a running stitch or connected using a GI endostapler.
6. The surgeon uses the ESU to incise the bowel laterally to the suture in the two loops. The medial edges are oversewn with 3-0 or 4-0 silk.
7. The mesentery is cleared on the limb segments, and the lumens are intussuscepted into the open pouch.
8. Synthetic mesh is used to serve as a strut to prevent peristomal herniation and to fix the base of the efferent nipple to the abdominal wall, facilitating catheterization. The TA or similar endostapler is used to form each nipple and to attach the nipples to the back wall of the pouch.
9. An 8F stenting catheter is placed inside the nipple of the efferent conduit to prevent the formation of a collar that is too tight.
10. The surgeon secures the limbs with 3-0 or 4-0 silk suture.
11. The pouch is closed with sutures or the endostapler.
12. The ureters are anastomosed, as described in the "Ileal Conduit" discussion, to the afferent limb.
13. A small stoma site is prepared, as described in the "Ileal Conduit" discussion. A catheter of choice is placed in the stoma for postoperative care. Stents may be placed in the ureters for the immediate postoperative period. This will necessitate initial placement of an ileostomy appliance until all systems are functioning.
14. A drain is placed, which exits through a separate stab wound.
15. The surgeon closes the wound. Retention sutures may be employed. Bulky absorbent dressings are applied; Montgomery straps may be used.

Indiana Pouch

PROCEDURAL CONSIDERATIONS. The Indiana pouch technique is a modification of the original ileocecal diversion. The surgeon constructs a continent reservoir from the right side of the colon, which may include the ileum and cecum, the ileocecal valve, and ascending colon. Surgery proceeds as for any diversionary procedure. The ileocecal valve is reinforced with nonabsorbable suture. Two rows of nonabsorbable suture are used to then imbricate the ileal segment, which serves as a limb that can be catheterized once it is exteriorized to the skin level as a stoma. The cecal segment is detubularized by incising along the taenia and anastomosing the distal edge horizontally to the proximal portion. Intussusception of the ileocecal valve into the cecum and narrowing of the ileal segment attached to the skin allow for continence.

OPERATIVE PROCEDURE

1. The large bowel is split down the antimesenteric border for approximately three fourths of its length.
2. The U-shaped defect is closed.
3. The surgeon sutures the terminal ileum along its length over a small Robinson catheter in an intestinal fashion.
4. The pouch is filled with 400 ml of saline, and a larger catheter is placed to determine ability to be catheterized.
5. The ureters are tunneled into the cecum through its taenia and then tacked to the outer bowel wall. The cecum is secured to the pelvic wall. Ureteral stents may be placed.
6. The pouch is secured to the abdominal wall.
7. The surgeon prepares the stomal site as described in the "Ileal Conduit" discussion.
8. A 22F Malecot drain is placed in the reservoir to drain the cecostomy, exiting through a separate stab wound.

SURGERY OF THE URETERS AND KIDNEYS

Stones, infections, and tumors are the most common causes of urinary tract obstruction, necessitating surgery to prevent renal obstruction and subsequent renal failure. Obstruction may also result from congenital malformations or previous operations on the urinary tract (Figure 14-75).

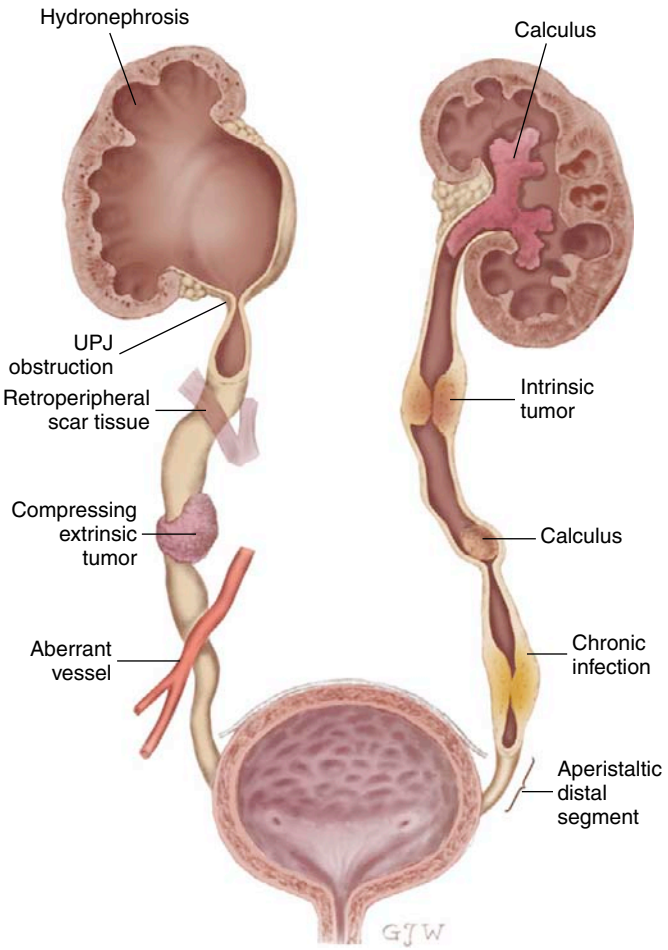

FIGURE 14-75 Some common causes of urinary tract obstruction. *UPJ,* ureteropelvic junction.

The ureter has three areas of narrowing where calculi may become lodged and pose a potential problem with pain and obstruction: (1) the ureteropelvic junction (UPJ), (2) the crossing of the ureter over the external iliac vessels, and (3) the ureterovesical junction (UVJ). Urine may sometimes cause calculi to be washed down the ureter to produce severe ureteral colic. The majority of renal calculi are spontaneously passed into the bladder. However, if they become lodged in the ureter, surgical intervention may be indicated.

Although the causes of many kidney stones are obscure, certain conditions, such as obstruction, stasis, and imbalance of metabolism, predispose to their formation. Stones consist of various elements: calcium oxalate, calcium phosphate, magnesium ammonium phosphate, uric acid, calcium carbonate, and cystine. An increase in the concentration of any of these compounds can cause tiny crystals to form; as these clump together, they begin to form a stone. Stones removed during surgery are subjected to chemical analysis and should be submitted in a dry jar. Fixative agents such as formalin should not be used.

Stones in the renal pelvis may fall into the ureteropelvic junction and obstruct the flow of urine. However, stones less than 3 cm in diameter may also pass down the ureter and lodge at a more distal location. A stone may remain in a renal calyx and continue to enlarge, eventually filling the entire renal collecting system (staghorn calculus). Diverticula may form and harbor stones that can be difficult to reach and treat. Hydroureteronephrosis, infection, and destruction of renal parenchyma frequently result from unrelieved obstruction.

Hypothermia may be used as an adjunct to renal stone surgery as a means of prolonging the safe period of renal ischemia. Several methods enable renal cooling: ice slush or cold saline solution, surface cooling coils, perfusion of cold solutions through the renal artery, or a variation of these basic techniques, such as perfusion of the renal pelvis with saline that has been cooled by a coil immersed in ice slush.

A refrigeration unit "slush machine" that produces sterile slush provides a cost-effective, time-saving alternative to the other methods of slush preparation. Commercially synthesized ultrafiltrate of sterile plasma in liter bottles is also available for use as the slush. Alternatively, a rigid plastic container of 1000 ml of normal saline or lactated Ringer's solution may be placed on its side in a freezer several hours before surgery. To prevent the solution from solidifying, the container should be rotated one-half turn every 20 to 30 minutes. Sterile slush may then be poured directly into a sterile basin as required.

The surgical approach in renal surgery depends on the patient's condition, the amount of exposure needed, and the surgical procedure to be performed. There are three principal surgical approaches to the kidney. The simple *flank,* or *transabdominal,* incision is most frequently used and may include removal of the eleventh or twelfth rib. The incision begins at the posterior axillary line and parallels the course of the twelfth rib. It extends forward and slightly downward between the iliac crest and the thorax. For the *lumbar* incision, the patient may be initially positioned supine and then rotated to lateral and slightly forward over protective bolsters with the operative side up. This effectively places the flank in an oblique position, causing the abdominal viscera to fall away from the operative incision, and affords an excellent approach to the renal pedicle. Alternatively, the patient may be placed prone with bolsters under the affected side to provide elevation. The *thoracoabdominal* exposure is employed primarily for large upper-pole renal neoplasms. The tenth and eleventh ribs are usually removed, and the chest cavity is opened, collapsing the lung. The leaves of the diaphragm are separated to expose the kidney.

Ureteral Surgery

Ureterostomy (ureterotomy) is opening the ureter for continued drainage from it into another body part. Cutaneous ureterostomy is diversion of the flow of urine from the kidney, through the ureter, away from the bladder, and onto the skin of the lower abdomen. A suitable urinary collecting device is then placed over the ureteral stoma.

Ureterectomy is complete removal of the ureter. This procedure is generally employed in collecting system tumors and includes nephrectomy and the excision of a cuff of bladder.

Ureteroureterostomy is segmental resection of a diseased portion of the ureter and reconstruction in continuity of the two normal segments.

Ureteroenterostomy is diversion of the ureter into a segment of the ileum (ureteroileostomy, or more commonly, ileal urinary conduit) or into the sigmoid colon (ureterosigmoidostomy). Ureteroneocystostomy (ureterovesical anastomosis) is division of the distal ureter from the bladder and reimplantation of the ureter into the bladder with a submucosal tunnel.

Reconstructive operations may be indicated because of a pathologic condition of the bladder or lower ureter that interferes with normal drainage. Conditions requiring urinary diversion or reconstruction of the urinary tract include malignancy, cystitis, stricture, trauma, and congenital ureterovesical reflux. Invasive vesical malignancy requiring surgical removal of the bladder necessitates urinary diversion.

Ureterocutaneous transplant, ureterosigmoid anastomosis, and ileal conduit are urinary diversionary procedures performed when the bladder is no longer functioning as a proper urine reservoir. Etiologic factors causing irreparable vesical dysfunction are chronic inflammation, interstitial cystitis, neurogenic bladder, exstrophy, trauma, tumor, and infiltrative disease (amyloidosis). Ureterolithotomy is incision into the ureter and removal of an obstructing calculus.

Procedural Considerations. The site of the incision and position of the patient depend on the nature of the proposed surgery. The patient may be placed in the supine position for abdominal surgery, in the modified Trendelenburg's position for low abdominal or pelvic surgery, or in the lateral position for high- or mid-ureteral obstructing calculi. The perioperative nurse ensures that the patient's arms are supinated when on armboards; in lateral position the upper arm is placed on an overbed armboard such as the Allen lateral arm support and the lower arm is supinated on a padded armboard. The kidney rest should lie just under the dependent iliac crest.

Instruments include the nephrectomy set, plus plastic instrumentation for pyeloplasty. Additional instruments may be required, depending on the type of operation and the surgical approach used.

Operative Procedure

URETERAL REIMPLANTATION

1. The surgeon exposes the ureter through an incision determined by the location of the pathologic condition. A ureteral catheter, passed retrograde, may be used to facilitate identification and isolation of the ureter.

2. The ureter is dissected free with long forceps and scissors, picked up with fine traction sutures, freed from the surrounding tissues, and severed at the desired level.
3. The surgeon ligates the distal end of the ureter and transfers the proximal stoma to the site of anastomosis. The anastomosis is accomplished with fine dissection instruments and fine atraumatic sutures.
4. A soft splinting stent is usually left in place until healing has taken place and free drainage is ensured. The wound is closed in layers and dressings applied.

URETEROCUTANEOUS TRANSPLANT (ANASTOMOSIS). The surgical approach is the same as that for a low ureterolithotomy.

1. The ureter is divided as far distally as possible.
2. The surgeon passes the severed ureter retroperitoneally through the lower abdominal wall and sutures it to the skin with an absorbable everting suture of 4-0 on an atraumatic needle to form a stoma. The ureter is handled gently with plastic instruments, fixation forceps, and iris scissors.
3. A small Silastic stenting catheter is passed up into the ureter and left in place for 48 to 72 hours, as ureteral edema subsides. The patient requires a urine-collecting device after surgery.

URETEROSIGMOID ANASTOMOSIS

1. The surgeon enters the peritoneal cavity through a lower left paramedian incision.
2. The major portion of the large bowel is protected with moist laparotomy packs.
3. Deep retractors are placed, and the surgeon uses long forceps and scissors to incise the posterior peritoneum.
4. The ureters are identified, divided close to the bladder, mobilized, and brought through the posterior peritoneal incision to lie near the sigmoid. Traction sutures and smooth tissue forceps are used to handle the ureters.
5. The sigmoid colon is mobilized to prevent tension on the ureteroenteric anastomosis.
6. Using 3-0 nonabsorbable suture material, the surgeon sutures the sigmoid colon to the pelvic peritoneum at a point where the ureter falls easily on the bowel.
7. Using a scalpel with a #15 blade, the surgeon makes an incision into the taenia of the sigmoid down to the mucosal layer. The edges of the taenia are undermined to create two parallel flaps.
8. The ureter is laid on the bowel mucosa, and a small slit is made through the mucosa into the lumen of the colon.
9. With fixation forceps and iris scissors, the surgeon bevels the ureter to lie flat in the tunica incision.
10. The distal ureter is anchored to the bowel mucosa with 4-0 absorbable ureteral sutures on atraumatic needles. The other ureter is anastomosed in the same manner in a position slightly above the first.
11. The tunicae are then loosely reapproximated over the ureter with 4-0 absorbable sutures, creating an antireflux anastomosis.
12. The surgeon closes the posterior peritoneum with absorbable sutures. Drains are exteriorized retroperitoneally. The incision is closed and dressings applied.

Ureterolithotomy

PROCEDURAL CONSIDERATIONS. A KUB x-ray examination should be done immediately before surgery to determine the exact location of the stone. The surgeon may also schedule a cystoscopic examination preoperatively and may attempt to remove the stone endoscopically. The location of the stone determines the surgical approach. A stone high in the ureter requires a flank incision with possible removal of the twelfth rib; a more distal ureteral stone requires a lower abdominal incision.

OPERATIVE PROCEDURE

1. After exposure of the ureter, the stone may be kept stationary with Babcock clamps or vessel loops applied above and below it.
2. With a #15 blade, the surgeon makes an incision in the ureter directly over the stone, which may be easily removed with Randall stone forceps.
3. A 10F catheter is passed proximally up and distally down the ureter while irrigating with saline to check for ureteral patency and to dislodge any remaining stone fragments.
4. The surgeon closes the ureter with 4-0 or 5-0 absorbable sutures. All stones should be placed in dry receptacles and sent to the chemistry laboratory for analysis.

Kidney Surgery

See Box 14-3 for terms pertaining to kidney surgery.

Procedural Considerations. Patient preparation and instrument setup are as described for ureteral surgery.

Operative Procedure

PYELOTOMY AND PYELOSTOMY

1. The surgeon incises the pelvis of the kidney with a small scalpel blade. Fine traction sutures may be placed at the edges of the incision for gentle retraction while the pelvis and calyces are explored.
2. In pyelostomy a small Malecot or Foley catheter is placed through the incision into the renal pelvis. Pyelotomy is used only for very short periods of renal drainage because tubes tend to be dislodged easily from the renal pelvis.

BOX 14-3

Terms Pertaining to Kidney Surgery

Term	Definition
Nephrostomy	Creation of an opening into the kidney to maintain temporary or permanent urinary drainage. A nephrostomy is used to correct an obstruction of the urinary tract and to conserve and permit physiologic functioning of renal tissue. It is also used to provide permanent urinary drainage when a ureter is obstructed or for temporary urinary drainage immediately after a plastic repair on the kidney.
Nephrotomy	Incision into the kidney, usually over a collecting system containing a calculus
Pyelolithotomy	Removal of a calculus through an opening in the renal pelvis
Pyelostomy	Making an opening in the renal pelvis for temporarily or permanently diverting the flow of urine
Pyelotomy	Incision into the renal pelvis used as an access to stones in the renal pelvis or collecting system

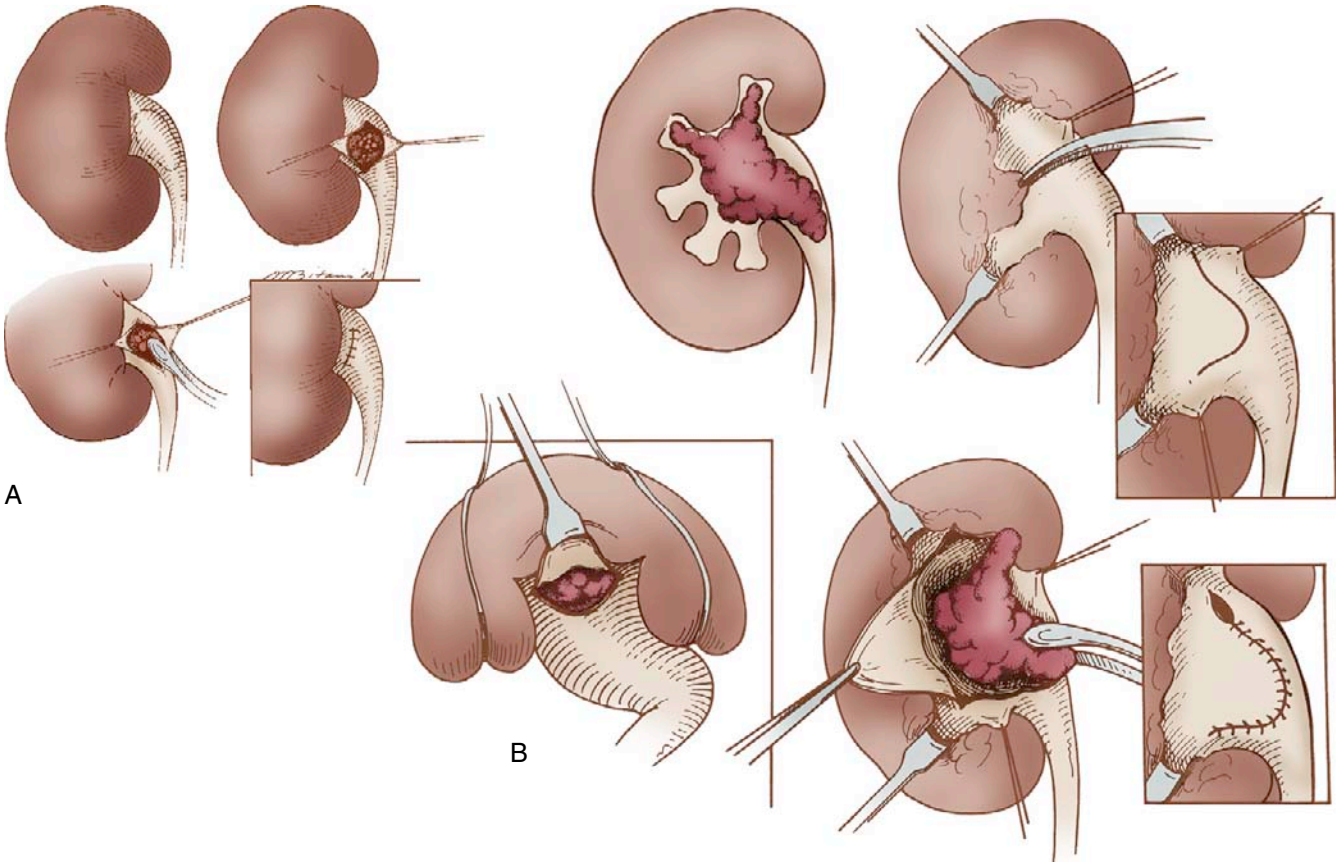

FIGURE 14-76 Pyelolithotomy. **A**, Technique of simple pyelolithotomy. **B**, Technique of extended pyelolithotomy.

NEPHROSTOMY

1. The surgeon passes a curved clamp or stone forceps through a pyelotomy incision into the renal pelvis and then out through the substance of the renal parenchyma through a lower pole minor calyx.
2. The tip of a Malecot, Foley, or Pezzer catheter is drawn into the renal pelvis, and the pyelotomy incision is sutured closed.
3. The distal end of the nephrostomy tube is exteriorized through a separate stab incision in the flank.
4. A drain is placed at the level of the pyelotomy incision, and the wound is closed.

PYELOLITHOTOMY AND NEPHROLITHOTOMY

1. The surgeon opens the renal pelvis (Figure 14-76, *A*), and removes the calculus.
2. The pelvis and collecting systems are thoroughly irrigated with saline using an Asepto syringe to dislodge and remove any small remaining stones from the kidney.
3. Nephrolithotomy or extended pyelolithotomy is employed when stones are locked in the calyceal system and cannot be removed through a pyelotomy incision. In such cases, the renal parenchyma above the stone is incised and the stone removed. In many instances, such a situation is associated with a calyceal diverticulum (Figure 14-76, *B*).
4. After the stone is removed, the collecting system is closed and the renal cortex reapproximated with deep hemostatic 2-0 absorbable sutures.
5. A nephroscope is sometimes used to localize and remove calyceal stones. The nephroscope is also useful with staghorn calculi to remove residual fragments in the pelvic portion of the calculus.
6. An incision in the renal pelvis may be closed with 4-0 absorbable atraumatic sutures.
7. The renal fossa is drained and closed, as described for nephrectomy. Reinforced absorbent dressings are useful because some urinary leakage occurs for 3 to 4 days after surgery.

PERCUTANEOUS NEPHROLITHOTOMY. Percutaneous nephrolithotomy facilitates the removal or disintegration of renal stones using a rigid or flexible nephroscope (Figure 14-77) passed through a percutaneous nephrostomy tract. Accessory instrumentation, such as the ultrasound wand, electrohydraulic lithotripter probe, laser fiber, stone basket, and stone grasper, is passed through the lumen of the nephroscope.

Ideally, the patient is in good health and not obese and the calculus is 1 cm or less in diameter, free-floating, radiopaque, and solitary. However, advances in technology complemented by the experience gained by the uroradiology team have allowed patients with more complex problems to be managed in this manner. Patients who have undergone previous renal surgery, have stone recurrence, or have an established nephrostomy tract may also benefit from this procedure.

Creation of the nephrostomy tract and removal of the stone can be accomplished by three different methods. Proper placement of the nephrostomy wire can decrease the operating time significantly. In the *one-step procedure,* creation of the nephrostomy tract, tract dilation, and stone removal are completed in a

FIGURE 14-77 Kuntz laser working element.

single session. This method is generally preferred unless there are contraindications. In the *immediate two-step procedure,* the radiologist places the nephrostomy tube under radiographic guidance and the urologist removes the stone later the same day or the next morning. The second step is usually done in the OR with the patient administered a general anesthetic. In the *delayed two-step procedure,* the nephrostomy tract is established after the patient has been administered a local anesthetic. The patient is discharged the following day with a 22F or 24F nephrostomy tube connected to drainage. The patient is readmitted to the hospital 5 to 7 days later for the percutaneous removal of the stone after the patient has been administered a general anesthetic.

Of basic concern during the operative phase are the patient's position and body temperature, the potential for sudden and rapid blood loss, the type of anesthesia, medications required during surgery, and catheter management during and after the procedure. The patient's position, which may be prone or up to 30 degrees prone-oblique, and the draping procedure depend on whether the surgery is performed in the radiology department or the OR and the type of x-ray equipment that will be used.

Extracorporeal Shock-Wave Lithotripsy (ESWL). ESWL units use water-filled cushions adjacent to the kidney area. An x-ray image intensifier with two monitors is used to visualize the kidney stone at the focal point of the shock wave. After every 100 shocks, fluoroscopy is used to locate remaining stone particles. Adjustments are made, and the patient is repositioned before further treatments. ESWL is often used with percutaneous nephrolithotomy and transurethral ureteropyeloscopy if the patient does not pass the gravel.

Stones that are treated with ESWL are fragmented by the energy focused on the stone with the lithotripter. The shock waves are administered over a time that can vary from 30 minutes to 2 hours. Shock waves reverberate inside the stone, causing fragmentation with ultimate complete or partial destruction of the calculus. The amount of destruction depends on the number and energy of the shock waves delivered and the hardness of the stone. This technique is effective because shock waves can be transmitted and focused through tissue without loss of energy. A loud, reverberating, popping sound occurs each time a wave pulse is activated. It is advisable that earplugs be worn.

The requirement for anesthesia is determined by the power of the shock wave, the area of shock-wave entry at the skin level, and the size of the shock-wave focal point. The summation of shock waves used during the procedure can cause pain at the skin level. Typically, a general, spinal, or local anesthetic is used with the older lithotripters. Modern versions allow for lithotripsy with only IV sedation, oral sedation, or a transcutaneous electric nerve stimulator (TENS) unit.

The use of a stent before ESWL depends on the patient and the character of the stone or stones. The patient should have a negative urine culture before stent placement. Studies show that complication rates decrease if a stent is used with a stone larger than 1.5 cm. A stent placed before ESWL tends to decrease the need for ancillary interventions, reduces overall complications, and assists in proper positioning for ESWL by delineating the ureteral anatomy and the precise stone location. On the other hand, those patients who tend to readily form stones may demonstrate calcification of the ureteral stent in a relatively short time. Without a stent, the risk of silent renal obstruction resulting in loss of kidney function, obstruction of the ureter, nephritis, and sepsis is increased.

Complications related to ESWL are attributable to the cavitation effects of treatment and are proportional to the number of shocks. The ability of the kidney's tubular cells to survive shock waves is related to the number of shock waves to which the kidney is exposed and not to the energy level. Gross hematuria is seen almost universally, resolves in 12 to 48 hours, and is believed to be attributable to parenchymal edema that spontaneously heals within 1 week. Subcapsular or perirenal hematoma caused by perinephric fluid collections may occur and appears to be higher in the hypertensive patient. Subcapsular hematoma may resolve in 6 weeks or may take up to 6 months, whereas perirenal hematoma will be relieved usually in a matter of days. Impairment of renal function may be seen in patients with solitary kidneys. Iliac artery and vein thromboses have been reported with lithotripsy for ureteral stones. The majority of lithotripsy patients will demonstrate little or no long-term morbidity (Gayer, 2006).

Laser Lithotripsy. Laser lithotripsy has become an exciting alternative to ESWL and electrohydraulic lithotripsy (EHL). The Ho:YAG (holmium:yttrium-aluminum-garnet), tunable pulse-dyed (coumarin), Er:YAG (erbium:yttrium-aluminum-garnet), the tunable Alexandrite (a chromium-doped mineral), or the Q-switched Nd:YAG (neodymium:yttrium-aluminum-garnet) laser systems have the ability to disintegrate stones without damaging soft tissue. The technique may be used during a ureteropyeloscopy or nephroscopy or to manage ureteral stones instead of performing a ureterolithotomy. When the laser probe is discharged in direct contact with the calculus, plasma (ionized gas) coats the stone's surface. This plasma expands with repeated firings, creating a shock wave that fractures the stone. Normal saline is used for continuous irrigation throughout the procedure. It is not necessary to immobilize the calculus. All persons in the room wear laser goggles, and all laser precautions apply (see Chapter 7).

Dismembered Pyeloplasty. *Pyeloplasty* is revision or plastic reconstruction of the renal pelvis. Pyeloplasty is performed to create a better anatomic relationship between the renal pelvis and the proximal ureter and to allow proper urinary drainage from the kidney to the bladder. A temporary nephrostomy is often included to protect the plastic reconstruction of the ureteropelvic junction (UPJ). Tissue healing usually occurs in 10 to 12 days, and the nephrostomy tube is removed once

ureteral patency is demonstrated. *Ureteroplasty* is reconstruction of the ureter distal to the UPJ. A *dismembered pyeloplasty* is the combined correction of the redundant renal pelvis and resection of a stenotic portion of the UPJ.

PROCEDURAL CONSIDERATIONS. The instrument setup is as described for nephrectomy, plus fine plastic and vascular instrumentation and Randall stone forceps. A ureteral stent and red rubber catheters will also be employed. The perioperative nurse assists with positioning the patient in the lateral position.

OPERATIVE PROCEDURE

Open Approach

1. The surgeon exposes the kidney and upper ureter through a supracostal flank incision.
2. Gerota's fascia is entered, and the renal pelvis and ureter are freed while the kidney is rotated medially.
3. The surgeon frees the ureter and stabilizes it with a vessel loop below the level of the UPJ.
4. A 4-0 stay suture is placed in the tip of the ureter, and the ureter is incised, trimmed, and shaped to the desired contour with fine forceps and scissors.
5. Anchoring sutures of 4-0 material are placed for traction during reconstruction of the renal pelvis. A diamond-shaped incision is made into the renal pelvis, and the tissue is removed. The Y-V-plasty technique may be followed. It converts a Y-shaped surgical incision of the renal pelvis into a V by drawing the apex of the arms of the Y to the foot of the Y with absorbable sutures.
6. Sutures are placed at each end of the refashioned renal pelvis, passed to the ureteral stoma, and tagged. The pelvis is irrigated free of clots. The sutures are run in a continuous manner, creating the anastomosis.
7. A Silastic tubing may be used to stent the repaired pelvis until adequate healing has occurred. A nephrostomy tube is also placed within the pelvis to divert urine safely while the edema in the area of the repair resolves.
8. The surgeon closes Gerota's fascia over the repair.
9. A drain is placed where the pelvis was reconstructed, and the surgical incision is closed in layers.

Laparoscopic Approach. UPJ obstruction has recently joined the rank of surgeries that may be treated laparoscopically. Generally, a standard transperitoneal approach is used. The patient may be placed supine with a lateral tilt or in lateral decubitus and the bed rotated to access the ports.

After placement of four trocars as in laparoscopic nephrectomy, the surgeon frees the proximal ureters and renal pelvis. The obstruction at the UPJ is excised, and a spatulated anastomosis is performed using running or interrupted sutures. A ureteral stent is usually left in place.

Decreased postoperative pain and shorter hospitalization make this approach appealing. A higher degree of skill is required for this technique, however, making it an option that has not become standard treatment as yet.

Nephroureterectomy—Open Approach. Nephroureterectomy is removal of a kidney and its entire ureter. This procedure is indicated for hydroureteronephrosis of such a degree that reconstructive repair is impossible. It is also employed for collecting system tumors of the kidney and ureter.

PROCEDURAL CONSIDERATIONS. Open nephroureterectomy requires an extension of the incision anteriorly with the patient positioned semilaterally and fully prepped and draped for the surgeon to access the flank and lower abdomen. Only one instrument set is required, but a second skin-prep setup and set of sterile drapes may be necessary. An alternative to open nephroureterectomy is laparoscopic nephroureterectomy.

OPERATIVE PROCEDURE

1. The surgeon exposes the kidney and upper ureter and performs a nephrectomy as described in the following procedure. The kidney may be placed in a plastic bag to prevent possible spillage of tumor cells.
2. The ureter is mobilized as far distally as possible. The OR bed is adjusted so that surgery on the lower ureter may proceed. The lower ureter and bladder are identified and mobilized.
3. The ureter and a small cuff of the bladder are removed in continuity, and the bladder is repaired with a single layer of 2-0 absorbable interrupted sutures. The ureter and cuff of bladder are pulled superiorly, and the intact kidney and ureter are removed.
4. An 18F or 20F Foley catheter is left in the bladder, and a drain is placed behind the bladder. The incision is closed in layers.

Nephrectomy—Open Approach. Nephrectomy is the surgical removal of a kidney. It is performed as a means of definitive therapy for many renal problems, such as congenital UPJ obstruction with severe hydronephrosis, renal tumor, renal trauma, calculus disease with infection, cortical abscess, pyelonephrosis, and renovascular hypertension.

In routine renal surgery the patient is placed in the lateral position with the dependent iliac crest over the kidney rest. The operative flank is uppermost, with the patient's back brought to the edge of the OR bed. The upper arm is supported on an overhead arm support, and the lower arm is supinated on a padded armboard. It may be flexed slightly at the elbow and angled cephalad to promote better access to the flank. The patient's legs are positioned by placing a pillow between them and flexing the lower leg at the knee. The upper leg remains extended. The kidney rest is then raised, and when the desired bed flexion is achieved, 3-inch adhesive tape is used to stabilize the patient throughout surgery. Routine skin preparation and draping procedures are carried out.

PROCEDURAL CONSIDERATIONS. The nephrectomy setup includes a routine laparotomy setup; kidney instruments (Figure 14-78); a variety of red rubber, Malecot, or Pezzer catheters; a wound drainage system; and vessel loops. In certain nephrectomies the chest or the GI tract may be opened. If the chest is opened, appropriate instruments and postoperative chest drains are needed. Rib resection requires the addition of a Finochietto rib retractor, a large Matson costal periosteotome, an Alexander costal periosteotome, right and left Doyen rib raspatories, a Bethune rib cutter, a double-action duckbill rongeur, a Bailey rib approximator, and a Langenbeck periosteal elevator. When the GI tract is opened, GI technique is used for the anastomosis.

OPERATIVE PROCEDURE

1. The incision is carried through the skin, fat, and fascia. Bleeding vessels are clamped and ligated.
2. The surgeon exposes and incises the external oblique, internal oblique, and transversalis muscles in the direction of the initial skin incision.

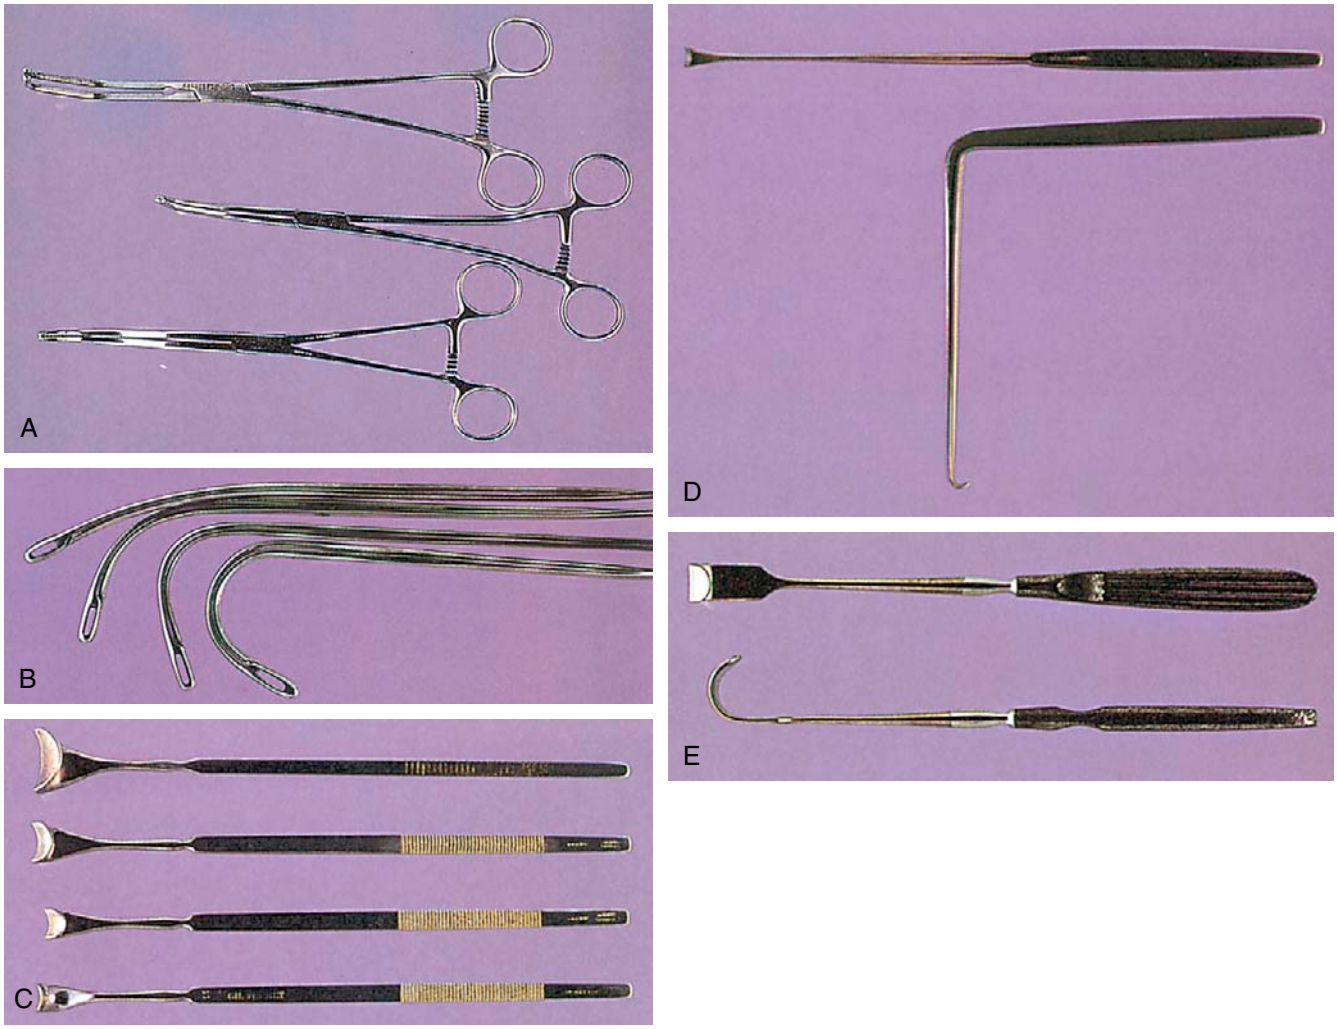

FIGURE 14-78 **A**, Kidney clamps. *Top to bottom,* Satinsky (vena cava) forceps; Herrick kidney forceps; Mayo-Guyon kidney forceps. **B**, Randall stone forcep tips. *Top to bottom,* ¼ curved, ½ curved, ¾ curved, full curved. **C**, Gil-Vernet retractors, front view. **D**, *Top to bottom,* Love nerve retractors: straight, front view; 90-degree angle, side view. **E**, *Top to bottom,* Little retractors, medium: front view, side view.

3. If necessary, a rib or ribs (eleventh and/or twelfth) may be resected to provide better access to the kidney. The surgeon strips the periosteum with an Alexander costal periosteotome and Doyen rib raspatory. A scalpel and heavy scissors are used to cut through the lumbocostal ligaments. The rib is grasped with an Ochsner clamp and cut with rib shears, removing the portion necessary to expose the kidney. Gerota's fascia is identified and incised with Metzenbaum scissors.
4. The surgeon extends the incision and uses blunt and sharp dissection to expose the kidney and perirenal fat. The surgical technologist should save all perirenal fat that is removed during surgery, placing it in a small basin of normal saline for possible use as a bolster to stop bleeding.
5. The ureter is identified, separated from its adjacent structures, doubly clamped, divided, and ligated with absorbable 0 suture.
6. The kidney pedicle containing the major blood vessels is isolated and doubly clamped; each vessel is triply ligated with heavy nonabsorbable ties. Each vessel is then severed, leaving two ligatures on the pedicle, and the kidney is removed (Figure 14-79).
7. The renal fossa is explored for bleeding, and necessary hemostasis is achieved. The fossa is then irrigated with normal saline, and the irrigant is removed by suction.
8. The surgeon closes the fascia and muscle in layers with interrupted absorbable sutures. Retention sutures may be used in obese or chronically ill patients in whom wound healing may be delayed.
9. The skin edges are approximated with sutures or skin staples, and the dressing is applied.

Laparoscopic Nephrectomy. The approach for laparoscopic nephrectomy may be transabdominal (transperitoneal), extraperitoneal (retroperitoneal), or intraperitoneal. Transabdominal is the most common approach. Indications for laparoscopy are generally for benign disease, although more radical surgeries have been accomplished in this manner. A full mechanical antibiotic bowel prep is prescribed. Although surgery time is

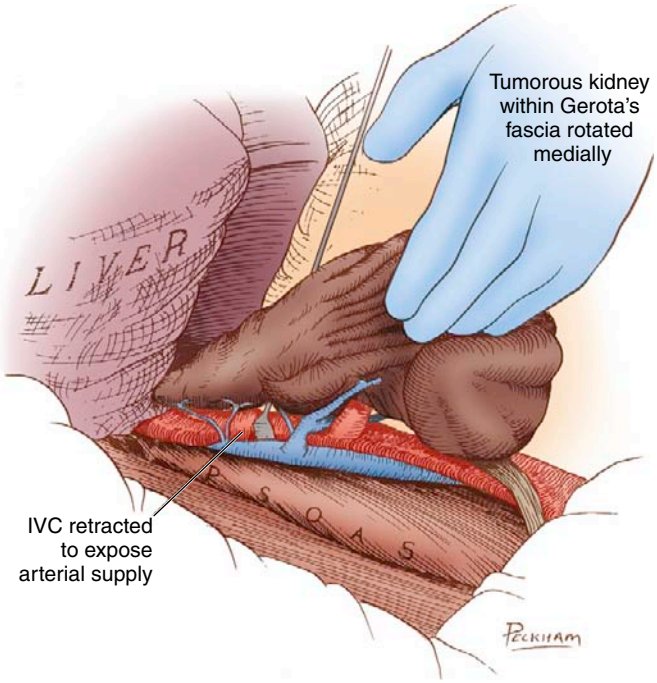

FIGURE 14-79 Nephrectomy. *IVC,* inferior vena cava.

longer (an average of 3½ to 5 hours), postoperative recovery time, analgesia requirements, and total hospital stay are lessened. The procedure always includes cystoscopy with placement of a renal balloon catheter, a ureteral catheter, and a Foley urethral catheter under C-arm fluoroscopy. Indigo carmine may be injected into the skin overlying the renal pelvis.

The patient is initially placed on a beanbag in the supine position. A standard laparoscopy instrument and equipment setup that includes three 5-mm trocars, an insufflation needle, and two 10-mm to 12-mm trocars is used. Cystoscopic and ureteroscopic supplies will be needed, as well as an 0.035-gauge Bentson guidewire, an occlusion balloon catheter, an 0.035-gauge Amplatz stiff guidewire, a 16F Foley catheter and drainage bag, indigo carmine, an irrigator-aspirator, a 1-liter bag of saline, a 1-liter pressure bag (to pressurize the irrigant to 250 mm Hg), a #12 or #11 knife blade, 10-mm clip appliers, the entrapment sack, and tissue morcellator. An open setup should always be available in the event laparoscopy is unsuccessful.

PROCEDURAL CONSIDERATIONS. The patient is prepped and draped as for laparotomy. Use of a draping pack with four large adherent drape sheets, instead of a standard laparotomy sheet, affords better access for the port sites.

The patient may be placed in lateral decubitus position on a deflated beanbag positioner at the outset or turned after endoscopic intervention. Ensuring that the patient is adequately secured to the OR bed is critical. Before prepping the patient, the bed is tilted laterally to afford a central abdominal access. The patient is prepped and draped, and access of the first three ports is achieved. Before the surgeon inserts the remaining trocars, the anesthesia provider returns the bed to its normal configuration so that the patient is again in lateral decubitus position. The kidney rest is then elevated, and the operation continues.

Some surgeons begin the procedure with the patient supine. The contralateral arm is padded with thick foam from the shoulder to the fingertips. The patient is prepped and draped for thoracoabdominal surgery. Extra draping materials are used when the patient is repositioned.

OPERATIVE PROCEDURE

1. The surgeon accesses the peritoneal cavity through a 1-cm transverse, subumbilical, stab-wound incision. After elevation of the anterior abdominal wall with towel clips, the Veress needle is inserted with the stopcock valve control in the closed position.
2. Once the Veress needle is in place, sterile saline is dropped into the lumen of the needle and the valve of the needle is opened. If the saline enters freely (a successful test), the abdominal cavity is inflated with CO_2 until a pressure of 15 to 20 mm Hg is obtained. If saline does not enter freely, it indicates improper placement of the needle.
3. The surgeon nicks the rectus fascia with the knife blade, and replaces the Veress needle with the 10-mm trocar. Towel clips are again used on each side of the incision to stabilize the abdominal wall during insertion.
4. The 10-mm laparoscope is inserted.
5. A second incision is made immediately below the costal margin in the midclavicular line, and a 10-mm to 12-mm trocar is inserted.
6. The surgeon inserts the first of three 5-mm trocars through a small incision 2 cm below the umbilicus in the midclavicular line.
7. The last two 5-mm trocars are placed, one in the anterior axillary line level with the umbilicus and one subcostal in the anterior axillary line. All trocars are then withdrawn until 2 to 3 cm of each sheath protrudes into the abdomen. The surgeon may use polypropylene suture to secure the side arm ports to the patient's skin. Each trocar site is laparoscopically inspected after trocar insertion to identify any bleeding or perforation. On occasion, it may be necessary to extend the incision for trocar insertion.
8. The ascending or descending colon is completely mobilized with electrosurgical scissors and deflected medially. The retroperitoneum is opened.
9. Using gentle motion on the ureteral catheter, the surgeon identifies and dissects the ureter. A Babcock forceps is clamped around the dissected ureter for retraction.
10. The ureter is dissected until the lower pole of the kidney is visualized (Figure 14-80). Any veins encountered are clipped twice proximally and twice distally. The kidney is cleared of surrounding tissue and freed laterally and superiorly. Gerota's fascia is entered to free the adrenal gland and exclude it from the dissection.
11. The renal artery and vein are identified and cleared to create a 360-degree window around each vessel. The clip applier is inserted through the 10-mm to 12-mm port. Two clips are placed on the specimen side, and three clips are placed on the stump side of both the artery and the vein, which are then sharply incised.
12. Two pairs of clips are placed proximally and distally on the ureter, which is sharply incised. The specimen end is grasped, and the kidney is moved into the upper abdominal quadrant.
13. The surgeon introduces the entrapment sac through the 10-mm to 12-mm port. The bottom of the sac is pulled into the abdomen with graspers until the neck of the sac clears the end of the port and is then unfurled.

FIGURE 14-80 Interior view of exposing right kidney laparoscopically.

14. The sac is opened, and the ureteral stump with attached kidney is placed inside. The drawstrings are pulled tight, closing the mouth of the sac.
15. The anesthesia provider returns the patient to the supine position by tilting the OR bed, and the sac strings are extracted through the umbilical port. Under laparoscopic observation, the surgeon removes the port and the neck of the sac is brought to lie on the abdominal surface. The tissue morcellator is inserted into the sac, and the kidney is morcellated under suction in a clockwise fashion.
16. The abdominal cavity is exited with laparoscopic observation of each trocar site, during and after removal, to ensure that hemostasis has been achieved. Fascial layers at the 12-mm trocar sites are closed with 2-0 or 3-0 absorbable suture in a figure-of-eight pattern.
17. Using a 4-0 absorbable suture, the surgeon performs a subcuticular closure of all port sites.

Heminephrectomy. Heminephrectomy is removal of a portion of the kidney. It is usually indicated for conditions involving the lower or upper pole of the kidney, such as calculus disease, or trauma limited to one pole of a kidney. In rare instances in which a patient has only one kidney, such surgery may be used for renal neoplasms to avoid the need for dialysis and subsequent renal transplantation.

PROCEDURAL CONSIDERATIONS. The setup is as described for nephrectomy with the addition of vascular and bulldog clamps.

OPERATIVE PROCEDURE

1. The kidney and its pedicle should be completely mobilized as described for nephrectomy. The main vessels may be temporarily occluded for only 20 to 30 minutes, after which progressive renal damage may occur. Local hypothermia may be indicated to prolong ischemic operating time.
2. The renal capsule is incised and stripped back.
3. A wedge of kidney tissue containing the diseased or damaged cortex is excised. The surgeon clamps the interlobar fat or arcuate and interlobular arteries with Hopkins clamps and suture-ligates them with 4-0 absorbable suture on urologic needles.
4. The surgeon reapproximates the open collecting system with a continuous 4-0 suture.

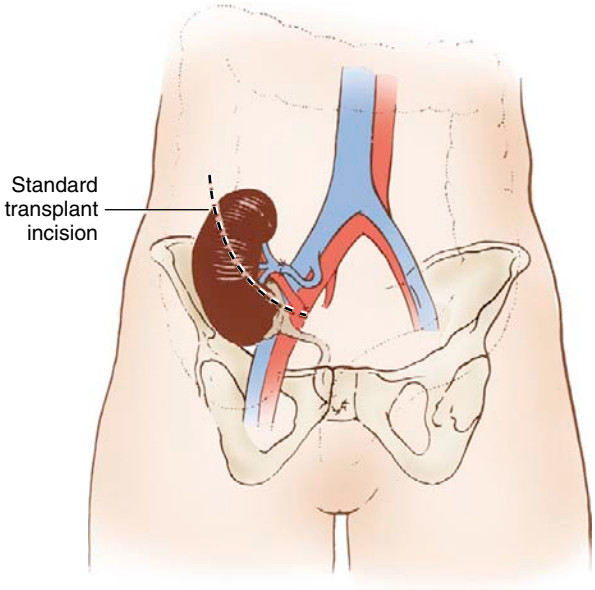

FIGURE 14-81 Transplanted kidney in recipient's iliac fossa.

5. Perirenal fat is placed in the area in which tissue was excised, and the renal parenchyma is reapproximated with horizontal mattress sutures.
6. If possible, the renal capsule is reapproximated with a continuous 2-0 suture.

Radical Nephrectomy. Radical nephrectomy is excision of the kidney, perirenal fat, adrenal gland, Gerota's capsule (fascia), and contiguous periaortic lymph nodes. This procedure is performed for parenchymal renal neoplasms. In the open approach, a lumbar, transthoracic, or transabdominal approach to the kidney is used, depending on the size and location of the lesion. The transthoracic or transabdominal approach is preferred because the blood vessels of the kidney can be more easily reached and ligated before the tumor is mobilized, decreasing the possibility of tumor embolization into the bloodstream. For the laparoscopic approach a retroperitoneal or transperitoneal approach may be employed.

PROCEDURAL CONSIDERATIONS. The setups are as described for open nephrectomy and laparoscopic nephrectomy.

OPERATIVE PROCEDURE. In general, the procedure is as described for nephrectomy with two exceptions: (1) the renal pedicle is ligated before the kidney is mobilized, and (2) Gerota's capsule is not incised but is removed en bloc with the kidney. Involved lymph nodes surrounding the renal pedicle are excised. A chest tube is inserted if the transthoracic approach is used.

Kidney Transplant

Kidney transplant entails transplantation of a living-related or cadaveric donor kidney into the recipient's iliac fossa (Figure 14-81). It is performed in an effort to restore renal function and thus maintain life in a patient who has end-stage renal disease.

Transplant from a Living Donor. The kidney donor must be in good health. ABO (blood typing) and histocompatibility (human leukocyte antigen [HLA] tissue typing) along with a negative white cell (lymphocyte) crossmatch determine

donor-recipient compatibility. It is not necessary to match the Rh factor. Once the donor has been chosen, a complete workup that includes history, physical examination, chest x-ray examination, ECG, CBC, BUN and creatinine values, blood chemistry profiles, coagulation studies, viral titers, and serologic testing is performed. Renal function is assessed by monitoring three creatinine clearances, urinalysis, and blood and urine cultures if hospitalized 72 hours or longer, followed by IVP and excretory urography. A flush aortogram assesses the vascular anatomy, and renal angiography pinpoints the kidney of choice while ruling out the presence of renal lesions. A kidney with a single renal artery is preferred, but kidneys with double and triple arteries may be used if necessary. If there is a family history of diabetes, a 5-hour glucose tolerance test is also performed (UNOS, 2009).

The ideal living donor is an identical twin, although any immediate family member (usually a sibling or parent) may be a donor. The donor is given an IV solution of 1000 ml of 5% dextrose in lactated Ringer's on the evening before nephrectomy. This is followed with 500 ml of 5% dextrose in water over the next 10 to 12 hours. The morning of surgery, about 45 minutes before transport to the OR, 12.5 g of mannitol is administered to ensure diuresis during the induction of anesthesia.

PROCEDURAL CONSIDERATIONS. Two adjacent ORs are prepared for the procedures; surgery on the donor and surgery on the recipient proceed simultaneously.

Usually the right kidney is chosen for removal because of its smaller size, leaving the donor patient with the left and larger kidney. Two IV lines are required. The patient is placed on a beanbag positioning device and moved into the left lateral decubitus position following endotracheal intubation. The lower arm is positioned extended outward on a well-padded armboard at a right angle to the torso; the upper arm is positioned on an elevated lateral armboard. The sternum and anterior superior iliac spine are brought near the edge of the OR bed. A pillow is placed between the patient's legs, and the ankles and feet are appropriately padded. The bed is flexed to 30 degrees, and the upper portion is angled downward to approximately 140 degrees. The skin is prepped from midchest to midthigh and draped to expose the flank area.

Required instruments and equipment are identical to those for a nephrectomy plus an IV pole and supplies for the sterile perfusion table. These include electrolyte solution (placed in an iced basin until needed), two IV extension tubes, a kidney basin with cold (4° C) IV saline solution, a three-way stopcock, an 18-gauge needle catheter, mosquito hemostats, vascular forceps, Metzenbaum scissors, suture scissors, and Kelly hemostats.

An electrolyte solution of Ringer's lactate that contains procaine and heparin may be used to perfuse the harvested kidney. A more common perfusion is CUW (Chelex-treated University of Wisconsin) solution. It contains hydroxyethyl starch, providing a better metabolic substrate for organ metabolism.

Collins or Sachs solution may be used to perfuse cadaveric kidneys after harvest but should never be used to perfuse a kidney from a living donor because of the potential effect of elevated potassium in the recipient from residual perfusate in the kidney.

OPERATIVE PROCEDURE

Open Approach

1. The donor nephrectomy procedure is as described for nephrectomy; however, the ureter and renal vein and artery require meticulous dissection.
2. Maximum length of the ureter is achieved by dividing it at or below the pelvic rim if possible. To preserve adequate ureteral vascularization, the surgeon is cautious not to skeletonize the ureter.
3. Particular care is taken to remove the maximum length of the renal vein and artery. Obtaining the maximum length of the right renal vein sometimes requires partial occlusion of the inferior vena cava with a Satinsky clamp and dissection of a portion of the inferior vena cava. This is done after the ureter has been freed.
4. Repair of the inferior vena cava is made with a continuous 4-0 or 5-0 vascular suture.
5. Five minutes before the surgeon clamps the renal vessels, 5000 units of heparin sodium and 12.5 g of mannitol are systemically administered to the patient to prevent intravascular clotting and maximize diuresis.
6. Immediately after the kidney is removed from the donor, the anesthesia provider administers 50 mg of protamine sulfate intravenously to reverse the heparinization.
7. Furosemide, mannitol, and IV fluids are administered to the donor to maintain adequate urinary output from the donor's remaining kidney.
8. Gentle handling of the kidney is essential. Team members must prevent undue traction on the vascular pedicle, which may induce vasospasm and reduce perfusion of the kidney.
9. To reduce warm ischemia time, the surgeon double-clamps the vein and the artery, excises the kidney, and immediately places it in cold saline solution on a sterile back table, where the kidney is flushed with the designated electrolyte solution. Warm ischemia time (from the clamping of renal vessels to a point at which the kidney is perfused with cold electrolyte solution) should be kept to a minimum to prevent acute tubular necrosis and to maintain maximum renal function after transplantation.
10. Mosquito clamps and fine vascular forceps are used to expose the renal artery to permit insertion of a needle catheter. The cold electrolyte solution passes through the IV tubing and the needle catheter, flushing any remaining donor's blood from the kidney. This also decreases the kidney's metabolic rate by lowering its temperature. Flushing time is usually 2 to 5 minutes.
11. After flushing, the surgeon may trim the vessels of adventitia to facilitate the vascular anastomosis to the recipient's iliac vessels.
12. The kidney, in cold saline solution, is covered with sterile drapes and taken by the surgeon to the room in which the recipient's iliac vessels have been exposed.
13. Wound closure for the donor is as described for nephrectomy.

Laparoscopic Approach. Five trocars are used (four trocars if the left kidney is chosen). Generally the operating trocar is 12 mm, the second and third trocars are 10 mm, and the last two trocars are 5 mm. Instruments required include the following: four 5-mm fenestrated graspers, 5-mm straight and curved dissecting scissors, a coagulating hook, a bipolar grasper, ultrasonic scissors, two 5-mm curved graspers and a 10-mm curved grasper, two needle holders, a clip applier, a vascular stapler, and an atraumatic retrieval bag without a system for opening and closing it and a minimal opening of 15 cm. In addition, the standard open setup needs to be ready with open vascular

instrumentation, a smooth perfusion tip, sterile IV tubing, and sterile ice for ex vivo perfusion.

1. The first 12-mm trocar is introduced through an open technique at a level 2 to 5 cm cephalad to McBurney point to allow access to the superior pole and as far caudad as possible so the renal vein may be divided parallel to the vena cava.
2. The surgeon inserts the second 10-mm trocar in the periumbilical position about 3 cm lateral and cephalad to the umbilicus. This will be used for the laparoscope.
3. The third 10-mm trocar is placed 6 to 8 cm cephalad to the second trocar.
4. A 5-mm trocar is inserted into the flank at the convex border of the kidney.
5. The surgeon places the final 5-mm trocar below the xiphoid process to the left of the round ligament.
6. The OR bed is rotated vertically, and the small intestine and omentum are pushed into the inferior pelvic cavity.
7. Beginning at the foramen of Winslow, the subhepatic parietal peritoneum is incised and followed by division of the triangular ligament of the liver. Grasping forceps are placed posterior to the liver and used to retract the right lobe ventrally.
8. The surgeon incises the pericolic gutter beginning at the cecal base, extending to the hepatic flexure, and ending at the duodenum.
9. The duodenum is then freed of its attachments to the mesenteric root. The entire length of the subhepatic vena cava is exposed to the level of the iliac bifurcation.
10. The renal vein is identified and a vessel loop placed around it. Dissection of the right border of the subhepatic vena cava is carried out along the entire length. The right gonadal vein is clipped and divided at its caval origin.
11. A vessel loop is then passed around the right renal artery.
12. The ureter lies anterior to the iliac vessels. It is located, controlled with a vessel loop, and dissected caudad to cephalad, also removing areolar tissue. Once dissection reaches the inferior pole of the kidney, Gerota's fascia is incised and dissection continues to the renal parenchyma.
13. Pararenal fat is removed and a dissection plane is created against the renal capsule. When the anterior surface of the kidney has been freed the superior pole is separated from the adrenal gland.
14. Dissection is now directed to the inferior renal pole to free the kidney posteriorly from pararenal fat. Once free it is rotated ventrally to expose the vessels already marked with the vessel loops. The vessels are circumferentially dissected, and the kidney is freed.
15. The surgeon clips the distal end of the ureter and divides it at its bifurcation with the iliac vessels. Copious diuresis generally occurs at this point.
16. A 6-cm incision is made just above the pubic symphysis. The aponeurosis is transversely divided, and the rectus abdominis muscles are retracted.
17. The retrieval bag is introduced directly into the peritoneal cavity. It is placed around the kidney and held firmly without obstructing the vessels.
18. The grasper that has been placed in the suprapubic area is used to keep the retrieval bag closed and exert enough traction on the renal vessels to promote maximum length.
19. The renal side of the renal artery is left open while the surgeon applies one or two clips on the aortic side. This is divided in two steps to ensure occlusion.
20. The vein is divided with a vascular stapler, including a small cuff of the vena cava to add extra length.
21. The suprapubic peritoneal opening is widened manually, allowing the kidney to be extracted. It is immediately perfused on ice with 4° C CUW solution. Vessels are individually perfused. The volume corresponds to about 300 ml. This continues until the outflow from the vein becomes completely transparent.
22. The surgeon irrigates the peritoneum and achieves hemostasis. A drain may be inserted into the peritoneal space for a short time postoperatively.
23. The wounds are sutured and dressings applied.

Transplant from a Cadaveric Donor. The ideal cadaveric donor is young, free from infection and cancer, normotensive until a short time before death, and under hospital observation several hours before death. Permission to harvest the donor kidney must be obtained from the family and the medical examiner after brain death has been unequivocally established. Awareness of existing state legislation in this complex area is advisable.

The donor is completely evaluated. The medical history is reviewed for any possible contraindications, such as chronic disease, ongoing systemic infection, IV drug abuse, malignancy, heart or lung disease, trauma to the donor organ, and the presence of human immunodeficiency virus (HIV). Laboratory studies include blood typing, urinalysis, urine and blood cultures, BUN, serum creatinine, CBC, hepatitis B antigen evaluation, Venereal Disease Research Laboratories (VDRL) for the presence of venereal disease, and p24 antigen capture assay for the presence of HIV antigen. Evaluation of arterial blood gases, electrolyte values, and liver enzymes is also necessary. Because of improvements in medical therapy, the only absolute contraindications to organ donation are HIV and metastasis.

Preoperative management of the cadaver donor is vital to the success of the transplant. Organ perfusion, oxygenation, and hydration must be maintained. Arterial blood gas (ABG) evaluation determines ventilatory support, and dopamine may be administered if fluids alone are not able to maintain an adequate systolic blood pressure. Urine output is monitored, and antibiotics may be administered to combat and prevent infection.

PROCEDURAL CONSIDERATIONS. After brain death has been established, the donor is taken to the OR with respiratory and cardiac function maintained mechanically. The donor is placed in the supine position and is prepared for a laparotomy. Anticoagulant and α-adrenergic receptor blocking agents are administered systemically during the procedure. Adequate renal perfusion and function are maintained with IV fluids and diuretics.

Instruments and equipment are the same as those for nephrectomy, with the addition of Metzenbaum scissors, suture scissors, vascular forceps, DeBakey forceps, Dean hemostatic forceps, mosquito hemostats, DeBakey clamps, angled clip appliers with medium and large clips, bulldog clamps, vascular clamps, Deaver retractors, Harrington splanchnic retractors, vascular needle holders, a sternal saw or Lebsche knife and mallet, umbilical tapes, electrolyte solution (lactated Ringer's, Sachs, or Collins), cold packing in an iced basin until needed, an IV pole, IV extension tubes, a kidney basin with cold (4° C) IV saline solution, a three-way stopcock, an 18-gauge needle catheter, a centimeter ruler, the perfusion machine or kidney transplantation equipment, and ice.

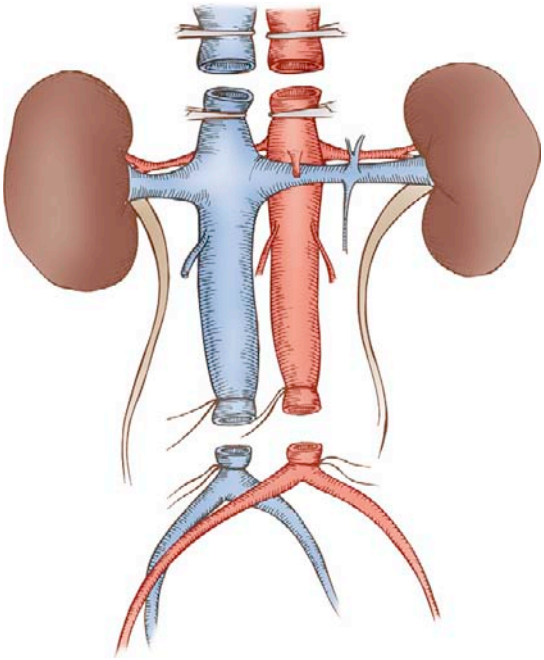

FIGURE 14-82 En bloc resection.

OPERATIVE PROCEDURE

1. The surgeon makes a midline incision from the xiphoid process to the symphysis pubis with bilateral supraumbilical transverse extensions through the skin, subcutaneous layer, fascia, and muscle.
2. Hemostasis is obtained with clamps, ties, suture ligatures, and electrocoagulation.
3. The kidney, renal vessels, and ureter are carefully dissected with Metzenbaum scissors, DeBakey forceps, and Dean hemostatic forceps.
4. The anesthesia provider administers 15,000 units of heparin sodium intravenously 5 to 10 minutes before the renal vessels are clamped.
5. The usual method of resection is en bloc resection (harvesting of donor kidneys) (Figure 14-82), which involves the removal of sections of the inferior vena cava and aorta with both kidneys in continuity.
6. The surgeon makes an incision along the route of the small bowel mesentery up to the esophageal hiatus.
7. The entire GI tract, spleen, and inferior portion of the pancreas are mobilized by dividing the celiac axis and the superior mesenteric artery, exposing the entire retroperitoneal region.
8. Using vascular clamps, the surgeon clamps and divides the inferior vena cava and aorta below the renal vessels.
9. Lumbar tributaries are secured with metal clips and are divided.
10. The kidneys and ureters are freed from their surrounding soft tissues.
11. The ureters are divided distally at the pelvic brim.
12. The surgeon clamps and divides the suprarenal aorta and inferior vena cava at the level of the diaphragm, close to the bifurcation.
13. The vessels and kidney are severed and the aorta and vena cava ligated.
14. After removal of the kidneys, immediate perfusion with cold (4° C) CUW or electrolyte solution is carried out. The kidneys are placed in a container of cold saline solution and surrounded by saline slush in an insulated carrier or placed on a hypothermic pulsatile perfusion machine for transport. While kidney perfusion is begun, the abdominal lymph nodes and spleen are removed for use in tissue typing.
15. The incision is closed with interrupted sutures, and artificial life-support systems are terminated. The perioperative nurse cares for the patient's body, preserving privacy, dignity, and humanity at the patient's death.

Transplant Recipient. Each potential recipient is judged individually in regard to kidney transplantation. Most persons younger than 55 years are acceptable; older patients are less tolerant of postoperative complications. Contraindications for renal transplantation include (1) systemic disease that precludes major surgery, (2) oxalosis (a metabolic disorder), (3) a positive HLA cytotoxic antibody screen, (4) untreatable cardiovascular disease, (5) active cancer, and (6) noncompliance (Ibrahim and Kasiske, 2008). If required, a patient may need to undergo bilateral nephrectomy before renal transplantation for uncontrollable hypertension, for kidney infections, or for reflux when there is a significant history of infections. Occasionally a large polycystic kidney may need to be removed to create a space for the new kidney. Splenectomy may be performed at this time to improve leukopenia and enhance the effects of myelosuppressive and immunosuppressive drugs.

The transplant recipient requires optimal nutritional support and adequate dialysis. All potential sources of infection must be treated. Most commonly these include teeth, bladder, nasal sinuses, and skin. The patient may need a short hemodialysis to control fluid overload or electrolyte imbalances. A repeat cytotoxic crossmatch with fresh serum specimens should follow hemodialysis. Preoperative antibiotics are commonly administered. Other important diagnostic tools for preoperative evaluation are chest x-ray examination, abdominal ultrasonography, voiding cystourethrography, liver function studies, hematologic assays, and serum values for screening hepatitis, HIV, and viral diseases.

PROCEDURAL CONSIDERATIONS. The perioperative nurse positions the patient in the supine position. A Foley catheter with an attached Silastic stenting catheter is inserted into the bladder by sterile technique. From 50 to 75 ml of antibiotic solution is instilled into the bladder through a sterile, catheter-tipped syringe, allowed to remain for 20 minutes, and drained. The patient is prepped from nipples to knees and draped.

OPERATIVE PROCEDURE

1. The surgeon makes a curved right lower quadrant incision through the skin, subcutaneous layer, fascia, and muscle.
2. Bleeding is controlled with clamps, ties, and electrocoagulation.
3. The inferior epigastric vessels are divided between suture ligatures.
4. Retroperitoneal dissection is performed by mobilizing the peritoneum superiorly and medially.
5. A Balfour self-retaining retractor is placed in the wound for exposure, and a wide Deaver retractor used to reflect the peritoneum superiorly and medially.

6. Using Metzenbaum scissors and DeBakey forceps, the surgeon dissects along the entire length of the hypogastric artery and the external and common iliac arteries to the bifurcation of the aorta, continuing down the internal iliac artery.
7. The internal iliac artery is ligated distally and divided, with proximal control maintained by a vascular clamp.
8. The iliac vein may be dissected free by ligating and dividing the internal iliac venous branches with 3-0 nonabsorbable sutures or ligating clips. More commonly, only the hypogastric artery and that portion of iliac vein to be anastomosed are dissected free.
9. The donor kidney is brought into the operative field and placed in cold (4° C) IV saline solution.
10. The surgeon uses mosquito hemostats, 4-inch DeBakey forceps, and curved and straight fine scissors to make the necessary alterations on the donor kidney vessels to facilitate the anastomoses.
11. The donor kidney is returned to the cold IV saline solution until the time of the anastomosis.
12. Two angled DeBakey vascular clamps are placed on the internal iliac vein.
13. A #11 blade is used to make a 1-cm incision in the iliac vein between the clamps.
14. The vessel is rinsed with heparin sodium solution (10 units/ml) in the Asepto syringe.
15. Angled Potts scissors are used to extend the incision to accommodate the donor renal vein.
16. The donor kidney is placed in a 3-inch by 10-inch, cold saline–soaked stockinette, with the renal vessels leaving from a hole in the side. Use of the stockinette prevents direct contact with the kidney and therefore trauma.
17. The surgeon performs the anastomosis of the donor kidney renal vein to the side of the recipient's iliac vein with 5-0 double-armed vascular sutures.
18. In like manner the renal artery is anastomosed end-to-end with the proximal portion of the internal iliac artery using 5-0 vascular sutures.
19. Before placing the final sutures, the vessels are irrigated proximally and distally with heparin sodium solution by using the 10-ml syringe attached to a catheter.
20. The stockinette is removed for adequate visualization of the entire kidney. The angled DeBakey clamps are removed from the venous vessels, and the anastomosis is checked for leakage.
21. The clamps on the internal iliac artery are then released, and the anastomosis is checked.
22. Meticulous inspection is made of the hilum and surface of the kidney for bleeding and infarction.
23. The anesthesia provider administers diuretics intravenously as needed.
24. Attention is then directed to the ureter and bladder.
25. Two long Martius forceps are used to grasp the anterior bladder wall.
26. Using a scalpel with a #10 knife blade, the surgeon makes a 4-cm anterior incision.
27. Two narrow Harrington retractors and one narrow Deaver retractor are inserted into the bladder for exposure.
28. The ureter is passed through the bladder wall and tunneled suburothelially for 2 to 2.5 cm.
29. The surgeon sutures the spatulated end of the ureter into the bladder urothelium with four to six 4-0 or 5-0 atraumatic absorbable sutures, creating a ureteroneocystostomy.
30. A 5F pediatric infant feeding tube is passed through the ureteroneocystostomy, up to the renal pelvis, and out through the urethra with the Foley catheter. This stenting catheter will remain in place for 36 to 48 hours to ensure ureteral patency during a period in which ureteral edema may occur.
31. Retractors are removed, and the bladder is closed in three layers.
32. Continuous 4-0 absorbable suture is used for urothelial closure and interrupted 2-0 absorbable suture for closure of bladder muscles.
33. An overlapping layer of 2-0 nonabsorbable material is used to bury the suture line.
34. The bladder is irrigated with an antibiotic solution to check for leaks.
35. The renal anastomoses are again checked for bleeding.
36. The surgeon places three metal clips on the superior, inferior, and lateral aspects of the kidney to radiographically measure renal size and determine postoperative swelling.
37. Retractors are removed from the incision.
38. Closed-wound suction drains are inserted into the wound, exteriorized through the skin laterally, and secured with 2-0 nonabsorbable suture on a cutting needle.
39. Muscle and fascial layers are closed with a single layer of 0 nonabsorbable sutures on a large atraumatic needle.
40. The subcutaneous layer is closed with 3-0 absorbable sutures on an atraumatic needle.
41. Skin closure is accomplished with skin staples, and dressings are applied.
42. The bladder is irrigated with 50 to 75 ml of antibiotic solution to prevent infection and free any blood clots.

Adrenalectomy

Adrenalectomy is partial or total excision of one or both adrenal glands. It may be performed for several reasons: hypersecretion of adrenal hormones; neoplasms of the adrenal gland; secondary treatment of neoplasms elsewhere in the body that depend on adrenal hormonal secretions, such as carcinoma of the prostate and breast; and pheochromocytoma.

Care of the patient with pheochromocytoma carries with it particular concerns for the perioperative nurse. These patients are subject to extreme elevations in blood pressure, often accompanied by tachycardia, and hypovolemic states that can induce vascular collapse. If an adrenal tumor is being excised, early ligation of the adrenal vein is crucial in avoiding a sudden blood pressure elevation from the manipulation of the gland. After tumor removal there will be a rapid drop in blood pressure that can be minimized by maintenance of blood volume and administration of norepinephrine. With bilateral adrenalectomy, cortisone replacement will be instituted.

Procedural Considerations. Adrenalectomy may be approached as a laparoscopic or an open procedure. The laparoscopic approach is generally associated with less morbidity and shorter hospital stays. For unilateral adrenalectomy, the patient may be placed in the lateral or supine position, depending on the intended approach. If both glands are to be removed the supine or prone position is selected. The prone position is especially useful for a known disorder, such as aldosteronism, localized benign lesions, and solitary adenomas of Cushing's disease, and for debilitated patients with an advanced neoplasm.

The setup for a lateral approach is like that described for nephrectomy, including rib resection instruments, vascular instruments, and vessel clips and appliers. The setup for an abdominal approach is like that described for laparotomy, including vascular instruments, extralong scissors, tissue forceps, Rochester-Péan forceps, Mixter forceps, and needle holders. Penrose tubing is needed for retraction. Vessel clips and appliers also may be needed, as well as various sizes of nonabsorbable braided sutures.

The setup for the posterior approach is like that described for the lateral approach. The patient is placed prone in a 35-degree jackknife position with the kidney rest under the inferior margin of the anterior rib cage. Both arms should be carefully extended cephalad with adequate support under each shoulder.

Operative Procedure

LAPAROSCOPIC APPROACH

1. A 1.5-cm incision is made at the tip of the twelfth rib. The thoracolumbar fascia is entered by blunt dissection, and the 12-mm balloon dissector is placed behind Gerota's fascia and along the anterior axillary line. The balloon is inflated with 800 ml of saline, and the laparoscope is used to confirm balloon placement.
2. The operating balloon trocar is then placed in this position.
3. The surgeon inserts two 10-mm trocars on each side of the initial trocar, along the costal margin, in the anterior and posterior axillary line.
4. The fourth trocar is placed along the posterior costal margin.
5. Dissection begins near the renal hilum, incising into Gerota's fascia.
6. The surgeon identifies, clips, and divides the adrenal arteries.
7. The anterior, lateral aspect of the gland is freed from the upper pole of the kidney.
8. The adrenal vein is clipped and divided.
9. The surgeon mobilizes the posterior, superior, and anterior surfaces of the adrenal gland. A fan retractor is employed to retract the pancreas and spleen, or pancreas and liver, depending on which side the gland is being excised.
10. The adrenal branches of the inferior phrenic vessels and any accessory vessels are clipped and divided. The gland is removed through the original port using a retrieval sac. Hemostasis is achieved. The trocars are then sequentially removed, the incisions closed, and dressings applied.

LATERAL APPROACH—OPEN

1. A flank, thoracolumbar, or transthoracic incision is performed as described for nephrectomy.
2. The rib underlying the chosen approach is resected or deflected for optimum exposure of the upper pole of the kidney.
3. Entry is between the eleventh and twelfth ribs in a flank approach, the tenth and eleventh ribs in a thoracolumbar approach, and the ninth and tenth ribs in a transthoracic approach.
4. An opening is made with scissors through the transverse fascia.
5. The pleura and diaphragm are protected with moist laparotomy packs, and Gerota's fascia is incised to expose the kidney and adrenal gland.
6. The surgeon identifies the gland and dissects it free from the upper pole of the kidney with scissors and Babcock forceps.
7. The blood supply of the gland is identified, clamped or clipped, fescia and divided. Bleeding vessels are ligated.
8. To release the gland, the left adrenal vein, a branch of the left renal vein, is separated by clamping and cutting. The right adrenal vein, a tributary of the vena cava, is also divided. Fine vascular sutures may be required to repair inadvertent injury to the vena cava.
9. When hemostasis has been ensured, the wound is closed sequentially in layers: muscle, fascia, subcutaneous tissue, and skin. Dressings are then applied.

ABDOMINAL APPROACH

1. The abdominal wall is incised with an upper abdominal incision, and the peritoneal cavity is opened and explored.
2. Hemostasis is established.
3. The abdominal wound is retracted, and the surrounding organs are protected with moist laparotomy packs.
4. The surgeon opens the retroperitoneal area near the diaphragm on the left side, exposing the renal fascia.
5. The renal fascia is opened to reveal the left kidney and adrenal gland.
6. Using blunt and sharp dissection, the surgeon frees the adrenal gland from the kidney, clamps all bleeding vessels, and ligates them with 3-0 nonabsorbable sutures.
7. After all bleeding is controlled, the surgeon replaces the kidney in the renal fascia, and closes it with interrupted 0 absorbable sutures.
8. The peritoneum is closed over the left kidney and renal fascia.
9. The abdominal retractors are rearranged to provide access to the peritoneum over the right kidney and adrenal gland. Care must be taken to prevent trauma to the liver.
10. The surgeon repeats the procedure on the right side, taking care to clamp and ligate the short adrenal vein.
11. The abdomen is inspected for bleeding vessels, which are clamped and ligated.
12. The wound is closed and dressings applied.

POSTERIOR APPROACH

1. The surgeon makes an incision over the eleventh or twelfth rib.
2. The periosteum is elevated, avoiding the nerve and vessels on the inferior margin.
3. The diaphragm and pleura are displaced superiorly, and the appropriate rib is resected.
4. Hemostasis is achieved.
5. Gerota's fascia is incised, and through sharp and blunt dissection the surgeon exposes the posterior aspect of the upper pole of the kidney.
6. The upper pole is mobilized, and a padded retractor is placed to deflect the kidney downward for the approach to the adrenal gland.
7. The suprarenal fat is meticulously dissected.
8. Vessel clips are used for control of smaller vessels.
9. Dissection continues superiorly, laterally, and inferiorly while the integrity of the hilum of the adrenal gland is maintained.
10. With right-angled clamps, the adrenal vein and artery are freed, divided, and ligated with 0 or 2-0 braided nonabsorbable ties.
11. Babcock clamps are employed for manipulation and removal of the adrenal gland.
12. Bleeding is controlled, and the wound is inspected for injury to renal structures.
13. The surgeon closes Gerota's fascia with interrupted absorbable sutures.
14. The wound is closed and dressings applied.

CHAPTER 15

Thyroid and Parathyroid Surgery

JOANNE WENTZELL

The first documented thyroid surgery occurred in the twelfth century (History box). Today surgeons continue to perform surgical procedures on the thyroid gland for various underlying causes. Surgery ranges from lobectomy and isthmectomy for papillary microcarcinomas (lesions smaller than 1 cm) to near-total and total thyroidectomies for symptomatic multinodular goiters. Technologic advances have added new approaches to thyroid and parathyroid surgery, such as minimally invasive surgery (MIS) techniques.

Surgical Anatomy

Thyroid Gland

The thyroid gland (Figure 15-1) is a highly vascular organ that lies in the anterior portion of the neck, deep to the paired strap muscles, resting on the midline of the trachea. It is attached to the cricoid and trachea by the ligament of Berry. The inferior border of the thyroid varies and may be located above or below the sternal notch. It consists of right and left lobes united by a middle portion, the isthmus, and it weighs approximately 20 g (Figure 15-2). The isthmus is situated near the base of the neck, between the second and fourth tracheal rings, and the lobes lie beside the larynx, trachea, and esophagus. The pyramidal lobe, a long, thin projection of thyroid tissue protruding cephalad from the isthmus, is found in about 30% of patients at surgery; it is the vestige of the embryonic thyroglossal duct and migrates from the foramen cecum at the base of the tongue. If the migratory tract fails to degenerate, a fistula or cyst may be present (Loevner and Mukherji, 2008).

Blood supply to the thyroid is from the superior thyroid artery, which originates from the external carotid artery, and from the inferior thyroid artery, which originates from the thyrocervical trunk of the subclavian artery. The points at which these two arteries enter the thyroid gland are referred to as "poles" of the thyroid and are important anatomic landmarks during surgery. The thyroid gland is drained by three pairs of veins (superior, middle, and inferior thyroid veins). Occasionally a single thyroid artery (thyroidea ima) may arise directly from the arch of the aorta or the innominate artery and rise in front of the trachea to enter the midline of the gland inferiorly.

The recurrent laryngeal nerve, a branch of the vagus nerve, innervates the intrinsic muscles of the larynx. The right recurrent laryngeal nerve loops under the subclavian artery and ascends in an oblique direction lateral to the tracheoesophageal groove. The recurrent laryngeal nerve contains both motor and sensory fibers. The motor component innervates the abductor muscles of the true vocal cords. The sensory component supplies sensation to the larynx below the vocal cords. During surgery, care is taken to identify and protect this nerve. Immediate hoarseness occurs if the nerve is divided on one side. If the recurrent nerve is injured bilaterally, acute paralysis of both vocal cords may obstruct the airway and require emergency tracheotomy. Injury to the external branch of the superior laryngeal nerve, which innervates the cricothyroid muscle, results in difficulty shouting or singing high notes.

The thyroid gland produces three hormones: thyroxine (T_4) and triiodothyronine (T_3) (together known as the *thyroid hormones [TH]*) and calcitonin. T_3 and T_4 cannot be synthesized without iodine. Calcitonin increases calcium storage in the bone and decreases blood calcium levels. The primary function of thyroid hormones is to regulate energy metabolism, but they also play an important role in growth and development. Thyroid-stimulating hormone (TSH) is synthesized by the anterior pituitary, and stimulates the production and release of thyroid hormones and the uptake of iodine.

Parathyroid Gland

The parathyroid glands usually consist of four small, mahogany-to-yellow, flat, ovoid masses (Figure 15-3) (Gauger and Doherty, 2004). Normal parathyroid glands are generally small, lobular, and yellow in color, about the size of a lentil bean. It can be challenging to differentiate the gland from a lobule of fat, a thyroid nodule, or lymph node. Thyroid adenomas generally, although not always, tend to be larger, asymmetric, and more of a red-brown hue than normal parathyroids (Figure 15-4). The upper pair of glands lies in proximity to the posterior portion of the superior pole of the thyroid; the lower pair usually (about 60% of the time) lies near the posterior lateral aspect of the lower pole of the thyroid. Ectopic parathyroid glands, more common in the inferior parathyroid glands, may be found in the superior mediastinum, especially within the thymus and as low as the pericardium. Parathyroids may also be buried under the strap muscle, in the carotid sheath, or embedded in the thyroid beneath the capsule (Loevner and Mukherji, 2008). Each parathyroid gland measures approximately 3 mm × 3 mm × 3 mm and generally weighs less than 50 mg; the upper glands are generally smaller than the lower ones. Both the upper and lower parathyroid glands receive their blood supply from the inferior thyroid artery (Figure 15-5). As the blood supply to the superior parathyroid stems from that of the supply to

HISTORY

Formerly Hazardous, Thyroid Surgery Now Minimally Invasive and Focused

Since 2700 BC, long before the thyroid gland was identified, goiters (from Latin *gutter* for "throat") have been described. Europeans living 2000 years ago, especially those living in the Alps, noted a swelling in the neck and called it *bronchocele,* ancient Greek for "tracheal out-pouching." Thousands of years later, Hieronymus Fabricius ab Aquapendente in 1619 recognized that goiters arose from the thyroid gland.

With the Italian Renaissance came an expansion of inquiry into the human body. During this time, the thyroid gland was identified. Around 1500 Leonardo da Vinci depicted the gland and in 1543 Vesalius called the thyroid gland the "laryngeal glands." da Vinci's drawings portrayed the thyroid as two separate glands on either side of the larynx. Thomas Wharton, with his 1656 publication *Adenographia,* is credited for replacing the term "laryngeal gland" with the term "thyroid gland" (Greek *thyreoeides,* for "shield shaped").

In 1170 Roger Frugardi first described thyroid surgery. Thyroid surgery was hazardous, with death rates of more than 40%. High death rates continued until the 1800s when increased knowledge and advances in general anesthesia, antisepsis, and hemostasis became the norm.

In the late 1800s two notable thyroid surgeons—C.A. Theodor Billroth (1829 to 1894) and Emil Theodor Kocher (1841 to 1917)—revolutionized the treatment of thyroid diseases. Despite Billroth's earlier success with thyroidectomies, Kocher is regarded as the father of thyroid surgery. Kocher performed more than 2000 thyroid surgeries in the late 1800s, with only a 4.5% death rate, and he received the Nobel Prize in 1909 for his contributions to this field. In 1914 Kendall isolated the hormone *thyroxine (T_4).* Since 1941 thyroidectomy as treatment of thyroid mass (goiter) has become less frequent because of the use of radioactive iodine (RAI) and antithyroid drugs, which reduce the activity of the thyroid gland.

Over the last 10 years new technology and techniques have been introduced that have greatly improved thyroid and parathyroid surgeries. Minimally invasive and focused approaches have enhanced and refined treatment and surgery for thyroid and parathyroid disease.

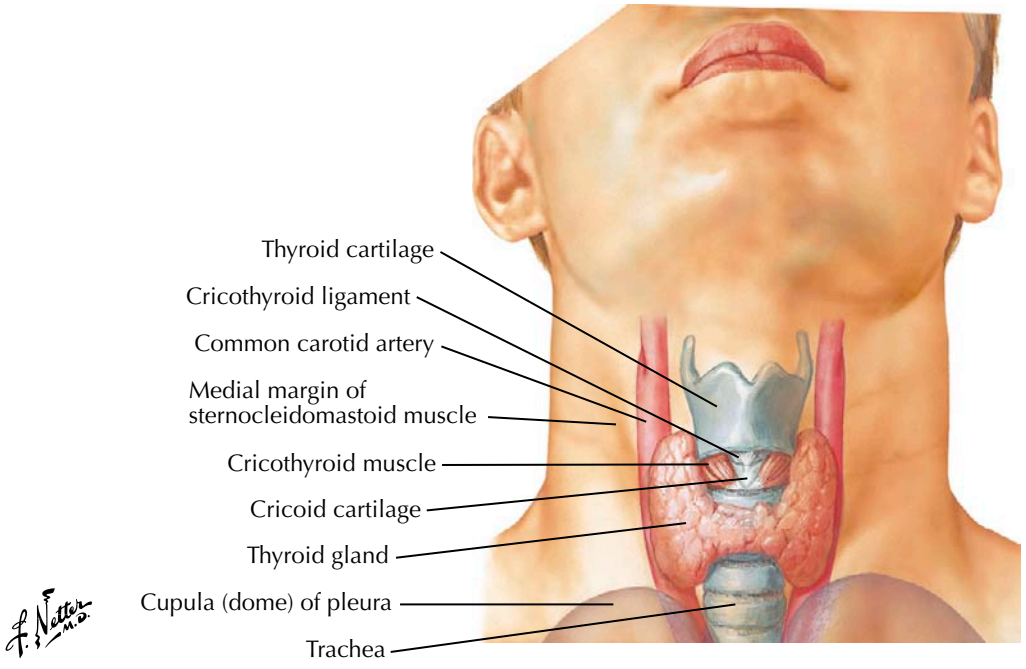

FIGURE 15-1 The thyroid gland.

the inferior parathyroid, disrupting supply to the inferior parathyroid necessarily compromises the supply to the upper parathyroid.

The parathyroid glands secrete parathyroid hormone (PTH), an antagonist to calcitonin. Both PTH and calcitonin work together to maintain calcium homeostasis by increasing calcium removal from storage in bone and increasing absorption of calcium by the intestines.

Perioperative Nursing Considerations

Assessment

Preoperatively, the patient with hyperthyroidism most likely has had appropriate drug therapy that has returned thyroid hormone levels and metabolic state to normal (Elberling et al, 2004).

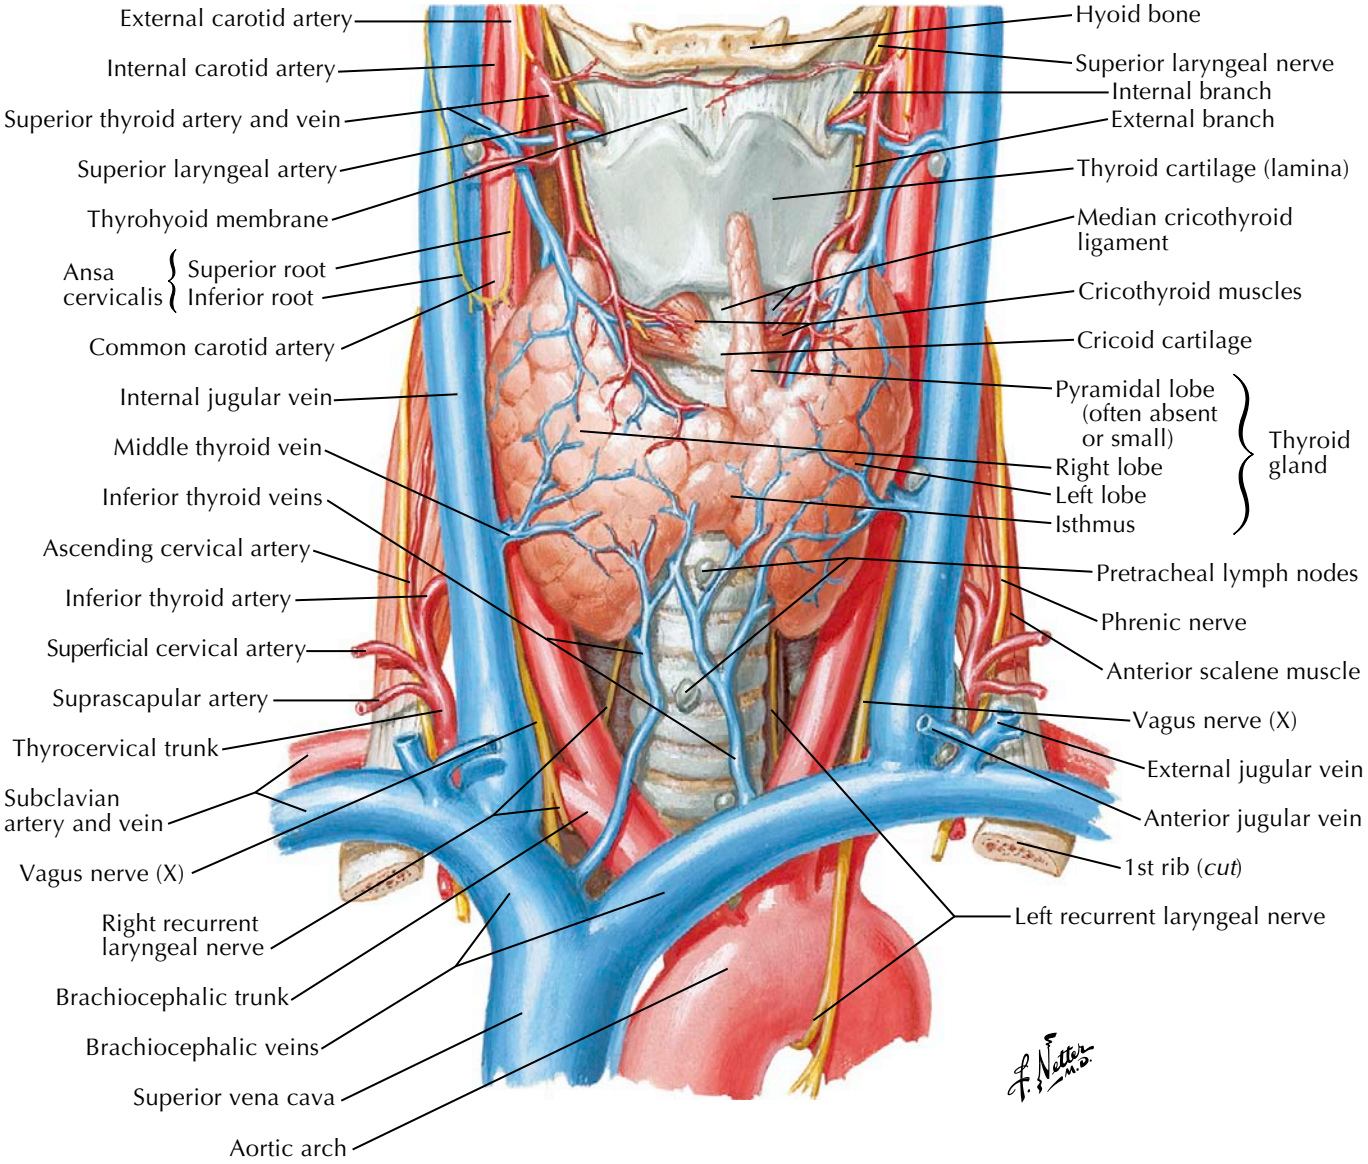

FIGURE 15-2 Thyroid in relation to surrounding structures.

Nonetheless, the perioperative nurse should assess for any symptoms that relate to accelerated metabolism (Box 15-1). The patient's baseline vital signs should be noted for an abnormally elevated resting pulse rate, elevated systolic blood pressure, and cardiac symptoms, such as palpitations or atrial fibrillation. Atrial fibrillation is the most common cardiac complication of hyperthyroidism (Frost et al, 2004). For this reason, the perioperative nurse should confirm whether anticoagulation medication is being taken. The patient's cardiac and respiratory rates, muscle strength, elimination patterns, history of weight loss, heat intolerance, and emotional status should all be noted. The patient, especially a young one, may be anxious about the disease state and the success of surgery, and may express concerns about neck surgery and its cosmetic results. Patients who are concerned about body image should have the opportunity to discuss these issues with the perioperative nurse. Vocalists may be especially concerned about whether surgery will adversely affect their voice. The anesthesia provider may choose to use an endotracheal tube with a smaller diameter than usual in order to minimize any trauma to the vocal cords. Skin integrity should be determined; patients with hyperthyroidism may have finely textured skin and edema in the lower extremities, placing them at higher risk for skin breakdown. The most typical complications specific to thyroid surgery, although infrequent, are hypoparathyroidism and injury to the recurrent laryngeal nerve. Preoperative assessment of the patient's voice tone and quality should therefore be noted.

Large thyroid nodules may cause tracheal shift and present a challenge to the anesthesia provider for intubation and airway management. The size of thyroid enlargement should be noted preoperatively and steps taken to prepare the OR in anticipation of a difficult intubation. The "difficult airway" anesthesia cart should be in the room along with, preferably, two anesthesia providers and the circulating nurse standing by to assist with induction. The anesthesia provider will not extubate a patient who has been difficult to intubate until the anesthesia

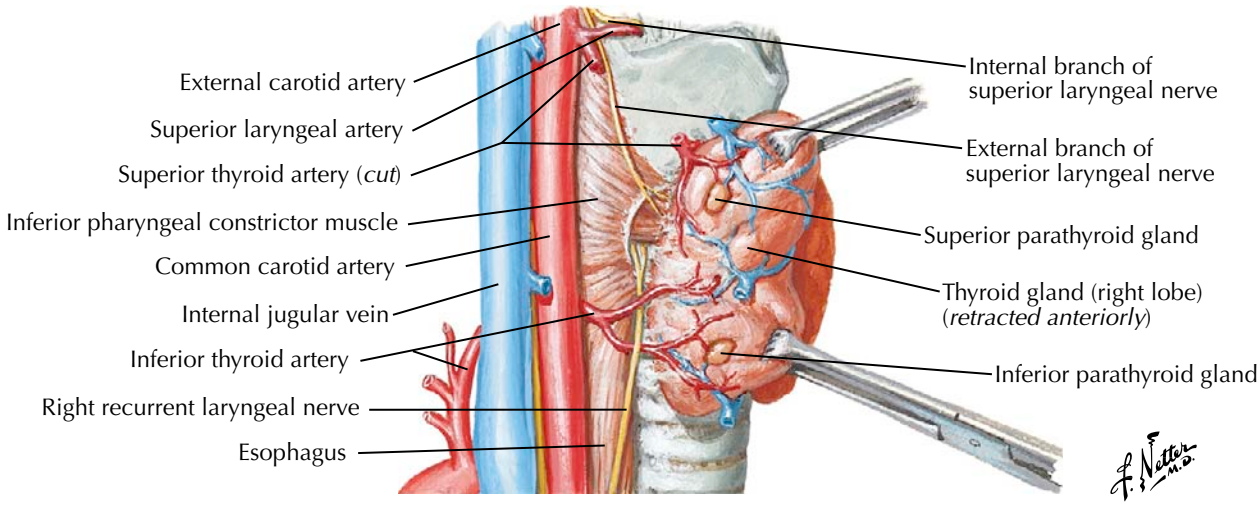

FIGURE 15-3 Right lateral view of thyroid and parathyroids. Note their relation to each other and to the trachea.

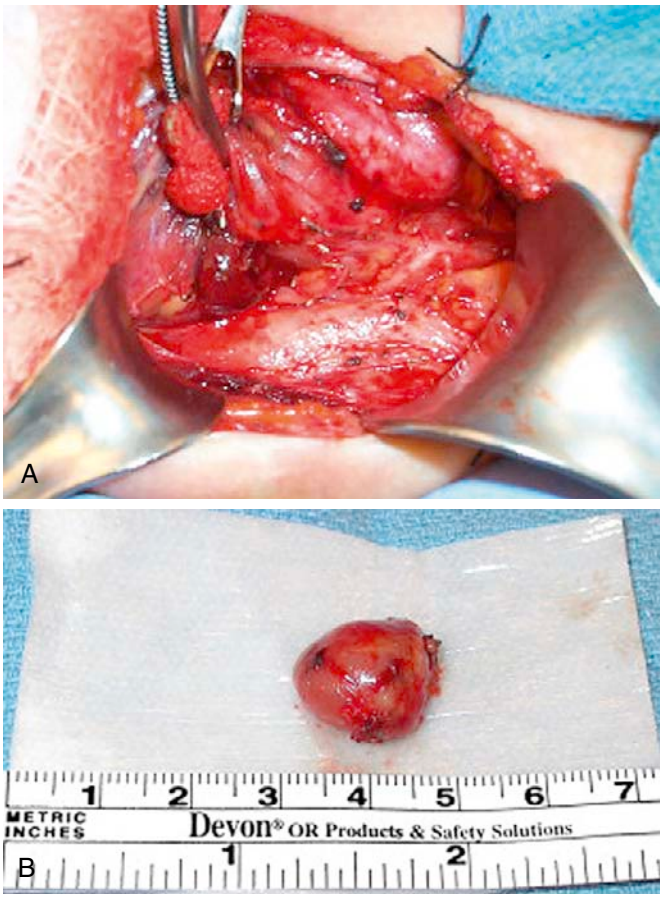

FIGURE 15-4 **A**, A right upper parathyroid adenoma in situ. The thyroid gland is retracted to the midline. The recurrent laryngeal nerve enters the operative field inferiorly and tracks superiorly in the tracheoesophageal groove. The carotid sheath lies lateral to the nerve. The adenoma is the lobular mahogany mass located at the superior pole of the thyroid. **B**, Parathyroid adenoma after removal.

gases have dissipated and the level of consciousness is such that the patient can protect his or her own airway and maintain oxygen saturation with spontaneous breathing. If there is concern about postoperative edema and ensuing airway obstruction from a difficult induction, the anesthesia provider will administer steroids intraoperatively and may chose to leave the tube in postoperatively.

Grossly enlarged thyroids are also more difficult to excise, and intraoperative bleeding is more common and profuse. Finger dissection may be unavoidable and small vessels that retract and contract may rupture during emergence or postoperatively, leading to hemorrhage. Hemorrhage may cause tracheal compression and airway compromise. Patients with thyroidectomies of larger glands generally require a drain and must be closely monitored during emergence from anesthesia and postoperatively. Excessive swelling at the operative site, with or without poor air exchange, must be treated as a potentially life-threatening emergency. The instrument table should be kept sterile until the patient is extubated and out of the room patients who present with large thyroids and/or challenging airway management. A tracheostomy tray with tubes should be readily available should an emergency tracheostomy be necessary.

In addition to clinical signs and symptoms, results of diagnostic tests should be reviewed (Evidence for Practice). Tests performed most commonly before thyroid surgery include measurements of TSH, T_3, and T_4 levels; radioisotope or ultrasonic scans; and a current electrocardiogram (ECG). Adult normal ranges for TSH, T_3, and T_4 levels are as follows (Pagana and Pagana, 2009):

- TSH: 2 to10 microunits/ml
- T_3: 20 to 50 years old, 75 to 205 ng/dl; >50 years old, 40 to 180 ng/dl
- T_4: males, 4 to 12 mcg/dl; females, 5 to 12 mcg/dl; >60 years, 5 to 11 mcg/dl

Thyroid function tests are interpreted in light of the patient's clinical presentation. They complement the findings of the physical examination. The single best test to measure thyroid status in a given person is a TSH assay.

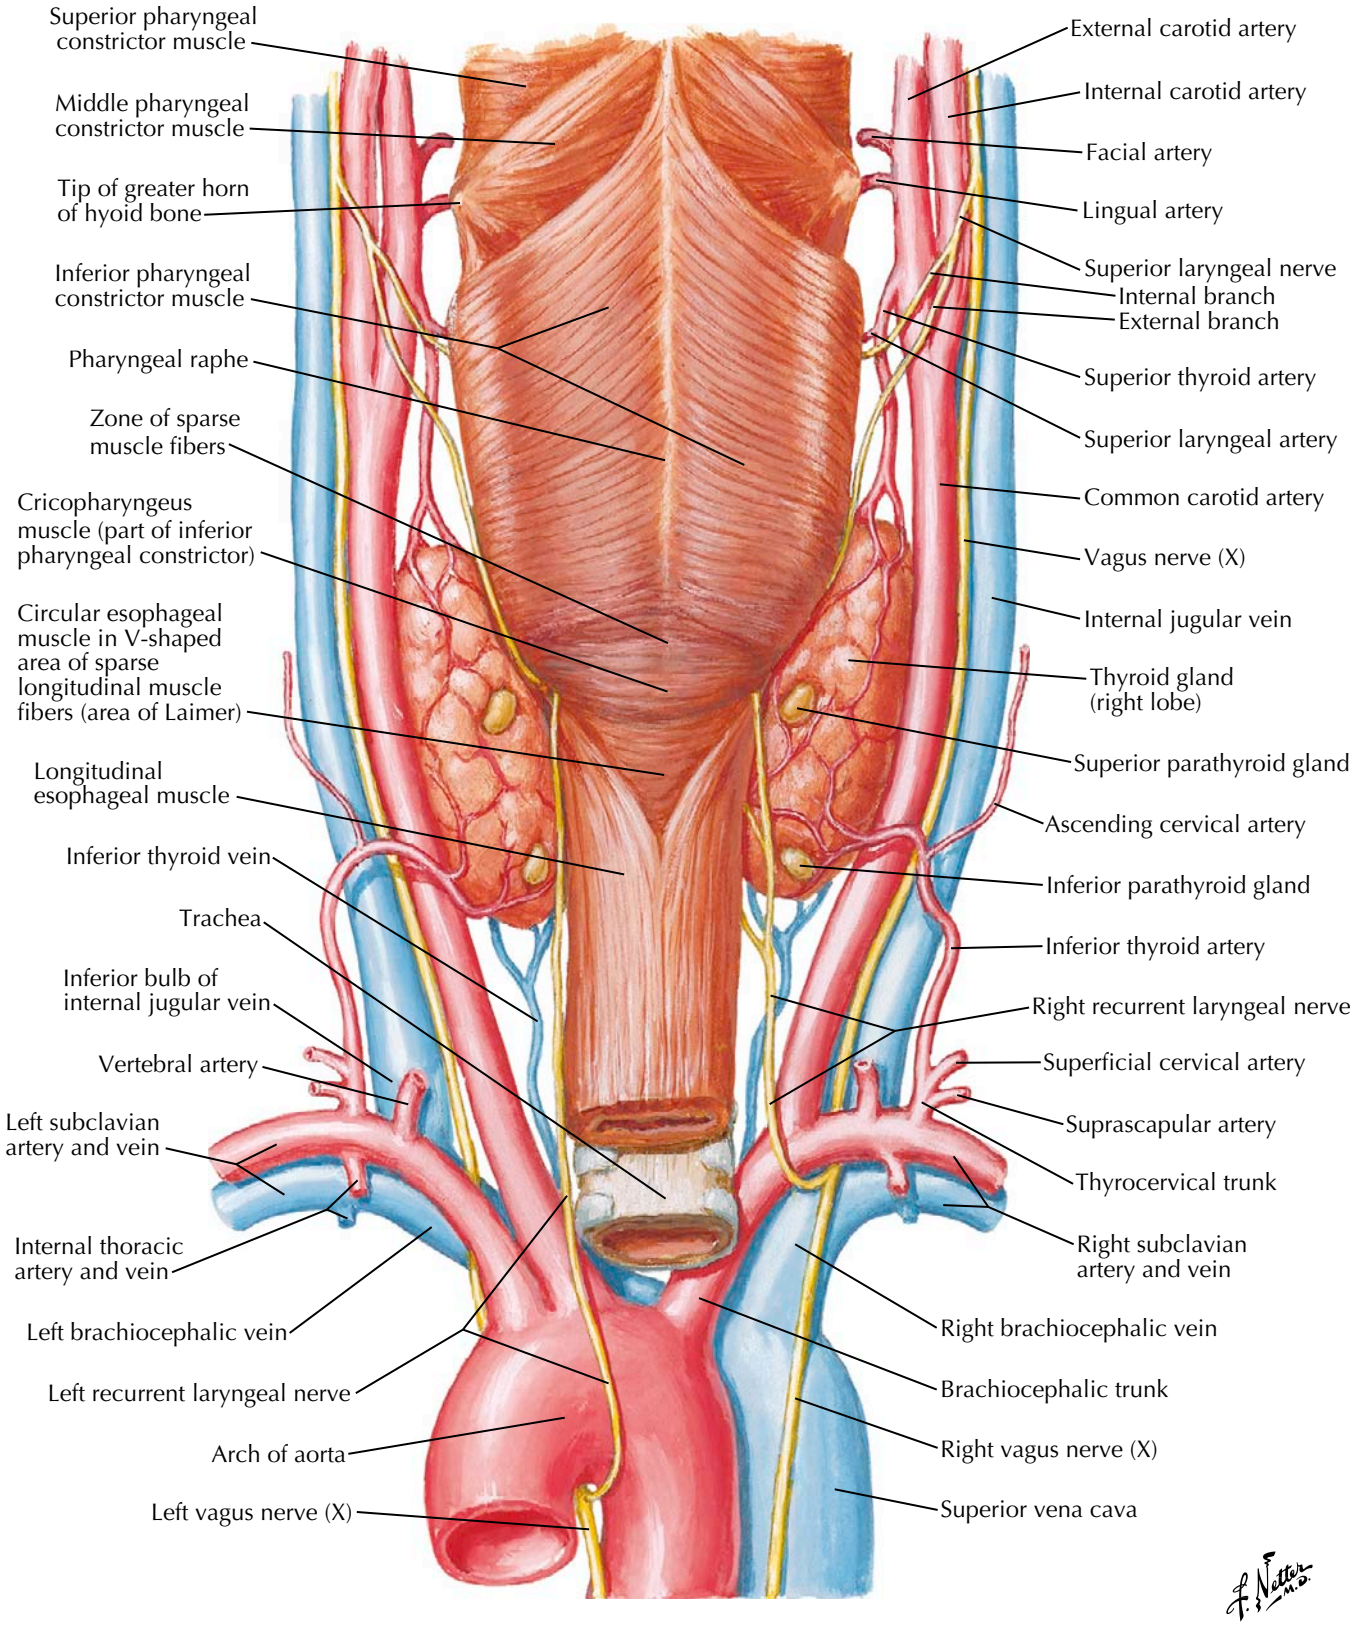

FIGURE 15-5 Posterior view of thyroid and parathyroids. Note relation to carotid sheath and esophagus. Note pathway of recurrent laryngeal nerves.

BOX 15-1

Common Symptoms and Signs of Thyroid Dysfunction

HYPOTHYROIDISM

- Fatigue
- Weight gain
- Cold intolerance
- Hair dryness or loss
- Dry skin
- Depression
- Hoarse voice
- Poor concentration
- Muscle stiffness and pain
- Edema
- Bradycardia
- Constipation
- Menstrual irregularity (especially heavy menses; infertility)

HYPERTHYROIDISM

- Vision changes—myopathy, ophthalmopathy, such as extraocular muscle enlargement, visual loss with prolonged optic nerve compression
- Emotional lability, mood changes
- Irritability
- Exercise intolerance
- Fatigue
- Weight loss
- Heat intolerance and flushing
- Hyperactivity—especially children
- Increased sweating
- Insomnia
- Tremor
- Muscle weakness
- Dyspnea
- Frequent bowel movements
- Menstrual irregularity (oligomenorrhea; infertility)
- More common in elderly—tachycardia and atrial tachydysrhythmias, palpitations, cardiomegaly

Modified from Roberts CG, Ladenson PW: Hypothyroidism, *Lancet* 363(9411):793-803, 2004; Surks MI et al: Subclinical thyroid disease: scientific review and guidelines for diagnosis and management, *JAMA* 291(2):228-238, 2004.

Thyroid Assessment. In addition to palpation of the thyroid gland for size, contour, consistency, lymph nodes, fixation, tenderness, and bruits (Wilson and Giddens, 2009), scans are used to clarify thyroid anatomy. CT and MRI scans are used to assess a thyroid with suspected malignancy for encroachment of the tumor outside the thyroid capsule into the adjacent tissue of the neck. Scans are the most effective means to evaluate local invasion of surrounding tissue.

While palpable thyroid nodules are present in 3% to 5% of healthy adults, ultrasound and autopsy studies show rates of more than 50%. Although most nodules are benign, 7% to 29% will be cancerous. Consequently, the most common endocrine malignancy is thyroid cancer, estimated to be the thirteenth most common cause of any new malignant neoplasm in the United States for 2007, ranking seventh in women (25,480 cases; 3.8%), while causing just over 1% of new cases in men. Prevalence figures are likely to increase further, as the yearly incidence of thyroid cancer has been growing exponentially from 7800 cases in 1974 to 33,550 cases in 2007 (Tuttle, 2007).

EVIDENCE FOR PRACTICE

Screening for Thyroid Dysfunction

A number of symptoms and signs are well-established manifestations of thyroid dysfunction (see Box 15-1). A thorough history and physical is indicated in screening for thyroid cancer. A history of being exposed to neck or whole-body radiation or being raised in iodine-poor areas should be assessed. A rapidly expanding neck mass, new onset of hoarseness, neck or ear pain, or cough are symptoms of concern. Patients with a fixed, immobile mass and/or hoarseness, dysphagia, or respiratory symptoms require CT or MRI imaging as part of evaluation. These symptoms may be indicative of metastasis (Loevner and Mukherji, 2008). Although calcifications were formerly considered a benign finding, some thyroid cancers demonstrate eggshell calcifications.

The American Association of Clinical Endocrinologists (AACE) practice guidelines for the diagnostic evaluation of hyperthyroidism and hypothyroidism recommend TSH assay as the single best screening test. Hyperthyroidism results in a lower-than-normal TSH level (suppressed TSH secretion). To diagnose hyperthyroidism accurately, TSH assay sensitivity, the lowest reliably measured TSH concentration, must be 0.02 milliinternational unit/liter or less.

Serum TSH level is the most sensitive test for detecting mild (subclinical) thyroid hormone excess or deficiency. An elevated serum TSH concentration is present in both overt and mild (subclinical) hypothyroidism. In the latter, the free thyroid hormone (fT_3 and fT_4) levels are, by definition, normal.

Hypothyroidism results from undersecretion of thyroid hormone. In the United States, hypothyroidism affects close to 11 million people each year. The most common cause of primary hypothyroidism is chronic autoimmune thyroiditis (Hashimoto's disease). The most valuable laboratory test is a sensitive measurement of TSH level. Clinical hypothyroidism is treated with levothyroxine replacement therapy. The AACE supports treating subclinical hypothyroidism if TSH levels are greater than 10 microunits/ml or if TSH levels are between 5 and 10 microunits/ml in conjunction with goiter or positive antibodies or both.

Serum TSH measurement is the single most reliable test to diagnose all common forms of hypothyroidism and hyperthyroidism, with high sensitivity (98%) and specificity (92%).

fT_3, Free triiodothyronine; *fT_4,* free thyroxine; *TSH,* thyroid-stimulating hormone.

Modified from American Association of Clinical Endocrinologists: Medical guidelines for clinical practice for the evaluation and treatment of hyperthyroidism and hypothyroidism, *Endocr Pract* 8(6):457-469, 2002; Loevner LA, Mukherji SK: *Thyroid and parathyroid glands: imaging, treatment, and beyond,* Philadelphia, 2008, Saunders; Mauk KL: Rooting out hypothyroidism in the elderly, *Nursing 2005* 35(12):65-66, 2005; Screening for thyroid disease: *Recommendation statement, U.S. Preventive Services Task Force* 140(2):125-127, 2004.

Thus thyroid cancer is poised to become one of the most common cancer diagnoses in living cancer patients (Grebe, 2009).

PREOPERATIVE TESTING

Thyroid Isotope Scan (Thyroid Scintigraphy). A thyroid nodule, the most common endocrine problem in the United States, is any abnormal growth of thyroid cells. Most nodules are discovered during routine physical examination, because they rarely are symptomatic. Imaging of the normal thyroid with radionuclide agents shows normal size, shape, position, and function of the thyroid, with no areas of decreased or increased

uptake. Nodules that are *hot* demonstrate increased uptake of radionuclide agent; this may indicate benign adenoma or localized toxic goiter. *Cold* nodules are hypofunctioning or nonfunctioning and may indicate cyst, nonfunctioning adenoma or goiter, lymphoma, localized area of thyroiditis, or carcinoma. Two commonly used agents in thyroid imaging are radioactive iodine and technetium 99m-pertechnetate ($^{99m}TcO_4^-$).

Ultrasonic Scan. Ultrasonic scans are the treatment of choice to evaluate thyroid nodules and are useful to determine the size and number of nodules within the thyroid as well as to monitor size progression during follow-up. Involvement of the vessels in the neck or mediastinum, although rare, can occur. It is critical that the surgeon and operative team know this before surgery. Radiologic evaluation frequently dictates the extent of the surgery. Several new ultrasonic techniques have been applied to the thyroid. The three-dimensional (3D) ultrasound has proven to be more accurate. Tissue harmonic imaging (THI) uses the first harmonic of the transmitted frequency for image formation and results in images with less "noise." These new techniques improve image clarity but do not improve lesion characterization.

Ultrasonography also helps to facilitate accurate needle placement and sampling of the target nodule during fine needle aspiration (FNA). Ultrasound-guided FNA with cytologic evaluation remains the mainstay for palpable and incidentally found thyroid nodules (Loevner and Mukherji, 2008).

Fine Needle Aspiration. FNA is the most useful diagnostic tool currently available in the management of thyroid nodules. It is the accepted standard of care for all patients who have palpable nodules with normal functioning thyroids, has high accuracy and low risk, and is cost-effective (Lansford and Teknos, 2006). The procedure is usually performed under ultrasound guidance, but may be performed in the surgeon's office. Several samples are usually taken from various parts of the nodule. Pathologic examination of FNA specimens reveals a benign nodule in 70% of biopsies, a nondiagnostic or inadequate biopsy 15% of the time, a suspicious nodule in 10% of cases, and malignancy in 5% of biopsies (*American Thyroid Association,* 2005). A suspicious nodule usually implies a follicular neoplasm, which can be benign or malignant, and requires removal for histologic evaluation.

Patient preparation for FNA should include the following information:

- You will be lying down for the procedure and may expect coldness on your neck from the prepping solution.
- Local anesthesia may or may not be used.
- Once the prick of the needle is felt, no talking, swallowing, or moving is allowed.

FNA may be an emotionally stressful procedure for the patient. Vials of ammonia should be kept in the room in case the patient feels faint. Lowering the head (using Trendelenburg's position or sitting with the head down) is also important to treat vasovagal syncope. Postprocedure education should include (1) the necessity of refraining from using aspirin or aspirin-containing medications or nonsteroidal antiinflammatory drugs (NSAIDs) for the next 24 hours, and (2) the expectation of seeing a half-dollar–size bruise at the FNA site. There are no restrictions on food or activity.

PREOPERATIVE PATIENT EDUCATION. Preoperative patient education for partial or total thyroidectomy includes an explanation of perioperative events, discussion of the incision site and type of dressing to be used, and explanation of any drains, if anticipated. Pain assessment and pain management therapy are reviewed. Patients are advised that there are various ways of protecting their eyesight during surgery, and if ointment is used, they can expect temporary blurred vision when they first open their eyes. If sequential compression devices (SCDs) are to be used for prophylaxis of deep vein thrombosis (DVT), their use and sensation is explained. The patient is encouraged to flex and extend the neck slowly early in the postoperative period. A baseline description of vocal cord function should be noted preoperatively. (For further discussion of patient education, see Patient and Family Education and Discharge Planning section later in this chapter.)

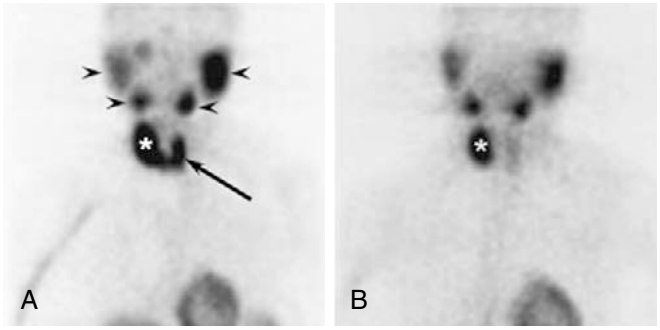

FIGURE 15-6 **A**, Early three-dimensional sestamibi image shows uptake in mass *(asterisk)*, in salivary glands *(arrowheads)*, and in thyroid gland *(arrow)*. **B**, Late three-dimensional sestamibi image shows retention of radiotracer in the adenoma *(asterisk)*, with absence of radiotracer in the thyroid gland. Salivary glands normally retain radiotracer on late images.

Parathyroid Assessment. Elevation of serum PTH level in association with hypercalcemia is diagnostic of hyperparathyroidism in most cases. PTH normal levels are between 10 and 65 pg/ml (values vary with specific laboratory); the concentration of serum ionized calcium (4.5 to 5.6 mg/dl) is usually measured at the same time (Pagana and Pagana, 2009). Causes of primary hyperparathyroidism are single adenoma (80% to 85%), four-gland hyperplasia (10% to 15%), and rarely parathyroid carcinoma (less than 1%). Preoperative localization studies with a parathyroid sestamibi scan (Figure 15-6) or high-resolution ultrasonography can identify parathyroid adenomas with high sensitivity (70% to 80%). Sensitivity decreases significantly for hyperplasia (less than 50%).

Hyperparathyroidism causes an increase in the level of serum calcium and a decrease in the level of serum phosphate. Nursing diagnoses and plans of care are based on these imbalances and the severity of associated symptoms. Some patients are asymptomatic while others have symptoms that manifest themselves as disturbances in the central nervous system or cardiovascular, renal, gastrointestinal, or musculoskeletal system (Box 15-2).

Assessment includes determining whether the patient is apathetic or emotionally irritable; whether there is muscle weakness and atrophy, back or joint pain, nausea, vomiting, constipation, peptic ulcer disease, or cardiac dysrhythmia; and whether there is renal damage, stones, or disease (Canobbio, 2006). If any of these are present, the plan of care is adjusted. Otherwise, perioperative patient education and nursing

BOX 15-2

Parathyroid Dysfunction

HYPERPARATHYROIDISM

Definition

Overactivity of one or more of the parathyroid glands; excessive secretion of parathyroid hormone causes an increase in the level of calcium (hypercalcemia)

Signs and Symptoms

- Polyuria, polydipsia, kidney stones
- Abdominal pain, constipation, nausea, anorexia
- Fractures of ribs, spine
- Joint or back pain
- Depression, paranoia, mood swings
- Muscle weakness and atrophy

Complications

- Cardiac dysrhythmias, cardiac failure
- Gastric ulcer
- Pathologic fractures
- Renal disorders: kidney stones, urinary tract infections, renal failure
- Pancreatitis
- Stupor/coma

HYPOPARATHYROIDISM

Definition

Deficiency of parathyroid hormone, necessary to maintain normal levels of serum calcium; may occur as a result of radiation therapy for head and neck cancer or as a postoperative complication from thyroid or parathyroid surgery; symptoms are related to reduced calcium levels (hypocalcemia)

Signs and Symptoms

- Personality disturbances: anxiety, depression, irritability
- Tetany: muscle cramps, spasms (hands, face, feet); paresthesias: numbness and tingling (around mouth, lips, and tongue)
- Dry, scaly skin; brittle nails; thin, patchy hair
- Weak tooth enamel/dental caries
- Cataracts

Complications

- Cardiac dysrhythmias
- Seizures
- Psychoses
- Cardiac arrest

Modified from Canobbio MM: *Mosby's handbook of patient teaching,* ed 3, St Louis, 2006, Mosby; Workman LM: Care of patients with problems of the thyroid and parathyroid glands. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, Philadelphia, 2010, Saunders.

management of the patient undergoing parathyroidectomy are essentially the same as those for thyroidectomy. In the early postoperative period for both thyroidectomy and parathyroidectomy, the patient is closely observed for any signs of hypocalcemia. The serum calcium level reaches its lowest level in 48 to 72 hours after surgery and returns to normal within the following 2 to 3 days. Symptoms include numbness and tingling of extremities and around the lips. Hyperactive tendon reflexes and a positive Chvostek's sign (tapping on the facial nerve elicits contraction of facial muscles) can be demonstrated on physical examination. Tetany may develop and is exhibited by carpopedal spasms, tonic-clonic convulsions, and laryngeal stridor, which can be fatal.

Nursing Diagnosis

Nursing diagnoses related to the care of patients undergoing thyroid and parathyroid surgery might include the following:

- Impaired Swallowing related to mechanical obstruction (enlarged thyroid preoperatively; edema or hematoma postoperatively)
- Risk for Imbalanced Body Temperature related to altered metabolic rate and surgical environment
- Disturbed Body Image related to surgical scar in prominent location
- Ineffective Airway Clearance related to obstruction (enlarged thyroid preoperatively; edema or hematoma postoperatively) or bilateral recurrent laryngeal nerve injury
- Impaired Gas Exchange related to postoperative bleeding or swelling or inability to move secretions

Outcome Identification

Outcomes identified for the selected nursing diagnoses may be stated as follows:

- The patient will maintain normal swallowing.
- The patient will maintain normal body temperature.
- The patient will verbalize decreased disturbance in feelings related to body image.
- The patient will maintain a patent airway.
- The patient will maintain effective gas exchange.

Planning

The entire surgical team has mutual accountability for patient safety (Banschbach, 2008). The perioperative nurse and surgical technologist should know the OR team members who will participate in the procedure as well as the roles each team member will assume (Haynes et al, 2009). Careful planning, assessment, and tailoring the plan of care to the surgery and specific patient needs reduce inherent risks (Risk Reduction Strategies). The perioperative nurse should consider a patient who is not at optimal weight at high risk for pressure ulcer development and plan on padding pressure areas to prevent skin and tissue damage. Intraoperatively, warm saline should be provided for irrigation and a forced-air warming device used. Patients with hypothyroidism are at increased risk of becoming hypothermic (Hegarty et al, 2009).

A rapidly progressive and potentially fatal complication for patients with hyperthyroidism is thyroid storm (thyrotoxic crisis) (Kuwajerwala et al, 2007). The perioperative staff must recognize and differentiate between uncomplicated thyrotoxicosis and thyroid storm (Box 15-3) and be prepared to act quickly. The use of a rapid response team (RRT) for patients in crisis impacts treatment and patient outcomes (Rapid Response Team box) (Steel and Reynolds, 2008). Thyroid storm can occur in patients who have been partially controlled or whose hyperthyroidism is untreated. Thyrotoxic crisis can be precipitated by a stressful event, such as surgery. By planning a quiet, calm atmosphere and helping the patient relax, the perioperative nurse can reduce the risk of thyroid storm. Collaborating with the surgical and anesthesia team, the perioperative nurse can plan for appropriate interventions to assist in reducing body temperature and heart rate, provide oxygen and intravenous solutions, and administer medications

RISK REDUCTION STRATEGIES

Perioperative Care of Thyroid and Parathyroid Surgery Patients

Risk reduction springs from the adage that "an ounce of prevention is better than a pound of cure." It is much better to prevent a problem than to treat one. A strong base of knowledge coupled with skills, experience, clinical judgment, and caring helps ensure the best possible patient outcomes (Benner et al, 2009).

Risk reduction strategies for patients undergoing thyroid and/or parathyroid surgery include the following:

PREOPERATIVELY

- The appropriate scans and preadmission testing are done.
- Patients are thoroughly screened for inpatient versus ambulatory status (Patient Screening and Assessment in Ambulatory Surgical Facilities, 2009).
- A detailed history and physical is completed.

INTRAOPERATIVELY

- Appropriate body alignment and padding are used to prevent nerve injury and postoperative discomfort.
- The OR team recognizes and is prepared for patients who are at risk for difficult intubation.
- Attention to sterile technique is a core team value.
- Gentle tissue handling reduces the risk of damage to nerves, parathyroid glands, and surrounding structures.
- Achieving and maintaining hemostasis promotes visibility and reduces postoperative bleeding.
- Hypertension is treated and controlled.
- The scrub person keeps instruments sterile for those patients who are at risk for postoperative bleeding. This would include patients with large thyroids that necessitated finger dissection and those who were difficult to intubate.

POSTOPERATIVELY

- The patient is monitored closely for airway difficulty.
- Hypertension is treated and controlled.
- The incision site is observed for swelling and/or bleeding. Ice packs may be applied to reduce swelling.
- Coughing should be minimized and neck support during coughing demonstrated.
- Complications of hemorrhage, compromised airway, thyroid storm, and hypocalcemia are recognized and treated immediately.
- The patient's condition is carefully assessed to determine that criteria are met for discharge to home on the day of surgery.
- Discharge instructions are clear, concise, and thorough; reviewed verbally; and provided in written format. Patients "teach-back" the instructions in their own words (TJC, 2007). Questions are encouraged and time allotted for answering them.

BOX 15-3

Thyroid Storm

MORTALITY/MORBIDITY

Thyroid storm is a fulminating state that is fatal if untreated, with death rates of 20% to 30%.

PHYSICAL SYMPTOMS

- Thyroid storm may be difficult to differentiate from signs of uncomplicated thyrotoxicosis. It is an accentuation of the same signs. Onset is heralded by high-grade fever, mental obtundation, and decompensation of one or more organ systems as a result of severe hypermetabolism.
- Only guidelines are presented in the following table that compares symptoms of uncomplicated thyrotoxicosis and thyroid storm.

Uncomplicated Thyrotoxicosis	Thyroid Storm
Heat intolerance, diaphoresis	Hyperpyrexia, temperature in excess of 106° C, dehydration
Sinus tachycardia, heart rate 100-140 beats/min	Heart rate faster than 140 beats/min, hypotension, atrial dysrhythmias, congestive heart failure
Diarrhea, increased appetite with weight loss	Nausea, vomiting, severe diarrhea, abdominal pain, hepatocellular dysfunction with jaundice
Anxiety, restlessness	Confusion, agitation, delirium, frank psychosis, seizures, stupor, or coma

CAUSES

Causes of rapid rise in thyroid hormone levels:

- Thyroid or parathyroid surgery
- Radioiodine therapy
- Withdrawal of antithyroid drug therapy
- Vigorous thyroid palpation
- Iodinated contrast dye
- Thyroid hormone medication

Other common precipitating factors:

- Infection
- Emotional stress
- Tooth extraction
- Diabetic ketoacidosis
- Hypoglycemia
- Trauma
- Bowel infarction
- Parturition
- Pregnancy toxemia
- Pulmonary embolism
- Cerebrovascular accident
- Gestational trophoblastic disease

Modified from Kuwajerwala NK et al: *Thyroid, thyrotoxic storm following thyroidectomy,* available at emedcine.medscape.com/article850924. Accessed January 24, 2009.

as prescribed in the event thyrotoxic crisis occurs (Surgical Pharmacology).

A Sample Plan of Care for a patient undergoing thyroid and parathyroid surgery is on p. 576.

Implementation

Positioning. Proper patient positioning on the OR bed is crucial for optimal exposure of the thyroid gland. The patient is positioned supine. Some surgeons prefer a beach chair position or a wedge under the back. Hyperextension of the neck is required for maximal exposure. A headrest provides proper support, keeps the head straight, and prevents aggravation of prior neck problems. Alternatively, a shoulder roll may be used. The arms are tucked at the side, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly, but not

RAPID RESPONSE TEAM

Rapid response teams (RRTs) handle many critical situations, all of which require skill, knowledge, quick thinking, and immediate action. RRTs are called to treat patients who show signs of developing rapidly deteriorating conditions. Early response and treatment by a specialized, proficient, and experienced team can prevent further deterioration and greatly enhance outcomes for many patients.

The team's assessment and diagnostic skills must complement their abilities to respond to and treat the particular crisis appropriately. The team members should have advanced certification in critical care, PALS and ACLS. They are called a team because they must be able to work together efficiently and smoothly.

Staff nurses and other caregivers, and in some institutions members of the patient's family, should be encouraged to initiate the RRT early when there is a concern about a patient's condition or they believe that "something's not right." The earlier the treatment, the less likelihood there is of a problem escalating out of control.

There must be a rapid response cart with all the medications and equipment needed to deal with a crisis. Supplies should also include airway equipment, a defibrillator, IV supplies, and monitoring equipment.

In the instances of potential patient complications described in this chapter, the RRT would treat hypocalcemia, hemorrhage, or thyroid storm appropriately.

SURGICAL PHARMACOLOGY

Thyroid Storm

PREOPERATIVE PROPHYLACTIC CARE FOR THYROID STORM

Potassium iodide (KI) is used preoperatively in thyrotoxicosis to decrease thyroid blood flow.

EMERGENCY CARE DURING THYROID STORM

- Maintain a patent airway and adequate ventilation.
- Give antithyroid drugs as prescribed: propylthiouracil (PTU, Propyl-Thyracil), 300-900 mg/day; methimazole (MMI) (Tapazole), up to 60 mg/day.
- Administer sodium iodide solution, 2 g/day IV as prescribed.
- Give propranolol (Inderal, Detensol), 1-3 mg IV as prescribed. Administer slowly, over 3 minutes. The patient should be connected to a cardiac monitor and a central venous pressure line should be in place.
- Esmolol (Brevibloc), 500 mcg/kg IV followed by 50-200 mcg/kg, minimum maintenance dose, is useful in patients at risk for complications from beta-blockade.
- Guanethidine or reserpine is substituted for propranolol in patients with congestive cardiac failure, bronchospasm, or history of asthma, although they cannot be used for patients who are in cardiovascular shock or collapse.
- One hour after administration of PTU or MMI, hormone release can be inhibited by large doses of iodine, which reduce thyroidal iodine uptake. Lugol's solution, 30 gtt/day PO in 4 divided doses, or a saturated solution of potassium iodide, 5 gtt orally or via an NG tube q6hr, can be used.
- Ipodate sodium, 0.5-3 g/day PO, can be administered instead of iodine.
- Patients unable to take PTU or MMI also can be treated with lithium 300 mg PO q6hr in conjunction with iodine. The lithium dose is adjusted as necessary to maintain levels at about 1 mEq/L.
- Plasmapheresis, plasma exchange, peritoneal dialysis exchange transfusion, and charcoal plasma perfusion are other techniques used to remove excess circulating hormone for patients who do not respond to the initial line of management.
- Monitor continuously for cardiac dysrhythmias.
- Monitor vital signs every 30 minutes.
- Provide comfort measures, including a cooling blanket.
- Give nonsalicylate antipyretics such as acetaminophen (FeverAll, Panadol) as prescribed (normally 650 mg PO q4hr).
- Aggressive fluid and electrolyte therapy, 3-5 L/day, is needed for dehydration and hypotension. Therefore invasive monitoring is advisable in elderly patients and in those with congestive cardiac failure. Fluid therapy should include glucose.
- Multivitamins, especially vitamin B_1, are added to prevent Wernicke's encephalopathy.
- Glucocorticoids reduce iodine uptake and antibody titers of thyroid-stimulating antibodies with stabilization of the vascular bed. They must be used with caution, however, as they have significant adverse effects. Dexamethasone (Decadron, Dexone), 2 mg IV q6hr, or hydrocortisone (Cortef, Solu-Cortef), 100 mg IV q8hr, may be given.
- Hypertension must be controlled with agents such as guanethidine (Ismelin), 1-2 mg/kg/day PO, or reserpine, 2.5-5 mg IM q4-6hr.
- Treat heart failure if present.

IM, Intramuscularly; *IV,* intravenously.

Modified from Kuwajerwala NK et al: *Thyroid, thyrotoxic storm following thyroidectomy,* available at emedcine.medscape.com/article850924. Accessed January 24, 2009; Workman LM: Care of patients with problems of the thyroid and parathyroid glands. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, Philadelphia, 2010, Saunders.

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Impaired Swallowing related to mechanical obstruction (enlarged thyroid preoperatively; edema postoperatively)

OUTCOME
Patient will maintain normal swallowing.

INTERVENTIONS
- Keep suction line and suction catheter connected and ready until patient is discharged from OR.
- Monitor for and report difficulty swallowing during emergence from anesthesia or transport to PACU.
- Gently suction oropharyngeal secretions as required.
- Keep vein open postoperatively until patient can swallow without difficulty.

NURSING DIAGNOSIS
Risk for Imbalanced Body Temperature related to altered metabolic rate

OUTCOME
Patient's body temperature will be maintained within normal range.

INTERVENTIONS
- Monitor patient's temperature; report abnormalities.
- Provide light covers if temperature is elevated or patient states that he or she is too warm.
- Use forced-air warming device intraoperatively as needed to maintain temperature.
- Use fluid warmer for intravenous fluids as needed to maintain body temperature.
- Change linens preoperatively and postoperatively if wet from perspiration.
- Avoid using plasticized drapes.

NURSING DIAGNOSIS
Disturbed Body Image related to surgical scar

OUTCOME
Patient will verbalize decreased disturbance in feelings related to body image.

INTERVENTIONS
- Explain that incision is made in natural fold of skin.
- Explain that techniques used for surgical closure minimize scarring.
- Instruct patient in postoperative turning measures that decrease strain on suture line.
- Suggest that jewelry, scarves, and certain necklines can be used to cover scar until normal fading occurs.
- Advise patient to refrain from prolonged exposure to direct sunlight or tanning salons while incision is healing.

NURSING DIAGNOSIS
Ineffective Airway Clearance related to obstruction secondary to enlarged thyroid (preoperatively), edema (postoperatively), or laryngeal nerve injury

OUTCOME
Patient's airway will remain patent.

INTERVENTIONS
- Position patient so that enlarged gland does not obstruct airway. Head of transport vehicle may need to be elevated preoperatively.
- Assist anesthesia provider during induction and extubation. Have oxygen and suction available.
- Monitor respiratory rate and signs of respiratory distress (stridor, wheezing, dyspnea, labored respirations).
- If distress occurs because of recurrent laryngeal nerve injury, a tracheotomy may be required. Have oxygen, suctioning equipment, and a tracheotomy tray available.
- Observe neck dressing and back of neck for signs of edema or bleeding (postoperatively). Hemorrhage at the incision site or respiratory distress from tracheal compression may require urgent reintubation for airway protection and a return to the OR for wound re-exploration.

NURSING DIAGNOSIS
Impaired Gas Exchange related to postoperative bleeding or swelling, bilateral recurrent laryngeal nerve surgical injury, or inability to move secretions

OUTCOME
Patient's gas exchange will remain effective.

INTERVENTIONS
- Monitor respiratory status and results of pulse oximetry.
- If patient is extubated in OR, be prepared to assist anesthesia provider; closely observe for respiratory stridor or respiratory obstruction (recurrent laryngeal nerve malfunction). Tracheotomy may be required; oxygen, suctioning equipment, and a tracheotomy tray should be available.
- Assess color of nailbeds.
- Monitor surgical site for swelling and bleeding.
- Suction patient's secretions as needed.
- Monitor patency of surgical drain and amount/nature of drainage in collection device, as applicable.
- Instruction in coughing and deep breathing should include supporting the neck; placing both hands behind the neck when coughing reduces strain on the suture line.

OR, Operating room; *PACU,* postanesthesia care unit.

tightly, under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail. All pressure points should be padded, especially for patients not at optimal weight. Should the patient be too large to tuck the arms safely at the sides, arm sleds or side extensions for the OR bed may be used to accommodate the arms. Reduction of venous congestion can be accomplished by a 30-degree reverse-Trendelenburg's tilt of the OR bed (see Chapter 5 for a full discussion of surgical positioning).

Skin Preparation. The operative area (chin and anterior neck region, lateral surfaces of the neck from the earlobes down to the outer aspects of the shoulder, and upper anterior chest region to the nipples) is prepped with an antimicrobial solution. Appropriate precautions must be taken to prevent pooling of solution under the neck or in the axillary area. Alcohol-based prep solutions around the head and neck area present a risk for surgical fire. They must be used with caution, allowing time for the prep to dry and the fumes to dissipate. Bed sheets that become soaked with a flammable prep solution should be

removed from the OR. After the skin prep, the patient is draped with sterile towels and a fenestrated sheet. A sterile towel, lap sponge, or self-adherent tape strips may be placed on each side of the neck to prevent pooling of blood under the neck during surgery. Self-adherent tape strips or drapes also promote maintenance of the integrity of the sterile field and reduce the risk of intraoperative fire hazard by sealing off the operative site from anesthetic vapors that may have leaked and become trapped under the drapes. If lap sponges are used, they should be noted on the count sheet to avoid confusion in accounting for all counted items. After draping is complete, the time-out is taken. The following must be verified: correct patient, correct site, and correct procedure to be performed; and supplies may also be included (Perioperative Grand Rounds, 2009). The time-out is documented. The surgeon then marks the incision site with a marking pen or the pressure of a full-length fine silk tie to help ensure a wound line that blends with the patient's neck creases and skin lines.

Evaluation

Evaluation of intraoperative interventions determines the effectiveness of the plan of care. The hand-off report to postanesthesia care unit (PACU) or ambulatory recovery personnel includes the surgical procedure, type of anesthesia used, local anesthetics administered, location of drain (if any), dressing used, condition of skin postoperatively, and any other information specific to the patient's postoperative care. Documentation, using hospital protocol, reflects achievement of patient outcomes related to planned interventions; these should also be included in the hand-off nursing report to PACU personnel. Outcomes identified for the selected nursing diagnoses may be stated as follows:

- The patient maintained normal swallowing.
- The patient maintained normal body temperature.
- The patient verbalized decreased disturbance in feelings related to body image.
- The patient maintained a patent airway; there was no edema or hematoma at the surgical site or signs of respiratory distress.
- The patient maintained adequate gas exchange; O_2 saturation remained normal. The patient was extubated without incident.

Patient and Family Education and Discharge Planning

Patient education and discharge planning include any family members, significant others, or even friends who will help the patient at home (Patient and Family Education). Written discharge instructions are provided and orally reviewed, with clarification of information and correction of misperceptions. The name and telephone number of the physician or nurse to call with questions is provided, as is information regarding a follow-up office appointment, if that is available. General information, such as the name of the thyroid or parathyroid procedure and any changes that will occur as a result of the surgery, is explained. Signs and symptoms to report include those of hypocalcemia. If hypocalcemia occurs, it usually manifests itself within 2 days after surgery (Burman, 2005). The patient should report any numbness or tingling around the lips or extremities, twitching, or spasms. Time is also spent to discover the patient's concerns, anxieties, thoughts, and feelings. Patient education begins with the perioperative nursing assessment and continues through discharge and perhaps even home care. The advent of thyroidectomies and parathyroidectomies performed in ambulatory surgery centers has introduced a new set of needs and challenges for the patient, family, and perioperative staff (Mirnezami et al, 2007) (Ambulatory Surgery Considerations).

Surgical Interventions

UNILATERAL THYROID LOBECTOMY, SUBTOTAL LOBECTOMY, BILATERAL SUBTOTAL LOBECTOMY, NEAR-TOTAL THYROIDECTOMY, AND TOTAL THYROIDECTOMY

Unilateral thyroid lobectomy or hemithyroidectomy is the removal of one thyroid lobe with excision of the isthmus. The isthmus is completely removed to prevent postoperative hypertrophy in response to the lobectomy with subsequent airway impingement. *Subtotal lobectomy* is a lobectomy that spares the posterior capsule and a portion of adjacent thyroid tissue. *Bilateral subtotal thyroidectomy* is removal of both lobes of the thyroid in the fashion stated for subtotal thyroidectomy. *Near-total thyroidectomy* is a total lobectomy with contralateral subtotal thyroidectomy. *Total thyroidectomy* is the removal of both lobes of the thyroid and all thyroid tissue present. For patients with cancer of the thyroid, total thyroidectomy is the desired surgical treatment (Sarkar, 2004; Tuttle, 2007), followed by iodine-131 remnant ablation. Preventing thyroid cancer recurrence does not depend on surgical approach, but on complete surgical excision of the tumor (Loevner and Mukherji, 2008). Following surgery, the thyroid cancer patient is prescribed thyroid hormone suppression therapy and monitored by physical examination, laboratory studies (serum thyroid function and thyroglobulin levels), and scans.

The purpose of the surgical intervention relates to the patient's medical diagnosis. *Goiter* refers to any enlargement of the thyroid gland and includes both benign and malignant nodules; the enlargement is visible over the anterior neck (Wilson and Giddens, 2009). *Benign adenomas* are encased in a fibrous capsule, distinct from surrounding thyroid tissue. *Malignancies* occur most commonly in patients under 20 or over 60 years of age. Excising the lymph nodes with suspected or known cancer of the thyroid remains a standard therapy. Radiologic studies aid in the understanding of nodal metastasis and determining which levels of the neck to dissect. Contralateral metastasis is generally associated with large tumors. Young patients tend to respond favorably to treatment and have a better prognosis than older patients (Loevner and Mukherji, 2008).

Graves' disease, the most common cause of hyperthyroidism, is associated with diffuse, bilateral enlargement of the thyroid gland. Surgery is not the first response for Graves' disease, but is reserved for those patients who fail medical therapy (antithyroid drugs and radioactive iodine) or have a contraindication to medical therapy. *Hashimoto's thyroiditis* is believed to be an autoimmune disease in which nontender enlargement of the gland occurs. Surgery is performed to relieve tracheal obstruction. *Nontoxic nodular goiter* involves production of insufficient hormones and is noninflammatory in character; in

PATIENT AND FAMILY EDUCATION

Home Care After a Thyroidectomy

- Give both patient and caregiver *verbal* and *written* instructions. Provide them with the name and telephone number of a physician or nurse to call if questions or problems arise. Have patient and/or caregiver teach back instructions in own words. Allow time for questions.
- Make sure the patient knows to sit up slowly and allow his/her legs to dangle for 1-2 minutes before getting up. The caregiver should accompany the patient on the first walk at home.
- Explain and discuss with patient the surgical procedure performed. The patient should be able to state the name of the surgical procedure performed.
- Wound/incision care
  - Teach patient to keep the surgical site clean and dry.
  - Teach methods to conceal surgical site without affecting healing. Suggest loosely buttoned collars, high-neck blouses, jewelry, or scarves.
  - Explain that paper strip over wound will peal off in 7 to 10 days; when ends curl, it may be removed.
  - Inform patient that lotion may soften healing scar and improve its appearance (if approved by physician).
- Warning signs: review signs and symptoms that should be reported to physician or nurse.
  - General: respiratory distress, bleeding
  - Wound infection: redness, warmth, swelling, persistent drainage from site, unrelieved tenderness
  - Total thyroidectomy: signs and symptoms of hypothyroidism: intolerance to cold; decreased body temperature; dry, rough, or scaly skin; puffy face, hands, and feet; periorbital edema; decreased blood pressure; bradycardia; nonspecific fatigue, weakness; decreased exercise tolerance; weight gain; constipation; anorexia; delayed deep tendon reflexes; muscle aches and joint stiffness; speech changes (slowed, slurred, monotonous); somnolence, lethargy; impaired memory, inattentiveness, slow cognition; loss of initiative; paranoia, depression, agitation; decreased libido; female: decreased or missed menstrual cycles; abdominal distention
  - Parathyroid damage: signs of hypocalcemia: numbness, tingling, twitching, spasm, tetany
- Medication management
  - Explain purpose, dosage, schedule, and route of administration of any prescribed drugs, as well as side effects to report to physician or nurse.
  - Provide list of all medications patient is to take (including those that are not newly prescribed; this is part of discharge medication reconciliation and safety) (Risk Reduction Strategies)
  - Discuss importance of not taking over-the-counter medications without first checking with physician or nurse.
  - If patient had total thyroidectomy, explain importance of taking thyroid replacement medication regularly.
  - If patient has parathyroid damage, explain need for calcium supplements.
- Activity
  - Encourage patient to discuss allowances and limitations with respect to occupation, recreation, and activities.
  - Teach prescribed head and neck exercises: flexion, lateral movement, hyperextension.
  - Teach importance of balance between activity and rest.
- Diet
  - Discuss need to maintain well-balanced diet.

FOLLOW-UP CARE

- Stress importance of regular follow-up visits to monitor thyroid levels: thyroid-stimulating hormone (TSH), thyroxine (T_4). Make sure patient has necessary names and telephone numbers.

Modified from Canobbio MM: *Mosby's handbook of patient teaching,* ed 3, St Louis, 2006, Mosby; Workman LM: Care of patients with problems of the thyroid and parathyroid glands. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, Philadelphia, 2010, Saunders.

such cases thyroid tissue proliferates in an apparent attempt to produce the minimal hormonal requirement. Surgery may be indicated to relieve tracheal or esophageal obstruction or to rule out a malignant nodule of the thyroid. *Total thyroidectomy* may be done for malignant tumors (Box 15-4). An intraoperative frozen section may be indicated to confirm the diagnosis. If the diagnosis is not definitive on frozen section, a hemithyroidectomy may be the treatment of choice. If the permanent histologic report is benign, the patient has the unaffected thyroid lobe preserved and intact. If the pathology, however, proves to be carcinoma, a complete thyroidectomy is then performed as soon as possible.

Minimally invasive approaches to thyroid surgery arose in the late 1990s and early twenty-first century for treatment of small thyroid nodules. These include minimally invasive open thyroidectomy (MIT) and minimally invasive video-assisted thyroidectomy (MIVAT). Minimally invasive thyroid surgery is performed for both partial and total thyroidectomies (Dhingra, 2008). Researchers are conducting studies on natural orifice transendoscopic surgery (NOTES); in the future, skin incisions may become obsolete for some surgeries (Research Highlight, p. 580, top).

Minimally invasive thyroidectomies reduce postoperative pain, decrease hospital length of stays, and improve cosmetic results (Research Highlight, p. 580, bottom) and may be done using a local anesthetic. Minimizing dissection and resultant dead space eliminates the need for external drains in most cases. Smaller incisions, minimal use of surgical drains, and prophylactic calcium supplementation have enabled thyroid surgery to be performed safely on an ambulatory basis (Dinghra, 2008).

AMBULATORY SURGERY CONSIDERATIONS

Patient Teaching, Preparation, and Screening

If the patient will be discharged home on the same day as surgery, thorough patient teaching and preparation with written instructions is critical. It is paramount that nursing staff have strong critical thinking and assessment skills to screen patients for problems that may preclude same-day discharge. Safe and successful ambulatory surgery depends, in part, on recognizing which patients can be sent home and which patients should be admitted.

The nursing staff must verify that the patient has arranged for someone to drive him/her home and for a caregiver (family/friend) to assist during the first 24 hours at home. Surgery cannot be done on an ambulatory basis if these arrangements have not been made.

Patients must be thoroughly and carefully screened as to eligibility for ambulatory thyroidectomy or parathyroidectomy (Patient Screening and Assessment, 2009). Ambulatory surgery is contraindicated in patients with grossly enlarged thyroids or comorbid medical conditions, such as cardiac disease, uncontrolled hypertension, brittle diabetes, and sleep apnea. Intraoperatively, patients who had a difficult intubation or who bled excessively should be excluded from discharge on the same day as surgery.

The nursing staff should ascertain the patient's ability to understand and cooperate with discharge instructions.

The patient is sent home with prescriptions for pain management, calcium supplements, thyroid hormone (if indicated), and other medications specific to preexisting conditions. All medications should be reviewed (discharge reconciliation) and a list provided.

The patient must meet discharge criteria: the patient must be fully awake, alert, and oriented and be able to void, swallow, and drink fluids without nausea or vomiting.

The need for deep breathing, mobility, and hydration must be emphasized.

The patient should be cautioned not to drive or drink alcohol for at least 24 hours.

Patients and families are under physical and emotional stress and often will find the environment and information received overwhelming. Standardized printed discharge instructions from the surgeon, specific to the surgery performed, with space available to customize information for the patient, provide a valuable tool and reference resource for the patient and family/caregiver to use at home.

Perioperative staff must ascertain that the patient and caregiver understand the symptoms indicating a significant problem that needs immediate attention, as well as actions to take and persons to contact in case of an emergency. These include signs and symptoms of dyspnea, hemorrhage, thyroid storm, and hypocalcemia.

The patient should be instructed to call the physician's office for a follow-up visit if this has not been arranged.

RISK REDUCTION STRATEGIES

Discharge Medication Reconciliation

Medication reconciliation is an ongoing National Patient Safety Goal (NPSG). Up to 75% of potential adverse drug events occur during discharge (Pippins et al, 2008) as patients and their caregivers review, as part of discharge preparation, new medications and must understand which medications to stop or change. Their ability to concentrate or ask questions may be compromised by other needs such as making follow-up appointments and planning for multiple, and sometimes complex, changes in routine activities. In one study, only 27.9% of discharged patients were able to identify their medications, 37.2% knew the purpose of all their medications, 14.0% were able to state the common side effect(s) of all their medications, and 41.9% were able to state their diagnosis or diagnoses (Makaryus and Friedman, 2005).

Discharge reconciliation has several specific aspects. Drug formulary and related changes that occurred at admission must be addressed. If, for example, the patient's home medication was one drug but the patient was switched to another in the drug formulary, this change must be reconciled. A resolution must be made and clearly communicated to prevent the patient from taking both, or neither, of these medications. Prescriptions must be provided. The full medication list must be communicated clearly to both the patient and the caregiver. A simple printed discharge summary that includes details of the medications, including dose, indication, and directions, can reduce postdischarge medication errors. This same form can be sent to the next provider of care (i.e., primary care provider or specialist).

Adapted from Makaryus AN, Friedman EA: Patients' understanding of their treatment plans and diagnosis at discharge, *Mayo Clin Proc* 80:991-994; 2005; Meisel S: *Falling through the cracks: medication reconciliation at admission and discharge,* Medscape CME, March 2009, available at cme.medscape.com/viewprogram/19223?src=cmemp. Accessed April 6, 2009; Pippins JR et al: Classifying and predicting errors of inpatient medication reconciliation, *J Gen Intern Med* 23:1414-1422, 2008; The Joint Commission, Accreditation Program for Hospitals: *National Patient Safety Goals,* Oakridge, Ill, 2009, Author.

MIVAT is generally reserved for thyroid nodules within specific size limits as well as for low-stage papillary thyroid carcinomas. As MIVAT has evolved and surgeons have become more proficient with the technique, the only absolute contraindications for its use are thyroid malignancies beyond low-stage papillary carcinoma and preoperative evidence of lymph node metastasis. Relative contraindications include prior conventional thyroidectomy, nodules larger than 35 mm and 30 ml, and a history of thyroiditis (Dinghra, 2008). Studies indicate that it is safe to perform MIVAT thyroidectomies as ambulatory procedures under certain conditions (Terris, 2006).

Procedural Considerations

The patient is positioned supine. A drape pack with fenestrated sheet is required along with a basic instrument set and the addition of thyroid instruments. An electrosurgical unit (ESU), an exhaust system for surgical smoke (AORN, 2008), gauze dissectors, and a small drain (optional) are commonly used. A headlight for the surgeon and assistant may be required. A nerve monitor may be used during surgery to protect the laryngeal nerve. The patient is prepped from the chin to the upper chest, using fire safety precautions (see Chapter 2 for a discussion of fire prevention strategies in surgical settings).

RESEARCH HIGHLIGHT

Transoral Access for Endoscopic Thyroid Resection

Advances in thyroid surgery have been facilitated by intraoperative neuromonitoring to prevent laryngeal nerve paralysis, early measurement of intraoperative parathyroid hormone (IoPTH) levels to avert symptomatic hypocalcemia, and improved devices for hemostasis and dissection to better control bleeding. The authors of this study suggest the sublingual transoral approach as a promising minimally invasive endoscopic access to the thyroid gland from outside the neck region.

Sublingual transoral access was first evaluated in two fresh human cadavers. An experimental investigation then was performed using a porcine model. A total of 10 endoscopic transoral thyroidectomies were performed using a modified axilloscope with an obturator, ultrasonic scissors, and a neuromonitoring system to identify the recurrent laryngeal nerve.

Complete transoral thyroid resection was achieved with both human cadavers and live pigs. Despite the complexity of the anatomic region, the transoral procedure was successfully and smoothly performed. The neuromonitoring system ensured normal function of the recurrent laryngeal nerves on both sides after removal of the thyroid gland. No complications occurred during the procedures or afterward.

Endoscopic transoral thyroid resection is possible. A follow-up study undertook preclinical investigation in human cadavers, again demonstrating adequacy of access and feasibility of the procedure. The next step will be its broad application in living pigs before it may be applied in humans. Finally, large prospective, randomized trials comparing the outcomes of different endoscopic procedures are needed to establish levels of evidence and grades of recommendation for transoral access.

Modified from Benhidjeb T et al: *Natural orifice surgery on thyroid gland: totally transoral video-assisted thyroidectomy (TOVAT): report of first experimental results of a new surgical method,* 2009, available at www.ncbi.nlm.nih.gov/pubmed/. Accessed April 4, 2009; Witzel K et al: Transoral access for endoscopic thyroid resection, *Surg Endosc* 22(8):1871-1875, 2007.

BOX 15-4

Malignant Thyroid Nodules

PAPILLARY CARCINOMA
- Most common form (>70%)
- Poorly encapsulated
- Calcifications present—uncommon in other carcinomas

FOLLICULAR CARCINOMA
- Second most common form (15%)
- Well-differentiated
- Associated with iodine deficiency

HÜRTHLE CELL TUMOR
- Derived from follicular epithelium
- Associated with regional nodal metastasis

MEDULLARY CARCINOMA
- Undifferentiated tumor
- Higher death rate than differentiated

ANAPLASTIC CARCINOMA
- More common in females and elderly
- Highly aggressive
- Rapidly fatal; death usually occurs within 1 year of diagnosis

UNCOMMON CARCINOMAS
- Primary lymphoma
- Primary squamous cell
- Metastatic thyroid tumors

Modified from Deitch M: Thyroid Cancer, *Adv Nurses* 10(14):24, 2008.

RESEARCH HIGHLIGHT

Cosmetic Surgery Techniques Can Enhance Thyroid Surgery Results

As noted in the plan of care for patients undergoing thyroid and parathyroid surgery, concern about appearance after surgery is not unusual. This prospective analysis included 248 patients (198 women and 50 men) who underwent varying approaches to thyroid surgery—from a standard (i.e., several inches long) neck incision for large thyroids, to minimally invasive techniques that cut the incision size in half, to endoscopic approaches that further reduced incision size. The following techniques were reported to improve aesthetic results:

- Having the patient sit or stand while incision sites were marked to ensure that they blend with the natural lines of the body
- Minimizing incision size
- Trimming skin edges at the incision sites. In minimal access techniques, skin edges sometimes become frayed as large nodules are removed from relatively small incisions. Rather than make a bigger incision, skin edges are excised to improve reapproximation.
- Using surgical glue instead of sutures. Surgical glue allows accurate skin edge apposition without the risk of "railroad-tracking" from skin sutures. It is also convenient for patients. Instead of returning for suture removal, they can peel the glue off.
- Minimizing trauma to surrounding skin. Instead of creating extensive flaps, as described in conventional approaches, a modified approach involves minimal flap creation, sparing extensive tissue dissection.
- Avoiding use of drains
- Using other techniques, such as the ultrasonic harmonic scalpel, to reduce overall surgical trauma

In this analysis, only 1 of the 248 patients required additional treatment for the surgical scar; that female patient required steroid injections for hypertrophic scarring. The application of well-known cosmetic surgery principles improved optimal outcomes relating to the appearance of postoperative incision sites.

Modified from Terris D: *Cosmetic surgery techniques can enhance thyroid surgery results,* Medical College of Georgia, available at https://my.mcg.edu/portal/page/portal/News/archive/2007. Accessed January 24, 2009.

Surgeons may use the harmonic scalpel or LigaSure Precise. The heated blade of the harmonic scalpel retains its heat longer than an electrosurgical unit blade. Appropriate precautions must therefore be used to avoid inadvertent burning of adjacent tissue. Thyroidectomies are done through a small incision and visualization is critical for successful extraction. Bleeding can obscure the view and hinder the progress of the surgery. Therefore, surgeons may use hemostatic agents intraoperatively to maintain hemostasis (Research Highlight).

RESEARCH HIGHLIGHT

Dissection and Hemostasis with Hydroxylated Polyvinyl Acetal Tampons in Open Thyroid Surgery

The objectives for thyroidectomy are avoidance of injury to the recurrent laryngeal nerves, conservation of the parathyroid glands, accurate hemostasis, and excellent cosmesis. To achieve these objectives major improvements and new technologies have been proposed and applied in thyroid surgery; among these are performing mini-invasive thyroidectomies, using a regional anesthetic, conducting intraoperative neuromonitoring, and implementing new devices for dissection and hemostasis. Minor bleeding from small vessels, however, can still present major complications in thyroid surgery. Bleeding obscures visualization and is the major cause of converting minimally invasive to open thyroidectomies.

Hydroxylated polyvinyl acetal (HPA) tampons are made with a synthetic, open cell foam structure able to absorb fluids up to 25 times their initial weight. Their surface is smooth and they do not stick to tissues. They have an initial, mildly hard, firmness that allows their use as blunt dissection devices. They are designed in different shapes, forms, and sizes. Specific tests demonstrated that HPA tampons are fully biocompatible and able to reduce bacterial growth.

Studies were performed to test the efficacy of HPA tampons for tissue dissection and minor bleeding control during several thyroid procedures. They were found to be exceptionally useful for absorbing blood from minor and diffuse loss, helping to control bleeding by a combined action of fluid absorption and local compression. The tampon's porous design allowed use of a suction device through the tampon itself. The initial mildly hard consistency of the HPA tampons allowed their use in blunt tissue dissection.

The authors concluded that the use of HPA tampons was efficient for controlling minor bleeding, removing fluids, and performing blunt tissue dissection during thyroid surgery.

Modified from Dionigi G et al: Dissection and hemostasis with hydroxylated polyvinyl acetyl tampons in open thyroid surgery, *Ann Surg Innov Res* 1:3, 2007, available at www.aornjournal.org/article/S0001-2092(07)00583-2/fulltext#further-reading. Accessed April 6, 2009.

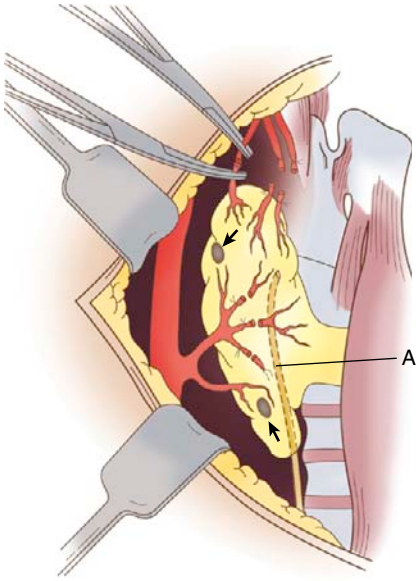

FIGURE 15-7 Safe thyroid principles emphasize the following: division of all branch vessels on the capsule of the thyroid with fine mosquito hemostats to prevent injury to the superior laryngeal nerve while detaching the superior thyroid artery and to prevent injury to the parathyroid glands while detaching the inferior thyroid artery; mobilization of parathyroid glands *(arrows)* by medial-to-lateral dissection to preserve their vascular pedicle; constant awareness of the location of the recurrent laryngeal nerve *(A)*, especially near its penetration into the larynx.

Open Thyroidectomy Operative Procedure

Figure 15-7 provides an overview of safe thyroidectomy principles.

1. A transverse incision (slightly curved and symmetric) is made parallel to the normal skin line crease of the neck, through the skin and first layers of the cervical fascia and platysma muscle, about 2 cm above the sternoclavicular junction.
2. An upper skin flap is undermined to the level of the thyroid notch of the thyroid cartilage; double skin hooks or Allis clamps are placed on the dermis and retracted anteriorly and superiorly to facilitate dissection. A lower flap is then undermined to the sternoclavicular joint. A knife, fine curved scissors, tissue forceps, and gauze sponges are used to undermine the flaps. Bleeding vessels are clamped with hemostats and ligated with fine nonabsorbable sutures. Lateral retraction with a vein retractor or Army-Navy retractor helps identify the plane for dissection.
3. Flaps are held away from the wound with stay sutures inserted through the cervical fascia and platysma muscle or by a self-retaining retractor.
4. The fascia in the midline is incised between the strap (sternohyoid and sternothyroid) muscles with a knife. Care must be taken to preserve the anterior jugular veins. The fascia may be lifted on either side with forceps during the dissection to help define the plane of dissection and protect the jugular vessels. The sternocleidomastoid muscle may be retracted with a loop retractor. Ordinarily, it is not necessary to divide the strap muscles. However, if additional exposure is required, such as with a very large gland, they may be divided between clamps using Mastin muscle clamps, Kocher clamps, or hemostats and a knife. The divided muscles are retracted from the operative site to expose the target lobe.
5. The inferior and middle thyroid veins are ligated with fine nonabsorbable sutures or hemoclips, and divided with Metzenbaum scissors.
6. The lobe is first rotated medially, and loose areolar tissue is then divided posteriorly and medially toward the tracheoesophageal sulcus with hemostats and Metzenbaum scissors. Small sponges are used for blunt dissection. Bleeding is controlled with hemostats, hemoclips, and ligatures,

as well as with the ESU; a bipolar ESU may be used. The recurrent laryngeal nerve, which enters the cricothyroid muscle at the level of the cricoid cartilage, is identified and carefully preserved. Electrocoagulation should not be used in the vicinity of the recurrent or superior laryngeal nerve because the spread of current could damage the nerve. Nerve integrity monitoring systems (NIMSs) are helpful in identifying the branches of the laryngeal nerve. NIMSs should supplement, not replace, good surgical technique and anatomic awareness (Loevner and Mukherji, 2008). Vigorous suction and dissection may cause injury to the nerve and parathyroid glands. The scrub person should prepare a radiopaque 4 × 8 inch sponge on the end of a forceps for the surgeon or assistant to use in gently blotting the area.

7. The thyroid lobe is pulled downward, a Lahey goiter or polar retractor inserted as necessary, and the avascular tissue between the trachea and upper pole of the thyroid dissected by means of Metzenbaum scissors.
8. The superior thyroid artery is defined by blunt dissection with a peanut sponge on a clamp; it is then isolated with a right-angle clamp. The artery is ligated with nonabsorbable suture or clamped with hemoclips, and divided. Care is taken here to avoid injury to the superior laryngeal nerve. The upper parathyroid gland is often identified at this time.
9. The inferior thyroid artery is identified and preserved. The inferior parathyroid is likewise identified. Only branches of the inferior thyroid artery that do not supply the parathyroid glands are ligated, using fine forceps, sutures, and scissors. The thyroid lobe is then dissected away from the recurrent laryngeal nerve with Metzenbaum scissors and hemostats. Bleeding vessels are clamped with hemostats or hemoclips, and ligated with fine nonabsorbable sutures.
10. The lobe is elevated with Babcock clamps and freed from the trachea with fine scissors, forceps, knife, and hemostats, or with cautious electrodissection. The fibrous bands attached to the trachea and cricoid cartilage are divided.
11. The isthmus of the gland is elevated with fine forceps and divided between hemostats with scissors, removing the lobe and isthmus. The cut edge of the remaining thyroid may be oversewn to maintain hemostasis. If a pyramidal lobe is present, it is removed, along with the lobe to which it is attached, to its termination in the neck, which may reach the hyoid bone. If it is necessary to transect the hyoid bone, a small bone cutter is used.
12. The cut surface of the opposite lobe requires careful hemostasis. Interrupted sutures may be used for this purpose as well as for reapproximation to the pretracheal fascia.
13. The excised thyroid is examined for inadvertent parathyroid inclusion. If a parathyroid is present, it is removed and reimplanted.
14. The strap muscles, if severed, are reapproximated with fine interrupted absorbable or nonabsorbable sutures. If necessary, a drain is inserted into the thyroid bed and exteriorized through the midline. Some surgeons prefer to drain the wound laterally through the sternocleidomastoid muscle and the lateral extremity of the incision, believing that this produces better healing and cosmetic results. A hemostatic agent may be placed in the lateral gutter to facilitate hemostasis.
15. The edges of the platysma muscle are reapproximated. The skin edges are then reapproximated with subcuticular fine absorbable sutures.
16. Wound closure tapes (e.g., Steri-Strips) are applied to the wound edges and gauze dressings, if required, are placed on the wound with minimal tape.

SUBSTERNAL OR INTRATHORACIC THYROIDECTOMY

Extensions of goiters enlarging into the substernal and intrathoracic regions may occur. If they cause tracheal and esophageal obstruction, they are usually excised surgically. Longer instruments are sometimes required. Splitting the sternum is rarely necessary because access to the substernal part of the gland is usually satisfactory through the standard thyroid incision.

MINIMALLY INVASIVE THYROIDECTOMY

Minimally Invasive Open Thyroidectomy

The length of the incision is the major difference between minimally invasive and traditional thyroidectomy. An incision of less than 6 cm is considered minimally invasive. Because of its smaller size, the site of the incision is critical for optimum access and visualization. After the incision is made, the remaining procedure is the same as that for conventional thyroidectomy (Dinghra, 2008).

Minimally Invasive Video-Assisted Thyroidectomy (MIVAT)

Procedural Considerations. The possibility of conversion to open thyroidectomy should be included on the operative consent form. Instruments and supplies for a possible open procedure are readied. Surgical skin preparation is done as in an open procedure in the event conversion is necessary. A set of long Miccoli instruments is added to the standard thyroid or neck dissection setup (Figure 15-8, *A*). A 30-degree endoscope and harmonic scalpel with scissors are used to ligate and divide vessels (Figure 15-8, *B*). Fire safety precautions are implemented for illuminated light cords, endoscopes, light sources, and cable connections.

Intraoperative Procedure

1. The patient is positioned and draped as for thyroidectomy. A horizontal incision of 3 cm or less is marked and then carefully made between the sternal notch and cricoid cartilage, usually less than 2 cm inferior to the cricoid (Figure 15-9).
2. Subcutaneous tissue is electrodissected and the raphe of strap muscle is then separated superiorly and inferiorly for about 3 cm. The anterior jugular veins are preserved.
3. Blunt dissection is used to separate the strap muscle from the thyroid.
4. The middle thyroid vein is clipped and divided.
5. Miccoli retractors are used to retract the strap muscles and soft tissue, exposing the superior lobe and vascular bundle.
6. The endoscope is introduced to visualize the upper pole. Three persons are needed: the surgeon, an assistant for retraction, and an endoscopist.

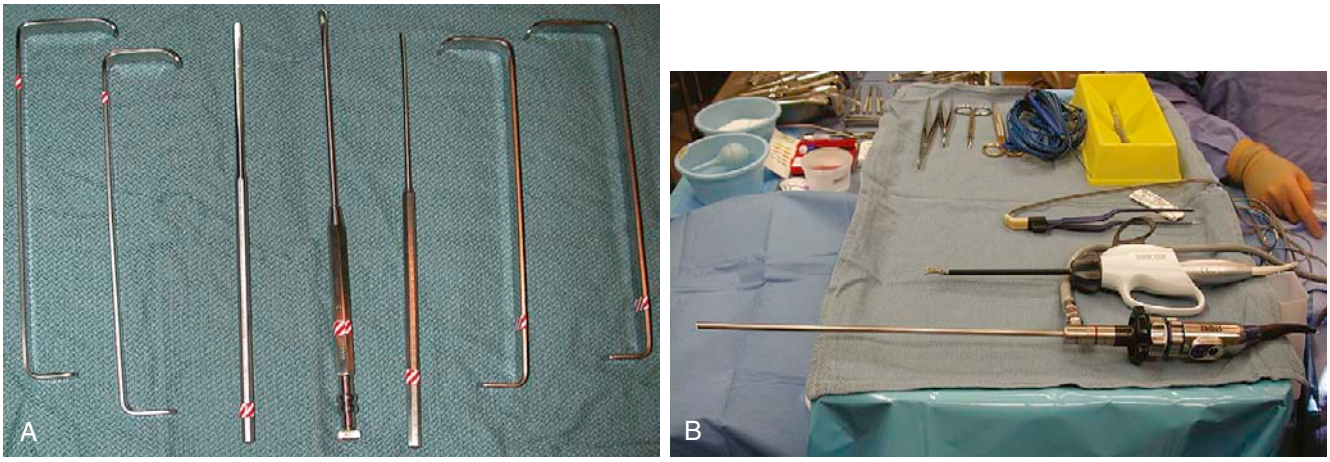

FIGURE 15-8 **A**, Miccoli instrument set designed for MIVAT. **B**, Endoscope and harmonic scalpel.

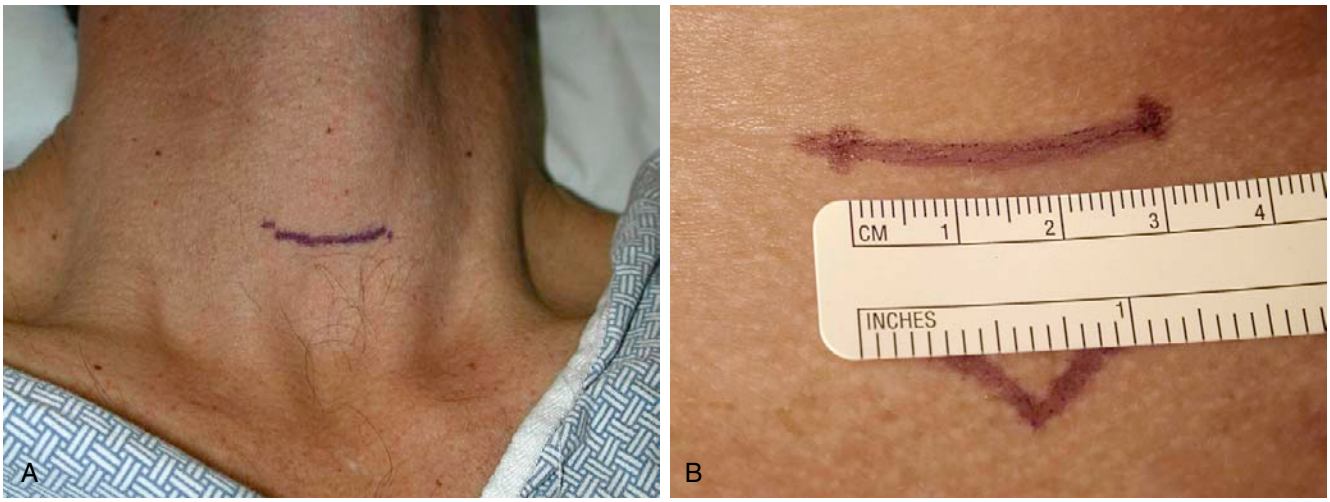

FIGURE 15-9 **A**, MIVAT incision location. **B**, MIVAT incision length.

7. Miccoli spatula-shaped and aspirator dissectors are used to dissect the superior pole and vascular bundle (Figure 15-10). Care is taken to identify and preserve the external branch of the superior laryngeal nerve.
8. The thyroid lobe is then retracted medially and its lateral and posterior attachments are dissected. The recurrent laryngeal nerve and parathyroids are protected and preserved (Figure 15-11).
9. After sufficient mobilization of the lobe, the remainder of the procedure is accomplished under direct visualization. The isthmus is transected to complete the lobectomy.
10. The same procedure is repeated on the other side for complete thyroidectomy.
11. Hemostasis is achieved, the wound is irrigated, strap muscles are reapproximated, and the skin is closed (Figure 15-12).

Postoperatively, analgesics, antiemetics, and prophylactic antibiotics are administered in PACU. Preoperative thyroid hormone supplementation is continued. For inpatients, ionized calcium and albumin levels are checked in PACU and then every 6 to 8 hours. Hypocalcemia is a serum calcium level below 8.0 mg/dl. If patients are discharged the same day as surgery, prophylactic calcium supplements will be prescribed for several weeks. Ambulatory patients are provided with contact information and told to notify their surgeon immediately if they experience signs of hypocalcemia. Early signs include perioral numbness or paresthesia and a positive Chvostek's sign.

THYROGLOSSAL DUCT CYSTECTOMY

Thyroglossal duct cyst is the most common congenital cyst found in the neck. Although this cyst may be found in patients of any age, 50% usually are seen before 20 years of age and about 70% by 30 years of age. The thyroglossal duct is an embryonic structure arising from the descent of the thyroid gland into the anterior portion of the neck. When present in an adult, it exists as a pretracheal cystic pouch attached to the hyoid bone, with or without a sinus tract to the base of the tongue at the foramen cecum (Figure 15-13). Thyroglossal duct cystectomy requires complete excision of the cyst in continuity with its tract, the central portion of the hyoid bone, and the tissue above the hyoid bone extending to the base of the tongue to avoid recurrent cystic formation and to prevent infection (Warner, 2004).

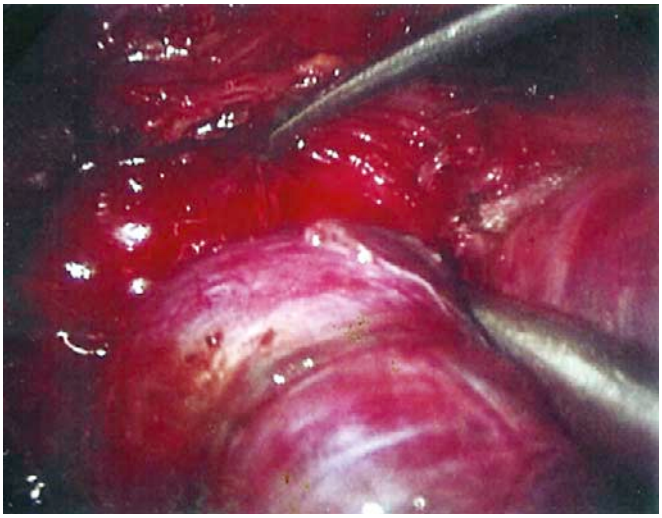

FIGURE 15-10 Video-assisted dissection of the right superior pole.

FIGURE 15-11 Identification of the recurrent laryngeal nerve during video-assisted right thyroid lobectomy. A parathyroid gland is also identified.

Procedural Considerations

The perioperative nursing assessment should be appropriate to the patient's age because the patient is frequently a child or teenager (see Chapter 25 for a detailed discussion of the needs of younger patients). Reassurance and age-appropriate information about the procedure are given. The patient is positioned supine, with the neck supported in extension. Bone instruments are needed in addition to the basic instrument set.

Operative Procedure

1. After the head is extended and the chin elevated, a transverse incision is made between the hyoid bone and thyroid cartilage through the subcutaneous tissue.
2. The platysma muscle is incised and flaps raised as described for thyroidectomy.
3. The strap (sternohyoid and sternothyroid) muscles are separated in the midline.
4. Sharp and blunt dissection is used to mobilize the cyst and duct, up to the attachment to the hyoid bone. The hyoid bone is transected twice, removing the center section with bone-cutting forceps. The segment of bone and the cyst are freed from adjacent structures.
5. The duct is traced superiorly through or near the hyoid up to the musculature of the tongue and removed completely. Methylene blue dye injection is used occasionally to visualize the whole tract.
6. The cyst is removed and the strap muscles closed with interrupted fine nonabsorbable sutures. A drain may be placed. The skin is then closed with subcuticular fine absorbable sutures and dressings are applied.

NECK DISSECTION

Neck dissection for metastatic node disease remains controversial as there is a high correlation of recurrence of cancer with little impact on long-term survival despite neck dissection. Lateral neck dissection is reserved for patients who have clinically proven lateral neck disease or gross metastasis along

FIGURE 15-12 **A**, Surgical scar at 2 weeks. **B**, Surgical scar at 6 weeks.

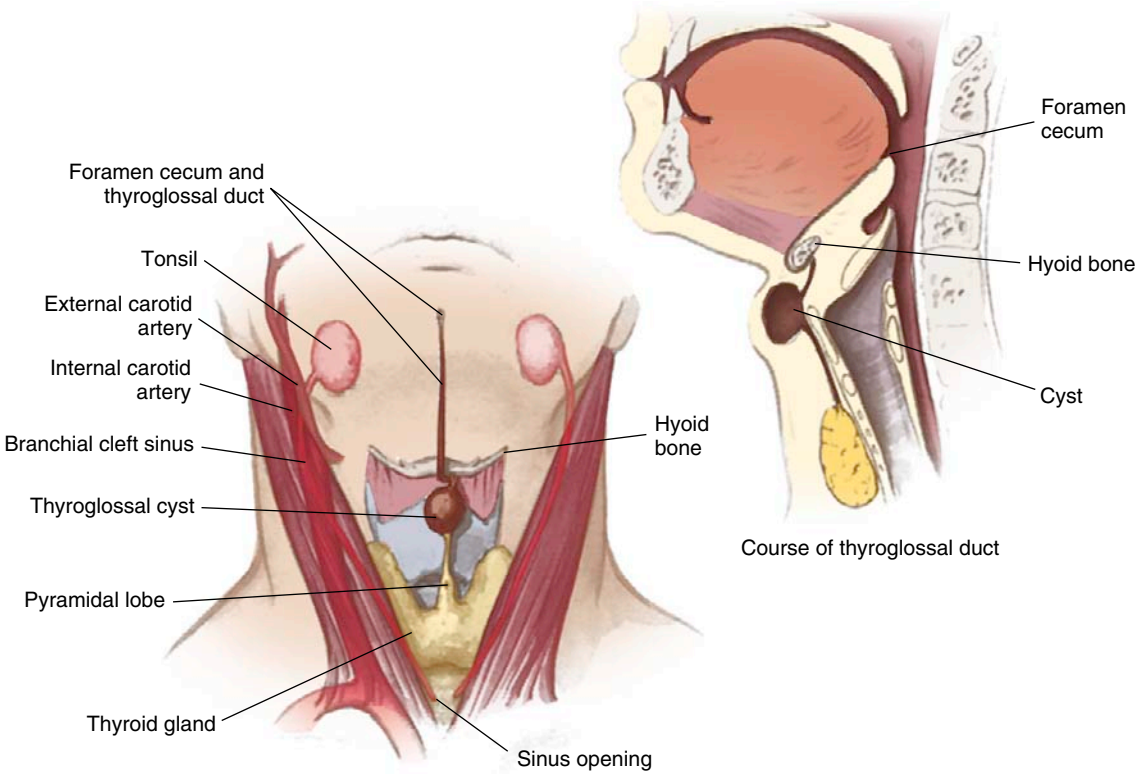

FIGURE 15-13 Thyroglossal cyst showing both anterior and lateral views.

the jugular vein. Central compartment dissection is reserved for those who have clinically apparent or suspicious nodes first noted during the primary surgery.

Patients are closely monitored postoperatively with ultrasound and thyroglobulin to screen for recurrence. Adjuvant radioactive iodine ablation is used for high-risk thyroid cancer patients, including those with residual disease in the thyroid bed, large tumors, multifocal disease, nodal metastasis, vascular and extrathyroidal invasion, and cancer with an aggressive history well as younger patients with distant metastasis (Loevner and Mukherji, 2008). Surgery is the treatment of choice for resectable recurrent thyroid carcinoma. The overall 10-year survival rate is 90%.

PARATHYROIDECTOMY

Parathyroidectomy is excision of one or more parathyroid glands. Normal or atrophic glands are generally not removed. The presence of adenomas (hypersecreting neoplasms), hyperplasia, or carcinoma requires surgical excision. For carcinomas, resection of the ipsilateral thyroid lobe and lymph nodes is essential, although metastasis may still occur by way of the bloodstream. Any residual parathyroid cancer may secrete parathormone, causing hypercalcemia and its attendant problems.

Previously, the gold standard for parathyroidectomy was bilateral neck exploration with biopsy of all four glands to confirm the presence of adenoma or hyperplasia. New technologies, however, have offered less invasive surgical options that pinpoint the affected gland and obviate the need to biopsy, and potentially damage, healthy parathyroid glands. The four-gland exploration for single-gland involvement is being replaced by radio-guided, minimally invasive ambulatory procedures utilizing intraoperative PTH levels and/or the gamma probe. Patients with a negative sestamibi scan are excluded from minimally invasive parathyroidectomy protocols although intraoperative PTH levels are still helpful in identifying multiple adenomas (Loevner and Mukherji, 2008). Often, the diagnosis of an adenoma can be made by gross inspection of the glands by the surgeon, but such diagnoses must be confirmed histologically by the pathologist.

Minimally invasive techniques cannot be used for hyperplasia. Hyperplasia requires removal of three and one-half glands through a bilateral neck exploration. A portion of a gland must remain to prevent hypocalcemia and its complications.

Procedural Considerations

During bilateral neck exploration multiple biopsies may be performed to determine the presence or absence of parathyroid tissue. Numerous specimen containers should be available (Patient Safety). Some surgeons perform parathyroidectomy using a minimally invasive approach with intraoperative parathyroid hormone assays to determine if the gland removed was the cause of hypersecretion. The perioperative nurse should ascertain that a pathologist is alerted and ready to analyze blood samples and tissue specimens. Preoperative localization studies, if done, should be conducted in the OR. If the surgeon is performing a focused parathyroidectomy (as described under Minimally Invasive, Focused Parathyroid Surgery), several blood tubes will be required to measure parathyroid levels intraoperatively. The circulating nurse will note excision

PATIENT SAFETY

Handling Multiple Specimens

The perioperative nurse is accountable for specimen collection, identification, and handling. During parathyroidectomy, multiple specimens may be collected. To accurately identify and safely manage these specimens, the perioperative nurse should do the following:

- Verify specimen collection and handling needs with the surgeon. This should occur before the procedure starts and may be part of the time-out or preoperative briefing (Paige et al, 2008).
- Have available an adequate number of specimen containers, labels, laboratory forms, and appropriate preservative.
- Take an additional time-out when the specimen is collected, in which the surgeon, scrub person, and nurse agree on the name of the specimen, its type, and source location.
- Label the specimen with a patient label naming the contents of the container. When multiple specimens are collected, they may be labeled A, B, C, etc. to indicate the order of harvesting.
- Communicate to the pathology department the nature of the procedure and anticipated specimens. Plan for direct communication about specimens between the surgeon and pathologist or perform a read-back or repeat-back of pathology findings.
- Use Standard Transmission–Based Precautions.
- Log (chain of custody) specimens according to institutional protocol.
- Arrange for timely transport of specimens to the pathology department.
- Document specimen collection in the intraoperative nursing record according to institutional protocol.

Modified from AORN recommended practices for the care and handling of specimens in the perioperative environment. In *Perioperative standards and recommended practices,* Denver, 2009, The Association.

time and collaborate with the anesthesia provider to anticipate and handle postexcision blood samples. Mediastinotomy instruments should be available (see Chapter 22). The patient is positioned, prepped, and draped as described for thyroidectomy. Hemoclips should be available.

Operative Procedure (Open Approach)

Although it is quickly being replaced with the focused approach to parathyroidectomy, in the classic open approach, with the thyroid gland visible, bilateral neck exploration of the "normal" locations of the four parathyroid glands is conducted. Meticulous hemostasis by means of mosquito hemostats and fine ligatures is a prerequisite to location and identification of these small glands.

The thyroid gland is gently rotated anteriorly to provide access to the posterior thyroid sulcus, where the parathyroid glands are almost always found. Identification of the parathyroid vascular pedicle, as it leaves either the superior thyroid artery or the inferior thyroid artery, is a means of locating both the inferior and superior glands. Metzenbaum scissors, mosquito hemostats, hemoclips, and gauze dissector (Kittner or peanut) sponges are used during dissection.

Attention then turns to the posterior lateral surface of the thyroid lobe or just beneath the lower thyroid pole, where the lower parathyroid glands are frequently found. Finding the vascular pedicle from the inferior thyroid artery may aid in identification (see Figure 15-5). Occasionally, the lower pair is found in the thymic capsule or tissue, in which case a portion of the thymus is resected. A mediastinotomy is indicated for a small percentage of patients. Thoracoscopy (see Chapter 22) is also a successful, minimally invasive technique that may be used to remove parathyroid tumors that are deep in the mediastinum.

If one of the parathyroid glands shows evidence of disease, an effort is made to find other glands on the same side to ensure that they are disease-free. When found, biopsy is performed, using a marker such as a hemoclip. The surgeon resects the diseased gland by clamping the vascular pedicle with mosquito hemostats, dividing with small scissors or a knife, and ligating with a fine nonabsorbable suture or hemoclip. The amount of parathyroid tissue that should be removed remains controversial and relates to whether single or multiple glands are involved. As previously noted, a portion of a gland must remain to prevent hypocalcemia and its complications.

A current alternative for multiple gland involvement is to excise all four glands and to transplant a portion of one in an accessible site, such as the neck or forearm, for later removal if hypercalcemia recurs. The amount of remaining parathyroid tissue can then be adjusted to regulate PTH to the desired level. This eliminates reexploration and potential injury to the recurrent laryngeal nerve. The parathyroid is morselized and divided into several segments. An incision is made in the forearm or neck and four separate grooves with purse-string sutures are made in the muscle. Some parathyroid tissue is placed and secured in each groove. The sites are then marked with one, two, three, and four hemoclips, respectively. If PTH levels remain high, the sites can be easily identified by the clips and more parathyroid tissue excised.

The neck region is then explored for aberrant parathyroid tissue, which is also resected. The remainder of the procedure is as described for the thyroid gland.

Minimally Invasive, Focused Parathyroid Surgery

A variety of minimally invasive techniques have evolved over the last decade. The most widely used is the focused minimally invasive open approach (focused parathyroidectomy, [FP]) where imaging has identified a single parathyroid lesion (Simpson et al, 2007). A localization study with sestamibi scan or ultrasound is used to identify the offending adenoma and to determine an optimum incision site. FP can be performed using a local anesthetic. Ambulatory surgery patients are provided specific education about postoperative oral calcium supplementation. In their study, Norman and Politz (2007) concluded that use of a specific calcium dosing protocol prevented postoperative development of symptomatic hypocalcemia in 93% of patients, identified patients at high risk of hypocalcemia, and allowed most patients who developed symptoms of hypocalcemia to self-medicate in a simple and predictable fashion.

PTH-Guided Parathyroidectomy. One relatively new approach is the intraoperative intact, rapid assessment PTH approach. Given that blood samples must be drawn before, during, and after the procedure to measure PTH levels, an arterial line is inserted and a baseline PTH measurement is taken preoperatively.

A small 2-cm incision is made in the neck based on the localization studies. Once the suspect parathyroid gland is exposed, a pre-excision blood sample is taken. As a result of manipulation, the pre-excision blood level may test higher than the baseline level. The pre-excision level becomes the marker for measuring the post-excision drop in PTH level.

The excised gland is placed in sterile saline and kept on the instrument table until the pathologist confirms a sufficient drop in PTH blood levels. A drop of 50% or more is considered verification that the parathyroid adenoma was excised. Blood levels are also drawn at 5, 10, and 20 minutes post-excision. When the adenoma is excised a dramatic drop in PTH level is frequently achieved by the 10-minute post-excision PTH sample. If the 10-minute drop is significant, the surgeon may opt not to have the pathologist run a 20-minute post-excision blood sample. If the hormone level fails to drop sufficiently, the ipsilateral parathyroid is explored as the next most likely adenoma. False positives have been reported in patients who have slow metabolic rates, are renal insufficient, or have large adenomas, 3 g or greater (Loevner and Mukherji, 2008).

Any normal parathyroid that was excised and placed in saline is then morselized with a #15 blade to increase surface area and then reimplanted. After the fascia is reapproximated, a clamp or scissors is used to create a groove in the strap muscle. A purse-string stitch of fine nonabsorbable suture is placed around the groove. The morselized parathyroid tissue is placed inside the groove and the purse-string tightened and tied. Parathyroids respond well to reimplantation.

Sestamibi-Guided Parathyroidectomy. Another minimally invasive technique is the sestamibi-guided, or radio-guided, parathyroidectomy. Sestamibi is given preoperatively and a gamma probe used intraoperatively to pinpoint the adenoma. When this technique is used postoperative normocalcemia has been reported in 97% of patients (Loevner and Mukherji, 2008).

CHAPTER 16

Breast Surgery

ELIZABETH B. PEARSALL

Most surgical procedures on the breast are performed to establish a definitive diagnosis or to treat breast cancer. Changing hormone levels from puberty throughout the remainder of life affect breast tissue in its physical and microscopic characteristics. In association with these changes, numerous aberrations and tumors can occur.

The occurrence of breast changes, benign or malignant, are some of the most emotionally upsetting health problems confronting women. Breast cancer is the most common cancer in women (Weaver, 2009); it accounts for nearly one of every three cancers diagnosed. The probability of developing breast cancer increases with age. Estimates are that one in eight women in the United States will develop breast cancer during her life. If the cancer is detected early, there is a 97% 5-year survival rate. Breast cancer risk increases if a woman's mother, sister, or daughter had breast cancer, especially if the cancer developed before menopause. Early menarche (before 12 years of age) and a late natural menopause (after 50 years of age) are associated with a slightly increased risk for developing breast cancer. Further, a woman who has cancer in one breast is at increased risk for cancer in the other breast (American Cancer Society, 2009). Heightened public awareness, an increased number of women practicing self-examination, and early detection of breast masses by mammography have started to slow the annual increase in breast cancer mortality.

Surgical Anatomy

The breasts are bilateral mammary glands that lie on the pectoralis major fascia of the anterior chest wall. They are surrounded by a layer of fat and are encased in an envelope of skin. The breasts extend from the second to the sixth rib and horizontally from the lateral edge of the sternum to the anterior axillary line. The largest part of the mammary gland rests on the connective tissue of the pectoralis major muscle and laterally on the serratus anterior (upper outer quadrant of the breast), with a normal globular contour occurring as a result of fascial support (Cooper's ligaments). An elongation of mammary tissue normally extends laterally on the pectoralis major toward the axilla and is known as the *tail of Spence* (Figure 16-1).

Each breast is made up of 12 to 20 glandular lobes separated by connective tissue. Each lobe drains by a single lactiferous duct that opens on the nipple. The nipple, located at about the fourth intercostal space, forms a conical projection into which the ducts open independently of each other on the surface. A pigmented circular area called the *areola* surrounds the nipple. Smooth muscle fibers of the areola contract to allow for nipple projection.

Three major arterial systems (Figure 16-2) supply the mammary glands with blood. The two main sources are branches of the internal mammary and lateral branches of the anterior aortic intercostal arteries, all of which form an extensive network of anastomoses over the breast. The third source is the pectoral branch, deriving from a branch of the axillary artery. The veins that mainly drain the breasts follow the course of the arteries. Superficial veins frequently dilate during pregnancy.

Lymph drainage generally follows the course of the vessels. Lymphatics drain into two main areas represented by the axillary nodes and the internal thoracic chain of nodes (Figure 16-3). The internal thoracic nodes are few, but are responsible for most lymph drainage from the inner half of the breast. Thus the lymph system can also be a channel for the spread of malignant disease from the breast to associated areas of the chest wall or to the axilla.

The breast's sensory nerve supply is primarily threefold: the anterior cutaneous branches of the upper intercostal nerves, the third and fourth branches of the cervical plexus, and the lateral cutaneous branches of the intercostal nerves.

The mammary glands are affected by three types of physiologic changes: (1) those related to growth and development, (2) those related to the menstrual cycle, and (3) those related to pregnancy and lactation. The mammary glands are present at birth in both males and females. Hormonal stimulation, however, produces the development and function of these glands in females. Estrogen promotes growth of the ductal structures, whereas progesterone promotes lobular development. Occasionally, developmental errors of the breast occur. Additional nipples or extramammary tissue in the axilla or over the upper abdomen may be present. Absence of one or both nipples may also occur and may be associated with absence of the underlying pectoral muscle and chest wall.

BENIGN LESIONS OF THE BREAST

Fibrocystic change in the breast is an all-encompassing term used to describe many different breast changes. Examples of benign lesions that are generally considered when fibrocystic changes are discussed are multiple lesions of fibrous disease, intraductal papillomas, cysts, and solid masses, such as fibroadenomas (Table 16-1). These changes affect almost all women at some time in their lives. Frequently pain is present, which calls attention to the problem. Pain, fluctuations in size, and multiple lesions are common features that help differentiate these generally benign lesions from cancer.

Nipple discharge is more commonly associated with benign lesions than with cancer. A postmenopausal woman who has

some duct ectasia or who has borne children can manually produce nipple discharge. Discharge is usually significant only if it is spontaneous and persistent. Chronic unilateral nipple discharge, especially if bloody, should prompt an investigation for occult carcinoma.

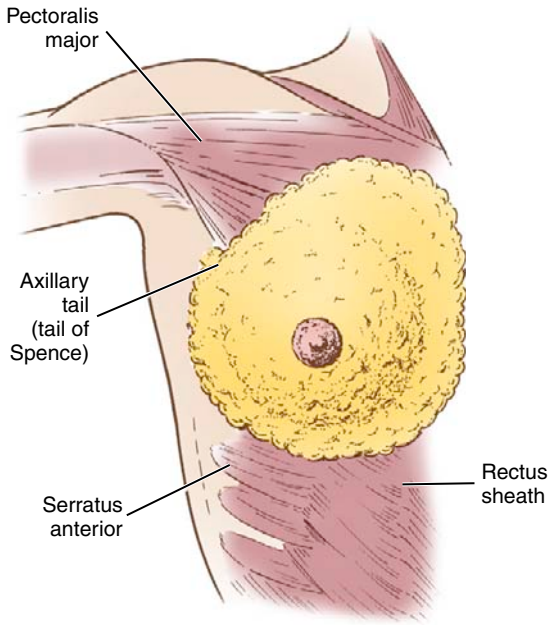

FIGURE 16-1 Normal distribution of mammary tissue of adult female breast.

BREAST CANCER

Breast cancer affects primarily women, although it can occur in the mammary gland of men. Until it can be prevented, early detection is the best hope for cure. All women should practice monthly self-examination to detect palpable lesions, and they should immediately report any changes or masses to a physician. External physical changes, such as dimpling of the skin, can also indicate the presence of a benign or malignant pathologic process. The older the patient, the more likely it is that a mass is malignant. The most common form of breast cancer is infiltrating ductal carcinoma (Table 16-2).

The cause of breast cancer remains unknown. Many factors, including environmental, dietary (National Cancer Institute, 2007), and familial influences, have been suggested as contributors to its development (Table 16-3). The belief that breast cancer spreads by direct extension from its initial site in the breast to adjacent lymph nodes may not always be correct. Breast cancer may be a systemic condition at the time of diagnosis (History box). Distant metastases may have already occurred without adjacent lymph node involvement at the time of its palpable detection. This could explain why radical breast surgery of the past, which involved removal of the affected breast and all axillary and thoracic lymph nodes, did not greatly lower mortality. Survival from breast cancer is best when detected early, reducing axillary lymph node involvement and improving long-term survival. Tumor size can usually be correlated with involvement of lymph nodes. The larger a tumor is, the more likely it is that lymph nodes are involved.

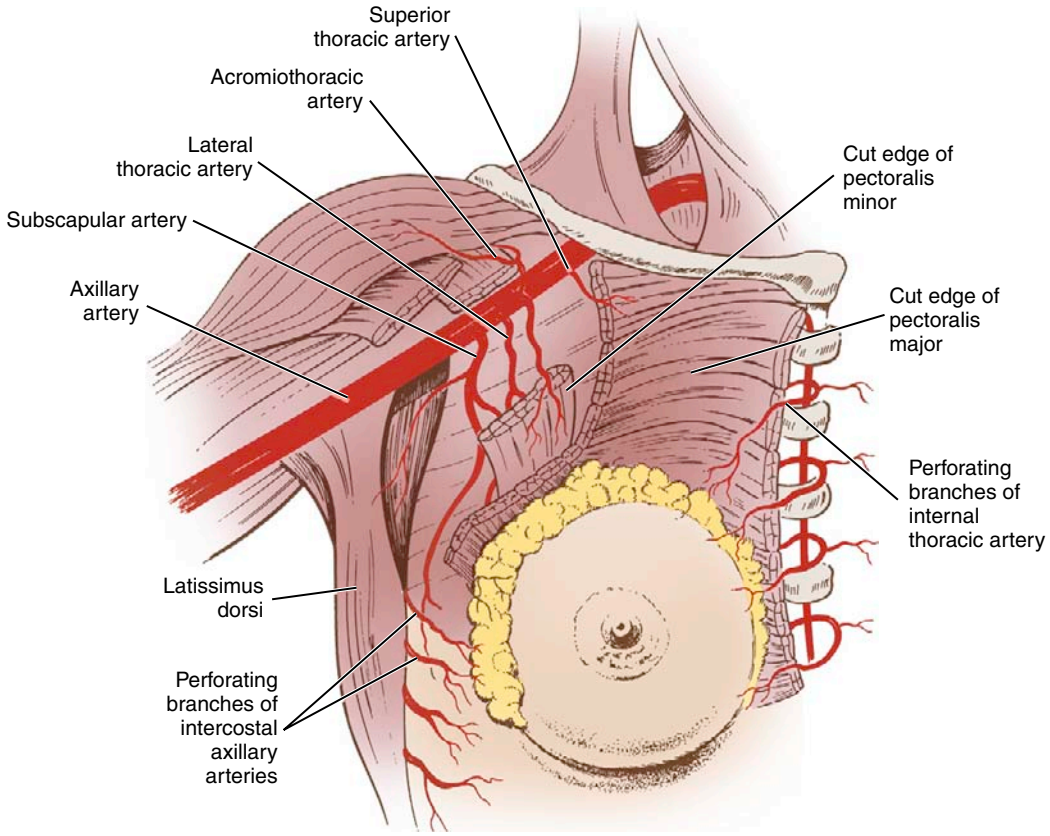

FIGURE 16-2 Normal arterial blood supply of the breast.

Less radical surgery is the treatment of choice today. Surgical excision of the tumor, the use of radiation therapy alone, or a combination of surgery, chemotherapy, and radiation therapy are current treatment recommendations. The use of adjuvant chemotherapy is particularly recommended for premenopausal women with axillary-node metastasis. Studies show that similar therapy can benefit node-negative breast cancer patients. New studies and new therapeutic options are continually being developed and tested. Clinical use of accelerated partial breast irradiation (APBI) is the subject of ongoing clinical trials.

HISTORY

Breast Surgery through the Ages

Over 3500 years ago, ancient Egyptians first noted breast cancer, describing it as "bulging tumors" with no cure. In 460 BC, Hippocrates described breast cancer as a "humoral" disease caused by an excess of black bile. Hippocrates believed the body consisted of four "humors" (blood, phlegm, yellow bile, and black bile) and any imbalance of the humors caused sickness or death. He claimed surgery was dangerous because he had noted that women who had the tumor excised died quickly and those who did not have surgery lived longer. Galen, in 200 AD, believed that some tumors were worse than others and surgery was not an option.

By the eighteenth century, the humoral theory of the origin of breast cancer was losing credibility. Some theories of the cause of breast cancer were that it was derived from curdled milk or a sedentary lifestyle, or that it occurred more frequently in childless women. People also thought the disease was localized. Dr. LeDran, a French physician, and Dr. LeCat were both of the opinion that surgery was the only way to cure the cancer.

By the mid-nineteenth century, most doctors agreed that surgery was the answer. Dr. William Halstead of New York dominated breast cancer surgery with radical mastectomy for most of the next century. He theorized that the cancer was a cellular disease. He urged women to have radical mastectomies before the tumor spread to the lymph nodes. Scottish physician Bealson discovered that a bilateral oophorectomy shrank his patients' breast tumors. Surgeons then began to perform radical mastectomy and bilateral oophorectomy, but the surgery was debilitating to the patient. Other radical surgeries to halt estrogen supply to the breast tumor were removal of the pituitary gland and adrenalectomy.

In 1955 Dr. George Crile argued cancer was not localized, but it spread throughout the body. Dr. Bernard Fisher theorized that cancer cells spread systemically by the circulatory and lymph system and that surgery could not cure cancer. Crile and Fisher both advocated a more systemic approach to breast cancer.

In the 1990s, after an initial increase in breast cancer rates, the number of breast cancer deaths reached a plateau in 1995 and then started to decline. By 1995 less than 10% of women inflicted with breast cancer had a mastectomy. Improvements in chemotherapy, radiation, hormone treatment, mammography, and surgery helped reposition breast cancer from an urgent disease to a chronic condition. Breast cancer theory has come full circle, from Hippocrates' theory of systems of imbalanced humors to the present view of breast cancer as a systemic condition.

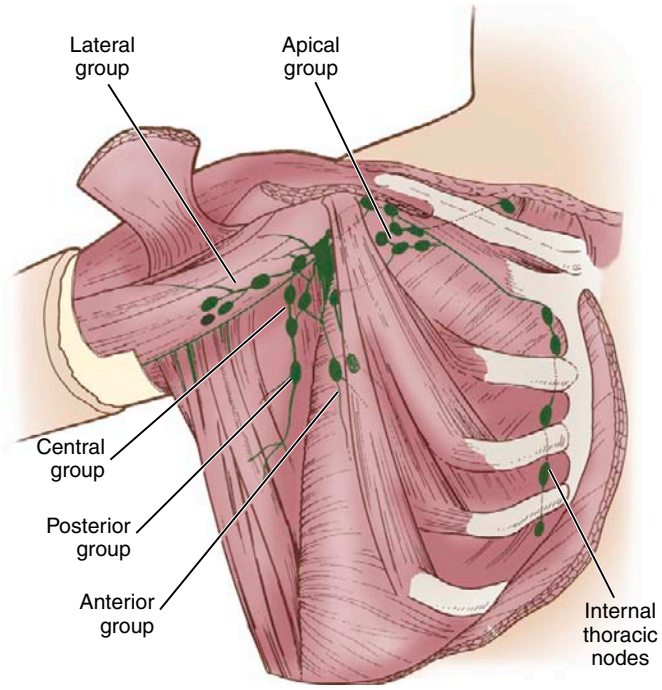

FIGURE 16-3 Distribution of axillary and thoracic lymph nodes.

TABLE 16-1

Typical Presentation of Benign Breast Disorders

Breast Disorder	Description	Incidence
Fibroadenoma	Most common benign lesion; solid mass of connective tissue that is unattached to surrounding tissue	Teenage years into 30s
Fibrocystic breast disease (FBD)	*First stage:* characterized by premenstrual bilateral fullness and tenderness *Second stage:* presence of bilateral, multicentric nodules *Third stage:* presence of microscopic and macroscopic cysts	Late teens and 20s
Ductal ectasia	Hard, irregular mass or masses with nipple discharge, enlarged axillary nodes, redness, and edema; difficult to distinguish from cancer	Women approaching menopause
Intraductal ectasia	Mass in duct that results in nipple discharge; mass is usually not palpable	Women 40-55 yr of age

Data from American Cancer Society: *Noncancerous breast conditions, 2009,* Atlanta, Author; Ignatavicius DD, Workman ML: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, St Louis, 2010, Saunders.

TABLE 16-2

Types of Invasive Breast Cancer

Breast Cancer Type	Percent of Breast Cancers	Specific Features
Ductal carcinoma	≈80	Can appear as microcalcifications, can vary widely in appearance, can have features of other histologic subtypes of breast cancer
Lobular carcinoma	10-15	Begins in milk (lobules) glands of breast, high rate of bilaterality, grows as single file of malignant cells around ducts and lobules, poorly defined mass
Medullary carcinoma	1-5	Forms distinct boundary between tumor tissue and normal tissue, well circumscribed, frequent phenotype of *BRCA1* hereditary breast cancer
Tubular	2	Infrequently metastasizes to lymph nodes, slow growing, long-term survival approaches 100%
Inflammatory carcinoma	≈1	Rapidly growing, often with metastasis present at diagnosis, first manifestations are breast skin edema and redness and warmth with dimples or ridges

Data from Imaginis: *What is breast cancer? 2008,* available at www.imaginis.com/breasthealth/breast_cancer2.asp. Accessed June 1, 2009; Mulholland M et al: *Greenfield's surgery: scientific principles & practice,* ed 4, Philadelphia, 2006, Lippincott Williams & Wilkins; Brunicardi FC et al: *Schwartz's principles of surgery,* ed 8, New York, 2005, McGraw-Hill.

TABLE 16-3

Risk Factors for Breast Cancer

Factors	Comments
HIGH INCREASED RISK (RELATIVE RISK >4.0)	
Female gender	99% of all breast cancers occur in women.
Age >65 yr	Incidence increases with age and peaks in sixth decade.
Genetic factors	Inherited mutations of *BRCA1* and/or *BRCA2* increase risk.
Family history	Two or more first-degree relatives with breast cancer at an early age increases risk.
History of previous breast cancer	Risk for developing cancer in opposite breast is 5 times greater than average population at risk.
Breast density	Dense breasts contain more glandular and connective tissue.
MODERATE INCREASED RISK (RELATIVE RISK 2.1-4.0)	
Family history	One first-degree relative with breast cancer moderately increases risk.
Biopsy-confirmed atypical hyperplasia	Overactive growth of cells increases risk.
Ionizing radiation	Women who received frequent low-level radiation exposure to thorax have increased risk, especially if exposure occurred during periods of rapid breast formation.
High postmenopausal bone density	High estrogen levels over time both strengthen bone and increase breast cancer risk.
LOW INCREASED RISK (RELATIVE RISK 1.1-2.0)	
Reproductive history	Childless women have an increased risk, as do women who bear their first child near or at age 30.
Menstrual history	Risk for breast cancer rises as interval between menarche and menopause increases. Women who undergo bilateral oophorectomy before age 35 have only 40% of risk for breast cancer compared to women who undergo natural menopause.
Oral contraceptives	There is a slight increase in breast cancer risk in women taking oral contraceptives.
Hormone replacement therapy (HRT)	Recent and long-term use of hormone replacement therapy slightly increases risk.
Obesity	Postmenopausal obesity (especially increased abdominal fat), increased body mass, insulin resistance, and hyperglycemia have been reported to be associated with increased risk for breast cancer.
OTHER RISK FACTORS	
Alcohol	The equivalent of two drinks per day may increase risk by 21%.
High socioeconomic status	Breast cancer incidence is greater in women of higher education and socioeconomic background. This relationship is possibly related to lifestyle differences, such as age at first birth.
Jewish heritage	Women of Jewish Ashkenazic heritage have higher incidences of *BRCA1* and *BRCA2* genetic mutations.

Modified from American Cancer Society: *Breast cancer facts and figures 2007-2008,* Atlanta, 2009, Author; Ignatavicius DD, Workman ML: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, St Louis, 2010, Saunders.

In APBI the radiation is focused on the area of greatest risk for tumor recurrence, the lumpectomy site, instead of whole breast irradiation (WBI). Such focused radiation treatment therapies reduce the traditional 6-week radiation treatment plan to 1 week (Fearmonti et al, 2007).

Minimally invasive cryoablation technology to freeze and destroy core biopsy–proven fibroadenomas has been approved by the U.S. Food and Drug Administration (FDA) and is now performed safely in an office setting (Bland et al, 2009). Another breast surgery alternative is focused ultrasound (FUS) with magnetic resonance guidance (MRgFUS), which allows for imaging and tissue temperature monitoring while controlling the FUS beam direction during ablation of breast lesions (Bland et al, 2009).

SCREENING TECHNOLOGIES

Imaging methodologies, such as mammography and ultrasonography, have helped to detect breast masses too small for clinical detection (Hulvat et al, 2009). The American Cancer Society recommends clinical breast exams by a physician every 3 years for women ages 20 to 39 years and annual clinical breast exams and mammograms for women 40 and older (Table 16-4). The American College of Physicians recommends that women who are not at high risk for breast cancer should have regular mammograms starting at age 50. High-risk women, such as those who have a family history of breast cancer or who have detected a lump in the breast, should start annual mammograms at age 40 (Zuckerman, 2007).

The most common screening mechanism for asymptomatic women is x-ray (film-screen) mammography (Figure 16-4). In mammography, the entire breast is visualized as x-ray beams are directed in several planes through it. Mammograms detect abnormal-appearing densities, irregular or spiculated margins, microcalcifications, and clusters of calcium deposits that are clinically nonpalpable. These masses may be as small as 1 cm in diameter (Mulholland et al, 2006). Often, previous mammograms are used for comparison. Screening mammography has led to identification of more nonpalpable breast masses. The accuracy of mammography depends on careful x-ray technique and breast size, structure, and density. Radiation dosage varies with individuals and techniques. As a result of improved radiologic techniques, radiation exposure in a mammogram is very low. The benefits of this screening mechanism far outweigh the minute risks of radiation exposure. Advances in computer-assisted detection allow the computer to analyze the mammogram, placing asterisks and triangles on small potential problem areas, which a radiologist then reviews. If screening mammography reveals a suspicious area, the patient is asked to return for diagnostic mammography (explained in the following paragraphs).

Digital mammography takes an electronic image of the breast and stores it directly in a computer. Digital mammography uses less radiation than film mammography and improves image storage and transmission, as images are stored and sent electronically. Radiologists also can use software to interpret digital mammograms. One obstacle to greater use of digital mammography is its cost, currently about 1.5 to 4 times more than film systems. Digital screening mammograms are more accurate than film screening mammograms, with a 70% detection rate compared with 55% for film screens. Women most likely to benefit from digital screening are those younger than 50 with dense breast tissue and who are premenopausal or perimenopausal (Hulvat et al, 2009).

When there is a palpable mass or other abnormality identified on screening mammography, a diagnostic imaging evaluation is done (Mikula, 2008). Additional diagnostic mammographic views are obtained, and the radiologist assigns a BI-RADS (Breast Imaging Reporting and Data System) score (Box 16-1). An ultrasound may then be ordered.

Ultrasonography differentiates between solid and cystic lesions. As a screening methodology, its sensitivity and specificity are less definitive than mammography. Ultrasonography can be useful with dense or dysplastic breasts and in pregnant or lactating women.

Magnetic resonance imaging (MRI) is another technique used as an adjunct to mammography in the detection of breast lesions. Breast MRI can image dense breast tissue,

TABLE 16-4

American Cancer Society Breast Cancer Screening Guidelines for Asymptomatic Women*

Age	Screening Activity
20-39 yr	Breast self-examination (BSE) monthly
	Clinical breast examination (CBE) every 3 yr
40 yr and older	BSE monthly
	CBE annually
	Screening mammography (two views of each breast) annually

*Asymptomatic women who are identified to be at higher risk need to have an individualized screening plan that may differ from these guidelines. From American Cancer Society: *Breast cancer facts and figures 2007-2008,* Atlanta, 2009, Author.

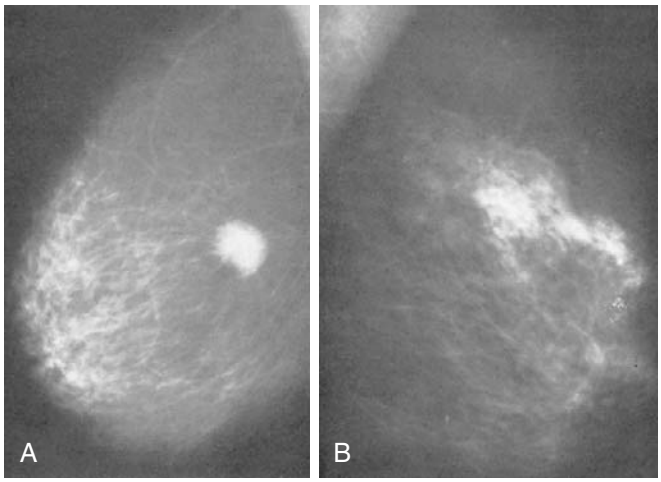

FIGURE 16-4 Mammographic features of malignancy. **A**, A stellate mass. The combination of a density, surrounding spicules, and distortion of the breast architecture strongly suggests a malignancy in this mammogram. **B**, Clustered microcalcifications. Fine, irregular, and branching forms suggest malignancy in this mammogram. Fine calcifications, less than 0.5 mm in size, are more often associated with cancer than are larger, coarse calcifications.

which shows poorly with conventional mammography. There is interest in the use of MRI to improve selection for breast-conserving therapy (BCT). In 2007 the American Cancer Society recommended that MRI be used for women at high risk. Such women include those who have known breast cancer–associated *BRCA1* or *BRCA2* gene mutations, have a first-degree relative with a *BRCA1* or *BRCA2* gene mutation, have a lifetime risk of breast cancer of 20% to 25% or greater according to risk assessment tools, had radiation therapy to the chest between 10 and 30 years of age, or have certain rare syndromes. The 2008 study by Martinez-Cecilia found that preoperative MRI improved tumor staging and changed the surgical approach for 13% of study patients; MRI discovered an additional malignant lesion in 8% of patients, and showed a tumor larger than originally believed in 16 patients, altering the planned surgery.

Molecular breast imaging (MBI) involves injection of a short-lived radiotracer, which is absorbed by breast tissue and preferentially so by breast tumors. MBI is especially useful in detecting breast cancer in women with dense breasts and who are at higher risk of developing the disease. This new technique has shown good promise as a helpful adjunct to screening mammography (U.S. Department of Health and Human Services, 2008).

Positron emission tomography (PET) scans with the glucose analog 2 are also being used for breast cancer detection. This scan is about 88% accurate for large breast tumors. For lesions less than 1 cm, the sensitivity of PET is 57% (Hulvat et al, 2009).

DNA-based genetic testing for *BRCA1* and *BRCA2* is not recommended for women without family histories that suggest risk for these gene mutations. A recent meta-analysis estimated that the lifetime risk for breast cancer was 47% to 66% in carriers of *BRCA1* and 40% to 57% in carriers of *BRCA2*. Other studies have shown even higher estimates. Managing breast cancer risk for women with these mutations includes frequent screening and prophylactic surgeries (Nelson, 2009).

In some instances, such as when a lesion previously detected by mammogram is too small to palpate, mammograms are repeated immediately before surgery. The lesion is localized by the insertion of a needle or a wire within a needle (the procedure is often referred to as "needle" or "wire" localization). The wire is placed within the suspect area, and the distal end is left on the outside of the skin. The needle may be left in place or removed after insertion of the wire (Figure 16-5). The needle or wire is then taped in place, and the patient sent to the OR for surgical biopsy. Wire localization and surgical biopsy occur on the same day. After biopsy, the specimen is sent to the radiology department for mammographic validation of correct surgical excision of the questionable breast tissue. The tissue is then sent for pathologic examination.

BOX 16-1

BI-RADS Assessment Scores

Category 0: The screening mammogram indicates additional screening is necessary. Prior mammograms, if available, are used for comparison. Additional imaging may include spot compression, magnification, special mammographic views, or ultrasound.
Category 1: The results are negative.
Category 2: The findings are benign.
Category 3: The findings are probably benign. Short-term follow-up is advised.
Category 4: The findings are suspicious. Biopsy is considered.
Category 5: The findings are highly suggestive of malignancy. Preliminary biopsy is needed; surgical treatment likely required.
Category 6: Known biopsy-proven malignancy. This category may be used for a second opinion before excisional biopsy, radiation therapy, chemotherapy, or mastectomy or for following tumor response during chemotherapy.

Modified from Mikula C: Mammography and biopsy, *Adv Nurs* 10(9):21-23, 2008.

DIAGNOSTIC TECHNIQUES

Once a mass is identified, the physician has multiple techniques to establish a diagnosis. During a fine needle aspiration biopsy (FNAB), the physician anesthetizes a small area of the breast with lidocaine. A 22- or 25-gauge needle attached to a 20-ml syringe is inserted into the mass, and a small amount of the contents is aspirated. Cytologic examination of the aspirate can assist in microscopic evaluation of the mass. FNAB yields greater diagnostic accuracy if the physician has been thoroughly trained in the technique. In a review of 31,340 procedures, FNAB sensitivity ranged from 65% to 98%. False-positive rates were less than 1%. As diagnosis of malignancy by FNAB is extremely reliable, treatment options can then be discussed with the patient and definitive surgery performed without the need for a surgical biopsy (Mulholland et al, 2006).

Advances in instrumentation now allow for simultaneous biopsy and removal of mammographic densities that are up to 20 mm in size using digital stereotactic imaging and minimally invasive instruments to locate and remove tissue for diagnosis. The patient is assessed preoperatively for neck or back problems. In addition, the patient should not be receiving anticoagulant therapy. Masses located near the patient's areola, high in the axilla, or near the chest wall are not appropriate for this technique. The patient is placed on a specially designed table (Figure 16-6) in the prone position with the affected breast through the table's 10-inch aperture to the work area below. The patient's head is turned away from the physician. Padding is placed under bony prominences to improve comfort. When the suspicious area in the breast is located through stereotactic imaging, its coordinates are transferred to the table's automated instrument. After preparing the skin with an antiseptic

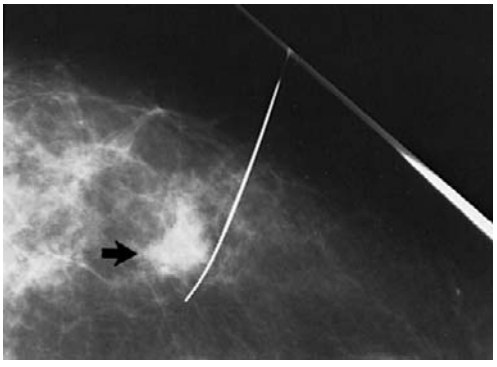

FIGURE 16-5 Mammogram section. Craniocaudal view of breast. Arrow indicates breast lesion localized by wire before surgical excision.

solution while the patient is administered a local anesthetic, the physician makes a small incision in the breast. The physician positions the disposable device to remove the identified tissue. Additional biopsies can be made if indicated, and coagulation can be used if necessary. A titanium vessel clip can be placed at the base of the biopsy specimen as a point of reference for future evaluations. A postoperative dressing is then applied to the area. The benefits to the patient include small incisions for cosmetic results, decreased disfigurement, shortened time between detection and diagnosis, and elimination of the need for more involved surgical intervention (Stephan, 2009).

SURGICAL TREATMENT OPTIONS

Surgical treatment ranges from minimally invasive breast biopsy, lumpectomy, and wide excision of the tumor mass; to modified radical mastectomy involving the breast and axillary lymph nodes; to salpingo-oophorectomy (Research Highlight). The goal of surgery is removal of the cancerous mass with a margin of normal tissue and a good cosmetic result. When a specimen of breast tissue is sent to the laboratory, it is inked to mark the relationship between the tumor and the surgical margins of the excision. The pathologist evaluates these margins on all sides of the tumor for malignant cells. If a margin is positive, it indicates that malignant cells may remain in the breast. Additional surgery is usually required until the margins contain only normal tissue (Re-excision for Close Margins, 2008).

The choice of procedure depends on the size and site of the mass, the characteristics of the cells, the stage of the disease, and the patient's choice. A breast cancer diagnosis is usually staged to measure the extent of the disease and to classify patients for possible treatment modalities (Figure 16-7). The TNM (T = tumor; N = node; M = metastasis) classification has been adopted as a mechanism to clinically stage this disease. Staging results are used in designing a specific treatment plan. Radiation therapy, chemotherapy, or hormonal therapy may be used with surgery or as alternative treatment methods. An intravenous (IV) access port may be surgically placed for later infusion of chemotherapeutic drugs, fluids, or nutrition as well as to withdraw blood and laboratory specimens (Ambulatory Surgery Considerations).

Excised tumors or core needle biopsies are evaluated for their estrogen-binding and progesterone-binding abilities. Techniques have been developed to assess the ability of breast cancer to bind with estrogen and progesterone.

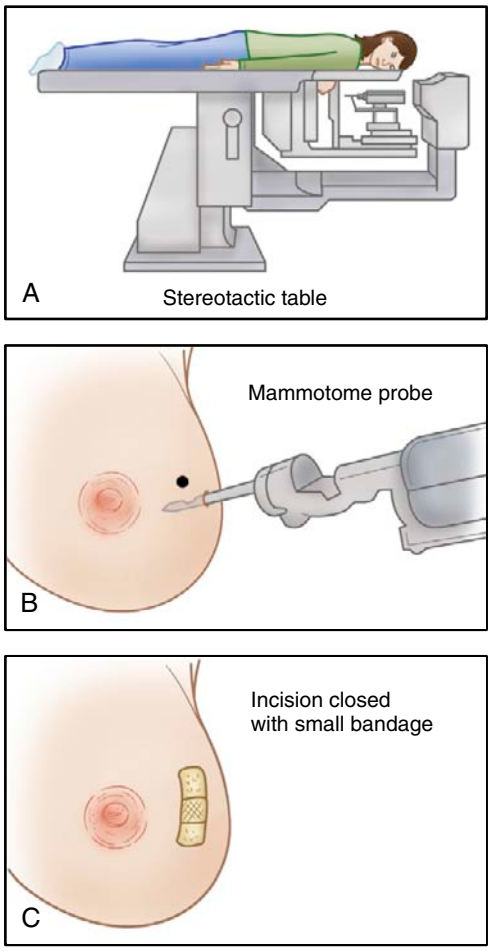

FIGURE 16-6 A, In stereotactic procedures, patients lie facedown on a special table. The woman's breast protrudes through a hole in the table's surface, where it is lightly compressed and immobilized while a computer produces detailed images of the abnormality. B, Once the biopsy area has been located and mapped, the Mammotome probe is inserted through a small ¼-inch incision in the breast, where it gently vacuums, cuts, and removes breast tissue samples. C, The incision is then closed with a small adhesive bandage.

RESEARCH HIGHLIGHT

Salpingo-Oophorectomy to Reduce Cancer Risk in Women with *BRCA* Mutations

According to a meta-analysis undertaken by Rebbeck and colleagues, prophylactic salpingo-oophorectomy reduces the risk for breast cancer by 50% and the risk for ovarian and fallopian tube cancer by 80% in women who carry mutations in the *BRCA1* or *BRCA2* gene. Their study quantified cancer risk reduction and is currently the most authoritative review. Salpingo-oophorectomy surgery reduces risk but is not 100% risk-eliminating. These new risk estimates should help women decide whether to undergo this surgery. Researchers and clinicians need to find ways to improve the efficacy of this surgical intervention by using optimal timing and type of surgery. Breast cancer reduction with prophylactic salpingo-oophorectomy was greater in *BRCA1/2* mutation carriers younger than 50 years than in women ages 50 and older. However, removal of both ovaries before age 45 increases risk for cardiovascular death 20 to 30 years later. Women with inherited mutations in *BRCA1* or *BRCA2* genes have a substantially elevated risk for breast and ovarian cancer, with a lifetime risk for breast cancer of 56% to 84%. This meta-analysis provides strong data about risk reduction estimates, which provide surgeons and patients with better information about risk-reducing salpingo-oophorectomy (RRSO). Discovering that RRSO is associated with a large reduction in *BRCA* mutation–related breast cancer risk, especially among women who are premenopausal at RRSO, makes this surgery much more acceptable to high-risk women.

Adapted from Greene MH, Mai PL: What have we learned from risk-reducing salpingo-oophorectomy? *J Natl Cancer Inst* 101(2):70-71, 2009; Rebbeck TR et al: Meta-analysis of risk reduction estimates associated with risk reducing salpingo-oophorectomy in *BRCA1* or *BRCA2* mutation carriers, *J Natl Cancer Inst* 101(2):80-87, 2008.

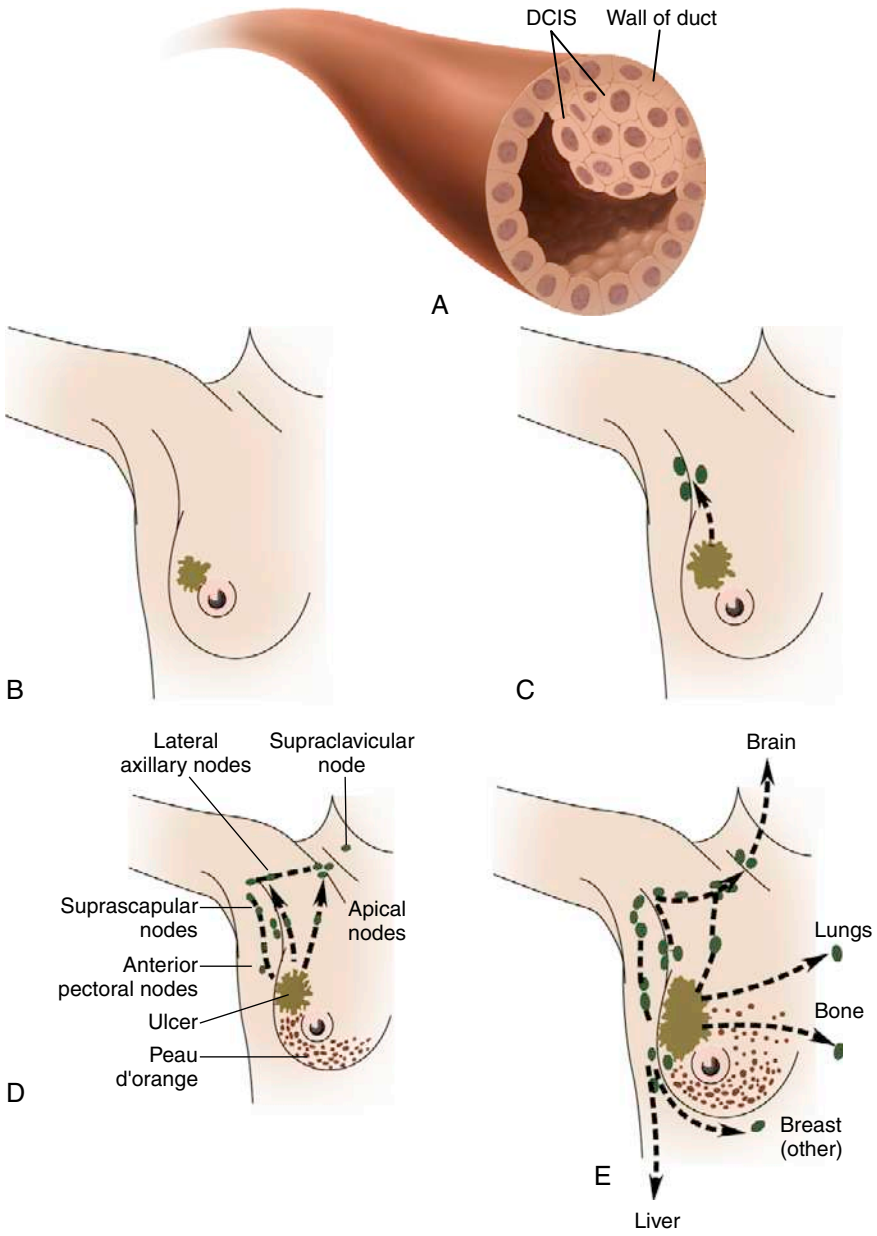

FIGURE 16-7 Staging of breast cancer. **A,** *Stage 0* is carcinoma in situ. Lobular carcinoma in situ (LCIS) is defined as abnormal cells that are in the lining of a lobule. LCIS seldom becomes invasive cancer. However, having LCIS in one breast increases the risk of cancer for both breasts. Ductal carcinoma in situ (DCIS) is defined as abnormal cells that are in the lining of a duct. DCIS is also called intraductal carcinoma. The abnormal cells have not spread outside the duct. They have not invaded the nearby breast tissue. DCIS sometimes becomes invasive cancer if not treated. **B,** *Stage I:* tumor <2 cm with no axillary lymph node involvement. **C,** *Stage IIa:* cancer cells found in axillary lymph nodes, or tumor ≤2 cm with metastasis to axillary lymph nodes, or tumor >2 cm but not >5 cm with no metastasis to axillary lymph nodes. *Stage IIb:* tumor >2 cm but not >5 cm with positive axillary lymph node involvement, or tumor >5 cm with negative axillary lymph node involvement. **D,** *Stage IIIa:* tumor ≤5 cm with metastasis to axillary lymph nodes that are attached to each other or to other structures, or has spread to lymph nodes behind breast bone; or tumor >5 cm and has spread to axillary lymph nodes that are alone or attached to each other or to other structures, or has spread to lymph nodes behind the breast bone. *Stage IIIb:* tumor of any size that has grown into the chest wall or skin of the breast, causing swelling of the breast or nodules in breast skin; may have spread to axillary lymph nodes that are attached to each other and to other structures and may have spread to lymph nodes behind the breast bone. Inflammatory breast cancer: breast is red, swollen (at least stage IIIb). *Stage IIIc:* tumor of any size that has spread either to the lymph nodes behind the breastbone and axillary lymph nodes or to the lymph nodes above or below the collarbone. **E,** *Stage lV:* distant metastatic cancer.

AMBULATORY SURGERY CONSIDERATIONS

Port Insertion

A breast cancer patient who needs further medical treatment may opt to have an implanted venous access port placed under the skin in either the chest, abdomen, or upper arm. This access port is used for repeated infusions of chemotherapeutic agents, solutions, other drugs, pain management medication, or blood products as well as for procurement of blood samples. Consequently, the patient's veins do not need to be repeatedly accessed. Port insertion is commonly done in an ambulatory surgery setting by a surgeon or in an interventional radiology department by a radiologist. The port has a soft, pliable plastic catheter that is threaded into the subclavian vein or right atrium by way of the subclavian or internal jugular vein under x-ray guidance. The catheter is then attached to a metal base with a rubber dome, which is placed under the skin by the interventionist. Preoperatively, the patient is instructed to refrain from consuming solid foods or full liquids for at least 6 hours before the procedure. Clear liquids may be ingested 2 hours before the procedure. Regular medications may be taken the morning of the insertion unless instructed otherwise. No aspirin, aspirin products, or antiinflammatory medications may be taken for 1 week before port insertion. Drug allergies are noted. The Universal Protocol is observed. After the procedure, the patient will be observed for approximately 1 hour before discharge. Discharge instructions are as follows:

- Give both the patient and the caregiver verbal and written instructions and the telephone numbers of the physician and nurse so that questions or concerns can be addressed.
- Review the purpose of the port insertion and discuss how long it will stay in place.
- Discuss protecting the skin over the port and keeping the incision clean and dry.
- If fever, chills, swelling, redness, bleeding, discharge, shortness of breath, or chest pain develops, seek prompt medical attention.
- No blood pressure measurement or blood draws are to be done from the arm containing an arm port.
- The port needs to be flushed monthly to keep it patent. Demonstrate this technique and have the patient repeat critical steps for port flushing.
- Explain that removal of the port will be an outpatient procedure when it is no longer needed medically.

Adapted from Canobbio MM: *Mosby's handbook of patient teaching,* ed 3, St Louis, 2009, Mosby; Department of Radiology, Abington Memorial Hospital Interventional Radiology: *Patient information—implanted venous access device,* available at www.abingtonir.com/images/uploaded/Abington/venousaccess_Info.pdf. Accessed May 12, 2009.

This positive binding capability identifies the patient with a hormone-dependent tumor (Figure 16-8). It is estimated that about two thirds of all breast cancers are positive for estrogen binding, and a majority of these tumors are also positive for progesterone binding. The presence of these receptor sites is conducive to hormone manipulation, with the goal of preventing breast cancer cells from receiving stimulation from estrogen. The use of anti-estrogen tamoxifen, in addition to surgery and chemotherapy, increases disease-free survival in premenopausal women with positive binding for estrogen.

Another therapy can be offered by aromatase inhibitors (AIs). These may be nonsteroidal, such as anastrozole and letrozole. Aromatase inhibitors are only effective in postmenopausal women. They appear to work better than tamoxifen on certain breast cancers, with fewer side effects. A large study found that anastrozole may prevent 70% to 80% of the most common breast cancer tumors that occur in postmenopausal women; this was compared with 50% for tamoxifen (Hulvat et al, 2009). A new class of parenteral hormone therapy, estrogen receptor (ER) down-regulators (e.g., fulvestrant [Faslodex]), is available for the treatment of metastatic breast cancer (Hormonal Therapy Changes, 2007).

Some of the most promising data reported in recent years for advanced breast cancer have involved HER-2 (human epidermal growth factor receptor 2), a cellular proto-oncogene coding for a transmembrane receptor. Agents such as trastuzumab (Herceptin) to target HER-2 were first approved for treatment of metastatic HER-2–positive breast cancer in 1998 (Surgical Pharmacology). Research and understanding of the immune system, the development of methods to evaluate aspects of the immune response, and ongoing development of monoclonal antibodies are transforming the field of immunotherapy and breast cancer treatment.

A new drug class in experimental targeted therapy medicine called poly (ADP-ribose) polymerase enzyme (PARP) inhibitors

SURGICAL PHARMACOLOGY

Herceptin

Trastuzumab (Herceptin) is a recombinant humanized immunoglobulin B (IgB) monoclonal antibody that targets the extracellular domain of HER-2. Trastuzumab interferes with the many steps in the tumor cell cycle and sensitizes HER-2–positive cancers to other cytotoxic therapies. HER-2–positive patients usually have more aggressive disease. Data from trials sponsored by the National Cancer Institute, which were terminated prematurely because of the superiority in the groups treated with trastuzumab, reported a 52% reduction in the risk of recurrence and a 33% reduction in the risk of death in the trastuzumab group compared with patients who received standard regimens. A major limitation to the use of trastuzumab in all studies is cardiotoxicity, especially when given concurrently with Adriamycin. Cardiotoxicity lowers considerably when given after Adriamycin therapy. Resistance to trastuzumab eventually occurs in most metastatic breast cancer patients who initially respond to the treatment. Additional research is being conducted on other members of the epidermal growth factor family. One agent is lapatinib, which targets epidermal growth factor and HER-2. Lapatinib in combination with trastuzumab in vitro shows a synergistic effect. Lapatinib also inhibits growth of HER-2–overexpressing breast cancer cells when long-term trastuzumab therapy becomes resistant. Observed side effects are tachycardia, congestive heart failure, nausea, vomiting, diarrhea, anemia, leukopenia, edema, arthralgia, bone pain, rash, acne, herpes simplex virus, anaphylaxis, and flulike symptoms of fever, headache, and chills. It is contraindicated in patients hypersensitive to Chinese hamster ovary cell protein. Teach patients to take acetaminophen for fever, avoid hazardous tasks, report signs of infection, and notify the physician if emotionally labile.

Modified from Hulvat MC: Multidisciplinary care for patients with breast cancer, *Surg Clin North Am* 87:133-164, 2007; Skidmore-Roth: *Mosby's nursing drug reference,* St Louis, 2010, Mosby.

is being studied for triple-negative breast cancer patients (O'Shaugnessy et al, 2009). The biopsy of patients with triple-negative breast cancer (TNBC) is estrogen and progesterone hormone receptor negative and HER-2/neu negative (Kassam et al, 2009). TNBC is found in younger women, women of African American or Hispanic descent, and women with lower socioeconomic status (Winkeljohn, 2008).

Breast cancer patients are increasingly seeking and using complementary and alternative medicine (CAM) and integrative therapies to enhance their surgical and medical treatment (Table 16-5). (See Chapter 29 for a full discussion of integrative therapies.) Besides using products such as green tea, vitamins E and C, and flaxseed, breast cancer patients are incorporating massage therapy and meditation and enlisting the help of dietitians and nutritionists (Boon et al., 2007) as they battle breast cancer.

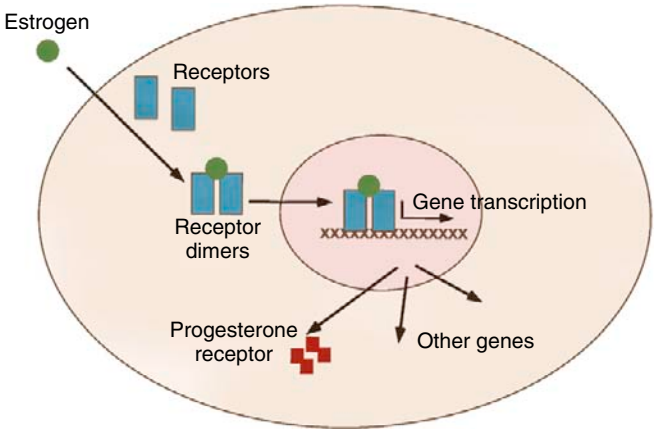

FIGURE 16-8 Physiology of estrogen and the estrogen receptor, shown schematically. Estrogen binds to estrogen receptors, translocates to the nucleus of the cell, and interacts with cellular deoxyribonucleic acid (DNA). This interaction results in the transcription of estrogen-responsive genes, such as the receptor for progesterone. In addition, other genes are induced by the estrogen receptors that influence cell growth and differentiation.

TABLE 16-5

Complementary and Integrative Therapies for Breast Cancer Patients

Symptom	Complementary and Integrative Therapies
PHYSICAL	
Pain	Acupuncture, chiropractic therapy, hypnosis, massage, music, reiki, shiatsu
Nausea/vomiting	Acupuncture, aromatherapy, ginger, hypnosis, progressive muscle relaxation, shiatsu
Fatigue	Acupuncture, massage, meditation, reiki, tai chi, yoga
Hot flashes	Acupuncture, black cohosh, flaxseed
Muscle tension	Aromatherapy, massage, shiatsu
EMOTIONAL	
Anxiety/stress/fear	Aromatherapy, guided imagery, hypnosis, journaling, massage, meditation, music therapy, progressive muscle relaxation, prayer, support groups, tai chi, yoga
Depression	Aromatherapy, yoga, journaling, progressive muscle relaxation

Perioperative Nursing Considerations

Assessment

A patient undergoing breast surgery will likely be extremely apprehensive about the possibilities of having a malignancy, losing a body part, facing a negative reaction from her spouse and family, and experiencing a negative change in self-image. During a preoperative interview the perioperative nurse should assess the patient's level of anxiety and possible causes, such as the possibility of a cancer diagnosis. Identification of the patient's fears and concerns helps in planning appropriate nursing interventions. The patient should identify the breast (and, if possible, the quadrant of the breast) where the mass is located and participate in surgical site marking. The perioperative nurse should also assess the patient's understanding of the proposed surgical procedure. Reinforcement of knowledge or correction of misunderstandings is possible only if the patient's current level of knowledge is discerned. Identifying the patient's psychologic support system will help to manage anxiety during the patient's stay and enhance the discharge planning process. If the patient has lost a relative or close friend to breast cancer, her coping mechanisms may be affected because of memories of that loss.

Nursing Diagnosis

Based on the nursing assessment, the perioperative nurse uses nursing diagnoses to develop a plan of care. Nursing diagnoses related to the care of patients undergoing breast surgery might include the following:

- Anxiety related to fear of cancer, the surgical intervention, or biopsy results
- Disturbed Body Image related to loss of body part
- Risk for Injury related to use of electrosurgery
- Deficient Knowledge related to unfamiliarity with perioperative routines

Outcome Identification

Outcomes are derived from the nursing diagnoses. They direct the perioperative nurse in selecting nursing interventions that will prevent, or intervene in, the actual or high-risk areas identified in the nursing diagnoses. Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient will verbalize a level of anxiety that is personally acceptable.
- The patient will discuss feelings regarding body image changes resulting from the surgical procedure.
- The patient will experience no untoward injury from electrosurgery.
- The patient will verbalize an understanding of perioperative procedures.

Planning

Using nursing diagnoses and desired outcomes, the perioperative nurse can individualize a plan of care for each patient and allow for communication with other colleagues on the patient care team. The plan of care for a patient undergoing

breast surgery can include nursing interventions that allow the patient freedom to express concerns, have specific questions answered, and discuss breast reconstruction options, as appropriate. The Sample Plan of Care below shows such an example. As part of planning patient care, priorities are established and a method of ensuring continuity of care ensured.

Implementation

Before surgery, the perioperative nurse should procure the necessary medical and surgical supplies, instruments, and equipment for the planned operation. The patient's operative site should be marked by the surgeon outside of the OR room before any medications are given. Mammogram films or other imaging studies should be available in the OR for the surgeon's review; their presence may be confirmed during the preop briefing and/or time-out. The facility protocol for identifying the correct surgical site should be followed. Often this consists of a checklist that is initiated during the time-out and includes verbal communication among surgical team members, review of the medical record and the informed consent, confirmation of imaging studies, and direct observation of the marked surgical site. IV antibiotics, started within 1 hour before the incision is made, may be administered (Evidence for Practice). For breast surgery, the site and side must be verbally verified with each member of the surgical team during the time-out. A breast biopsy, performed after the patient has received a local anesthetic, will require adjunct sedation and monitoring equipment (e.g., electrocardiogram [ECG], pulse oximeter, blood pressure apparatus). Patient allergies should be reviewed to avoid allergic or toxic reactions to local anesthetics. For a mastectomy, extra sponges and instrumentation are often needed. An electrosurgical unit (ESU) or a surgical laser is used to provide both hemostasis and tissue dissection. Safe practices when using devices that generate surgical smoke require the use of a smoke evacuation system and accessories in both open and laparoscopic

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Anxiety related to fear of cancer, the surgical intervention, or obtaining biopsy results

OUTCOME
The patient will verbalize a level of anxiety that is personally acceptable.

INTERVENTIONS
- Encourage questions and allow time for verbalization of fear, distress, and anxiety. Use active listening and reflective questions.
- Review the surgeon's explanation of the planned procedure and the reason for it (as appropriate).
- Assess verbal and nonverbal signs of anxiety.
- Provide emotional support and comfort measures (warm blankets, touch as appropriate).
- Maintain quiet, calm environment.
- Demonstrate warmth and acceptance of the patient's anxiety.
- Determine the patient's personally effective coping techniques (or recommend some), such as relaxation, rhythmic breathing, or guided imagery. Support the patient in using these.
- Record patient's reactions.

NURSING DIAGNOSIS
Disturbed Body Image related to loss of body part

OUTCOME
The patient will discuss feelings regarding body image changes resulting from the surgical procedure.

INTERVENTIONS
- Allow patient to discuss concerns about her sexual attractiveness, loss of confidence, and perceived loss of femininity.
- Promote an environment of support, respect, and comfort.
- Discuss available resources and options (external prosthesis, alternatives in garments and dress, reconstructive surgery, as appropriate). Make referrals to nurse on discharge unit or community agency as indicated.
- Maintain patient's privacy.
- Encourage a visit by a *Reach to Recovery* volunteer (as applicable).

NURSING DIAGNOSIS
Risk for Injury related to use of electrosurgery

OUTCOME
The patient will experience no untoward injury from electrosurgery.

INTERVENTIONS
- Position dispersive pad as close to operative site as possible.
- Note any metal implants the patient may have and do not use the dispersive pad over these sites.
- Select a site that is clean and dry, with good muscle mass; note and document the condition of the skin at the selected site.
- Protect pad from fluids and contact with metal objects.
- Ensure that all prep solutions have dried before activating the unit.
- Activate electrosurgical unit after dispersive pad and active electrode are connected.
- Set power setting as low as possible to achieve desired effect. Document power settings used.
- Use holster for active electrode on the sterile field.
- Provide supplies to remove excess char buildup from active electrode (as applicable).
- Check dispersive pad contact and all connections after changes in position or requests to increase power.
- Evaluate and document the condition of the skin on removal of the dispersive pad.

NURSING DIAGNOSIS
Deficient Knowledge related to unfamiliarity with perioperative routines

OUTCOME
The patient will verbalize understanding of perioperative procedures.

INTERVENTIONS
- Assess the patient's experience with previous surgical procedures.
- Review the need for correct site surgery verification protocols.
- Explain that the skin will be cleansed with antiseptic solution at the surgical site and that solution may feel cold.
- Provide clear and concise explanations of all nursing interventions.
- Explain roles of the healthcare team members.
- Encourage questions.
- Describe the types of dressings and equipment that may be used postoperatively. If lymph node dissection is performed, describe the presence of incisional closed wound drainage systems.

procedures (AORN, 2009). (See Chapter 7 for a full discussion of the ESU and surgical smoke evacuation.) The incision site may be drained postoperatively with a closed wound suction device. Ensuring the availability of supplies before the procedure allows the nurse to maintain a comforting presence while supporting, monitoring, and observing the patient.

During the intraoperative phase, the patient is placed supine on the OR bed with the operative side near the edge of the bed. The arm on the involved side, with the palms up and fingers extended, is carefully placed on a padded armboard at no greater than 90 degrees to prevent brachial plexus stretch. If there are surgical reasons to tuck the arms at the side, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained in a neutral position (Denholm, 2009). Depending on the location of the lesion and the planned surgery, a small pad can be placed under the operative side to facilitate exposure of the incision area. Positioning the OR bed in slight Fowler's position with a lateral tilt away from the surgeon can also facilitate exposure.

Skin preparation depends on the location of the lesion and the surgery intended. Skin prep solutions vary, depending on the surgeon's preference. For a breast biopsy, the area prepped is usually the affected breast and the immediate surrounding skin. For a mastectomy, the area prepped can extend from above the clavicle to the umbilicus and from the opposite nipple to the bed line of the operative side, including the axilla, and possibly the upper arm on the operative side. Some surgeons caution against vigorous scrubbing of the surgical site to prevent possible seeding of cancer cells from the main mass. The surgeon may request that only an antiseptic solution be applied to the breast. Appropriate precautions to prevent pooling of solution under the patient and to reduce the risk of surgical fire are taken during skin prep procedures.

Surgical draping exposes the affected breast and the preoperative site mark. For mastectomy, the arm on the operative side is draped free, using a stockinette and drapes that allow free movement of the arm to facilitate access to the axilla. If a breast biopsy is to be immediately followed by a modified radical mastectomy, the surgeon may prefer to repeat the skin prep and surgical draping before proceeding with the definitive surgery.

During implementation of the plan of care, the perioperative nurse continues to collect data, continuously reassesses the patient's needs and the needs of the surgical team, initiates nursing interventions, and documents all care delivered. Formats for documenting perioperative patient care vary from institution to institution. However, documentation of patient problems and nursing interventions addressing these problems is essential. For the patient undergoing breast surgery, consideration should be given to documenting the patient's level of anxiety, the surgical position and accessory positioning devices used, the time-out, the location of the ESU dispersive pad, unit settings and identification number, results of perioperative monitoring, medications administered by the perioperative nurse or from the sterile field, specimens collected, and any closed wound drainage systems inserted into the surgical wound.

Evaluation

Evaluation of the patient before discharge from the OR includes both general observation parameters important for every surgical patient and specific evaluation of the goals of the plan of care. The patient's skin at dependent pressure sites, skin prep sites, and the dispersive pad placement site is assessed and any change in skin integrity documented. The hand-off report to the nurse in the postanesthesia care unit (PACU) includes any unusual events or patient problems during surgery, the incorporation of any closed wound drainage systems in the wound, and achievement of identified patient outcomes. These outcomes, based on the nursing diagnoses selected, should be part of documentation

EVIDENCE FOR PRACTICE

Preventing Surgical Site Infection

Surgical site infections (SSIs) are classified as superficial, which involves only skin or subcutaneous tissue of the incision; deep incisional, which involves fascia and/or muscular layers; and infection of organ and/or space. Approximately 500,000 SSIs occur each year. SSIs are believed to account for up to $10 billion annually in healthcare expenditures. Infection rates for breast surgery are more common than previously believed. In a study by Olsen and colleagues (2008), 5.3% of patients developed infections within 1 year of surgery; the rate increased to 7% for women who had mastectomy followed by breast reconstruction with an implant.

The Centers for Medicare & Medicaid Services created the Surgical Infection Prevention Collaborative (SIPC) in 2002 and their expert panel identified the following three performance measures for quality improvement related to antimicrobial prophylaxis:

- Deliver intravenous antimicrobial prophylaxis within 1 hour before incision (2 hours for vancomycin and fluoroquinolones).
- Use an antimicrobial prophylactic agent consistent with published guidelines.
- Discontinue use of the antimicrobial prophylactic agent within 24 hours after surgery (48 hours for cardiothoracic surgery patients).

Many hospitals that followed SIPC performance measures decreased their SSI rates. An extension of SIPC is the Surgical Care Improvement Project (SCIP), a multiagency collaboration started in 2003. SCIP focused on the three SIPC medication improvements and the following:

- Discontinuation of hair removal from the surgical site (if imperative, however, remove hair with clippers)
- Control of blood glucose levels during postoperative period for cardiac surgical patients
- Maintenance of perioperative normothermia

The Institute for Healthcare Improvement recommends the previously listed six measures (i.e., three SIPC and three SCIP measures) and has included them in the *100,000 and 5 Million Lives* campaign. Other measures to reduce SSIs include, but are not limited to, reduction of patient risk factors; optimal cleaning and disinfection of equipment and environment; preparation and disinfection of operative site; adherence by surgical team members to meticulous hand hygiene; traffic control in the individual OR; timely removal of wound drains; and education of surgeons, perioperative personnel, patients, and families about SSI prevention.

Modified from Anderson DI et al: Strategies to prevent surgical site infections in acute care hospitals, *Infect Control Hosp Epidemiol* 29:S51-S61, 2008; Olsen MA et al: Hospital-associated costs due to surgical site infection after breast surgery, *Arch Surg* 143(1):53-60, 2008; Patterson P: Surgical Care Improvement Project: 4 years later, what's the status? *OR Manager* 25(8):1, 7-9, 2009; McCahill LE et al: Enhancing compliance with Medicare guidelines for surgical infection prevention: experience with a cross-disciplinary quality improvement team, *Arch Surg* 142(4):355-361, 2007.

as well as the nursing report. Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient verbalized an acceptable level of anxiety; she communicated her specific anxieties, her facial expression and body structures were relaxed, and her vital signs remained within her normal range.
- The patient discussed feelings regarding possible body image changes resulting from the surgical procedure; her preferred coping strategies were reviewed and supported during the procedure.
- The patient experienced no untoward injury from electrosurgery; there were no skin changes at the site of the dispersive pad.
- The patient verbalized an understanding of perioperative procedures; she cooperated with requests and was provided with ongoing explanations.

Patient and Family Education and Discharge Planning

Discharge planning should begin as soon as the patient is informed of the necessity for surgery or when the nurse first meets the patient. According to the extent of the anticipated surgery, information about appropriate exercises to enhance recovery, prosthetic devices, reconstruction options, and available community support groups should be explained to the patient. The perioperative nurse provides or reinforces information based on the patient's desire for information, readiness to learn, and anxiety level.

The patient is often discharged within hours of or the day after surgery. The patient and other caregivers need to be instructed regarding aseptic wound care, care for the closed wound drainage system (if present), and pain management. Possible signs of complications should be included, along with instructions regarding when and how to notify the physician. Postoperative exercises need to be taught to the patient to facilitate her return to normal activities. Nursing home care may be necessary and should be coordinated with the physician and the patient. A follow-up telephone call to the patient can help the nurse assess the patient's ability to cope with her diagnosis and surgery. The Patient and Family Education box provides sample discharge information for the patient undergoing breast surgery.

Late and long-term effects of breast cancer treatments should be reviewed with the patient. Fatigue, insomnia, loss of appetite, fear of recurrence, anxiety, depression, and "chemobrain" (Research Highlight, p. 601) are common symptoms seen in cancer survivors. These signs and symptoms should be reported to the physician and nurse so intervention can be initiated (Barclay, 2009).

PATIENT AND FAMILY EDUCATION

Discharge Instructions and Home Care for Breast Surgery Patients

Give both the patient and the caregiver *verbal* and *written* instructions. Provide them with the name and telephone number of a physician or nurse to call if questions arise. Use visual aids to assist in instruction.

GENERAL INFORMATION

- Review explanation of the disease, the surgical procedure performed, and adjuvant therapy to be carried out.
- Explain that if the axillary nodes were removed, the affected arm may swell and is less able to fight infection. Discuss measures to prevent lymphedema (see Risk Reduction Strategies, p. 602):
  - Exercise arm daily (provide specific exercises).
  - Report loss of shoulder or joint mobility.
  - When healing is complete, begin strengthening and stretching exercises.

Wound/Incision Care (Select Applicable Education Based on Surgical Procedure Performed)

- Encourage the patient to look at her incisions so she can see what is normal. Teach her how to care for the skin at the site of surgery:
  - Advise the patient that there may be a dry gauze dressing over the incision site and the drain site.
  - Provide information regarding dressing changes, amount of fluid leakage at closed wound drainage system site that is normal, when to change soiled drain-site dressing (including emptying and measuring drain reservoir) and what to report to a physician or nurse.
  - Discuss numbness in the area of surgery and typical sensations (heaviness, tingling, "pins and needles"). These are likely to resolve by 1 year after surgery.
- For modified radical mastectomy:
  - Teach the patient to change the dressing, assess the appearance of the incision and closed wound drainage system site, milk or strip clots through the drainage tubing to maintain patency, empty the drainage container, and record the amount and character of drainage.
  - Caution the patient not to abduct the affected arm or elbow above the shoulder until closed wound drainage systems are removed.
  - Instruct the patient to report any redness or drainage around the closed wound drainage system.
  - Instruct the patient to avoid use of deodorants or antiperspirants until stitches and drains have been removed from the axilla and the wound has healed. If no closed wound drainage system is present, the patient may shower.
  - Caution the patient not to allow injections, placing of intravenous lines, drawing of blood, or taking of blood pressure in the affected arm if axillary dissection was done.
  - Instruct the patient to avoid wearing constricting clothing or jewelry on the affected arm and to carry her handbag on the unaffected arm if axillary dissection was done.
  - Discuss the types of temporary and permanent prostheses available; assist with referral as needed.
  - Advise the patient not to use an external prosthesis or bra pad until swelling has subsided and healing of the incision is complete. Tell her to check with a physician or nurse before getting fitted for a breast prosthesis. This usually occurs about 6 weeks after surgery as long as wounds are healing and any postoperative edema has resolved.
  - Discuss the types of reconstruction available.
  - Stress the importance of continuing breast self-examination and mammography of the unaffected breast.

PATIENT AND FAMILY EDUCATION—cont'd

Discharge Instructions and Home Care for Breast Surgery Patients

Warning Signs

- Review the signs and symptoms that should be reported to a physician or nurse:
  - Swelling of arm
  - Drainage from incision, excessive drainage or blood in drainage unit, difficulty keeping container flat
  - Infection: redness, purulent drainage, pain, incision warm to touch

Medications

- Explain the purpose, dosage, schedule, and route of administration of any prescribed medications, as well as side effects to report to a physician or nurse. If the patient is taking an opioid analgesic, initiate a bowel protocol (including a laxative and stool softener) to prevent constipation.
- Discuss alternative methods of postoperative pain management: visualization, guided imagery, meditation, relaxation, biofeedback, music, other personally effective techniques.

Activity

- Encourage discussion of allowances and limitations with respect to occupation, recreational sports, or activities.
- Encourage resumption of self-care activities (feeding, combing hair) and activities of daily living as tolerated.
- Explain that sexual activity may be resumed when desired. The partner should use a position that does not place pressure on the chest wall.
- Discuss the need to continue post-mastectomy exercises to regain full range of motion (as applicable).

FOLLOW-UP CARE

- Stress the importance of regular follow-up visits. Make sure the patient has the necessary names and telephone numbers.
- Prepare the patient for adjuvant therapies: hormone therapy, chemotherapy, and radiation therapy.

PSYCHOSOCIAL CARE

- Encourage verbalization about feelings and fears regarding diagnosis, adjunctive therapy, actual and perceived changes in body image and sexuality.
- Encourage patient and family to seek individual or group counseling to reduce emotional stress and help with effective coping.

REFERRALS

- Provide referrals for home health services and social services as indicated.
- Assist the patient to obtain referral services to breast cancer survivorship programs (see Research Highlight, p.602) and contact support groups, such as the American Cancer Society's *Reach to Recovery* program, to cope with alterations in body image and other concerns.

Modified from Canobbio MM: *Mosby's handbook of patient teaching,* ed 3, St Louis, 2006, Mosby; Weaver C: Caring for a patient after mastectomy, *Nursing 2009* 39(5):44-48, 2009.

RESEARCH HIGHLIGHT

Understanding "Chemobrain"

Chemobrain refers to a wide range of problems experienced by breast cancer survivors who have received treatment with chemotherapeutic agents. These changes usually first become apparent during chemotherapy (hence the name). Some literature reports that 75% of women with breast cancer experience chemobrain after therapy. These symptoms include short-term memory loss, difficulty concentrating and staying focused, reduced verbal and visual memory, difficulty managing daily activities and multitasking, fatigue, disorganization, and confusion. Some cancer-related causes could include chemotherapy, hormonal treatment, radiation therapy, and surgery; complications of cancer treatment; and emotional reactions to cancer diagnosis, treatment, and medications. The severity and duration of the symptoms differ with the individual. A recent study used magnetic resonance imaging to compare regional brain-volume differences between breast cancer survivors exposed to adjuvant chemotherapy and unexposed controls. It showed that there were physical changes in the brains of breast cancer survivors; parts of their brains were smaller. Also, in a study using positron emission tomography (PET) imaging, breast cancer survivors who had received chemotherapy in the previous 5 to 10 years used more of their brains to perform a short-term memory task than control subjects who never received chemotherapy, a sign that their brains had to work harder to complete tasks. Treatments for chemobrain are in the early stages. Some evidence suggests that central nervous system medications may ease adverse cognitive effects.

Modified from Hafner DL: Lost in the fog: understanding "chemo brain," *Nursing 2009* 39(8):42-45, 2009; Mayo Clinic Staff: *Chemobrain,* Mayo Clinic, 2009, available at www.mayoclinic.com/health/chemobrain/ncbi-n:DS01109. Accessed April 27, 2009; National Cancer Institute: Delving into possible mechanisms for chemobrain, *NCI Cancer Bull* 6(6), March 24, 2009.

RISK REDUCTION STRATEGIES

Decreasing Lymphedema Associated with Breast Surgery

Lymphedema after breast surgery is caused by a disruption of the axillary bed by excision of lymph nodes and/or radiation therapy to the area. Patients are at a lifetime risk of edema in the upper extremity and/or in the ipsilateral upper quadrant and breast tissue. Risk factors that affect the occurrence of lymphedema include axillary node dissection, radiation therapy, tumor in the upper outer quadrant of the breast, stage of cancer at diagnosis, age, obesity, hypertension, chemotherapy, and radiation treatment. Risk reduction starts at the preoperative evaluation with education. Baseline girth and volume measurements of both upper extremities are taken and recorded. Note any factors that put the patient at increased risk for development of lymphedema. Educate the patient about arm and hand precautions. Risk reduction practices also include providing good skin care to prevent infection, preventing injury and muscle strain, avoiding limb constriction, promoting lymph drainage with elevation, using compression garments, avoiding extreme temperatures, and performing regular, light aerobic exercise. If lymphedema is diagnosed, intervention is necessary. Various approaches, including surgery, pharmacotherapy, low-level laser therapy, and complete decongestive treatment (CDT), can decrease and maintain the size of the limb. CDT is a two-phase program that consists of a treatment phase and a maintenance phase. The International Society of Lymphology considers CDT the standard of care for lymphedema. Once a diagnosis of lymphedema is made, the patient must be monitored over the course of her life. Fu's research supports provision of information about lymphedema to improve practice of risk reduction behaviors with breast cancer survivors. Compliance with the maintenance phase is related to better outcomes.

Modified from Fu MR, Ridner SH, Armer J: Post-breast cancer lymphedema, *Am J Nurs* 109(8):34-41, 2009; Johnstone PAS, Mondry TE: *Prevention and treatment of lymphedema related to breast cancer, 2007,* available at www.medscape.com/viewartcle/566471. Accessed April 14, 2008; Mulcahy N: *Recognizing lymphedema is vital in assisting oncology patients, 2009,* available at www.medscape.com/viewarticle /587127. Accessed April 15, 2009.

RESEARCH HIGHLIGHT

Cross-Cultural Relevance of Breast Cancer Survivorship Programs

Breast cancer survivorship programs to assist women in dealing with the multiple concerns they have after breast cancer treatment are important. However, few of these programs have been evaluated for cultural relevance with diverse groups. One such program, Taking CHARGE, is a theory-based self-management program developed to assist women with survivorship concerns that arise after breast cancer treatment. This research appraised both the utility and the cultural relevance of the program for African American (AA) breast cancer survivors, during which they assessed Taking CHARGE program content, format, materials, and the self-regulation process. Content analysis of audiotapes was conducted using an open, focused coding process to identify emergent themes regarding program relevance as well as topics requiring enhancement and/or further emphasis. Although findings indicated that the program's content was relevant to participants' experiences, AA women identified need for cultural enhancements in spirituality, self-preservation, and positive valuations of body image. Content areas requiring more emphasis included persistent fatigue, competing demands, disclosure, anticipatory guidance, and age-specific concerns about body image/sexuality. Suggested improvements to program materials included portable observation logs, additional resources, photographs of AA women, vivid colors, and images depicting strength. These findings can be used for program enhancements to increase the utility and cultural relevance of Taking CHARGE for AA survivors and underscore the importance of evaluating other interventions for racially/ethnically diverse groups.

Adapted from Chung LK et al: Breast cancer survivorship program: testing for cross-cultural relevance, *Cancer Nurs* 32(3):236-245, 2009.

Surgical Interventions

BIOPSY OF BREAST TISSUE

Biopsy removes suspicious breast tissue for pathologic examination. In a *core needle biopsy (CNB),* a disposable, cutting-type needle is introduced and advanced into the breast mass to entrap a core or plug of tissue. The needle is withdrawn, and the tissue specimen sent to a pathologist for diagnostic examination. CNB may also be performed with a vacuum-assisted core biopsy (VACB) device (Breast Health, 2006). In an *incisional biopsy,* a portion of the mass is surgically excised using a curved incision line. The tissue is sent for pathologic examination (Mulholland et al, 2006). In an *excisional biopsy,* the entire tumor mass is excised along with a small margin of normal tissue from adjacent tissue for examination as with incisional biopsy (Cornforth, 2009).

Procedural Considerations

Biopsy is usually performed after the patient has been administered a local anesthetic, a local anesthetic with IV moderate sedation/analgesia, a laryngeal mask airway (LMA), or a general anesthetic with intubation. The short delay between biopsy and further treatment has not been shown to adversely affect survival. However, when an extensive surgical procedure is anticipated in conjunction with the biopsy or when multiple lesions are to be excised and the amount of local anesthetic would exceed the maximum safe dose, general anesthesia is induced. In the instance of anticipated extensive surgery based on pathologic results, the patient must have preoperatively given informed consent to proceed with the more definitive surgery. A new surgical setup will be used. A minor instrument set is used for biopsy; the ESU is often requested. Perioperative staff should be sensitive to the fact that the patient may be alert during the procedure and use caution with oral pathology reports called over a speaker phone. Pathology reports, especially if the report confirms malignancy, should be discussed when the patient is fully awake and has a support system available.

Operative Procedure—Open Breast Biopsy

1. An incision in the direction of the skin lines (curvilinear) or along the border of the areola is made over the tumor mass. The circumareolar incision gives the best cosmetic result. If the lesion is located in an extremely lateral or medial site, a radial incision may be used.

2. Gentle traction is applied to the mass with holding forceps. If the lesion is small, the entire mass and an edge of normal tissue are removed by sharp dissection. If a large lesion is present, a small incisional biopsy of the main mass is done. The specimen should not be placed into a formalin solution if a frozen section is to be done at the time of surgery; instead, it is sent fresh, as exposure to formalin prevents frozen-section examination. The specimen may be marked with a sterile marker as to its orientation in the breast and/or may be placed on a sterile towel that is marked with a sterile marker to orient the specimen. This assists the surgeon in reexcision if the pathologist finds positive margins on the specimen. The tissue is examined by frozen section to determine immediate diagnosis while the patient is still anesthetized. If a 48-hour permanent section is required for definitive diagnosis, the patient is scheduled at a later time for any further surgery that may be necessary.
3. If the lesion is benign, hemostasis is checked and the subcutaneous breast tissue of the wound is approximated with absorbable suture. The skin is closed with fine sutures or skin staples, and a firm pressure dressing is applied.
4. If the lesion is malignant, the incision is tightly closed with a continuous locking suture on a cutting needle.
5. If a more extensive operation is required, it may be performed immediately. Team members regown and reglove to avoid transfer of cancerous cells to healthy tissue. The operative site is again prepped and draped. A separate sterile setup and set of instruments for a more radical procedure are then used.

Operative Procedure—Open Breast Biopsy with Needle (Wire) Localization

A radiologist performs wire placement before the patient's arrival in the OR. Care is taken during transfer to the OR bed and gown removal not to dislodge or bump the wire. Similar care is taken during positioning, prepping, and draping.

1. The skin incision is placed precisely over the expected location of the mammographically determined lesion to minimize tunneling through the breast tissue.
2. Dissection is carried out using the wire as a guide.
3. Tissue around the wire is removed en bloc with the wire and sent for specimen mammography in the radiology department.
4. The patient is kept on the OR bed with the sterile field maintained until confirmation that the lesion has been excised. It is then sent from radiology to the pathology department.

INCISION AND DRAINAGE FOR ABSCESS

Incision of an inflamed and suppurative area of the breast is performed to drain an abscess. Breast abscesses occur most frequently during the first 4 weeks of breastfeeding. Staphylococcal or streptococcal organisms enter the breast through abraded or lacerated nipple surfaces or through the lactiferous ducts. Chronic abscesses are rare. Drainage is required when the breast abscess around the nipple or in breast tissue is apparent. Biopsies may be done for additional diagnosis.

Procedural Considerations

Breast abscess is very painful and may require surgery with the patient administered a general anesthetic. Instruments are the same as those for a biopsy.

Operative Procedure

1. Generally, a radial incision extending outward from the nipple or a circumareolar incision is preferred. A short incision into the thoracomammary fold may be used for deep breast abscesses in the lower or outer quadrant.
2. After skin incision, the wound is deepened until pus is encountered.
3. A curved hemostat is directed into the cavity to determine the extent of the abscess. Specimens for aerobic and anaerobic organisms are usually taken for culture.
4. Loculations are broken up by exploring the cavity with the index finger.
5. The opening is enlarged to ensure adequate drainage, the cavity is irrigated with warm saline solution, and bleeding vessels are ligated with absorbable sutures or coagulated.
6. The wound is drained or loosely packed with gauze. Healing occurs by granulation.

LUMPECTOMY (SEGMENTAL RESECTION)

Lumpectomy is removal of a tumor mass with a margin of 1 to 1.5 mm of normal tissue. Surgical clips may be left in the operative site to assist the radiation oncologist (Lind et al, 2005). Lumpectomy, with subsequent radiation therapy, is often the treatment of choice for small tumors. It is not an option for patients who have two or more cancer sites in separate quadrants of the breast, persistent positive margins after reasonable surgical attempt, or diffuse malignant-appearing microcalcifications, as well as for patients who have undergone previous radiation to the affected breast (Mulholland et al, 2006). A lumpectomy, combined with sentinel node or axillary node dissection (Figure 16-9) and irradiation in stage I and stage II breast cancers, appears to provide results equal to a more radical procedure. If one or more axillary nodes are involved, chemotherapy also is recommended.

Procedural Considerations

In patients with large breasts, increased bleeding may occur, requiring the ESU, a smoke evacuation system, and additional hemostatic clamps.

Operative Procedure

The procedure is as described for excisional biopsy.

SENTINEL LYMPH NODE (SLN) BIOPSY

Identification and microscopic examination of the sentinel lymph nodes (SLNs), the first lymph nodes along the lymphatic channel from the primary tumor site, will help to determine the need for additional or more extensive surgeries and treatments of early-stage invasive breast cancer for patients thought to have low to moderate risk for involvement of lymph nodes (Sentinel Lymph Node Dissection, 2008). It is believed that if the cancer cells have traveled through the lymph nodes, the cells will lodge in the first nodes. The sentinel node is not located in the same site in every patient. If sentinel nodes are negative, no other nodes in the lymph node channel are likely to be involved. Evidence of a positive node requires an axillary node dissection and adjunct therapy (Sentinel Node Biopsy, 2009). Complications of SLN biopsy include risk of allergic reactions to the blue dye (Patient Safety), rare instances of sensory or motor nerve damage, and pain. Contraindications

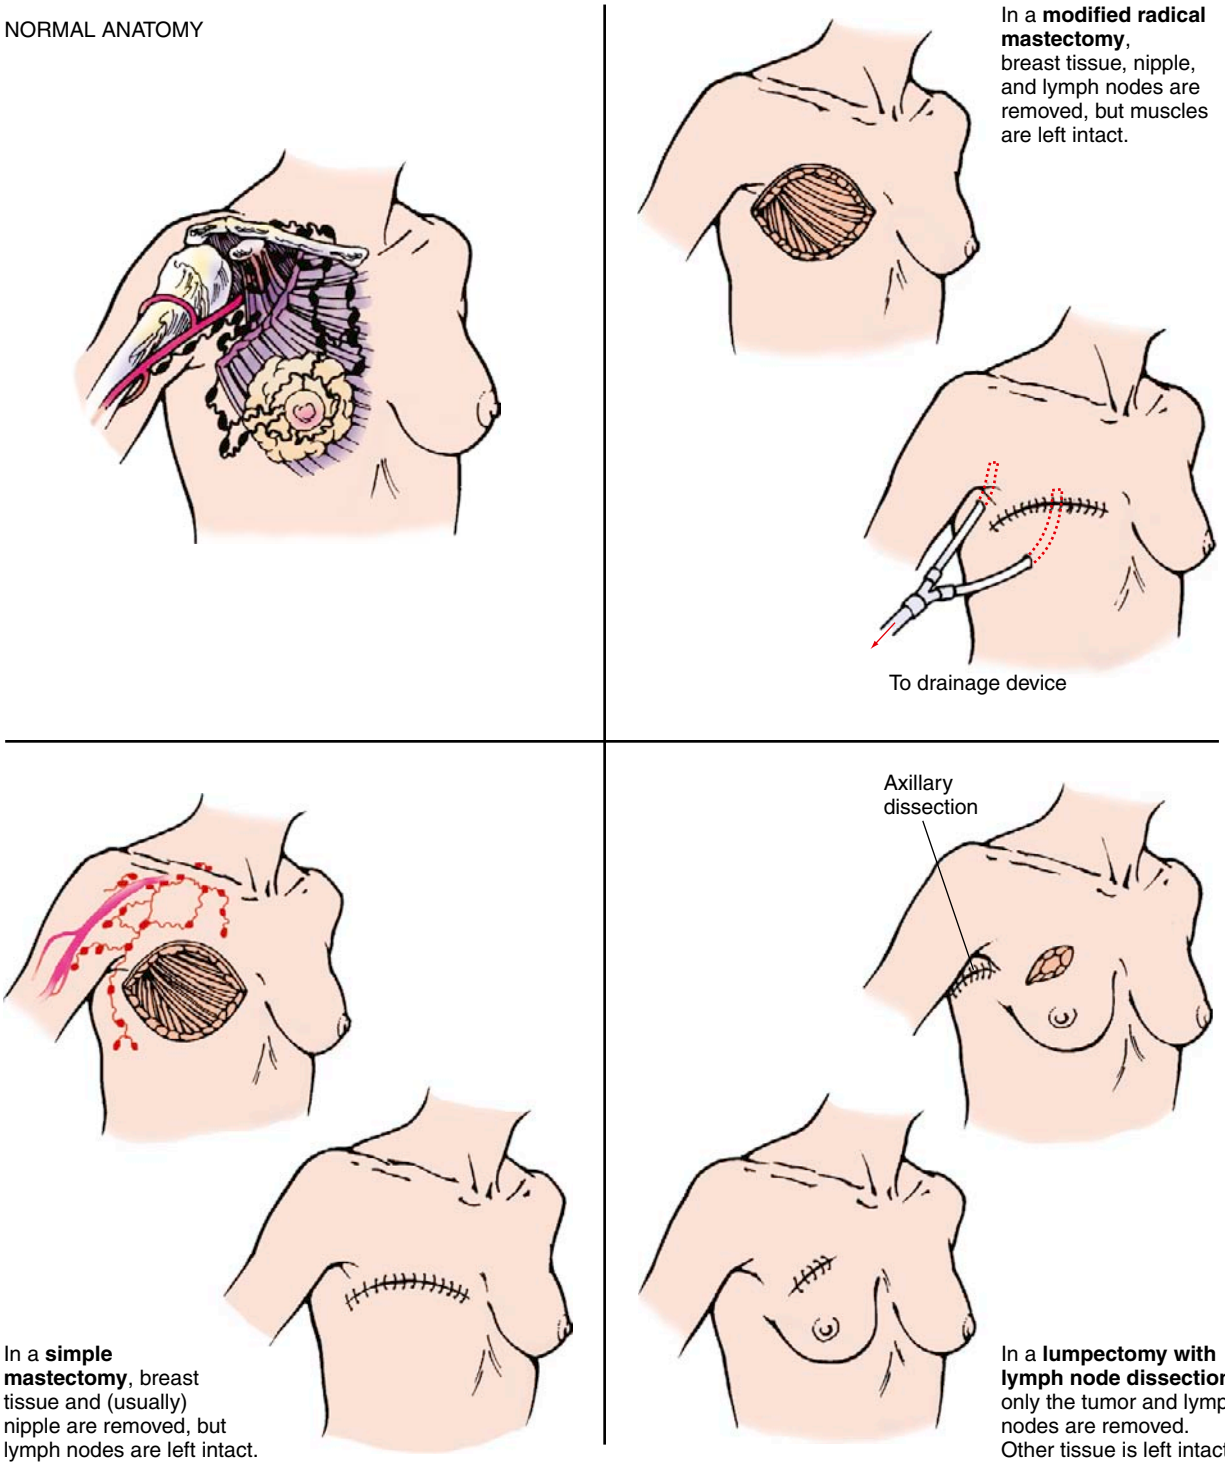

FIGURE 16-9 Surgical management of breast cancer.

to SLN biopsy include palpable axillary nodes, large or locally advanced breast cancers, prior axillary surgery, and pregnancy or lactation (Lind et al, 2005).

Procedural Considerations

The procedure for SLN biopsy is similar to that for breast biopsy. Sentinel node identification is accomplished by injection of either isosulfan blue dye or a radiocolloid (technetium 99 [^{99m}Tc]), a gamma-emitting material. Isosulfan blue is contraindicated in patients with known hypersensitivity to the dye; careful patient monitoring and observation are mandatory, and a crash cart should be available in the instance of severe anaphylactic reaction (Rapid Response Team box). The procedure is coordinated with staff of the nuclear medicine department and requires use of a handheld detector if technetium is used. In addition to a minor instrument set, if isosulfan blue is used, a 5-ml syringe,

a 25-gauge needle, an alcohol wipe, and the dye are required. For technetium, the gamma-tracer probe, counter, and sterile sleeve for the probe are required. Multiple specimen containers should be on hand along with pathology request forms. The surgeon may request that each specimen be numbered on the specimen container and the pathology request form. Safe practices for handling surgical specimens are implemented. A combination of technetium and isosulfan blue can also be used for lymphatic mapping (Mulholland et al, 2006). SLN biopsy is quickly replacing levels I and II axillary lymph node dissection as the standard procedure for staging an axillary lymph node–negative patient (Morrow and Harris, 2009).

PATIENT SAFETY

Sentinel Lymph Node Biopsy and Anaphylactic Reaction

Sentinel lymph node biopsy (SLNB) is the standard procedure for staging of the axilla in patients with clinically node negative breast cancer. The sentinel lymph node is located by intraparenchymal injection of blue dye alone or in combination with intradermal administration of radiolabeled colloid near the tumor site. The combination of blue dye and radiotracer has been shown to increase the sensitivity of SLNB. The most commonly used blue dye in the United States is Lymphazurin 1%. Use of this dye is contraindicated in those people who have a known sensitivity to triphenylmethane or related compounds. Severe allergic reaction and anaphylaxis have been observed in 1% to 3% of patients who received the dye during SLNB. The incidence of anaphylaxis continues to increase. During general anesthesia, the recognition of systemic anaphylaxis depends almost entirely on the observation of clinical symptoms and observations such as urticaria, erythema, respiratory complications, and/or cardiovascular collapse. The patient usually develops symptoms within 30 minutes. Although rare, anaphylactic shock from blue dye is a potentially lethal situation. Early recognition as well as aggressive hemodynamic management can significantly reduce mortality and morbidity. Patients may have a biphasic anaphylaxis to blue dye within 1 hour and up to 6 to 8 hours after surgery. Patients who experience anaphylaxis from blue dye should be observed for up to 24 hours.

Modified from Liang MI, Carson WE: *Biphasic anaphylactic reaction to blue dye during sentinel lymph node biopsy, 2008,* available at www.wjso.com/content/6/1/79. Accessed April 10, 2009; eMedicine Health: *Sentinel node biopsy, 2009,* Web MD, LLC, available at www.emedicinehealth.com/sentinel_node_biopsy/page6_em.htm. Accessed May 18, 2009.

Operative Procedure—Using Isosulfan Blue Dye

1. Dye is injected around or near the tumor, or dye may be injected into the area of the breast mass that has been exposed as part of a breast biopsy (Sentinel Node Biopsy, 2009).
2. This may be followed by a three-stage axillary lymphatic massage (Kirby et al, 2007).
3. The sentinel nodes stained with the blue dye are identified and excised.
4. The nodes are sent fresh to the pathology department for examination.
5. Based on the results, the surgeon proceeds with the planned surgery or may elect breast conservation.

Operative Procedure—Using Technetium

1. The tumor or previous biopsy site is injected with a small amount of radioactive tracer 20 minutes to 8 hours before the surgery. It can also be injected after anesthesia is induced (Sentinel Node Biopsy, 2009).
2. This may be followed by massage.
3. A handheld detector is passed over the top of the patient's chest to identify the area of the sentinel node by a positive reading. The probe may also be used with the addition of a sterile sleeve during excisional biopsy. Isosulfan blue dye may be used in conjunction with technetium during a procedure to enhance visibility of nodes.
4. The surgeon marks the skin with a skin scribe to indicate the reactive area.
5. The area is prepped, and the surgeon proceeds with the planned procedure for excisional biopsy of the sentinel lymph node.

AXILLARY NODE DISSECTION

Axillary node dissection (Figure 16-10) is removal of axillary nodes through an incision in the axilla after determining that the sentinel node is malignant. Removal and examination of the axillary nodes allow staging (see Figure 16-7) of the disease. Adjunct treatment can be more accurately planned when the pathologic stage is determined.

Procedural Considerations

The patient is placed supine on the OR bed with the operative side near the bed edge. The arm on the operative side is extended to less than 90 degrees on an armboard. The skin is prepped and draped as previously described.

RAPID RESPONSE TEAM

Anaphylactic shock from Lymphazurin 1% can occur 6 to 8 hours after the first episode of anaphylaxis. At this time, the patient may be in the ambulatory surgery recovery (see Patient Safety) or the medical-surgical unit. A rapid response team may be called when the symptoms of anaphylactic shock are observed, such as oxygen desaturation, systolic blood pressure in the range of 30 to 40 mm Hg, and urticaria. These teams are part of a formal interdisciplinary system to reduce death or disability through early identification, assessment, and stabilization of patients with a deteriorating medical condition before the patient's condition requires resuscitation or transfer to a higher level of care. The patient in anaphylactic shock is treated appropriately, admitted to the hospital for observation, and, when fully recovered, discharged with appropriate medications and instructions, especially with information about the allergy to Lymphazuin. The patient should inform all medical personnel of this allergy and wear a medical alert bracelet.

Modified from Liang MI, Carson WE: *Biphasic anaphylactic reaction to blue dye during sentinel lymph node biopsy, 2008,* available at www.wjso.com/content/6/1/79. Accessed April 6, 2009; Administrative Policy and Procedure Manual, Taylor Hospital, effective date April 2006.

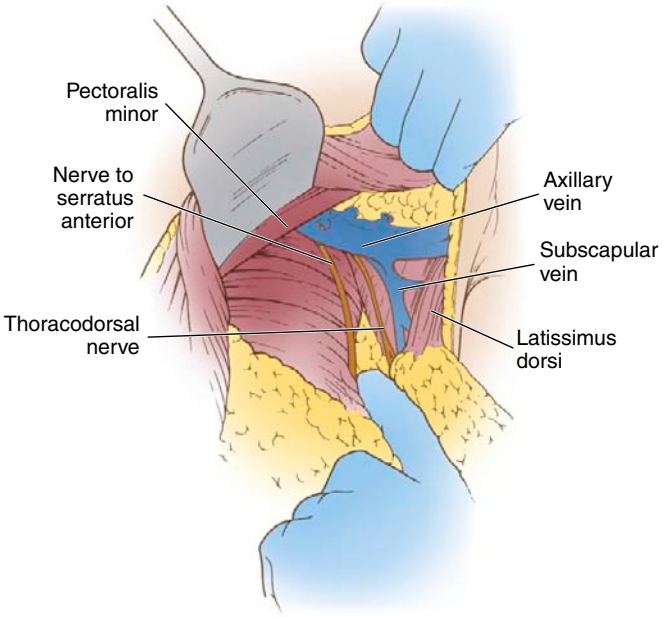

FIGURE 16-10 Axillary dissection.

Operative Procedure

1. An incision is made slightly posterior and parallel to the upper lateral border of the pectoralis major muscle or transversely across the axilla.
2. The fascia is incised over the pectoralis muscle and the pectoralis minor muscle is exposed. Major blood and lymphatic vessels are clamped and ligated. The use of electrosurgery is avoided around the axillary vessels and nerves to reduce the risk of inadvertent injury and subsequent impaired muscle function.
3. The tissue over the axillary vein is incised.
4. Lymph nodes between the pectoralis major and pectoralis minor muscles are removed. Care is taken not to injure the medial and lateral nerves of the pectoralis major muscle.
5. Axillary fat and lymph nodes are freed from the axillary vein and chest wall. The long thoracic nerve is identified along the chest wall near the axillary vein, and the thoracodorsal nerve posteriorly is dissected free from the specimen.
6. The fat and nodes are removed. The incision is closed with sutures and staples, and a dressing is applied. A closed wound drainage system is usually placed through a separate stab incision for lymphatic drainage.

SUBCUTANEOUS MASTECTOMY

Subcutaneous mastectomy is removal of all breast tissue with the overlying skin and nipple left intact. This procedure is recommended for patients who have central tumors of noninvasive origin, chronic cystic mastitis, hyperplastic duct changes, or multiple fibroadenomas or who have undergone several previous biopsies. Breast reconstruction may be undertaken at the time of mastectomy or at a later date if desired.

Procedural Considerations

The patient is positioned as for a biopsy. If reconstruction is to be undertaken, appropriate equipment and supplies (see Chapter 21) are also required.

Operative Procedure

1. An incision is usually begun in the inframammary crease and may be made on the medial or the lateral aspect of the breast. Some surgeons initially remove and preserve the nipple areola complex by employing lateral extensions of wide circumareolar incisions.
2. Blunt dissection is performed to elevate the breast from the pectoral fascia.
3. The breast tissue is separated from the skin with an attempt made to remain in a plane between the subcutaneous tissue and the breast. Dissection is carried out toward the axilla. With care, 90% or more of the breast tissue, including the tail of Spence, can be removed. Some lymph nodes in the axillary area also may be removed. Bleeding vessels are clamped and ligated.
4. If a preoperative decision was made for immediate reconstruction, that procedure follows at this time. Provided that the subareolar tissue shows no signs of tumor, as verified by a pathologist, the salvaged areolar complex is placed on a deepithelialized dermal bed.
5. A closed wound suction catheter typically is inserted. The wound is closed, and a light pressure dressing is applied.

SIMPLE MASTECTOMY

Simple mastectomy is removal of the entire involved breast without lymph node dissection (see Figure 16-9). A simple mastectomy is performed to remove extensive benign disease, if malignancy is believed to be confined only to the breast tissue, or as a palliative measure to remove an ulcerated advanced malignancy.

Procedural Considerations

The patient is positioned as for a biopsy.

Operative Procedure

1. Through a transverse elliptic incision (Figure 16-11, *A*), using a knife, curved scissors, and the ESU, the skin edges are freed from the fascia. Bleeding vessels are clamped with hemostats and ligated with sutures or electrocoagulated.
2. The skin edges of the wound can be protected with warm, moist laparotomy pads; the breast tissue is grasped with Allis forceps and is dissected free from the underlying pectoral fascia with curved scissors, a knife, or an ESU.
3. The tumor and all breast tissue are removed. Bleeding vessels are clamped and ligated or electrocoagulated.
4. A closed wound drainage catheter is inserted and anchored to the skin with a fine suture. The wound is closed with fine sutures or staples; a dressing is applied.

MODIFIED RADICAL MASTECTOMY

Modified radical mastectomy is performed after a tissue biopsy with a positive diagnosis of malignancy and removes the involved breast and axillary contents (all three levels of nodes—axillary, pectoral, and superior apical) (see Figure 16-9). The underlying pectoral muscles are not removed before or after removal of axillary nodes. A modified radical mastectomy is done to remove the involved area with the hope of decreasing the spread of the malignancy. This surgery's elliptic incision encompasses the nipple-areolar complex, a biopsy scar if an

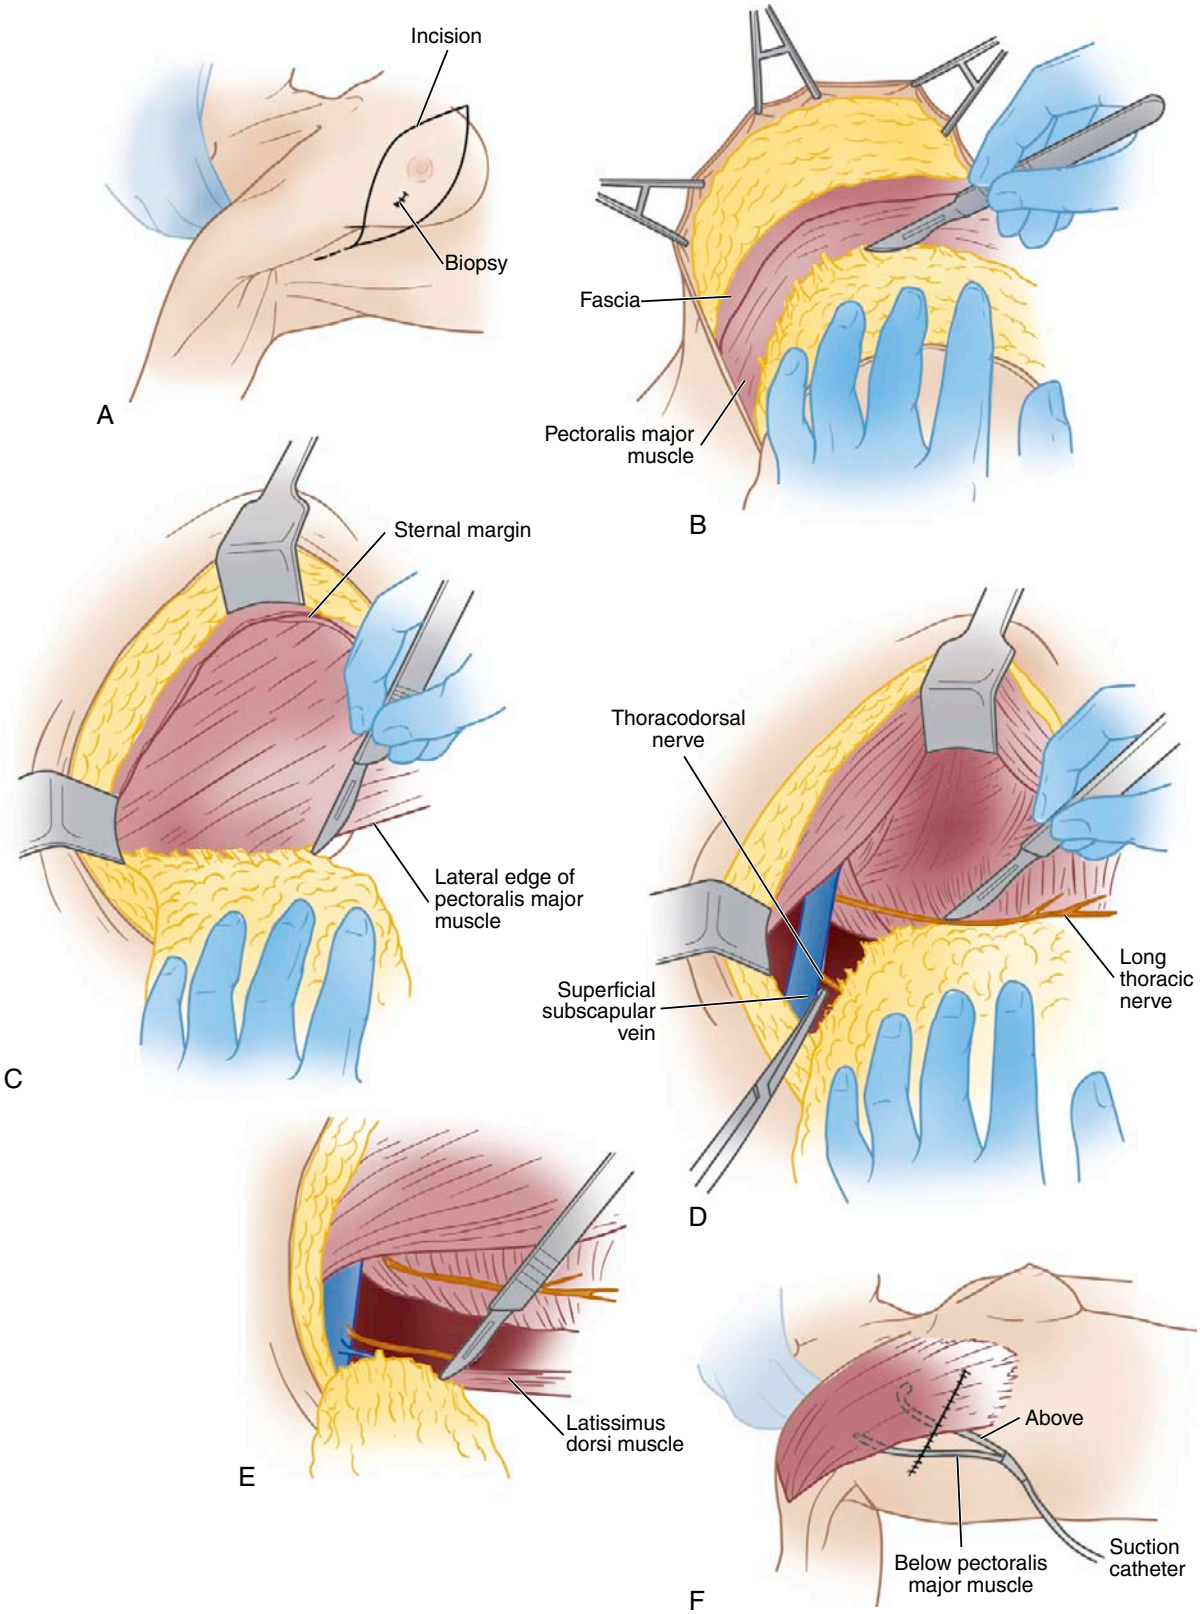

FIGURE 16-11 Modified radical mastectomy. **A**, Lines of incision. **B**, Resection of breast from lateral edge of pectoralis major muscle. **C**, Dissection of breast from lateral edge of pectoralis major muscle. **D**, Thoracodorsal and long thoracic nerves identified. **E**, Resection from latissimus dorsi muscle. **F**, Incision is closed, and closed wound drainage systems are placed.

open biopsy has been performed, and excess skin of the breast. If skin is needed for reconstruction (see Chapter 21), it can be preserved and exposure obtained through incision rather than excision (Mulholland et al, 2006).

Procedural Considerations

The patient is placed supine on the OR bed with the operative side near the bed edge. The arm on the operative side is extended to less than 90 degrees on a padded armboard. The skin is prepped and draped as previously described. Tissue removed during surgery will be submitted for microscopic analysis to further classify it (type, tumor size, grade, invasion, lymphocytic response, clean margin size). Additional analysis such as hormone receptor status (estrogen and progesterone positive or negative) and HER-2/neu (human epidermal growth factor receptor 2) expression may also be performed. This information assists the oncologist in planning subsequent adjuvant therapies (Ignatavicius and Workman, 2010).

Operative Procedure

1. An oblique elliptic incision with lateral extension toward the axilla is made through the subcutaneous tissue (see Figure 16-11, *A*). The bleeding points are controlled with hemostats and ligatures or electrocoagulation.
2. The skin is undercut in all directions to the limits of the dissection by means of a #3 knife handle with a #10 blade, curved scissors, or the ESU. Knife blades need to be changed frequently to ensure precise dissection.
3. The margins of the skin flaps are covered with warm, moist laparotomy pads and then retracted. The fascia and breast are resected from the pectoralis major muscle (Figure 16-11, *B*), starting near the clavicle and extending down to the midportion of the sternum. The pectoralis muscle is left intact.
4. The intercostal arteries and veins are clamped and ligated.
5. The axillary flap is retracted for dissection of the axilla. Careful attention is directed to preventing injury to the axillary vein and to the medial and lateral nerves of the pectoralis major muscle.
6. The fascia is dissected from the lateral edge of the pectoralis muscle (Figure 16-11, *C*). Vessel ligation is performed in the axilla and adjacent to the sternum. The fascia is then dissected from the serratus anterior muscle. The thoracic and thoracodorsal nerves are preserved (Figure 16-11, *D*).
7. The breast and axillary fascia are freed from the latissimus dorsi muscle and suspensory ligaments (Figure 16-11, *E*). The specimen is then passed off the field.
8. The surgical area is inspected for bleeding sites, which are ligated and electrocoagulated. The wound is irrigated with normal saline. Closed wound suction catheters are inserted into the wound through stab wounds and secured to the skin with a nonabsorbable suture on a cutting needle (Figure 16-11, *F*).
9. A few absorbable sutures may be used in the subcutaneous tissue to approximate the skin edges. The incision is closed with interrupted nonabsorbable sutures, staples, or a running subcuticular stitch for a better cosmetic result.
10. The dressing can be a simple gauze dressing, a bulky dressing held in place by a Surgi-Bra, or a gauze or elastic bandage wrap.

CHAPTER 17

Ophthalmic Surgery

VICTORIA DREGER

Statistics about vision loss are staggering: throughout the world, more than 161 million people have significant vision loss and that number is expected to double by 2020; more than 37 million people are completely blind, with someone going blind every 5 seconds. Ninety percent of eye accidents, thousands of which occur daily, are preventable with the use of proper safety eyewear (Prevent Blindness America [PBA], 2005). Preventable or treatable conditions cause 80% of blindness worldwide (Lighthouse International, 2007).

Early detection of eye disease through regular eye exams can provide the most effective treatment and ultimately preserve vision (Figure 17-1). However, a national telephone survey of more than 3000 adults found that most Americans are not aware of risks and warning signs of the diseases that could blind them. Over 70% said that losing their eyesight would have the greatest impact on their daily life. Many considered losing their eyesight to be worse than losing an arm or leg, or losing hearing or the ability to speak (National Eye Institute [NEI], 2008a). As a result of the survey, the National Eye Institute is increasing its efforts to educate healthcare professionals about methods of communicating with patients to better maintain eye health (NEI, 2008a). At the same time, outpatient surgeries have been increasing: cataract is the leading diagnosis for ambulatory surgery visits, with more than 3 million lens extractions performed yearly (Cullen et al, 2006). The perioperative nurse must keep abreast of changes in technology, procedural techniques, safety issues, and patient education resources to provide optimal care to ophthalmic surgery patients (Research Highlight).

Surgical Anatomy

The major eye structures and normal eye function will be reviewed here; conditions requiring surgery will be discussed under Surgical Interventions. The perioperative nurse uses this combined knowledge to understand the surgeon's plan of treatment and to prepare the patient, instrumentation, supplies, and equipment for the procedure.

Bony Orbit

The two orbital cavities are situated on either side of the midvertical line of the skull between the cranium and the skeleton of the face. The seven bones that form the orbit are the maxilla, palatine, frontal, sphenoid, zygomatic, ethmoid, and lacrimal bones.

Each orbit is in the shape of an irregular, four-sided pyramid, with its base at the front of the skull and its axis pointing posteromedially toward the apex. The orbit contains the globe; orbital fat; extraocular muscles, nerves, and blood vessels; and part of the lacrimal apparatus. The orbit also acts as a distribution center for certain vessels and nerves that supply the facial areas around the orbital aperture.

The *orbital septum* is a sheet of connective tissue that descends from the periosteum of the orbital margin to the eyelid retractors near the skin surface. The septum protects the contents of the bony orbit, and divides the area into anterior (preseptal) and posterior (postseptal) spaces.

Lacrimal Apparatus

The lacrimal apparatus effectively functions like a sink, with a faucet (main and accessory lacrimal glands) and drain (lacrimal puncta, canaliculi, sac, and nasolacrimal duct). The lacrimal gland produces tears and secretes them through a series of ducts onto the anterior ocular surface, thereby keeping the cornea moist and washing away any debris. The tears then flow inward to the puncta, from which they are conducted by the canaliculi to the lacrimal sac and finally pass into the nasolacrimal duct (Figure 17-2).

Eyelids

The palpebral fissure refers to the space between the margins of the two eyelids (Figure 17-3). When the eye is closed, the fissure becomes a mere slit and the cornea is completely covered by the upper eyelid. The upper eyelid is more mobile and larger than the lower. The upper and lower lids meet at the medial and lateral angles (canthi) of the eye. The eyelids are closed by the orbicularis oculi muscle, innervated by the seventh cranial nerve. The upper lid is opened by the levator muscle, which is innervated by the third cranial nerve.

The anterior eyelid layers contain the eyelid skin, ocular adnexa (eyelashes and associated glands), and subcutaneous tissue, lymphatics, and muscles.

The tarsus is a plate of dense fibrous tissue that forms the main scaffolding of the eyelids. The tarsus is anchored to the walls of the orbit by the medial and lateral palpebral ligaments. Within the tarsus are the meibomian glands, which secrete the oily component (sebum) of the tear film. The orifices of these sebaceous glands are found at the eyelid margin just posterior to the eyelashes.

Conjunctiva

The conjunctiva is a thin, transparent mucous membrane divided into a palpebral portion (lining the inside of the eyelids) and a bulbar portion (lining the surface of the globe) (see Figure 17-3). The junction between the palpebral and bulbar conjunctivae forms a forniceal sac.

RESEARCH HIGHLIGHT

Review of Impaired Vision Among Midlife Adults and Geriatric Patients

Existing nursing research on low vision and blindness is scarce, and of those studies that exist, most have a small sample size and tend to be qualitative in nature. One article reviewed nursing research regarding blindness and impaired vision among midlife adults and geriatric patients. In contrast, the number of American patients in this age range with visual impairment is expected to double by the mid-2020s, with an eventual 1.6 million blind Americans and 3.9 million Americans with low vision. Visual impairment is associated with decreased quality of life and shortened life expectancy.

The authors suggest that the limited number of nursing research studies involving this population is of concern considering the number of persons affected. They suggested four broad categories for research endeavors:

1. Questions within the context of holistic nursing frameworks (e.g., How does visual impairment affect capacity for self-care, coping, adaptability, socialization, economic security, access to care, self-esteem, and/or spiritual well-being?)
2. The capacity of advanced practice nurses to assess and refer visually impaired patients (e.g., developing an evidence base regarding common age-related eye diseases)
3. Efficacy testing for how all health conditions are managed and adapted for accessibility by blind or low vision patients
4. Availability and testing of reengineered work designs for nurses with visual impairment, to retain valuable and experienced workers during an upcoming nursing shortage; a related issue is whether electronic medical records enhance the functioning of visually impaired health professionals because the font size can be enlarged and darkened

Another review suggested other future research to assess the relationship between age-related macular degeneration and involvement in motor vehicle collisions. Certain programs, such as those in which patients utilize miniature telescopes mounted into ophthalmic corrective lenses (e.g., bioptic telescopes) while driving, should also be explored. The authors state that well-designed studies would be important to inform both clinical and policy audiences about safety and quality of life, while using bioptics for driving.

Nurse scholars are called upon to expand the nursing knowledge base for the anticipated surge in patients with low vision and blindness and those who suffer from those conditions. Are you ready for the challenge?

Modified from Owsley C, McGwin G: Driving and age-related macular degeneration, *J Vis Impair Blind* 102(10):621-635, 2008; Sharts-Hopko N: Low vision and blindness among midlife and older adults: a review of the nursing research literature, *Holist Nurs Pract* 23(2):94-100, 2009.

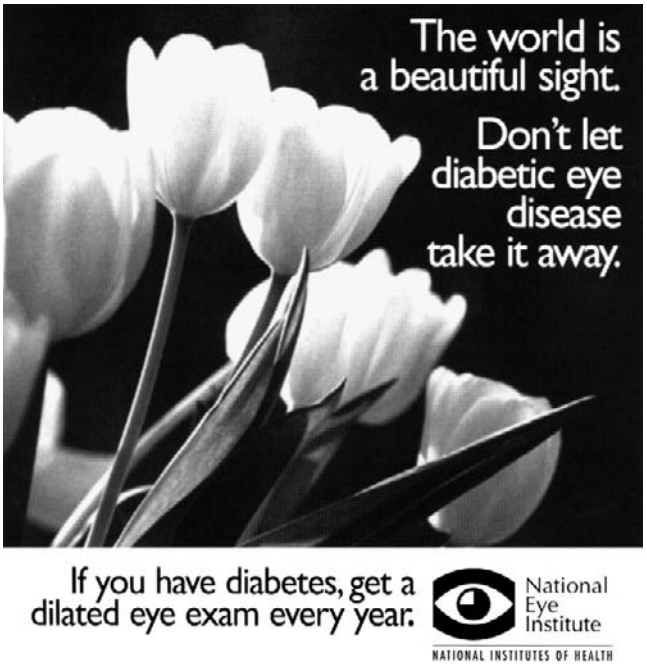

FIGURE 17-1 Public service announcement on prevention of diabetic eye disease.

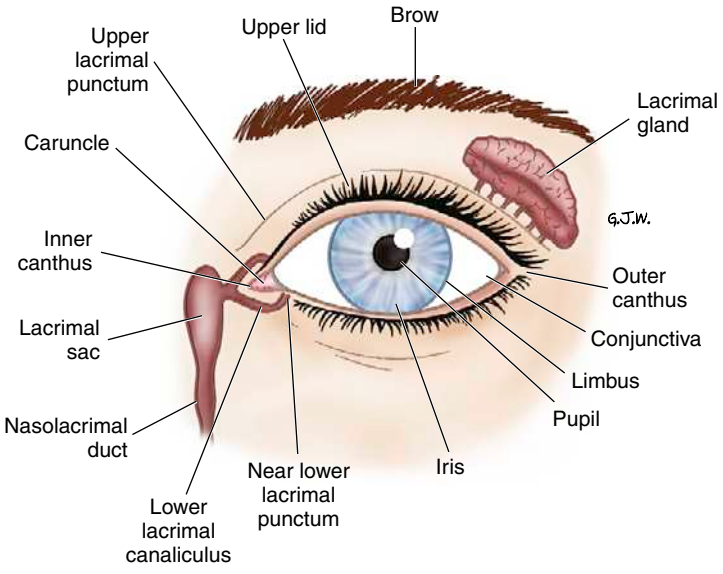

FIGURE 17-2 Lacrimal apparatus.

Muscles

Named according to their relative position on the eyeball, the extraocular muscles of the eyeball include the four recti (the *superior rectus, inferior rectus, medial rectus, and lateral rectus*) and two oblique muscles (the *superior oblique and inferior oblique*) (see Figure 17-3). Except for the inferior oblique muscle, these muscles originate from the back of the orbit. The muscles work in yoked pairs, with ocular movements generated by an increase in the tone of one set of muscles and a decrease in the tone of the antagonistic muscles. The extraocular muscles are supplied by cranial nerves III (oculomotor, supplying the superior, inferior and medial recti), IV (trochlear, supplying the superior oblique), and VI (abducens, supplying the lateral rectus).

Globe

The eyeball (globe) is supported in the orbital cavity on a cushion of fat and fascia. The fibrous external layer includes the clear cornea and white sclera; the middle, vascular pigmented layer comprises the iris, ciliary body, and choroid; and the internal layer is the sensory retina. The globe is filled with two clear liquids: the aqueous humor (anterior to the lens) in the

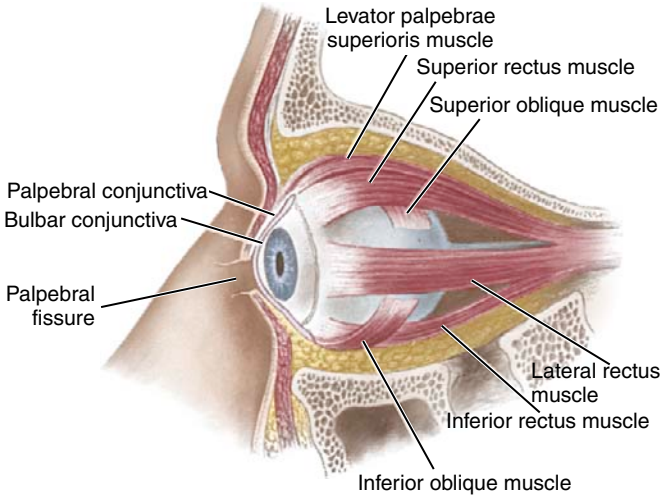

FIGURE 17-3 Orbit and muscles. Medial rectus is located on nasal side of globe.

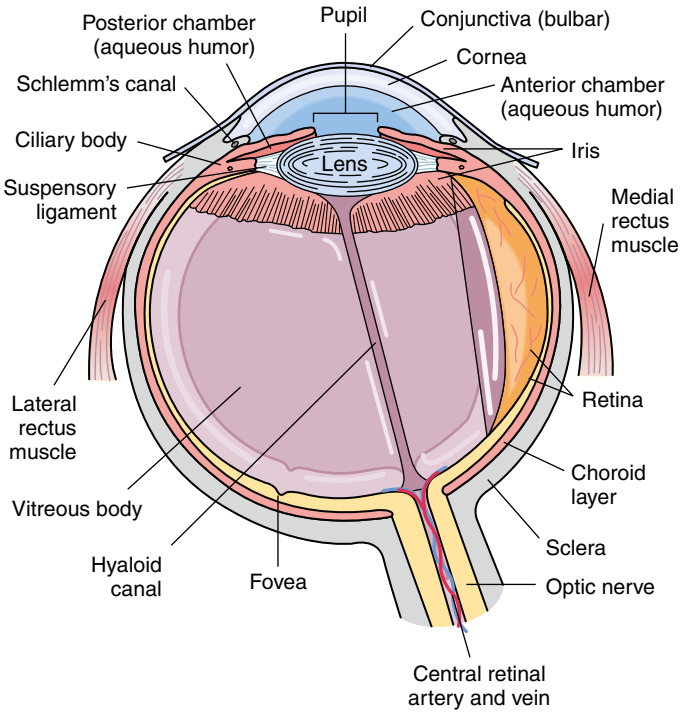

FIGURE 17-4 Horizontal section through left globe.

anterior segment and the vitreous humor (behind the lens) in the *posterior segment*. Light and images are focused *(refracted)* by the lens, suspended behind the pupillary opening of the iris, and the cornea (Figure 17-4).

Refractive Apparatus

Cornea. The *cornea* is the transparent, avascular window through which light rays pass to the retina; it joins the sclera at a transitional zone called the *limbus*. Corneal sensation is provided via ophthalmic branches of the fifth cranial nerve. The cornea is composed of five layers: the epithelium, Bowman's membrane, the stroma, Descemet's membrane,

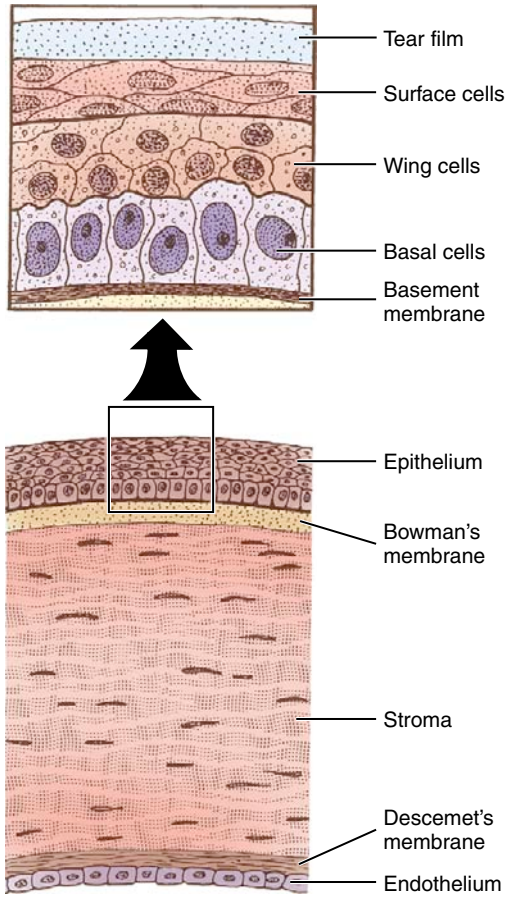

FIGURE 17-5 Five layers of cornea. *Inset,* Layers of epithelium.

and the endothelium (Figure 17-5). The epithelium consists of constantly renewing cell layers with many nerve endings, accounting for the cornea's great sensitivity to foreign bodies and abrasions. Bowman's membrane is connective tissue thickening that forms a barrier to trauma and infection under the epithelium. If damaged, Bowman's membrane does not regenerate and a permanent scar is formed. The stroma accounts for 90% of the corneal thickness and is composed of precisely layered fibers. If this layering is disrupted (for example, by edema), the corneal clarity decreases. Descemet's membrane is a thin layer between the endothelial layer of the cornea and the stroma. The corneal endothelium is a single layer of hexagonal cells that acts as a fluid pump to keep the cornea clear by maintaining the proper level of stromal dehydration. Because corneal endothelial cells do not regenerate, damage to this layer may cause persistent corneal edema and loss of transparency.

The *sclera* is the opaque "white" part of the external layer, and is made up of collagenous fibers loosely connected with fascia. The sclera receives attachments of the extraocular muscle tendons, and is pierced by the ciliary arteries and nerves posteriorly by the optic nerve.

Visual images are refracted (focused) by the cornea, the aqueous humor, the lens, and the vitreous body. The cornea has the greatest refractive power of the ocular structures. Variations in the curvature of the cornea change its refractive power (Figure 17-6).

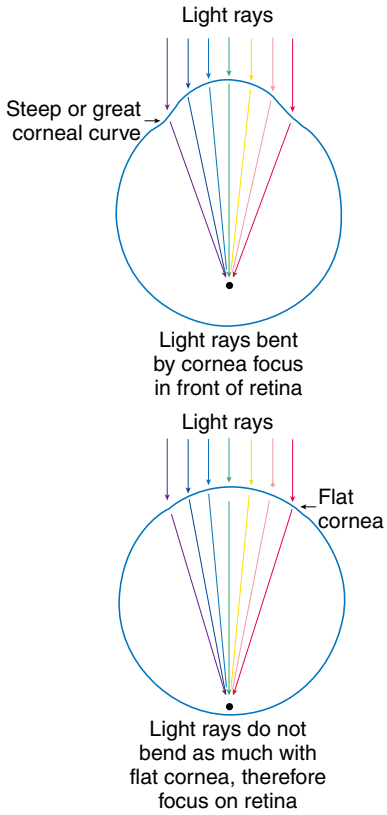

FIGURE 17-6 Variations in the curvature of the cornea change its refractive power.

Lens. The biconvex lens is suspended behind the iris and connected to the ciliary body by delicate collagenous strings called *zonules* (Figure 17-7). The lens changes shape and focus (accommodation) by relaxation and tightening of the zonular fibers. Over time (particularly after age 40), the lens and lens zonules become progressively less elastic, resulting in *presbyopia*. This loss of accommodative power is typically corrected with reading glasses or bifocals.

Vitreous. The vitreous body is a glasslike, transparent, gelatinous mass composed of 99% water and 1% collagen and hyaluronic acid. It fills the posterior four fifths of the eyeball and is adherent to the retina at the vitreous base.

The eye functions similarly to a camera. Light rays from an object pass through the system of refractory devices—the cornea, aqueous humor, lens, and vitreous—and are refracted (bent) so that the rays strike the retina. For information to be received correctly and sent to the cerebral cortex, all structures must function together to focus the light rays. The lens must be able to bend the light waves correctly and bring an object into clear focus. Refractive errors, or errors in focusing ability, occur when the cornea is misshapen or when the lens cannot appropriately change shape to focus images.

Nerve and Blood Supply

The optic nerve (second cranial nerve) extends between the posterior eyeball and the optic chiasm. This cranial nerve carries visual impulses, as well as the sensations of pain, touch, and temperature, from the eye and its surrounding structures

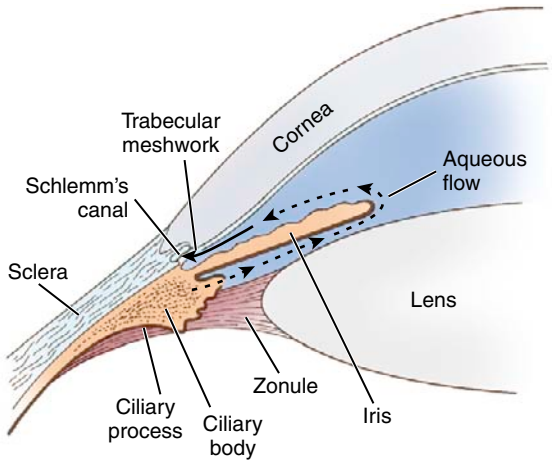

FIGURE 17-7 Anterior chamber, ciliary body, and aqueous circulation.

to the brain. The third cranial nerve (oculomotor) is the primary motor nerve to the inferior oblique as well as all rectus muscles except the lateral rectus, which is innervated by the sixth cranial nerve (abducens). The fourth cranial nerve (trochlear) innervates the superior oblique muscle.

The ophthalmic artery, the main arterial supply to the orbit and globe, is a branch of the internal carotid artery. It divides into branches supplying the globe, muscles, and eyelids. The central retinal artery and central retinal vein travel through the optic nerve and provide a separate blood supply for the retina.

Physiology of Vision

Clear vision requires all of the following: healthy, functioning eye structures; adequate light; intact neurovascular communication with the brain; and the brain's effective interpretation of the images relayed. Since the eye is similar to a camera with a lens system, the following cycle, if completed in the full sequence, leads to accurate visual images:

1. Light rays emanate from an object in the field of vision and transmit to the eye.
2. Iris muscles control the size of the pupil, thereby determining the intensity of light (similar to the shutter of a camera).
3. These light rays pass through the optical system (cornea—"window of the eye"), aqueous fluid, lens, vitreous to reach the retina (which is similar to the film in a camera). The flexible lens bends the light rays to form the image on the retina, ideally striking at the macula, the area of highest sensitivity for details.
4. The visual sensory nerve endings of the retina pass the images as nerve impulses through nerve fibers of the optic nerve to the brain, where the occipital area interprets the images.

Since early treatment for various eye diseases can potentially save sight, people 60 years of age or older should have a comprehensive dilated eye exam every 2 years as a minimum (NEI, 2008b). Any condition that disrupts eye health or the process of these steps impairs vision. Other structures within the eye exist, but it is beyond the scope of this chapter to adequately cover all details of the complex organ of sight. Specific conditions requiring surgical intervention will be explained under Surgical Interventions.

Perioperative Nursing Considerations

Assessment

Patients undergoing eye surgery range from premature infants with retinopathy of prematurity or congenital conditions to elderly patients whose conditions result from the aging process. These patients need assessment of both their vision and their general health status. A preoperative visit to the eye clinic or surgeon's office typically completes the diagnostic testing and physical exam pertinent to the presenting eye condition subsequently requiring surgery. Communication with the physician's office staff to coordinate patient preparation and teaching and to collate preoperative test results increases the efficiency and effectiveness of preoperative procedures. Perioperative nurses contact patients preoperatively by phone to provide needed information concerning the day of surgery and to obtain initial preoperative assessment information. The perioperative nurse reviews the data provided from the office chart and conducts additional interviewing/history-taking in conjunction with the physical exam to complete the assessment process.

The perioperative nursing staff must be prepared to meet the specific needs of each patient and family, collaborate and communicate effectively for continuity of patient care, and prepare the patient for home care. Most patients are admitted through an ambulatory admission area adjacent to the surgical suites (Ambulatory Surgery Considerations). On admission, a staff member should fully orient the patient to the physical surroundings. Constant description and reinforcement are important to visually impaired patients. Approaching the patient from the unaffected side increases the patient's independence and decreases the possibility of startling the patient.

The assessment is designed to collect and disseminate pertinent information and must be carried out in a comprehensive, yet efficient, manner. A standard set of parameters should provide enough information to facilitate appropriate care in the event of an emergency. Physiologic information (e.g., height, weight, vital signs), psychosocial factors (e.g., support systems, fears, anxiety), and environmental, education, and self-care needs are assessed. The general health history includes completing a comprehensive list of current medication therapy (often the patient is asked to bring currently prescribed medications to the appointment). The medical history is very important in cueing the nurse to evaluate for ocular manifestations of systemic disease. For example, the patient may present for retinal surgery as a consequence of retinopathy related to diabetes mellitus. Additional discharge planning factors are also explored.

Data may be collected from family or significant others and/or directly from physicians or their office staff. Throughout the assessment process, the nurse encourages the patient toward self-actualization and assuming an active role in his or

AMBULATORY SURGERY CONSIDERATIONS

Ophthalmic Surgery in Elderly and Team Communications/Hand-Off

Anesthetic management impacts the success of eye surgeries. Safe outpatient surgery, especially in the elderly population, depends on patient selection, preoperative evaluation, preparation, monitoring, and local anesthesia techniques. In addition to standard preoperative evaluation, special considerations apply for anesthesia in ophthalmic surgery. For example, elderly patients scheduled for eye surgeries may have co-morbidities of congestive heart failure, hypertension, diabetes, angina, chronic lung disease, senility, parkinsonism, and/or arthritis, any of which may disrupt the surgical procedure. Some patients with Alzheimer's disease, head tremor in Parkinson's disease, claustrophobia, chronic cough, or shortness of breath while lying flat may benefit from general anesthesia because of difficult management with regional anesthesia and light sedation. Patients may benefit from leaving dentures in place since they may even breathe easier.

It is essential that the patient understand the procedure and routine. Thorough explanations (technique, monitoring, and safety precautions) regarding regional anesthesia for eye surgery can relieve patient anxiety and enhance cooperation. Most importantly, the preoperative anesthesia interview can set the tone and obtain patient acceptance. Premedication can serve as an adjunct to decrease anxiety and provide amnesia during injection of the block. Monitoring and titration of IV medications selected should achieve proper sedation levels and effect. Narcotic doses must be adjusted (decreased) in the elderly because increasing age alters pharmacodynamics.

Established regimens of cardiac medications should be continued in the perioperative period with beta-blocker use considered to prevent complications associated with increased heart rate; regional anesthesia is generally safe, even for elderly patients with a history of myocardial infarction. Following outpatient surgery, the patient needs to have the services of a responsible adult (assistance with walking, eating, and home care) for up to 24 hours after discharge.

Amato-Vealey and colleagues (2008) state, "Care provided in all phases of the perioperative process is driven by the need for rapid turnover; for increased volume and efficiency; to improve physician satisfaction; and to accelerate throughput for the surgical patient." Such a hurried environment can lead to communication errors and mistakes that could be fatal. Errors can occur throughout multiple phases of perioperative care. Active communication should be used to verify and clarify accurate exchange of information (e.g., correct person, correct site, correct procedure, special concerns) between all healthcare personnel, such as at the following transition of care points:

- Between the surgeon's office scheduling and the healthcare facility
- Between the healthcare facility scheduling and the preoperative area
- Between preoperative and intraoperative areas
- From intraoperative to phase I PACU
- From phase I to phase II recovery and discharge

"Effective and standardized communication between care providers at hand-off points during the perioperative process will help them facilitate safety and anticipate and limit complications. Communication that is timely, accurate, complete, unambiguous, and understood by the recipient reduces error and results in improved patient safety" (Amato-Vealey et al, 2008).

Modified from Amato-Vealey EJ et al: Hand-off communication: a requisite for perioperative patient safety, *AORN J* 88(5):763-770, 2008; Donlon JV et al: Anesthesia for eye, ear, nose and throat surgery. In Miller RD, editor: *Miller's anesthesia,* ed 4, Philadelphia, 2005, Churchill-Livingstone.

her healthcare needs (Patient Safety). All information should be documented so that it is readily available to others. Some healthcare systems have computerized health records (electronic medical records and health information technologies) that are accessible to appropriate healthcare providers in various locations. This supports continuity of care and can prevent errors (omissions), which are more likely when information is not readily available.

PATIENT SAFETY

Asking Questions

Various healthcare organizations have emphasized the importance of patient safety considerations. The Joint Commission's 2009 *National Patient Safety Goal* #13 states, "Encourage the patient's active involvement in their care as a patient safety strategy." Since 2002 The Joint Commission and the Centers for Medicare & Medicaid Services have encouraged patient participation through the "SPEAK UP" initiative (each letter of the acronym denotes a safety-related activity). Suggestions include basics of speaking up about any questions or concerns, emphasizing the right to know information about one's own care and the importance of asking again if one does not understand explanations given.

Various initiatives are intended to help prevent errors, such as avoiding mistakes during surgery, preventing infection, and accurately administering medications. Patients are encouraged to know their rights, understand instructions from healthcare providers, and be active in their pain management plan. A majority of healthcare institutions using the initiatives adds value to accreditations and certification processes; in fact, some institutions even advertise their accreditations.

The National Institutes of Health also provides information about *Talking to Your Doctor.* Questions pertaining to diseases, treatments, and tests along with general communication tips are available on the internet to help patients participate in and understand their care plan. Of course, "an eye care professional who has examined the patient's eyes and is familiar with his or her medical history is the best person to answer specific questions" (NEI Health Information, 2008).

Besides patient information, nurses need to be actively engaged in activities promoting safety; this influence can be exercised in many ways. Siefert (2008) notes "One of the simplest and most effective [ways] is to verbalize that something does not seem right. Motivate novice nurses to articulate concerns, encourage experts to scrutinize assumptions, and promote a workplace that respects curiosity and inquiry. The question not asked may lead to an error not prevented." Speaking up might take the form of strictly adhering to institutional policies concerning time-outs, patient identification, or sponge and instrument counts or even questioning a drug order, such as when Diamox is ordered for a patient who has a sulfa allergy.

Modified from Blanchard J: Clinical issues: National Patient Safety Goals update, *AORN J* 88(5):822-823, 2008; Seifert PC: Want to improve safety? Ask questions, *AORN J* 88(5):707-708, 2008; The Joint Commission: *Speak up*: *facts about speak up initiatives,* 2008, available at www.jointcommission.org/GeneralPublic/Speak+Up/about_speakup.htm. Accessed March 25, 2009; National Eye Institute, National Institutes of Health: *NEI health information*: *Talking to your doctor,* 2009, available at http://nei.nih.gov/health/talktodoc. Accessed March 25, 2009; National Eye Institute, National Institutes of Health: *NEI health information*: *Facts about cataracts,* 2008, available at www.nei.nih.gov/health/cataract/cataract_facts.asp. Accessed March 25, 2009.

An ocular history, which includes the patient's primary problem, history of the present condition, symptoms, and visual limitations, is collected from the patient's initial visit to the eye care provider's office, and the nurse confirms these findings. Some common forms of ocular examination are shown in Figure 17-8.

An external examination of the eye, including lids, lashes, conjunctiva, and lacrimal apparatus, should have been performed to detect any deviations from normal. The corneal reflex should have been tested and the cornea inspected for superficial irregularities. Pupil size and contour, as well as pupillary reaction, both direct and consensual, should be noted. Shallow anterior chamber depth alerts staff members to the potential for high pressures resulting from angle closure with dilation of the pupil.

The function of the extraocular muscles should have been determined. Movement should be synchronous, and visual lines should meet on a fixed object. Documentation of this examination must be descriptive, accurate, and concise. It is of value later in assessing the outcome of the procedure. The following observations are also important:

- General appearance of the eye (edema, asymmetry, redness, condition of conjunctiva, sclera, and skin around eyes)
- Symptoms of irritation (itching, burning)
- Position of eyelids (opened and closed), condition of upper and lower lid surfaces, eyelid spasm
- Visual acuity, pupillary dilation (note if pupils are equal, round, reactive to light, and accommodative), visual fields
- Extraocular muscle movement
- Drainage from eye
- Current and significant past medical problems (eye disease, diabetes, cardiovascular disease, hypertension, allergies)
- Current medication history, including anticoagulants, analgesics, herbs, and nutritional supplements
- General: vital signs; restlessness, discomfort, anxiety; limitations in mobility; presence of prosthesis

Laboratory Studies. The specific laboratory studies requested are derived from the more general standards for preanesthesia care established by the American Society of Anesthesiologists (ASA) (ASA, 2005). Although some eye procedures are completed with only local anesthesia, many, if not most, are performed in collaboration with an anesthesia care provider. Thus the results of laboratory studies that were performed should be reviewed during the nursing assessment. Deviations from normal should be noted, documented, and reported, verifying the anesthesia care provider's awareness of the same. The following tests might be routinely ordered; they are typically based on each facility's preanesthesia guidelines (delineating the age at which testing is needed) or the provider's medical judgment (relating to the patient's medical history):

- Serum enzymes, blood count, and other blood work: hemoglobin: males 14 to 18 g/dl, females 12 to 16 g/dl, elderly values slightly decreased; hematocrit: males 42% to 52%, females 37% to 47%, elderly values slightly decreased (Pagana and Pagana, 2009).
- Blood glucose: 70 to 105 mg/dl; increase in normal range after age 50 years; may be higher or lower depending on intake; critical levels are less than 50 mg/dl or more than 400 mg/dl in adult males and less than 40 mg/dl or more

FIGURE 17-8 **A**, A direct ophthalmoscope allows the eye care professional to examine the retina and optic nerve. **B**, After the eyes are dilated, an indirect ophthalmoscope provides the eye care professional with a wider view of the retina. **C**, A slit lamp, with its high magnification, allows the eye care professional to examine the front of the eye.

than 400 mg/dl in adult females. Some facilities may postpone surgery at a certain maximum level for elective cases. Urgent cases may be allowed insulin drip administration according to protocol (Pagana and Pagana, 2009).

- Serum potassium: adults, including elders: 3.5 to 5 mEq/L; critical values are less than 2.5 mEq/L or greater than 6.5 mEq/L. Some facilities may require that results were obtained within 24 hours; usually mandatory for renal failure or hemodialysis patients (Pagana and Pagana, 2009).
- Coagulation studies (prothrombin time [pro-time, PT])—for patients taking warfarin (Coumadin): 11.0 to 12.5 seconds, critical value more than 20 seconds; INR: 0.8 to 1.1, with possible critical value greater than 5.5; activated partial thromboplastin time [APTT]—for patients taking heparin: 30 to 40 seconds, critical value more than 70 seconds; desired ranges for therapeutic anticoagulation are 1.5 to 2.5 times normal, or around 70 seconds; partial thromboplastin time [PTT]—for patients taking heparin: 60 to 70 seconds, critical value more than 100 seconds. Coagulation studies may also be ordered for patients recently discontinued from taking anticoagulants (Pagana and Pagana, 2009).

Electrocardiogram and Chest X-ray Examination. In older adults, chest x-ray examination and an electrocardiogram (ECG) may be prescribed; if so, these reports should be included in the patient's record. The older adult is more predisposed to respiratory tract infection from less elastic alveoli, decreased heart size (unless there is enlargement associated with hypertension or heart disease), and ECG changes secondary to cellular alteration, conduction system fibrosis, and neurogenic changes. The physician team (surgeon, anesthesia provider) caring for the patient may determine further need for medical, pulmonary, or cardiac workup and/or clearance by a specialist. All decisions are made for safety and risk reduction according to medical judgment.

After the assessment information has been compiled, nursing diagnoses are identified and the plan of care for the entire perioperative period is developed.

Nursing Diagnosis

Nursing diagnoses related to the care of patients undergoing ophthalmic surgery might include the following:

- Deficient Knowledge or Readiness for Enhanced Knowledge related to diagnosis, surgical intervention, and home care management
- Anxiety related to vision loss, surgical intervention, awake status during surgical intervention, fear of the unknown and surgical outcome
- Disturbed Sensory Perception related to visual impairment, surgical intervention, and patching of operative eye or both eyes
- Acute and/or Chronic Pain related to increased intraocular pressure and surgical intervention
- Risk for Infection related to surgical intervention

Outcome Identification

Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient, family, or significant others will verbalize knowledge of the diagnosis, planned surgical intervention, medication management, and requirements for home care maintenance before discharge.

- The patient will verbalize an acceptable level of anxiety and use personally effective coping mechanisms.
- The patient will demonstrate ability to safely adapt to visual sensory perception disturbances.
- The patient will remain comfortable during surgical intervention as determined by response on a verbal pain scale
- The patient will be free from signs and symptoms of postoperative infection.

Planning

Plans of care are the framework for organizing activities in the perioperative period. Although ophthalmic surgery is often perceived as minor because of the small incision site and because many procedures generally are not lengthy, the perioperative nurse must be fully prepared for potential complications or emergencies (Rapid Response Team box). Patients who are admitted for ophthalmic surgery often have complex medical histories. After a review of the patient's record, supplemented by a patient or family interview or collaboration with colleagues, data collected are incorporated into an individualized perioperative plan of care. A Sample Plan of Care for a patient undergoing ophthalmic surgery can be found on p. 618.

Implementation

Managing and Monitoring Patient Safety Needs. A key aspect of the perioperative nurse's role is patient safety. Because many ophthalmic procedures are performed with local anesthesia, the circulating nurse or an additional perioperative nurse must be prepared to monitor the patient according to the *Perioperative Standards and Recommended Practices* (AORN, 2009) and provide supportive care. Reassurance is especially important for patients who are awake. Ophthalmic patients, like other surgical patients, have increased sensitivity to noise and activities within the room. The room should be kept quiet and peaceful to decrease anxiety and increase cooperation, thereby reducing the need for deep sedation.

Both the scrub person and the perioperative nurse must also manage additional patient safety needs. Foreign substances must not be introduced intraocularly. Lint-free drapes should be used to create the sterile field. If powder-free gloves are not used, gloved hands must be wiped with moistened gauze sponges to remove starch powder particles before the procedure begins. Gloved hands should not touch the portion of an instrument used in an intraocular wound, and debris should be cleansed from instruments with cellulose sponges. The entire surgical team must be knowledgeable about their roles and be prepared to function quickly in the event of a complication or emergency.

Members of the perioperative nursing team have several important responsibilities in the preparation of the room and the equipment (History box). Technologic advances in ophthalmic surgery require that perioperative nurses be familiar with equipment and check each piece carefully before the patient arrives in the OR. The availability of specially ordered implants or prostheses needs to be checked to prevent delay or cancellation of the procedure. Scrupulous attention to aseptic technique is essential in preventing endophthalmitis (infection within the eye). Safety-focused communication within the perioperative nursing team includes the following:

1. Identification: The perioperative nurse asks the patient to state his or her name and compares the name on the wristband with the name on the chart and surgical schedule while verbally confirming it with the patient or a family member. The use of two identifiers, such as birth date or medical record number, is recommended.
2. Verifications: The patient or family member should also state which eye is the operative site and which procedure is being performed. The nurse reviews the surgical consent, surgeon's preoperative orders, and OR schedule to determine if the correct operative eye has been prepared (including verification of operative eye using the word "right" or "left" [abbreviations are not accepted], marking of operative site, and dilation, if appropriate) and other procedures have

RAPID RESPONSE TEAM

The goal of a rapid response team is to intercede in a clinical situation before the patient deteriorates and requires advanced life support. The underlying principle of the rapid response team, proactive intervention, has applicability in the care of patients undergoing ophthalmic procedures.

The oculocardiac reflex (OCR) is a trigeminal-vagal response that can occur during eye surgery in response to traction on extraocular muscles, pressure on the globe, or retrobulbar block. The most common symptom of OCR is sinus bradycardia, which can lead to asystole. The patient may become hypotensive and may experience a wide range of other dysrhythmias attributable to negative inotropic and conduction effects. The incidence of OCR reported ranges from 32% to 90%; in as many as 1 in 2200 strabismus surgeries, transient cardiac arrest may ensue.

The goal in treating OCR is to prevent progression to sinus arrest, which coincides with the philosophy of the rapid response team—intervening before the patient becomes critical and requires cardiopulmonary resuscitation. Heightened awareness of the patient's overall status is imperative for safe eye surgery.

Gentle surgical technique in traction on eye muscles is one method of preventing OCR. When OCR develops and treatment is required, the surgeon should immediately stop stimulating the eye and release the traction. The surgeon may also inject lidocaine near the eye muscle in an effort to block the response. Depending on the dysrhythmia noted, the anesthesia provider may administer atropine 0.007 mg/kg IV, ensure adequate depth of anesthesia and adequate ventilation (as hypoventilation and hypercarbia significantly increase the incidence of bradycardia in strabismus surgery), and request that the surgeon stop all operative manipulation. The perioperative nurse provides supportive assistance as required by the situation. Teamwork and communication during critical times (such as during an episode of cardiac dysrhythmia) in conjunction with prevention, vigilance, and early intervention can help avoid a more urgent emergency rescue.

Modified from Donlon JV et al: Anesthesia for eye, ear, nose and throat surgery. SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Deficient Knowledge or **Readiness for Enhanced Knowledge** related to diagnosis, surgical intervention, and home care management

OUTCOME
The patient, family, or significant others will verbalize knowledge of the diagnosis, planned surgical intervention, medication management, and requirements for home care maintenance before discharge.

INTERVENTIONS
- Determine knowledge level.
- Identify barriers to communication.
- Assess readiness to learn.
- Identify psychosocial status.
- Assess coping mechanisms.
- Implement measures to provide psychologic support.
- Develop individualized plan of care.
- Evaluate psychosocial response to plan of care.
- Elicit perception of surgery.
- Encourage patient participation in decision-making and planning for postoperative care.
- Reinforce physician's explanations and clarify any misconceptions.
- Provide instructions based on age and identified needs.
- Include family members in preoperative teaching.
- Evaluate response to instructions.
- Evaluate environment for home care.
- Identify expectations of home care.
- Ensure continuity of care.

NURSING DIAGNOSIS
Anxiety related to vision loss, surgical intervention, awake status during surgical intervention, fear of the unknown and surgical outcome

OUTCOME
The patient will verbalize an acceptable level of anxiety and use personally effective coping mechanisms.

INTERVENTIONS
- Allow the patient time to verbalize concerns.
- Assist the patient in identifying sources of anxiety.
- Help the patient identify existing personal strengths and external resources; reinforce personally effective coping mechanisms.
- Offer alternative methods to minimize anxiety (e.g., music, humor).
- Encourage independence by having the patient participate in his or her plan of care; involve patient in identifying diversional activities.
- Observe for increased anxiety demonstrated through behavior (e.g., hand tremor, shakiness, restlessness, facial tension, voice quivering, increased perspiration).
- Broadly classify the patient's level of anxiety, based on nursing observation (low, moderate, high).
- Offer comfort measures (e.g., warm blankets, a pillow for under knees).
- Provide emotional support; reinforce information the patient has been previously given.
- Use touch (as appropriate) to communicate reassurance.
- Control environmental stimuli in the OR.
- Introduce staff members.
- Orient patient to environment and routines.
- Assure patient that a member of the staff is nearby.
- Provide information and answer questions honestly.
- Provide status reports to family members.

NURSING DIAGNOSIS
Disturbed Sensory Perception related to visual impairment, surgical intervention, and patching of operative eye or both eyes

OUTCOME
The patient will demonstrate ability to safely adapt to visually disturbed sensory perception.

INTERVENTIONS
- Note sensory impairments.
- Introduce self and other team members so that patient can recognize voices.
- Familiarize and orient patient to immediate surroundings; continuously reorient patient.
- Approach patient from unaffected side.
- Before discharge, review and have the patient repeat back in his or her own words safety measures to prevent falls and other injuries.
- Make referral to appropriate agency if home assistance is required.

NURSING DIAGNOSIS
Acute Pain and/or **Chronic Pain** related to increased intraocular pressure and/or surgical intervention

OUTCOME
The patient will remain comfortable during surgical intervention as determined by response on a verbal pain scale.

INTERVENTIONS
- Instruct patient to verbalize pain during procedure performed using local anesthetic or sedation; use a validated pain rating scale.
- Identify cultural and value components related to pain.
- Observe for physical signs of pain, such as facial grimacing, groaning, muscle tightening, or changes in vital signs.
- If using local anesthesia, alert physician to any patient reports of significant pain from the injection or signs of toxicity (e.g., tinnitus, tingling around the mouth).
- During procedure, make sure patient understands what is happening (e.g., stinging or pressure from local anesthetic injection) and how long it will last.
- Monitor the presence of or an increase in eye pain, pain around orbit, blurred vision, reddened eye, abdominal pain, nausea, vomiting, neurologic changes, and changes in visual fields; initiate appropriate action.
- Implement measures to provide psychologic support.
- Implement pain guidelines; administer medications as prescribed.
- Instruct the patient to refrain from excessive exertion, such as crying, coughing, straining, overlifting, bending, rubbing the eyes, and blowing the nose postoperatively.
- Discuss other methods to promote patient comfort, such as music, guided imagery, relaxation techniques.

NURSING DIAGNOSIS
Risk for Infection related to surgical intervention

OUTCOME
The patient will be free from signs and symptoms of surgical site infection.

INTERVENTIONS
- Preoperatively, document whether the patient has a preexisting infection, is immunocompromised, or has other conditions that compromise resistance to infection.
- Maintain an aseptic perioperative environment.
- Adhere to good handwashing practices.

SAMPLE PLAN OF CARE—cont'd

- Minimize length of invasive procedure by planning care.
- Initiate traffic control.
- Maintain continuous surveillance.
- Determine and record the wound classification.
- Instruct the patient and family in self-care, including postoperative antibiotic therapy if prescribed.
- Teach the patient and family to wash hands before the instillation of any ophthalmic medications.
- Instruct the patient and family to watch for redness, pain, swelling, drainage, and changes in visual acuity postoperatively and to report these problems promptly to the physician.

HISTORY

Developments in Ophthalmic Nursing as a Specialty

Journal articles from the 1960s offered perspectives from both nurses and surgeons on the perioperative nurse's role in ophthalmic surgery. Both perspectives are interesting, especially in illustrating how some attitudes have changed and other principles still remain the same.

The nursing perspective at the time emphasizes, "Our precious gift of sight oftimes is taken for granted. We give little thought to the truly wondrous gift that it is. A patient coming to the hospital, however, is acutely aware of this gift, and sight becomes a valued possession as he contemplates eye surgery. This patient temporarily entrusts in our care God's great gift to him. Unfortunately not all OR nurses enjoy assisting on eye surgery. There is a vast difference in the skills applied to ophthalmic surgery and the needed skills in general surgery.... The time and effort spent by a nurse to learn the proper approach to patient care during eye surgery can be rewarding."

"The role of the circulating nurse requires that she maintain an atmosphere of efficient, peaceful tranquility.... Extreme care must be taken in regard to the instillation of eye drops. The RIGHT drug in the RIGHT strength in the CORRECT eye is of paramount importance. The exact number of drops at the correct interval and number of times designated by the surgeon must be carefully carried out.... A good ophthalmic nurse gives herself ample time to set up [instrumentation] .... The eye is a delicate organ and everything related to the operation should be delicate and precise. Sharp points and cutting edges must be carefully handled. Perfect approximation of teeth on closing edges of the instruments is absolutely necessary. All eye instruments are precision manufactured and one has to develop a light touch in regard to their handling. Such instruments should never be tossed on top of one another, thrown together in a basin during or after the operation or in any way allowed to become entangled with one another. It is best to place instruments for sterilization in a carrier or tray that is large enough to accommodate all the instruments side by side without any overlapping."

A surgeon's perspective from the same time period states: "The fact that ophthalmic surgery differs from all other types of surgery in many ways is well established.... The adult eye patient...enters the hospital to preserve vision or restore lost vision. He is rational, awake and alert and, in many cases because of his diminished vision, peculiarly sensitive to sounds and odors that surround him.... The nurse should be familiar with the type of surgery and be knowledgeable about the local anesthesia.... A patient who is admitted for an enucleation...has a tremendous psychological problem. He knows that after surgery he will be missing an eye, which is a great loss in his mind, even though he knows that the eye is painful and blind. Many times the question of disfigurement is not discussed with the surgeon, but the patient may speak of it to the nurse. The nurse should say the removal of the eye would provide relief from pain and worry and the artificial eye will be satisfactory cosmetically.... The nurse must be acquainted with the various types of eye medications and their actions and the more common surgical procedures, so that she can function more intelligently and efficiently. A well informed nurse can explain the reasons for the medications and the procedures which are experienced by the patient.... The following should be checked prior to surgery: ...(very important again) the eye to be operated.... An operating room which is noisy and in which the personnel are inordinately garrulous is a very disturbing and tension-producing area for the eye patient who is under sedation. If he cannot doze quietly and is wakened fitfully with a start, he is not well-prepared for the operation. The patient should be kept quiet until the time for his positioning in the operating room...quiet and decorum should be maintained in the operating room...the circulating nurse should assist the surgeon in getting the appropriate medications and treatments accomplished rapidly. The equipment used in ophthalmic surgery has recently become much more sophisticated. New instrumentation includes laser units, operating microscopes with camera or television attachments, light coagulator, etc. All equipment should be tested prior to surgery. The door to the operating room should be kept closed and the surgeon should not be disturbed during the procedure. During a moment which is not critical, messages may be given.... The surgeon's entire attention at this point is directed to the area enclosed by the drape. The assistant is responsible for giving instructions to the scrub nurse who will then transmit those that are appropriate to the ever-attentive and constantly present circulating nurse.... The paperwork should have been done during the surgery by the circulating nurse so that at the end of the procedure the surgeon need only sign the various forms.... Nurses who are interested in this specialty and who have gained experience in the field will perform much more effectively than those who have only general nursing experience.... Intraocular infection is so devastating that infected cases should never be done in such a room. The highest peak of efficiency is reached when a team has been assigned to the eye service alone and can anticipate the needs of ophthalmic surgeons."

Modified from Ballen PH: Ophthalmic surgery: the nurse's role, *AORN J* 8:35-38, 1967; Rogers C: Nursing skills in ophthalmic surgery, *AORN J* 8:39-45, 1967.

been carried out according to facility policies on correct-site surgery. Such a policy may require that, before the administration of eyedrops or medication, the nurse asks the awake patient which eye is the operative site. If there is any discrepancy among the patient's response, the informed consent, the physician's orders, ophthalmic history, and exam, the discrepancy is corrected during the preoperative verification process. Immediately before the incision, this information, along with any implants or special needs, is reconfirmed during the time-out (Menke, 2008).

Safety Measures in Administering Medications. Medications used in the perioperative period are extremely important to the outcome of the procedure and the safety of the patient. Drugs for diagnosing and treating eye disorders are potent. One error could result in total, irreversible blindness.

The patient's medical and ocular histories determine the selection of an appropriate ophthalmic agent. The perioperative nurse should be knowledgeable about the specific medication ordered, including purpose, strength, action, duration, adverse reactions, route of administration, and contraindications. This information should be included in the patient's initial assessment. For example, mydriatic and cycloplegic eyedrops may be contraindicated in narrow-angle glaucoma.

The nurse checks the medication label for name, strength, and expiration date during preparation and before medication administration. This precaution is especially important because many ophthalmic drugs are distributed in single-dose units that closely resemble one another. The patient must be positively identified, and the site of the administration must be clearly translated from the physician's orders. Abbreviations should not be used. The words "right eye," "left eye," or "both eyes" should be used in writing orders. Handwashing between patients when administering eyedrops is imperative, and Standard Precautions should be followed. The nurse ensures that intraocular solutions are separated from those not used intraocularly.

All solutions on and off the sterile field must be clearly labeled. To meet The Joint Commission's *2009 National Patient Safety Goals,* medications in a procedural setting must have labels that include drug name, strength/concentration, and amount (TJC, 2009). Medication errors are the most common medical errors. Compliance with requirements can be an issue. One facility found that staff are more likely to label medications when preprinted labels are provided (Jennings and Foster, 2007). Preprinted labels are commercially available. Sterile waterproof pens and labels are also available to avoid smearing from liquids.

Instillation of Eyedrops. Before administering eyedrops, the perioperative nurse should perform hand hygiene. The patient may be supine or sitting, with the head tilted back slightly. The nurse instructs the patient to look upward and then gently pulls the lower eyelid open to expose the lower conjunctival sac (Figure 17-9). The prescribed number of drops is then administered without touching the tip of the dropper to the eye or the nurse's fingers. The natural blinking of the lids distributes the drug evenly onto the eye surface. When anesthetic eyedrops are instilled for topical anesthesia, they are placed on the cornea.

To minimize systemic absorption of certain eyedrops, such as atropine, the nurse may instruct the patient to press on the nasolacrimal duct for 1 minute to prevent absorption into the circulatory system. When a toxic drug is instilled, the nurse uses a tissue or clean cotton ball to dry the inner corners of the patient's eyelids after each drop to minimize systemic absorption of the drug.

The nurse provides teaching about the expected effect of each medication so the patient is able to evaluate its effectiveness, detect signs and symptoms of adverse reactions, and know when to notify the perioperative personnel concerning problems. The patient should also be well-informed of the special considerations associated with specific medications so that appropriate safety precautions can be taken.

FIGURE 17-9 An eye care professional applies eyedrops to dilate a patient's pupils.

Ophthalmic Pharmacology. Numerous medications are used during ophthalmic surgery. See the Surgical Pharmacology table on pp. 621-623 for the purpose and description of each.

Anesthesia

GENERAL ANESTHESIA. Youth, deafness, language barriers, dementia, severe anxiety, specific systemic diseases, known sensitivity to local anesthetics, potential of blood entering the airway (such as in tear duct procedures), and long duration of the operative procedure are among the conditions that may dictate use of general anesthesia.

LOCAL ANESTHESIA. Local anesthesia or monitored anesthesia care (MAC) is used for most eye surgery. Consideration must be given to the patient's age, systemic condition, and discharge plan in determining whether to use preoperative sedation, such as sublingual or oral midazolam hydrochloride (Versed). Intraoperative sedation, when indicated, may be prescribed and managed by either the anesthesia provider or the surgeon. The perioperative nurse, however, is often accountable for monitoring the patient's response to the sedation and the local anesthetic in the perioperative period.

The perioperative nurse assembles the sterile local anesthesia setup as required by the surgeon before the patient enters the OR, checking to ensure correct medications, proper concentrations and dosages, and appropriate sizes and gauges of needles and syringes. Local anesthetics should not be mixed far in advance of the time of intended use, because they may deteriorate, producing a reduced effect for the patient. The addition of epinephrine prolongs the duration of action of most local anesthetics and the vasoconstrictive effect can reduce bleeding, often present in eyelid procedures.

Administration Methods of Local Anesthesia. The *topical method* of local anesthesia has gained popularity for cataract-extraction procedures. A combination of anesthetic eyedrops

SURGICAL PHARMACOLOGY

Medications Used During Ophthalmic Surgery

Drug/Name	Purpose/Description
MYDRIATICS	
Phenylephrine (Neo-Synephrine, Mydfrin), 2.5%, 10%	Mydriasis (dilates pupil but permits focusing); used for objective examination of retina, testing of refraction, easier removal of lens; used alone or with a cycloplegic
CYCLOPLEGICS	
Tropicamide (Mydriacyl), 0.5%, 1%	Cycloplegia (paralysis of accommodation; inhibits focusing); dilates pupil; anticholinergic, used for examination of fundus, refraction
Atropine, 1%	Anticholinergic, dilates pupil, inhibits focusing; potent, long duration (7-14 days)
Cyclopentolate (Cyclogyl), 0.5%, 1%, 2%	Anticholinergic, dilates pupil, inhibits focusing
Scopolamine hydrobromide (Isopto Hyoscine), 0.25%	Anticholinergic, dilates pupil, inhibits focusing
Homatropine hydrobromide (Isopto Homatropine), 2%, 5%	Anticholinergic, dilates pupil, inhibits focusing
Epinephrine (1:1000) preservative free (PF)	Dilates pupil; added to bottles of balanced salt solution for irrigation to maintain pupil dilation during cataract or vitrectomy procedure
MIOTICS	
Carbachol (Miostat), 0.01%	Potent cholinergic, constricts pupil, used intraocularly during anterior segment surgery
Carbachol (Isopto Carbachol), 0.75%, 1.5%, 2.25%, 3%	Potent cholinergic, constricts pupil, used topically for lowering intraocular pressure in glaucoma
Acetylcholine chloride (Miochol-E), 1%	Cholinergic, rapidly constricts pupil, used intraocularly during anterior segment surgery; reconstitute immediately before using
Pilocarpine hydrochloride, 1%, 4%	Cholinergic, constricts pupil, used topically for lowering intraocular pressure in glaucoma
TOPICAL ANESTHETICS	
Tetracaine hydrochloride (Pontocaine), 0.5%	*Onset:* 5-20 sec; *duration of action:* 10-20 min
Proparacaine hydrochloride (Ophthaine), 0.5%	*Onset:* 5-20 sec; *duration of action:* 10-20 min
INJECTABLE ANESTHETICS	
Lidocaine (Xylocaine), Lidocaine MPF,* 1%, 2%, 4%	*Onset:* 4-6 min; *duration of action:* 40-60 min, 120 min with epinephrine; MPF solution is preservative free
Bupivacaine (Marcaine, Sensorcaine), Bupivicane MPF, 0.25%, 0.50%, 0.75%	*Onset:* 5-11 min; *duration of action:* 480-720 min with epinephrine; often used in 0.75% combination with lidocaine for blocks; MPF solution is preservative free
Mepivacaine (Carbocaine), 1%, 2%	*Onset:* 3-5 min; *duration of action:* 120 min; duration of action greater with epinephrine
Etidocaine (Duranest), 1%	*Onset:* 3 min; *duration of action:* 300-600 min
ADDITIVES TO LOCAL ANESTHETICS	
Epinephrine 1:50,000-1:200,000	Combined with injectable local anesthetics to prolong anesthesia and reduce bleeding
Hyaluronidase	Enzyme mixed with anesthetics (75 units/10 ml) to increase diffusion of anesthetic through tissue, improving effectiveness of block; contraindicated if skin inflammation or malignancy present
VISCOELASTICS	
Sodium hyaluronate (Healon, Amvisc, Provisc, Vitrax) in a sterile syringe assembly with blunt-tipped cannula	Lubricant and support; maintains separation between tissues to protect endothelium and maintain anterior chamber intraocularly; removed from anterior chamber to prevent postoperative increase in pressure; should be refrigerated (except Vitrax); allow 30 min to warm to room temperature
Sodium chondroitin/sodium hyaluronate (VisCoat) in a sterile syringe assembly with blunt-tipped cannula	Maintains a deep chamber for anterior segment procedures, protects epithelium of cornea, and enhances visualization; may be used to coat intraocular lens before implantation; should be refrigerated
DuoVisc	Packages of separate syringes of Provisc and VisCoat in same box
VISCOADHERENTS	
Hydroxypropyl methylcellulose 2% (Occucoat) in a sterile syringe assembly with blunt-tipped cannula	Maintains a deep chamber for anterior segment procedures, protects epithelium of cornea, and may be used to coat intraocular lens before implantation; removed from anterior chamber at end of procedure; stored at room temperature
Hydroxyethylcellulose (Gonioscopic Prism Solution); Hydroxypropyl methylcellulose 2.5% (Goniosol)	Used as coupling solution for gonioscopy; stored at room temperature

SURGICAL PHARMACOLOGY

Medications Used During Ophthalmic Surgery—cont'd

Drug/Name	Purpose/Description
IRRIGANTS	
Balanced salt solution (BSS, Endosol)	Used to keep cornea moist during surgery; also used as internal irrigant into anterior or posterior segment
Balanced salt solution enriched with bicarbonate, dextrose, and glutathione (BSS Plus, Endosol Extra)	Used as internal irrigant into anterior or posterior segment; need to reconstitute immediately before use by addition of part I to part II with transfer device
HYPEROSMOTIC AGENTS	
Mannitol (Osmitrol)	Intravenous osmotic diuretic; increases osmolarity of plasma, causing osmotic pressure gradient to pull free fluid from eye to plasma, and reduces intraocular pressure
Glycerin (Osmoglyn, Glyrol)	Oral osmotic diuretic given in chilled juice or cola; increases osmolarity of plasma, causing osmotic pressure gradient to pull free fluid from eye to plasma, and reduces intraocular pressure
ANTIINFLAMMATORY AGENTS	
Betamethasone sodium phosphate and betamethasone acetate suspension (Celestone)	Glucocorticoid; injected subconjunctivally after surgery for inflammation prophylaxis; also used to treat severe allergic and inflammatory conditions
Dexamethasone (Decadron)	Adrenocortical steroid; injected subconjunctivally after surgery for inflammation prophylaxis; also used to treat severe allergic and inflammatory conditions and intraocularly for endophthalmitis
Methylprednisolone acetate suspension (Depo-Medrol)	Glucocorticoid; injected subconjunctivally after surgery for inflammation prophylaxis; also used to treat severe allergic and inflammatory conditions
ANTIINFECTIVES	
Polymyxin B/bacitracin (Polysporin ointment)	Topical treatment of superficial ocular infections of conjunctiva or cornea; used prophylactically after surgery
Polymyxin B/neomycin/bacitracin (Neosporin ointment)	Topical treatment of superficial infections of external eye; used prophylactically after surgery; potential hypersensitivity to neomycin
Neomycin and polymyxin B sulfates and dexamethasone (Maxitrol ointment or suspension)	Topical treatment of steroid-responsive inflammatory ocular conditions or bacterial infections of external eye; potential hypersensitivity to neomycin
Tobramycin/dexamethasone (TobraDex)	Topical treatment or prevention of superficial infections of external part of eye; also has antiinflammatory properties
Cefazolin (Ancef, Kefzol)	Prophylactically injected subconjunctivally after procedure; also topically, intraocularly, and systemically for endophthalmitis
Gentamicin sulfate (Garamycin)	Prophylactically injected subconjunctivally after procedure; also topically, subconjunctivally, and intraocularly for endophthalmitis
Ceftazidime (Fortaz, Tazicef, Tazidime)	Injected subconjunctivally and intraocularly for treatment of endophthalmitis
MISCELLANEOUS	
Cocaine, 1%-4%	Topical use, never injected; used on cornea to loosen epithelium before debridement and on nasal packing to reduce congestion of mucosa
5-Fluorouracil (5-FU)	Antimetabolite used topically to inhibit scar formation in glaucoma-filtering procedures; handle and discard in compliance with Occupational Safety and Health Administration (OSHA) and facility policies for safe use of antineoplastics
Mitomycin (Mutamycin)	Antimetabolite used topically to inhibit scar formation in glaucoma-filtering procedures and pterygium excision; handle and discard in compliance with OSHA and facility policies for safe use of antineoplastics
Tissue plasminogen activator (TPA) (Activase)	Thrombolytic agent; used to treat fibrin formation in postvitrectomy patients; lysis of clots on retina
Fluorescein	Yellowish-green fluorescence of this IV diagnostic aid is used in fluorescein angiography to diagnose retinal disorder; topical stain—fluorescein strip temporarily stains cornea yellow-green in areas of denuded corneal epithelium

SURGICAL PHARMACOLOGY

Medications Used During Ophthalmic Surgery—cont'd

Drug/Name	Purpose/Description
Timolol maleate (Timoptic)	Beta-adrenergic receptor blocking agent; treatment of elevated intraocular pressure in ocular hypertension or open-angle glaucoma
Acetazolamide sodium (Diamox)	Carbonic anhydrase inhibitor; given IV to decrease secretion of aqueous humor and results in a drop in intraocular pressure; diuretic effect

**MPF,* Methylparaben free.

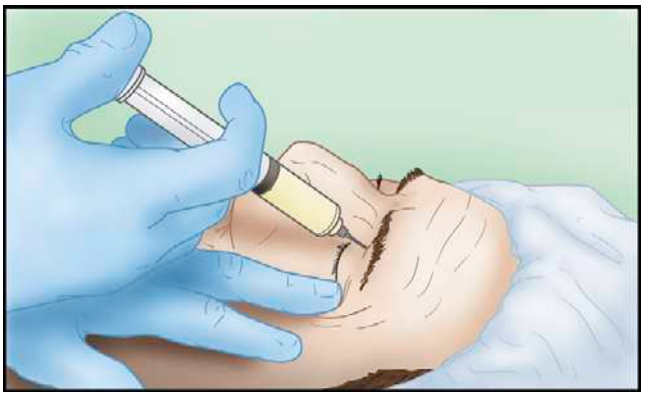

FIGURE 17-10 Peribulbar block.

is instilled into the eye and may be supplemented with infiltration of preservative-free anesthetic into the anterior chamber. Selection of patients for the topical method requires that they can cooperate and follow verbal commands to keep their eyes open and look up or down. Conditions that render the patient a poor candidate for topical anesthesia include inability to tolerate eyedrops, Alzheimer's disease, extreme anxiety, and communication problems (e.g., language barriers, hearing impairment, auditory aphasia).

The *infiltration method* involves the surgeon injecting the anesthetic solution beneath the skin, beneath the conjunctiva (subconjunctival), or into Tenon's capsule, depending on the type of surgery.

The most common technique for regional anesthesia in eye surgery is a *peribulbar block*. The anesthetic is injected around the soft tissue of the globe after the needle is directed to the floor (inferior) or roof (superior) of the orbit (Figure 17-10).

Retrobulbar block is injection of anesthetic solution into the base of the eyelids at the level of the orbital margins or behind the eyeball to block the ciliary ganglion and nerves (Figure 17-11). The surgeon administers the retrobulbar injection 10 to 15 minutes before surgery to produce temporary paralysis of the extraocular muscles. Since the tip of the needle cannot be visualized, training and experience are key. Potential complications of retrobulbar injection are brainstem anesthesia and death, oculocardiac reflex, perforation of the globe, and retrobulbar hemorrhage (Bollinger and Langston, 2008). Additional risks include ptosis, conjunctival or eyelid bruising, optic nerve damage, and central vein and artery occlusion.

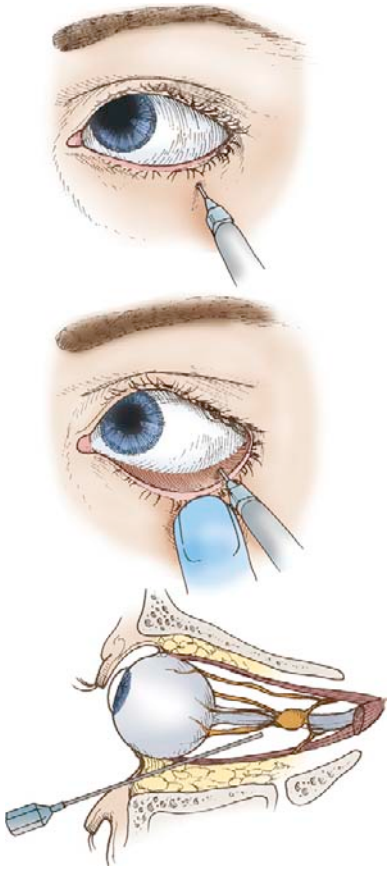

FIGURE 17-11 Retrobulbar block.

A systematic review found no evidence of difference in pain perception in surgery with retrobulbar or peribulbar anesthesia; both were largely effective. Similarly, the review found no evidence of difference in complete akinesia or need for further injections of the local anesthetic. Retrobulbar hemorrhage was uncommon; severe local or systemic complications were rare in both approaches. Overall, retrobulbar and peribulbar anesthesia were found to be equal in efficacy and safety, including acceptability to patients (Alhassan et al, 2008).

For eyelid repairs, the surgeon injects the solution through the upper or lower lid. For operations on the lacrimal apparatus, the anesthetic is injected at the level of the anterior ethmoidal

foramen to anesthetize the internal and external nasal nerves. Injection of local anesthetic into the lateral adipose compartment from an inferior temporal needle insertion blocks the nasociliary, lacrimal, frontal, supraorbital, and supratrochlear branches of the ophthalmic division of the trigeminal nerve and infraorbital branch of the maxillary division; this may be used before retrobulbar block.

Positioning. Positioning the patient for ophthalmic surgery generally requires additional devices for stabilizing the head, protecting bony prominences, and providing appropriate alignment to prevent peripheral neurovascular injury. The ophthalmology stretcher, which is a combination transport device and OR bed, is often used for convenience and comfort as the surgical bed. This special bed, with a tapered head end, allows for closer access to the patient's face and eliminates several transfers for the patient. The perioperative nurse positions the patient with a foam donut or headrest under the head and a pillow under the knees. The nurse tucks the patient's arms at the side, padding the elbows to protect the ulnar nerve, facing the palms inward and maintaining the wrists in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail.

If patients are to be sedated, the nurse asks if they are comfortable and offers reassurance that there are ways to increase comfort. Some elderly patients prefer not to discuss their discomfort for fear of being bothersome.

Intraocular surgery is usually carried out with the use of a microscope. A special wrist rest may be used to stabilize the surgeon's hands and may include a perforated tubing or bar to provide oxygen under the drapes. The nurse should attach it to the bed and secure it approximately 2.5 cm below the patient's lateral canthus before draping. The wrist rest may be placed unilaterally or may encircle the head. A strip of tape may be placed over the patient's forehead (avoiding the eyebrows) and secured to the operative bed to stabilize the head.

Prepping. The operative site is prepped under aseptic conditions, usually after the anesthetic is administered. A sterile prep tray commonly contains sterile normal saline solution, irrigation bulb, basins, gauze sponges, cotton-tipped applicators, towels, and antimicrobial skin disinfectant.

Some surgeons order one or two drops of 5% povidone-iodine solution administered to the eye surface before the prep of the face and eyelids to decrease the number of surface microbes. Unless the patient has been administered a general anesthetic, a topical anesthetic drop is placed to minimize the stinging sensation. Povidone-iodine solution may be contraindicated in patients with allergic reactions to *topical* iodine. For these patients, hexachlorophene can be used as the agent for the facial prep; however, it is not applied directly to the ocular surface because of its surface toxicity.

The nurse cleans the patient's lid margins by everting the lids and cleaning with cotton-tipped applicators moistened with antimicrobial skin disinfectant, taking care to prevent the solution from entering the patient's ears. The eye or eyes may be then irrigated with normal saline solution using an irrigating bulb. When toxic chemicals or small particles of foreign matter must be removed, the eye surface and conjunctival sac are thoroughly flushed with tepid sterile normal saline solution using an irrigation bulb or an Asepto syringe. The nurse dries the prep area so the drape will adhere.

Draping. Special concerns for eye surgery draping include repelling water, eliminating lint and fiber particles, and providing adequate air exchange for patients receiving local anesthetics. A cardboard bridge that adheres to the sides of the patient's face may be used to support the drape above the patient's mouth and nose. The surgeon may request that the nurse place a Mayo stand above the patient before the draping process to provide a platform to decrease the weight of the drapes and surgical handpieces/tubing on the patient. The use of a one-piece disposable drape, with a self-adherent, fenestrated plastic section for the eye, eliminates the need to lift the patient's head during draping and facilitates drape removal at the end of the procedure. The eyelids may be separated when applying the self-adherent plastic eye drape to keep the eyelashes out of the operative eye. A fluid drainage bag with wicking strip may also be adhered to the plastic eye drape.

In an alternative method, the surgeon may drape the head with a half-sheet and two towels, use a large sheet or U-drape/split sheet to cover the patient and OR bed, and place a fenestrated plastic eye drape over the operative site.

Instrumentation. Basic eye instruments are shown in Figure 17-12. Additional instruments, depending on the type of procedure, can be added to the basic instrument set. Special surface finishes are used to reduce light reflection. Instruments are designed with round handles for smoother motion and rotation under the microscope. The instruments to be placed on the Mayo stand and the order of their use can also be listed on the preference card or computerized picklist.

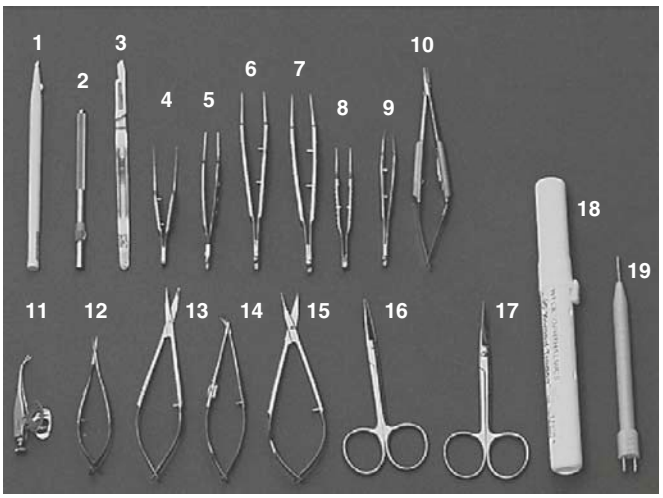

FIGURE 17-12 Basic eye instrument setup. *1,* Super blade (disposable); *2,* Beaver knife handle; *3,* #9 Bard-Parker knife handle; *4,* Colibri corneal forceps; *5,* Bishop-Harmon suturing forceps; *6,* Castroviejo suturing forceps, 0.5 mm; *7,* Castroviejo suturing forceps, 0.12 mm; *8,* Castroviejo tying forceps; *9,* Kelman-McPherson suturing forceps; *10,* Harper needle holder; *11,* Barraquer iris scissors; *12,* Vannas iridocapsulotomy scissors; *13,* Westcott tenotomy scissors; *14,* Castroviejo corneal scissors; *15,* Westcott stitch scissors; *16,* Knapp strabismus scissors; *17,* iris scissors; *18,* eye electrosurgical unit, disposable; *19,* bipolar eraser-tip eye electrosurgical unit, disposable.

A variety of ophthalmic forceps are designed for specific use with different tissues of the eye. Fixation forceps, used to hold tissue firmly in place or provide traction before incision, have an angled tooth that overlaps for secure fixation. Suturing forceps, used to pick up wound edges for dissection or suturing, are single-toothed forceps with the tooth at a right angle to the shank of the forceps. Tying forceps have a flat platform for holding suture as it is tied. The tips of the most commonly used forceps are illustrated in Figure 17-13.

CARE AND HANDLING. To maintain the quality and precision of all ophthalmic instruments, including microsurgical instruments, strict criteria for care and handling must be followed. Storage cases protect instrument tips and cutting surfaces. The instruments should be inspected under magnification when purchased and before and after each use, observing for burrs on tips, nicks on cutting surfaces, and alignment of jaws. Eye instruments should be cleaned during use with nonfibrous sponges to avoid damaging delicate instrument tips. Personnel handling instruments should know the name and purpose of each instrument. Tissue can be damaged by the use of an inappropriate instrument, and instruments can be damaged by inappropriate use. After use, the instruments should be cleaned, thoroughly dried, and terminally sterilized before storage in protective containers. A broader and more rigorous look at the entire flash sterilization process—from cleaning, decontaminating, and sterilizing to transporting—is found in The Joint Commission's focus on optimal patient outcomes. This coincides with the *AORN Perioperative Standards and Recommended Practices* (AORN, 2009) in that "flashing or abbreviated cycles should not be performed for convenience, as an alternative to purchasing additional instrument sets or to save time" (Mitchell, 2009).

It is recommended that microsurgical instruments undergo ultrasonic cleaning with distilled water and an appropriate enzymatic cleansing agent. They can be individually handheld or immersed together in the ultrasonic cleaner as long as they are not touching each other. Instruments should be rinsed with distilled water and thoroughly dried. A hot air blower (never a towel) should be used for drying instruments. Instrument lubricant should not be used on irrigating cannulae because residue can be introduced into the eye and cause damage (Risk Reduction Strategies).

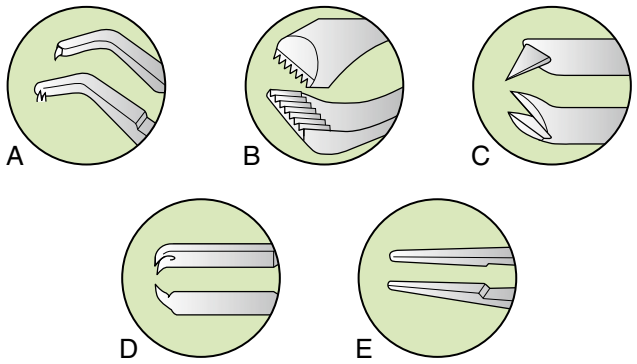

FIGURE 17-13 Close-up of tips of micro instruments used in phacoemulsification procedures and for inserting intraocular lenses (IOLs). **A**, Colibri forceps. **B** and **C**, Fixation forceps. **D**, Suturing forceps. **E**, Tying forceps.

In addition to basic care and handling, a routine preventive maintenance program should be established for sharpening, realigning, and adjusting the precision eye instruments. Keeping an instrument in good repair is much less expensive than buying a new one. Disposable instruments (Figure 17-14) are becoming popular with surgeons because of accessibility and quality assurance; for example, forceps are properly aligned for each use because they have not been used on other procedures. Benefits for the institution include elimination of costs related to repairs. Knives are available that have safety features of retractable blades to be in compliance with the Needlestick Safety and Prevention Act, requiring implementation of safer medical devices to minimize occupational exposure to bloodborne pathogens from accidental sharps injuries, which remains a serious problem (Harris, 2008).

RANGE OF EQUIPMENT USED. A wide range of equipment is used in ophthalmic surgery. The perioperative team's knowledge of proper functioning and troubleshooting should be confirmed through inservice education and training specific to new equipment. For safety, all items must be used according to the manufacturer's directions and tested for proper performance before the patient enters the OR. Although the products and manufacturers may vary, the following are some of the typical pieces of equipment and accessories used in ophthalmic surgeries:

- *Phacoemulsification machines:* Similar to the action of a jackhammer, these machines use ultrasound to break up the cataract. Irrigation and aspiration ("I&A") handpieces are used as well. Bipolar electrosurgical unit (ESU) and anterior vitrectomy handpieces may also be attached when needed. The surgeon controls the foot pedal and chooses one of the following modes by depressing the pedal to a certain position: irrigation alone; irrigation and aspiration; and irrigation, aspiration, and phacoemulsification combined. Some machines also have an anterior vitrector. As the surgeon manipulates the handpiece and operates the foot pedal to emulsify the lens nucleus, the perioperative nurse is responsible for monitoring the function of the instrument and operating the console controls to change settings such as irrigation bottle height. Displays may show cumulative density of energy and other settings, even video input of the procedure.
- *Posterior vitrectomy machines:* Functions on these machines may include vitrectomy with cutter handpieces for removal of vitreous; extrusion for gentle aspiration near sensitive retina and macula; oil infusion; bipolar electrosurgery/diathermy;

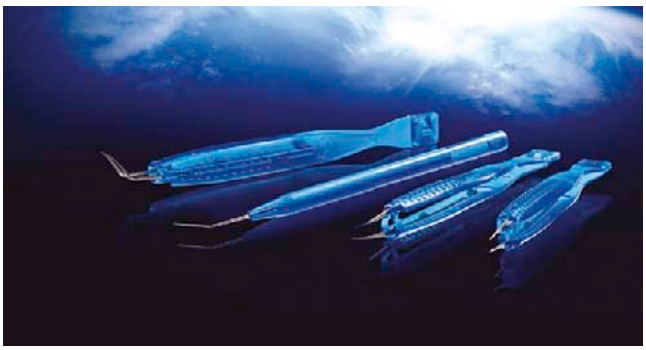

FIGURE 17-14 Disposable ophthalmic (cataract) instruments.

RISK REDUCTION STRATEGIES

Prevention of Toxic Anterior Segment Syndrome

Toxic anterior segment syndrome (TASS), also known as sterile endophthalmitis, is a sterile noninfectious form of acute inflammation that occurs after eye surgery (typically cataract surgery). The onset of the syndrome typically begins within 24 hours after surgery and is characterized by decreased vision, significant corneal edema, and moderate to severe inflammation in the anterior chamber of the eye. Patients may report blurred vision, eye pain, and eye redness. The cornea is most often affected by TASS because the corneal epithelium is the most sensitive tissue in the anterior chamber. Complications of TASS may include permanent iris damage, in which the pupil does not dilate or constrict appropriately, or ocular hypertension or glaucoma. Overall, TASS can be a very serious and sight-threatening condition.

TASS is thought to be a response to the introduction of a noninfectious, toxic substance into the anterior segment of the eye during surgery. Substances that have been implicated include irrigating solutions and other agents such as anesthetics and antibiotics. TASS may also be related to the improper cleaning or sterilization of instruments.

The perioperative nurse plays a key role in implementing risk reduction strategies for TASS, not only in prevention through the vigilant implementation of recommended practices for the use, cleaning, disinfection, and sterilization of equipment and instrumentation, but also in the provision of effective patient education. Timing is critical with TASS, and treatment must be initiated quickly to prevent permanent damage; therefore the perioperative nurse must ensure that discharge instructions for the patient include a directive to contact the surgeon immediately at the first indication of visual disturbance, no matter how mild.

Members of professional organizations (including cataract surgeons and ophthalmic and surgical nurses), infection control personnel, manufacturers of cataract surgical instruments, the Centers for Disease Control and Prevention (CDC), and the U.S. Food and Drug Administration have provided the following recommendations for the prevention of TASS:

- Basic principles for cleaning and sterilization must be followed to prevent TASS.
- Manufacturer directions for use should be followed. For example, directions for use of many intraocular instruments require or recommend sterile distilled or sterile deionized water for most cleaning steps. Sterile distilled or sterile deionized water is required for final rinsing. Rinsing serves the purpose of removing all cleaning solutions along with debris loosened during the cleaning process. (NOTE: Agitation in a basin of water is not considered a final rinse.)
- Manufacturer recommendations for sterilizer maintenance must be followed.
- All steps of cleaning and sterilization should be completed; adequate time should be allotted for the task.
- Sufficient numbers of instrument sets (including phacoemulsification, irrigation and aspiration handpieces, and lens inserters) should be available to allow sufficient time for cleaning and sterilization between procedures.
- Precise measurements of water and detergent should be used in mixing cleaning solutions.
- Disposable cannulae and tubing should be used if possible and discarded after use.
- Instruments used in the eye should be cleaned separately from nonophthalmic surgical instruments.
- Ultrasonic cleaning machines must be emptied, cleaned, disinfected, rinsed, and dried daily at minimum, but preferably after each use.
- Cleaning tools (e.g., syringes, brushes) should be discarded after each use.
- Cleaning solutions should be discarded after each use.
- Rinse water flushed through an instrument should be discarded and not reused.
- Only lint-free materials should be used in cleaning/drying and on the sterile field.
- Surgeons should check instruments under the microscope before use and reject any with notable debris or defect.
- The minimum interval for verifying quality of water used in a facility's steam sterilizing system is yearly.
- Staff involved in the cleaning and sterilization process of ophthalmic instruments should undergo competency testing and performance evaluation through direct observation and with a competency checklist so that all staff are evaluated consistently.
- Each healthcare facility should develop and write specific procedures for instrument cleaning and sterilization.

Modified from American Society of Cataract and Refractive Surgery, Ad Hoc Task Force on Cleaning and Sterilization of Intraocular Instruments: *ASCRS, ASORN Special Report: Recommended practices for cleaning and sterilizing intraocular surgical instruments,* Fairfax, Va, 2007, Author; Conner RL: Clinical issues: Toxic anterior segment syndrome, *AORN J* 84(5):841-844, 2006; Forster DJ: Phacogenic uveitis. In Yanoff M, Duker JS, editors: *Yanoff & Duker: Ophthalmology,* ed 4, St Louis, 2008, Mosby; Johnston J: Toxic anterior segment syndrome—more than sterility meets the eye, *AORN J* 84(6):969-984, 2006.

and motorized cutting with electric scissors attachment. Foot pedal or manual control can set eye pressure and cut and suction rates.

- *Cryotherapy machine:* The cryotherapy machine is generally used to cause an inflammatory reaction in the retinal tissue that seals a break or tear. The unit uses nitrous oxide as the freezing agent. Adequate pressure settings are needed for acceptable levels of freeze. Either external or intraocular handpieces are available.
- *Lasers:* Lasers are used for various applications in eye procedures, whether for clearing an opacified posterior capsule after cataract surgery, for reshaping or creating a flap of the cornea, or for direct use inside the eye during posterior vitrectomy. Settings must be confirmed with the surgeon. All persons present in the OR when the laser is in use must wear appropriate protective eyewear according to the laser's wavelength. Warning signs are posted on doors and windows are covered to avoid scatter outside the room.
- *ESU units:* Bipolar or monopolar ESU may be used. The return electrode monitor placement must follow manufacturer guidelines. Fire precautions must be observed, especially in the presence of oxygen.
- *Operating microscope:* Proper care and maintenance of the operating microscope are essential to ensure optimal functioning and durability of this sophisticated, expensive piece of equipment typically used for intraocular procedures (Figure 17-15). The perioperative nurse must be familiar with how to adjust pupillary distance (PD—distance between pupils

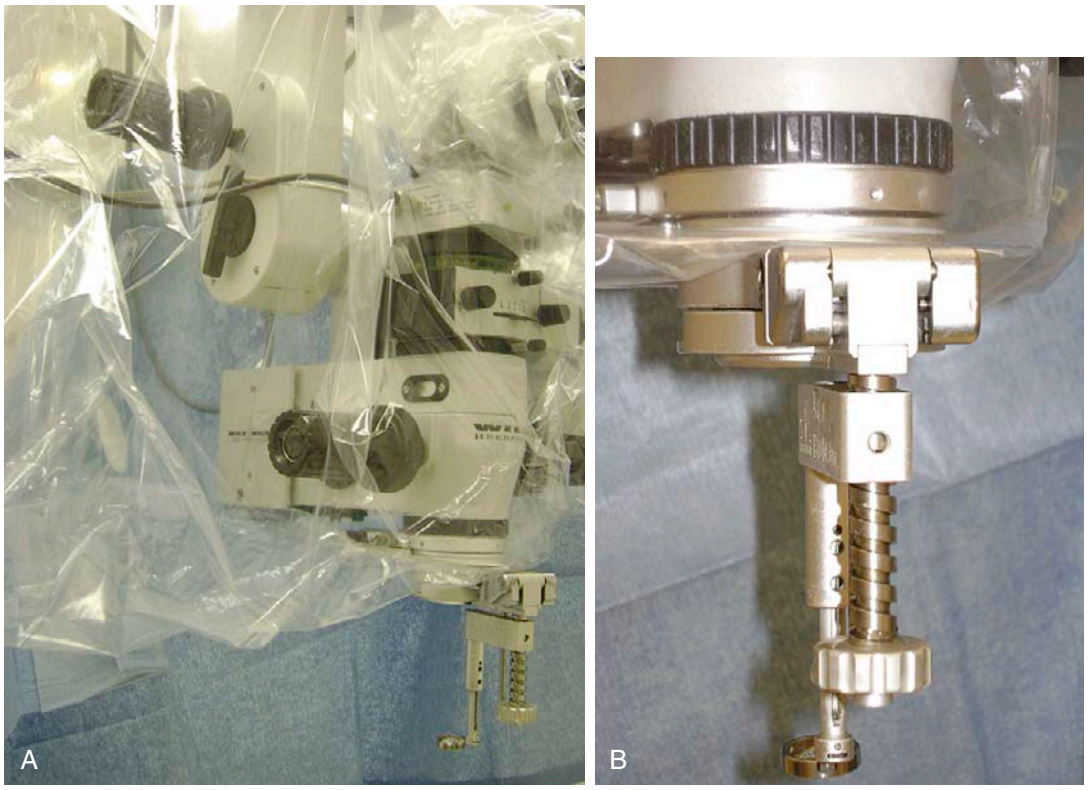

FIGURE 17-15 **A**, Draped microscope with attachment for wide-angle view inside the eye. **B**, Close-up of wide-angle attachment that can swing out of the way to use contact lens on eye.

FIGURE 17-16 Oculars of microscope set for surgeon's pupillary distance and diopter adjustments for clear viewing.

of the user's eyes) and diopter settings on the oculars (eyepieces) for operator vision correction to work without eyeglasses (Figure 17-16). Users who have astigmatism should wear their eyeglasses and set the oculars at zero. Some microscopes used for other applications such as plastic surgery may utilize light sources that are so bright they can damage the retina. The nurse must ensure that the microscope used in ophthalmic surgery is specifically intended and safe for use in eye surgery.

FIGURE 17-17 A patient wearing a protective eye patch.

Ophthalmic Sutures. Sutures used in ophthalmic surgery are very fine and range in size from 4-0 to 10-0. Handling and arming these sutures can be a challenge for the perioperative nurse with uncorrected presbyopia. Fine eye sutures produce minimum reaction and discomfort for the patient. They should be handled as little as possible to avoid weakening and fraying. Ophthalmic needles also are very delicate and must be handled with extreme care and inspected for evidence of burrs before use.

Ophthalmic Dressings. At the completion of the operation, the operative eye area is cleansed with saline sponges. After plastic procedures on the lids or lacrimal ducts, antibiotic

ointment may be thinly spread over the skin and eyelashes to prevent adhesion of the bandage.

The initial dressing is a sterile eye pad secured with nonallergenic tape (Figure 17-17). After intraocular operations, when external pressure on the eyes might be harmful, the initial dressing is covered with a protecting, perforated aluminum plate or plastic eye shield. Postcataract dressings range from traditional eye pads, to collagen corneal shields rehydrated in an antiinfective-antiinflammatory solution, to no dressing at all. A pressure bandage, consisting of a folded eye patch covered with a second single-layer eye patch, may be used when a compression effect is desired.

Evaluation

The nurse evaluates the patient's general condition before transport to the postanesthesia care unit (PACU) or observation unit. The general appearance of the skin is assessed, with areas around the face and bony prominences noted for redness or other changes from the preoperative condition.

A hand-off report to the receiving nurse in the PACU or observation area should include postoperative positioning requirements, potential problems specific to the patient, and preoperative anxiety level and use of coping mechanisms. Eye patching may produce disturbed sensory perception.

Evaluation should address whether the patient met the desired perioperative nursing outcomes; the patient's responses may be documented as outcome statements. The following examples are based on the nursing diagnoses identified in the plan of care:

- The patient, family, or significant others verbalized knowledge regarding the diagnosis, planned intervention, medication management, and requirements for home care maintenance.
- The patient verbalized an acceptable level of anxiety and used coping mechanisms that were effective.
- The patient safely adapted to visually disturbed sensory perception.
- The patient remained comfortable during the intervention as determined by pain scale response.
- The patient will remain free from signs and symptoms of surgical site infection.

Patient and Family Education and Discharge Planning

Patient education is one of the nurse's greatest contributions. Some facilities have programs with group teaching for patients; in other settings, education is provided individually. Depending on the setting, the nursing role in patient education may include review of preoperative expectations, individual patient needs, surgeon's instructions, cataract procedure, intraocular lens (IOL) choices, and cataract surgery explanations and overview of the surgery experience (Burlew-Quartey, 2008).

Implementation of the plan of care actually begins during the patient interview. Planning to meet the patient's educational needs should play an equal role with meeting other needs. Verbal review and reinforcement of information initially provided in the physician's office ensures consistency in teaching. Written material and audiovisual media (closed circuit television, videocassettes, photos, and patient information websites) may be used to enhance patient education programs but do not eliminate the need for direct interchange with patients and feedback from them.

Family members or friends should be included to add support and increase understanding of the planned surgery. The loss of sight produces the same staged coping behaviors of grieving that move the individual from denial to acceptance. Thorough preoperative preparation of the patient and in most cases the family, who will assist with care at home in the postoperative period (Patient and Family Education), plays a vital role in the successful outcome of the surgical procedure.

Patient and family education for the patient undergoing ophthalmic surgery should include the following:

- Purpose and desired results of preoperative eyedrops and sedation
- Explanation of what to expect from the anesthetic
- Activities and routines of the intraoperative period
- What to expect immediately after surgery
- Designated driver after procedures using sedation
- Verbal and written instructions for use of eyedrops and other medications
- Any limitations on activities (bending, lifting, eye rubbing, special positioning)
- Wound care, protective sunglasses
- Signs and symptoms of complications
- Follow-up postoperative phone calls from the ambulatory surgery center, as applicable
- Who to call with questions or concerns
- Follow-up appointments

See the Patient and Family Education box for additional examples of instructions specific to cataract surgery. The National Quality Forum describes truly high-quality care as also culturally competent care. Provision of culturally appropriate care can increase efficiency and improve patient satisfaction besides improving outcomes. One of the guidelines that NQF developed suggests translating written materials into languages that reflect the local community demographics (NQF, 2009).

Surgical Interventions

SURGERY OF THE GLOBE AND ORBIT

Surgery of the globe (eyeball) and orbit is usually performed because of trauma. Rupture of the eyeball may be direct at the site of injury or, more frequently, indirect from an increase in intraocular pressure that causes the wall of the eyeball to tear at weaker points, such as the limbus. When the intraocular contents have become so deranged that useful function is prohibited or the blind eye becomes painful, removal of the eye contents (evisceration procedure) or of the entire eyeball (enucleation) is indicated. If either procedure is required, an inert globe or a coralline hydroxyapatite (coral) implant may be inserted as a space filler and to aid in the movement of a prosthesis (artificial eye). Fractures of the orbit are discussed in Chapter 21.

Enucleation

Enucleation is removal of the entire eyeball, with the severing of its muscular attachments and optic nerve. This life-altering procedure is indicated for a blind, painful eye; intraocular tumors; and as a last resort after trauma (Dodge-Palomba, 2008). Usually, a round implant is inserted into the socket to replace the globe and provide support for a prosthetic eye.

PATIENT AND FAMILY EDUCATION

Discharge Instructions and Home Care after Cataract Surgery

HOME CARE

- Give both the patient and the caregiver *verbal* and *written* instructions. Provide them with the name and telephone number of a physician or nurse to call if questions arise.
- Advise the patient to avoid squeezing the eyelids shut or touching the eyes postoperatively; encourage elderly patients to wear glasses during the day to avoid rubbing the eyes.
- Review the signs and symptoms that should be reported to a physician or nurse such as:
  - Increased intraocular pressure: sudden onset of eye pain, photophobia, sudden decrease in vision, sudden severe headache
  - Infection: redness and watering of eyes, swelling, blurred vision, pain
- Special instructions
  - Discuss the need to wear an eye shield at night for 2 to 6 weeks to avoid eye injury.
  - Warn that depth perception may be lost and that 50% of peripheral vision will be lost because of the eye patch.
  - Review safety precautions, especially with elderly patients.
    - Instruct the patient to avoid falls by turning the head fully to the affected side to view objects.
    - Advise the patient to use up-and-down head movements to judge stairs and oncoming objects and to move slowly.
  - Discuss the need to wear dark glasses during the day to avoid pupil constriction and glare, since the eye is sensitive to light after surgery.
  - If the patient had cataract surgery without a lens implant, warn that vision will be diminished in one or both eyes until prescription eyeglasses or contact lenses are obtained (in about 4 to 8 weeks).
  - If the patient is receiving eyeglasses, explain that images will be magnified 30%, peripheral vision will be impaired and distorted, and lenses will be bifocal or trifocal. Review safety precautions.
    - Advise the patient to turn the head side-to-side to see peripherally.
    - Advise the patient to judge distances when descending stairs or viewing oncoming objects.
  - If the patient is receiving contact lenses, explain that images will be magnified 7% to 10%, peripheral vision will be intact, and reading glasses may also be prescribed.
  - Review the care, insertion, and removal of lenses. Advise the patient of the importance of routine appointments with the physician for removal, cleansing, and reinsertion of extended-wear lenses.
  - If the patient is receiving an intraocular lens implant, explain that the lens implant aids in focusing but that glasses will be prescribed for close vision in 8 to 12 weeks; there will be no loss in depth perception.
- Medications
  - Review the name, purpose, dosage, schedule, and route of administration of all prescribed drugs; the length of time to take the prescribed medication; and the side effects to report to a physician or nurse.
  - Review the correct procedure for instilling eyedrops and ointments and applying an eye shield (without touching or applying pressure on the eyeball) to avoid self-inflicted injury.
  - Advise the patient to avoid over-the-counter medications, eyedrops, or ointments without checking with the physician.
  - Encourage the patient to share the list of medications with all providers of care, including primary care and specialist physicians, nurses, pharmacists, and other caregivers.
- Activity
  - Explain the need to avoid activities that can increase intraocular pressure: heavy lifting, straining with elimination, bending over at the waist, coughing, vomiting.
  - Instruct the patient to take medications for nausea and constipation as ordered.
  - Instruct the patient to avoid sleeping on the operative side.
  - Explain the need to avoid any strenuous exercise for 6 weeks; tell the patient to check with the physician before resuming occupational or recreational activities.
  - Explain that it will be necessary to adjust to mild magnification when performing daily activities.

FOLLOW-UP CARE

- Stress the importance of regular follow-up visits. Make sure the patient has the necessary names and telephone numbers.

Modified from Canobbio MM: *Mosby's handbook of patient teaching,* St Louis, 2006, Mosby; Using medication reconciliation to prevent errors, *Joint Commission Sentinel Event Alert,* issue 35, January 23, 2006, available at www.jointcommission.org/sentinelevents/sentineleventalert/sea_35.htm. Accessed May 28, 2009.

Sphere implants may be coralline (hydroxyapatite) or synthetic though glass and silicone implants are still commonly used. Hydroxyapatite, a lightweight, coral-like material, may be used as the foundation for a prosthetic eye because its porous structure encourages fibrovascular ingrowth. The hydroxyapatite implant is wrapped in human donor sclera or Silastic sheeting before insertion into the orbital space. New porous polyethylene implants have the advantage of allowing the rectus muscles to be sutured directly to the implant, thus eliminating the wrapping and expense of donor sclera. Suturing rectus muscles to the orbital implant enables improved postoperative movement of the ocular prosthesis.

The patient typically consults with an ocularist 4 to 6 weeks after enucleation or evisceration surgery for a prosthetic eye. A temporary prosthesis may be inserted while a custom-made prosthesis is fabricated. Ocularists may belong to an international professional and educational organization for professionals who specialize in fabricating and fitting custom-made ocular prosthetics (artificial eyes). The American Society of Ocularists (ASO) promotes research in the development of

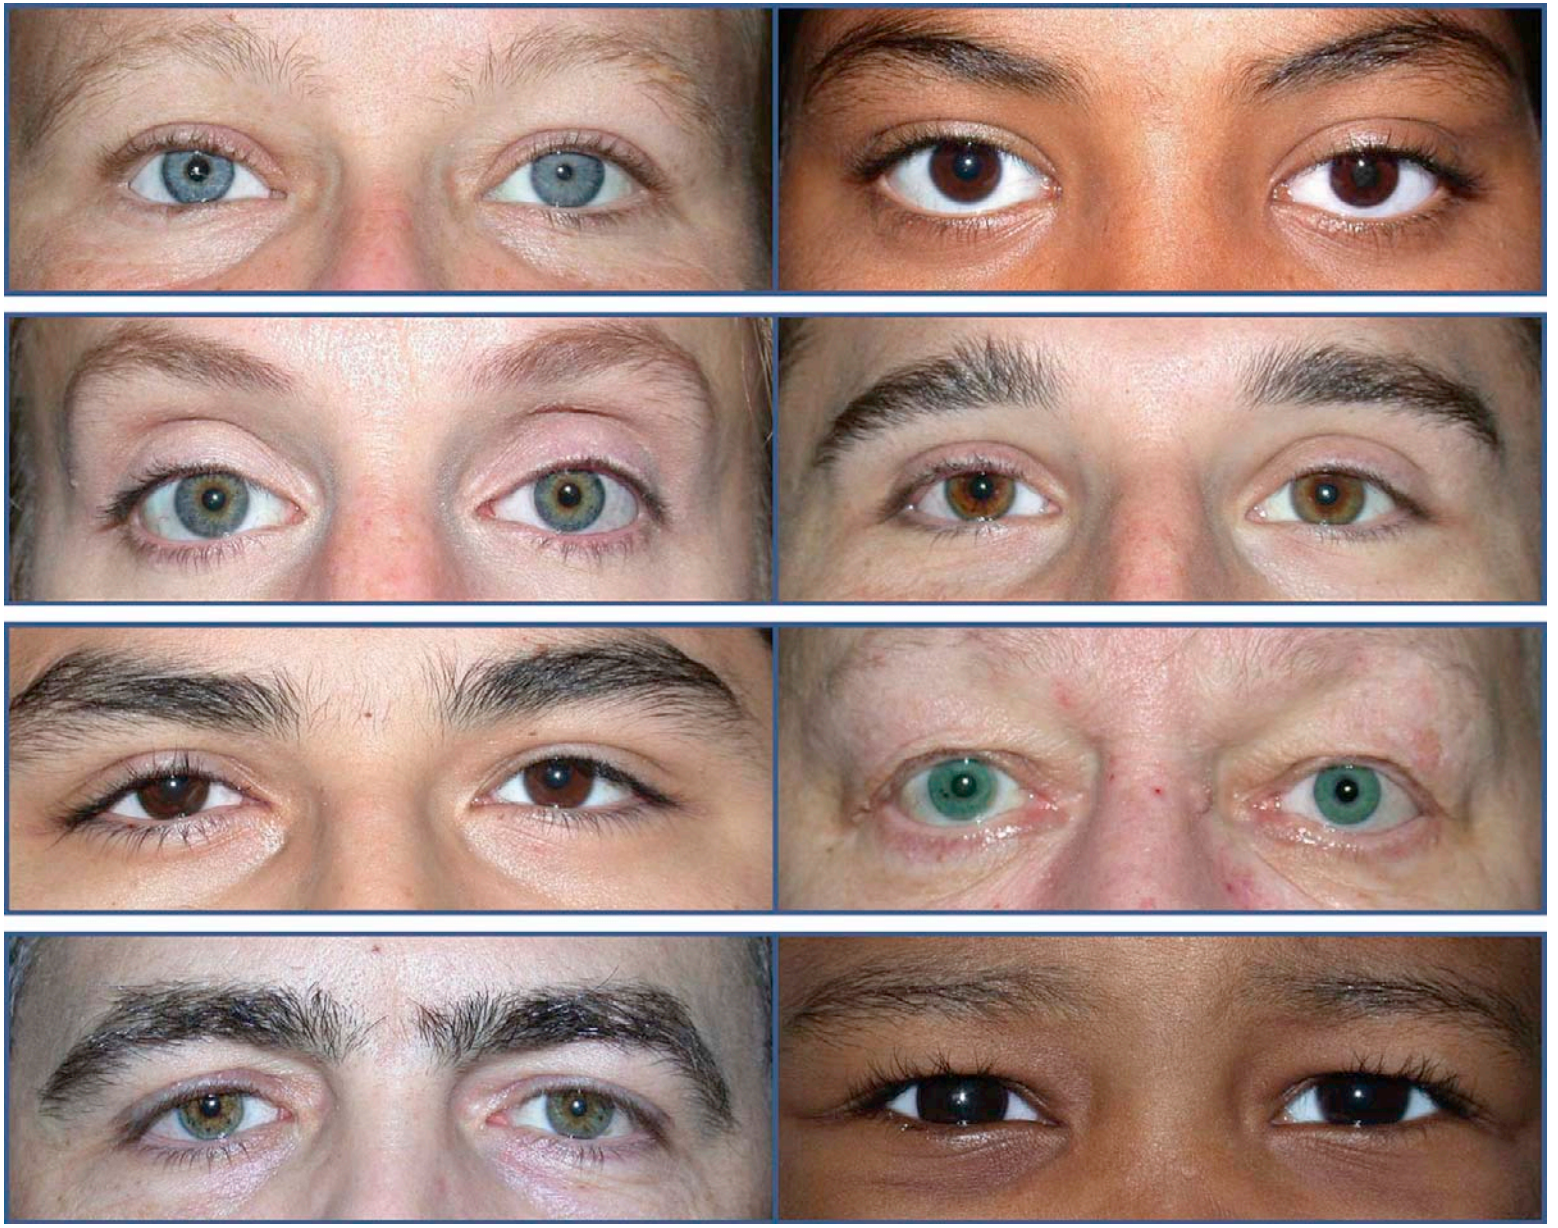

FIGURE 17-18 Patients who have an enucleation can have excellent cosmetic results when fitted with an ocular prosthesis designed by a board certified ocularist.

ophthalmic prosthetics and advancement of the methods, techniques, and skills of its members, thereby providing the public with continual improvements (ASO, 2009). Figure 17-18 provides examples of patients using ocular prostheses made by an ocularist certified by the National Examining Board of Ocularists. Medicare and most insurance companies in the United States provide benefits for prosthetic devices. Ready-made or mass-produced eyes are for short-term use (less than 3 months) only. After the prosthesis is created and fitted, the patient will follow up with the ocularist every 1 to 6 months to evaluate its size and to resurface (polish) the prosthesis to maintain the health of surrounding socket tissue. An appointment is warranted if the prosthesis becomes uncomfortable, feels rough to the touch, or changes in appearance, such as the lids appearing droopy or the eye turning in, out, up, or down (Nichols, 2009). The nurse should stress the importance of protecting the visually viable eye, such as using safety eyewear when participating in sports (Dodge-Palomba, 2008).

Operative Procedure

1. The surgeon places a speculum retractor into the palpebral fissure.
2. The conjunctiva is divided around the cornea with sharp and blunt dissection.
3. The medial, lateral, inferior, and superior rectus muscles are divided, leaving a stump of medial rectus muscle. If a coralline hydroxyapatite implant with donor sclera will be used, the four rectus muscles and two oblique muscles are identified and secured with 6-0 suture (to be used to reattach muscles to cut-out areas in donor sclera) before the muscles are disinserted. The two oblique muscles are similarly detached, but are often not subsequently secured to the orbital implant.
4. Using blunt-pointed curved scissors, retractors, hemostats, and forceps, the surgeon separates the globe from Tenon's capsule. The eye is rotated laterally by grasping the stump of the medial rectus muscle.
5. A large, curved hemostat is passed behind the globe, and the optic nerve is clamped for 60 seconds. The hemostat is removed, the enucleation scissors are passed posteriorly, and the optic nerve is transected. The oblique muscles are severed as the eye is lifted out of the socket by the stump of the medial rectus muscle.
6. Hemostasis is provided with either pressure via a sterile test tube or packing with saline-soaked sponges.
7. The muscle cone is filled with an implant, and the rectus muscles may then be sutured to the surface. Tenon's capsule and the conjunctiva are carefully closed over the implant in separate layers.
8. A plastic socket conformer is placed into the cul-de-sac.
9. A pressure dressing is applied.

Evisceration

Evisceration is removal of the contents of the eye, leaving the sclera and the attached muscles intact.

Operative Procedure

1. The conjunctiva is not separated from the sclera as it is for enucleation. A sharp-pointed knife is inserted through the limbus anterior to the iris.
2. The surgeon removes the contents of the eye (iris, vitreous, lens).
3. The choroid adhering to the sclera is removed with curettes.
4. Bleeding is controlled with delicate hemostatic forceps, electrocoagulation, and sutures.
5. A plastic or coral implant is placed within the empty shell.
6. Using nonabsorbable 4-0 or 5-0 sutures, the surgeon approximates the conjunctival and scleral edges.
7. A pressure dressing is applied.

Exenteration

Exenteration is removal of the entire orbital contents, including the periosteum, for certain malignancies of the globe or orbit. The procedure may also include removal of the external structures of the eyelids.

Procedural Considerations. General anesthesia is usually administered.

Operative Procedure

1. Depending on circumstances, exenteration of the eye may include the removal of the lids. An incision is made down to the orbital rim, through the periosteum, and around the entire orbit.
2. The surgeon frees the periosteum from the orbital walls and apex of the orbit with periosteal elevators.
3. The optic nerve is clamped, and the entire contents of the orbit are removed en bloc.
4. Hemostasis is obtained using the ESU and bone wax.
5. A skin graft or temporal muscle implant may be used to fill the orbital cavity or iodoform gauze is used to fill the cavity.
6. A pressure dressing is applied. The cavity is allowed to granulate.

SURGERY OF THE LACRIMAL GLAND AND APPARATUS

Surgery of the lacrimal gland is usually performed for treatment or diagnosis of tumors of the lacrimal fossa or to correct epiphora, which is abnormal overflow of tears related to a congenital or acquired obstruction of the lacrimal drainage system.

Surgery of the Lacrimal Fossa

Surgery of the lacrimal fossa is performed for biopsy of any structure in the lacrimal fossa.

Operative Procedure. The lacrimal fossa, which is in the upper temporal quadrant of the orbit, may be approached directly through the lid or through the conjunctiva by everting the upper lid. The lacrimal gland is divided into a palpebral and an orbital part by the orbital septum. Surgery on the palpebral portion may produce a dry eye.

Nasolacrimal Duct Procedures

Operative Procedure

SIMPLE PROBING

1. Using a punctual dilator the surgeon widens the tear duct opening along the medial aspect of the upper and lower eyelids.
2. A lacrimal probe (sizes vary from 00 to 4) is passed through the punctum, canaliculus, lacrimal sac, and nasolacrimal duct into the nasal cavity (under the middle meatus)

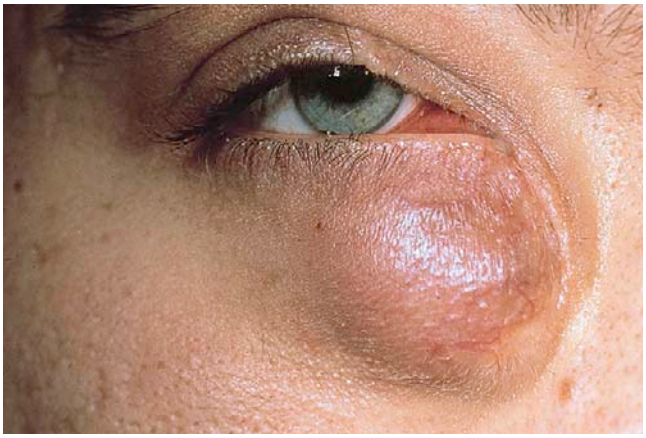

FIGURE 17-19 Chronic infection of lacrimal sac (dacryocystitis) causes swelling of inner lower corner of eye socket.

3. Adequacy of the duct opening is confirmed via metal-on-metal contact with the probe within the nasal cavity or via irrigation of fluorescein-tinged saline through the tear duct, aspirated in the nose.

PROBING WITH INTUBATION

1. After opening the duct as described in the previous procedure, the surgeon may place a Silastic tube or stent in one or both canaliculi to reduce the chance of postoperative reobstruction.
2. The surgeon threads the polyglactin leader on the stent through a stylet inserted in the punctum and retrieves it from the nasal cavity in the nose with a hook. Bicanalicular stents may employ a pliable metal rod attached to the Silastic tube. Such Crawford tubes require a special hook to engage the terminal bulb within the nose before removal.

Dacryocystorhinostomy

Dacryocystorhinostomy (DCR) is the establishment of a new tear passageway for drainage directly into the nasal cavity. The minimally invasive approach to DCR surgery includes the use of a transconjunctival incision, lasers, and endoscopic techniques.

Dacryocystitis (Figure 17-19) is an infection in the lacrimal sac, which may result in a localized cellulitis. Chronic or recurrent dacryocystitis in adults may necessitate probing or DCR because of resistant obstruction of the nasolacrimal duct related to infection-associated scarring, dacryolith (calculus in the duct), or trauma. Another indication for DCR surgery may be intolerable epiphora (tearing) resulting from tear duct laceration following medial orbital wall fracture.

Procedural Considerations. The nasal cavity is anesthetized topically with cocaine just before surgery. The surgery is performed after the patient has been administered a local or general anesthetic.

Operative Procedure

1. An external incision is made in the medial canthal area or inside the nose when an internal approach is used (Figure 17-20).
2. Blunt dissection is carried through the orbicularis down to the nasal bone. The orbicularis is separated from the bone with a Freer elevator. The lacrimal fossa sac is exposed.

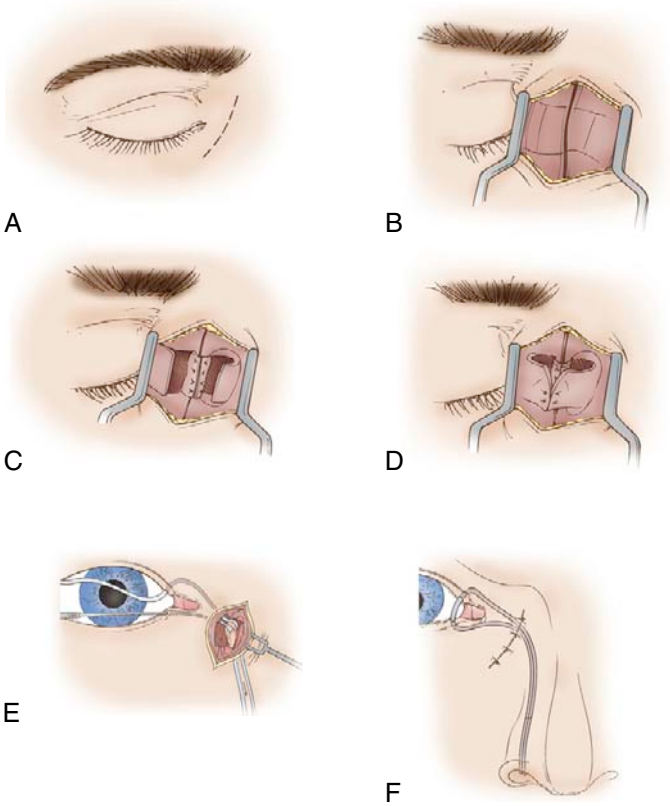

FIGURE 17-20 Dacryocystorhinostomy. **A**, Skin incision for dacryocystorhinostomy or dacryocystectomy. **B**, Lacrimal sac and lacrimal bone exposed. Opening made in lacrimal bone and lacrimal crest. **C**, Posterior flap of wall of sac sutured to posterior flap of nasal mucosa. **D**, Anterior flap of wall of sac sutured to anterior flap of nasal mucosa (drawing is somewhat distorted for visualization of relative positions). **E**, Canaliculi are intubated with Silastic tubes. **F**, Tubes are secured to lateral nasal wall and allowed to slide back into nose.

3. The surgeon uses a hemostat to press an opening through the lacrimal bone. If this is unsuccessful, the anterior lacrimal crest is perforated with a power burr or mallet and chisel. The opening is enlarged to a 10-mm circle with a Kerrison rongeur, and hemostasis is obtained with bone wax if necessary.
4. The inferior punctum is dilated, and a probe is passed into the lacrimal sac.
5. The lacrimal sac and nasal mucosa are incised with H flaps. The surgeon sutures the posterior nasal mucous membrane flap to the posterior lacrimal sac flap with 4-0 absorbable sutures.
6. The surgeon passes the first end of the wire stylet of a Silastic lacrimal duct intubation set through the upper canaliculus, through the opening, and out through the nose (under the inferior meatus). The procedure is repeated for the lower canaliculus.
7. The anterior nasal mucous membrane flap is sutured to the anterior lacrimal sac flap with 4-0 absorbable sutures to create a bridge over the Silastic tubing. The tubing remains in place until the sutures become absorbed, thereby acting as a stent around which epithelial union between the lacrimal and nasal mucosa can occur.

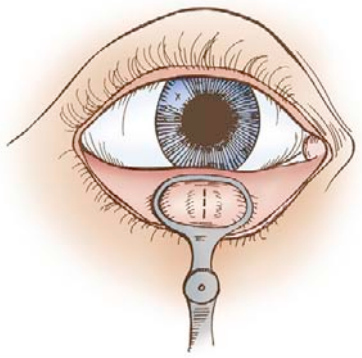

FIGURE 17-21 Transconjunctival approach. Clamp everts eyelid during surgery for chalazion. Viscous contents of chalazion will be removed with curette.

8. The orbicularis is closed with 6-0 absorbable sutures. Skin margins are approximated and closed with nonabsorbable 6-0 sutures. Antibiotic ointment is applied to the incision.
9. The surgeon cuts the wire stylets off the Silastic tubing, and ties the ends of the tubing together. The tubing is sutured to the lateral nasal wall with 6-0 nonabsorbable suture. The tubing is cut so that it retracts into the nostril. An absorbent sponge may be taped under the nostrils.

SURGERY OF THE EYELIDS

Oculoplastic procedures performed on the eyelids include treatment of chalazion, entropion, ectropion, dermatochalasis, and ptosis; biopsy and excision of eyelid tumors; and repair and reconstruction of eyelid trauma or post-biopsy damage.

Removal of Chalazion

Obstruction of meibomian gland secretion may lead to a chalazion, manifesting as a variably firm bump in the eyelid. Although chalazia can become infected, this is not primarily an infectious process. If persistent, incision of the chronic chalazion may be warranted.

Procedural Considerations. Incision of chalazion is often performed in an office setting, but pediatric and very anxious patients may require intravenous sedation. Local anesthesia, with 1:100,000 epinephrine in the local anesthetic, is usually employed. The majority of chalazia are surgically approached from the conjunctival side of the tarsal plate, but cutaneous incisions or repair of friable cutaneous tissue may be required (Figure 17-21).

Operative Procedure (Transconjunctival Approach)

1. Using a chalazion clamp, the surgeon everts the affected lid to expose the chalazion.
2. A vertical incision is made on the inner lid surface with a sharp blade; the small lesion is curetted, or the chalazion wall is excised, in part or in toto.
3. Hemostasis is achieved through use of the bipolar ESU.
4. The wound is left open for drainage. Cutaneous sutures are placed when needed. Pressure eye patching may be performed.

Repair of Entropion

Entropion occurs when the eyelid margin inverts. It may cause significant corneal irritation, attributable to rubbing of inturned eyelashes against the ocular surface. The most common type is *involutional entropion,* when laxity and degeneration of facial attachments between the pretarsal muscle and the tarsus permit the pretarsal muscle to override the lid margin during contraction. *Cicatricial entropion* is attributable to contraction of either the upper or the lower tarsus and its conjunctiva, causing inturned lashes (trichiasis) to abrade the cornea. Commonly employed surgical techniques for entropion repair include lateral tightening of a lax eyelid via either a *tarsal strip* procedure or a *pentagonal wedge resection,* and suture eversion (via either a *Wies* or a *Quickert suture technique*).

Procedural Considerations. The causes of entropion vary, and corrective procedures also vary depending on the pathologic process. Local anesthetic is typically used, and antiinfective ointment is applied postoperatively.

Operative Procedures

BLEPHAROPLASTY OF LOWER LID FOR INVOLUTIONAL ENTROPION

1. The surgeon injects local anesthetic into the lower lid through the conjunctiva using an angled needle.
2. The skin is marked, and an incision is made in the lateral canthus.
3. The orbicularis is dissected off the orbital septum.
4. The skin excision is extended across the lower lid.
5. The orbital septum is incised to expose fat pockets.
6. The surgeon removes extra fat, and hemostasis is achieved.
7. After incising the lateral canthus, the surgeon pulls the lower lid laterally and shortens (tightens) it to correct entropion.
8. The tarsus is reattached to the lateral canthal tendon, and the lower lid fascia is reattached to the orbicularis.
9. The excess skin is pulled up, marked, and excised.
10. The skin incisions are closed.

WIES PROCEDURE FOR CICATRICIAL ENTROPION

1. A marking pen is used to draw a parallel line 4 mm below the lower lid margin; the local anesthetic is then injected.
2. The surgeon places a double-armed 4-0 nonabsorbable retraction suture through the conjunctiva and lower lid 4 mm from the lateral canthus and 4 mm from the medial canthus.
3. A lid plate retractor is placed behind the lower lid as it is pulled up with the traction suture. The surgeon uses a #15 blade to make the skin incision on the marked line.
4. The lid plate retractor is placed in front of the lid, and the lower lid is everted using the traction suture. The conjunctiva is incised with the #15 blade.
5. A full-thickness blepharotomy is extended laterally and medially with scissors.
6. The surgeon passes one end of the double-armed 4-0 suture through the conjunctiva and lower lid tendons and between the orbicularis and tarsus on the medial aspect of the lower lid. This process is repeated approximately 4 mm laterally with the other end of the 4-0 suture.
7. Six mattress sutures are placed and tied to evert the lower lid (Figure 17-22).
8. Excess skin is excised, and the skin incision is closed with 7-0 nonabsorbable sutures.

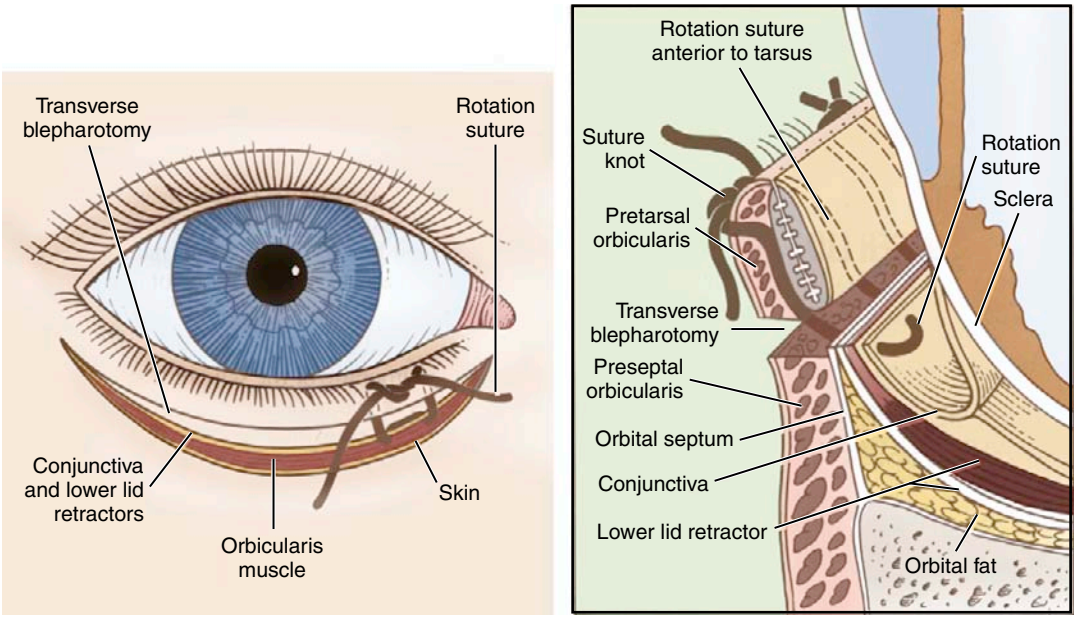

FIGURE 17-22 Wies procedure for entropion. Placement of an everting mattress suture across a transverse blepharotomy.

Repair of Ectropion

Ectropion (sagging and eversion of the lower lid), usually bilateral, is common in older persons (Figure 17-23). Ectropion may be caused by the relaxation of the orbicular muscle and canthal tendons. Symptoms include tearing, conjunctival infection, irritation, and inadequate corneal protection leading to injury to the cornea. Surgery is indicated when facial paralysis is permanent or when scarring follows lacerations, lesions, or penetrating injuries and the cornea becomes exposed, resulting in ulceration and photophobia.

Procedural Considerations. The causes of ectropion vary, and corrective procedures also vary depending on the pathologic process. Local anesthetic is typically used, and antiinfective ointment and ice compresses are applied postoperatively.

Operative Procedure

LATERAL CANTHAL SLING PROCEDURE

One method of correction for ectropion is the lateral canthal sling procedure (Figure 17-24), which repositions and tightens the lower lid in a horizontal direction.

1. The lateral canthus is incised, and a strip of tarsus and lateral canthal tendon is isolated.
2. The surgeon sutures the tarsus/tendon to the periosteum along the inner surface of the lateral wall of the orbit, thereby tightening the lid and correcting the ectropion.

Plastic Repair for Dermatochalasis

Dermatochalasis is a condition of drooping skin and herniated fat of the upper and lower lids that causes the skin of the upper eyelids to hang down over the palpebral fissure, sometimes obscuring vision. It may occur in older persons who have lost normal elasticity in the skin of their upper lids or in persons who have persistent angioneurotic edema with stretching of the skin of the eyelids. If ptosis is present, it accentuates the condition.

FIGURE 17-23 Ectropion, or eyelid eversion (turning out of lid), is most commonly caused by relaxation of eyelid framework.

Procedural Considerations. Dermatochalasis is corrected with blepharoplasty of the redundant skin of the upper or lower eyelids. A segment of skin and fat is removed. In the lower lid, a transconjunctival excision that leaves no external incision may be performed. Brow droop, or ptosis, may also be corrected alone or in combination with blepharoplasty to correct dermatochalasis. Procedures for correcting brow ptosis include direct brow lift, coronal brow lift, and endoscopic brow lift. Most procedures are performed using a local anesthetic with IV sedation.

Operative Procedure

BLEPHAROPLASTY OF UPPER LID FOR DERMATOCHALASIS

1. The surgeon marks the amount of skin to be excised in the upper lid above the lid crease and injects local anesthetic.
2. Stretching the skin of the upper lid tautly, the surgeon incises along the predrawn lines.

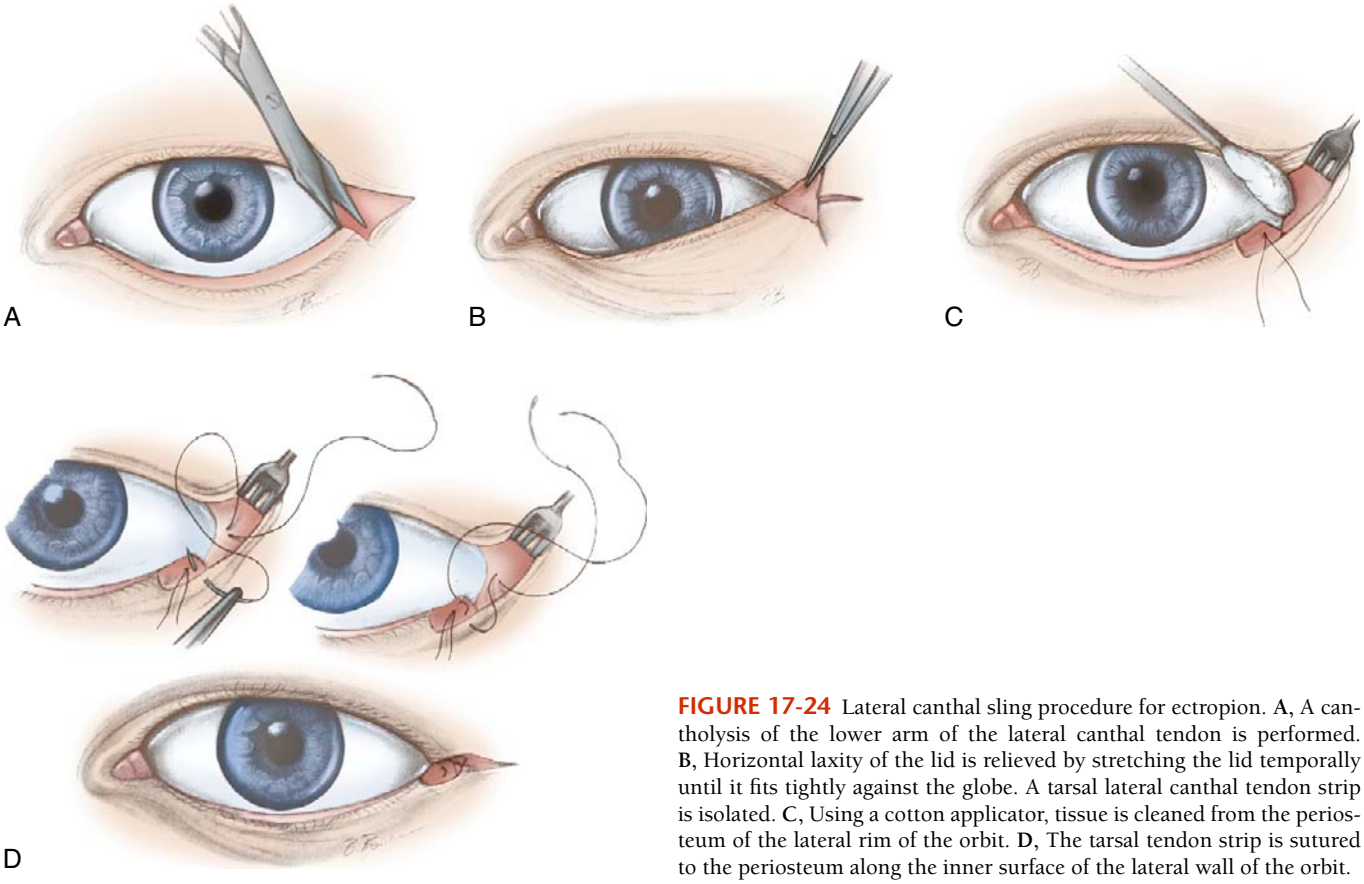

FIGURE 17-24 Lateral canthal sling procedure for ectropion. **A**, A cantholysis of the lower arm of the lateral canthal tendon is performed. **B**, Horizontal laxity of the lid is relieved by stretching the lid temporally until it fits tightly against the globe. A tarsal lateral canthal tendon strip is isolated. **C**, Using a cotton applicator, tissue is cleaned from the periosteum of the lateral rim of the orbit. **D**, The tarsal tendon strip is sutured to the periosteum along the inner surface of the lateral wall of the orbit.

3. The skin between the marked lines is excised, the orbicularis between the incision edges is excised, and hemostasis is achieved.
4. The surgeon incises the septum; applies finger pressure on the globe; and clamps, cuts, and electrocoagulates the bulging fat.
5. If fat is found in the temporal pocket, it may contain a prolapsed lacrimal gland. The lacrimal gland should be resuspended with 5-0 nonabsorbable suture.
6. The surgeon restores the lid crease by suturing the lower skin muscle incision line to the levator at the upper edge of the tarsus.
7. The skin is closed with 6-0 nonabsorbable suture in a continuous running fashion.

TRANSCONJUNCTIVAL BLEPHAROPLASTY OF LOWER LID

1. The surgeon injects local anesthetic into the lower lid through the conjunctiva using an angled needle.
2. Finger pressure is placed on the upper lid while the lower lid is being retracted to expose the conjunctiva of the inferior cul-de-sac.
3. The surgeon incises the conjunctiva and exposes the fat pockets. Prolapsed fat is clamped and removed, and hemostasis is achieved.

Surgery for Unilateral or Bilateral Ptosis

Ptosis is true drooping of the upper lid and may be congenital or acquired. In congenital ptosis there usually is developmental weakness of the levator muscle. The condition may be unilateral or bilateral. The child often compensates by raising the eyebrow or tilting the chin upward.

Acquired ptosis can be neurogenic, myogenic or involutional, which is manifested by a gradual stretching or dehiscence of the levator aponeurosis. The eyelid crease may be high or absent.

Procedural Considerations. The objective of ptosis surgery is to achieve a good cosmetic result, expand the superior visual field, and restore function with elevation of the lid. Many surgical procedures have been devised, directed at the levator aponeurosis, frontalis muscle, or the levator-Müller muscle complex. These muscles are the elevating forces of the upper lids. Local anesthesia may be preferred in cooperative individuals so that intraoperative adjustments can be made. Frontalis suspension uses fascia lata or synthetic materials to attach the tarsus to the frontalis, bypassing the ineffective levator muscle. Harvesting fascia lata requires an additional incision in the leg.

Operative Procedure

LEVATOR APONEUROSIS REPAIR

1. The surgeon marks the existing or potential eyelid crease. With the skin of the upper lid held taut, the skin incision is made (Figure 17-25).
2. An incision is made through the orbicularis. The surgeon dissects the orbicularis off the orbital septum and the levator aponeurosis anterior to the tarsus.

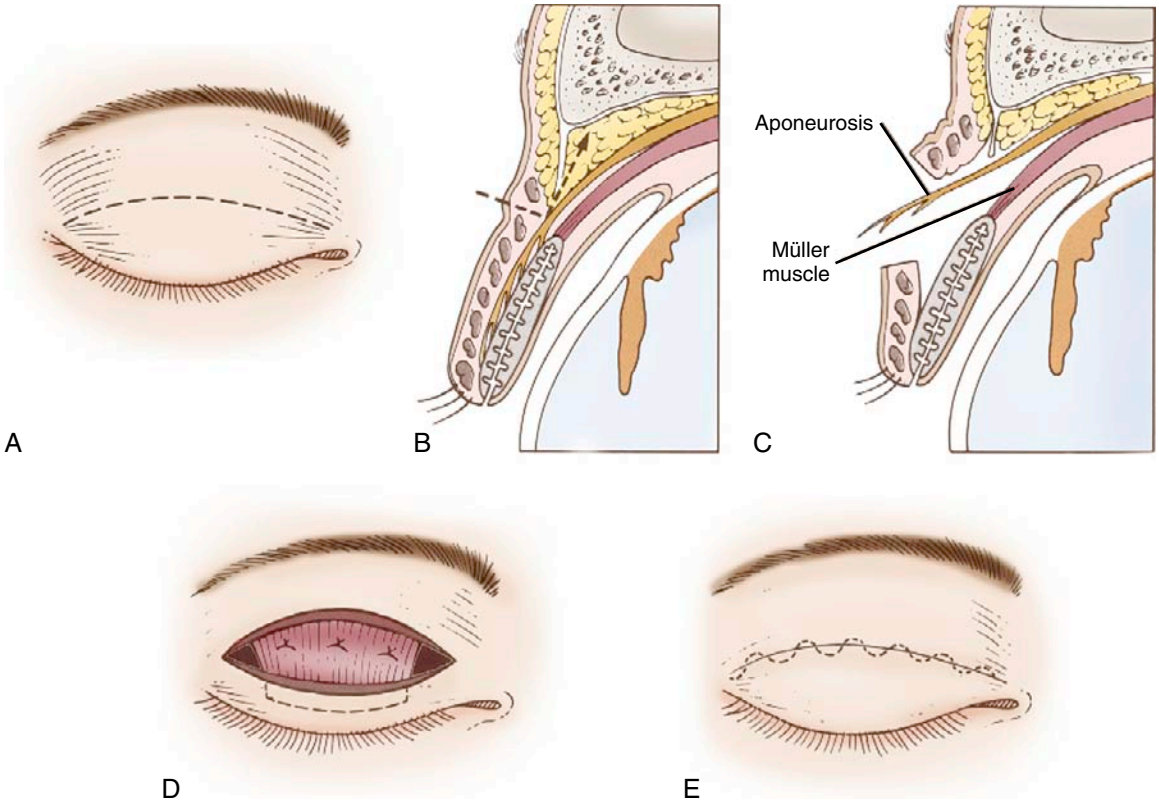

FIGURE 17-25 Levator aponeurosis repair for ptosis. **A**, Eyelid crease is marked. **B**, Skin incision is made, and the orbicularis and orbital septum are divided while dissection proceeds toward the orbital rim. **C**, The anterior surface of the tarsus is exposed, and the aponeurosis is separated from the Müller muscle. **D**, The aponeurosis is reattached to the tarsus with partial-thickness permanent sutures. Lid contour and position are adjusted. **E**, The eyelid crease is created by suturing the pretarsal orbicularis muscle to the aponeurosis, and the skin is closed.

3. The aponeurosis is incised across the tarsus and dissected off the orbicularis. The levator is reattached to the tarsus with interrupted 6-0 suture.
4. If the patient is awake, he or she is asked to look forward and the sutures are adjusted as needed.
5. The pretarsal orbicularis is sutured to the aponeurosis to reconstruct the lid crease.
6. The surgeon closes the skin incision with a running 6-0 nonabsorbable suture.

FRONTALIS SUSPENSION

1. The upper lid is marked, one incision is made in the lid crease, and two incisions are made above the eyebrow (Figure 17-26, *A* and *B*).
2. The surgeon places a lid plate behind the upper lid, exposes the tarsus, and secures the suspension material (fascia graft or a synthetic implant) to the tarsus with nonabsorbable sutures (Figure 17-26, *C*).
3. Using a Wright needle, the surgeon passes the suspension material away from the globe deeply into the orbital septum and out through one eyebrow incision (Figure 17-26, *D*).
4. The remaining end of the suspension material is passed in the same manner.
5. The surgeon sutures the pretarsal orbicularis to the tarsus to form the lid crease (Figure 17-26, *E*).
6. The lid incision is closed with a running 6-0 nonabsorbable suture (Figure 17-26, *F*).
7. The surgeon passes the long end of the suspension material under the skin between the brow incisions to complete the loop, and sutures the ends of the material together.
8. The brow incisions are closed with interrupted 6-0 nonabsorbable suture.

Excisional Biopsy

Excisional biopsy is removal of lesions for diagnostic examination. Basal cell carcinomas account for 95% of neoplastic lesions of the lid; the treatment of choice is excision with frozen-section analysis or Mohs' technique.

Operative Procedure. Through-and-through excision of skin, muscle, tarsus, and conjunctiva is followed by careful structural closure of anatomic spaces. Depending on the type, extent, and location of the lesion, rotation flaps or free grafts may be necessary.

Plastic Repair for Traumatic Injuries

Lacerations of the lids, including damage to the inferior canaliculus, are repaired surgically. Paramount for success is the careful approximation of the borders of the lid margin and the ends of a torn canaliculus.

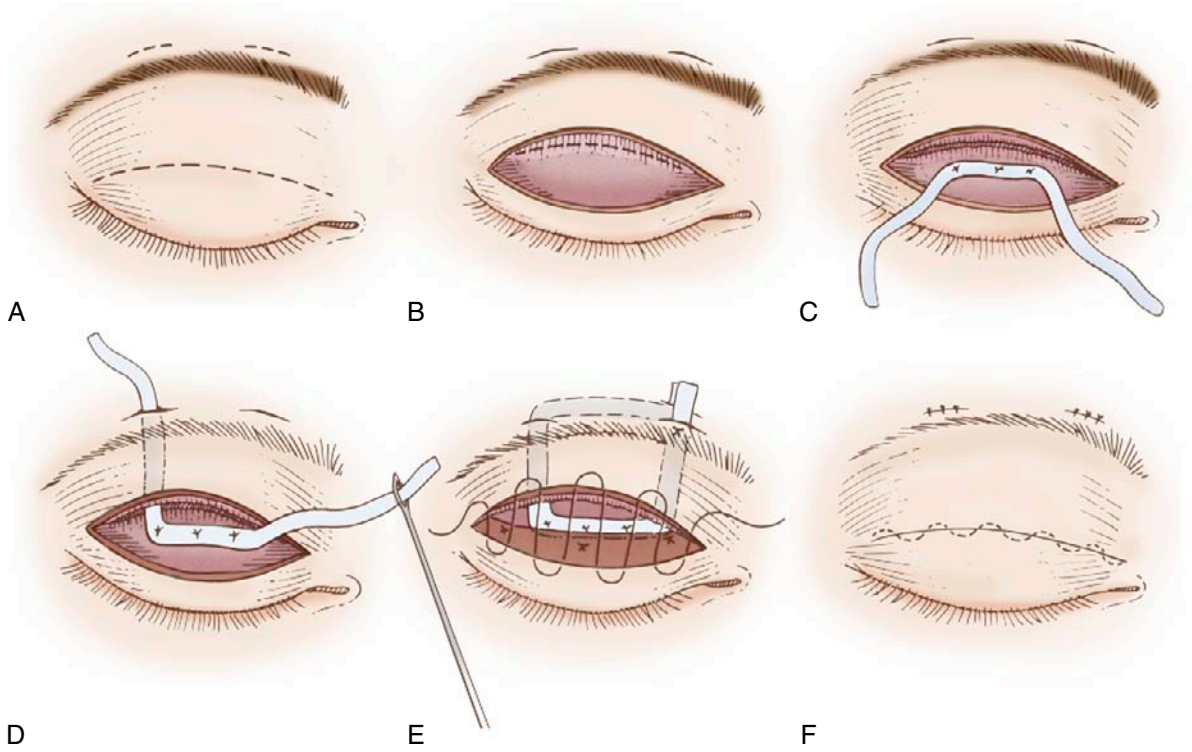

FIGURE 17-26 Frontalis suspension for ptosis. One method used to suspend the eyelid from the brow.

Operative Procedure. Lacerations of the lid margin are closed with a 6-0 silk suture to align the gray line of the lid that lies between the lash follicles and the orifices of the meibomian glands. Once this anatomic line has been approximated, all other sutures are placed, maintaining the approximation. If the canaliculus has been lacerated, the lacrimal drainage system is intubated with a silicone tube and the canaliculus and lid are reconstructed around the tube.

SURGERY OF THE CONJUNCTIVA

The conjunctiva of the eye is a transparent and elastic membrane that lines the inner surface of the eyelids and covers the sclera. Lacerations caused by injury as well as deficits resulting from excision of tumors, cysts, nevi, or pterygia can usually be repaired by simple undermining and suturing.

Pterygium Excision

A pterygium is a fleshy, triangular encroachment of conjunctiva onto the peripheral area of the cornea. Because pterygia tend to recur, surgery is delayed until vision is affected by encroachment on the visual axis.

Operative Procedure. The major steps in the McReynolds technique are illustrated in Figure 17-27. A pterygium can also be excised totally and the limbus treated with an eye cautery or bipolar ESU. The conjunctiva can then be closed, or the sclera can be left bare.

Surgery may be combined with beta-radiation, application of mitomycin, conjunctiva autologous grafts, and lamellar corneal grafts, and more recently with amniotic membrane graft.

Excisional Biopsy

Any suspect lesion of the conjunctiva can be removed by simple elliptic excision and sent for pathologic examination. The conjunctiva may or may not be closed, depending on the surgeon's particular technique.

Strabismus Surgery

Strabismus refers to ocular misalignment. Although often neurogenic rather than muscular in origin, surgery on the extraocular muscles may be indicated to improve this misalignment. Strabismus surgery is described in Chapter 25.

SURGERY OF THE CORNEA

Surgery of the cornea is indicated for a variety of conditions in which cosmetic, therapeutic, restorative, and refractive outcomes are desired.

Repair of Lacerations

Corneal lacerations may be closed with direct appositional suturing with 10-0 suture viewed through an operating microscope or with a tissue adhesive, such as cyanoacrylate monomers. The sterile tissue adhesive is applied to well-dried tissue that has been properly oriented anatomically. It polymerizes and seals the wound on contact with the tissue.

Culture specimens are usually obtained at the time of surgery. Antibiotics are injected subconjunctivally before the dressing is applied.

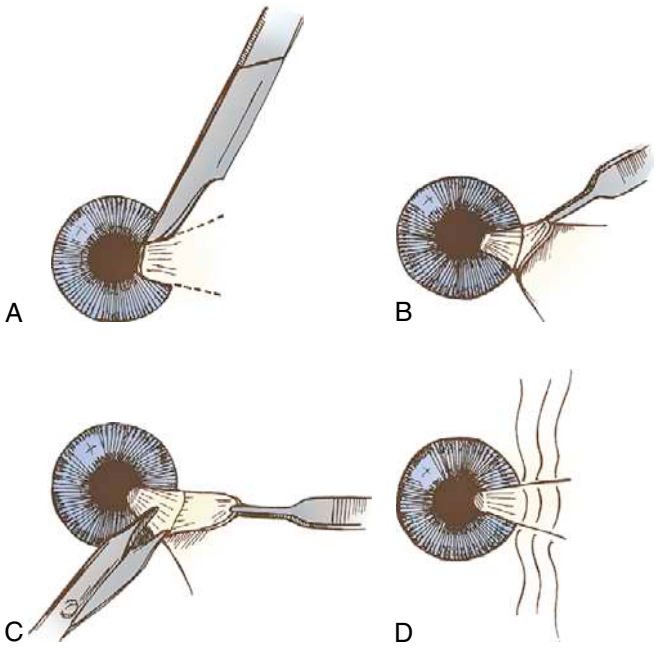

FIGURE 17-27 McReynolds technique for pterygium excision. **A**, Cornea around head of pterygium is incised. **B**, Pterygium flap is dissected upward, leaving clear cornea. **C**, Lower margin of pterygium is dissected, and whole pterygium is freed from sclera. **D**, Sutures are placed for closure of conjunctiva.

Corneal Transplantation (Keratoplasty)

A corneal transplantation (keratoplasty) is performed when the patient's cornea is thickened or opacified by disease and degeneration. The transparency of the cornea may be impaired as a result of scars, infection (bacterial, fungal, or viral), thermal or chemical burns, Fuchs' dystrophy, edema after cataract surgery, or keratoconus (abnormal steepening). Ocular surgery such as phacoemulsification, vitrectomy, or intraocular lens implant can potentially damage the corneal endothelium. Corneal transplantation, in which corneal tissue from one human eye is grafted to another, is done to improve vision when the retina and optic nerve are functioning properly; it was first performed in 1905. Because the cornea is tissue that lacks blood vessels, it can be transplanted with less rejection and at a 90% success rate. Keratoplasty may be performed as a lamellar (partial-thickness) graft or a penetrating (full-thickness) graft. Over 50,000 grafts were made available in 2007. Corneal transplant is one of the most frequently performed human transplant procedures, with more than 700,000 performed since 1961 (Eye Bank Association of America [EBAA], 2009.)

Phototherapeutic keratectomy (PTK) procedures use excimer laser ablation to remove superficial corneal lesions and smooth the corneal surface. PTK can be used on conditions that would require corneal transplant and may delay or replace the occurrence of penetrating keratoplasty in some cases.

Procurement of Corneas. The eye bank may be a central community agency or may be owned and operated by a hospital. Eye banks help coordinate the procurement of eyes from recently deceased persons under the Eye Bank Association of America (EBAA) guidelines. Persons of any age can be eye donors, and poor eyesight or cataracts do not influence eye viability (EBAA, 2009). The donor's family, medical, and social histories are reviewed. It is not necessary to perform antigen matching as with other tissue or organ transplants, but blood serum tests for human immunodeficiency virus (HIV) and hepatitis B virus are performed on the donor. The procurement team removes donor eyes within 6 hours of death in accordance with legal regulations. Tissue, such as a cornea, must be recovered, processed, and transplanted in controlled surgical environments. If the donor eye is unsuitable for the cornea to be transplanted, the eye can be used for research or education.

Many individuals have signed donor cards or eye-donor designation on their drivers' licenses. A special consent form is required and should be signed by the authorized next of kin and by a hospital representative designated by institutional policy. Federal regulations require hospitals to report all deaths and imminent deaths to organ procurement organizations. With the collaboration of hospitals, organ procurement organizations, and eye and tissue banks, the family of every potential donor is informed about the option to donate organs or tissues.

The enucleations may be done in the hospital morgue or emergency department under aseptic conditions. The procured cornea is placed in Optisol GS sterile buffered tissue culture medium within 12 hours of death and transplanted within 3 to 7 days. Optisol GS sterile buffered tissue culture medium contains polypeptides, dextran, and antibiotics (gentamicin and streptomycin) and can preserve a donor cornea for 14 days under refrigeration. It is best if corneal transplantation is performed in 2 or 3 days because the cornea may become boggy from constant exposure to the tissue culture solution.

PROCEDURAL CONSIDERATIONS. Postmortem preparation includes elevating the donor's head with a pillow to minimize edema in the face or near the eye. The eyes are irrigated and lightly taped closed to avoid pressure on the eye. A small ice pack may be applied to the forehead or over the eyes if the donor is not in a refrigerated morgue within 1 hour of death.

For the procurement procedure, the eyes are washed and irrigated in the routine manner of preparation for eye surgery. The sterile field, drapes, and instruments are essentially the same as those for an enucleation on a living patient. For the transplant procedure, the nurse positions and preps the patient in the same fashion as a cataract procedure.

OPERATIVE PROCEDURES

Donor Tissue Procurement

1. Eye specimen jars are labeled for right and left eyes.
2. The speculum is inserted, and after routine enucleation the donated eye is placed with the cornea up and secured in a metal eye cage or on gauze in the sterile specimen jar.
3. The eye sockets are packed with cotton, and the lids are closed.
4. Specimen jars are sealed with tape and labeled with the donor's name or identification number, time of death, time of enucleation, and date. The jars are placed on wet ice in an insulated carrier and transported to the eye bank. The entire cornea with a scleral rim will be placed in Optisol GS before transplant.

Penetrating Keratoplasty

1. After insertion of the eye speculum the surgeon places superior rectus and inferior rectus bridle sutures if a Flieringa ring is not to be used. If a ring is used, the surgeon secures it in place with four 5-0 sutures (Figure 17-28).

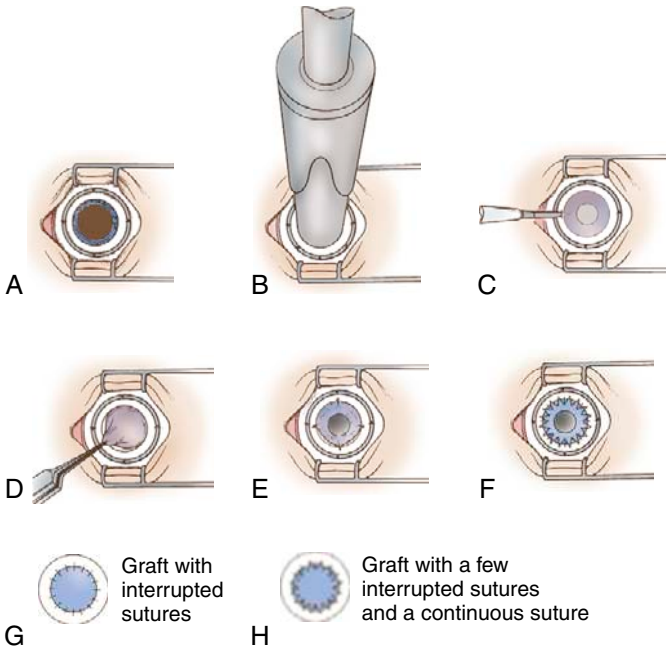

FIGURE 17-28 Corneal transplantation. **A**, Eye of patient who will undergo corneal transplantation. Flieringa fixation ring is sutured in place with 5-0 nonabsorbable sutures. **B**, Corneal trephine is placed on recipient cornea, and partial penetration is made approximately three fourths through stroma. **C**, Anterior chamber is entered through groove, and the remainder of button is excised with right and left corneal microscissors. **D**, Corneal button is removed. **E**, Donor cornea graft is sutured in place with four sutures. **F**, Donor cornea graft is sutured in place with interrupted or continuous 10-0 nonabsorbable suture (**G** and **H**).

2. A corneoscleral button that has been refrigerated and stored in tissue culture medium (Optisol GS) is removed from its container.
3. The surgeon places the donor corneoscleral button on a sterile Teflon block with the epithelial (outside) surface down. Using the corneal trephine as a punch, the surgeon presses out the button. A drop of Optisol GS may be used to cover the donor button until it is implanted.
4. Using a handheld trephine or a disposable suction trephine, the surgeon excises a corneoscleral button from the recipient's cornea. The section of cornea removed from the recipient's eye is usually 0.25 mm in diameter smaller than the graft taken from the donor's eye.
5. Peripheral iridectomies or iridotomies may be performed at this time at the surgeon's discretion, or a cataract extraction with IOL implantation may also be performed if the lens is opaque.
6. The surgeon places the graft into the opening of the recipient's eye and anchors it in place by means of four single-armed sutures placed at the four cardinal meridians, viewed through an operating microscope. Some surgeons preplace sutures in the graft. The surgeon sutures the graft to the host with either continuous or interrupted 10-0 nonabsorbable sutures.
7. Air or sodium hyaluronate (Healon) may be injected into the anterior chamber of the recipient's eye to keep the iris from adhering to the suture line. Mydriatic or miotic solutions are used at the surgeon's discretion.
8. A subconjunctival injection of antibiotic solution or a topical application of antibiotic drops may be used at the completion of the procedure. Antibiotic ointment is applied, followed by an eye pad and a protective shield.

Lamellar Keratoplasty

1. The surgeon inserts the eye speculum and then places the superior rectus and inferior rectus bridle sutures (if needed).
2. The perioperative nurse presents the donor eye from the eye bank to the sterile field; the surgical technologist washes it in balanced salt solution.
3. The surgeon wraps the donor eye in a surgical dressing and makes a groove at the desired depth in the cornea with the trephine. The Castroviejo keratome is set at the desired depth, and the lamellar sheet of cornea is removed and placed into a petri dish.
4. The recipient cornea is grooved with the same trephine to the appropriate depth. Using the operating microscope, the surgeon performs a lamellar resection, that is, removes the anterior part of the cornea at a predetermined depth with a Gill knife, Beaver knife blade #64, or other corneal splitter.
5. The surgeon sutures the donor tissue in place with a continuous 10-0 nonabsorbable suture.
6. A mydriatic agent and subconjunctival or topical antibiotics may be used.
7. The eye is patched.

DEEP LAMELLAR ENDOTHELIAL KERATOPLASTY. Deep lamellar endothelial keratoplasty (DLEK) is an emerging technique. It consists of replacing the endothelium without transplanting the cornea to restore vision. This technique offers the potential for highly predictable corneal power for extended periods without the astigmatism that often occurs with penetrating keratoplasty. The transplanted endothelium is inserted into the host through a small incision, greatly reducing the risk of infection.

Keratorefractive Procedures

Keratorefractive procedures are corneal procedures designed to correct myopia, hyperopia, astigmatism, and aphakia. These procedures require reshaping the cornea with relaxing incisions or cryolathing corneal tissue to change the refractive power of the cornea. They include photorefractive keratectomy (PRK), which uses the excimer laser to treat myopia (nearsightedness), and laser-assisted in-situ keratomileusis (LASIK), which uses the excimer laser for photoablation of the corneal stroma bed to alter the curvature of the cornea and correct myopia or hyperopia (farsightedness).

PRK is a surface ablation technique that involves manual scraping, alcohol, and a brush. Surface ablation avoids the complications of flap formation and provides excellent visual results. A major drawback, however, is delayed visual rehabilitation and pain, though it can be controlled with topical and oral therapy. Epi-LASIK, another form of surface ablation, mechanically separates the epithelial layer from Bowman's membrane with the use of a mechanized keratome but without alcohol. After ablation the epithelial flap is positioned on the cornea followed by a bandage contact lens. Some strategies to promote healing include careful preoperative testing for dry eye and using nontoxic antibiotics (Donnenfeld, 2008).

More than 800,000 Americans underwent LASIK surgery in 2007. Excimer laser technology was introduced in 1975 and exploration of ophthalmic applications began in 1983. Stuart (2008) notes that improvements in performance and reliability, combined with a host of complementary techniques and innovations, have turned excimer refractive surgery into the most popular elective surgical procedure worldwide. Thus it is especially important for the perioperative nurse to keep updated with emerging technologies and techniques as they develop.

LASIK Surgery. With the LASIK procedure, the curvature of the cornea is reshaped using an excimer laser. The purpose is to permit the individual to see well at a distance without glasses. For nearsighted patients the central curvature of the cornea is flattened. To flatten the cornea, the surgeon removes stromal tissue from the center of the cornea (Figure 17-29, *A*). For farsighted patients the central curvature of the cornea is steepened. To steepen the cornea, stromal tissue is removed from the periphery of the cornea, leaving the center untreated (Figure 17-29, *B*).

PROCEDURAL CONSIDERATIONS. An extensive preoperative evaluation (refraction, topography, wavefront analysis, and determination of targets for desired refraction) is necessary to be sure that the patient is a candidate for the LASIK procedure. Before surgery, a topical antibiotic and topical anesthetic are placed in the patient's eye. If the patient has astigmatism, he or she is taken to a slit lamp and a mark is made on the conjunctivae to assist in the correction of the astigmatism. Circular corneal markers (3 mm and 4 mm) may be used. The LASIK complication rate has been dramatically reduced by the development of new-generation microkeratomes and the improvement in the femtosecond laser. The three basic steps in LASIK are: (1) prepare stroma or create flap, (2) perform photoablation to change refraction, and (3) reposition flap (Donnenfeld, 2008).

OPERATIVE PROCEDURE

1. The patient is positioned supine, and the surgeon positions a locking lid speculum. The patient's head position is adjusted to account for the astigmatism.
2. The surgeon marks the cornea to assist in the placement of the "corneal cap" after the procedure. A suction device is placed on the eye to immobilize it.
3. A microkeratome (e.g., Hansatome, ACS, Moria, Amadeus) is used to create a lamellar keratectomy of 0.130 to 0.180 micrometers in thickness. This piece of cornea is reflected out of the way with a flat cornea spatula, and the laser treatment is applied to the base of the lamellar keratectomy.
4. The surgeon replaces the corneal cap on the stromal bed using a Slade irrigating cannula on a 3-ml syringe with saline. The corneal cap is permitted to dry for several minutes. The corneal cap stays in position because of capillary attraction.
5. Antibiotic drops and nonsteroidal antiinflammatory drops are placed in the eye. A goggle is placed over the eye to prevent slippage of the corneal cap for the next 24 hours.

LASEK Surgery. Laser epithelial keratomileusis (LASEK) is similar to PRK, because the procedure is performed on the surface of the cornea. After numbing the eye with topical anesthetic drops, the surgeon loosens the epithelium with a diluted alcohol solution and pushes it aside. A laser is then used to treat the corneal surface, similar to PRK and LASIK procedures. The epithelial flap is then returned to its original position, and a bandage contact lens is placed for the duration of the healing process, which may last several days.

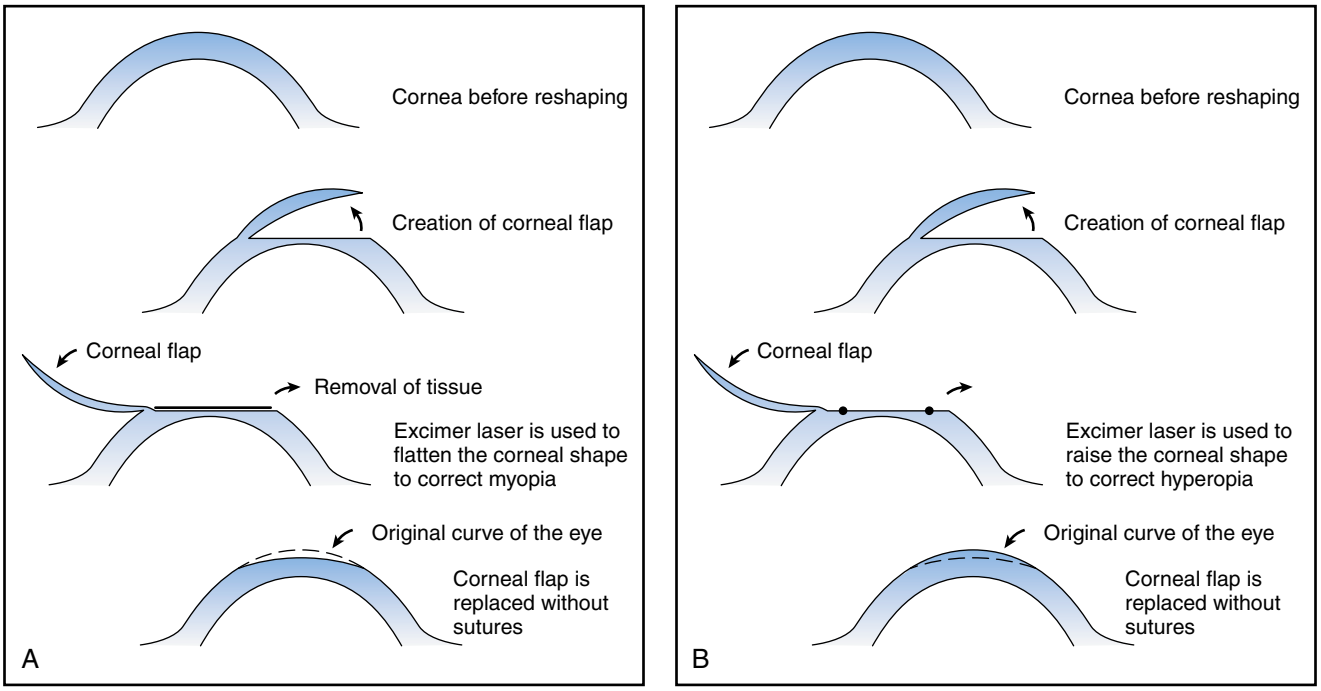

FIGURE 17-29 Laser-assisted in-situ keratomileusis (LASIK) surgery. **A**, Diagram of LASIK correction for nearsightedness. **B**, Diagram of LASIK correction for farsightedness.

SURGERY OF THE LENS

Cataract Extraction

A cataract is defined as any opacification of the lens. Cataracts may be congenital, posttraumatic, or induced by medications (particularly corticosteroids), but are most commonly the result of age-related changes.

Normally, light passing through a clear lens projects a sharp image onto the retina. When the lens becomes cloudy (cataractous) through the aging process, vision becomes blurred. A cataract can be compared to a window that is frosted or yellowed (Burlew-Quartey, 2008). More than half of all Americans over age 80 have a cataract or have undergone surgery for it. The lens is made of mostly water and protein; over time, some of the protein may clump together, leading to clouding of the lens (cataract). The vision gradually gets worse as the lens changes from clear to a yellow/brown color (Figure 17-30); the pupil may appear gray. The tinting eventually makes it difficult to differentiate certain colors like purple or blue, and difficult to read or perform routine activities. Cataract removal is warranted when there is interference with everyday activities such as driving, reading, and watching television (NEI, 2008b). Other symptoms include having poor night vision, noticing glare from headlights or lamps, and perceiving that sunlight is too bright. Halos may be noticed around lights as well. Double vision might also be noticed. These symptoms may indicate other eye problems so an eye exam would be warranted to determine the exact cause. See Figure 17-31 for a depiction of a person's view with normal vision, cataract, glaucoma, and diabetic retinopathy.

Besides age-related cataracts, the following other types of cataracts exist:

- *Congenital*—Children may be born with cataracts or develop them throughout their youth.
- *Traumatic*—After eye injury or electric shock, cataracts may develop even years later.
- *Secondary*—After eye surgery for other conditions, cataracts may develp, or they may be associated with other health problems such as diabetes, steroid use, smoking, and prolonged exposure to sunlight (NEI, 2008b).

A cataract extraction is removal of the opaque lens from the interior of the eye and can be accomplished by several methods.

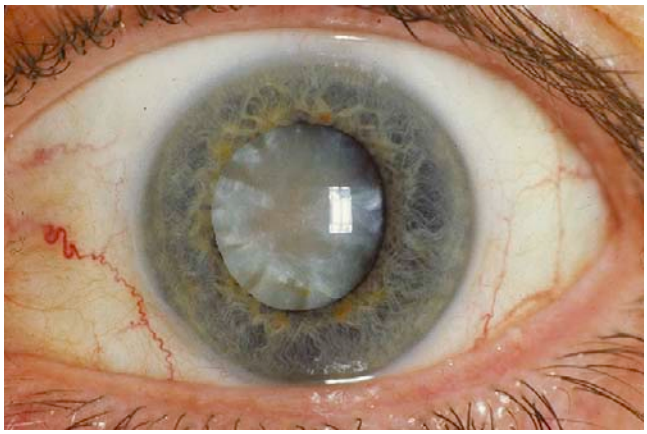

FIGURE 17-30 A hypermature age-related cortico-nuclear cataract with a brunescent (brown) nucleus.

The *intracapsular cataract extraction* (ICCE) method of cataract removal consists of removing the lens within its capsule with a cryoprobe and is rarely performed today except in the event of a dislocated lens. If an ICCE is scheduled, alpha-chymotrypsin (Catarase, Chymar), an enzyme that acts on the zonules of the lens, and a cataract cryoprobe need to be procured.

In the extracapsular method (ECCE), the anterior portion of the capsule is first ruptured in a controlled manner and removed. The surgeon expresses the lens cortex and nucleus from the eye, leaving the posterior capsule behind. Restoration of functional vision is necessary after removal of the crystalline lens (aphakia). Contact lenses can be used to correct aphakia. They offer an excellent option for visual correction and can be used for monocular aphakia.

Over the past years numerous microsurgical techniques have been developed for lens removal through a small self-sealing incision and most recently through a clear corneal incision. ECCE with phacoemulsification is still performed, especially with very mature or hard cataracts, and may be performed in combination with trabeculectomy for patients with glaucoma. Patients receiving long-term glaucoma therapy (which causes pupil constriction) may not dilate well and may need iris retractors during surgery. Adequate pupil dilation is necessary for safe visualization of all affected intraocular structures.

Basically, each technique involves opening the lens capsule and using a phacoemulsification unit with irrigation and aspiration (I/A). Pressures in the anterior and posterior chambers are generally equal. Once the surgeon makes the incision into the anterior chamber, aqueous fluid leaks from it. Pressure in the anterior chamber falls below that in the posterior chamber, and vitreous from the back of the eye tries to push forward and could carry other structures with it. To minimize the risk from these pressure gradients, early in the procedure the surgeon will inject thick viscoelastics, which do not leak.

The high-frequency ultrasonic energy of phacoemulsification fragments the hard lens material (similar to a jackhammer), which can then be aspirated from the eye. Some phacoemulsification units utilize oscillating movements (side-to-side). All perioperative personnel using specialized instruments and equipment must have thorough knowledge of the operation as well as problems that may be encountered and actions to correct them.

Roughly 90% of people who have cataract surgery have better vision afterward. Cataract surgery not only is one of the most common surgeries performed in the United States but also is one of the safest and most effective surgeries (NEI, 2008b). Patients with cataracts in both eyes that need surgery will generally have their procedures performed at separate times, usually 4 to 8 weeks apart. Months or years after cataract surgery, cells may grow back, causing opacification of the posterior capsule and a haze in the vision. The YAG laser may then be indicated for capsulotomy, creating a hole in the center of the capsule to allow light to pass through and restore clear vision (Burlew-Quartey, 2008).

Potential complications, though rare, are discussed as part of informed consent. In a patient with vision in only one eye, the risks/benefits of surgery must be carefully evaluated. The potential problems include infection, bleeding, inflammation, loss of vision, double vision, and high or low eye pressure (NEI, 2008b). The American Society of Cataract and Refractive

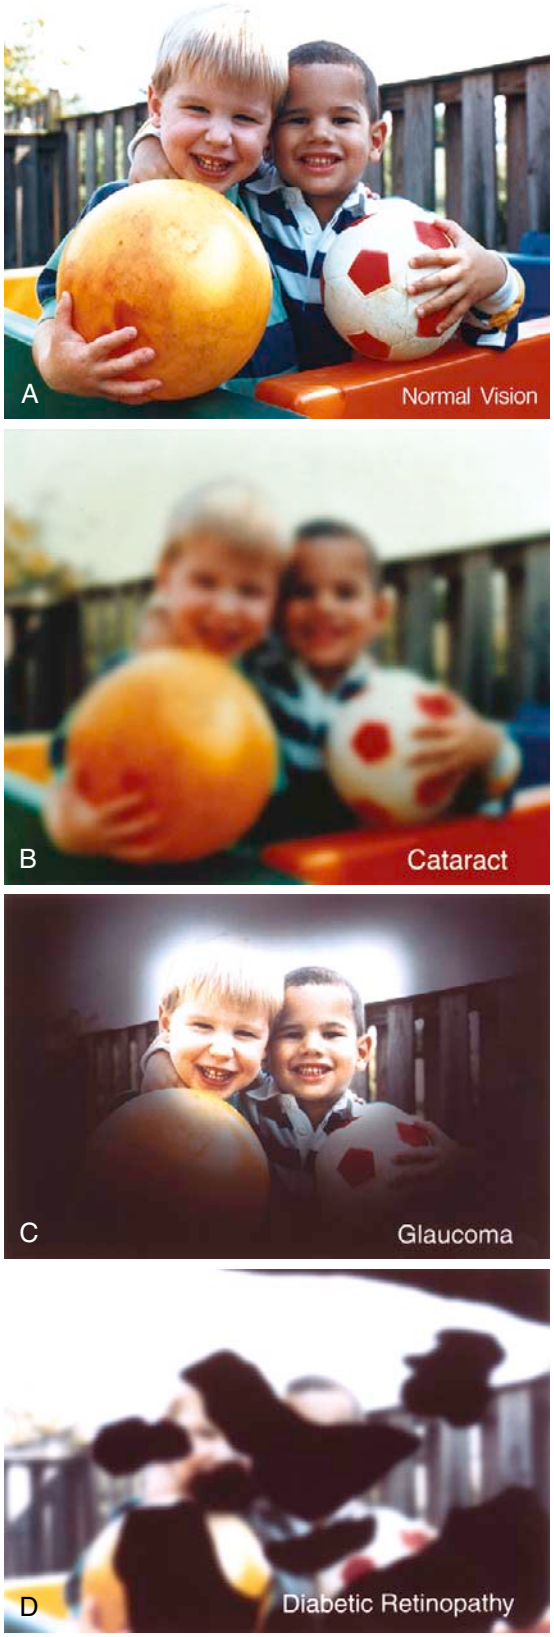

FIGURE 17-31 Comparative views with (**A**) normal vision, (**B**) a scene as it might be viewed by a person with cataract, (**C**) a scene as it might be viewed by a person with glaucoma, and (**D**) a scene as it might be viewed by a person with diabetic retinopathy.

Surgery and the American Academy of Ophthalmology (AAO) have issued a joint clinical *Information Statement and Patient Advisory,* recommending that "patients taking alpha-blockers to treat prostate enlargement or other conditions inform their ophthalmologist about these medications before undergoing eye surgery. Prior to being started on this class of drugs, patients with cataracts should be informed that alpha-blockers, in general, and Flomax (tamsulosin), in particular, may increase the difficulty of cataract surgery" (AAO, 2009). The condition of intraoperative floppy iris syndrome (IFIS), first reported in 2005, is explained: "The iris, the part of the eye that gives it its color, opens and closes in response to varying light levels. Because the iris is located in front of the cataract, the pupil (opening in the iris) must be widely dilated to perform the surgery. A large pupil is obtained, in part, by using dilating drops that stimulate the iris dilator muscle. Alpha-blockers, such as Flomax, block this iris muscle, leading to poor dilation and sometimes causing the pupil to suddenly constrict during surgery." The patient advisory emphasizes the importance of communicating any history of Flomax use as the complication may occur even if the drug has been discontinued. This communication for proper medical judgment for each individual patient is essential for positive outcomes: "The overall risk of serious cataract surgical complications is low, and when the ophthalmologist is informed of the patient's history of alpha-blocker use, the success rate of cataract surgery remains very high."

Although various manufacturer's systems and platforms exist for cataract surgery, basic considerations remain. Parameters are not interchangeable between formats; power and vacuum settings are measured differently in different machines. Even the height of the irrigation bottle may be measured differently. The nurse and team must challenge themselves to new ideas in evaluating new technology and adjusting to varied practice settings. Foot pedals also are different; for example, positions 1, 2, and 3 have different functions in each machine. Overall, through teamwork and adequate training and monitoring for competency, the surgical team can optimize technology for safety and efficiency in cataract surgery regardless of the equipment used.

Intraocular Lens. Extraction of the cataractous lens removes one of the major refractive components of the eye. Three options for replacing this lost refractive power are (1) use of aphakic glasses, (2) use of aphakic contact lenses, and (3) intraocular lens (IOL) implantation. IOLs offer many advantages to patients, including reduced dependence on spectacles, reduced thickness of any spectacle correction needed, and elimination of aberrations produced by aphakic glasses or contact lenses.

Current generation IOLs are made of silicone or acrylic resin. Foldable and injectable designs and new implantation techniques challenge perioperative nursing personnel to keep abreast of changes in techniques for IOL implantations. Posterior chamber lenses (PCLs) can be implanted only when the cataract was removed by extracapsular cataract extraction (ECCE). Placement behind the iris is the most physiologic position for an artificial lens (posterior chamber lens) and is the most common method. Anterior chamber lenses (ACLs), placed in front of the iris, are used in the absence of capsular support, including after vitreous loss or ICCE and for secondary lens implantation (when the cataract was previously removed without lens replacement) (Burlew-Quartey, 2008).

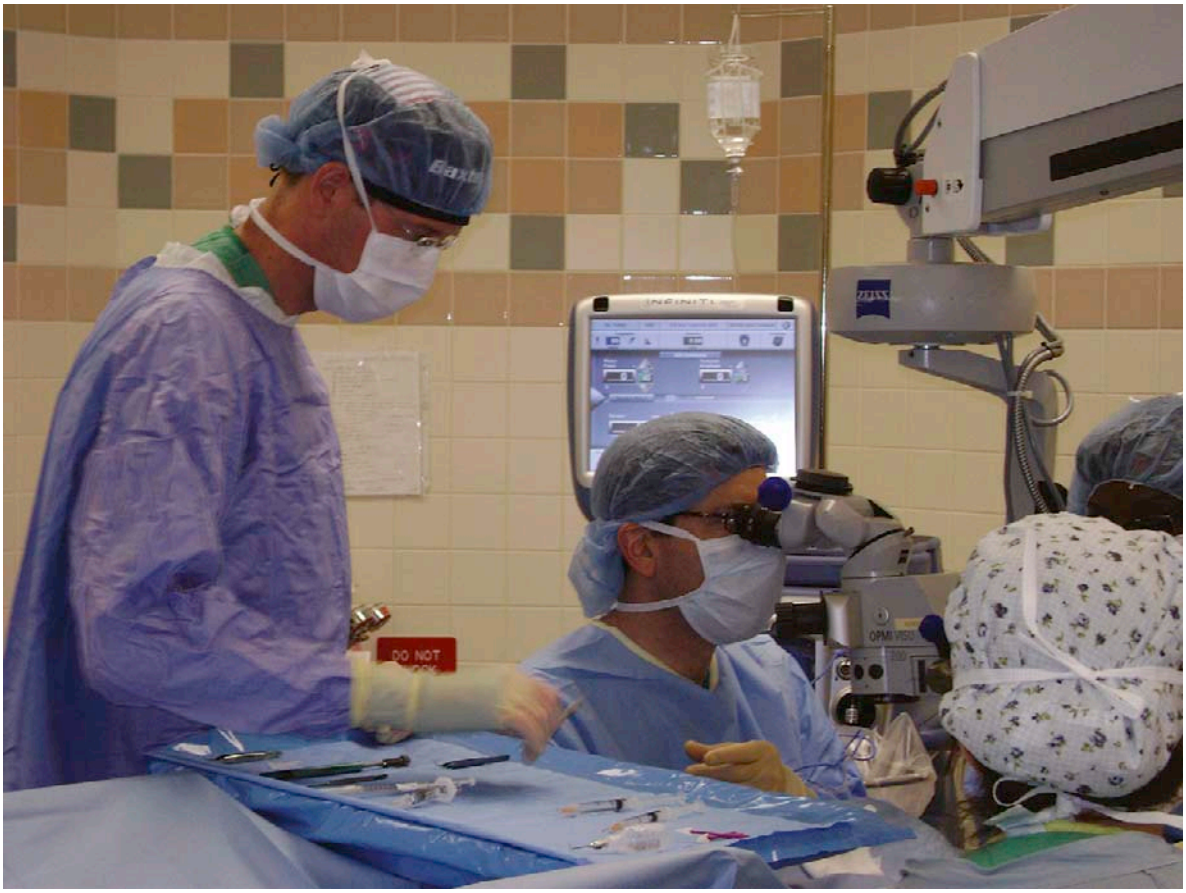

FIGURE 17-32 Cataract surgery in progress. Note irrigation bottle and phacoemulsification unit in background; surgeon sitting at side of patient (temporal approach); scrub person ready to anticipate surgeon's needs; anesthesia provider at patient's side for reassurance and comfort. Circulating nurse, not shown, is coordinating all activities and monitoring for safety.

IOLs are available in various diopter powers. The necessary power customized for each patient is determined by measuring the curvature of the patient's cornea (keratometry) and the axial length (length from cornea to retina). A mathematical formula is then used to calculate the correct lens power. IOLs are also available in bifocal and multifocal types. Some feature ultraviolet protection.

Sutureless cataract techniques have become increasingly popular because of rapid visual rehabilitation. Clear corneal microincisions (3 mm wide or less) with the use of topical anesthesia and insertion of foldable IOLs have produced even better visual results with the opportunity to fully correct refractive errors.

Procedural Considerations. Instrumentation varies with surgeon's preference but usually includes forceps to insert the lens and lens haptics and a hook to aid in rotating and positioning the lens. Perioperative nursing personnel must be familiar with institutional policies pertaining to IOLs and their use. For example, the American Academy of Ophthalmology (AAO, 2008) developed recommendations to minimize the occurrence of preventable errors such as wrong IOL implant (i.e., to ensure the highest level of patient safety in surgery). The tenets encompass the importance of communication with surgery staff. The recommendations emphasize the importance of heightened communication and verifications of preoperative calculations of lens style and power ordered, and documenting it as a written order. Besides verifying the implant during the time-out, it is recommended that the surgeon have some form of written documentation regarding the case and IOL (white board, or copy of operative plan taped to microscope) available to view when scrubbed, gowned, and gloved and seated at the surgical microscope.

Surgical techniques vary based on surgeon training and experience. Some surgeons sit at the head of the bed whereas others use a temporal approach (Figure 17-32). Some use topical drops, and others use anesthetic gel. Regardless, the surgery follows certain basic steps.

TOPICAL CLEAR CORNEAL CATARACT PROCEDURE. Developments with the use of topical anesthetics, new materials for foldable IOLs, and diamond knives for self-sealing or no-stitch wounds led to clear cornea incisions and new techniques for phacoemulsification and lens implantation for cataracts. Clear cornea microincisions create the opportunity for full correction of refractive errors during the surgical procedure.

Topical anesthesia replaces retrobulbar anesthesia for cataract surgery, and because the patient can fixate, this allows for refractive surgical techniques. Patients must be able to hear

and follow directions so that they can cooperate with verbal instructions to fixate on the microscope light. Various medications and protocols are used for administering topical anesthetics before cataract surgery.

Procedural Considerations. The nurse administers a drop of topical tetracaine 0.5% into the operative eye before the patient enters the OR. The patient is instructed to keep this eye closed to prevent the cornea from drying. As the patient is being positioned, the nurse administers another drop of tetracaine. An armrest is positioned on the operative side, and the patient's head and the microscope are adjusted. The patient is instructed to look at the light of the microscope and told where to fixate. If the patient cannot open his or her eye, a facial nerve block should be considered. If the patient cannot fixate on the light at all, a retrobulbar block should be considered.

Operative Procedure

1. The surgeon places an eyelid speculum with an open temporal area.
2. A 1-mm-wide stab incision (paracentesis, tiny incision in cornea opposite the main incision) is made at 5 o'clock in the left eye or at 11 o'clock in the right eye into the anterior chamber.
3. Intercameral anesthesia may be used: 1 ml of unpreserved lidocaine is slowly injected into the anterior chamber through a 30-gauge cannula using a tuberculin syringe.
4. The surgeon injects viscoelastic material into the anterior chamber to deepen the chamber and widen the pupil.
5. The temporal cornea incision is made with a (diamond or single-use) keratome. Some surgeons may use a caliper to mark the incision width, and may use a second knife to make a vertical cut before the horizontal pass with the keratome (Figure 17-33, *A*).
6. A capsulotomy and capsulorrhexis are performed with a capsulorrhexis forceps (Figure 17-33, *B*). This step of tearing the capsule in a controlled manner is critical in creating a round, stable opening into the capsular "bag."
7. Using a 30-gauge cannula and saline, the surgeon performs hydrodissection (and sometimes hydrodelineation) to separate the center/nucleus from the capsule and maneuver the lens within the capsule (Figure 17-33, *C*).
8. The surgeon uses a phacoemulsification tip to sculpt the nucleus with the ultrasound vibration.
9. A second instrument is inserted through the left-handed paracentesis incision to help rotate and divide the cataractous nucleus into quadrants (Figure 17-33, *D*).
10. Cataractous nucleus removal usually proceeds in two phases: nuclear sculpting, wherein the nucleus is cracked or sculpted into smaller fragments, and quadrantic emulsification of those fragments.
11. Following removal of the lens nucleus, the surgeon places an irrigation/aspiration (I/A) tip into the eye and uses it to remove the remaining cortical material (Figure 17-33, *E*). This combination of irrigation and aspiration intends to maintain equilibrium within the eye. Removing the cortex minimizes postoperative inflammation.
12. Some surgeons may polish the posterior capsule or aspirate anterior lens epithelial cells.
13. The surgeon injects viscoelastic material to inflate the anterior chamber and capsular bag.
14. A posterior chamber IOL is folded and placed into the eye with an injector or forceps and then into the capsular bag (Figure 17-33, *F* and *G*). The IOL is positioned with a Sinsky hook or the I/A tip. Some surgeons may need to widen the corneal incision before placing the IOL.
15. The surgeon uses the I/A tip to remove any remaining viscoelastic material. Leaking of the wound may be controlled or prevented by hydrating the wound edges. Occasionally a 10-0 nylon suture is necessary.
16. Topical antibiotics or combination antibiotic-corticosteroid ointment or drops are placed on the eye. The eye is not patched, but a shield is commonly used.

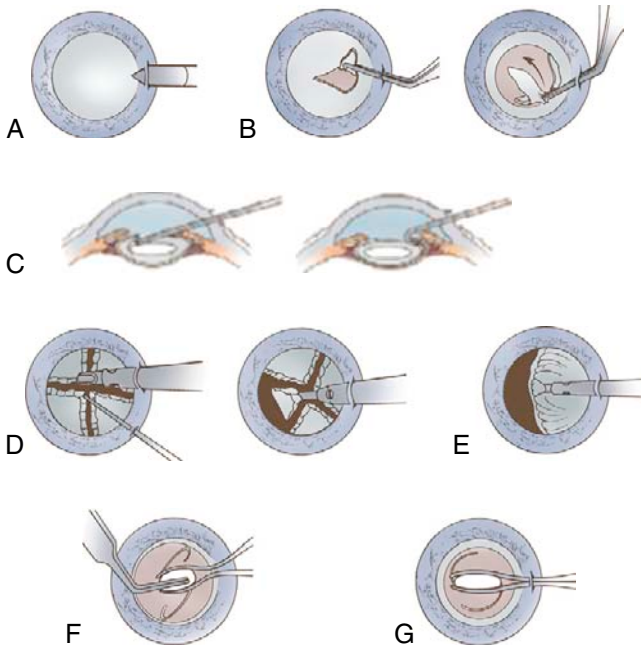

FIGURE 17-33 Clear cornea cataract extraction. **A**, A 2.6-mm incision is made into the cornea. **B**, Capsulorrhexis is performed on anterior capsule of lens. **C**, Nucleus of lens is loosened by hydrodissection. **D**, Nucleus of lens is "cracked" into four quadrants and removed with phacoemulsification. **E**, Irrigation and aspiration (I/A) handpiece is used to strip the remaining cortex from the capsule. **F**, Intraocular lens (IOL) is folded. **G**, IOL is placed into the capsular bag.

EXTRACAPSULAR METHOD WITH PHACOEMULSIFICATION

Operative Procedure

1. After a superior rectus bridle suture is placed, a small limbus-based flap is dissected superiorly.
2. Using sharp dissection with a Beaver knife blade the surgeon cleans the surgical limbus. Hemostasis is obtained with the bipolar ESU.
3. A 3-mm or smaller incision is made into the eye with either a keratome or a sharp microknife.
4. The surgeon opens the lens capsule with capsulorrhexis forceps or a cystotome. The anterior chamber may be kept formed with air or an irrigating solution.
5. The lens nucleus is loosened from the cortex with the cystotome or a blunt cyclodialysis spatula.
6. The surgeon checks the ultrasonic handpiece for appropriate vacuum control and introduces it into the eye. *The vacuum control check is critical and must be performed before the handpiece is introduced into the eye.*

7. When the lens nucleus has been emulsified and removed, the surgeon removes the lens cortex with the I/A handpiece.
8. If a foldable IOL is to be implanted, the surgeon may use a keratome to widen the incision to 3.2 mm before folding and inserting the lens. If a rigid IOL is to be implanted, the wound is extended to 5.1 mm to accommodate the lens diameter. Acetylcholine may be introduced to constrict the pupil.
9. The corneoscleral wound is closed with a 10-0 nonabsorbable suture.
10. The conjunctival flap is closed with a suture or using the bipolar ESU.
11. An eye pad and shield are applied.

Anterior Segment Vitrectomy

The main indications for vitrectomy in the anterior segment are as follows:

- Vitreous loss during cataract extraction
- Opacities in the anterior segment
- Complications associated with vitreous in the anterior chamber
- Miscellaneous causes, such as hyphema, pupillary membranes, and residual soft lens material

Procedural Considerations. The procedure varies according to the surgeon's preference. A pathologic condition in the anterior segment can be approached through a limbal incision, as in lens extraction with vitreous loss, or through an "open sky" approach, after trephine incision for penetrating keratoplasty. Most phacoemulsification equipment has a vitrector that can be quickly attached if needed.

Operative Procedure

ANTERIOR VITRECTOMY FOR VITREOUS LOSS DURING CATARACT EXTRACTION

1. The surgeon introduces the vitreous cutter into the eye through the cataract wound. Infusion may be through the handpiece or a separate cannula and infusion line.
2. The cutter is placed in the middle of the pupil, posterior to the iris, and enough vitreous is removed to ensure that no vitreous remains in the anterior chamber and that the iris has fallen back into its normal position.
3. The pupil is constricted with acetylcholine. The anterior chamber may be re-formed with balanced salt solution (BSS).
4. The procedure is completed as for a lens extraction.

ANTERIOR VITRECTOMY FOR ANTERIOR SEGMENT OPACITIES, HYPHEMA, PUPILLARY MEMBRANES, AND RESIDUAL SOFT LENS MATERIAL

1. Appropriate fixation sutures or a lid speculum is placed.
2. The surgeon makes an incision at the limbus either through clear cornea or under a conjunctival flap. One to three incisions are made, depending on the vitreous cutter chosen and the technique.
3. If a multifunction probe is not used, the surgeon places an infusion cannula into one incision and the vitreous cutter into another incision. A third incision may be used for an accessory instrument. The vitreous, blood, or other material is removed.
4. The incisions are closed, and the eye is patched.

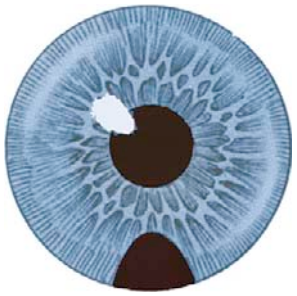

FIGURE 17-34 Peripheral iridectomy.

SURGERY FOR GLAUCOMA

Iridectomy

Peripheral iridectomy is removal of a section of iris tissue (Figure 17-34). Peripheral iridectomy is usually performed as part of a trabeculectomy procedure or may be performed when laser iridotomy is not feasible because of cloudy cornea or uveitis. Peripheral iridectomy is done in the treatment of acute, subacute, or chronic angle-closure glaucoma when extensive peripheral anterior synechiae have not formed. This operation is performed to reestablish communication between the posterior and anterior chambers, thus relieving pupillary block and permitting the iris root to drop away from the trabecular meshwork to reestablish the outflow of aqueous fluid through Schlemm's canal.

Operative Procedure

1. The speculum is introduced. The globe is fixed with a 4-0 traction suture passed under the superior rectus and fastened to the drape with a hemostat.
2. A small beveled incision is made at the superior limbus, or a perpendicular incision is made in the clear cornea.
3. The surgeon grasps the peripheral iris with forceps, pulls it through the incision, and excises it.
4. The iris is repositioned by gently stroking the cornea with a blunt spatula or muscle hook. The iris can also be repositioned by irrigating with BBS.
5. A clear corneal incision is closed with 10-0 nonabsorbable suture, and a limbal incision is closed with absorbable suture. Subconjunctival antibiotics may be administered, and an eye pad is applied.

Trabeculectomy

Trabeculectomy is a filtering procedure accomplished by incising a conjunctival flap and a scleral flap, creating a fistula, performing an iridectomy, and creating the filtering bleb. Trabeculectomy is often combined with cataract removal (phacoemulsification) and insertion of an IOL.

Procedural Considerations. Adjunctive medical therapy to decrease postoperative fibrosis includes application of an antimetabolite-soaked sponge (5-fluorouracil [5-FU] or mitomycin C) placed under the conjunctival flap. Because 5-FU and mitomycin C are antimetabolites, nursing precautions for handling hazardous waste must be carried out. The perioperative nurse must wear gloves while drawing up the antimetabolite from the vial to transfer to the operative field. All items used with the medication should be disposed as hazardous waste. Instruments that contact antimetabolites should be washed separately.

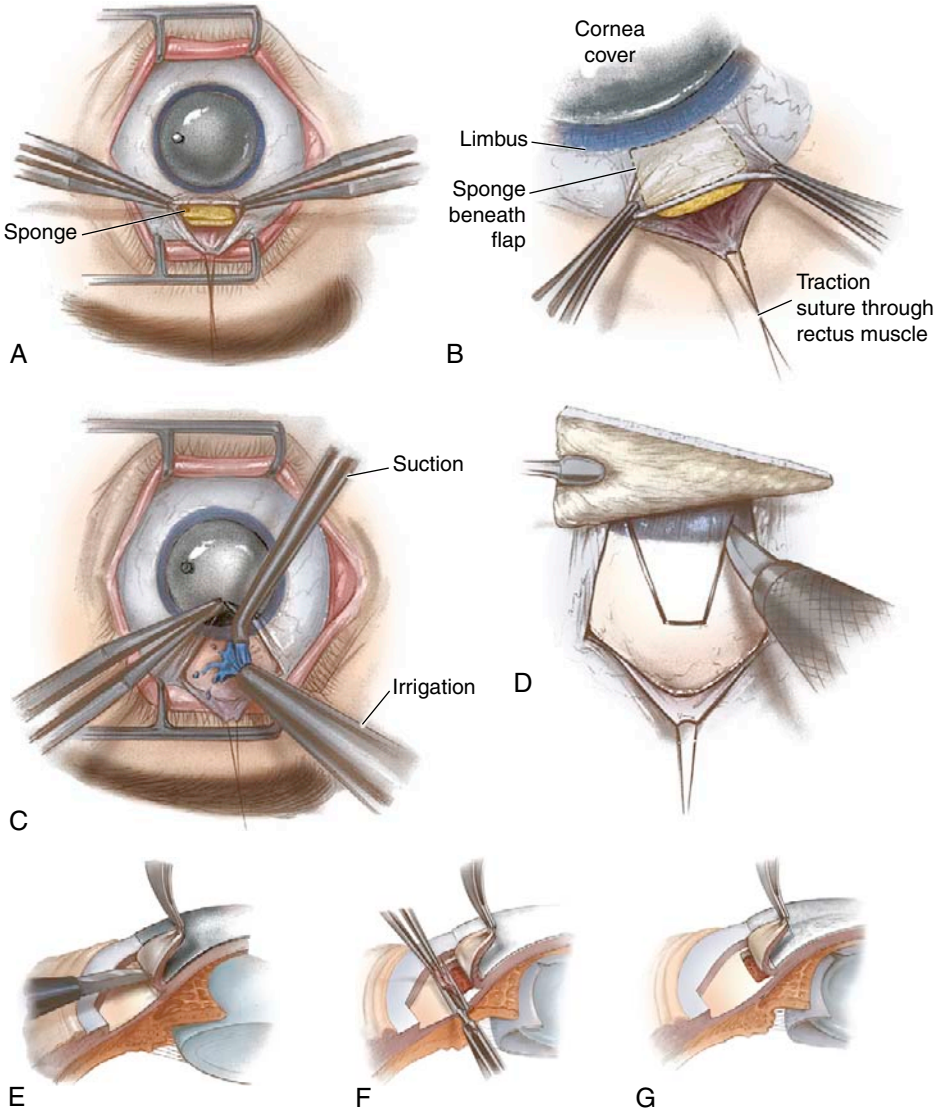

FIGURE 17-35 Trabeculectomy. **A**, Sponge soaked in antimetabolite is placed on sclera and (**B**) held in place for 3 to 5 minutes. **C**, Area is thoroughly irrigated. **D**, Scleral flap is formed. **E**, Incision is made into anterior chamber. **F** and **G**, Fistula is created by removing a flap of limbal tissue.

Operative Procedure

1. Incisions are made into the conjunctiva and Tenon's capsule, dissection is done, and a conjunctival Tenon's capsule flap is created. Hemostasis is obtained with bipolar coagulation (Figure 17-35).
2. If antimetabolite is to be used, the surgeon applies it to the sclera before making any incision into the sclera. A small piece of sponge is saturated in the antimetabolite (5-FU or mitomycin C) and placed between the conjunctival Tenon's capsule flap and the sclera. The sponge is left in place for 3 to 5 minutes, and then the site is irrigated vigorously with copious amounts of BSS.
3. The surgeon creates a square or triangular partial-thickness scleral flap.
4. The scleral flap is retracted, and the surgeon makes an incision into and through the limbus into the anterior chamber with the tip of the blade. The limbal incision is extended to a rectangular flap of deep limbal tissue, which is then excised to create the fistula.
5. An iridectomy is performed. The eye cautery is applied to bleeding sites and to the ciliary processes.
6. The surgeon replaces the scleral flap and closes it with interrupted 10-0 nonabsorbable sutures. The conjunctival Tenon's capsule flap is closed with a running suture, and the conjunctiva is closed.
7. BSS is injected through a cannula into the anterior chamber to deepen the anterior chamber and elevate the conjunctival bleb.
8. An eye pad and shield are applied.

Glaucoma Drainage Devices

Several types of drainage devices (Figure 17-36) have been implanted into the posterior subconjunctival space with varying success when filtering procedures have been unsuccessful. These include the Molteno implant, Krupin valve, Ahmed

FIGURE 17-36 Glaucoma drainage devices (GDDs). **A**, Components of GDD. **B**, Photo of Molteno3 implant. **C**, GDD in place. Tip of drainage tube in anterior chamber. Donor scleral patch or pericardium covering tube from plate to edge of cornea.

EVIDENCE FOR PRACTICE

Systematic Review of Aqueous Shunts in Glaucoma Surgery

When surgeons are unable to control primary or secondary glaucoma with medication, laser treatments, or standard surgical techniques (e.g., trabeculectomy), they may have to utilize an aqueous shunt. A variety of commercially produced shunts are available for use. Shunts lower intraocular pressure (IOP) by providing a passageway for aqueous fluid to drain from the eye and be absorbed via the capillaries into the general circulation.

Numerous studies and clinical trials have been conducted to determine which type of shunt is most effective and if shunts are more effective than other forms of therapy aimed at reducing IOP. A Cochrane Database Review examined 15 trials with a total of 1153 participants with mixed diagnoses. Other researchers reported findings to the American Academy of Ophthalmology after examining 17 previously published randomized trials, 1 prospective nonrandomized comparative trial, 1 retrospective case-control study, 2 comprehensive literature reviews, and published English language, noncomparative case series, and case reports. Both groups concluded that at this time there is no demonstrable evidence of superiority of one type or brand of shunt over another but stated that aqueous shunts do offer benefits comparable to trabeculectomy; they agree that further long-term, comparative studies are necessary to determine efficacy and note that the physician's judgment should be the key factor when making treatment decisions for patients with IOP.

Modified from Mickler DS et al: Aqueous shunts in glaucoma, *Cochrane Database Syst Rev* 19(2):CD004919, 2006; Mickler DS et al: Aqueous shunts in glaucoma: a report by the American Academy of Ophthalmology, *Ophthalmology* 115(6):1089-1098, 2008.

device, Baerveldt device, and Schocket implant. Complications have been reduced through modifications in design and technique (Evidence for Practice).

Procedural Considerations. The glaucoma drainage device may be soaked in an antibiotic solution, and the pericardium or donor patch graft will also need to be hydrated or soaked. The drainage device and graft are documented as implants per facility procedure.

Operative Procedure

1. The surgeon incises the conjunctiva and exposes the sclera.
2. Two rectus muscles are isolated using silk ties as traction sutures.
3. The surgeon takes measurements for placement of the plate of the device. The plate is then sutured to the sclera.
4. After the patency of the device is checked, the surgeon inserts an occluding suture into the drainage tube.
5. With a needle, a tunnel is created into the anterior chamber for the tube and paracentesis tract.
6. The tube is trimmed and inserted into the anterior chamber. The surgeon sutures the tube to the sclera with 9-0 nonabsorbable suture.
7. The tube is covered with patch graft of donor sclera or pericardium.
8. The occluding suture is passed through Tenon's capsule and the conjunctiva into the inferior cul-de-sac, secured with absorbable suture, and trimmed.
9. The surgeon removes the traction sutures from around the rectus muscles, and closes the conjunctiva with a continuous 7-0 absorbable suture.
10. Antiinfective agents are injected subconjunctivally. The eye is dressed with an eye pad and shield.

VITREORETINAL SURGERY

Vitreous fluid fills about two thirds of the eye, helps keep the round shape of the eyeball, and is originally attached to the retina. The vitreous slowly liquefies, atrophies, and shrinks as we age. The vitreous then can become stringy, and shadows can be cast onto the retina, causing "floaters" ("cobwebs" or specks that float in the field of vision). They may look like spots, threadlike strands, or squiggly lines. Floaters are more noticeable when looking at bright objects, such as a white piece of paper. Floaters are more common in patients who have diabetes, have undergone cataract surgery, or are nearsighted. Over time, the floaters usually settle below the line of sight but do not completely disappear. Floaters in and of themselves generally do not require treatment. However, if a patient experiences a sudden increase in the number of floaters, retinal examination is warranted to rule out a retinal tear, break, or hole (NEI, 2008c).

The retina, the light-sensitive layer of tissue lining the eye, sends visual signals via the optic nerve to the brain. Attached to the retina are millions of fine fibers intertwined with the vitreous. The shrinking vitreous in an aging eye causes the fine fibers to pull on the retinal surface. When the fibers break, the vitreous separates and shrinks from the retina, causing traction on the retina. Normally, the vitreous detaches from the retina (a posterior vitreous detachment). However, sometimes the vitreous can create traction on the retina and pull a piece of the retina with it, creating a retinal tear. Fluid can then leak under the retina into the subretinal space, leading to a retinal detachment; symptomatic breaks (manifested as new floating objects or flashing lights) are likely to progress to a retinal detachment.

Posterior vitreous detachments (PVDs) are usually not sight-threatening and, like floaters, typically do not require treatment. Patients at risk for the development of PVD are those who are nearsighted and more than 50 years of age. The condition is very common after age 80. Again, it may not be noticeable, or will simply be annoying because of an increase in floaters. A small but sudden increase in new floaters is a symptom of vitreous detachment. Flashes of light in side vision may also occur (NEI, 2008d).

Occasionally, some of the vitreous fibers pull so hard on the retina that it causes a retinal detachment (RD)—that is, the sensory retina (neural layer) is separated from the underlying retinal pigment epithelium layer. RD is considered an emergency and should be treated immediately. Anyone who has a sudden increase in floaters or an increase of lightning flashes in peripheral vision (a result of separation of the retina) should see a retinal specialist as soon as possible for an eye exam. The dilated eye exam is the only way to diagnose the exact cause of the vision problem; potentially, permanent loss of vision can occur without timely treatment (NEI, 2008e).

An additional symptom of retinal detachment is the appearance of a "curtain" in the field of vision, from above, below, or the side. Retinal detachment may occur because of the presence of intraocular neoplasms originating in the retina or choroid (exudative type) or, more commonly, as a result of retinal tears or holes associated with injury, degeneration, or vitreous contraction. One in 10,000 people develops a retinal detachment each year; 1 in 3 patients who have undergone cataract surgery develop it. Males are more likely to develop retinal detachment than females (Gutierrez and Peterson, 2007). The most common cause is diabetic retinopathy. Retinal detachment is more common in people older than 40 years. Caucasians are affected more than African Americans. Other risk factors include history of nearsightedness or retinal detachment in the other eye, family history of RD, presence of lattice degeneration (thinning of the retina in nearsighted people), and occurrence of an eye injury.

Other retinal diseases can be grouped into categories. Treatment of specific conditions partly depends on the category, such as surgical repair for structural disorders or laser repair for vascular conditions. Retinal disease categories and examples include the following:

- *Traumatic/structural:* retinal detachment, intraocular foreign body
- *Neoplastic:* choroidal melanoma, retinoblastoma
- *Immune/infectious:* endophthalmitis (infection inside the eye including pus)
- *Vascular:* diabetic retinopathy, retinal vein occlusions
- *Toxic:* systemic tamoxifen retinal toxicity

Prevention is a key emphasis to avoid the need for treatments. Studies show that optimal management of systemic disease can potentially and dramatically prevent vision loss. For example, one study demonstrated strict glucose level control over 5 to 10 years reduces the onset of diabetic retinopathy by 75% and reduces progression of retinopathy by 50%; another study showed a 35% reduction in the need for retinal laser treatment through strict control of high blood pressure (Gariano, 2008).

Microvascular disease is related to the eye's vulnerability as a result of its dense network of capillary vessels. Diabetes leads to retinal changes (diabetic retinopathy). The presence of diabetes for more than 15 years significantly increases the likelihood of developing some form of retinopathy, typically bilaterally. However, the severity may be different between eyes. Retinopathy is classified in either of the following ways:

- *Background, or nonproliferative:* In this form of retinopathy disease is confined to the retinal surface. Retinal capillary walls develop microaneurysms (bulges) that can lead to leakage and the development of exudates under the retina. Hemorrhages occur within the retina and are reabsorbed. Capillary membrane changes result in blocked capillaries and, thereby, retinal ischemia. Eventually deterioration progresses to the next stage.
- *Proliferative:* Neovascularization, or the formation of new retinal blood vessels, can develop within the retina in an attempt to relieve ischemic anoxia secondary to microvascular damage caused by diabetes. These new vessels are fragile and can rupture spontaneously, causing bleeding, and they are very permeable, causing leakage. Hemorrhage into the retina and/or vitreous can consequently ensue, leading to severe visual loss (Phillips, 2007).

The presence of retinopathy predisposes the patient to retinal detachment. In retinal detachment, pigment or blood cells are freed in the vitreous, causing the previously mentioned symptoms of flashes and floaters. Fluid from the vitreous cavity can seep through the retinal tears into the subretinal space and progressively detach the retina. The part of the retina that has separated from its nutritional source becomes damaged and relatively nonfunctional. On occasion, inflammatory/scar tissue can develop on the retinal surface, leading to an epiretinal membrane that can distort vision. As the inflammatory/scar tissue, which is firmly attached to the retina, contracts, the retina can wrinkle or "pucker." When the wrinkle is over the area of the macula, the central vision becomes blurred and distorted. Diabetic retinopathy can also lead to the macular pucker.

In the same manner, as the shrinking vitreous pulls the retina, it can cause microscopic damage. The retina heals itself by scarring, and the macular pucker can result. If the shrinking vitreous pulls too hard, the retina can tear at any location. When the macula is affected, it is more serious because of the effect on central vision, and is called a macular hole. Both macular pucker and macular hole have the same symptoms—distorted, blurred vision (NEI, 2008f). Additionally, a macular hole may present with distortion of straight lines, and difficulty reading. Vision ranges from 20/25 to 20/400 (the latter for untreated macular hole). Fifty percent of very early macular holes close on their own. Vision recovery potential is better for patients who had a macular hole for 6 months (American Society of Ophthalmic Registered Nurses [ASORN], 2007).

Various types of retinal detachment exist:

- *Rhegmatogenous:* This is the most common type. Fluid exudate from a tear or break in the retina leaks under the retina, separating it from the retinal pigment epithelium (RPE).
- *Tractional:* This form of retinal detachment is often secondary to diabetic retinopathy, especially if untreated. The retina also separates from the RPE, but this time it is attributable to the contraction of scar tissue on the retina's surface.
- *Exudative or serous:* In inflammatory retinal disease or trauma, fluid exudate leaks under the retina. In this type, however, there are no breaks or tears in the retina.

Location of the pathology on the retina affects visual symptoms. Macular pucker, for example (also called epiretinal membrane, preretinal membrane, retina wrinkle, or internal limiting membrane disease), generally affects the macula, located in the center of the retina. The macula normally provides sharp, central vision needed for reading, driving, and fine detail work, and when puckered can cause blurred, distorted central vision.

Various modalities for surgical treatment include laser treatments, scleral buckling, vitrectomy, and retinopexy. In addition to any of these therapies, freeze treatment (cryopexy) may be performed in the surgeon's office for small holes and tears to help "weld" and reattach the retina (NEI, 2008d).

LASER TREATMENT IN DIABETIC RETINOPATHY

Laser energy is used to apply burns to peripheral retinal tissue to help neovascularization regress. The pathophysiologic mechanism for regression of neovascularization is not completely understood, but is thought to occur as a result of the reduced retinal oxygen requirement as a result of the scarred retinal tissue. This method of eliminating abnormal vascularization is called panretinal photocoagulation (PRP). Again, in principle, early diagnosis and control of blood glucose levels are paramount, as laser treatment does indeed partially destroy the retina in order to help arrest neovascularization. Thus surgeons use the laser before excess damage occurs, electrocoagulating minute hypoxic areas to prevent the new vessels from forming (Phillips, 2007) (Figure 17-37). Laser treatments may initially begin in an office setting or later within the OR in conjunction with surgeries. The laser may be applied through the slit lamp, with the indirect ophthalmoscope, or directly during vitrectomy surgery using an intraocular endolaser probe.

VITRECTOMY

Vitrectomy is narrowly defined as removal of all or part of the vitreous gel (body). In the broader clinical sense of the term, vitrectomy surgery can also include the excision and removal of fibrotic membranes, removal of epiretinal membranes, and electrocoagulation of bleeding vessels. In its normal state, the vitreous gel of the eye is transparent. In certain disease states, bleeding from damaged or newly formed vessels may cause the vitreous to become opaque, which may severely decrease vision. In addition to the patient's inability to see, the surgeon is unable to visualize the retina and therefore treat the underlying pathologic condition before permanent damage can occur. In these cases, vitrectomy surgery is indicated to restore the patient's vision and to allow the surgeon to institute treatment if indicated.

Formation of membranes may block the visual axis and may cause decreased vision. Contraction of these membranes may produce traction-type or rhegmatogenous retinal detachment. In these cases, vitrectomy surgery is indicated to relieve the underlying pathologic processes leading to decreased vision.

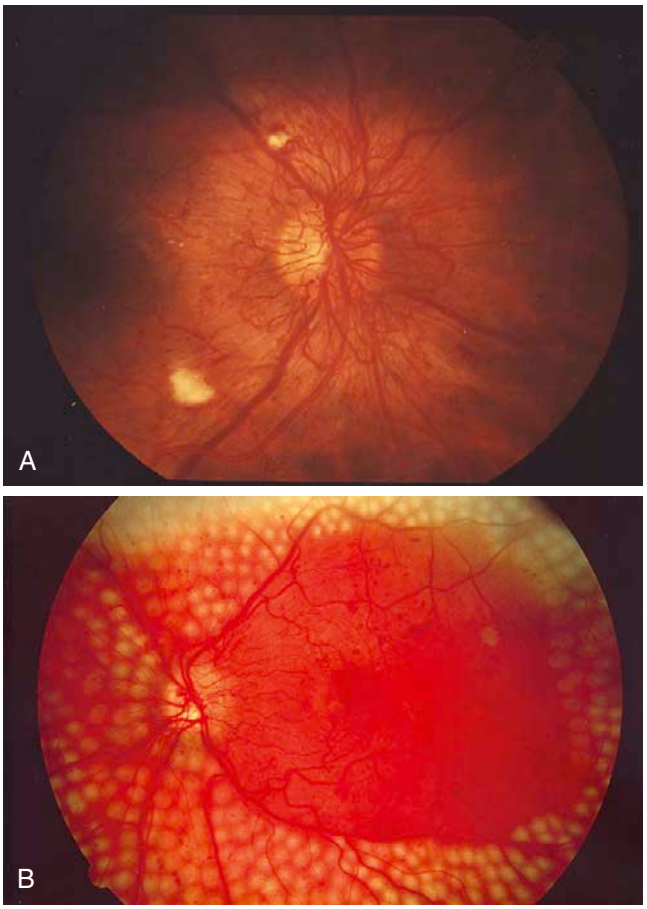

FIGURE 17-37 **A**, Proliferative retinopathy, an advanced form of diabetic retinopathy, occurs when abnormal new blood vessels and scar tissue form on the surface of the retina. **B**, Fundus photo showing scatter laser surgery for diabetic retinopathy.

Posterior Segment Vitrectomy

A pathologic condition in the posterior segment is usually approached through the pars plana, which is tissue that is anterior to the anterior attachment of the retina, typically located 3 to 4 mm from the limbus (corneoscleral junction). Since the pars plana has no retinal tissue, entry at this site poses little risk for retinal detachment (Phillips, 2007). The main indications for posterior segment vitrectomy through the pars plana are as follows:

- Long-standing vitreous opacities
- Advanced diabetic eye disease
- Severe intraocular trauma
- Retained foreign bodies
- Proliferative vitreoretinopathy
- Retinal detachment from giant tears
- Endophthalmitis
- Diagnostic vitreous biopsy

Essentially, vitrectomy vacuums any pooled blood to enhance clarity. Complications of vitrectomy include retinal detachment, retinal tears, cataract, and infection. Of course, the risk of no treatment can be total loss of vision.

Procedural Considerations. Vitrectomy of the posterior segment is a microsurgical procedure requiring a viewing system (operating microscope with an X-Y coupling, zoom lens, and fine focus), contact lens system or noncontact wide-angle viewing system (e.g., Biom), an illumination system, a cutting-suction-infusion system, and accessory instruments.

The surgeon can hold the contact lens in place by hand or can suture it for stabilization. Another option to a sew-on lens is the use of a noncontact panoramic wide-angle viewing system. This system allows a wide, noncontact view of the macula and is mounted to the microscope and swings out of the way for extraocular phases of the vitrectomy. Other advantages are that it provides a good view under air, eliminates the time needed to sew on a lens, and does not require an assistant to hold the lens. The eye may be rotated freely to view the extreme periphery. The image is inverted by a manual knob, foot pedal, or hand control.

The infusion system consists of a 500-ml bottle of buffered BSS, such as BSS Plus or Endosol Extra, a standard IV administration set, and an infusion needle or sleeve. The level of intraocular pressure can be varied by elevating or lowering the infusion bottle in relation to the patient's eye and by adjusting the digital readout of the nitrogen gas–forced infusion.

The suction and cutting systems vary in sophistication and technology. All cutters engage tissue into a port and then cut it by the shearing action between the edges of a moving and a nonmoving part. Guillotine cutters have a linear, back-and-forth action, whereas reciprocating or oscillating cutters rotate in a clockwise-counterclockwise fashion. Suction is operated with a pump controlled by a foot switch to maintain the level of aspiration. The cutter may be part of a single-use multifunction handpiece.

An endolaser or indirect laser delivery system is usually available for photocoagulation. Illumination for vitrectomy is *external,* using the operating microscope for anterior segment vitrectomy; and *internal,* using a fiberoptic light pipe (endoilluminator) for posterior segment vitrectomy. A special light pipe (cannonball) that illuminates a wider area is needed if a wide-angle viewing system is used on the microscope. See Figure 17-38 for the Mayo stand setup of vitrectomy machine attachments.

Replacement of the vitreous with air is facilitated with a special air-exchange unit that may be incorporated into the multifunction vitrectomy machine. Other substances for intraocular tamponade are liquid perfluorocarbons, silicone oil, perfluoropropane gas (C_3F_8), and sulfur hexafluoride gas (SF_6).

Accessory instruments originally had a 20-gauge diameter so that they can be interchanged throughout the procedure. Several accessory instruments may be used for pars plana vitrectomy, depending on the extent of the procedure. Microhooks, picks, and subretinal forceps and scissors (Figure 17-39) are used for dissection, peeling, and removal of membranes. These instruments can be manually operated with a thumb control or run with compressed air from the automated vitrectomy console. Even smaller 23-gauge and 25-gauge trocars allow for finer instrumentation without the need for suturing the trocar sites. This microincisional sutureless surgery has become increasingly prevalent with retinal surgeons. Foreign-body microforceps and various magnetic devices are used to retrieve foreign objects of glass, metal, or other substances.

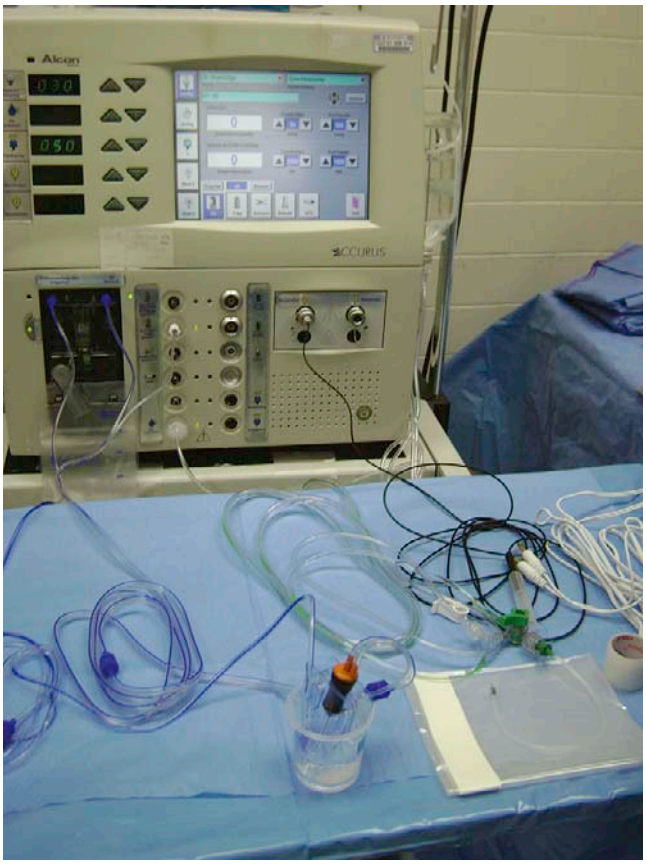

FIGURE 17-38 Mayo stand setup for posterior vitrectomy. *Left to right:* Extrusion tubing for aspiration with soft-tip cannula; vitrectomy cutter handpiece tested in BSS; infusion cannula; intraocular light pipe; bipolar electrosurgery cord. Note bottle hangs at level of patient's eye.

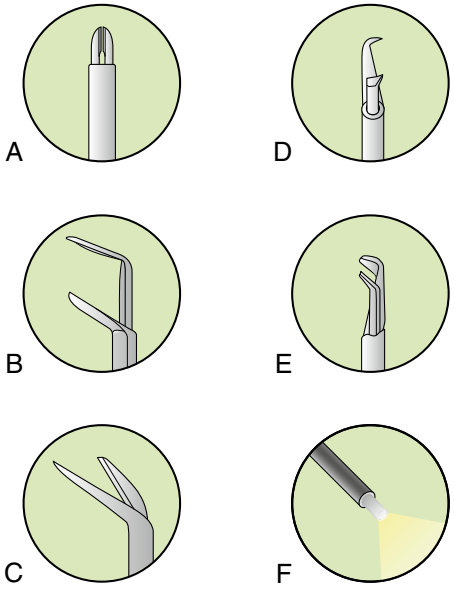

FIGURE 17-39 Tips of micro instruments used in vitrectomy procedures. **A** and **B**, Peeling forceps. **C**, Horizontal scissors. **D**, Vertical scissors. **E**, Membrane peeler and cutter (MPC). **F**, Lighted pick.

An intraocular cryoprobe for cryocoagulation directly on the retina surface can be attached to the cryotherapy device. Flute needles or disposable soft-tipped cannulae are handheld or attached to an extrusion or aspiration line for evacuating pools of blood or for fluid-gas exchange. The soft silicone tips can come into close proximity to the retina without scratching or damaging the tissue.

To prepare for a vitrectomy procedure, the perioperative nurse must know the location of the ocular problem, the surgeon's plan to address the problem, the instrumentation to be used, and the anticipated extent and length of the procedure. Instrument and equipment functioning should be thoroughly checked before the patient is transferred into the OR. When preparing for pars plana vitrectomy in the posterior segment, the perioperative nurse must be aware that a combined scleral buckling procedure may be necessary. Clear communication with surgeons paves the way for effective preparations.

In the case of giant retinal tears, C_3F_8, SF_6, liquid per fluorocarbons, and silicone oil can be used to provide retinal tamponade. Intraocular expansible gases (C_3F_8, SF_6) can be used to provide retinal tamponade, but usually require the patient to be positioned facedown for several weeks in order to help reattach the retina. The expansible gas will slowly be absorbed by the body (usually over a period of 2 to 3 months) as aqueous humor produced by the ciliary body slowly displaces it (Research Highlight). Silicone oil can be used for complicated cases and when positioning would be difficult for patients. The disadvantage of silicone oil is that the patient will require another surgery to remove the silicone oil in the future as the index of refraction of silicone oil is significantly different than that of vitreous, giving patients the impression that they are "looking through a crystal ball."

RESEARCH HIGHLIGHT

Patient Perspective of Extended Facedown Positioning Revealed through Journaling

Facedown positioning is required after certain ophthalmic procedures, such as macular hole surgery, to optimize retinal reattachment. Adherence is often difficult because of physical and psychologic challenges. The experience according to a patient's perspective is rarely documented in research literature.

In a separate study on functional outcomes of macular hole surgery, a self-motivated patient presented to researchers the diary that she had written during her 77-day recovery period. When the researchers requested a qualitative analysis of her journal, she consented.

Seven categories of content emerged: emotional state, quality of sleep, nutritional considerations, visual functioning, physical status, social support, and entertainment needs. Overall, this study gives patients and their caretakers (including nurses) a better understanding of what facedown positioning means to an individual during the extended recovery period. This patient's successful coping can provide hope for other potential patients. Guidelines can be developed and refined for overcoming both physical and psychologic barriers.

Modified from Wittich W, Southall K: Coping with extended facedown positioning after macular hole surgery: a qualitative diary analysis, *Nurs Res* 57(6):436-443, 2008.

Liquid perfluorocarbons such as perfluorooctane (PFO) or Perfluoron, being heavier than BSS, will allow the retina to be pushed posteriorly and so are used as a tamponade to help repair a giant retinal tear. The liquid is then removed from the posterior segment. Silicone oil is a highly viscous oil with a high surface tension that mechanically limits fibrovascular proliferation. The oil may be left in place, but it is recommended that it be removed within 1 year if the retina is reattached and stable. Silicone oil may cause increased intraocular pressure and secondary glaucoma. The National Eye Institute supported a nationwide clinical trial comparing treatment of proliferative vitreoretinopathy with silicone oil or long-acting intraocular gas. The results indicate that either treatment is effective and surgeons thus have options in treating such cases (NEI, 2008d).

Vitrectomy procedures vary in length from less than 1 hour to more than 3 hours. When a long procedure is anticipated, care must be taken to protect the patient's skin and reduce pressure areas. A foam mattress pad, heel and elbow protectors, and elasticized stockings may be used. A wrist support may be placed around the patient's head to support the surgeon's wrist during manipulation of the intraocular instruments.

Because of the amount of fluid used in the operative field during this procedure the perioperative nurse carefully assists with draping to allow for removal of infusion fluid from the field and ensures the electric foot pedals are protected from fluid damage.

Operative Procedure

PARS PLANA VITRECTOMY

1. The eye is prepped and draped using standard sterile conditions for ophthalmic surgery. The surgeon places a lid speculum and incises the conjunctiva (Figure 17-40).
2. The surgeon sutures the infusion line in place with a purse-string suture (for 20-gauge surgeries) and checks it for proper placement.
3. Generally, three incisions are made through the pars plana: one for infusion, one for endoillumination, and one for a vitreous cutter or other instrumentation (e.g., pick, forceps, scissors, laser probe, extrusion needle). In the right eye, these incisions are placed at clock hours 8, 10, and 2; for the left eye, this corresponds to 2, 4, and 10. An illuminating chandelier can also be placed (typically at the 6 o'clock position) for bimanual surgery.
4. The operating microscope is aligned. A wide-angle viewing system is swung into position, or a fundus lens is fixed on the anterior surface of the cornea.
5. The perioperative nurse confirms that the proper infusion rate, cutting rate, and aspiration rate are set on the machine console. If a dense cataract or retained lens material blocks the view of the retina, a lensectomy may be performed with a Fragmatome or other ultrasonic handpiece at this time.
6. The surgeon removes the vitreous under direct visualization. Once the medium has been removed and the retinal condition visualized, the necessary injections or treatments (endolaser photocoagulation, repair of macular pucker, insertion of silicone oil, gas-fluid exchange) (Figure 17-41) are completed. A scleral buckling procedure may also be performed.
7. The trocars are removed from the pars plana incisions. Cultures from the vitreous washings are taken if necessary.
8. Subconjunctival injections of steroids or antibiotics are given. An eye pad and shield may be applied for protection of the eye, although some surgeons opt not to use them.

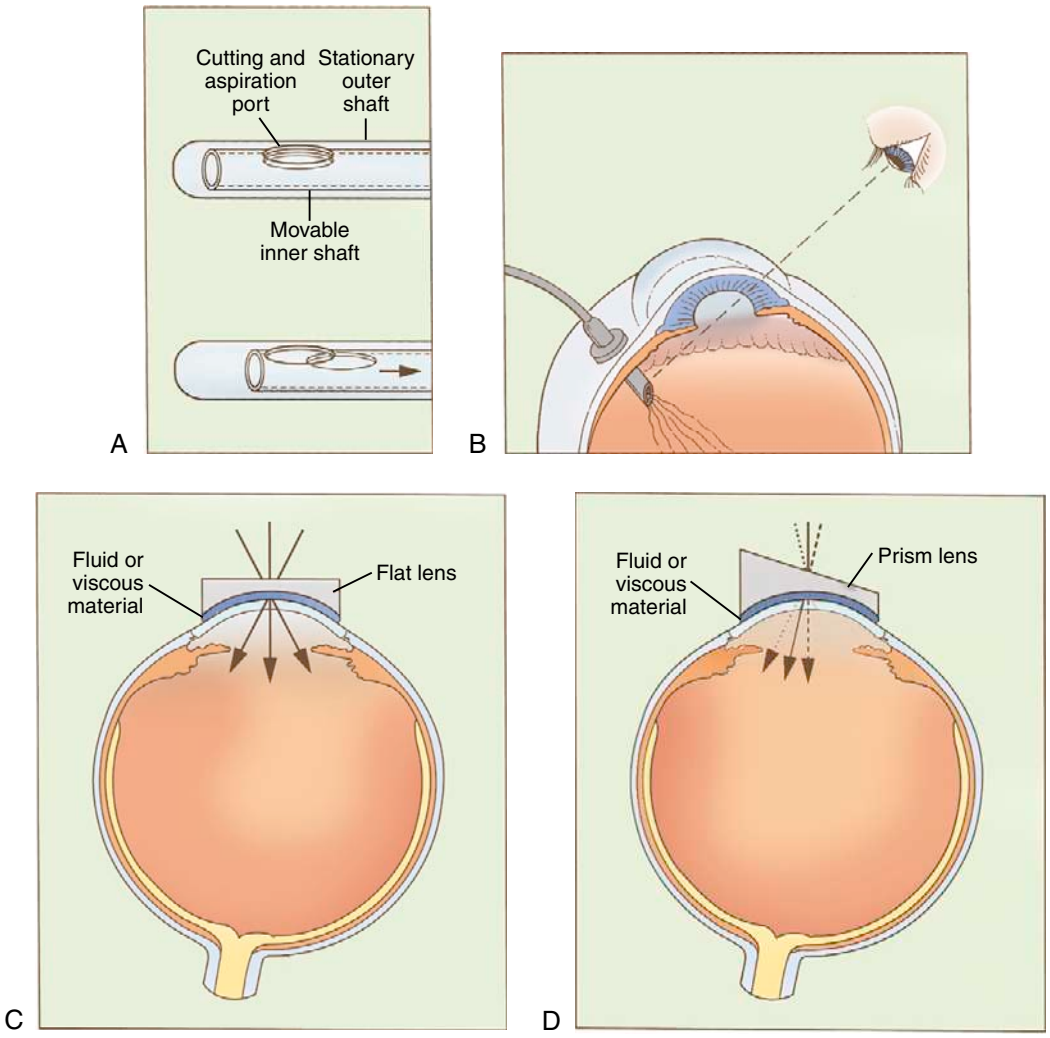

FIGURE 17-40 Essential components for vitrectomy. **A**, Vitrector probe with its cutting/aspirating port close to the tip of the intraocular portion of the handpiece. **B**, Infusion cannula, placed in pars plana, is viewed for correct position. **C**, Flat contact lens, resting on cushion of fluid or viscoelastic material on the cornea, is used for viewing posterior half of the vitreous cavity and retina. **D**, Prism contact lens used for viewing anterior structures in the vitreous cavity.

Scleral Buckling

Procedural Considerations. In the treatment of retinal detachment, the aim is to return the retina to its normal anatomic position. For this specific procedure, repair is done from outside the globe. The purpose of the scleral buckling procedure for retinal detachment is to cause an intrusion or push into the eye at the site of the pathologic source. Treatment by diathermy or cryotherapy causes an inflammatory reaction that leads to a permanent adhesion between the detached retina and underlying structures. The surgery also involves sealing off the area in which the tear or hole is located and may include drainage of the subretinal fluid.

The procedure may be performed using general anesthesia or MAC with local blocks. The scleral buckling may be done using episcleral (working outside of the sclera) technique or by scleral dissection (making a partial-thickness incision into the sclera and creating flaps to expose the underlying tissue). Both techniques may use drainage of subretinal fluid, encircling bands, diathermy, light coagulation, or cryotherapy. Cryosurgery or light coagulation may be used alone or in combination with a buckling procedure.

Operative Procedure

1. A detailed drawing of the retina may be made before surgery and is displayed in the operating suite according to surgeon preference. On the basis of this drawing, the surgeon opens the conjunctiva to a previously determined extent, for example, 90 degrees for a simple horseshoe tear or 360 degrees for an aphakic detachment (Figure 17-42).
2. The inferior, superior, lateral, and medial rectus muscles are isolated using 0 silk ties as traction sutures.
3. Using the indirect ophthalmoscope, the surgeon locates the detachment and tear and marks the site with nonpenetrating diathermy by indentation or with a methylene blue marking pen.
4. Under direct visualization, the surgeon applies the retinal cryoprobe to the external surface of the globe in the area of the pathologic condition and treats the area. An ice ball is seen to form in the proper areas until the entire lesion has been treated.

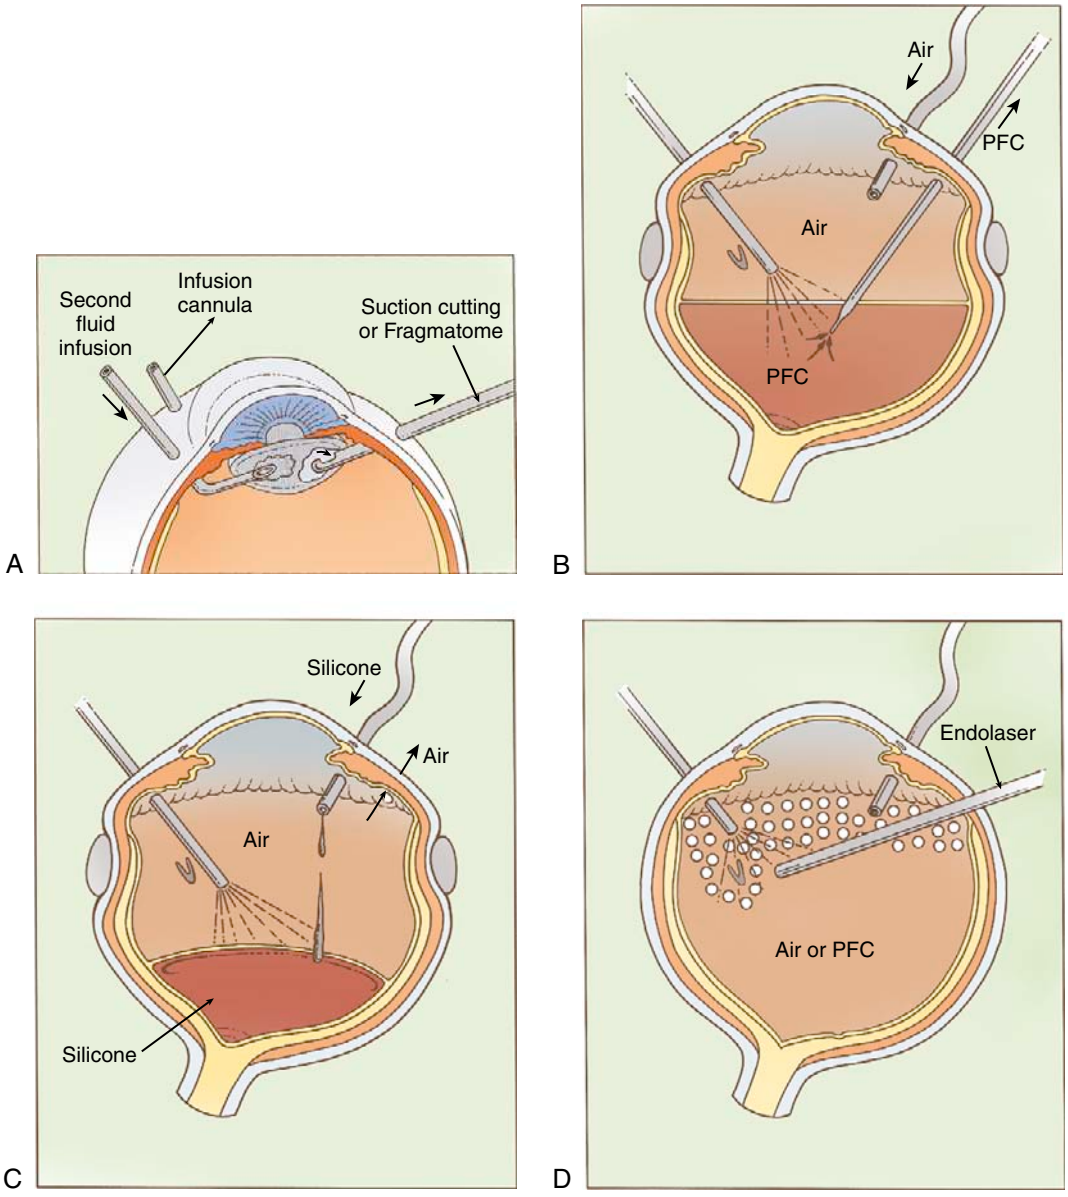

FIGURE 17-41 Procedures done with vitrectomy. **A**, Pars plana lensectomy performed with a second infusion line. **B**, Air/perfluorocarbon (PFC) exchange. The PFC has been placed in the vitreous cavity for removal of subretinal fluid and anatomic reattachment of the retina. Air under positive pressure is then placed through the infusion cannula as the PFC is simultaneously extruded through the tapered needle. **C**, Silicone/air exchange. Silicone is inserted through the infusion cannula as a temporary intraocular tamponade. Silicone is heavier than air and fills the globe from the bottom up, and the air escapes through the sclerotomy site. In silicone/fluid exchange, the silicone floats on the fluid and the fluid is removed with an extrusion needle. **D**, Endolaser photocoagulation is performed after the retina is returned to its normal position.

5. The buckling component of the procedure secures silicone bands, sponges, plates, or tires to the sclera. The surgeon places nonabsorbable sutures (4-0 or 5-0) into the sclera surrounding the lesion and ties them over the silicone sponge, causing the outer shell of the eye to be pushed toward the elevated retina.
6. If an encircling band is to be used, the surgeon places mattress sutures into the sclera in four quadrants. A silicone band is passed 360 degrees around the eye under the sutures and the rectus muscles. The sutures are tied, and a self-holding Watzke sleeve is applied to the band to maintain a predetermined circumference. This causes a 360-degree constriction of the outer coats into the eye.
7. If drainage of subretinal fluid is desired, the surgeon chooses an area under direct visualization in which a significant fluid level exists under the retina, and places a diathermy mark on the sclera. The sclera is split to the choroid, and a small amount of diathermy is applied to the choroid bed. A 27-gauge ½-inch needle is then used to puncture the choroid into the subretinal space to permit drainage of fluid.

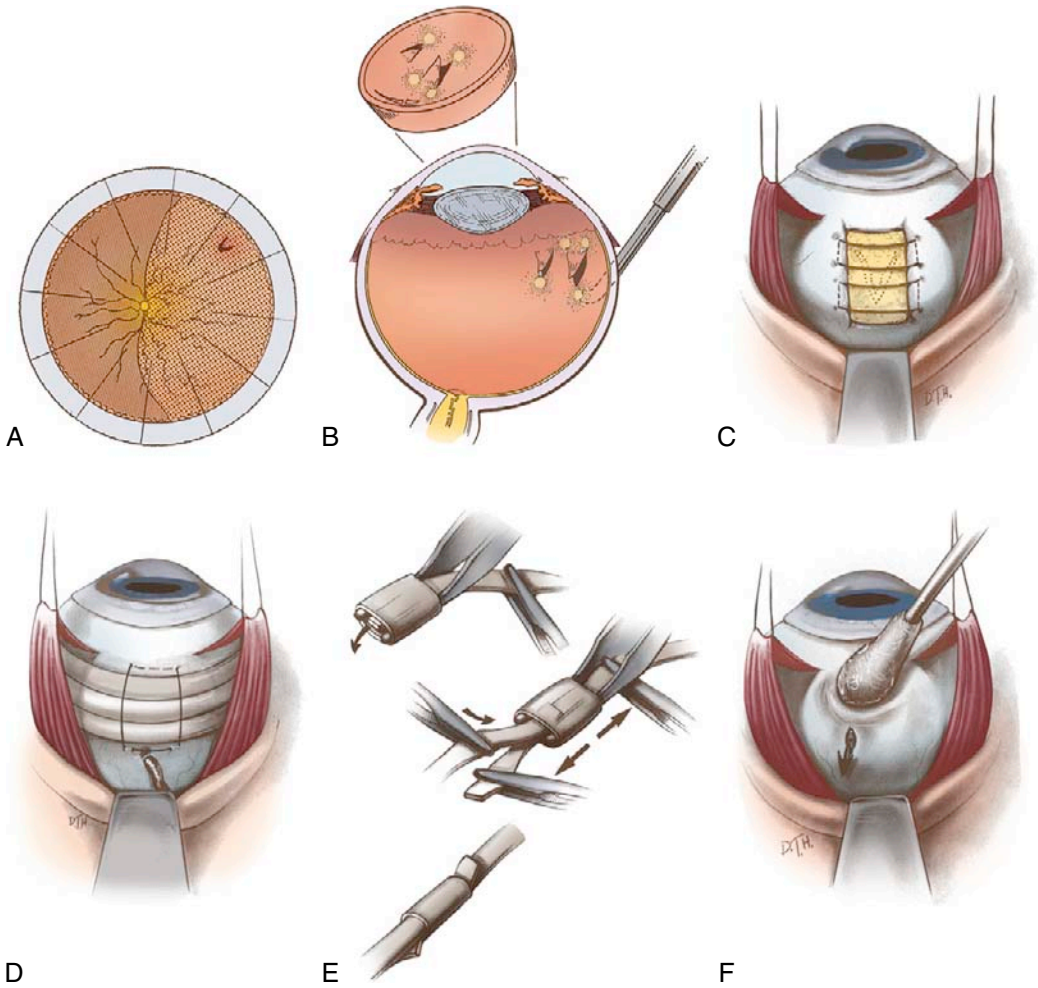

FIGURE 17-42 Scleral buckling operation for treatment of retinal detachment. **A**, Diagram of retina showing detachment of retina of temporal half of left eye, with retinal tear at equator of globe at 1:30 o'clock position. **B**, Examination of fundus by means of ophthalmoscope and handheld lens and depression of sclera with diathermy electrode. Surgeon visualizes field and places electrode beneath retinal tear; burn mark is made on sclera at site of retinal tear with diathermy electrode. **C**, A sponge is sutured in place over treated site of retinal tear. **D**, Band and tire are used to encircle the eye. **E**, Placement of Watzke silicone sleeve is one method to secure edges of encircling band. **F**, Small incision is made through sclera, and choroid is finely incised to allow subretinal fluid to drain.

8. Air or replacement fluids may be introduced into the eye after the drainage of subretinal fluid. This is usually done through the pars plana under direct visualization.
9. The surgeon removes the traction sutures from around the muscles and closes the conjunctiva with 7-0 absorbable suture. A subconjunctival injection of an antibiotic, steroid, or both may be given, and an eye pad is applied.

Retinopexy

In pneumatic retinopexy (Figure 17-43) an intraocular injection of a bubble of air or therapeutic gases provides pressure against retinal breaks, allowing the detached retinal breaks to approximate the pigment epithelium. Retinopexy may be used in combination with scleral buckling and posterior vitrectomy; it may be performed as part of an ambulatory procedure for treatment of certain retinal detachments, using laser photocoagulation with injection of the gas bubble followed by specific postoperative positioning. The gases are drawn through a Millipore 0.22-micrometer filter and may be mixed with filtered air so that the concentration may be varied. The gas bubble is a ratio mixture of gas and air. The higher the concentration of gas to air, the longer the bubble remains in the eye before being "absorbed." Patient positioning after retinopexy is often facedown for several days to weeks but may include tilting the head to one side or the other as well. The head position is determined by the location of the retinal tear/hole. For example, if the retinal tear/hole is located superior temporal in the right eye, the patient would be instructed to tilt the head down and to the left, so the bubble will float upward and to the right where the tear/hole is located. The larger the tear/hole, the longer the bubble needs to be in contact with the area to be reattached.

Sulfur hexafluoride gas (SF_6) is colorless, odorless, and nontoxic. It increases 2.5 times in volume within 48 hours after injection by drawing other gases, specifically nitrogen and oxygen, from the surrounding tissues. SF_6 bubbles remain for at least 10 days (Donlon et al, 2005).

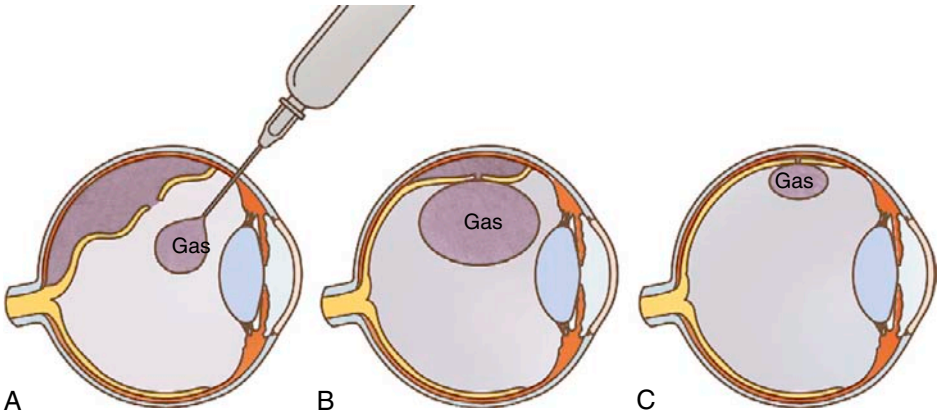

FIGURE 17-43 Pneumatic retinopexy. **A**, Gas bubble is injected through the pars plana. **B** and **C**, The bubble closes and supports the retinal break. After a 7- to 10-day healing period and when the retina is returned to normal position, laser surgery or cryotherapy can be performed to seal the break.

Perfluoropropane gas (C_3F_8) is colorless, odorless, and nontoxic. It quadruples its volume within 48 hours after injection. A 1-mm bubble can remain up to 30 to 50 days.

Because SF_6 and C_3F_8 are expansible gases, certain precautions are required. Patients are given a wristband to wear that states what kind of gas bubble is in their eye and when it was instilled. If they would require surgery, they need to alert the anesthesia provider of the presence of the gas bubble. The intent of instilling a gas bubble is to sustain its size and hold the retina in place. SF_6 and C_3F_8 are inert, very insoluble in water, and poorly diffusible. Since nitrous oxide (N_2O) is 117 times more diffusible than SF_6, it rapidly enters the gas bubble. With continued administration of N_2O the injected gas bubble can increase to three times its original size. Intraocular pressure (IOP) can increase from 14 to 30 mm Hg; 18 minutes after discontinuation of N_2O, IOP will decrease along with the smaller bubble size. Such quick and wide variations in bubble size can negatively affect the surgical outcome. Therefore N_2O should be discontinued at least 20 minutes before an intravitreal gas injection to ensure stable bubble size and IOP. Some anesthesia providers avoid using N_2O for any case where intravitreal gas injection is anticipated. Patients are instructed to avoid air travel until the gas bubble is completely resolved or decreased to a level of 5% of the vitreous volume. Cabin pressurization in air travel will cause severe enlargement of the gas bubble with an increase in intraocular pressure and eye pain. Car or train travel to high elevations should also be avoided unless the change in altitude is done gradually. N_2O should be avoided for 3 to 4 weeks after intravitreal gas injection. The exposure to N_2O could reexpand the bubble, increase IOP, and thereby occlude the retinal artery with loss of vision (Donlon et al, 2005).

Overall, 90% of patients with retinal detachment can now be successfully treated. This is a great advance considering some of the same conditions were inoperable 40 years ago. Visual outcomes, however, are not always predictable, and additional treatment may be necessary. A successful anatomic result of retinal reattachment unfortunately does not always correlate with improvement in visual function. It may take up to several months to evaluate the final visual result. Occasionally, even with the best efforts and multiple attempts at repair, treatment may fail; sight may not be able to be restored. This discussion is part of informed consent. Repairing a detachment before the macula detaches provides the best visual results.

CHAPTER 18

Otorhinolaryngologic Surgery

TROY J. DeROSE and GREGORY ARTZ

Otorhinolaryngology is the study and science of the human ear (*oto*), nose (*rhino*), and throat (*laryngo*). It is a specialty that continues to evolve as a result of cutting-edge technology; high-powered surgical microscopes; narrower, flexible endoscopes; computer imaging; wound care improvements; and navigation systems that communicate with radiologic imaging. Such advances yield significant gains in improving the health and surgical outcomes of patients with physical ailments of the head and neck. This chapter comprehensively and respectively reviews perioperative care of patients undergoing surgical procedures to the ear, nose, head, and neck.

Surgical Anatomy

EXTERNAL, MIDDLE, AND INNER EAR

The ear is a sensory organ for the identification, localization, and interpretation of sound as well as for the maintenance of equilibrium. Hearing is the sense by which sounds are appreciated. Referred to as the "watchdog of the senses," hearing is the last sense to disappear when one falls asleep and the first to return when one awakens. The physical nature of sound results from the compression and rarefaction of pressure waves and moving molecules, but the sensations humans actually experience are the product of complex mechanical, electrical, and psychologic interactions in the ear and central nervous system. Three anatomic segments—the external ear, middle ear, and inner ear—work together to provide hearing and balance (Figure 18-1).

The *external ear* includes the auricle (or pinna) and external auditory canal, and is composed of cartilage covered with skin. The auricles are fixed in position and lie close to the head; they concentrate incoming sound waves and conduct them into the external auditory canal. Both ears provide stereophonic hearing that gives us very specific sound localization capabilities. Without binaural hearing, determining where sounds emanate can be difficult; this is a common problem for patients with unilateral or asymmetric hearing loss.

The external auditory canal, an S-shaped pathway leading to the middle ear, is approximately 2.5 cm in length in adults and shelters the tympanic membrane. Its skeleton of bone and cartilage is covered with very thin, sensitive skin. The canal lining is protected and lubricated with cerumen, a waxy substance secreted by sebaceous glands in the distal third of the canal. Cerumen helps to trap foreign material, and has a mildly acidic pH that reduces bacterial levels in the outer ear.

Located at the end of the external auditory canal is the *tympanic membrane* (eardrum) (Figure 18-2). It is a thin structure with three distinct layers: an outer squamous epithelial layer in continuity with the skin of the external ear canal, a fibrous middle layer for strength and support, and a medial mucous membrane layer that is continuous with the lining of the middle ear.

The *middle ear* is filled with air, which flows from the nasopharynx through the eustachian tube. It is divided into three areas: the epitympanum (upper), mesotympanum (middle), and hypotympanum (lower). Posteriorly, the epitympanic portion of the middle ear communicates with the mastoid air cells of the temporal bone via the mastoid antrum. The mucous membrane of the middle ear is continuous with that of the pharynx and the mastoid cells, making it possible for infection to travel to the middle ear (otitis media) and mastoid cells (mastoiditis). The eustachian tube serves to aerate the air-filled spaces of the temporal bone and to equalize pressure in the middle ear with atmospheric pressure. It is normally closed at rest and actively opens during yawning, sneezing, or swallowing. A chain of three small articulated bones (ossicles) extends across the middle ear cavity and conducts vibrations (airborne sound waves) from the tympanic membrane across the middle ear into the oval window and the fluid-filled inner ear (Figure 18-3).

The *malleus* (hammer) consists of a head, neck, handle, and short process. The handle and short process are attached to the undersurface of the eardrum, and the head articulates with the body of the incus in the upper segment of the middle ear called the epitympanum or "attic." The *incus* (anvil) consists of a body and long and short processes (see Figure 18-2). The distal end of the long process of the incus is called the lenticular process and articulates with the capitulum (head) of the stapes, which is the third, innermost bone. The *stapes* (stirrup) consists of a head, neck, anterior and posterior crura, and a mobile footplate that is secured to the oval window by an annular ligament. The movable joints between these ossicles contribute to a lever system that amplifies the received sound and transmits and converts vibrations from ambient air to the fluid of the inner ear.

The inner ear is protected from loud noise by the *tensor tympani* muscle, which draws the drum inward to increase tension and restricts its ability to vibrate, and the *stapedius* muscle, which contracts and tightens the stapes in the oval window to reduce the intensity of vibrations passing through the ossicles into the inner ear. The middle ear and mastoid are supplied with blood from the branches of the internal and external carotid artery systems.

The *inner ear* is a membranous, curved cavity located in the petrous portion of the temporal bone; it contains hair cell receptors that provide us with both hearing and balance. The inner ear consists of a bony labyrinth filled with a watery fluid (perilymph) that surrounds and bathes a membranous labyrinth

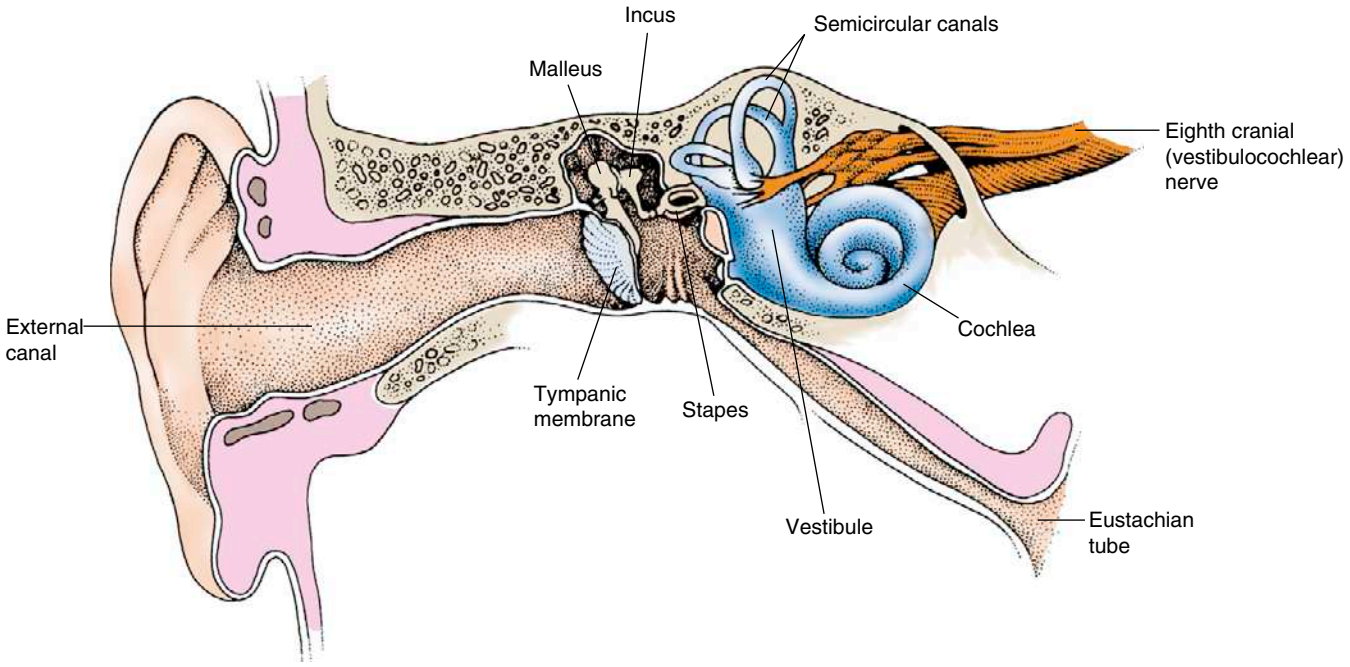

FIGURE 18-1 Anatomic structures of external ear, middle ear, and inner ear.

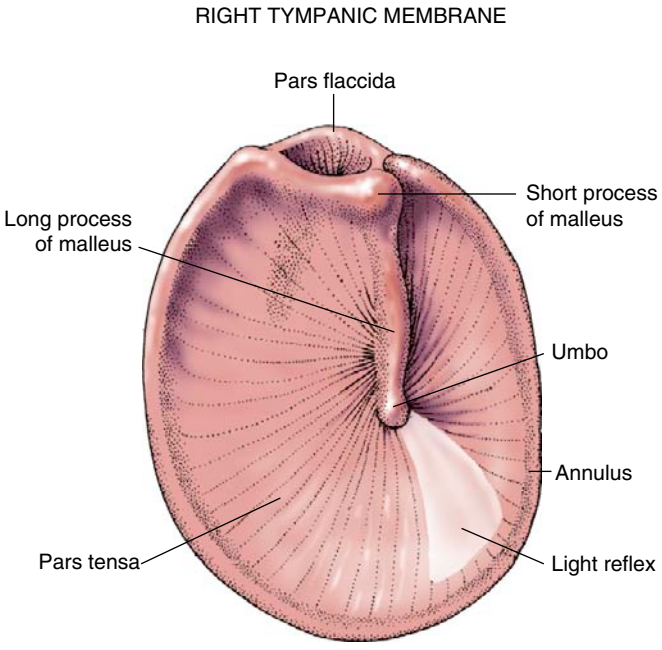

FIGURE 18-2 Structural landmarks of tympanic membrane.

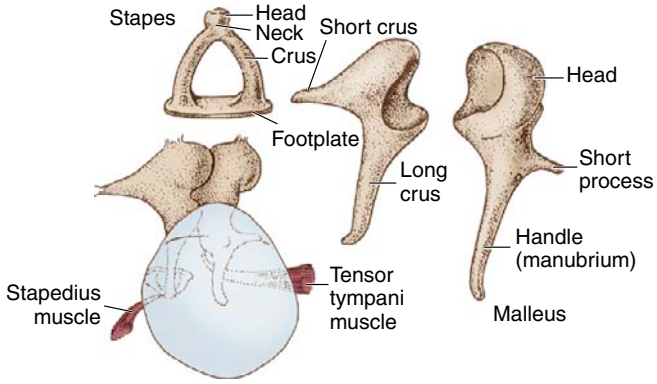

FIGURE 18-3 Articulated ossicles of right middle ear.

filled with another fluid with distinct electrolyte characteristics, called the endolymph. The bony labyrinth includes the cochlea and the vestibular labyrinth.

The *cochlea* resembles a snail shell. It is divided into three compartments: the scala vestibuli, which is associated with the oval window; the scala tympani, which is associated with the round window; and the cochlear duct. The scala vestibuli and scala tympani are filled with perilymph, whereas the cochlear duct contains endolymph. On the basilar membrane of the cochlea lies the organ of Corti—the neural end organ for hearing. Its neuroepithelium projects thousands of hair cells that are set into motion by vibrations passing through the ossicles and oval window to the perilymph. The hair cells convert the mechanical energy of wave movement from vibration in the perilymph into electrochemical impulses. The *vestibular labyrinth* is composed of the utricle, the saccule, and three semicircular canals, referred to as the *lateral, superior,* and *posterior canals.* They are positioned at right angles to one another and are responsible for detecting angular acceleration that can be elicited with any head or body movement. Each canal contains a sense organ (crista) that responds to fluid movement in the endolymph, which triggers impulses in the vestibular branch of the acoustic nerve. Cristae are stimulated by angular accelerations and movements, such as head turning. The maculae of the utricle and saccule of the vestibular labyrinth are gravity-oriented. Linear accelerations are detected by the utricle and saccule; they both have a mat of sensory cells *(otoconia)* imbedded in a gelatinous material covered with calcium deposits. The weight of these otoconia constantly orients us to the direction

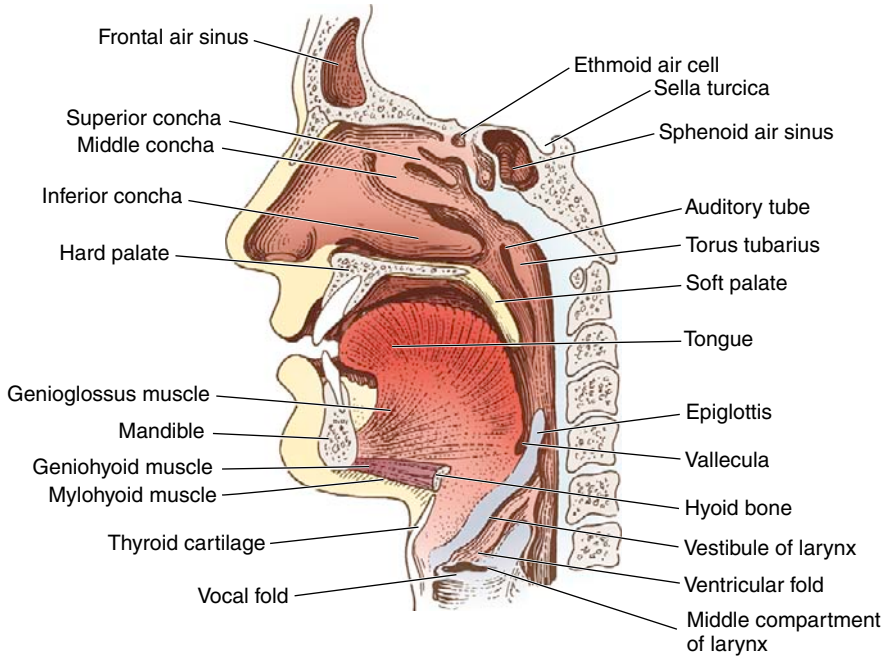

FIGURE 18-4 Sagittal section of face and neck.

of gravity. Their inertia gives information about linear accelerations. The combined signals from the cristae of the semicircular canals and the sensory cells of the utricle and saccule provide a sense of balance and orientation in space. The internal auditory branches of the basilar artery supply the inner ear.

NASAL ANATOMY

The nose is covered with skin and is supported internally by bone and cartilage. The two external nares provide openings for the passage of air through the nasal cavity. These openings contain internal hairs for the filtration of coarse particles that are sometimes carried by air. The nose is divided into the prominent external portion and the internal portion known as the *nasal cavity* (Figure 18-4). The chief purpose of the nose is to prepare air for use in the lungs.

The nasal bones and the frontal process of the maxilla form the upper portion of the external nose, and the lower portion is formed by a group of nasal cartilages and connective tissue covered with skin (Figure 18-5). The nostrils and the tip of the nose are shaped by the major alar cartilages. The nares are separated by the *columella,* which is formed by the lower margin of the septal cartilage, the medial parts of the major alar cartilages, and the anterior nasal spine, all of which are covered with skin. The nasal cavity is divided medially into right and left portions by the *nasal septum.*

The *nasal septum* is composed of three structures: the nasal cartilage, the perpendicular plate of the ethmoid bone, and the vomer bone. The septum is covered by mucoperichondrium on either side that contains blood vessels and mucus-secreting cells. The rich blood supply warms and moistens the air while the sticky mucus traps dust, pollen, and other small particles.

The nasal cavity communicates with the outside by its external openings, called the *nares.* The nares open into the nasopharynx through the choanae. The nasal cavity is also

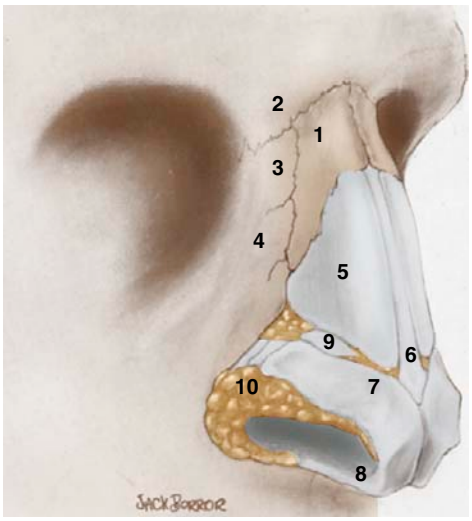

FIGURE 18-5 Nasal bony framework. *1,* Nasal bone; *2,* frontal bone; *3,* lacrimal bone; *4,* maxillary bone; *5,* upper lateral cartilage; *6,* nasal septum; *7,* lower lateral cartilage, lateral crus; *8,* lower lateral cartilage, medial crus; *9,* sesamoid cartilage; *10,* fibrofatty tissue.

associated with each ear, sharing the torus tubarius (opening of the eustachian tube in the nasopharynx) with the paranasal sinuses (frontal, maxillary, ethmoidal, sphenoidal) through their respective orifices (meatus). The nasal cavity also communicates with the conjunctivae through the nasolacrimal duct. The nasal cavity is separated from the lingual cavity by the hard palate and soft palate (see Figure 18-4) and from the cranial cavity by the ethmoids. It is held together by periosteal covering over bone and by perichondrium, which extends over the cartilages. The turbinate bones of the nasal structure are arranged one above the other, separated by grooves that

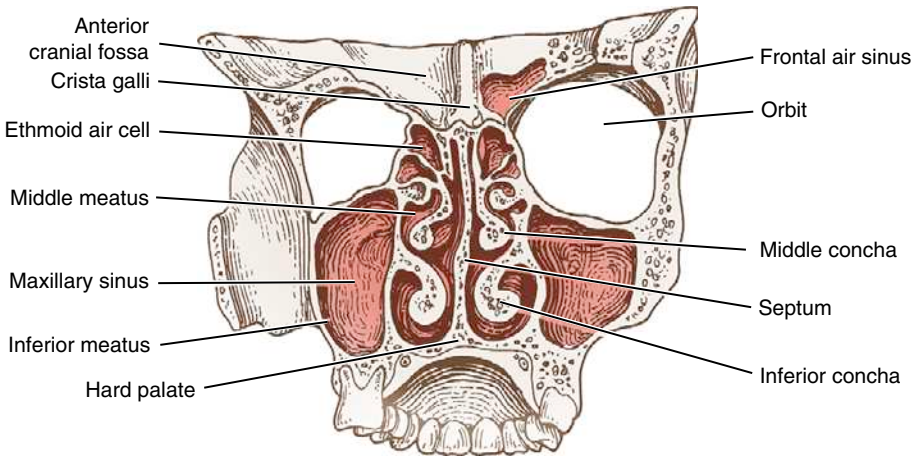

FIGURE 18-6 Vertical section through nose. Plane of section passes slightly obliquely through left first molar tooth and behind second right premolar tooth. Posterior wall of right frontal sinus removed.

are comprised of pseudostratified columnar ciliated respiratory epithelium. The turbinates act as drainage passages of the accessory sinuses and also increase the turbulence of airflow to humidify the air that is nasally inspired. This area is commonly referred to as the *sphenoethmoidal recess* and contains these bony shelves known as the *superior, middle,* and *inferior meatus* or *turbinates* (Figure 18-6).

The nasal sinuses serve as air spaces and communicate with the nasal cavity through the meatus. Anteriorly, on each side of the skull, the frontal sinus, the anterior ethmoidal sinus, and the maxillary sinus (antrum of Highmore) drain into the middle meatus; posteriorly, the ethmoidal and the sphenoidal sinuses drain into the superior meatus and the sphenoethmoidal recess (see Figure 18-6). A passageway for the flow of air is provided by the irregular air spaces between these structures.

THROAT ANATOMY

Oral Cavity

The *oral cavity* is comprised of the mouth and salivary glands. The mouth is formed by the cheeks, the hard palate, the mandible, and the tongue. It extends from the lips to the junction of the hard and soft palates. The portion of the mouth outside the teeth is the buccal cavity, and that on the inner side of the teeth is the lingual cavity. The hard palate forms the upper boundary of the oral cavity. The hard palate is formed by the maxilla and palatine bones. The mandible and floor of the mouth form the lower boundary of the oral cavity (Figure 18-7).

The *salivary glands* consist of three paired glands: the sublingual, the submandibular, and the parotid. They communicate with the mouth and produce saliva, which serves to moisten the mouth and initiate digestion of carbohydrates. The minor salivary glands exist in the submucosa of the cheeks, tongue, palates, and floor of the mouth, pharynx, lips, and paranasal sinuses.

The *sublingual gland* lies on the undersurface of the tongue beneath the mucous membrane on the floor of the mouth and the side of the tongue, on the inner surface of the mandible. The many tiny ducts of each gland separately enter the oral cavity on the sublingual fold.

The *submandibular gland* lies partly above and partly below the posterior half of the base of the mandible and on the mylohyoid and hyoglossus muscles. Its duct (Wharton's duct) runs superficially beneath the mucosa of the floor of the mouth and enters the oral cavity behind the central incisors.

The *parotid gland,* the largest of the salivary glands, lies below the zygomatic arch in front of the mastoid process and behind the ramus of the mandible; it is divided into a superficial portion and a deep portion. The parotid duct (Stensen's duct) pierces the buccal pad of fat and the buccinator muscle, finally opening into the oral cavity opposite the crown of the upper second molar tooth.

Pharynx

The pharynx extends from the posterior portion of the nose to the esophagus and larynx and serves as a channel for both the digestive and respiratory systems (Figure 18-8). It is composed of muscular and fibrous layers with a mucous membrane lining. It is approximately 13 cm long and lies anterior to the cervical vertebrae and posterior to the nasal and oral cavities. The pharynx is associated above with the sphenoid sinus and the basilar part of the occipital bone, and it joins the esophagus below. Seven cavities communicate with the pharynx: the two nasal cavities, the two tympanic cavities, the mouth, the larynx, and the esophagus. The pharynx comprises three groups of constrictor muscles. Each muscle fits within the one below, and each inserts posteriorly in the median line with its mate from the opposite side. The constrictor muscles provide constriction of the pharynx for swallowing. Between the origins of the constrictor muscle groups are so-called *intervals,* through which ligaments, nerves, and arteries pass. The pharynx is divided anatomically into three sections: the nasopharynx, the oropharynx, and the hypopharynx.

Nasopharynx. The nasopharynx lies posterior to the nasal cavity and extends over the soft palate. It communicates with the oropharynx through the pharyngeal isthmus, which is closed by muscular action during swallowing. Infection can spread from the nasopharynx to the middle ear through the eustachian tube.

Oropharynx. The oropharynx lies posterior to the oral cavity and extends from the palate to the level of the hyoid bone. The tonsils are situated on each side of the oropharynx, lodged in a tonsillar fossa that is attached to folds of membrane-containing

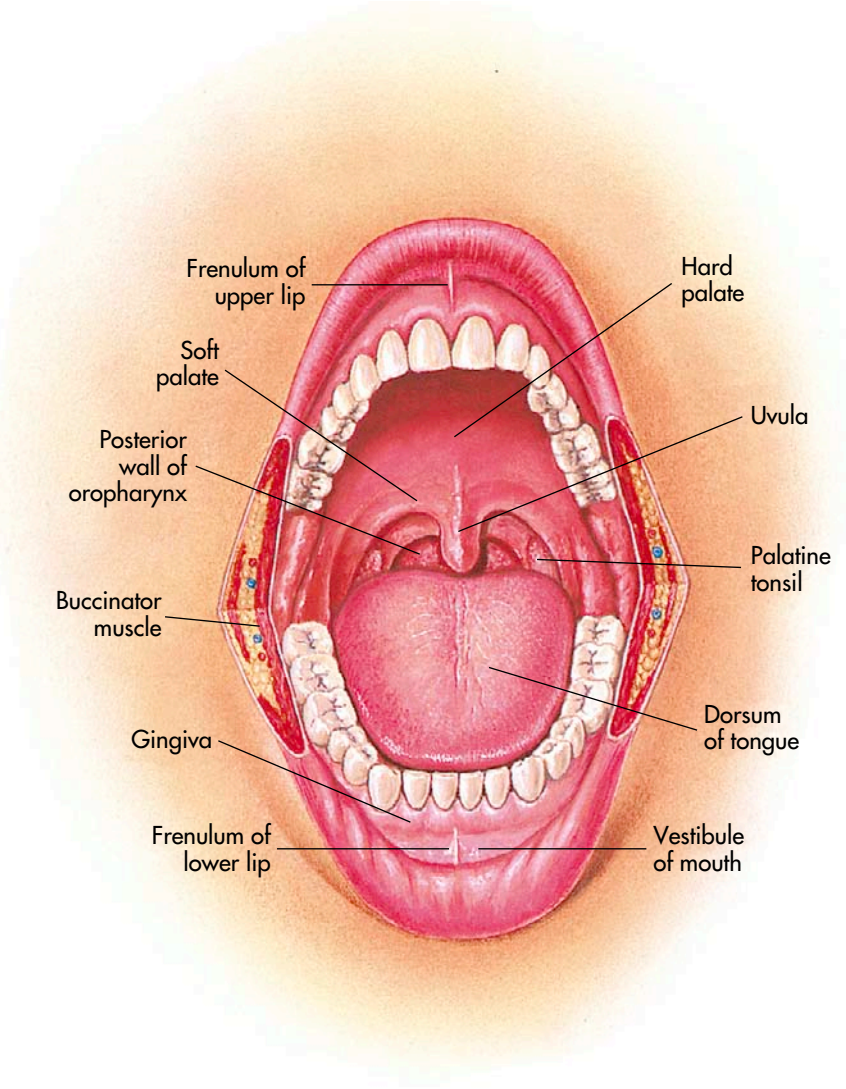

FIGURE 18-7 Anatomic structures of the oral cavity.

muscle. The palatine tonsils (a pair of oval structures) are the only lymphatic organs covered with stratified squamous epithelium. The lateral surface of each tonsil is usually covered with a fibrous capsule. The anterior and posterior tonsillar pillars join to form a triangular fossa, with the posterior lateral aspects of the tongue at its base. The lingual tonsils are lodged in each fossa. The adenoids, or pharyngeal tonsils, are suspended from the roof of the nasopharynx and consist of an accumulation of lymphoid tissue.

Hypopharynx. The hypopharynx extends from the hyoid bone and empties into the esophagus posteriorly and the larynx anteriorly. The piriform sinuses are bound medially by the arytenoepiglottic fold and laterally by the thyroid cartilage and hypothyroid membrane. The fossae are involved in speech.

Larynx and Associated Structures

Larynx. The larynx is a cartilaginous box that lies midline in front of the fourth, fifth, and sixth cervical vertebrae between the trachea and the root of the tongue, at the upper front part of the neck. The location of the larynx between the gastrointestinal (GI) and respiratory systems is strategic in protecting the airway during swallowing and breathing. The larynx has three main functions: as a passageway for respiration, as a valve to prevent aspiration, and as a vibratory source for vocalization.

The larynx can be divided into three portions: *supraglottis* (or upper portion above the true vocal cords), *glottis* (level of the true vocal cords), and *subglottis* (below the true vocal cords). The upper portion of the larynx is continuous with the pharynx above and includes the epiglottis, vallecula, and the laryngeal cartilages. Its lower portion joins the trachea. The skeletal structure provides for patency of the enclosed airway. The complex muscle action and arrangement of tissues within the larynx provide for closure of the lumen, to protect against trauma and entrance of foreign bodies, and for speech.

Laryngeal Cartilages. The skeletal framework of the larynx consists of cartilages and membranes. Of the nine separate cartilages, three are single and six are arranged in pairs. The main cartilages of the larynx include the thyroid, the cricoid, the

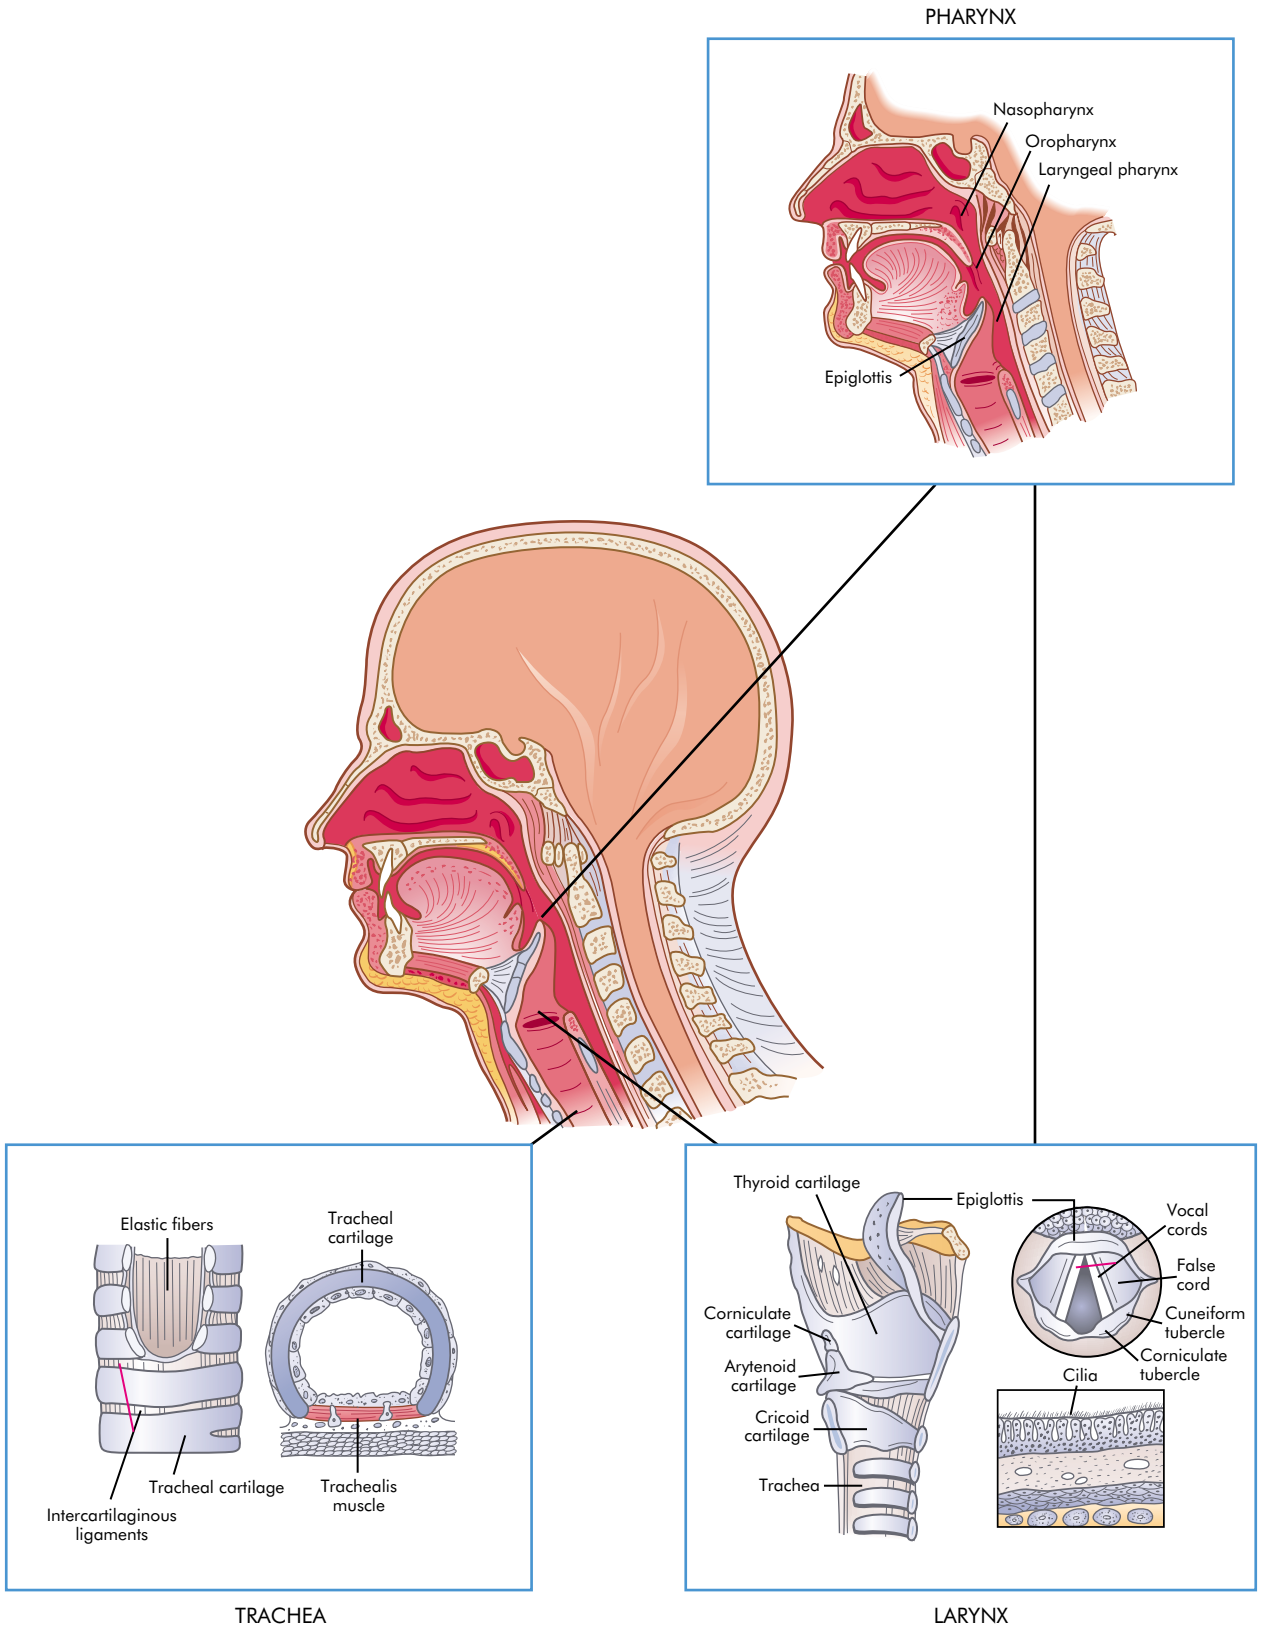

FIGURE 18-8 Structures of the upper airway.

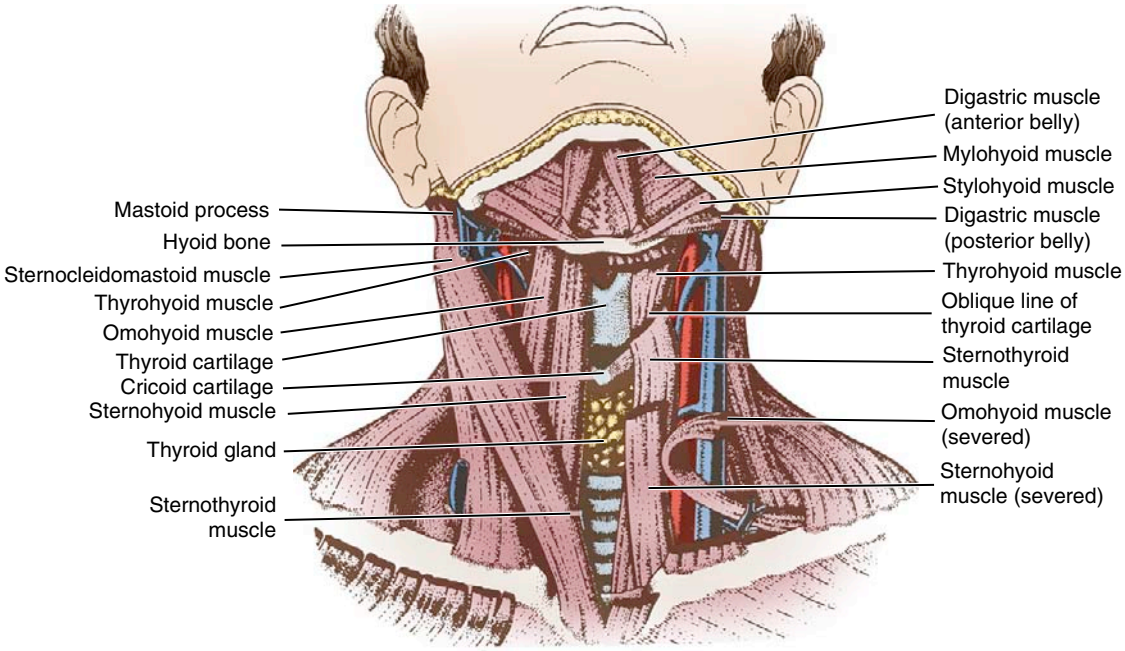

FIGURE 18-9 Extrinsic muscles of larynx.

epiglottis, two arytenoid, two corniculate, and two cuneiform. The thyroid cartilage, or Adam's apple, forms the anterior portion of the voice box. The cricoid cartilage is a complete cartilaginous ring that resembles a signet ring; it rests beneath the thyroid cartilage and supports the airway (see Figure 18-8). The epiglottis is a slightly curled, leaf-shaped, elastic, fibrous membrane that is attached in the midline to the upper border of the thyroid cartilage. The epiglottis helps to protect the larynx during swallowing. Contraction of the cricothyroid muscle pulls the thyroid cartilage and the cricoid cartilage to tighten the vocal cords and close the glottis. The arytenoid cartilages, which rest above the signet-ring portion of the cricoid cartilage, support the posterior portion of the true vocal cords.

Laryngeal Ligaments. The extrinsic ligaments of the larynx are those connecting: (1) the thyroid cartilage and epiglottis with the hyoid bone and (2) the cricoid cartilage with the trachea. The intrinsic ligaments of the larynx are those connecting several cartilages of the organ to each other. They are considered the elastic membrane of the larynx.

The mucous lining of the larynx blends with fibrous tissue to form two folds on each side of the larynx. The upper set is known as the *false vocal cords*. The lower set is called the *true vocal cords* because they are concerned primarily with the speaking voice and protection of the lower respiratory channels against the invasion of food and foreign bodies. The region of the larynx at the true vocal cord level is called the *glottis*, a triangular space between the vocal cords. During swallowing, the rising action of the muscular larynx, the closure of the glottis, and the doorlike action of the epiglottis all serve to guide food and fluid into the esophagus.

Laryngeal Muscles. The laryngeal muscles perform two distinct functions: the extrinsic muscles (Figure 18-9) regulate the degree of tension on the vocal cords, and the intrinsic muscles open and close the glottis. The spoken voice also depends on the sphincter action of the soft palate, tongue, and lips. The muscle action of the larynx permits the glottis to close either voluntarily or involuntarily by reflex action. The closure of the inlet by this mechanism protects the respiratory passages. The closure of the glottis and the action of the vocal cords are precisely coordinated to produce the voice.

Trachea. The trachea is a cartilaginous tube about 15 cm in length and 2 to 2.5 cm in diameter. It begins in the neck and extends from the lower part of the larynx, on a level with the sixth cervical vertebra, to the upper border of the fifth thoracic vertebra. It descends anteriorly to the esophagus, enters the superior mediastinum, and divides into right and left main bronchi. The trachea is composed of a series of C-shaped rings of hyaline cartilage. The posterior surface of the trachea is flattened rather than round because the cartilaginous rings are incomplete. The carina is a ridge on the inside of the bifurcation of the trachea. It is a landmark during bronchoscopy and separates the upper end of the right main branches from the upper end of the left main branches of the bronchi. Branches from the arch of the aorta—the brachiocephalic (innominate) and left common carotid arteries—are in close relation to the trachea. The cervical portion of the trachea is related anteriorly to the sternohyoid and sternothyroid muscles and to the isthmus of the thyroid gland.

Musculature of the Neck

A layer of deep cervical fascia surrounds the neck like a collar and is attached to the trapezius and sternocleidomastoid muscles. The sternocleidomastoid muscle extends from the upper part of the sternum and medial third of the clavicle to the mastoid process. The trapezius muscle extends from the scapula, the lateral third of the clavicle, and the vertebrae to

the occipital prominence. The relationship of these muscles to each other and to the adjacent bone creates triangles used as anatomic landmarks.

The pretracheal fascia of the neck lies deep in the strap muscles (sternothyroid, sternohyoid, thyrohyoid, and omohyoid) and partially encloses the thyroid gland, trachea, and larynx. The pretracheal fascia is pierced by the thyroid vessels. It fuses with the front of the carotid sheath on the deep surface of the sternocleidomastoid muscle. The carotid sheath consists of a network of areolar tissue surrounding the carotid arteries and vagus nerve.

Laterally the carotid sheath is fused with the fascia on the deep surface of the sternocleidomastoid muscle; anteriorly it is fused with the middle cervical fascia along the lateral border of the sternothyroid muscle. Lying between the floor and roof of this triangular formation of muscles are the lymph glands and the accessory nerve. Arteries and nerves traverse and pierce this triangle.

PROXIMAL STRUCTURES

Cranial Nerves

The trigeminal (fifth cranial) nerve supplies sensory innervation to the face, oral cavity, nose, nasal cavity, and maxillary sinuses. It provides motor innervation to the muscles of mastication.

The right and left facial (seventh cranial) nerves are responsible for all the movements of the facial muscles. Both nerves have a very complex and tortuous course from the brainstem to the motor endplates of the facial musculature. The facial nerve enters the internal auditory meatus along with the eighth (vestibulocochlear) cranial nerve and travels through the internal auditory canal, passing through the labyrinthine portion of the temporal bone to the geniculate ganglion, where it turns sharply and passes superior to the oval window. It then turns inferiorly through the mastoid and exits through the stylomastoid foramen. There are three primary branches of the facial nerve in the temporal bone: the greater superficial petrosal nerve controls lacrimation; the stapedial branch controls the stapedius muscle; and the chorda tympani nerve carries the taste sensation to the anterior two thirds of the tongue.

The vestibulocochlear (eighth cranial) nerve connects the inner ear to the brain through its brainstem nuclei and ascending neural pathways. The recurrent laryngeal branch of the vagus (tenth cranial) nerve is the important motor nerve of the intrinsic muscles of the pharynx and larynx.

Lymphatic System

The lymphatic system serves both immunologic and circulatory functions. Interstitial fluid, which may contain bacteria, viruses, or tumor cells, is returned to the blood circulation through the lymphatic channels. As the lymph nodes trap the foreign matter, the nodes may become enlarged, infected, or the focus of metastatic cancer (Figure 18-10).

The nasal cavity, the paranasal sinuses, and the pharynx drain into the retropharyngeal nodes. The mouth, lips, and external nose are drained by the submandibular nodes. The lymphatics of the tip and lateral aspects of the tongue drain to the submental nodes, and the posterior tongue lymphatics drain to the cervical nodes.

FIGURE 18-10 Advanced cancer of the mouth with metastasis to the neck.

The lymphatic drainage of the neck can be divided into superficial and deep nodes (Figure 18-11). Lymph nodes of the neck can be further classified into subzones. Level Ia nodes are submental nodes; level Ib nodes are submandibular nodes. Level IIa nodes are upper jugular nodes anterior to cranial nerve IX. Level IIb nodes are upper jugular nodes posterior to cranial nerve IX. Level III nodes are middle jugular nodes. Level IV nodes are lower jugular nodes. Level Va nodes are posterior triangle nodes of the spinal accessory group, and level Vb nodes are posterior triangle nodes of the transverse cervical artery and supraclavicular group. Level VI nodes are anterior tracheal nodes. Level VII nodes are superior mediastinum nodes.

Perioperative Nursing Considerations

Assessment

Assessment is a systematic and intentional process of collecting and interpreting data concerning a patient's health history and status with diagnoses related to the head and neck. Familiarity with otorhinolaryngologic conditions is essential for effective patient assessment. Information obtained helps to develop nursing diagnoses, which direct nursing plans, interventions, and evaluation. A nursing preoperative assessment is usually obtained either in person during scheduled preoperative evaluation or by telephone before the day of surgery. The perioperative nurse should review this assessment as well as the physician's evaluation to prepare for patient care in the OR. The assessment should include a review of the following:

- *Communication status.* Approximately 17% (36 million) of American adults report some degree of hearing loss severe enough to cause problems with communication and about 2 to 3 of every 1000 children in the United States are born

EVIDENCE FOR PRACTICE

Strategies for Communicating with a Hearing-Impaired Patient

Hearing deficits in patients must be considered when performing assessment, planning and implementing interventions, and providing education. Preexisting and postoperative hearing deficits can present a communication challenge for patients, their families, and perioperative nurses. Recommended strategies for communicating with a hearing-impaired patient include the following:

- Position yourself directly in front of the patient. Most people who have hearing loss rely heavily on seeing the speaker's face (best distance is about 3 feet).
- Ensure that the room is well lighted, making sure the light is shining at the speaker and not in the eyes of the patient.
- Get the patient's attention before beginning to speak.
- Ask the patient what you need to do so that he or she can best understand you.
- If one ear is better than the other, move closer to the less-affected side.
- Speak clearly and slowly using a good elocutionary style (do not exaggerate mouth movements).
- Do not shout. Shouting raises the frequency of sound and makes understanding more difficult.
- Try not to mumble or lower the sound intensity of words at the end of sentences.
- Decrease background noise as much as possible; turn off medical equipment alarms if possible when attempting communication with the patient.
- Do not chew gum and speak at the same time.
- Keep hands and other objects away from your mouth and the speaker's mouth when talking to the patient.
- When family members are present, speak directly to the patient. Do not refer to the patient in the third person.
- Minimize distractions.
- Rephrase rather than repeat—the patient may not have understood a particular word or phrase.
- Have the patient repeat back, in his or her own words, your statements to assess understanding.
- Use appropriate hand motions.
- Be patient and relax. By working together, you can help maximize effective communication.
- Write messages on paper if the patient is able to read.

deaf or hard-of-hearing (National Institute on Deafness and Other Communication Disorders [NIDCD], 2009). Hearing loss may be classified as conductive, sensorineural, or mixed (Table 18-1). Nurses must determine the best way to communicate with the patient who is hard-of-hearing (Evidence for Practice). Patients who are unable to speak because of vocal cord dysfunction must be provided an alternate means of communication (e.g., pen and paper, erasable board). Nurses must assess for adaptive responses—lip reading, sign language, written communication—and the effect of the patient's communication status on daily life (e.g., inability to hear traffic, alarms, or telephone; inability of voice to be heard because of hoarseness; voice volume issues; reluctance to communicate).

- *Respiratory status.* Observe and note the quality and character of respirations; observe and note the quality and character of the voice—hoarseness, "hot potato" voice, or hyponasal speech; note inspiratory stridor, expiratory stridor, hemoptysis, or dyspnea.
- *Physical status.* Observe problems in range of motion in all four extremities; note joint replacements, back or neck stiffness or pain, or trismus. Assess facial symmetry, landmarks, color, position, and presence of deformities, lesions, and nodules; note presence or absence of rhinorrhea or otorrhea. Note any cranial nerve involvement (e.g., inability to look downward, nystagmus, facial asymmetry, and facial paresis).
- *Presence of a mass.* Note the length of time the mass has been evident; note if the size of the mass decreased after antibiotic therapy; note a fixed mass versus a mobile mass.
- *Nutritional status.* Note any weight loss, including length of time weight loss occurred. Patients with diagnosed and

TABLE 18-1

Types of Hearing Loss

Classification	Definition	Causes
Conductive	Loss of hearing acuity resulting from failure to conduct sound from external ear to middle ear	Blockage of external canal with cerumen or foreign bodies Edema Trauma Infection Tympanic perforation Otosclerosis, ossicular chain fixation
Sensorineural	Loss of hearing acuity resulting from failure to conduct sound to inner ear (cochlea or acoustic nerve)	Ototoxic medications Exposure to loud noise Trauma Meniere's disease Tumor Presbycusis Infectious disease (measles, mumps, meningitis)
Mixed	Loss of hearing acuity resulting from combination of conductive and sensorineural factors	Develops secondary to either conductive or sensorineural loss (e.g., patient with presbycusis and impacted cerumen)

undiagnosed neoplasms may be nutritionally depleted from dysphagia, tumor, chemotherapy, or radiation therapy.

- *Emotional status and anxiety level.* Observe for restlessness, poor eye contact, facial tension, or increased perspiration.
- *Pain.* Observe location and character of odynophagia, sore throat, facial pain, or otalgia. Note preoperative medications and the time they were administered. Begin education for pain management before discharge (Ambulatory Surgery Considerations).
- *Allergies.* Note allergic reactions to medications, foods, or latex.
- *Medication history.* Note medications taken by the patient for the presenting condition and any other diagnosed medical condition. Medications should include prescription medications, over-the-counter medications, vitamins, herbals, nutraceuticals, ototoxic drugs taken, including salicylates, aminoglycosides, furosemide, streptomycin, quinine, ethacrynic acid, or any history of chemotherapy. Ensure key participants in the patient's care are aware of the medication history (Patient Safety).
- *Past responses to anesthesia.* Local anesthetics are often used either as the sole means of anesthesia for minor procedures or as an adjunct to procedures performed using monitored anesthesia care or general anesthesia. The patient's account of previous dental experiences with local

AMBULATORY SURGERY CONSIDERATIONS

Pain Assessment and Management for Outpatient Otorhinolaryngologic Procedures

Management of pain is an important consideration for otorhinolaryngologic patients undergoing same-day surgery. If pain is not effectively managed, the patient is unduly stressed and complications (e.g., hypertension, tachycardia, nausea, vomiting) may ensue and delay discharge. Unmanaged pain may also lead to readmission or evaluation in the emergency department. Other consequences include immobility, delayed healing, interference with ADLs, and lost productivity. Perioperative nurses must be cognizant of the impact of pain in this population and can use these guidelines to provide effective pain management and education for patients before discharge.

The Joint Commission has established standards for pain management. The underpinning element of these standards is the patient's right to appropriate assessment and management of pain. Among other things, the standards also stipulate education of patients and families regarding pain management, after consideration of their personal, cultural, spiritual, and ethnic beliefs. Expected outcomes in pain management and comfort, which may help patients heal more quickly and have improved outcomes, were researched to develop the following clinical guidelines:

PREOPERATIVE PAIN ASSESSMENT

- Patient states understanding of plan of care and priority of individual needs.
- Patient states understanding of pain intensity scale, comfort scale, and pain-relief/comfort goals.
- Patient states understanding of methods to communicate pain levels to the provider during the operative phase of care (patients receiving local or managed anesthesia care).

POSTANESTHESIA PHASE I

- Patient maintains hemodynamic stability, including respiratory/cardiac status and level of consciousness.
- Patient states achievement of pain-relief/comfort treatment goals.
- Patient shows effective use of at least one nonpharmacologic method.
- Patient verbalizes evidence of receding pain level and increased comfort with pharmacologic and nonpharmacologic interventions.

POSTANESTHESIA PHASE II/III

- Patient states acceptable level of pain relief and comfort with movement or activity at time of transfer or discharge to home.
- Patient verbalizes understanding of discharge instruction plans (specific drug, frequency of administration, potential side effects of medication, potential drug interactions, precautions or limitations when taking drugs, name and telephone number of the physician/resource to contact with emergencies or problems).
- Patient states understanding or shows effective use of nonpharmacologic methods.
- Patient states achievement of pain/comfort treatment goals and level of satisfaction with pain-relief and comfort management in the perianesthesia setting.

PATIENT SAFETY

Medication Reconciliation

A National Patient Safety Goal (NPSG) established by The Joint Commission is to "accurately and completely reconcile medications across the continuum of care." Reconciliation of medication information can prevent prescribing errors, such as duplicate prescriptions, incompatible medications, and overprescribing. Whether undergoing an inpatient or outpatient procedure, the patient entering the perioperative setting may be at risk for medication errors because of decreased communication with the patient's primary care physician or other treatment specialists. Otorhinolaryngologic patients may also have communication challenges (auditory or vocal) that increase the risk of error in obtaining an accurate medication history. In ambulatory surgery, perioperative nurses typically review the patient's medication history in the preoperative period and then review medications again in the postoperative/discharge phase. Nurses can positively impact patient safety and reduce the risk for prescribing errors by following medication safety practices, using medication reconciliation processes, and implementing these risk reduction strategies:

- Collect a current home medication list (including dose and frequency along with allergies, drug intolerance information, and immunization history) for each patient on admission.
- Validate the home medication list with the patient whenever possible; a family member, significant other, or surrogate decision-maker may be involved. This involvement should occur at all interfaces of care, and on admission to and discharge from the facility.
- Have the home medication list available for the physician whenever writing orders; place the reconciling form in a consistent highly visible location within the patient chart.
- Assign primary responsibility for collecting the home medication list to someone with sufficient expertise, within a context of shared accountability.
- Assign to someone with sufficient expertise the responsibility for comparing admission orders with the home medication list; identifying discrepancies or interactions; and reconciling variances.
- Reconcile medications within specified time frames (within 24 hours of admission; shorter time frames for high-risk drugs, potentially serious dosage variances, and/or upcoming administration times).
- On discharge from the ambulatory surgery setting, in addition to communicating the updated medication list to the next provider of care during the hand-off report, provide the patient with the complete list of medications that he or she will be taking after discharge as well as instructions on how and how long to continue taking newly prescribed medications. Encourage the patient to carry the list and share it with any providers of care, including primary care and specialist physicians, nurses, pharmacists, and other caregivers.
- Adopt a standardized form to use for collecting the home medication list and for reconciling the variances (includes both electronic and paper-based forms).
- Develop clear policies and procedures for each step in the reconciliation process.
- Provide access to drug information and pharmacist advice at each step in the reconciliation process.
- Provide orientation and ongoing education on procedures for reconciling medications to all healthcare providers.
- Provide feedback and ongoing monitoring.
- When the patient is unable to actively or fully participate in the medication reconciliation process and has requested assistance from another person(s) (e.g., family member, significant other, surrogate decision-maker), involve the authorized person(s) in the medication reconciliation process.

Modified from The Joint Commission: *Sentinel Event Alert,* issue 35, available at www.jointcommission.org/SentinelEvents/SentinelEventAlert/sea_35.htm. Accessed August 9, 2009.

anesthetics can provide a clue as to how the patient will respond to local anesthetic agents. Cardiac status should be noted because many surgeons use epinephrine as an additive to the local anesthetic to achieve vasoconstriction and minimize blood loss. The epinephrine effect may contribute to cardiac dysrhythmias and an increased potential for cardiac arrest.

- *Patient's knowledge and understanding of the surgical procedure.* Note questions and provide answers, or ask surgeon to clarify information for the patient. Review equipment and care (e.g., suctioning, packing, drains) that will be part of the postoperative regimen and possible communication deficits related to the procedure (e.g., inability to speak after laryngeal procedures, decreased hearing after otologic procedures).
- *Patient's support system.* Note family members' names and their location during the surgical procedure, and explain that a nurse will communicate with them during the procedure regarding the patient (as applicable).

In addition to standard office diagnostic procedures performed by the surgeon, several other tests may be performed before the patient arrives in the OR. Study results of most significance to the perioperative team that should be available in the OR may include the following.

Laboratory Data

Red blood cell (RBC) count (may be increased with dehydration or decreased with dietary deficiencies)

- *Male:* 4.7 to 6.1 million/mm^3
- *Female:* 4.2 to 5.4 million/mm^3
- *Child:* 4 to 5.5 million/mm^3

Hemoglobin (values for the elderly may be slightly decreased; may be increased with dehydration, congestive heart failure [CHF], or chronic obstructive pulmonary disease [COPD]; may be decreased with cancer, nutritional deficiency, or severe hemorrhage)

- *Male:* 14 to 18 g/dl
- *Female:* 12 to 16 g/dl
- *Child:* 10 to 15.5 g/dl

Hematocrit (may be increased with trauma or dehydration; may be decreased with hyperthyroidism, cirrhosis, hemorrhage, malnutrition, dietary deficiency, or in the elderly)

- *Male:* 42% to 52%
- *Female:* 37% to 47%
- *Child:* 32% to 44%

White blood cell (WBC) count (may be increased with infection, trauma, stress, tissue necrosis, and inflammatory process; may be decreased with dietary disease, autoimmune disease, and overwhelming infections)

- *Adult:* 5000 to 10,000/mm^3
- *Child ≤2 years old:* 6200 to 17,000/mm^3

Platelet count: 150,000 to 400,000/mm^3 (may be increased with malignant disorders, polycythemia vera, postsplenectomy syndrome, rheumatoid arthritis, iron deficiency anemia; may be decreased with hemorrhage, liver disease, kidney disease, or systemic lupus erythematosus [SLE]) (Pagana and Pagana, 2009)

- Urinalysis (observe glucose level; if positive, check blood glucose level)
- Prothrombin time (PT), partial thromboplastin time (PTT), and activated partial thromboplastin time (APTT)
  - PT: 11 to 12.5 seconds (may be increased with cirrhosis, hepatitis, vitamin K deficiency, salicylate intoxication, or disseminated intravascular coagulation [DIC])
  - PTT: 60 to 70 seconds
  - APTT: 30 to 40 seconds (may be increased with clotting factor deficiencies, biliary obstruction, hepatocellular diseases, vitamin K deficiency, or DIC; may be decreased with early stages of DIC or extensive cancer) (Pagana and Pagana, 2009)
- Blood chemistry analysis
  - Chloride—adult and elderly: 98 to 106 mEq/L (may be increased with dehydration, kidney dysfunction, or anemia; may be decreased with CHF, diuretic therapy, or hypokalemia)
  - Potassium—adult and elderly: 3.5 to 5 mEq/L (may be increased with acute or chronic renal failure; may be decreased with diuretic therapy, diarrhea, vomiting, or insulin, glucose, or calcium administration)
  - Blood urea nitrogen (BUN)—adult: 10 to 20 mg/dl (elderly may be slightly higher; may be increased with renal disease, CHF, or dehydration; may be decreased with liver failure, overhydration, or malnutrition) (Pagana and Pagana, 2009)
- If the thyroid gland is suspect, the following tests may be indicated:
  - Serum calcium levels (to determine parathyroid function)—adult: 9 to 10.5 mg/dl
  - Serum calcitonin (to assess potential for medullary carcinoma)
  - Thyroid scan (to assess presence of "cold" nodule, which is often indicative of carcinoma)
  - Thyroid antibody tests (may show decreased levels in carcinoma): titer less than 1:100
  - Serum thyroxine (T_4): *male,* 4 to 12 mcg/dl; *female,* 5 to 12 mcg/dl
  - Thyroid-stimulating hormone (TSH): 2 to 10 milliunits/ml
  - Triiodothyronine uptake, resin (T_3RU): *20 to 50 years,* 75 to 220 ng/dl; *older than 50 years,* 40 to 180 ng/dl (Pagana and Pagana, 2009).

Computed Tomography. CT scans are radiographic studies that visualize structures by producing serial sections, many times clinically referred to as "cuts," through planes of the head and neck. CT imaging provides visualization of bone, soft tissue, and adjacent intracranial and extracranial pathologic conditions. Intravenous (IV) injection of iodine contrast agents produces visual enhancement of some anatomic structures and pathologic tissues, including highly vascularized tumors. CT is the study of choice to assess intratemporal bone pathologic conditions and to evaluate the paranasal sinuses and adjacent structures. It is also used in the assessment of the oral cavity and neck.

Magnetic Resonance Imaging. Magnetic resonance imaging (MRI) is an imaging modality using powerful magnetic and radiofrequency waves to reproduce cross-sectional images of the human body without exposing the patient to ionizing radiation. On an MRI scan, fat and fluid produce high-intensity signals, which appear as bright areas, whereas bone and air emit weak signals and appear as darkened areas on the scan. MRI is often used with CT imaging in a complementary fashion when evaluating lesions in and around bone for a variety of head and neck conditions including tumors in the oral cavity, external auditory canal, middle ear, and mastoid.

Audiogram. Patients scheduled for otologic surgery may have undergone evaluation of their hearing through audiograms to determine whether they have normal hearing, conductive hearing loss, or sensorineural hearing loss (see Table 18-1). Two types of audiometric testing, pure tone and speech audiometry, are performed on patients with suspected hearing loss.

Nursing Diagnosis

Nursing diagnoses related to the care of patients undergoing otorhinolaryngologic surgery might include the following:

- Anxiety
- Acute Pain
- Risk for Ineffective Breathing Pattern
- Risk for Bleeding
- Disturbed Sensory Perception
- Disturbed Body Image
- Impaired Verbal Communication

Outcome Identification

Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient will be able to identify factors that cause anxiety and verbalize an ability to cope.
- The patient will communicate adequate pain control and display absence of physiologic indicators of pain (e.g., tachypnea, tachycardia, pallor, hypertension).
- The patient will demonstrate effective breathing patterns.
- The patient will maintain a hematocrit level of 30 mg/dl or greater or a hemoglobin level of 12 to 14 mg/dl.
- The patient will verbalize understanding of the anticipated postoperative alterations in hearing, smell, or taste as appropriate to the surgical diagnosis.
- The patient will experience a sense of self-worth and self-respect.
- The patient will establish an effective communication method with staff and family.

Planning

The development of a plan of care is based on the preoperative assessment, nursing diagnoses, expected outcomes, and the surgery being performed. Patients undergoing otolaryngologic procedures may have special communication needs that must be considered in planning effective care. The perioperative nurse should determine the best way to communicate with patients who have hearing deficits or impaired

vocalization. Information given to the patient should be reinforced as needed throughout the perioperative experience. The OR environment must be quiet and free of any loud noise. Intraoperative noises, such as those from suction, electrosurgical units (ESUs), and other equipment, should be explained to the locally anesthetized patient before they are generated. This will help avoid startling the patient and adversely affecting the success of the surgery. Patients receiving local anesthetics need to remain still during the procedure, so providing for comfort measures becomes especially important. The room temperature should be regulated at a comfortable setting, and the patient should be adequately covered to maintain normal body temperature.

Preparation of the OR includes checking the availability and functional capacity of suction, the surgeon's headlight and light source, and the ESU. It is essential that the x-ray view box is in working order and appropriately located so that scans may be easily viewed by the surgeon during the procedure. In endoscopic cases, the navigation tower and monitor should be rolled to the head of the table and tested to ensure proper functioning of the light source for the camera wands and suction. If the surgeon plans on video-recording the case, assurance that the video recorder is adequately working is needed before the start of the case.

A Sample Plan of Care for a patient undergoing otorhinolaryngologic surgery follows.

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Anxiety

OUTCOME
The patient will be able to identify factors that cause anxiety and verbalize an ability to cope.

INTERVENTIONS
- Assess patient's level of anxiety (alertness, ability to comprehend, ability to perform activities of daily living [ADLs]).
- Maintain calm and safe environment.
- Assist patient in identifying possible sources of stress.
- Allow patient to ventilate and ask questions. Assess patient for desire for preoperative visit by persons with altered communication methods.
- Following the protocol in place, inform the patient and family what to expect on the day of surgery and the environment of care (preoperative area, OR, postanesthesia care unit).
- Introduce members of the surgical staff. Explain activities performed by the nursing staff in simple language the patient can understand.
- Assure the patient that he or she will be informed before any procedure is done.
- Provide time for the patient and family to express fears and concerns. Provide factual, accurate information.
- Note expressions of distress and anxiety.
- Prevent unnecessary body exposure during transfer and positioning.
- Control external stimuli and noise levels.

NURSING DIAGNOSIS
Acute Pain

OUTCOME
The patient will communicate adequate pain control and display absence of physiologic indicators of pain (e.g., tachypnea, tachycardia, pallor, hypertension).

INTERVENTIONS
- Review with patient normal coping mechanisms that are personally effective; support and encourage these during surgical intervention. As appropriate, consider nonpharmacologic measures, such as guided imagery, music, and relaxation exercises.
- Describe the anticipated sequence of perioperative events.
- Explain that some initial discomfort (e.g., pinprick followed by slight burning and then numbness) may be felt during the administration of local anesthetic.
- Inform the patient before the injection of local anesthetic; provide support and reassurance; evaluate patient response.
- Observe for, document, and report any changes in the patient's vital signs (blood pressure, heart rate and rhythm, respiratory rate, oxygen saturation), skin condition, and mental status.
- Be aware of the maximum recommended dosage of local anesthetics and be alert for signs of allergic reactions or toxic responses.
- Ask the patient whether he or she is experiencing any pain; communicate the presence of pain sensation to the surgeon.
- Administer sedation or analgesics as ordered by the surgeon. Describe the purpose and expected response to the medication administered. Document medications administered.
- Verify with the patient that desired response has been achieved.

NURSING DIAGNOSIS
Risk for Ineffective Breathing Pattern

OUTCOME
The patient will demonstrate effective breathing patterns.

INTERVENTIONS
- Assess respiratory status and breathing pattern. Monitor respiratory rate, rhythm, and depth and oxygen saturation (pulse oximetry). Maintain oxygen saturation at greater than 90%. Report any variances from normal.
- Note any restlessness, apprehension, agitation, lethargy, or repeated swallowing. Use a penlight to examine the throat for bleeding if nasal, oral cavity, or laryngologic procedures were performed. Notify the surgeon if bleeding is present.
- Have emergency medications and airway equipment available.
- Elevate head of the bed (to decrease edema, which can interfere with breathing).
- Increase humidification with a bedside humidifier or a humidified facemask.
- Encourage patient and family to increase frequency of oral hygiene.

NURSING DIAGNOSIS
Risk for Bleeding

OUTCOME
The patient will maintain a hematocrit of 30 mg/dl or greater or a hemoglobin of 12 to 14 mg/dl.

Continued

SAMPLE PLAN OF CARE—cont'd

INTERVENTIONS
- Assist with the insertion of intravenous (IV) lines and fluid replacement therapy. Keep IV lines patent.
- Provide blood or blood products for fluid replacement; assist in replacement therapy and patient monitoring.
- Estimate blood loss on sponges and drapes; communicate to anesthesia provider and surgeon.
- Record the amount of irrigation used.
- Document the contents of the suction canisters.
- Monitor and document hourly urine output (as applicable); communicate results of measurements.
- Observe for signs of shock (e.g., hypotension, abnormal ECG); report signs, and initiate corrective nursing actions.
- Observe for signs of excess blood loss (e.g., rapid, weak pulse; rapid respirations; cool, moist skin; early, slight rise in blood pressure); report signs, and initiate corrective nursing actions.
- Collaborate with the collection and interpretation of intraoperative blood analyses.

NURSING DIAGNOSIS
Disturbed Sensory Perception

OUTCOME
The patient will verbalize understanding of the anticipated postoperative alteration in the senses of smell and taste.

INTERVENTIONS
- Explain to the patient and family that a "mustache" dressing and packing might be in place postoperatively and will interfere with the sense of smell.
- Inform the patient and family that the sense of taste will also be altered, similar to having a head cold.
- Assure the patient and family that these alterations are usually temporary.
- Encourage the patient to maintain proper dietary intake even if the food does not smell or taste as it should.
- Encourage frequent mouth care; rinse with water or half hydrogen peroxide and half normal saline.
- Assess any degree of hearing impairment.
- Agree on a method of communication preoperatively to be used postoperatively.
- Allow patient to wear hearing aid to the OR.
- Identify a method by which patient can communicate basic needs if and when the hearing aid needs to be removed.
- Maintain a quiet surgical environment.
- Speak slowly and deliberately into the dominant ear.
- Reorient patient as needed, and provide frequent explanations and reassurance.
- Provide interpreters (e.g., sign language interpreter, oral interpreter, cued speech interpreter) as needed to facilitate communication.

NURSING DIAGNOSIS
Disturbed Body Image

OUTCOME
The patient will experience a sense of self-worth and self-respect.

INTERVENTIONS
- Acknowledge normalcy of emotional response to actual or perceived change in body structure or function. Experiencing stages of grief over loss of a body part or function is normal, and typically involves a period of denial, the length of which is variable.
- Encourage patient to verbalize feelings and self-perceived changes related to health status and surgical procedure.
- Involve family or significant others in initial communication with patient.
- Encourage patient to ask questions.
- Discuss referrals for support groups.

NURSING DIAGNOSIS
Impaired Verbal Communication

OUTCOME
The patient will establish an effective communication method with staff and family.

INTERVENTIONS
- Plan in advance to obtain necessary assistive devices or interpreters.
- Inform the entire healthcare team of the patient's communication challenges and any interpretive services to be used.
- Agree on a method of communication preoperatively to be used postoperatively. Suggestions include the following:
  - Writing with a pen or pencil and paper, or using an erasable slate
  - Hand signals or signs, body expressions
  - Picture board
- Consult with surgeon regarding requirements for voice rest.
- Place intravenous (IV) lines in nondominant hand.
- Adapt written materials (e.g., consent forms, discharge instructions) as necessary; include visual information such as symbols, pictures, or diagrams to help understanding.

Implementation

The following nursing interventions should be instituted for the patient:

1. Use the institutional verification process immediately before surgery to identify the correct surgical site. This should include verifying the operative side and site with the patient or family and confirmation through review of the medical record, informed consent, diagnostic test reports, and other members of the surgical team during the time-out.
2. Verify that the patient has maintained nothing-by-mouth (NPO) status as directed and that requested laboratory studies are on the medical record.
3. Provide calm, careful, and comforting nursing measures to reduce the patient's anxiety. Allow the patient time to comply with requests, and explain the sequence of perioperative events.
4. Allow patients who wear hearing aids to wear them to the OR. Properly remove them at the time of or after anesthesia induction, or leave them in place if local anesthesia is used. Prescription eyewear should be brought into the holding area because hearing-impaired patients may require them to assist in lip reading when instructions and procedures are explained. If the patient has impaired vocalization, the nurse should ensure that the patient's preferred method of communication (e.g., pen and paper, artificial larynx) is

available. Disposition of any assistive devices brought into the OR must be documented on the record.

5. Protect patients with impaired communication from injury. The perioperative nurse must control the environment because excess stimulation interferes with the patient's ability to hear, vocalize, and comply with instructions and explanations.
6. Carefully review instructions for patients receiving local anesthetics. Remind the patient of the need to remain immobile during the procedure and report any adverse symptoms related to the anesthetic. Symptoms of adverse drug reactions include skin changes, such as rash or itching; restlessness; unexplained anxiety or fearfulness; diaphoresis; and complaints of blurred vision, tinnitus, dizziness, nausea, palpitations or acute changes in heart rate, disturbed respiration, pallor or flushing, and syncope. Emergency drugs, suction apparatus, and resuscitation equipment, including a defibrillator should be readily available.
7. Remain with the patient throughout the induction phase of anesthesia.
8. Perform any hair removal by clipping. Protect the patient's eyes during skin preparation.
9. Promote normothermia through the use of thermal warming blankets, forced-air warming units, and warm IV and irrigating solutions.
10. Use sequential compression devices (SCDs) to decrease the risk of deep venous thrombosis (DVT) and pulmonary embolism (PE) during long surgical procedures.
11. Document the serial number and lot numbers of any implanted materials according to institutional policy.
12. Initiate and document laser safety precautions if the laser is used (see Chapter 7).

Preoperative Room Preparation. Before the patient enters the OR, the nurse and scrub person (who could be a surgical technologist or a nurse) gather the equipment and supplies for the scheduled procedure. A well-organized surgical environment can significantly reduce anesthesia time and enable the perioperative nurse to spend more time attending to the preoperative and intraoperative needs of the patient. Planning includes identifying equipment, instrumentation, furniture, and positioning accessories necessary to perform the surgery. Such equipment may include the operating microscope, video system, monopolar and bipolar ESUs, suction, nerve integrity monitors, specialty instrument sets, prosthetic devices, drill and irrigation accessories, and the laser. A dedicated otorhinolaryngologic specialty storage cart centrally houses assorted prostheses, drill burrs and accessories, and dressing and packing materials, which contributes to efficiency when providing intraoperative care.

Positioning. The supine position with modifications is used during otorhinolaryngologic procedures. The perioperative nurse gathers the supplies necessary to ensure comfort of the patient in a supine position. These usually include a foam headrest or a pillow for under the knees, and warm blankets. The nurse pads the patient's extremities at pressure points and at major nerves. A pillow should be placed under the thighs and the legs should be slightly angled to decrease pressure on the patient's back; this positioning should be carried out before the patient is anesthetized to ensure comfort. Arms are placed on padded armboards with the palms up and fingers extended. Armboards are maintained at less than a 90-degree angle to prevent brachial plexus stretch. If there are surgical reasons to tuck the arms at the side, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail. The placement of IV lines in an arm that is to be tucked at the side should be avoided, but in cases where this is not avoidable, patency of those lines must be ensured.

OTOLOGIC SURGICAL POSITIONING. Microscopes are used for most otologic procedures. Based on the design of the microscope and the OR bed used, the patient may be placed on the bed in the reverse position—with the patient's head at the foot of the bed—to facilitate proper placement of the microscope mounted on a floor stand and to allow adequate space for the surgeon and assistant to be positioned on sitting stools near the surgical site.

The patient is placed supine with the operative side as close to the edge of the OR bed as possible, with the head turned and the operative ear upward. This positioning gives the surgeon access in viewing all areas of the middle ear and mastoid. One or more safety/restraining belts are used to secure the patient on the OR bed to ensure safety when turning or rotating the bed. During some procedures, such as mastoidectomy, the patient's head may be secured in position by placing tape across the head and attaching it to the frame of the OR bed. For other procedures, such as myringotomy, the patient's head may be immobilized and supported on a foam headrest. A donut-shaped foam head support helps to immobilize the head and permits easy adjustment of the angle while the operating microscope is being used.

To protect the nonoperative ear, the perioperative nurse should ensure that it is in the center of the donut hole and that the headrest does not cause any pressure on the ear. The dependent arm on the nonoperative side must also be well padded and properly positioned to minimize pressure injury; the patient's body weight could cause injury when the OR bed is rotated laterally to optimize surgical access. Special consideration must be given when the patient's head is positioned for surgery, especially when general anesthetics are used. Extremes in neck extension and head torsion can cause injury to the brachial plexus or cervical spine. Other options to assist in patient positioning are determined by the otologic procedure to be performed and by the surgeon's preference. They may include ophthalmic headrests with a crescent-shaped pad, a padded horseshoe-shaped headrest, or a headrest with skull pins such as the Mayfield, which is used in certain neurologic procedures.

Positioning of the surgeon is equally important to the success of the surgery. The surgeon's chair should be positioned at a height and distance that allow comfortable access to the operative site. The use of hydraulic or electric chairs enables the surgeon to adjust the position to meet these needs.

RHINOLOGIC SURGICAL POSITIONING. A standard headrest may be used to maintain the head in normal position but is not necessary. The entire bed is turned 90 degrees to allow the right-handed surgeon to work from the patient's right side, and the right arm is tucked in at the patient's side. Pad the elbows to protect the ulnar nerve; place the palms

FIGURE 18-12 Nasal procedure with scrub person on right side of surgeon.

facing inward and the wrist in a neutral position. Depending on the procedure, the left arm may be maintained by the anesthesia provider and usually has the IV line placed in it for easier access. The anesthesia provider will be at the patient's head. Raising the head of the bed greater than 45 degrees uses gravity to help minimize intraoperative bleeding. The scrub person may stand at the patient's head or near the patient's waist next to the surgeon's right arm (Figure 18-12). The Mayo stand can be positioned at the head and to the side of the bed; however, it is most commonly positioned over the patient's chest, depending on where the scrub person is standing. If indicated for the procedure, the perioperative nurse assists with setting up the navigation towers and video monitor equipment at this time.

ORAL CAVITY/LARYNGOLOGIC/NECK SURGICAL POSITIONING. The nurse assists with placing the patient in the supine position. A shoulder roll may be used for hyperextension of the neck. The headrest should allow easy movement of the head from side-to-side yet should maintain support. The patient's arms are often tucked at the sides as described earlier in this section to allow access of the surgical team to the operative site. If a microscope or video equipment is used, the OR bed may be turned to accommodate this equipment.

Anesthesia. Both the use of general anesthesia and the infiltration of a local anesthetic agent (local anesthesia) have advantages during otorhinolaryngologic surgery. General anesthesia provides airway control and allows the patient to remain still throughout the procedure, thereby making surgery technically easier to perform, but requires particular attention to extremes in head positioning, possible air emboli, the control of bleeding, and, for otologic procedures, the effects of nitrous oxide in the middle ear (Box 18-1). All anesthetics create an oxygen-rich atmosphere and the perioperative team must consider the patient's safety in this environment (Risk Reduction Strategies).

Local anesthesia is used alone or as an adjunct to many procedures. Safe administration of medication is essential for achieving optimal outcomes (Surgical Pharmacology). Lidocaine is frequently combined with epinephrine. A concentration of 1:200,000 provides maximum vasoconstriction, but some surgeons prefer a concentration of 1:100,000. Cocaine 4% topical solution is the second medication that is used commonly for rhinologic procedures. It is a good vasoconstrictor with the added benefit of anesthetic properties. Some surgeons use a nasal decongestant instead of cocaine for nasal vasoconstriction. These decongestants do not produce some of the cardiac effects seen with cocaine. Because nasal and sinus surgeries are performed in such a confined space, vasoconstriction becomes crucial for appropriate visualization of the surgical field. Hypertension can increase bleeding despite the use of vasoconstrictive agents and may need to be managed medically by the anesthesia provider intraoperatively if the visual field becomes compromised and surgery is impaired.

For rhinologic procedures, before the patient arrives in the OR the nurse prepares a separate prep table, which includes a labeled container of the vasoconstrictor solution, x-ray–detectable cottonoid sponges (usually ½ inch × 3 inches with attached strings), bayonet forceps, and a small nasal speculum. The surgeon soaks the cottonoid sponges with the vasoconstrictor solution and usually packs the nose with the

BOX 18-1

Nitrous Oxide and the Middle Ear

The middle ear and paranasal sinuses are normal body air cavities and consist of open, nonventilated spaces. The middle ear cavity is vented periodically when the eustachian tube opens. During general anesthesia, inhaled nitrous oxide diffuses into the middle ear space through the capillaries of the middle ear mucosa. This results in increased middle ear pressure. Rapid increases in middle ear pressure proportional to inhaled levels of nitrous oxide and abnormal eustachian tube function may cause nausea, vomiting, and rupture of the tympanic membrane in susceptible patients. This includes patients having previous ear surgery, otitis media, sinusitis, upper respiratory tract infections, enlarged adenoids, or other disorders of the nasopharynx.

When nitrous oxide is discontinued, the gas is rapidly reabsorbed and strong negative pressure in the middle ear may occur. This negative pressure may result in nausea, vomiting, serous otitis, hemotympanum, disarticulation of the stapes, and impaired hearing. Some practitioners believe the use of nitrous oxide as an anesthetic inhalation agent is hazardous to hearing in patients who have undergone previous reconstructive middle ear surgery.

RISK REDUCTION STRATEGIES

Managing the Risk of Fire in Oxygen-Rich Environments

Some estimates suggest that between 50 and 200 OR fires occur in the United States every year, with as many as 20% of reported fires resulting in serious injury or death (Caplan, 2008). Three elements must be present for fire to occur: heat, fuel, and oxygen. All elements are present in the OR.

Patients undergoing otorhinolaryngologic procedures are at greater risk for fire injury because of the proximity of the surgical field to high concentrations of oxygen. Devices used in this specialty (e.g., lasers, fiberoptic light cables, ESU, high-speed surgical drills and burrs) further contribute to risk by providing heat and fuel.

The tenets of fire safety are discussed in length in Chapter 2. Specific recommendations that perioperative nurses caring for otorhinolaryngologic patients must consider include:

- Awareness of risk factors. Oxygen vents into the atmosphere from facemasks, nasal cannulae, and uncuffed endotracheal tubes, accumulating under surgical drapes. This creates an oxygen-enriched atmosphere within the proximity of the surgical site for otorhinolaryngologic procedures.
- Discussion of risk. The perioperative nurse and scrub person should collaborate before procedures to plan for risk and ensure that sterile saline is available on the surgical field, the holster is used for the active ESU electrode, and the volumes of music, conversation, and ambient room noise are reasonable so that the audio from the ESU or laser can be heard. A careful review of the facility protocol for handling fire in the OR, including verification of the location of fire pull alarms, extinguishers, and evacuation routes, is essential and should not be minimized.
- Implementation of specific safety protocols for the use of the laser and the ESU in the airway:
  - Use only air for open delivery on the face for spontaneous breathing sedated patients who can maintain safe blood oxygen saturation without supplemental oxygen.
  - A laser-resistant endotracheal tube should be used, specific to the laser used for the procedure (e.g., CO_2, Nd:YAG). The cuff of the laser tube should be filled with saline and colored with an indicator dye such as methylene blue. Before activating the laser the surgeon should inform the anesthesia provider so that the oxygen concentration delivered to the patient can be safely reduced. Additionally, the surgeon should wait a few minutes before activating the laser to allow the oxygen concentration to diminish.
  - Cuffed endotracheal tubes should be used whenever possible for airway procedures. Before activating the ESU inside the airway, the surgeon should give the anesthesia provider adequate notice that the ignition source is about to be activated. The anesthesia provider should reduce the oxygen concentration to the minimum required to prevent hypoxia and the surgeon should wait a few minutes before using the ESU to allow the oxygen concentration to diminish.
  - Scavenging with the wound suction may be used to reduce the oxygen concentration in the operative field.
  - Sponges and cottonoids (and cottonoid strings) should be moistened when used in oxygen-rich environments to reduce the ignition potential from sources such as the laser or ESU.
  - If an uncuffed endotracheal tube must be used, moistened sponges should be used around the field to minimize leakage and reduce potential heat buildup.
- An immediate halt to the procedure when early warning signs of a fire are noticed. For fire in the airway or breathing circuit, the endotracheal tube should be removed and all flammable and burning materials should be removed from the airway. Delivery of all airway gases should stop, and saline should be poured into the patient's airway to extinguish any residual embers and cool the tissues.

SURGICAL PHARMACOLOGY

Medications Commonly Used in Otorhinolaryngologic Surgery

Category	Dose/Route/Mechanism	Purpose/Action	Adverse Reactions	Nursing Implications
LOCAL ANESTHETICS				
Lidocaine, 0.5% or 1%	Local injection	Blocks pain and temperature fibers, used as medium to dilute epinephrine	Cardiovascular, hypotension, confusion, dizziness, headache, somnolence, tremor, injection site pain, cardiac arrest, cardiac dysrhythmia, seizure	Contraindicated in hypersensitivity to amide locals. Use with caution in CHF, bradycardia, hypovolemia, liver disease, renal impairment.
Tetracaine (Pontocaine)	Topical; 0.25%-0.5% by nebulization or direct application	Blocks pain, suppresses gag reflex	Pain, redness, irritation on initial contact	Solution must be refrigerated. Frequently given by way of an atomizer. Remind patient not to eat, drink, or chew gum for at least 1 hour after procedure or until cleared by physician; return of gag reflex should be determined before discharge from PACU.
Benzocaine/ tetracaine/butamben (Cetacaine)	Topical; available in gel, liquid, and spray	Blocks pain, suppresses gag reflex	Dry mouth, dizziness	Spray is given by way of metered applicator; 1- to 2-sec spray is approximately 200 mg/sec. Should not be used over prolonged periods. Remind patient not to eat, drink, or chew gum for at least 1 hour after procedure or until cleared by physician; return of gag reflex should be determined before discharge from PACU.
Benzocaine	Topical; available in 20% gel and 20% spray	Blocks pain, suppresses gag reflex	Dry mouth, dizziness	Spray delivers 180-200 mg/sec when container is full, 60-80 mg/sec when inverted. Remind patient not to eat, drink, or chew gum for at least 1 hour after procedure or until cleared by physician; return of gag reflex should be determined before discharge from PACU.
Lidocaine hydrochloride	Available as 4% solution, 2% viscous solution	Local anesthetic	High doses may cause cardiac dysrhythmias, minor burning and stinging of mouth and throat on initial contact	Provide patient with emesis basin to expectorate any secretions. Patient may be instructed to gargle or swish with viscous solution to numb oral cavity in preparation for introducing Abraham cannula with 4% solution.
Cocaine hydrochloride	4% topical swab, packing instilled into cavity or spray, may be applied directly to vocal cords or other laryngeal structures on pledgets to promote vasoconstriction	Local anesthetic (also used as vasoconstrictor)	CNS depression, CNS stimulation, anxiety, tachydysrhythmia, seizures; may interact with cannabis, promethazine (Phenergan), and St. John's wort	Contraindicated in hypersensitivity to cocaine products. Use with caution in acutely ill patients or children, on severely traumatized mucosa, or when sepsis is present in area of intended application.

VASOCONSTRICTORS				
Oxymetazoline hydrochloride (Afrin Nasal Spray, Neo- Synephrine 12 Hr, Nasacon)	0.05% nasal spray	Nasal decongestant used for vasoconstriction	Headache, insomnia, nervousness, nasal congestion, rebound congestion, dry nasal mucosa, nasal stinging/ burning, sneezing, cardiac dysrhythmia, hypertension, tachydysrhythmia	Contraindicated in patients hypersensitive to oxymetazoline or other adrenergic agents, narrow-angle glaucoma. Use with caution in patients with cardiovascular disease, concurrent MAOI or tricyclic depressant therapy, diabetes, hypertension, prostatic enlargement, thyroid disease.
Epinephrine	1:100,000 to 1:200,000	Used for vasoconstriction	Palpitations, tachydysrhythmia, paleness and sweating, nausea and vomiting, asthenia, dizziness, headache, tremor, pain in eye, anxiety, apprehension, nervousness, dyspnea, cardiac dysrhythmia, hypertensive crisis, pulmonary edema	Should not be used in patients with hypersensitivity to epinephrine products, narrow-angle glaucoma (ophthalmic form) within 2 wk of MAOI (inhalational form). Proceed with caution in presence of cerebrovascular insufficiency, diabetes, geriatrics, heart disease, coronary insufficiency, hypertension, thyroid disease, pregnancy.
ANTIBIOTICS				
Mupirocin (Nasal Bactroban)	2% topical	Antibacterial and lubricant for nasal packing, applied topically to skin incisions	Dermatologic, nasal stinging and burning, disorder of taste, headache	Do not use with patients hypersensitive to mupirocin products. Prolonged use may result in overgrowth of nonsusceptible organisms including fungi; not intended for open wounds or mucous membranes.
Bacitracin	Topical ointment, 500 units/g	Antibacterial, antibiotic	Swelling, contact dermatitis, pruritus	See implications for mupirocin.
STEROIDS				
Triamcinolone acetonide (Aristocort, Kenalog)	Topical	Used topically to lubricate packs or expand packing	Hypertension, atrophic condition of skin	Use with caution in patients with hypertension, hypothyroidism, pregnancy. Do not use with hypersensitivity to triamcinolone acetonide; local, viral, fungal, or bacterial infections.
Cortisporin Otic suspension (neomycin and polymyxin B sulfates/hydrocortisone)	Topical	Used after otologic surgery as an antiinflammatory/ antibiotic agent	Itching, pain, stinging, burning, ototoxicity	When administering to patient, do the following: Tilt patient's head in opposite direction of affected ear. Instill prescribed number of drops toward ear canal, not directly on eardrum. (Tip: To promote correct placement of drops in children pull auricle down and posterior; in adults pull auricle up and posterior.)

CHF, Congestive heart failure; *CNS,* central nervous system; *MAOI,* monoamine oxidase inhibitor; *PACU,* postanesthesia care unit.
Modified from Dimmitt P: A review of topical anesthetics and decongestants, *ORL Head Neck Nurs* 23(2):21-24, 2005; Skidmore-Roth L: *Mosby's drug guide for nurses with 2010 update,* ed 8, St Louis, 2010, Mosby; Hodgson BB, Kizior RJ: *Saunders nursing drug handbook 2010,* St Louis, 2010, Saunders; Chow AW: Infections of the oral cavity, neck, and head. sponges before prepping and draping, to allow time for the vasoconstrictive properties to take effect. The cottonoids are left in place. Some surgeons will also inject local anesthetic at this time, but others may wait to inject at the time of surgery. Maximum vasoconstriction occurs in approximately 10 to 12 minutes after the administration of epinephrine. If a local anesthetic is to be injected next, the prep table should also include a 10-ml Luer-Lok syringe, appropriate-size needle (usually 25 gauge, 1½ inches), and labeled lidocaine (0.5% to 2%, according to surgeon's preference). Additional syringes, needles, and labeled local anesthetic solution should be available on the sterile field for additional administration intraoperatively. Additional labeled cocaine solution and cottonoids should be available on the sterile field as well. The nurse and scrub person ensure that the cottonoids are counted before and at the end of the procedure. (If a cottonoid is placed extremely posterior along the nasal floor, it can slide past the palate and be may swallowed or aspirated by the patient.)

Topical agents used in laryngeal surgery include epinephrine, phenylephrine hydrochloride, or cocaine. These agents may be applied on a cottonoid or sprayed directly on the vocal cords. Lidocaine 4% (Xylocaine) may be instilled into the trachea to decrease the cough reflex when it becomes an obstacle to a thorough physical assessment.

Local anesthesia combined with sedation or monitored anesthesia care is often employed for surgery in the preme-atal region and for stapedectomy and uncomplicated middle ear procedures of less than 2-hours' duration, some rhinologic procedures, and some excisional neck procedures. Sedation should render the patient calm, comfortable, cooperative, and able to understand and communicate. Patients should not be overmedicated to the point of demonstrating obtunded reflexes or being out of touch with their surroundings. Documentation should follow institutional policy for recording intraoperative medications administered (AORN, 2009a).

Preparation of the Operative Site. If hair removal is absolutely necessary, clipping is preferred because shaving may injure the skin and increase the risk of infection. Postauricular and endaural incisions extending upward from the meatus require hair to be about 1 to 2 cm away from the proposed incision site so that hair will not be in the operative field. Long hair is easily managed and kept out of the way with tape or lubricant. It is good practice to pull the top hair out of the way and only clip under the hair, to help maximize normal hair aesthetics postoperatively. Plastic adhesive drapes can be applied circumferentially around the proposed incision site, or a clear sterile drape laid over the entire surgical area. Parotid surgery may require hair removal from just below the temple to a line even with or slightly behind the pinna of the ear. Head and neck surgeries may require removal of hair on the chest to the nipple area on both sides. Thorough drying of the surgical area after the prep has been applied is critical for proper adhesion of the drapes to the skin so sterility is maintained throughout the operative procedure.

A povidone-iodine solution is generally used (unless the patient is allergic to iodine) to prep the surgical site for otologic and head and neck procedures. Povidone-iodine 10% (i.e., Betadine) is generally considered safe for the middle ear space and has not been found to be ototoxic in animal studies; however, in the presence of a tympanic membrane perforation, swabbing of the ear canal skin is preferred to gross spillage in the ear canal to prevent large volumes of prep solution from entering the middle ear space. All other surgical prep solutions, such as chlorhexidine and alcohol, are considered ototoxic and should be strictly limited to the outer ear and surrounding skin. Head and neck procedures may involve extensive skin preparation and usually include the entire area from the chin to the nipples; it may also include a donor skin graft site if a defect or large flap coverage is anticipated. Some surgeons prefer the patient's face to be included in the prep, depending on the type of surgery anticipated and the site of the lesion. If a flap may be raised to reconstruct a defect, saline should be available to remove the discoloration from the skin to allow the surgeon to check for flap viability.

Prepping of the nose and face may or may not be done for rhinologic and laryngeal/oral cavity procedures, depending on the surgical procedure and institutional policy. These areas are considered "dirty" and not possible to prep as effectively as other surgical sites, such as an abdomen. The surgical field is maintained in sterile fashion, and these procedures usually have a "clean contaminated" wound classification (see Chapter 3).

Facial Nerve Monitoring. Audible facial nerve monitors are used intraoperatively during procedures in which the facial nerve is at risk. The purpose of this monitoring technique is to assist in the early identification of the nerve, to increase the possibility of its preservation by minimizing trauma, and to assess its integrity after dissection (Mahlan et al, 2005). Electrodes are placed into the facial muscles before the patient is draped. Consultation and communication with the anesthesia provider are essential because the use of muscle relaxants and long-term paralyzing agents must be avoided. In the setting of a tympanic membrane perforation, lidocaine should not be allowed to spill into the middle ear space when injecting the ear canal, as temporary facial paralysis can ensue from topical anesthesia of a dehiscent facial nerve in the tympanic segment. Facial nerve monitoring is commonly used during acoustic neuroma and mastoid surgery (Figure 18-13).

Draping. Barrier draping minimizes the risk of postoperative infection. Draping technique is based on the surgeon's preference and the procedure to be performed.

OTOLOGIC DRAPING. Draping may be minimal for procedures such as myringotomy. For major otologic procedures,

FIGURE 18-13 Nerve integrity monitor system for intraoperative facial nerve monitoring.

plastic adhesive drapes are applied around the ear to keep the patient's hair out of the surgical field. Sterile, plastic, aperture drapes may be placed over the surgical site with the ear exposed through the opening. The surgeon may elect to expose a portion of the face on the affected side to observe facial movement.

Three or four towels are draped over the aperture drape around the ear and may be secured with nonpenetrating towel clips. A fenestrated drape is unfolded over the patient, with the opening centered over the operative site. An alternative method is the use of a split sheet with the split end secured at the base of the ear and the open flaps wrapped around the patient's head. Disposable drapes with adhesive backing may be used to secure the sheet to the patient.

During mastoid surgery and for resections of acoustic tumors, fluid-collection pouches may be attached to the drape. These pouches will catch fluid runoff when drilling and irrigation are planned. The operating microscope is draped to extend the sterile field (Figure 18-14).

Special consideration must be given to the selection of draping material used during ear surgery and to the technique for removing powder from surgical gloves. Powder and lint cling to gloves and can be transferred to instruments and introduced into the ear. They act as a foreign body in the wound, causing the formation of granulomas in the middle and inner ear, and may contribute to irreversible hearing loss. Therefore gloves worn by the surgical team should be rinsed to remove powder and lint. Lint-free drapes should be used.

RHINOLOGIC DRAPING. Draping is done for most rhinologic cases. A small sheet with a towel on top of it is placed under the patient's head, and the towel is secured around the hairline with a nonpenetrating towel clip. A split sheet is then placed around the head. It is good practice to place a towel over the endotracheal (ET) tube if one is in place; this helps prevent the adhesive portion of the split sheet from sticking to the ET tube and inadvertently pulling on the tube once the procedure is completed and drapes are removed. Except during certain endoscopic procedures, the patient's eyes should be covered with moist gauze or towels if the patient is awake or taped closed if the patient has received a general anesthetic, protecting the eyes from nasal drainage or injury from instruments.

ORAL CAVITY/LARYNGOLOGIC/NECK PROCEDURE DRAPING. Draping of the patient for a laryngeal procedure for a benign lesion (intraoral approach) is minimal, with the primary focus being protection of the patient's eyes and face. This may be accomplished by (1) placing ointment in the patient's eyes, (2) taping the eyelids closed with a nonabrasive, nonirritating tape, (3) applying moist padding over the tape (if use of a laser is anticipated), and (4) placing self-adhering eye pads over the moistened pads. A head drape may be placed over the patient's face to expose only the lips and chin.

Draping for neck procedures often varies according to surgeon preference and is similar to the draping procedures described for rhinologic surgery. Additional drapes may be needed if skin grafts or flaps will be used for reconstructive procedures.

Surgical Microscope. The surgical microscope is often used to provide illumination and magnification for complex procedures to the ear, laryngeal surgery, or reconstructive free flap procedures following neck surgery. Several kinds of

FIGURE 18-14 Draped microscope for otologic surgery with surgeon in correct sitting position.

surgical microscopes with different attachments are available for otologic and laryngologic surgery. The microscope may be floor- or ceiling-mounted. Optimal light is provided by a xenon or halogen light source. Numerous types of monocular and binocular heads are available for the microscope. These heads may be fixed in a straight or angled plane, or they may be designed to be adjustable in an inclinable plane. For operations through an ear speculum, the microscope provides direct light and permits the surgeon to select a magnification of ×6, ×10, ×16, ×25, or ×40. A common eyepiece magnification for an otologic microscope is ×12.5, and the usual objective (lens) is 250- or 300-mm focal length (f). A 400-mm lens is used for laryngeal surgery. The total magnification is determined by multiplying the magnification of the eyepiece times that of the microscope body times that of the objective. The type of head and objective selected is based on the surgeon's preference. Microscopes equipped with a variable distance feature allow the surgeon to adjust the focal length from 200 mm to 400 mm without changing the lens objective. Video equipment may be attached to the microscope, which allows other team members to follow the procedure and to anticipate the necessary instrumentation. Before lenses are placed into the microscope, they should be checked to ensure that they are free from lint, dust, fingerprints, and soil. The surgeon adjusts the microscope before it is draped for surgery and manipulates it during the procedure. The microscope is draped with a sterile cover for otologic surgery, but is often left undraped for laryngeal procedures. It is necessary to keep the drape material away from the light source fan of the microscope. Doing so will allow cool air to continue to circulate and will avoid overheating of the fan, which could prematurely burn out the lamp and possibly cause a fire. When micromanipulators are secured to transmit laser energy to tissue through the operating microscope, special microscope laser drapes must be used. These drapes have an opening in the plastic at the base of the micromanipulator covering the objective, allowing laser energy to pass through the opening of the drape without risk of burning the drape.

Care should be taken when removing the drapes from the microscope to avoid discarding the eyepieces with the drapes or dropping them on the floor. Eyepieces have been lost or damaged in this manner, necessitating costly repair or replacement.

When the microscope is not in use, it should be kept in a locked, upright position and stored in an area that is away from traffic, free from dust, and properly ventilated. Ideally, a set of eyepieces should be left in the scope to prevent the inside of the scope from becoming dusty. The microscope may also be covered with either a protective cover or a plastic bag.

Equipment and Instrumentation. Equipment that may be used in otorhinolaryngologic surgery includes an ESU (both monopolar and bipolar), a forced-air warming unit or other device to maintain normothermia, and headlights. Lasers assist in vaporization of scar tissue, granulomas, and cholesteatomas without damaging surrounding tissue and may be used for select otolaryngologic procedures. Lasers used in this specialty include the carbon dioxide (CO_2), potassium titanyl phosphate (KTP), erbium:yttrium-aluminum-garnet (Er:YAG), and neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers. Lasers can be secured to the operating microscope and laser energy delivered to the tissue by means of a micromanipulator. Laser energy is delivered directly to tissue by fiberoptic probes, which can be navigated around obstructing structures.

For complex reconstructive procedures in the neck, a Doppler unit (to determine the viability of blood vessels) and an electromyographic nerve monitor (to determine the location and quality of nerves) may be employed.

Specimen cups, labels, and a marking pen should be available on the sterile field because often several specimens are obtained. Institutional procedure for correct patient and specimen identification should be followed (AORN, 2009b).

The basic principles of care, handling, and sterilization of instruments are discussed in Chapter 3. The instrumentation used in otorhinolaryngologic surgery is quite specific and is discussed with each surgical intervention. Head and neck instrumentation combines general surgical instruments and procedure-specific instruments. Many otolaryngologic procedures use delicate microinstruments that should be handled individually and should not be allowed to physically contact each other (Figure 18-15). Fine tympanoplasty and stapedectomy instrumentation should be kept in special storage and sterilization trays. These trays help separate instruments, aid in quick identification, protect the instruments from damage, and facilitate handling during surgery. Instruments used in the path of the operating microscope may have an ebony glare-reducing finish. Handles of assorted knives and dissectors may be flat, hexagonal, or round for better gripping or handling during surgery (see Figure 18-15). The shaft of these instruments may be straight, angled, or bayonet-shaped.

Powered Equipment. A powered sagittal saw is used for complex neck procedures. A power drill and assorted rotating burrs are essential for middle ear surgery and some sinus procedures. Many drills are commercially available that are pneumatically or electrically driven. Pneumatic drills must have high torque (power) and more than 20,000 revolutions per minute (rpm) (speed). Some surgeons believe electrically powered drills offer equal torque but better control of the drill tip.

A selection of burrs including assorted sizes of round cutting burrs and diamond polishing burrs should be available. A diamond burr cuts slowly and grinds the bone away rather then tearing into it; it is commonly used around vital structures. Cutting burrs assist in quickly removing bone from areas not close to vital structures. The grooves or teeth of burrs must be clean of bone dust. Bone-cutting burrs tend to clog more easily than coarse-toothed burrs. A sterile wire brush may be used to keep burrs clean intraoperatively. Bone dust must be prevented from settling in areas such as those in stapedectomy, tympanoplasty, endolymphatic sac, or fenestration surgery. A sterile field continuously flooded with irrigation solution helps to lessen clogging of the burr and washes away bone dust.

Evaluation

Perioperative nursing care should be evaluated at the completion of the procedure before the patient is transported to the postanesthesia care unit (PACU) or ambulatory recovery area. If the patient has received a local anesthetic, the nurse will have had the opportunity to evaluate care on an ongoing basis, communicating with the patient throughout the procedure.

At the conclusion of the procedure, the patient should be assessed for any difficulties in breathing. Patients who have undergone nasal surgery may have packing, which can inhibit

breathing; however, the patient should be able to breathe normally through the mouth. Patients who have undergone oral cavity or laryngeal surgery are at risk of airway edema (Rapid Response Team box). The head of the PACU bed should be elevated before transport to the unit for all otorhinolaryngologic patients. Because of the proximity of the facial nerve to many structures within the anatomic field for otorhinolaryngologic procedures, the nurse must evaluate the patient's facial nerve function. This evaluation requires the patient's cooperation in smiling, closing the eye, and wrinkling the nose on the operative side. If facial palsy is observed and not resolved within 2 hours of the procedure, it may be caused by surgical trauma. Skin integrity at positional pressure sites and the ESU dispersive electrode site should be assessed and documented. The amount of drainage present on any dressings should be noted.

During evaluation, the perioperative nurse determines if the patient met the outcomes in the plan of care. Some outcomes can be reached during the preoperative and intraoperative phases of care; they are evaluated before the patient's discharge from the OR. Others require ongoing monitoring and measurement in the postoperative phase. A complete hand-off report allows the postanesthesia care unit (PACU) or intensive care unit (ICU) nurse to detect significant changes in the patient's condition at an early stage. Special considerations should also be included, such as the necessity for flexion of the neck to avoid disruption of the suture line of the trachea in a patient who has undergone tracheal resection. Repeated swallowing should be noted, because this may indicate posterior nasal or oral cavity bleeding. Part of the hand-off report to the PACU or nursing unit should include the outcomes of care provided:

- The patient identified factors that caused anxiety and verbalized effective coping; frequent explanations were provided, which assisted in coping with an unknown environment.
- The patient communicated adequate pain management using a pain scale and demonstrated effective coping with the physical and psychologic effects of pain. Vital signs remained stable; there were no electrocardiogram (ECG) or central nervous system (CNS) changes.
- The patient demonstrated effective breathing patterns. Respiratory rate and depth were within normal limits, and the respiratory pattern appeared effective with no cyanosis or other signs of hypoxia.
- Intraoperative bleeding was kept at a minimum during the case, keeping the patient safe from a dangerous amount of surgical blood loss.
- The patient verbalized understanding of anticipated postoperative alteration in the senses of hearing or smell and taste.

RAPID RESPONSE TEAM

A 57-year-old male underwent a 6-hour tympanoplasty and mastoidectomy for treatment of a recurrent cholesteatoma, facial nerve dehiscence, and perilymph fistula in his right ear. On arrival to the PACU the patient was alert and responsive and complaining of pain to his left shoulder and arm. The perioperative and PACU nurses assessed the patient and observed the patient's left arm to be swollen and slightly dusky. As part of the rapid response protocol at the facility, the PACU nurse notified the surgeon, who determined the patient had compartment syndrome related to prolonged positioning during the otologic procedure. The patient was treated and recovered without incident.

The concept of rapid response is to improve patient care by providing prompt recognition, early advanced assessment, enhanced communication with physicians, and appropriate intervention to patients with perceived changes in or deterioration of the condition. In response to The Joint Commission's National Patient Safety Goal 16.01.01, many facilities have instituted rapid response teams (RRTs). Patients who undergo otorhinolaryngologic procedures at facilities with RRTs benefit from earlier interventions in the face of possible postoperative complications such as:

- Airway compromise caused by swelling related to rhinolaryngologic/oral cavity procedures
- Hypoxia
- Facial nerve dysfunction after otologic procedures
- Hemorrhage
- Hypotension or hypertension
- Mental status changes

In most facilities, the RRT may be activated by any bedside clinical provider including, but not limited to, the nurse, nursing assistant, physical therapist, respiratory therapist, resident, or attending physician. It would be ideal to have an RRT summoned at least 6 to 8 hours before a sentinel decline in condition occurs. RRT activation alerts the multidisciplinary healthcare professionals comprising the rapid response team to begin early interventions and treatment for patients with a change or deterioration in their condition that requires further investigation.

The rapid response team includes the following members (though it may be adjusted depending on the facility's unique resources and patient care needs):

- Staff nurses
- Responding medicine RRT physician
- Responding surgery RRT physician
- Anesthesia provider
- ICU nurse
- Nurse supervisor/manager
- Respiratory therapist

The procedure for activating the RRT often involves calling a STAT in-house telephone number, prompting the operator to alert the ICU, pharmacy, lab, and radiology. The ICU nurse with the rest of the team arrives at the announced room with a crash cart. The team will determine the necessity for physical assessment, laboratory tests, radiologic tests, ECG, drugs, transfusion of IV fluids, vascular access, cardioversion, intubation, or ventilation, or the need to transfer the patient to the next level of care. At this time the team may also decide to discuss with the family end-of-life decisions if no further intervention is necessary. The attending physician of the patient must be notified within 30 minutes of the RRT.

Specific documentation is recorded pertaining to the different staff members of the team and each member of the team is responsible for his or her own identifiable roles and responsibilities.

Modified from Thomas Jefferson University Hospital, Hospital Policies and Procedures, policy number 113.55, 2009.

FIGURE 18-15 **A**, Microsurgical ear forceps including various sizes of cup forceps and alligator forceps. **B**, Forceps out of tray. **C**, Close-up of types of forceps tips. *Left to right,* Straight cup forceps, right cup forceps, large cup forceps.

- The patient verbalized feelings regarding disturbances in body image, interacted positively with perioperative staff, maintained eye contact, and identified personally effective coping strategies.
- The patient is able to communicate effectively (ongoing) and use alternative method (specify) of communication.

Patient and Family Education and Discharge Planning

Patient and family education is an important component of the age-appropriate and culturally sensitive care provided by perioperative nurses. Visual teaching aids, teaching brochures, and written discharge instructions provide the patient with knowledge of the surgery and what to expect during the postoperative period. Preoperative patient education includes preparing the patient for alterations in body image and function, if applicable to the planned procedure. Altered methods of communication must be discussed before disruption of oral or laryngeal function, or hearing. The presence of edema, drains, or dressings; changes in mobility; side effects of surgery or anesthesia; possible complications of surgery; and the pertinent signs and symptoms of these complications must be discussed. The OR environment and presence of equipment should be described to the patient preoperatively to keep anxiety at a minimum. Specific instructions based on the type of surgery performed must be reviewed with the patient, focusing on important areas, such as management of pain and discomfort, restriction of activity levels, and observation for signs of infection. Printed information should be reviewed with the patient, and the patient should repeat back the key points that are essential to a successful recovery (Canobbio, 2006). By the time of discharge, patients and family members should have a thorough knowledge and understanding of what to expect during the postoperative recuperation period. General instructions for otologic surgery are detailed in the Patient and Family Education box.

Surgical Interventions

OTOLOGIC PROCEDURES

The majority of otologic procedures are performed either through the ear canal or from behind the ear. Incisions through the ear canal include endaural and transcanal approaches. The postauricular approach is made through an incision from behind the ear.

PATIENT AND FAMILY EDUCATION

Patient Education for Otorhinolaryngologic Surgery

The following information is applicable to all otorhinolaryngologic procedures. Instructions unique to specific procedures are also included. Teaching is best accomplished using a variety of methods (e.g., conversation, printed materials, written instructions) and should include evaluation of the patient's understanding of the material, such as by having the patient or caregiver "teach back" the concepts previously discussed.

PREPROCEDURAL TEACHING—ALL PROCEDURES

- Review the physician's explanation of the procedure and its purpose; encourage the patient to ask questions and to discuss any fears or anxieties. Discuss the need for informed consent for surgery and anesthesia.
- Tell the patient that nothing-by-mouth (NPO) status must be maintained as directed by the anesthesia provider.
- Describe the OR environment and sequence of events that occur, explaining what the patient will see, feel, and hear during the perioperative experience.
- Provide information about what to expect if a local anesthetic is used (e.g., some discomfort may occur during the initial administration of a local anesthetic; if epinephrine is used with the local agent, the resulting weak, quivering feeling and increased heart rate are effects of the epinephrine and disappear after a few minutes).
- Remind the patient undergoing a local procedure that there will be pressure at some point but not pain. Encourage the patient to inform the perioperative nurse and surgeon if any discomfort is felt during the procedure. Discuss a mechanism to communicate when unable to speak. A gesture as simple as raising the hand nearest to the nurse monitoring the patient may be appropriate.
- Inform the patient that the skin will be cleansed with bactericidal soap or antiseptic solutions to remove bacteria.

OTOLOGIC/LARYNGOLOGIC PROCEDURES

- Review the use of an erasable board, paper and pencil, flash cards, or other communication board if applicable to the surgery performed.
- Encourage questions and verbalization of fears and anxieties regarding possible loss of voice or hearing.

REVIEW OF POSTPROCEDURAL CARE—ALL PROCEDURES

- Explain that the patient will be in high Fowler's position to lessen edema, improve coughing and deep breathing, and provide comfort. Advise patients to use pillows or a wedge to elevate their head by 30 degrees for the first 24 hours after discharge. Note that some patients utilize a recliner chair at home for comfort.
- Discuss the importance of frequent deep breathing and coughing.
- Explain the presence of any dressings and drainage tubes.
- Review pain management, encouraging the patient to use mild analgesics when possible.
- Remind the patient to limit the Valsalva maneuver (e.g., coughing, straining at stool) to prevent tissue damage/bleeding.
- Inform the patient that some bruising and swelling can be expected after many procedures, but it will gradually subside.
- Note that some numbness may be noted postoperatively but gradually disappears.
- Heavy lifting or strenuous activity should be avoided until directed by the surgeon.

RHINOLOGIC PROCEDURES

- Inform the patient that if a nasal pack is inserted, there may be some difficulty in swallowing. When the patient attempts to swallow, a sucking action occurs in the throat because the packing does not allow air passage through the nose, thereby creating a partial vacuum.
- Review the procedure for changing the mustache dressing (or drip pad) that is in place postoperatively to absorb any drainage. This is usually a folded 2-inch × 2-inch gauze pad placed under the nose and secured by tape. Blood-tinged secretions in the nasopharynx are normal in the first few hours after the procedure.
- Advise the patient that forceful nose blowing must be avoided for a time to prevent movement of the rearranged nasal structures. If necessary to clear nasal passages, the patient should sniff gently.
- Review the importance of humidification. As directed by the surgeon, patients may use a humidifier at home to reduce nasal dryness.
- Note that the sense of smell is diminished for a time after surgery but gradually returns.

OTOLOGIC PROCEDURES

- Avoid rapidly moving the head, bouncing, or bending over for 3 weeks.
- Exercise caution when coughing or blowing the nose; open both the nose and mouth if sneezing is unavoidable.
- Avoid drinking through a straw.

ORAL CAVITY/LARYNGOLOGIC PROCEDURES

- Rinse the mouth as directed by the surgeon; avoid contact with agents that may inflame the mouth, such as mouthwashes that contain alcohol.
- Perform oral hygiene after each meal or as often as needed.
- Use a soft toothbrush, Toothette, or gauze for oral care.
- Use and apply topical analgesics and anesthetics as ordered by the physician.
- Observe voice rest as directed by the surgeon.
- Use humidification to decrease dryness and increase comfort.

PATIENT AND FAMILY EDUCATION

Patient Education for Otorhinolaryngologic Surgery—cont'd

HOME CARE—ALL PROCEDURES

Give both the patient and the caregiver *verbal* and *written* instructions. Provide them with the name and telephone number of a physician or nurse to call if questions arise. Use visual aids to assist in instruction.

- General information
  - Review any explanation about the procedure and any specific follow-up care.
  - Review the signs and symptoms that should be reported to the surgeon or nurse:
    - Infection of the incision: redness, drainage, pain, warm to touch
    - Fever
    - Dyspnea without exertion
    - Difficulty swallowing
    - Bleeding or discharge of clear fluid from the ear or nose
    - Vertigo—lasting more than 24 to 48 hours after surgery
- Activity
  - Remind the patient to plan frequent rest periods.
  - Assist the patient to begin self-care as soon as possible.
  - Review any restricted activities, such as driving, swimming/diving, air travel.
- Follow-up care
  - Stress the importance of regular follow-up visits. Make sure the patient has the necessary names and telephone numbers to contact the surgeon.

Modified from Canobbio MM: *Mosby's handbook of patient teaching,* ed 3, St Louis, 2006, Mosby; Russek JA: Care of patients with ear and hearing problems. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, Philadelphia, 2010, Saunders; Dietzen KK: Care of patients with oral cavity problems. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, Philadelphia, 2010, Saunders.

Endaural Approach

The endaural incision is made in two steps, using a #15 blade scalpel. The first incision starts at the superior meatal wall about 1 cm in from the outer edge of the meatus and extends down the posterior meatal wall to the edge of the conchal cartilage. The second incision on the superior meatal wall extends upward to a point halfway between the meatus and upper edge of the auricle. This approach offers direct access to the external auditory meatus and tympanic membrane and may be used for meatoplasty, canalplasty, selected tympanic membrane perforations, and stapes surgery.

Transcanal Approach

The transcanal approach is used for those procedures that are limited to the mesotympanum, hypotympanum, and tympanic membrane. The incision entails a superiorly based tympanomeatal flap through the ear canal and involves making a semilunar canal skin incision anywhere from to 2 to 10 mm lateral to the tympanic membrane. For exposure, the skin, fibrous annulus, and tympanic membrane are elevated as a unit. Posterior tympanomeatal flaps may be used in stapedectomy, labyrinthectomy, myringoplasty, tumor biopsy, ossiculoplasty, and removal of glomus tympanicum tumors. Congenital cholesteatomas are best approached by superior tympanomeatal flaps, whereas perforations of the tympanic membrane may be accessed through an inferior tympanomeatal flap (Chole and Suddath, 2005).

Postauricular Approach

The postauricular incision is made 2 to 5 mm behind the ear as the surgeon follows the curve of the posterior auricular fold, providing wide-field exposure and a versatile and adaptable incision. It is commonly used for tympanoplasty procedures and it is also used to expose the mastoid process for a mastoidectomy, endolymphatic sac procedure, labyrinthectomy, or translabyrinthectomy resection of an acoustic neuroma.

Myringotomy

A standard myringotomy is an incision in the pars tensa of the tympanic membrane. Myringotomy is often accompanied by the aspiration of fluid under pressure in the tympanum, and the subsequent placement of small, hollow, pressure equalization tubes (PETs) (also known as *tympanostomy* or *myringotomy tubes*). It is indicated for acute otitis media in the presence of an exudate that has not responded to antibiotic therapy. Acute otitis media (AOM) occurs in 84% to 93% of all children. Otitis media with effusion (OME) occurs in 80% of children under the age of 10 years. The majority of children with AOM have spontaneous resolution. Hearing loss is the main concern when fluid is present in the middle ear (OME) (Thrasher, 2009). If left untreated, hearing loss can affect language development. If the fluid persists more than 8 to 12 weeks and is accompanied by hearing loss, removal of the fluid and placement of ventilating tubes in the eardrum are necessary.

Otitis media, although more common in the pediatric population, is also seen in adults. Tympanic fibrosis is common in adults and is a result of repeated infections that occurred in childhood. Acute otitis media is a collection of infected pus in the middle ear. The patient may have severe pain and bulging of the tympanic membrane (Figure 18-16). Failure to respond to oral antibiotics and analgesics or other complications, such as facial nerve paralysis, may require a myringotomy. By release of the pus or fluid, hearing is restored and the infection can be controlled. The procedure may be performed for chronic

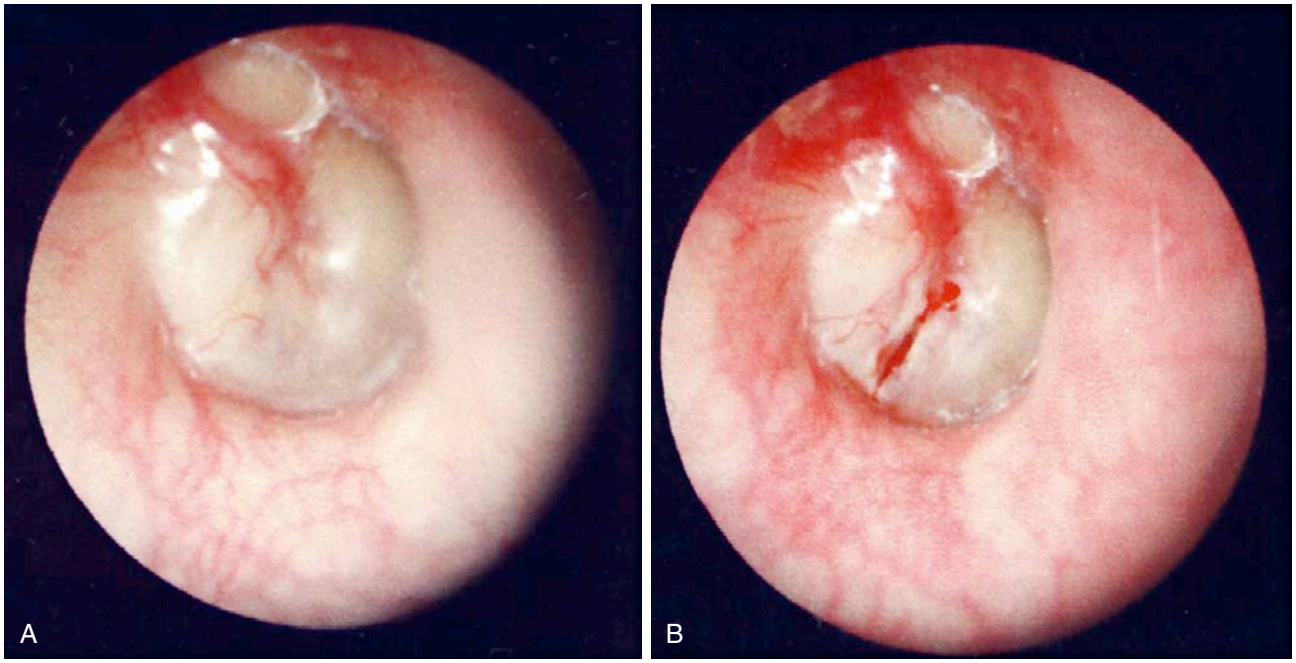

FIGURE 18-16 **A**, In purulent otitis media, pus under pressure pushes eardrum outward, resulting in bulging tympanic membrane. **B**, Radial myringotomy incision.

serous otitis media in which the presence of fluid in the middle ear produces a hearing loss. Frequently, tubes are inserted into the tympanic membrane (Figure 18-17) to allow ventilation of the middle ear. Myringotomy tubes may be used for the treatment of colds and fluid in the ear on a short-term basis (a few months), on an intermediate basis (6 to 18 months), and in long-term treatment (years) for chronic situations. Tubes may also be placed in patients undergoing hyperbaric therapy to prevent ear pain and tympanic rupture while in the hyperbaric chamber. Care must be taken to avoid getting water in the ears while the tubes are in place. Myringotomy is usually performed on an ambulatory surgery basis. A recent alternative to tube placement is CO_2 laser–assisted myringotomy, in which the laser energy is used to create a precise hole in the tympanic membrane. This remains open for 4 to 6 weeks. Laser-assisted myringotomy is done using a topical anesthetic and may be performed in the physician's office.

Procedural Considerations. Myringotomy with tube placement is considered a clean procedure. In adult patients, the procedure may be performed using a topical anesthetic. Pediatric patients generally require general anesthesia. The surgeon may wear gown and gloves or gloves only, depending on the policy related to Standard Precautions at the institution in which the procedure is performed. Myringotomy procedures require a sharp knife for making incisions into the tympanic membrane. Sterile, disposable, single-use blades are supplied with integrated handles or as single blades that may be secured into reusable handles. Myringotomy blades are spear-, lancet-, and sickle-shaped and are a matter of the surgeon's preference. The instrument setup includes a myringotomy knife and disposable blade, assorted sizes of aural specula, ear curettes, suction tip and tubing, a delicate Hartmann forceps, metal aural applicators, a curved needle, a culture tube (if cultures are to be taken), and myringotomy tubes (as applicable). Several types of disposable myringotomy tubes are available for implantation, depending on the length of time the surgeon wishes the tube to remain in place (see Figure 18-17). Once the tube falls out, the tympanic membrane incision usually heals.

Operative Procedure

1. With the head and microscope in position, the surgeon inserts the aural speculum into the ear canal. The external canal is cleaned of excess cerumen using a wire loop curette. With a sharp myringotomy knife, the surgeon makes a small, curved or radial incision in the anterior inferior quadrant of the pars tensa (see Figure 18-16).
2. A culture may be taken to determine the type of organism present. Pus and fluid are suctioned from the middle ear.
3. A tube may be inserted into the incision with alligator forceps or a tube inserter. Care should be taken to consult the manufacturer's directions for handling the tube.
4. Antibiotic drops may be instilled after positioning the tube. Ofloxacin 0.3% otic drops may be instilled to 10 drops per ear.
5. A cotton ball may be placed in the external canal at the end of the procedure.

Tympanoplasty

Tympanoplasty is the surgical repair of the tympanic membrane and the tympanum and the reconstruction of the ossicular chain. It is indicated for conductive hearing losses caused by perforation of the tympanic membrane as a result of trauma or infection; for ossicular discontinuity; for chronic or recurrent otitis media; for progressive hearing loss; and for the inability to safely bathe or participate in water activities as a result

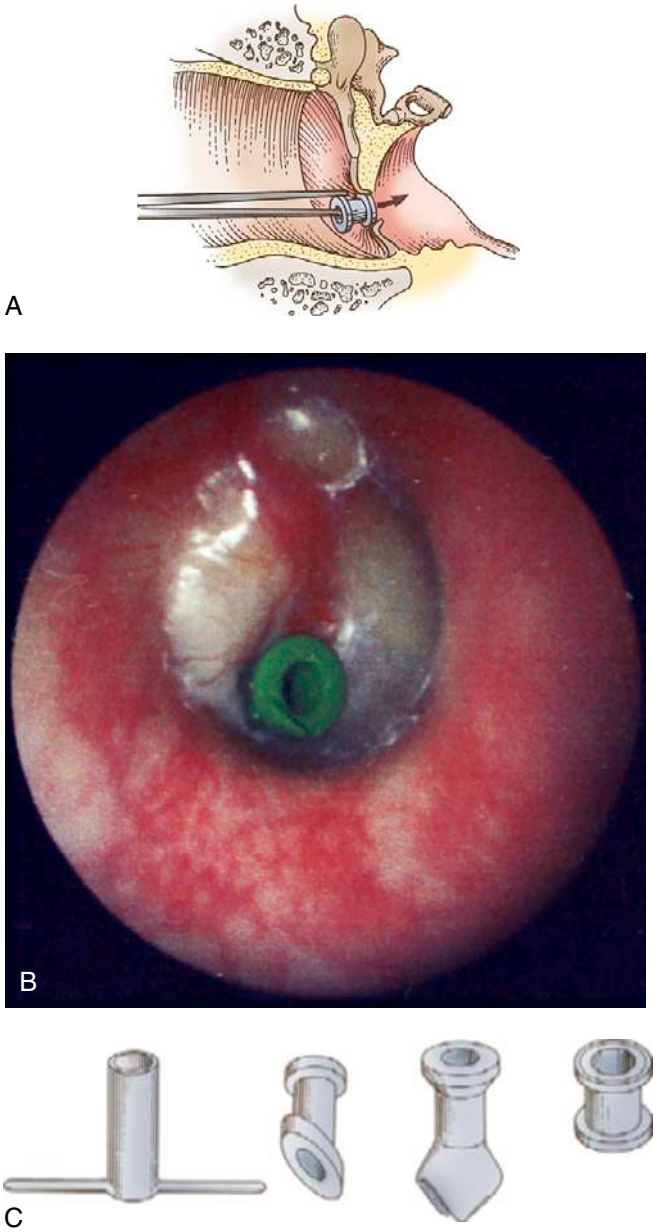

FIGURE 18-17 **A**, Tube (placed on end of alligator forceps) being inserted into tympanic membrane. **B**, Tube in place. **C**, Several types of plastic tubes that may be inserted into tympanic membrane. Purpose of tubes is to aerate middle ear and reduce middle ear infections.

of perforation of the tympanic membrane with or without hearing loss.

Perforation of the tympanic membrane is the most common ear injury necessitating surgical intervention. Perforations may result from (1) direct injury (e.g., cotton applicators, pencil), (2) blow to the ear, and (3) injury from temporal bone fractures. Early diagnosis is the key to proper management.

Conductive hearing loss is caused by an obstruction in the external canal or middle ear, which impedes the passage of sound waves to the inner ear. It may be attributable to disease of the middle ear or tympanic membrane. Occasionally the tympanic membrane does not heal after myringotomy.

Ossicular discontinuity may result from chronic otitis media, trauma, or cholesteatoma—a skin cyst that erodes bone. Various methods and materials are presently used in constructing a closed, air-contained middle ear cavity and restoring a sound-pressure transforming action. Among these materials are high-density polyethylene, silicone, hydroxyapatite, and titanium prostheses.

Procedural Considerations. The ear is prepped and draped as previously described. An endaural or postauricular approach may be used. Both approaches provide similar functional results. The procedure most often is performed after the patient has been administered a general anesthetic.

Operative Procedure

1. The following three approaches may be used when performing a tympanoplasty:
   - **a.** When an *endaural approach* is used, a Lempert speculum is introduced into the external meatus of the ear canal, and the microscope is appropriately positioned. The surgeon injects lidocaine with epinephrine postauricularly and into the external meatus and external auditory canal. The endaural incision is made as detailed previously and then the tympanomeatal incision is made using a sharp, round knife.
   - **b.** When a *postauricular approach* is used, the surgeon injects lidocaine with epinephrine postauricularly. An ear speculum is introduced, and the microscope is appropriately positioned. Additional lidocaine is injected into the external auditory canal. The microscope head is moved from directly over the patient's ear. The surgeon incises the skin behind the fold of the ear with a #15 knife blade. Bleeding vessels are coagulated. An incision is then made into the periosteum down to the bone, and the periosteum is elevated from behind the incision with a Lempert elevator.
   - **c.** During the *transcanal approach,* the surgeon injects the four quadrants of the fibrocartilaginous canal with a 1% or 2% lidocaine solution with 1:100,000 epinephrine. An endaural speculum gently compresses the tissue edema resulting from the injection and assists in the placement of a speculum within the confines of the bony canal. A 30-gauge needle is used to inject the skin of the bony canal. There are various canal incisions that can be made, all of which accomplish the same goal of lifting the posterior ear canal skin and the tympanic membrane in continuity. Once the incisions have been made, the skin is elevated to the tympanic annulus, subcutaneous tissue at the tympanomastoid suture is dissected, and bleeding is controlled before the middle ear is reached.
2. At this point, the surgeon or the assistant harvests a section of temporalis fascia for the graft material used in the repair of the tympanic membrane. Lidocaine with epinephrine may be injected under the fascia to separate it from the temporalis muscle. The surgeon uses a narrow Shambaugh elevator or duckbill elevator to separate the fascia and excises the amount needed using small, sharp scissors or a knife blade. The fascia is trimmed of excess tissue with small, sharp scissors and set aside to dry on a Teflon cutting block that is standard in most otologic instrument trays. Some surgeons prefer to thin the fascia by using a House Gelfoam press before placing the graft on the cutting block.

3. The canal skin may be elevated from the canal with a duckbill elevator, curved needle, gimmick, or similar microinstrument, or it may be removed (lateral/overlay tympanoplasty), depending on the size and location of the tympanic membrane perforation.
4. The surgeon uses a sickle knife, curved needle, 45- or 90-degree pick, or cup forceps to remove all the epithelium from the drum surrounding the perforation edges of the tympanic membrane in preparation for receiving the graft. This is referred to as "freshening the edges" and is a critical step in promoting reepithelialization of the graft.
5. If an edge of the perforation or tympanic membrane cannot be visualized because of the bony canal, the surgeon uses a microcurette or drill to remove the overhang of bone.
6. The middle ear is explored with a pick or similar instrument, and any epithelium present is removed with an alligator, or cup, forceps. The surgeon inspects each ossicle to ensure that it is intact and mobile.
7. If the malleus or incus is diseased or eroded, it may be removed and replaced with a partial ossicular replacement prosthesis (PORP). Ossicles that are removed may be reshaped with the aid of a drill and small burr and replaced. If all ossicles are diseased or eroded, they may be removed and replaced with a total ossicular replacement prosthesis (TORP). This step is accomplished with microinstrumentation, such as Bellucci scissors, cup forceps, malleus nipper, incudostapedial joint knife, sickle knife, picks, and a curved needle.
8. The surgeon prepares the graft for insertion. The edges are trimmed with a #15 knife blade or sharp scissors to fit the shape of the ear canal and the size of the perforation. The surgical site is suctioned with a microsuction device. Hemostasis may be achieved by applying very small, epinephrine-soaked Gelfoam balls with an alligator forceps.
9. Different tissues—such as temporalis fascia or loose connective tissue, tragus perichondrium, and vein grafts—have been used for a tympanoplasty procedure. The most common tissue used is temporalis fascia. Most surgeons prefer to use autograft tissue, although homograft tympanic membranes have also been used. The risk of transmission of infectious disease has reduced homograft use. For easier manipulation, the graft may be dipped in water or saline before its insertion with alligator forceps. A gimmick, sickle knife, pick, curved needle, or similar microinstrument is used to position the graft into place. Small pieces of absorbable gelatin sponge may be packed below the graft in the middle ear space to ensure support and position. The graft and tympanomeatal flap are then laid back into place and Gelfoam packing is used to secure the flap, remnant tympanic membrane, and graft in the proper position. This outer ear canal packing is left in place for 1 to 2 weeks postoperatively and removed in the surgeon's office.
10. The external ear canal is then packed with MeroGel; moistened, absorbable, gelatin sponge pledgets; or antibiotic ointment.
11. The incision is closed with suture of the surgeon's preference.
12. A pressure dressing consisting of fluffed gauze placed around the ear and an elastic gauze wrapped around the affected ear and the head may be applied for the first 24 hours to reduce swelling. Commercially prepared postauricular incision dressings are available.

FIGURE 18-18 Cholesteatoma.

Mastoidectomy

Mastoidectomy is the removal of diseased bone of the mastoid process and mastoid space. Before the introduction of antibiotic therapy, mastoidectomy was commonly performed for infection. Although occasionally still performed for eradication of infection, it is more frequently used in the treatment of cholesteatoma. Cholesteatoma is the result of accumulation of squamous epithelium and its products in the middle ear and mastoid. It occasionally forms a cystlike mass (Figure 18-18). As it expands, it is destructive to the middle ear and mastoid. As a result, the diseased bone (ossicles and mastoid bone) must be removed to prevent recurrence of the cholesteatoma.

There are three types of mastoidectomy. A *simple mastoidectomy* is removal of the diseased bone of the mastoid with preservation of the ossicles, eardrum, and canal wall. This procedure is performed to eradicate chronic infections unresponsive to antibiotics or to remove cholesteatoma. A *modified radical mastoidectomy* is removal of the diseased bone of the mastoid along with some of the ossicles and the canal wall. The eardrum and some of the ossicles remain, leaving a mechanism for the patient to hear. A canal-wall-up mastoidectomy is similar to the modified mastoidectomy without removing the posterior ear canal wall. The benefit of a canal-wall-up mastoidectomy is that the patient's ear canal will appear and function normally. Canal-wall-down mastoid cavities require maintenance with debridement of aculeate debris at least yearly.

A *radical mastoidectomy* is removal of the canal wall along with the ossicles and tympanic membrane. It is rarely performed except for unresectable disease. With either the modified radical or the radical mastoidectomy, a meatoplasty is performed to enlarge the ear canal opening. This facilitates cleaning the mastoid bowl that has been created.

Procedural Considerations. The patient is prepped and draped as for a tympanoplasty. An endaural or postauricular incision may be used (Figure 18-19), but most surgeons believe that the postauricular incision offers better exposure to all areas of the mastoid and middle ear. A drill is used to remove diseased bone and tissue. Facial nerve monitoring is used to alert the surgeon to the proximity of the nerve within the surgical field.

Operative Procedure. Steps 1 through 6 from the tympanoplasty procedure are performed.

7. The surgeon uses a drill with a large cutting burr to drill the mastoid bone under direct vision. As the mastoid cavity

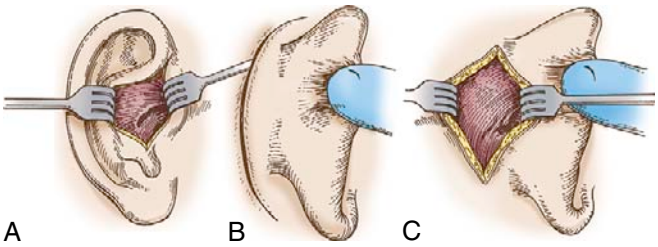

FIGURE 18-19 Mastoidectomy incision. **A**, Endaural. **B**, Postauricular. **C**, Postauricular incision retracted.

is created, the scrub person should be able to anticipate changes needed in burr size. Once the vital structures have been identified, diseased bone is removed by use of diamond burrs of the appropriate size. The surgeon may interrupt drilling to explore areas of the mastoid with a pick, curved needle or annulus elevator or with other microinstruments to identify surrounding structures.

8. On completion of the mastoidectomy, the surgeon focuses on the middle ear. Diseased ossicles are removed, middle ear mucosa is inspected and removed if necessary, and all evidence of cholesteatoma is removed. Depending on the extent of the disease and the reliability that the patient will be available for follow-up care, the surgeon then reconstructs the ossicular chain or prepares the cavity created by a radical mastoidectomy. Some surgeons do not reconstruct at the time of mastoidectomy but reconstruct as a second-stage operation, which serves the added purpose of reexploring the middle ear and mastoid for residual or recurrent cholesteatoma.
9. The mastoid cavity and middle ear may be packed with an absorbable gelatin sponge or MeroGel. The external auditory canal may be packed with MeroGel, an absorbable gelatin sponge, or antibiotic ointment.
10. The incision is closed and dressing applied in similar fashion to that used for postauricular tympanoplasty (as detailed previously).

Stapedotomy

Stapedotomy is removal of the stapes superstructure and creation of a fenestra (opening) in the fixed stapes footplate for treatment of otosclerosis and placement of a prosthesis to restore ossicular continuity and alleviate conductive hearing loss. Otosclerosis is the formation of abnormal bone around the stapes footplate, resulting in immobility of the footplate. Sound waves cannot be transmitted adequately through the oval window and round window to be changed into electrochemical impulses in the cochlea.

There are two types of procedures for replacing the immobile stapes. In *stapedotomy,* the footplate of the stapes is not removed; only the superstructure is removed. A hole is made in the stapes footplate, and the prosthesis is secured laterally to the long process of the incus and positioned medially over the hole created in the footplate. The carbon dioxide (CO_2) laser may also be used for stapedotomy—to create (drill) a hole in the footplate of the stapes for insertion of a prosthesis or to vaporize the stapedial tendon. Ideally, laser energy should be completely absorbed by the footplate and should not heat the perilymph or damage the inner ear (House and Cunningham, 2005). The laser stapedotomy offers improved postoperative hearing results while reducing postoperative dizziness and sensorineural hearing loss. An older procedure that is still used today, however not as frequently as in years past, is the *stapedectomy.* In stapedectomy, the entire stapes (superstructure and footplate) is removed, a graft is placed over the oval window, and a prosthesis is attached laterally to the long process of the incus and positioned medially on the graft over the oval window. Both of these procedures may be performed using monitored anesthesia care (MAC) or local anesthesia for adults, enabling the surgeon to test hearing before the conclusion of the surgery. Certain patient populations, such as children, patients with anxiety, and non–English-speaking patients, may find it difficult to remain immobile during the procedure, and general anesthesia is recommended in these populations to facilitate surgery and patient comfort.

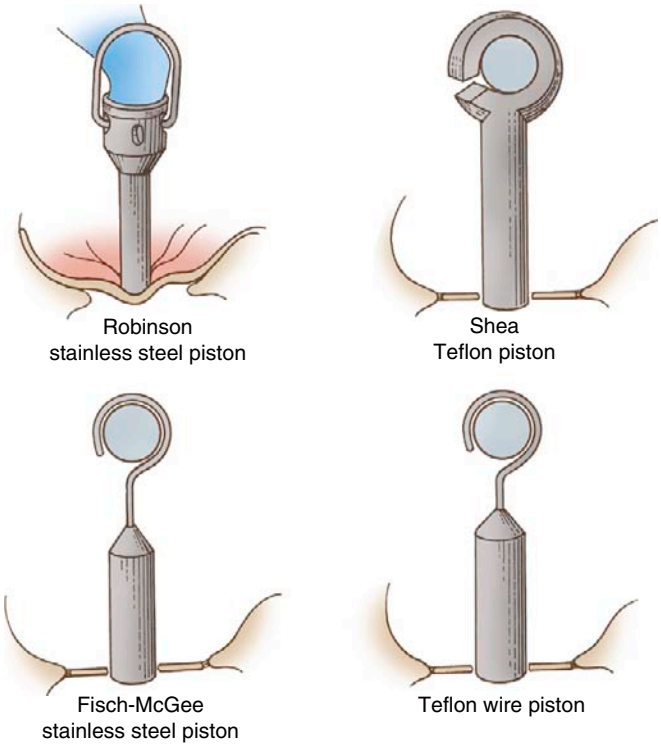

FIGURE 18-20 Stapedectomy prostheses. *Top left,* Prostheses used after the footplate has been removed. *Top right and bottom,* Footplate had been "drilled" to accept a prefabricated piston precisely.

Procedural Considerations. Various materials are used as the prosthesis for the stapes; the most common are stainless steel, titanium, platinum, nitinol, and Teflon. The most common types are either bucket-handle or piston prostheses (Figure 18-20). Both are secured to the incus and extend to the stapes footplate to reconstitute the ossicular chain. The use of stainless-steel materials may present a risk for prosthesis displacement and subsequent sensorineural hearing loss if the patient undergoes MRI studies in the future.

The prosthesis of choice is determined by the surgeon's experience and preference. The scrub person must be aware of each step in the procedure and hand the instruments to the

surgeon expediently. Because the oval window is left uncovered, some perilymph may leak from the inner ear into the middle ear. This leak subjects the patient to the possible complication of a sensorineural hearing loss postoperatively.

Microsuction tips (18- to 26-gauge) are used in this procedure because large suction tips may suction perilymph from the oval window, resulting in permanent hearing loss as well as promoting bleeding in the middle ear. After the incision and reflection of the flap, footplate hooks are used because the tips on picks are too large and long and may cause damage rather than assist in the procedure.

Operative Procedure—Stapedotomy

1. The surgeon or the assistant may harvest a temporalis fascia, fat, perichondrium, or vein graft at the start of the procedure to cover the oval window. Depending on the surgeon's graft preference, the ear, hand, or a portion of the abdomen may be prepped for the graft. Most surgeons use temporalis fascia or postauricular subcutaneous tissue as it is within the surgical field and easily accessible.
2. The ear speculum is introduced, and the microscope is appropriately positioned. The surgeon cleans any cerumen or debris from the ear canal and may gently wash the canal with physiologic irrigating solution.
3. The surgeon injects lidocaine with epinephrine into the ear canal.
4. An ear speculum is inserted, the tympanomeatal flap is created, and the tympanic membrane is reflected forward, exposing the middle ear.
5. If visualization of the ossicles is inadequate because of the overhang of bone, the surgeon may use microcurettes or a drill to remove enough bone to allow proper visualization. Attempts to save the chorda tympani nerve are made because it controls taste from the anterior two thirds of the tongue. If this nerve obstructs the view of the stapes, it may on rare occasion be divided for exposure, and at the conclusion of the procedure the neural ends are reapproximated.
6. The surgeon may measure the distance from the incus to the stapes footplate at this time or after the removal of the stapes. It is accomplished with a depth gauge and done to ensure the proper fit of the prosthesis.
7. The incudostapedial joint is disarticulated to allow fracture and subsequent removal of the stapes, usually accomplished through the use of a joint knife or right-angle hook.
8. Both crura of the stapes are treated with a laser or fractured laterally, usually with a footplate pick or curved needle, and the superstructure is removed with alligator forceps. The surgeon may take this opportunity to ensure hemostasis, using tiny sponges soaked in epinephrine and applying suction with a microsuction tip. The laser helps coagulate middle ear vessels, thus improving hemostasis.
9. An opening is created in the footplate with a laser or a sharp footplate pick. If the footplate is extremely thick, a microdrill may be used. If a stapedectomy is to be carried out, each half of the footplate is removed using a Hough hoe, footplate pick, or footplate hook.
10. The oval window is inspected to ensure that it is long enough, and then a measuring stick is used to approximate the correct size prosthesis required for reconstruction.
11. Holding the prosthesis with alligator forceps, the scrub person passes it to the surgeon. The prosthesis is introduced into the middle ear with the shaft resting against the oval window graft.
12. The wire is positioned over the long process of the incus using picks, Hough hoes, or footplate hooks. Once it is in proper position, the surgeon crimps the wire onto the long process of the incus to ensure its attachment.
13. The surgeon may test the patient's hearing by softly whispering to the patient (if the procedure is performed with the patient administered a local anesthetic) or by touching the malleus with a pick and observing for mobility of the malleus, incus, and stapes prosthesis (if performed with the patient administered a general anesthetic).
14. Tiny pieces of the previously harvested graft tissue are then placed around the base of the prosthesis to ensure its stability. Alligator forceps, picks, a gimmick, and similar instruments may be used for this step.
15. The tympanomeatal flap is returned to its original location. The external ear canal may be packed with an antibiotic gel or ointment or a moistened, compressed gelatin sponge.
16. Cotton is placed in the concha of the ear, and a Band-Aid or small dressing is usually applied to the graft site.

Ossicular Chain Reconstruction

Ossicular reconstruction may be required for long-standing recurrent ear infections. It is commonly performed for the replacement of the incus portion of the ossicular chain. There are many surgical techniques for ossicular reconstruction.

Natural and synthetic prosthetic materials are available for ossicular reconstruction or replacement. The autologous ossicle (incus or head of malleus) taken from the patient's ear is often used, particularly in children who do not have a cholesteatoma. A synthetic PORP (partial ossicular reconstruction prosthesis) or TORP is indicated for reconstitution of the ossicular chain.

Alloplastic materials for partial and total ossicular reconstruction prostheses are available. Hydroxyapatite is used in many prostheses because its mineral content is very similar to that of bone and it is well tolerated by the middle ear, thereby decreasing extrusion rates. Because it is brittle, it is often combined with other materials to allow it to be more easily trimmed for a precise fit in the middle ear. Titanium is another material being used more frequently in middle ear prostheses. Titanium is ideal for ossicular reconstruction because of its properties of being rigid and lightweight. Regardless of the type of prosthesis used, the surgeon must sculpt/trim it to bridge the ossicular gap by simulating the ossicular configuration and preserving the lever mechanism of the middle ear.

Procedural Considerations. *Minor columella* is a term that refers to an ossiculoplasty with a strut from the head of the stapes to the tympanic membrane (or graft) or manubrium. *Major columella* refers to a strut extending from the footplate to the tympanic membrane (or graft) or manubrium. The patient is prepped and draped as for stapedotomy or tympanoplasty.

Operative Procedure. The procedure steps are similar to those for stapedotomy, except that the stapes footplate is not removed or opened.

Endolymphatic Sac Decompression or Shunt

An endolymphatic shunt procedure is the creation of an opening into the endolymphatic sac and the insertion of a shunt to allow drainage of excess endolymph into the cerebrospinal fluid (CSF) or into the mastoid cavity. In Meniere's disease, the endolymphatic sac cannot resorb endolymph, resulting in an overaccumulation. This surplus leads to vertigo, in which patients feel a spinning sensation. Movement usually increases the vertigo, which may be accompanied by severe nausea and vomiting. The vertigo attacks occur unpredictably and may last from several minutes to several hours. Most patients with Meniere's disease complain of tinnitus, pressure or fullness in the affected ear, and a fluctuating hearing loss that begins in the lower frequencies. Diagnostic audiometry reveals the hearing loss to be sensorineural. The vertigo may be so severe that it disrupts the patient's lifestyle. With a medical regimen of tranquilizers, diuretics, vasodilators, and a low-sodium diet, the majority of patients are able to adequately control their symptoms. About 10% to 15% of persons eventually fail medical therapy and may seek surgical intervention (Furman, 2008).

Procedural Considerations. Preoperative assessment should confirm that the patient's electrolyte levels (especially potassium) are adequate; this provides a basis for the support system to be carried out intraoperatively and postoperatively. Because Meniere's disease may develop bilaterally in some patients, conservative therapy is often employed (Schessel et al, 2005). The patient is prepped and draped as for a mastoidectomy.

Operative Procedure. The procedure that follows describes decompression with a shunt. Some surgeons perform endolymphatic sac decompression only, without the shunt. The majority of the bone overlying the sac is removed to allow for more compliance of the sac and the membranous labyrinth.

Steps 1 through 7 of the decompression with shunt are the same as those for mastoidectomy.

8. The surgeon continues drilling with a diamond burr over the posterior fossa dura until the endolymphatic sac is identified.
9. Using a microknife, such as a sickle, Beaver blade, or Ziegler, the surgeon incises the lateral wall of the sac.
10. A shunt (commercially prepared tube, silastic tubing, or silastic sheeting) is inserted with microforceps and manipulated into place using microinstruments, such as a curved needle, fine pick, or gimmick (Figure 18-21).
11. The incision is closed and a pressure dressing applied to the affected ear.

Labyrinthectomy

Labyrinthectomy is a procedure that eliminates the vestibular and auditory function of the labyrinth to relieve severe vertigo. The procedure is usually performed when the disease is unilateral, a shunt/decompression procedure has been ineffective, and the affected ear has severe or total loss of hearing. Because the inner ear is removed, the patient may be very dizzy for several days until the brainstem begins to compensate for the destroyed labyrinth. The operation also leaves the ear with no residual hearing.

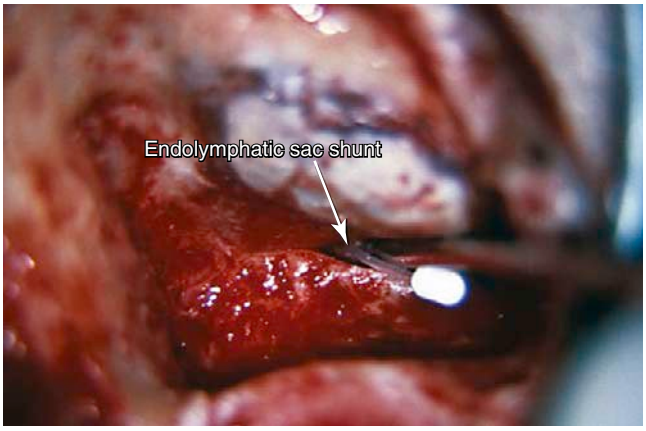

FIGURE 18-21 Endolymph silastic shunt in place.

Procedural Considerations. The procedure is most commonly performed via the transmastoid approach. The patient is prepped and draped as described for the tympanoplasty/mastoidectomy procedure.

Operative Procedure

1. The surgeon creates a postauricular incision and performs a simple mastoidectomy.
2. The vertical segment of the facial nerve is identified, and the incus is disarticulated and removed.
3. The horizontal, posterior, and superior semicircular canals are drilled and removed. The neuroepithelium is completely removed from the ampullae of the three semicircular canals. The vestibule is exposed and the neuroepithelium from the utricle and saccule is removed.
4. The incision is closed in layers. An external pressure dressing of elastic gauze is applied.

Vestibular Neurectomy

Vestibular neurectomy is the division of the vestibular portion of the eighth cranial nerve (acoustic nerve) with preservation of the cochlear portion of the eighth cranial nerve. It may be performed for a unilateral ear disorder, including classic Meniere's disease, recurrent vestibular neuronitis, traumatic labyrinthitis, or vestibular Meniere's disease. It may also be performed when attacks of vertigo severely affect a patient's lifestyle. Vestibular neurectomy is performed when a patient has adequate hearing and accepts elimination of vestibular function on the affected side.

Procedural Considerations. Vestibular neurectomy is most commonly performed through a retrosigmoid craniotomy. Refer to Chapter 20 for procedural considerations related to craniotomy.

Operative Procedure

1. The surgeon creates a 4-cm curvilinear incision 4 cm behind the postauricular sulcus.
2. A craniotomy is drilled posterior/inferior to the junction of the transverse and sigmoid sinuses.
3. The surgeon incises the dura, retracts the cerebellum, and identifies the seventh and eighth cranial nerve complex.

4. The vestibular and cochlear portions of the nerve are correctly identified and the surgeon divides the vestibular portion.
5. The dura is closed with suture and the craniotomy reconstructed with hydroxyapatite cement or titanium mesh plating.

Facial Nerve Decompression

Facial nerve decompression is a procedure designed to identify and relieve an area of compression of the facial nerve. Damage to the facial nerve may occur from trauma, infection, or tumors and may result in a facial nerve palsy, but the most common form of facial paralysis is Bell's palsy. The cause is unknown, although clinical and laboratory evidence indicates a virus of the herpes simplex group may be involved. The patient experiences multiple problems, such as decreased tearing, inability to close the affected eye, and drooping of the affected corner of the mouth with pooling of oral secretions. The facial nerve may be decompressed by a translabyrinthine approach when trauma has destroyed hearing and caused facial nerve paralysis. The narrowest segment of the bony canal compressing the facial nerve is deep in the temporal bone and may also be accessed through the middle cranial fossa approach when hearing is to be preserved. Both approaches may be useful under selected circumstances.

Transmastoid, Translabyrinthine Approach

PROCEDURAL CONSIDERATIONS. The patient is prepped and draped as described for mastoidectomy. Neurologic intensive care is required for the first 24 hours. Preoperatively, ointments protect the eye and the eyelid is taped closed, or an adhesive bubble is placed over the eye to trap moisture. This protection is continued into the postoperative period unless a tarsorrhaphy (suturing the eyelid closed) is performed intraoperatively.

OPERATIVE PROCEDURE. Steps 1 through 7 are the same as those for mastoidectomy.

8. After completing the mastoidectomy, the surgeon continues the dissection using cutting and diamond burrs until the internal auditory canal and the posterior fossa bone are removed.
9. The bone immediately over the facial nerve is removed by the use of nerve excavators and picks.
10. Using a facial nerve knife, neurectomy knife, sickle knife, neurectomy scissors, or micropick, the surgeon incises the facial nerve sheath. The majority of surgeons do not incise the epineurium of the facial nerve, and decompression only is felt to be equally efficacious and less traumatic to the nerve itself.
11. Hemostasis is achieved by the use of moistened, absorbable gelatin sponge; cottonoids; oxidized cellulose; bipolar ESU; or a combination of these.
12. The incision is closed and a pressure dressing of elastic gauze applied.

Middle Cranial Fossa Approach

PROCEDURAL CONSIDERATIONS. The patient's hair is clipped almost to the midline on the affected side. Povidone-iodine solution generally is used for the prep, which includes the portion of the head that has been clipped, the affected side of the face, and the neck. Lidocaine with or without epinephrine usually is injected subcutaneously above the ear to assist in hemostasis. The patient's eye on the affected side is protected as previously described.

OPERATIVE PROCEDURE

1. The surgeon incises the temporalis muscle and elevates it with a Lempert, Shambaugh, or similar type of elevator.
2. Hemostasis is achieved by clamping and tying vessels or by electrocoagulation.
3. The surgeon drills a square of bone from the temporal bone to expose the middle cranial fossa dura. (The bone is saved for replacement at the end of the procedure.)
4. A self-retaining retractor with a blade for retraction of the middle fossa (e.g., Fisch middle fossa retractor, House-Urban retractor) is inserted.
5. The microscope is positioned appropriately, and the surgeon elevates the dura from the floor of the middle fossa with a Freer elevator, a gimmick, or similar instruments.
6. Once hemostasis is achieved and the blade is inserted over the dura to expose the middle fossa, drilling may proceed.
7. When the bone becomes quite thin, the surgeon may remove the remaining bone with excavators to avoid damaging the nerve sheath.
8. The facial nerve sheath can be incised with a facial nerve knife, neurectomy knife, neurectomy scissors, or microknife.
9. The retractor is removed when hemostasis is achieved, and the bone flap is replaced.
10. The temporalis muscle is approximated and sutured, the incision closed, and a pressure dressing applied.

Removal of Acoustic Neuroma (Vestibular Schwannoma)

Acoustic neuromas arise from the Schwann cells of the vestibular portion of the eighth cranial (acoustic) nerve and are therefore more appropriately termed *vestibular schwannomas*. These tumors are benign but may grow to a size that produces symptoms of cerebellar and brainstem origin. Bilateral vestibular schwannomas are a common finding in patients with neurofibromatosis type 2 (NF2) (Gantz and Meyer, 2005).

Most patients experience unilateral tinnitus and hearing loss—the main symptoms of a possible acoustic neuroma. However, depending on the rate and direction of tumor growth, signs and symptoms may include hearing loss, tinnitus, vertigo, headaches, double vision, diplopia, decreased corneal reflex, decreased blink reflex, impaired taste, reduced lacrimation, facial paralysis, diminished gag reflex, vocal cord paralysis, atrophy or fasciculation of the tongue, weakness of the sternocleidomastoid and trapezius muscles, disturbance in balance and gait, hydrocephalus, lethargy, confusion, drowsiness, and coma.

Several surgery centers have developed great expertise in acoustic neuroma surgery, which requires the combined team of a neurologist and a neurosurgeon.

Procedural Considerations. The translabyrinthine approach for the removal of an acoustic tumor reduces mortality and morbidity and offers a good chance of saving the facial nerve if the tumor has not directly invaded it. The patient should be informed about the presence of a Foley catheter, arterial line, temperature probe, clipped hair, and graft-site incision.

The patient's hair is clipped to the midline of the affected side. Some patients prefer to have the entire head clipped to facilitate wearing a wig. This option should be presented preoperatively to enable the patient to make a decision before surgery. The patient is prepped and draped as described for labyrinthectomy. Lidocaine with or without epinephrine may be injected subcutaneously behind the ear. A facial nerve monitor is routinely used in the excision of cerebellopontine angle tumors. A sequential compression device (SCD) is used intraoperatively and for the first 24 to 48 hours postoperatively or until the patient is ambulatory to decrease the risk of deep vein thrombosis (DVT) and pulmonary embolism (PE).

Operative Procedure

1. The surgeon makes a postauricular incision slightly longer and more posterior than the incision for mastoidectomy and elevates the periosteum from the mastoid bone with a Lempert, Shambaugh, or similar type of elevator.
2. Self-retaining retractors are inserted, and the cortical mastoidectomy is begun with a large cutting burr.
3. The microscope is positioned, and the attic is opened to visualize the ossicles. The sigmoid sinus, middle fossa dura, and superior petrosal sinus are left in place with a thin covering of bone. The semicircular canals are exposed. The incus is removed with alligator forceps or cup forceps and suction.
4. The surgeon excises the semicircular canals with the drill. The utricle and saccule are removed, and the aqueduct of the vestibule is drilled out to expose the internal auditory canal 270 degrees circumferentially.
5. Using nerve excavators, Fisch dissectors, or picks, the surgeon removes the remainder of bone from the dura of the internal meatus, posterior fossa, middle fossa, and petrosal angle. The wedge of bone between the facial and superior vestibular nerves (Bill's bar) is removed.
6. The dura is opened with microscissors or a dura knife. The surgeon dissects the tumor with a gimmick, Freer microelevator, microinstrument, and bipolar forceps (with or without suction). Hemostasis is achieved with a moistened, absorbable gelatin sponge; cottonoids; oxidized cellulose; or the bipolar ESU.
7. The tumor is removed by the use of pituitary cup forceps, long alligator forceps, and similar instruments.
8. Graft material (e.g., fat, fascia, or muscle) is obtained to pack the mastoid cavity created from the drilling. The packing is performed meticulously to avoid a cerebrospinal fluid leak.
9. The wound is closed and a thick pressure dressing applied.

Assistive Hearing Devices

A variety of assistive devices are available to patients with hearing loss, including phone amplifiers, closed captioning broadcasts, Telecommunication Device for the Deaf (TDD), and electronic devices, such as hearing aids. Technology has evolved tremendously in the field of otology, enabling surgeons to use surgically implantable devices in the treatment of hearing loss. These devices have greatly benefited the recipients, allowing some to distinguish sounds for the first time. Research continues in this field to develop applications for conditions previously considered untreatable and to refine and improve existing technology.

Cochlear Implantation. Technologic advances have given the deaf patient new hope in the area of cochlear implantation (Research Highlight). The device is implanted in the cochlea, with the receiver resting in the mastoid (Figure 18-22). As the device receives sound through the receiver, it emits electrical impulses through the transmitter into the cochlea and along the acoustic nerve. These impulses are interpreted as sound in the auditory area of the brain, which is in the temporal/parietal area of the cerebral cortex. The patient must be taught to interpret these sounds, which requires extensive training. Adult candidates for cochlear implantation generally possess the following characteristics: (1) severe or profound hearing loss with pure-tone average of 70-dB hearing loss, (2) use of appropriately fitting hearing aids or a trial with amplification, (3) aided scores on open-set sentence tests of less than 50%, (4) no evidence of central auditory lesions or lack of an auditory nerve, and (5) no evidence of contraindications for surgery in general (Wackym et al, 2005). Pediatric candidates (1) are 12 months through 17 years of age, (2) have profound sensorineural hearing loss, (3) experience minimal benefit from hearing aids,

RESEARCH HIGHLIGHT

Evaluating Language Outcomes in Children After Cochlear Implantation

The impact of hearing loss on the pediatric population is significant. Of every 1000 children in the United States, 1 is born with profound hearing loss. Before the availability of cochlear implants, children with hearing loss were treated with hearing aids. While hearing aids do provide sound amplification, children who use them often display delays in written and spoken communication. Language and cognitive development are closely related and language is a known predictor of academic success in children.

Cochlear implants provide an improved auditory experience for children with hearing loss, and the positive impact on speech perception and development is well documented in the literature. This study sought (1) to assess receptive language scores in children after cochlear implantation and compare them with scores from normal hearing children and children with hearing loss that use hearing aids, and (2) to determine how demographic factors, such as age of implantation, impact language outcomes. Researchers hoped to identify factors that impact language skills and gain a better understanding of language development in pediatric patients after cochlear implantation.

A group of 56 pediatric patients aged 6 months to 12 years were evaluated. Participants were educated in the oral communication mode after implantation and were administered language tests at intervals varying from 6 months to 5 years after implantation. Analysis of the data showed that more than 50% of children with cochlear implants had receptive language scores that were within the average range for normal hearing children, and scores that exceeded language skills of children who used conventional hearing aids.

This research serves to validate existing knowledge about the impact of cochlear implantation on pediatric language skills.

Modified from Baldassari CM et al: Receptive language outcomes in children after cochlear implantation, *Otolaryngol Head Neck Surg* 140: 114-119, 2009.

(4) have no evidence of central auditory lesions or lack of an auditory nerve, and (5) have no evidence of contraindications to surgery (Wackym et al, 2005). Appropriate auditory training and psychologic counseling are needed after appropriate selection of candidates.

OPERATIVE PROCEDURE

1. A *modified postauricular incision is used*. The posterior flap, including the temporalis muscle, is elevated, exposing the underlying bone. The site of the internal receiver is identified, and with a special drill a circular depression in the squamous portion of the temporal bone is made to house the receiver.
2. A mastoidectomy is performed with preservation of the bony ear canal and opening of the facial recess.
3. The surgeon secures the internal receiver in the depressed area in the temporal bone, and introduces the intracochlear electrode through the facial recess via a cochleostomy into the cochlea. It is secured in place with a piece of temporalis fascia.
4. The wound is closed. The patient is observed for 2 to 4 weeks until the wound is completely healed. Then the external signal processor is fitted and programmed. This allows transmission of an electrical signal, picked up at an ear-level microphone and processed in a microprocessor worn on the body.

Implantable Hearing Aids. Conventional hearing aids transmit sound using air conduction and bone conduction. Traditional bone-conduction hearing aids are external and secured to the head with a spring device. Their design makes them uncomfortable and obtrusive, causing headaches and skin abrasions. The quality of sound is inferior, and they often require a higher battery consumption. Air-conduction devices use an ear mold that fits into the ear canal. These devices may be contraindicated for patients with physical abnormalities that prevent the insertion of the ear mold into the canal and for those who have chronic eczema, ear drainage, or inflammation in the ear canal. Implantable hearing devices are designed for patients with moderate to severe conductive and sensorineural hearing loss (unilateral or bilateral). Ideally, implantable hearing devices should improve sound quality, provide comfort, improve appearance, and reduce the risk of chronic ear infections. Surgical implantation of hearing devices may be performed on an ambulatory basis using local or general anesthetics. The device is usually implanted in the ear with the best cochlear function.

BONE-ANCHORED HEARING AIDS. Conventional bone-conduction hearing aids transmit sound vibrations transcutaneously to the skull, bypassing a diseased or impaired external or middle ear and going directly to the cochlea. Disadvantages to using traditional bone-conduction hearing aids include discomfort, poor sound quality, poor aesthetics, and shifting of the transducer, which affects speech recognition (Palmer and Ortmann, 2005).

The bone-anchored hearing aid (BAHA, by Cochlear Corp., NSW, Australia) eliminates many of the disadvantages associated with traditional external bone-conduction hearing aids. It is designed for patients 5 years of age and older with moderate to severe conductive hearing loss (unilateral or bilateral) caused by congenital malformations but who maintain good cochlear function (down to 45-dB hearing loss) and for patients with otitis media, cholesteatoma, otosclerosis, microtia, and canal atresia who are unable to benefit from conventional amplification. More recently it has been approved and increasingly used in patients with single-sided deafness, most commonly from sudden profound hearing loss or after surgical excision of an acoustic neuroma. The BAHA system consists of a conventional microphone and amplifier, a specially designed transducer, and a coupling device to attach the device to the skin-penetrating and bone-anchored implant (Figure 18-23). The area behind the ear is prepped and draped, and the implant site is marked. It is important to ensure that the hearing aid does not touch the pinna, which may cause acoustic feedback. A semicircular incision is made around the proposed fixture site.

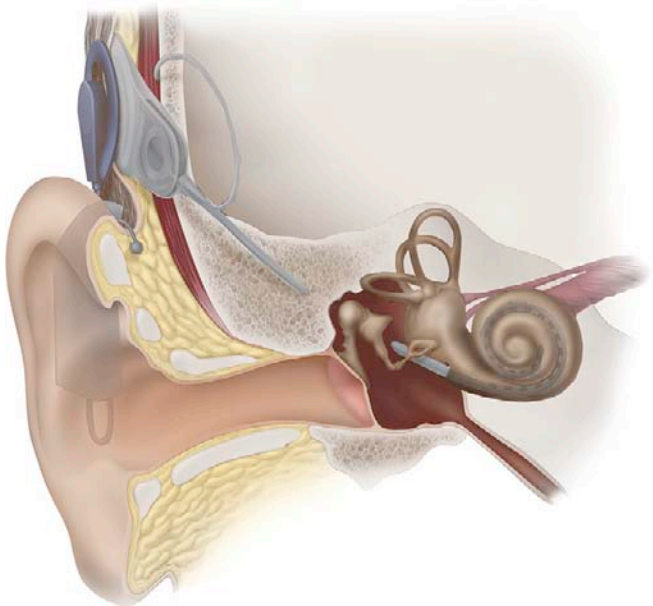

FIGURE 18-22 Cochlear implant system. Sound is transformed into electrical signal in speech processor. Signal is transmitted from external to internal induction coil, which is connected to electrode implanted near cochlear nerve.

FIGURE 18-23 Bone-anchored hearing aid (BAHA) components. *Top to bottom,* External processor, abutment, fixture.

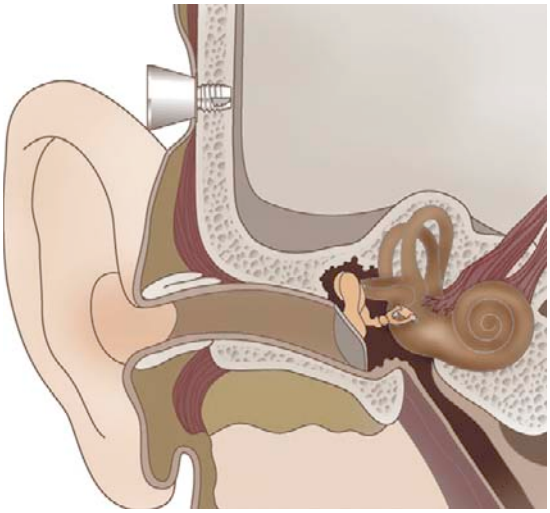

FIGURE 18-24 Cross section showing fixture and abutment.

FIGURE 18-25 Bone-anchored hearing aid (BAHA) abutment.

A titanium fixture is permanently implanted (tapped) into the mastoid bone, and a permanent skin penetration is made with a titanium snap coupler (Figures 18-24 and 18-25). A sound processor is fitted and adjusted to the patient's hearing loss 8 to 12 weeks after the implantation, depending on the age of the patient and ensuring the osseointegration process has taken place (Santina and Lustig, 2005) (Figure 18-26). When the BAHA is placed in young children, the sound processor is fitted in 3 to 6 months to ensure adequate osseointegration.

SEMI-IMPLANTABLE HEARING AIDS. Semi-implantable hearing aids are used in the middle ear and provide sound through direct stimulation of the ossicles; they allow for comfort because the external ear canal remains open. They consist of a microphone speech processor connected to a transmitter with an external coil that transmits electrical energy transcutaneously to an internal device. The internal device consists of an internal receiving coil connected to a receiver, which provides electrical energy to a mechanical driver connected to the ossicular chain. The driver vibrates the ossicles, mimicking the normal vibrations that occur as a result of acoustic sound input (Santina and Lustig, 2005). The internal receiver is implanted in the temporal bone, and the driver is attached to the incus. The external processor is fitted approximately 3 to 6 weeks after the surgery.

Research is ongoing in the development of semi-implantable and fully implantable hearing devices, which are currently considered experimental.

FIGURE 18-26 Patient with implanted bone-anchored hearing aid. The implant is positioned to avoid contact with the pinna, which could cause acoustic feedback if the device is driven at maximum output.

RHINOLOGIC (NASAL) PROCEDURES

Rhinologic surgery is performed to correct structural issues of the nose and to treat sinusitis and other conditions; it is also used an as adjunctive procedure to treat other disorders (e.g., pituitary neoplasms). Procedures that involve both internal and external nasal reconstruction can be done with local anesthetics, usually supplemented with IV sedation and analgesia. If the patient is particularly apprehensive or anxious, a general anesthetic may be more appropriate.

Nasoseptoplasty or Submucous Resection of the Septum (SMR)

A nasoseptoplasty is straightening of either the cartilaginous or the osseous portions of the septum that lie between the flaps of the mucous membrane and the perichondrium. When the nasal septum is deformed, fractured, or injured, normal respiratory and nasal function may be impaired, interfering with airflow and sinus drainage. Deviations of the septum involving cartilage, bony parts (spurs), or both may block the meatus and compress the middle turbinate on that side, thereby resulting in an obstruction of the sinus opening. Septal deviations tend to produce sinus disease and nasal polyps.

The objective of the procedure is to establish an adequate partition between the left and right nasal cavities, thereby

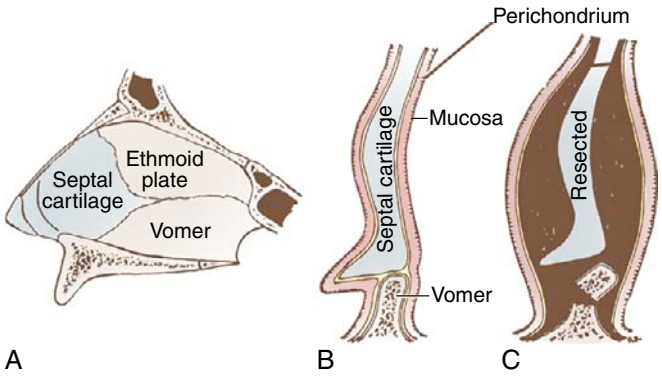

FIGURE 18-27 **A**, Primary components of septum. Incision line is for Killian type of submucous resection. **B**, Septum with deviated cartilage and spur at junction of vomer and septal cartilage. **C**, Resection of obstructive parts after careful elevation of mucoperichondrium and mucoperiosteum.

providing a clear airway through both the internal and external cavities of the nose.

Procedural Considerations. The procedure may be performed using local anesthesia, MAC, or general anesthesia. Regardless of the method chosen, the surgeon will use topical and injected anesthetics to aid in hemostasis. In most cases, the surgeon will opt to wear a headlight to improve visualization of the intranasal structures.

Operative Procedure

1. The surgeon opens the nostril with a nasal speculum and incises through the mucoperichondrium of the septum with a #15 blade. Using a Freer elevator, the tissues are separated and elevated (Figure 18-27).
2. The cartilage is incised with a knife, and the mucous membrane is elevated with a septal elevator.
3. Deviated cartilage and bony, thickened structures are trimmed or removed with a septum punch and a nasal cutting forceps.
4. The surgeon trims the bony septal spurs with a punch forceps or chisel, gouge, and mallet. Suction is used to expose the field. Bleeding is controlled by insertion of additional cottonoids soaked with a topical hemostatic agent or by using the ESU.
5. The perpendicular plate of the ethmoid as well as the vomer may be removed by means of a suitable septum-cutting forceps.
6. The incision is sutured with 4-0 absorbable atraumatic suture on a small, straight needle.
7. Nasal splints made of plastic or Silastic may be inserted to prevent adhesions and maintain the septum. Some surgeons use mattress sutures to provide a patent airway while maintaining support for the septum.
8. A mustache dressing (i.e., a piece of 2-inch × 2-inch gauze folded and placed below the nose and secured with tape across the face or bridge of the nose) is applied. A small ice bag (e.g., a surgical glove filled with ice) may be applied to the nose.

Closed Reduction of Nasal Fracture

The nose is the structure most susceptible to trauma because it is seated midface. The paired nasal bones are thin and project like a tent on the frontal process of the maxilla. If the trauma

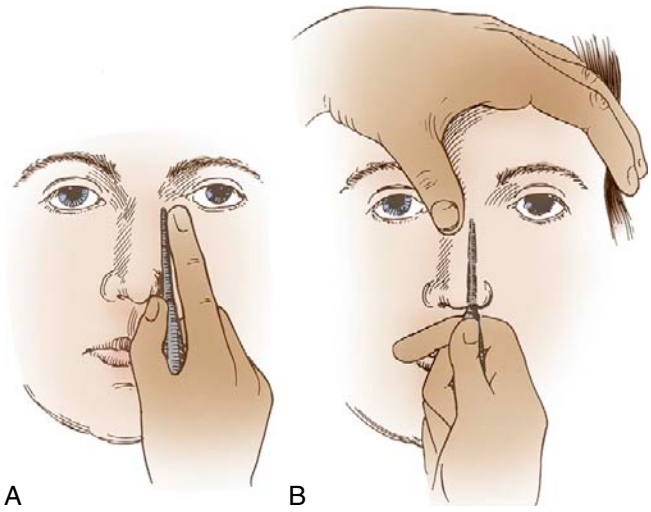

FIGURE 18-28 Reduction of nasal fracture. **A**, Boies elevator is placed along lateral wall of nose to point below nasofrontal angle. Distance to ala is marked with thumb. **B**, Elevator is then placed under depressed nasal bone, lifting it into position; opposite thumb carefully exerts downward pressure on elevated contralateral bone.

is caused by a direct frontal blow, usually both nasal bones are fractured, displaced outward, and depressed into the ethmoid sinus, and the septal cartilages become displaced. Noncontrast CT scans of the sinuses may be performed with protocols compatible with endoscopic navigation systems to have an accurate sense of extension of deviation or possible injury to surrounding sinuses and structures.

Procedural Considerations. Simple nasal fractures often can be managed with topical and local anesthesia. However, as with most nasal procedures, if the patient is significantly anxious, general anesthesia may be necessary. Topical and local anesthetics are used with a general anesthetic to provide vasoconstriction and enhance visualization for the procedure. The patient is prepped and positioned for nasal surgery.

Operative Procedure

1. The nose is packed with nasal cottonoids saturated with 4% cocaine. The local anesthetic is injected as previously described. When epinephrine is used, 10 minutes is the optimum time to wait for the effects of the hemostatic agent. This period of time will vary with other agents.
2. A Boies elevator is inserted into the nostril, and the nasal bones are elevated and molded into place by external manipulation (Figure 18-28).
3. Nasal packing or a Denver splint may be used to stabilize the reduction because sometimes the bony fragments tend to return to a depressed status.

Treatment of Epistaxis

The treatment of patients with epistaxis dates back more than two centuries (History box). Patients with nasal bleeding usually control the problem themselves with direct pressure application. When their efforts fail, they seek help from their physician or an emergency department. When more conservative measures (which involve vasoconstrictive agents and

HISTORY

History of Epistaxis Control

It is well accepted that today's current management of epistaxis is based on sound principles. In the past epistaxis led to many folklore beliefs, such as "its occurrence indicates that you are in love" and "one drop of blood from the nose commonly foretells death or a very severe illness." Preventive measures included a morning drink of whey taken with raisins and wearing a skein of scarlet silk thread with nine knots down the front. Other thoughts about epistaxis and possible remedies advocated through the ages included those suggested by the following individuals:

- Lupton in 1601 advocated the use of the patient's own blood to write the words "consummatum est" on the forehead.
- Moncrief in 1716 fried the patient's own blood and applied it as snuff.
- Hippocrates was one of the earliest physicians to appreciate that pressure on the alae nasi was an effective way of controlling nosebleeds.
- Ali Ibn Rabban Al-Tabiri (AD 850) wrote that the complaint of epistaxis was "due to the swelling of a vein and its rupture, or perhaps a reduction in the force which confines the blood within."
- Giovanni Battista Morgagni observed the extremely turgid blood vessels located about a finger's breadth from the bottom of the nostril.
- Carl Michel (1871), James Lawrence Little (1879), and Wilhelm Kiesselbach identified the plexus of veins situated on the anterior part of the cartilaginous septum as a source of epistaxis.
- Pilz (1868) tied the common carotid artery for the treatment of epistaxis.
- Alfred Seiffert (1928) first introduced ligation of the internal maxillary artery via a transantral approach.
- Henry Goodyear (1937) was the first to tie the anterior ethmoid artery for epistaxis.

Modified from Cordes S, Quinn FB: *Grand rounds on epistaxis,* October 16, 1996, University of Texas Medical Branch, available at www.otohns.net/default.asp?id=14086. Accessed May 8, 2009.

nasal packing) taken in the emergency department fail, surgical intervention becomes necessary.

When epistaxis occurs, it is an important first step to spray oxymetazoline nasal spray in both nares and apply direct pressure to the nose. An initial hold of 15 minutes is recommended. Thereafter, inspection of the anterior nose and posterior oral pharynx should be performed to determine if the site of bleeding is anteriorly based in the nose or posteriorly located deep in the nasal cavity. Evidence of a posterior bleed is usually demonstrated by a trickling flow of blood from the nasopharynx running down along the posterior pharyngeal wall during an oral inspection. Blood may also appear on the tongue and the patient may complain of swallowing blood. Anterior epistaxis characteristically trickles down the front of the face upon the upper lip. If oxymetazoline spray and direct pressure fail to arrest the bleed, packing with nasal tampons or posterior packs should be considered.

The length of the pack should be based upon the suspicion of where the bleed originates. Longer packing (8- or 10-cm packing) is considered when bleeds are more posterior in the nasopharynx. More anterior bleeds can be packed with 4.5-cm packing. Packing should be generously coated with antibiotic ointment and inserted in a horizontal angle following the floor of the nose. The packing is then sprayed with saline or oxymetazoline spray and expands. The patient should receive broad-spectrum antibiotics, such as oral third-generation cephalosporins, and instructed to follow up in 3 to 5 days for removal of packing.

Posterior nasal packing has an exterior balloon along the tube length as well as an anchoring balloon on the end (Figure 18-29). The anchoring balloon is first inflated to keep the tubes in place, and then the pressure balloons are inflated to compress bleeding vessels. If packing is used, it is placed directly against the bleeding site. Posterior nasal packing is placed by inserting a catheter-based tube, usually surrounded with packing, through the nostril. The tube is expanded with saline or oxymetazoline spray and 3 to 5 ml of air is pushed into the port, inflating a distal balloon. The proximal end of the catheter is pulled through the oral cavity with a Kelly clamp (while the distal end remains extending from the nostril).

If this fails to stop the oozing and other hemostatic agents, such as gelatin-based packing, silver nitrate sticks, or oxidized cellulose, fail to halt the bleed, an endoscopic approach to control the epistaxis is warranted. The endoscopy is performed in the OR with the use of general anesthesia or conscious sedation. Occasionally, ligation or embolization of the ethmoid, carotid, or maxillary artery is necessary and should be considered for persistent bleeds.

The setup for endoscopic control of epistaxis is the same as that for all nasal case prepping and draping. Once the navigation mask is applied to the patient and the video monitor is calibrated and functional, attention should be focused on Kiesselbach's plexus in the anterior nasal cavity and on the sphenopalatine artery as these are common sites of persistent bleeds. Suction electrosurgery should be used to electrocoagulate any visual bleeding and to clear the nasal passages of any clot or oozing. Other surgical options include transmaxillary internal maxillary artery ligation, transoral internal maxillary artery ligation, anterior/posterior ethmoid ligation, external carotid ligation, transnasal endoscopic sphenopalatine artery ligation, and submucosal supraperichondrial septoplasty.

Sinus Surgery

Sinusitis can be either recurrent, acute, or chronic. It is caused by bacteria and/or fungi and may be associated with anatomic abnormalities of the nose, such as a deviated septum or poor drainage pathways from the sinuses. Medical management of acute bacterial sinusitis involves a course of appropriate antibiotic therapy for 10 days to 2 weeks. If a patient does not respond to medical treatment for acute bacterial sinusitis or if sinus complaints persist, surgical drainage of the sinuses is indicated. Sinus procedures can be performed intranasally with or without the aid of endoscopes and video or through an open approach determined by which sinus cavity is involved. Generally, surgical treatment involves endoscopy to create a nasal window in acute maxillary sinusitis; a Caldwell-Luc procedure for chronic maxillary sinusitis; ethmoidectomy for ethmoid or sphenoidal sinusitis; and creation of an osteoplastic flap to drain the frontal sinus. Acute fungal sinusitis is treated by serial endoscopic debridements followed by a prolonged course of antifungals.

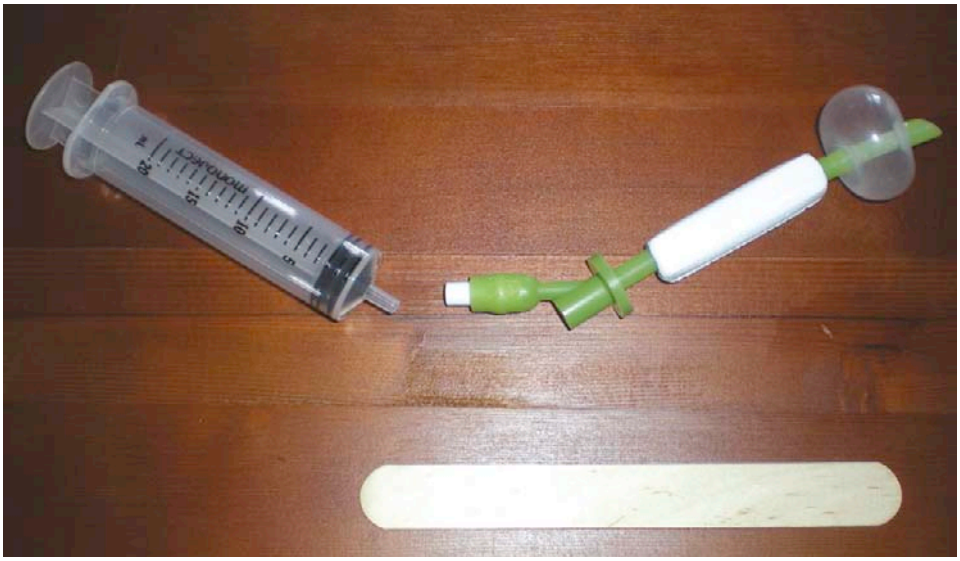

FIGURE 18-29 Posterior nasal packing with syringe for balloon inflation.

Functional Endoscopic Sinus Surgery (FESS). The field of FESS provides a more physiologic type of drainage by reducing trauma to normal tissues. Using direct endoscopic visualization, the surgeons' experience has expanded as technology and instrumentation have improved. Procedures performed endoscopically decrease trauma to normal structures and reduce morbidity. Fewer traumas mean a shortened healing process for the patient (Research Highlight). Many procedures that were once done with an open approach are now performed endoscopically and are considered safer because they are performed under direct visualization by means of an endoscope. Dedicated endoscopic sinus and skull base suites present a popular option for FESS because of the ease of setup and the comfort of multiple monitors, improving exposure (Figure 18-30).

FESS involves the endoscopic resection of inflammatory and anatomic defects of the sinuses. Because of the anatomic relationship to multiple systems, this procedure has many risks, which should be incorporated into the informed consent process. It is considered to be a technically demanding surgery, and techniques vary significantly. Most surgeons now prefer the endoscope to be attached to a video monitor, but some prefer to look directly through the eyepiece. The operative instruments are introduced into the nose alongside the endoscope.

The purpose of FESS is to ensure adequate ventilation and restore mucociliary clearance in the sinuses. If there is contact between the mucosa and the sinus, mucociliary clearance is inhibited and secretions are retained in the sinus. This predisposes the patient to sinus infections and mucocele.

The following sections are discussed with the understanding that they are more commonly performed endoscopically but may be done with an open approach as necessary.

PROCEDURAL CONSIDERATIONS. FESS can be performed after induction of general anesthesia or MAC, depending on the surgeon's and patient's preference. The setup for FESS is the same as the setup for any nasal surgery in terms of prepping, draping, and positioning. The instruments required are the basic nasal set, video equipment including monitor, and light source with the appropriate light cord adapted to the type of endoscope used. The endoscopes used in sinus surgery are much like endoscopes used in other procedures. They are 4 to 5 mm in diameter and have different directions of view: 0, 30, 70, 90, or 120 degrees. Depending on which sinus will be the operative site, the appropriate lens will be requested. Often if

RESEARCH HIGHLIGHT

Endoscopic Sinus Surgery and Symptom Relief

Functional endoscopic sinus surgery (FESS) is an established treatment for a variety of sinus disorders. FESS offers the advantage of targeting and removing small areas of disease in very specific regions, thereby opening the sinuses for better aeration. Multiple studies have demonstrated the efficacy of FESS in reducing symptoms related to sinus disease, but no reports (including a large-scale evaluation of specific symptom response) existed before the meta-analysis conducted by researchers from Georgetown University and St. Louis University School of Medicine.

Researchers evaluated 21 relevant studies involving a total of 2070 patients with chronic rhinosinusitis who were followed for a mean of 13.9 months after surgery. The study dates evaluated ranged from 1980 through 2008. Inclusion criteria included studies with 20 or more adult participants, studies published in the English language, and studies in which the participants had three or more symptoms as defined by the American Academy of Otolaryngology–Head and Neck Surgery Rhinosinusitis Task Force. Individual meta-analyses were conducted for each symptom reported to compare preoperative and postoperative scores of symptom severity.

Results of the study demonstrated that nasal obstruction, facial pain, headache, smell, and postnasal discharge improved by approximately 59%, 61%, 53%, 49%, and 47%, respectively, providing a large body of evidence that symptom improvement is noted generally after FESS.

Modified from Chester AC et al: Symptom-specific outcomes of endoscopic sinus surgery: a systematic review, *Otolaryngol Head Neck Surg* 140:633-639, 2009.

FIGURE 18-30 Endoscopic suites demonstrating navigation systems and monitors.

work is to be done in several sinus cavities, the surgeon may change lenses intraoperatively to obtain the optimal view in each cavity.

In addition to endoscopes, other instruments that may be used in FESS include endoscopic suction tips and suction elevators, biopsy forceps, forceps for retracting and cutting/excising tissue, and scissors. Patients undergo preoperative CT studies to determine the specific areas affected by the sinusitis. These CT scans should be available in the OR and will be referenced by the surgeon during the surgery (Figure 18-31).

The video equipment is located at the head of the bed. The surgeon operates from the right side of the patient, the scrub person stands at the right of the surgeon, and the first assistant usually stands across from the surgeon on the opposite side of the table. More commonly, the surgeon, the first assistant, and the scrub person stand during the procedure. With the use of a navigational system, the surgical procedure can also be viewed on a computer monitor by the rest of the surgical team.

Navigational systems are especially useful in revision sinus surgery, in which the familiar anatomy of the sinuses has been altered by previous surgery and the typical landmarks of the sinuses are now changed. Unfortunately, because of the nature of sinus disease itself in terms of allergic tendencies and mucous membrane irritation that are often chronic conditions, sinus disease can recur. Some patients may decide that their symptoms have recurred to the troublesome point where they elect to undergo surgery more than once. From a safety standpoint and to reduce the risk of a revision surgery, many surgeons will not attempt a revision sinus procedure without having an image-guided system available.

FIGURE 18-31 Computed tomography (CT) scan of maxillary and ethmoid sinuses. Note septal deviation, maxillary sinus ostia, turbinates, and ocular muscles.

Several navigational systems are available, and many of these systems have applications for different types of surgeries, so the initial expense of the machine itself can be defrayed if it is shared with different surgical specialties, such as neurosurgery. Also, technical components to facilitating this type of sinus

surgery must be mastered by the perioperative nursing staff, who must develop competence in system setup, transfer of the CT scan data into the system, and maintenance procedures.

To avoid possible injury, instruments should be passed to the surgeon or first assistant in the closed position and never over the patient's face. They should be passed smoothly and carefully so that the surgeon's or practitioner's eyes do not leave the endoscope or video monitor, limiting distractions. Some surgeons will request a suction-irrigation device that provides visualization of the sinus recesses by allowing simultaneous suction and irrigation of the operative field.

An antifog solution can be used to treat the lens of the endoscope. The solution should not be wiped off the lens; it should be applied to the lens in a thin layer. Another consideration that is crucial to a successful outcome in FESS is to maintain the integrity of the patient's periorbital cavities. The patient's eyes must be visible to the surgeon at all times to avoid injury to the orbit or to immediately recognize injury if it occurs. The surgeon will monitor for movement of the eyeball or appearance of an intraorbital hematoma.

Encroachment of the orbit can be recognized if yellow tissue is seen because orbital fat is yellow. This finding should be communicated immediately to the surgeon. Another good technique is for the scrub person to place all tissue removed by the surgeon into a small labeled container of normal saline or lactated Ringer's solution on the surgical field. If any of the tissue "floats," the surgeon should be notified immediately. The surgeon will push the tissue in question with an instrument and rotate it a few times to release any small air bubbles that may be trapped in it, which could be causing it to float. If this is the case, the tissue will then sink to the bottom of the container; it should then be considered diseased tissue that needs to be removed. However, any tissue that continues to float naturally is presumed to be fat or brain tissue. In this case, it is presumed that the orbit has been encroached, and the situation is treated as a potentially serious complication.

OPERATIVE PROCEDURE

1. The surgeon applies topical anesthetic and administers the local anesthetic.
2. The lens of the endoscope is treated with antifog solution before the endoscope is introduced into the nose.
3. The natural ostium of the maxillary sinus is enlarged with a Lusk probe to provide physiologic drainage through the middle meatus. This creates a maxillary antrostomy and allows a larger drainage pathway into the ostiomeatal complex (Figure 18-32).
4. The diseased tissue is visualized through the endoscope, and straight or angled true-cuts are used to remove it.
5. If an anterior ethmoidectomy is indicated, the surgeon inserts the endoscope into the ostiomeatal complex and performs the ethmoidectomy by taking small bites of the honey-combed bones with straight true-cuts and removing them manually and/or with suction. This reduces the many-celled ethmoid labyrinth into one large cavity to ensure adequate drainage and aeration.
6. A sphenoidotomy is created by biting an opening into one or both of the sphenoidal sinuses with a straight true-cut. It is usually performed only if sphenoid sinus disease is present on CT. Sphenoidotomies are often done with ethmoidectomies because once the ethmoid labyrinth is removed, the surgeon has excellent access through a lateralized middle turbinate exposing the sphenoidal sinuses.

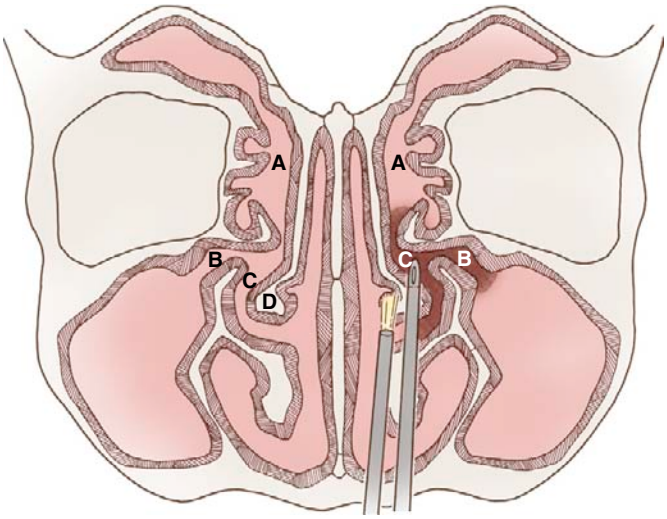

FIGURE 18-32 Surgery is performed using endoscope and forceps by intranasal approach. Diseased tissue is being removed from shaded areas depicting ethmoid sinus area *(A)*, maxillary sinus ostia *(B)*, and middle meatus *(C)*. Middle turbinate is unaffected *(D)*.

7. Because no incisions are made, no sutures are required. Epistaxis should be controlled endoscopically until it becomes a slow ooze.
8. Absorbable gelatin film may or may not be placed into the patient's middle meatus to maintain patency and reduce stenosis. If used, it is rolled into a cylindric splint and set in place with bayonet forceps. An antibiotic ointment may be applied to the splint first, according to the surgeon's preference. The gel splints dissolve gradually, or they may be removed with irrigation.
9. A mustache dressing is applied.

Frontal Sinus Trephination and Obliteration

Frontal sinus trephination is the creation of a hole in the frontal sinus to drain pus or fluid accumulation. It is performed to treat the signs and symptoms of frontal sinusitis, which may include fever and headaches. A catheter may be surgically sewn into place at the incision site of the opening made into the affected frontal sinus; this serves as a drain and medium with which to irrigate the sinus until the disease resolves. If chronic suppuration with repeated acute attacks of frontal sinusitis persists, further surgery via a coronal craniotomy may be performed to remove the diseased lining of the sinus, obliterate the cavity with a fat graft, and reconstruct the nasofrontal duct to provide the necessary drainage. The procedure for a frontal sinus trephination follows.

PROCEDURAL CONSIDERATIONS. The patient's face is prepped according to the surgeon's preference. The head is draped as in nasal procedures. Local anesthetic may be injected in the skin under the eyebrow. Culture tubes should be available as should drainage catheters.

OPERATIVE PROCEDURE

1. The incision is made medially below the eyebrow, along the same contour of the brow (Figure 18-33).
2. The periosteum is elevated from the bone, and a small diamond or cutting burr is used to drill a hole into the sinus.
3. Cultures may be taken of any pus present in the sinus, followed by irrigation.

4. A large Silastic or Teflon tube or appropriate-size catheter may be placed through the incision into the sinus.
5. The incision is closed with suture of the surgeon's preference.
6. A small dressing is usually applied to absorb drainage from the incision and catheter.

Endoscopic Transnasal Repair of Cerebral Spinal Fluid Leak

Cerebral spinal fluid (CSF) leaks are usually created by surgery or trauma. Although rare, spontaneous CSF leaks do occur. Patients usually complain of clear rhinorrhea with a salty taste from the nose, worse when either leaning forward or lying flat. Headache may accompany the rhinorrhea because of low spinal column pressures. Diagnosis is confirmed by sending the nasal fluid to the laboratory to test for β_2-transferrin, a protein specifically found in cerebrospinal fluid. A CT cisternogram assists with diagnosing the leak and often helps locate the site of dehiscence. Prepping and draping of the patient are performed in the same sterile fashion as for an endoscopic transsphenoidal approach to resection of pituitary mass, including prepping one lateral thigh and abdomen for potential graft use. All steps are followed as in a transsphenoidal resection of mass while paying close attention to the location of the carotids on the navigation system. Once the leak is found, a decision on what type of closure to use will be made by the otolaryngologist.

FIGURE 18-33 Incision to expose ethmoidal and frontal sinuses. Resulting scar is almost invisible.

Caldwell-Luc with Radical Antrostomy

The purpose of a radical antrostomy is to establish a large opening into the wall of the inferior meatus, which ensures adequate gravity drainage and aeration. This large opening allows removal of the diseased tissues in the sinuses under direct vision. The Caldwell-Luc approach is also used to access the maxillary artery in cases of extreme epistaxis. The procedure requires an incision into the canine fossa of the upper jaw and exposure of the antrum for removal of bony diseased portions of the antral wall and contents of the sinus (Figure 18-34).

FESS can be used to treat patients with chronic sinusitis, obviating the need for radical procedures, such as Caldwell-Luc. FESS allows the surgeon to target the ostiomeatal complex (OMC) in the anterior ethmoid sinus region, where thickened and diseased tissue often blocks the OMC. Obstruction in this area leads to subsequent infection in the maxillary, frontal, and sphenoidal sinuses. FESS permits removal of only the diseased

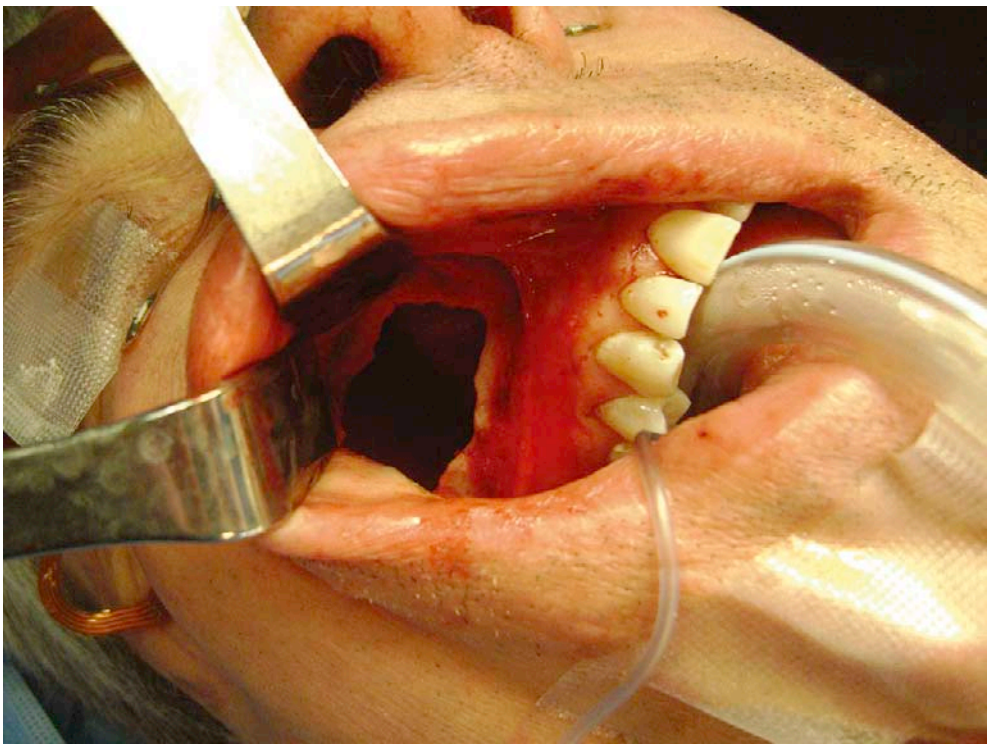

FIGURE 18-34 Caldwell-Luc operation.

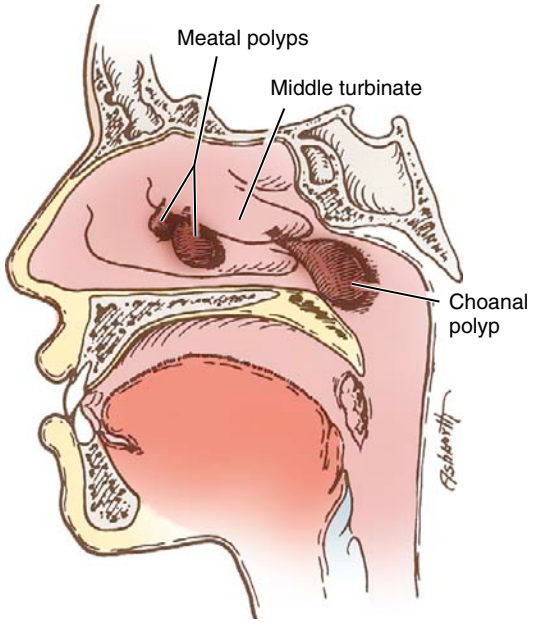

FIGURE 18-35 Nasal polyps. A choanal polyp is usually single and originates in maxillary sinus; however, most polyps are found in middle meatus.

tissue; recovery is more rapid, with minimal and usually temporary effects on the patient's appearance.

Nasal Polypectomy

A nasal polypectomy is the removal of polyps from the nasal cavity (Figure 18-35). Nasal polyps are benign, grapelike clusters of mucous membrane and connective tissue. When the polyps become large, they obstruct the free passage of air, make breathing difficult, and cause a change in speech quality. Performed endoscopically, nasal polypectomies are often done with other sinus procedures that also require removal of diseased tissue. Because of the viscous nature of polyps, microdebriders are particularly helpful in these cases. They can greatly shorten surgical time by their mechanism of morcellating the polyp and removing it by immediate suctioning while controlling bleeding, as opposed to each polyp being manually extracted with an instrument in small pieces. Cases involving inverting papilloma may recur and may require repeat polypectomies as symptoms recur.

Procedural Considerations and Operative Procedure. Nasal polypectomy setup is as for any intranasal procedure, with the addition of endoscopic equipment. Additional instruments may include a nasal polyp snare if a microdebrider is not used. Packing is typically not needed or used.

ORAL CAVITY/LARYNGOLOGIC/ NECK PROCEDURES

Surgery of the Oral Cavity and Pharynx

The oral cavity is susceptible to both benign and malignant lesions, in part because of environmental risk factors. It is estimated that in 2009 (ACS, 2009) 35,720 men and women (25,240 men and 10,480 women) will be diagnosed with cancer of the oral cavity and pharynx, and 7600 will die. Oral malignancies can be linked to specific carcinogens, the most important one being tobacco use. Incidence rates are more than twice as high in men as in women and are greatest in men who are older than 50 years.

Benign or malignant lesions of the tongue, floor of the mouth, alveolar ridge, buccal mucosa, or tonsillar area are excised depending on extensiveness of disease, involvement of surrounding vessels and nerves, and candidacy for surgery (Figures 18-36 and 18-37). Benign or small malignant tumors of the oral cavity may be excised without a neck dissection, though in the presence of diagnosed or highly suspicious metastatic disease, a selective neck dissection may be performed in an effort to control a cancerous growth in the upper jugular lymphatic chain of the neck.

In the treatment of carcinoma of the floor of the mouth with involvement of the mandible, a CT scan and/or MRI of the face and neck should be obtained to evaluate extension of the disease. A portion of the tongue is resected and may require a combined operation with reconstructive surgeons. A tracheostomy, percutaneous endoscopic gastric tube, neck dissection, and composite resection of both the mandible and the tongue with free flap reconstruction must be considered for extensive disease. When the primary intraoral lesion is confined to the tongue, a neck dissection and a hemiglossectomy are performed without resection of the mandible. In the presence of a lesion of the tonsil or an extensive lesion of the base of the tongue with pharyngeal wall involvement, resection of the mass may require removal of portions of the base of the tongue, pharyngeal wall, and soft palate to secure an adequate margin of normal tissue around the lesion. In recent years nonsurgical management with chemoradiotherapy has advanced for select oropharyngeal tumors. A free flap may be considered to fill a soft tissue defect if one is created from surgical resection. Psychologic preparation of the patient is extremely important because these procedures may be done for a minor lesion in the oral cavity or may be the first stage of much more extensive surgery in the head and neck area. A supportive and accepting family is important to the patient because of the possibility of disfigurement after surgery.

Procedural Considerations. The patient is placed in a supine position with shoulders elevated. Generally, endotracheal anesthesia is used and a pharyngeal pack of moist gauze may be inserted in the mouth. Instruments and supplies vary, depending on the surgical intervention.

Operative Procedure. Although the procedure may be scheduled as a local excision, frequently lesions of the oral cavity require more extensive excision. The setup should be designed to include the instruments for a neck dissection, or they should be readily available. For some tumors of the oral cavity, a tracheostomy is performed to ensure a patent airway after surgery. A laser may be used to excise locally confined lesions of the oral cavity.

Salivary Gland Surgery

Disorders of the salivary glands typically fall into one of three categories: inflammatory, obstructive, and neoplastic. Inflammatory conditions, such as bacterial or viral infections, can

FIGURE 18-36 Carcinoma of the dorsal tongue.

lead to salivary gland abscesses and ductal stone formation. Obstructive conditions can be a secondary consequence of inflammatory processes. Masses of the salivary glands may be benign or malignant, and 70% of them occur in the parotid gland. Three fourths of these parotid masses are benign (Elluru and Kumar, 2005). Perioperative nurses will facilitate surgical care for patients experiencing any of these conditions.

Excision of the Submandibular Gland. Excision of the submandibular gland is performed to remove mixed tumors and calculi associated with extensive chronic inflammation. An incision is made below and parallel to the mandible and extending to beneath the chin to remove the gland and tumor.

PROCEDURAL CONSIDERATIONS. The patient is placed on the OR bed in a supine position, with the affected side up and is prepped for neck surgery. The instruments include a minor neck dissection setup. A set of lacrimal probes should also be added to the instrument setup if exploration of the submandibular (Wharton's) duct is necessary during surgery. The perioperative nurse must ensure that no local anesthetic is delivered to the sterile field if identification of major nerves is anticipated. A nerve stimulator and bipolar ESU may be requested.

OPERATIVE PROCEDURE

1. The surgeon makes a small skin incision below and parallel to the mandible, extending forward to beneath the chin (Figure 18-38, *A*). The platysma is incised with scissors; the skin flaps and undersurface of the platysma and cervical fascia covering the gland are undermined with fine hooks, tissue forceps, and Metzenbaum scissors (Figure 18-38, *B*).
2. The mandibular branch of the facial nerve is retracted with a small loop retractor or nerve hook.
3. The submandibular gland is elevated from the mylohyoid muscle (Figure 18-38, *C*). The edge of the muscle is retracted anteriorly to expose the lingual veins and nerve and the hypoglossal nerve, which is identified and preserved.

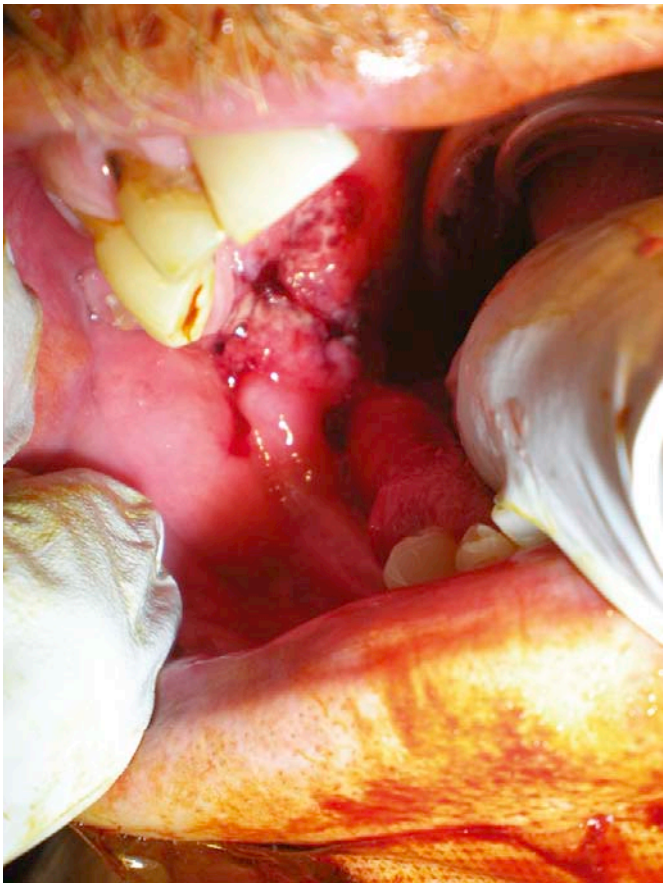

FIGURE 18-37 Carcinoma of the right tonsil.

4. The gland is freed by blunt dissection, and the submandibular duct is clamped, ligated, and divided with care to prevent injury to the lingual nerve.
5. The facial artery is clamped, ligated, and divided. The submandibular gland is removed (Figure 18-38, *D*).
6. The wound is closed with interrupted absorbable sutures. The skin edges are approximated with nonabsorbable sutures. A drain is inserted into the submandibular bed and secured to the skin. Dressings are applied.

Parotidectomy. Parotidectomy may be performed to treat recurrent parotiditis, but it is more commonly performed as part of the management of parotid gland tumors. In parotidectomy for tumor removal, the tumor and a portion of or the entire parotid gland are removed through a curved incision in the upper neck, in front of the earlobe, or through a Y type of incision on both sides of the ear and below the angle of the mandible. Even when a mass in the parotid gland is benign, the closeness of the facial nerve makes removing the entire mass surgically challenging (Figure 18-39). The facial nerve exits the stylomastoid foramen, enters the substance of the salivary gland, and then bifurcates into the temporofacial and cervicofacial branches, variably communicating with the gland. These branches then further divide into the temporal, zygomatic, buccal, and marginal mandibular and cervical branches near the edge of the parotid. The gland is divided artificially into a *superficial* and a *deep* lobe according to its relationship to the facial nerve. The possibility of damaging

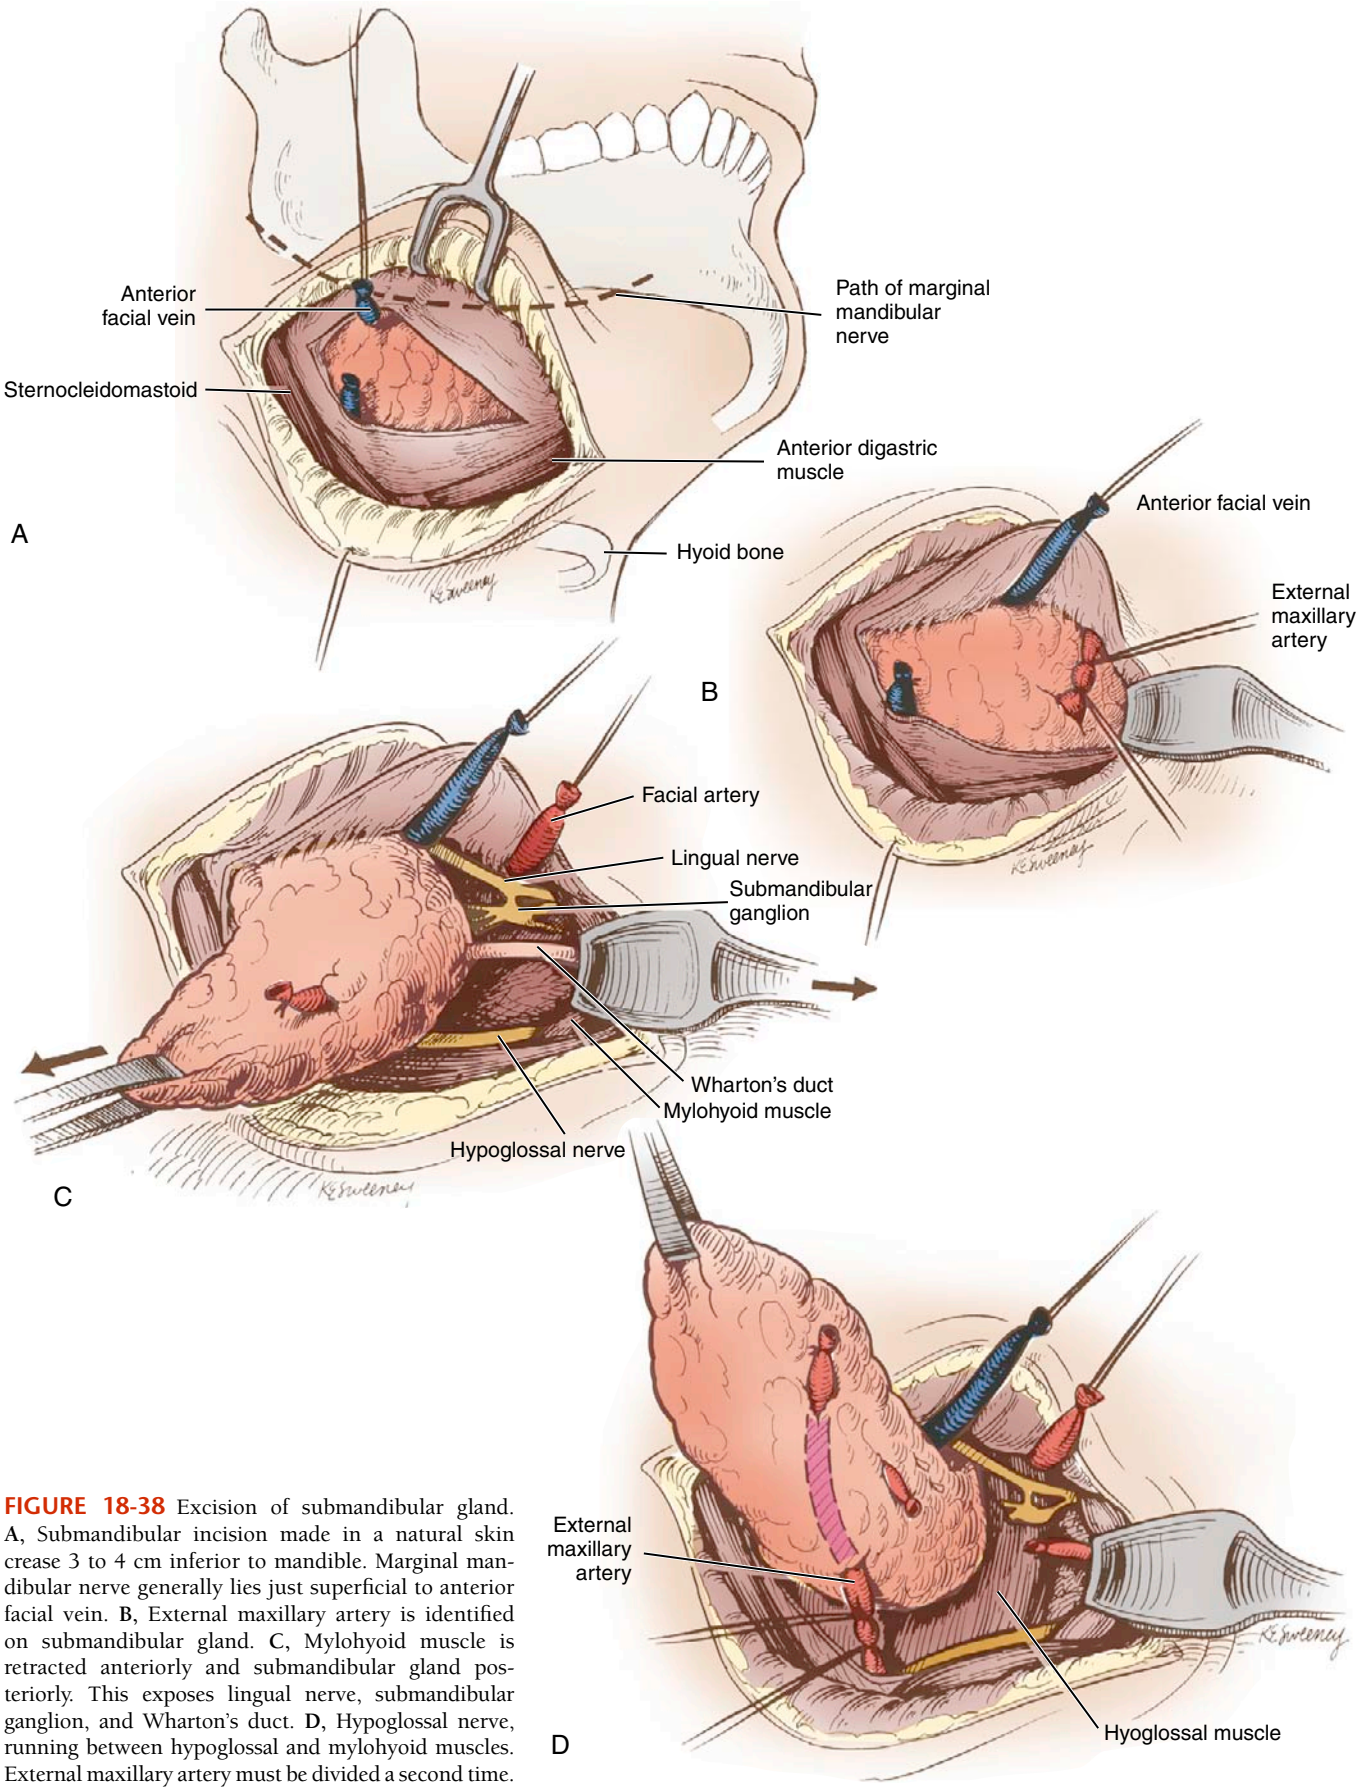

FIGURE 18-38 Excision of submandibular gland. **A**, Submandibular incision made in a natural skin crease 3 to 4 cm inferior to mandible. Marginal mandibular nerve generally lies just superficial to anterior facial vein. **B**, External maxillary artery is identified on submandibular gland. **C**, Mylohyoid muscle is retracted anteriorly and submandibular gland posteriorly. This exposes lingual nerve, submandibular ganglion, and Wharton's duct. **D**, Hypoglossal nerve, running between hypoglossal and mylohyoid muscles. External maxillary artery must be divided a second time.

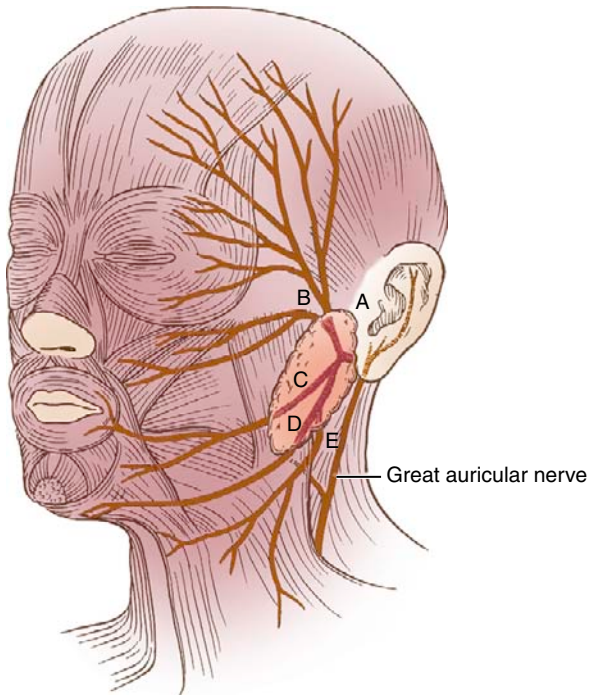

FIGURE 18-39 Branches of facial nerve. *A,* Temporal; *B,* zygomatic; *C,* buccal; *D,* mandibular; *E,* cervical.

the facial nerve (resulting in facial nerve weakness or paralysis) during the dissection of the gland should be considered carefully by all patients contemplating parotidectomy. Therefore the surgeon must understand that the most definitive way of avoiding damage to the facial nerve is to identify it early in the procedure. In addition, the patient should understand that a more radical procedure might be required if a malignant tumor is discovered to involve adjacent structures.

PROCEDURAL CONSIDERATIONS. The patient is placed on the OR bed in a supine position with the entire affected side of the face up. The entire side of the face, the mouth, the outer canthus of the eye, the ear, and the forehead are prepped and left exposed.

The instrument setup is a neck dissection set. A nerve stimulator or nerve integrity monitor should be available. A set of lacrimal probes should be included in the setup if exploration of the ductal system of the parotid is necessary during the course of surgery. Bipolar ESU may also be required.

OPERATIVE PROCEDURE

1. The incision (Figure 18-40) may extend from the posterior angle of the zygoma downward in front of the tragus of the ear and behind the lobule of the ear backward; the incision continues over the mastoid process and then downward and forward on the neck parallel to and below the body of the mandible. (A chin incision may also be used.) Bleeding vessels are controlled by hemostats and fine ligatures or with the ESU.
2. Using fine-toothed tissue forceps and scissors, the surgeon elevates the skin flaps as described for thyroidectomy (see Chapter 15) and retracts the flap with silk sutures fastened to clamps.
3. The upper portion of the sternocleidomastoid muscle is exposed and retracted, the auricular nerve is identified, and the lower part of the parotid gland is elevated with curved hemostats.
4. The superficial temporal artery and vein and external jugular vein are identified by means of blunt dissection. The parotid tissue is dissected from the cartilage of the ear and the tympanic plate of the temporal bone. The temporal, zygomatic, mandibular, and cervical branches of the facial nerve are identified and preserved.
5. The diseased portion of the parotid gland is removed, which can be superficial or deep.
   a. The *superficial portion* of the parotid gland containing the tumor is removed. In some cases the entire superficial portion is removed, followed by ligation and division of the parotid duct (Figure 18-41).
   b. When the *deep portion* of the parotid gland must be removed, the facial nerve is gently retracted upward and outward and then the parotid tissue is removed from beneath the nerve. Kocher retractors are used to retract the mandible. The external carotid artery is identified. In many cases the internal maxillary and superficial temporal arteries are clamped, ligated, and divided.
6. The wound is closed in layers with absorbable suture. If a divot is observed or anticipated overlying the resected portion of the parotid gland, abdominal fat may be harvested. A small drain is inserted, the skin is closed with fine nonabsorbable suture, and a pressure dressing may be applied depending on the surgeon's preference.

Uvulopalatopharyngoplasty. Uvulopalatopharyngoplasty (UPPP) is performed primarily to relieve obstructive sleep apnea (OSA) and snoring (Figure 18-42) (Research Highlight). UPPP is not a substitution for the use of continuous positive airway pressure (CPAP), though the procedure may be considered when conventional use of CPAP fails. Two or more of the following indications are reason to perform the operation:

- An O_2 saturation that drops below 80%
- Apnea index worse than 20
- Significant daytime sleepiness
- Heroic snoring, producing social or marital problems
- Cardiac dysrhythmias, other than tachycardia or bradycardia, during sleep

PROCEDURAL CONSIDERATIONS. On occasion, tracheostomy may be performed with UPPP because of postoperative edema with subsequent risk of airway obstruction. The tracheostomy tube is removed and the incision is closed when the danger of postoperative edema and bleeding has passed. Because some of these patients are obese (causing the tissue of the pharynx to sag during sleep), preoperative planning should include obtaining an assortment of tracheostomy tubes, including extra long tubes, before the start of the procedure. Care must be taken in positioning the obese patient to ensure proper body alignment. Emergency tracheotomy or bronchoscopy should be anticipated in the event of airway obstruction after anesthesia induction. The surgeon may choose to administer a local anesthetic with the anesthesia provider monitoring the patient. The ease of intubation should have already been determined by this time, choosing the safest method of intubation (i.e., fiberoptic intubation, GlideScope). Once the method of intubation has been established and an airway is secured, a general anesthetic may be delivered. If the tonsils are present, a tonsillectomy is performed along with the UPPP.

RESEARCH HIGHLIGHT

Obstructive Sleep Apnea and Surgical Risk

Obstructive sleep apnea (OSA) is the most prevalent sleep disorder. An estimated 82% of men and 92% of women with moderate-to-severe sleep apnea have not been diagnosed. Patients with undiagnosed OSA may have increased perioperative complications. The goal of this study was to determine whether a simple screening protocol for OSA-related signs and symptoms performed at the time of preoperative assessment for elective surgery, followed by home nocturnal oximetry in selected cases, could identify patients who were at increased risk of perioperative complications.

Participants for the study were identified during preanesthetic evaluation based on at least two clinical features suggestive of OSA as determined by a standardized screening questionnaire and physical examination (e.g., snoring, excessive daytime somnolence, witnessed apneas, or crowded oropharynx). Based on the initial screening, 172 patients, ranging in age from 27 to 85 years, were selected for home nocturnal oximetry testing. The oximetry results were interpreted by sleep medicine–trained physicians before the scheduled surgery and they established a baseline for the incidence of oxygen desaturation episodes at 4% or more.

Analysis of the data showed correlation between documented oximetric preoperative oxygen desaturation episodes and postsurgical complications. A complication was defined as an adverse event affecting a major organ system that required further monitoring, additional diagnostic testing, or direct therapeutic intervention. A significantly higher rate of complications was noted in patients who experienced five or more desaturation levels based on preoperative screening as compared to patients who had fewer than five episodes. The patients who had experienced 5 to 15 episodes of desaturation had a complication rate of 13.8% and those who had more than 15 episodes had a complication rate of 17.5%. The majority of complications were respiratory in nature, followed by cardiovascular, bleeding, and gastrointestinal complications.

While nocturnal oximetric testing does not confirm the presence of OSA, it may have usefulness as a screening tool for patients with this disorder. Effective screening will allow physicians to identify patients who are at risk for complications related to OSA and better plan their perioperative course to improve outcomes.

Modified from Hwang D et al: Association of sleep-disordered breathing with postoperative complications, *Chest* 133:1128-1134, 2008; Chung F, Elsaid H: Screening for obstructive sleep apnea before surgery: Why is it important? *Curr Opin Anaesthesiol* 22(3):405-411, 2009.

OPERATIVE PROCEDURE

1. The McIvor mouth gag is inserted.
2. The tissue to be resected may be outlined by an electrosurgical blade. A #3 knife handle with a #15 blade or a #7 knife handle with a #12 blade may be used to make the incision, though surgical technique has changed from resection with scalpel to completing the entire resection with the ESU. The incision is made in the soft palate and anteriorly to the tonsillar pillar (if the patient has not previously undergone a tonsillectomy) or posteriorly to the tonsillar pillars (if the patient has undergone a tonsillectomy) (Figure 18-43).

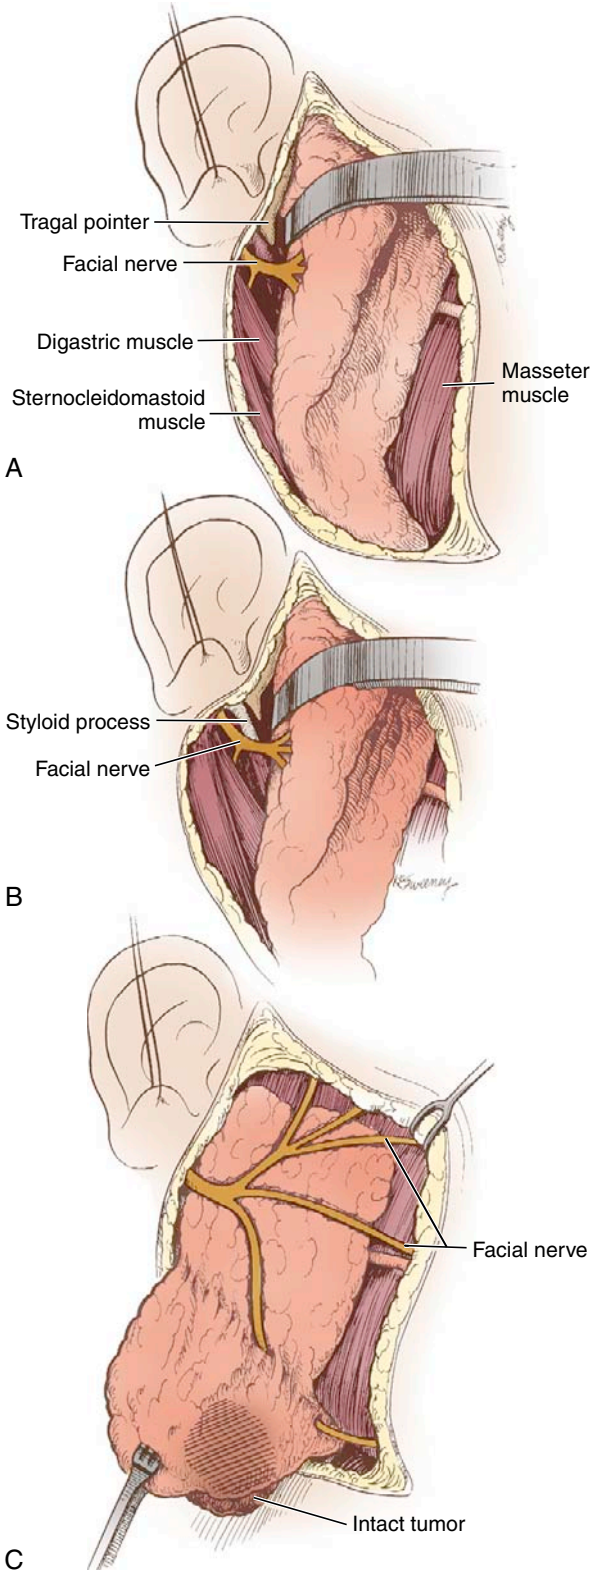

FIGURE 18-40 Operative technique for parotidectomy. **A**, Blunt dissection of parotid gland from external auditory canal cartilage exposes tragal pointer. Facial nerve lies approximately 1 cm deep and slightly anteroinferior to pointer and 6 to 8 mm deep to tympanomastoid suture line. **B**, Facial nerve exits stylomastoid foramen to run anteriorly between styloid process and attachment of digastric muscle to digastric ridge. **C**, Nearly completed process with tumor within intact superficial parotidectomy specimen.

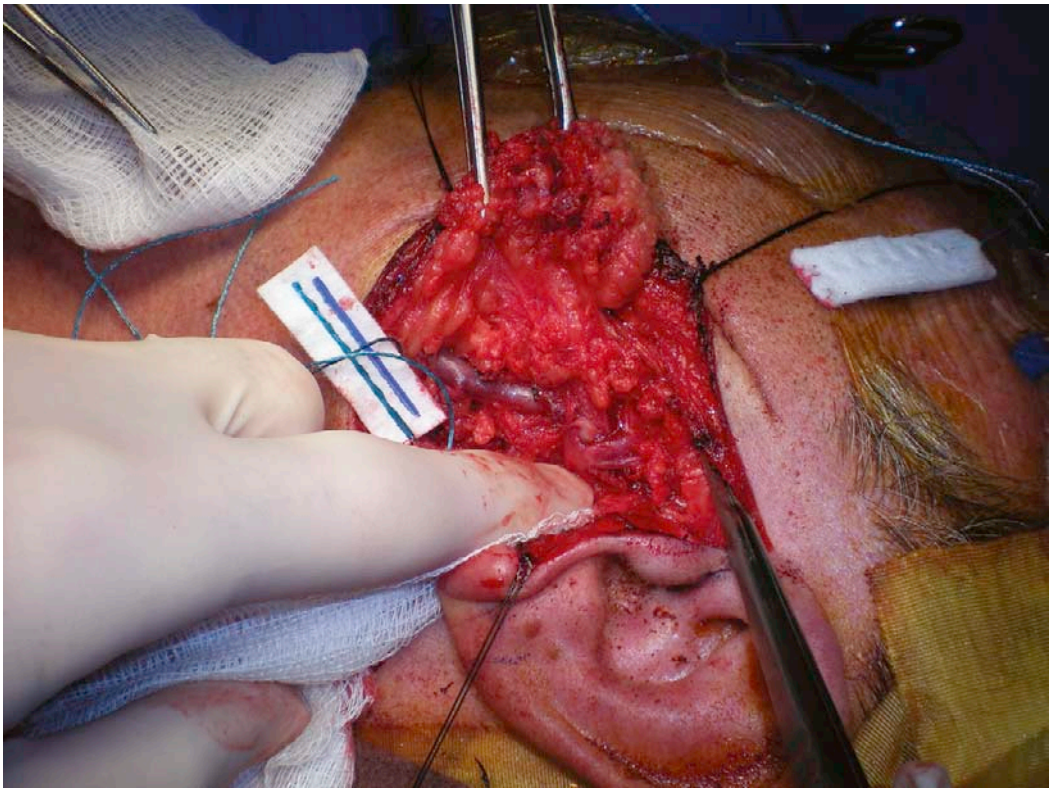

FIGURE 18-41 Surgical removal of superficial parotid mass.

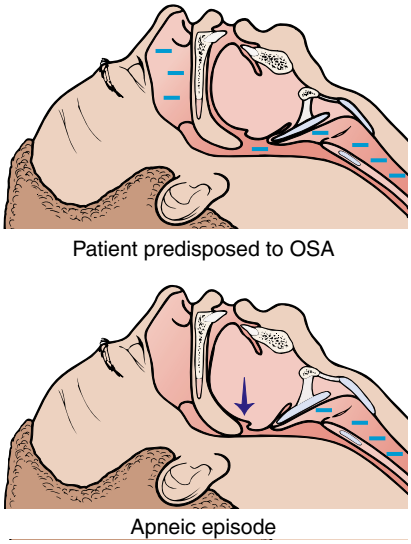

FIGURE 18-42 Sleep apnea syndrome is a condition in which airflow is temporarily obstructed during sleep. Airflow obstruction occurs when the tongue and the soft palate fall backward and partially or completely obstruct the pharynx. The obstruction may last from 10 seconds to as long as 2 minutes. During the apneic period, the patient experiences severe hypoxemia (decreased PaO_2), hypercapnia (increased $PaCO_2$), and acidosis. These changes interrupt sleep and cause the patient to partially awaken. When the patient begins to awaken, the tone of the muscles of the upper airway increases. The tongue and soft palate move forward, and the airway opens. Apnea and arousals occur repeatedly during the night, separated by several normal breaths. The cause of sleep apnea is not definitely known. However, three factors appear to be involved: (1) shape of the upper airway, (2) neural control of the respiratory muscles, and (3) hormonal balance. *OSA,* obstructive sleep apnea.

3. Larger blood vessels may be clamped until the tissue is removed, or a suction coagulator or hand-controlled electrosurgical pencil may be used to obtain hemostasis as the tissue is excised.
4. Once the tissue is removed and hemostasis is achieved, absorbable sutures are used to approximate the edges of the mucosa. Depending on the surgeon's preference, 2-0 and 3-0 absorbable suture should be available. Needle holders should be long enough to allow the surgeon ease in delivering the atraumatic needle to the edges of the mucosa.
5. The oral cavity should be rinsed of blood and debris and the incision inspected before the patient is transferred from the OR.

When inspecting the incision in the postoperative period, care should be taken not to disturb it with a tongue blade, if one is used to provide access for inspection. The patient must not use a straw for fluid intake because it might disturb the suture line. Gentle oral cavity rinsing is recommended several times daily to decrease the chance of postoperative infection and to increase patient comfort.

Laryngeal Surgery

Laryngeal surgery may be performed for diagnostic reasons or as a means of treatment for both benign and malignant conditions. This type of surgery involves both endoscopic and traditional "open" approaches and always has the potential to alter the patient's ability to communicate verbally in the postoperative period. As is the case with oral cavity malignancies, cancerous lesions within the laryngeal structures are often attributed to environmental factors, such as tobacco and alcohol use (Figure 18-44). Benign conditions, such as vocal cord polyps and nodules, are often treated with laryngeal surgery.

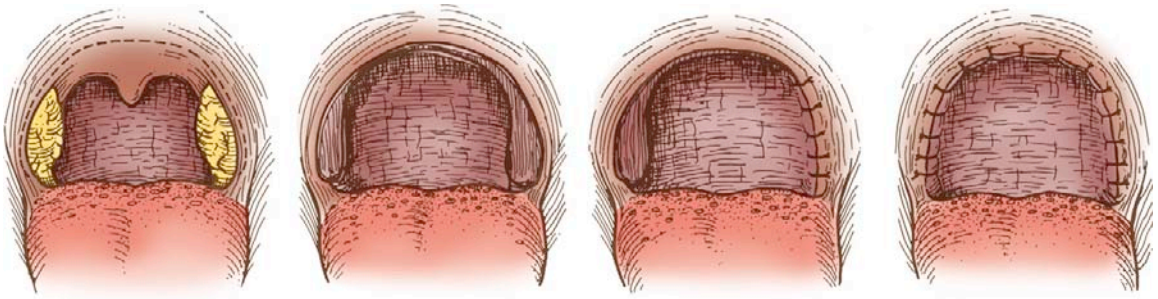

FIGURE 18-43 Technique of palatopharyngoplasty as advocated by Simmons and associates.

FIGURE 18-44 Large granular tumor on the true cord.

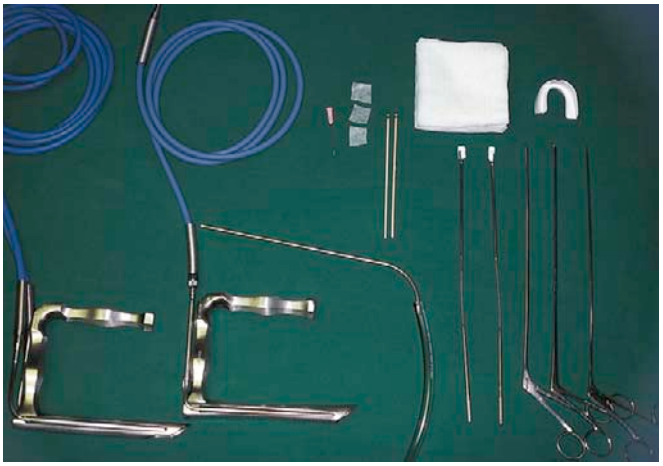

FIGURE 18-45 Instrument setup for direct laryngoscopy includes Jako and Dedo laryngoscopes, laryngeal suction, assorted laryngeal forceps, and sponge carriers.

ENDOSCOPIC PROCEDURES

Laryngoscopy

Laryngoscopy is direct visual examination of the interior of the larynx by means of a rigid, lighted speculum known as a *laryngoscope* (Figure 18-45) to obtain a specimen of tissue or secretions for pathologic examination. Vocal cord visualization may also be accomplished in the office setting with a flexible, fiberoptic nasopharyngoscope.

Procedural Considerations. Most rigid laryngoscopies are performed with the patient receiving a general anesthetic. If the patient is unable to tolerate general anesthesia, a local or topical anesthetic of lidocaine, tetracaine, cocaine, or benzocaine/tetracaine will be administered. The patient should be sufficiently relaxed by reassurance and by pharmacologic preparation if the procedure is performed using local anesthesia. Sedatives may be administered before surgery. Immediate preoperative assessment should include the presence of any dental appliances and loose teeth and the condition of dental work. Any stiffness or immobility of the neck or shoulders should be evaluated. Respiratory problems such as asthma must receive careful attention. The patient should be cautioned about not eating or drinking after surgery until the gag reflex has returned and swallowing occurs without difficulty.

The setup includes the following:

- Labels for all medications and solutions used in the sterile field
- Local anesthesia setup
- Gauze sponges, 4 × 4 inches
- Laryngeal mirror
- Cotton balls
- Small cup of hot water (to warm the laryngeal mirror so that it does not fog when inserted into the mouth to view the vocal cords) or an antifog solution
- Emesis basin
- Syringe, 5 ml; and Abraham cannula
- Medication cup
- Jackson laryngeal application forceps
- Anesthetic spray, with angulated tip, or other topical anesthetic for the oral mucosa
- Instrument setup:
  - One laryngoscope
  - Two laryngeal suction tubes
  - One light carrier, fiberoptic
  - Two laryngeal biopsy forceps, one straight and one up-biting
  - Two sponge-carrier forceps with extra sponges
  - One tooth guard
  - One fiberoptic light cord
  - Zero-degree telescope: may be requested for close visualization or attached to the camera for photographs of specific areas
  - One laryngeal probe: may be used to retract tissue or assess mobility of tissue

Accessory items include suction tubing, a specimen container, a basin with sterile saline, gauze sponges, sterile towels, and gloves.

If the surgeon wishes to perform a suspension laryngoscopy, a self-retaining laryngoscope holder is added to the instrument table, as well as microlaryngeal instruments, which include scissors, cup forceps, and alligator forceps. A special platform may be mounted onto the OR bed or a Mayo stand may be placed above the patient's chest and over the OR bed to provide a place for the laryngoscope holder to rest. The surgeon normally uses the operating microscope with a 400-mm lens during suspension laryngoscopy. The patient is placed in a supine position to facilitate visualization of the vocal cords. A shoulder roll should be available if slight hyperextension of the neck is necessary to assist in visualization of the larynx.

Operative Procedure

1. Moist gauze pads or tape should be placed over the patient's eyes to protect them from the instrumentation and to prevent injury and irritation from secretions during the procedure. The head may also be wrapped in a sterile towel. A sterile drape may be used to cover the patient. A tooth guard or moist 4-inch × 4-inch gauze sponge is placed to protect the patient's teeth.
2. The surgeon introduces the spatula end of the laryngoscope into the right side of the patient's mouth and directs it toward the midline; then the dorsum of the tongue is elevated so that the epiglottis is exposed.
3. The patient's head is first tipped backward and then lifted upward as the laryngoscope is advanced into the larynx.
4. The larynx is examined, a biopsy is taken, secretions are aspirated, and bleeding is controlled.
5. The patient's face is cleansed.

Laryngoscopy instrumentation should remain set up in the room until the patient is transferred because the equipment may be needed if the patient experiences laryngospasm postoperatively.

Microlaryngoscopy

Microlaryngoscopy facilitates improved diagnosis and allows the laryngologist to view with relative ease areas that previously were inaccessible or difficult to visualize. It may also be used for minor surgery of the larynx, especially for the removal of polyps or nodules on the vocal cords (Figure 18-46). Intralaryngeal surgery using the laryngoscope is often referred to as *phonosurgery*. Instrumentation may vary according to surgeon preference. Research is currently under way to determine the feasibility of using robotics for laryngeal surgery.

Procedural Considerations. If the procedure is done to remove polyps or nodules from the vocal cords, the patient must be cautioned to observe complete voice rest or to whisper postoperatively. The patient should be provided with a pencil and paper or erasable slate to aid in communication. The patient's restriction on speaking should be noted on the nursing plan of care and on the front of the chart.

The basic instrument setup for laryngoscopy is used. Microlaryngeal instruments are added to the setup and include the following:

- Self-retaining laryngoscope holder
- Jako microlaryngeal grasping forceps
- Jako microlaryngeal cup forceps, straight and up-biting cups

FIGURE 18-46 Bilateral vocal cord polyps.

- Jako microlaryngeal scissors, straight, angled, and up-biting
- Jako microlaryngeal knives, straight and curved
- Laryngeal probe
- Microlaryngeal mirror
- Open-ended microlaryngeal suction tube
- Laryngoscope (dual light channel)

The aforementioned instruments are 22 cm long to allow use with the microscope, and are long enough to keep the surgeon's hands out of the visual field. The patient's head is adjusted to allow visualization of the larynx. The surgeon usually adjusts the microscope. The microscope lens should have a 400-mm focal length. Focal length is the distance from the lens to the operative area and is the point at which the field can be clearly viewed through the microscope. Beyond this point the field becomes fuzzy. The 400-mm lens gives the surgeon a 40-cm focal length, or working distance.

Carbon Dioxide Laser Surgery of the Larynx

Laryngologists often use the CO_2 laser to treat lesions of the larynx and vocal cords. This laser is efficient and has a high power output. The beam destroys tissue at a precise point with minimal destruction of the surrounding tissue. It is especially useful in surgeries such as removal of webs in the larynx, vocal cord papillomas, and carcinoma in situ of the larynx, as well as benign endobronchial lesions.

Procedural Considerations. The basic setup for laryngoscopy and microlaryngoscopy is used. All instrumentation used for laser laryngoscopy should be ebonized. A general anesthetic is usually administered. The operating microscope with a 400-mm lens is used, with the laser micromanipulator attached to the microscope head. The beam should also be tested for proper working order before use on the patient. Extreme care should be used when handling this delicate piece of equipment. A smoke evacuator should be used to remove the laser plume—a smokelike steam rising from the impact site; high-filtration laser masks should be worn by personnel. Where minimal plume is generated, a central wall suction with an in-line filter may be used for plume evacuation (AORN, 2009c). All other laser precautions apply (see Chapter 7).

Adjunctive Procedures

Although the following procedures do not technically involve the larynx, they are often performed by otorhinolaryngologists in conjunction with laryngeal surgery and are of particular use in the diagnostic arena.

Bronchoscopy. The trachea, bronchi, and lungs are visualized directly with a rigid or flexible bronchoscope that has a fiberoptic lighting system. A rigid scope gives a larger viewing area, whereas a flexible scope is easily inserted into the patient and manipulated. Bronchoscopy is fully described in Chapter 22. The Nd:YAG laser may be used for lesions of the trachea or bronchi, depending on the type of lesion. Most diagnostic bronchoscopies are performed using topical anesthetics and moderate sedation, requiring careful patient monitoring by the perioperative nurse.

Esophagoscopy. Esophagoscopy is the direct visualization of the esophagus and the cardia of the stomach. This procedure is used to observe the area for extension of tumor, to remove tissue and secretions for study, or to evaluate for second primary tumor sites.

PROCEDURAL CONSIDERATIONS. Esophagoscopy facilitates the diagnosis of esophageal carcinoma, diverticula, hiatal hernia, stricture, benign stenosis, and varices. Patients with suspected obstruction, symptoms of bleeding, or regurgitation may require endoscopy. The Nd:YAG laser may be used in the treatment of some of these lesions. Esophagoscopy may also be used for therapeutic manipulations, such as removal of a foreign body or insertion of an esophageal bougie to treat esophageal stenosis.

The setup includes the following:

- Esophagoscopes of desired type, size, and length (Figure 18-47)
- Suction tubing
- Fiberoptic light source and light cords
- Bougies, if desired
- Forceps of desired type and length
- Specimen containers
- Water-soluble lubricating jelly
- Gauze sponges
- Basin with sterile saline
- Suction tips (with velvet-eyed tips to avoid suctioning the mucosa of the esophagus into the tip)

OPERATIVE PROCEDURE

1. The fiberoptic light carrier is inserted into the esophagoscope and the fiberoptic light cord attached. A thin layer of lubricant is applied to the scope. The scope is passed into the mouth. The tongue, epiglottis, laryngeal inlet, and cricopharyngeal lumen are identified. If necessary, a person holding the patient's head may be required to tip the head backward while extending the neck anteriorly. Usually the esophagoscope is passed to the right side of the tongue, and the patient's head is turned slightly to the left.
2. When the scope has passed the inferior constrictors, the patient's head is moved in various directions so that all areas of the esophageal wall may be examined.
3. Specimens of secretions from the esophageal lumen may be obtained with an aspirating tube and suctioning apparatus. In some cases, saline may be injected through the esophagoscope's aspirating channel and the fluid is withdrawn immediately for histologic study. A tissue biopsy may be taken. After biopsy, the area is assessed for bleeding and the esophagoscope is then removed.

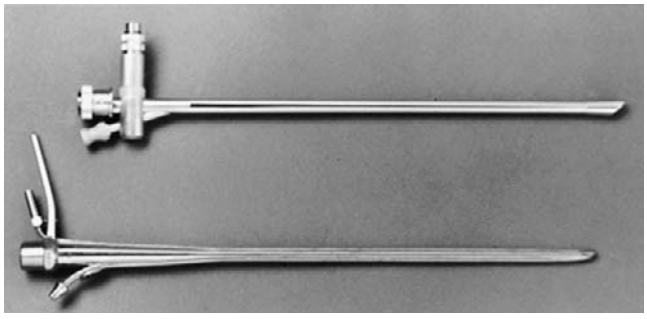

FIGURE 18-47 Pediatric and adult esophagoscopes.

Triple Endoscopy. When laryngoscopy, bronchoscopy, and esophagoscopy are performed in a single session on a patient, the procedure is termed *triple endoscopy* or *panendoscopy.* The order in which the procedures are performed depends on the surgeon's preference. The purpose of triple endoscopy is usually diagnostic. While inspecting for a malignancy, the surgeon views the structures, takes specimens for biopsy, and possibly makes smears or washings of the suspect areas. For any of the aforementioned endoscopy procedures, all equipment or instrumentation should be set up and be in working order (i.e., light carriers in place; light cables connected and working). Instrumentation to be used through the various scopes (i.e., suction tips, telescopes, biopsy forceps) should be checked for appropriate length. Specimens taken during endoscopic procedures should be labeled and removed from the back table as soon as possible. In some instances, it may be helpful to indicate on the label that the specimens are microscopic.

OPEN NECK AND LARYNGEAL PROCEDURES

Tracheostomy

Tracheostomy is the opening of the trachea and the insertion of a cannula through a midline incision in the neck, below the cricoid cartilage. A tracheostomy may be permanent or temporary. It is used as an emergency procedure to treat upper respiratory tract obstruction, which can be caused by bilateral vocal cord paralysis, swelling of the neck or airway caused by trauma, allergic reactions, or neoplasms. It is also used as a prophylactic measure in the presence of chronic lung disease, in extensive neck resections where massive upper airway edema is anticipated, or if radiation-induced edema is expected during the treatment of cancers involving the tongue and neck. Tracheostomy is also considered the "gold standard" in treating sleep apnea in which obstruction may occur. Tracheostomy may be performed to permit easy and frequent pulmonary toileting on patients having a difficult time managing and expectorating their own secretions. Additionally, tracheostomy should be performed on patient's experiencing prolonged intubation to avoid overgrowth of granulation tissue and subsequent subglottic stenosis.

The patient's psychologic status should be carefully evaluated because of the altered body image, which may be either temporary or permanent, depending on the disease entity

involved. Tracheostomy care should be explained carefully and thoroughly so that the patient will understand why self-care should be performed frequently. Reinforcement should be given regarding the ability to communicate with others by means of a pencil and paper or message board. As recovery progresses and secretions diminish, the patient can be shown how to occlude the opening of the tube for brief periods to be able to speak a few words. The patient also must be taught the mastery of tracheostomy self-care (Patient and Family Education). If a tracheostomy tube with a disposable inner cannula is inserted, the nursing staff must ensure that the patient has replacement cannulae in the event occlusion or blockage occurs in the immediate postoperative period

Procedural Considerations. Before tracheostomy tube cuffs are inserted, they should be tested for air leaks by inflating and then deflating the balloon. Cuffed tracheostomy tubes are used on patients at risk for aspiration, patients receiving positive-pressure ventilation, or patients who have undergone skull base surgeries involving open communication of the sinuses into the intracranium, where it is desirable to avoid pneumocephalus. The patient is placed in a supine position, with the shoulders raised by a small rolled sheet to slightly hyperextend the neck and head. Using a skin marker the surgeon marks a midline incision site, halfway between the sternal notch and the cricoid cartilage, between the second and third tracheal rings. The neck is prepped, and sterile drapes are applied. A soft suction catheter should be available on the sterile field for suctioning after the tube is inserted.

Operative Procedure

1. The surgeon injects lidocaine with epinephrine into the subcutaneous tissue across the tracheotomy site previously marked with a surgical marker.
2. A horizontal incision is made with a #10, #15, or #11 blade. Soft tissues and muscle are divided, using blunt hemostats and sharp dissection through the platysma and the overlying strap muscles. The thyroid gland is identified; attention is directed to the isthmus with the intention of transecting this area of the gland. Occasionally, the isthmus can be retracted from the surgical site without transection (Figure 18-48).
3. The plane between the isthmus and the trachea is separated by the surgeon with a blunt hemostat, exposing the thyroid gland so the surgical assistant can carefully transect it with the ESU knife. This exposes the underlying tracheal rings—usually the second and third. In some cases, two curved clamps may be inserted through this incision across the isthmus and then the isthmus is transected.
4. The transected ends of the isthmus are oversewn or suture-ligated with absorbable sutures.
5. Once the trachea is identified, a horizontal incision is made with a #11 blade through the second and third tracheal rings. The incision is extended and the tracheotomy tube is inserted. Two 2-0 silk sutures are then sewn into the trachea for future use during the first tracheostomy change. In two motions, one silk suture is inserted into the trachea, and then retrieved with the needle driver through the horizontal incision. This is then repeated with another silk suture through the bottom half of the horizontal incision. Air knots are tied into each of the sutures and secured with tape onto the chest so they are ready for easy retrieval for retraction during the first tracheostomy change, about 5 to 7 days later. By tradition, one air knot is placed in the upper stay suture and two air knots are placed in the lower stay suture to allow for easy identification and proper retraction at the time of tracheostomy tube change or in the event of tracheostomy tube dislodgement. The air knots are cut and removed once the first tracheostomy change takes place.

An additional tracheostomy tube of the same size and the obturator should be kept with the patient at all times, in the event the tube becomes dislodged or plugged with secretions. This practice expedites changing the tracheostomy tube with minimal potential for complications to the patient.

Laryngofissure

Laryngofissure is an opening of the larynx for exploratory, excisional, or reconstructive procedures that cannot be accomplished endoscopically.

Procedural Considerations. A laryngofissure may be performed when access to the intrinsic larynx is necessary. The thyroid cartilages are split in the midline, and the true vocal cords and false vocal cords are incised at the midline anteriorly. A neck dissection instrument set is required, plus an oscillating power saw.

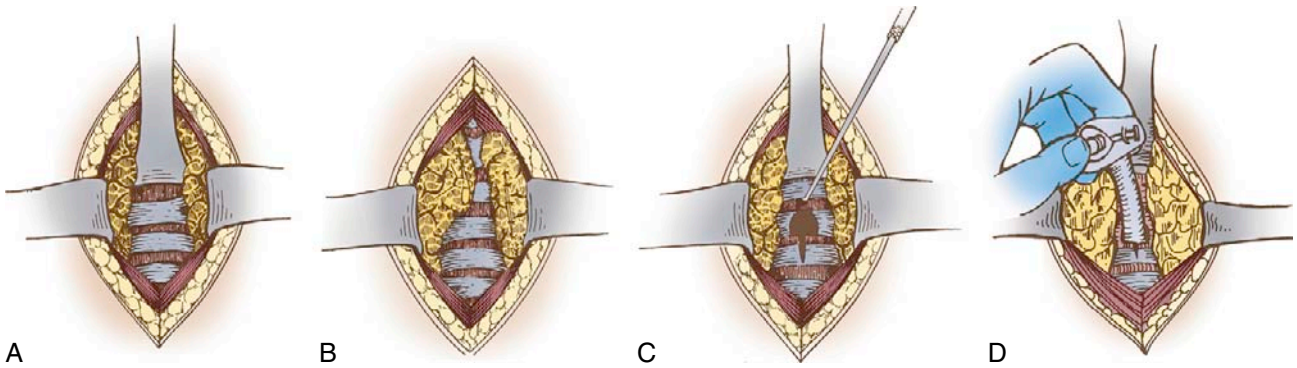

FIGURE 18-48 Operative technique for elective tracheostomy. **A**, Retractor exposing trachea by drawing isthmus of thyroid upward. **B**, Alternative method to that shown in (**A**). Isthmus of thyroid is divided to expose trachea. **C**, Two tracheal rings are cut, and upper ring is partially resected. Tracheal hook pulls trachea from depth of wound nearer surface. **D**, Insertion of tube.

PATIENT AND FAMILY EDUCATION

Patient Education for Tracheostomy Patients

The following information is a sample of a printed teaching tool that can be provided to patients and their caregivers after tracheostomy procedures.

GOAL #1: SAFETY
- Know how to call your nurse for help.
- Use handheld call button.
- Do not get out of bed alone.

GOAL #2: PAIN CONTROL
- If you are having pain, ask for pain medicine.

GOAL #3: COUGH AND BREATHE DEEPLY
- Coughing and deep breathing speed your recovery. If you feel pain when you cough or deep breathe ask your nurse or doctor for pain medicine.
- Coughing clears your lungs and airway.
- Deep breathing helps keep your oxygen levels high and helps prevent pneumonia.

GOAL #4: LEARN
- The nurses will teach you, and your family, how to take care of yourself.
- Learning as much as possible should speed your recovery.
- It is normal to have lots of secretions (mucus) coming out of your tracheotomy (neck) for a few days after surgery. The secretions should decrease shortly thereafter.

WHAT YOU NEED TO KNOW

Airway

You breathe through your mouth or nose. The air goes down your trachea. The trachea (windpipe) is the tube that runs down the inside of the front of your neck. The trachea connects to your lungs. This path is called your airway.

Tracheostomy

A tracheotomy is surgery to put a plastic or metal tube in your trachea. An incision (cut) called a tracheostomy is made in your neck. A tracheotomy tube is placed through the incision into the trachea. This tube allows air to reach your lungs so you can breathe easier and safely.

Secretions

Fluids that come out of your tracheostomy can be a combination of mucus, blood, and saliva (spit). Secretions can be the result of the surgery or infection. You may have large amounts of secretions right after surgery for a few days. They will decrease as you heal and learn how to clear them from your airway.

Stoma

The opening in the trachea where the trach tube is placed.

Trach

Trach is short for tracheotomy tube—the plastic or metal tube that maintains the opening in your neck. When first placed, the cuff may be inflated and you may not be able to talk.

Daily Care Routine (Every Hour While Awake)
- Every hour while awake, take 10 deep breaths.
- Every 3-4 hours, or when you feel congested:
  - Remove and clean your inner cannula.
  - Instill with saline bullets (pink squirts).
  - Change your position (get out of bed with help).
  - Rinse your mouth if allowed by your doctor twice a day, or more if large amounts of secretions.

Stoma Care (Cleaning Around Your Trach)

Once a day, check your neck for signs of infection:
- Redness
- Swelling
- Tenderness
- Drainage

Check to see if your temperature is greater than 101.5° F.
Check your trach ties and change when soiled if allowed by the doctor.

SPECIAL CONSIDERATIONS

Avoid irritants that may hamper your breathing. Things to avoid include smoke-filled rooms, powders (e.g., baby powder) and dust, and all aerosols (spray deodorants, hair sprays, spray perfumes, or after shaves). Avoid anything that creates a cloud, or can be breathed in through your trach tube.

PATIENT AND FAMILY EDUCATION

Patient Education for Tracheostomy Patients—cont'd

INSTILLING AND COUGHING

Instilling sterile saline solution and coughing is the best way to clear your secretions. Deep breathing and coughing will help keep your lungs and trach tube clear. Coughing can reduce your need for suctioning.

1. Gather supplies: 4 × 4 gauze and lavage bullets (pink squirts).
2. Wash your hands.
3. Twist off lavage bullet cap, and place bullet point in the inner cannula of the trach tube.
4. Take 3-4 deep breaths.
5. While inhaling, squeeze the lavage bullet to squirt the saline solution into your trach tube (this will make you cough).
6. Immediately cover your trach tube with gauze to catch your secretions. Do not use tissues.
7. Throw out gauze promptly and properly wash your hands.

REMOVING AND CLEANING THE INNER CANNULA

1. Gather supplies: 4 × 4 gauze and trach cleaning kit.
2. Wash your hands.
3. With one hand, hold the flat plate on one side of the trach tube with your thumb and forefinger. Then turn the inner cannula to your right. This releases the lock.
4. Slowly pull the inner cannula out. Continue to hold the flat plate; this helps to prevent stimulating a cough.
5. Rinse the inner cannula under cool running tap water and clean the inside with a small narrow brush or pipe cleaner. Wipe or shake off excess water.
6. Hold the flat plate on one side of the trach tube. Replace the inner cannula into the trach tube. Align the notch with the opening; when the cannula is completely inserted, turn the tube counterclockwise until you feel the lock snap. The inner cannula is locked when the two blue dots are in line.

STOMA CARE (CLEANING)

1. Gather supplies: 4 × 4 gauze, Q-tips, cleaning solutions, and cleaning kit.
2. Wash your hands.
3. Breathe deep cough/self-instillation (if needed).
4. Apply cleaning solution #l (½ hydrogen peroxide, ½ pure saline solution) with Q-tips to areas around trach.
   a. Allow solution to bubble in order to loosen crusting and secretions.
   b. Be sure to clean under trach back plate.
   c. Use a new Q-tip after it touches your skin or trach (prevents contamination of solution).
5. Apply rinse solution #2 (all pure saline solution) with Q-tips to same areas.
   a. Rinse all areas that have been cleaned with solution #1.
   b. Use a new Q-tip after it touches your skin or trach (prevents contamination of solution).
   c. Rolling the Q-tip between your fingers helps to remove loosened crust.

CLEARING YOUR AIRWAY

1. Breathe deeply.
2. Cough to bring up secretions.
3. Remove, clean, and replace inner cannula.
4. Instill yourself (with a pink squirt).
5. Suction yourself.

CALL THE DOCTOR/NURSE

Call your doctor/nurse if you begin to have any difficulty breathing or if you have any of the following:

1. Increased redness, local pain, and discomfort around your stoma
2. Increase in body temperature (fever) to 101° F or more for 2 days
3. Change in color, odor, amount, or thickness of secretions
4. Persistent cough or change in normal coughing pattern
5. Congestion, wheezing, or chest discomfort or pain
6. Coughing up food or liquids

From Merek J: Tracheostomy and airway patients, Thomas Jefferson University Hospital.

Operative Procedure

1. A tracheotomy is performed, and an endotracheal tube is inserted. A general anesthetic is administered.
2. A transverse incision is made through the skin and first layer of the cervical fascia and platysma muscles, approximately 2 cm above the sternoclavicular junction or in the normal skin crease. The upper skin flap is undermined to the level of the cricoid cartilage, and the lower flap is undermined to the sternoclavicular joint.
3. Bleeding vessels are clamped with mosquito hemostats and ligated. The strap muscles are elevated and incised in the midline.
4. The thyroid cartilages are cut with an oscillating saw, and the true vocal cords are visualized through an incision into

the cricothyroid membrane. The true vocal cords are divided in the midline (anterior commissure), and the interior of the larynx is exposed.

5. The tracheostomy tube must be left in place after surgery to ensure an airway.

Phonosurgery

Phonosurgery refers to various operations on the laryngeal framework to improve phonation for patients with communication disorder. Type I thyroplasty is used to change or improve the voice. Thyroplasty types II and III are used to alter vocal cord tension and voice pitch.

Thyroplasty. Type I thyroplasty is a form of phonosurgery for the treatment of unilateral vocal cord paralysis, which may be caused by trauma, neoplasms, paralysis from thyroidectomy, paralysis after extensive aortic and mediastinal vascular surgery, and mechanical and central nervous system dysfunctions. A window is created surgically in the thyroid cartilage, into which a silicone implant is placed. The implant pushes the paralyzed cord medially, which allows the moving cord to touch the paralyzed cord and close the opening.

PROCEDURAL CONSIDERATIONS. As the preoperative assessment is being done, the perioperative nurse explains to the patient that his or her voice will need to be rested postoperatively in an effort to minimize edema and stress of the vocal cords. An alternative method of communicating can be determined, such as writing.

The procedure is done using monitored local anesthesia to allow the patient to speak during surgery. This allows the surgeon to evaluate the quality of the patient's voice in an effort to attain the best result.

OPERATIVE PROCEDURE

1. The patient is positioned on the OR bed in a semisitting position. A laryngoscopy is done by means of a flexible fiberoptic laryngoscope.
2. As the patient is asked to speak, the surgeon determines the extent of approximation of the vocal cords as well as the patient's breath control. After a thorough evaluation, the patient is then prepped and draped.
3. A local anesthetic is injected into the surgical site. A horizontal incision is made at the middle level of the thyroid ala. Gelpi retractors are used to maintain exposure as dissection to the thyroid cartilage is completed. Measurements for the placement of the window are taken and marked with a marking pencil. A #15 blade is used to create a window in the thyroid cartilage. In some cases, a power drill with a cutting burr may be used. A periosteal elevator may be used to displace the vocal cords during phonation in an effort to determine voice quality.
4. When voice quality is satisfactory, the implant is placed into the window. Final laryngoscopy is done to view approximation of the vocal cords with the implant in place. The incision is then closed, and a dressing is applied.

Partial Laryngectomy

Partial laryngectomy is removal of a portion of the larynx. It is done to remove superficial neoplasms that are confined to one vocal cord or to remove a tumor extending up into the ventricle or the anterior commissure or a short distance below the cord. A cancer confined to the intrinsic larynx is generally a low-grade malignancy and tends to remain localized for long periods. The patient should be prepared for an altered voice quality postoperatively as well as for the possibility of total laryngectomy if the tumor proves too extensive for partial resection (Table 18-2). Types of partial laryngectomies include a vertical hemilaryngectomy, supraglottic laryngectomy, and supracricoid laryngectomy. With the advancements of cancer treatment (including the surgical excision of the tumor along with postoperative administration of chemotherapy concurrently with external beam radiation therapy), cure rates have increased while preserving some function of the larynx. The goal of partial laryngectomy is to avoid removing the entire larynx and to preserve the patient's natural swallowing ability. A successful partial laryngectomy should leave the patient with the ability to phonate, though usually with a more hoarse voice quality. The otolaryngologist must carefully stage the laryngeal cancer via a panendosopy with biopsy and determine the overall candidacy of the patient who may receive a partial laryngectomy. If tumor extension does not warrant a partial laryngectomy, a total laryngectomy must be performed. Steps and procedural considerations for a total laryngectomy are described next.

Total Laryngectomy

Total laryngectomy is the complete removal of the cartilaginous larynx, the hyoid bone, and the strap muscles connected to the larynx and possible removal of the preepiglottic space with the lesion. A wide-field laryngectomy is done when there is a loss of mobility of the cords and to treat cancer of the extrinsic larynx and hypopharynx (Figure 18-49). Malignant tumors of the extrinsic larynx are more anaplastic and tend to metastasize. When laryngeal carcinoma involves more than the true cords, a prophylactic (preventive) modified, or selective, neck dissection is done to remove the lymphatics. Depending on the extent and severity of disease in the neck, a radical neck dissection may be warranted though rarely routinely performed.

Laryngectomy presents many psychologic problems. The loss of voice that follows total laryngectomy is traumatic for the patient and family. The patient may be taught to talk by using either an esophageal voice or an artificial larynx. The esophageal voice is produced by the air contained in the esophagus rather than by that in the trachea. Speech requires a sounding air column. With instruction and practice, the patient is able to control the swallowing of air into the esophagus and the reintroduction of this air into the mouth with phonation. The sounding air column is then transformed into speech by means of the lips, tongue, and teeth. A tracheoesophageal fistula facilitates insertion of a Blom-Singer duckbill prosthesis for the purpose of speech (Figure 18-50, *A*). This fistula may be created during the initial surgical procedure (primary tracheoesophageal puncture [TEP]) or at a later date when healing has occurred (Figure 18-50, *B*).

Because the stump of the trachea is exteriorized to the skin of the neck to form a permanent stoma, all the patient's breathing is done directly into the trachea and no longer through the nose and mouth. The nose no longer moistens this air. Drying and crusting of the tracheal secretions occur. Humidification may be provided with a humidified tracheostomy collar or a humidified moisture exchange system later during the healing process. The patient will be anxious to know about postoperative voice quality, which depends on the specific procedure performed.

TABLE 18-2

Surgical Procedures for Laryngeal Carcinomas and Predictions of Vocal Quality after Surgery

Structures Removed	Structures Remaining	Postoperative Condition
TOTAL LARYNGECTOMY		
Hyoid bone	Tongue	Loses voice
Entire larynx (epiglottis, false cords, true cords)	Pharyngeal walls	Breathes through tracheostoma
Cricoid cartilage	Lower trachea	No problem swallowing
Two or three rings of trachea		
SUPRAGLOTTIC OR HORIZONTAL LARYNGECTOMY		
Hyoid bone	True vocal cords	Normal voice
Epiglottis	Cricoid cartilage	May aspirate occasionally, especially liquids
False vocal cords	Trachea	Normal airway
VERTICAL LARYNGECTOMY (OR HEMILARYNGECTOMY)		
One true vocal cord	Epiglottis	Hoarse but serviceable voice
One false cord	One false cord	Normal airway
Arytenoid	One true vocal cord	No problem swallowing
Half thyroid cartilage	Cricoid	
PARTIAL LARYNGECTOMY		
One vocal cord	All other structures	Hoarse but serviceable voice; occasionally almost normal voice No airway problem No swallowing problem
TRANSORAL CORDECTOMY		
Portion or all of one vocal cord	All other structures	May have normal/hoarse voice No other problems
LASER SURGERY		
Tumor only removed	All other structures	Normal/hoarse voice

From Workman ML: Interventions for clients with noninfectious problems of the upper respiratory tract. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, Philadelphia, 2010, Saunders.

Procedural Considerations. The patient is placed on the OR bed in a supine position with the neck extended and shoulders elevated by a shoulder roll or folded sheet. A general anesthetic is administered. Airway considerations are paramount when approaching a patient with laryngeal cancer. An awake tracheostomy may be performed initially to control the airway, and occasionally patients have previously placed tracheostomy tubes. If the tracheostomy is performed initially or is pre-existing, the use of a cuffed, wire-reinforced, flexible endotracheal tube will ensure effective delivery of the anesthetic and give the surgical team flexibility as the larynx and trachea are manipulated during the surgical procedure. An effective suction apparatus is essential. The proposed operative site, including the anterior neck region, the lateral surfaces of the neck down to the outer aspects of the shoulders, and the upper anterior chest region, is prepped and draped in the usual manner. The instrument setup is a neck dissection set.

Operative Procedure

1. The surgeon makes a midline incision from the suprasternal notch to just above the hyoid bone. Skin flaps are undermined on each side. The sternothyroid, sternohyoid, and omohyoid muscles (strap muscles) on each side are divided by means of curved hemostats and a knife.
2. The suprahyoid muscles are severed from the portion of the hyoid to be divided. The hyoid bone is skeletonized with care to preserve the hypoglossal nerves. Bleeding vessels are clamped and ligated.
3. The superior laryngeal nerve and vessels are exposed and ligated on each side with long, curved fine hemostats and fine ligatures.
4. The isthmus of the thyroid gland is divided between hemostats. Each portion of the thyroid gland is dissected from the trachea with Metzenbaum scissors and fine tissue forceps. The superior pole of the thyroid is retracted. The superior thyroid vessels are freed from the larynx by sharp dissection. Sometimes, one or both lobes of the thyroid gland are included in the resection for oncologic purposes.
5. The larynx is rotated. The inferior pharyngeal constrictor muscle is severed from its attachment to the thyroid cartilage on each side.
6. The endotracheal tube is removed. The trachea is transected with care to keep an adequate margin from the tumor. The upper resected portion of the trachea and the cricoid cartilage are held upward with Lahey forceps. A balloon-cuffed, wire-reinforced endotracheal tube is inserted into the distal portion of the trachea.
7. The larynx is freed from the cervical esophagus and attachments by sharp and blunt dissection. A moist pack is placed around the endotracheal tube to help prevent leakage of blood into the trachea.
8. The pharynx is entered. In most cancers of the intrinsic larynx, the pharynx is entered above the epiglottis. The mucous membrane incision is extended along either side of the epiglottis; the remaining portion of the pharynx and cervical esophagus is dissected well away from the tumor

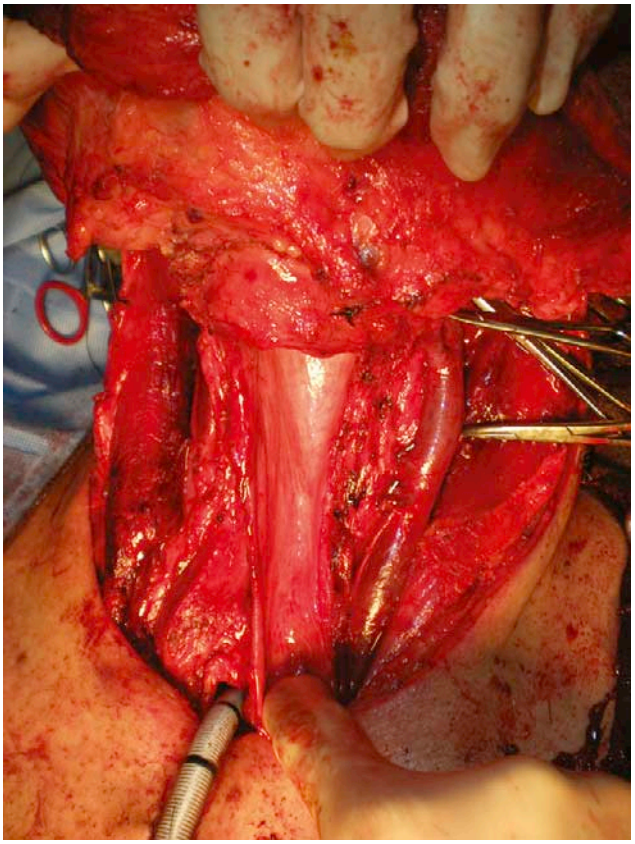

FIGURE 18-49 Wide-field defect following removal of the larynx.

by means of fine-toothed tissue forceps, Metzenbaum scissors, knife, and fine hemostats. The specimen is removed en bloc (Figure 18-51).

9. A nasal feeding tube is inserted through one naris into the esophagus; closure of the hypopharyngeal and esophageal defect is begun with continuous inverting fine 3-0 absorbable sutures. The nasal tube is guided down past the pharyngeal suture line.
10. The pharyngeal suture line is reinforced with running horizontal or vertical mattress Vicryl sutures; the suprahyoid muscles are approximated to the cut edges of the inferior constrictor muscles.
11. The diameter of the tracheal stoma is increased by means of a knife and heavy scissors. The two portions of the thyroid behind the tracheal opening are approximated with interrupted nonabsorbable sutures, thereby obliterating dead space posterior to the upper portion of the trachea.
12. Using a scalpel, the surgeon makes a small puncture wound through the neck, lateral to the incision, using the tips of a hemostat inserted on the inner wound bed as a guide.
13. The hemostat is then switched into the puncture wound, grasping the distal drain tubing and pulling it through until the fluted portion of the drain is visible in the wound bed. The drain is trimmed and measured to fit into the wound.
14. The drain is secured to the skin just lateral to where the puncture wound was made and an air knot is tied using square knots.
15. The edges of the deep cervical fascia and the platysma are closed separately.

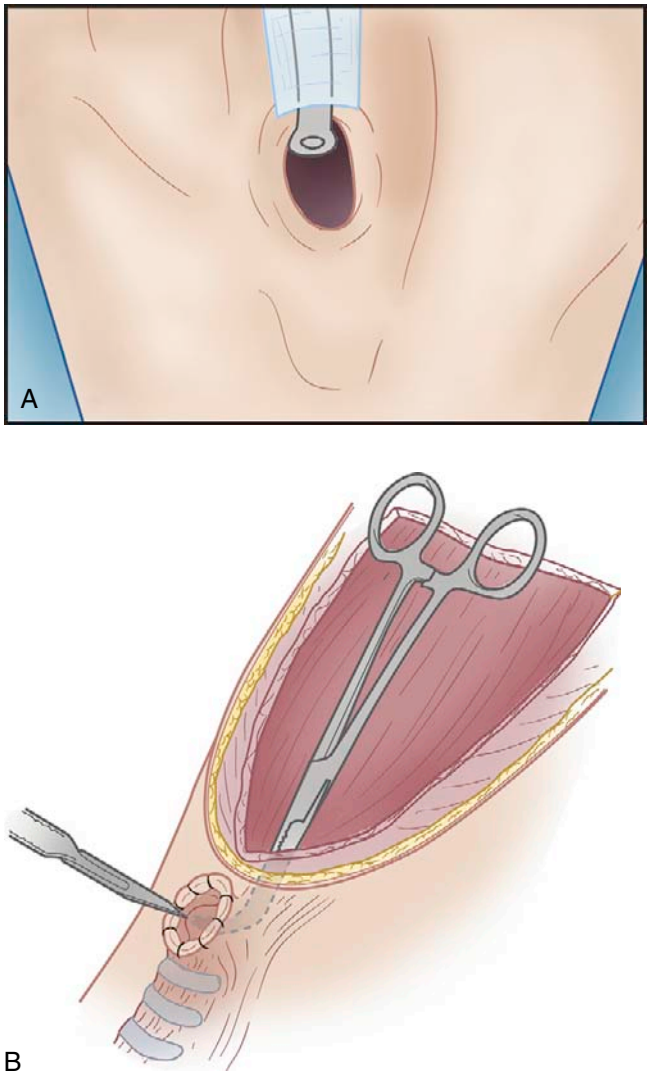

FIGURE 18-50 Artificial larynx to facilitate speaking. **A**, Speech valve in place. **B**, Primary tracheoesophageal puncture technique. Note preliminary repair of stoma to allow accurate positioning of puncture site before pharyngeal closure. Feeding tube (14F) is inserted through puncture down esophagus to the stomach.

16. A laryngectomy tube of desired size is inserted into the tracheal stoma; a pressure dressing may be applied to the wound and neck, although some surgeons prefer leaving the wound without dressings to observe the skin flaps.

Radical Neck Dissection

In a radical neck dissection, the tumor, all soft tissue from the inferior aspect of the mandible to the midline of the neck to the clavicle end posterior to the trapezius muscle, and lymph nodes are removed en bloc from the affected side of the neck. This procedure is done to remove the tumor and metastatic cervical nodes present in malignant lesions as well as all nonvital structures of the neck (Figure 18-52). Metastasis occurs through the lymphatic channels by way of the bloodstream. Diseases of the oral cavity, lips, and thyroid gland may spread slowly to the neck. Radical neck surgery is done in the presence of cervical node metastasis from a cancer of the head and neck that has a reasonable chance of being controlled. Sentinel node

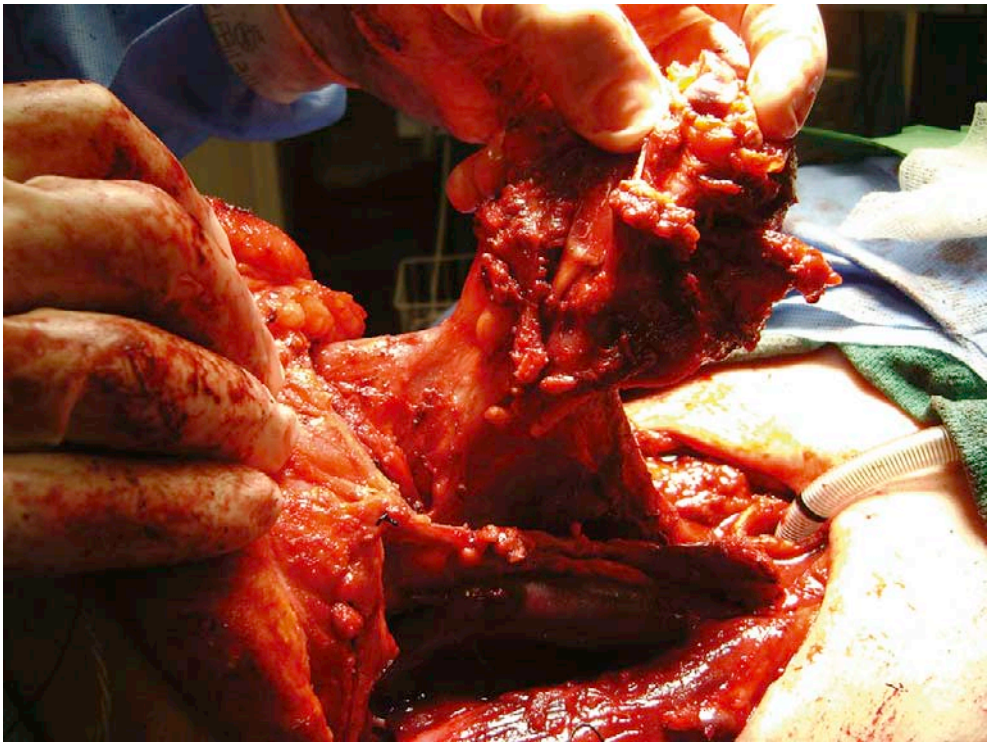

FIGURE 18-51 Removal of the larynx en bloc.

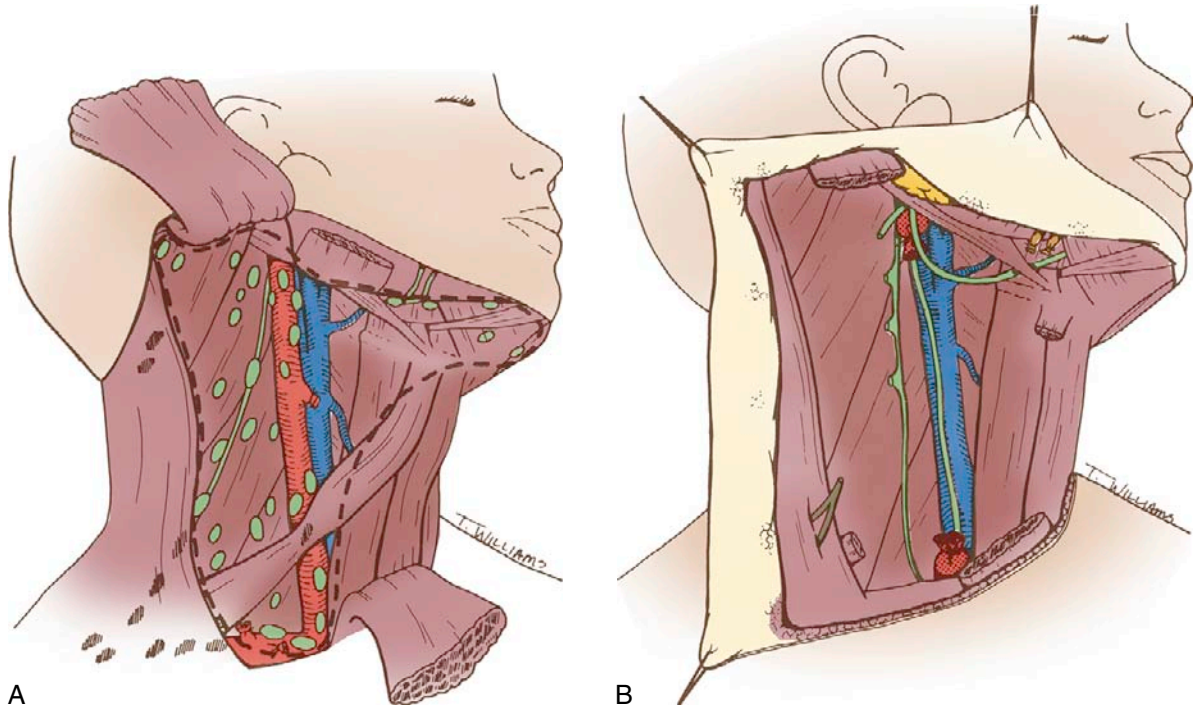

FIGURE 18-52 Radical neck dissection. **A**, Diagram of extent of operation. **B**, Diagram of operation.

biopsy may also be performed in conjunction with a neck dissection (Box 18-2).

A prophylactic neck dissection implies an elective neck dissection when there is no clinical evidence of metastatic cancer in the cervical lymph nodes.

Procedural Considerations. The patient is placed on the OR bed in a supine position. General endotracheal anesthesia is induced before the patient is positioned for surgery. A shoulder roll may be placed to slightly hyperextend the neck with the head slightly turned to the contralateral side. The

BOX 18-2

Sentinel Lymph Node Mapping and Biopsy

In many oral cancers, the nearby lymph nodes are routinely removed during surgery (known as a lymph node dissection). The sentinel node procedure can help the surgeon determine whether the cancer has already spread to these nodes, which may allow the patient to avoid more extensive surgery if the cancer has not metastasized. Sentinel node mapping and biopsy allow the surgeon to identify and examine the "sentinel node(s)"—the first node(s) affected by the cancer before metastasis to other lymph nodes. If the sentinel node does not contain cancer, it is very unlikely that any other nodes would contain cancer.

In this procedure, the surgeon injects a radioactive material around the tumor, usually the day before surgery. The material will travel the same route that any cancer cells would likely have taken if they had spread to the lymph nodes. On the day of surgery a blue dye is injected into the tumor site, which will also travel to the nearby lymph nodes.

During surgery, the surgeon can use a radiation detector to identify the lymph node region that is the source of radioactivity (and presumably cancer). The surgeon then cuts into the area to look for radioactive or blue-stained lymph nodes. These are removed and examined by a pathologist. If there is no cancer, then no further surgery is needed. If there is cancer, then all the lymph nodes in the area will be removed.

This procedure is still experimental, and more work is needed to determine if this can replace routine lymph node removal.

Modified from *What's new in oral cavity and oropharyngeal cancer research and treatment?*, available at www.cancer.org/docroot/CRI/content/CRI_2_4_6X_Whats_new_in_oral_cavity_and_oropharyngeal_cancer_research_and_treatment_60.asp. Accessed August 9, 2009.

head of the bed may be slightly elevated to reduce venous bleeding.

During the operation the anesthesia provider works behind a sterile barrier at the patient's unaffected side. The preoperative skin prep is extensive, including the neck, lower face, and upper chest. The patient's neck is draped so as to leave a wide operative field. On occasions, local muscle flaps are harvested to cover and protect the carotid artery (as when a patient has received extensive previous radiation therapy). If this is the case, the thigh area is also prepped and draped with sterile towels in readiness for obtaining a dermal graft before closure of the neck wound. It is usually more convenient to use the thigh on the same side as the neck dissection. Patient and family education includes tracheostomy care (if applicable), pain management, care of the surgical incision, reportable signs and symptoms, healthful behaviors, and review of physical therapy exercises.

Operative Procedure

1. One of several types of incisions may be used, including the Y-shaped, H-shaped, or trifurcate incision (Figure 18-53), all of which aim for complete lymphadenectomy while preserving good, viable skin flaps.
2. The upper curved incision is made through the skin and platysma with a knife, tissue forceps, and fine hemostats; ligatures are used for bleeding vessels. The upper flap is retracted; then the vertical portion of the incision is made, and the skin flaps are retracted anteriorly and posteriorly with retractors. The anterior margin of the trapezius muscle is exposed by means of curved scissors. The flaps are retracted to expose the entire lateral aspect of the neck. Branches of the jugular veins are clamped, ligated, and divided.
3. The sternal and clavicular attachments of the sternocleidomastoid muscle are clamped with curved Péan forceps and then divided with a knife. The superficial layer of deep fascia is incised. The omohyoid muscle is severed between clamps just above its scapular attachment.
4. By sharp and blunt dissection, the carotid sheath is opened. The internal jugular vein is isolated by blunt dissection and then doubly clamped, doubly ligated with medium silk, and divided with Metzenbaum scissors. A transfixion suture is placed on the lower end of the vein.
5. The common carotid artery and vagus nerve are identified and protected. The fatty areolar tissue and fascia are dissected and removed using Metzenbaum scissors and fine tissue forceps. Branches of the thyrocervical artery are clamped, divided, and ligated.
6. The tissues and fascia of the posterior triangle are dissected, beginning at the anterior margin of the trapezius muscle and continuing near the brachial plexus and the levator scapulae and scalene muscles. During the dissection, branches of the cervical and suprascapular arteries are clamped, ligated, and divided.
7. The anterior portion of the block dissection is completed. The omohyoid muscle is severed at its attachment to the hyoid bone. Bleeding is controlled. All hemostats are removed, and the operative site may be covered with warm, moist laparotomy packs.
8. The sternocleidomastoid muscle is severed and retracted. The submental space is dissected free of fatty areolar tissue and lymph nodes, from above downward.
9. The deep fascia on the lower edge of the mandible is incised; the facial vessels are divided and ligated.
10. The submandibular triangle is entered. The submandibular duct is divided and ligated. The submandibular glands with surrounding fatty areolar tissue and lymph nodes are dissected toward the digastric muscle. The facial branch of the external carotid artery is divided. Portions of the digastrics and stylohyoid muscles are severed from their attachments to the hyoid bone and on the mastoid. The upper end of the internal jugular vein is elevated and divided. The surgical specimen is removed.
11. The entire field is examined for bleeding and then irrigated with warm saline solution. Although rarely necessary, a skin graft may be placed to cover the bifurcation of the carotid artery, extending down approximately 4 inches, and sutured with 4-0 absorbable suture on a very small cutting needle.
12. Closed wound suction drains are placed into the wound.
13. The flaps are carefully approximated with interrupted fine nonabsorbable sutures or with skin staples. A bulky pressure dressing may be applied to the neck, depending on surgeon preference.

Modified Neck Dissection

Modified neck dissection (Figure 18-54) is removal of neck contents, except for the sternocleidomastoid muscle, internal jugular vein, and eleventh cranial nerve.

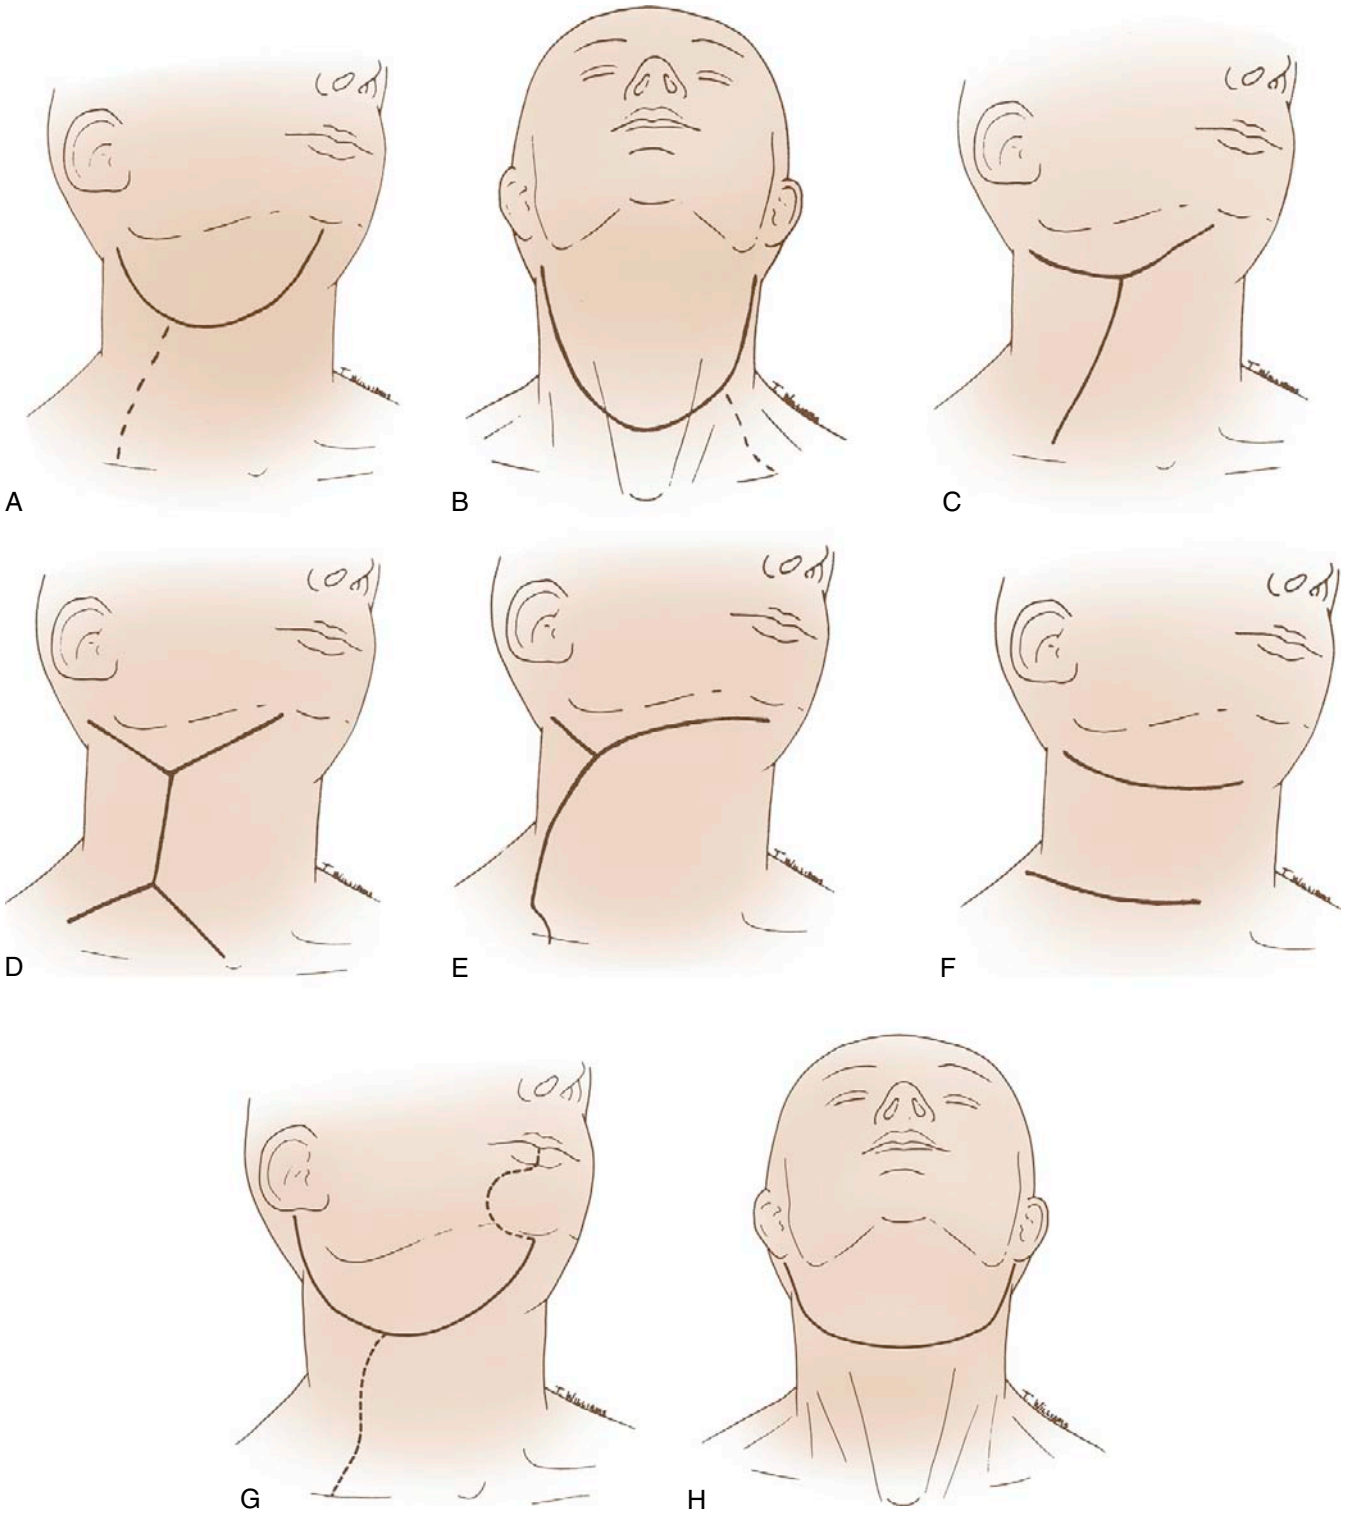

FIGURE 18-53 Dissection incisions. **A**, Latyshevsky and Freund. **B**, Freund. **C**, Crile. **D**, Martin. **E**, Babcock and Conley. **F**, McFee. **G**, Incision used for unilateral supraomohyoid neck dissection. **H**, Incision used for bilateral supraomohyoid neck dissection.

Procedural Considerations. This modified type of neck dissection facilitates removal of a tumor and lymph nodes suspected of metastases and allows the patient a minimal defect and minimally impaired shoulder function. With radical and modified neck dissection, the surgeon and medical and radiation oncologists may decide on a course of postoperative radiation therapy or chemotherapy. The decision depends on the type and location of tumor, stage of disease, and condition of the patient. Research on chemotherapy protocols to avoid extensive surgical dissection is ongoing.

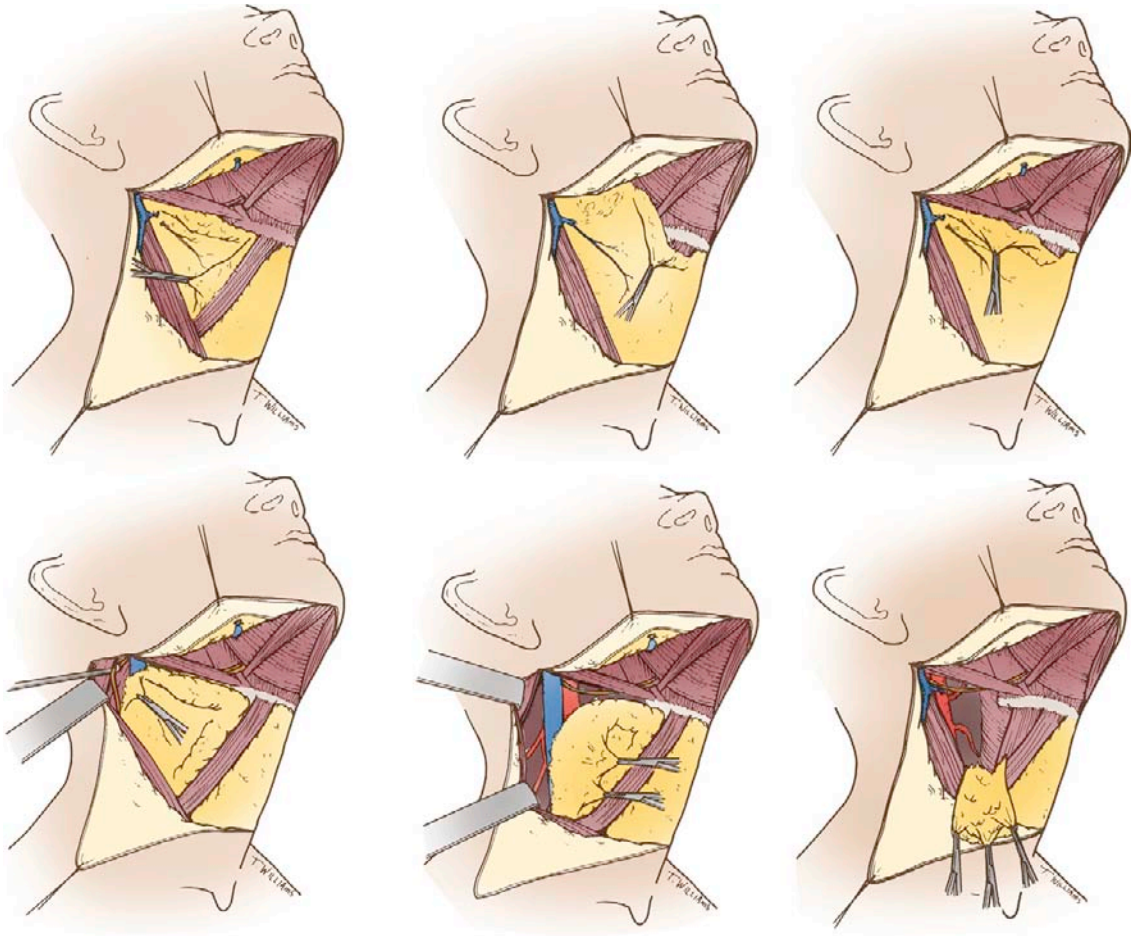

FIGURE 18-54 Steps of modified radical neck dissection with preservation of spinal accessory nerve, internal jugular vein, and sternocleidomastoid muscle.

Reconstructive Procedures

Depending on the surgical defect, head and neck surgical procedures to remove malignant tumors also involve reconstructive procedures. The wound may be closed primarily, or local flaps and split-thickness skin grafts (as for facial and intraoral defects) or full-thickness skin grafts (as for nasal and facial defects) may be used. Regional flaps (e.g., pectoralis major musculocutaneous flap), microvascular tissue transfer (e.g., radial forearm, lattisimus dorsi, anterior lateral thigh free flap), or microvascular osteocutaneous flaps (e.g., fibula free flap) may be used to restore function as well as cover defects. Combinations of these grafts and flaps are often necessary when large defects are created. Skin grafts and flaps are discussed in Chapter 24.

If microvascular flaps are used, surgical and anesthesia time is extended significantly (approximately 8 to 12 hours); since veins and arteries are microscopically connected, nerve grafts may be used, and bone must be connected with the use of plates and screws.

The use of a Doppler unit (intraoperatively and postoperatively) and thorough nursing assessment skills are paramount in detecting occlusions or spasms of the vessels and subsequent survival of the transplanted flap.

CHAPTER 19

Orthopedic Surgery

BARBARA BOWEN

The word *orthopédie* is derived from the Greek *orthos,* meaning "straight," and *paideia,* meaning "rearing of children." It was first used by Nicholas Andry in 1741 in the title for a book addressing the prevention and correction of skeletal deformities in children. Orthopedic surgery has been defined by the American Association of Orthopaedic Surgeons' Board of Orthopaedic Surgery as "a broad based medical and surgical specialty dedicated to the prevention, diagnosis, and treatment of diseases and injuries of the musculoskeletal system" (American Board of Orthopaedic Surgeons [ABOS], 2009).

Orthopedic surgery is an ever-changing field that is a challenge for the perioperative nurse. Technologic advances in the multitude of systems and hardware used have resulted in improved treatment of orthopedic disorders. In addition to understanding anatomic and physiologic responses, the perioperative nurse should have a general understanding of the concepts and purposes of these systems to provide the most safe and efficient care. Knowledge of the principles of bone fixation and healing and the relationship of bone and soft tissues will provide a strong basis to ensure continued understanding of the care required for the orthopedic patient.

Surgical Anatomy

Anatomic Structures

The 206 bones of the body form the appendicular or axial framework that supports soft tissues, provides storage areas and reservoirs for minerals, and serves as a site for formation of blood cells (Figure 19-1). The skeletal system is composed of varied elements, including bone, muscle, and associated structures.

Bone remains in a constant state of formation and resorption, preventing development of excessive thickness or thinness. These processes are related to individual metabolism and absorption of calcium, vitamin D, and phosphorus. Levels of minerals affect disease processes, causing bone changes. A layer of connective tissue called *periosteum* covers all bone.

Muscles are masses of tissue that cover bones and provide movement to the skeletal system. Muscles interact with nerves, minerals, skin, and other connective tissue to contract and extend. Individual muscles are short or long and vary in diameter, depending on their position on a specific bone.

Ligaments, tendons, and cartilage also form the skeletal structures. Ligaments are bands of dense connective tissue that hold bone to bone. They provide stability to a joint by encircling or holding ends of bone in place. Tendons are tough, long strands of fibers that form the ends of muscles. They transmit forces to bone or cartilage without being damaged. Cartilage is a layer of elastic, resilient supporting tissue found at the ends of the bones. It forms a cap over the bone end to protect and support the bone during weight-bearing activities and provides a smooth gliding surface for joint movement. Cartilage is aneural (without nerves), alymphatic (without lymph tissue), avascular (without blood vessels), and high in water content. The lack of vascularity and loss of water from cartilage during a lifetime are causes of resulting degenerative disease, such as arthritis. Weight bearing and joint movements keep cartilage from becoming thin or damaged and help prevent degenerative conditions.

Joints are articulations where bones are joined to one another or where two surfaces of bones unite. Joints are classified by the type of material between them or according to movement. Material between joints is fibrous, cartilaginous, or synovial. The type of movement is synarthrotic (immovable), amphiarthrotic (slightly movable), or diarthrotic (freely movable). Synarthrotic joints are connected by fibrous tissue or ligaments (e.g., the suture type of joints holding the bones of the skull; connections between two bones, such as the radius and ulna). Amphiarthrotic joints are connected by cartilage. Joints of this type include the symphysis pubis, intervertebral joints, and manubriosternal joint. The majority of joints are diarthrotic; these are the only joints with one or more ranges of motion. These joints are lined with a synovial membrane and are called *synovial joints.* Examples include the knee, cervical vertebrae 1 and 2 (C1 and C2), the radius articulating on the wrist bones, the hip, and the shoulder.

The two types of bone tissue are *cortical* and *cancellous.* Cortical bone is the hard bone forming the outer shell—the main supporting tissue. Cancellous bone is soft and spongy—located at the iliac crest, tibia, sternum, and ends of long bones. It contains the red bone marrow for hematopoiesis.

Bones are divided according to their shape: long, short, flat, irregular, and round (Figure 19-2). Long bones are present in the limbs and consist of a shaft and two ends; the ends generally flare out, are covered with articular cartilage, and provide a surface for articulation and musculotendinous attachment. Short bones, such as the carpals and tarsals (in the wrist and midfoot areas, respectively), are present where the structure is strong but limited movement is required. Flat bones are the scapula, the sternum, and the pelvic girdle. Irregular bones are found in the skull and vertebral column. Round bones, or sesamoid bones (resembling a sesame seed), are found within tendons. The patella is a large sesamoid bone; however, most are small, such as the two found on the head of the first metatarsal, which form the "ball" of the foot.

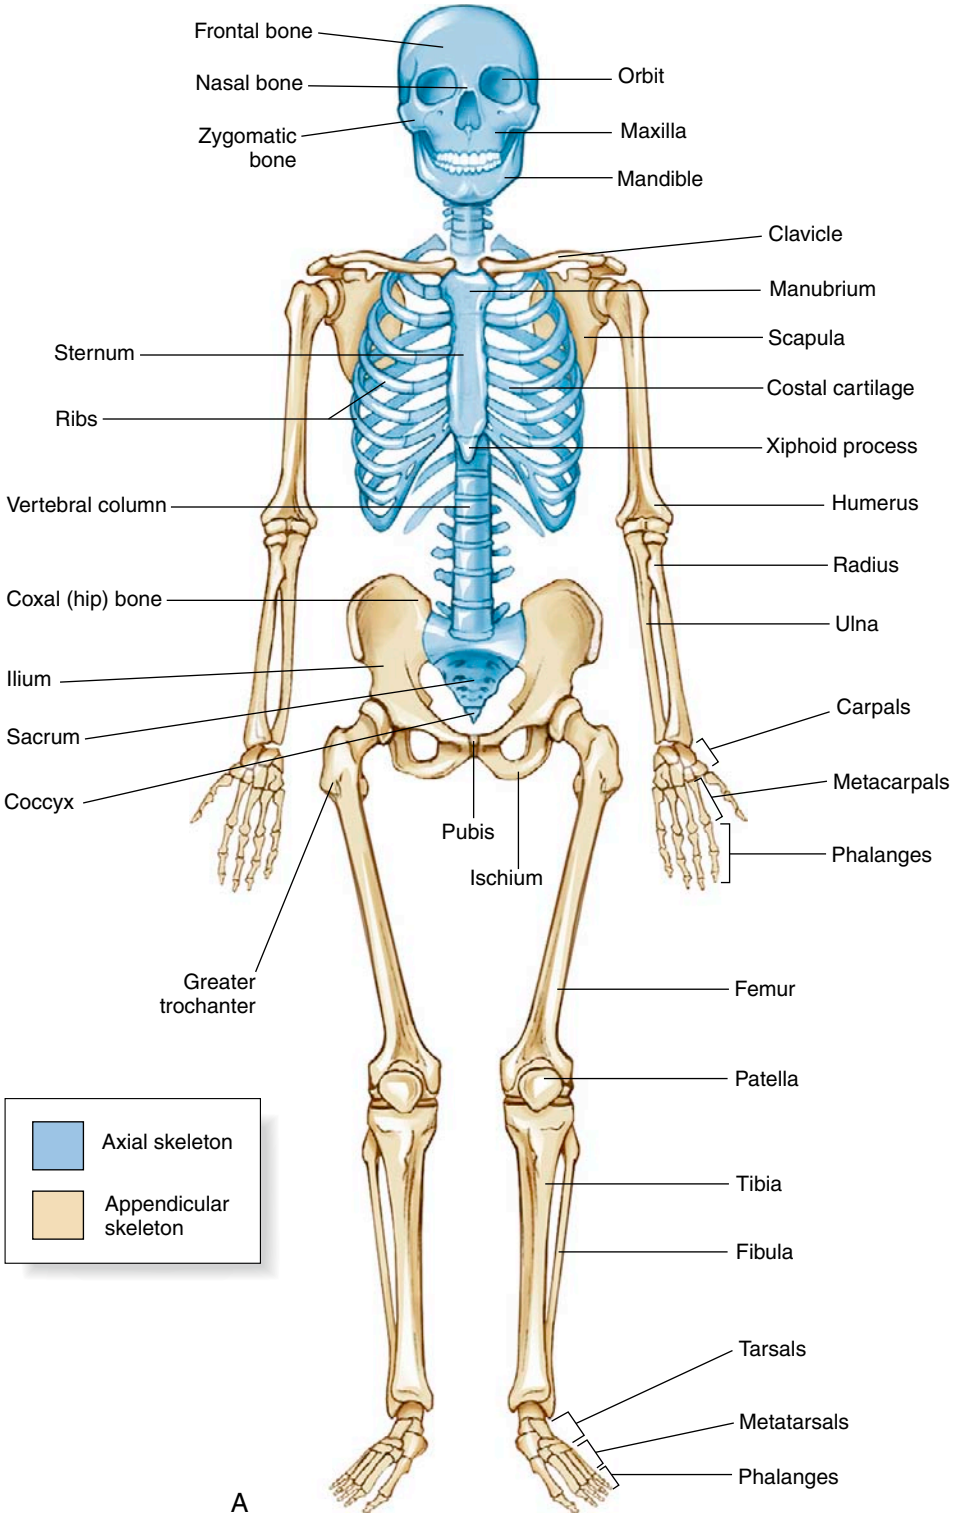

FIGURE 19-1 A, Anterior view of the skeleton.

Long bones consist of a shaft (diaphysis) and two ends (epiphyses). The shaft is composed of compact bone. The epiphyses flare out and consist of cancellous bone. They are covered by cartilage, which provides a cushion and offers protection during weight bearing and movement. Until skeletal maturity, a line of cartilage called the *epiphyseal plate* separates the epiphysis from the diaphysis. Fractures in this region by children can be devastating because they often lead to malformation and permanent limb shortening.

Trabeculae are located within cancellous bone and consist of an interconnecting network of bone oriented along the lines

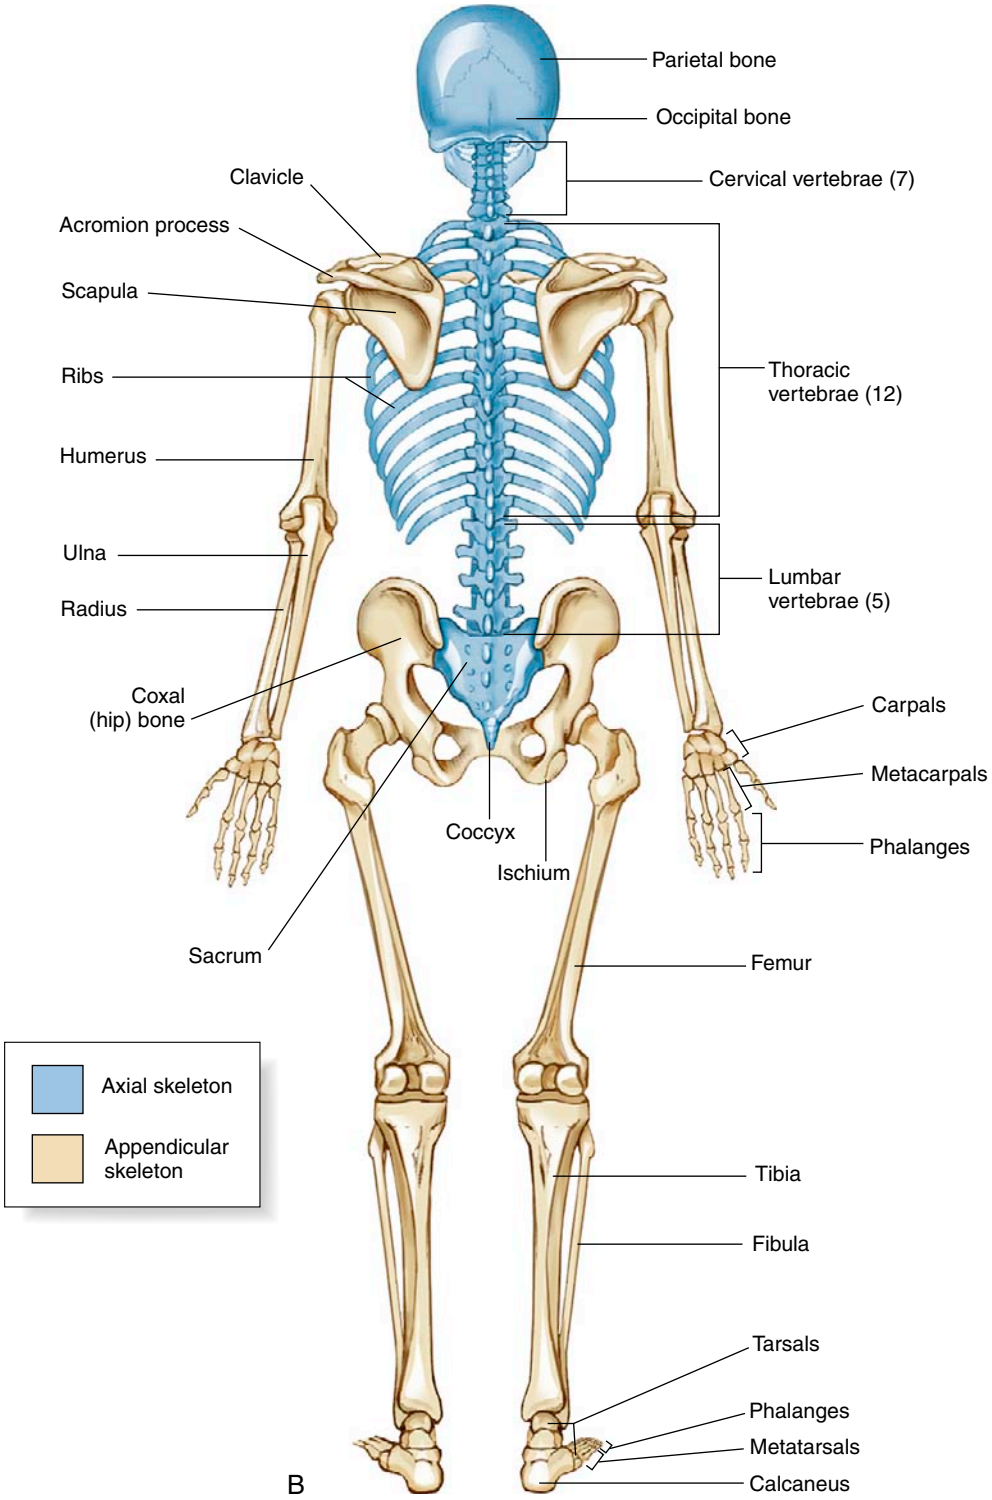

FIGURE 19-1, cont'd B, Posterior view of the skeleton.

of stress. These structures are important for weight bearing, providing strength to withstand stress placed on the bone. The periosteum is a thin, outer covering of bone containing nutrient arteries for nourishment of bone cells. Disruption of these periosteal vessels after bone trauma can influence the ability of bone to heal. The haversian system consists of thousands of microscopic units found in the cortical bone. These units of matrix cells, canals, and conduits allow flow of nutrients and facilitate calcium absorption.

Vertebrae

Vertebrae form the longitudinal axis of the skeleton. The vertebral bodies are connected by several cartilaginous joints, which enable the vertebrae to flex, extend, or rotate

while being held together. Intervertebral discs and ligaments connect the bodies of adjacent vertebrae. The ligamenta flava bind the laminae of adjacent vertebrae together. Other ligaments connect the spinous processes and vertebral bodies.

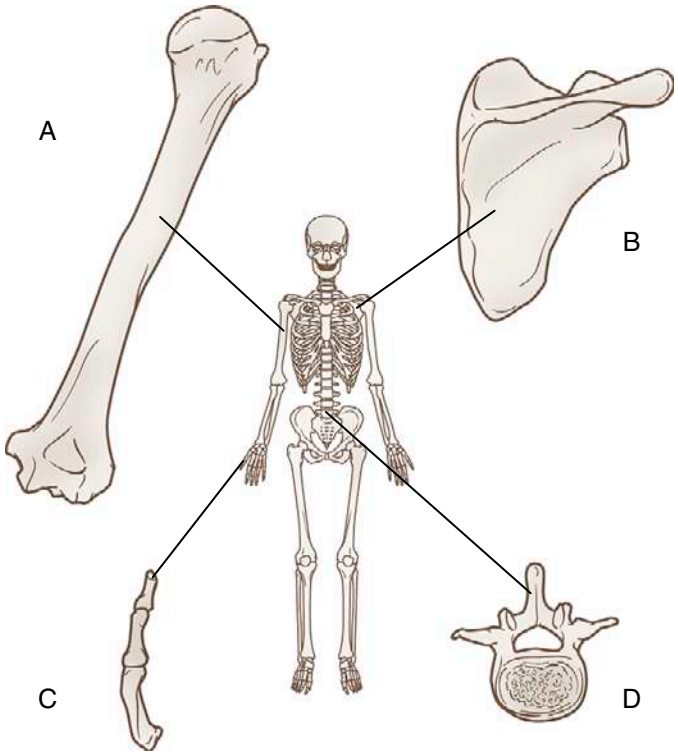

FIGURE 19-2 Types of bones, as examples. **A**, Long bones (humerus). **B**, Flat bones (scapula). **C**, Short bones (phalanx). **D**, Irregular bones (vertebra).

Seven cervical vertebrae form the skeletal framework of the neck. Twelve thoracic vertebrae support the thoracic region, and five lumbar vertebrae support the small of the back. Below the lumbar vertebrae lie the sacrum and coccyx. Each of these bones is composed of fused vertebrae—five for the sacrum and four for the coccyx.

The vertebral column is curved. After birth, there is a continuous posterior convexity. As development occurs, secondary posterior concavities develop in the cervical and lumbar regions, resulting in improved balance.

Each area of the vertebral column has specific bony structures. General features include a body (except the first two cervical vertebrae) on the anterior part. The posterior portion of the vertebrae consists of a neural arch formed by pedicles and laminae and the spinous and transverse processes.

Shoulder and Upper Extremity

The clavicle, which is a long, doubly curved bone, serves as a prop for the shoulder and holds it away from the chest wall. The clavicle rests almost horizontally at the upper and anterior part of the thorax, above the first rib. It articulates medially with the manubrium of the sternum and laterally with the acromion of the scapula; it is tethered to the underlying coracoid process of the scapula by the coracoclavicular ligaments.

The scapula (shoulder blade) is a flat, triangular bone that forms the posterior part of the shoulder girdle, lying superior and posterior to the upper chest. The glenoid cavity on the lateral side of the scapula provides a socket for the humerus (the bone of the upper arm). The acromion process articulates with the clavicle medially. The scapula is attached to the thorax by muscles.

The shoulder (pectoral) girdle consists of the glenohumeral, sternoclavicular, and acromioclavicular (AC) joints (Figure 19-3). The glenohumeral joint has a multidirectional range of motion, whereas the latter two joints have limited motion.

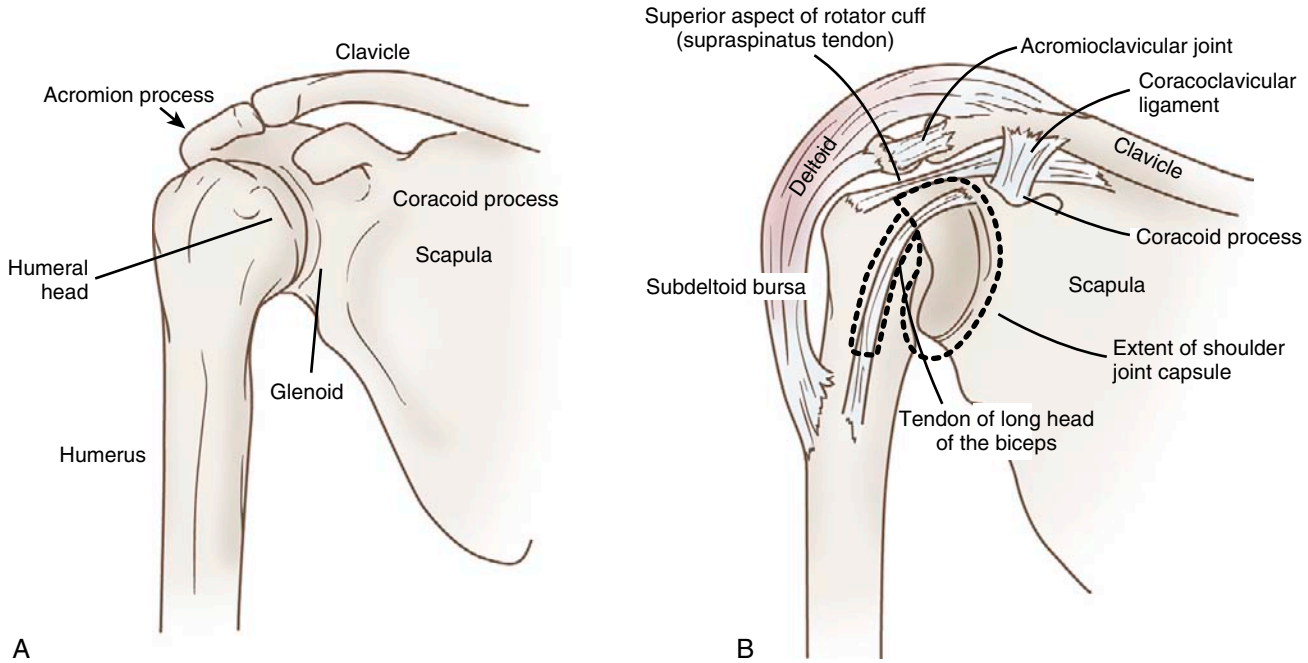

FIGURE 19-3 Shoulder. **A**, Joint showing anterior view. **B**, Girdle showing articulations.

The AC joint, located at the top of the shoulder, is the articulation between the outer end of the clavicle and a flattened articular facet situated on the inner border of the acromion. The muscles immediately surrounding the shoulder joint are the supraspinatus, infraspinatus, teres minor, and subscapularis muscles; together they are referred to as the *rotator cuff*. These muscles stabilize the shoulder joint, whereas the powerful deltoid, pectoralis major, teres major, and latissimus dorsi muscles move the entire arm. Shoulder girdle strength and stability are maintained by the soft tissue integrity—not the bony structures. A pathologic condition in this area can be the result of bone, soft tissue, or combined injury.

The humerus is the longest and largest bone of the upper extremity. It is composed of a shaft and two ends. The proximal end, or head, has two projections—the greater and lesser tuberosities (Figure 19-4). The circumference of the articular surface of the humerus is constricted and is termed the *anatomic neck*. The anatomic neck marks the attachment to the capsule of the shoulder joint. The constriction below the tuberosities is called the *surgical neck* and is the site of most fractures.

The greater tuberosity is situated at the lateral aspect of the humeral head. Its upper surface has three impressions where the supraspinous, infraspinous, and teres minor tendons insert. The lesser tuberosity is situated in the anterior neck and has an impression for the insertion of the tendon of the subscapular muscle. The attachment sites for the rotator cuff, the tuberosities, are separated from each other by a deep groove (bicipital groove), in which lies the tendon of the long head of the biceps muscle of the arm. The tendon of the pectoralis major inserts on the lateral margin of the bicipital groove, and the latissimus dorsi and teres major insert on the medial margin.

The distal humerus flattens and ends in a broad articular surface. The surface is divided into the medial and lateral condyles, which are separated by a slight ridge. On the lateral condyle, the rounded articular surface is called the *capitulum,* which articulates with the head of the radius. On the medial condyle, the articular surface is termed the *trochlea,* which articulates with the ulna.

The ulna is located medial to the radius. The proximal portion of the ulna, the olecranon, articulates with the trochlea of the humerus at the elbow. The radius rotates around the ulna. At the proximal end is the head, which articulates with the capitulum of the humerus and the radial notch of the ulna. The tendon of the biceps muscle is attached to the tuberosity just below the radial head. The distal end of the radius is divided into two articular surfaces. The distal surface articulates with the carpal bones of the wrist, and the surface on the medial side articulates with the distal end of the ulna.

Wrist and Hand

The skeletal bones of the wrist and hand consist of three distinct parts: (1) the carpals, or wrist bones; (2) the metacarpals, or bones of the palm; and (3) the phalanges, or bones of the digits (Figure 19-5).

The eight carpal bones are arranged in two rows. The distal row, proceeding from the radial to the ulnar side, includes

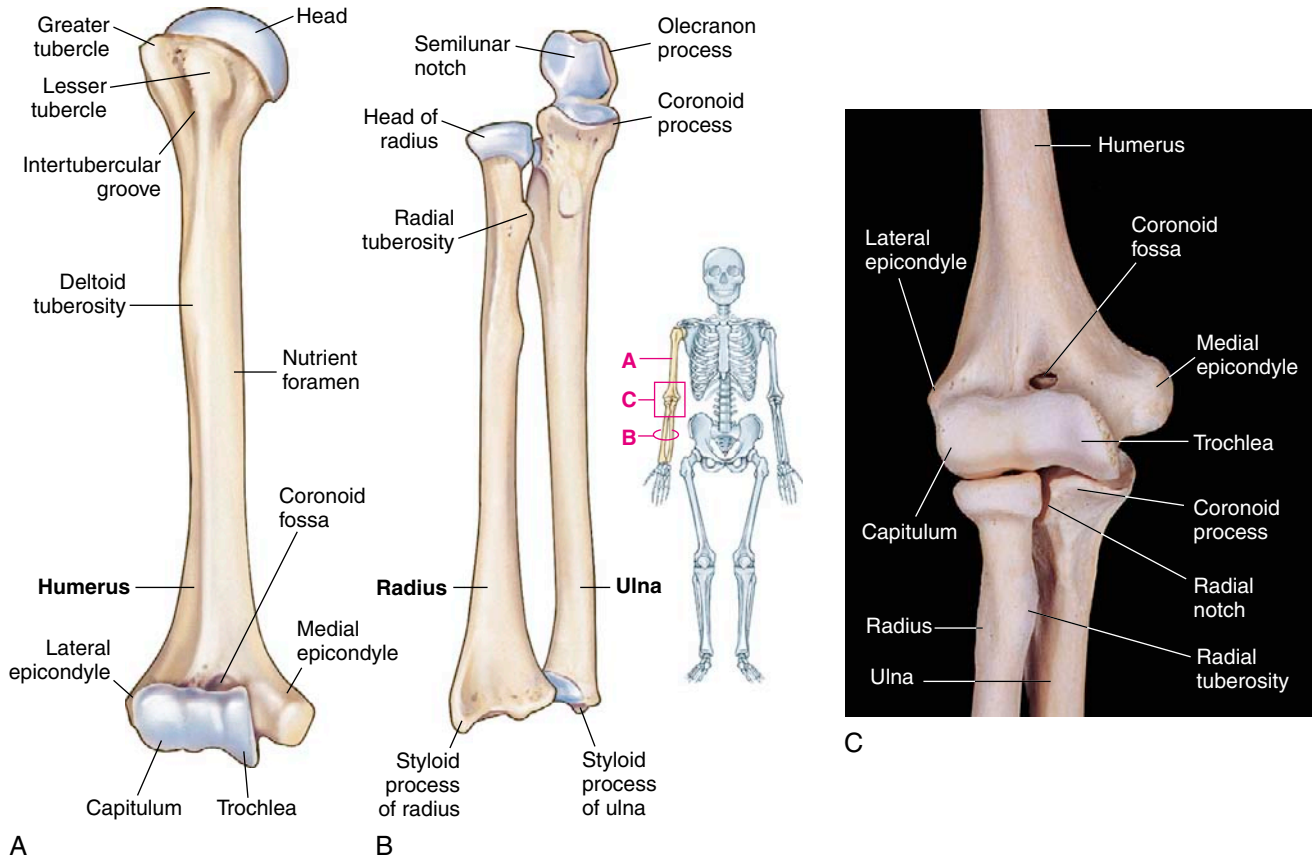

FIGURE 19-4 Bones of the arm, anterior view, showing the humerus, radius, and ulna.

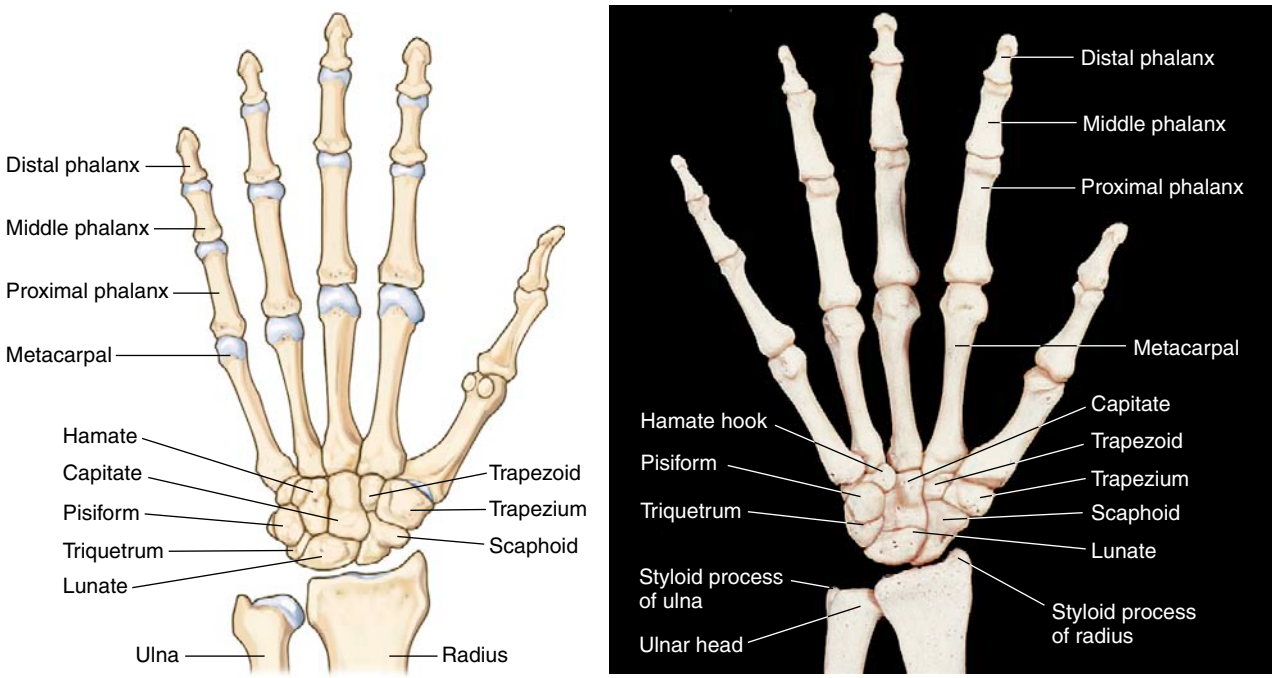

FIGURE 19-5 Bones of the wrist and hand, palmar view.

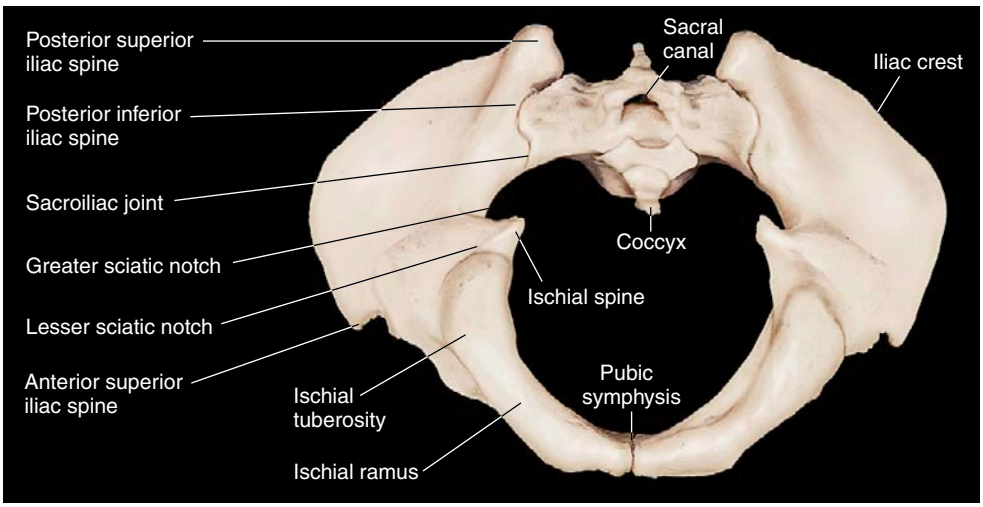

FIGURE 19-6 Pelvis, superior view.

the trapezium, trapezoid, capitate, and hamate; the proximal row consists of the scaphoid (also called the *navicular*), lunate, triquetrum, and pisiform. Functionally, the scaphoid links the rows as it stabilizes and coordinates the movement of the proximal and distal rows. Each carpal bone consists of several smooth articular surfaces for contact with the adjacent bones, as well as rough surfaces for the attachment of ligaments. The five metacarpal bones (long bones) are situated in the palm. Proximally they articulate with the distal row of carpal bones, and distally the head of each metacarpal articulates with its proper phalanx. The heads of the metacarpals form the knuckles. The phalanges, or fingers, consist of 14 bones in each hand—2 in the thumb and 3 in each finger. Each phalanx consists of a shaft and two ends.

Pelvis, Hip, and Femur

The pelvis (Figure 19-6) is a stable circular base that supports the trunk and forms an attachment for the lower extremities. It is a massive, irregular bone created by the fusion of three separate bones. The largest and uppermost of the three bones is the ilium, the strongest and lowermost is the ischium, and the anterior-most is the pubis. Together these are termed the *os coxae,* or innominate bone.

The acetabular portion of the innominate bone and the proximal end of the femur (Figure 19-7) form the hip, which is a ball-and-socket joint. The hip joint is surrounded by a capsule, ligaments, and muscles that provide stability. The iliofemoral ligament connects the ilium with the femur anteriorly and superiorly, and the ischiofemoral and pubofemoral

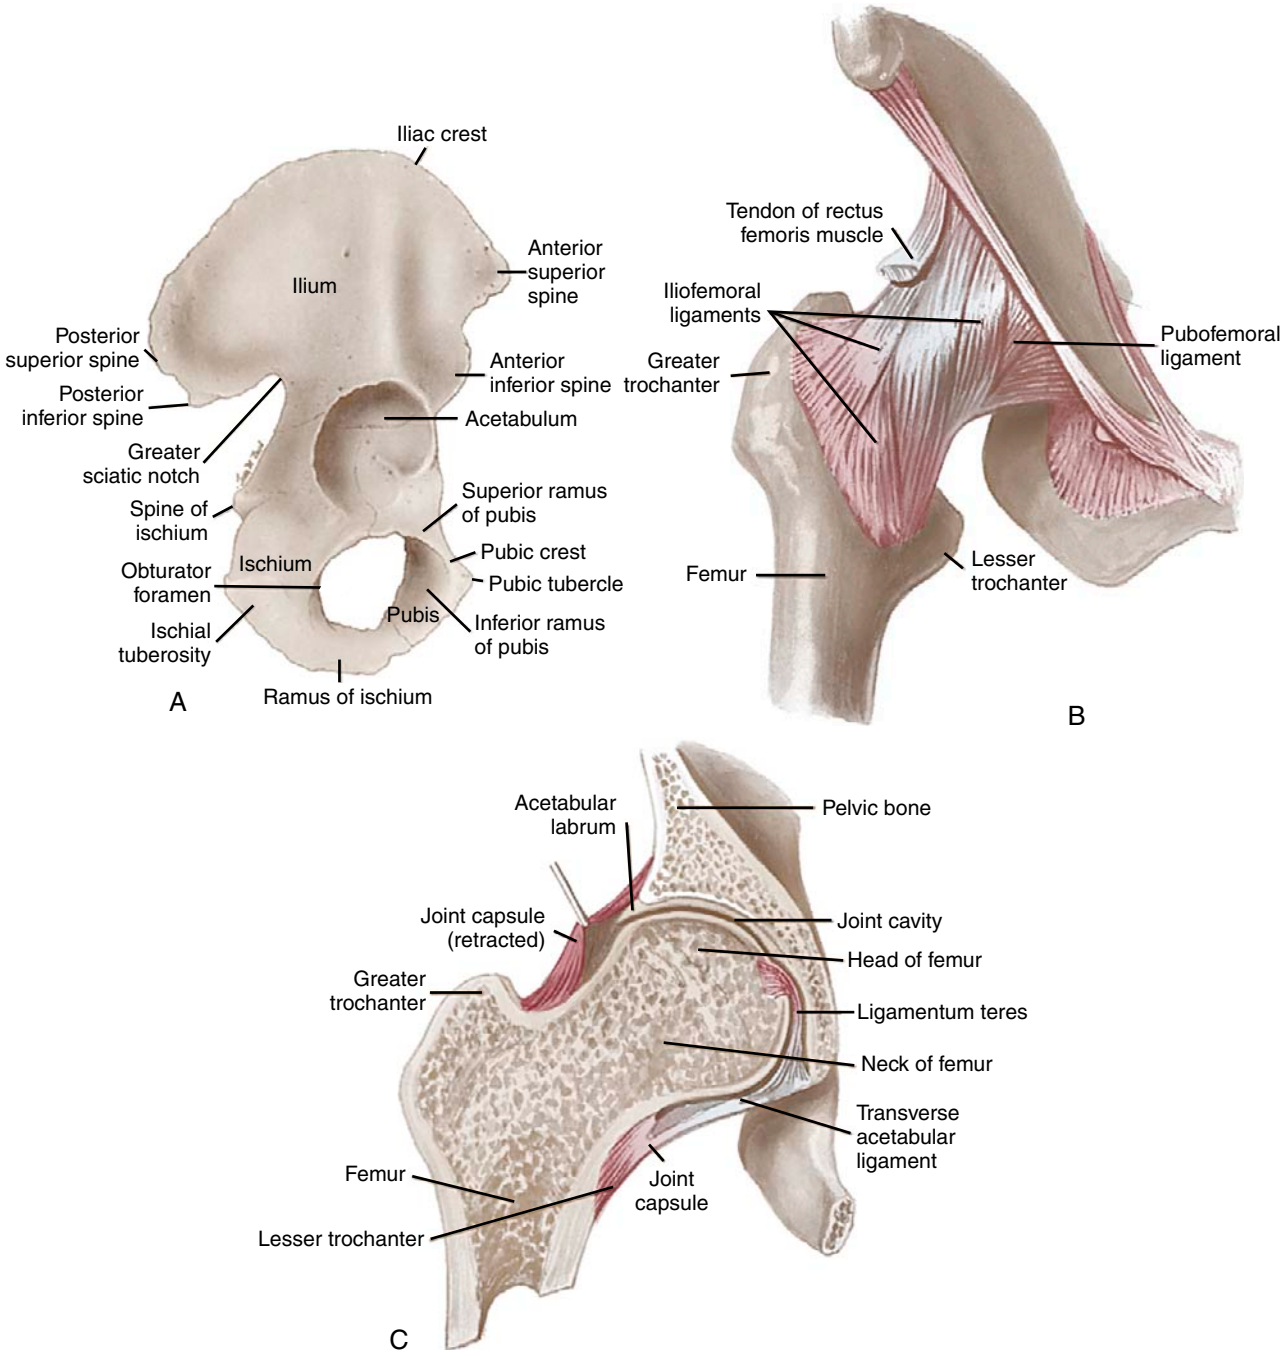

FIGURE 19-7 Hip joint. **A**, Coxal bone disarticulated from the skeleton. **B**, Ligamentous structure. **C**, Bone structure.

ligaments attach the ischium and pubis to the femur, respectively. The acetabulum is a deep, round cavity that articulates with the head of the femur. The proximal end of the femur consists of the femoral head and neck, the upper portion of the shaft, and the greater and lesser trochanters (Figure 19-8).

The greater trochanter is a broad process that protrudes from the outer, upper portion of the shaft and projects upward from the junction of the superior border of the neck with the outer surface of the shaft. It serves as a point of insertion for the abductor and short rotator muscles of the hip.

The lesser trochanter is a conical process projecting from the posterior and inferior portion of the base of the neck of the femur at its junction with the shaft. It serves as a point of insertion for the iliopsoas muscle. The lower end of the femur terminates in the two condyles. Anteriorly, the condyles are separated from one another by a smooth depression, called the *intercondylar,* or *patellar, groove,* forming an articulating surface for the patella. Posteriorly, they project slightly, and the space between them forms the intercondylar fossa—a supporting structure for neurovascular structures.

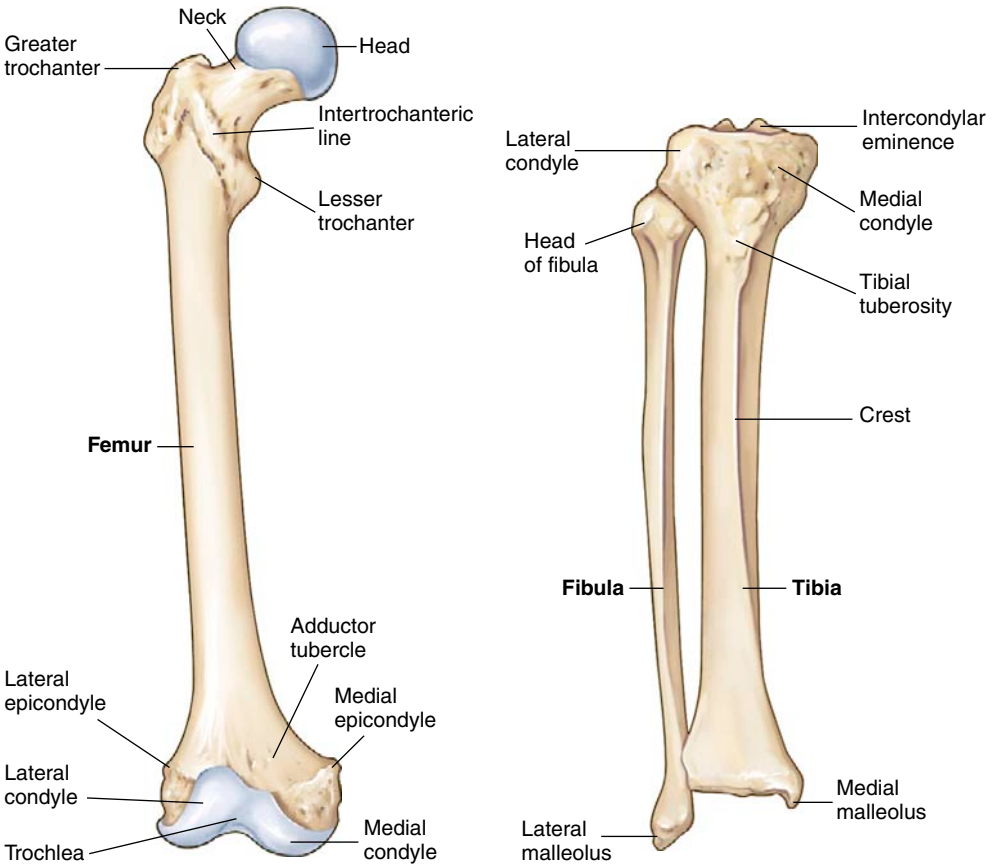

FIGURE 19-8 Bones of the upper and lower leg.

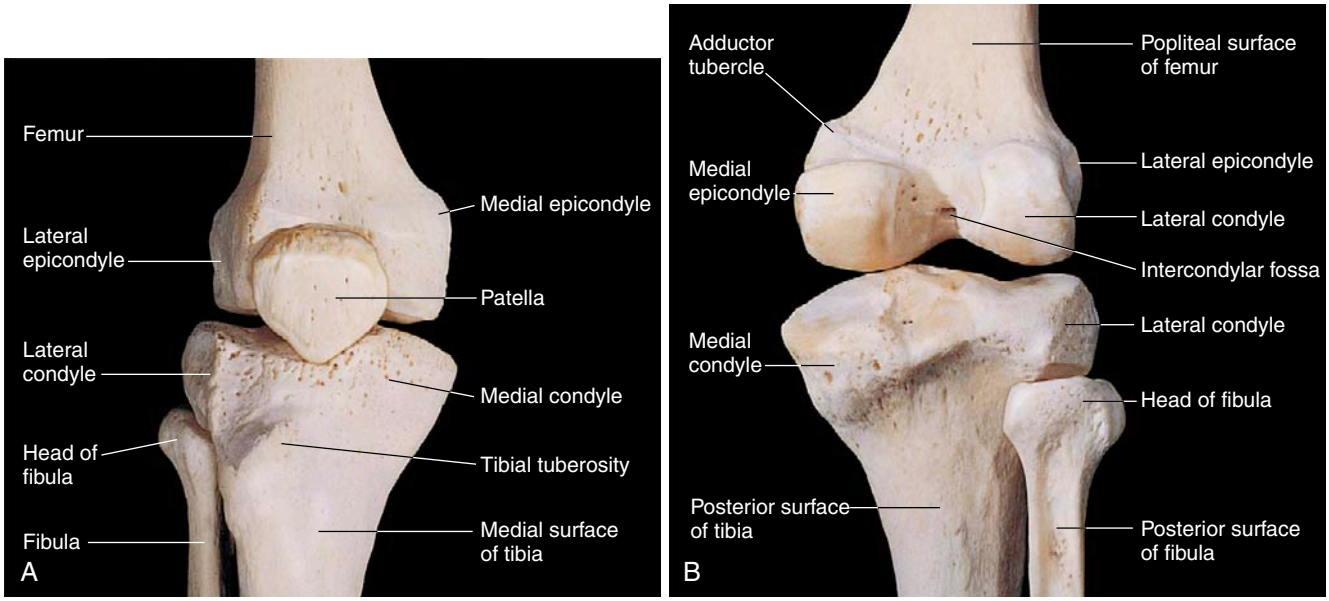

FIGURE 19-9 Bones of the knee showing the tibia and fibula. **A**, Anterior aspect. **B**, Posterior aspect.

The upper or condylar end of the tibia presents an articular surface corresponding with those of the femoral condyles. The articular surface of the two tibial condyles forms two facets, which are deepened by the semilunar cartilage into fossae for the femoral condyles.

Knee, Tibia, and Fibula

The knee joint (Figure 19-9) consists of two articulations. One articulation is between each condyle of the femur and the tibial plateau; the other is between the patella and the femur. These areas are subject to degenerative changes, often requiring

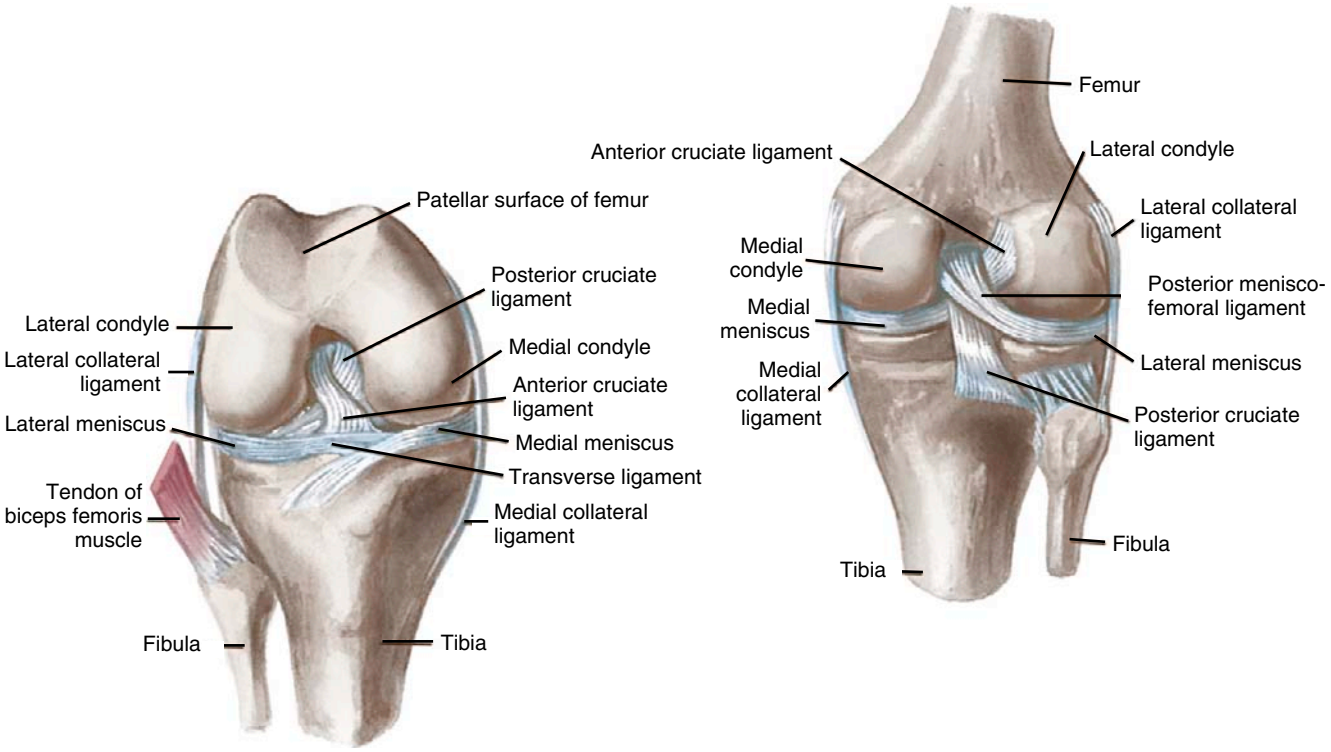

FIGURE 19-10 Bony structures of the knee joint.

reconstructive surgery. The bones of the knee joint are connected by extraarticular and intraarticular structures. The extraarticular attachments consist of the joint capsule, multiple muscular attachments, and two collateral ligaments. The intraarticular ligaments consist of the two cruciate ligaments and the attachments of the menisci.

The patella, or kneecap, is anterior to the knee joint in the intercondylar groove, or trochlea, of the distal femur. It is a sesamoid bone contained within the quadriceps tendon. The anterior surface of the patella is united with the patellar tendon as the tendon originates and inserts above and below the knee joint. The posterior surface of the patella articulates with the femur.

The capsule of the knee joint is attached proximally to the femoral condyles, and it is attached distally to the condyles of the tibia and to the upper end of the fibula. The capsule is reinforced anteriorly by the patellar and quadriceps tendon, on the sides by the medial and lateral collateral ligaments, and posteriorly by the popliteus and gastrocnemius muscles.

The cruciate ligaments (Figure 19-10), consisting of two fibrous bands, extend from the intercondylar fossa of the femur to attachments anterior and posterior on the intercondylar surface of the tibia.

The menisci are interposed between the condyles of the femur and those of the tibia (see Figure 19-10). Each meniscus is attached to the joint capsule. The ends of the cartilage are attached to the tibia in the middle of its upper articular surface. These structures are almost totally avascular, and degenerative changes are usually permanent.

Synovial membrane lines the capsule of the joint and covers the infrapatellar fat pad, parts of the cruciate ligaments, and portions of the bone. The portion of the knee joint cavity that extends upward in front of the femur is called the *suprapatellar pouch*, or *bursa* (Figure 19-11).

The tibia is the larger and stronger of the lower leg bones. The fibula is smaller and located more laterally, articulating at the proximal end with the lateral condyle of the tibia. The proximal end of the tibia articulates with the femur to form the knee joint. Distally the tibia articulates with the fibula and with the talus, forming the ankle joint.

Ankle and Foot

The ankle is a hinge joint, formed by the distal end of the tibia and fibula and the proximal end of the talus. The tibia (medial and posterior malleoli) and fibula (lateral malleolus) form a mortise (notch) for the reception of the upper surface of the talus and its facets. The talus is an irregular bone consisting of a body, neck, and head. The bones are connected by ligaments, which spread out from the malleoli to attach to the talus, calcaneus, and navicular bones (Figure 19-12). A thin capsule surrounds the joint.

The bony framework of the foot (Figure 19-13) comprises 7 tarsal bones, 5 metatarsal bones, and 14 phalanges. The calcaneus forms the heel and gives support to the talus. The cuboid bone articulates proximally and posteriorly with the calcaneus and distally with the fourth and fifth metatarsals and the third cuneiform bones.

The navicular bone articulates with the cuneiform bones, which lie side by side just anterior to it. The metatarsal bones articulate proximally with the tarsal bones and distally with the bases of the first phalanges of the corresponding toes. There are two phalanges for the great toe and three for each of the other toes.

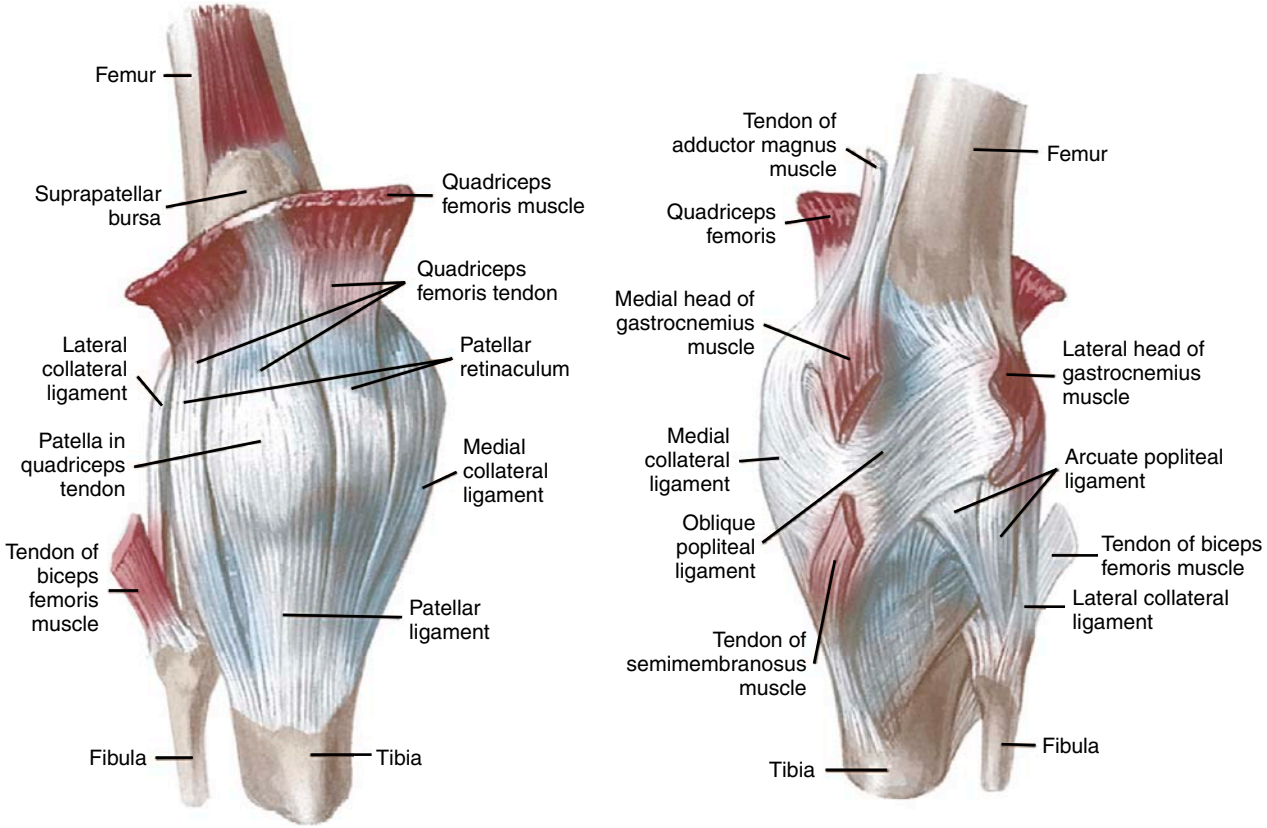

FIGURE 19-11 Superficial aspect of the knee joint.

Perioperative Nursing Considerations

Assessment

Assessment of the orthopedic patient is dynamic, beginning with initial patient consultation. The history and physical are done in the usual fashion. Preoperatively, the nurse takes special care to document any functional losses that are caused by the disability. The social situation of the patient should also be documented both in the physician's office and again in the hospital chart, as this may impact discharge planning. Familiarity with orthopedic procedures and anticipated patient outcomes improves the ability to gather appropriate information and complete the nursing process. Obtaining patient-specific information from the physician also enhances the perioperative nursing assessment. The signed operative consent provides information to confirm the scheduled procedure or procedures and verify the operative site and side as discussed by Guido (2005) and per The Joint Commission's (TJC) standards of universal protocol for correct site surgery (TJC, 2009). The consent is usually obtained before admission to the surgery suite and should be reviewed for accuracy and completeness.

Additional measures that should be undertaken to verify the correct operative side and site include marking the surgical site and having the patient verify the site with the surgeon during the marking process; using a verification checklist (which includes documents such as the medical record, x-ray films, imaging studies); using verbal verification by the patient of his or her identity, surgical site/side, and planned surgical procedure; confirming this information during the time-out by each member of the surgical team; and monitoring safe site protocol compliance with these procedures (Evidence for Practice).

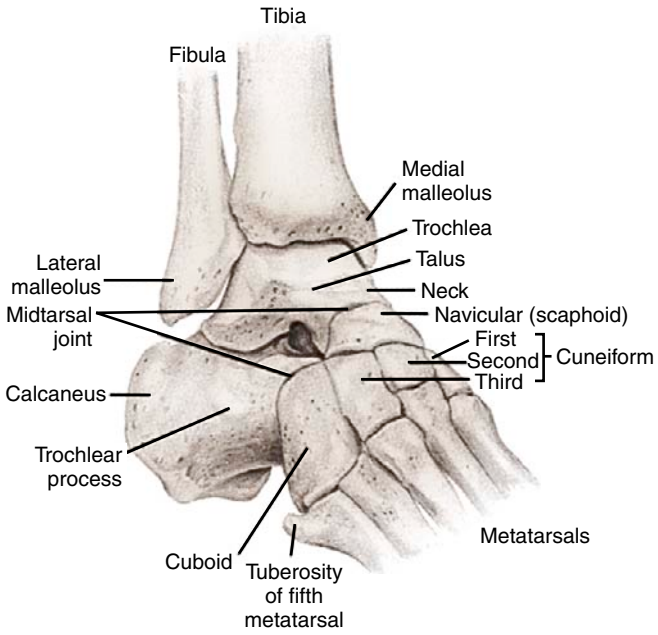

FIGURE 19-12 Anatomy of the ankle.

EVIDENCE FOR PRACTICE

Universal Protocol for Preoperative Site Verification As Indicated for Orthopedic Surgery

The Joint Commission's Universal Protocol for correct patient, procedure, and surgical side and site as well as the AORN Position Statement on correct site surgery both emphasize verification and marking of the surgical site (or invasive procedure site), especially when it involves laterality, levels, or multiples. As part of this process, protocols are used to verify the correct patient, correct procedure, correct patient position, and availability of necessary equipment, implants, imaging studies/equipment, or other special requirements. These protocols are part of the preoperative verification process as well as the time-out before the start of the surgical procedure.

For surgery, a recommended protocol may involve these additional steps:

- Preoperative skin marking of the procedure site is present.
- Preoperative films or images are present in the OR or procedure room.
- The time-out includes patient identity (using two unique identifiers); procedure to be performed; correct patient position; correct procedure side, level, or site; and presence of necessary implants, imaging, equipment, or other special requirements.
- If there are any discrepancies by any members of the surgical team the procedure will not proceed until the institution's reconciliation procedure is initiated and the results of the reconciliation should be documented.
- Should intraoperative imaging be necessary, opaque instruments marking the specific bony landmarks are placed accordingly and x-rays are taken and compared with the preoperative films or images by the surgeon performing the procedure.

Modified from Institute for Clinical Systems Improvement: *Health care protocol—safe site protocol for all invasive, high-risk, or surgical procedures,* January 2006, available at www.icsi.org/perioperative_protocol_36011/perioperative_protocol.html. Accessed June 23, 2009; The Joint Commission: *Universal protocol UP.01.01.01,* available at www.jointcommission.org/NR/rdonlyres/E5943278-3B89-469F-A265-E5AFB8729AD0/0/NPSG_UniversalProtocol_AHC_20090512.pdf. Accessed March 15, 2009.

The perioperative nurse reviews the patient record, noting relevant aspects of the history and physical examination; the nature of the problem and its onset; and results of radiographic studies, laboratory data, and other findings. The nursing history is reviewed to determine physical, psychosocial, cultural, spiritual, and other needs. The nurse assesses the patient's range of motion, neurovascular status, and general condition. The patient's understanding of the surgical procedure and postoperative rehabilitation is determined, and patient education is begun.

Assessment information helps the nurse to determine specific needs related to surgical positioning, skin preparation, equipment, instrumentation, and supplies. Environmental safety is also considered, including room temperature, traffic flow, lighting, and personnel attire.

The nurse communicates information with other members of the perioperative team. The information collected helps the perioperative nurse plan and coordinate activities, facilitate a smooth transition, and reduce operative time.

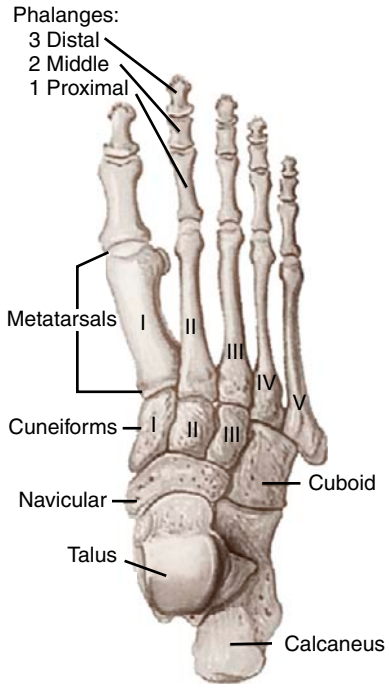

FIGURE 19-13 Bones of the foot viewed from above.

Nursing Diagnosis

Nursing diagnoses related to the care of patients undergoing orthopedic surgery might include the following:

- Anxiety
- Risk for Peripheral Neurovascular Dysfunction
- Risk for Perioperative Positioning Injury
- Impaired Gas Exchange
- Risk for Infection
- Risk for Imbalanced Body Temperature

Outcome Identification

Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient will verbalize concerns and apprehension related to surgery and recovery.
- The patient will be free from peripheral neurovascular dysfunction.
- The patient will be free from perioperative positioning injury.
- The patient will maintain adequate ventilation and oxygen exchange.
- The patient will be free from postoperative surgical site infection.
- The patient will maintain appropriate body temperature intraoperatively.

Planning

The care of surgical patients undergoing any type of surgery requires planning for routine procedures that are always followed, as well as anticipating the unexpected. The perioperative nurse should be consistent and systematic in the planning process to expedite actual steps required to facilitate the surgical procedure. Care of the orthopedic patient presents unique challenges because of the psychosocial, physical, and technical

aspects of patient care. Planning includes attention to environmental factors, positioning, transfusion supplies, equipment, and instrument needs, in addition to practices that will prevent complications.

The optimal environment is comfortable for the patient and surgical team. The patient should feel relaxed and secure enough to allow the surgical team to become his or her advocates during the procedure. Physical preparation of the environment changes with individual patients. At the time the procedure is posted in the OR, traffic flow is considered to determine room location. The temperature is selected for the procedure with consideration given to the age and general health of the patient, attire worn by the operative personnel (body exhaust suits), or use of polymethylmethacrylate (PMMA) (bone cement). Temperature should be monitored for all but very brief surgical procedures, such as those lasting less than 30 minutes. To maintain normothermia, the perioperative nurse might consider using warming blankets preoperatively to prewarm the patient in the holding area, warming the ambient room temperature, warming intravenous fluids, warming the skin surface with a forced-air warming device intraoperatively, and using warm cotton blankets at the end of the surgical procedure.

Equipment and instrumentation needed for the procedure are planned before the patient's arrival in the OR; orthopedic procedures may vary significantly because of the patient's physical condition or age. It may be necessary to communicate with the manufacturer's representative to facilitate obtaining items needed for the procedure. It is common for healthcare industry representatives to bring requisite orthopedic instruments to the OR or to act as a product resource regarding new equipment. However, industry representatives must comply with all institutional policies and AORN standards defining requirements and procedures and restrictions that govern their presence in the OR (AORN, 2006).

The nurse reviews the procedural information to plan positioning and protective measures. Aseptic technique is essential in the perioperative environment and should be considered a priority when caring for the orthopedic patient. Osteomyelitis is an infection of the bone that can remain unrecognized for a long time and requires expensive, intensive treatment. Osteomyelitis can lead to severe bone loss and possible loss of a limb. Preventive measures, including administration of antibiotics within 60 minutes of the initial incision, have been demonstrated to be efficacious in preventing surgical site infection.

OR equipment such as defibrillators and resuscitative equipment must always be available, functional, and familiar to staff. This includes supplies needed for emergency treatment of a patient condition, such as malignant hyperthermia or unanticipated blood loss. All medications and solutions along with their containers should be labeled both on and off the surgical field. Equipment alarms should be activated with appropriate settings and should be sufficiently audible. Orthopedic procedures may also require a change in the plan of care in the event of a fracture, damage to vascular integrity, or changes in the patient's condition, requiring an understanding of methods and equipment needed to manage these situations.

The nursing process requires continual reassessment and modifications. An effective plan entails communication, creating a culture that supports patient safety, creation of an optimal environment, and effective use of human and physical resources (AORN, 2007). A Sample Plan of Care for a patient undergoing orthopedic surgery follows.

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Anxiety

OUTCOME
The patient will verbalize concerns and apprehension related to surgery and recovery.

INTERVENTIONS
- Encourage verbalization of feelings, expression of fear, and questions about procedure, anticipated outcome, postoperative rehabilitation, pain management, and home care/self-care requirements.
- Explain anticipated routine activities (diagnostic studies, OR environment, preoperative holding area, postanesthesia care unit [PACU]), and encourage questions.
- Encourage patient and family participation in decision-making activities related to discharge planning.
- Demonstrate respect, and attend to patient's individual needs and those of the family or significant others.
- Remain with patient; ensure other personnel are introduced.
- Provide comfort and care, for example, through the use of warm blankets, touch, hand holding.
- Discuss any other concerns with the patient and family, and initiate appropriate referrals.

NURSING DIAGNOSIS
Risk for Peripheral Neurovascular Dysfunction

OUTCOME
The patient will be free from peripheral neurovascular dysfunction.

INTERVENTIONS
- Complete and document a preoperative neurovascular assessment including skin color and temperature, pulses, motor strength and movement, and sensation; reassess and document at procedure conclusion.
- Position patient with proper body alignment, considering range of motion or any limitations in mobility.
- Protect vulnerable neurovascular structures and prevent pressure by properly padding bony prominences and pressure points.
  - For the brachial plexus, pad the elbow, avoid excessive abduction, secure arm gently on locked armboard.
  - For the radial nerve, pad the wrist and secure it gently on an armboard or at the patient's side.
  - For the medial or ulnar nerves, pad and tuck the arm carefully at the patient's side or on an armboard.
  - For the peroneal nerve, place a pillow at the knee (but not under it) and support the lower extremities; ensure that restraining straps are not tight and do not compress the knee.
  - For the tibial nerve, keep equipment off the lower extremities.

SAMPLE PLAN OF CARE—cont'd

- Apply pneumatic tourniquet correctly, observing, verifying, and documenting pressure settings and tourniquet inflation time.
- Provide padding (air mattress or gel pads) when long surgical times are expected or patients are predisposed to peripheral vascular compromise.
- Anticipate patient's and surgical team's needs to minimize surgical time.

NURSING DIAGNOSIS
Risk for Perioperative Positioning Injury

OUTCOME
The patient will be free from perioperative positioning injury.

INTERVENTIONS
- Assess range of motion; identify joints at risk for injury caused by immobilization, pain, trauma, or arthritic or other disease processes.
- Position arthritic joints carefully to prevent strain.
- Observe and document condition of patient's skin before transfer to the OR bed and again at conclusion of procedure.
- Use proper lifting and transfer techniques when transferring the patient to and from the OR bed to prevent shearing forces on skin.
- Keep sheets on OR bed dry and wrinkle-free.
- Ensure that personnel with knowledge of the patient's condition and equipment are available to supervise and assist with transfer of the patient.
- Use proper restraint devices to protect patients from falls or movement of the extremities.
- Avoid extending or flexing extremities beyond range of motion when there is resistance.
- Protect skin in dependent areas from pooling of solutions.
- Use positioning devices, such as pillows, to maintain position; use a small head pillow under the head if head and neck are normally bent slightly forward.
- Pad all dependent pressure sites; provide extra padding for patients with decreased circulation.
- Protect vulnerable neurovascular areas from compression.

NURSING DIAGNOSIS
Impaired Gas Exchange

OUTCOME
The patient will maintain adequate ventilation and oxygen exchange.

INTERVENTIONS
- Review preoperative evaluation of the patient's pulmonary status.
- Assist anesthesia provider in airway management.
- Ensure full chest excursion when positioning, particularly in the lateral and prone positions.
- Collaborate with anesthesia provider in monitoring vital signs, oxygen saturation, ventilation, cardiac rhythm, and blood loss.
- Complete a vascular assessment (pulse, sensation, movement, temperature, and color check) preoperatively, and compare with postoperative status.

NURSING DIAGNOSIS
Risk for Infection

OUTCOME
The patient will be free from postoperative surgical site infection.

INTERVENTIONS
- Confirm that the patient has complied with preoperative skin cleansing (as appropriate).
- Implement strict aseptic practices for preparing the patient's skin, draping the patient and equipment, opening supplies and equipment for the procedure, removing hair (as necessary), and controlling traffic patterns in the OR.
- Prepare for pulsatile lavage or irrigation (as needed).
- Initiate antibiotic therapy preoperatively and/or intraoperatively per physician's orders; check for medication allergies before antibiotic administration.
- Implement procedure-specific activities, such as using body exhaust systems and pulsatile lavage.
- Anticipate equipment needs, and check equipment function; implement safety precautions when using equipment.
- Sterilize instruments according to policy and procedure and the manufacturer's guidelines.
- Handle implants according to manufacturer's recommendations.

NURSING DIAGNOSIS
Risk for Imbalanced Body Temperature

OUTCOME
The patient will maintain normothermia intraoperatively.

INTERVENTIONS
- Obtain and document baseline preoperative temperature.
- Initiate preoperative warming with either warmed blankets or forced hot air warming device.
- Maintain temperature in the OR between 68° and 73° F (20°–23° C) if possible.
- Monitor patient temperature throughout the procedure.
- Use warming devices and warming blankets during the procedure.
- Warm fluids as necessary.
- Minimize patient exposure to room air.
- Place warm blankets on patient immediately after surgery.

Implementation

Implementing care for the orthopedic surgical patient requires an understanding of anatomic, physiologic, psychologic, cultural, spiritual, and technical patient needs. Orthopedic surgical procedures demand special equipment, instruments, and psychomotor skills that differ from those required by other specialties. Implementation includes an understanding of the procedures, patient needs, perioperative practices, and perioperative nursing interventions to protect the patient while delivering care.

The nurse should provide explanations to the patient about the intraoperative phase, including the anticipated sequence of events, personnel, environment, required positioning, and procedures such as administration of a regional anesthetic and application of a tourniquet. The patient may be alert during the procedure; therefore noise from power equipment and activities that will occur should be explained. Immobilization devices, such as splints, casts, braces, and drains, should also be explained.

Positioning and Positioning Aids. The orthopedic patient requires proper positioning on the OR bed or specialty bed to provide adequate exposure of the operative area, maintain body alignment, minimize strain or pressure on nerves and muscles, allow for optimal respiratory and circulatory function, and provide adequate stabilization of the body. Selection of position depends on several factors, including the type of procedure, the location of the injury or lesion, and the preference of the surgeon. Guidelines for placing the patient in the supine or recumbent position are followed (see Chapter 5), with modifications to facilitate the specific orthopedic procedure.

Procedures performed in lateral, prone, or modified positions require use of positioning aids and devices to support these positions. Patients undergoing surgical procedures risk neuromuscular and skin injury. The nurse's preoperative assessment should be thorough to plan the position, taking into consideration the prevention of neurovascular compromise, the potential for impaired chest excursion, and the danger of falls. The safety strap does not always provide adequate security, and other methods of securing the patient on the OR bed may need to be implemented. The surgeon is responsible for selecting the position and ensuring that adequate exposure can be obtained. The perioperative staff must understand the meaning of terms such as *flexion, extension, abduction,* and *adduction* when positioning the patient. The staff must also be thoroughly familiar with the function of the orthopedic surgical bed and its various attachments (e.g., the leg attachment for arthroscopy, the three-point positioner for lateral position, and positioning devices for shoulder procedures).

Many orthopedic operations require a device for holding the extremities. Various holders are available for both upper and lower extremities. Positioners used intraoperatively can be sterilized for the procedure, resulting in the ability to reposition as needed throughout the procedure. These types of positioners include the shoulder positioner (Figure 19-14), Alvarado foot holder (Figure 19-15), and ankle distractor (Figure 19-16). Many other orthopedic positioning devices are also available.

The lateral position is sometimes used for a total hip arthroplasty. Padded anterior and posterior supports may be positioned at the umbilicus and lumbar regions, respectively, to hold the patient in the lateral position. A vacuum beanbag can also achieve this position. Pressure points on the lateral area of the skull, ear, axilla, hip, knee, and ankle should be adequately padded. The feet are placed in the neutral position to prevent excessive plantar flexion or dorsiflexion. A conscientious effort should be made by the surgical team to avoid leaning on the patient during the procedure.

The patient is positioned prone for surgery on the posterior aspect of the body, including the back; posterior portion of the shoulder, arms, and legs; and Achilles tendon; and for posterior iliac bone graft harvesting. This position presents a challenge for the anesthesia team to monitor and manage the airway because of the potential for impaired chest excursion and gas exchange. Extremities need to be moved through a normal range of motion when transferring and positioning into the prone position. Vascular integrity is always assessed before the patient is moved into position and reassessed after the patient is positioned; the nurse should note the quality of pulses, extremity warmth, and capillary refill.

The prone position is often attained with the use of adjunctive frames, such as the Wilson, Hastings, Canadian, Relton-Hall, Cloward saddle, or Andrews, or with the Andrews bed (Figure 19-17). Each frame has qualities that meet the patient's or physician's needs. The Hastings and Andrews frames and the Andrews bed maintain the patient in a modified knee-chest position. The frames require assembly and are labor-intensive when positioning; some can be used only with certain beds. The Andrews bed is similar to the Andrews frame but has the attachments built in and is used exclusively for this position.

On an OR fracture bed (Figure 19-18), generally used for femoral neck and shaft fixation, the team places the patient in

FIGURE 19-14 Shoulder positioner allows distraction of the joint for visualization.

FIGURE 19-15 Alvarado foot holder used during total joint procedures to position the extremity for exposure.

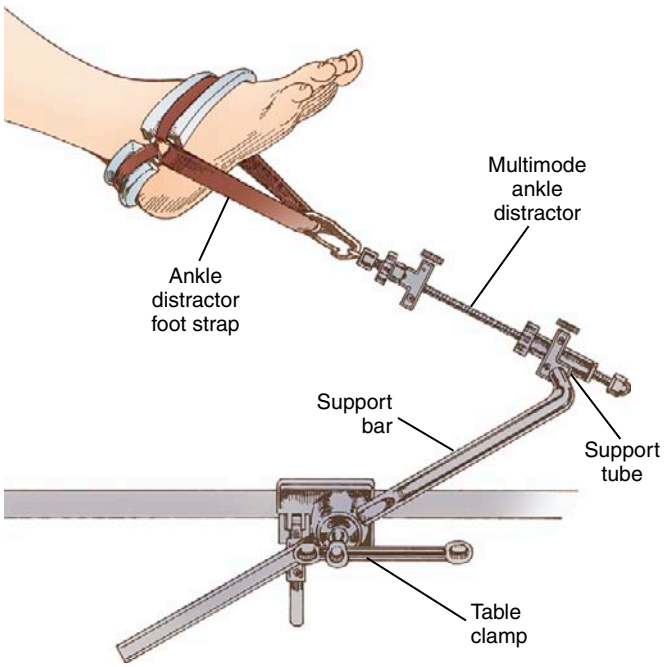

FIGURE 19-16 Ankle distractor, noninvasive, for distraction of the joint and visualization.

FIGURE 19-17 Andrews bed used for prone positioning.

supine or lateral position to allow exposure of the surgical site while maintaining alignment. The patient's legs are positioned on outriggers, allowing access by the image intensifier to obtain multiple radiographic views. Applying or releasing traction can be done to reduce the fracture or aid in intramedullary surgical techniques. Like all positioning devices, the fracture bed must be set up by experienced personnel and padded adequately. There are several moving parts, which can lead to injury if not operated properly.

If the patient is positioned supine, special attention must be paid to the arms. Arms are placed on padded armboards with the palms up and fingers extended. Armboards are maintained at less than a 90-degree angle to prevent brachial plexus stretch. If there are surgical reasons to tuck the arms at the side, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly under the patient, not under the mattress. This

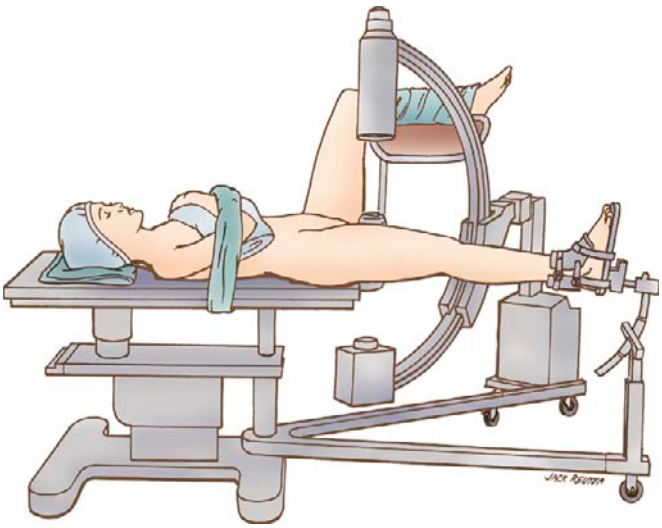

FIGURE 19-18 Patient positioned on the orthopedic fracture bed for femoral neck, femoral shaft, or tibial fixation, with image intensifier in position.

prevents the arm from shifting downward intraoperatively and resting against the OR bed rail.

Surgical Prep. A primary concern in orthopedic surgery is the prevention of infection. The orthopedic surgical prep must be meticulously carried out using aseptic technique. Physicians often instruct patients to complete a scrub prep with an antimicrobial agent before arrival for surgery. The surgical prep for the orthopedic patient may include preoperative removal of hair from the surgical site. Surgical shave preps contribute to the possibility of infection caused by abrasion and cutting of the skin. If hair removal from the incisional site is ordered, it should occur immediately before surgery, using clippers or a depilatory. If a razor is required, the site should be lathered with soap before shaving. Trauma patients require precautions during the skin prep to prevent further injury caused by solution contact with membranes or injury to the bone and soft tissue from movement.

Skin preparation is performed to remove microorganisms from the operative site. The site should be prepped with a broad-spectrum antimicrobial agent. The prep proceeds from the incision site to the periphery. Pooling of the prep solution beneath the patient or tourniquet must be avoided. Prep solutions should be allowed to dry before draping; this is a fire safety precaution and may be included in the time-out. The groin and anal areas should be isolated when the surgical site is on the upper third of the leg.

Devices such as leg stirrups may help support an extremity to complete a circumferential prep. When multiple extremities or other areas, such as a bone graft site, are prepped, cross-contamination of previously prepped areas must be prevented. Knowledge of aseptic technique and the ability to organize the activity are important in proper preparation of the surgical site.

Draping. Application of sterile drapes is the final step in preparing the patient for the operation. The surgeon and surgical technologist cover the patient's extremities with a cloth or water-impervious stockinette—a cylindric drape that is rolled up the arm or leg. Impervious sheets are essential when large

amounts of fluid are used, such as during arthroscopy and wound irrigation. Prefabricated disposable drapes with fenestrations for the upper and lower extremities are available.

Antimicrobial incise drapes can be used to isolate the surrounding area from the incisional site. Many of these drapes contain iodophor-impregnated adhesive, which slowly releases iodine during the procedure, inhibiting proliferation of organisms from the patient's skin. They are contraindicated for patients with an allergy to iodophors. An alcohol skin wipe may be done before placement of the antimicrobial incise drape.

Equipment and Supplies. Orthopedic ORs require a variety of special equipment and accessories in addition to routine OR equipment. Nitrogen-powered, battery-powered, and electrically powered equipment, video systems, pneumatic tourniquets, laminar airflow systems, x-ray equipment, lasers, and special orthopedic tables are included in the operative armamentarium. Manufacturers' pamphlets with illustrations and directions on equipment use and sterilization should be readily available for reference.

RADIOGRAPHIC INTERVENTION. Radiographic intervention is widely used in orthopedic surgery (History box). Many procedures require portable x-ray or fluoroscopy machines. Fluoroscopy, also known as *image intensification* or *C-arm,* allows the team to view the progression of the procedure, confirming fracture reduction or intramedullary reaming of the humerus, femur, or tibia. An x-ray technician operates radiographic equipment. An understanding of equipment placement, function, and safety precautions is necessary. The perioperative nurse is responsible for communicating with the radiology personnel concerning the procedure, aseptic technique, and traffic flow in the OR. X-ray cassettes brought onto the sterile field are draped with a sterile plastic cover. Lead aprons and thyroid shields are to be worn by all personnel in proximity to the x-ray equipment, and personnel should be monitored for exposure to radiation. Measures should be taken to protect patients from direct and indirect radiation exposure, and these should be documented on the perioperative nursing record.

PNEUMATIC TOURNIQUETS. Pneumatic tourniquets are frequently used for procedures involving the extremities (Figure 19-19). A tourniquet is a fabric-covered cylindric bladder inflated by compressed gas or ambient air. It applies circumferential pressure on arterial and venous circulation, which results in a relatively bloodless surgical field; this promotes visualization of structures during the procedure. Limb exsanguination is achieved by elevating the limb or by wrapping it, distally to proximally, with an Ace or Esmarch rubber bandage before tourniquet inflation. The majority of tourniquets used today are run by a microprocessor for regulation of pressure and time setting, providing both auditory and visual feedback for the user.

Tourniquet safety should be a priority; the surgical team should understand recommended parameters and precautions. Safety guidelines for the use of tourniquets include preventive measures and evaluation (AORN, 2009). Preoperative assessment of the patient includes determining contraindications for use, including compartment syndrome, McArdle disease (e.g., glycogen storage disease), hypertension, or other vascular problems. If the tourniquet must be used for patients with these conditions, specific guidelines must be observed.

Before application, the nurse checks tourniquet equipment for proper functioning. Inflation pressures are established

HISTORY

History of Medical Imaging

As humans became more aware of injuries and how to treat them, certain people in each culture accepted the responsibility and honor of healing. In some tribal cultures, that person was a medicine man, or bonesetter. Neolithic people may have had fractures splinted—probably with bark and sticks. Other tribes used clay, soaked strips of rawhide, and linen. Hippocrates described using a wooden rack to treat a fracture of the femur and using techniques such as traction and countertraction. However, bone healing as we know it today depended much on the development of imaging techniques.

The era of medical imaging began with the publication of *De Humani Corporis Fabrica* in 1543 by Andreas Vesalius. This comprehensive, detailed, and accurate set of anatomic illustrations set new standards in the art of medical observational science and research. Through direct observation, Vesalius conveyed his knowledge of the anatomy of the human body. These works were undisputed and stood the test of time until 1895, when Wilhelm Konrad Roentgen accidentally discovered x-rays (roentgenograms). Composed of high-energy electrons, x-rays are absorbed in varying degrees by structures in the body, based on their density and mass. The image is produced in two dimensions on photographic film and allows for indirect observation through a noninvasive technique. For the next 70 years, x-rays remained the standard in medical imaging until computerized axial tomography, or CAT scan, was introduced in 1972 by Godfrey Hounsfield. Detailed images of the body could be created by directing narrow x-ray beams at various angles. This was the first technique that incorporated computers into medical imaging. Since then, medical imaging has dramatically expanded, facilitating the surgical team's understanding of anatomy, physiology, and pathophysiology.

Modified from Gray JE, Orton CG: Medical physics: some recollections in diagnostic x-ray imaging and therapeutic radiology, *Radiology* 217(3):619-625, 2000.

FIGURE 19-19 Pneumatic gauge.

based on the systolic blood pressure, age of the patient, and circumference of the extremity. Duration of tourniquet inflation should be kept to a minimum. It is recommended in the average, healthy 50-year-old person to apply continuous tourniquet pressure less than 1 hour on the upper extremity and less than 2 hours on the thigh. Tourniquet pressure should not exceed the recommended maximum cuff pressure limits of 300 to 350 mm Hg for the thigh and 250 to 300 mm Hg for the arm and the lower leg. Kleinert and colleagues (2007) notes the interval between inflation and deflation should be 5 minutes for every 30 minutes of tourniquet ischemia to minimize effects on muscle and nerves.

The tourniquet should be placed on the extremity without compression on bony structures and superficial neurovascular structures. The person placing the cuff should ensure it is positioned as high as possible without pinching skinfolds. Soft padding or stockinette is wrapped around the extremity and kept free of wrinkles and gatherings beneath the cuff. Cuffs should overlap a minimum of 3 inches and a maximum of 6 inches; excess overlap can pinch skinfolds. A tourniquet cuff that is too short can loosen after inflation. Care must be taken to ensure that the line from the air supply to the cuff is not kinked.

Tourniquet equipment should be checked periodically and serviced when problems arise. Injury from tourniquets may result from inadequate precautions, faulty preparation, or use of inaccurate equipment. The gauges and other related equipment should be checked with commercially available test equipment. Patient evaluation requires assessment of the extremity (skin color, temperature, pulses, movement, sensation) after removal of the tourniquet. Abnormal findings need to be reported to the surgeon and documented (Evidence for Practice).

TRACTION. The surgeon uses traction preoperatively, intraoperatively, or postoperatively for prevention or reduction of muscle spasm, immobilization of a joint or body part, reduction of a fracture or dislocation, and treatment of a joint disorder. Traction alignment must be constant.

EVIDENCE FOR PRACTICE

Tourniquet Use

Recommended practices from AORN help the OR nurse effectively manage cases that involve tourniquets. Patient safety is the primary concern when using tourniquets intraoperatively. All OR personnel responsible for the tourniquet should be familiar with current standards. The primary purpose of the tourniquet is to occlude blood flow to the extremity, providing a bloodless surgical site. Competency associated with the use of tourniquets should be demonstrated by the OR staff. All tourniquets should be maintained according to manufacturers' guidelines including cleaning, sterilizing, and testing. Disposable tourniquets are now available for single use. The integrity and function of the base unit should be tested before each use. Personnel should be familiar with the application of the tourniquet, recommended pressures, maximum times for inflation for extremities, and contraindications for tourniquet use. OR personnel should be aware of the risks of exceeding the time limits and should inform the surgeon at regular intervals of the tourniquet inflation time. The nurse is responsible to assess and document patient outcomes at the end of the procedure.

Modified from Association of periOperative Registered Nurses (AORN): *Perioperative standards and recommended practices,* Denver, 2009, The Association.

Various traction techniques can be used, including manual, skin, and skeletal (Figure 19-20). In manual traction, the hands provide the forces pulling on the bone being realigned. Skin traction uses strips of tape, digital straps, moleskin, or an elastic bandage applied directly to the skin. Common forms of skin traction are Buck's extension and Russell traction. Skeletal traction applies forces directly to the bone, using pins. Manual and skin traction can be applied in the emergency department or patient room, whereas skeletal traction is applied preoperatively in the emergency department or in the OR.

Skeletal traction is often used in conjunction with the OR fracture bed, using the traction attachment to aid in reduction of a long bone fracture. Postoperatively the patient may be confined to bed with balanced skeletal traction using a Thomas splint (Figure 19-21) and a Pearson attachment. Some cervical spine fractures or injuries may require Crutchfield or Gardner-Wells tongs or a cervical halo inserted directly into the skull to stabilize the vertebrae and reduce spinal cord damage or further injury. Application of skeletal traction requires the use of sterile supplies, including a traction bow, pins, and drill.

The perioperative nurse ensures the patient's postoperative bed is prepared with the correct traction frames. Nursing care of the patient in traction should include ensuring that the traction is continuous and skin tapes or skeletal pins are secured. Neurovascular status should be checked routinely, including skin color, pulse, temperature, and sensation. Changes from baseline or normal value must be reported.

POSTOPERATIVE IMMOBILIZATION. Postoperative immobilization may require use of a cast, splint, or other supplies designed for the specific anatomic part. A cast is a common method of immobilizing a fractured bone during healing (Patient and Family Education). The forces of distraction, rotation, and malalignment can be overcome with the application of a cast. Closed reduction with a cast may be an option, thus minimizing the disadvantages and complications of open reduction, such as infection and tissue damage.

The surgeon uses plaster or synthetic materials such as fiberglass for casting. Plaster is less expensive, with a greater weight/strength ratio (it requires a greater weight of plaster to produce the same strength of fiberglass). Plaster casts may be burdensome if the casts are too heavy. They are routinely used as the primary cast after surgical procedures and are replaced later with a lighter fiberglass cast to promote patient mobility.

Casting material sets up and hardens rapidly once activated with water, and such a property necessitates that it be prepared with all necessary materials. Soft padding or stockinette should be applied to the extremity before the cast is applied to protect the skin from thermal injury while the plaster sets, as well as to protect the skin from undue abrasion and pressure. The plaster must be prepared, applied, and handled carefully and safely.

Figure 19-22 shows types of casts. After wrist fractures, the surgeon applies a short arm cast from below the elbow to the metacarpal heads. A long arm cast extends from the axilla to the metacarpal heads, immobilizing forearm or elbow fractures. The surgeon uses a short leg cast, applied from the tibial tuberosity to the metatarsal heads, to immobilize the ankle and foot. The long leg cast is used for fractures involving the femur, tibia, or fibula or for complicated ankle fractures. The femoral cast brace is used in the treatment of femoral shaft fractures.

PATIENT AND FAMILY EDUCATION

Casts

EXPLANATION OF THE CAST

The cast is only one of several devices used to promote the healing of broken bones. Surgeons also use traction and pins, or a combination of these three devices, to help heal broken bones. The cast has the advantage of being less expensive, requiring little care on the patient's part, and allowing them to move around. The cast also encloses and immobilizes the broken bone and injured soft tissues to prevent movement that could cause further injury and to keep the bone in place for proper healing. The cast may be made of plaster or of a synthetic material, such as fiberglass. Although the plaster cast is heavy, the surgeon can mold a plaster cast more easily for a close fit over severe injuries. The synthetic cast is lightweight and easier to move around.

CAST CARE

- Keep a plaster cast dry; cover it or wrap it in a plastic bag when bathing or going out in the rain or snow.
- Check with the surgeon about immersing a fiberglass (or other synthetic) cast in water. The surgeon may permit immersion if there are no surgical wounds under the cast.
- Maintain good skin care around the cast. However, do not:
  - Insert objects, such as a coat hanger, under your cast.
  - Put any creams, lotions, or powder inside the cast.

THINGS TO WATCH FOR AND REPORT TO YOUR SURGEON OR NURSE

The skin under the cast will feel warm at first because of the reaction that occurs during the setting process. However, warm areas on the cast later may indicate infection, and notify the surgeon or nurse at once.

Watch for increased pain or soreness under the cast, particularly around a bony prominence such as the wrist or ankle, that is not relieved by repositioning the body. Check the skin color and temperature periodically. When the tip of a finger or the big toe that extends from the cast is squeezed until it is white, the pink color should return within 4 to 6 seconds. If skin color does not return within 4 to 6 seconds or if the skin is red, blue, white, or otherwise discolored, notify the physician. If fingers or toes are cool, cover them. If they do not warm up in 20 minutes, call the physician. Call the physician immediately if any of these other symptoms occur:

- An increase in swelling and pain. Some swelling is common at first. The surgeon may have advised to elevate the cast after it was applied. The cast should feel snug for the first 48 hours. If it continues to feel too snug and causes pain and swelling, call the surgeon.
- A tingling or burning sensation.
- An inability to move muscles around the cast.
- A foul odor detected around the edges of the cast.
- Any drainage that may show through the cast.
- Any cracks or breaks in the cast.
- Marked loosening of the cast, allowing the parts inside the cast to move fairly easily.

Modified from Canobbio MM: *Mosby's handbook of patient teaching,* ed 3, St Louis, 2006, Mosby.

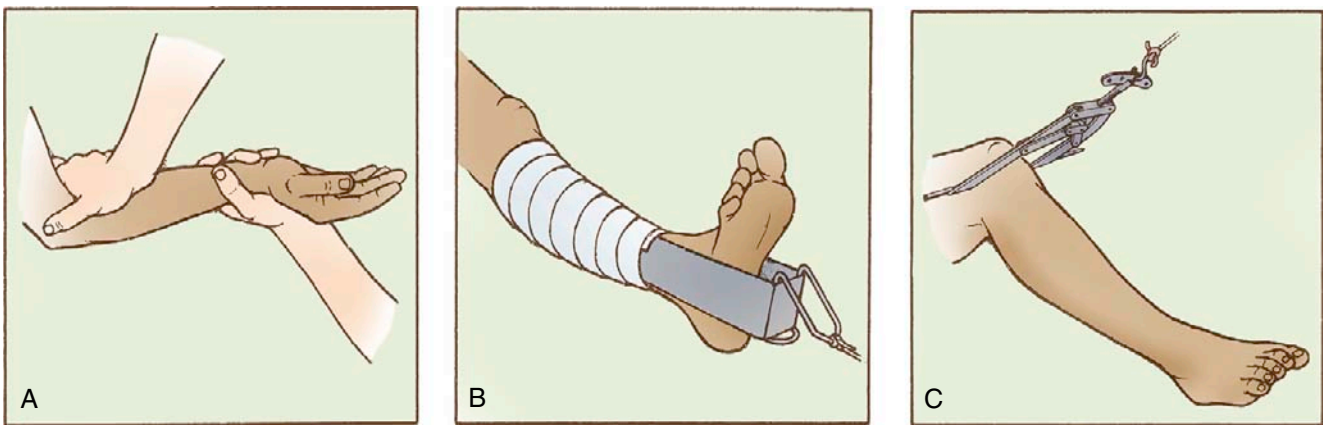

FIGURE 19-20 Traction techniques. **A**, Manual. **B**, Skin. **C**, Skeletal.

A snug-fitting thigh cast and short leg cast are hinged at the knee joint. The cast brace is generally used after 4 to 6 weeks of skeletal traction after initiation of callus formation at the fracture site. A cylinder cast incorporates the leg from the groin to the ankle and is applied when complete knee immobilization is required. This is often required after surgery involving soft tissue reconstruction around the knee.

The hip spica cast is used when complete leg immobilization is desired. The patient's trunk, affected side, and unaffected side may all be incorporated into the cast. Spinal immobilization is accomplished with a body jacket.

Splints may also be employed for postoperative immobilization but are not circumferential and allow for swelling and closer observation of the surgical site.

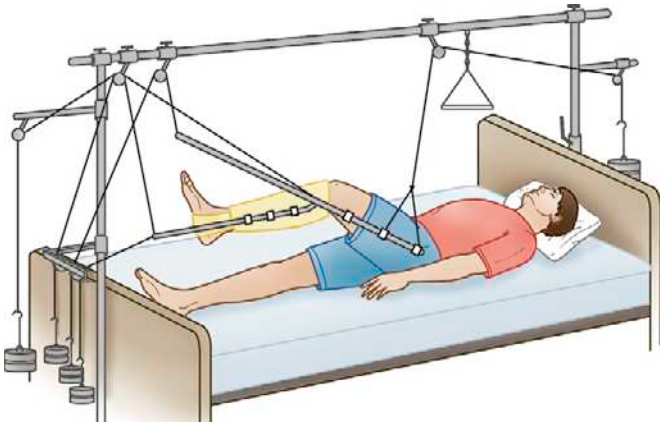

FIGURE 19-21 Thomas splint balanced suspension.

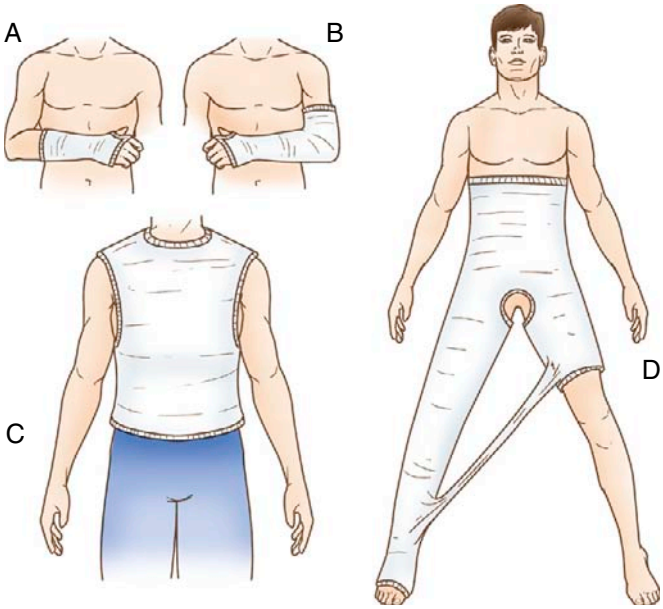

FIGURE 19-22 Types of casts. **A**, Short arm cast. **B**, Long arm cast. **C**, Plaster body jacket cast. **D**, One and one half hip spica cast.

Another immobilization device is the abduction pillow, used after total joint replacement. This prevents the patient's leg from adducting, or rotating internally, and the hip from flexing, which could cause dislocation of the hip. Further discussion of this and other devices is included with the description of various surgical interventions.

LASERS. Laser application has been increasing in the field of orthopedics. Their use mandates safety precautions, certification, patient consent, and protective attire (see Chapter 7 for a full discussion of lasers and laser safety). Laser types include carbon dioxide, holmium:yttrium-aluminum-garnet (Ho:YAG), neodymium:YAG (Nd:YAG), potassium titanyl phosphate (KTP), erbium:YAG (Er:YAG), and excimer. Laser technique differs for use on bone, muscle, tendon, and cartilage. Lasers have been used successfully for osteotomy, revision arthroplasty (removal of polymethylmethacrylate), nerve and tendon repair, arthroscopy, and discectomy.

AIRFLOW CONTROL. Airflow control in the orthopedic OR is critical to prevent introduction of microorganisms.

FIGURE 19-23 Body exhaust system used in arthroplasty.

FIGURE 19-24 Continuous passive motion (CPM) machine used for passive range of motion.

Surgical site infections may result from airborne bacteria or transient bacteria from the patient or surgical team (AORN, 2009). Laminar airflow is a system designed to provide highly filtered air and continuous air exchange for reducing airborne bacteria. Body exhaust suits are also used as a defense against airborne bacteria (Figure 19-23). Aseptic practices, sterile technique, and conscientious behaviors in ORs using conventional airflow can be used to maintain low rates of surgical site infections.

POSTOPERATIVE MANAGEMENT. The nurse begins planning the patient's postoperative management during the preoperative period. Special equipment may include continuous passive motion (CPM) machines, pain management devices and techniques, compression devices, and blood salvage. CPM machines (Figure 19-24) stimulate the healing effect on articular tissues, including cartilage, tendon, and ligaments, without interfering with healing incisions over the moving joint. The benefits of CPM include inhibition of adhesion formation and joint stiffness, decreased pain and swelling, early functional range of motion, and decreased effects of immobilization. The device is applied early in the postoperative period.

PATIENT AND FAMILY EDUCATION

Educating the Patient and Family on Pain Management at Home

Give the patient and the caregiver both *verbal* and *written* instructions. After reviewing instructions, have the patient or caregiver "repeat back" the instructions in his or her own words. Provide the patient or caregiver with the name and telephone number of a physician or nurse to call if questions arise.

GENERAL INFORMATION

- Explain the relationship of pain to the disease process. Assist the patient to understand the source of pain.

SPECIAL INSTRUCTIONS

- Assist the patient to identify factors or actions that trigger pain, such as activity, movements, and temperature extremes.
- Discuss past effective and ineffective pain-relief measures and their effects, such as sleepiness, lethargy, and decreased energy or sexual activity.
- Assist the patient to localize and describe the intensity of pain using a scale (e.g., 0 to 10, with 0 meaning absence of pain and 10 meaning intense pain) and to identify any alleviating or aggravating factors.
- Encourage use of a log to record pain rating and effectiveness of management strategies.
- Discuss alternative strategies patients can use to relieve pain without taking prescribed drugs, and explain that these techniques may also augment the effect of pain medication (see Pain Management Techniques below).
  - *Sensory interventions: massage*—to relax muscular tension and increase local circulation; *range-of-motion exercises* (passive, assistive, or active)—to relax muscles, improve circulation, and prevent pain related to stiffness and immobility; *cold application*—used initially to decrease tissue injury response (swelling) and decrease pain; *heat application*—used after cold to aid in clearance of tissue toxins and mobilize fluids; *transcutaneous electrical nerve stimulation (TENS)*—pocket-size, battery-operated device used to send mild continuous electrical impulses through the skin by means of electrodes placed on the body
  - *Emotional interventions:* to increase pain threshold by controlling or reducing anxiety, fatigue, or depression: prevention or control of anxiety—to reduce muscle tension and increase pain tolerance through relaxation exercises and slow, controlled breathing; *promotion of self-control*—to reduce feelings of helplessness and lack of control that contribute to anxiety and pain; pacing of activities
  - *Cognitive interventions: distraction*—focus on something unrelated to pain (e.g., conversing, watching television or videos, listening to music); *humor; guided imagery*—use of images to alter a physical or emotional state, promote relaxation, and decrease pain sensation
- Discuss the need to identify body positions of comfort; encourage attention to proper posture and body alignment. Advise the patient to immobilize or rest the affected area.
- Tell the patient to relieve pressure areas by turning or using pressure-reduction devices.

PAIN MANAGEMENT TECHNIQUES

- *Relaxation:* relieves pain by easing muscle tension. This can also help you feel less tired and nervous and help other pain-relieving methods work better.
- How to relax:
  - Sit or lie down in a quiet place. Be sure you are comfortable. Do not cross your legs or arms. Take a deep breath, and tense your muscles (you may tense your entire body or concentrate on one set of muscles at a time, such as your facial muscles or those in your arms and hands).
  - Hold your breath, and keep your muscles tense. Release your breath and your muscles at the same time. Let your body go limp (repeat for other muscle areas if you are concentrating on one set at a time).
  - You can add imagery or music to help you relax. Relaxation tapes are available from your healthcare agency or local music store.
  - Do not be discouraged if relaxation does not help immediately. Practice the relaxation technique for at least 2 weeks before you give it up. If you find that it aggravates your pain, try another method.
- *Imagery:* involves using your imagination to create mental scenes that use all your senses: sight, sound, touch, smell, and taste. You can imagine exotic locations or revisit one of your favorite places. You can create stories and characters to add to your scenes. Imagery can take your mind off your fear, boredom, and pain.
- How to use imagery:
  - Close your eyes. A few moments of the relaxation techniques (see above) will help your body and mind prepare for imagery. Let your mind begin forming its image. The following is an example of imagery: Imagine that you are at the seashore. You are sitting in the wet sand; the afternoon sun is warm on your shoulders. The ocean rolls into the shore in gentle waves, and the water laps teasingly at your toes. A hungry pair of seagulls cries overhead and takes swift, darting dives at a dog that is scavenging along the shore. Your tension lessens with each wave that touches your toes and retreats. You close your eyes and take a deep, slow breath of air. You are completely relaxed. Stay on the beach as long as you like. To end the image, count to three and open your eyes. Resume your regular activities slowly.
- *Distraction:* any activity that takes your mind off your pain and focuses your attention elsewhere. Doing crafts, reading a book, watching television, or listening to music through headphones can distract your mind. Distraction works well when you are waiting for drugs to take effect or if you have brief bouts of pain. Sometimes people can take their minds off their pain for long periods, especially if the pain is mild.
- *Skin stimulation:* used to block pain sensation in the nerves. Pressure, massage, hot and cold applications, rubbing, and mild electrical current are all ways to stimulate the skin. If you are having radiation therapy, consult your physician before applying any skin stimulation. You can do the stimulation at the site of the pain, near it, or on the side opposite the pain. For example, stimulating the left wrist when the right wrist is in pain can actually ease the pain in the right wrist.

PATIENT AND FAMILY EDUCATION

Educating the Patient and Family on Pain Management at Home—cont'd

PAIN MANAGEMENT TECHNIQUES—cont'd

- How to use skin stimulation:
  - *Pressure:* using your entire hand, the heel of your hand, your thumb, your knuckles, or both hands, apply pressure for at least 15 seconds at the point where you feel pain. Keep trying spots around the painful area if you find no relief the first time. You may extend the time you apply pressure to 1 minute.
  - *Massage:* you or someone else can perform the slow, circular motions of massage. The feet, back, neck, and scalp can be massaged to relieve tension and pain anywhere in the body. Some people prefer to use oils or lotions during the massage. If deep massage is too uncomfortable, try light stroking. Do not massage red, raw, or broken skin.
  - *Heat and cold:* some people prefer cold; others prefer heat. Use whichever works better for you. A convenient way to use cold is to freeze gel-filled packs and wrap them in towels. Ice cubes can also be used. Heat can be applied with a heating pad; hot, moist towels; or a hot water bottle; or by taking a hot bath. Be careful not to burn your skin with water that is too hot or to go to sleep with a heating pad on. Do not expose your skin to intense cold for long periods.

MEDICATIONS

- Explain the purpose, dosage, schedule, and route of administration of any prescribed drugs, as well as side effects to report to a physician or nurse. Be sure the patient or caregiver knows the name of the medication.
- Give the patient general guidelines for the use of pain medication.
- Explain that a variety of pain-relief measures may be necessary for some types of pain.
- Instruct the patient to use pain-relief measures before pain becomes severe.
- Encourage the patient to try a pain-relief measure at least twice before abandoning it as ineffective.
- Urge the patient to keep trying to relieve the pain and not to become discouraged.
- Discuss the use of non-narcotic analgesics:
  - Inform the patient that non-narcotic analgesics include acetaminophen, aspirin, and nonsteroidal antiinflammatory drugs, such as ibuprofen, indomethacin, and naproxen.
  - Explain that these medications are generally well tolerated but have the potential to cause gastrointestinal ulceration, renal and hepatic toxic effects, and inhibition of platelet aggregation.
  - Tell the patient that if the non-narcotic does not have a therapeutic effect initially, the dosage should be increased before another type of drug is tried.
- Discuss the use of narcotics, which are indicated for severe postoperative pain or intractable pain such as that associated with cancer:
  - Inform the patient that narcotics include morphine, hydromorphone, and methadone and that these may be administered by intravenous drip, intrathecally, or epidurally to enhance the analgesic effect.
  - Explain that fixed dosage schedules with adequate doses for pain relief provide more constant blood levels and predictable pain relief. Suggest that additional doses may be needed for breakthrough pain.
  - Discuss the side effects of narcotic analgesics: constipation, vomiting, and respiratory and central nervous system depression.
- Discuss and demonstrate the use of equipment for administering pain-relief medications:
  - External and implantable pumps for intravenous, epidural, and intrathecal administration of narcotic analgesics
  - Patient-controlled analgesia (PCA), particularly for the management of acute pain such as postoperative pain
  - Continuous subcutaneous infusion with an ambulatory infusion pump
- Discuss the treatment for side effects of narcotics. For example, constipation requires the use of laxatives and stool softeners (e.g., senna [Senokot]).

Modified from Canobbio MM: *Mosby's handbook of patient teaching,* ed 3, St Louis, 2006, Mosby.

RISK REDUCTION STRATEGIES

Deep Vein Thrombosis Prevention in Orthopedic Procedures

Prevention of venous thromboembolism is a major consideration for patients undergoing orthopedic surgery, especially total joint arthroplasty. The *American College of Chest Physicians Evidence-Based Clinical Guidelines* for use of antithrombic and thrombolytic agents and therapy contain review of the literature, expert opinions, and recent clinical trial evaluations. Approximately 40% to 60% of orthopedic hip and knee arthroplasty patients develop deep vein thrombosis postoperatively. Additional risk factors for orthopedic patients include age greater than 75, malignancy, immobilization, and the use of certain medications. Currently, surgeon preference influences which anticoagulation therapy is initiated after surgery (see Surgical Pharmacology, p. 742). The ACCP recommendations include that all hospitals have a formal, institutional-wide written policy addressing thromboprophylaxis. The policy would include dividing patients into categories of low, moderate, or high risk. Thromboprophylaxis would be provided when its benefit outweighs the risk. Regular reassessment is necessary.

From Geerts WH et al: Prevention of venous thromboembolism: American College of Chest Physicians evidence-based clinical practice guidelines, *Chest* 133:381S-453S, 2008; *Joint Commission National Patient Safety Goals, NPSG.03.05.01,* available at www.jointcommission.org/NR/rdonlyres/31666E86-E7F4-423E-9BE8-F05BD1CB0AA8/0/HAP_NPSG.pdf. Accessed June 16, 2009.

RAPID RESPONSE TEAM

Rapid response teams (RRTs) were developed and implemented as a challenge from the Institute for Healthcare Improvement. Evidence showed cardiac arrest or unplanned ICU visits were preceded by signs of physiologic instability. Development of RRTs led to patient intervention before cardiac or respiratory arrest, preventing further deterioration of the patient, and improved patient outcomes. Cardiac emergency teams and rapid response teams were clearly defined by the Consensus Conference of Medical Emergency Teams in 2005. RRTs are nurse-led with intermediate interventional capabilities, as compared to physician-led medical emergency teams.

McFarlan and Hensley reported that the University of Kentucky Hospital (UKH) implemented such a program. The UKH used Failure to Rescue criteria as defined by the Agency for Healthcare Research and Quality. Failure to Rescue includes the development of the following diagnoses during an inpatient admission that result in death: sepsis, acute renal failure, venous thromboembolism, gastrointestinal hemorrhage or acute ulcer, pneumonia, shock, and cardiac arrest. The goals of the UKH RRT included an interdisciplinary approach for early recognition and intervention of the signs of clinical decline in the acute adult care setting and to expedite a higher level of care as needed. Roles and responsibilities were defined and physician support was elicited. The RRT formulated an "early warning signs" list, created an algorithm for activation of the RRT, and used the situation, background, assessment, and recommendation (SBAR) format for communication among healthcare providers. Education of the staff was key. Initial evaluation after the implementation of the UKH program was encouraging. Patient tracking included cardiac arrests, which showed an 8% decline within the first 2 years after implementation. Continued data analysis has led to future goals of the RRT at UKH including preadmission assessment for prediction of admission to ICU and patient outreach.

From McFarlan SJ, Hensley S: Implementation and outcomes of a rapid response team, *J Nurs Care Qual* 22 (4):307-313, 2007.

Pain management may include insertion of an epidural catheter, use of a patient-controlled analgesia (PCA) pump, or local administration of pain medication through a pain pump. The advantages of using these techniques include rapid pain relief, increased patient satisfaction, and, often, less use of medication than with traditional intramuscular analgesics. These techniques can be used independently or in combination. In using the PCA pump, a predetermined intravenous dose of the prescribed pain medication is administered. It allows continuous infusion of analgesic as well as bolus administration when the patient feels it is necessary (Patient and Family Education).

Management of fluid and electrolyte balance may include use of intraoperative autologous transfusion or postoperative blood salvage. A potential problem with salvage of large amounts of blood is depletion of clotting factors; therefore coagulation problems should be identified (Risk Reduction Strategies). Postoperative blood salvage is accomplished with a closed-drainage system. It requires a complete understanding of the system for safe use (Rapid Response Team box).

Instruments and Accessory Items. Orthopedic surgical procedures require an extensive inventory of instruments and implants and specific instruments to implant and apply hardware. Revision surgery requires that the perioperative staff be prepared with the appropriate tools and extractors needed to remove an old implant and an understanding of equipment use.

IMPLANT INVENTORIES. Implant inventories include plates and screws, intramedullary nails and rods, total joint implants, and a host of accessory items. Surgeon preference, patient population, and equipment cost are considered when selecting stock items. The surgical team must ensure these items are stocked in a timely fashion to prepare for consecutive implant use.

Inventory should be organized by manufacturers, type of implants (e.g., total hip, knee), and comparative sizes. Some may be provided on a loaner or consignment basis. Staff must be familiar with the varied types and refer to manufacturer's information pertaining to each implant. Practices should ensure that the correct implant is opened on the operative field to prevent unnecessary expense or error in placement.

Many different alloys are used in the manufacturing of implants. However, all devices implanted in a patient must be of the same metallic composition to prevent galvanic corrosion; internal fixation implants used during an orthopedic procedure should be of the same metal. Screws, for example, should be of the same composition as the metal plate affixed to the bone. Alloys that are used most frequently include stainless steel, cobalt-chromium, and titanium-vanadium-aluminum.

Internal fixation devices should never be reused. Resulting imperfections, such as abrasions or scratches, increase the potential for corrosion and weakening of the implant. Bending implants to conform to the contour of the bone should be avoided whenever possible to prevent loss of strength. When bending is necessary, the proper bending press should be used. Once an implant is bent, it should not be reshaped or straightened; doing so may weaken the implant.

Orthopedic equipment and implants require special care, storage, and handling. When possible, implants should be individually wrapped and processed. Today's implants, excluding some plates and screws, are packaged separately by the manufacturer. During sterilization, implants should not be placed in a position in which knocking or bumping might occur. Appropriate sterilizing cases and trays should be used, and implants should be sterilized according to the manufacturer's instructions. An internal fixation device that has become damaged as a result of improper storage or handling must be discarded.

The perioperative nurse assigned to orthopedic patients should have a working knowledge of the general types and sizes of implants that might be selected. Templates of radiographs are often made preoperatively, providing a general idea of the size of the implants needed.

The U.S. Food and Drug Administration (FDA) requires strict guidelines in properly documenting and tracking implant devices. Documentation should include, but not be limited to, the patient's permanent record, the operative record, and an implant registry maintained by the OR. Many manufacturers

now include mailers to return information to the company for data collection. Information to be recorded includes the lot and serial numbers of those implants used and the manufacturer, size, type, and anatomic position of the implants.

ORTHOPEDIC INSTRUMENTATION. Orthopedic instrumentation varies from very small to large instruments. Some procedures require multiple instrument containers (sets). Organization of instrument sets for multiple uses prevents the need for duplication and requires thoughtful consideration of anatomic and physiologic needs. When preparing for a procedure, the perioperative nurse should open the minimum number of instruments yet be prepared for unexpected or untoward events. Careful planning and preparation of instrumentation ensure efficient use of time and equipment.

Instruments that do not function properly (as a result of dullness, poor adjustment, lack of lubrication, damage, improper fit, or incomplete cleaning) are primary sources of complaints and problems in the OR. Instrument maintenance is vital to ensure availability for the procedure and ease in completion of the procedure. Instruments should be used for the intended purpose during the procedure. Movable parts should be lubricated after each cleaning and checked for cracks or damage after each use. The perioperative nurse is responsible for instrument maintenance and familiarity with sterilization and packaging procedures.

The following basic bone instrument sets should be available in the orthopedic OR. Soft tissue instrument sets appropriate for the size of the anatomic site are used for procedures not requiring bone instruments or in addition to the sets. Additional instruments and special equipment are mentioned with the discussion of various surgical interventions.

- *Incision hip set:* total hip arthroplasty or fractures of the neck and proximal femur
- *Total knee set:* total knee arthroplasty or supracondylar and distal femoral fractures
- *Shoulder set:* shoulder arthroplasty and other shoulder procedures
- *Large bone set:* bone work on the large bones, including hip, knee, upper arm, and elbow
- *Extremity or small bone set:* bone work on the hand or foot
- *Fusion or bone graft instruments:* additional instruments necessary for an autograft

POWERED SURGICAL INSTRUMENTS. Powered surgical instruments (Figure 19-25) used in the OR have eliminated the need for many hand-operated tools, thereby reducing operative time and improving technical results. They are available as air-driven, battery-driven, or electrically driven equipment. Fingertip control provides the surgeon speed and power. Variable-speed saws, drills, and reamers offer wide flexibility. Power equipment has a safety control that prevents inadvertent activation; this should be engaged when passing the instrument to the surgeon or assistant. The perioperative nurse and surgical technologist should monitor the sterile field to make certain that powered instruments are not rested on the patient when they are not in use.

It is important to follow the manufacturer's recommended cleaning, sterilizing, and lubricating instructions. With proper care, powered surgical instruments have a long life span and many uses.

SUTURE MATERIAL. Suture material requires increased tensile strength and minimal degradability for the select type of tissue. Tendons and ligaments are fibrous, avascular tissues, resulting in a slower healing process than that occurring in tissues rich in blood supply. Absorbable suture may be used for sewing tendon or ligaments to bone. Nonabsorbable sutures, including polyester and surgical steel, are also used. For various ligament replacement grafts, a harvested tendon may be customized with multiple strands of suture material, increasing tensile strength and length of time until fibrous union occurs.

POLYMETHYLMETHACRYLATE. PMMA (bone cement) is an acrylic, cementlike substance composed of a liquid methylmethacrylate monomer and a powder methylmethacrylate-styrene co-polymer. The powder component is 10% barium sulfate, U.S. Pharmacopoeia (USP), which provides radiopacity

FIGURE 19-25 Pneumatic-powered surgical instruments for large bone procedures. **A**, Reciprocating saw. **B**, Oscillating saw. **C**, Single-trigger modular handpiece.

to the finished product. The liquid monomer is highly flammable, and the OR should be properly ventilated. Caution should be exercised during mixing of the two components to prevent excessive exposure of OR personnel to the vapors of the monomer. This exposure can cause irritation of the respiratory tract and eyes. Personnel in a room where methylmethacrylate is being mixed should not wear soft contact lenses. Many special hoods and mixing devices are available to minimize staff exposure to the fumes.

Adverse patient reactions with PMMA include transitory hypotension, cardiac arrest, cerebrovascular accident, pulmonary embolus, thrombophlebitis, and hypersensitivity reaction. Cardiac arrest and death, although uncommon, have resulted after insertion of bone cement. Adverse reactions have been attributed to a combination of factors, including a rise in intramedullary canal pressure causing embolic phenomena, a possible chemical and blood reaction causing sudden hypotension, and certain preexisting patient conditions. More research is needed to discover the exact cause of adverse reactions. Patient care should include collaborating with the anesthesia provider before insertion of PMMA and then monitoring for side effects after insertion.

Medications. Antibiotics, hemostatics, and antibacterial agents are used commonly. Antibiotics are delivered both intravenously and locally in irrigation solutions. Common antibiotics used in irrigation include polymyxin and bacitracin. Irrigation may also be delivered using pulsatile lavage, with antibiotics added to the solution. Hemostatic agents may include bone wax, gelatin foam, thrombin, microfibrillar collagen, and parecoxib sodium. Parecoxib sodium is a liquid, sprayable hemostatic agent consisting of collagen, thrombin, the patient's own platelets, and fibrinogen. Antibacterial ointments are preimpregnated in gauze dressings from the manufacturer or are applied before the application of the dressing. Other medications used during orthopedic procedures include steroids, local anesthetics, and normal saline. Local anesthetics are often injected near the end of the surgical procedure to minimize postoperative pain.

SURGICAL PHARMACOLOGY

Anticoagulation Therapy

Venous thromboembolism (VTE), including deep vein thrombosis (DVT) and pulmonary thromboembolism (PE), is one of the most common preventable causes of hospital death. More than 900,000 Americans experience DVT each year, and 500,000 of these persons develop PE, which causes approximately 300,000 deaths. Analysis of related data has suggested that fewer than 50% of patients diagnosed and hospitalized with DVT had received prophylaxis. In 2003, recognizing that the incidence of DVT/VTE was a significant patient safety issue, the National Quality Forum (NQF) endorsed Safe Practice 17: *Evaluate each patient upon admission, and regularly thereafter, for the risk of developing DVT/VTE. Utilize clinically appropriate methods to prevent DVT/VTE,* and Safe Practice 18: *Utilize dedicated anticoagulation services that facilitate coordinated care management.*

In addition, the Surgical Care Improvement Project (SCIP) targeted DVT as a key area for improvement in surgical patient care. SCIP is a national partnership of organizations committed to improving the safety of surgical care through the reduction of postoperative complications, with a goal of reducing the incidence of surgical complications nationally by 25% by the year 2010. SCIP identified two process measures in the reduction of VTE: (1) that surgery patients have the appropriate VTE prophylaxis ordered and (2) that it be administered within 24 hours before their surgery or within 24 hours after it.

More than 50% of major orthopedic procedures are complicated by DVT, and up to 30% by PE, if prophylactic treatment is not instituted. DVTs in the perioperative period involve several components, including venous stasis, acquired hypercoagulable state, endothelial injury, and the positioning of the limb intraoperatively. Despite the well-established efficacy and safety of preventive measures, studies show that prophylaxis is often underused or used inappropriately. Both low-dose unfractionated heparin (LDUH) and low-molecular-weight heparin (LMWH) have similar efficacy in DVT and PE prevention.

Some common drugs used to prevent DVT and their mechanisms of action are as follows:

- *Ardeparin*—LMWH; prevents conversion of fibrinogen to fibrin and prothrombin to thrombin by enhancing inhibitory effects of antithrombin III; used for preventing DVT after total knee arthroplasty (TKA)
- *Danaparoid*—glycosaminoglycan; prevents conversion of fibrinogen to fibrin and prothrombin to thrombin by enhancing inhibitory effects of antithrombin III; used for DVT prevention in total hip replacement or hip fracture surgery
- *Desirudin (Iprivask)*—thrombin inhibitor; prevents thrombin, resulting in prolongation of clotting time; used for DVT prophylaxis in hip replacement surgery
- *Enoxaparin (Lovenox)*—LMWH; prevents conversion of fibrinogen to fibrin and prothrombin to thrombin by enhancing inhibitory effects of antithrombin III and produces higher ratio of anti–factor Xa to anti–factor IIa; used for prevention of DVT and PE in hip and knee replacement surgery
- *Heparin (Calcilean, Calciparine, Hepalean, heparin sodium, Heparin LEO, heparin lock, Hep-Lock)*—anticoagulant and antithrombotic; prevents conversion of fibrinogen to fibrin and prothrombin to thrombin by enhancing inhibitory effects of antithrombin III; used for prevention of DVT and PE
- *Warfarin (Coumadin, Sofarin, warfarin sodium, Warfilone Sodium)*—anticoagulant; interferes with blood clotting by indirect means; depresses hepatic synthesis of vitamin K–dependent coagulation factors (II, VII, IX, X); DVT and PE prevention

Patient education should include the reason for DVT prophylaxis, the name (both generic and trade) of the drug, dosage, time of administration, and side effects. Because bleeding is a dangerous complication, signs and symptoms of both minor bleeding and major bleeding should be reviewed. Patients should receive both oral and written information along with the name of a physician or nurse to call if complications or questions arise.

Modified from Canobbio MM: *Mosby's handbook of patient teaching,* ed 3, St Louis, 2006, Mosby; SCIP: *A national quality partnership,* available at www.qipa.org/shared/content/pa_documents/Patient%20Safety%209SOW. Accessed June 23, 2009; Skidmore-Roth L: *Mosby's drug guide for nurses with 2010 update,* ed 8, St Louis, 2009, Mosby.

Protective Measures. Orthopedic procedures require caution as a result of the use of fluids for irrigation or bloody procedures. Personnel protective measures include handling items (blades, sharp instruments, bone) cautiously to prevent inadvertent punctures or cuts and wearing protective masks, eyewear, or a face shield as well as protective attire, including gowns and boots. Sharp bone edges are a hazard and can puncture gloves and skin. Double-gloving or use of protective gloves should be employed to protect the patient and personnel.

Bone Banking. The American Association of Tissue Banks (AATB) accredits and periodically inspects bone-banking programs to ensure that specific standards are followed in the retrieval, processing, storage, and distribution of bone allografts (AATB, 2008). Allografts are frozen until use. Vacuum-sealed freezers are monitored with an alarm. When requested for a procedure, the bone allograft is delivered to the field, slightly thawed, cultured, and washed with an antibiotic solution. Banked bone is available in many shapes of cortical and cancellous tissue.

Records are maintained on both donors and recipients. Donor records provide the donor identification, medical history (with circumstances of death if applicable), laboratory results, and graft description. Recipient records include recipient identification, surgeon and organization implanting the graft, surgical procedure, culture results, and any adverse reactions. Like other implants, the recipient's operative record should include the name of the bone bank from which the allograft was received, type of allograft, tissue number, and expiration date if applicable.

Evaluation

Evaluation is an ongoing process, occurring throughout the procedure. The perioperative nurse evaluates the patient, considering the nursing diagnosis and achievement of identified outcomes. This part of the nursing process provides feedback regarding the effectiveness of the plan, its implementation, and alterations needed for improving patient care. Was the patient protected from peripheral neurovascular injury? Was the patient free from perioperative positioning injury? Was adequate oxygenation maintained? Does the patient have more questions pertaining to recovery and rehabilitation? The answers will dictate whether there is a need to maintain or modify the plan. The evaluation information is shared with the nurse caring for this patient postoperatively to provide continuity of care.

The following sample outcome statements apply to evaluating care of the orthopedic patient when using the nursing diagnoses identified earlier in this chapter:

- The patient verbalized fears and feelings and indicated that anxiety and apprehension were lessened.
- The patient was free from peripheral neurovascular dysfunction on discharge to the postoperative area as evidenced by presence of pulses, warmth of the extremity, good capillary refill, and intact movement and sensation.
- The patient was free from injury related to perioperative positioning as evidenced by maintenance of skin integrity and absence of reddened areas.
- The patient maintained adequate ventilation and perfusion as evidenced by blood gases, arterial saturation, and vital signs within normal limits.
- The patient was free from surgical site infection as evidenced by temperature within normal limits and a clean and dry incision site.

Patient and Family Education and Discharge Planning

Discharge planning and patient education should be initiated when the healthcare provider evaluates the patient for surgery. It should continue when the patient comes into contact with the healthcare system and should involve a multidisciplinary approach. A method of planning the overall care from preadmission to discharge is to place a patient on a clinical guideline or care path based on "best practice"—a multidisciplinary case management tool. "Best practices" define the expected processes of care. Essentially they are strategies of care developed with the intent of encouraging physicians and other healthcare providers who care for the same surgical patient population to agree to a specific sequence of common interventions. Included with the clinical guideline on the patient's medical record is a set of orders that mirrors the guideline and allows the physician to make minor changes to the protocol. Receiving feedback from all disciplines involved in the patient's care and discharge planning is beneficial in reducing variance and improving efficiency, outcomes, and costs.

For the patient undergoing orthopedic surgery, patient and family education and discharge planning in the following areas are essential: wound care and dressing changes, pain control, wound assessment, physical and occupational therapy, personal care, housekeeping, mobility, nutrition, prescriptions other than pain medication, extended anticoagulant therapy (Surgical Pharmacology), application and removal of orthopedic appliances, and follow-up with a physician. Information concerning these content areas should be described, discussed, and reinforced with written instructions. Perioperative nurses should ensure that the patient and family understand the instructions, have the opportunity to demonstrate a requisite skill if that is part of home care and convalescence, and have time to ask questions and address concerns. A sample of written educational material that might be provided to the orthopedic surgical patient with a cast is presented in the Patient and Family Education box on p 736. Relevant content for devising patient and family educational material on pain management at home is presented in the Patient and Family Education box on pp. 738-739.

Surgical Interventions

ALLOGRAFTS/AUTOGRAFTS

Bone grafting using allografts or autografts may be used (1) to fill cavities after removal of large amounts of bone that might result in instability, (2) to fill bony defects, and (3) to promote union of fractures at the time of open reduction. The type of graft used depends on the location of the fracture or defect, the condition of the bone, and the amount of bone loss as a result of injury. Bone grafts may be used for procedures involving revision of joints if there is significant bone loss caused by resorption or mechanical destruction after removal of bone cement.

The bone graft may be the patient's own bone (autogenous in origin and referred to as *autograft*) or bone obtained from a tissue bank (homogeneous in origin and referred to as *allograft*). Autografts are often harvested from the iliac crest,

where there is cortical and cancellous bone. Various harvesting techniques are used. Struts of cortical bone from the iliac crest can be fashioned to the desired shape and used in areas needing structural strength. The amount of cancellous bone is plentiful. It is used to promote bone growth in areas of defect. Local bone graft material may be taken from the site of injury. Allografts are used when bone is not available from the patient because of the lack of sufficient quantity or because a secondary procedure is undesirable for the patient.

Procedural Considerations

Cancellous grafts may be taken from the ilium, olecranon, or distal radius; cortical grafts may be taken from the tibia, fibula, iliac crest, or ribs. When the recipient site of an autogenous graft is diseased, instruments used for the recipient site must be separated from donor graft site instruments. The operating team must change their gowns and gloves to take the bone graft and again follow the procedure to prevent cross-contamination. The patient is positioned to allow exposure to the surgical site. A sandbag may be placed beneath the area for easier access.

The instrumentation for taking a bone graft includes soft tissue instruments and a bone graft set. Grafts may be harvested with hand instruments, power tools such as an oscillating saw, or high-speed tools such as the Midas Rex. Power tools may be necessary if a uniformly shaped graft is needed to fill a defect. Because hemostasis is sometimes difficult to achieve as a result of the vascular nature of bone, wound drains may be desirable.

Operative Procedure

Harvest of Bone Graft. A cancellous bone graft consists of spongy bone usually taken from the anterior or posterior crest of the ilium. A cortical bone graft, consisting of hard, dense bone, is removed from the crest of the ilium or the tibia. The location of the crest of the ilium is subcutaneous, allowing exposure without difficulty.

1. The surgeon makes an incision along the border of the iliac crest, and strips, elevates, and retracts the muscles on the outer table of the ilium.
2. Strips of the iliac crest can be removed with an osteotome or oscillating saw.
3. A cortical window may also be made in the outer table, and the surgeon may use curettes or gouges to remove cancellous bone chips.
4. A drain may be inserted. The surgeon closes the wound in layers and applies a pressure dressing.

ELECTRICAL STIMULATION

The healing process in bone involves several stages (Figure 19-26). When a bone is damaged, such as during a surgical procedure or fracture, bleeding occurs. The amount of extravasated blood depends on the vascularity of the fracture site. The blood exudate infiltrates the surrounding area, where a clot is formed. Fibroblasts invade the hematoma and form a fibrin meshwork.

As osteoblasts invade the fibrin meshwork, blood vessels develop to build collagen. After several days, calcium deposits may form in the granulation tissue. These deposits eventually form new bone, known as *callus*. Within the callus, cartilage cells develop a temporary semirigid tissue that helps stabilize the bone fragments. The callus is immature bone that is remodeled by new connective tissue cells (osteoblasts) of the periosteum and the inner membrane of the bone cavity. Through this process, mature bone is formed, excess callus is resorbed, and trabecular bone is placed.

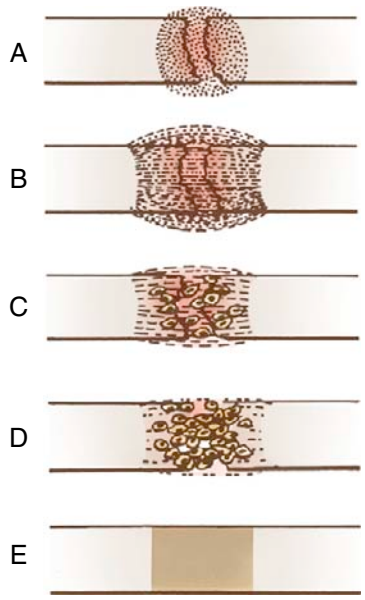

FIGURE 19-26 Bone-healing process. **A**, Hematoma formation. **B**, Fibrin network formation. **C**, Invasion of osteoblasts. **D**, Callus formation. **E**, Remodeling.

After several months, depending on the age and physical condition of the individual, the bone becomes firmly united, although the ossification process is not yet completed. Complete union of the fractured bone or joint is determined by means of clinical and radiologic examination.

Healing of bone is classified by degree. *Delayed union* signifies that healing has not occurred within the average time. The average time depends on many factors, and delayed unions must not be considered nonunion until the healing process has ceased without bony union. *Malunion* signifies that the fracture has united with deformity sufficient to cause impairment of the function or a significant angulation of the extremity. *Nonunion* signifies that the process of healing has ended without producing bony union; in this case, electrical stimulation may be used.

Electrical stimulation is artificially applied electrical current that induces or influences the formation of new bone. Various types of stimulators (Figure 19-27) are available for treatment of nonunion, including invasive (implantable), semi-invasive (percutaneous), and noninvasive (capacitance coupling). The bone stimulator of choice depends on the patient, pathologic condition, and the physician's comfort with the device.

The bone-growth stimulator is used in patients with high risk of nonunion. It can be used to provide electrical stimulation for treatment of nonunion, delayed union, congenital pseudarthrosis, and bone defects. It may be used with or without internal fixation devices, external fixation devices, or bone grafting. Patients who have undergone previous surgery, who have sustained significant tissue loss, or in whom bone grafting is contraindicated are candidates. Electrical stimulation requires long periods of immobilization of the site. This prolonged immobilization may impede rehabilitation.

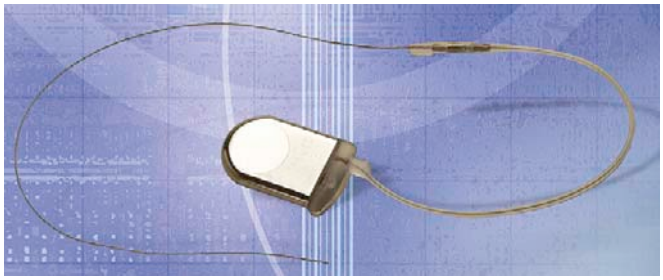

FIGURE 19-27 Bone-growth stimulator used after procedures to induce bone formation.

Procedural Considerations

Instructions for implanting and components selected vary according to the type. The position of the patient depends on the implant site.

In addition to the implant of the surgeon's choice and the implant-specific instrumentation, a soft tissue set is used. Curettes, osteotomes, or bone rasps are used for bony debridement and to scarify the donor bed. Power drills with drill bits may be necessary to create access through the bone for the electrical leads.

Operative Procedure

1. The surgeon exposes the site and debrides it as necessary. A stimulator may be implanted after the surgical procedure.
2. A bone slot is fashioned, spanning the nonunion site.
3. The surgeon makes a second incision about 8 to 10 cm from the first one and dissects the tissue. Before the generator is implanted, hemostasis must be achieved. The use of electrosurgical equipment may interfere with function of the bone-growth stimulator.
4. Using blunt or sharp dissection, the surgeon creates a subcutaneous channel for the cathode.
5. The surgeon guides the long cathode lead through the channel.
6. The generator is carefully implanted near the skin surface. The generator should be inserted into soft tissue—not against bone or metal fixation devices; it should not create a bulge beneath the skin.
7. The surgeon places the electrical coils in the prepared bone slot in equal lengths above and below the fracture site.
8. Cancellous bone grafts are placed between the coils if large bony defects are being treated.
9. Routine closure of the subcutaneous and skin tissue is carried out.

Once union has occurred (5 to 6 months), the surgeon removes the generator after a local anesthetic has been administered.

FRACTURES AND DISLOCATIONS

A fracture is a break in the continuity of a bone. The care of fractured bones or dislocation of a joint is complicated when there is trauma to the soft tissues, including muscles, nerves, ligaments, and blood vessels. Bone diseases, which can increase the risk of a fracture, can be metabolic, infectious, or degenerative. Metabolic diseases are disorders of bone remodeling. The most common are osteoporosis, osteomalacia, and Paget's disease, all of which may result in bone fractures. The most common infectious process is osteomyelitis. Degenerative musculoskeletal conditions are associated with aging. Osteoarthritis is the most common degenerative change.

Osteoporosis is one of the most common and serious of bone diseases and is responsible for more than 2 million fractures a year. Osteoporosis-related fractures most commonly occur in the hip, spine, and wrist, but any bone can be affected. The number of fractures caused by osteoporosis is expected to rise to more than 3 million by 2025 (National Osteoporosis Foundation [NOF], 2009).

Osteoporosis is characterized by excessive loss of calcified matrix, bone mineral, and collagenous fibers, causing a reduction of total bone mass. Decreasing levels of estrogen and testosterone in the older adult result in reduced new bone growth and maintenance of existing bone. Inadequate intake of calcium or vitamin D; lack of weight-bearing activities, exercise, and physical activity; smoking; and caffeine intake are other contributing factors. Osteoporotic bone is porous, brittle, and fragile, fracturing easily under stress. This results in susceptibility to spontaneous fractures and pathologic curvature of the spine (Barclay et al, 2008).

Osteomalacia is a metabolic bone disease characterized by inadequate mineralization of bone as a result of vitamin D deficiency, which leads to a reduced absorption of calcium and phosphorus. Risk factors for development of osteomalacia include malabsorption problems, vitamin D and calcium deficiencies, chronic renal failure, and inadequate exposure to sunlight. Medical treatment includes dietary supplements and exposure to sunlight.

Paget's disease is a disorder affecting older adults. It is characterized by proliferation of osteoclasts and compensatory increased osteoblastic activity, resulting in rapid, disorganized bone remodeling. The bones are weak and poorly constructed.

Types of Fractures

Fractures are classified into two main groups: closed fractures and open or compound fractures. *Closed fractures* are those in which there is no communication between the bone fragments and the skin surface. *Incomplete closed fractures* are those in which the whole thickness of the bone is not broken but is bent or buckled, such as in greenstick fractures, which commonly occur in prepubertal children. *Open fractures* exist when the break in the bone communicates with a wound in the skin. These fractures are usually considered contaminated, requiring measures to control potential infection.

The many varieties of fracture architecture (Figure 19-28) include (1) transverse fracture, in which the fracture line runs at a right angle to the longitudinal axis of the bone; (2) longitudinal fracture, which runs along the length of the bone; (3) oblique fracture and spiral fracture, in which bone is twisted apart (similar except that oblique is shorter than spiral); (4) comminuted fracture, in which the bone fragments splinter into more than two pieces; (5) compression fracture, in which one fragment is driven into the other end and is relatively fixed in that position; and (6) pathologic fracture, in which a bone will fracture easily because it is weakened by disease. A fracture in the shaft of a long bone is described as being in the proximal, middle, or distal third or at the junction of one of these two divisions. A fracture of one of the bony prominences of the end of a long bone is described as a fracture of that prominence by

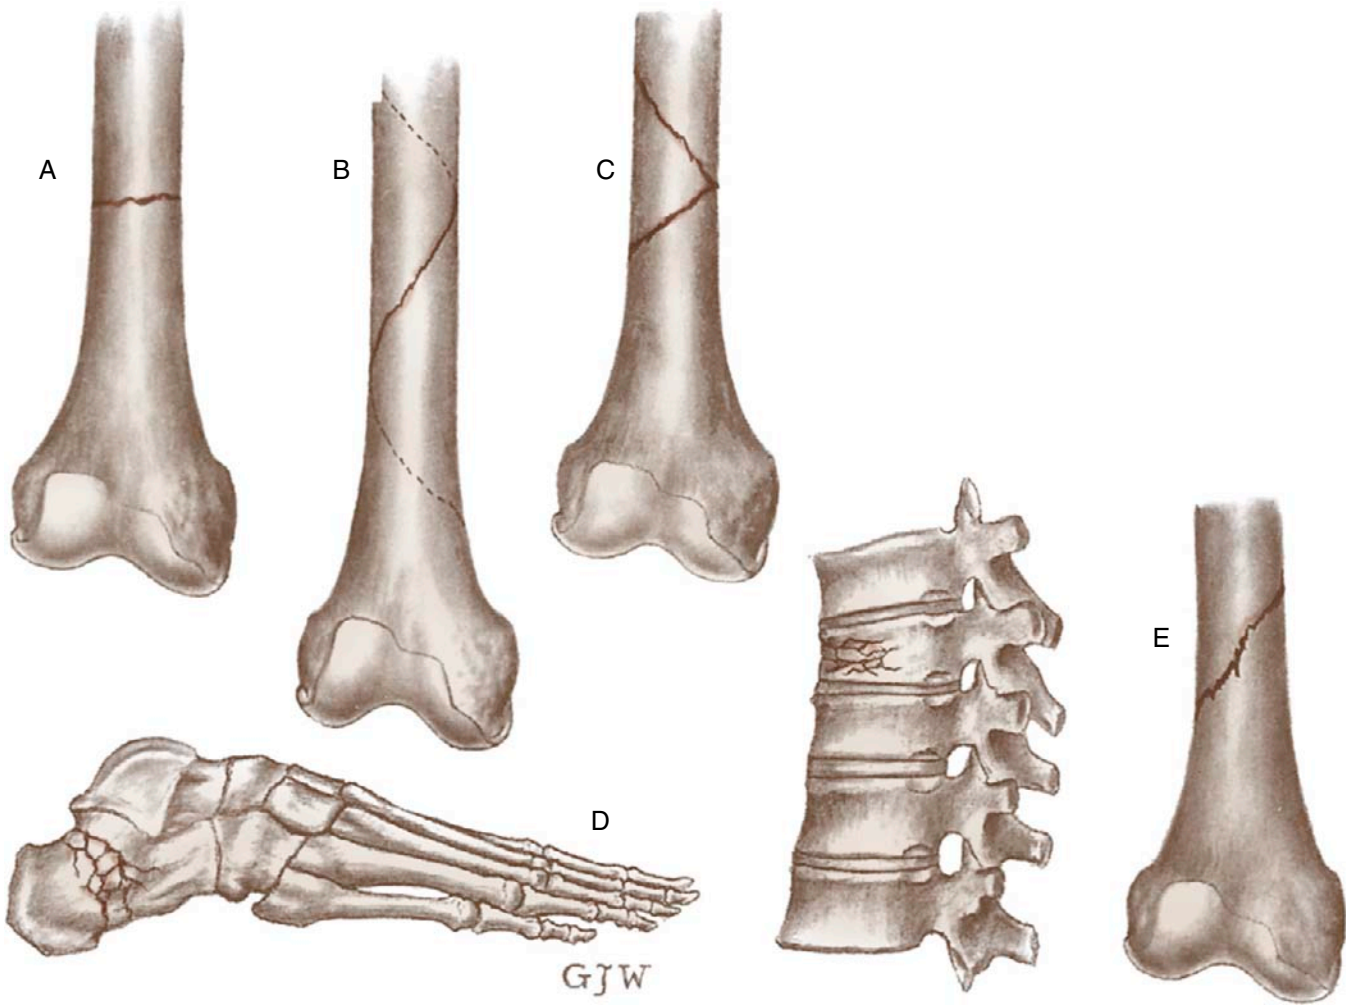

FIGURE 19-28 Fracture types, which may be open or closed. **A**, Transverse. **B**, Longitudinal or spiral. **C**, Comminuted. **D**, Compression. **E**, Oblique.

name. Examples include a fracture of the olecranon, medial malleolus, or lateral condyle of the femur.

An epiphyseal separation occurs when a fracture passes through or lies within the growth plate of a bone. When this occurs in a child with immature bone, retardation of limb length and growth may occur. These injuries require immediate and expert treatment.

An avulsion fracture results in a ligamentous attachment remaining intact on a separated bone fragment. This may occur after joint dislocation or rotational injury, such as the femoral condyle separating from the tibial plateau. A dislocation (luxation) is a complete displacement of one articular surface from another. This injury can disrupt neurovascular structures, requiring immediate attention. A subluxation is a partial dislocation, often indicated by ligamentous instability.

Principles of Treatment

The purpose of fracture treatment is to reestablish the length, shape, and alignment of the fractured bones or joints and restore anatomic function. Acute fracture treatment is necessary to alleviate neurovascular compromise. The surgical team should consider the following principles when providing care for the patient: (1) the patient's extremity or fracture site must be handled gently; (2) initial general medical treatment must be provided; (3) equipment and personnel must be readily available to treat impending or existing shock and to control hemorrhage; (4) aseptic technique must be maintained; (5) positioning must allow adequate circulatory and respiratory function with adequate exposure; and (6) patient comfort must be considered.

The primary goal in treatment of an upper extremity fracture is to preserve mobility and restore range of motion, enabling the individual to perform skilled and delicate work. In fractures of a lower extremity, the objectives of surgery are to restore alignment and length and provide stability of the extremity for weight bearing.

In the presence of open fractures involving soft tissues, several associated conditions may arise, including (1) secondary hemorrhage, (2) infection, (3) severe damage to soft tissues, (4) damage to blood vessels and nerves, and (5) Volkmann's contracture (ischemic paralysis).

Basic Treatment Techniques

Closed Reduction. The surgeon may treat fractures with closed reduction—manipulating the fragments into position without incising the skin. When possible this is the treatment of choice because it decreases the opportunity for infection,

improves results (including bone union of the fracture), and minimizes the recovery period. Significant bone comminution, periosteal damage, or soft tissue entrapped within the fracture site may result in complications.

PROCEDURAL CONSIDERATIONS. The choice of anesthesia depends on the site of fracture and the patient's condition. A closed reduction can be performed with (1) infiltration of local anesthetic agent into the fracture site (hematoma block), (2) intravenous regional anesthesia (Bier block), (3) regional or spinal nerve block, or (4) general anesthesia. Closed reduction may take place before an open procedure to reduce the fracture site. Skeletal traction may also be applied to the fracture site (Figure 19-29), requiring a surgical skin prep and application of drapes. The perioperative nurse consults with the surgeon to determine the appropriate casting or brace materials and makes certain they are readily available to prevent loss of fracture reduction. Instrumentation and supplies should be available in the event it is necessary to open the fracture site and apply fixation.

OPERATIVE PROCEDURE

1. The surgeon uses manual traction to manipulate the fragments into alignment.
2. Reduction is confirmed using radiography (x-ray or fluoroscopy).
3. After reducing the fracture the surgeon immobilizes it with casting material or bracing techniques.

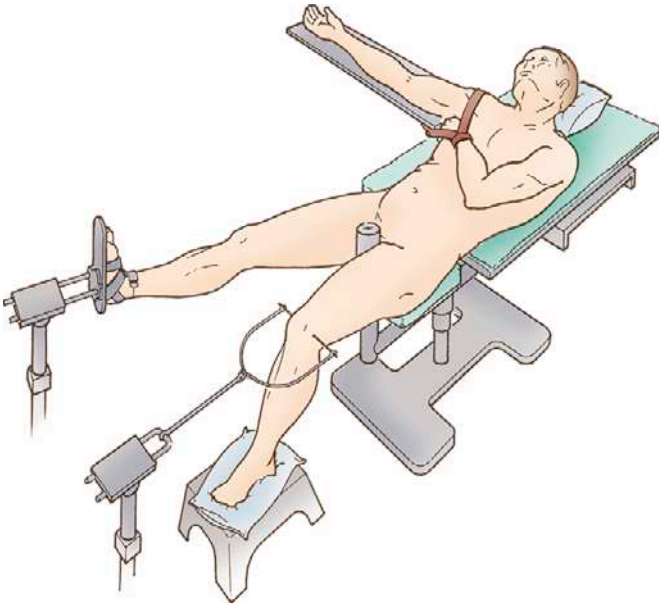

FIGURE 19-29 Application of skeletal traction with the patient positioned supine on the OR fracture bed.

External Fixation. External fixation of fractures provides rigid fixation and reduction with the ability to manage severe soft tissue wounds. Because of the increased chance of infection in patients with an open fracture, external fixation is often the preferred treatment. Advantages of external fixation include the absence of casting material, fracture stabilization at a distance from the injury site, ability to perform subsequent procedures such as skin grafts or vascularized grafts, minimal joint interference, early mobilization, and the ability to use internal fixation or other skeleton-fixation devices at the same time or sequentially.

Indications for external fixation include (1) severe open fractures, (2) highly comminuted closed fractures, (3) arthrodesis, (4) infected joints, (5) infected nonunion, (6) fracture stabilization to protect arterial or nerve anastomoses, (7) major alignment and length deficits, (8) congenital deformities, and (9) static contractures. External fixation provides a bridge between fracture reduction and insertion of an internal fixator such as an intramedullary nail, allowing time for vascular recovery. Internal fixation can take place at a later date.

Many improvements have been made in the design and articulations of external fixation devices. The fixators can be applied to most anatomic sites. The available external fixators vary greatly in design; however, all contain three main components: (1) bone-anchoring devices (threaded pins, Kirschner wires), (2) longitudinal supporting devices (threaded or smooth rods), and (3) connecting elements (clamps and partial or full rings). Improvements have resulted in the use of lightweight and stronger materials, which are radiopaque, for use as connecting rods. The radiopaque feature prevents postoperative radiographic interference when viewing the fracture site for progress in healing.

The Ilizarov device uses principles of tension-stress and distraction to correct bone defects and limb-length discrepancies. It is not routinely used for acute fracture fixation; however, the principles and technique are similar. Limb length may be adjusted with gradual bone distraction of bone ends, stimulating new bone formation.

PROCEDURAL CONSIDERATIONS. External fixators are applied using sterile technique after the patient has been administered a general or regional anesthetic. Radiographic imaging ensures fracture reduction after closed manipulation; it also ensures proper pin placement. Because the incision site is small to allow introduction of pins, a soft tissue set appropriate to the site will be necessary. Many different external fixators are available for use. Some examples are shown in Figures 19-30 to 19-33. Irrigation and debridement at the fracture site and surrounding soft tissue may be necessary if soft tissue is damaged, so pulsatile lavage with 3000 ml of normal saline solution should be available. The surgeon will use a power drill at the pin sites, and a periosteal elevator if necessary for blunt or sharp dissection. An appropriate-size pin cutter should also be available to shorten the pins if the need arises. The dressing consists of an antibacterial ointment, antibiotic-impregnated gauze, or nonadherent gauze with gauze overwrap.

OPERATIVE PROCEDURE

1. The fracture is reduced manually.
2. The surgeon incises the skin.
3. Using a periosteal elevator, the surgeon dissects the periosteum from the bone if necessary.
4. The surgeon predrills the cortex, using a drill sheath to protect surrounding soft tissue.
5. Hand drilling or low-speed power drilling is used to insert the half pins above and below the fracture.
6. Universal joints are slipped over the pins and joined with a connecting rod.
7. The surgeon tightens the frame using the appropriate wrenches.
8. Radiography or fluoroscopy is used to confirm reduction and alignment.
9. Dressings are applied to the pin sites.

FIGURE 19-30 Synthes external fixator.

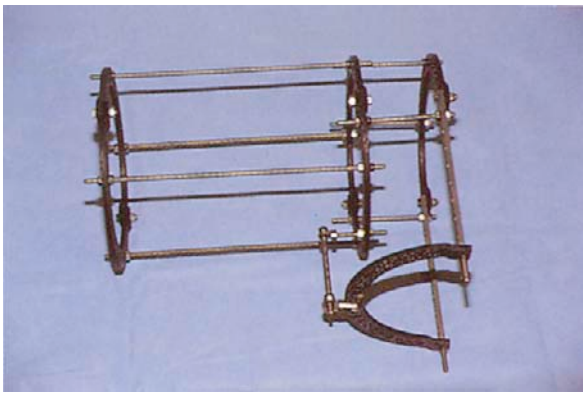

FIGURE 19-31 Ilizarov tibial external fixator.

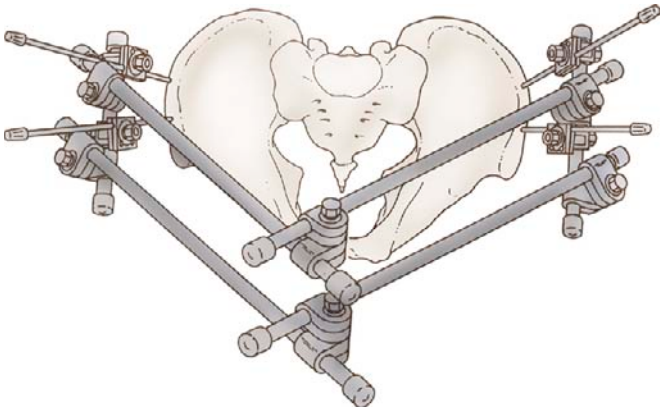

FIGURE 19-32 AO/ASIF pelvic external fixator, double frame using tube-to-tube clamps.

Internal Fixation. Internal fixation is often the treatment of choice for correction of fractures of long bones or those in the hip region. Application of compression plates and screws and insertion of pins, intramedullary rods, nails, or wiring are methods of internal fixation. Fractures of most anatomic parts in adults can be repaired using internal fixation.

Many principles and techniques apply when using internal fixation. Types of screws (Figure 19-34) include cortical, cancellous, lag, pretapped, and self-tapping. Cortical bone screws have threads that are closer together and narrower than other types of threads. These threads run along the entire length of the screw and transfix bone, gaining purchase (grab) of bone cortex.

Cancellous bone screws feature threads that are broader and farther apart than those of cortical screws. Cancellous screws are used in cancellous bone, which is less dense than cortical bone; the bone accumulates within the threads to provide the purchase for fixation. Like cortical screws, cancellous screws

FIGURE 19-33 Dynawrist dynamic wrist external fixator.

FIGURE 19-34 Types of screws used for fixation with or without plating systems.

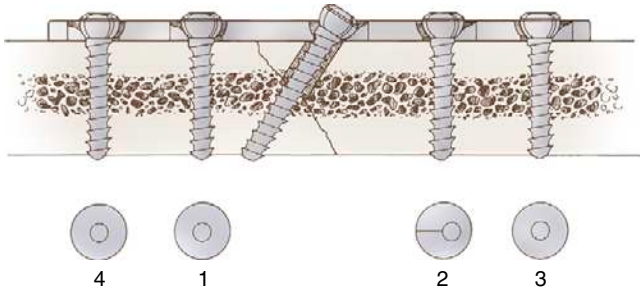

FIGURE 19-35 Plating a closed forearm fracture using dynamic compression showing final position of the screw insertion.

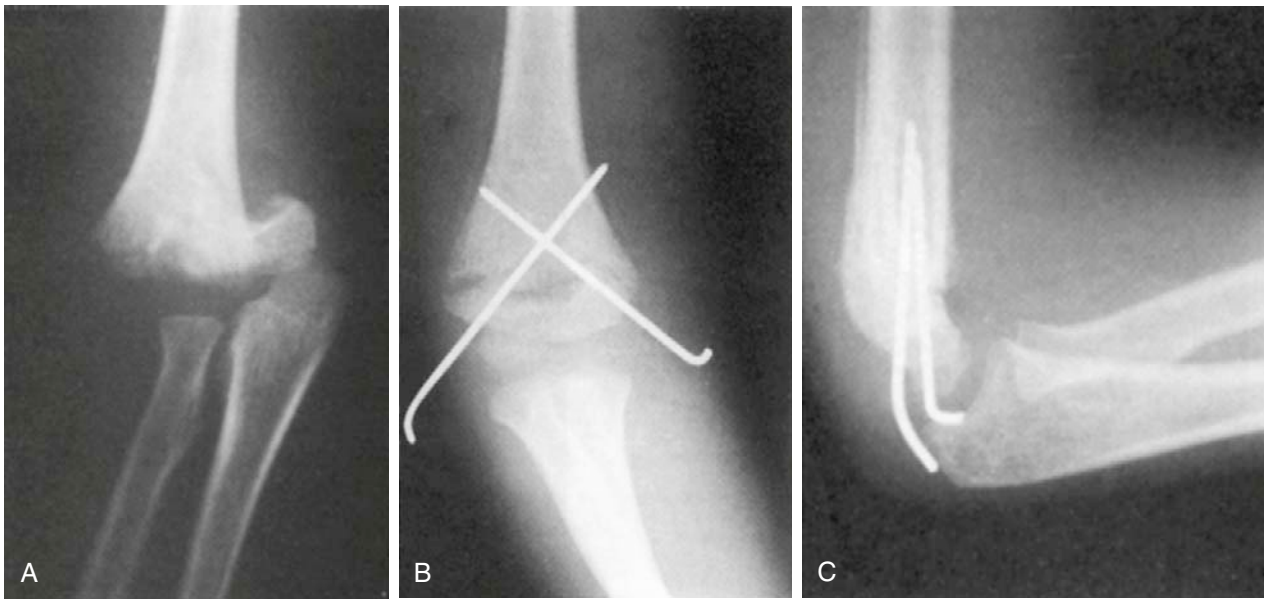

FIGURE 19-36 Percutaneous pinning of a supracondylar fracture. **A**, Severely displaced supracondylar fracture. **B** and **C**, Treated by closed reduction and percutaneous pinning.

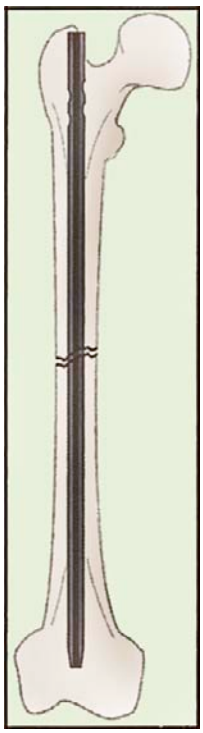

FIGURE 19-37 Rod placement for femoral fracture.

can traverse fracture sites and hold plates onto bone. The screw threads do not completely traverse the bone through the opposite cortex. Cancellous screws are commonly used when fractures occur at the condylar ends of the shaft.

Plating of a fracture may occur with or without dynamic compression (Figure 19-35). Dynamic compression uses screw and plate configurations to apply forces through the fracture site. Semitubular plates are less rigid and do not have the ability to produce dynamic compression. This type of plate is used in the forearm and fibula, where weight bearing, which could break the plate, is not a factor.

CLOSED REDUCTION METHOD. The surgeon may reduce fractures using closed reduction methods of manipulation and traction combined with percutaneous insertion of pins, intramedullary nails, or rods. Pins can be placed percutaneously (Figure 19-36) to fix fractures involving the digits, wrist, elbow, and foot. A rod or nail is placed percutaneously (Figure 19-37) in a large bone such as the humerus or femur. Closed reduction is, however, a misnomer, since small openings in the soft tissue and bone are made to facilitate introduction of the devices. These incisions are considerably smaller than those created when repairing the fracture using open reduction. The advantages of closed reduction over open reduction and internal fixation are (1) a lower incidence of infection and (2) absence of additional soft tissue or vascular damage.

OPEN REDUCTION AND INTERNAL FIXATION. Open reduction and internal fixation is a method of providing exposure of the fracture site and using pins, wire, screws, a plate and screw combination, rods, or nails to correct the fracture (Figure 19-38). Surgeons use open reduction and internal fixation when they are unable to reduce a fracture by closed methods and skeletal traction is not indicated. The advantage is that anatomic alignment of the fracture can usually be obtained and verified through direct observation. Fractures that are comminuted or difficult to reduce can be more effectively treated using this technique. The incidence of infection and nonunion, however, is increased when the wound is opened.

The procedure varies for each anatomic site, using the principles for specific fixation devices. Several procedures described in the text identify steps for completion of open reduction and internal fixation. Reference examples include the following:

- *Pin fixation:* application of a unilateral frame
- *Wire fixation:* reduction of patellar fracture, tension banding of the olecranon
- *Screw fixation:* correction of scaphoid fractures

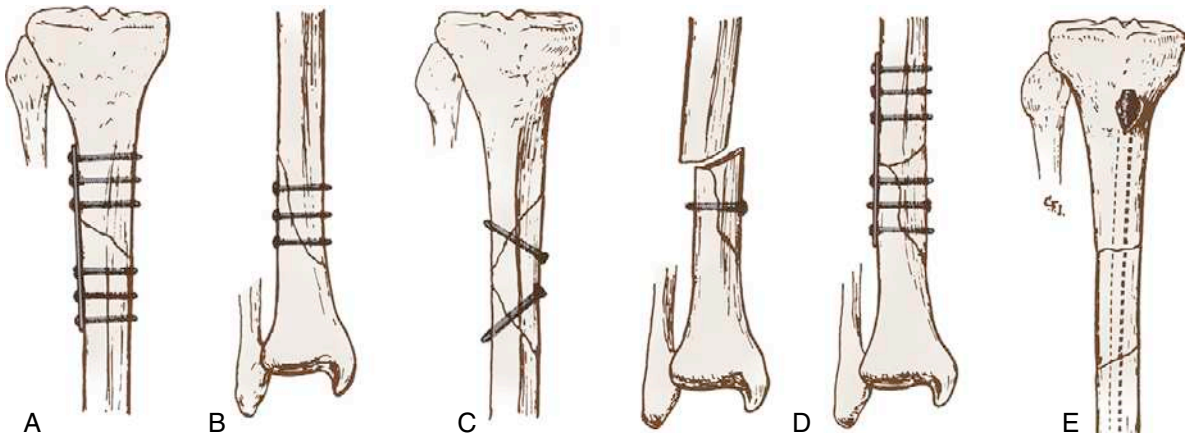

FIGURE 19-38 Types of internal fixation for fracture repair. **A**, Plate and screws for transverse or short oblique fracture. **B**, Transfixion screws for long oblique or spiral fractures. **C**, Transfixion screws for long butterfly fragment. **D**, Fixation for short butterfly fragment. **E**, Medullary fixation.

- *Plate and screw fixation:* repair of a comminuted distal humeral fracture
- *Rod or nail fixation:* correction of fractures of the shaft of the humerus, femoral shaft, or tibial shaft

SURGERY OF THE SHOULDER

Correction of Acromioclavicular Joint Separation

Acromioclavicular joint separation (Figure 19-39), a common occupational and athletic injury, results from a force applied downward, most commonly from a fall, directly to the top of the shoulder. The ligamentous support of the distal clavicle in the form of the coracoclavicular, coracoacromial, and acromioclavicular ligaments is disrupted. The result is either a posterior or a superior displacement of the lateral end of the clavicle.

The purpose of surgery in an acutely injured patient is to reestablish the proper relationship between the clavicle and the acromion, thereby reducing long-term shoulder pain and increasing function. This is accomplished by replacing the coracoclavicular ligaments with heavy suture or Mersilene tape or by inserting a screw through the clavicle and into the coracoid process. It may also be necessary to stabilize the acromioclavicular joint by placing a smooth Steinmann pin across the acromion and into the clavicle. Sometimes the distal end of the clavicle is also resected. If resection of the clavicle is the only treatment required, this may be completed arthroscopically. Shoulder arthroscopy is detailed in the Arthroscopy of the Shoulder section of Arthroscopy, p. 806.

Procedural Considerations. The perioperative nurse assists in placing the patient in the supine or semisitting position with a sandbag or folded sheet under the affected shoulder. The patient's shoulder is positioned slightly off the OR bed (Figure 19-40) to allow full range of motion, or if mobility of the arm is unnecessary, a shoulder positioner is used. The head is turned to the opposite side, taking care not to overstretch the nerves of the brachial plexus. The surgical technologist assists with draping the patient's arm with a stockinette to the midhumeral level.

A soft tissue set and bone instrumentation specific for the shoulder (Figure 19-41) are required. Depending on the technique used, bone screws and their instrumentation, free-cutting needles, bone-anchoring devices, and power instruments may be necessary.

Operative Procedure

CORACOCLAVICULAR SUTURE FIXATION

1. A curved incision is made to expose the acromioclavicular joint, the distal end of the clavicle, and the coracoid process.
2. The surgeon exposes the acromioclavicular joint and removes any loose fragments or debris.
3. Mattress sutures are placed in the ruptured coracoclavicular ligaments but not tied.
4. The surgeon places drill holes in the clavicle above the coracoid in the anteroposterior (AP) plane.
5. A #5 nonabsorbable suture is placed beneath the base of the coracoid and superiorly through the two holes in the clavicle. With the joint reduced, the sutures are tied.
6. If instability is still a concern, the surgeon places small Kirschner wires across the acromioclavicular joint, through the lateral border of the acromion. The ends of the wires are bent 90 degrees at the lateral border to prevent proximal migration.
7. The surgeon ties the sutures previously placed in the coracoclavicular ligaments.
8. The acromioclavicular joint capsule and the origins of the deltoid and trapezius muscles are repaired.
9. A sling-and-swathe bandage is then applied to the extremity.

Correction of Sternoclavicular Dislocation

Traumatic dislocation of the sternoclavicular joint usually occurs from an indirect blow on the anterior shoulder while the arm is abducted. The clavicle most frequently is displaced anteriorly, but posterior or retrosternal dislocations can occur. Posterior dislocation can be more severe because injury to the trachea, esophagus, thoracic duct, and large vessels of the mediastinum is possible. Except in severe cases, dislocation of the sternoclavicular joint is treated nonoperatively with manual traction and immobilization bandages.

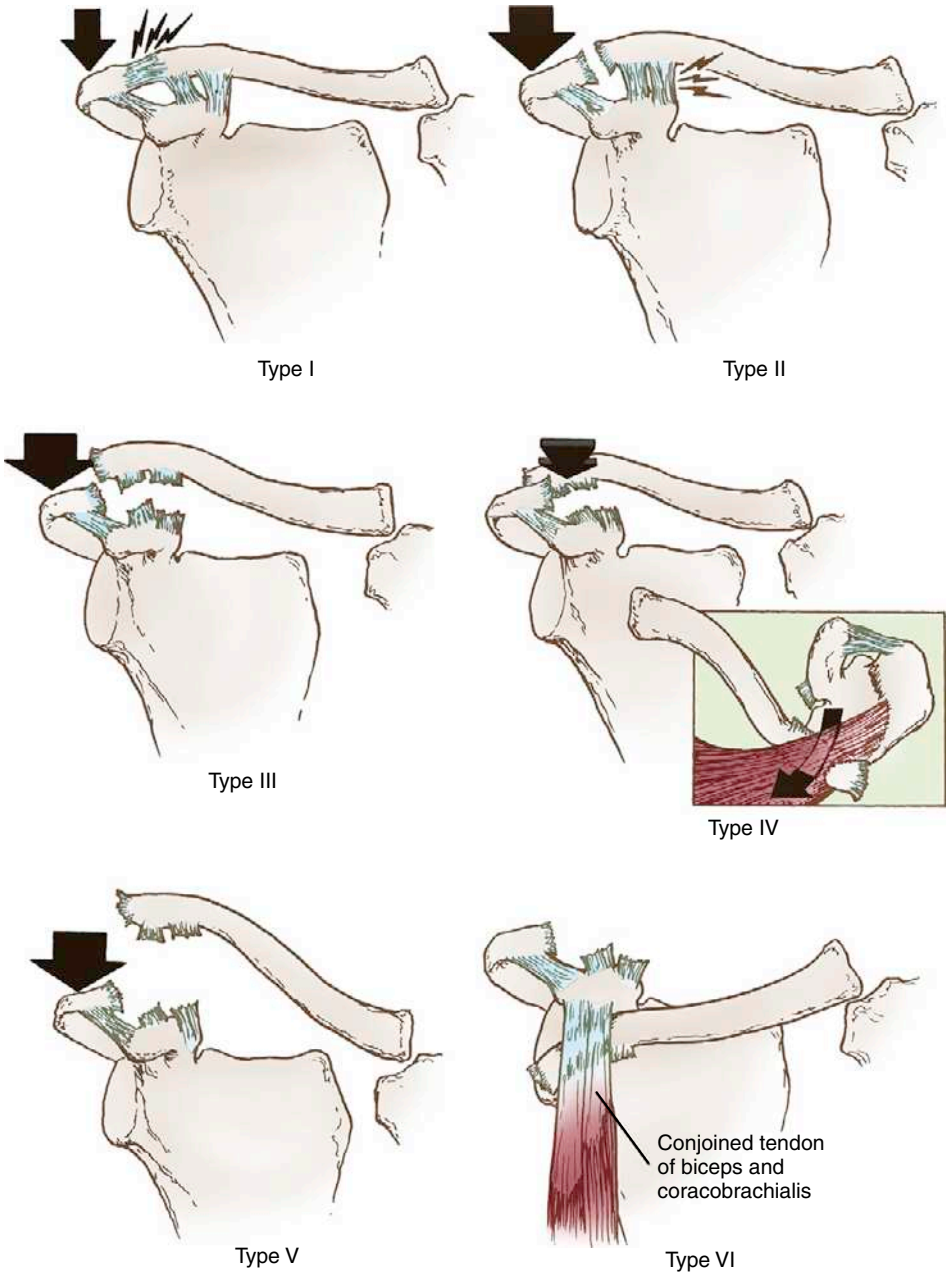

FIGURE 19-39 Classification of acromioclavicular injuries. *Type I,* Neither acromioclavicular nor coracoclavicular ligaments are disrupted. *Type II,* Acromioclavicular ligament is disrupted, and coracoclavicular ligament is intact. *Type III,* Both ligaments are disrupted. *Type IV,* Ligaments are disrupted, and distal end of clavicle is displaced posteriorly into or through trapezius muscle. *Type V,* Ligaments and muscle attachments are disrupted, and clavicle and acromion are widely separated. *Type VI,* Ligaments are disrupted, and distal clavicle is dislocated inferior to coracoid process and posterior to biceps and coracobrachialis tendons.

Clavicular Fracture

Fractures of the clavicle are some of the most common bony injuries. These injuries rarely require surgical intervention. The majority of clavicular fractures are the result of an indirect or direct blow on the clavicle or shoulder. The most common site of clavicular fractures is the middle-third portion of the bone, mainly at the middle- and outer-third junction.

Clavicular fractures are usually treated by immobilization in a figure-of-eight splint. The chances of nonunion are greatly increased when open reduction is used for a clavicular fracture. The outcome may result in a bony prominence, which may be disturbing to the patient; the overriding fragments are resorbed with time.

Clavicular fractures may require open reduction and internal fixation after nonunion, neurovascular compromise that cannot be resolved with reduction, distal clavicular fracture with torn coracoclavicular ligaments in the adult, or persistent wide separation of the fragments with soft tissue entrapment.

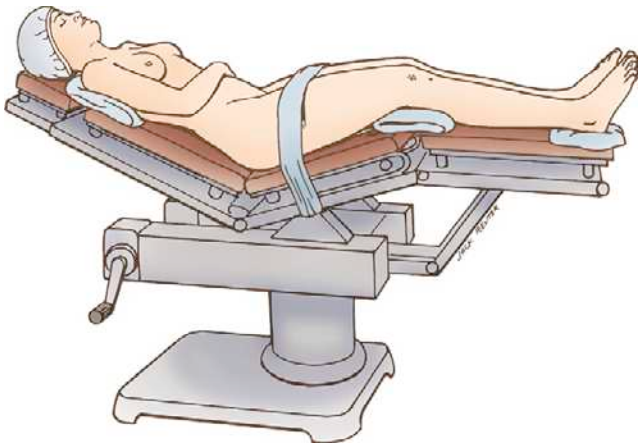

FIGURE 19-40 Positioning for a surgical procedure on the shoulder with the patient in a semisitting position and support beneath the affected shoulder.

FIGURE 19-41 Shoulder instrumentation set including humeral head retractors, glenoid neck retractor, modified Gelpi retractors, Goulet retractors, conjoined tendon retractor, subscapularis retractor, and glenoid awl.

Surgery is necessary when the fracture is displaced enough to cause underlying damage to the vessels and brachial plexus. Open reduction is accomplished with a tubular plate and screws or intramedullary pin fixation.

Procedural Considerations. The perioperative nurse assists with positioning the patient in the supine or semisitting position with a sandbag or folded sheet under the affected shoulder. The patient's head is turned to the opposite side, and care is taken to not stretch the nerves of the brachial plexus. The surgical technologist assists the surgeon with draping the entire extremity after it is prepped. Soft tissue instruments and bone instruments are used for dissection. Bone-reduction forceps and clamps will be used to obtain reduction, and Kirschner wires may be used to temporarily hold the reduction. Permanent reduction will be held with either Steinmann pins or plate and screws. A power drill will be necessary to apply these. In the case of a nonunion, bone grafting will be used.

Operative Procedure

1. The surgeon makes a 2.5-cm incision over the fracture site. The incision may need to be extended for comminuted fractures.
2. Dissection is carried down to the clavicle, taking care not to strip periosteum or disrupt vessels or nerves.
3. The surgeon exposes the fracture site and reduces the fracture with bone-holding forceps.
4. If pinning the clavicle is to be done, a Steinmann pin is passed into the medial fragment medullary canal and removed.
5. The pin is then passed in the same manner into the distal fragment.
6. The surgeon reduces the fracture again, and uses a threaded Steinmann pin across the fracture site through both fragments to transfix it.
7. If plating the clavicle is to be done, a small semitubular plate is used with at least two screw holes on each side of the fracture site.
8. The surgeon strips a small portion of the periosteum from the clavicle so that a plate can be applied to the anterior surface.
9. Extreme care must be taken when drilling screw holes to avoid damage to the subclavian vein and thoracic contents.
10. After closure, an immobilization sling is applied.

Correction of Rotator Cuff Tear

Most rotator cuff tears occur through the insertion of the tendinous fibers of the supraspinatus muscle that attaches onto the greater tuberosity of the proximal humerus. In severe tears, the remaining tendons of the cuff, the subscapularis, infraspinatus, and teres minor, may also be involved. Supraspinatus syndrome, also known as *impingement syndrome,* can involve multiple pathologic conditions, such as calcium deposits, bicipital tendonitis, subacromial bursitis, tenosynovitis, and other nonarticular lesions along with a cuff tear. The approach to diagnosis and treatment is similar for both partial and complete rotator cuff tears.

Partial rotator cuff tears and impingement usually affect people in the middle decades of life or later and are often attributable to a long-term degenerative process. Complete tears of the rotator cuff occur after accidental injury of younger patients, such as pitchers and football quarterbacks. Patients with rotator cuff tears may not be able to initiate abduction of the shoulder because the stabilizing forces of the ruptured tendons on the humeral head are lost. Many rotator cuff tears can be treated conservatively with physical therapy and nonsteroidal antiinflammatory drugs (NSAIDs).

A variety of procedures may be performed for these conditions when conservative treatment is unsuccessful. Methods of repair depend on the size and shape of the tear. The common goal is to restore joint stability, alleviate pain, and allow the patient to return to normal activities. In some instances a significant reduction in preinjury activity may be permanent.

Procedural Considerations. The perioperative nurse assists the surgeon in positioning the patient in the supine or semisitting position with a sandbag or folded towel under the affected

shoulder. The patient's head is gently turned to the opposite side, taking care to avoid undue stretch to the brachial plexus. A shoulder positioner can be used if intraoperative mobility of the arm is not a factor. In addition to a bone set and a soft tissue set, shoulder instruments will be required. The remaining equipment needs will depend on the severity of the tear. Minor tears may require no more than heavy nonabsorbable suture. Major tears will require a power drill and burr and possibly a microsagittal saw. Fixation may be gained with bone-anchoring devices. Free needles will be necessary if these are used.

Operative Procedure

1. The surgeon makes an anterosuperior deltoid incision and divides the coracoacromial ligament at the acromial attachment.
2. A subacromioplasty (resection of the undersurface of the acromion) is completed. This is also primary treatment for impingement syndrome.
3. Small, simple tears can be repaired by suturing the torn edges with heavy nonabsorbable sutures.
4. Massive tears may require attaching the torn edges to the greater tuberosity using bone-anchoring devices.
5. If the defect cannot be bridged, the surgeon may transpose a flap from the subscapularis tendon and suture it to the supraspinatus and infraspinatus muscles.
6. If impingement is involved or solely the cause of a rotator pathologic condition, other measures involving the same approach are taken.
7. The surgeon excises any calcium deposits encased in the tendon to alleviate mechanical obstruction or performs an acromioplasty.
8. After closure, a sling is applied.

Patients with small tears may begin motion on the third to fourth postoperative day. Larger tears may require immobilization for 2 to 8 weeks.

Correction of Recurrent Anterior Dislocation of the Shoulder

The anterior fibers of the shoulder capsule are stretched and weakened as a result of frequent dislocations of the shoulder joint. More than 150 operations or modifications have been devised to treat recurrent anterior dislocation. The goals are to (1) prevent recurrence, (2) prevent surgical complications, (3) prevent creation of arthritic changes, (4) maintain joint motion, and (5) correct the problem. The surgeon selects the procedure appropriate for the patient's condition that will satisfy the conditions necessary for correction of the problem. A stapling procedure was once common treatment of recurrent dislocation, but it has been replaced by other accepted procedures.

Procedural Considerations. The surgeon and perioperative nurse place the patient in the supine or semisitting position with a sandbag or folded sheet under the shoulder. The patient's arm is draped free so that the extremity can be manipulated. The surgeon will make an anterior curved incision or a longitudinal incision in the anterior axillary fold over the shoulder joint, depending on the location of the tear and procedure planned. A soft tissue set and a bone set will be required, as well as a set of instruments specific to shoulder surgery, power drill and burr, bone-anchoring devices, and free needles.

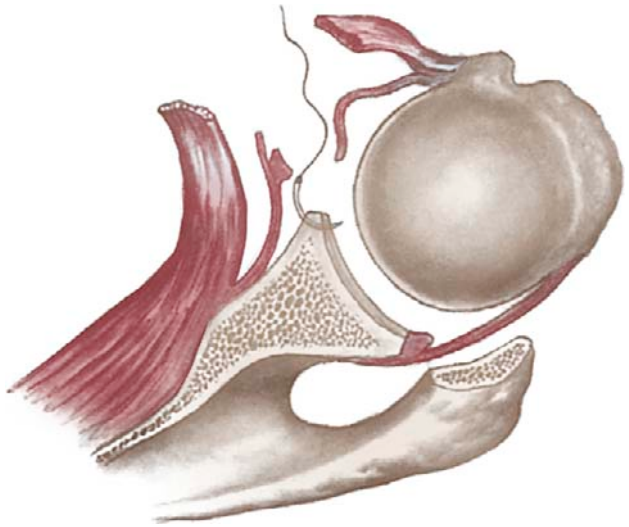

FIGURE 19-42 Bankart procedure for restoration of shoulder stability. Holes are made in the rim of the glenoid, and the free lateral margin of the capsule is sutured to the rim of the glenoid. The medial margin of the capsule is sutured to the lateral surface.

Operative Procedure

BANKART PROCEDURE. For the Bankart procedure (Figure 19-42), the scapula is not elevated with a sandbag or folded sheet. The surgeon reattaches the attenuated anterior capsule to the rim of the glenoid fossa with heavy sutures. The glenoid fossa rim is decorticated with a curette to provide a raw surface to which the capsule is attached. Special instruments designed for the Bankart procedure, such as the curved awl and humeral head retractor, facilitate the surgery, although the capsule may be attached with bone anchors, obviating the use of the awl. If the coracoid process is to be removed to obtain better operative exposure, a drill, bone screws, and washer should be available for reattachment. Postoperatively the extremity is immobilized in a sling or shoulder immobilizer. Shoulder motion is begun at 3 days postoperatively, and the patient may return to contact sports or heavy labor after approximately 6 months.

PUTTI-PLATT PROCEDURE. The steps of the Putti-Platt procedure are similar to those of the Bankart procedure in that the joint capsule is sutured to the glenoid rim. In addition, the Putti-Platt procedure requires the lateral advancement of the subscapularis. This produces a barrier against dislocation of the shoulder. This procedure is rarely useful when the anterior capsular mechanism is of poor quality.

The surgeon divides the subscapularis tendon 2.5 cm medially to its insertion. The glenoid and humeral head are inspected using palpation to assess osteochondral changes. The lateral portion of the subscapularis is sutured to the anterior glenoid rim. The medial portion of the subscapularis is sutured to the rotator cuff at the greater tuberosity. The layers of the shoulder joint are imbricated (overlapped), a technique used often in soft tissue reconstruction. The incision is closed, and a shoulder immobilizer is applied. The immobilizer is worn for approximately 3 weeks. External rotation of the arm should be avoided immediately after the repair.

BRISTOW PROCEDURE. In the Bristow procedure, the coracoid process, along with the attached muscles, is detached and inserted onto the neck of the glenoid cavity, where it is attached

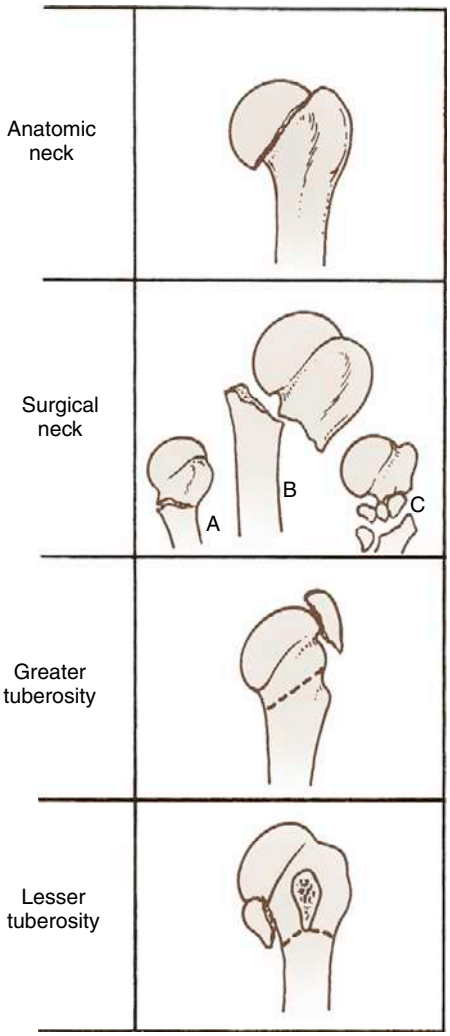

FIGURE 19-43 Fractures and fracture-dislocations relate to the pattern of displacement. Fractures can occur in two, three, or four parts.

with a screw through the subscapularis muscle. This stabilizes the anterior joint capsule and prevents recurrent dislocation. A Bristow procedure is considered an appropriate alternative when the anterior capsular mechanism is of poor quality. Disadvantages of this procedure are (1) internal rotation contracture, (2) inattention to labrum or capsule disorders, (3) potential for injury to the musculocutaneous nerve, (4) reduction of internal rotation power by shortening of the subscapularis muscle, (5) possible limitation of external rotation, (6) possible penetration of the screw into the articular surface of the glenoid, and (7) later development of early joint disease of the shoulder.

Correction of Humeral Head Fracture

Comminuted fractures of the humeral head (Figure 19-43) with displacement may require open reduction and internal fixation with screws or pins or closed reduction with a humeral nail or rod. However, if the fracture is badly comminuted, a prosthetic replacement is indicated. Traumatic or degenerative arthritic shoulder joints may be so painful or dysfunctional that a total shoulder joint replacement is necessary.

Extensive rehabilitation for the shoulder is required. Surgery should be performed as soon as possible as delay can allow time for increasing scar formation, contracture of the muscles, and increasing osteoporosis of the bone fragments. The shoulder is the most difficult joint in the body to rehabilitate because it has (1) the greatest range of motion, (2) a second space beneath the acromion that must be mobilized, and (3) many muscles that enter into complex movements.

SURGERY OF THE HUMERUS, RADIUS, AND ULNA

Fractures of the Humeral Shaft

Closed manipulation and immobilization usually reduce a fractured humerus as well as minimize the risk of nonunion and infection. When closed reduction is impossible or when nonunion of the fracture has occurred, surgery is indicated. The fracture is reduced and held with intramedullary fixation, a compression plate, a lag screw, or a rigid locking nail, with distal and proximal bone screws that will transfix the rod within the canal. This last device can control rotation of the fracture fragments and prevent distraction at the fracture site (Figure 19-44). Multiple flexible nails may be used if more rigid nails are not available. A bone graft may be used, depending on both the extent of the fracture and the length of time since injury. Compression plating of shaft fractures is usually reserved for supracondylar involvement or when other treatment has failed.

Procedural Considerations. Fluoroscopy and permanent radiographs are required to ensure proper alignment, reduction, and placement of implants. The perioperative nurse arranges for intraoperative radiology support and a radiolucent OR bed before the patient's arrival in the OR suite. The surgeon and nurse position the patient supine with the body near the edge of the bed to facilitate moving the arm. The extremity is prepped and draped from the middle of the chest to below the elbow.

A soft tissue set and a large bone set are required. In addition, the intramedullary fixation device of choice and the required instruments for its insertion will be needed. PMMA may be used in the case of pathologic fractures. Instruments that are required for harvesting bone graft might be needed as well. A traction tray could be used to gain reduction. A power drill will be necessary if screws are used to lock the device. Sterile x-ray cassette covers will be needed for permanent intraoperative films.

Operative Procedure

MEDULLARY FIXATION: ANTEGRADE TECHNIQUE

1. Proper length and alignment of the fracture must be attained with traction. Nail length should ensure proximal burying to avoid subacromial impingement and be 1 to 2 cm proximal to the olecranon fossa. The surgeon makes a skin incision from the lateral point of the acromion over the tip of the greater tuberosity. The fascia is incised, and the greater tuberosity is palpated.
2. Using a small awl, the surgeon enters the greater tuberosity and confirms placement with fluoroscopy in both anteroposterior (AP) and lateral views.
3. The surgeon removes the awl and inserts a ball-nosed reamer guidewire, advancing it down the medullary canal (periodically verified with fluoroscopy). Confirmation is made with each step to ensure that the wires, reamers, or implant has not fractured through the cortex along the shaft.

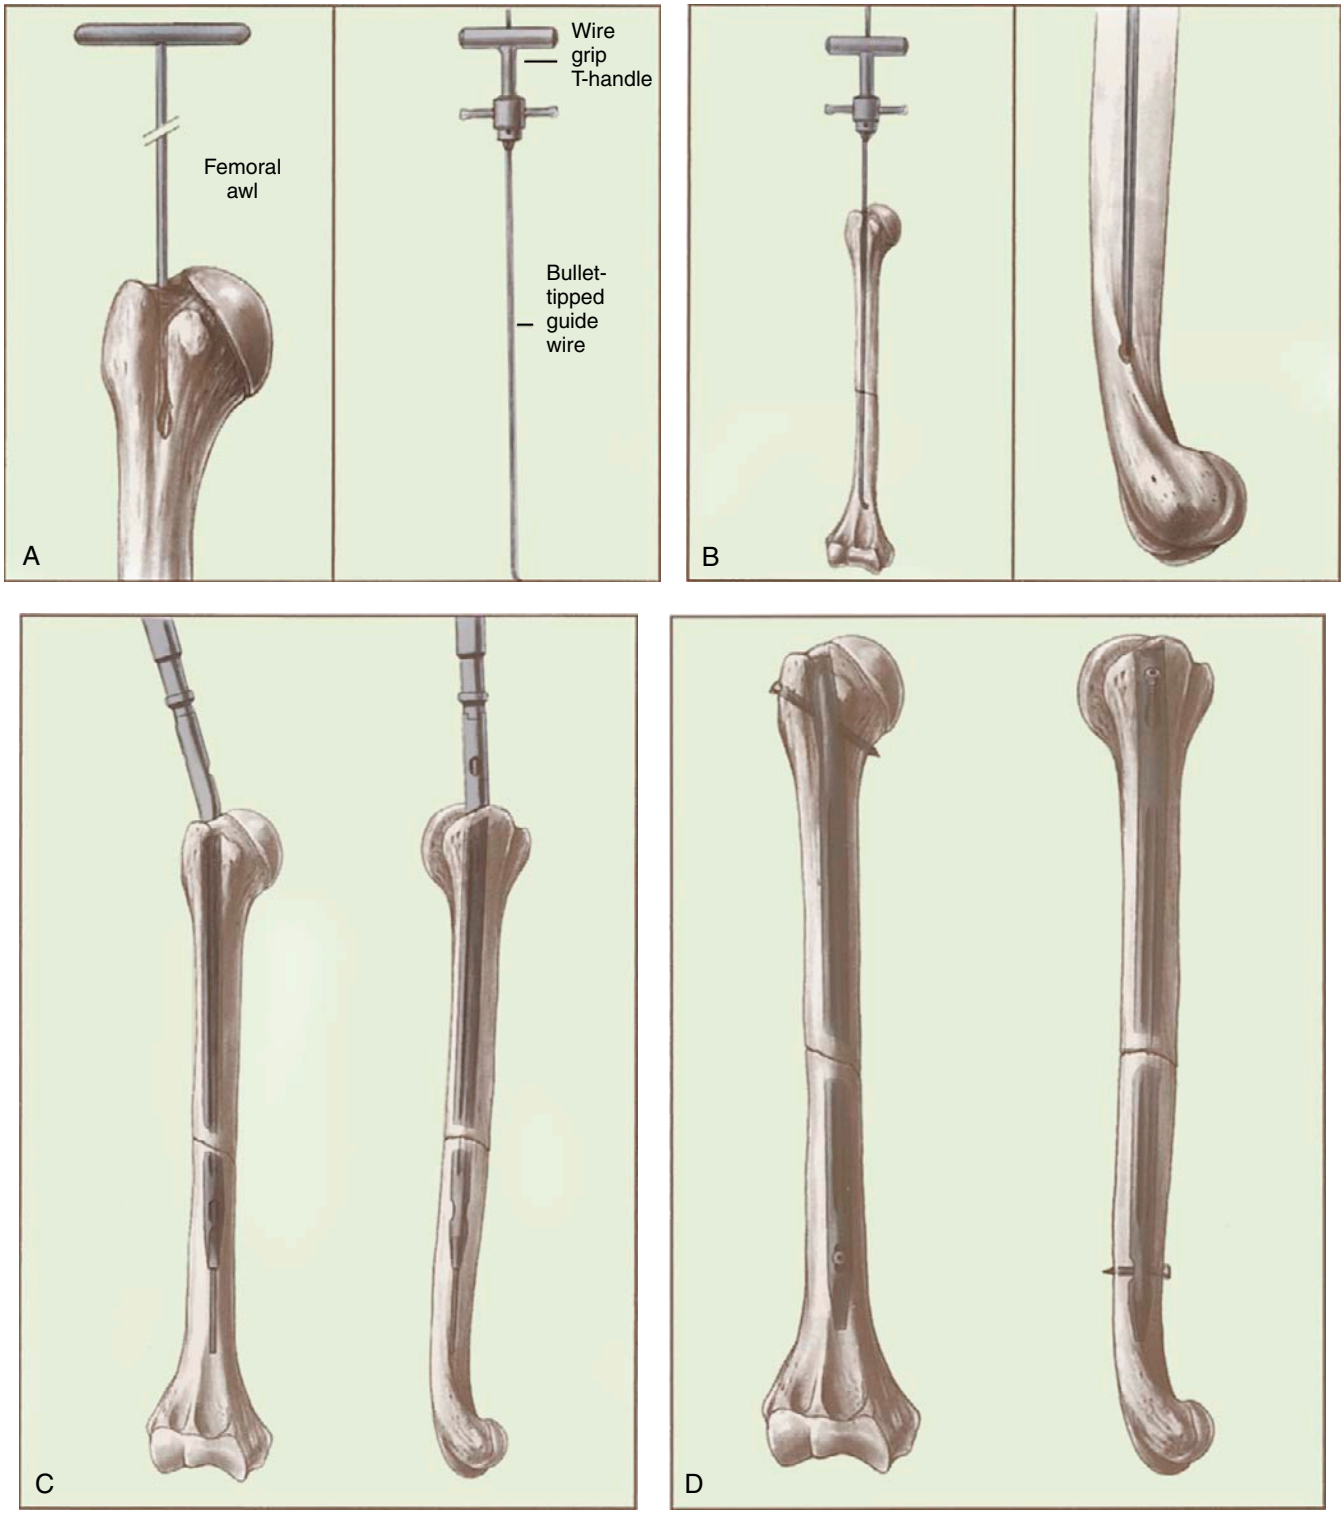

FIGURE 19-44 Placement of the humeral rigid locking nail with distal and proximal screws. **A**, After incision and exposure, a femoral awl is used to make an entry portal. **B**, Guidewire is advanced into the center of the epicondylar region. **C**, After reaming, the nail is advanced over the fracture site and seated. **D**, Proximal and distal locking takes place after the correct screw placement is determined.

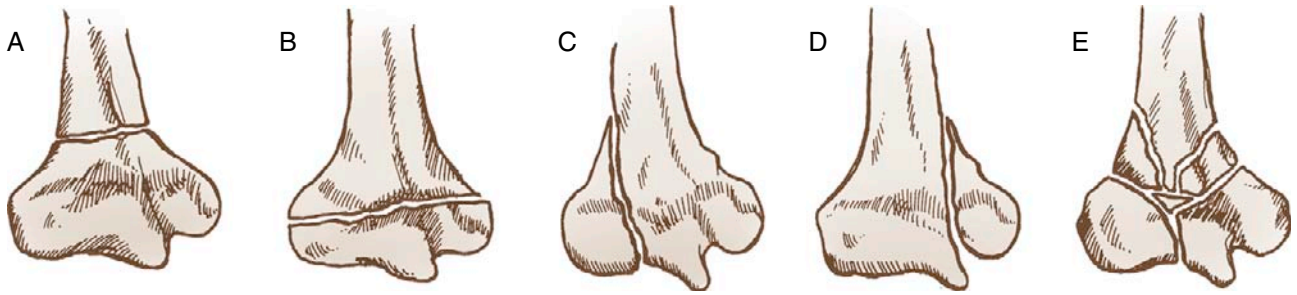

FIGURE 19-45 Classification of distal humeral fractures. **A**, Supracondylar. **B**, Transcondylar. **C**, Lateral condyle with trochlea. **D**, Medial condyle. **E**, Intercondylar with comminution.

4. The guidewire is advanced to within 1 to 2 cm of the olecranon fossa, avoiding distraction or shortening.
5. If Enders nails are being used, each one is advanced in the same fashion as the guidewire.
6. Nail length can be determined by using a second guidewire of the same length held against what remains extended from the humerus. The difference between the length protruding and the length remaining on the second rod is the approximate length requirement of the humeral nail. Another method uses a nail-length gauge that is held directly against the upper arm, viewed with fluoroscopy, and read directly on the gauge.
7. Enders nails may be held directly against the arm and viewed with fluoroscopy to determine proper length. If Enders nails are used, the surgeon drives two or three nails down the shaft, across the fracture site, and into the distal fragment. Fluoroscopy is used to confirm proper placement and reduction.
8. If intramedullary nailing is to be accomplished, the surgeon may use a cannulated reamer over the guidewire to ream the humerus. Reaming of the canal is completed in 0.5-mm increments. The humerus becomes smaller in diameter. Reaming is gentle to ensure that protrusion through the bone does not occur. The bone is reamed 0.5 to 1 mm larger than the selected nail diameter.
9. The surgeon uses a medullary exchange tube to maintain fracture reduction.
10. The ball-tipped guidewire is replaced with a non–ball-tipped guidewire.
11. The medullary nail is assembled for impaction with the appropriate outrigger and drill guides.
12. The nail is guided into the proximal end of the humerus, and the humeral nail driver is used to impact the nail within the canal. Care must be taken to avoid splitting the humerus or creating a supracondylar fracture by wedging the tip of the nail.
13. As the nail approaches and crosses the fracture site, manual reduction must be maintained.
14. The surgical technologist attaches the proximal drill guide to the nail impactor with the nail coupled; the surgeon makes a stab wound in the skin and pushes the nail to reach the bone.
15. An 8-mm drill sleeve is inserted through the drill guide, followed by a 2.7-mm drill guide into the first guide.
16. The surgeon scores the cortex with the 2.7-mm trocar, and transfixing of the hole is completed with a 2.7-mm drill from the lateral to distal areas of the cortex.
17. The humeral screw-depth gauge is inserted and read directly to determine the appropriate screw size.
18. A 4-mm fully threaded humeral screw is inserted to the selected length. The surgeon confirms the screw position by inserting a guidewire down the end of the nail, where it is impeded by the transfixing screw.
19. Fluoroscopy is used to target the distal humeral locking screw.
20. The surgeon creates a second percutaneous access from the anterior to posterior cortex of the bone to the bone surface of the humerus.
21. With the freehand technique, the cortex of the bone is scored followed by insertion of the 8-mm handheld drill sleeve and the 2.7-mm drill bit.
22. The selected size of humeral screw is gauged and inserted. Placement is confirmed with fluoroscopy, and the impactor assembly is removed from the nail.
23. Full-view radiographs are obtained in both dimensions, and the wound is irrigated and closed.

NOTE: Many variations of approach and technique are used, depending on the complexity of the fracture and any associated injury. Often the fracture site may have to be opened if it is comminuted or will not reduce properly through closed techniques. The radial nerve or other neurovascular structures may become entrapped or traumatized, requiring exploration and repair.

Although this type of antegrade fixation, using locked rods, is preferred for this type of fracture, it is not the only method. Often a retrograde technique is used, with the patient in the prone or lateral decubitus position. The retrograde technique, used more commonly in the care of femoral shaft fractures, is described on p. 767.

Distal Humeral Fractures (Supracondylar, Epicondylar, and Intercondylar)

Distal humeral fractures are classified into several types, depending on location and the presence or absence of articular involvement (Figure 19-45). Supracondylar fractures of the humerus do not involve the articular surface and can generally be treated with closed reduction and casting. Transcondylar fractures may or may not have articular involvement, and this will dictate treatment. Intercondylar fractures involve both condyles with a comminution of injury, are intraarticular, and present the greatest challenge for the surgical team. Fractures of the articular components—the capitulum and the trochlea—are usually the result of a fall on an outstretched arm. The force drives the radial head to shear off the capitulum, producing an intraarticular fragment. The lateral or medial condyles and epicondyles are also subject to fracture by various mechanisms.

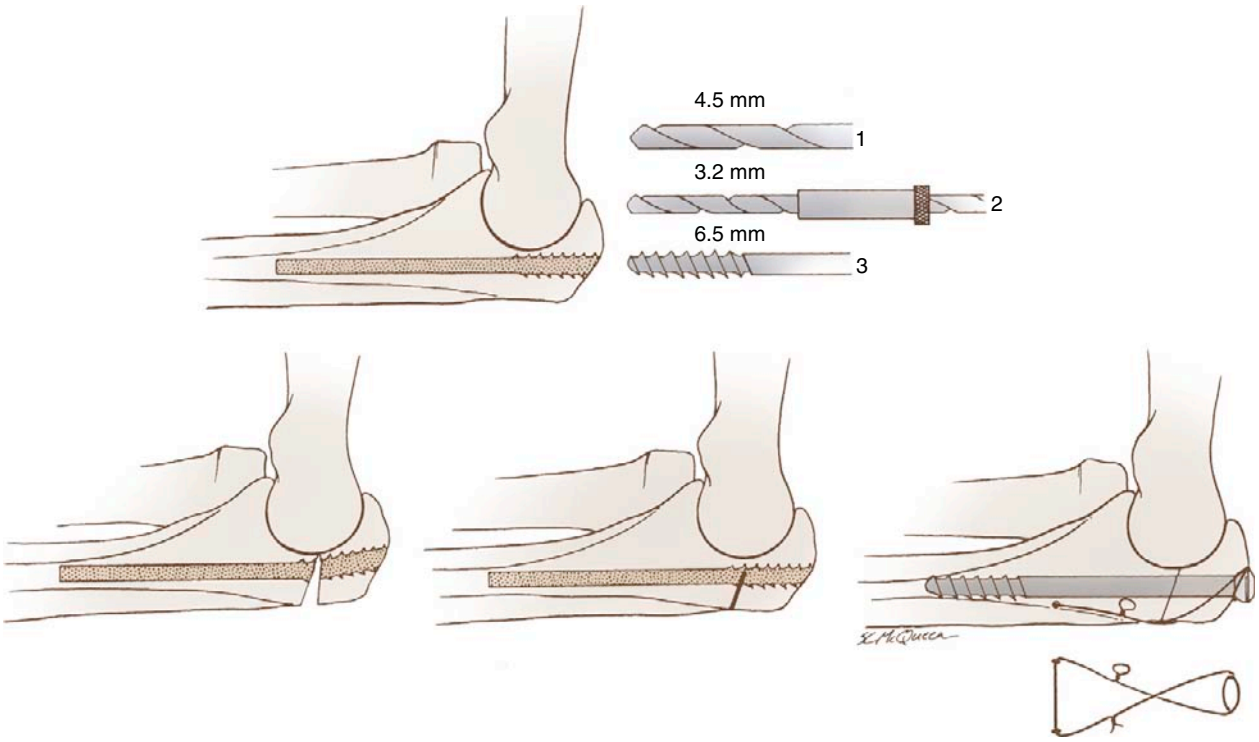

FIGURE 19-46 Osteotomy of the olecranon with placement of a lag screw and tension band wire fixation.

Patients may present with a single isolated fracture or any combination, as previously mentioned. Neurovascular and other soft tissue trauma is considered in selecting the type of reduction and fixation. Screws, pins, a variety of different plates, and dynamic compression technique can be used for internal fixation. Certain fixation techniques of the distal portion of the humerus may require an osteotomy of the olecranon (proximal ulna) to properly align and affix hardware (Figure 19-46). The general goals of treating these injuries are to (1) maintain neurovascular integrity, (2) restore normal joint articulation, (3) preserve motion of the joint, and (4) correct other soft tissue injuries.

Procedural Considerations. Regional anesthesia can be used for procedures on the distal end of the humerus. Bone graft harvesting may require use of general anesthesia. The patient may be prone with the elbow flexed over a small table, supine with the arm over the chest, supine with the arm on a hand table, or in the lateral position. A tourniquet is placed before the surgical prep and inflated during surgery as needed.

A soft tissue set, a large bone set, and a bone graft set are needed, in addition to a compression set, bone-holding clamps, reconstruction plates, and smooth Kirschner wires. A power drill and Kirschner wire driver will be needed to apply the hardware.

Operative Procedure

COMMINUTED DISTAL HUMERAL FRACTURE
(Figure 19-47)

1. The surgeon makes an incision over the distal humeral fracture site.
2. The fracture is exposed and reduced using bone-reduction clamps and temporary small, smooth Kirschner wires, driving them across the fracture site with the power drill.

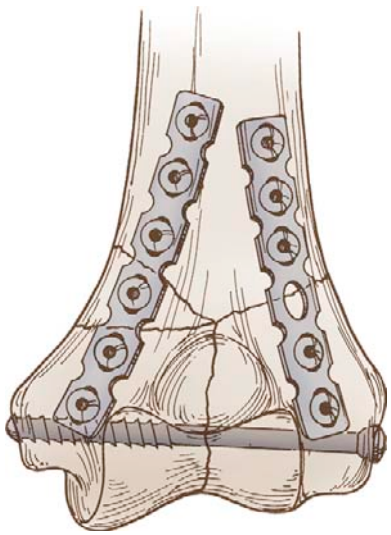

FIGURE 19-47 Repair of the distal comminuted humeral fracture with 3.5-mm reconstruction plates.

3. A cancellous bone screw is placed using drill and tap to transfix from one condyle to the other. The surgeon is careful not to violate the joint surface with the threads of the screw.
4. If the reduction is maintained, the surgeon removes the Kirschner wires.
5. A one-third tubular or reconstruction plate is contoured to the shape of the distal humeral fracture and applied to bridge the fracture fragments.

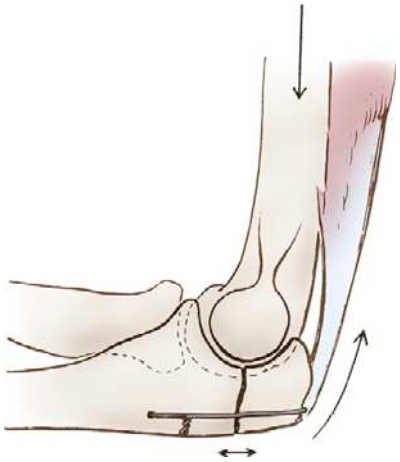

FIGURE 19-48 Tension band technique used for repair of the olecranon.

6. Throughout the entire procedure, the articular surface is periodically inspected to ensure integrity. The plates are held in place by hand while the patient's elbow is moved through its range of motion. The plates should not encroach on the olecranon or coronoid fossa (distal end of the ulna), since this will limit flexion and extension of the arm.
7. The bone is drilled and tapped from one cortex to the other with the appropriate drill and tap. The screw is inserted and seated to the bone surface on the plate. This is done for all subsequent screws, observing the fracture site and articular surface.
8. Interfragmentary screws may be used in addition to the cortical screws spanning the condyles. If osteotomy of the olecranon was previously done for exposure, it is reattached using the tension band technique with a cancellous bone screw and heavy-gauge (18 or 20 gauge) wire (Figure 19-48).
9. The surgeon irrigates the wound, places a drain (as needed), and closes the incision. A long arm posterior splint is applied.

Olecranon Fracture

If the olecranon fracture fragment is small, it may be excised and the triceps tendon reattached to the ulnar shaft. This does not result in loss of stability of the elbow joint. However, larger fragments must be reduced and held with internal fixation. Osteotomy of the olecranon is often done electively for surgical exposure (see previous section) and repaired in the same fashion as for a traumatic fracture.

Procedural Considerations. The patient is placed in the prone position with the arm on an armboard or hand table. A soft tissue set, a bone set, AO/ASIF instrumentation (AO/ASIF is the abbreviation for Swiss Association of Osteosynthesis/Association for the Study of Internal Fixation), heavy stainless-steel wire (16 and 18 gauge in long lengths), a wire tightener, Kirschner wires, bone-reduction clamps, a power drill, and Kirschner wire driver will be needed.

Operative Procedure

TENSION BANDING (Figure 19-49)

1. The surgeon makes an incision over the olecranon and exposes the fracture.
2. A drill hole is made in the distal fragment, traversing the bone.

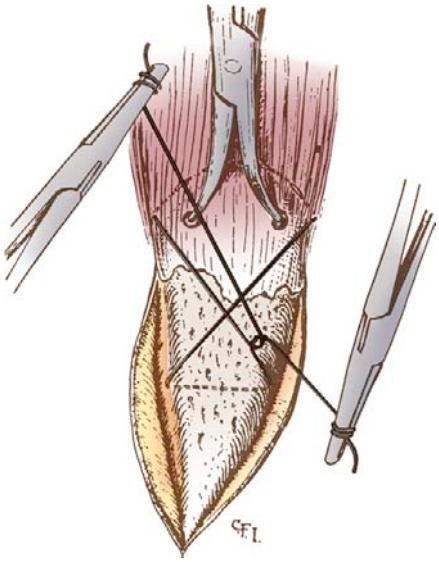

FIGURE 19-49 Operative procedure: tension banding with stainless-steel wire passed through drill holes; figure-of-eight adds stability to the fracture.

3. Stainless-steel wire is passed through the drilled holes, crossed over, and pulled toward the tip of the olecranon.
4. After using the drill and tap, the surgeon uses a cancellous bone screw to attach the proximal fragment to the distal, stopping short of totally seating the screw.
5. The surgeon pulls the wire and loops it around the exposed shaft of the screw while reduction is maintained manually or by using a reduction clamp. The wire can be tightened using the wire tightener. Two smooth Steinmann pins, bent over the exposed portion to hook the loop of wire, can substitute for the cancellous screws.
6. The remaining screw is threaded into the bone; the fracture site is observed for opposition.
7. The wound is irrigated and closed. Drains are generally not necessary. A long arm posterior splint is placed.

NOTE: Using this technique requires early active motion of the arm. Compression of the fracture site is achieved by moving the elbow through its range of motion and applying force by the hardware.

Transposition of the Ulnar Nerve

Transposition of the ulnar nerve involves freeing the nerve from a groove at the back of the medial epicondyle of the humerus and bringing it to the front of the condyle. The ulnar nerve is frequently divided or damaged after fracture or wounds to the elbow caused by trauma. Dislocation of the elbow may also cause ulnar nerve damage. Late traumatic neuritis may occur after an old injury, resulting in stretching of the ulnar nerve. The hand appears atrophied, and sensory loss is extensive. In severe cases, a clawhand deformity develops.

Procedural Considerations. The perioperative nurse assists with positioning the patient supine with the extremity slightly flexed on a hand table or over the chest. A tourniquet is applied to the upper arm, and the entire arm (fingers to tourniquet) is prepped and draped. A soft tissue set is required. Bone instruments may be required.

Operative Procedure

1. The surgeon makes an incision on the lateral aspect of the elbow near the epicondyle.
2. The fascia and the flexor carpi ulnaris muscle are divided.
3. The surgeon frees the ulnar nerve and dissects the medial intermuscular septum.
4. The nerve is then drawn anteriorly and placed deep into the brachialis flexor muscle origin.
5. The wound is irrigated and closed. A drain is not necessary. A short arm posterior splint is applied to the elbow postoperatively.

Excision of the Head of the Radius

Fractures of the radial head can be displaced or nondisplaced, segmental, or comminuted. Complications can arise when treatment is delayed, causing limitation of motion, pain, and posttraumatic arthritis. A congruous radial head is essential for proper rotation of the forearm at the elbow. Consequently, in an adult it is necessary to excise the radial head if a severely comminuted fracture with angulation interferes with rotation. The radial head should never be excised in children. The outcome for the patient undergoing radial head excision may result in some permanent loss of pronation and supination of the forearm. Noncomminuted fractures that are easily reduced can be treated using closed reduction and casting.

Procedural Considerations. The patient is supine with the arm over the chest or on a hand table. A tourniquet is applied. A soft tissue set, a small bone set, and an oscillating microsaw with blades are needed.

Operative Procedure

1. The surgeon makes an incision on the shaft of the radius from 5 cm distal to the radial head, extending proximally over the lateral humeral condyle.
2. Dissection is continued between the extensor carpi ulnaris and extensor digitorum muscles onto the joint capsule.
3. With the head and neck of the radius exposed through the joint capsule, the surgeon irrigates the joint to clear bone debris and blood clots.
4. The surgeon excises the radial head just proximal to the radial tuberosity, and removes all the periosteum to limit new bone formation. The remaining annular ligament is also excised. The fragments of the radial head should be saved and readily available so that they may be reassembled to ensure that all fragments have been retrieved.
5. The wound is closed, and a long arm posterior splint is applied with the elbow at 90 degrees.

Fractures of the Proximal Third of the Ulna with Radial Head Dislocation (Monteggia)

The Monteggia type of fracture presents with a proximal ulnar fracture and dislocation of the radial head. The fracture is rarely treated with open reduction in children. The open technique is often used to treat adults. A direct blow to the ulnar aspect or a fall while the arm is hyperextended produces this type of injury. If the open reduction approach is chosen, closed reduction of the radial dislocation is attempted and often is successful. At times the annular ligament may prevent reduction of the radial head dislocation, and open reduction becomes necessary. Deforming forces of the forearm vary, depending on the location of the fracture in relation to the insertion of muscles. These forces are often encountered when treating forearm injuries. The dynamic compression technique uses compression plates that are stockier and stronger than the semitubular plates mentioned earlier for distal humeral fractures. They are used to plate shaft fractures, where stress forces on the shaft are greater and stronger plates are required.

Procedural Considerations. The patient is placed in the supine position with or without a hand table. A tourniquet is applied and inflated as needed. A soft tissue set and a large bone set are required, as well as bone-reduction clamps and bone-grasping forceps, AO/ASIF instrumentation, plates and screws, and a power drill.

Operative Procedure

FIXATION WITH DYNAMIC COMPRESSION PLATE
(Figure 19-50)

1. The surgeon performs a closed reduction to reduce the radial head dislocation.
2. An incision is made; the ulnar fracture site is dissected.
3. The surgeon strips the periosteum and reapproximates the fragments using bone-reduction and bone-grasping forceps.
4. The bone is assessed for placement of a small- or large-fragment dynamic compression plate (DCP), with at least three screw holes proximal and three distal to the fracture site.
5. A concentric (neutral) hole is drilled into the ulna (through one of the screw holes on the plate) to the opposite cortex.
6. After the hole is gauged, the selected size of screw is inserted, with purchase of the opposite cortex ensured. A second screw is inserted on the opposite fragment in the neutral position.
7. On either side of the fracture site, an eccentric (loading) hole is drilled in the same fashion to the opposite cortex. The hole is gauged and tapped, and the screw is inserted.
8. The selected screw is entered eccentrically into the plate. As the screw seeks the center of the screw hole while riding the bevel of the screw hole, it compresses the fracture site. This screw should be tightened completely, and the other screws should be slightly loosened.
9. The fracture site is now visualized radiographically as the action of the screw in the plate compresses the fracture site.
10. The remaining bone screws are inserted following the same procedure.
11. The wound is irrigated and closed; a drain may or may not be inserted.
12. A long arm posterior splint is placed with the arm in 110 to 120 degrees of flexion.

Correction of Colles' Fracture with External Fixation

Colles' fracture is a dorsally angulated fracture of the distal end of the radius. Most of these fractures can be managed successfully with closed reduction and immobilization, but external fixation is especially useful in the case of a comminuted intraarticular fracture. Internal fixation is indicated when the distal end of the radius is severely comminuted and displaced. In these cases, Kirschner wires are used for internal fixation.

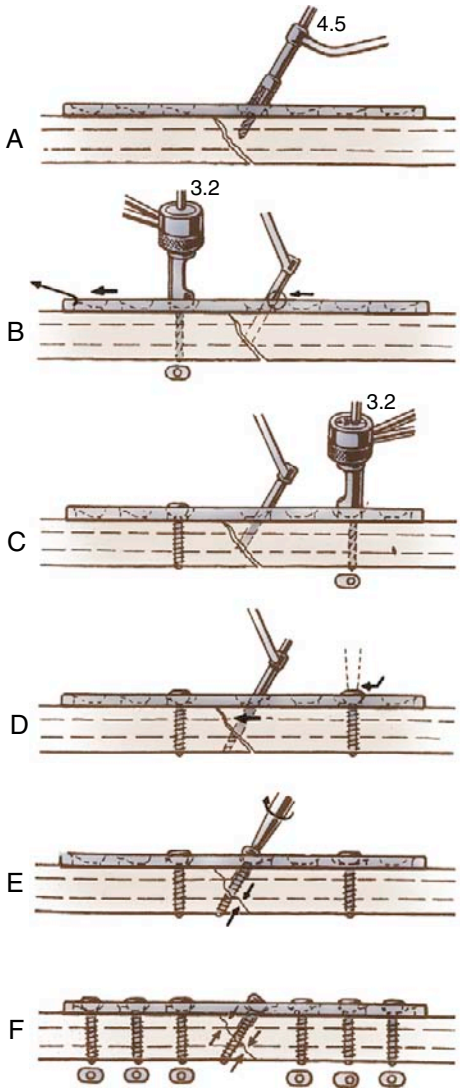

FIGURE 19-50 Fixation with dynamic compression plate. **A**, Gliding hole with drill bit. **B**, Fracture is reduced, drill sleeve is inserted, the fracture is drawn together, a hole is drilled, and a screw is inserted in the neutral position to correct the fracture. **C** and **D**, One screw is inserted in load position (eccentric) into the other fragment; as the screw is tightened, axial compression is generated. **E**, Lag screw inserted across the fracture site. **F**, Remaining screws inserted in the neutral position.

Procedural Considerations. The patient is in the supine position with the arm extended on a hand table and may require traction by means of finger traps. A soft tissue set and a small bone set are required, along with a power drill, small elevator, and the external fixation device of choice. Fluoroscopy is necessary.

Operative Procedure

1. Small incisions are made, and the surgeon places two pins through the second metacarpal—one at the base and the other distalward a distance equal to the span between the openings in the fixator.
2. Two pins are placed in the radius 8 cm from the styloid.
3. The surgeon confirms pin placement radiographically in both the AP and lateral views.
4. A frame is constructed to incorporate all four pins.
5. Reduction of the fracture is obtained, and the surgeon secures the frame.
6. Postreduction films are obtained to check alignment and pin position.

SURGERY OF THE HAND

Hand surgery has become highly specialized. The perioperative nurse encounters numerous procedures for treating bone, soft tissue, or both. Many of the techniques and principles used to treat large bone defects are used in the treatment of hand injuries. Hand procedures range from carpal tunnel release to complex digit reimplantation.

Tourniquets and regional anesthetics are often used for hand surgery. The OR team usually sits down at a hand table but may move to areas such as the iliac crest for bone grafting. The instruments for hand surgery are common to orthopedics but on a smaller scale. Many instruments and reconstruction systems have been developed primarily for hand surgery. Air- or battery-powered drills and saws are frequently used. The surgery often requires the use of eye loupes (glasses for magnification) or the microscope.

Carpal Tunnel Release

Carpal tunnel syndrome results from entrapment of the median nerve on the volar surface of the wrist; it is caused by thickened synovium, trauma, or aberrant muscles. Carpal tunnel syndrome is frequently seen in patients with rheumatoid synovitis or malaligned Colles' fracture and is associated with obesity, Raynaud's disease, pregnancy, and occupational injuries. The symptoms are pain, numbness, tingling of the fingers, and weakness of the intrinsic thumb muscles. These symptoms are usually reversible after the flexor retinaculum is incised so that the compressed median nerve is relieved. Carpal tunnel release may be completed endoscopically or by open incision.

Procedural Considerations. The patient is placed in the supine position with the arm extended on a hand table. A tourniquet is applied to the forearm or upper arm. A hand set is required. The endoscopic approach requires use of specialized equipment.

Operative Procedure—Open Approach

1. The surgeon makes a curvilinear, longitudinal volar incision from the proximal side of the palm, paralleling the thenar crease and extending to the crease of the wrist across the wrist joint.
2. The deep transverse carpal ligament is divided, taking care to avoid damage to the median nerve.
3. At this point the release is completed.
4. If indicated, the surgeon performs a tenosynovectomy.
5. The wound is closed, and a compression dressing and volar splint are applied.

Excision of Ganglions

A ganglion is a cystic lesion arising from a joint capsule or tendon sheath and containing glassy, clear fluid. Ganglions are most common on the dorsum of the wrist, palm of the hand, and dorsolateral aspect of the foot. Ganglions appear as firm masses that vary in size. They may resolve spontaneously but

occasionally require excision because of discomfort or for cosmetic reasons.

Procedural Considerations. The perioperative nurse assists with positioning the patient supine with the arm extended on a hand table, and applies the tourniquet as directed by the surgeon. A hand set is required.

Operative Procedure

1. The surgeon makes a transverse incision over the ganglion.
2. The ganglion is excised with a rim of normal joint capsule or tendon sheath at its base.
3. The wound is irrigated and closed, and a pressure dressing is applied. A plaster splint may also be applied to immobilize the affected joint.

Fractures of Carpal Bones

Most fractures of the carpal bones are treated by closed reduction and immobilization. However, it is occasionally necessary to operate on a fracture because of acute instability, delayed union, or nonunion. The scaphoid is the most commonly fractured carpal bone. Internal fixation is accomplished with Kirschner wires, small compression screws, or minifragment compression plates and screws. A bone graft from the distal end of the radius or olecranon may be taken.

For displaced or unstable scaphoid fractures, the Herbert bone screw (Figure 19-51) has several advantages: (1) strong internal fixation, (2) compression at the fracture site with reversed threads at each end of the screw, and (3) reduced time required for external immobilization.

Procedural Considerations. The patient is supine with the arm extended on a hand table. A tourniquet is applied and fluoroscopy should be available. A soft tissue set and a small bone or hand set are required in addition to the Herbert screw set. If a minifragment compression set is used, a power drill and smooth Kirschner wires will also be needed. A bone graft set should also be available.

Operative Procedure (Figure 19-52)

1. The surgeon makes a longitudinal skin incision over the palmar surface of the wrist.
2. The superficial palmar branch of the radial artery is ligated and divided.
3. The surgeon incises the flexor carpi radialis tendon sheath and retracts it to expose the capsule of the wrist.
4. The capsule is entered, and the scaphoid fracture is identified and inspected to determine the need for bone grafting.
5. The surgeon manipulates the fracture to reduce it and inserts small Kirschner wires to temporarily hold the reduction.
6. The scaphoid fracture is reduced and held with the Herbert jig.
7. A short drill bit and then a long drill bit are inserted to create a channel for the screw.
8. The surgeon inserts the Herbert screw and turns it until it is seated within the scaphoid.
9. Bone graft is placed around the fracture site if needed. (The loss of significant bone can often be corrected by fashioning a strut of bone from graft.)
10. The wound is irrigated and closed.
11. A splint is applied with a thumb spica or long arm cast incorporating the thumb.

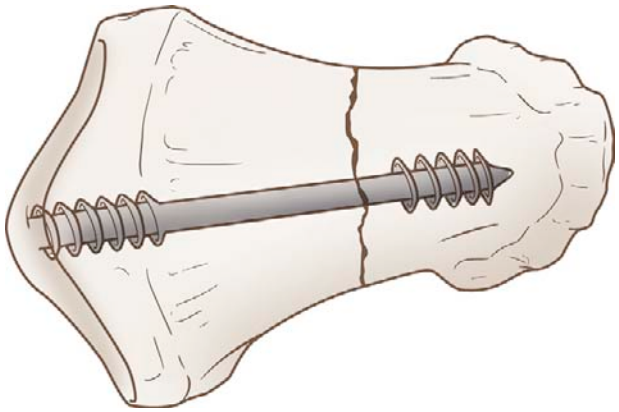

FIGURE 19-51 Herbert bone screw placement.

SURGERY OF THE HIP AND LOWER EXTREMITY

Fractures of the Acetabulum

Fractures of the acetabulum usually result from high-energy injuries such as motor vehicle accidents and falls with a landing on the extended extremities. The fracture is directly related to the force transmitted to the femoral head through the greater trochanter or lower leg. Management of these fractures can often present the surgical team with a complex and challenging task. Indications for internal fixation of acetabular fractures include (1) greater than 2 mm of displacement, (2) presence of intraarticular loose bodies, (3) inability to reduce under closed methods, (4) unstable fractures of the posterior acetabular wall, and (5) open fractures. Internal fixation is usually delayed 3 to 10 days to allow time for the patient to be evaluated and clinically stabilized. Until internal fixation is undertaken, the fracture is reduced by means of closed methods and the patient is maintained in skeletal traction. General anesthesia may be required for closed reduction and placement of skeletal traction when the acetabular fracture is severely displaced or dislocated. The fractures are divided into five basic groups: (1) fractures of the posterior wall, (2) posterior column, or (3) anterior wall; (4) anterior column and (5) transverse fractures (Figure 19-53). Internal fixation is accomplished with reconstruction plates and screws, total hip replacement with bone grafting (see Total Hip Arthroplasty, p. 782), or fusion if the fracture cannot be reduced.

Procedural Considerations. The surgical approach depends on the type and area of the fracture and the surgeon's preference. The perioperative nurse assists in placing the patient on a fracture or standard OR bed in the lateral or supine position. A general anesthetic is usually administered, but the procedure can be performed solely with a regional block or concurrent epidural infusion. Procedures of this magnitude can be lengthy and involve considerable blood loss. Appropriate measures should be taken to avoid complications attributable to these factors. The room should remain warm, the patient protected from pressure injury, and red blood cell salvaging techniques employed.

A soft tissue set, large bone and acetabular instruments, pelvic reduction clamps, reconstruction plates and screws (both 3.5 and 4.5 mm), plate-bending irons, and a femoral distractor will be necessary. A total hip set should be available. Also

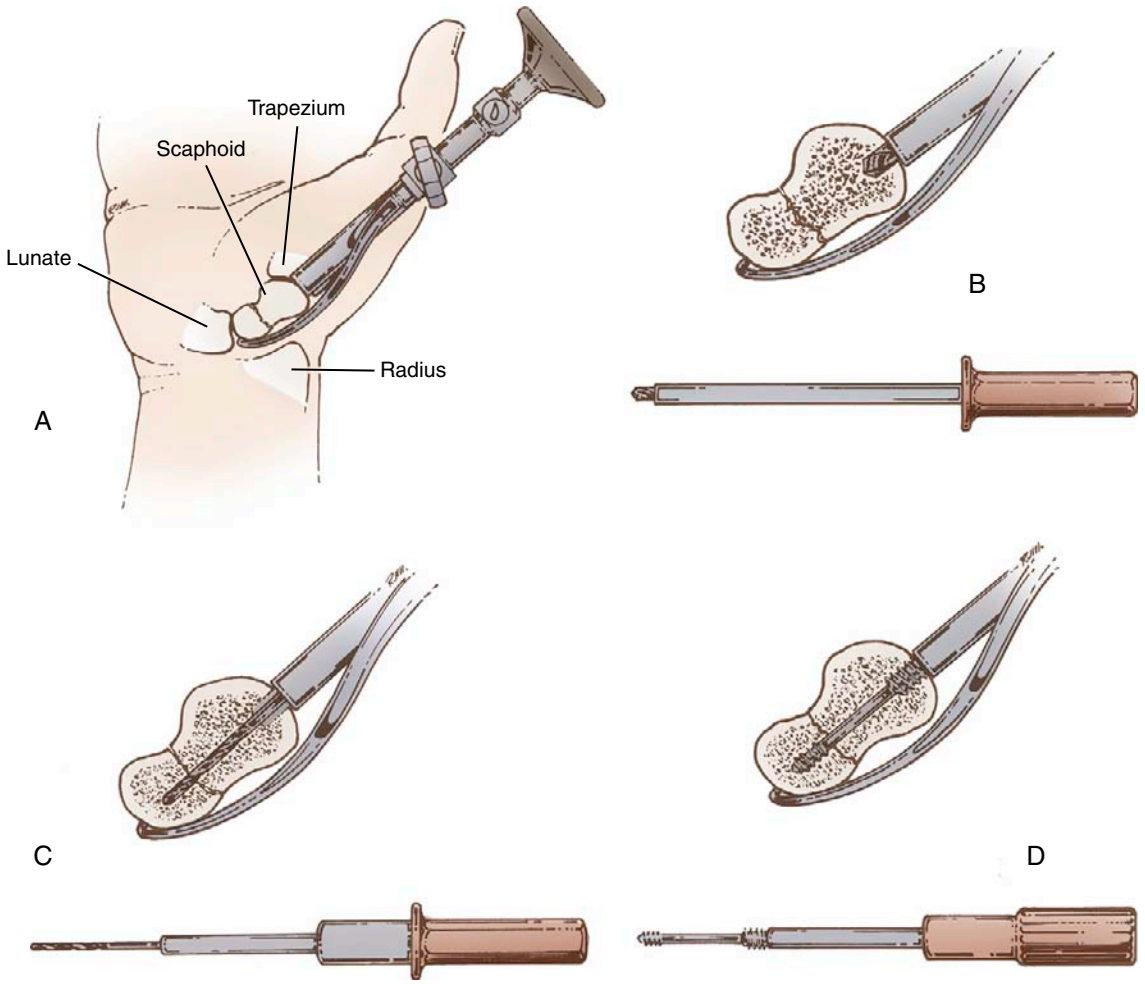

FIGURE 19-52 Repair of the scaphoid. **A**, Fracture site is exposed. **B**, Alignment guide reduces the fracture and guides all subsequent instrumentation. **C**, The screw hole is drilled by hand, and the tap is inserted. **D**, The Herbert bone screw is inserted through the drill guide.

needed are Kirschner wires and Steinmann pins, large-fragment bone screws, pulsatile lavage supplies, and power drill and reamer. Fluoroscopy may be used for this procedure.

Operative Procedure

POSTEROLATERAL APPROACH

1. The surgeon makes a lateral incision over the acetabular fracture site.
2. The joint is opened and the femur dislocated from the acetabulum.
3. The surgeon uses self-retaining or handheld hip retractors to maintain exposure of the acetabulum.
4. Femoral distraction or osteotomy of the trochanter may be used to improve visualization and access to the fracture.
5. The surgeon reduces the fracture using bone clamps, forceps, and a ball spike.
6. Reduction is accomplished in gradual steps using Kirschner wires to hold the fragments temporarily in place.
7. Reconstruction plates are fitted and contoured to the fracture site and secured with screws.
8. The surgeon may also use long cancellous lag screw fixation to provide interfragmentary compression, particularly in column fractures.
9. A bone graft may be needed for additional fixation. A femoral head allograft technique is sometimes used, in which the allograft is mushroomed to create a new acetabulum.
10. The surgeon uses pulsatile lavage to irrigate the wound with antibiotic solution to ensure the articular surfaces are free from loose bodies.
11. The wound is closed, drains are inserted, and pressure dressings are applied.

The leg is maintained in abduction and external rotation with traction. Once the fracture is stabilized, traction is no longer necessary.

NOTE: If there is associated traumatic dislocation of the hip with the acetabular fracture, the dislocation should be treated promptly. The dislocation should be reduced as soon as possible and skeletal traction inserted if needed to maintain reduction. Acetabular fractures often accompany femoral shaft fractures, which also need to be treated concurrently with the surgeon's desired method (see Femoral Shaft Fractures: Internal Fixation, p. 767).

Hip Fractures

Hip fractures are classified by anatomic location and can be categorized as femoral neck fractures, intertrochanteric fractures, and subtrochanteric fractures (Figure 19-54), and these can

each be subclassified. Fracture-dislocations also have a classification system and treatment protocol. Fractures of the greater or lesser trochanters alone are less common and can usually be treated nonoperatively.

Femoral neck fractures and intertrochanteric fractures commonly require open reduction and internal fixation. Neck fractures are more common in women because of several factors, including osteoporosis. Most elderly patients require a comprehensive preoperative medical evaluation to define and treat anesthetic risks. However, efforts should be made to correct the fracture as soon as possible to avoid complications related to immobility, skin pressure, pulmonary congestion, and thrombophlebitis. Avascular necrosis and degenerative changes can occur as a result of diminished blood supply to the femoral head, resulting in irreversible changes. Buck's traction may be placed preoperatively to reduce discomfort from muscle spasm caused by overriding of fracture fragments.

Manipulation, reduction, and internal fixation of these fractures are greatly facilitated by use of the OR fracture bed, which also permits adequate radiographic examination to determine placement of the internal fixation.

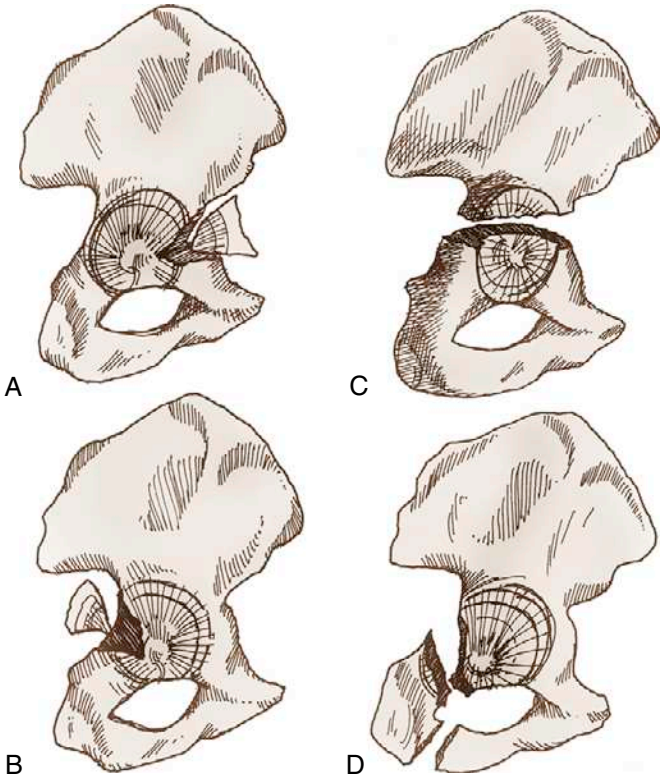

FIGURE 19-53 Acetabular fractures. **A**, Anterior wall. **B**, Posterior wall. **C**, Transverse. **D**, Posterior column.

Intertrochanteric Fractures. Intertrochanteric fractures occur most frequently in older patients. The fractures usually unite without difficulty. However, because the lower extremity is externally rotated at the fracture site, internal fixation is necessary to prevent malunion. Internal fixation allows patients to be mobilized earlier, thereby decreasing mortality and morbidity.

PROCEDURAL CONSIDERATIONS. The patient is placed in the supine position on the OR fracture bed, and the surgeon reduces the fracture by manipulating the extremity and then confirming with fluoroscopy. Various internal fixation devices, including Ambi, Free-Lock, dynamic hip screw (DHS), and medullary fixation, may be used. Success of the procedure is determined by bone quality, fragment configuration, adequate reduction, implant design, and implant-insertion technique. Intraoperative blood loss is minimized because the hip joint is not opened.

A soft tissue set and a large bone set are required in addition to the compression hip screw instrumentation and implants, bone-reduction and plate-holding clamps, and a power drill and reamer.

OPERATIVE PROCEDURE

Free-Lock Compression Plate and Lag Screw (Figure 19-55)

1. The surgeon reduces the fracture as previously described.
2. Reduction is checked in both the AP and lateral views with fluoroscopy.
3. The surgeon makes an incision from the greater trochanter distally to accommodate the length of the implant.
4. The dissection is completed through the fascia lata, and the vastus lateralis is exposed.

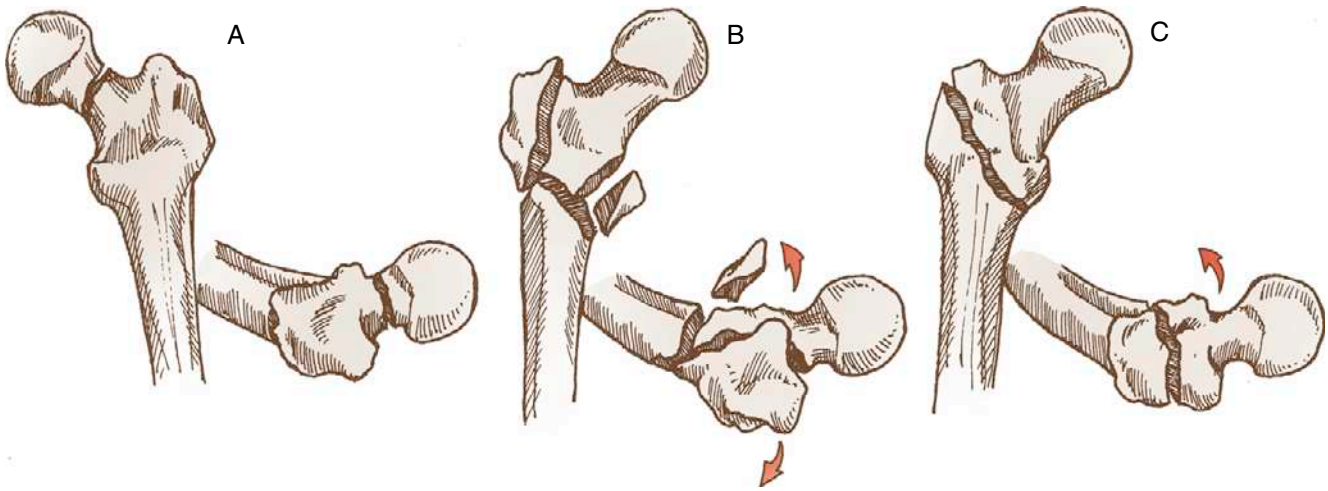

FIGURE 19-54 Proximal femur fractures. **A**, Midcervical. **B**, Comminuted subtrochanteric. **C**, Intertrochanteric.

5. The reduction is visually confirmed and the surgeon inserts the guide pin after determining the angle plate to be used. A 135-degree angle plate is commonly used.
6. The pin should be centralized in the femoral head approximately 1 cm short of the femoral articular surface. Care must be taken to not enter the joint space, since this might result in arthritic changes. Further penetration of the pin through the acetabulum and into the pelvis can potentially damage large vessels or bowel. A second pin can be used to control rotation in high neck or unstable fractures.
7. The surgeon uses a conical cannulated drill bit over the guide pin to open the lateral cortex.
8. The depth gauge is placed over the guide pin. The size of the required lag screw is determined from the guide.
9. A double-barrel reamer is adjusted to correspond to the depth of the guide pin. The cortex is reamed over the guide pin to create a channel for the lag screw and barrel of the compression plate.
10. The lag screw channel is tapped to the full distance of reaming to allow proper seating of the lag screw, particularly in young patients with firm bone. Reaming depth of osteoporotic bone is reduced 5 mm, and the tap depth is reduced approximately 1 to 2 cm to allow sufficient screw purchase.
11. The surgeon may confirm the plate angle with a trial. Once confirmed, the nurse opens the implants (plate and lag screw) to the back table.
12. The surgical technologist assembles the plate, lag screw, and insertion wrench with the centering sleeve. A screw stabilizer is passed through the center of the insertion wrench and threaded into the lag screw.
13. The surgeon places the entire assembly over the guide pin, and advances the lag screw to the desired depth with periodic verification with fluoroscopy. Penetration of the lag screw through the femoral articular surface must be avoided.
14. The insertion wrench is disassembled, and the barrel of the compression plate is placed over the lag screw. The barrel of the plate should fully cover the lag screw. The plate is seated on the lateral femoral shaft.
15. The surgeon secures the plate to the shaft of the femur with plate-holding forceps. The guide pin is removed. At this point, traction can be released to allow compression of the fracture site.
16. Screw holes are made using the drill guide and a 3.5-mm drill bit. The length is determined, and cortical screws are inserted through the screw hole on the plate with sufficient purchase on the opposite cortex of the shaft. The top screw hole on the plate can accept a 6.5-mm cancellous screw, which can be angled for better purchase in comminuted fractures.
17. Traction is released if not done previously. The surgeon inserts a compression screw into the barrel of the screw and threads it into the back of the lag screw, compressing the fracture site. The compression screw exerts a powerful

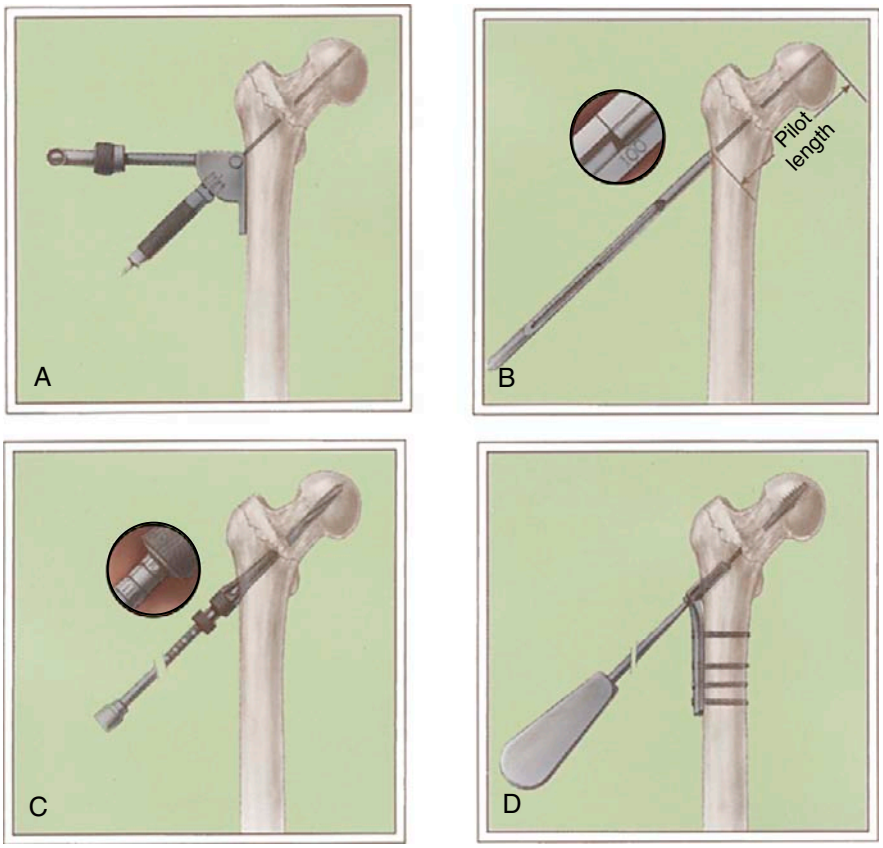

FIGURE 19-55 Intertrochanteric fracture repair with compression plate. **A**, Guide pin is inserted. **B**, Depth of guide is measured. **C**, Lag screw channel is reamed. **D**, Tube/plate is applied, and lag screw is inserted.

force. The amount of compression applied should correlate with the quality of the bone.

18. The wound is irrigated and closed. Two closed suction drains may be inserted during closure.

Weight bearing may begin as early as the first postoperative day, depending on reduction and quality of bone.

NOTE: Many of the same techniques and principles of long bone fracture fixation are used in treatment of various types of hip fractures. The different screw types, dynamic compression, and lag screw effect are described throughout the chapter.

Femoral Neck Fractures: Internal Fixation. Anatomic reduction is necessary before internal fixation of femoral neck fractures because of the high incidence of associated complications, such as nonunion and avascular necrosis of the femoral head. The degree of displacement, tamponade pressure from intracapsular bleeding, and delays in reduction and fixation can affect the blood supply to the femoral head. These factors contribute to death of the femoral head and failed fixation. Growing children may sustain fractures through the epiphyseal growth plate (slipped capital femoral epiphysis). These injuries are treated by reduction and internal fixation of the femoral head, similar to the procedures used in the adult. The Garden and AO nomenclatures are the most popular classifications for grading the fractures. Pins of various designs, such as Knowles and Hagie pins, and universal cannulated screws (Figure 19-56) are used for fixation (Figure 19-57). In cases of severe comminution or avascular necrosis of the femoral head, the patient may require a prosthetic replacement (see Total Joint Arthroplasty, p. 781).

PROCEDURAL CONSIDERATIONS. The perioperative nurse assists with positioning the patient on the OR fracture bed and a general or regional anesthetic (spinal or epidural) is administered. Slight traction and external rotation are adjusted on the affected side. A soft tissue set and a large bone set are required, as well as the fixation device of choice with instrumentation, Kirschner wires, Cobra retractors, a power drill, and fluoroscopy.

OPERATIVE PROCEDURE

Cannulated Screw Fixation for Nondisplaced Femoral Neck Fractures

1. The surgeon makes a 5-cm lateral incision over the greater trochanter and exposes the fracture.
2. The dissection is carried through the subcutaneous and fascial layers; the vastus lateralis is detached anteriorly and retracted, exposing the femoral neck.
3. Two guide pins are driven into the middle of the femoral head, one anterior and one posterior, within 5 mm of subchondral bone; a third pin is placed adjacent to the medial cortex at a 135-degree angle. The surgeon is careful to not violate the articular surface.
4. The guide pins are measured for correct screw length, and the cannulated screws are inserted over the guide pin without applying compression until all are seated.
5. Compression of the anterior screws is completed first and the posterior screws last to avoid collapse of the posterior aspect of the neck.
6. Traction is released, and the fracture site is visualized with fluoroscopy while the hip is rotated through a full range of motion.
7. Radiographs are taken to verify the position of the screws; the wound is irrigated and closed.

NOTE: Screw protrusion into the joint space can be disastrous to the articular surface. Radiopaque dye can be injected to rule out communication with the joint.

Femoral Head Prosthetic Replacement: Unipolar and Bipolar Implants. With the development of current cement fixation techniques and the evolution of the modular bipolar

FIGURE 19-56 Cannulated screw system.

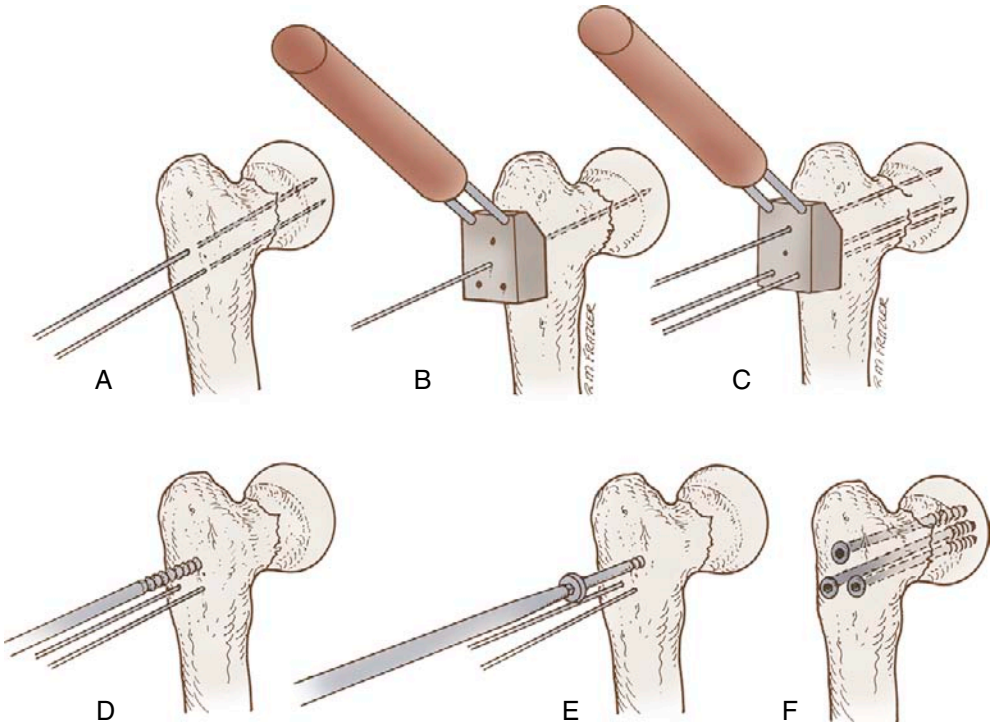

FIGURE 19-57 Internal fixation with cannulated screws (AO technique). **A,** Guidewire parallel to anteversion wire. **B,** Guidewire placed over positioning wire through diamond-patterned positioning holes. **C,** Guidewire placed through each outer triangle of holes. **D,** Cannulated tap passed over guidewire to tap near cortex. **E,** Large cannulated screw inserted over guidewire. **F,** Remaining screws inserted in same manner.

and monopolar design, the use of fixed endoprostheses such as the Austin-Moore and Thompson designs declined. During the early 1980s the bipolar system in conjunction with a cemented femoral stem became popular. Bipolar endoprostheses (Figure 19-58) were introduced to reduce the shear stresses affecting the acetabular surface, decreasing the motion and friction between the prosthetic head and the acetabulum that is seen with conventional (unipolar) endoprostheses. A femoral head prosthesis is snapped into a rotating polyethylene-lined cup that, when inserted, moves as one unit. Friction occurs between the ball and plastic instead of between the head and the acetabulum. This was a revolutionary design in the mechanics of hip motion and stresses. Current data, however, have some surgeons and engineers reevaluating the use of bipolar prostheses. It is believed that bipolar motion subsides after fibrous growth has taken place, allowing for only unipolar motion. There have also been reports of bone resorption and subsequent prosthetic loosening in cases in which bipolar prostheses were used. Researchers are evaluating evidence of metallic head wear of the polyethylene cup, creating microscopic debris with a subsequent chemical lysis of bone. Thus there has been resurgence in the use of unipolar heads for femoral head replacement.

Trends in healthcare toward cost reduction precipitated the development of the *diagnosis-related group (DRG) prosthesis*. The modular design was retained, allowing for different combinations of head size, neck length, and stem size. Instead of being bipolar, the head is solid, or unipolar, and the stem is the result of a less costly manufacturing process. The most cost-effective prosthesis is still the original Austin-Moore design, which may be selected for those patients whose life expectancy is short and who have a minimal level of activity. If major deficiencies in the acetabular side of the joint are present, a total joint arthroplasty may be performed. In deciding between the hemiarthroplasty and total hip reconstruction,

FIGURE 19-58 Modular bipolar endoprostheses.

the patient's medical condition, age, and level of activity must be considered.

Current biomaterials, methods of fixation (cemented versus uncemented), prosthetic life, and modular components allow conversion of a hemiarthroplasty (reconstruction of one side of the joint) to a total hip arthroplasty, provided that the femoral component is adequately fixed. Depending on the patient's condition, the acetabulum may eventually require arthroplasty as a result of degenerative changes. Improved technology and surgical technique have increased the life span of implanted components. The portion of the implant that articulates within the acetabulum can be removed and replaced with a smaller femoral head. The acetabulum is then prepared for prosthetic implantation by various means of fixation. The ability to convert from hemiarthroplasty to total arthroplasty reduces the amount of surgery required.

PROCEDURAL CONSIDERATIONS. The patient is placed in the lateral position after the administration of a general or regional anesthetic. The perioperative nurse preps the patient from the umbilicus down to and including the foot. Instrumentation for total hip replacement should be available but not opened until inspection of the resected joint is completed to determine if a total arthroplasty is required.

The soft tissue and the large bone sets are required, as well as the endoprosthesis instruments, trials, and implants. A power reciprocating or sagittal saw may be necessary. Templates or a caliper will be used to measure the size of the femoral head. Bone cement and the supplies for preparing and inserting it should also be available.

OPERATIVE PROCEDURE

Modular Austin-Moore Endoprosthesis

Both posterior and anterior approaches can be made to the hip to place an endoprosthesis. The posterior approach is quicker and generally involves less blood loss, but detractors suggest that there is a higher dislocation rate and a greater chance of infection because of the proximity of the incision to the anus. Although both approaches are widely used, the posterior approach is described as follows:

1. The surgeon makes a linear incision from 5 cm below the posteroinferior iliac spine toward the posterior aspect of the greater trochanter and distally along the posterior aspect of the proximal femur for 7 mm.
2. The capsule is entered, and the femoral head is removed and gauged with the template. Fragments that may be loose in the acetabulum or attached to the ligamentum teres are removed.
3. The surgeon inserts a trial cup into the acetabulum, and applies axial compression while checking clearance of the extremity's lateral motion.
4. The femoral neck is fashioned to achieve an accurate prosthetic fit.
5. Using a punch, the surgeon opens the medullary canal from the femoral neck. The intramedullary canal is reamed and rasped to accommodate the prosthesis.
6. Once the canal is prepared, the surgeon inserts the prosthesis of choice with or without bone cement.
7. A unipolar or bipolar assembly is snapped onto the neck of the femoral stem. The height of the head determines the neck length and is selected after trial reduction.
8. The hip is reduced, and closure is accomplished in layers over suction drains.

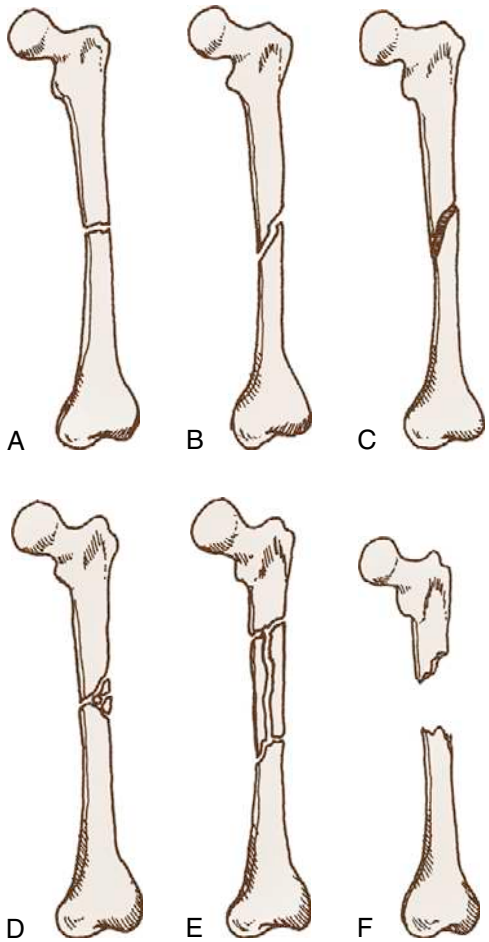

FIGURE 19-59 Femoral shaft fractures. **A**, Transverse. **B**, Oblique. **C**, Spiral. **D**, Comminuted. **E**, Longitudinal split. **F**, Complete bone loss.

Femoral Shaft Fractures: Internal Fixation. Fractures involving the femoral shaft are very common in today's orthopedic OR. Prolonged immobility, with its attendant complications, and disability can result if femoral shaft fractures are not managed appropriately. The femur is the largest principal load-bearing bone in the body. Fractures of the femoral shaft can be surgically treated with several available techniques. Considerations for treatment are type and location of fracture (location on shaft), the number of segments involved, the degree of comminution (Figure 19-59), and the activity level of the patient. Femoral shaft fractures are often associated with ipsilateral (same-side) trochanteric or condylar fractures. Pathologic fractures often occur in this region.

Possible treatment methods for femoral shaft fractures are closed reduction, skeletal traction, and femoral cast bracing. External fixation has limited utility when fractures associated with surgical site infection or neurovascular compromise are treated, but it may serve temporarily until internal fixation can be performed. Although plates and screws are used for femoral shaft fractures, their use has been widely disputed because of complications such as bent or broken plates, refractures, and deep surgical site infections. Intramedullary (IM) fixation devices have become the preferred method of treatment. IM nails and rods increase the load sharing of the bone, making the implant less likely to fracture. Bone healing requires a load

across the fracture site to promote osteosynthesis and prevent refracture. The open or closed method of intramedullary nailing can be used with locked and nonlocked nails. Closed methods of intramedullary fixation often minimize exposure of the surgical site and decrease surgical time, resulting in less opportunity for infection.

Intramedullary nail and rod designs vary: (1) flexible nails such as the Rusch or Enders type, (2) standard rods such as the Sampson and AO rods, and (3) interlocking nails (see Fractures of the Humeral Shaft, p. 754) such as the Grosse-Kempf and Russell-Taylor varieties. Closed reduction and intramedullary nailing with or without locking screws have become the method against which other methods are measured. Incidences of scarring, blood loss, and infection are all favorable. Fracture hematoma remains intact at the fracture site, which is important in bone healing, and the rate of bone union is increased.

PROCEDURAL CONSIDERATIONS. General or epidural anesthetics are used. The patient is placed on the OR fracture bed in the supine position, traction applied, and the fracture manually reduced and confirmed with fluoroscopy. If the fracture is profoundly unstable, the surgeon must take care during manipulation to prevent neurovascular complications. For open IM fixation, extra retractors and bone instruments may be required. For a percutaneous reduction, a soft tissue set and a large bone set are required in addition to the IM nail implants and associated instruments, a power reamer and drill, and long guidewires for reamers. This procedure requires the use of fluoroscopy. A skeletal traction tray with Steinmann pins may be necessary.

OPERATIVE PROCEDURE

Russell-Taylor Rod With or Without Locking Screws

1. The surgeon makes an incision over the tip of the greater trochanter and continues it proximally and medially for 6 to 8 cm. The fascia of the gluteus is incised, and the piriformis fossa is palpated.
2. With a threaded guide pin followed by cannulated reamers or by use of an awl, the surgeon identifies the trochanteric fossa and penetrates the cortex. A 3.2-mm guide rod is inserted to the level of the fracture. A curved guide pin is available for more severely displaced fractures.
3. Under fluoroscopy, the surgeon advances the guidewire across the fracture site and into the distal fragment until the ball tip of the guidewire reaches the level of the epiphyseal scar. A second guidewire is held against the portion of the guidewire extending out of the proximal femur, and the length is measured. That measurement is subtracted from 90 mm (total guidewire length) to determine the length of the intramedullary nail required.
4. The cannulated reamers are placed sequentially over the guidewire. The entire femur is reamed at 0.5-mm increments. The entire shaft, and especially the fracture site, should be visualized with fluoroscopy as the reamers pass.
5. The final reamer size should be verified with the reamer gauge. The femur is reamed 1 mm over the selected nail diameter. Inserting a nail in an inadequately reamed femur or inserting a nail that is too large can cause severe bone splitting and comminution.
6. The proximal screw guide/slap hammer is assembled onto the nail. The nail is oriented to match the curve of the femur.
7. Using the handle of the inserter, the rotation of the nail is controlled and the nail is driven into the femur. The nail is fully seated when the proximal screw guide is flush with the greater trochanter. The surgeon disengages the inserter from the slap hammer.
8. Using the power drill and correct drill sleeves, the surgeon drills a 4.8-mm hole through both cortexes and measures the depth directly off the bit.
9. Through the appropriate drill sleeve, a 6.4-mm self-tapping locking screw is inserted and the drill sleeve is removed.
10. By fluoroscopy, the distal screw holes are confirmed as perfect circles on the screen. The distal targeting device is mounted on the nail, followed by the left or right adapter block. The adapter block is adjusted until the calibration reads the length of the nail. The cross hairs are aligned in the adapter to the holes in the distal nail, with confirmation by fluoroscopy.
11. The surgeon makes an incision through the adapter block over the distal femur to the lateral cortex. Following the same steps as those for placing the proximal screw, one or two distal locking screws are inserted. There are various freehand techniques for inserting distal locking screws.

SURGERY OF THE LOWER LEG (DISTAL FEMUR, TIBIA, AND FIBULA)

Many procedures on the lower leg use the same principles of fracture fixation already mentioned. Meticulous detail is required to ensure proper alignment and optimal surgical results for the patient. As in the hip, fractures around the knee require secure fixation to allow bone healing, preserve motion, and provide joint mobility as early as possible. Fracture treatment for the various described injuries is based on location and the pattern of fracture. Methods of fixation for the distal end of the femur and proximal end of the tibia include pins, wire, compression plates, intramedullary nails, supracondylar plates, and cannulated screws. Multiple-trauma patients with one or a combination of fractures may require more than one method of fixation. Open reduction and internal fixation must ensure anatomic restoration of the joint surface and rigid fixation, and allow early motion of the knee joint.

Most operations on the knee are performed with the patient in the supine position and the leg prepped and draped from the groin to the middle of the calf or including the entire foot. It is occasionally necessary for the surgeon to operate with the foot of the OR bed dropped and the patient's knee flexed to 90 degrees. Consequently, it is important for the nurse to position, the patient so that the knee is at a break in the bed; if it is necessary, the lower leg can then be flexed at the knee during the operation. A tourniquet is often used.

Femoral Condyle and Tibial Plateau Fractures

The joint surfaces are often involved with fractures of the distal end of the femur and proximal end of the tibia. Anatomic alignment of the articular surfaces is necessary to provide joint stability and decrease the chance of posttraumatic arthritis. Nonunion is the most common complication in supracondylar fractures, leading to failure of surgery. As with humeral head and hip fractures, it is important that the articular surfaces are reopposed as close as possible to avoid future degenerative changes. Unfortunately, these often cannot be avoided, and

patients with this type of injury often face future joint arthroplasty and replacement (see Total Joint Arthroplasty, p. 781).

Distal femoral fractures result in varying degrees of comminution. Condylar fractures can be unicondylar or bicondylar, with separation of both condyles (Figure 19-60). Type A fractures are extraarticular. Type B are single condyle fractures in the sagittal or coronal planes, whereas type C fractures are T and Y configurations. Type C fractures have varying degrees of shaft and condylar comminution, presenting the greatest treatment challenge.

Simple, nondisplaced distal femoral fractures can be treated with closed reduction and immobilization by casting if anatomic

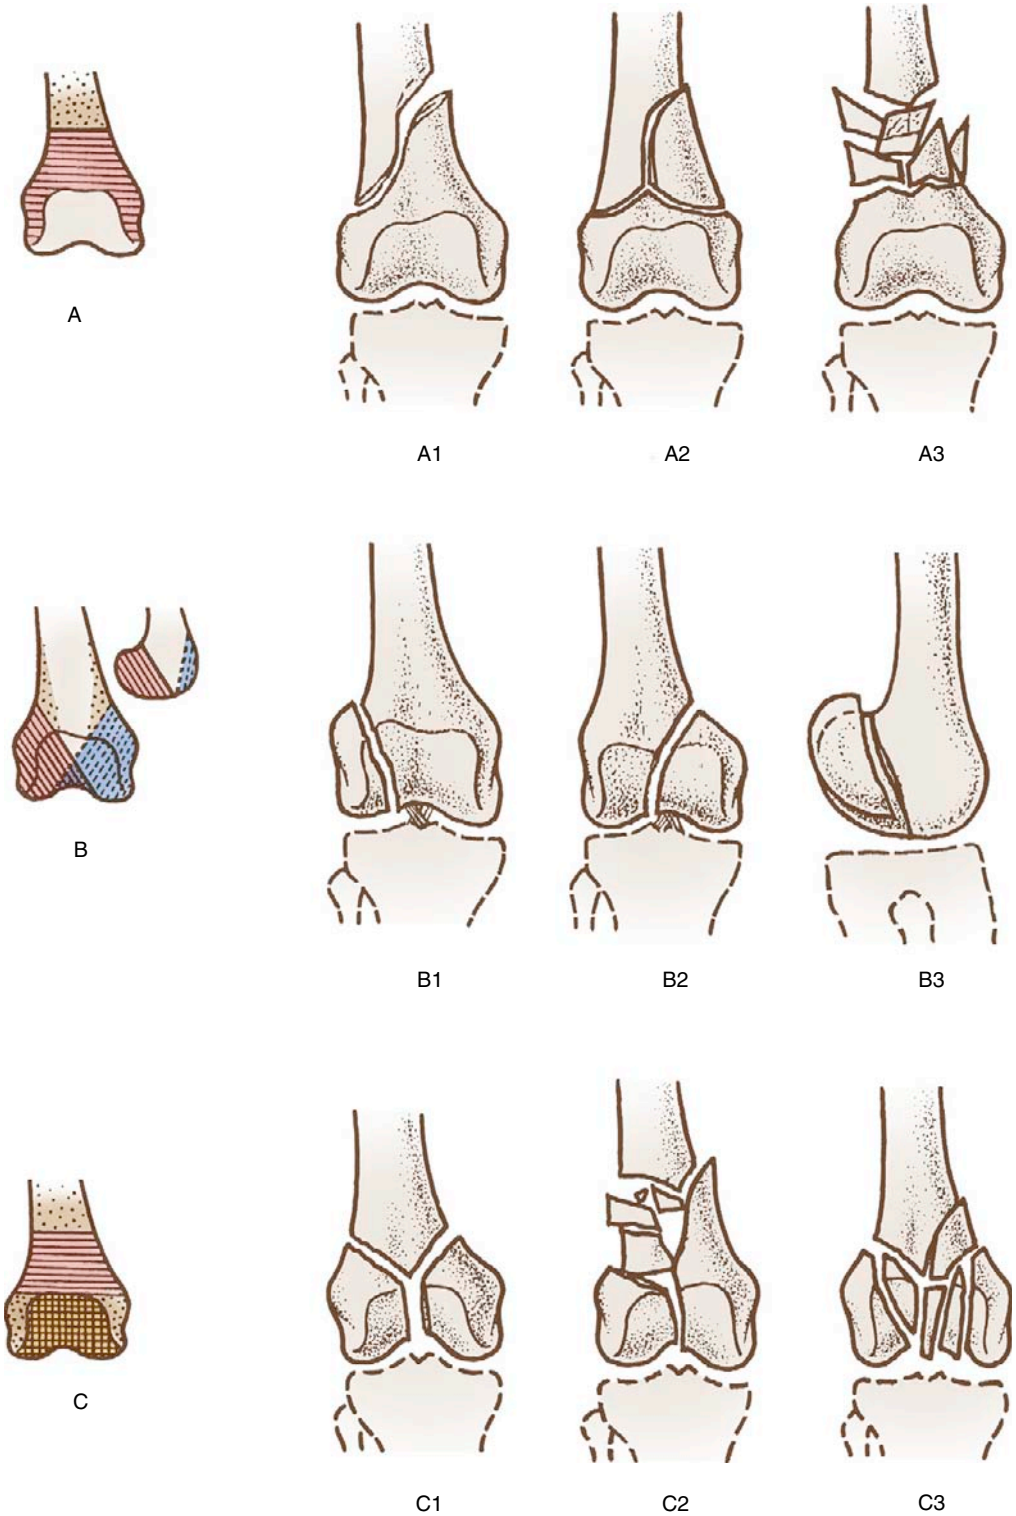

FIGURE 19-60 Classification of fractures of distal femur described by Müller and associates.

reduction is achieved. Nondisplaced, extraarticular fractures can be treated with a hinged cast brace. Comminuted fractures in this region can also be treated in this manner if shortening and angulation are minimal. Traction can be used initially to augment this type of treatment. Distal femoral fractures are treated with open reduction if distal tibial traction and manipulation attempts fail. Flexible nails, locking intramedullary nails, blade plates, condylar compression screws, and condylar buttress plates are accepted methods of treating condylar fractures. Attention must be given to the attachment of the cruciate ligaments, which originate in the condylar notch and may require fixation of a partial or full disruption as a result of the injury to the knee (see "Arthroscopic Anterior Cruciate Ligament Repair," p. 804).

Tibial plateau fractures historically have been attributed to bumper or fender injuries, but a variety of falls or other traumas frequently are the cause. Compression force of the distal end of the femur on the tibia produces the various types of plateau fractures. Commonly this occurs from abduction of the tibia while the foot is planted, driving the lateral femoral condyle into the lateral tibial plateau (also called the *condyle*). There are several classification systems based on fracture and dislocation patterns. The general theme of these fracture classifications and examples of their treatment can be summarized by the following types (Figure 19-61): (1) pure cleavage, unicondylar fracture, (2) cleavage fracture combined with local depression, (3) pure central depression, (4) medial condylar wedge with depression or comminution, (5) bicondylar but with continuity of diaphysis and metaphysis, and (6) comminution with dissociation of metaphysis from diaphysis. Fractures of the tibial plateau are often associated with dislocation, which may spontaneously reduce at the time of trauma.

Special attention must be given to the possibility of neurovascular insult, which must be addressed immediately. Elevation and fixation of the depressed fracture are the focus for treatment of plateau fractures. As with distal femoral fractures, the articular surfaces and cruciate insertion require reapproximation and fixation. Repair to the menisci and ligaments should occur simultaneously to prevent knee instability.

Blade plates, buttress plates, and cannulated screws are all methods by which fractures of the tibial plateau are fixed. Severe fractures are treated using multiple buttress plates and screws (Figure 19-62). Bone graft from the iliac crest and fibular head autograft are often used when there is a significant amount of bone lost to comminution with proximal tibial fractures.

Supracondylar Fractures of the Femur

Fractures of the distal femur in the multiple-trauma patient are treated early to promote rapid ambulation, which decreases complications caused by immobility. In an effort to deliver quick fracture reduction and stabilization, many orthopedic trauma systems have been developed. Often these are the same systems used in daily orthopedic procedures with modifications to expedite implantation and fixation. Some of the intramedullary devices do not require reaming.

Procedural Considerations. Initial stabilization of the patient may immediately precede the nailing procedure. Often other team members are attending to treatment of other systems. The perioperative nurse is challenged to control traffic, coordinate team efforts, and protect the patient from increased risk of infection by the inadvertent contamination of instruments and implants. The patient is placed in the supine position after induction of general or regional anesthesia. If possible, the patient is positioned on the OR fracture bed; if not, a radiolucent OR bed is used. A pneumatic tourniquet may be applied as high up on the femur as possible, taking care to protect the genitals during placement. The nail can be inserted using the closed or open technique.

The soft tissue set and large bone set are required, as well as the intramedullary supracondylar nail implant (Figure 19-63) and the instruments necessary for its insertion. A power drill, guidewires, intramedullary rod set, and fluoroscopy will also be needed. In addition, Steinmann pins, Kirschner wires, bone-reduction clamps, and a bone graft set should be available. Occasionally a primary total knee arthroplasty will be performed, and the appropriate instruments should be available should that possibility exist.

Operative Procedure

INTERCONDYLAR FRACTURE OF THE FEMUR, T TYPE (AIM SUPRACONDYLAR INTRAMEDULLARY NAIL)

1. The surgeon makes a standard midline skin incision with parapatellar arthrotomy. Depending on the degree of intraarticular extension, the incision may be as small as 2.5 cm or involve lateral eversion of the patella to gain visualization of the entire joint.
2. Articular fractures should be anatomically reduced and secured with 6.5-mm or 8.0-mm cannulated screws placed in the anterior and posterior aspects of the condyles to allow adequate space for the placement of the nail.
3. Using an awl, the surgeon makes an entry hole into the femoral canal just anterior to the femoral insertion of the posterior cruciate ligament. Care is taken to ensure anatomic alignment of the condyles to avoid varus or valgus femoral alignment.
4. The hole is enlarged with the nonadjustable step reamer to accept the largest diameter of the chosen nail. Further reaming of the canal is necessary only in the case of nonunion, when the canal is reamed 0.5 to 1 mm larger than the size of the selected nail.
5. The selected nail is attached to the screw-targeting jig, which is then locked into place by the jig adapter. Before the nail is inserted, the alignment of the jig and nail holes is carefully checked by manually inserting the sheath and trocar through the selected holes.
6. The surgeon places the nail in the prepared canal and advances it retrograde either by hand or with gentle blows of a mallet on the jig adapter. The nail should be countersunk approximately 3 to 5 mm below the articular surface.
7. The screws may then be placed using the targeting jig, and sheath and trocar assembly. The surgeon makes a small lateral incision and advances the sheath and trocar to the femoral cortex. A 5.3-mm drill bit is advanced through the medial cortex, and the length is measured from the calibrated drill bit or by use of a depth gauge. The appropriate 6.5-mm cortical screw is inserted, and the process is repeated for placement of the second screw.
8. Proximal locking of the nail is then performed in a similar fashion, taking care to use the appropriate holes in the targeting jig for the length of nail inserted. The 3.8-mm drill bit and 4.5-mm self-tapping screws are used to fill these holes after femoral rotation and alignment are confirmed with fluoroscopy.

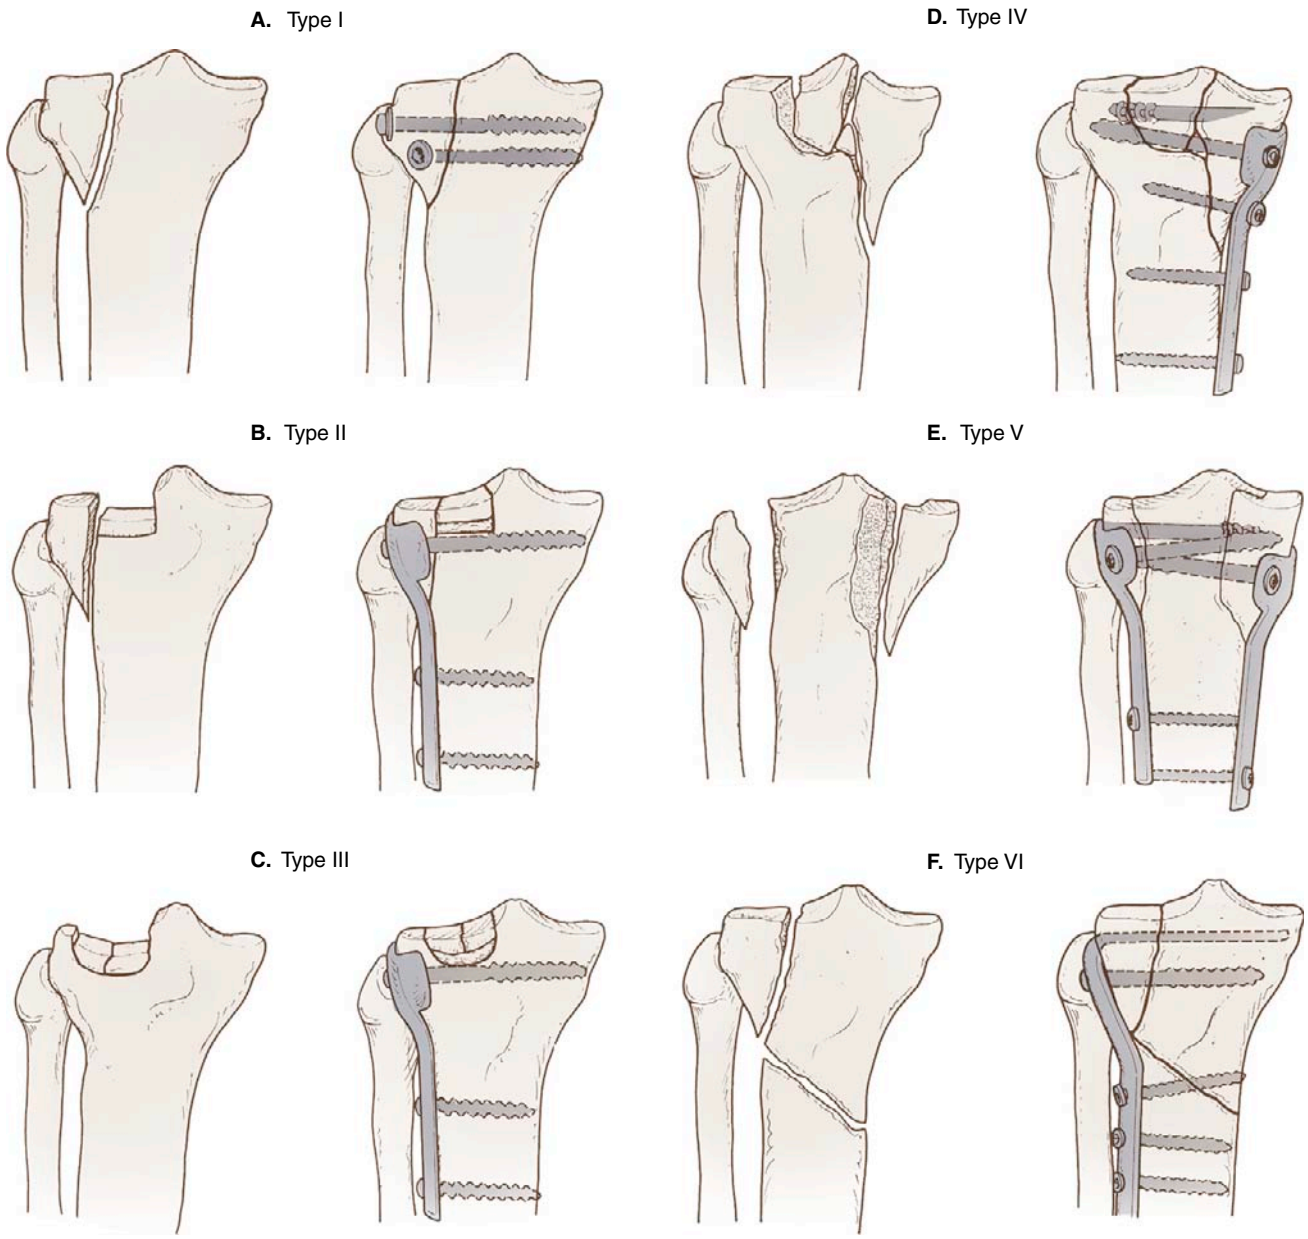

FIGURE 19-61 Classification of fractures of the tibial plateau. **A**, *Type I:* Pure cleavage fracture. **B**, *Type II:* Cleavage combined with depression. Reduction requires elevation of fragments with bone grafting of resultant hole in metaphysis. Wedge is lagged on lateral aspect of cortex protected with buttress plate. **C**, *Type III:* Pure central depression. There is no lateral wedge. Depression may also be anterior or posterior or involve whole plateau. After elevation of depression and bone grafting, lateral aspect of cortex is best protected with buttress plate. **D**, *Type IV:* Medial condyle either is split off as wedge or may be crumbled and depressed, which is characteristic of older patients with osteoporosis (not illustrated). **E**, *Type V:* Note continuity of metaphysis and diaphysis. In internal fixation, both sides must be protected with buttress plates. **F**, *Type VI:* Essence of this fracture is fracture line that dissociates metaphysis from diaphysis. Fracture pattern of condyles is variable, and all types can occur. If both condyles are involved, proximal tibia should be buttressed on both sides.

9. The jig adapter and screw-targeting jig are removed, and an end cap is placed into the distal end of the nail. The surgeon irrigates the wounds and closes them in layers. A compression dressing is applied.

Range-of-motion and muscle-strengthening exercises are begun on the first postoperative day. Care is taken to protect against varus and valgus stresses. The patient is discouraged from bearing weight on the extremity until there is radiographic evidence of healing.

SUPRACONDYLAR FRACTURE (COMPRESSION PLATE)

1. The lateral area of the distal end of the femur is exposed above and below the knee joint.
2. The surgeon reduces the fracture site and inserts multiple Kirschner wires for fixation.

FIGURE 19-62 Severe fractures are treated by use of multiple buttress plates and screws.

FIGURE 19-63 Supracondylar nail.

3. A calibrated Steinmann pin is placed transversely across the condyles parallel to the joint line. The pin must stop 8 to 10 mm short of the medial cortex.
4. The length of the lag screw is gauged when it is read directly on the calibrated Steinmann pin, and adjustable double reamers are used to ream to this depth.
5. A lag screw is inserted across the condyles, followed by the compression screw.
6. The surgeon secures the plate to the femoral shaft with cortical bone screws and confirms the repair by fluoroscopy.
7. The incision site is irrigated and closed. A knee immobilizer is placed.

MEDIAL AND LATERAL Y-TYPE TIBIAL PLATEAU FRACTURES

1. The surgeon makes a long anterolateral incision, starting 2.5 cm above the superolateral aspect of the patella and tendon and proceeding distally around the patella to the anterior aspect of the tibia just below the tibial tuberosity. The distal end of the tibial shaft should be exposed.
2. The level of the prepatellar bursa is identified. The surgeon uses blunt dissection beneath the skin and retracts the proximal end of the tibia to expose it from midline medially to midline laterally.
3. Using a tibial bone plug, the surgeon detaches the patellar tendon and exposes both the medial and lateral articular surfaces. The articular surface is reconstructed using temporary Kirschner wires. A contoured T-plate is attached to the medial aspect of the tibia using cancellous screws in the proximal portion and cortical screws in the distal portion. A smaller T-plate is inserted on the lateral side and secured in the same manner. The Kirschner wires are removed. Care should be taken to ensure that the screws do not interfere with each other as they traverse from opposite sides of the tibia.
4. The surgeon reattaches the patellar tendon using a 6.5-mm cancellous screw through the bone plug.
5. The wound is closed and immobilized at 30 degrees with a posterior splint.

Patellectomy and Reduction of Fractures of the Patella

Patellectomy was a frequently performed procedure until the early 1970s. It is possible to excise a portion of the patella (for comminuted fracture) or the entire patella (for painful degenerative arthritis) without significantly affecting ordinary activities. However, patellectomy has been shown to significantly reduce power of extension as the joint extends, which is the most important function of the knee. Other complications associated with patellectomy are (1) slow return of quadriceps mechanism strength, (2) quadriceps muscle atrophy, and (3) loss of knee protection from the patella. Removal of the entire patella may result in relative lengthening of the knee extensor mechanism, which necessitates overlapping of the quadriceps tendon at the time of operation to prevent a lag in knee extension. Patellectomy should be performed only when comminution is extensive and reconstruction of the articular surface of the patella is not possible.

If the fracture consists of two large fragments that can be anatomically reduced, fixation is accomplished with a tension band, a circumferential loop technique, or bone screws. Tension band wiring produces compression forces across the fracture site and results in earlier union and immediate mobility of the knee.

Procedural Considerations. The patient is supine. The tourniquet is applied, and the leg is prepped and draped. A soft tissue set and a bone set are required, along with a power drill and bits, bone-reduction clamps, 18-gauge wire, heavy needle holders, and a wire tightener.

Operative Procedure

1. The surgeon makes a transverse curved incision over the patella.
2. Using sharp and blunt dissection the surgeon exposes the surface of the patella, the quadriceps, and the patellar tendons.
3. The joint is irrigated, and the fracture is reduced with bone-reduction clamps.
4. One length of wire is passed around the insertion of the patellar tendon and then around the quadriceps tendon. A second wire is passed more superficially through the bone fragments.
5. The fracture is overcorrected, and the wire is tightened with the wire tightener. In flexing the knee or contracting the quadriceps, the condyles press against the patellar fragments, producing compression at the fracture site.

Correction of Recurrent Dislocation of the Patella

Recurrent dislocation of the patella can be the result of violent initial dislocation or more commonly from underlying anatomic abnormalities. The underlying condition causes an abnormal excursion of the extensor mechanism over the femoral condyles. Dynamic forces, such as the vastus lateralis, and static forces, such as those arising from the shape of the patella, tend to displace the patella laterally. Dislocations occur when there are extreme displacing forces combined with internal rotation of the femur and flexion of the knee. If untreated, patellar dislocations will deteriorate the knee by causing abnormal patellofemoral articulation, chondromalacia, and meniscal tears.

Conservative treatment aimed at quadriceps strengthening may be indicated in some patients. Numerous procedures have been designed to realign the knee extensor mechanism. All the procedures include incising the lateral quadriceps tendon and shifting the insertion of the patellar tendon medially or distally to the original insertion of the tibia.

Procedural Considerations. The patient is supine. The tourniquet is applied, and the leg is prepped and draped. A soft tissue set and a bone set are required, along with a large-fragment screw set, a power drill, a microsagittal saw (Figure 19-64), and osteotomes.

Operative Procedure

PATELLAR REALIGNMENT (ELMSLIE-TRILLAT)
(Figure 19-65)

1. The surgeon makes a lateral parapatellar incision beginning proximally to the patellar pole, laterally around the patella, and extending to 2 cm distally and just laterally to the tibial tuberosity.
2. A skin flap is developed and retracted medially to expose the capsule. A medial arthrotomy is completed, the joint is inspected, and any pathologic condition present is repaired.
3. The lateral retinaculum is released from the vastus lateralis proximally and the patellar tendon distally.
4. Using a ½-inch osteotome, the surgeon scores the tibial tuberosity medially and laterally, just below the fat pad and under the patella.
5. The surgeon continues the osteotomy using a microsagittal saw distally for 4 to 6 cm, and leaves the periosteum hinged at the distal-most part of the osteotomy.

FIGURE 19-64 Microsagittal saw.

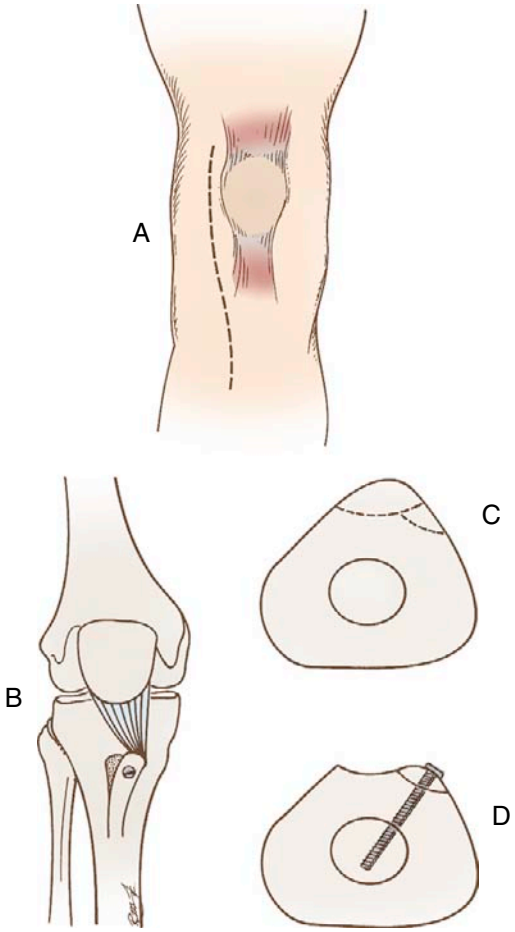

FIGURE 19-65 Elmslie-Trillat procedure as modified by Cox. **A**, Skin incision. **B**, Completed procedure. **C**, Cross section of tibia at level of tibial tuberosity to show bone cuts made to free tuberosity in center and to create new bed for transposed tuberosity to right. **D**, Cross section of tuberosity fixed with screw in new location anteromedially. Screw should not penetrate posterior aspect of cortex.

6. The entire segment, with patellar tendon attached, is displaced medially and manually held in place while moving the knee through a range of motion. Tracking of the patella on the femoral groove is completed by systematically moving the knee medially in increments.
7. A cancellous bone bed is prepared at the point of reattachment of the tibial tuberosity.
8. The surgeon displaces the tuberosity medially and places a 6.5-mm cancellous bone screw.
9. The wound is irrigated and closed, and a long leg cylinder cast is applied. The cast is bivalved immediately.

Repair of Collateral or Cruciate Ligament Tears

The stability of the knee depends on the integrity of the cruciate and collateral ligaments. If any of these supporting structures is damaged, an unstable knee is likely unless properly

repaired. Injuries to these supporting structures are usually not isolated. More frequently, several of the ligaments are injured at the same time. For example, the injury commonly referred to as the "terrible triad" includes a torn anterior cruciate ligament (ACL), torn medial meniscus, and torn medial collateral ligament.

The knee demonstrates grave disability with major ligamentous disruption. The *collateral ligaments* reinforce the knee capsule medially and laterally. They resist varus and valgus stresses on the knee. The *cruciate ligaments* control anterior-posterior stability. Along with the ligaments, the muscle groups stabilize the joint and control movement. Because muscle strength is the first line of defense for the knee, damage is repaired to protect the ligaments. For optimum function of the joint, damaged structures should be reconstructed as close as possible to the original anatomic structures. If the knee is left untreated, osteoarthritis will develop.

Injury to a single cruciate ligament may not significantly compromise knee function. When the injury is combined with other injuries, surgery may be warranted. Surgeons may use various types of ligament grafts to replace or augment the cruciate ligaments. Autografts, allografts, and artificial substitutes are available. Ligament substitutes act as a scaffold, stent, or augmentation of the torn cruciate ligaments. Scaffolds support the soft tissue initially to allow ingrowth of the host tissue. Stents protect the joint from excessive stress while the permanent ligament substitute is healing. Augmentation, as by the patient's own iliotibial band, protects the graft initially after repair of a partial tear. Synthetic ligaments, which are less popular, include carbon-fiber grafts, polyglycolic acid material, Dacron, polyester, and polytetrafluoroethylene.

All synthetic grafts are subject to mechanical failure from weakening with fragmentation and synovitis. These are recommended for salvage procedures only when conventional reconstruction has failed and when other autogenous tissue is unavailable for substitution. Biologic materials from animals, such as bovine xenografts, are also available for ligament substitution, although they are subject to increased risk of infection, synovitis, and rejection. Homogeneous allografts are the substitute of choice for knee reconstruction when no autogenous graft is available from the patient. Disadvantages of homogeneous allografts include long-term weakening, possible rejection, and the possibility of infectious disease transfer.

Autogenous tissues are currently the substitute of choice, with the middle third of the patellar tendon and a block of patella being the most reliable. To minimize necrosis and maintain graft strength, the fat pad with its blood supply may be preserved along with the patellar tendon. Using this graft and other soft tissue autografts, the cruciate-deficient knee can be reconstructed arthroscopically (see Operative Arthroscopy, p. 802). A combination of a torn ACL, medial meniscus, and medial collateral ligament in the past often indicated the need for an open procedure (arthrotomy). With developing technology, many of these procedures can now be done arthroscopically. When reconstructing the cruciate ligament, the surgeon must have the graft biomechanically correct to maintain proper function. Many devices and systems are used to provide placement assistance and gauge appropriate graft tension. These devices are used either separately or in some combination. Though the variations are many, the principles are the same.

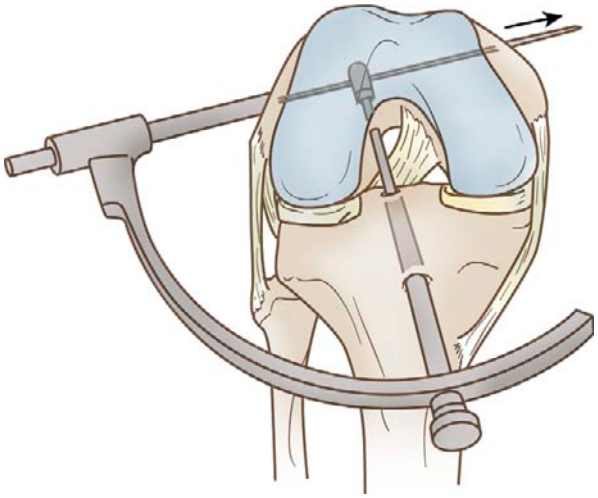

FIGURE 19-66 Reconstruction guide used for ligament repair.

Procedural Considerations. The patient is positioned supine with a tourniquet applied to the upper area of the thigh. The perioperative nurse preps the patient from the upper area of the thigh down to and including the foot. Soft tissue instruments, arthroscopy instruments, ACL reconstruction instruments, Steinmann pins, reconstruction guides (Figure 19-66), and a tension isometer are required. A power drill, microsagittal saw, and burrs are essential. The fixation device of choice should also be available. Meniscal repair instruments should be in the room.

Operative Procedure

ANTERIOR CRUCIATE REPAIR. An examination under anesthesia (EUA) is performed immediately after induction of anesthesia, when the ligaments are completely lax, to evaluate the severity of the injury.

1. The surgeon makes a straight midline or slightly medial incision across the knee.
2. Meniscus tears in the vascular zone (peripheral) are repaired with arthroscopic meniscal repair instruments or cutting needles with a heavy absorbable suture to repair the meniscofemoral and meniscotibial ligaments. If the meniscus is not repairable, the surgeon will perform a partial meniscectomy.
3. Using a power saw and osteotome, the surgeon harvests patellar and tibial bone plugs from the middle third of the patellar tendon.
4. A notchplasty is then performed, debriding and smoothing the lateral intercondylar wall with a burr and curette.
5. The surgeon uses the ligament guide to develop the femoral and tibial osseous tunnels and passes guidewires from the lateral area of the femoral condyle and tibial tubercle into the intercondylar notch at isometric points near the anatomic attachment site of the ACL.
6. The pins are then overdrilled with cannulated drills as close to the size of the patellar tendon graft as possible. The tunnels are smoothed with a curette.
7. Sutures are placed through drill holes at both ends of the graft to pass the graft through the tunnels.
8. The surgeon passes the graft through the femoral and tibial osseous tunnels and fixes it at both ends with interference screws, staples, or polyethylene buttons.

9. The medial collateral ligament and posterior oblique ligament are then individually repaired at their insertion sites with bone screws and spiked washers.
10. Additional extraarticular repair is done if necessary.
11. The surgeon closes the wound over intraarticular and subcutaneous drains, and a locking knee brace or knee immobilizer is applied.

Popliteal (Baker) Cyst Excision

Baker cysts occur in joints, frequently affecting the popliteal fossa. Baker cysts are often painful and can become very large, especially when associated with rheumatoid arthritis. Cysts in the popliteal fossa occur without a precipitating cause in children; in adults they often indicate an intraarticular disease process, such as rheumatoid arthritis, or a torn meniscus.

Procedural Considerations. In contrast to many other operative procedures on the knee, the patient is placed in the prone position. A soft tissue set and a bone set are required.

Operative Procedure

1. The surgeon makes an oblique incision in the popliteal area over the mass and divides the fascia to expose the mass.
2. Using blunt dissection, the surgeon frees the cyst and clamps it at the base of its attachment to the joint capsule.
3. The cyst is divided, and the pedicle is inverted and closed.
4. After the mass has been removed, the surgeon irrigates and closes the wound.

Postoperatively, the knee may be immobilized in extension with a posterior splint.

Fractures of the Tibial Shaft

The location of the tibia results in frequent exposure to injury. Open fractures are more common in the tibia than in other major bones because one third of its surface is subcutaneous. Tibial shaft fractures are difficult to treat. The blood supply to the tibia is more precarious than that of other long bones because of its lack of enclosure by heavy muscle. The presence of hinge joints at the knee and ankle allows no adjustment for rotational deformity after fracture, so special care is required to correct for rotation during reduction and fixation. Rotational deformities are often seen. Delayed union, nonunion, and infection are fairly common complications. Closed reduction and casting provide excellent healing without significant complications, but this treatment can require casting for 6 months or more. Surgical reduction and internal fixation generally allows for earlier weight bearing and a shortened period of casting; however, the rate of complications is higher.

In general, torsional fractures seem to heal better and are more amenable to treatment than transverse fractures. It is theorized that twisting injuries cause less damage to endosteal vessels than that caused by transverse fractures, in which periosteum and endosteal vessels are torn circumferentially. The important prognostic indicators for tibial fractures are as follows: (1) the amount of initial displacement, (2) the degree of comminution, (3) the presence or absence of infection, and (4) the severity of soft tissue injury, excluding infection. As a rule, high-energy fractures, such as those caused by motor vehicle accidents or crushing injury, have a much worse prognosis than low-energy fractures, such as those caused by falls on ice or skiing accidents.

Because intramedullary tibial nailings do not cause a significant increase in infections, external fixation of open tibial shaft fractures is less commonly performed. However, in the presence of gross contamination, severe soft tissue and vascular injury, bone infection, and delayed treatment, external fixation is the treatment of choice. The Ilizarov external fixation device is indicated when bone loss is significant and limb lengthening is required. Plate and screw fixation is another method in which tibial shaft fractures can be treated, although infection and nonunion of tibial shaft fractures are twice as likely with this method. Plate and screw fixation is indicated when intraarticular fragments of the knee and ankle are associated with the injury. Closed intramedullary nailing is the treatment of choice in tibial shaft fractures because infection is less likely to occur and the periosteal blood supply is preserved. Static locking nails (locking both proximal and distal ends of the nail) are indicated for fractures with comminution, bone loss, and lengthening osteotomies. Dynamic locking nails (locking the end closest to the fracture site) are indicated for proximal or distal tibial fractures, nonunions, and malunions. Locking tibial nails include the Russell-Taylor and the Grosse-Kempf tibial nail.

The key to successful treatment of open tibial fractures, as in all open fractures, is meticulous and systematic debridement of all foreign matter and devitalized tissue. The surgeon is careful to minimize devascularization when reducing and fixing the fracture. Systemic antibiotics and those delivered by pulsatile lavage help reduce the chance of infection.

Procedural Considerations. The patient is usually administered a general or regional anesthetic while still on the hospital bed or in the transport vehicle and then transferred to the OR fracture bed. The perioperative nurse assists with positioning the patient supine with the affected hip flexed approximately 45 degrees and the knee at 90 degrees. This positioning provides a horizontal orientation of the tibia. Using a calcaneal traction pin or table foot holder, traction is applied and rotational alignment obtained. After rotational alignment is obtained, a tourniquet is applied and the leg is prepped and draped. Some surgeons prefer to use a standard OR bed, breaking it at the knee. This obviates the need to insert the calcaneal traction pin and allows for easier maneuvering of the tibia during insertion of the locking screws.

A soft tissue set and a large bone set are required, in addition to the intramedullary nail and insertion instruments of choice. A power drill and reamer-driver will be needed to use the necessary intramedullary reamers (Figure 19-67). Fluoroscopy will be needed as well. If open plating is being considered, the plates of choice and the large-fragment screws need to be available as well as bone-reduction clamps.

Operative Procedure

CLOSED OR OPEN TIBIAL INTRAMEDULLARY NAILING (Figure 19-68)

1. If the open technique is required, the fracture site is exposed, reduced, and irrigated as necessary. Focus is then turned toward the nailing procedure.
2. The surgeon makes a 5-cm incision medial to the patellar tendon to just below the tibial tuberosity.
3. Using a curved awl, the surgeon opens the medullary canal just proximal to the tibial tuberosity.
4. A guide rod (3.2 mm) is inserted into the shaft of the tibia down to the fracture site. The proximal fragment is reduced distally and the guide rod advanced into the distal fragment. Rod types include the straight guide rod for simple

FIGURE 19-67 Intramedullary flexible reamer system.

fractures, a curved guide rod for displaced fractures, and a cutting tip for an obstructed canal.

5. The length of the required nail is determined by the guide rod method (see Operative Procedure under Femoral Shaft Fractures: Internal Fixation, pp. 767-768) or by using the nail-length gauge and confirming with fluoroscopy.
6. With cannulated reamers over the guide rods, the surgeon reams the entire tibia 1 mm larger than the nail to be inserted. Inserting a nail too large for the canal can have a detrimental effect.
7. The driver, proximal drill, guide, and hexagonal bolt are assembled onto the tibial nail.
8. The surgeon inserts the nail over the guide rod and, with a mallet, drives it down the proximal fragment to enter the distal fragment, crossing the fracture site. The nail is not fully seated.
9. The guide rod is removed to prevent incarceration, and the surgeon completes the seating of the nail. The proximal tip of the nail should be flush with the tibial entry site.
10. Proximal locking is accomplished with the corresponding drill and tap through the proximal drill guide for 5-mm cortical bone screws.
11. Using the distal targeting device or a freehand technique, the surgeon inserts the distal screws. The 5-mm cortical bone screws are inserted, traversing the tibia through the tibial nail.
12. The surgeon irrigates the wounds. If bone graft is to be used, the surgeon places it around the fracture site and then closes the wound. Dressings are applied, and a cast or splint for immobilization may be applied.

Dynamization, or removal of either the proximal or the distal screws, may take place after 3 months for fractures that are stable but lack callus. Dynamization produces compressive forces at the fracture, thereby promoting osteogenesis.

TIBIAL DYNAMIC COMPRESSION PLATING

1. The surgeon makes a longitudinal incision large enough to accommodate the selected plate lateral to the tibial crest and exposes the fracture site.
2. The periosteum is stripped only enough for application of the plate. Circumferential stripping can diminish blood supply.
3. The surgeon reduces the fracture, places a plate across the fracture site, and secures the plate with bone-holding and plate-holding forceps. The plate may have to be contoured with a handheld or plate-bending press.
4. Using the neutral drill guide, the surgeon drills a 3.2-mm bicortical hole into the plate screw hole close to the fracture site, gauges it, and taps to 4.5 mm. The first bone screw is inserted, ensuring purchase of the screw on the opposite cortex.
5. Using the load drill guide (eccentric), the surgeon drills a second hole next to the fracture line in the opposite fragment. Drill and tap are accomplished as in the previous step. As the screw enters the bone, it will seek the center of the screw hole (the screw is eccentric, and the screw hole is beveled). The fracture site is brought under compression as the screw seats into the hole.
6. The wounds are irrigated. If bone graft is to be used, the surgeon places it around the fracture site and then closes the wound. Dressings are applied, and a cast or splint for immobilization may be applied.

SURGERY OF THE ANKLE AND FOOT

Ankle Fractures

Ankle fractures include fractures of the medial malleolus (tibia), lateral malleolus (fibula), and posterior malleolus (posterior aspect of the articular surface of the distal end of the tibia). They may or may not be associated with ligamentous injury. Ankle fractures can be classified in anatomic lines as unimalleolar, bimalleolar, and trimalleolar. Because medial malleolar and posterior malleolar fractures involve the distal weight-bearing articular surface of the tibia, open reduction and anatomic alignment are necessary. Fixation of the lateral malleolus is also important because it forms the ankle mortise—the socket formed by the distal tibia and fibula into which the body of the talus fits.

Anatomic reduction prevents the occurrence of degenerative joint disease. Displaced fractures are treated with pins, malleolar or bone screws, or plates and screws (Figure 19-69). Bimalleolar fractures can be treated with closed reduction and casting, but approximately 10% of these eventually develop a nonunion. The lateral malleolus (distal end of the fibula) is important for lateral and rotational stability of the joint. Open reduction and internal fixation using Steinmann pins or screws placed obliquely into the tibia is a common technique. Lateral malleolar fractures can be fixed with the cancellous lag technique—overdrilling the first fragment and allowing compression of the fragments. Fracture of the lateral malleolus can also be treated with a Rush rod, inserted through the fragment and into the fibular canal. Compared to the other varieties of fractures, trimalleolar fractures require surgery more frequently. The posterior lip of the articulating surface of the tibia is usually involved and needs to be anatomically reduced to minimize degenerative changes. Cannulated screws can provide efficient reduction of a posterior fragment.

Procedural Considerations. The patient is in the supine position. The affected leg is prepped and draped after application of a pneumatic tourniquet. If the lateral ankle is involved,

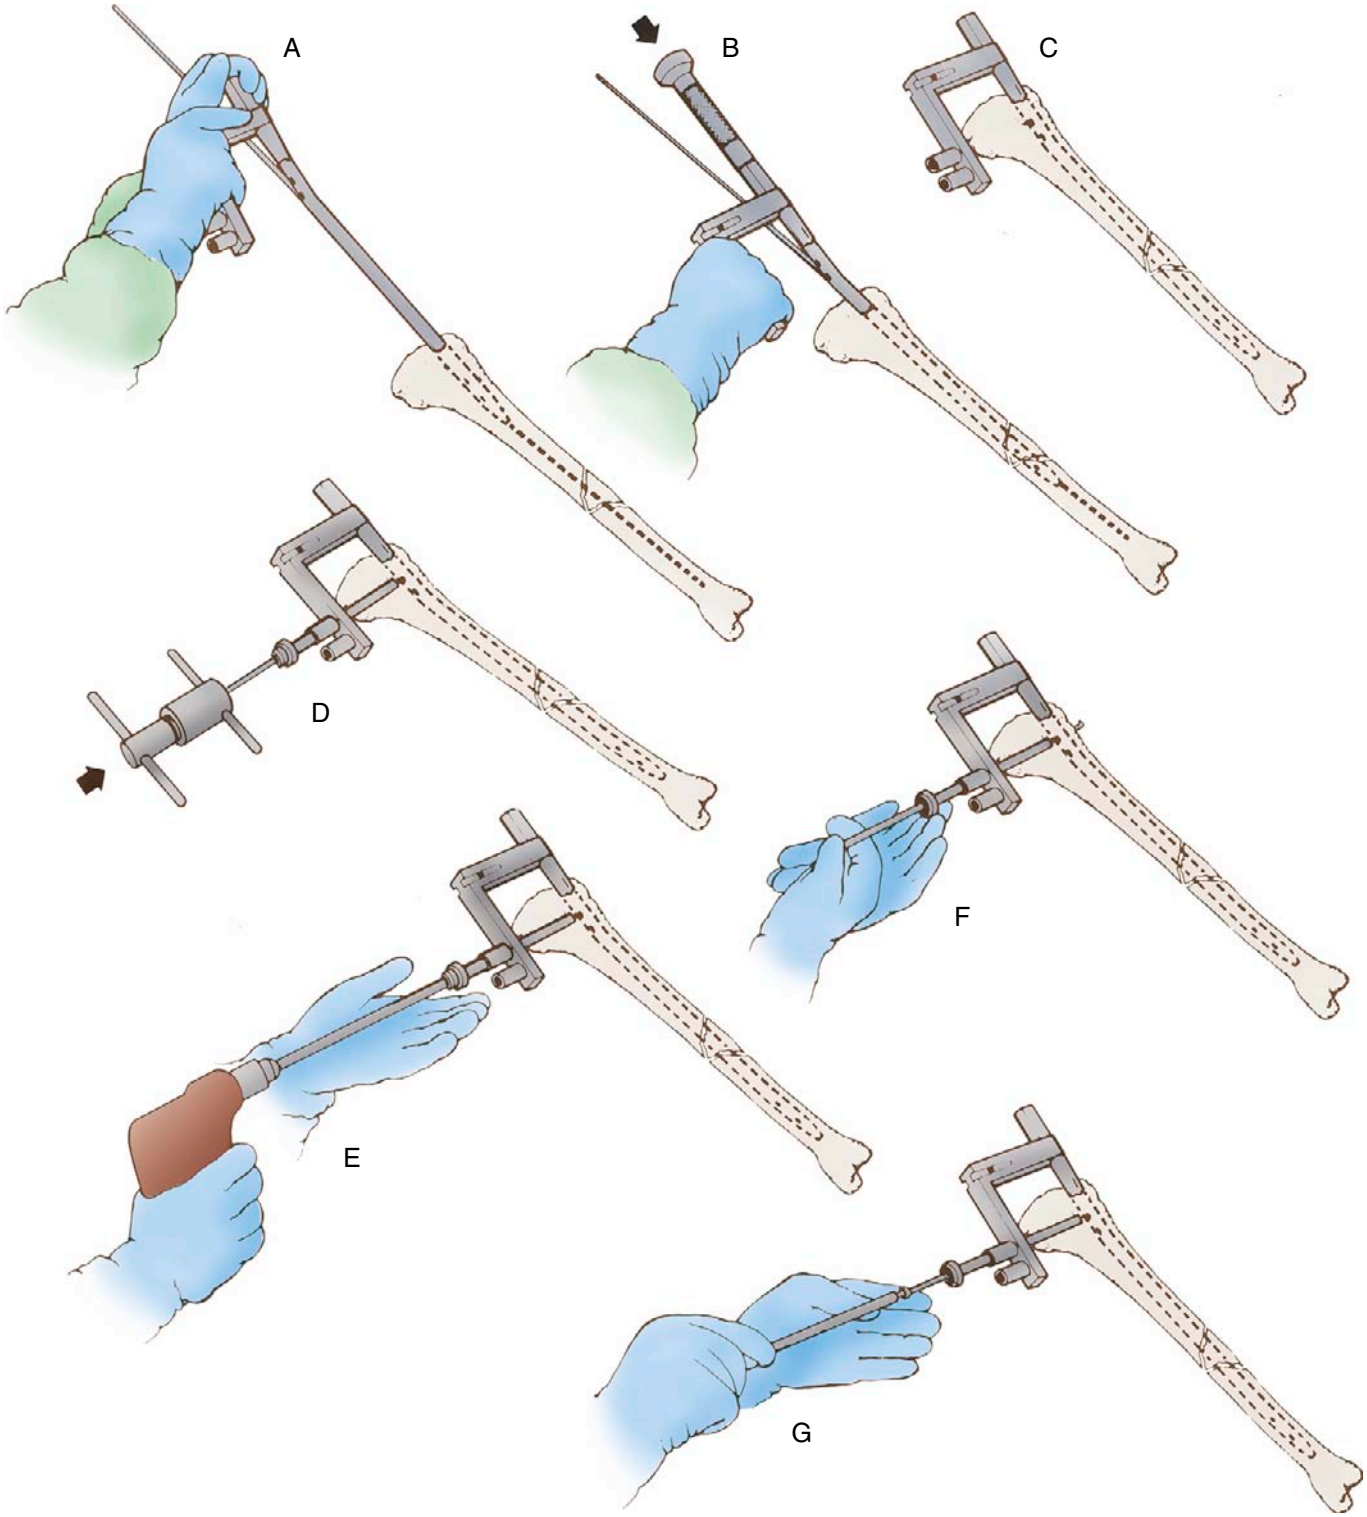

FIGURE 19-68 Tibial intramedullary nailing. **A**, Attachment of nail to proximal drill guide. **B**, Driving nail over guide rod. **C**, Final seating of nail with its tip flush with tibial entry portal. **D**, For proximal interlocking, cortex is dimpled. **E**, Depth measurements are made. **F**, Locking screw length is confirmed. **G**, Self-tapping screw is inserted through drill sleeve.

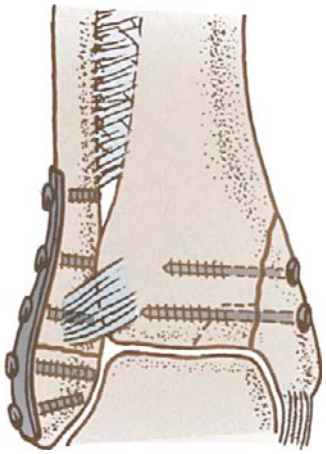

FIGURE 19-69 Plate-screw placement for lateral malleolar fragment repair using one-third tubular plate.

a padded sandbag is placed beneath the hip to internally rotate it. A soft tissue set; a small bone set; a small-fragment set with plates, screws, and pins; a power drill; and bone-reduction clamps are required.

Operative Procedure

TRIMALLEOLAR FRACTURE

1. The surgeon makes medial and lateral incisions across the ankle.
2. The posterior malleolar fracture is exposed and reduced with bone-holding clamps and manipulation.
3. The surgeon inserts two Kirschner wires above the anterior tibial lip to temporarily reduce the fracture. The wires are directed anteriorly to posteriorly, to engage both fragments.
4. A drill hole is made anteriorly to posteriorly through both fragments. After measuring with a depth gauge, a malleolar, small cancellous, or other preferred screw is inserted through the fracture. The wires are removed.
5. The surgeon manipulates the lateral malleolar fracture into reduction.
6. If the fracture is oblique and not comminuted, the surgeon reduces it with one or two lag screws placed anteriorly to posteriorly. If the fracture is transverse, the surgeon inserts a long screw or medullary pin across the fracture line into the canal of the proximal fragment. A small semitubular or one-third tubular plate is applied if the fracture occurs above the syndesmosis.
7. Once the posterior and lateral malleolar fractures have been fixed, the medial malleolar fracture is finally reduced using bone clamps.
8. The reduction is held with two Kirschner wires while a hole is drilled through the medial malleolus into the metaphysis of the tibia.
9. Using a depth gauge, the surgeon determines the screw length. The malleolar screw is inserted across the fracture site and the Kirschner wires are removed.
10. If rotational stability is needed, the surgeon may add an additional smaller screw or compression wiring.
11. Intraoperative radiographs are taken in AP, lateral, and mortise views.
12. The wounds are irrigated and closed, and a short or long leg cast or splint is applied.

Triple Arthrodesis

The talocalcaneal (subtalar), talonavicular, and calcaneocuboid joints must be fused in patients with pronounced inversion or eversion deformities of the foot. Such deformities occur in clubfoot, poliomyelitis, and rheumatoid arthritis. Occasionally this operation is necessary for patients who have pain resulting from degenerative or traumatic arthritis, such as that occurring after intraarticular fractures of the calcaneus. Triple arthrodesis limits motion of the foot and ankle to plantar flexion and dorsiflexion.

Procedural Considerations. The perioperative nurse assists with positioning the patient in the supine position and preps the patient from the midcalf down to and including the foot. The perioperative nurse should consult with the surgeon before the procedure to determine if bone grafting is anticipated so the patient's iliac crest area can be prepped.

A soft tissue set; a small bone set; a power saw, drill, or rasp; a bone graft set; and the AO compression plates and screws or bone staples to hold the fusion are required. Kirschner wires can be used to provide temporary fixation. A small lamina spreader is helpful in providing exposure.

Operative Procedure

1. An anterior or anterolateral approach is used.
2. The surgeon exposes the subtalar and calcaneocuboid joints and the lateral portion of the talonavicular joint.
3. The surgeon incises the capsules of the talonavicular, calcaneocuboid, and subtalar joints circumferentially to obtain as much mobility as possible. If this release allows the foot to be placed into a normal position, removal of large bony wedges is not required.
4. Using an osteotome, power saw, or power rasp, the surgeon removes the articular surfaces of the calcaneocuboid joint, the subtalar joint, and the talonavicular joint. The small lamina spreader is used to expose these surfaces. Care is taken to save all bone removed for later use in the fusion.
5. The removed bone is cut into small pieces to be used for bone grafting. If the quantity is insufficient, the surgeon will harvest additional bone from the anterior ilium. Most of the bone is placed around the talonavicular joint and in the depth of the sinus tarsi.
6. Smooth Steinmann pins, staples, or screws are used for internal fixation.
7. The wound is closed over a suction drain. A short leg cast or splint is applied.

Bunionectomy

A bunion (hallux valgus) is a soft tissue or bony mass at the medial side of the first metatarsal head. It is associated with a valgus deformity of the great toe (Figure 19-70). A bunion is caused by a basic structural defect of the foot, which predisposes to the development of this deformity. Ill-fitting shoes accentuate the situation and speed the development of bunions. Bunions are more common in women because of shoe styles, including high heels and pointed toes. Other factors that may contribute to this deformity are heredity, flatfeet, foot pronation, longer first toe, muscle imbalance, and inflammatory disturbances of the feet.

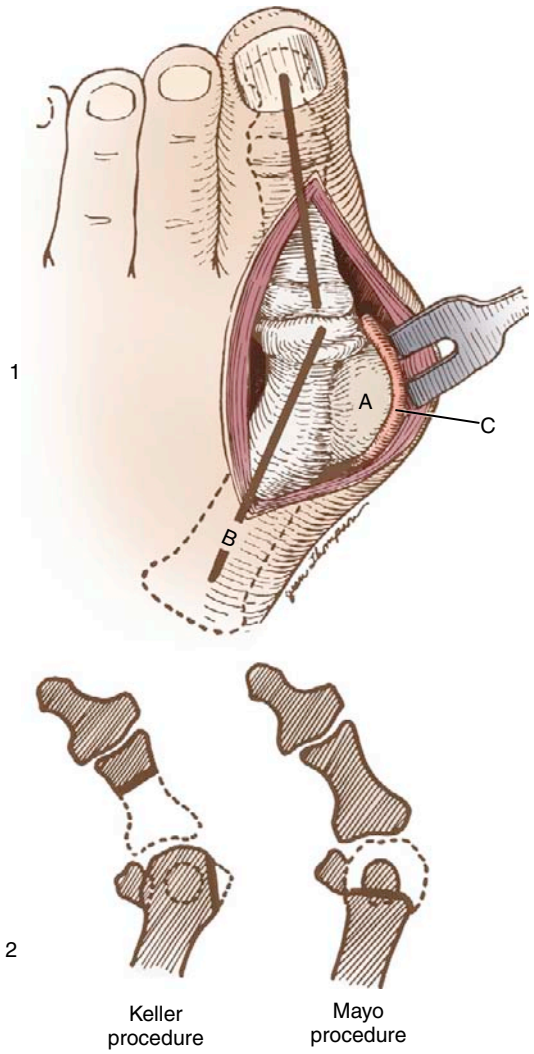

FIGURE 19-70 Bunionectomy. *1,* Bunion. *A,* Exostosis of metatarsal head; *B,* hallux valgus deformity; *C,* overlying bursa. *2,* Operations for hallux valgus.

Symptoms include pain on the dorsomedial aspect of the first metatarsal head or directly over the medial exostosis, swelling of the big toe, painful plantar callus, and plantar keratosis. Discomfort to the entire foot occurs as the forefoot becomes more fatigued and symptomatic, with pain radiating to the leg and knee.

Hallux valgus is treated with a variety of surgical procedures (Figure 19-71). All these procedures remove the exostosis and attempt to realign the great toe by removal of bone, transfer of tendons, osteotomy of the first metatarsal shaft, or appropriate imbrication of soft tissue.

The goals of surgery are correction of the deformity (cosmesis), resection of the abnormal bony components (reconstruction), and restoration of normal or near-normal range of motion (function).

Procedural Considerations. The anesthesia provider administers a general or regional anesthetic, and a tourniquet is applied. The foot and leg are prepped and then draped using a sterile stockinette.

A soft tissue set, a small bone set, Kirschner wires, a power wire driver, and a microsagittal saw are required.

Operative Procedure

KELLER PROCEDURE

1. The surgeon makes a midline, straight, medial incision beginning at the neck of the proximal phalanx and extended proximally.
2. Using blunt and sharp dissection, the surgeon exposes the joint capsule. A flap incision is made to expose the underlying hypertrophic bone found at the dorsomedial aspect of the first metatarsal head.
3. All soft tissue attachments are removed from the base of the proximal phalanx.
4. The surgeon uses a power-oscillating saw to resect the proximal third of the proximal phalanx.
5. Proper alignment of the toe is maintained as one or two 0.062-inch Kirschner wires are placed in the center of the medullary canal of the phalanx and then driven into the metatarsal head, neck, and shaft.
6. The surgeon irrigates and closes the wound. A bandage is applied to maintain the toe in the correct position.
7. Postoperative convalescence requires a minimum of 6 weeks.

Correction of Hammer Toe Deformity

The term *hammer toe* is most often used to describe an abnormal flexion posture of the proximal interphalangeal joint of one of the four lesser toes. This deformity causes painful calluses to develop on the dorsal joints of the four lesser toes, since the cocked-up digits rub against the shoes. Incising the long extensor tendon to the toes and fusing the proximal interphalangeal joint treat the deformities. A smooth Kirschner wire is frequently used to stabilize the fusion and position the toe properly during the postoperative period.

Procedural Considerations. The patient is positioned supine. An ankle tourniquet is applied. The foot is prepped and draped. A soft tissue set, a small bone set, Kirschner wires, and a power wire driver are required.

Operative Procedure

1. The surgeon makes an elliptic incision over the proximal interphalangeal joint measuring 5 to 6 mm wide with a 2-mm or 3-mm lateral extension on either side.
2. The capsular tissue of the distal third of the proximal phalanx and proximal interphalangeal joint is entered to expose the defect completely.
3. Using a small rongeur or microsaw, the surgeon resects the distal third portion of the proximal phalanx. Once the capital fragment is excised, the surgeon debrides the remaining portion of the distal proximal phalanx with a rongeur or rasp.
4. Digital alignment can be maintained with small Kirschner wires.
5. The surgeon irrigates and closes the wounds. A sterile dressing and orthopedic shoe are applied for postoperative recovery.

Metatarsal Fractures

Metatarsal fractures occur in various sites. These fractures have a reduced healing potential because metatarsals consist mainly of cortical bone, which lacks vascularity. Treatment is

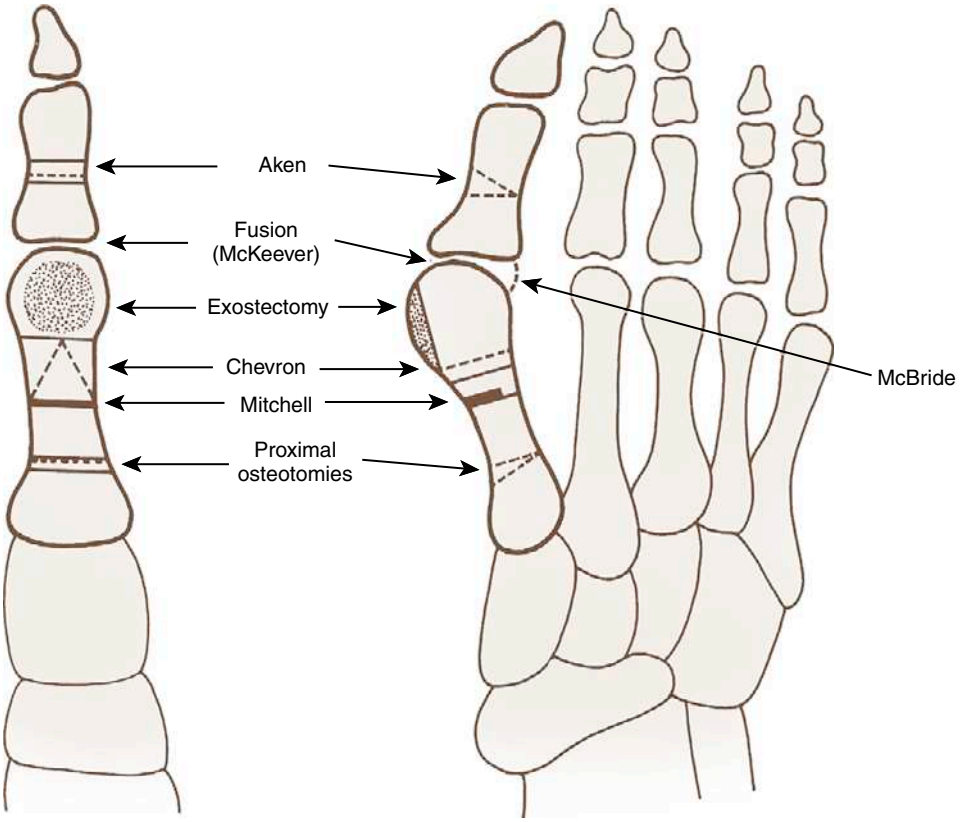

FIGURE 19-71 Types of bunionectomies.

determined by the extent of the fracture—the greater the displacement, the greater the need for reduction. In general, transverse and short, oblique, midshaft fractures of the metatarsals are internally fixed because of their instability and displacement. Pins, wires, screws, and plates are used for internal fixation of metatarsal fractures. The simplest method is Kirschner wire fixation.

Procedural Considerations. The patient is placed in the supine position, a tourniquet is applied, and the foot is prepped and draped. A soft tissue set, a small bone set, Kirschner wires, and a power wire driver are required.

Operative Procedure

1. The surgeon makes a small incision over the fracture and identifies and retracts the distal fragment.
2. A smooth Kirschner wire is driven distally, exiting the skin.
3. The surgeon uses a wire driver to drive the wire proximally into the canal of the proximal fragment.
4. If the fracture is more complex or comminuted, the surgeon may cross two Kirschner wires through the fracture to transfix the fracture site.
5. The incision is closed, and a postoperative shoe is applied.

Metatarsal Head Resection

Patients with rheumatoid arthritis frequently have dorsally dislocated toes and prominent and painful metatarsal heads on the plantar surfaces of their feet. Excision of all the metatarsal heads commonly relieves the pain and corrects an associated bunion deformity.

Procedural Considerations. The patient is placed in the supine position, a tourniquet is applied, and the foot is prepped and draped. A soft tissue set, a small bone set, Kirschner wires, a power wire driver, and a power microsagittal saw are required.

Operative Procedure

CLAYTON TECHNIQUE

1. A transverse plantar incision is made, and tissue is dissected to the metatarsal heads.
2. Using a microsagittal saw the surgeon removes the metatarsal heads and half the proximal phalanges.
3. The surgeon transects the extensor tendons; they are not repaired.
4. The skin is closed, and a dressing and postoperative shoe are applied.

PELVIC FRACTURE AND DISRUPTION

Patients with multiple trauma often present with multiple fractures that can be life-threatening. Complications of pelvic fractures include injury not only to major vessels and nerves but also to major visceral organs, such as the intestines, bladder, and urethra. Factors influencing mortality include associated visceral injury, hemorrhage, and head injury.

Pelvic fracture classification is divided into three main groups (Table 19-1). *Type A fractures* are stable, without ring involvement (A1) or minimally displaced fractures of the ring (A2). *Type B fractures* are rotationally unstable and vertically stable and are also subclassified: B1 is an open book fracture, B2 has ipsilateral compression, and B3 has contralateral compression.

TABLE 19-1

Classification of Pelvic Injuries

Type A	Stable
	A1—Fractures of pelvis not involving ring
	A2—Stable, minimally displaced fractures of ring
Type B	Rotationally unstable, vertically stable
	B1—Open book
	B2—Lateral compression: ipsilateral
	B3—Lateral compression: contralateral (bucket handle)
Type C	Rotationally and vertically unstable
	C1—Unilateral
	C2—Bilateral
	C3—Associated with an acetabular fracture

Type C fractures are both rotationally and vertically unstable: C1 is unilateral, C2 is bilateral, and C3 is associated with the acetabulum. Radiographic films, computed tomography (CT) scan, and magnetic resonance imaging (MRI) all prove useful in determining the type and appropriate treatment for pelvic trauma.

Treatment is based on classification and may include closed manipulation and reduction or internal and external fixation. Internal and external fixation can be used concurrently in the treatment of some pelvic fractures.

Type A fractures are stable and can be treated nonoperatively. Type B1 fractures may be treated with external fixation or anterior plate fixation. Type C fractures usually require open procedures to fix the fractures with plates and screws, and reduction of sacral disruptions with transiliac rods or screws. Type C fractures may be treated with external fixation when the patient is hemodynamically unstable and a quicker, simpler procedure is prudent.

External fixation is the most widely recommended treatment for type B fractures of the pelvis. A technique similar to that of external fixation of extremity fractures is done in the OR with anesthesia and sterile conditions. If external fixation is to be used, the earlier it is attempted the greater the chance of success.

Procedural Considerations

This procedure is often done during other emergent and trauma resuscitative efforts. The patient's entire pelvic area is prepped and draped. A pelvic skeleton in the room may help the team visualize maneuvers and pin placement to be attempted to complete the reduction. A soft tissue set is needed in addition to the external fixator of choice and the instruments for its insertion, including a power drill.

Operative Procedure

AO External Fixation

1. The surgeon reduces the pelvic disruption manually and confirms it radiographically. It may be impossible to completely reduce the disruption without skeletal traction using a distal femoral pin.
2. Kirschner wires are inserted percutaneously to determine the position of the pin placement, taking into consideration the inward and downward crest slope.
3. The surgeon places parallel rows of pins into the anterior iliac crest area by drilling the outer cortex and placing 5-mm half-pins medially and distally. The pins should enter cancellous bone between the outer and inner tables of ilium.
4. Three universal frames are placed over the pins as close to the skin as possible for maximum rigidity.
5. Optimal reduction of the fracture is visualized using radiography. The surgeon applies the crossbar, and compression and distraction maneuvers are used to maintain the reduction.
6. The surgeon removes the crossbar and applies the connecting rods with couplers.
7. After the couplers are in place, the surgeon reattaches the crossbar and tightens the joints of the frame.
8. The pin sites of tented skin are released. The wounds are dressed with iodine ointment and gauze.
9. The frames are left in place generally for 8 to 12 weeks.

TOTAL JOINT ARTHROPLASTY

Arthroplasty of the joints is performed to restore motion of the joint and function to the muscles and ligaments. It is indicated in individuals with a painful, disabling arthritic joint that is no longer responsive to conservative therapy. In the past, the procedure was reserved for those with a less active lifestyle, and surgeons treated patients with reconstructive procedures such as arthrodesis or osteotomy because of the unknown life expectancy of the materials used in the manufacturing of the prostheses. Technological advances in the prostheses used today allow the younger patient, or the very active older person, to undergo joint replacement. Many total hip and knee replacements are done each year. Improvements in implant design, materials, and fixation techniques are ongoing, as is research on enhancing soft and hard tissue healing (Kolisek et al, 2007).

The classic combination of metal on polyethylene is the mainstay of joint implants. Metals used in hip and knee implants include *cobalt-chromium* (weight-bearing femoral head) and *titanium* (stems of hips and tibial components). The acetabulum and tibial articulating surfaces continue to be substituted with *ultra-high-molecular-weight polyethylene* (UHMWPE), which provides superior wear characteristics. Other designs have emerged in total hip arthroplasty, including metal on metal and the use of ceramic femoral heads.

At one time it was thought that bone cement was the weak link in the longevity of a joint implant because of a relatively high rate of loosening of cement-fixed implants, especially in younger, more active patients. In response to this belief, alternative methods of fixation have been developed. One method involves the application of a precoat of PMMA to the femoral stem to enhance bonding of the prosthesis to the cement mantle. Another method involves the attachment of a porous metal surface to parts of the femoral stem and the entire outer surface of the acetabular component. Most of the porous surfaces are composed of multiple layers sintered in place, creating interconnecting, open pores among the various particles. This allows for the ingrowth of bone to occur, ultimately anchoring the prosthesis in place. "Porous coating" was an attempt to eradicate what was termed *cement disease*—a lysis of bone around the prosthesis causing early loosening. It is now believed that this condition is caused by "wear debris"—particulate matter being shed from metal-to-polyethylene interfaces—and not necessarily from the effects of PMMA.

Bone cement, or PMMA, is an area that has received considerable attention in the search for optimal bone-to-implant fixation. Cement seems to exhibit various degrees of porosity depending on mixing methods and cement pressurization

within the canal. Bone cement must prevent motion at the implant interface. Porosity can lead to fatigue and fracture, which ultimately can lead to implant loosening. Local tissue effects of PMMA may include (1) tissue protein coagulation caused by polymerization, (2) bone necrosis caused by occlusion of nutrient metaphyseal arteries, and (3) cytotoxic and lipotoxic effects of nonpolymerized monomer.

Despite the high rate of success of total joint implantation over the years, there are numerous potential complications. They are generally divided into medical complications, mechanical complications, and infections. Medical complications include, but are not limited to, cardiac dysrhythmias, myocardial infarction, hemorrhage, and pulmonary emboli. Mechanical complications are implant breakage, loosening, and wear. Infection in the patient with a total joint implant is a catastrophic complication that usually requires additional surgery and prolonged hospitalization.

Most surgeons recommend the routine use of antibiotics in primary and revision joint arthroplasty. Antibiotic coverage is initiated preoperatively, continued during lengthy procedures, and administered for 24 to 48 hours postoperatively. Pulsatile lavage systems are used to keep tissues moist, remove debris, and dilute bacteria that may be present. Additional antibiotics are often added to the physiologic saline solutions used for irrigation and to PMMA; however, data do not conclusively support or dispute this practice.

Total Hip Arthroplasty

Total hip arthroplasty is a common orthopedic procedure performed on patients with hip pain caused by degenerative joint disease, rheumatoid arthritis, or avascular necrosis. A total hip replacement can be cemented, noncemented, or hybrid. Hybrids involve cementing one component, usually the femoral stem, and then inserting a metal-backed, porous-coated acetabular component in a press-fit state. Hybrid arthroplasty is a controversial procedure for two reasons. The first relates to research that demonstrates that wear debris is increased with the larger metal-to-polyethylene interface present in the metal-backed, porous-coated acetabular component. The second relates to cost. The metal-backed, porous-coated acetabular component is significantly more expensive than the all-polyethylene component. Consequently, patient selection is very important in determining which type of component is best.

The primary function of the femoral component is the replacement of the femoral head and femoral neck after resection. The femoral head should ultimately sit where it reproduces the center of rotation of the hip. The neck length is variable and is built into several different heights of femoral heads that are eventually seated onto the Morse taper of the femoral stem. The version (implant rotation within the canal) is very important; too much anteversion or retroversion leaves the hip prone to dislocation. The normal position of the proximal femur is in 10 to 15 degrees of anteversion.

Femoral stems can be collarless or have collars that sit down on the resected femur. Collars will produce forces on the bone and may be desired in cases of osteoporotic bone, where bone genesis may be diminished because of the disease process.

Acetabular cups have also presented challenges in trying to maintain fixation within the socket. When cement techniques of the 1970s were used, femoral loosening plateaued about 5 years after surgery. Wear properties of the UHMWPE are also a concern. For this and other reasons associated with component failure, the idea of modularity was developed. Modular components, such as a polyethylene cup that snaps into a metal acetabular shell, greatly decrease the amount of surgery needed in the case of some revisions. In the case of excessive cup wear or a short femoral neck, surgery is minimized with the ability to exchange the modular components without removing the implants fixed to the bone.

Acetabular cups come with a textured back for cement fixation and may have standoff pegs to allow an appropriate cement mantle. Noncemented cups usually are porous-coated and may have screw holes present to aid in anchoring the less-than-stable cup. The presence of screw holes in an acetabular component is another controversial issue. Some believe that more wear debris is created with micromotion between the screw head and the cup as well as between the uneven surface of the screw and the polyethylene liner.

Prostheses are available for every patient's needs. Modular hip systems allow the orthopedic surgeon to choose from an array of interchangeable components that have been developed. Various femoral head sizes (22, 26, 28, and 32 mm) are available to maintain proper center of rotation. Acetabular cups may be snap fit, low profile, or deep profile, which adds additional thickness to the medial wall, where bone loss may be significant.

With modular systems, unipolar or bipolar cups are also an option when the acetabular articular surface is relatively normal. The unipolar and bipolar cups with appropriate head sizes are designed to fit on various modular system stems.

Custom prostheses or revision and extralong stems are available when bone loss is significant. These implants are employed in cases of revision where fixation is needed farther down the femoral canal or in oncologic cases where tumor and corresponding bone have been resected.

Young, active individuals with strong, healthy bones are ideal candidates for noncemented total hip replacement arthroplasties. Elderly patients with osteoporosis and poor-quality bone are usually candidates for cemented components because their bones may lack the compressive strength to support weight-bearing forces (Boughton, 2009a) (Research Highlight).

Hip Reconstruction (Cemented). Numerous implants are available for total hip implantation. Many of the implants can be used for the same surgical indications, and one implant may not function any better than another, provided that all other conditions and techniques are the same. The instruments required to implant any one device cannot be used for another. During the preoperative verification process and time-out the perioperative nurse and surgical technologist collaborate to ensure that all the instrumentation is available.

PMMA adheres to the polyethylene and metal but not to the bone. It fills the cavity and interstices of the bone and forms a mechanical bond. PMMA is manufactured as a liquid monomer and a powder, and is mixed under sterile conditions by the surgical technologist in the OR at the time of implantation. It usually takes 10 to 12 minutes to harden. Because of the potentially harmful effects of PMMA fumes to the nasal epithelium, an exhaust system should be used during the mixing process.

PROCEDURAL CONSIDERATIONS. The patient is positioned in the lateral decubitus position and secured in place with anterior and posterior bolsters. This position is essential

RESEARCH HIGHLIGHT

Increased Risk Factor for Death After Total Hip Arthroplasty (THA)

Patients undergoing a total hip arthroplasty for an acute hip fracture experience an increase in mortality. Other factors, including patient co-morbidities, general health, and delays in surgery, also impact mortality in the 30-day postoperative period. This retrospective study examined 3232 primary THAs, performed from May 1993 through May 2006. Of those surgeries, 75% were elective; the remaining 25% occurred after sustaining a hip fracture. Groups were matched for patient characteristics, at a ratio of four living patients to one deceased patient. The overall mortality for the 13-year period was 0.34%. Those patients who underwent THA after fracture had a higher mortality (1.15%) compared to patients who had an elective THA (0.08%). An anesthesia score of III to IV (ASA classification; see Chapter 4) increased mortality 13 times and cardiovascular disease elevated the risk of dying 8 times. A delay in surgery of 3 or more days also increased the risk for mortality. The use of aggressive thromboprophylaxis did not influence mortality. The most important reasons for death were cardiac events and pulmonary embolism.

Modified from Comba FM: *Certain factors increase risk for death after total hip arthroplasty, AAOS,* 2009, available at www.medscape.com/viewarticle/588980. Accessed April 22, 2009.

FIGURE 19-72 Pulse lavage used for pressurized irrigation when one is irrigating surgical wounds, debriding bone during a joint replacement, debriding open fractures or physically induced wounds, irrigating soft tissue injuries, or irrigating contaminated wounds.

to ensure correct anatomic placement of the acetabular cup. The perioperative nurse verifies that the patient's bony prominences are adequately padded. The skin prep is completed from the level of the umbilicus down to and including the foot; then the patient is draped. The radiographs are overlaid with the implant templates.

A soft tissue set and a large bone set are required. In addition, the total hip implants and corresponding instrumentation, acetabular reamers, hip retractor set, power reamer-driver and saw, and pulse lavage with a 3-L bag of normal saline solution (Figure 19-72) will be needed. If PMMA is used, femoral canal suction wicks, a cement restrictor and its inserter, and PMMA including its mixing supplies will be needed (Figure 19-73). If a trochanteric osteotomy is

FIGURE 19-73 Polymethylmethacrylate (PMMA) and supplies for mixing and delivery in the canal.

performed, the equipment of choice for its reattachment will be required.

Revision of total hip arthroplasties requires the same instrumentation as for cemented total hip reconstruction in addition to cement removal instrumentation, fluoroscopy, and the revision implants and their corresponding instrumentation.

OPERATIVE PROCEDURE

Cemented Modular Hip System, Posterior Approach

1. The surgeon makes an incision 2.5 cm distal and lateral to the anterosuperior iliac spine and curves the incision distally and posteriorly over the lateral aspect of the greater trochanter and lateral surface of the femoral shaft to 5 cm distal to the base of the trochanter.
2. The surgeon divides the tensor fasciae latae over the greater trochanter, and carries this distally to the extent of the incision. Dissection is carried proximally between the interval of the gluteus medius and the tensor fasciae latae muscles.
3. The anterior fibers of the gluteus medius tendon are tagged and detached from the trochanter. The surgeon incises the capsule longitudinally along the anterosuperior surface of the femoral neck. In the distal part of the incision, the origin of the vastus lateralis may be either reflected distally or split longitudinally to expose the base of the trochanter and proximal part of the femoral shaft.
4. After completing the capsulotomy, the surgeon dislocates the hip. Adduction and external rotation will present the femoral head anteriorly into the surgical site.
5. The surgeon places the femoral osteotomy guide over the lateral femur to identify the point on the femoral neck where the osteotomy should be made. Some femoral osteotomy guides also gauge the neck length required. The surgeon marks the level and uses an oscillating or a reciprocating saw to complete the femoral osteotomy.
6. The femur is retracted to expose the acetabulum, allow completion of the capsulotomy, and expose the bony rim of the entire acetabulum.

7. The surgeon inspects the acetabulum, removes any osteophytes, and reams the articular cartilage with bone-conserving reamers in a circumferential manner. The smallest reamer is progressed in a graduated method 1 or 2 mm at a time until the cartilage is reamed down to expose osteochondral bone. A hemispheric shape and bleeding bone should result.
8. Remaining soft tissue is curetted from the floor of the acetabulum, and cystic areas are filled with cancellous bone from the femoral canal and packed with a bone tamp. Any other bone grafting of major bony defects is accomplished using the fixation method of choice (bone screws).
9. Several 6-mm holes are drilled into the floor of the acetabulum, aimed into the ilium, ischium, and pubis. Holes are undercut using curettes. These prepared holes act as anchoring areas for the bone cement.
10. Trial acetabular components are placed on the positioning device and positioned in the socket. The surgeon assesses the cup for size, position within the socket, and the relationship of the component compared with the bony margins of the acetabulum.
11. The prepared acetabular socket is lavaged, dried with wicks, and filled with cement that has been injected and pressurized with an injection gun. The surgeon positions the acetabular shell component and holds it motionless until the cement polymerizes. Extruded cement is trimmed from around the edge of the component. A polyethylene insert is later snapped into the shell.
12. A sponge is placed in the acetabulum to protect the component from bone debris and subsequent cement as attention is turned to the femur.
13. Dropping the patient's foot toward the floor and internally rotating and pushing the leg proximally expose the proximal femur. The surgeon accesses the femoral canal using a box osteotome or trochanteric reamer followed by the T-handle canal reamer.
14. Beginning with the smallest broach, the surgeon alternately impacts and extracts the proximal femoral canal. Progressively larger broaches are used to crush and remove cancellous bone until cortical bone is reached. A broach that is not advancing should not be used as this could result in shattering the femur.
15. With the final broach seated to the desired depth in the canal, the neck is prepared with a calcar reamer. The broach remains while the surgeon places the femoral trial component along with the various-size head, neck, and offset trial components.
16. The trial component is removed, and the canal is lavaged and brushed to accommodate the PMMA.
17. A cement restrictor is inserted into the femoral canal. The femoral components are passed and assembled on the back table.
18. The cement is injected and pressurized within the femoral canal.
19. The femoral component, with the proximal and distal centralizers, is inserted into the canal with or without the femoral head.
20. The surgeon positions the appropriate size of femoral head onto the stem, and reduction is carried out. The joint is taken through a range of motion to check for positioning, stability, and the limit to which dislocation occurs.
21. Depending on the surgeon and the surgical approach, the greater trochanter may or may not have been removed for exposure of the hip joint. If removed, it is reattached with 18-gauge wire or a cable grip system.
22. The surgeon closes the wound in layers over suction drains. The skin is closed with staples, and a sterile dressing is applied to provide compression to the wound.
23. An abduction pillow or splint is placed between the patient's legs postoperatively if stability of the joint is of concern.

Hip Reconstruction (Noncemented). Fixation with a noncemented prosthesis is initially accomplished by a tight fit and intimate contact of the implants within bone of substantial strength. As with all prosthetic designs, it is essential to fill the medullary canal and wedge the prosthesis in as tightly as possible to provide temporary press-fit fixation. These prostheses closely follow normal anatomic shape. Only the instrumentation corresponding to the implant should be used. Precise machining of the femoral canal must be ensured. Acetabular components are usually press-fitted, but many systems provide holes for screw fixation if stability of the prosthesis is in doubt. Sufficient time is then allowed for the cancellous bone to heal by growing into the porous portions of the prosthesis.

The healing process requires the same amount of time as a long bone cortical fracture (approximately 3 months). The patient must be cautious after the procedure and protect the operative hip from excessive compression, rotation, and shear stresses.

PROCEDURAL CONSIDERATIONS. The position and incision are the same as those used for the cemented total hip replacement. The radiographs and implant templates are placed on the view box.

OPERATIVE PROCEDURE

Noncemented Anatomic Medullary Locking (AML) Hip System (Figure 19-74)

1. After the incision is made, the surgeon enters the capsule and dislocates the femoral head.
2. A pilot hole is established in the trochanteric fossa as an intramedullary reference point.
3. The surgeon uses progressively sized fully fluted rigid reamers to ream the intramedullary canal.
4. A femoral neck osteotomy is achieved by positioning an osteotomy template along the axis of the femur and cutting at the level of the collar.
5. The surgeon clears the soft tissue from the acetabulum and reams it with hemispheric reamers.
6. Trial acetabular sizers are placed to determine the correct position and size of the prosthetic component.
7. A hollow osteotome is used in the femoral canal to connect the pilot hole to the osteotomy site.
8. Femoral broaches are then inserted to enlarge the intramedullary space for trial insertion.
9. The surgeon may use a power calcar planer placed over the trunnion of the broach to contour the femoral neck.
10. A trial head and neck component is positioned onto the fitted broach, and a trial reduction is carried out.
11. If trial reduction is satisfactory, the surgeon removes all the trial components.
12. The appropriate size of acetabular component is inserted into the acetabulum, and a polyethylene insert is locked into place.

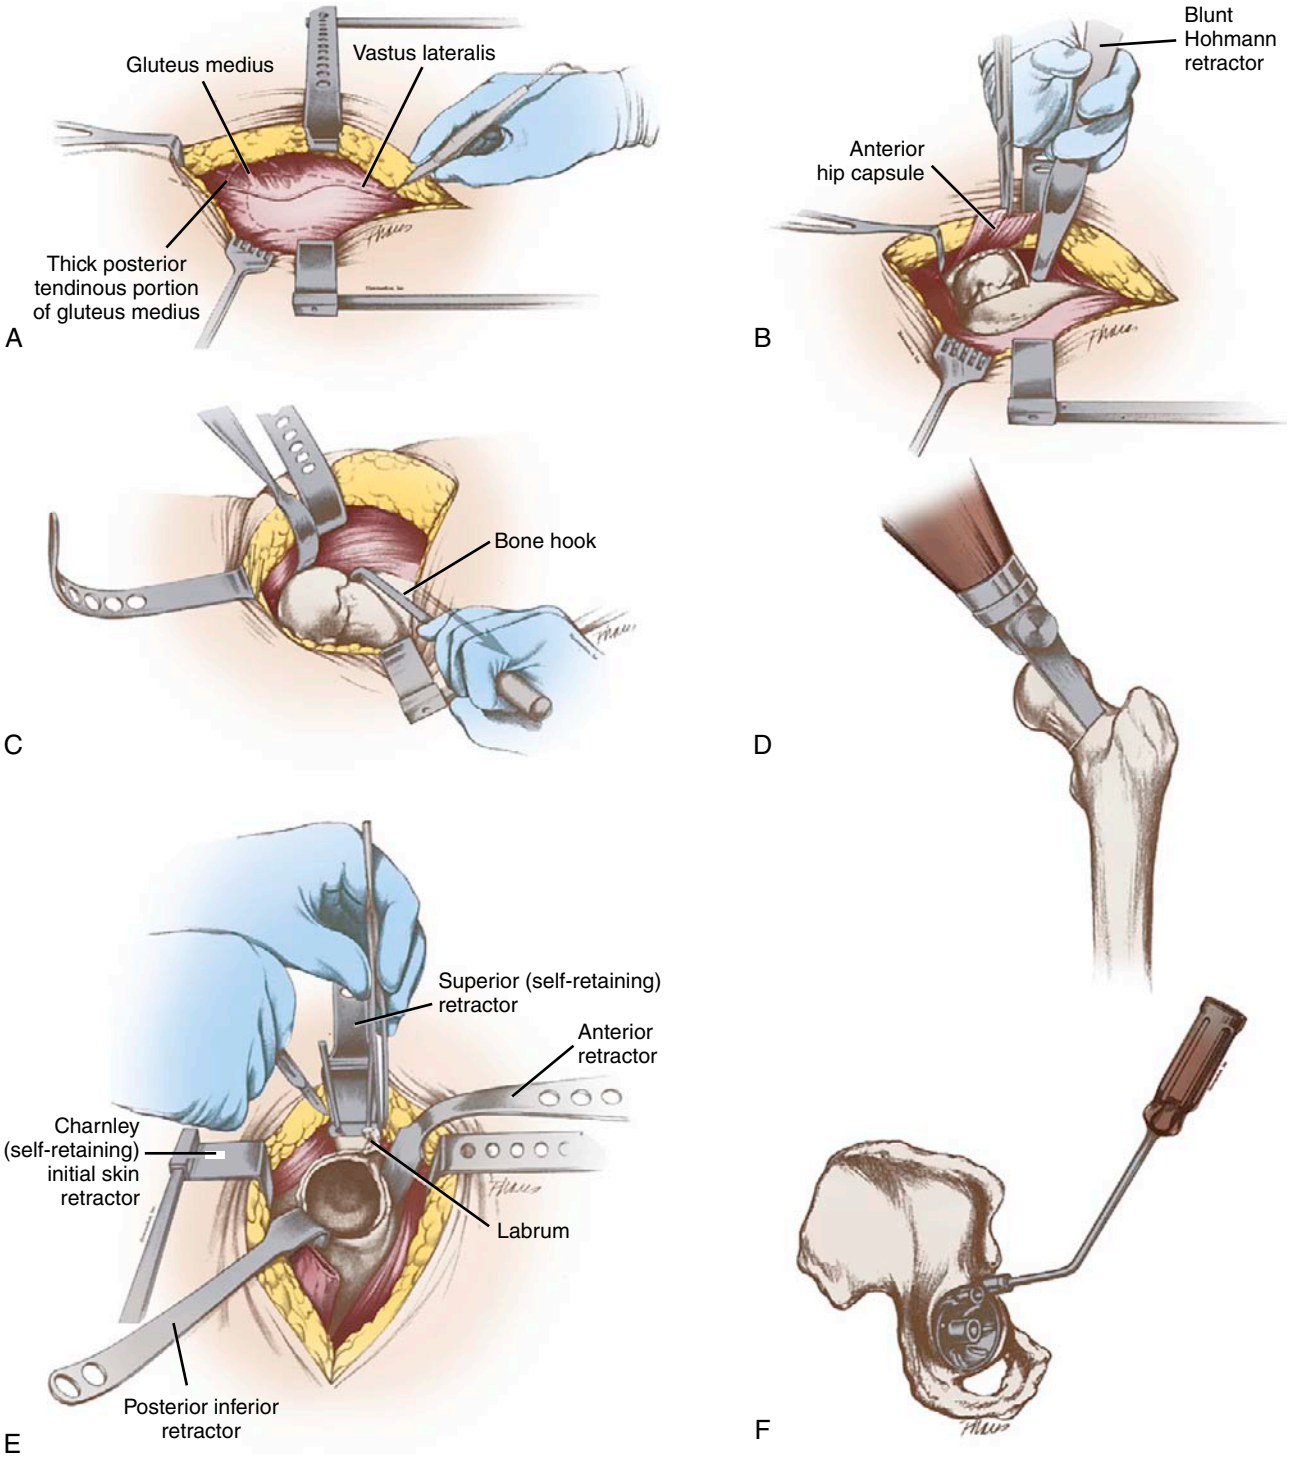

FIGURE 19-74 Noncemented hip reconstruction. **A**, After the incision, the Charnley retractor is placed, the fascia latae is incised, and the gluteus medius is detached. **B**, An anterior capsulotomy is completed. **C**, The hip is flexed, adducted, and externally rotated to dislocate from the acetabulum. **D**, The femoral neck is cut by use of an oscillating saw blade. **E**, The rim of the acetabulum is debrided of labrum, redundant capsule, and marginal osteophytes. **F**, The acetabulum is reamed; after reaming, the appropriate drill guide is inserted into the acetabulum.

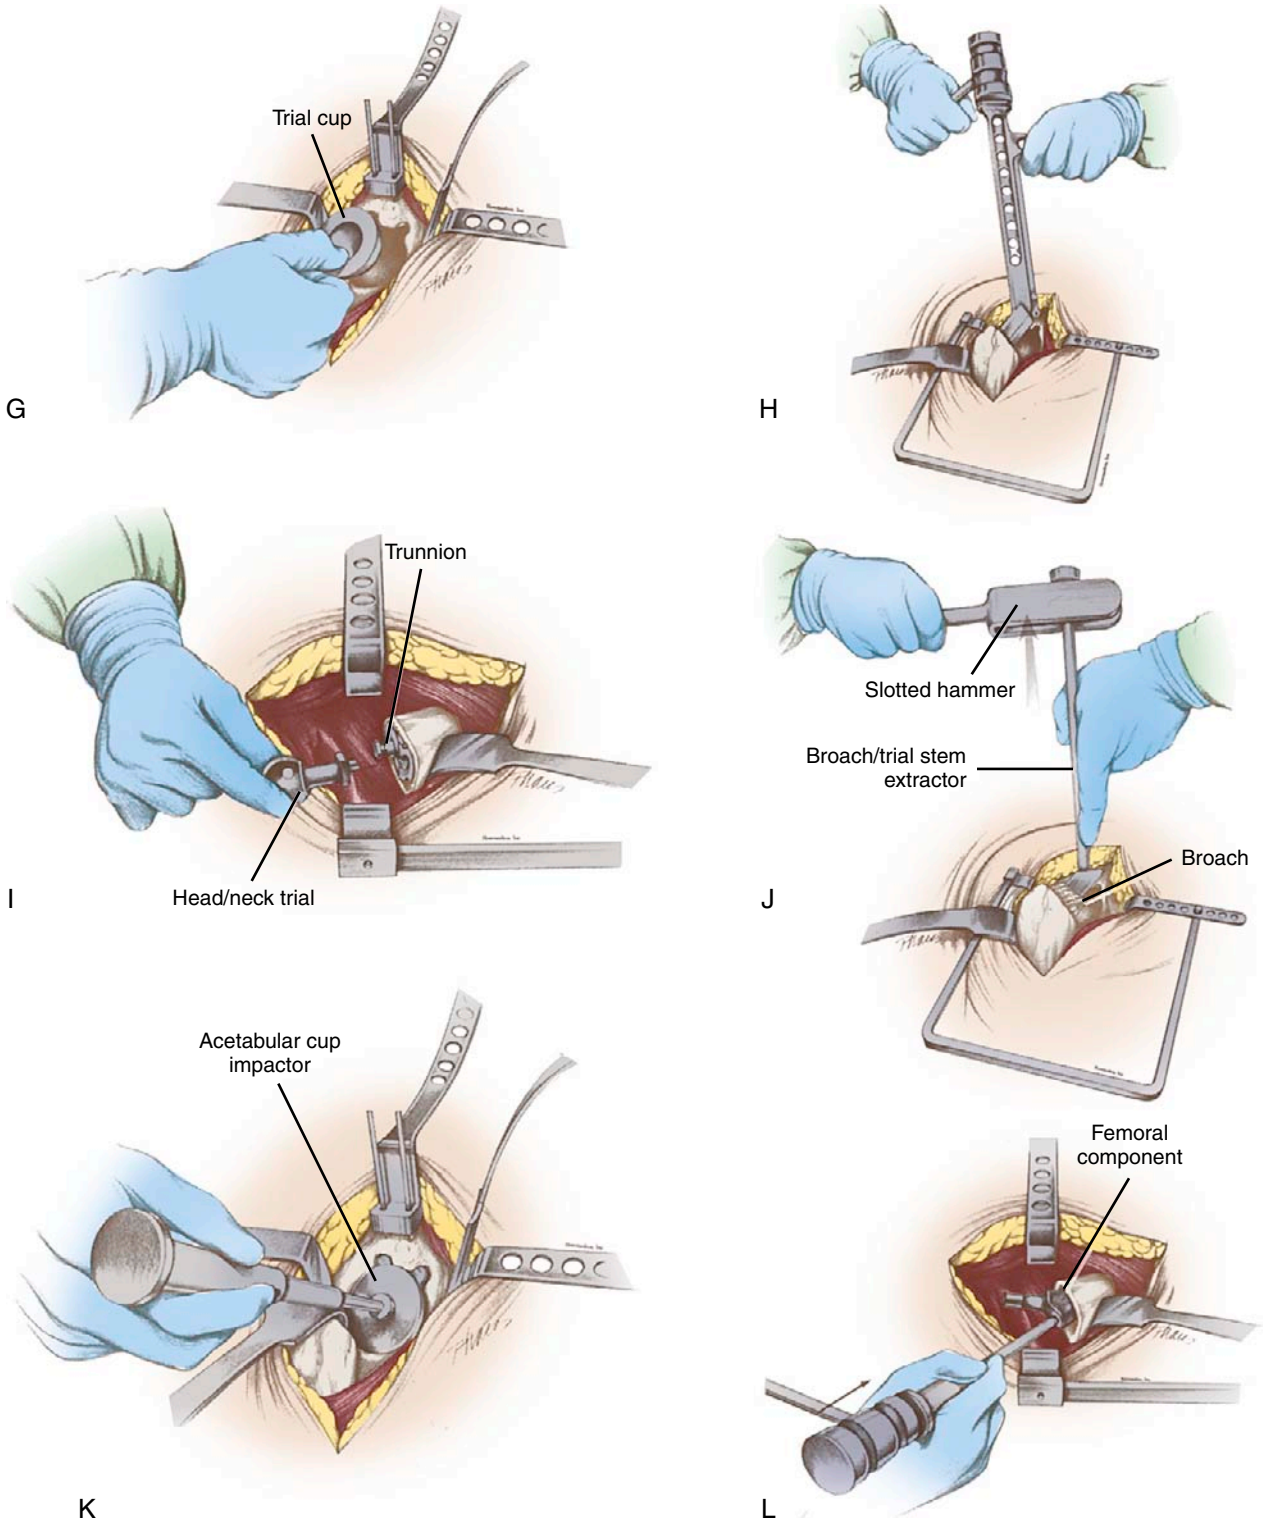

FIGURE 19-74, cont'd **G**, After drilling the holes for the acetabular fixation pegs, the trial acetabular cup is inserted. **H**, The proximal wedge of cancellous bone is removed, and the appropriate size of femoral broach is introduced down the axis of the femoral canal. **I**, The trial head is placed on the broach trunnion of trial reduction. **J**, With the slotted hammer, the femoral broach is extracted; the trial acetabular cup is removed. **K**, Acetabular fixation pegs are seated, the acetabular cup is introduced, and the component is seated. **L**, The femoral canal is irrigated with pulsatile lavage and dried with suction and sponges; the femoral canal is plugged and filled with methylmethacrylate; the femoral component is inserted.

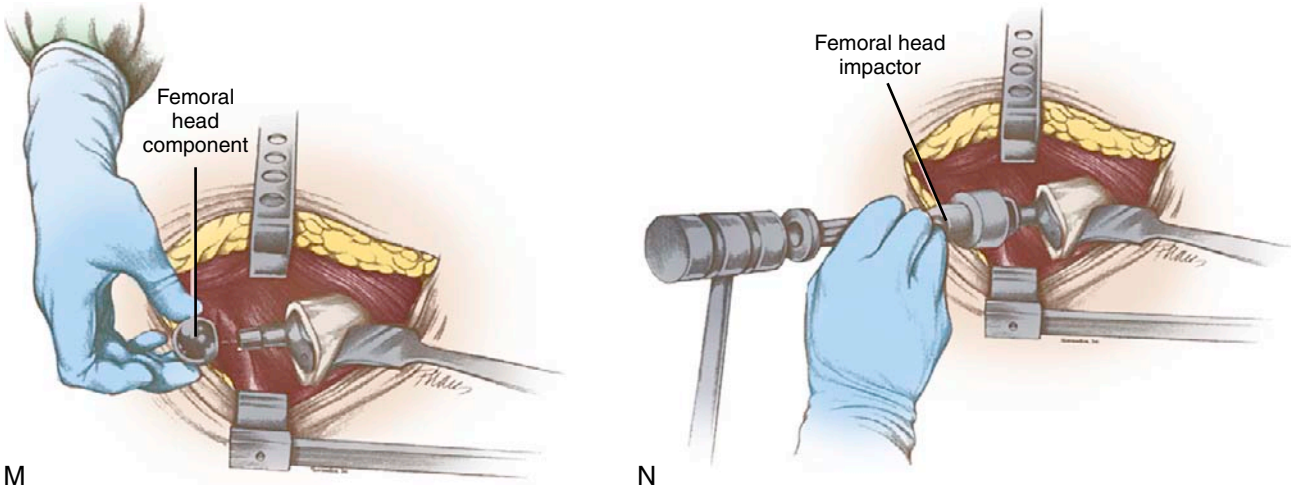

FIGURE 19-74, cont'd M, The femoral head component is placed on the trunnion. N, The femoral head is impacted, the femur is reduced, and the wound is irrigated before closure.

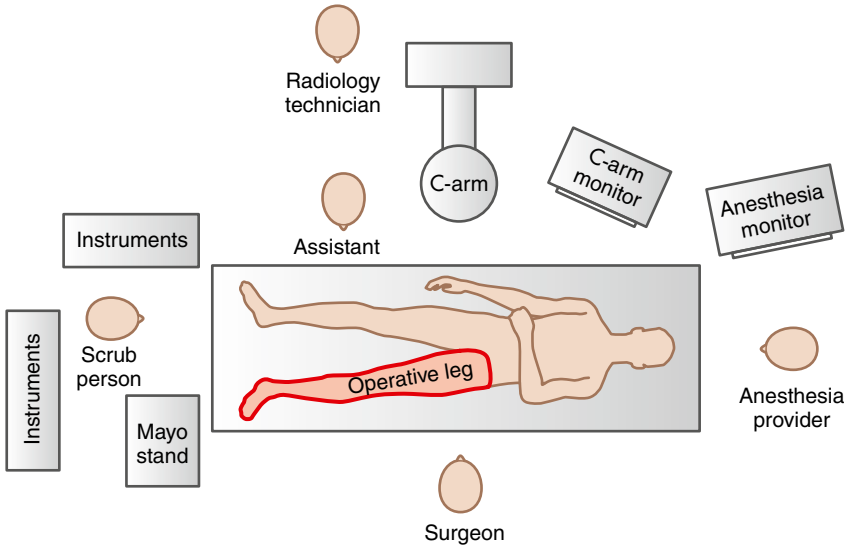

FIGURE 19-75 Illustration of room setup, including positioning of C-arm and monitor, for minimally invasive total hip arthroplasty (MITHA).

13. The femoral component is placed into the canal, and the modular head is seated on the trunnion.
14. Reduction of the hip is followed by standard closure with drains.
15. Abduction of the hip is maintained postoperatively with a foam abduction pillow if necessary.

Minimally Invasive Total Hip Arthroplasty. Minimally invasive total hip arthroplasty (MITHA) has resulted in minimized scarring, reduced patient morbidity, a shortened hospitalization period, and an accelerated rehabilitation process (Harby, 2005). MITHA can be performed with a single or double incision. For a single incision, the patient is placed in a lateral position; the patient is supine for a double-incision procedure. With double-incision MITHA, the acetabular and femoral components are inserted through two small incisions, one anterolateral and one posterolateral, each approximately 5 cm long. The technique spares the muscles and tendons around the hip.

PROCEDURAL CONSIDERATIONS. As with any joint replacement, templates of the x-rays preoperatively are recommended. A regular OR bed with x-ray capability is used. The perioperative nurse should alert the radiology department that fluoroscopy will be used. Equipment should be arranged carefully (Figure 19-75). The patient is positioned supine with a small bolster placed under the pelvis on the operative side. The patient's entire leg, from above the waist to the ankle, is then prepped and draped in the usual fashion. The time-out includes confirmation of the correct patient, site, side, procedure, position, and implants.

OPERATIVE PROCEDURE (VERSYS HIP SYSTEM)

1. The C-arm is used to define the femoral neck. The surgeon makes the anterior incision directly over the femoral neck from the base of the femoral head. The lateral femoral cutaneous nerve is identified and located, and then carefully retracted along with the sartorius using an Army-Navy retractor. A second retractor is used for the tensor fasciae latae laterally. This exposes the lateral border of the rectus femoris.

2. The surgeon uses the electrosurgical unit (ESU) for hemostasis of the lateral femoral vessels. The Army-Navy retractors are extended deeper as the rectus femoris is dissected with a #10 blade on a long handle. A long-tipped ESU pencil may also be used.
3. The surgeon incises the femoral capsule and fat pad. A Cobb elevator is used to move the tissue medially underneath the rectus muscles and laterally off the femoral neck, allowing exposure of the capsule over the femoral neck.
4. Two curved lit retractors are placed outside the capsule around the femoral neck, perpendicular to it. If additional leverage is needed, retractor handle extenders may be attached and used. The femoral capsule is incised in line with the femoral neck lateral to the midline to facilitate future placement of the head of the femoral prosthesis. Sutures can be used to retract the capsule so that the femoral head and neck are clearly visible.
5. Fluoroscopy may then be used to verify osteotomy position. Using the oscillating saw, the surgeon places a high femoral neck cut and uses a straight, 4-cm osteotome to complete it. A second cut is then made, and a threaded Steinmann pin is inserted to remove the small wafer of bone. This allows enough room for the surgeon to make the final femoral neck cut.
6. Fluoroscopy is used to check the angle and length of resection. It is important for the surgical team to help keep the leg in neutral position, especially during these cuts. The femoral head is then removed while the surgical assistant applies gentle traction on the leg.
7. Three lit anterior retractors are placed: one superiorly in the line of the incision, over the acetabulum, and the second and third at 90-degree angles to the first. Once the acetabulum is exposed, sharp and blunt dissection is used to remove remaining tissue and synovium.
8. Reaming starts with the acetabular reamer that is close to the template size. C-arm visualization is used during the reaming. Once reaming is completed to the acceptable size, the trial components are placed to determine fit. C-arm images are used to confirm location and size. The positioning bolster is removed at this time. The appropriate-size cup and liner are then chosen. The acetabular component is then seated using the offset shell inserter, retractors are removed, and the cup is impacted into place. Multiple images are taken to check the placement and position of the cup while impacting. The inserter is then removed. If screws are used, a drill, screws, drill guide, depth gauge, and flexible screwdriver will be required. Once the cup and screws are in place, their position is again checked with fluoroscopy. The liner is inserted.
9. The second incision is found by direct palpation. The nonoperative leg is adducted. The operative leg is fully adducted, externally rotated, and flexed over the nonoperative leg. Location is verified by fluoroscopy. A stab wound is made in the posterior lateral buttock and extended to 1.5 to 3 cm as needed. Sharp dissection is used to spread the tissue along the co-axial pathway to the piriformis fossa.
10. Downward pressure is applied to the operative knee to elevate the trochanter. The tissue protector is inserted. Reaming the femoral canal begins with the lateral reamers. All reamers should be inserted in the locked position. Once lateral reaming is complete, intramedullary reamers are used. Fluoroscopy is used at regular intervals throughout the reaming process to ensure centralization in the canal. The tissue protector is then removed.
11. The canal is rasped, with the initial rasp two to three times smaller than the template size of the canal. The rasp is tapped into place until fully seated; its position is verified with fluoroscopy. The canal is rasped until proper sizing and positioning are obtained. The C-arm is used to check the final depth, fill, and positioning of the rasp with the apex of the calcar.
12. Trial reduction is done with the final rasp in place. The provisional head is placed on the rasp, and the hip is reduced by providing longitudinal traction and internal rotation. The surgeon moves the hip through a full range of motion. Fluoroscopy may be used to check the levels of the lesser trochanters for possible leg length discrepancies. Once trial reduction is complete, the rasp is removed by way of a posterior exit and the head through the anterior incision.
13. Two lit anterior retractors are placed in the posterior incision to keep the tissue away from the stem as it is placed in the femoral canal. Once the implant is through the skin and properly rotated, the implant driver is attached. Gentle traction is placed on the leg in neutral abduction. Once the femoral component is within the capsule of the hip, the patient's operative leg is repositioned; it is fully adducted, externally rotated, and flexed over the nonoperative leg. The stem is impacted until it is fully seated. Fluoroscopy is used to ensure proper seating and alignment.
14. The surgeon pulls the neck of the femur through the wound and places the trial head. Traction is placed on the hip, and the hip is then turned into internal rotation. Range-of-motion and leg length assessment is then done.
15. After the final trial reduction is performed, the surgeon dislocates the hip to put the final head in place. Hip dislocation is done using a dull bone hook and external rotation of the hip. Two sutures are placed in the capsule: one medially and the other laterally. This is done before the head is reduced to prevent the capsule from invaginating posteriorly. The prosthetic head can then be seated and impacted. Gentle traction and internal rotation are used to reduce the hip. A final range-of-motion and leg length assessment is performed.
16. The surgeon irrigates the incisions with antibiotic irrigation. A local anesthetic such as bupivacaine (Marcaine) may be infiltrated into the incision, the two previously placed sutures tied, and additional sutures placed to fully close the capsule. A drain may be placed.

Total Knee Arthroplasty

Total knee arthroplasty is a surgical procedure designed to replace the worn surfaces of the knee joint. Patients complain of knee pain and instability. Degenerative rheumatoid or traumatic arthritis can result in severe destruction of the entire knee joint, or only the medial or lateral compartments of the knee joint can deteriorate as a result of extreme varus or valgus deformity. Arthroplasty of the knee has been successful in relieving these symptoms. Success depends on patient selection, component design, surgical technique, and rehabilitation.

The challenge of finding the optimal knee implant is in reproducing the complicated range of motion of the knee. Motion of the knee occurs in three planes: flexion and extension, abduction and adduction, and rotation. Designs of total

knees should allow preservation of the normal ligaments whenever possible while providing soft tissue balance when necessary to maintain stability.

Total knee implants may be classified into three different categories, according to the portions of the knee to be replaced. *Unicompartmental* implants are used to replace just one opposing articular surface (medial or lateral) of the femur and tibia. These implants, however, lost popularity as a result of biomechanical and technical pitfalls. *Bicompartmental* designs, mentioned only to demonstrate the progression of total knee design, replaced both the medial and lateral surfaces of the femur and tibia. Most of the total knee replacements completed today are *tricompartmental* implants, which replace not only the opposing femorotibial joint but also the patellofemoral joint.

The tricompartmental knees are further divided into three categories (Figure 19-76). *Unconstrained* prostheses have very little constraint built in between the femoral and tibial components and depend on the integrity of soft tissues to provide stability of the reconstructed joint. Where there is significant deformity and the need for soft tissue release, the surgeon may decide to use a *semiconstrained* prosthesis, which lends itself to more inherent stability necessitated by ligamentous deficiency. *Fully constrained* prostheses are linked together with pure hinges, rotating hinges, and nonhinged designs. They are used in the presence of considerable bone loss, instability, deformity, and revision surgery where bone loss has been significant. Fully constrained prostheses do not provide a normal range of motion, and such a lack of motion leads to excessive wear, implant loosening, and breakage.

Methods of fixation of total knee implants include both cemented and noncemented techniques. The noncemented variety encompasses both porous bony ingrowth and press-fit designs. The choice of implant and method of fixation depend on the predisposition of the bone, the patient's age and activity level, and the surgeon's comfort with a particular technique. Previous designs did not retain the posterior cruciate ligament, which possibly led to increased joint instability. Newer designs allow the posterior cruciate to be retained. Some surgeons believe that the retention of the posterior cruciate ligament dictates the need for absolute ligament balancing beyond what may be possible in the reconstructed knee.

In the interest of more cost-effective use of medical resources, new designs have been developed for the less-active patient with a shorter expected life span. The femoral component design is a symmetric design that can be used on either the left or the right knee. The tibial component is composed entirely of UHMWPE, thereby lowering manufacturing costs. Both components are placed with the use of PMMA.

Procedural Considerations. The perioperative nurse assists with positioning the patient supine. A tourniquet is applied to the upper thigh. The surgical prep is completed. A soft tissue set and a large bone set; the total knee instruments, trials, and implants of choice; a power drill and saw; PMMA and cement supplies; and a pulse lavage will be required.

Operative Procedure

NEXGEN TOTAL KNEE ARTHROPLASTY (Figure 19-77)

1. With the knee flexed, the surgeon makes a straight midline incision from 3 to 4 inches above the patella, ending at the patellar tubercle.
2. The capsule is entered medially. After making a median parapatellar incision, the surgeon places Kocher clamps on both lateral and medial sides of the capsule, and reflects the patella laterally to expose the entire tibiofemoral joint.
3. Hypertrophic synovium, a portion of the infrapatellar fat pad, is excised using a toothed forceps and knife or the ESU, and then the osteophytes are removed using a rongeur. This allows easy access to the medial, lateral, and intercondylar spaces and facilitates soft tissue releases, should the need arise.
4. The knee is flexed to 90 degrees, and Hohmann retractors are placed deep to the collateral ligaments and anterior to

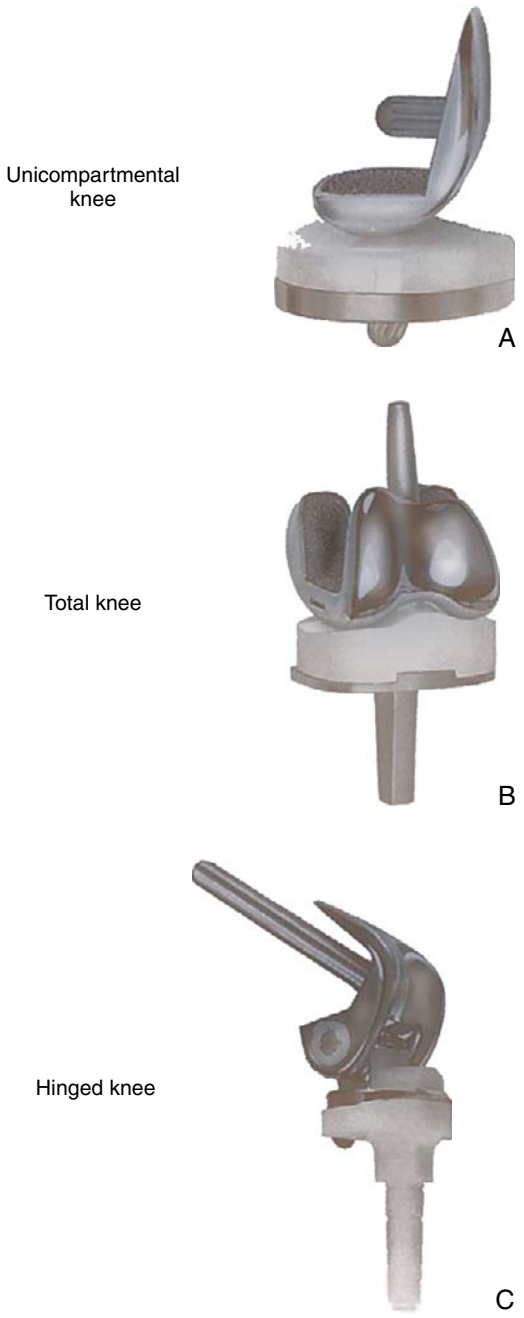

FIGURE 19-76 Knee arthroplasty implants. **A**, Unconstrained hinge. **B**, Semiconstrained hinge. **C**, Fully constrained hinge.

the posterior capsule as well as laterally to the patella to protect these structures during resection of the proximal tibia. A Richardson retractor is placed medially to protect the medial collateral ligament (MCL).

5. The surgeon positions the distal cutting alignment guide extramedullary and parallel to the proximal tibial spine. Proper rotational alignment is established by positioning the appropriate malleoli wings parallel to the transmalleolar axis. The alignment rod is proximally placed just slightly lateral to the tibial tubercle.
6. The osteotomy saw is then used to resect the proximal portion of the tibia. The distal cutting guide is removed. Alignment is checked with a Gerber guide (spacer block with the alignment rod) by placing the guide on the tibia. This checks the tibial cut for valgus alignment. The tibia is then sized with templates.
7. Before proceeding further, the surgeon ensures that the extremity can be moved into normal mediolateral (ML) alignment in extension. If not, additional soft tissue balancing is performed until the normal mechanical axis is obtained.

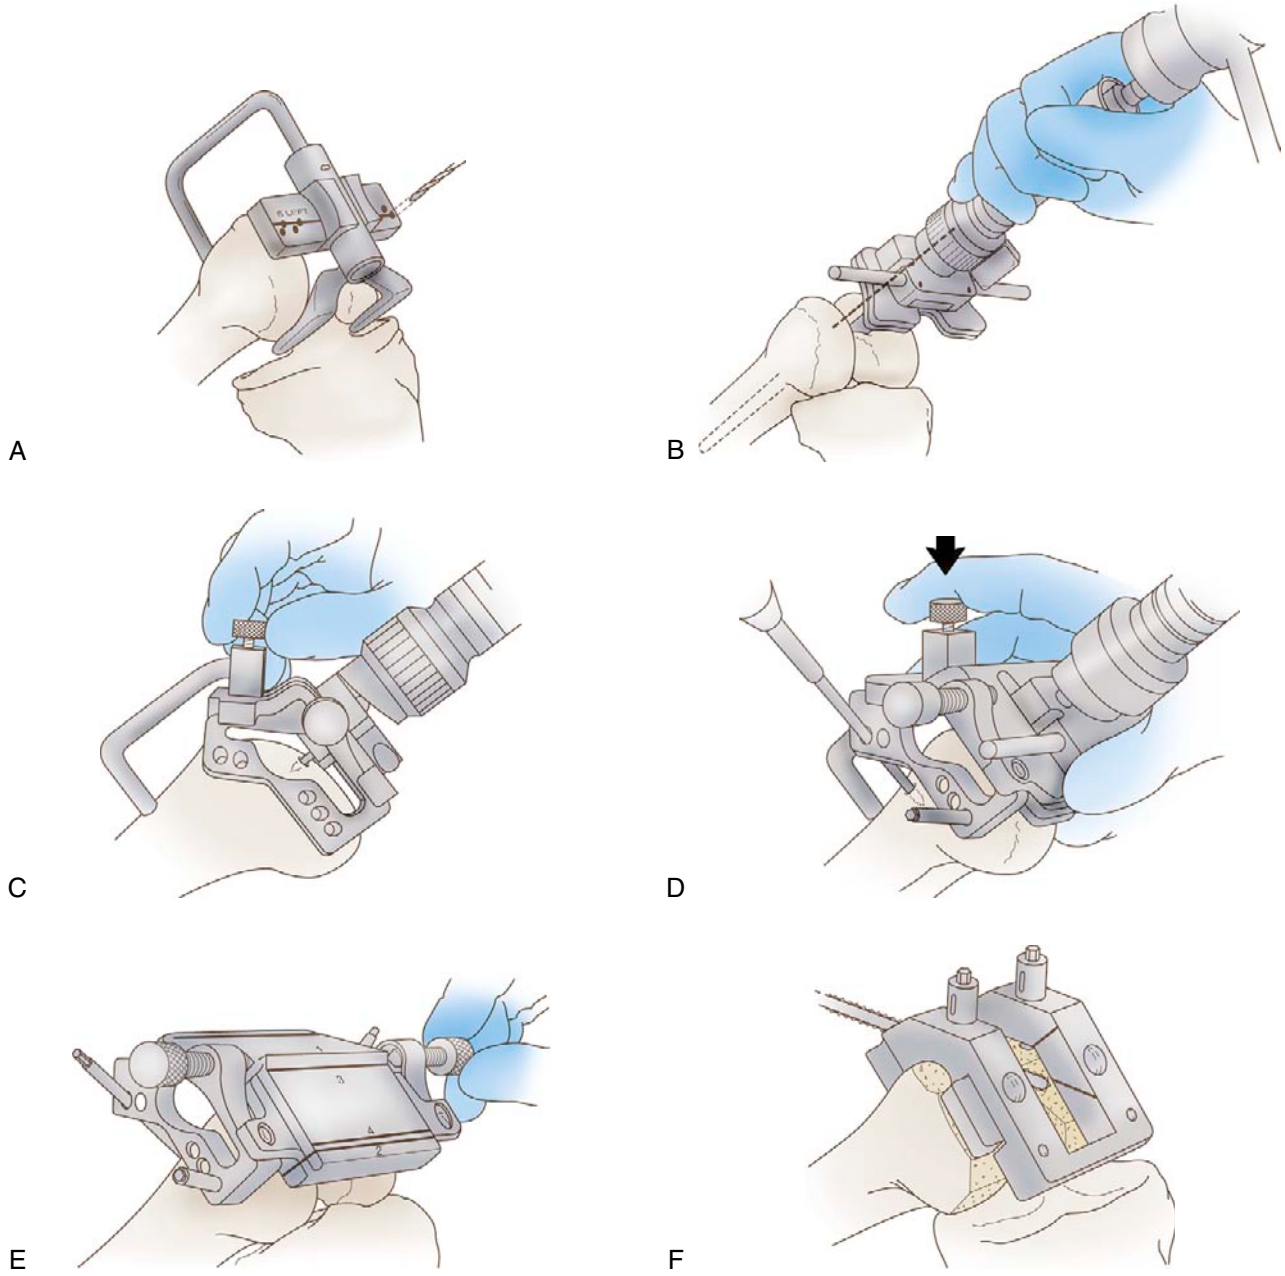

FIGURE 19-77 Total knee implant, instrumentation, and procedure. **A**, After exposure of the intercondylar notch, the femoral sizer is placed at the distal end of the femur. **B**, After the femoral canal is reamed, the femoral intramedullary alignment guide is inserted and passed up the medullary canal. **C**, Correct rotational alignment is maintained; the anterior femoral cutting guide is attached to the femoral intramedullary alignment guide. **D**, The femoral cutting guide is mounted in place. **E**, The femur is resected. **F**, Femoral cuts are completed.

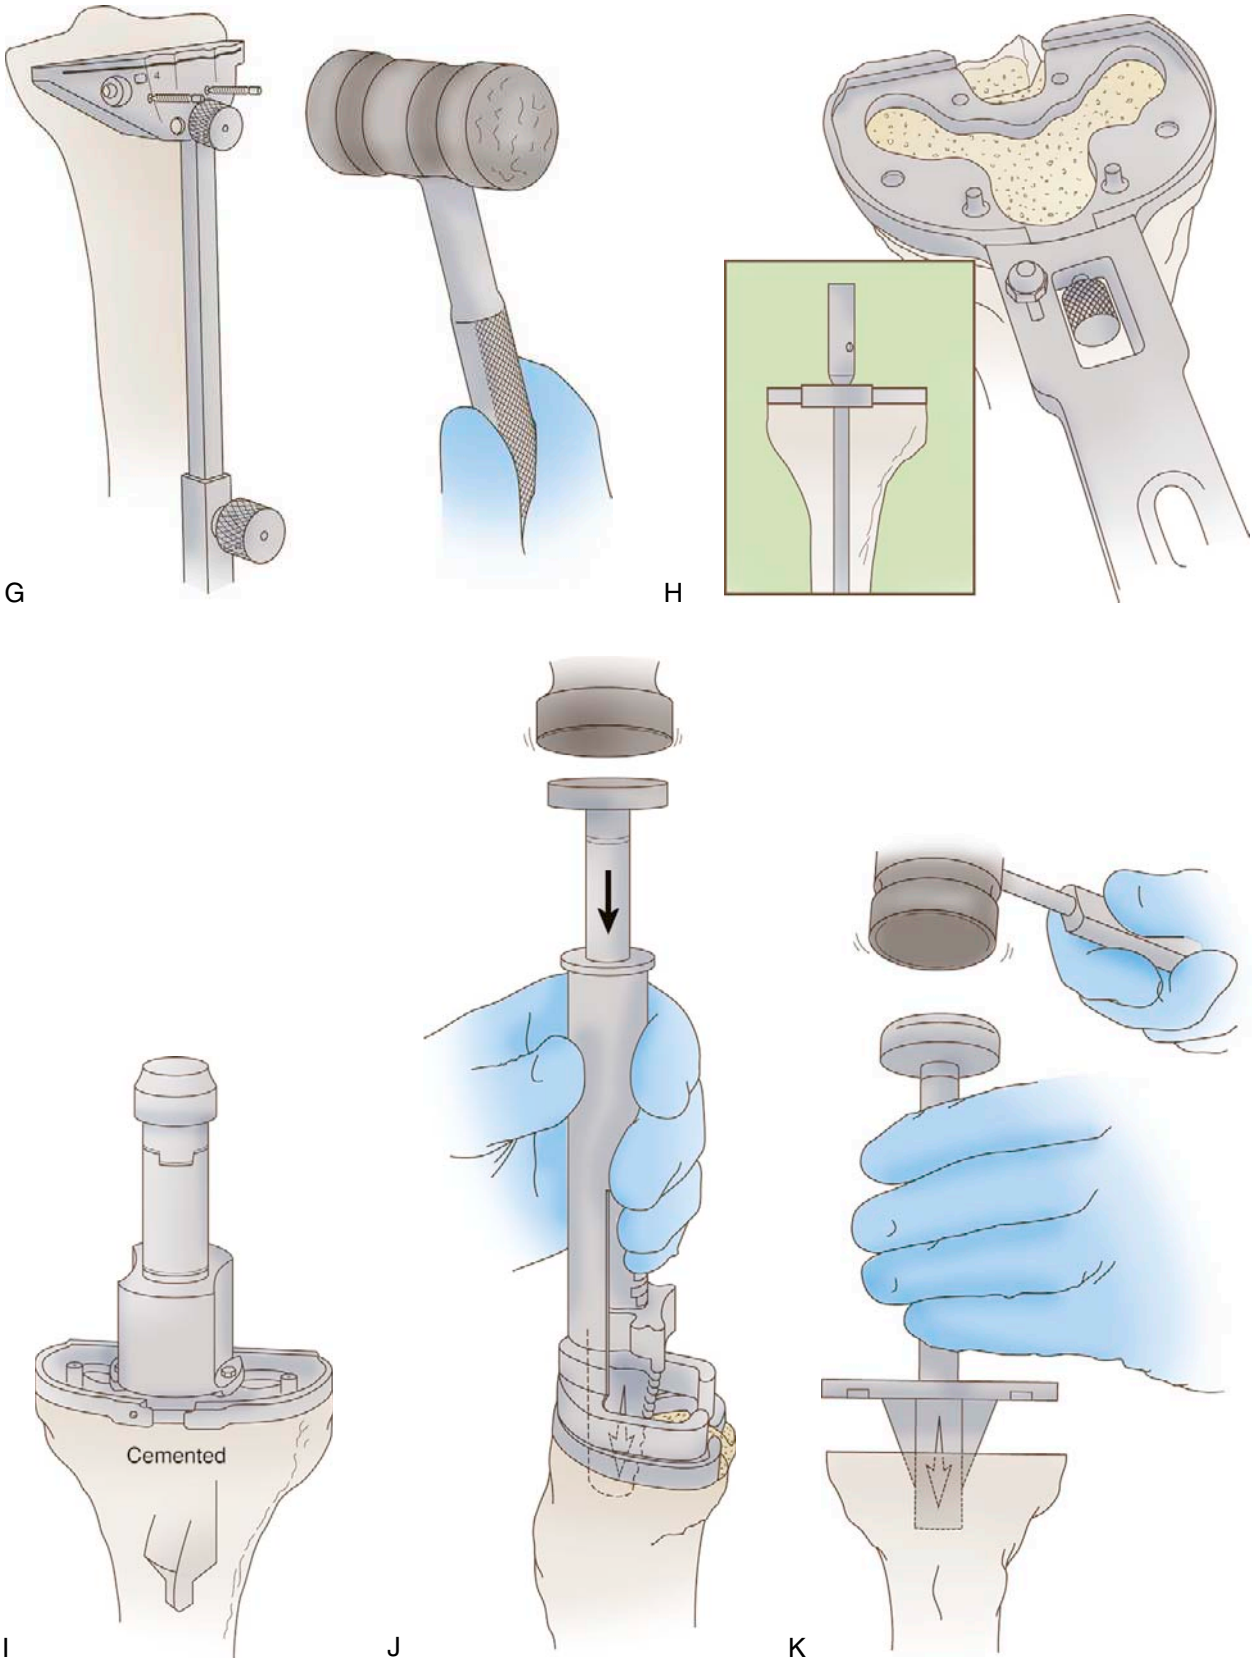

FIGURE 19-77, cont'd **G**, The tibial alignment guide is placed and secured; the tibia is resected. **H**, The tibia is sized. **I**, The tibia is reamed. **J**, The tibia is impacted. **K**, The tibial trial is inserted.

Continued

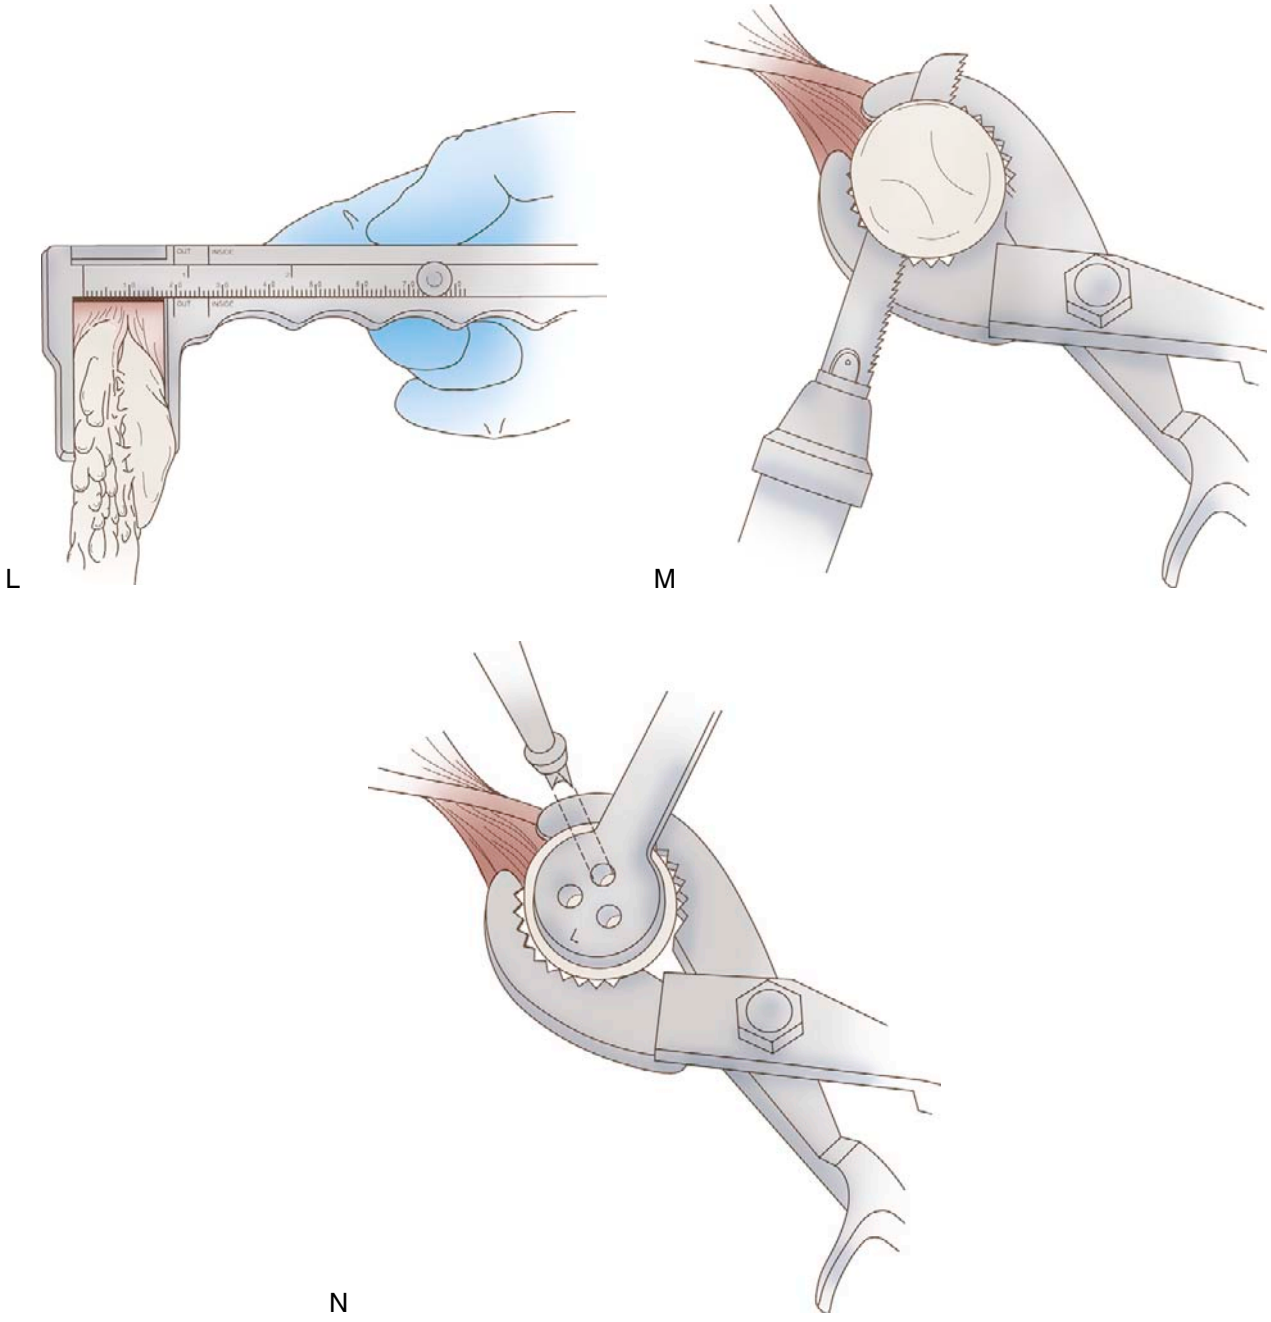

FIGURE 19-77, cont'd L, The patella is measured. M, The patella is sized. N, The patella is drilled.

8. The AP cutting guide is then used to size the femur. The guide yoke is attached to the AP block, and the yoke is slipped under the muscle anteriorly on the periosteum. The middle nail is hammered into place, while pressing down on the guide yoke. Then by pulling up on the yoke, the valgus alignment is achieved such that it is square with the tibial cut. The block is then nailed into place with two pins.
9. With the AP femoral guide in place, the surgeon positions right-angle retractors to protect the MCL and lateral collateral ligament (LCL). The anterior and posterior portions of the femur are resected. The tibial and femoral cuts are checked for balance and size at the same time with a tibial block.
10. Once the flexion balance is determined, the distal femoral cutting block is set. The tensor, placed in flexion, is then slowly moved into extension. Tension is placed on the extension gap by dialing between 30 to 40 pounds of pressure on the tensor. The amount of pressure dialed on the tensor is based on the patient's size and tightness of the ligaments. The distal cutting jig is then placed in the tensor. Once the jig is secured, the two pin holes are drilled and the tensor removed. The distal cutting guide is then placed in the exact two pin holes made by the distal cutting jig. The knee is then flexed, and the distal portion of the femur is resected.

11. The appropriate spacer block is then used to ensure equal tension in flexion and extension.
12. The knee is placed in flexion; the femoral notch and chamfer guide is centered between the epicondyles and impacted until fully seated. Three anterior fixation pins secure the guide to the femur. The surgeon drills two ¼-inch holes into the distal end of the femur, and cuts the anterior and posterior chamfers with the oscillating saw. The box osteotome is used to make the notch cut from the proximal end of the finishing guide. A power saw is used to resect the posterior femoral condyle remnants to ensure adequate flexion clearance. The femoral trial is then positioned.
13. The tibial size is reassessed using the tibial templates. The selected tibial template is then positioned rotationally and drilled, and the appropriate-size centering punch is used to cut through the subchondral bone. The tibial trial is then placed.
14. The surgeon measures the patella and places two towel clips onto the distal and proximal portions of the patella tendon, and then performs the appropriate amount of resection. The patellar template is placed over the resected surface, and the cruciate channels are created using the patellar drill through the slots in the template.
15. A trial reduction is performed. If this reduction proves satisfactory with regard to alignment and ligament laxity, the surgeon removes the trial components, irrigates with a pulsatile lavage, and places the permanent components. These can be inserted without bone cement, with bone cement, or with a combination of both.
16. Drains are placed in the joint depending on the surgeon's preference. The joint is closed in the usual fashion, and a compression dressing is applied to the leg. The tourniquet can be released before closure or after the dressing has been applied.

Postoperative care consists of rapid mobilization and strengthening, with a target discharge of 3 to 4 days postoperatively.

Stryker Navigation Total Knee Arthroplasty

PROCEDURAL CONSIDERATIONS (Figure 19-78). During the surgical approach, the company representative will be initializing (setting up) the Smart Tools instrumentation with the surgical technologist. Healthcare industry representatives can provide valuable technical support to the perioperative team. Integration of surgical instrumentation and computers results in the ability to build a customized, digital map of the patient's anatomy and navigate the surgical instruments according to this map. Successfully executed steps are marked with a blue checkmark and are graphically visualized. Proper setup is achieved when all Smart Tools are shown inside the camera's working space. Advantages to using a navigation system include the increased ability to verify the accuracy of cuts in less visible areas, decreased blood loss, and improved feedback to the surgeon about the patient's soft tissue balance.

A tourniquet, foot holder, and ESU are required. Antibiotics and heparin will usually be ordered.

OPERATIVE PROCEDURE

1. The capsule is entered medially. After making a median parapatellar incision, the surgeon places Kocher clamps on both lateral and medial sides of the capsule, and reflects the patella laterally to expose the entire tibiofemoral joint.

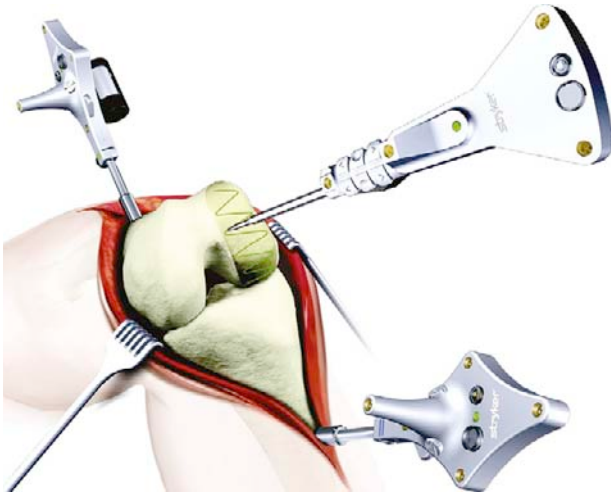

FIGURE 19-78 Stryker Navigation Tracking Equipment.

2. The surgeon begins to raise the medial flap using the ESU at the anterior tibia.
3. With a finger to retract medially, the surgeon places the tibial anchoring pin (self-tapping screws) at the distal aspect of the exposure. Drilling is then undertaken from the anterior to posterior tibial cortex using a 3.2-mm drill bit parallel to the joint line and rotated approximately 30 degrees medially.
4. Using a depth gauge, the surgeon rounds off to the size larger than measured (pins are available in 5-mm increments).
5. The surgical technologist places the pin on a T-handle for the surgeon to manually screw in the anchoring pin.
6. For the femoral anchoring pin, the surgeon next drills from the anterior to posterior femoral cortex, measures with a depth gauge, rounds up to the next larger size, and inserts the pin with a T-handle.
7. The blue tracker (B = bottom) is attached to the tibial pin and the green tracker to the femoral pin. Trackers should be placed so they are facing the camera attached to the navigation system.
8. The femoral head is registered. The hip is placed at 0 to 20 degrees of flexion and then at 45 degrees of flexion. As the leg is rotated, the LED locations yield a set of data points relative to the size of the femoral head.
9. The distal femur is then registered. The medial and lateral condyles, the center of the knee, and the AP axis of the knee are digitalized to identify the articulating surfaces.
10. The proximal tibia is then registered. The center of the tibia, AP axis, and medial and lateral tibial plateaus are traced in a similar fashion to the femur, which identifies the slope of the tibia.
11. The knee is moved through range of motion from full extension to full flexion. This kinematic datum is calculated and then recorded. Once data are recorded, the trackers are removed.
12. The surgeon excises any hypertrophic synovium and a portion of the infrapatellar fat pad using a toothed forceps and knife or ESU; the osteophytes are removed with a rongeur. This allows easy access to the medial, lateral, and intercondylar spaces and facilitates soft tissue releases, should the need arise.

13. The knee is flexed to 90 degrees, and Hohmann retractors are placed to the MCL and immediately anterior to the posterior capsule as well as laterally to the patella to protect these structures. A Richardson retractor is placed medially to protect the MCL. The surgeon uses a Kocher clamp and knife to resect the medial and lateral menisci as well as remnants of the anterior cruciate ligament (ACL) and posterior cruciate ligament (PCL).
14. The surgeon places the navigated tibial cutting guide on the proximal tibia. A cutting guide is attached to the horseshoe device and then the blue tracker to the tibial anchoring pin and the green tracker to the femoral anchoring pin. Using two pins, the guide is anchored. The position is confirmed with the navigation system and the trackers and horseshoe device are then removed.
15. The surgeon uses a 5.5-mm round burr to open the tibial surface and then drive the keel punch slightly anteriorly. The guide and pins are then removed.
16. The horseshoe device is placed with the opening posterior on the distal femur with two pins. The distal femoral cutting guide is attached to the device, and the blue tracker is attached to the blue anchoring pins. Finally, the green tracker is attached to the femoral anchoring pins.
17. The surgeon manipulates the cutting guide to the distal femur. The first pin is driven into the guide and adjusted, and then the second and third pins are placed. The horseshoe and pins are removed. The saw is flushed with the cutting guide, the green top is attached, and the blue Gurba guide is set on the tibial surface to check the cuts.
18. The femoral 4-in-1 cutting guide is placed, and the pin is placed and cut with the saw. The LCL and MCL are protected with a finger or right-angle retractors and the pins removed.
19. The Booth retractor is then placed over the tibia. After the notch guide and pin are placed, the surgeon cuts the tibia to an appropriate depth, using a saw as well as chamfer cuts. The pins and guide are then removed.
20. Next, the patella is measured; then two towel clips are placed onto the distal and proximal portions of the patellar tendon, and the appropriate resection is performed. The surgeon places the patellar template over the resected surface, and creates the cruciate channels using the patellar drill through the slots in the template.
21. Trial components are placed, trackers attached, and the knee moved through a full range of motion. The trials and anchoring pins are then removed.
22. PMMA is prepared. Bone surfaces are irrigated with a pulsatile lavage, and the permanent components are placed. These can be inserted without bone cement, with bone cement, or using a combination of both.
23. Drains are placed in the joint depending on the surgeon's preference. The joint is closed in the usual fashion, and a compression dressing is applied to the leg. The tourniquet can be released before closure or after the dressing has been applied.

Postoperative care consists of rapid mobilization and strengthening, with a target discharge of 3 to 4 days postoperatively.

Total Knee Revision Arthroplasty. Revision arthroplasty may be indicated if the patient's original knee replacement wears out or loosens, or fails as a result of repeated dislocation, infection, or trauma. Total joint revision can be a very demanding and complicated procedure. Attention to detail, anticipation, and preparation are essential. Important patient information includes the preoperative x-rays, bone scan, laboratory results (including aspiration results), and physical findings.

PROCEDURAL CONSIDERATIONS. The perioperative nurse assists with placing the patient in supine position with a footrest for the affected leg. An OR bed with x-ray capability is used. Following the induction of anesthesia, the surgeon performs an EUA. Although one of the most difficult aspects of revision surgery is that there is no clear-cut sequence of events, it is best, if possible, to approach revision surgery using the same logical sequence for each procedure. This allows all members of the surgical team to anticipate the steps in the procedure and the needs of the patient. In the case of revision arthroplasty for infection, antibiotics are held, usually at the surgeon's request, to allow for one final attempt to recover an organism. Tissue and fluid cultures are obtained when the initial incision is made through the capsule and into the joint space. Once the cultures are obtained, antibiotics are given.

Instrumentation includes a basic knee set, primary total knee instrumentation, and trials (in case only one portion of the prosthesis is revised); revision instrumentation to extract the components and cement; instrumentation and trials for the revision components; cementing system and extra cement (usually double the amount of cement used in a primary total knee arthroplasty); and power equipment including saw, reamer, and burrs.

OPERATIVE PROCEDURE The previous skin incision is usually used. This maintains adequate blood flow to the skin. The skin is marked to reapproximate the skin edges after surgery. A tourniquet is used after determining that there are no contraindications based on the patient's medical and surgical history.

1. Using a #10 blade, the surgeon incises through the scar from the original surgery.
2. With heavy tooth forceps and blade, the surgeon undermines skin on each side of the incision; this allows the skin to be more easily closed at the end of the procedure.
3. Once at the capsule, a clean #10 blade is used to make a medial parapatellar incision into the joint. A Kocher is placed on the medial side of the capsule, and a towel clip is placed laterally, immediate to the patella, to aid with eversion.
4. Both tissue and fluid cultures are taken. Antibiotics are then administered by the anesthesia provider.
5. Using heavy tooth forceps or a Kocher, the surgeon performs a synovectomy with a knife or the ESU. A clean dissection is needed to allow visualization of the bone-prosthesis interface and to remove any synovitis caused by poly debris or metallosis (metallosis is a nonsuppurative osteomyelitis that occurs around metal implants as a result of corrosion or hypersensitivity reaction).
6. The surgeon uses a periosteal elevator to peel away the medial ligament, which was stripped during the original surgery.
7. The knee is dislocated with posterior placement of a Hohmann retractor immediately behind the tibia. A second Hohmann retractor is placed laterally to the patella and LCL. Medially, a Richardson retractor provides protection of the MCL.

8. If possible, the surgeon removes the poly tibia insert to allow better visualization and an increased work space.
9. Using an osteotomy saw with a small blade, the surgeon will proceed to remove the tibial plate at the bone-prosthesis interface. If the saw is unable to complete the cuts, ¼- or ½-inch curved osteotomes may be used to gain access to the posterior lateral corner. Cement is then removed from the canal using a Kocher, ¼-inch straight osteotome, chisels, mallet, and curettes. If the cement is deep, a heavy toothed alligator forceps may be required.
10. Once the tibia and cement are removed, the surgeon recuts the tibia surface using an osteotomy saw and alignment guide. Sometimes, the tibia is completely revised before the next step. If so, the tibial template, pins, mallet, and punch will be needed.
11. With the patella everted, a Booth retractor is placed under the femur. Using a ½-inch curved osteotome and mallet, the surgeon removes the femoral component. A ¼-inch curved osteotome may be required if there are metal pegs at the distal end on the femoral component or at the posterior edge of the prosthesis. Once both sides of the prosthesis are loosened, it should fall off. If not, a femoral distractor will be used.
12. Any remaining cement is removed using osteotomes, chisels, or the saw. Any cement in the canal will be removed with a Kocher or alligator forcep.
13. Next the posterior capsule is addressed. With the leg in extension, the surgeon places a lamina spreader between the femur and tibia. Using curettes and a rongeur, the scar on the posterior capsule is removed to improve postoperative range of motion.
14. Once the capsule is released, attention is turned to rebuilding the femur. This is done by using a series of guides and trial components.
15. Augmentation of both tibia and femur components can be done using either metal augments or bone grafting. Balance between the femur and tibia is obtained first in flexion and then in extension.
16. The last component to be revised is the patella. Two towel clips are placed, distal and proximal on either side of the patella, and the button is removed, using a large-blade osteotomy saw. All poly buttons can be readily removed by this method. However, a metal-backed patella requires the additional use of a ¼-inch osteotome. Any remaining cement is removed from holes with a curette or 6.0-mm burr on a drill. The patella will be recut using a large-blade osteotomy saw.
17. The guide is placed on the patella, and the drill is used for new holes. The trial button is placed, the patella inverted, and the knee placed through a range of motion.
18. All components are removed, and the knee is irrigated with antibiotic solution using pulsatile lavage. The bone edges are dried with suction and clean sponges. This is done while the cement is being mixed.
19. Components can be cemented all at once or in stages, depending on the surgeon's preference.
20. The femur is usually cemented first. The Booth retractor is placed under the femur, and cement is put on the posterior phalanges of the femoral component and then on the distal edges of the bone. The component is placed on the end of the femur and impacted with an impactor and mallet. The cement is removed using glue knives anteriorly, laterally, and medially. Posterior glue is removed using curettes. The Booth retractor is then removed.
21. Hohmann retractors are placed posteriorly and laterally; a Richardson retractor can be placed medially if necessary. The surgeon applies cement on the tibia surface and on the tip of the tibial stem. The tibial component is then placed and impacted. Remaining cement is removed using glue knives or bayonet forceps. The retractors are removed, and the knee is relocated.
22. Cement is applied to the patella in the predrilled holes as well as on the patella button itself. The button is placed on the patella and held with a patella clamp. Remaining cement is again removed using a glue knife or bayonets.
23. Drains are used at the discretion of the surgeon, and the wound is closed.

Total Shoulder Arthroplasty

Physically induced or accidental injury or degenerative arthritis may necessitate prosthetic replacement of the shoulder joint. The procedure may be a hemiarthroplasty with reconstruction of the humeral side or a total arthroplasty with replacement of the humeral head and glenoid (Figure 19-79).

Procedural Considerations. The patient is placed in a 30-degree semisitting position with the arm draped free on a padded armboard and the shoulder hanging slightly off the OR bed to allow movement through the entire range of motion. The perioperative nurse confirms that the patient's head is supported to avoid neck extension. A pad is placed beneath the scapula.

A soft tissue set and a large bone set; shoulder instruments; PMMA and cement supplies; the implants with associated instrumentation and trials; a power drill, reamer, and saw; and a pulsatile lavage system will be needed.

Operative Procedure

NEER TOTAL SHOULDER ARTHROPLASTY
(Figure 19-80)

1. The surgeon makes a 16-cm incision from the midacromion distally along the deltopectoral groove.
2. The cephalic vein is identified, and the surgeon opens and retracts the deltopectoral groove.
3. The deltoid attachment may be removed if the patient is large or muscular, which may affect rehabilitation.
4. The long head of the biceps is identified as the landmark between the tuberosities and rotator interval.
5. The surgeon elevates the subscapularis from the underlying capsule and divides it 2 cm medially to the bicipital groove, and places a stay suture.
6. The subscapularis is retracted medially with the lesser tuberosity, thereby exposing the joint and associated structures.
7. The capsule is exposed by elevation. The surgeon uses an elevator placed beneath the capsule to protect the axillary nerve. The long head of the biceps is left undisturbed and free in its groove so that it will continue to function as a depressor of the head after surgery.
8. After external rotation, the fractured humeral head is removed. The incision site is irrigated to remove blood and clots from the joint.
9. The surgeon examines the proximal humeral shaft to select the appropriately sized stem, available in various lengths and diameters.

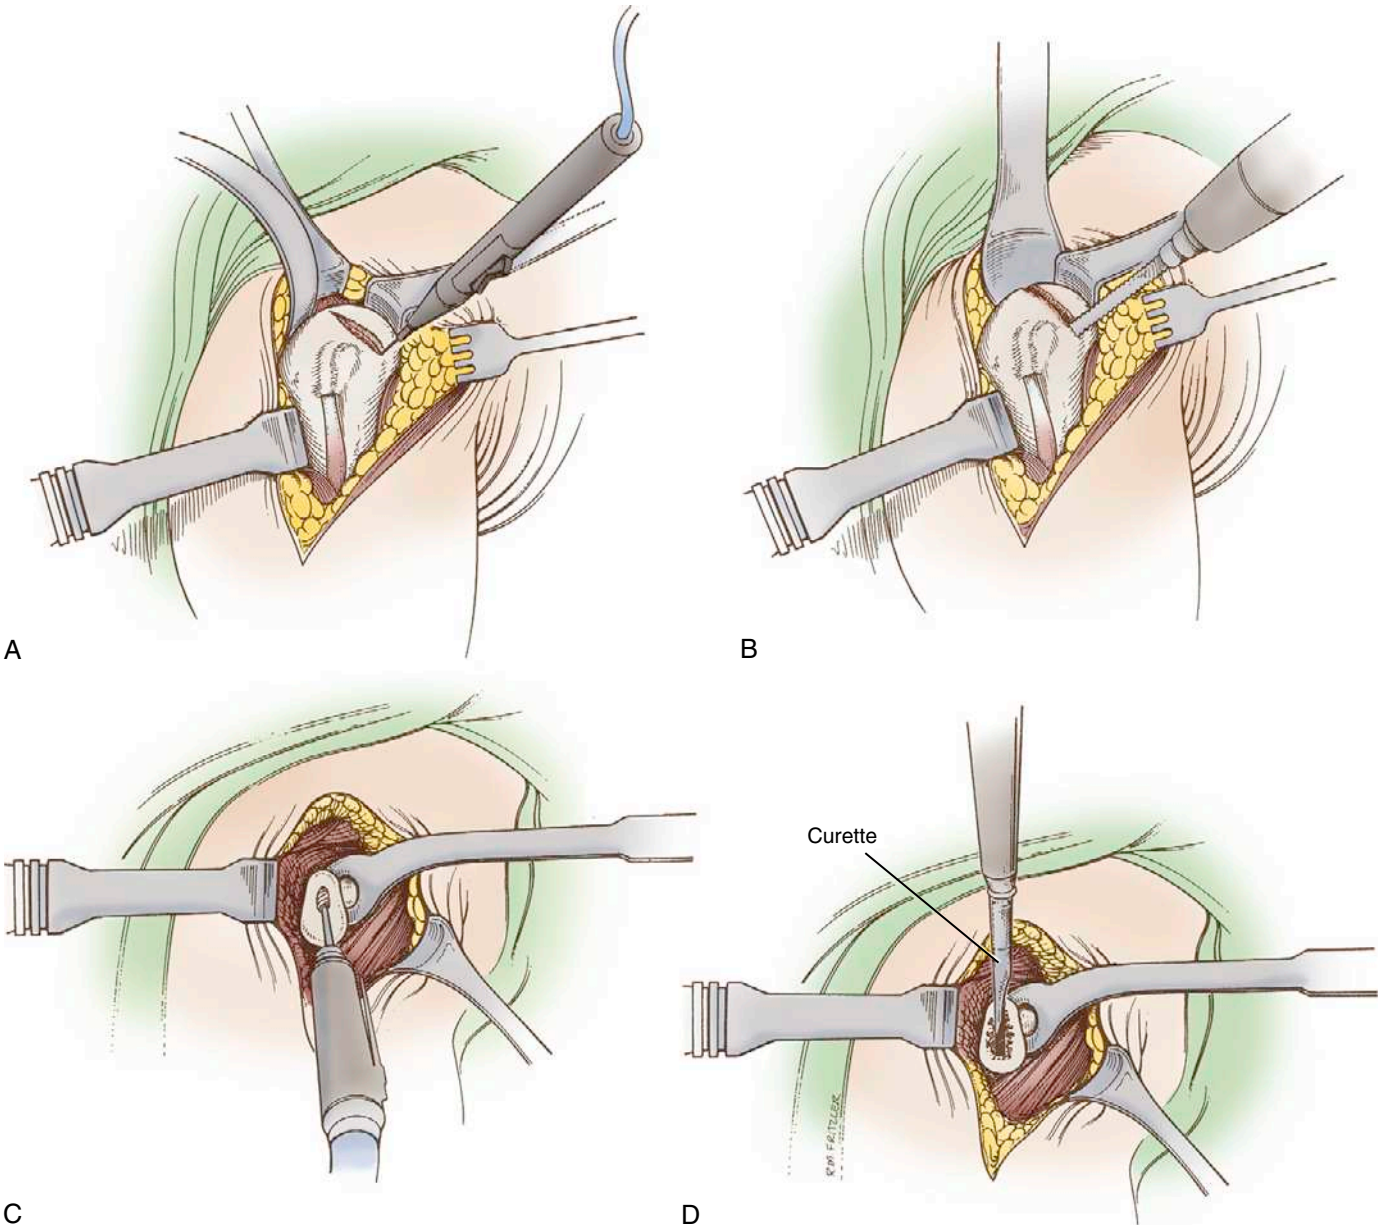

FIGURE 19-79 Total shoulder arthroplasty. **A**, The patient is positioned, and a deltopectoral incision is made to release the capsule. **B**, The humeral head is removed with a reciprocating saw. **C**, After exposure of the glenoid, a fenestration for the glenoid component is made. **D**, The glenoid bow is curetted.

10. Marginal osteophytes are trimmed.
11. The glenoid is inspected for integrity and sized for a prosthesis if it is to be replaced.
12. A central hole for a prosthesis fit is made into the glenoid with a high-speed burr and curette.
13. Stem diameter and length are estimated to check the prosthesis for fit. The largest stem diameter possible is used.
14. With the shaft held forward and upward, the surgeon locates the intramedullary canal with a long curette. A ¼-, ⅜-, or ½-inch drill bit is selected to correspond to the diameter of the canal; depending on the prosthesis stem length, the surgeon drills down the medullary canal 5 or 6 inches. Final preparation of the shaft is accomplished with the appropriately sized tapered reamer.
15. A heavy-gauge nonabsorbable suture is passed through holes that have been drilled on the tuberosities. The surgeon checks the length of the rotator cuff by pulling the tuberosities distal to the collar of the prosthesis.
16. Neck length and stability of the joint are determined before final impaction of the prosthesis.
17. A check for 35- to 40-degree retroversion is done by palpating the epicondyles at the elbow.
18. The implant is seated on the calcar with a driver and mallet, with its articular surface protected with a moist sponge. Just before final seating, further trimming of high spots with an osteotome or high-speed burr may be required. PMMA is used except in young patients, in whom a firm press-fit can be achieved.

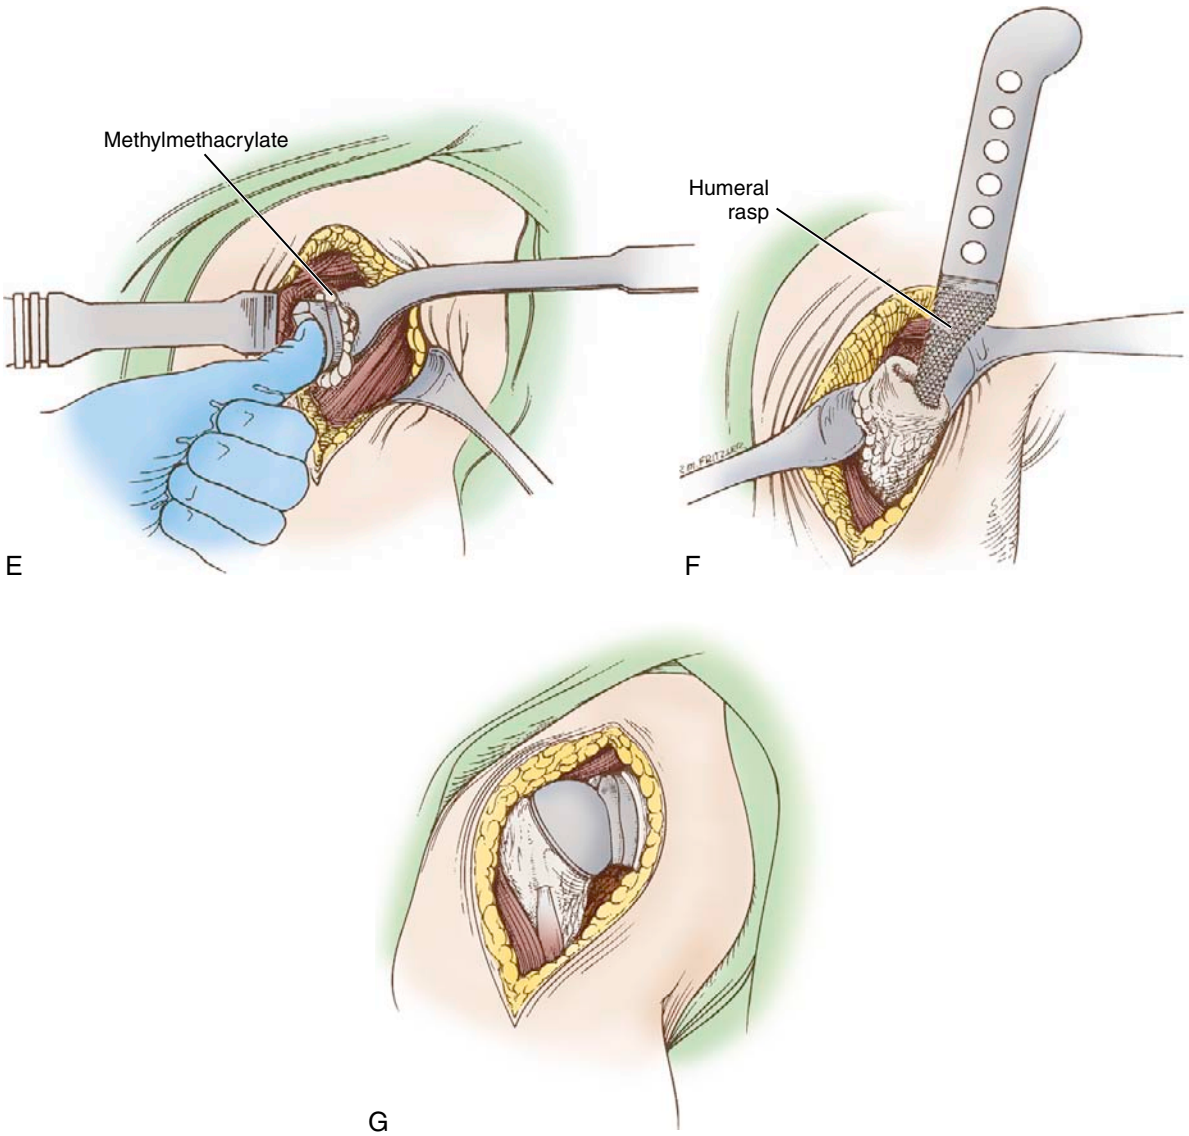

FIGURE 19-79, cont'd **E**, Cancellous bone is evacuated and cement impressed. **F**, The humeral shaft is rasped. **G**, The humeral component is inserted.

19. Wires or sutures are passed through the holes in the neck of the prosthesis, reducing the tuberosities beneath the collar, and are secured. If wires are used, they are buried in drill holes in the bone.
20. The surgeon reduces the shoulder. The interval of the rotator cuff is closed and the biceps tendon reattached if previously detached.
21. The joint is irrigated as each compartment and layer is closed.
22. A closed-drainage system is inserted between the rotator cuff and deltoid, avoiding contact of the drainage tubes with the axillary artery. Routine closure is accomplished.
23. Dressings are placed between the body and the arm. A shoulder immobilizer is applied.

Passive range-of-motion machines may be used for patients prone to adhesion or contracture. Pendulum and gentle exercise are permitted at 10 days.

Total Elbow Arthroplasty

While not as prevalent as arthroplasty of the shoulder, knee, or hip, total elbow replacement (Figure 19-81) is indicated for patients with traumatic lesions or excessive bone loss from rheumatic or degenerative arthritis, resulting in elbow instability and pain or bilateral elbow ankylosis. The design of implants and methods of fixation for postoperative stability have presented challenges that have been overcome in arthroplasty of other joints but remain a challenge in elbow arthroplasty. Postoperative stability of the elbow implant depends largely on the soft tissues surrounding the joint. There are devices that provide more constraint for the patient with significant soft tissue laxity or loss of bone stock. The Coonrad-Morrey, Tri-Axial, and Pritchard-Walker are just a few of the total elbow prostheses available.

The prosthesis may be used with or without PMMA, depending on the quality of the diseased bone and the design of the

FIGURE 19-80 Neer shoulder prosthesis.

implant. If PMMA is not employed, bone grafting with local bone that has been resected may be used to help seat the ulnar component snugly and achieve adequate bony contact against the porous coating of the metal ulnar component. After elbow arthroplasty, patients with degenerative arthritis generally have better results than those with injury.

Procedural Considerations. The perioperative nurse assists with positioning the patient in the supine or semi-Fowler position with the arm over the chest. A tourniquet is applied and can be inflated if needed. The arm is prepped from shoulder to fingers and draped. A soft tissue set and a small bone set; the total elbow implants and instruments; a power saw, drill, and burr; an awl; heavy-gauge wire; and a wire tightener will be needed. PMMA and cement supplies as well as a pulsatile lavage system are required if the prosthesis is placed with the use of PMMA.

Operative Procedure

1. The limb is exsanguinated, and the tourniquet is inflated to the desired pressure.
2. The surgeon makes a midline posterior incision, protecting the ulnar nerve.
3. The triceps mechanism is elevated in continuity with the periosteum, and the elbow joint is explored.
4. The surgeon explores the distal end of the humerus, proximal end of the ulna, and radial head while preserving the collateral ligaments.
5. The midportion of the trochlea is removed to allow access to the distal end of the humerus; the medullary canal is opened with a high-speed burr, and the canal is entered with a twist hand reamer.
6. The distal end of the humerus is notched with the appropriate cutting guide.
7. A high-speed burr is used to drill through subchondral bone to allow access to the medullary canal of the ulna and serially ream the canal.
8. After the humerus and ulna have been prepared for insertion of the trial prosthesis, the surgeon evaluates the elbow for flexion and extension. Bony adjustments are made where necessary.
9. The canals are cleaned of all bone fragments by irrigating with pulsatile antibiotic lavage.
10. The canal is dried before implant insertion, and the preparation is checked before the cement is mixed to ensure that the correct size of component is available.
11. The surgeon inserts the cement into the canals followed by the prosthesis. Flexion and extension of the elbow are avoided until the cement has hardened.
12. Any bone graft that may be required is secured with wire or pins.
13. The tourniquet is deflated, and hemostasis is achieved.
14. The triceps mechanism is repaired. The incision site is irrigated and closed. A drain may be inserted.
15. A long arm posterior splint is applied with the elbow at 90 degrees.

Total Ankle Joint Arthroplasty

Long-term results for total ankle arthroplasty, especially in the young population, are extremely poor. The procedure is reserved for older or more sedentary patients, especially those with subtalar or midtarsal arthritis. Ankle arthrodesis should be considered first in joint reconstruction. Indications for total ankle arthroplasty include (1) failed arthrodesis, (2) bilateral ankle arthritis when arthrodesis has already been performed on one ankle, (3) after talectomy because of avascular necrosis, and (4) revision of a previous arthroplasty. Total ankle replacement prostheses are made of high-density polyethylene and metal components.

Procedural Considerations. The patient is supine with the tourniquet placed. The leg is prepped and draped. A soft tissue set, a small bone set, the total ankle joint replacement instrumentation and implants, a power drill and saw, a pulsatile lavage system, and PMMA cement and supplies will be necessary.

Operative Procedure (Figure 19-82)

1. The surgeon makes an anterior incision over the ankle joint.
2. Using blunt and sharp dissection the surgeon exposes the tibiotalar joint and talus dome.
3. Once the center of the talus is identified and marked, a sizing template is used to mark the tibia.
4. A defect that is 1 inch wide by ⅜ inch deep is made using the air drill. Anchoring holes can be made in the tibia. The template is positioned in the defect while the foot is distracted.
5. The talus is marked, and using a reciprocating saw the surgeon makes a groove that is ½ inch deep by 3/16 inch wide to accommodate the talar component.
6. A trial fit is carried out to ensure that the talar unit is in the center of the talus and that the tibial unit is parallel to the plane of the floor, both centered over the dome of the talus.
7. Once trial reduction is complete, the talar and tibial components are cemented into place.
8. The ankle joint is irrigated and closed, a drain inserted, and a posterior splint applied.

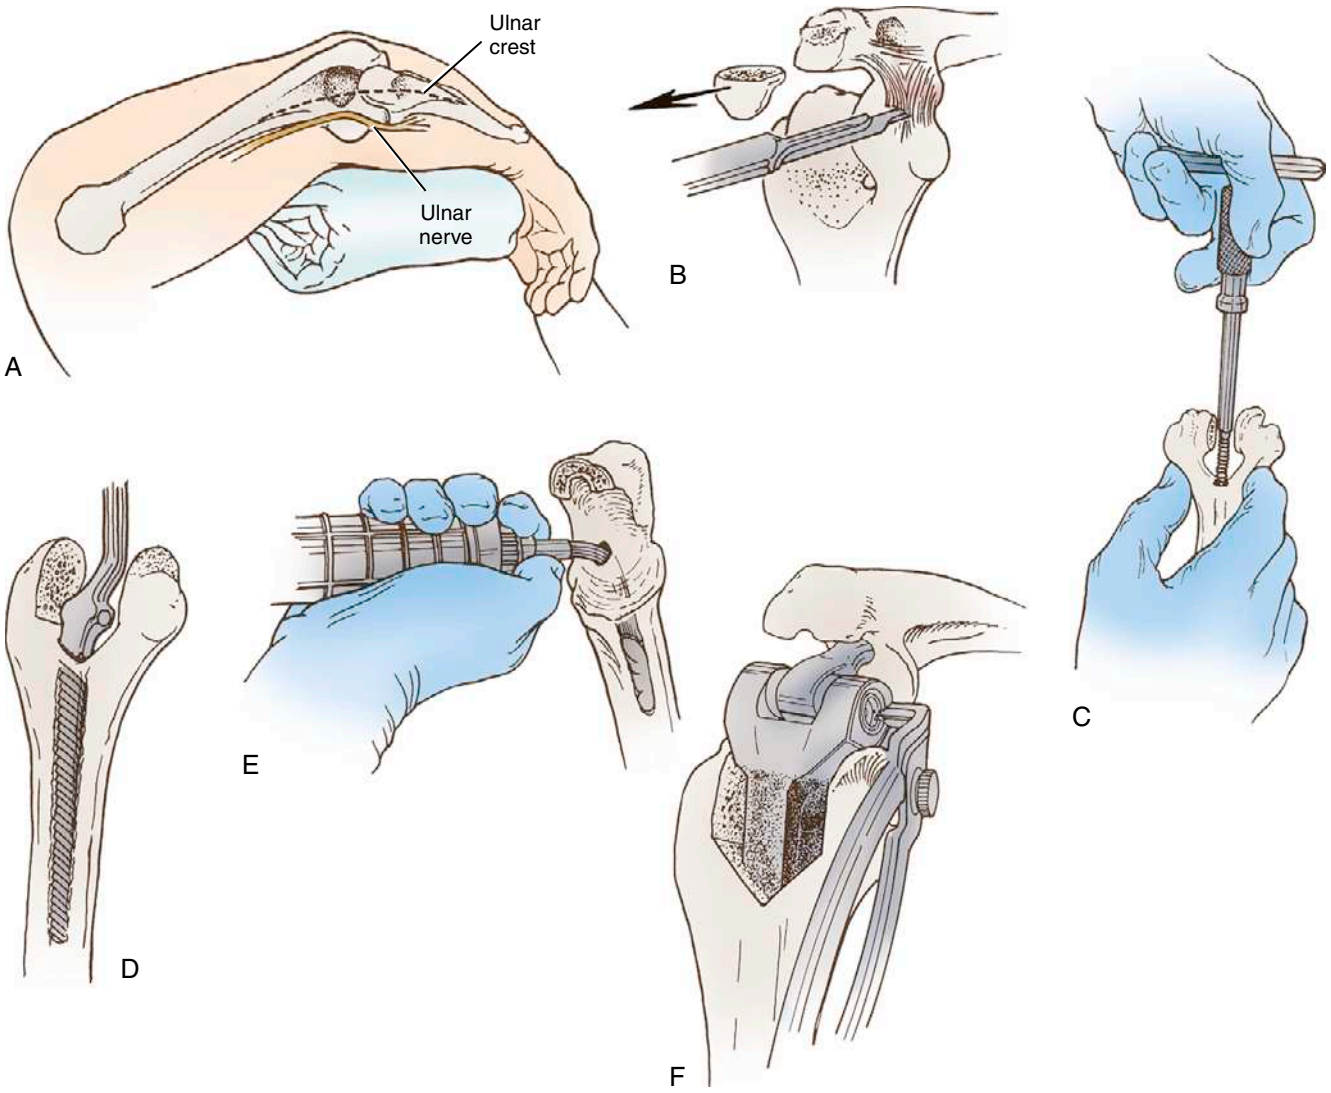

FIGURE 19-81 Total elbow arthroplasty. **A**, The arm is draped free, and the incision is made. **B**, The tip of the olecranon is excised with an oscillating saw. **C**, The canal is identified with a burr, and the canal is opened with a twist reamer. **D**, The capitellum is measured and cut. **E**, The medullary canal is cleaned and dried, and bone cement is inserted. **F**, The ulnar prosthesis is inserted, followed by cementing and inserting of the humeral components.

Metacarpal Arthroplasty

Metacarpal joint replacement is most often performed in patients who have pain or a disabling deformity associated with rheumatoid or degenerative arthritis of the metacarpophalangeal or interphalangeal joints. The results of rheumatoid reconstructive surgery are generally good, and pain can be eliminated and joint alignment and joint stability restored in the majority of patients. The greatest problems after surgery are weakness of grasp and pinch, and progression of the disease in adjacent joints.

Procedural Considerations. The patient is positioned supine with the arm extended on a hand table. A tourniquet is applied, and the entire extremity is prepped and draped. A hand set, instrumentation for implants, and implants are required, as well as a high-speed burr.

Operative Procedure

1. Incisions are made on the dorsum of the appropriate fingers.
2. The surgeon excises the proximal and distal portions of the joints and reams the intramedullary canals.
3. Sizers are used to facilitate a correct fit of the prosthesis.
4. Once the appropriately sized implant is determined, the surgeon positions it into the canal (Figures 19-83 and 19-84) and makes tendon and ligament repairs as indicated to improve stability.
5. The joint is irrigated and closed, and a bulky dressing is applied.
6. A short arm posterior splint is applied for immobilization.

Metatarsal Arthroplasty

Silastic implantation is indicated in the treatment of deformities associated with rheumatoid arthritis, hallux valgus, hallux rigidus, and a painful or unstable joint.

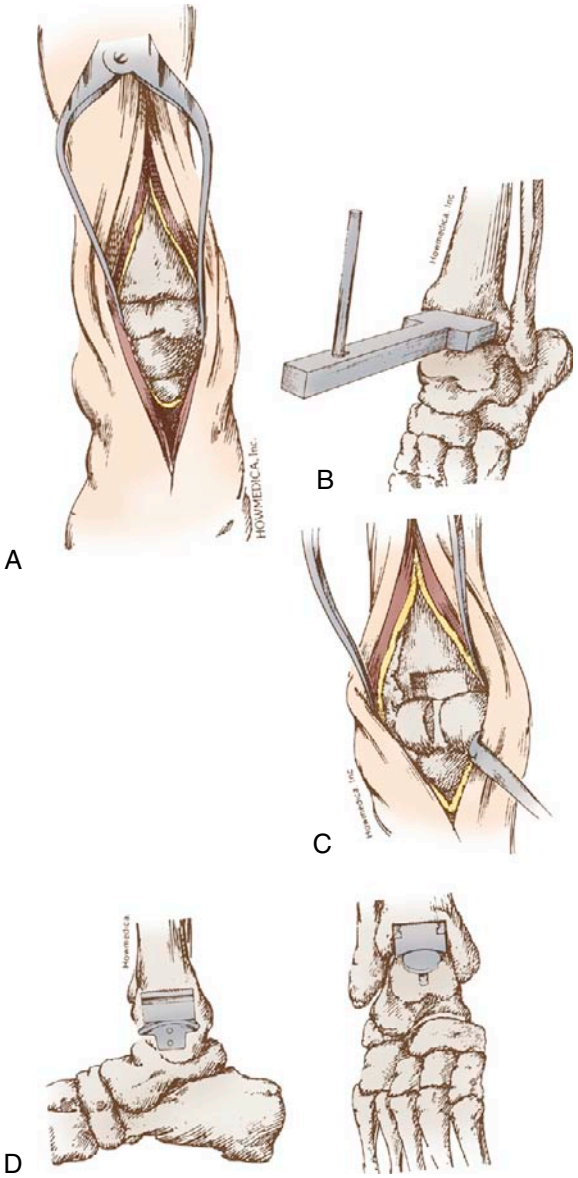

FIGURE 19-82 Total ankle arthroplasty. **A**, An anterior incision is made, and the tibiotalar joint and talus dome are exposed. **B**, The sizing template is used to mark the tibia. **C**, An air drill is used to create a defect, and anchoring holes are prepared. **D**, Trial reduction is completed, and the talar and tibial components are cemented into place.

FIGURE 19-83 Metacarpophalangeal implant.

Procedural Considerations. The patient is supine. A tourniquet is applied, and the entire extremity is prepped and draped. A small bone set is required, as well as the implant instruments and implants, a power wire driver, and the microsagittal saw.

FIGURE 19-84 Silastic implant for finger joint.

Operative Procedure

1. The incisions are made over the appropriate joints.
2. The surgeon resects the proximal phalanx and removes exostosis from the metatarsal head.
3. The medullary canal is reamed, and trial implants are fitted.
4. The surgeon determines the appropriate sized metatarsal implant and seats it.
5. The wound is irrigated and closed.
6. A bulky compression dressing and orthopedic shoe are applied for early ambulation.

ARTHROSCOPY

Progress and development of arthroscopy and arthroscopic procedures have changed the approach, diagnosis, and treatment of many joint ailments. Arthroscopic techniques require skill and accomplishment in identifying three-dimensional relationships. The advantages of arthroscopic surgery surpass the disadvantages. Among the advantages are (1) decreased recovery and rehabilitation time; (2) smaller incisions; (3) less inflammatory response; (4) less postoperative pain, scar, and extensor disruption; (5) reduced complications; (6) reduced hospital stay and cost; and (7) easier, more rapid surgical procedures (Ambulatory Surgery Considerations).

Disadvantages usually relate to the size and delicacy of the instruments. Maneuverability within a joint may be difficult and produce scuffing and scoring of the articular surfaces.

Improvements in scope and camera systems, sharper scope optics, and miniaturization have made operative arthroscopy a logical extension of diagnostic arthroscopy. Surgical arthroscopy has also been aided with the development of numerous second puncture instruments and devices to repair and excise defects. There are a multitude of motorized shaving and abrader systems. Irrigation systems provide regulated distention of the knee joint by infusing normal saline or lactated Ringer's solution. These systems may function by gravity flow or are mechanized with built-in microprocessors to monitor joint pressures and adjust accordingly. Lasers and ESUs can be used in tandem with arthroscopic equipment. Integrated video systems can record and store still and video images on film, tape, or digitally for education and documentation.

Arthroscopy is commonly performed on the knee, shoulder, and wrist. It is used less often in the elbow, hip, and ankle. Many corrective procedures that previously required an arthrotomy or other open procedure can be completed with the assistance of the arthroscope.

Arthroscopic equipment has certain requirements for care and handling. Fiberoptics, lenses, and cameras are heat-sensitive, requiring consideration for sterilization. Temperatures and moisture generated by steam autoclaves can damage materials used in video equipment or deteriorate the sealant, making the moisture accessible to the lens. Alternatives to steam sterilization for

AMBULATORY SURGERY CONSIDERATIONS

Arthroscopic Surgery

Ambulatory surgery has long been part of orthopedic surgery. Recent advances in minimally invasive surgery and postoperative pain management have led to even more orthopedic procedures being performed in an ambulatory setting.

The most important factor in ambulatory surgery is patient selection. Appropriate patient selection is essential for successful orthopedic ambulatory surgery. Surgical, anesthesia, and nursing departments should work together to define the criteria used to identify suitable candidates for ambulatory surgery. Red flags should identify any patient with potential problems that indicate inability to tolerate the surgical procedure as an outpatient.

Preoperative assessment can determine which patients are the best candidates for ambulatory surgery. Careful review of health history, social history, and potential limitations postoperatively is vital in the initial assessment. Special attention to mobility both preoperatively and postoperatively is key for the orthopedic ambulatory surgery patient. Patients who will experience significant limited mobility postoperatively, live alone with no help available postoperatively, and have multiple medical co-morbidities are not ideal candidates for orthopedic ambulatory surgery. Patient education is initiated during the preoperative assessment. Gait-training, pain management, postoperative instructions, and transportation should be addressed preoperatively. Arrangements for any special equipment necessary for postoperative recovery should be made preoperatively. Attention to postoperative details before surgery will prevent delays with patient discharge postoperatively.

The anesthesia evaluation is done during preadmission testing. At that time, the anesthesia provider will develop a plan of care best suited for the patient and the anticipated surgery. Patient co-morbidities, length of procedure, and positioning during the procedure as well as the surgery itself are taken into consideration when establishing a plan of care.

KNEE ARTHROSCOPY

Knee arthroscopy is a common orthopedic ambulatory surgery procedure. New technology and approaches in surgery allow additional procedures to be done through the arthroscope. Once the patient has been identified as a candidate for ambulatory surgery, preoperative planning for preadmission testing, anesthesia evaluation, and patient education begin. The popular choice of anesthesia is one of two types based on patient history. Choices include regional or general anesthesia. Most providers prefer regional anesthesia for knee arthroscopy because of the decreased complication rates postoperatively. On the day of surgery, the history and physical are again reviewed with the patient. The surgical site is marked according to standards established by The Joint Commission and hospital policy. The patient is taken to the OR, anesthetized, prepared, and positioned for surgery. With regional anesthesia, those patients who would like to remain alert during the procedure can do so, watch the surgery on the monitor, and even converse with the surgeon about the findings. Once the surgery is over, a local anesthetic is injected into the joint to minimize pain. The length of the postoperative period depends on the regional anesthetic and the dose used. Patients will regain sensation and motion from trunk down to toes. Strength should be taken into consideration when gait-training is initiated. Patients may be discharged once discharge criteria are met, physician orders are reviewed with the patient, written discharge instructions and prescriptions are given to the patient, and the responsible adult escort is present. Phone numbers for any emergency should be listed on both physician and hospital discharge sheets.

this equipment are ethylene oxide, cold sterilization, and high-level disinfection. Each requires consideration of patient care options for consistency. Equipment must be soaked according to the manufacturer's instructions, followed by complete rinsing and immersion in sterile water to prevent chemical burns. Cold-water sterilizing machines, which use bactericidal and sporicidal agents, can also be used to sterilize heat-sensitive equipment.

Scopes, lenses, and fiberoptic cords should be handled carefully, and cords should never be kinked or twisted. Gradual deterioration and fiber breakage occur in mishandled cables, and light cannot be transmitted. When stored, the cords should be loosely coiled or hung.

Two types of arthroscopy may be performed. *Diagnostic arthroscopy* is for patients whose diagnosis cannot be determined by history or physical examination or whose CT or MRI findings are insufficient to warrant surgical exploration. Diagnostic arthroscopy may be performed before an anticipated arthrotomy, and surgical treatment may be modified on the basis of the findings of the arthroscopic examination. *Operative arthroscopy* is for patients presenting with an intraarticular abnormality or ligamentous injury.

Arthroscopy of the Knee

The knee is the joint in which arthroscopy lends itself to the greatest number of diagnostic and surgical procedures (Patient Safety). Arthroscopic surgery of the knee is indicated for diagnostic viewing, synovial biopsies, removal of loose bodies, resection of plicae, shaving of the patella, synovectomy, partial meniscectomy, meniscus repair, and ACL reconstruction. Anesthesia for knee arthroscopy may be general, spinal, or local. Tourniquets are often placed on the thigh but are inflated only if bleeding obscures the view. If there are no contraindications, an epinephrine solution may be injected at the portal sites or diluted into the distention fluid.

Procedural Considerations. The perioperative nurse assists with positioning the patient in the supine position on a standard OR bed. The surgeon may perform EUA before the patient is placed in position for the arthroscopy. The foot end of the bed may be flexed 90 degrees (Figure 19-85). A lateral post can be attached to the bed at the level of the midthigh. This post can provide a method of countertraction to open the medial side of the joint, providing better visualization of structures. After the leg is prepped, the entire extremity is draped to allow complete range of motion and manipulation of the knee joint. The procedure requires specialized equipment for fluid collection and personnel protection.

Instruments and equipment needed for an arthroscopy depend on whether the procedure is diagnostic or operative. Diagnostic arthroscopy instruments include arthroscopy instrumentation (Figure 19-86); arthroscopes of 30 and 70 degrees; video with camera, light source, and peripheral equipment (Figure 19-87);

PATIENT SAFETY

Patient Safety in Office-Based Surgery

Recent trends to decrease healthcare costs have led to an evolution in surgery. Approximately 70% of patients are now undergoing surgery in outpatient settings, with up to 25% of those procedures performed in physician offices. Two thirds of all operations performed in 2006 were done as outpatient procedures. As we see a greater shift to office-based surgery (OBS), patient safety can be improved by clearly addressing particular issues within the physician office setting, including patient selection and informed consent, surgeon training, facility accreditation and maintenance, anesthesia guidelines, prevention of medication errors, CPR training and emergency transfer protocols, and reporting and disclosing of adverse outcomes. Nurses play an important part in OBS. Even though procedures are done in the office, the same standards of care apply. Equipment and instrumentation preparation, intraoperative patient monitoring, sterile technique, and specially trained personnel are vital. The use of preoperative and postoperative checklists by the surgeon guarantees patient safety during the perioperative period.

Modified from American Association of Orthopaedic Surgeons: *Patient safety in office-based surgery,* available at www3.aaos.org/member/safety/officeascreport.cfm. Accessed April 25, 2009.

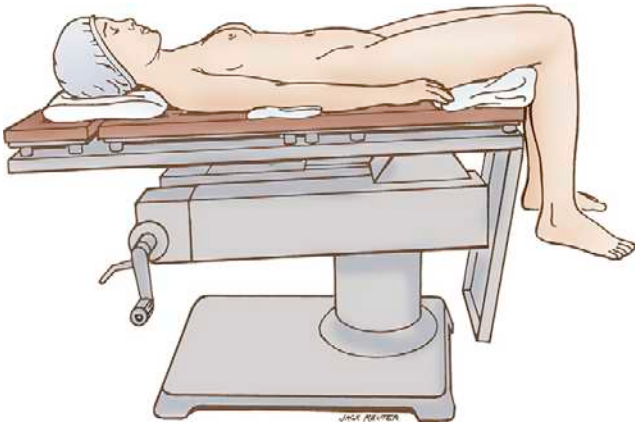

FIGURE 19-85 Positioning for a knee arthroscopy to enhance visualization.

an arthroscopy pump and tubing (Figure 19-88); inflow and egress cannulae (Figure 19-89); 3-L bags of normal saline or lactated Ringer's solution; and a spinal needle. Operative arthroscopy instruments depend on the procedure planned. Arthroscopic powered shavers and abraders (Figure 19-90) are almost universally used. Instruments specific for ACL reconstruction or meniscal repair will be needed if those procedures are planned.

Operative Procedure

DIAGNOSTIC ARTHROSCOPY

1. The surgeon marks the anteromedial and anterolateral joint lines and portal positions with a skin marker.
2. The skin areas for portal placement are infiltrated with 1% lidocaine with 1:200,000 epinephrine. If the knee has an effusion, the surgeon aspirates it with a 16-gauge needle on a 60-ml syringe, followed by injection of a small amount of distending fluid.
3. After a small stab incision with a #11 knife blade, the surgeon inserts the irrigation cannula and trocar into the lateral suprapatellar pouch near the superior pole of the patella. Lactated Ringer's or normal saline solution is connected to the cannula, and the joint is distended using gravity or a pressure-sensitive arthroscopy pump.
4. A stab incision is then made anterolaterally or anteromedially 2 to 3 mm above the tibial plateau or patellar tendon at the joint line. A sharp trocar and sheath are inserted through the stab wound and just through the capsule.
5. A blunt trocar is used to pass the sheath into the knee joint. The surgeon removes the trocar and inserts a 30-degree scope into the sheath. The light source and video camera are connected to the scope.
6. The inflow may remain in the suprapatellar area, and the egress tubing is connected to the arthroscope, or the position may be reversed.
7. A spinal needle can be introduced under direct vision to determine the best angle for an opposite portal for insertion of probes and operative instruments. The cruciates and menisci are probed to determine integrity and tears.
8. The scope is moved to the opposite portal to allow a complete examination to be performed.
9. The joint is irrigated periodically and at the end of the procedure to maintain good visualization and clear the joint of blood and tissue fragments.
10. The surgeon closes the portals with nylon or undyed polyglactin suture and ½-inch wound closure strips.
11. Bupivacaine (Marcaine) 0.25%, 30 ml, with epinephrine 1:200,000 may be injected intraarticularly to minimize bleeding and postoperative pain.
12. Gauze dressing, soft padding, and 4-inch and 6-inch elastic bandages are applied.

OPERATIVE ARTHROSCOPY. Operative arthroscopy includes procedures for resection of synovial plica, patellar debridement, excision of meniscal tears, partial or total meniscectomy, lateral retinacular release, removal of loose bodies, abrasion or drilling of osteochondral defects, synovectomy, treatment of osteochondritis dissecans, meniscal repairs, and ACL reconstruction.

Arthroscopic Resection and Repair of Meniscal Tear. Menisci are important structures in the knee joint that distribute load across the joint and provide capsular stability. A tear in the meniscus is the most common knee injury requiring arthroscopic surgery (Figure 19-91). Although both menisci can sustain tears, the medial meniscus is injured much more frequently than the lateral one.

Treatment of meniscus tears is aimed at preserving the structures. Some minor tears heal with cast immobilization, but some persist and cause symptoms. In these more severe cases, surgical intervention is necessary. A partial or complete meniscectomy may be necessary to alleviate troublesome symptoms such as locking, pain, and swelling (Figure 19-92). Partial meniscectomy is preferred, leaving a peripheral rim to share load bearing and stabilize the knee. Complete meniscectomy removes all of this load-bearing protection and also reduces knee stability. The goal is to leave an intact, balanced rim.

Arthroscopic meniscal repair is widely accepted as the standard of care. Arthroscopy provides better exposure than an arthrotomy does and enables the surgeon to approach the meniscus from the inner margin, where most tears begin.

FIGURE 19-86 Arthroscopy instrumentation.

FIGURE 19-87 Arthroscopy tower with video monitor, light source, camera, and shaver system.

FIGURE 19-88 Arthroscopy pump.

Suture repair is appropriate for meniscal tears occurring in the vascular zone (outer 10% to 25%), which heal predictably with repair and immobilization.

Operative Procedure

1. Steps 1 to 9 of the diagnostic arthroscopy procedure are repeated.
2. Working and scope portals are determined. The lateral bucket handle tear is identified, displaced, and reduced with a probe.
3. The attachment of the anterior horn of the meniscus is cut with a hook knife and clamped with a grasper.
4. An accessory portal is determined with a spinal needle.
5. The surgeon maintains traction and twisting motions on the meniscal horn to present a better edge to divide the remainder of the tear. Various scissors or push knives can be used to complete resection.
6. The motorized shaver is used to trim any frayed edges of the meniscus.

7. Limited debridement of chronic tears is completed to clean the edges.
8. When the medial meniscus is to be sutured, the surgeon places a cannula next to the inner edge of the tear. Two long meniscal-stitching needles with synthetic absorbable suture are inserted into the cannula, through the meniscus, across the tear, and through the capsule.
9. The surgeon palpates the needle tips beneath the skin, and makes a small incision to pull the suture out of the joint.
10. The sutures are tied over the capsule. Positioning the cannula enables either horizontal or vertical sutures to be placed.
11. After completing partial meniscectomy or suture repair, the surgeon irrigates the joint.
12. The incisions are closed, and the knee is lightly dressed and wrapped with soft rolled padding and elastic bandages.

FIGURE 19-89 Cannulae.

A

B

FIGURE 19-90 Arthroscopic shaver, **A**, with console, **B**.

Arthroscopic Anterior Cruciate Ligament Repair. The ACL is an important stabilizing structure of the knee and is the most frequently torn ligament. Injury is usually a result of simultaneous anterior and rotational stresses. Candidates for ACL reconstruction are active individuals with instability that is sufficient to interfere with their activities and that has failed to respond to bracing, rehabilitation, exercises, and other nonoperative treatment methods. The selected treatment method depends on the classification and severity of the tear, the experience and preference of the surgeon, and a history of a previous failed repair.

ACL reconstruction may be intraarticular, extraarticular, or a combination of both. Arthroscopic repair causes less patellar pain and decreased disturbance of extensor mechanisms and therefore is becoming the treatment of choice if there is no other significant capsular instability or gross disruption of the knee joint.

ACL repair most often involves replacement of the ligament with a substitute. Substitutes include autografts, allografts, and synthetic ligaments. Autografts are currently the method of choice, with a free central-third patellar tendon graft attached to patellar and tibial bone blocks used most often. The semitendinosus tendon and iliotibial band are sometimes used instead. Autografts may be used alone or augmented, although

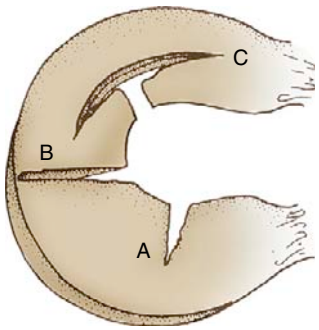

FIGURE 19-91 Meniscal tear. *A*, Incomplete. *B*, Complete. *C*, Incomplete longitudinal.

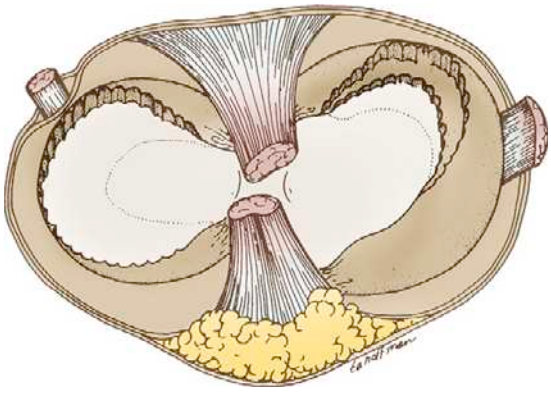

FIGURE 19-92 Lateral and medial meniscal excision.

synthetic augmentation devices have fallen out of favor because of the development of chronic synovitis.

Procedural Considerations. Instrumentation for an ACL repair includes all instruments required for an operative arthroscopy. In addition, an ACL reconstruction guide system, fixation device of choice (bone screws, staples, spiked washers, or interference screws), bone tunnel plugs (Figure 19-93), a power drill, and microsagittal saw will be needed. If the surgeon believes that isometric placement of the graft is important, a tension isometer will be needed, as well as a system for finding that intraarticular position.

Operative Procedure: Reconstruction of the Anterior Cruciate Ligament with Patellar Tendon Graft

1. The surgeon performs an EUA immediately after anesthesia induction to further evaluate the stability of the knee.
2. A diagnostic arthroscopy is then carried out through the standard anteromedial and anterolateral portals.

FIGURE 19-93 Example of a bone tunnel plug.

3. Any meniscal tears or other intraarticular injuries are treated before attending to the ligament.
4. The surgeon debrides any remaining ACL tissue with a full-radius resector.
5. A notchplasty is then performed, widening the intercondylar notch with a 4.5-mm arthroplasty burr, rasp, osteotome, and curettes. Notchplasty aids in arthroscopic visualization and protects the graft from abrasion and amputation.
6. After preparation of the intercondylar area, the surgeon makes a small incision on the distal lateral aspect of the femur and extends the incision to the flare of the lateral femoral aspect of the condyle. A femoral aiming device is positioned, and a guide pin is inserted from the femoral site into the posterosuperior region of the intercondylar notch at an isometric point (Figure 19-94). Another small incision is made anteriorly, below the knee and medial to the tibial tubercle.
7. The tibial aiming device is positioned, and the surgeon inserts a guide pin from the anterior tibial incision into the intercondylar notch, anterior and medial to the center of the tibial anatomic attachment site of the ACL.
8. The pins are then replaced with a heavy suture passing through the femoral and tibial pin sites.
9. Isometric placement of the guide pins is checked with a tensioning device that is attached to the heavy suture. The

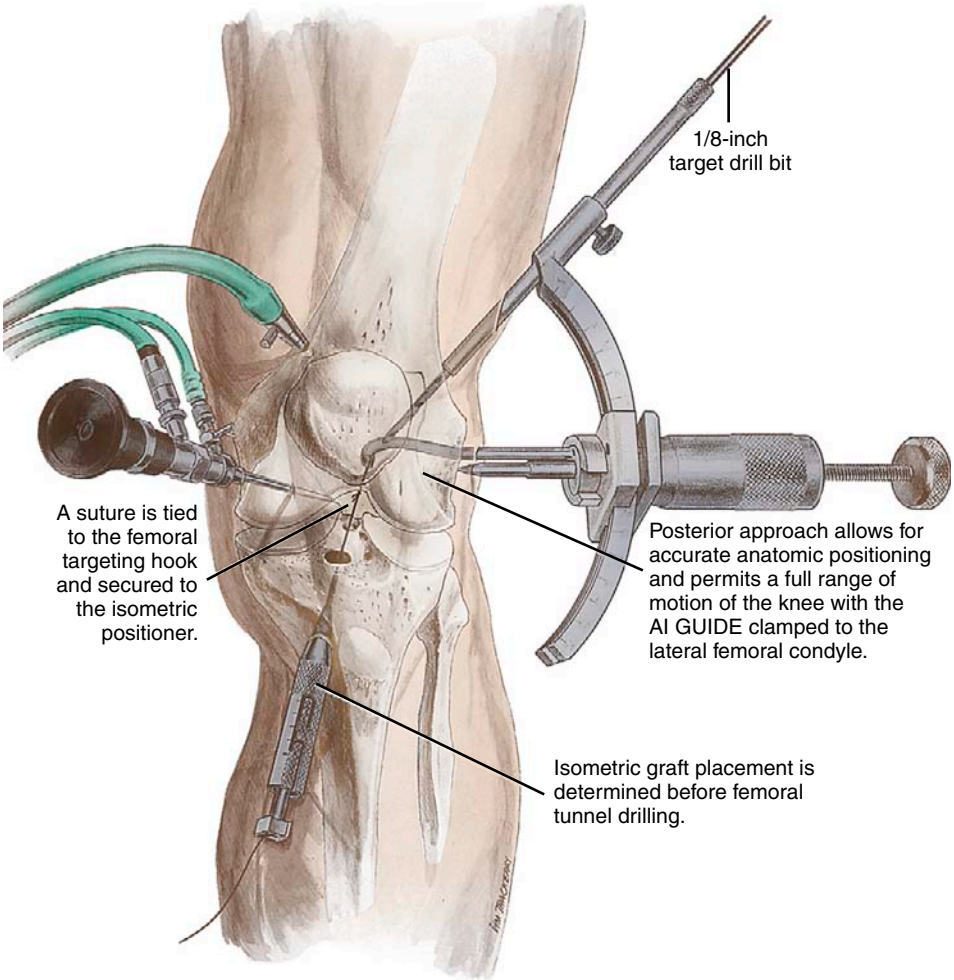

FIGURE 19-94 Femoral aiming device positioned for anterior cruciate ligament reconstruction.

knee is moved through a range of motion to determine correct isometric measurement.

10. Once isometric positioning is determined, the surgeon makes a longitudinal skin incision to the midline near the patellar tendon.
11. The central-third portion of the patellar tendon with tibial and patellar bone plugs is harvested with a mini-saw and osteotome. The graft is sized to the appropriate width, usually 10 to 12 mm, using sizing tubes (Figure 19-95).
12. Heavy nonabsorbable suture is placed through drill holes made at each end of the graft in the bone plugs (Figure 19-96).
13. The guide pins are then reinserted and overdrilled with cannulae that are close in width to the prepared graft. Overdrilling establishes the tunnels so that they are in the center of the previous insertion sites of the ACL.

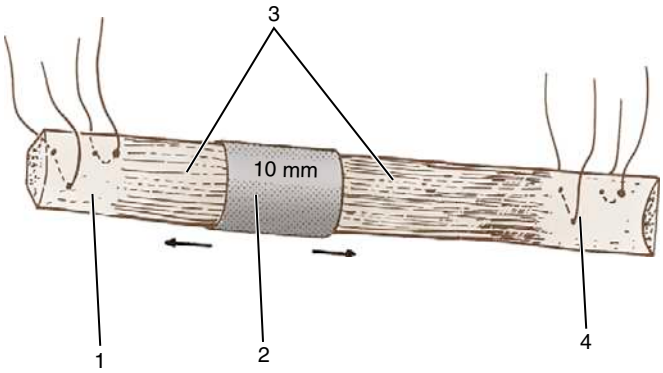

FIGURE 19-95 Sizing tubes are used to determine the minimum diameter of tunnel necessary for passage of the graft.

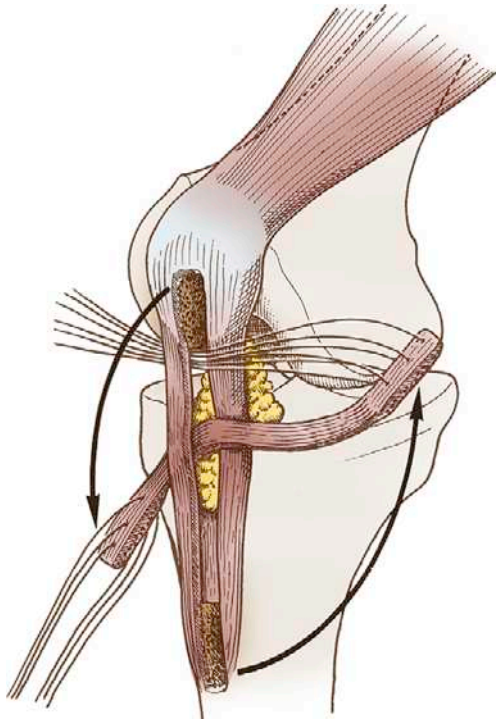

FIGURE 19-96 Three drill holes are placed into each bone block of the patellar graft, and a heavy suture is placed into each drill hole.

14. The surgeon smoothes the femoral and tibial osseous tunnels with curettes, a rasp, or an abrader. If the tunnels are made before the graft is harvested, they are temporarily occluded with bone tunnel plugs to minimize fluid extravasation.
15. Both ends of the graft are fixed with a barbed staple, bone screw with washer, interference screw, or ligament button (Figure 19-97).
16. The incisions and joint are irrigated and closed.
17. A hinged knee brace may be applied over the dressing. The brace allows 10 to 90 degrees of motion.

Arthroscopic Posterior Cruciate Ligament Repair. Surgical procedures for tears of the PCL are considered if significant disabling instability has occurred. Patients usually return to adequate function without operative treatment. The arthroscopic procedure for repair of the PCL is similar to the technique used to repair the ACL, except that isometric placement is posterior within the joint and the femoral attachment is proximal to the medial epicondyle.

Arthroscopy of the Shoulder

Shoulder arthroscopy is a useful diagnostic and therapeutic tool in the management of shoulder disorders. It is particularly beneficial in the evaluation and management of patients with chronic shoulder problems. Arthroscopy provides extensive visualization of the intraarticular aspect of the shoulder joint and is performed for removal of loose bodies; lysis of adhesions; synovial biopsy; synovectomy; bursectomy; stabilization of dislocations; correction of glenoid labrum, biceps tendon, and rotator cuff tears; and relief of impingement syndrome.

Procedural Considerations. The patient is either in the lateral position or in a sitting position using a "beach chair" positioner. The lateral position is maintained using a vacuum beanbag positioning device or lateral rolls with a kidney rest.

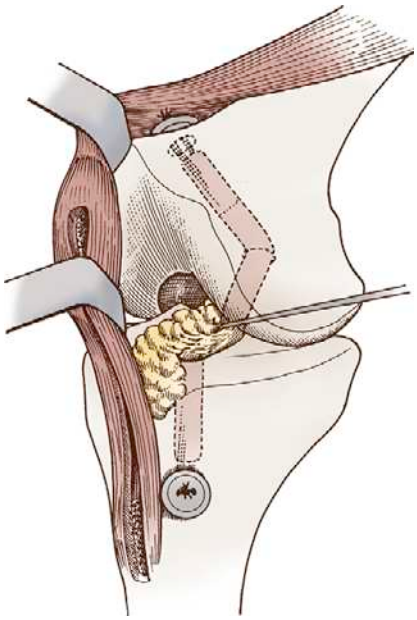

FIGURE 19-97 A patellar tendon graft is affixed by tying of sutures over bone buttons at the tibial and femoral drill holes.

Three-inch adhesive tape is secured across the patient's hips. Proper padding of the uninvolved axilla and lower extremity is important to prevent soft tissue or neurovascular problems. The affected extremity is placed in a shoulder suspension system, and Buck's traction or a Velcro immobilizer is applied to the forearm to achieve adequate distraction to the glenohumeral joint. The extremity is abducted 40 to 60 degrees and forward-flexed 10 to 20 degrees, with 5- to 15-pound weights placed on the pulley system. Weight may be added to further distract the glenohumeral joint, taking care not to overstretch the axillary artery.

The shoulder is prepped and draped free, permitting full range of motion during the procedure.

The operative instruments and arthroscope commonly used for the knee may also be used in the shoulder, plus an 18-gauge needle, switching sticks, and a Wissinger rod. A variety of fixation devices (screws and tacks) can be used to repair bony defects and tears of the labrum.

Operative Procedure (Figure 19-98)

1. An 18-gauge spinal needle is inserted through the posterior soft spot and directed anteriorly toward the coracoid process, where the surgeon's index finger has been positioned.
2. The glenohumeral joint is distended with normal saline or lactated Ringer's solution. This facilitates entry of the arthroscope.
3. Bupivacaine (Marcaine) 0.25%, 2 to 3 ml, with epinephrine 1:200,000 is injected along the needle track to minimize bleeding.
4. With the needle removed, the surgeon makes a stab incision with a #11 blade over the needle site.
5. The arthroscope sleeve and sharp trocar are then introduced through the posterior joint capsule.
6. Once the capsule has been penetrated, a blunt obturator replaces the sharp trocar to enter the joint.
7. The arthroscope is inserted and attached to inflow and outflow tubing, the video camera, and the light source.

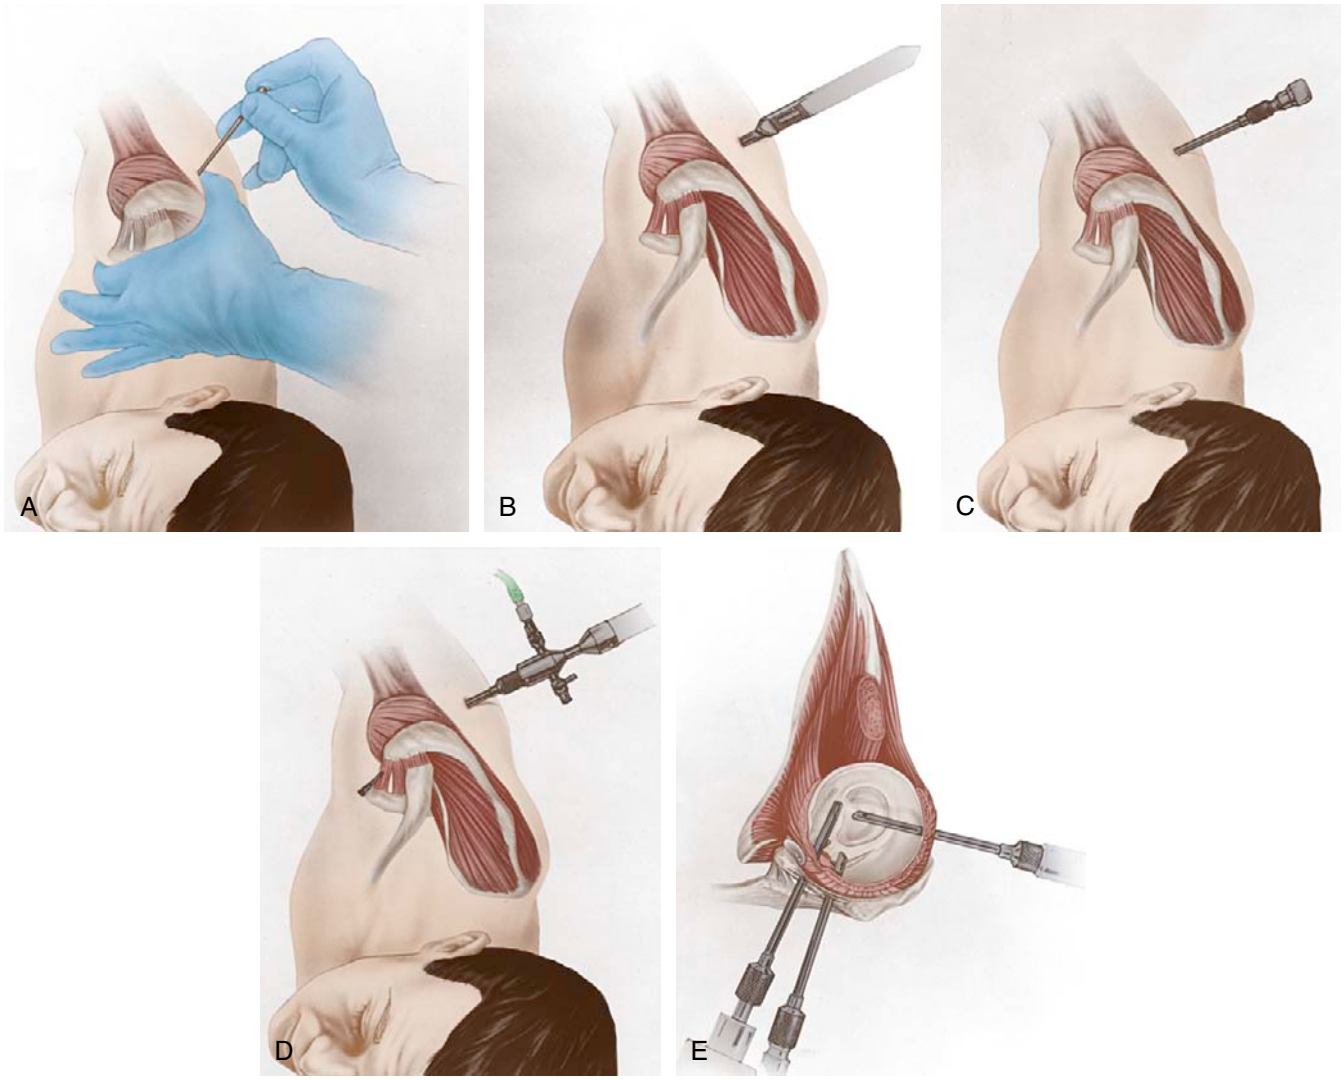

FIGURE 19-98 Shoulder arthroscopy. **A**, The spinal needle is inserted for dilation of the joint if indicated. **B**, An incision is made over the glenohumeral joint. **C**, The arthroscope sleeve and sharp trocar are inserted. **D**, The arthroscope is inserted and attached to the inflow and outflow tubing, video camera, and light source. **E**, Operative instruments are placed through the portal.

8. Operative instruments are placed through an anterior portal that is established laterally to the coracoid process by using a Wissinger rod. A third portal can be established near the anterior portal or supraspinous fossa portal. Switching sticks are used to change portals.
9. The surgeon moves the arm and rotates it as needed to visualize various structures in and around the joint.
10. Glenoid tears can be repaired with the insertion of an absorbable fixation tack.
11. At the conclusion of the procedure, the joint is irrigated. The surgeon may inject a long-acting local anesthetic into the joint and subacromial space through the portal to minimize postoperative discomfort.
12. The puncture wounds are closed and dressed with a sterile 4 × 4 gauze pad. The patient's arm is placed in a sling for recovery.

Arthroscopy of the Elbow

The elbow joint is accessible to arthroscopic examination, although it requires more attention to detail than the knee because instruments must be placed through deeper muscle layers and close to important neurovascular structures.

Arthroscopy of the elbow, both diagnostic and operative, has become fairly routine. Indications for its use include extraction of loose bodies, evaluation or debridement of osteochondritis dissecans of the capitulum and radial head, partial synovectomy in rheumatoid disease, debridement and lysis of adhesions of posttraumatic or degenerative processes at or near the elbow, diagnosis of a chronically painful elbow when the diagnosis is obscure, and evaluation of fractures of the capitulum, radial head, or olecranon.

Procedural Considerations. General anesthesia is preferred to local anesthesia because it affords complete comfort to the patient and provides total muscle relaxation.

The perioperative nurse assists with placing the patient in either the supine or the prone position. In the supine position, the forearm is flexed on an armboard or placed in a prefabricated wrist gauntlet connected to an overhead pulley device and tied off at the end of the OR bed. This provides excellent access to both the medial and lateral aspects of the elbow, allows the forearm to be freely pronated and supinated, and places the important neurovascular structures in the antecubital fossa at maximum relaxation.

A tourniquet is routinely used for hemostasis. The entire arm, including the hand, is prepped and draped.

The three portals most commonly used for diagnostic and operative arthroscopy of the elbow are the anterolateral, anteromedial, and posterolateral.

Operative arthroscopy instruments commonly used for the knee may also be used in the elbow. However, smaller-diameter scopes and instruments may be desired instead.

Operative Procedure

1. The surgeon outlines the bony anatomic landmarks with a sterile marking pen before initiation of the procedure. Lateral structures to be marked and identified are the radial head and the lateral epicondyle. The medial epicondyle is also marked.
2. An 18-gauge needle is inserted anteriorly to the radial head from the lateral side, and the joint is distended.
3. Once joint distention has been achieved with approximately 15 to 30 ml of lactated Ringer's or normal saline solution, the surgeon makes a stab wound incision with a #11 blade, and inserts the sharp trocar with cannula through the joint capsule.
4. The sharp trocar is replaced with the blunt obturator to provide safe entry of the cannula into the joint.
5. The scope replaces the blunt obturator and is attached to the video and light source.
6. A second portal and third portal are established anteromedially and posterolaterally for triangulation. With the patient's elbow flexed to 90 degrees and adequate distention maintained at the time of insertion of the instruments, the surgeon displaces the neurovascular structures anteriorly. This provides a greater area above the medial and lateral humeral epicondyles in which to insert the various instruments.
7. Outflow and inflow are controlled by alternating the valve on the scope or using a separate 18-gauge needle with drainage tubing.
8. After diagnostic and operative procedures have been completed, the joint is irrigated, the puncture sites are sutured, and a compression dressing is applied with soft rolled padding and elastic bandages.

Arthroscopy of the Ankle

The talocalcaneal articulations are complex and play an important role in the movements of inversion and eversion of the foot. The subtalar joints function as a single unit, but anatomically they are divided into anterior and posterior joints. The surgeon and perioperative nurse must be familiar with the extraarticular anatomy of the ankle to prevent neural or vascular damage.

Indications for ankle arthroscopy include osteochondral fragments or loose bodies, persistent ankle pain after trauma and despite adequate conservative treatment, biopsy, posttraumatic arthritis of the ankle joint, unstable ankle before lateral ligamentous reconstruction, and osteochondritis dissecans of the talus.

Procedural Considerations. General anesthesia is preferable because manipulation and distraction of the joint to obtain adequate arthroscopic viewing require muscle relaxation. The position of the patient is based on the surgeon's preference. The patient may be supine with the knee flexed approximately 70 degrees or supine with a sandbag under the buttock of the operative side. Ankle and thigh holders may be used; when better posterior visualization is necessary, a distractor may be used to increase the space between the tibia and talus. A tourniquet is placed around the upper thigh but is not used unless excessive bleeding, uncontrolled by irrigation, is encountered. Routine skin prepping and draping are done. Miniaturized instruments and needle scopes for the ankle are used.

Operative Procedure

1. Using a sterile marking pen, the surgeon outlines important extraarticular anatomic structures on the skin.
2. The ankle joint is then examined, using the anterolateral portal. The anteromedial joint line is palpated, and an 18-gauge, 1½-inch needle is inserted into the joint.
3. Sterile plastic extension tubing is attached to the needle, and a 50-ml plastic Luer-Lok syringe filled with normal saline is

connected to the tubing to distend the joint. Approximately 15 to 20 ml is needed.
4. After intraarticular injection is confirmed by the ease with which the saline can be injected and by palpation of the joint as it is distended, the surgeon makes a small incision with a #11 blade over the site of the anterolateral portal.
5. A hemostat is then inserted and used to dissect to the capsule.
6. The sheath of the arthroscope and sharp trocar are placed into the incision, angled approximately 30 to 45 degrees laterally, and inserted with a sharp plunge as joint distention is maintained. Entrance into the joint is felt as the sleeve and trocar "pop" through the capsule and is confirmed by the rush of saline on removal of the trocar from the sheath.
7. The arthroscope is inserted into the sheath, the needle is removed, and the plastic tubing and syringe are attached to the stopcock on the arthroscope sleeve. The video camera and light source are connected to the scope. Joint distention must be maintained.
8. Triangulation through other portals is easily done by first inserting the 18-gauge needle for localization while viewing with the arthroscope. Posterior viewing is done in the same fashion except that the patient is usually placed in the prone position and instruments are inserted through the posterior portals.
9. After the procedure is completed, the surgeon irrigates the joint, closes the wounds with wound closure strips or a single suture, and covers the wound with a dressing and short leg compression elastic wrap.

SURGERY OF THE SPINE

Treatment of Back Pain

Back pain is a natural result of degenerative and arthritic change, punctuated by protrusion or rupture of a disc. It gradually progresses but may also disappear gradually. With aging, a degenerative disc-space narrowing or facet arthropathy begins to appear radiologically. The lower lumbar spine carries the burden of the body's weight, holds a person upright, and returns the body to the vertical position from sitting, lying, or a bent-over position. Degenerative changes, ruptured disc, and facet arthropathy develop at the lowest two limb segments, where the greatest weight, torsion, and shearing stress occur. This degeneration sometimes extends into the upper and middle spine.

Cervical-spine degenerative disc narrowing also develops most often at the two lowest cervical spaces, which are also the levels of greatest stress resulting from movement of the head and neck. Sometimes lumbar or cervical degenerative changes develop early from excessive repetitive movements or injury.

Epidural steroid injections, electrodes, stimulators, braces, or traction may treat back pain. A natural recovery may result after 6 or 7 days of intense pain, subsiding between 6 weeks and 4 months. Motor and sensory deficits usually disappear with resolution of pain. The ability to recover without surgery depends on fragment size and compression on the nerve root. Neural compression remains the major indication for disc excision.

Spinal fusion is a consideration, usually for patients with demonstrable posttraumatic, postsurgical, rheumatoid, infectious, or neoplastic instability.

Procedural Considerations. After assessment, the patient-specific plan of care is implemented. Radiographs are obtained. The perioperative nurse assesses the patient's bilateral pulses and range of motion in all of the extremities. Elastic wraps or sequential compression devices may be placed. The patient is positioned prone to eliminate lordosis, reduce venous congestion, and keep the abdomen free with chest rolls or special frames after induction of general anesthesia. Depending on the extent of the procedure, blood availability may be required. The skin is prepped and the area draped. A spinal laminectomy set is used, in addition to a spinal retractor of choice and a bipolar ESU. Hemostatic adjuncts such as gelatin foam, oxidized cellulose strips, thrombin, and bone wax should be available.

Operative Procedure

LAMINECTOMY

1. The surgeon makes a midline incision over the affected disc and carries it sharply down to the supraspinous ligament.
2. The supraspinous ligament is incised, and the muscles are dissected subperiosteally from the spines and laminae of the vertebrae. These are retracted with a self-retaining retractor.
3. The surgeon denudes the laminae and ligamentum flavum with a curette.
4. A small part of the inferior margin of the lamina is removed with a rongeur.
5. The ligamentum flavum is grasped and incised where it fuses with the interspinous ligament, and this flap is then sharply removed to expose the dura.
6. The dura is then retracted medially, and the nerve root is identified.
7. Once identified, the nerve root is retracted medially so that the underlying posterior longitudinal ligament can be exposed.
8. The surgeon incises the posterior longitudinal ligament over the intervertebral space in a cruciate fashion, and enters the disc space with a pituitary grasping forceps.
9. The disc material is systematically removed, taking care not to exceed the distance to the anterior annulus. A complete search for additional fragments of nucleus pulposus, both inside and outside the disk space, is then carried out.
10. Residual bleeding is controlled with bipolar coagulation.
11. The surgeon closes the wound with absorbable sutures in the supraspinous ligament and subcutaneous tissue. Various nonabsorbable sutures or staples are used for skin closure.

Minimally Invasive Spine Surgery

Advances in technology have made minimally invasive spinal surgery (MISS) available to certain patients. Candidates for minimally invasive spine surgery are carefully selected by the surgeon. Conditions that may be amenable to MISS include disc herniation, spinal stenosis, and kyphosis. The need to convert from MISS to the traditional incision must be discussed with the patient before the surgery and the perioperative nurse and surgical technologist must prepare for that possibility. The microdiscectomy procedure, used to treat disc herniation, is described below.

Procedural Considerations. The perioperative nurse and surgical technologist ensure that all equipment is available and assembled before the patient's arrival into the OR. Equipment needed includes the C-arm, microscope, and radiolucent spinal table. After the administration of a general anesthetic,

FIGURE 19-99 Instruments used for tubular microdiscectomy.

the patient is positioned prone on the radiolucent spinal table. Care is taken to ensure proper padding of bony prominences and proper positioning of extremities. The skin is prepped and draped. Instrumentation for MISS includes the tubular microdiscectomy set and the tubular retractor (Figure 19-99). A high-speed drill and hemostatic agents such as gelatin foam, thrombin, and bone wax should be available. The perioperative nurse places sequential compression devices on the patient.

Operative Procedure

1. The surgeon inserts an 18-gauge spinal needle in the back at the level of the disc herniation and confirms the correct level with the C-arm.
2. The surgeon makes a 1- to 1.5-cm incision at the previously identified level.
3. A Cobb elevator and sequentially sized dilators are used to serially dilate the soft tissues, preserving the integrity of the muscles and ligaments.
4. The surgeon inserts a tubular retractor and connects the flex arm directly to the spinal table.
5. The tubular retractor is used as a viewing portal to visualize and operate on the spine (Figure 19-100).
6. The surgeon confirms the level again with x-ray and moves the draped microscope into position.
7. Using the long electrode on the ESU, the surgeon dissects the tissue.
8. A high-powered burr and/or assorted sizes of Kerrison punches are used to remove part of the caudal lamina.
9. Once nerve roots are identified, the surgeon enters the disc space and removes the extruded disc material with pituitary grasping forceps.
10. Gelatin foam and cotton pledgets are used to control bleeding along with the bipolar ESU.
11. The surgeon irrigates and closes the wound.

Pedicle Fixation of the Spine

Pedicle screw fixation (Figure 19-101) is a method of surgical fixation of the spinal column. Screw fixation was initially used in an attempt to avoid postoperative external immobilization and prolonged bed rest. Pedicle screw fixation has been used most often in degenerative processes, particularly iatrogenic instability after decompression, degenerative and isthmic spondylolisthesis, and diskogenic disease. It is also indicated for tumor, trauma, degenerative spinal disorders, postoperative hypermobility, and infection.

Three basic approaches for fixation have been described as the procedure has evolved. Each has improved on the first, based on anatomic placement of the screw. Positioning and placement of the screw within the spine are established after direct visualization of the pedicle.

Procedural Considerations. After the administration of a general anesthetic, the patient is positioned prone. The skin is prepped, and drapes are applied. A spinal laminectomy set is used in addition to the instrumentation and implants of choice, a spinal retractor, power equipment such as a high-speed motorized hand tool, and hemostatic adjuncts such as gelatin foam, thrombin, and bone wax. A bone graft set will be needed to harvest graft from the iliac crest.

Operative Procedure

1. The surgeon makes a standard midline incision. The surgeon follows the steps as described in the laminectomy procedure to expose the spine.
2. The areas of the pedicles to be fixated are located using external landmarks.
3. The surgeon removes the posterior cortical wall at the entrance site using a high-speed burr.

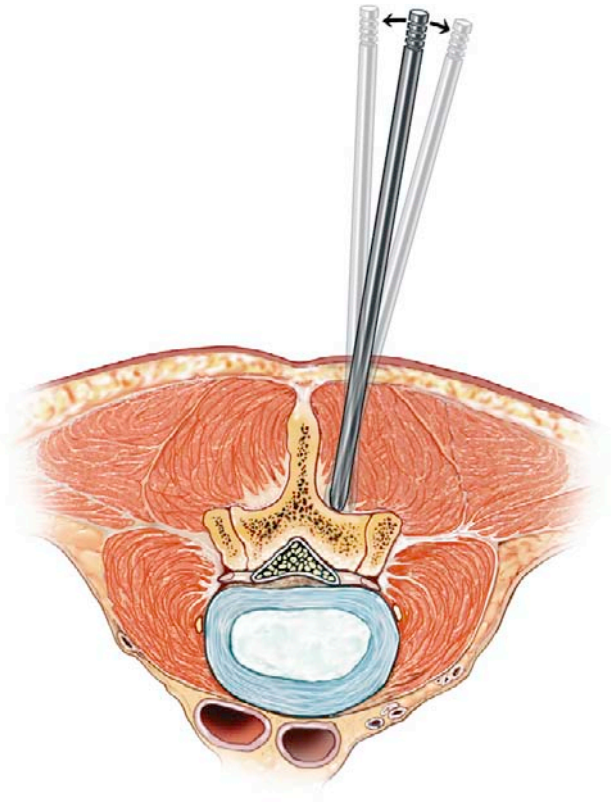

FIGURE 19-100 Wanding maneuver is used to change the position of the tubular retractor and reach different areas of the spine.

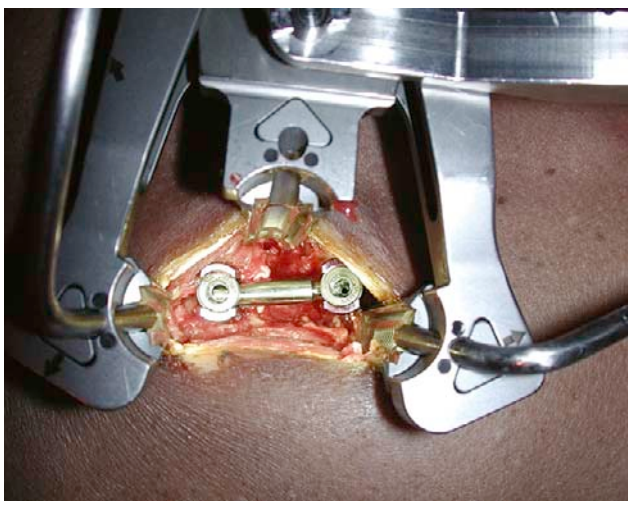

FIGURE 19-101 Pedicle screw placement using the MaXcess retractor and SpheRx fixation system by NuVasive, Inc.

4. A Penfield dissector is used to identify the entrance hole through the pedicle.
5. The surgeon inserts a gearshift probe to identify the path into the vertebral body.
6. The hole is tapped (5.5-mm tap) and widened.
7. The surgeon places the screw(s). Guidelines for screw sizes are 7 mm for S1, L5, and L4; 6.25 mm for L3 and L2; 5.5 mm for L1 and T12.

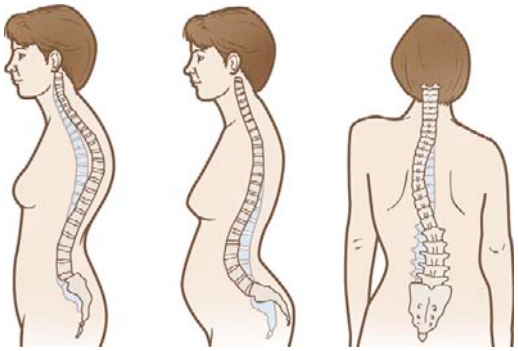

FIGURE 19-102 Scoliotic deformity.

8. A posterolateral graft is performed, using graft strips from the iliac crest.
9. The surgeon contours the plate or rod to approximate the patient's physiologic lordosis. The longitudinal device is locked onto the screws in the appropriate position.
10. A screw-plate system may require use of the oblique and transverse washers between the screw head and plate to provide a flush fit at the screw-plate interface.
11. The foramina are checked for patency before closure. The excess portion of the screw is cut close to the upper locking device.
12. A suction drain is placed; the wound is closed in layers.

Treatment of Scoliosis

Scoliosis is a three-dimensional deformity (Figure 19-102) with lateral deviation of the spinal column from the midline; it may include rotation or deformity of the vertebrae. Types are congenital, juvenile, adolescent, and adult. School screening programs provide quick and simple detection. For effective treatment of scoliosis, early detection is critical.

Scoliosis can be idiopathic (80% of the time) or congenital and may result from muscular or neurologic diseases or unequal leg lengths. Numerous posterior and anterior segmental spinal instrumentation systems are available for the treatment of idiopathic scoliosis. As a consequence, fixation strategies are more complex than they were with Harrington instrumentation. The newer systems provide better sagittal control and more stable fixation, allowing quicker mobilization of the patient. On thin patients, however, the bulk of these implants may be a problem.

Posterior Spinal Fusion with Harrington Rods. Posterior spinal fusion is most frequently performed in adolescence, when the laterally deviated curve is still flexible. Harrington rods are internal splints that help maintain the spine as straight as possible until the vertebral body fusion has become solid. Distraction rods are placed on the concave side of the curve, and compression rods are placed on the convex side. On the convex side of the curve, three to eight hooks are inserted in the transverse processes of the vertebrae and pulled together with a threaded rod. In this way the scoliotic deformity can be corrected as much as the flexibility of the spine allows.

The posterior elements of the vertebrae are denuded of soft tissue, and the bone graft is added. Blood loss can be expected, and an accurate record of the loss must be

maintained. After surgery the patient is placed in an immobilizing jacket.

Some disadvantages of the Harrington rod system over other systems are that there is only end-point fixation, rod breakage is increased, fixation is less, sagittal plane curves are difficult to manage, distraction for correction is not always desired, and the patient is required to wear a postoperative cast or brace. Other systems have evolved from the Harrington rods that are used for correction of some scoliotic deformities. It remains a feasible treatment of idiopathic scoliosis.

PROCEDURAL CONSIDERATIONS. The patient is placed in the prone position on a spinal table, or a spinal frame to facilitate respiration. Before the procedure begins, an x-ray cassette is placed under the patient so that a radiograph for accurate identification of the vertebrae to be fused can be taken during the operation. A single straight longitudinal incision is made down the midline of the back. Because of the amount of bleeding, the skin and subcutaneous tissues are often infiltrated with a vasoconstricting solution, such as epinephrine.

Basic spinal instrumentation and bone graft instruments are required, plus the Harrington rod instrumentation. A large pin cutter, designed to cut large pins but provided with a small end so that it will fit in the wound, should be available.

OPERATIVE PROCEDURE

1. The appropriate hooks are selected and inserted. A Harrington distraction rod of appropriate length is inserted through the two proximal self-adjusting hooks, which have been placed under the laminae.
2. A rod clamp is clamped onto the Harrington rod just below the hook, and a single regular spreader is used to obtain the first inch of distraction.
3. The Bobechko spreader is used to span over the first hook, closest to the smooth part of the rod, to apply distraction force on the most proximal hook.
4. Two C locking rings are inserted around the first ratchet immediately below the hook to prevent dislodgment of the hooks. The excessive length of protruding rod above the most proximal hook is removed with a rod cutter. The compression is tightened.

Luque Segmental Spinal Rod Procedure. The Luque segmental method employs smooth, L-shaped, stainless-steel rods, usually 3/16 or 1/4 inch in diameter, with sublaminar wires placed at every level possible. It is more secure and longer than the Harrington rod system and was the first system to employ multiple-point fixation. Luque instrumentation applies corrective forces to the spinal segments at each level, thereby spreading the corrective forces throughout the length of the deformity. Two Luque rods are wired to both sides of the spine. The rods are contoured to achieve no more than 10 degrees of increased correction beyond that exhibited on preoperative x-ray study.

PROCEDURAL CONSIDERATIONS. The patient is placed in the prone position as described for the Harrington rod procedure. Patient care is provided (see Laminectomy, p. 809). A straight midline incision is made in the back. Because of the amount of bleeding, the skin and subcutaneous tissues are often infiltrated with a vasoconstricting solution, such as epinephrine. Basic spinal instrumentation is required. In addition, Luque rods and instrumentation, a wire tightener and cutter, and bone graft instruments will be needed.

OPERATIVE PROCEDURE

1. The ligamentum flavum is detached, exposing the neural canal.
2. The surgeon passes doubled stainless-steel suture wire under the lamina. The wire loop is cut later to form two wires at each level.
3. Total bilateral facetectomies are made, forming posterolateral troughs for subsequent bone grafts.
4. Wedge osteotomies may be necessary in severe immobile curves to avoid stretching the spinal cord during correction.
5. The wire loop is cut, resulting in two separate wires at each level.
6. The L bend is secured to the base of the spinous process to prevent rod migration.
7. Initial placement of the convex rod is made.
8. Initial placement of the concave rod is made.
9. Transverse wiring is done to add increased stability to the system.
10. Stabilization of the lumbosacral joint is corrected by bending the rods distally to form sacral bars.

Cotrel-Dubousset System Procedure. The Cotrel-Dubousset system (Figure 19-103) provides three-dimensional correction of spinal deformities without sublaminar wiring and neurologic risks. This instrumentation permits distraction, compression, and derotation. The scoliotic curve is corrected by derotation and, at the same time, restores the normal sagittal contours. In addition to correction of scoliosis, the Cotrel-Dubousset system can be applied to correct kyphosis or lordosis and to stabilize and rebuild the spine after tumor resection or after injury. No external support is necessary. The Cotrel-Dubousset system has no ratchets or notches. It consists of metallic rods with diamond crosscut patterns on which hooks and screws can be positioned in any position, level, or degree of rotation. The rod is held in the open hooks with blockers. The rods are then interlocked by means of devices for transverse traction. The Cotrel-Dubousset system was the forerunner to the systems used today, such as the Texas Scottish Rite Hospital (TSRH) system and the Isola system.

PROCEDURAL CONSIDERATIONS. The patient is placed in the prone position after induction of general anesthesia. Patient assessment and precautions for the prone position are initiated. Basic spinal instrumentation is required in addition to the Cotrel-Dubousset system and instrumentation as well as the instruments used for harvesting the bone graft.

OPERATIVE PROCEDURE

1. Closed hooks are inserted at both ends of the surgical site, and open hooks are inserted at various levels between the closed hooks.
2. Decortication and facet excision are done at the remaining interposed vertebral levels for rod placement.
3. Bone graft is placed in the areas that will be under the rod.
4. The surgeon bends the appropriate concave rod to shape for sagittal-plane correction and manipulates it into the end hooks.
5. Stabilization along the length is achieved with blockers that anchor the rod into the open hooks.
6. The spine is then derotated using the rod holders. The frontal-plane scoliosis curve becomes the sagittal-plane kyphosis.
7. Hooks are reseated for secure fixation.

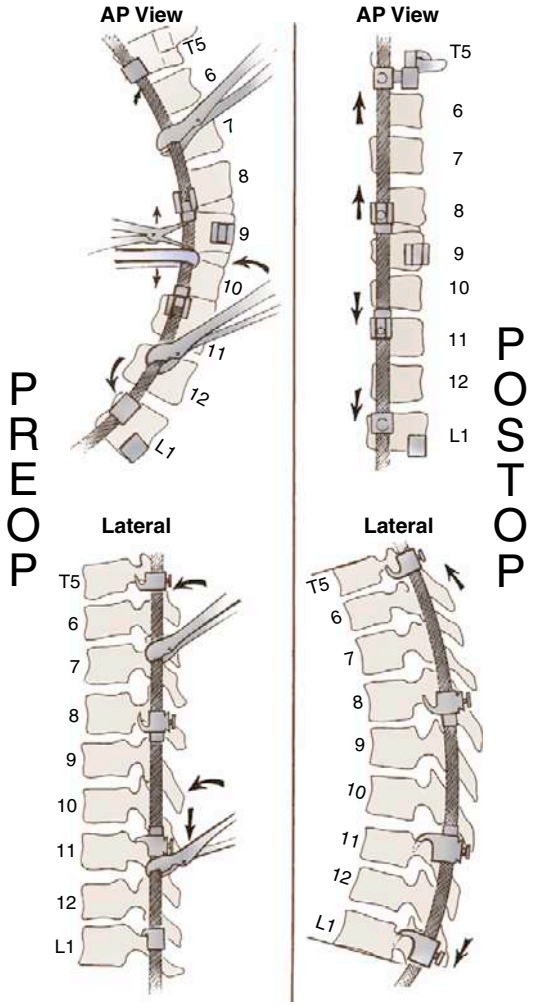

FIGURE 19-103 Cotrel-Dubousset system, representing rotation of rods.

8. To correct kyphosis, the surgeon bends the convex rod to shape and seats it.
9. Once the rods are placed, the surgeon applies the device for transverse traction (DTT), usually near the ends of the rods, to complete the stabilization.
10. Remaining bone graft is then applied to the fusion area.

Texas Scottish Rite Hospital (TSRH) Crosslink System. The TSRH crosslink system (Figure 19-104) is a multicomponent stainless-steel implant used to lock spinal rods together rigidly. Locking the rods increases construction stiffness and prevents rod migration. The system was originally designed for the Luque segmental system to prevent migration between the rods and wires before complete fusion occurred. By rigidly crosslinking the rods, loss of scoliotic correction was reduced. This system can also be used with the Harrington and Cotrel-Dubousset systems. Crosslinks are indicated when the rigidity of a spinal system alone is not sufficient to generate fusion in a reasonable amount of time.

PROCEDURAL CONSIDERATIONS. The patient is administered a general anesthetic and positioned prone. The skin is prepped, and drapes are applied. A spinal laminectomy set is used. Instrumentation and implants of choice, a spinal retractor, and power equipment such as a high-speed handheld tool will be necessary. Hemostatic adjuncts such as gelatin foam, thrombin, oxidized cellulose, and bone wax should be available.

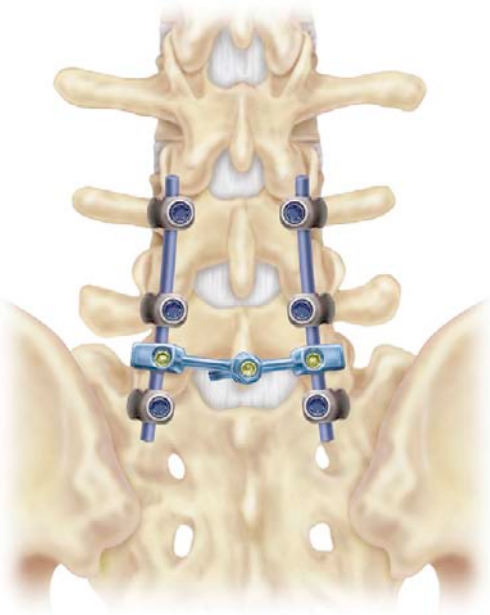

FIGURE 19-104 Texas Scottish Rite Hospital (TSRH) crosslink system.

OPERATIVE PROCEDURE

1. Eyebolts are placed on the spinal rods before the rods are implanted.
2. The rods are secured with hooks or wires, depending on the system used.
3. Once the rods are positioned, cross plates of varying widths accommodating different rod-to-rod distances are bolted in place between the rods and nuts.

Anterior Spinal Fusion with Isola Instrumentation. Isola instrumentation involves screw fixation into each vertebral body, complete disk excision and grafting, and segmental connection of the vertebral bodies. A semirigid rod connects the segments. The Isola anterior instrumentation is indicated in idiopathic scoliosis patients, approximately 10 to 30 years of age, with thoracolumbar or upper lumbar curves of 40 to 65 degrees.

PROCEDURAL CONSIDERATIONS. The patient is positioned in a lateral decubitus position so that posteroanterior and lateral intraoperative radiographs can be taken. The anesthesia provider should ensure incomplete pharmacologic paralysis, to allow for intraoperative neurophysiologic monitoring. In addition to a major soft tissue set and laminectomy set, the Isola instrumentation and implants, a vascular set, and power equipment will be needed.

OPERATIVE PROCEDURE

1. The surgeon approaches the spine through a transthoracic retroperitoneal (or retropleural retroperitoneal) approach, resecting the rib two vertebral levels above the upper instrumented vertebrae.
2. The sympathetic chain is mobilized laterally with the psoas.
3. The segmental vessels are temporarily occluded and, provided that there are no monitoring changes, ligated.
4. The discs are exposed to the far side to allow a full annulectomy. The bodies, however, are not exposed much beyond the midline.

5. A full 360-degree discectomy and annulectomy are done, exposing the posterior longitudinal ligament.
6. The surgeon places the screws in the vertebral body, placing the end screws first. Care is taken to place the longitudinal axis of the screw parallel to the endplate and at the apex of the vertebral body.
7. Screw placement is started with an awl and continued with a 5.5-mm tap, continuing until the tip just exits the far side of the cortex. The first one third of the hole is tapped with a 7.0-mm tap, and a 7.0-mm closed top screw with a washer is inserted. The screw must protrude through the opposite cortex by a thread or two. The same process is then repeated at the lower end vertebra.
8. The surgeon cuts the rod to the proper length and contours it to re-create the sagittal-plane angular position of the normal spine. It is then positioned in the end vertebra and used as a guide to locate the entry point for the intermediate screws.
9. Open-ended intermediate screws are inserted in a fashion similar to the end screws, taking care that their pathway is parallel to the end screws.
10. The rod is back-entered through the upper screw and then the lower screw and seated into the intermediate open screws. The open screws are capped, and the rod is rotated to place the sagittal-plane contour of the rod in the sagittal plane. An intermediate set screw is tightened to secure the new position of the rod.
11. As the remaining screws are tightened about the rod, it is essential that the disc spaces be opened completely. A Cobb elevator can be used to pry the disc space open.
12. Rib corticocancellous autograft is used to completely fill the disc spaces. The surgeon obtains the graft from the tenth rib (the usual site of entry), the twelfth rib (taken from inside the chest), and the eighth rib (taken from outside the chest).
13. The disc spaces are compressed to provide anterior column load-sharing. Care should be taken to ensure that the set screws are visited at least twice for the end-closed connections and three times for the center-capped connections.
14. Closure is in the standard manner, using chest tubes if the chest has been entered or a retropleural Hemovac if a retropleural retroperitoneal exposure has been done.
15. Postoperative care consists of an overnight intensive care stay with the patient sitting out of bed the next morning. A cast or brace is used at the physician's discretion. Activities are restricted for 6 to 12 months, until there is clear indication of graft incorporation.

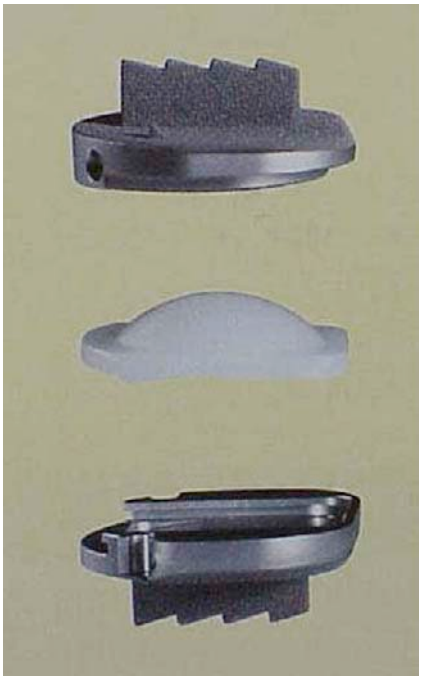

FIGURE 19-105 Three components of the ProDisc.

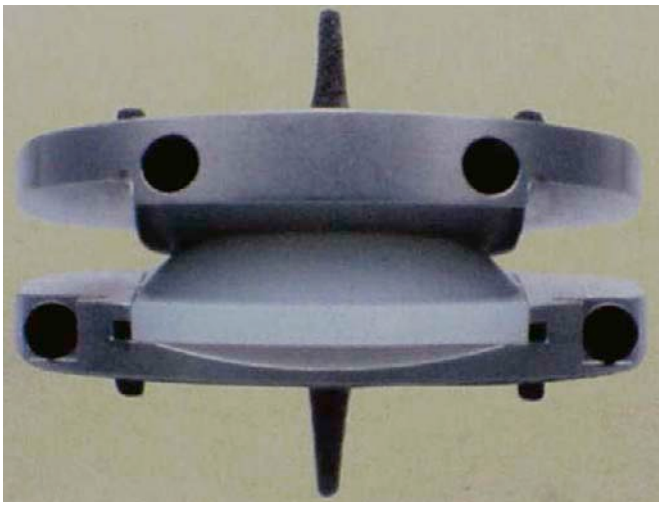

FIGURE 19-106 Assembled ProDisc.

Artificial Disc Replacement

Degenerative disc disease (DDD) occurs when the intervertebral disc (IVD) is worn because of aging or trauma. Discogenic back pain results from degeneration of the disc and is confirmed both by patient history and by radiographic studies. The IVD acts as the padding between the vertebrae. Once the IVD is worn out, pain, inflammation, and nerve impingement leading to numbness and muscle weakness can occur. Left untreated, nerve damage can be permanent. DDD occurs in 50% of people older than 40 years of age. Many patients are asymptomatic; however, those who are affected can be severely debilitated, changing their ability to cope with activities of daily living (ADLs) and affecting the quality of life. Artificial disc replacement (Figures 19-105 and 19-106) re-creates the natural disc function with preservation of spinal motion (Boughton, 2009b; Blumenthal et al, 2005; David, 2007).

Procedural Considerations. The perioperative nurse and surgical technologist collaborate to ensure the availability of implants with the manufacturer's representative and reconfirm this during the preoperative verification process. Other considerations for this procedure include the use of a blood salvaging system in both the intraoperative and postoperative periods. Templates of x-rays should be placed on the viewing box in the OR before the procedure. The patient is positioned supine on a Jackson table with the right arm draped across the body. A C-arm is used to identify the disc or discs to be replaced in the marked areas. In many institutions, laminar airflow is used.

Operative Procedure. The two general anatomic routes for anterior exposure to the lumbar spine are retroperitoneal and transperitoneal.

The *retroperitoneal approach* can proceed from a variety of incisions, including vertical midline, paramedian, oblique, and transverse. This is determined by both the spinal level and the number of lumbar levels to be exposed. An infraumbilical transverse incision can accommodate most approaches to the L4-L5 and/or S1 disc levels, whereas a more obliquely oriented incision is favored for accessing disc levels above L4.

The *transperitoneal route* is not generally used except in extenuating circumstances (e.g., prior extensive retroperitoneal surgery or revisional spine surgery).

1. The surgeon creates a midline incision and places a fixed retractor system to move the small and large bowel out of the field and facilitate direct visualization of the abdominal cavity. Trendelenburg's position can be used to assist with maintaining exposure.
2. For the L5-S1 level, the peritoneum superficial to the sacral prominence is incised.
3. The surgeon identifies the vascular structures, and uses blunt dissection to tease open the area of the facet of the disc.
4. The middle sacral vessels generally need to be divided to complete the exposure. Excessive electrocoagulation should be avoided to decrease the risk of injury to the sympathetic nerves.
5. Once the exposure is complete the surgeon will use a #3 long handle with a #15 blade to make an incision into the disc body.
6. The discectomy is completed using a rongeur and curettes to remove remaining disc tissue.
7. Correct sizing is determined using templates. Trial instrumentation is inserted and correct placement is verified with AP and lateral C-arm views.
8. The trial is centered in the AP plane, and the marker appears as a plus sign aligned with the spinous process. On the lateral x-ray, a hole in the trial represents the center of rotation.
9. Once correct placement of the trial is verified, the surgeon uses the ESU to mark the midline of the superior vertebral body and removes the trial.
10. Next, the pilot driver is aligned with the midline ESU mark.
11. The pilot driver that corresponds to the chosen footprint is then carefully impacted to verify the ability to accurately place endplates.
12. During this process, lateral C-arm imaging is used to accurately monitor the depths of the pilot driver.
13. Once the depth is achieved, the slap hammer is used, removing the pilot driver from the disc space.
14. The endplate insertion tips are then attached to the corresponding superior and inferior endplates.
15. The endplates are then carefully inserted into the disc space with the assistance of the guided impactor.
16. The insertion is monitored with fluoroscopy to accurately control the posterior depth and verify the appropriate lordotic angle.
17. With the superior and inferior endplates in place, the surgeon uses the spreading and insertion forceps to open the disc space.
18. Once the appropriate distraction is achieved, the size on the spacer can be used to select the appropriate core trial.
19. The appropriate core insertion tip is loaded into the core insertion instrument, and the sliding core is inserted between the endplates.
20. The surgeon releases the distraction on the spreading forceps, which allows the endplates to close around and engage the sliding core.
21. The core insertion instrument is removed and the final position verified using fluoroscopy (Figures 19-107 and 19-108).
22. The wound is irrigated and closed.

Vertebroplasty and Kyphoplasty

Vertebroplasty and kyphoplasty are used for the treatment of vertebral compression fractures attributable to osteoporosis or pathologic conditions. Bone cement is injected into the vertebral body to decrease back pain and prevent further vertebral body height loss. Ortiz (2008) describes the technique in the Research Highlight box.

PROCEDURAL CONSIDERATIONS. Patient selection is key in identifying appropriate candidates for this procedure. MRI is the most accurate radiologic diagnosis. Equipment includes C-arm, radiolucent OR table, and x-ray vests for staff as well as vertebroplasty system and cement injection system. Bone biopsy needles should be available. The C-arm must provide a good quality image; all key bony landmarks should be clearly visible. Positioning of the patient requires careful vigilance to prevent skin breakdown and nerve damage. After the administration of anesthetic, the patient is positioned prone with hyperextension of the vertebral compression fracture on the radiolucent OR table. The patient is then prepped and draped.

OPERATIVE PROCEDURE

1. After the patient is prepped and draped, the C-arm is placed in the area undergoing surgery.
2. Confirmation of the level of the vertebroplasty (or kyphoplasty) is determined.

RESEARCH HIGHLIGHT

Balloon Kyphoplasty

Physical function improved and patients experienced less disability following kyphoplasty than those patients who received conservative care. Immediate improvement in pain and quality of life was reported in 149 patients with compression fractures from osteoporosis, myeloma, or metastatic disease who underwent balloon kyphoplasty. The control group consisted of 151 patients who underwent conservative treatment of back pain. Conservative care included pain medications, bracing, physiotherapy, and bed rest. Based on SF-36 scores, results showed patients assigned to the kyphoplasty group had greater improvement than those patients randomized to nonsurgical care. In addition to improved physical capabilities, kyphoplasty patients also reported less back pain, less use of analgesics and walking aids, and fewer days of limited activity. There were no statistical differences between the groups in adverse events. Kyphoplasty is a minimally invasive surgery that produces improved quality of life with little risk.

From Boughton B: American Association of Orthopaedic Surgeons 2009: Balloon kyphoplasty produces better physical function, less disability than standard care, available at www.medscape.com/viewarticle/589132. Accessed April 25, 2009.

FIGURE 19-108 Implanted ProDisc with patient bending backward.

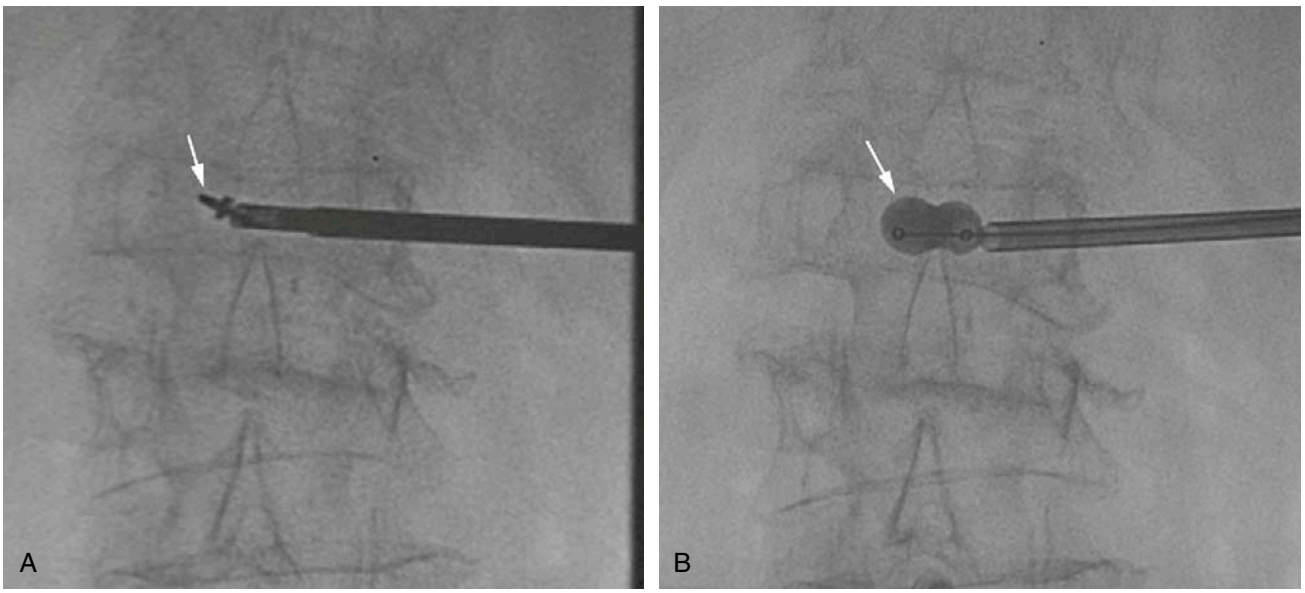

FIGURE 19-109 Vertebroplasty. **A**, Frontal fluoroscopic image shows multidirectional bone curette. **B**, Path of least resistance for subsequent balloon tamp inflation.

3. The surgeon inserts the appropriate gauge bone needle (11- to 13-mm gauge for vertebroplasty; 8- to 10-mm gauge for kyphoplasty) at the desired level and confirms the correct level with fluoroscopy (Figure 19-109, A).
4. For kyphoplasty:
   a. The inflatable balloon tamp is placed. Available tamps are 10, 15, or 20 mm in length, and styles include multi-, uni-, and bidirectional (Figure 19-109, *B*).
   b. After placing the tamp, the surgeon gradually inflates the balloon to 50 pounds per square inch (psi) and then continues inflation in increments of 25 psi until the desired pressure is achieved and either there is height restoration of the vertebral body or the tamp is in proximity to the cortical margin. Pressure is monitored by a manometer.
   c. Once the tamp has reach maximum inflation, the surgeon deflates the balloon. A cavity is left within the vertebral body.
5. Cement is mixed and then injected through the bone needle using a 1-ml syringe (Figure 19-109) under fluoroscopic control.
6. The needle is removed and a dressing is applied.

CHAPTER 20

Neurosurgery

DIANE L. FERRARA-HOFFMAN and SARAH J. KRIZMAN

Neurosurgery is possibly the most diverse, complex, and challenging specialty in surgery. Brain surgery is performed for head injury, tumors, vascular disorders, hydrocephalus, epilepsy, and Parkinson's disease. Neurosurgery also treats disorders of the spine from trauma and fractures, spinal cord injury, spinal stenosis, spinal tumors, and disk disease. In addition, neurosurgeons treat peripheral nerve disorders, carotid artery disease, chronic pain, and pediatric disorders. Advancements in the highly technical field of neurosurgery are constant.

Perioperative nurses and surgical technologists who care for neurosurgical patients are challenged by the need to have a working knowledge of neuroanatomy, function, and clinical presentations of the many neurologic conditions that require surgical interventions. Understanding the surgical procedure to be performed allows the perioperative nurse to anticipate and respond to the intraoperative needs of the patient and neurosurgical team, and also to surgical complications if they arise. Given the range and complexity of today's neurosurgical interventions an understanding of highly sophisticated equipment and instrumentation is necessary. Like all patients undergoing surgery, the neurosurgical patient is often vulnerable secondary to the presenting pathologic condition. For perioperative personnel to deliver sensitive, humanistic care in this highly technical environment, they must recognize and appreciate the individual's emotional and spiritual state, whether it is manifested by fear, pain, or grief. Reaching out and making the human connection allay the fear, moderate the pain, and facilitate the patient's grieving process. Information in this chapter will assist those working in neurosurgery to give optimal patient care.

Surgical Anatomy

The nervous system is the most complex and least understood of body systems. It is divided structurally into the central nervous system (CNS) consisting of the brain and spinal cord and the peripheral nervous system (PNS), which encompasses every neurologic structure outside the CNS, including the cranial and spinal nerves. The brain and spinal cord are protected by the skull and vertebral columns, respectively. The cranial nerves originate within the brain and emerge through openings in the skull to run peripherally. The spinal nerves that emerge from the spinal cord through the vertebral foramina also run peripherally.

The nervous system is divided functionally into a voluntary system and an autonomic, or involuntary, system. It provides a means of communication for the rest of the body. The functions of all body systems depend, in part, on nervous system function. In turn, the nervous system depends directly on circulatory system function to obtain life-sustaining glucose and oxygen. Nervous system functions include motor and sensory functions, orientation, coordination, conceptual thought, emotion, memory, and reflex response.

Nervous system tissue is composed of vast amounts of neurons and far more neuroglial cells. Neurons are intercommunicating nerve cells that encode, conduct, and transmit information to other neurons, muscle, and glandular tissue (Figure 20-1). They are composed of a body or soma with branches or extensions, called dendrites and axons, that communicate with other cells at synapses. Dendrites are short branches that conduct impulses toward the soma. Cell bodies and dendrites are mostly confined to areas of gray matter in the CNS. Axons are long branches, often encased in a white myelin sheath, that conduct impulses away from the soma. Axons pass into bundles of nerve fibers that tend to form tracts or pathways and are referred to as white matter. Tracts that cross midline to create a communication pathway from each side of the body to the opposite side of the brain are called commissures. Neuroglial cells support the neurons by creating and maintaining an appropriate environment in which neurons can operate efficiently. Glial cells include astrocytes, oligodendrocytes, ependymal cells, and microglia. The mutation of these cells can form a glioma, one of the more common brain tumors.

This chapter divides the nervous system into logical divisions within the framework of neurosurgical techniques. The brain and adjacent structures include the cranial nerves of the PNS, which are commonly encountered during brain surgery. Discussion of the spine and spinal cord includes the adjacent spinal nerves and the disks and ligaments that support the spine. Surgically significant pathology is incorporated with the normal anatomy of structures.

BRAIN AND ADJACENT STRUCTURES

Scalp

Scalp layers (Figure 20-2) include skin, subcutaneous tissue, galea, and periosteum. Scalp skin is thick. The subcutaneous tissue, which is exceptionally dense, tough, and vascular, is firmly attached to the galea. Most of the blood vessels lie superficial to the galea. The subgaleal space contains loose areolar tissue that permits mobility of the scalp. It is in this bloodless plane that the standard craniotomy scalp flap is created. The pericranium, or outer periosteum of the skull, separates the galea from the cranium.

The arterial supply of the scalp comes from the external carotid artery through the superficial temporal, posterior

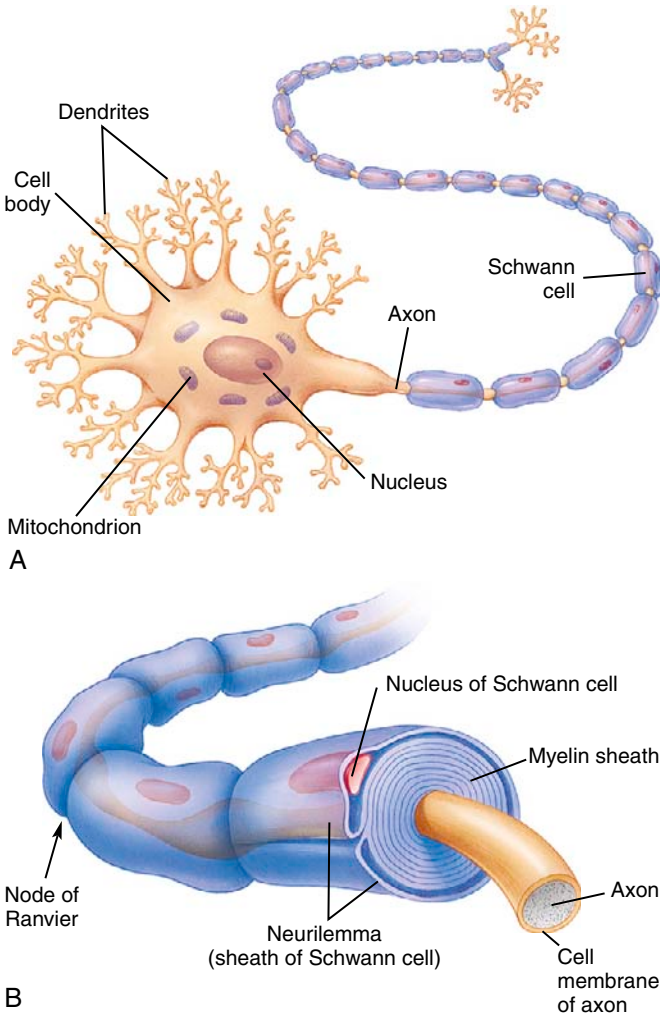

FIGURE 20-1 **A**, Many dendrites carry nerve impulses to the cell body, which then sends the nerve impulses along a single, long axon. Long axons are encased at intervals by a myelin sheath. **B**, A segment of myelinated fiber in cross section, showing myelin sheath composed of several layers of myelin, which insulate the axon.

auricular, occipital, frontal, and supraorbital branches. Most veins roughly follow the course of their corresponding arteries, except the emissary veins, which drain directly through the skull into the intracranial venous sinuses. The scalp, the extracranial arteries, and portions of the dura mater are the only pain-sensitive structures that cover the brain. The brain itself is insensate.

Skull

The skull provides protection for the brain. It is formed by 28 bones, most of which are paired although some in the median plane are single. Many of the bones are flat bones, consisting of two thin plates of compact bone encasing a spongy layer of cancellous bone containing bone marrow (see Figure 20-2). Infants are born with two fontanelles. These are openings in the skull that are located both anterior and posterior to the parietal bones (Figure 20-3). The posterior fontanelle is generally closed by 2 months and the anterior by about 18 months after birth. The bones of the skull are joined by bony seams called *sutures*. Eight bones form the walls of the cranial cavity, which houses the brain. There are four single bones (frontal, occipital, ethmoid, and sphenoid) and four paired bones (temporal and parietal) (Figure 20-4). The sagittal suture lies in the medial plane and joins the two parietal bones. The coronal suture joins the frontal and parietal bones. The squamous sutures border the squamous part of the temporal bones. The lambdoid suture joins the occipital and parietal bones. Skull bones vary in thickness and tend to be thinner where they are covered in muscles, for example, in the temporal and posterior fossae. The skull articulates with the first cervical vertebra to allow for flexion and extension of the skull. The skeletal surface landmarks of the head can be palpated and are commonly used to plan surgical approaches (Figure 20-5).

The interior of the skull is anatomically divided into three cranial fossae: anterior, middle, and posterior (Figure 20-6). The anterior fossa is limited posteriorly by the sphenoid ridge, along which pituitary tumors and aneurysms of the circle of Willis are generally approached. The frontal lobes and olfactory bulbs and tracts lie in the anterior fossa. The temporal lobes lie in the middle fossa, which is shaped like a butterfly. The sella turcica, formed by the sphenoid bone, is the most central part of the middle fossa and houses the pituitary gland. The floor and lateral walls of the middle fossa are shaped from the greater wings of the sphenoid bone and parts of the temporal bone, which house the internal and middle ear structures. The posterior fossa, the largest and deepest fossa, is formed by the occipital, sphenoid, and petrous portions of the temporal bones; the cerebellum and brainstem lie here, as do many cranial nerves. The foramen magnum, the largest opening in the skull, provides passage for the spinal cord to join the brainstem in the posterior fossa. Numerous other openings exist in the base of the skull for passage of arteries, veins, and cranial nerves.

Skull Fractures. The severity of skull fractures depends on the degree of resulting brain injury. Simple skull fractures can be serious if they cross major vascular channels in the skull. If vessels are torn, epidural or subdural hematomas may form. Depressed skull fractures require a surgical procedure to elevate the depressed bone. Open skull fractures should be irrigated copiously and closed to prevent infection. Basilar skull fractures may cause cerebrospinal fluid (CSF) rhinorrhea or otorrhea. A few patients with these CSF leaks require surgical repair if they do not resolve after 2 weeks.

Deformities of the Cranium. Craniosynostosis is the most common pediatric skull deformity seen and treated by the neurosurgeon. The phenomenon is a premature closure or lack of formation of cranial sutures, leading to cosmetic abnormalities, eventual life-threatening intracranial pressure (ICP) increases, and arrested brain development unless diagnostic and surgical interventions ensue. Cranial remodeling is most often undertaken during the first year of life, when brain capacity triples (see Chapter 25).

Meninges

The brain and spinal cord are completely enveloped by the meninges, which are three membranes that provide support and protection. The meningeal layers from superficial to deep are the dura mater, arachnoid mater, and pia mater (see Figure 20-2).

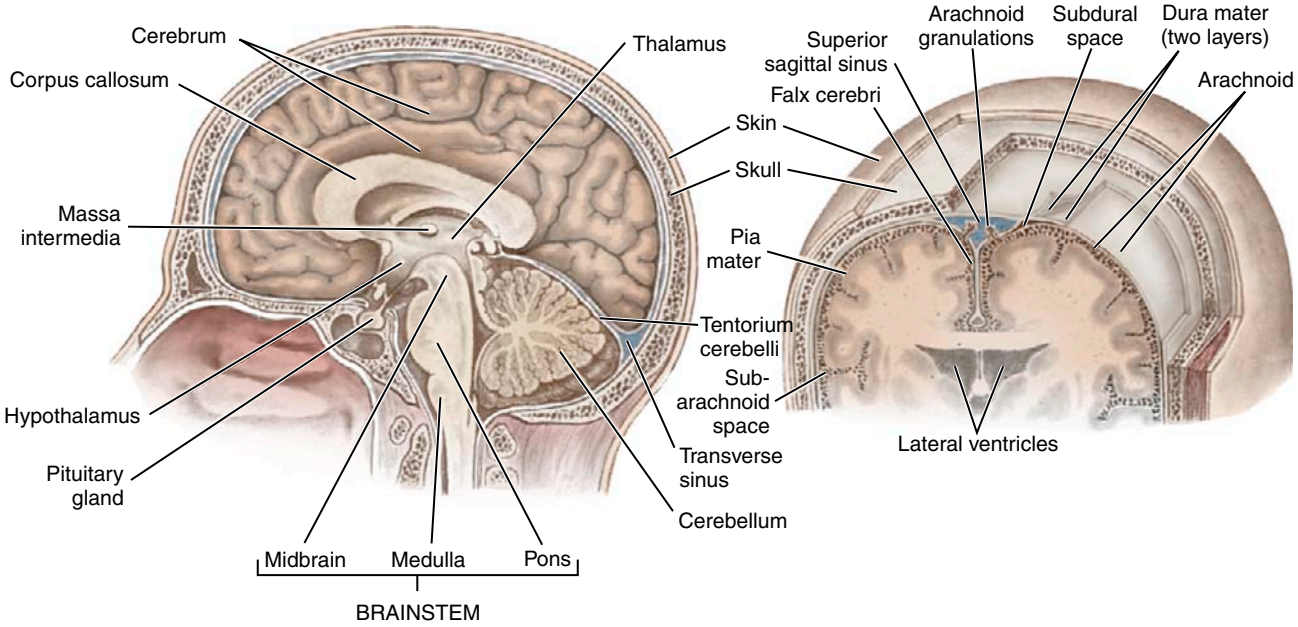

FIGURE 20-2 Scalp is composed of the following layers: skin, subcutaneous tissue, galea, and periosteum. Skull bone has three tables: outer, diploë (or spongy layer), and inner. Dura mater lies beneath skull and completely encapsulates brain. Other structures are identified for reference and are described in text.

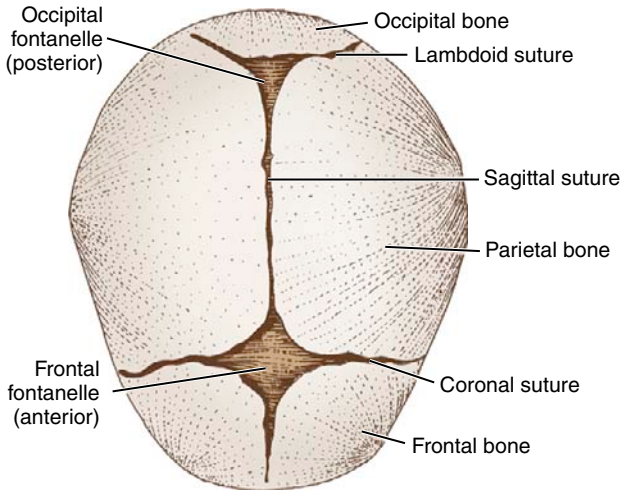

FIGURE 20-3 Skull at birth viewed from above.

The space superficial to the dura is known as the epidural space. The cranial meninges are located between the skull and the brain.

The dura mater is a tough, shiny, fibrous membrane that is close to the inner surface of the skull and folds to separate the cranial cavity into compartments. The largest fold is the falx cerebri—an arch-shaped, vertically placed, midline structure separating the right and left cerebral hemispheres (see Figure 20-2). A smaller fold of dura mater, the falx cerebelli, separates the cerebellar hemispheres vertically. A transverse fold, the tentorium cerebelli, forms the roof of the posterior fossa. The tentorium supports the temporal lobe and occipital lobes of the cerebral hemispheres. Below the tentorium lie the cerebellum and brainstem. Structures above the tentorium are referred to as *supratentorial* and those below as *infratentorial* (Figure 20-7). At margins of these dural folds lie large venous sinuses that drain blood from the intracranial structures into the jugular veins. Accidental breaching of a sinus during surgery can cause severe bleeding that is difficult to control and may put the patient at risk for a venous air embolism. Several arteries also lie within the layers of the dura. The largest is the middle meningeal, a source of serious epidural hemorrhage if torn by an overlying skull fracture. The rigid skull makes hemorrhage and swelling in the brain critical events. The volume of the intracranial cavity is fixed. Increasing the intracranial contents by a hemorrhage, tumor, or edema may lead to serious ICP problems. Pressure on brain tissue may cause irreparable damage.

Beneath the dura mater is a transparent membrane called the *arachnoid*. Although the outer layer of arachnoid closely approximates the dura mater, the space between is considered the subdural space. The inner arachnoid layer forms innumerable weblike filaments that bridge to the surface of the brain (see Figure 20-2). The arachnoid passes over the sulci and fissures of the brain, without dipping into them. The arachnoid is separated from the pia mater beneath it by the subarachnoid space, which is filled with CSF that bathes the brain. Around the base of the brain, particularly, this space becomes enlarged to form cisterns. The major intracranial nerves and blood vessels pass through these compartments. Intracranial approaches can be charted in terms of the basal cisterns.

The pia mater, the innermost membrane, closely follows the contours of the surface of the brain into the sulci and fissures. Only the microscopic subpial space separates the pia from the brain. The pia mater has a rich vascular network. Vascular fringes of pia mater project into the ventricles to form the choroid plexus of the ventricles, which produce CSF.

Brain

The anatomy of the brain, formally known as the encephalon, can be considered in multiple ways. Based on prenatal development, the principal divisions from rostral (head) to caudal (tail), descending toward the spinal cord, are the forebrain or prosencephalon, the midbrain or mesencephalon, and the hindbrain or rhombencephalon. The rhombencephalon is subdivided into the cerebellum, the medulla oblongata, and the pons. The prosencephalon includes the diencephalon and the telencephalon, or cerebrum. The medulla oblongata, pons, and midbrain are collectively referred to as the brainstem (Figures 20-7 and 20-8).

Cerebrum. The right and the left cerebral hemispheres are the largest parts of the brain and occupy the anterior and middle fossae. Each hemisphere is divided into frontal, parietal, occipital, and temporal lobes. The two hemispheres are separated by the longitudinal fissure and the falx cerebri but remain connected underneath the falx by a large transverse bundle of nerve fibers called the corpus callosum (see Figure 20-8). Each of the cerebral hemispheres controls sensation and motor activity to and receives sensory stimuli from the opposite half of the body.

The convoluted surface of the cerebrum consists of gray matter, called the *cerebral cortex,* which contains the cell bodies of the many nerve pathways of the brain. The underlying white matter contains millions of myelinated nerve axons and is relatively avascular compared with the cortex. The nerve pathways, or fiber tracts, are of three types: (1) commissural fibers, which pass from one cerebral hemisphere to the other; (2) association fibers, which connect regions of gyri and lobes longitudinally within a cerebral hemisphere; and (3) projection fibers, including the great motor and sensory systems, which run vertically to connect the cortical regions with other portions of the CNS.

The surfaces of the hemispheres form convolutions called *gyri* and intervening furrows called *sulci,* which serve as anatomic landmarks. Two sulci of particular anatomic importance during surgery are: (1) the lateral sulcus, or sylvian fissure, which divides the temporal lobe from the frontal and parietal lobes, and (2) the central sulcus, or fissure of Rolando, which separates the frontal from the parietal lobe. The central sulcus also separates the motor cortex (precentral gyrus) from the sensory cortex (postcentral gyrus). The motor cortex lies anterior to the central sulcus, and the sensory cortex lies posterior to the central sulcus. Both the motor cortex and the sensory cortex can be represented by a topographically organized map called a homunculus that proportionately represents each body part at the area of the gyri that controls it. The diagrams illustrate how the number of neurons corresponds to the degree of motor

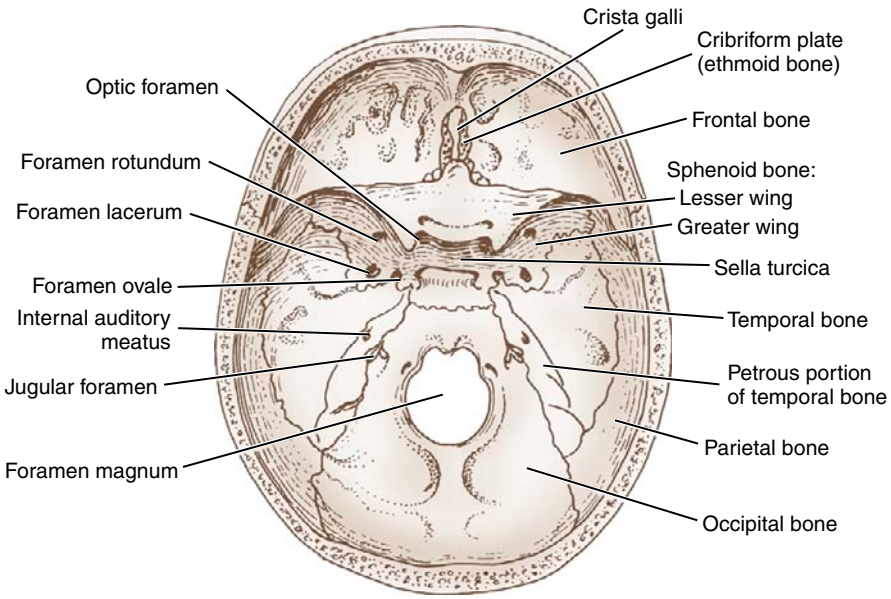

FIGURE 20-6 Floor of cranial cavity.

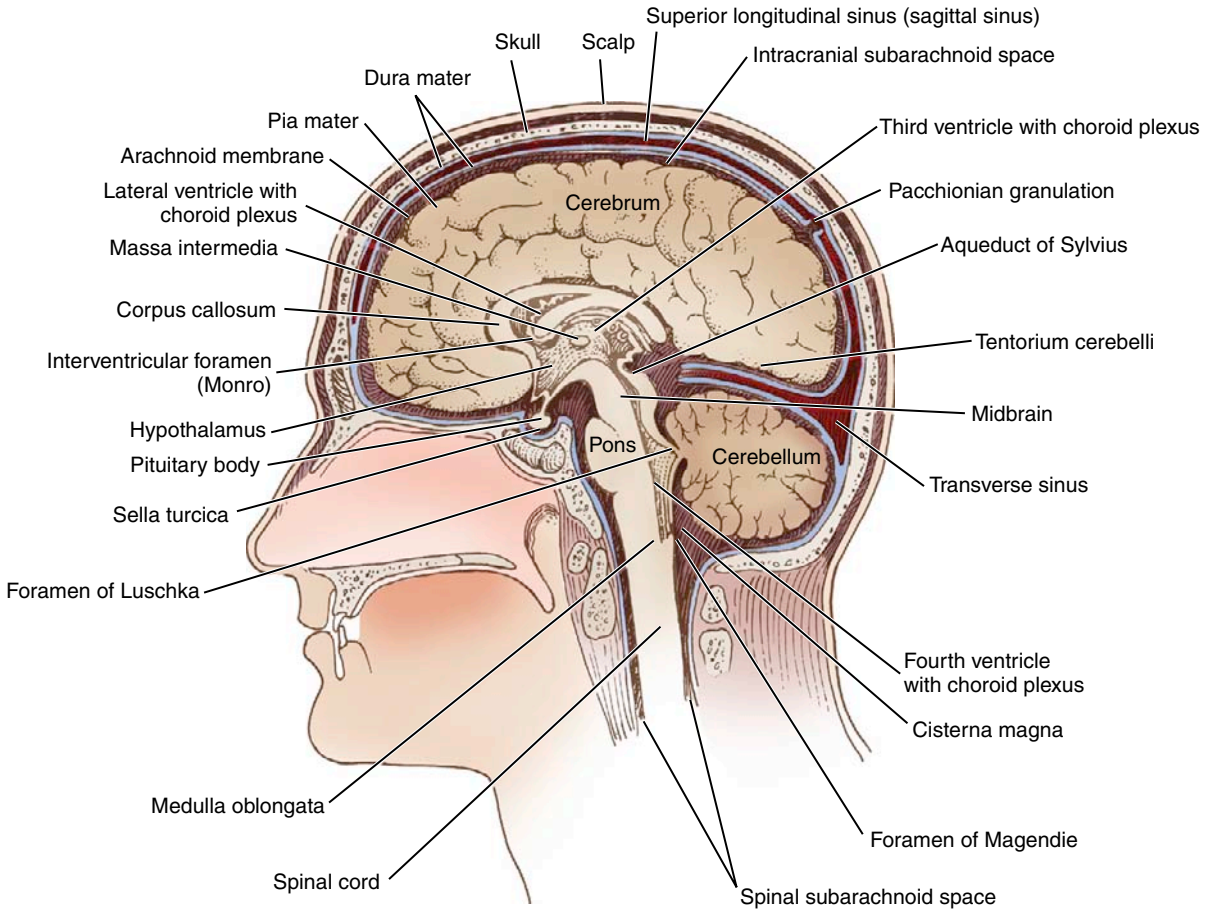

FIGURE 20-7 Sagittal section of head showing cerebrospinal fluid spaces and their relationship to venous circulation and their principal subdivision of the brain and its coverings.

and sensory control required. For example, areas that need more fine motor control, such as the fingers and face, have a higher concentration of neurons than other areas. Keep in mind that the left motor and sensory cortices control the right side of the body and vice versa (Figure 20-9). Destruction of an area of motor cortex results in loss of voluntary motor function on the corresponding area of the opposite side of the body (Figure 20-10).

The frontal lobe is anterior to the central sulcus and controls the higher functions of intellect and abstract reasoning,

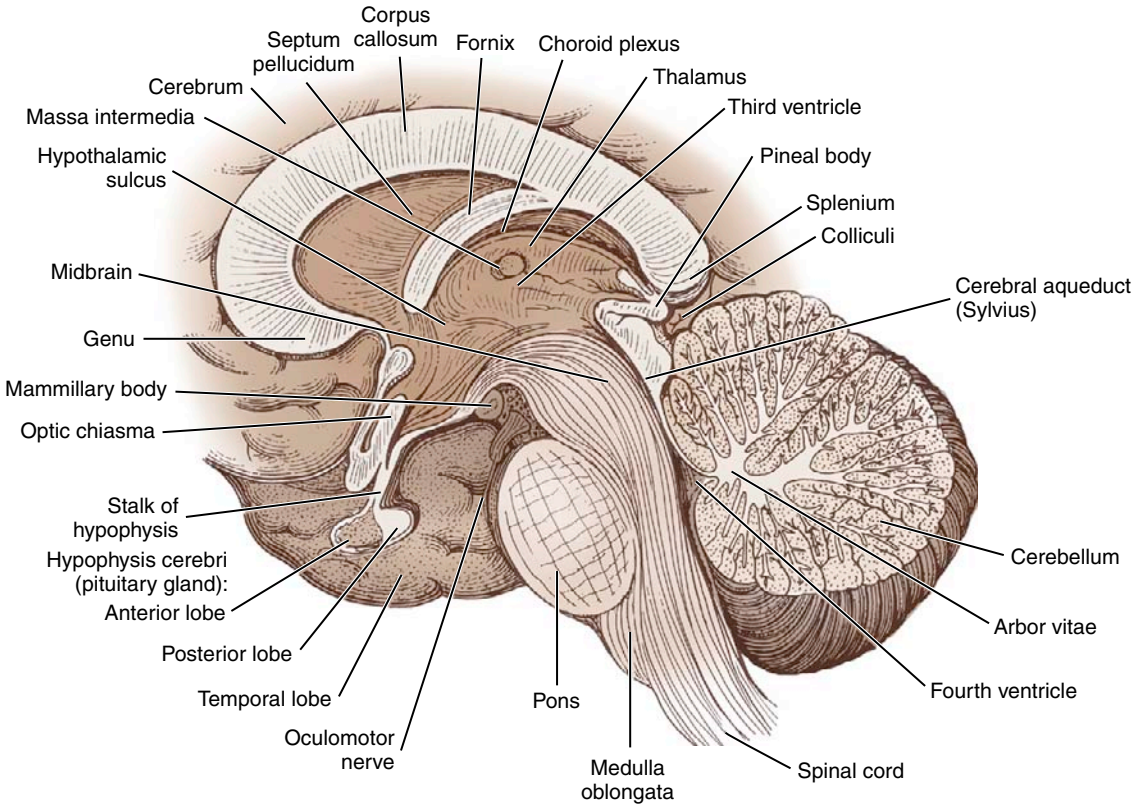

FIGURE 20-8 Sagittal section through midline of brain showing structures around third ventricle, including corpus callosum, thalamus, and hypothalamus.

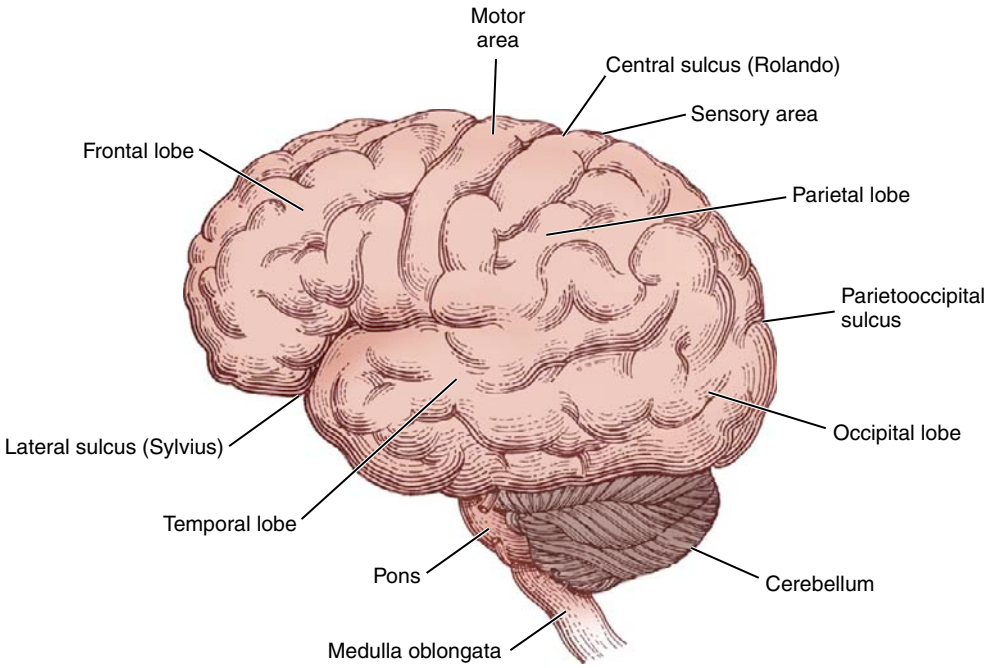

FIGURE 20-9 Lateral view of cerebral hemisphere (showing lobes and principal fissures), cerebellum, pons, and medulla oblongata.

along with movement, language, and personality. Posterior to the central sulcus is the parietal lobe, extending back to the parietooccipital fissure. This area contains the final receiving and integrating station for sensory impulses, such as pain and touch, from the contralateral side of the body. It is also involved with special relationships and object identification. The occipital lobe lies posterior to the parietooccipital fissure. It receives and integrates visual impulses and registers them as meaningful images (see Figures 20-9 and 20-10).

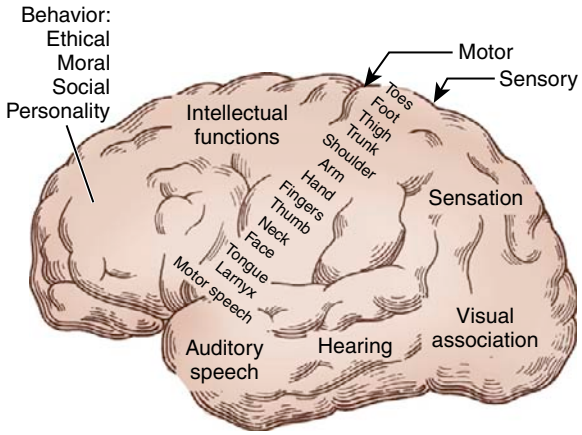

FIGURE 20-10 Principal functional subdivisions of cerebral hemispheres.

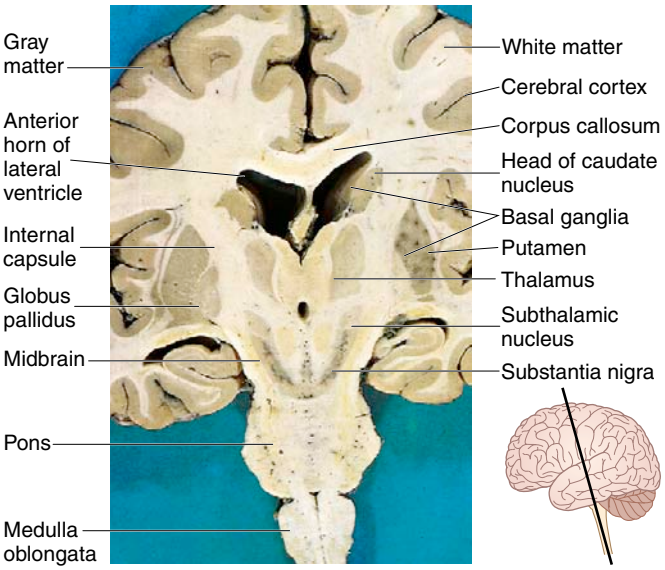

FIGURE 20-11 Oblique coronal section through the cerebral hemisphere and brainstem showing the disposition of gray and white matter, the basal ganglia, and the internal capsule.

Inferior to the lateral sulcus, in the middle fossa, is the temporal lobe, which is involved with memory, speech, and smell. Lesions of the left temporal lobe in right-handed persons and in many left-handed persons may affect the comprehension and verbalization of words, resulting in aphasia. The insula (island of Reil) is an area of cortex that lies deep within the lateral sulcus and can be exposed when the upper and lower lips of the fissure are separated. The insula is believed to be involved with smell, taste, touch, and possibly language.

The limbic system consists of large parts of the cortex near the medial wall of the cerebral hemisphere (cingulate and parahippocampal gyri) along with the hippocampus, amygdala, and septum. It is closely and significantly connected with the hypothalamus. It has a diffuse distribution in the brain, and many components of the limbic system have overlapping functions. The hippocampus is critical for learning and memory. The amygdala regulates the perceptive and expressive aspects of emotional and social behavior. The limbic system affects endocrine and autonomic functions of the body, recent memory, emotions, behaviors, and motivational and mood states. Restlessness and hyperactivity may result from lesions of this area.

The basal ganglia are subcortical collections of nuclei (gray matter) that include the caudate nucleus, putamen, and globus pallidus (collectively referred to as the *corpus striatum*); the substantia nigra (which is located in the midbrain); and the subthalamic nucleus (part of the diencephalon). The basal ganglia influence movement and behavior through projections to the thalamus and brainstem and subsequently the cortex (Figure 20-11). The basal ganglia function to promote and support patterns of behavior and movement that are appropriate in a given situation and to inhibit unwanted or inappropriate behavior and movements. Disorders of the basal ganglia are principally characterized by abnormalities of movement, muscle tone, and posture. Damage to these neural components may cause rigidity of the skeletal muscles and various types of spontaneous tremors.

Diencephalon. The diencephalon is composed of the thalamus, hypothalamus, epithalamus, and subthalamus and surrounds the third ventricle. The thalamus is the major relay station for incoming sensory stimuli. Except for some olfactory impulse transmission, all sensory information transmitted to the cerebral hemispheres is relayed through the thalamus. This is also true for motor pathways from the cerebellum and basal ganglia. Because of the central role of the thalamus in perception of body sensations, surgical lesions can be made in this area in an attempt to alleviate pain.

Along the floor of the third ventricle is the hypothalamus (see Figure 20-8), which is concerned principally with the autonomic regulation of the body's internal environment and is intimately connected with the pituitary gland. It controls fluid and electrolyte balance, appetite, reproduction, thermoregulation, immune response, and many emotional responses. It influences levels of attention and consciousness. The pituitary gland is suspended from the base of the hypothalamus by the pituitary stalk. It secretes multiple hormones that are regulated by the hypothalamus. A pituitary tumor can result in a hormonal imbalance. It can also encroach on the optic chiasma, causing vision changes.

The subthalamus is a complex region of nuclear groups and fiber tracts, including the subthalamic nucleus, which is considered with the basal ganglia. The epithalamus consists of multiple nuclei and the pineal gland, an endocrine gland that regulates the circadian rhythm.

Brainstem. The brainstem consists of the midbrain, pons, and medulla oblongata. It is located in the posterior fossa and forms the floor of the fourth ventricle. It is the site of many ascending and descending fiber tracts that allow for communication among the structures of the brain and between the brain and spinal cord. All but 2 of the 12 cranial nerves attach to the brainstem. The short, stocky portion of the brain, between the cerebral hemispheres and pons, is the midbrain (see Figure 20-7), also referred to as the *mesencephalon*. It is composed of the cerebral peduncles, the substantia nigra, numerous nerve tracts and nuclei, and association centers that control the majority of eye movements. Immediately below the midbrain is the pons, which contains control areas for horizontal eye movement and face movement. The medulla oblongata is continuous with the spinal cord at the foramen magnum. It contains the vital cardiovascular and respiratory

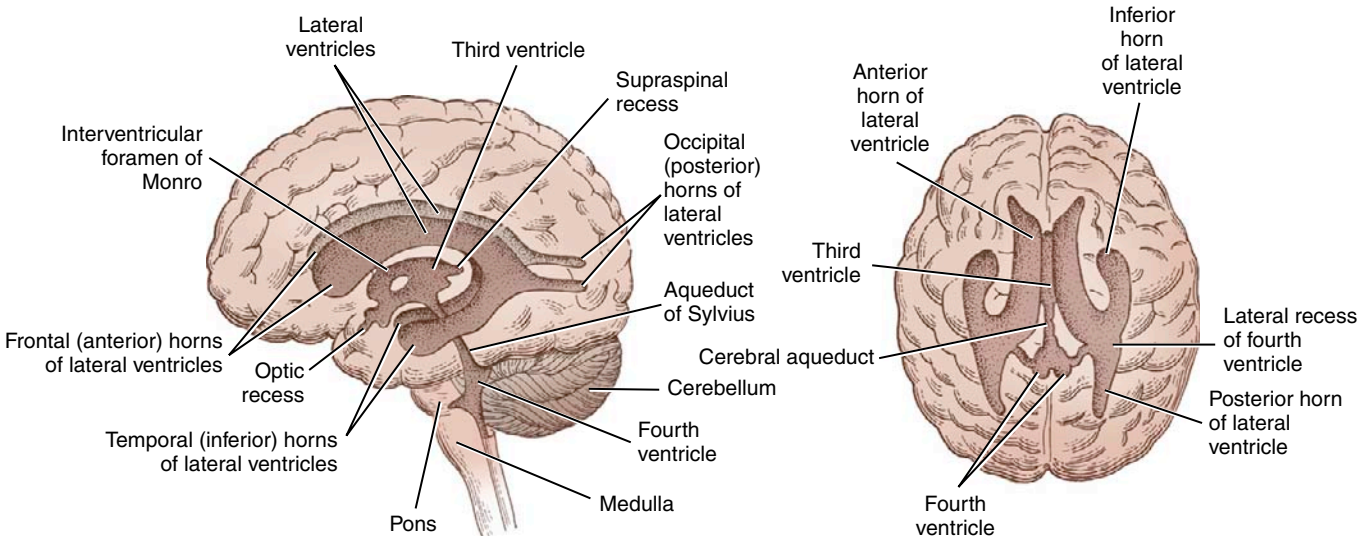

FIGURE 20-12 Ventricular system showing its relationship to various parts of brain.

regulatory centers (see Figure 20-9). Damage to the brainstem is often devastating and life-threatening, because it can affect movement, senses, consciousness, perception, and cognition.

Cerebellum. The cerebellum, which occupies most of the posterior fossa, forms the roof of the fourth ventricle (Figures 20-8 and 20-12). It has two lateral lobes, or hemispheres, and a medial portion, the vermis. The fissures of the cerebellum are small and run transversely. The cerebellum is concerned principally with balance and coordination of movement. It has many complex connections with higher and lower centers and exerts its influence unilaterally—in contrast to the cerebral hemispheres, which act contralaterally. By splitting the vermis in the exact midline, a satisfactory exposure of tumors that lie in the fourth ventricle is obtained without sacrificing the important cerebellar functions.

Pathologic Lesions of the Brain. An estimated new 22,070 brain and other nervous system cancers were estimated to occur in 2009 (American Cancer Society [ACS], 2009). Brain metastases outnumber primary neoplasms by at least 10 to 1, and they occur in 20% to 40% of cancer patients. Because no national cancer registry documents brain metastases, the exact incidence is unknown, but it has been estimated that 98,000 to 170,000 new cases are diagnosed in the United States each year (National Cancer Institute [NCI], 2009).

Multiple factors are suspected of playing a role in the pathogenesis of intracranial neoplasms. Early diagnosis simplifies surgical treatment because increased ICP and severe neurologic changes are not usually present. Brain tumors are either malignant or benign, depending on the cell type. Primary tumors generally do not resemble the carcinomas and sarcomas found elsewhere in the body and rarely metastasize outside the CNS. Both primary and metastatic tumors of the brain and its membranes are included in the term *intracranial tumors*.

Traditionally, tumors are classified by cell type; however, classification of brain tumors is an evolving process. The widely used World Health Organization (WHO) system lists more than 120 types of brain tumors (NCI, 2009). Table 20-1 gives the approximate percentage of CNS tumors by histologic type. A brief description of a select list of brain tumors follows:

TABLE 20-1

Frequency of Primary CNS Tumors in Adults

Tumor Type	Percentage
Glioblastoma	50
Meningioma	17
Astrocytoma	10
Pituitary adenoma	4
Oligodendroglioma	3
Ependymoma	2
Medulloblastoma	2
Neurilemmoma	2
Hemangioma	2
Craniopharyngioma	1
Pinealoma	1
Sarcoma	1
Others	5

Modified from Janus TJ, Yung WKA: Primary neurological tumors. In Goetz CG: *Clinical neurology,* ed 3, Philadelphia, 2007, Saunders.

1. *Tumors of intraepithelial tissue* encompass gliomas, tumors believed to originate from neuroglial cells.
   a. Astrocytomas are the most common of all primary brain tumors. They usually occur in the cerebellum of children and the cerebrum of adults. They are often cystic and discrete in children and infiltrating and ill-defined in adults. Astrocytomas are classified in the WHO system based on the principal cell type and on the degree of anaplasia as grade I to IV, with grade I being the more favorable type of tumor and grade IV being the most malignant. Glioblastoma multiforme (GBM), a grade IV astrocytoma, is an infiltrative, fast-growing, rapidly recurring cerebral tumor that occurs most frequently in the sixth and seventh decades of life. It is the most common type of primary brain tumor, accounting for about 50% of gliomas (Sloan et al, 2005). It is one of the few tumors that is capable of invading both cerebral hemispheres by crossing the midline. Areas of necrosis are characteristic.

Recent studies have consistently demonstrated the benefits of radical surgical resection. Postoperative radiation therapy significantly improves survival. Even with aggressive multimodality therapy, median survival is less than 1 year and 5-year survival is less than 5% (Sloan et al, 2005).

b. Oligodendroglioma, typically found in the cerebral hemispheres, is usually infiltrating but occasionally moderately well-defined. It frequently presents in middle age with seizure. It is now believed that the true incidence of oligodendrogliomas is 5% to 15% of gliomas, much higher than previously thought. Therapy usually consists of surgery followed by radiation therapy and chemotherapy (Sloan et al, 2005).

c. Ependymoma occurs most frequently in children and is likely to arise in or near the ventricular walls. It commonly occurs in the fourth ventricle, where it abuts or involves vital medullary centers. It also frequently metastasizes into the subarachnoid spaces. This tumor accounts for 3% to 4% of gliomas. Surgical resection followed by radiation therapy is the usual treatment. The 5-year survival rate is 73% (Central Brain Tumor Registry of the United States [CBTRUS], 2007-2008).

d. Medulloblastoma is a fast-growing, rapidly recurring tumor of the vermis of the cerebellum and fourth ventricle that usually occurs in young children. It characteristically metastasizes into the subarachnoid spaces, usually spreading to the base of the brain by this route. It accounts for 15% to 20% of childhood intracranial brain tumors and is the most common malignant pediatric brain tumor.

2. *Tumors of the meninges (meningiomas)* commonly occur in people in the fourth to sixth decades of life (Al-Mefty and Heth, 2005). They are usually benign, circumscribed, slow-growing tumors, arising from arachnoid cells with secondary attachment to the dura. Various factors have been implicated in the development of meningiomas. They typically involve the cortex and bone of the skull with growth. They can be very vascular and may adhere to the dural venous sinuses or major arteries, making their complete removal challenging. However, meningiomas often can be totally surgically removed.

3. *Tumors of the cranial nerves (vestibular schwannomas)* are benign; they usually arise from the neurilemma sheath cells of the vestibular portion of the eighth cranial nerve within the auditory meatus. The term *acoustic neuroma* is a misnomer. These tumors grow slowly to fill the cerebellopontine angle and may indent the brainstem. Presenting symptoms include hearing loss, tinnitus, and disequilibrium.

4. *Hemopoietic neoplasms and lymphomas:* CNS involvement with lymphoma may occur secondarily from a systemic lymphoma or may arise primarily in the CNS (CBTRUS, 2007-2008). The main role for surgery is for tumor biopsy. Stereotactic techniques are well suited for these often-deep tumors. The standard treatment after biopsy is radiation therapy, allowing for a median survival of 10 months. Adding chemotherapy can prolong survival (Greenberg, 2005).

5. *Germ cell tumors* occur in the midline (suprasellar and pineal region). Other than benign teratomas, all intracranial germ cell tumors are malignant and may metastasize by way of CSF and systemically. Tumors of the pineal region are very challenging to the neurosurgeon. Open microsurgery, endoscopy, and stereotactic biopsy are surgical options. Pineal region tumors often cause hydrocephalus. An endoscopic third ventriculostomy or a shunting procedure is routinely performed to alleviate the symptoms of hydrocephalus. Radiation therapy, chemotherapy, and radiosurgery are also treatment considerations.

a. Germinoma is a neoplasm arising from germ cells. Survival with germinomas is much better than with nongerminomatous tumors (teratoma, embryonal cell carcinoma, choriocarcinoma).

b. Teratoma is a congenital tumor containing embryonic elements.

c. Embryonal cell carcinoma consists of a highly primitive group of neoplasms that arise in childhood. Predominantly large hemispheric masses involving deep supratentorial structures, these tumors are highly vascular and have poor prognoses. The primitive neuroectodermal tumor (PNET) is one such tumor.

d. Choriocarcinoma is an extremely rare, very malignant neoplasm.

6. *Cysts and tumorlike lesions* include the following types:

a. Epidermoid and dermoid cysts are developmental, benign tumors typically located in the suprasellar region.

b. Colloid cysts are slow-growing benign tumors. They classically occur in the anterior third ventricle, blocking the foramen of Monro and causing obstructive hydrocephalus.

7. *Tumors of the sellar region* include the following types:

a. Pituitary adenomas can be classified as nonfunctioning or functioning. Nonfunctioning pituitary adenomas account for approximately 30% of pituitary tumors, usually occur in people in the fourth and fifth decades of life, and do not cause clinical hormone hypersecretion. They are typically large and cause hypopituitarism or blindness from regional compression. The usual treatment is endoscopic or microscopic transsphenoidal removal of the tumor (see Transsphenoidal Hypophysectomy, p. 876). Following operative decompression, vision improves in approximately 80% of patients (Oyesiku, 2005). Radiation therapy or stereotactic radiosurgery may also be used. Functioning pituitary adenomas secrete excess quantities of pituitary hormones. The question of medical versus surgical treatment is ever present in the management of this group of patients. Adenomas may be further subdivided into microadenomas, which are less than 1 cm in diameter and usually discovered because of an endocrinopathy, and macroadenomas, which are larger than 1 cm and usually present with compressive effects of the tumor (Oyesiku, 2005).

(1) Chromophobe tumors are relatively common in the anterior pituitary glands of adults. They cause compression of the pituitary, adjacent optic chiasma, and hypothalamus. Compression of the hypothalamus may lead to diabetes insipidus.

(2) Eosinophilic adenomas are secretory, causing an excessive amount of growth hormone in the serum.

(3) Basophilic adenomas are responsible for the excessive secretion of corticotropic, gonadotropic, and thyrotropic hormones. Acromegaly or, less commonly,

Cushing's syndrome may occur and cause the patient to seek help long before the tumor has expanded sufficiently to compromise the optic chiasma.

(4) Prolactin cell adenoma exhibits considerable differences in clinical presentation, depending on the gender of the patient. In women of reproductive age, the onset of amenorrhea and galactorrhea with associated infertility is an obvious sign. The diagnosis of a prolactinoma is established early in the course. In men, the clinical endocrinal symptoms, which include decreased libido and impotence, are not as conspicuous and initially may be disregarded by the patient. As a result, male patients frequently do not seek medical attention until the tumors are large and have spread beyond the confines of the sella turcica.

b. Craniopharyngiomas account for 2.5% to 4% of intracranial tumors, with 50% occurring in childhood (Greenberg, 2005). They arise from the region of the pituitary stalk and typically contain both solid and cystic components. Calcification above the sella turcica is often seen radiographically. In addition to headache, vertigo, vomiting, and papilledema, diabetes insipidus and visual field changes are common. Although complete surgical removal is often impossible if it adheres to the carotid artery or hypothalamus, a subtotal resection with radiation offers favorable results.

8. *Metastatic tumors* are the most common brain tumor seen clinically, making up about half of brain tumors. They usually arise from carcinomas, more rarely from sarcomas, and occasionally from melanomas and retinal tumors. The most common sources are lung and breast cancer. The management of brain metastasis is complex and controversial. The current principal options for treatment include whole-brain radiation therapy, surgery, and stereotactic radiosurgery. The most important prognostic variables are the extent of systemic disease and the patient's functional status and age. These factors, along with the size, number, and location of tumors, guide treatment decisions. Median survival only increases from 3 to 6 months with radiation therapy and steroids to 9 to 12 months with surgery and stereotactic radiosurgery (McCutcheon, 2005).

A brain lesion is diagnosed by history, neurologic examination, diagnostic studies (especially computed tomography [CT] scan and magnetic resonance imaging [MRI]), and biopsy. The manifestations of an intracranial tumor fall into two classes: those resulting from irritation or impairment of function in specific areas of the brain directly affected by the tumor and those resulting from diffuse increased ICP. The most common presentation of brain tumors is progressive neurologic deficit, usually motor weakness. Headache and seizures are also common presenting symptoms (Greenburg, 2005).

Large left or bifrontal lobe tumors may cause striking personality changes and depressive symptoms. Lesions in the left frontotemporal region, where motor speech originates, lead to aphasia. Parietal lobe lesions may result in contralateral weakness and sensory changes, along with defects in the perception of objects. Occipital tumors produce hemianoptic visual defects.

Cortical tumors frequently produce focal seizures of diagnostic value. The onset of epileptiform seizures in an adult is often associated with an intracranial neoplasm. Posterior fossa tumors often manifest their presence by blocking the CSF circulation, but they may also destroy cerebellar function, resulting in incoordination, ataxia, scanning speech, and deafness.

Treatment of brain tumors, although based on the characteristics of the tumor, can involve administration of steroids or antiepileptic medications, management of hydrocephalus, surgery, radiosurgery, radiation, and chemotherapy.

The presentation of multiple brain lesions in a patient is of grave concern, and an infective process should be considered along with the possibility of multiple tumors. Stereotactic biopsy of the lesion is most likely to provide a diagnosis. The operative team may be required to employ precautions to prevent the spread of an unknown infective process. Identification of the infective agent and process determines proper treatment.

Ventricular System and Cerebrospinal Fluid

Within the brain are four communicating cavities, or ventricles, filled with CSF. In the lower medial portion of each cerebral hemisphere lies a large lateral ventricle that resembles a wishbone and is separated anteriorly from its counterpart by a thin septum (see Figure 20-12). Each lateral ventricle has a body and three horns: frontal, occipital, and temporal. Below the bodies of the lateral ventricles is a central cleft, or third ventricle. It communicates anteriorly with the lateral ventricles through the foramen of Monro and posteriorly with the fourth ventricle through the aqueduct of Sylvius—a long, narrow channel passing through the midbrain. The fourth ventricle is a cavity in the posterior fossa, between the cerebellum and the brainstem. In the roof of the fourth ventricle is the foramen of Magendie, an opening into the cisterna magna; at the lateral margins are the two foramina of Luschka, which open into the cisterna pontis. These cisterns are cavities that serve as reservoirs for CSF.

Much of the CSF originates in the choroid plexuses of the ventricles. These are tufted, vascular structures that allow certain fluid elements of the blood to pass through their ependymal linings. The choroid plexus is found along the floor in each lateral ventricle, on the roof of the third ventricle, and in the posterior portion of the fourth ventricle. Most of the fluid is formed in the lateral ventricles and flows through the interventricular foramen of Monro to the third ventricle and through the aqueduct of Sylvius to the fourth ventricle, where it escapes into the subarachnoid space of the basal cisterns through the foramina of Magendie and Luschka. From the basal cisterns the fluid flows around the spinal cord, over the cerebellar lobes, around the medulla and the base of the brain, and over the cerebral hemispheres in the subarachnoid space. The fluid is absorbed into the venous circulation through villi of the arachnoid (pacchionian granulations) into the great dural venous sinuses, particularly the superior sagittal sinus, and by diffusion through perivascular, perineural, and periradicular channels (see Figure 20-7).

Spinal fluid bathes the brain and spinal cord, helps support the weight of the brain, and acts as a cushion for the brain and spinal cord by absorbing some of the force of external trauma. By variation in its volume, it aids in keeping ICP relatively constant. If the brain atrophies, the amount of CSF increases to fill the dead space; if the brain swells, the amount of CSF decreases to compensate for the increase in brain mass. The fluid can

carry certain drugs to diseased parts of the brain. It does not, however, play a significant role in supplying nutrition to the structures that it bathes. The total amount of circulating CSF averages 150 ml in the adult. The ventricles contain about 25 ml, and the remaining CSF circulates in the cranial and spinal subarachnoid space. CSF is secreted at a rate of between 21 and 24 ml/hr, or approximately 450 ml/24 hr. This means that in an adult, CSF is recirculated about three times each day.

Pathologic Conditions Related to Cerebrospinal Fluid. CSF can be examined by the lab to provide diagnostic information. CSF is most commonly obtained by way of lumbar puncture (LP). Because the subarachnoid space surrounding the brain is freely connected to the subarachnoid space of the spinal cord, any abnormal increase in ICP will be directly reflected as an increase at the lumbar site. Tumors, infection, hydrocephalus, and intracranial bleeding can cause increased intracranial and spinal pressure (Pagana and Pagana, 2009). LP is contraindicated when ICP is increased from a suspected intracranial mass that is causing neurologic symptoms. In this situation, the sudden reduction in pressure from the release of CSF could cause brain herniation. The ventricular fluid normally has a protein content of 5 to 15 mg/dl, whereas the protein content of spinal fluid is 25 to 45 mg/dl. These values may be considerably elevated in pathologic conditions of the CNS. The characteristics of normal spinal fluid are as follows:

- Appearance: clear and colorless
- Pressure: less than 20 cm H_2O
- Glucose: 50 to 75 mg/dl, or two thirds of blood glucose level
- Chloride: 700 to 750 mg/dl
- Cells: white blood cells (WBCs)—neonate, 0 to 30 cells/μl; 1 to 5 years, 0 to 20 cells/μl; 6 to 18 years, 0 to 10 cells/μl; adult, 0 to 5 cells/μl
- Protein: lumbar, 15 to 45 mg/dl
- Culture: no growth
- Gamma globulin: 3% to12% of total protein (Pagana and Pagana, 2009)

Elevations in CSF pressure can be caused by an expanding mass within the skull, such as a tumor, hemorrhage, or cerebral edema; an increase in formation or decrease in absorption of fluid, as in meningitis, encephalitis, and other febrile conditions; an increase in venous pressure within the skull from an obstruction to normal venous drainage; a blockage of absorption by inflammatory conditions of the arachnoid and perivascular spaces; any mechanical obstruction of the ventricular or subarachnoidal fluid pathways; or decreased absorption of CSF. These pathologic conditions can cause a dangerous increase in ICP, which ultimately could result in brain herniation and death.

The rate of absorption and production of CSF is related to the osmotic and hydrostatic pressures of the blood. Intravenous (IV) injection of hypertonic mannitol, commonly used with a nonosmotic diuretic, can be employed to pull fluid from tissue to the vascular space for excretion by the kidneys, resulting in systemic diuresis and a decrease in ICP.

Hydrocephalus is a condition marked by an excessive accumulation of CSF, resulting in dilation of the intracerebral ventricles where CSF is synthesized and circulated. Enlargement of cerebral ventricles is the result of CSF blockage and interruption of CSF circulation or CSF reabsorption. The causes of hydrocephalus are many, including congenital conditions, aqueductal stenosis, tumors or cysts of the ventricular system, subarachnoid hemorrhage (SAH), posterior fossa tumors, or trauma with increased ICP. Noncommunicating (obstructive) hydrocephalus involves an obstruction of CSF pathways. In communicating hydrocephalus, the normal CSF pathways are open; however, there is an abnormality in CSF absorption with increased ICP. Normal-pressure hydrocephalus (NPH) is a communicating hydrocephalus that produces a normal pressure on random LP (Greenberg, 2005). NPH most commonly develops in the elderly, probably because of abnormal CSF absorption; however, the cause may not be apparent. Symptoms of dementia, unsteady gait, and urinary incontinence are seen with normal pressure and chronic hydrocephalus. Those with acute hydrocephalus present with headache, nausea, vomiting, drowsiness, and papilledema.

The appropriate surgical procedure depends on the precise type of hydrocephalus. Whenever possible, an obstructing lesion that causes hydrocephalus should be surgically removed. For some cases of obstructive hydrocephalus, endoscopic third ventriculostomy may be possible. With endoscopic third ventriculostomy, CSF can be diverted by surgically creating an opening at the floor of the third ventricle, thus eliminating the need for a shunt. However, treatment of hydrocephalus in both the adult and pediatric populations is generally by placement of a ventriculoperitoneal (VP) shunt (Wang and Avellino, 2005). With acute symptoms, temporary placement of an external ventriculostomy catheter used to measure the ICP and drain CSF may be preferred, thus postponing or eliminating the need for a permanent VP shunt.

Cerebral Blood Supply

The brain requires 20% more oxygen than any other organ to maintain its high level of metabolic activity. The arterial supply to the brain enters the cranium through the two internal carotid arteries anteriorly and the two vertebral arteries posteriorly. These communicate at the base of the brain through the circle of Willis (Figure 20-13), which ensures continuity of the circulation if any one of the four main channels is interrupted. However, these connections are extremely variable and do not always have functional anastomoses. The main branches for distribution of blood to each hemisphere of the brain from the internal carotid arteries are the anterior and middle cerebral arteries. Each artery nourishes a specific area of the brain (Figures 20-13 and 20-14). The anterior cerebral artery supplies the anterior two thirds of the medial surface and adjacent region over the convexity of the hemisphere, thus including about half of the frontal and parietal lobes. The middle cerebral artery supplies most of the lateral surface of the hemisphere, including half of the frontal, parietal, and temporal lobes. The posterior cerebral artery, which originates at the basilar artery, supplies the occipital lobe and the remaining half of the temporal lobe, principally on the inferior and medial surfaces. The brainstem and cerebellum are supplied by branches of the basilar and vertebral arteries.

The cerebral veins do not parallel the arteries as the veins do in most other parts of the body. The external cortical veins anastomose freely in the pia mater, forming larger cerebral veins, and as such they pierce the arachnoid membrane, cross the subdural space, and empty into the great dural venous sinuses. A subdural hemorrhage after head trauma may arise from disruption of these bridging vessels; an epidural hemorrhage

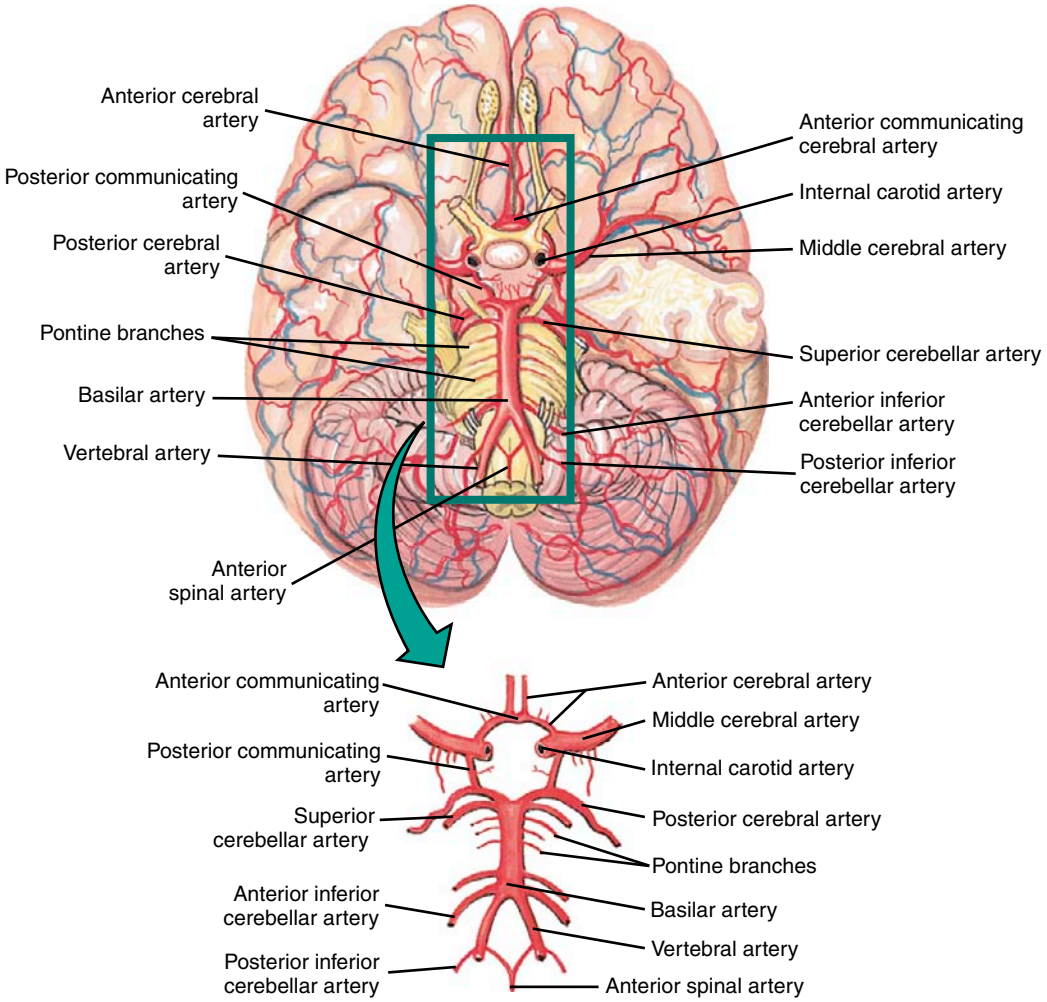

FIGURE 20-13 Principal cerebral arteries and circle of Willis *(box)*.

often results from lacerations of the middle meningeal artery—a branch of the external carotid artery that supplies the dura mater. The deep cerebral veins, which drain the interior of the hemispheres, empty principally into the great vein of Galen and the inferior sagittal sinus (Figures 20-15 and 20-16).

The blood transports oxygen, nutrients, and other substances necessary for the proper functioning of living tissue. The needs of the brain for oxygen and glucose are critical. The brain can store only small amounts of oxygen and energy-producing nutrients. Constant flow of blood to the brain must be maintained.

The brain uses oxygen in the metabolism of glucose—the chief source of energy. Protein and fat metabolism plays little part in energy production. In the face of an oxygen deficit, the survival time of CNS tissue is very short. In the presence of low levels of blood glucose, CNS function is compromised and unconsciousness results.

Generally, all factors affecting the systemic blood pressure indirectly affect the cerebral circulation. The brain normally receives 20% of the cardiac output. The cerebral blood flow is kept constant by an autoregulation phenomenon such that increases in blood pressure lead to vasoconstriction of cerebral arteries and decreases in blood pressure cause cerebral vasodilation to maintain a relatively constant cerebral blood flow. When the mean arterial pressure falls below 60 mm Hg, the autoregulation mechanism usually fails.

Vascular Pathologic Conditions of the Brain. Vascular lesions of the brain are most often diagnosed in people who present with acute, spontaneous intracranial hemorrhage.

ANEURYSMS. Aneurysms arise from a complex set of circumstances involving a congenital anatomic predisposition and local or systemic factors that weaken the arterial wall, leading to dilation. The majority of these lesions occur at the branching points of large subarachnoid conducting arteries. The greatest vulnerability to aneurysmal development occurs at points of vessel bifurcation. Acute SAH in this setting can lead to vessel vasospasm (with greatest risk at 4 to 10 days after the SAH), cerebral ischemia, hydrocephalus, increased ICP, diabetes insipidus, syndrome of inappropriate secretion of antidiuretic hormone (SIADH), respiratory failure, brain injury, and risk of rebleeding. The vessels of the circle of Willis are most often implicated, including the posterior communicating artery, anterior communicating artery, middle cerebral artery, carotid artery, posterior inferior cerebellar artery, vertebral artery, and basilar artery. Surgical intervention techniques are based on the characteristics of the aneurysm. Small neck aneurysms may be occluded using coils placed by means of

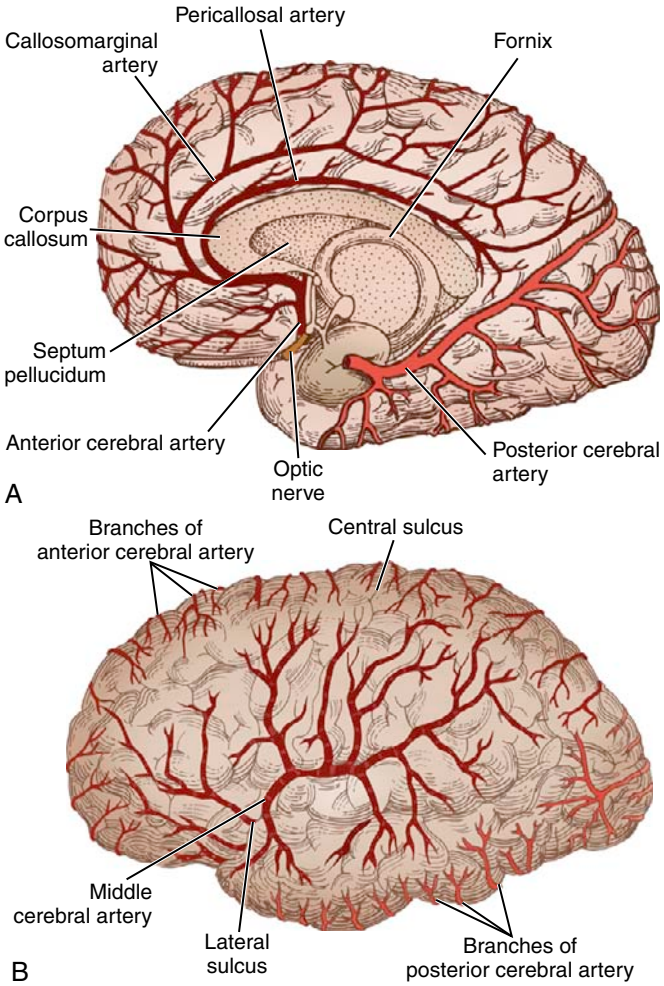

FIGURE 20-14 **A**, Arteries of medial surface of brain. **B**, Arteries of the lateral surface of brain.

interventional radiology techniques. Aneurysmal clipping by way of a craniotomy approach is most often used to treat broad neck aneurysms.

VASCULAR MALFORMATIONS. Vascular malformations of the CNS are characterized by congenital lesions that have the potential to produce symptoms any time during the life of an individual with the malformation. Types of vascular malformations include arteriovenous malformations (AVMs), cavernous malformations, capillary telangiectasias, and venous malformations. AVMs are complex lesions in which direct shunting of arterial blood to the venous system occurs. The vascular channels are tightly packed and have a propensity to hemorrhage. Capillary telangiectasias are small vascular malformations commonly seen in the pons. They rarely bleed. Cavernous malformations are cystic vascular spaces, similar to capillary telangiectasias but larger and with a tendency to bleed. Venous malformations are the most common type, comprising anomalous veins, a single tortuous vein, or a number of smaller veins joining at a single point. These are considered benign and rarely bleed. Surgical excision of the cavernous malformation and the AVM is recommended.

HEMATOMAS. Hematomas are collections of blood that coagulate to form space-occupying lesions. An intracerebral hemorrhage, the cause of stroke in many hypertensive patients, results in hematoma formation most often in the basal ganglia, subcortical white matter, cerebellum, and brainstem. These hematomas compress vital structures, depress consciousness, and can be catastrophic. They are often inoperable (Greenberg, 2005).

Intracranial trauma can cause a shearing of arterial and venous vessels that results in hematoma collections in the epidural and subdural spaces. These space-occupying lesions raise ICP and often result in serious neurologic disruption (Figure 20-17). Epidural hematomas are often the result of a blow to the head causing a tear in the middle meningeal artery, which lies on the dura under the skull. These arterial hemorrhages can be life-threatening in that they can cause rapid deterioration in level of consciousness secondary to size of the bleed and brain displacement by the hematoma (Figure 20-18). In contrast to an epidural hematoma, a traumatic subdural hematoma usually results from venous bleeding and collects more slowly. Bridging veins in the subdural space are torn; blood escapes, dissecting a space between the dura and the arachnoid, and collects over one cerebral hemisphere (Figure 20-19). Subdural hematomas may be acute, subacute, or chronic (Figure 20-20). Chronic hematomas can often be evacuated through burr holes, but acute hematomas may require a craniotomy to remove the clot and control bleeding.

CEREBRAL ISCHEMIA. Any area of the brain can become ischemic from an arterial occlusion or embolization. Symptoms may be gradual or sudden. Intracranial plaques most commonly form at the bifurcation of the internal carotid artery, into the middle and anterior cerebral arteries. In select cases, extracranial-intracranial arterial microanastomosis can be performed. Carotid endarterectomy can be performed for extracranial lesions of the carotid artery (see Chapter 26).

Cranial Nerves

Twelve pairs of cranial nerves arise within the cranial cavity (Figure 20-21). Although they are part of the PNS, from a surgical standpoint they are considered with the head.

First Cranial Nerve. The olfactory nerve, a fiber tract of the brain, is located under the frontal lobe on the cribriform plate of the ethmoid bone. It transmits the sense of smell. Frontal lobe tumors, fractures of the anterior fossa of the skull, and lesions of the nasal cavity may affect the olfactory nerve.

Second Cranial Nerve. The optic nerve is a fiber tract of the brain. It originates in the ganglion cells of the retina and passes through the optic foramen in the apex of the orbit to reach the optic chiasma. A partial crossing of the fibers occurs there; so the fibers from the nasal half of each retina pass to the opposite side. Posterior to the chiasma, the visual pathway is called the *optic tract*. Still farther back, it becomes the optic radiation. Lesions in various parts of this pathway produce characteristic defects in the visual fields. For example, a lesion near the chiasma usually destroys the temporal vision of each eye (bitemporal hemianopia), whereas a lesion of the occipital lobe produces impairment of vision (homonymous hemianopia), affecting the right or left halves of the visual fields of both eyes.

Lesions that affect the optic nerve and are treated by neurosurgery include primary gliomas of the nerve, pituitary tumors that press on the optic chiasma, and occasionally meningiomas of the optic nerve sheath or in the region of the sella turcica

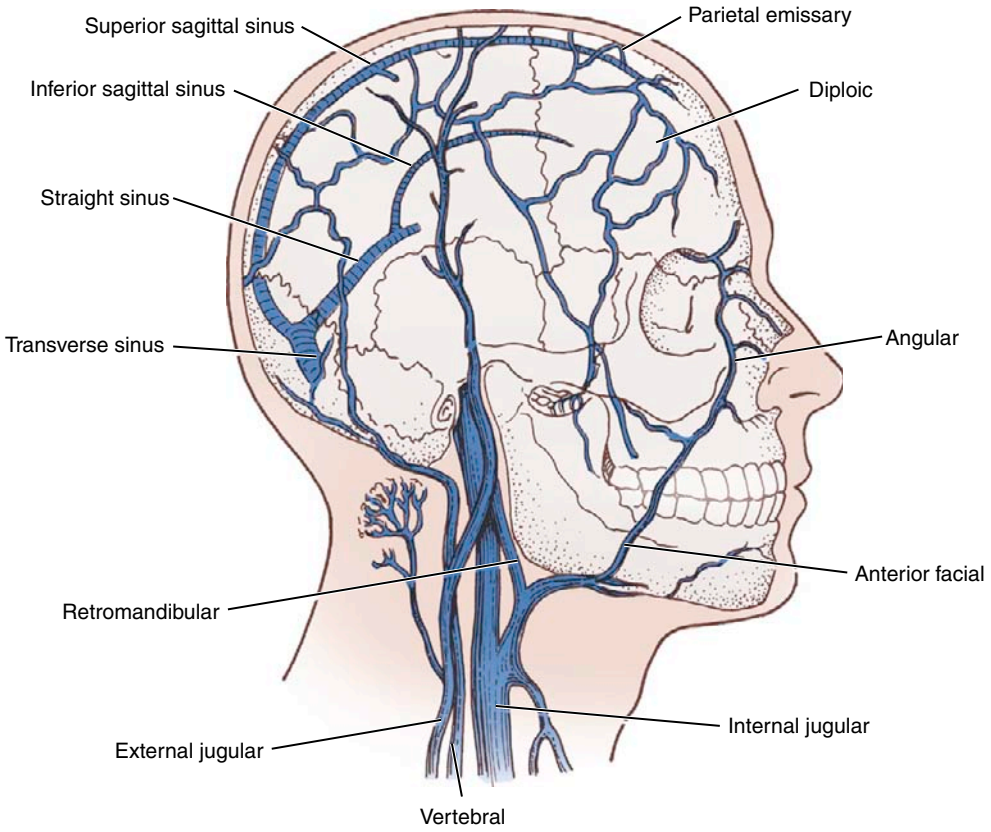

FIGURE 20-15 Semischematic projection of large veins of head. Deep veins and dural sinuses are projected on skull. Note connection (emissary veins) between superficial and deep veins.

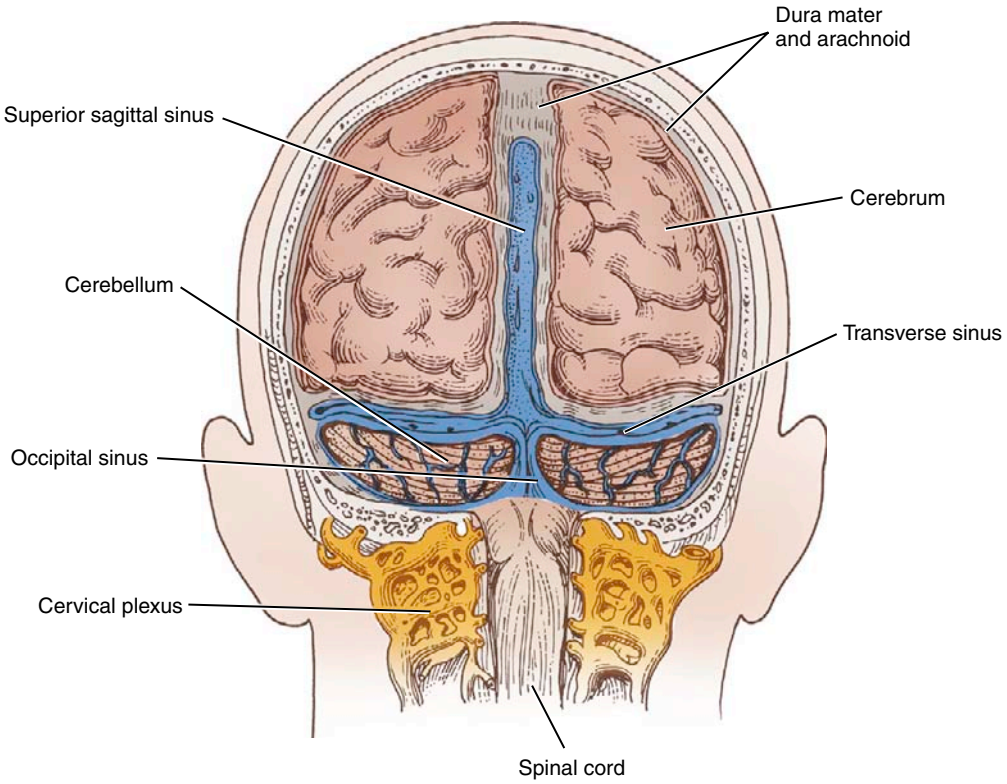

FIGURE 20-16 Venous sinuses shown in relation to brain and skull.

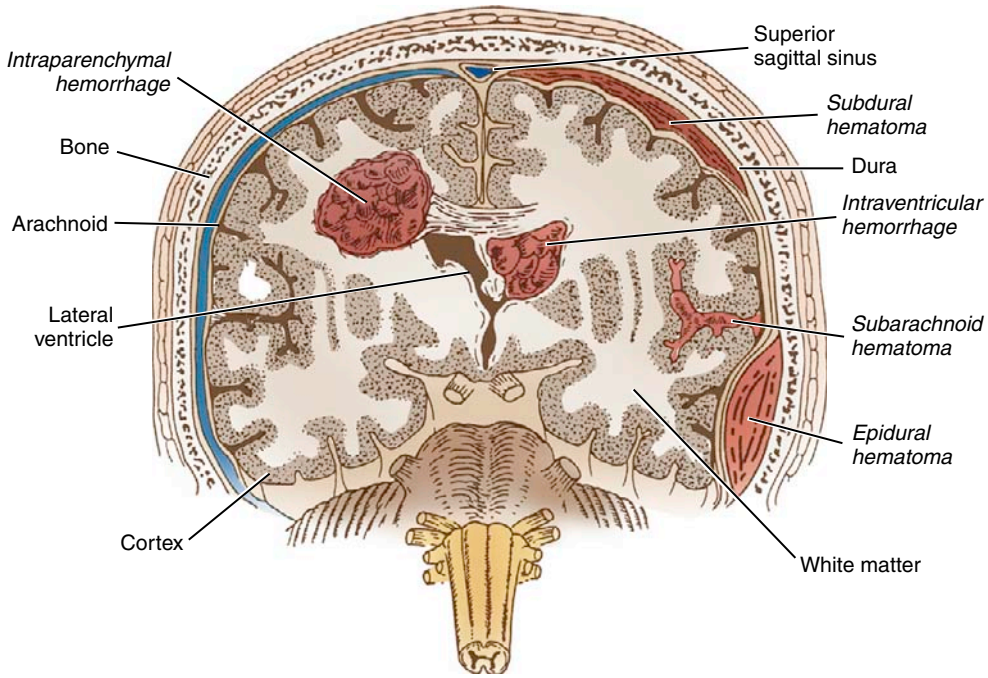

FIGURE 20-17 Types of intracerebral hemorrhage (in italics).

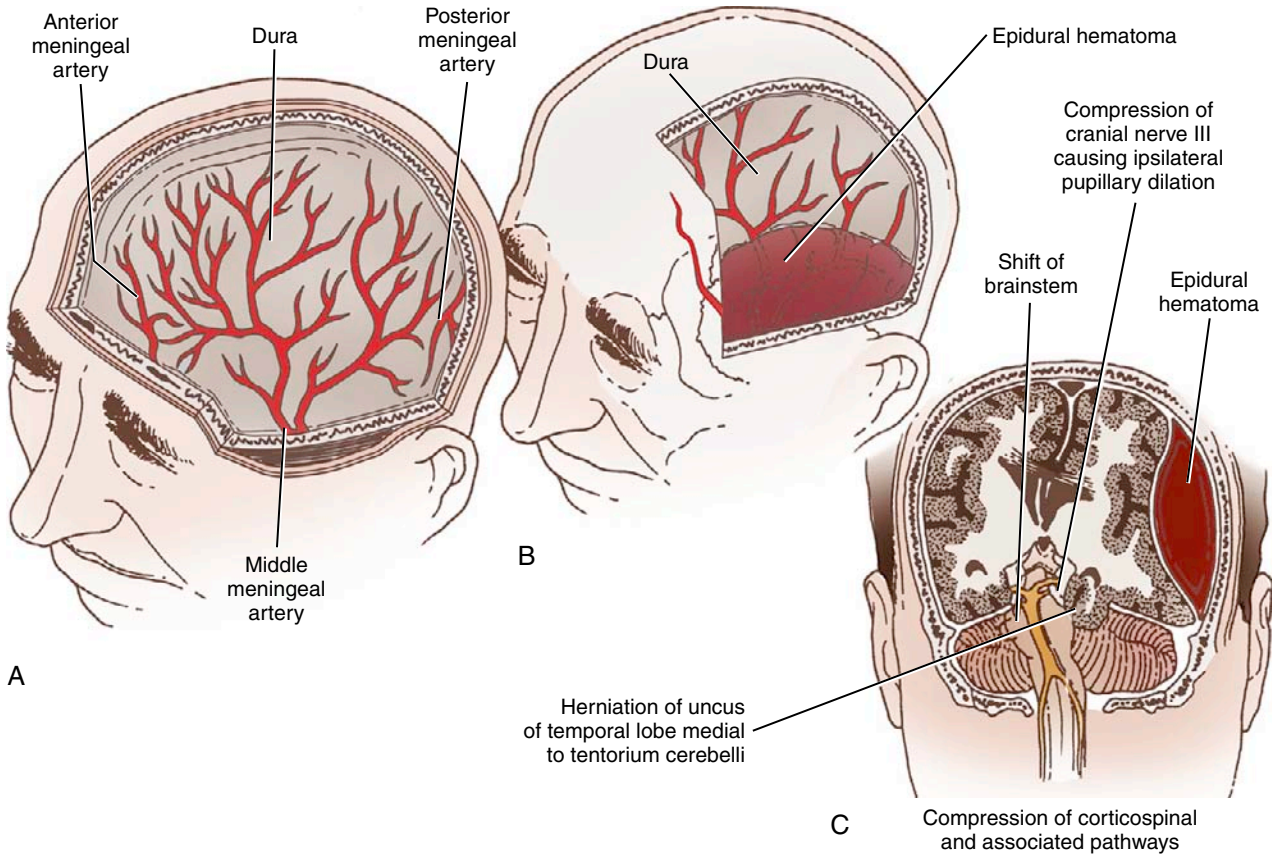

FIGURE 20-18 Epidural hematoma is typically caused by trauma resulting in laceration of the middle meningeal artery. **A**, The middle meningeal artery. The typical traumatic epidural hematoma is caused by a laceration of this vessel. **B** and **C**, A linear fracture of the squamous portion of the temporal bone has torn the middle meningeal artery, which has resulted in an epidural hematoma.

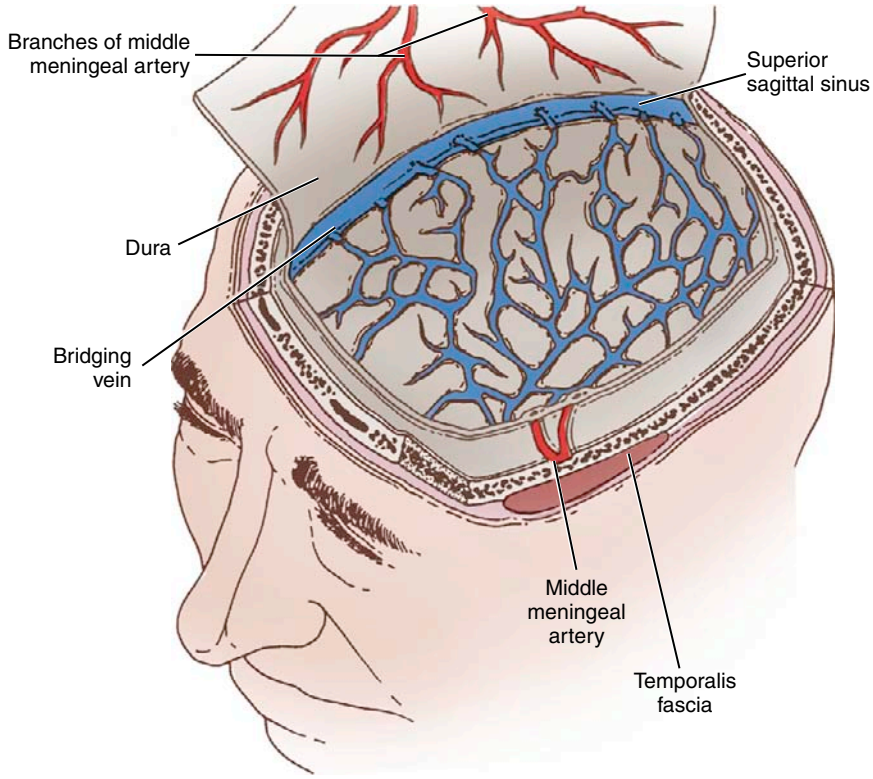

FIGURE 20-19 Veins are shown extending from the surface of the brain to the superior sagittal sinus. Differential movement of the brain within the skull at the time of injury may tear one or more of these veins, leading to the formation of a subdural hematoma.

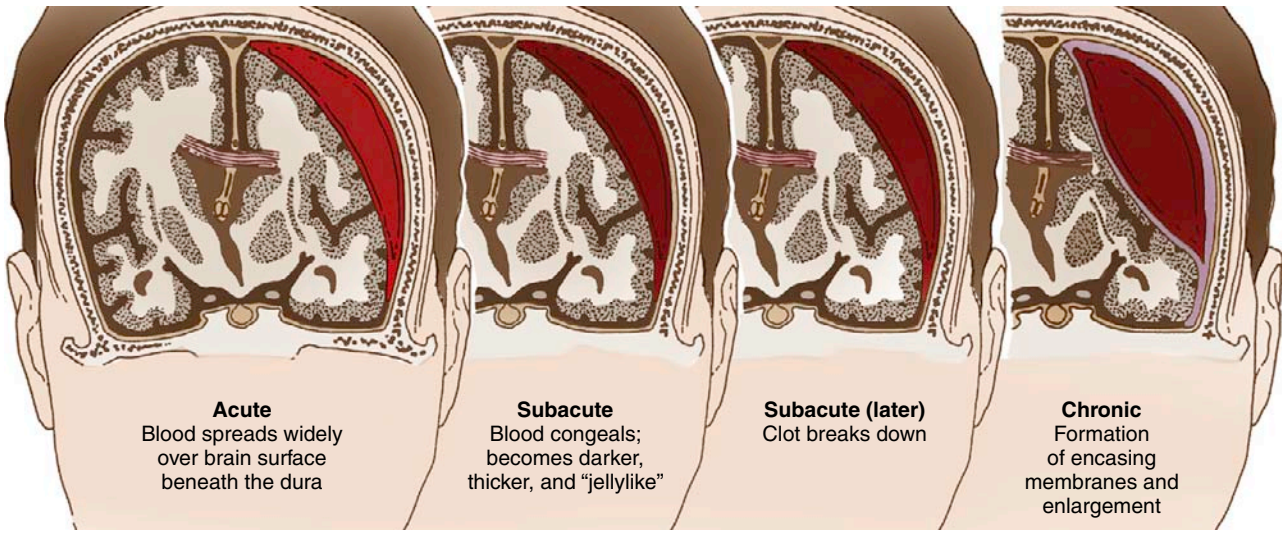

FIGURE 20-20 A subdural hematoma is liquid at first and subsequently clots. It is then reabsorbed or develops into a chronic subdural hematoma as a thick, vascular outer membrane. A thin, inner membrane develops around liquefying blood, starting about 2 weeks after injury. The chronic subdural hematoma enlarges as further bleeding occurs within it.

and olfactory groove. The optic nerves and chiasma are best exposed through a frontal craniotomy along the floor of the anterior fossa or through a frontotemporal approach along the sphenoid ridge. Cranial base approaches using an orbital osteotomy or orbital-zygomatic osteotomies improve access and exposure of the optic system.

Third, Fourth, and Sixth Cranial Nerves. The third, fourth, and sixth cranial nerves are three pairs of nerves—the oculomotor, the trochlear, and the abducens, respectively. They are conveniently considered together because they are the motor nerves to the muscles of the eyes. They are affected by many toxic, inflammatory, vascular, and neoplastic lesions. The third

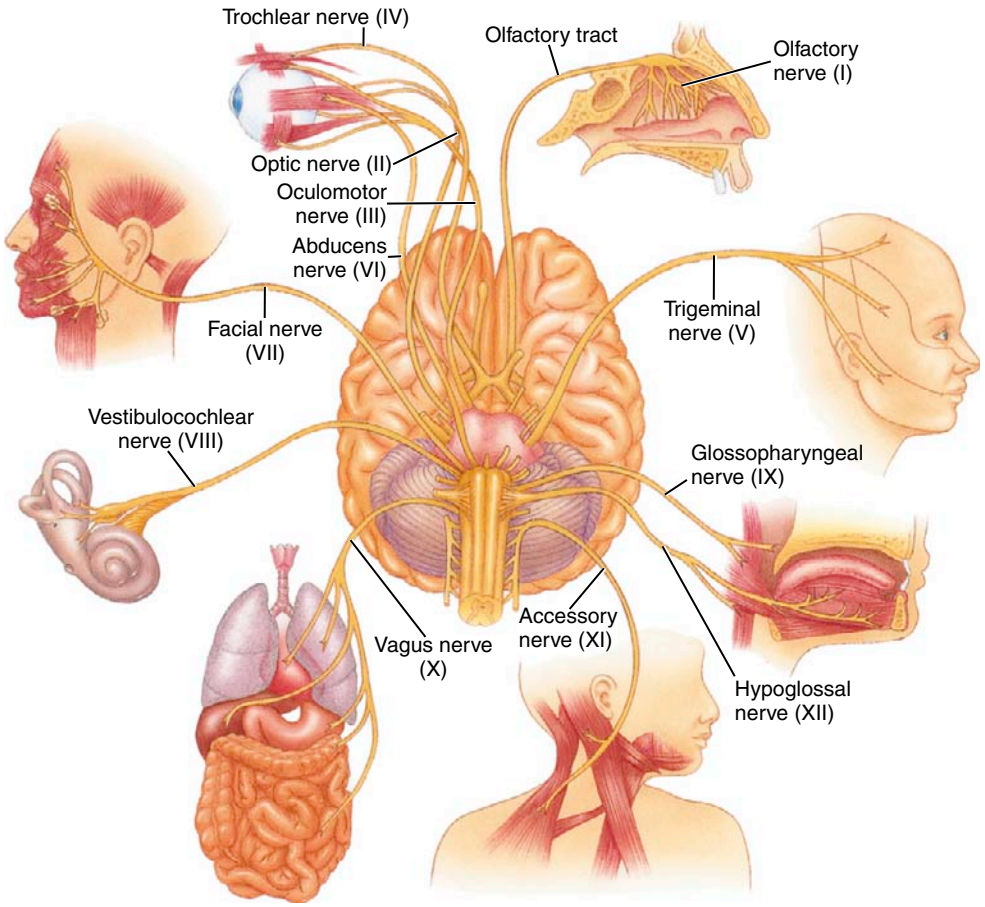

FIGURE 20-21 Ventral surface of brain showing attachment of cranial nerves.

nerve may be affected by aneurysms of the posterior communicating artery, and pressure against this nerve accounts for pupillary dilation when temporal lobe (uncal) herniation, resulting from increased ICP, is present.

Fifth Cranial Nerve. The trigeminal nerve has two functions: (1) sensory supply to the forehead, eyes, meninges, face, jaw, teeth, hard palate, buccal mucosa, tongue, nose, nasal mucosa, and maxillary sinus; and (2) motor innervation of the muscles of mastication. The sensory fibers that arise from cells in the trigeminal ganglion travel along the medial wall of the middle cranial fossa and then extend peripherally in three divisions: ophthalmic, maxillary, and mandibular. Behind the ganglion the fibers enter the brainstem by way of the sensory root. The motor root, which originates from cells in the brainstem, follows the course of the larger sensory component (Figure 20-22).

Trigeminal neuralgia (tic douloureux) is characterized by excruciating, piercing paroxysms of pain, affecting one or more of the major peripheral divisions. The recurrent attacks are usually instigated by stimulation of trigger zones present about the face, nares, lips, and teeth. This condition, believed to be caused by a high incidence of vascular compression on the root entry zone of the nerve leading to demyelination, tends to occur unilaterally and in older persons. Medical treatment is frequently unsuccessful in the long term. Types of neurosurgical procedures currently recommended for trigeminal neuralgia include percutaneous rhizotomy using glycerol, radiofrequency, or balloon compression; radiosurgery; and microvascular decompression (Research Highlight). Microvascular decompression requires a suboccipital craniotomy and is the most invasive of the techniques. However, it is the least destructive and probably the most durable treatment.

Seventh Cranial Nerve. The facial nerve supplies the musculature of the face and the sensation of taste for the anterior two thirds of the tongue. It originates in the brainstem, passes through the skull with the eighth nerve by way of the internal acoustic meatus, continues along the facial canal, and exits just posterior to the parotid gland. The nerve may be damaged by vestibular schwannomas (e.g., acoustic neuromas), fractures at the base of the skull, mastoid infections, and surgical procedures in the vicinity of the parotid gland.

Bell's palsy, a facial lower motor neuron paralysis, can affect the seventh nerve. It may last for a few weeks to a few months, but recovery usually takes place. When permanent interruption of the nerve occurs, useful operations for restoration of function include spinal accessory-facial anastomosis and hypoglossal-facial anastomosis. These operations are performed high in the neck behind the parotid gland by use of the operating microscope.

Eighth Cranial Nerve. The acoustic nerve has two parts, both sensory—the cochlear for hearing and the vestibular for balance. The former receives stimuli from the organ of Corti and the latter from the semicircular canals. The major surgical

RESEARCH HIGHLIGHT

Gamma Knife Therapy for Trigeminal Neuralgia

Trigeminal neuralgia is an extremely painful and debilitating condition characterized by unilateral intense pain in the ear, eye, lips, nose, scalp, forehead, teeth, or jaw. A variety of treatments, including microvascular surgical decompression, are offered to patients. These treatments have varying degrees of success and recurrence of the pain is an unfortunate phenomenon. Patients who have persistent or recurrent symptoms despite intervention represent approximately 10% to 30% of patients who undergo microvascular decompression (MVD), 20% to 50% of those who undergo a percutaneous destructive procedure, and 30% to 40% of those who undergo Gamma Knife radiosurgery. The Gamma Knife creates a lesion at the root entry of the trigeminal nerve, resulting in degeneration of the axons and ability to transmit impulses.

Researchers investigated the use of the Gamma Knife as a salvage procedure in patients who had recurrent or persistent pain after surgical treatment and/or failure of medical management. A total of 79 patients underwent salvage Gamma Knife radiosurgery as a treatment for their trigeminal pain. Pain outcome and quality-of-life indicators were measured 1 month after treatment during the patient follow-up visit and periodically after that via surveys and chart analysis.

The median follow-up period measured after the Gamma Knife therapy was 5.3 years. Analysis of the data showed that at 5 years, 20% of patients were pain free and 50% had pain relief; 41% of the group studied required a subsequent procedure.

Researchers concluded that while salvage Gamma Knife therapy for refractive trigeminal neuralgia is an effective and safe treatment, additional research is indicated to gain further understanding about the mechanism of action responsible for recurrent trigeminal dysfunction.

Modified from Little AS et al: Salvage gamma knife stereotactic radiosurgery for surgically refractive trigeminal neuralgia, *Int J Radiat Oncol Biol Phys* 74(2):522-527, 2009.

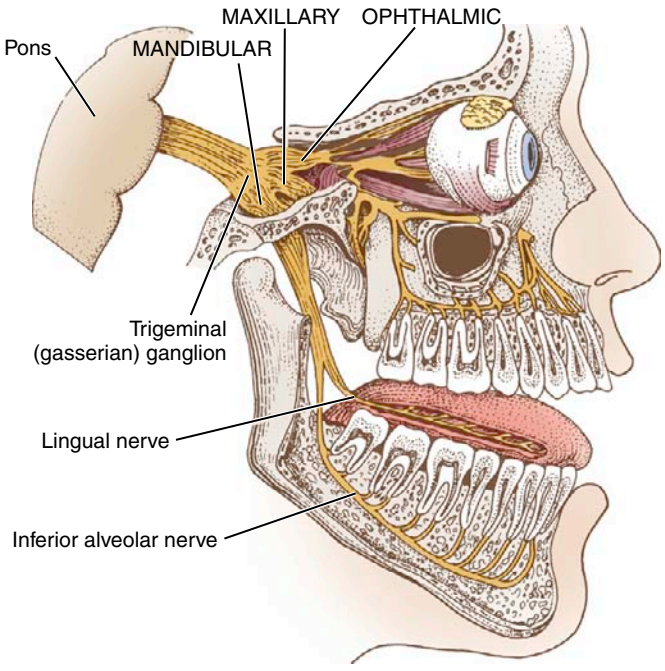

FIGURE 20-22 Trigeminal (fifth cranial) nerve and its three main divisions.

lesion of the eighth nerve is vestibular schwannoma (acoustic neuroma), a histologically benign tumor growing from the nerve sheath at its entrance into the internal auditory meatus. This tumor arises deep in the angle between the cerebellum and pons (cerebellopontine angle). Symptoms may include unilateral deafness, tinnitus, unilateral impairment of cerebellar function, numbness of the face from involvement of the fifth cranial nerve, and, late in the course, papilledema caused by increased ICP. The operative approach is usually through a retrosigmoid craniotomy, exposing the edges of the transverse and sigmoid sinuses. The surgeon must take great care to prevent injury to the pons and to preserve the facial nerve. Attempts are made to preserve the acoustic nerve with smaller tumors when hearing preservation is an option.

Meniere's disease is an affliction of the eighth nerve characterized by a recurrent and usually progressive group of symptoms including dizziness and a sensation of fullness or pressure in the ears. When medical measures fail to alleviate the problem, sectioning of the eighth nerve may be a surgical option.

Ninth Cranial Nerve. The glossopharyngeal nerve supplies the sense of taste to the posterior third of the tongue, supplies sensation to the tonsils and pharyngeal region, partially innervates the pharyngeal muscles, and primarily innervates the carotid sinus. Stimulation of the baroreceptors of the carotid sinus causes slowing of the heart, vasodilation, and decreased blood pressure. Its sensory component can be sectioned to treat a hypersensitive carotid sinus, or it can be sectioned in conjunction with the fifth nerve to treat painful malignancies of the face, mouth, and pharynx. The ninth nerve lies near the eighth nerve in the posterior fossa and is exposed in a similar way.

Tenth Cranial Nerve. The vagus nerve has many motor and sensory functions, primarily including innervation of pharyngeal and laryngeal musculature, control of heart rate, and regulation of acid secretion of the stomach. In neck surgery, the surgeon carefully avoids injury to the recurrent laryngeal branch because its injury results in vocal cord paralysis. In gastric surgery, the surgeon could sever the vagus nerve at the lower end of the esophagus to treat a peptic ulcer. The neurosurgeon is also concerned with preventing damage to the vagus nerve during posterior fossa surgery.

Eleventh Cranial Nerve. The spinal accessory nerve is a motor nerve to the sternocleidomastoid and trapezius muscles. To restore mobility to the face, it may be anastomosed to the peripheral end of a damaged facial nerve.

Twelfth Cranial Nerve. The hypoglossal nerve innervates the musculature of the tongue. Its neurosurgical interest is similar to that of the spinal accessory nerve.

Table 20-2 gives the function, origin, structures innervated, and assessment of the cranial nerves.

SPINE, SPINAL CORD, AND ADJACENT STRUCTURES

Vertebral Column

The primary roles of the spine are maintaining stability, protecting the neural elements, and allowing range of motion. The vertebral column has four distinct curves: cervical lordosis

TABLE 20-2

Understanding Cranial Nerves

Cranial Nerve	Function	Origin	Structures Innervated	Assessment
I Olfactory	Sensory	Olfactory bulbs below frontal lobes	Olfactory mucous membranes	Ability to identify familiar odors
II Optic	Sensory	Diencephalon	Retina of eye	Visual acuity Visual fields
III Oculomotor	Motor	Midbrain	Medial, superior, and inferior rectus muscles of eye Inferior oblique eye muscles Sphincter of iris	Extraocular movements Pupillary reaction to light and accommodation
IV Trochlear	Motor	Midbrain	Superior oblique muscle of eye	Extraocular movements
V Trigeminal	Mixed	Pons	*Sensory:* pain, touch, and temperature sensations in cheeks, jaw, and chin; corneal reflex *Motor:* muscles of mastication	Sensation in forehead, cheeks, jaw, and chin Mastication
VI Abducens	Motor	Pons	Lateral rectus muscle of eye	Extraocular movement
VII Facial	Mixed	Pons	*Sensory:* anterior two thirds of tongue *Motor:* muscles of face, forehead, and eye	Taste for anterior two thirds of tongue Movement of facial muscles (smile) Facial symmetry
VIII Acoustic	Sensory	Pons	Cochlear organ of Corti Vestibule and semicircular canals	Hearing acuity Balance
IX Glossopharyngeal	Mixed	Medulla	*Sensory:* posterior third of tongue *Motor:* muscles of pharynx	Taste for posterior third of tongue Movement of pharynx Gag reflex
X Vagus	Mixed	Medulla	*Sensory:* skin of external ear and mucous membranes *Motor:* muscles of larynx, pharynx, and esophagus; thoracic and abdominal viscera	Swallowing Movement of pharynx Gag reflex Cough
XI Spinal accessory	Motor	Medulla	Sternocleidomastoid and trapezius muscles	Shoulder shrug Turn head
XII Hypoglossal	Motor	Medulla	Tongue	Movement and strength of tongue

(a backward bend), thoracic kyphosis (a forward bend), lumbar lordosis, and sacral kyphosis. The spinal column consists of 33 vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused as 1 section), and 1 coccygeal, which may have 1 to 3 fused sections (Figure 20-23).

The first cervical vertebra, or atlas, supports the skull. The second cervical vertebra, or axis, can be identified by its odontoid process, a vertical projection extending into the foramen of the atlas like a stick in a hoop. It rests against the anterior tubercle of the first cervical vertebra. Ligaments hold the two together but allow considerable rotational movement. The other cervical, thoracic, and lumbar vertebrae are more alike in structure. Each has a body, an oval block of bone situated anteriorly. An intervertebral disk, a fibrocartilaginous elastic cushion, separates one body from another (Figures 20-24 and 20-25). The spinal cord lies in a canal formed by the vertebral bodies, pedicles, and laminae. Articular surfaces or facets project from the pedicles and form joints with the facets of the vertebrae above and below. Transverse processes extend laterally and serve as hitching posts for muscles and ligaments. Spinous processes extend posteriorly and can be palpated in most people. The vertebrae are held together by multiple ligaments and muscles (see Figure 20-25). Motion of the spine occurs at the articular facets and through the elastic intervertebral disks. The intervertebral disks bond the adjacent surfaces of the vertebral bodies. Each disk consists of a fibrous outer annulus that contains the inner nucleus pulposus.

Spinal Cord

The spinal cord is protected by the bony framework of the spinal column. The dura mater is separated from its bony surroundings by a layer of epidural fat. Beneath the dura mater is the arachnoid, a continuation of the same structure in the head. The subarachnoid space contains CSF. A thin layer of pia mater adheres to the cord, and CSF also circulates from the fourth ventricle into the central canal of the cord.

The spinal cord is a downward prolongation of the brainstem, starting at the upper border of the atlas and ending at the upper border of the second lumbar vertebra (Figure 20-26). The cord is oval in cross section. It is slightly flattened in the anteroposterior diameter. A cross section looks like a gray H

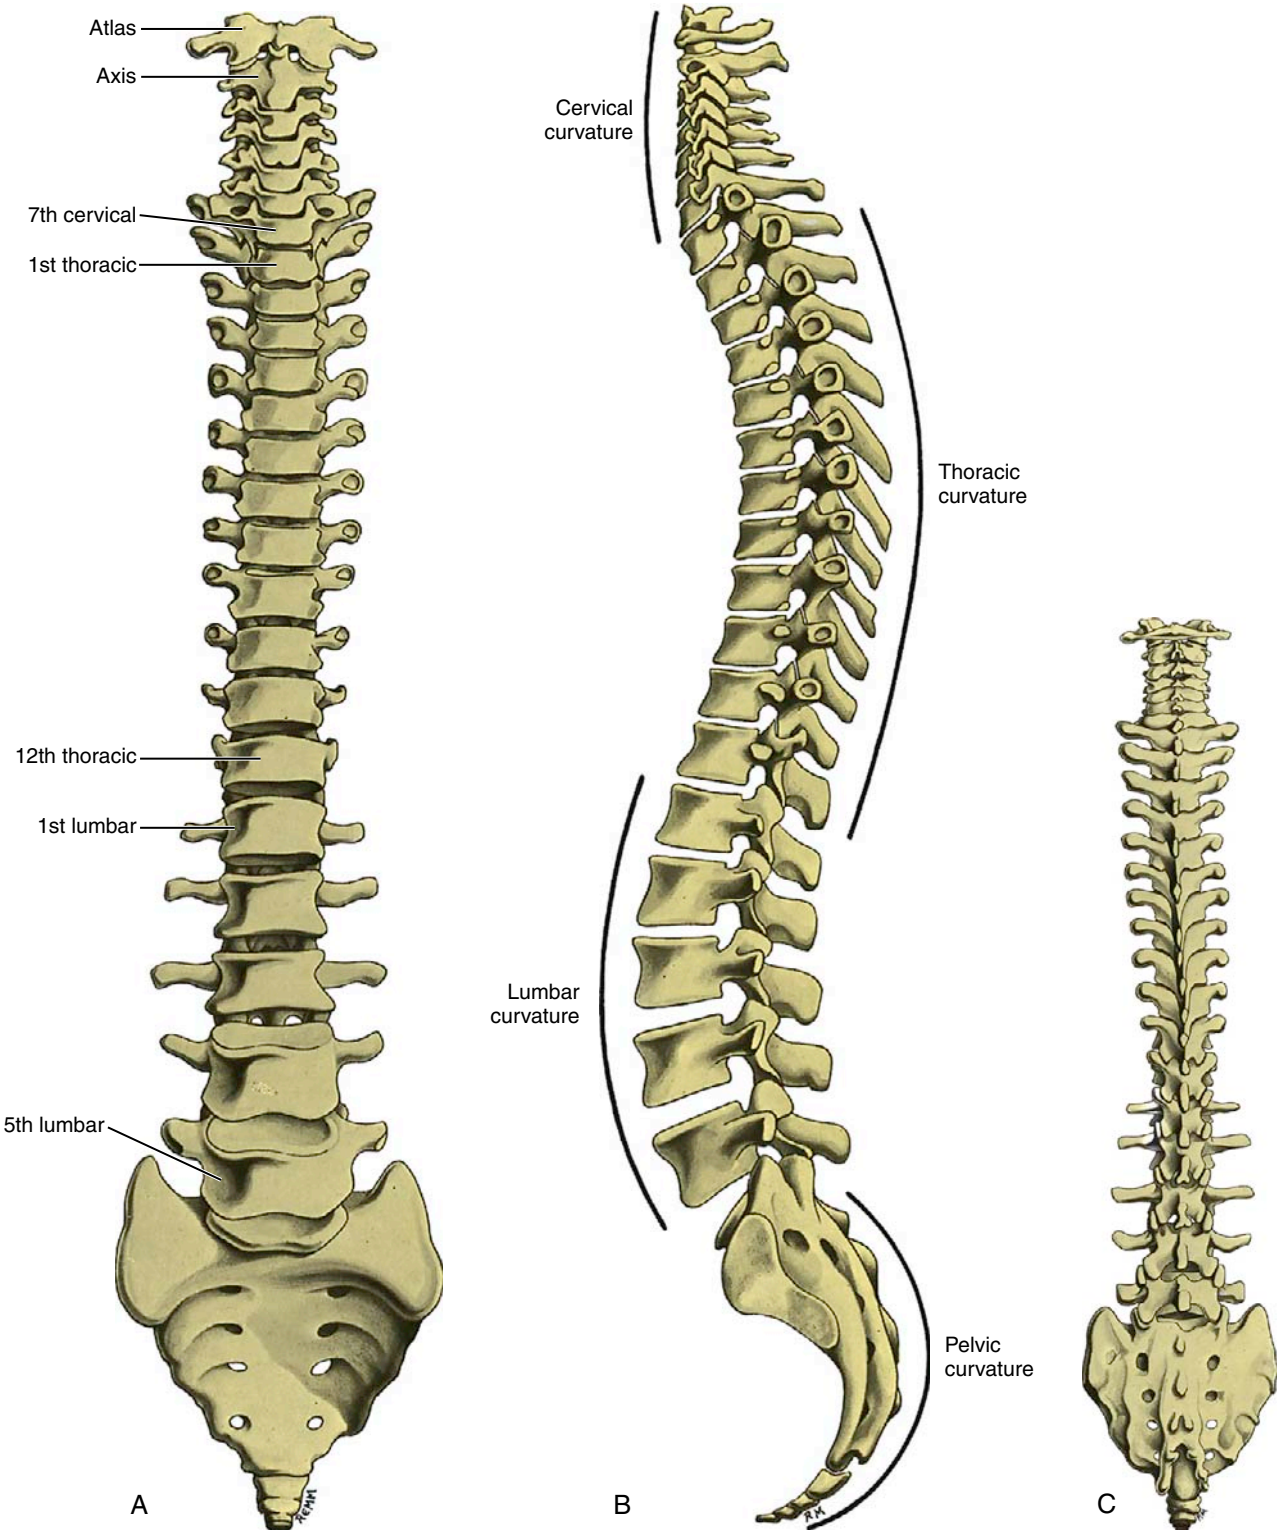

FIGURE 20-23 The vertebral column: **A**, anterior aspect; **B**, lateral aspect; **C**, posterior aspect.

surrounded by a white mantle split in the midline, anteriorly and posteriorly, by sulci (Figure 20-27).

The peripheral white matter carries long, myelinated motor and sensory tracts. The central gray matter consists of nerve cell bodies and short, unmyelinated fibers (see Figures 20-26 and 20-27). The principal long pathways are the laterally placed pyramidal tracts, carrying impulses down from the cerebral cortex to the motor neurons of the cord; the dorsal ascending columns, mediating sensations of touch and proprioception; and the anterolaterally placed spinothalamic tracts, carrying pain and temperature sensations to the thalamus—the sensory receiving station of the brain (Figure 20-28).

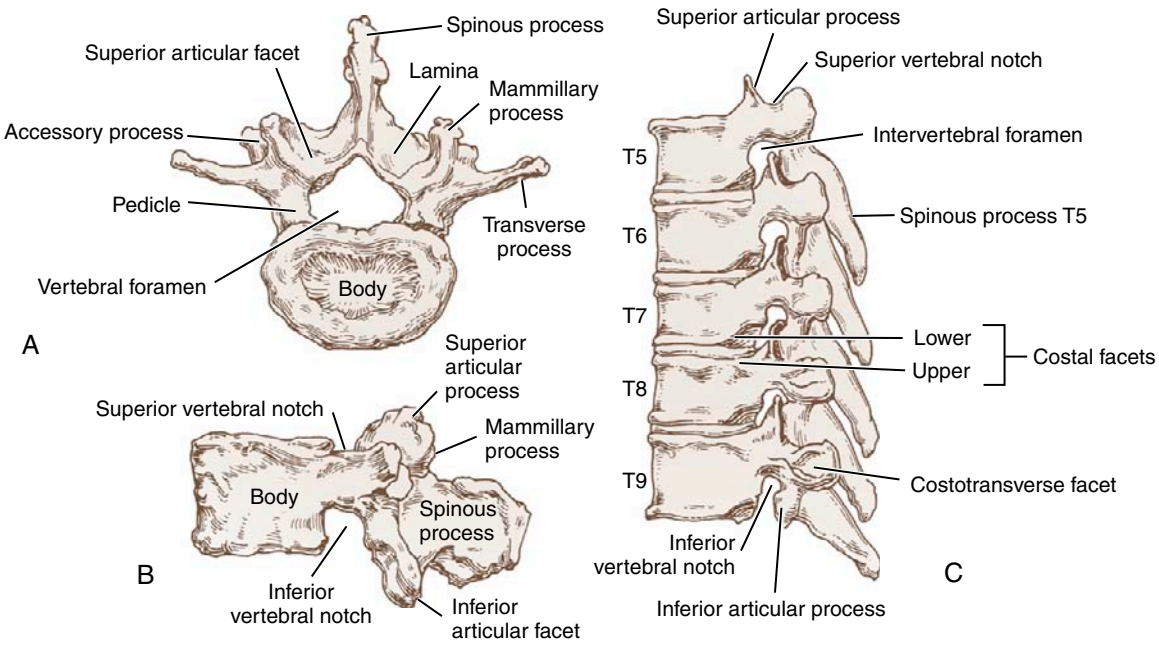

FIGURE 20-24 **A**, Fourth lumbar vertebra from above. **B**, Fourth lumbar vertebra from side. **C**, Fifth to ninth thoracic vertebrae, showing relationships of various parts.

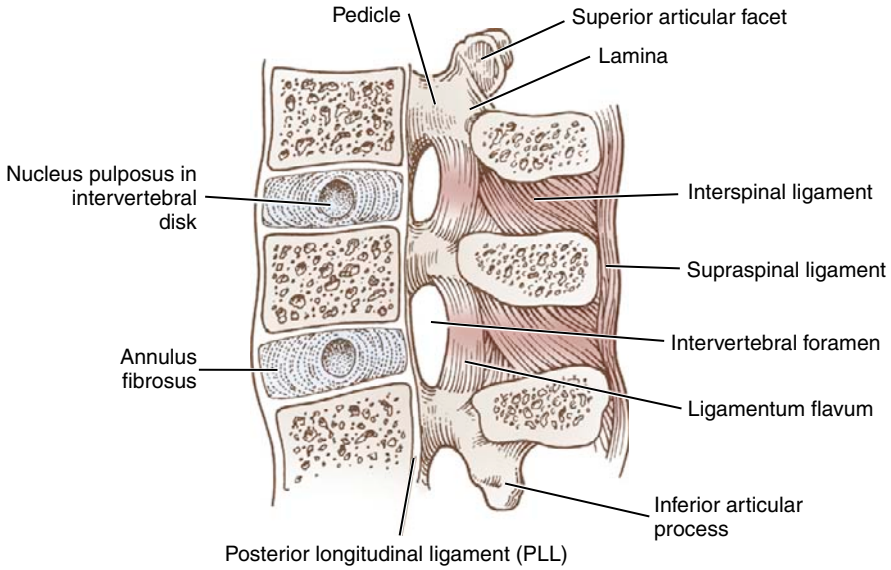

FIGURE 20-25 Median section through three lumbar vertebrae, showing intervertebral disks (nuclei pulposi).

Spinal Nerves

At each vertebral level is a pair of spinal nerves, each consisting of an anterior and a posterior root (see Figure 20-27). The anterior, or motor, root contains cell bodies that lie in the anterior horn of the spinal gray matter. The posterior, or sensory, root contains cell bodies that lie in the spinal ganglia located in the intervertebral foramina, the opening through which the nerves exit from the spinal canal and emerge from the cord. The course of the cervical nerves is horizontal, but at each lower level they assume an increasingly oblique and downward direction. In the lumbar region, the course of the nerves is nearly vertical, forming the cauda equina (see Figure 20-26).

The normal segmental sensory distribution is valuable in the anatomic localization of sensory disorders (Figure 20-29).

Dermatomes are bands of skin innervated by a sensory root of a single spinal nerve. Knowledge of these dermatomes aids the practitioner in locating neurologic lesions (Figure 20-30).

Spinal Vasculature

The vasculature of the spinal cord and vertebral column is a rich, delicate network. The arterial blood supply to the spinal cord arises from the vertebral arteries as the anterior spinal artery and the posterior spinal arteries. These vessels branch and anastomose on both sides of the cord and within the

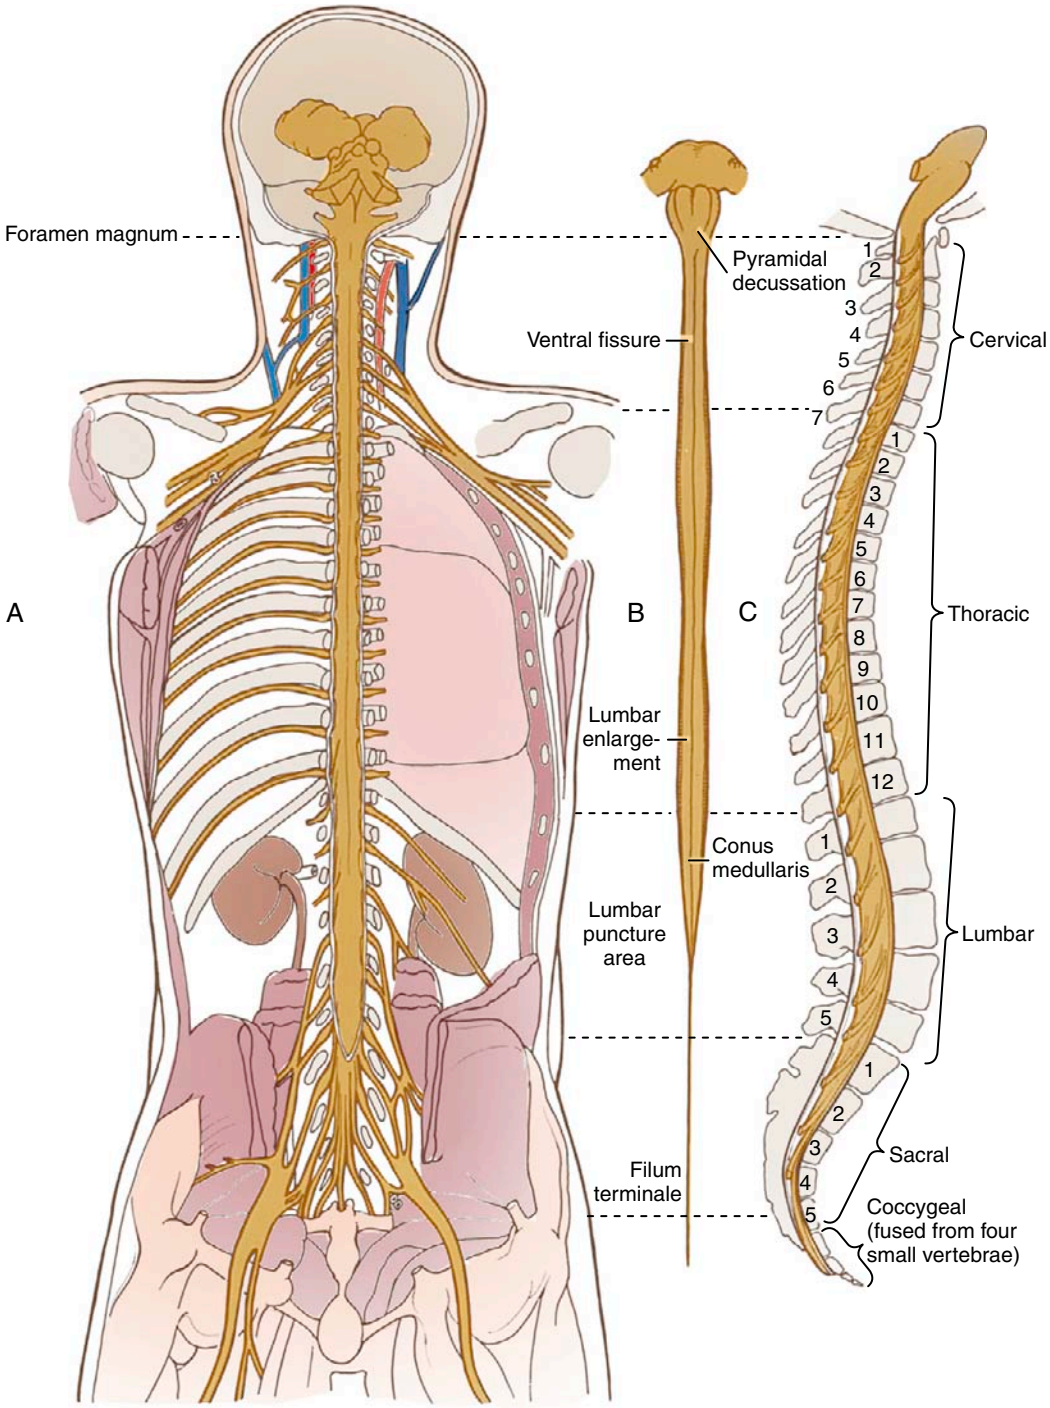

FIGURE 20-26 Posterior view of brainstem and spinal cord. **A**, Torso dissected from back is shown. Dura mater has been opened and cord exposed. Levels concerned can be easily determined by referring to ribs on left side of thorax. Cord proper terminates opposite body of second lumbar vertebra (**B**) as conus medullaris. **B**, Ventral surface of cord stripped of dura mater and arachnoid. It is symmetric in structure, two halves of which are separated by ventral fissure. This fissure stops at foramen magnum. Caudally, pia mater leaves conus medullaris as glistening thread, or filum terminale. **C**, Cord is exposed from lateral side. Dura mater has been opened. Because cord is shorter than canal and spinal nerves exit through intervertebral foramina, one at a time, lowest portion of canal is occupied only by a bundlelike accumulation of nerve roots—cauda equina. Caudal end of dural sac, enclosing spinal cord and cauda equina, lies somewhere between bodies of first and third sacral vertebrae. Size and position of the three views correspond, and elimination of major vertebral levels is indicated by transverse lines for all three figures.

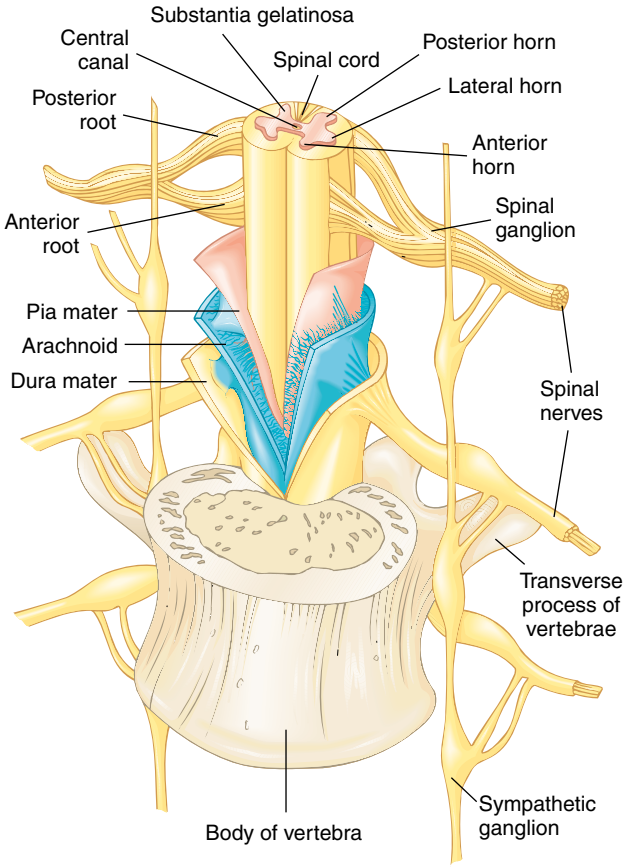

FIGURE 20-27 Spinal cord, showing meninges, formation of spinal nerves, and relationships to vertebra and to sympathetic trunk and ganglia.

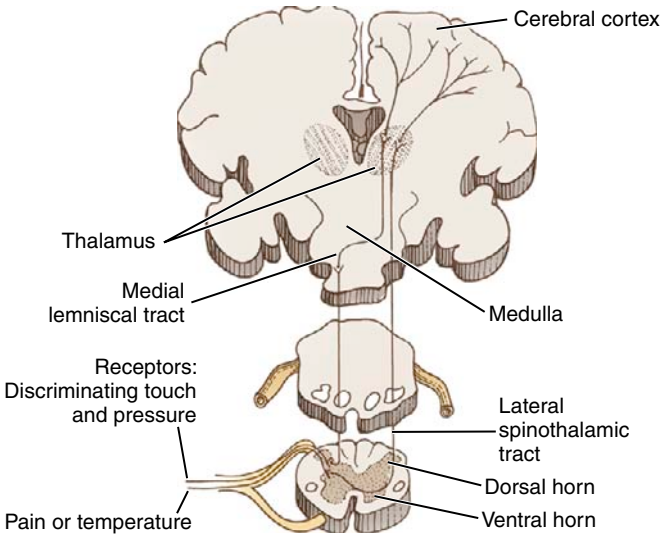

FIGURE 20-28 Lateral spinothalamic and medial lemniscal neural tracts.

substance of the cord. They also branch into anterior and posterior radicular arteries that form spinal rami as they accompany the spinal nerve roots through the intervertebral foramina.

A series of venous plexuses surround and innervate the spinal cord at each level in the vertebral canal. They anastomose with each other and form the intervertebral veins as they pass through the intervertebral foramina with the spinal nerves to join the intercostal, lumbar, and sacral veins. The lateral longitudinal veins near the foramen magnum empty into the inferior petrosal sinus and cerebellar veins. The venous network innervates the bony structures and musculature as well as the spinal cord and nerve roots. The perioperative nurse considers the possibility of venous bleeding during spinal surgery when planning care.

Pathologic Lesions of the Spinal Cord and Adjacent Structures

Surgery is performed to correct congenital malformations, traumatic injuries, tumors, abscesses, herniated and degenerative intervertebral disks, and intractable pain.

Meningocele. The most common congenital lesion encountered is a lumbar meningocele, or myelomeningocele—a failure of the union of the vertebral arches during fetal development. The fluid-filled, thin-walled sac often contains neural elements. This fetal anomaly is often diagnosed prenatally and is often seen with other CNS abnormalities, which include hydrocephalus, gyral abnormalities, and Chiari's malformation of the hindbrain. Refer to Chapter 25 for a discussion of the surgical treatment of meningocele.

Trauma. Trauma to the spine is most commonly caused by motor vehicle crashes and falls. The most common types of vertebral column injuries are fractures, subluxation (dislocation) injuries, and disk herniation, resulting in neurologic injury in 15% of trauma patients (Mendel et al, 2005). The cervical spine is the most vulnerable to injury. Spinal cord injury (SCI) occurs in males three to four times more often than females, usually between the ages of 15 and 30 years (Perrin and McBroom, 2005). Standardized trauma care and transport, early diagnosis, and closed reduction with surgical stabilization as necessary are part of spinal care focused on minimizing cord trauma and maximizing cord recovery. Spinal decompression, stabilization, and traction are all common interventions performed in trauma centers.

Spine and Spinal Cord Tumors. The most frequently occurring tumors of the spine are metastatic, and the spine is the most common site for skeletal metastasis. Although it is estimated that between 5% and 10% of cancer patients develop *symptomatic* spinal metastasis, it is estimated that as many as 30% to 90% of cancer patients actually develop skeletal metastasis (Donthineni, 2009). Pain is the earliest and most prominent symptom, followed by weakness. Secondary spinal tumors most often originate from carcinomas of the lung, breast, prostate blood. Approximately 17% of patients with other primary tumors may experience cord compression as a result of spinal metastases. Metastases to the spine have a predilection toward the thoracic spine, followed by the lumbar and cervical areas (Donthineni, 2009). Treatment goals for metastatic tumors of the spine are pain relief and preservation or restoration of neurologic function. Options include radiation, surgery, or a combination of these. Surgery involves both decompression of the spinal cord and nerve roots and stabilization of the spinal column.

Spinal tumors are classified according to location as *extradural* (outside the dura mater) or *intradural* (inside the dura mater). Intradural tumors may be either *extramedullary*

SURGICAL INTERVENTIONS

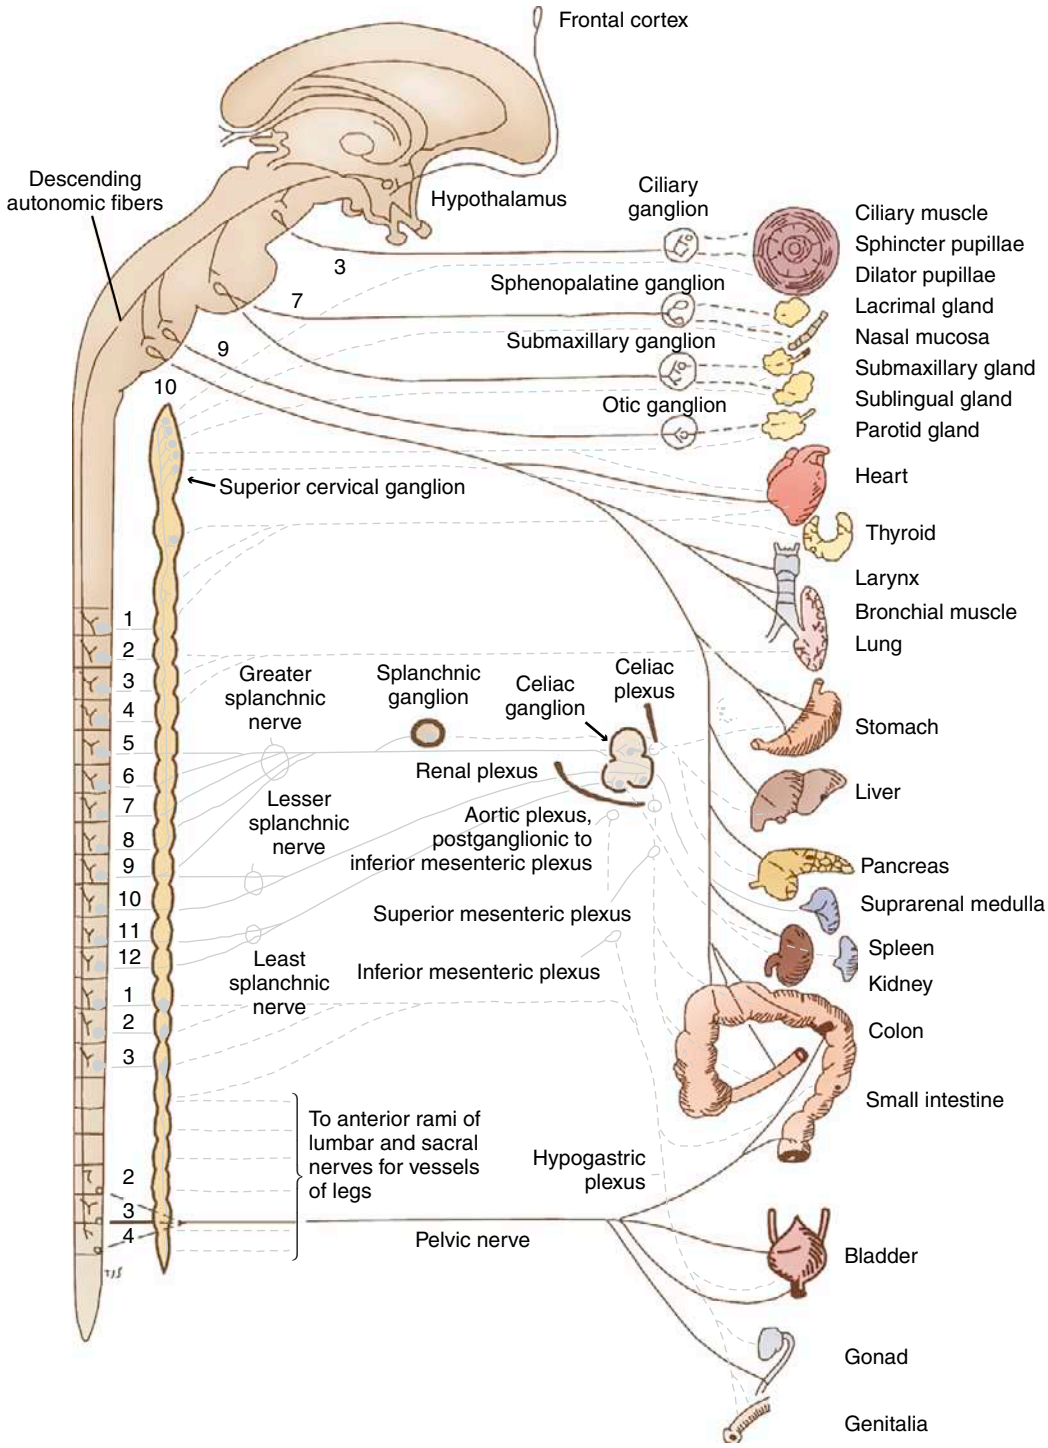

FIGURE 20-29 Sympathetic division of the autonomic nervous system.

(outside the cord) or *intramedullary* (within the cord). Although metastatic tumors may be found in each category, they are usually extradural. Spinal cord tumors account for approximately 15% of CNS tumors (Greenberg, 2005). Most primary CNS tumors are benign.

Extradural tumors arise outside the spinal cord in vertebral bodies or epidural tissues. They account for 50% to 60% of spinal cord neoplasms and include sarcomas and carcinomas, which may be metastatic from adjacent structures in or around the vertebrae (Harrop, 2005). Other extradural lesions include

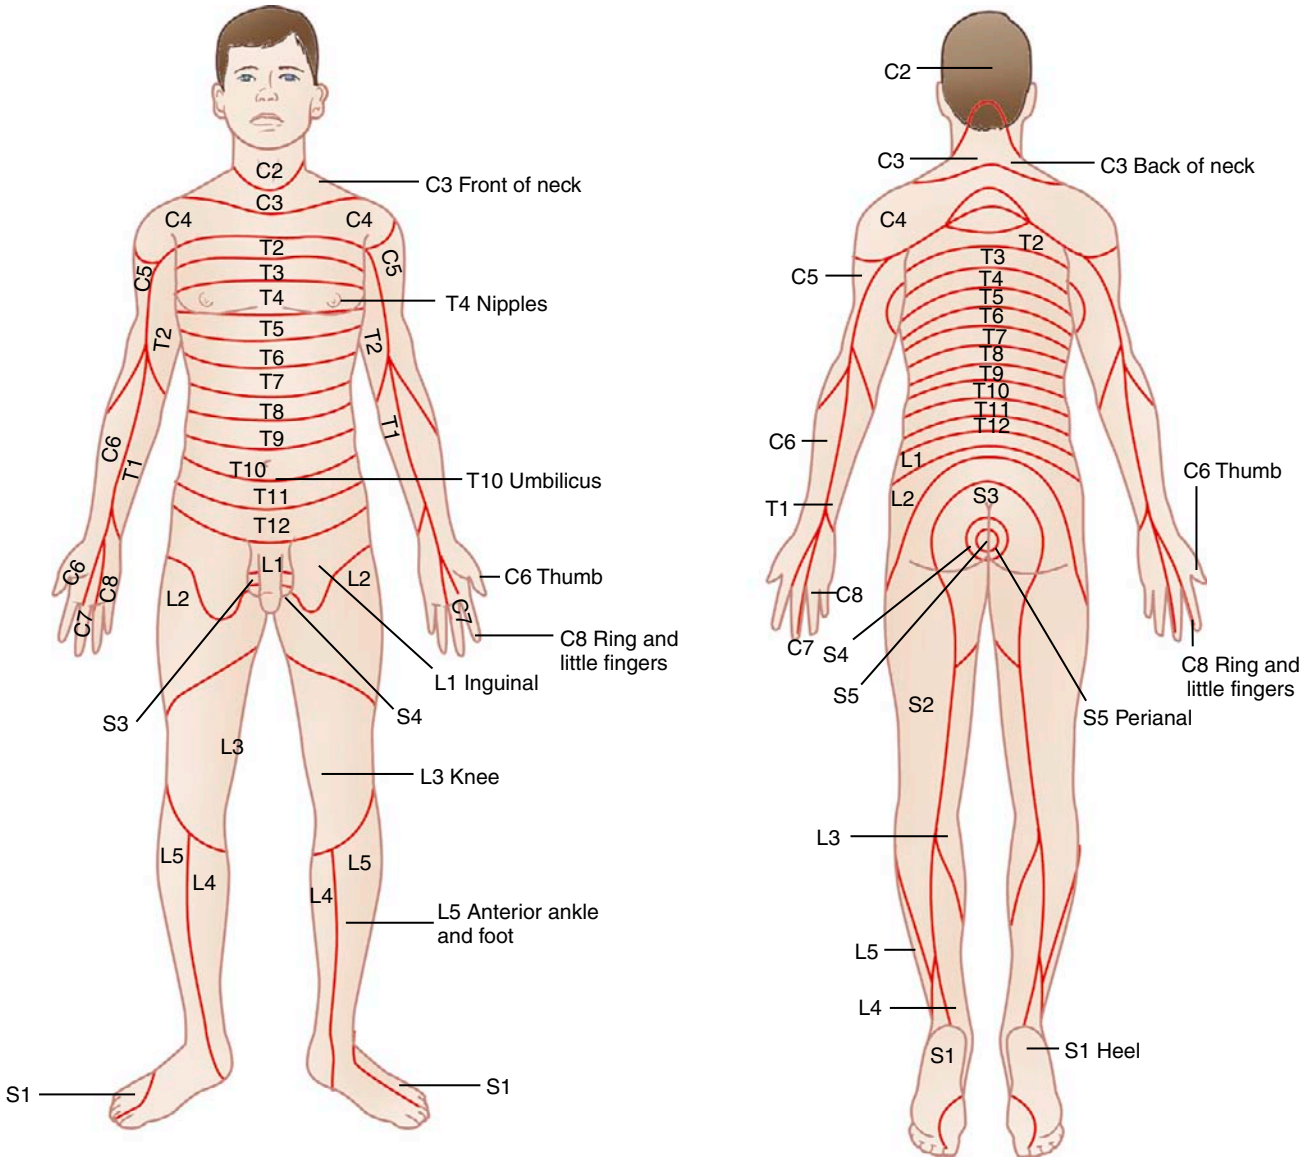

FIGURE 20-30 Dermatomes innervated by posterior nerve roots and their correlation on the body; both anterior and posterior views are shown. *C,* Cervical; *T,* thoracic; *L,* lumbar; *S,* sacral.

lymphomas, lipomas, neurofibromas, chondromas, angiomas, abscesses, and granulomas.

Most intradural tumors are extramedullary and benign and, if diagnosed early before severe neurologic deficits occur, offer an excellent prognosis. They manifest their presence by pain of a radicular nature and various motor and sensory disabilities below their segmental locations. Intradural extramedullary tumors represent 35% to 45% of spinal cord tumors (Harrop, 2005). They are usually benign and originate from the dura mater and arachnoid surrounding the cord and from the root sheaths of spinal nerves. Schwannomas (neuromas) are especially common in the thoracocervical area and may be part of generalized neurofibromatosis. Meningiomas also commonly occur in intradural extramedullary locations. Less frequently, lipomas or other types of tumors are found. Approximately 2% to 7% of spinal cord tumors are intradural intramedullary tumors (Harrop, 2005). These tumors infiltrate the cord tissue and are much more difficult to remove than are extramedullary tumors. Of the intramedullary tumors, the most common are ependymomas and astrocytomas.

Cord tumors frequently produce spinal fluid blockage and can be pinpointed accurately with MRI. Intraspinal injection of contrast material (myelography) is another option for diagnosis. Often, a standard laminectomy is used for exposure and removal.

Spinal Epidural Abscess. Spinal epidural abscess can develop from vertebral osteomyelitis, from infection originating at a distant source and transferred by the blood, or from direct inoculation caused by spinal surgery, LP, or epidural administration of anesthetic. Patients who are immunosuppressed are especially at risk for epidural abscesses. Clinical presentation involves spinal and radicular pain and muscle weakness that can progress to paralysis. Epidural abscess is most easily

diagnosed by MRI and typically treated with surgical decompression, culture, and irrigation, along with 4 to 8 weeks of IV antibiotic therapy.

Intervertebral Disk Disease. Intervertebral disk disease is the most frequently encountered neurosurgical problem. The axial skeleton bears both the body's weight and externally applied axial forces while maintaining mobility. Intervertebral disks serve as mechanical buffers that absorb axial loading, bending, and sheer forces. Bipedal posture further stresses the intervertebral disks, leading to degenerative disk disorders. Disk rupture occurs with radial fissuring of the annulus. The nucleus pulposus then escapes, extending to the margin of the annulus and posterior longitudinal ligament. Once the nucleus pulposus protrudes beyond the perimeter of the disk space into the epidural space, it results in nerve root compression and radiculopathy (pain produced by pressure or traction on the nerve roots) (Figures 20-31 and 20-32). Most disk protrusions occur at the L4-L5 and L5-S1 interspaces. Interventions include a medical trial of treatment with steroids and analgesics/narcotics, muscle relaxation, rest, epidural steroid injections, and, in failed cases, laminotomy or laminectomy with diskectomy. In far-lateral disk herniations, percutaneous lumbar diskectomy is often an alternative to laminotomy. This minimally invasive technique gains access to the disk space posterolaterally, using local anesthetic. The disk space is entered by way of a cannula. An aspiration probe may be used to remove the disk matter, or direct removal can be done microscopically or endoscopically.

Intractable Pain. Certain painful spinal lesions, usually of a malignant nature, can be controlled by use of epidural opiates, by use of fentanyl patches, or by temporary or permanent use of a medication pump. Another pain control measure is to divide the pain fibers supplying the affected area. This may be accomplished by sectioning the sensory roots intraspinally (posterior rhizotomy) or by incising the spinothalamic tracts that carry pain and temperature impulses (anterolateral cordotomy). Alternatively, spinal cord stimulation of the affected area can be achieved with the placement of electrodes in the epidural space. A laminectomy for exposure is necessary to perform these surgical procedures.

Peripheral Nerves. The PNS consists of those structures containing nerve fibers or axons that connect the CNS with motor and sensory, somatic and visceral, end-organs. The PNS includes the cranial nerves (III to XII), the spinal nerves, the autonomic nerves, and the ganglia.

The 31 pairs of spinal nerves are each numbered for the level of the spinal column at which they emerge: cervical, C1 through C8; thoracic, T1 through T12; lumbar, L1 through L5; sacral, S1 through S5; and coccygeal, 1. The first pair of cervical spine nerves emerges between C1 and the occipital bone. The eighth cervical nerves emerge from the intervertebral foramina between C7 and T1. The first thoracic nerves emerge between T1 and T2.

In the cervical and lumbosacral regions the spinal nerves regroup in a plexiform manner before they form the peripheral nerves of the upper and lower extremities. Those in the thoracic region form cutaneous and intercostal nerves. The principal nerves of the upper plexus include the musculocutaneous, median, ulnar, and radial. Those of the lumbosacral plexus include the obturator, femoral, and sciatic.

Each spinal nerve divides into anterior, posterior, and white rami. Rami are primary divisions of a nerve. Anterior and posterior rami contain voluntary fibers; white rami contain autonomic fibers. Posterior rami further branch into nerves innervating the muscles, skin, and posterior surfaces of the head, neck, and trunk. Most anterior rami branch to the skeletal muscles and the skin of the extremities and anterior and lateral surfaces. In the process they form plexuses, such as the brachial and sacral plexuses. Spinal nerves contain sensory dendrites and motor axons; some have somatic axons, and some have axons of preganglionic autonomic motor neurons.

The autonomic (involuntary) nervous system consists of all the efferent nerves through which the cardiovascular apparatus, viscera, glands of internal secretion, and peripheral involuntary muscles are innervated (see Figure 20-29). There is a major anatomic difference between the somatic and autonomic nervous systems. In the somatic nervous system an impulse from the brainstem or spinal cord reaches the end-organ through a single neuron. In the autonomic nervous system an impulse passes through two neurons—the first ending in an autonomic ganglion and the second running from the ganglion

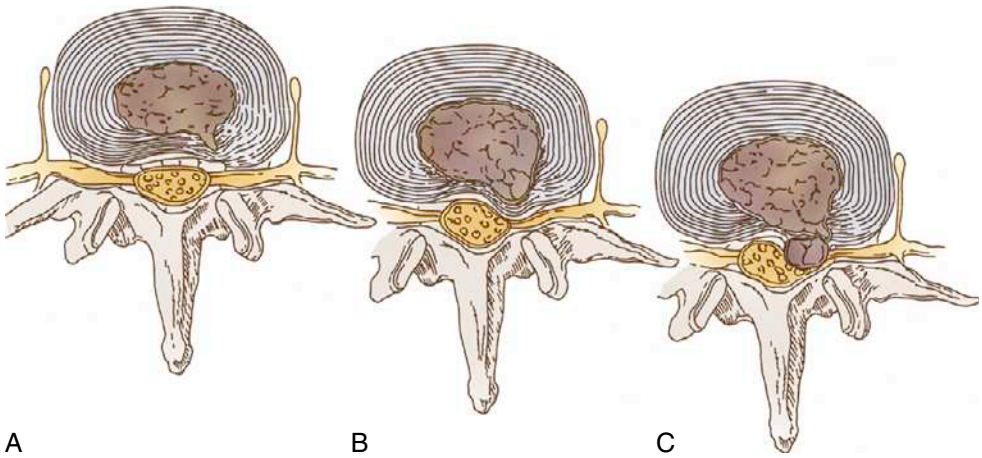

FIGURE 20-31 Stages in the herniation of an intervertebral disk. **A**, Tearing of the rings of the annulus fibrosus. **B**, Protrusion of the disk against the nerve root. **C**, Extrusion of part of the nucleus pulposus, with further nerve root compression.

to the end-organ. Some of the ganglia lie adjacent to the vertebral column to form the sympathetic trunks or chains; others are closely associated with the end-organs.

The preganglionic neurons from the brainstem (which traverse along the cranial nerves) and those from the second, third, and fourth sacral segments to the pelvic viscera end in ganglia in proximity to their end-organs; thus their postganglionic fibers are very short. This is known as the *parasympathetic,* or *craniosacral,* division of the autonomic nervous system. The preganglionic fibers from the thoracic and lumbar spinal cord terminate in the paravertebral ganglia, making up the sympathetic chain, and their postganglionic fibers are relatively long. This is termed the *sympathetic,* or *thoracolumbar,* division of the autonomic nervous system.

The two divisions are distinct anatomically and physiologically. The chemical substance mediating transmission of impulses at most postganglionic sympathetic nerve endings is *norepinephrine,* and the neurotransmitter at all parasympathetic and preganglionic sympathetic neurons is *acetylcholine.*

The majority of organs have dual innervation—part from the craniosacral division and part from the thoracolumbar division. The functions of these two systems are antagonistic. Together they work to maintain homeostasis. In general, the thoracolumbar division functions as an emergency protection mechanism, always ready to combat physical or psychologic stress. The craniosacral division functions to conserve energy when the body is in a state of relaxation.

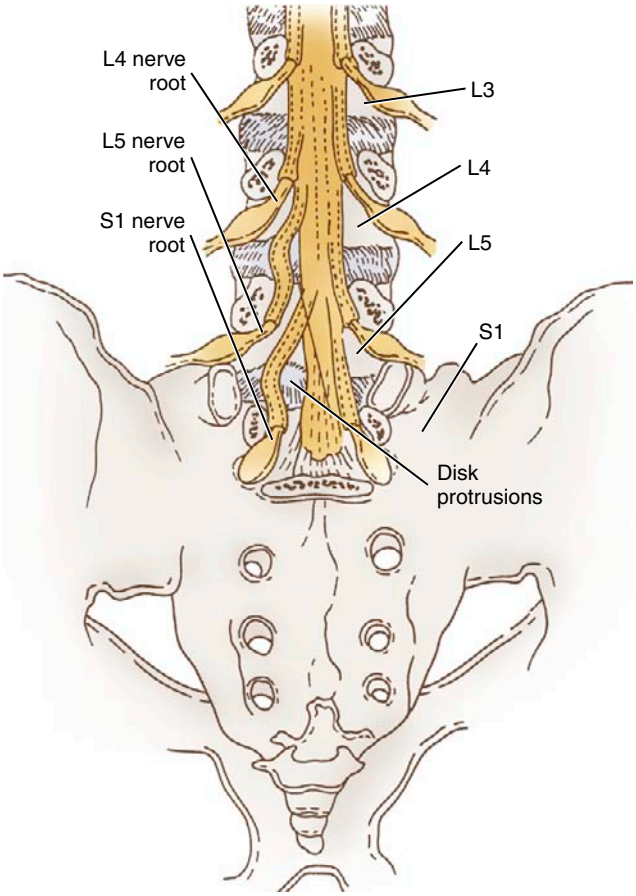

FIGURE 20-32 Posterior view of the lower lumbar spine. A disk protrusion at L4-L5 on the left results in compression of the L5 nerve root where it leaves the dural sac but before it exits from the spinal canal.

Stimuli arising from internal organs or from outside the body traverse visceral and somatic afferent nerve fibers to make reflex connections with preganglionic autonomic neurons in the brainstem and spinal cord. Such stimuli trigger activity of these involuntary systems automatically. When these automatic mechanisms break down or overact, surgery may be indicated. Thoracolumbar sympathectomy was once performed in hypertensive patients as an attempt to decrease blood vessel tone and lower blood pressure. Vagotomy can be performed to decrease acid secretion to the stomach in patients with peptic ulcers. Lumbar sympathectomy is used to relieve vasospastic disorders of the legs. T2 ganglionectomy is done to relieve palmar hyperhydrosis (sweaty palms). See Chapter 22 for a discussion of thoracic ganglionectomy.

Perioperative Nursing Considerations

Assessment

Neurologic Assessment Tools. A familiarity with basic neurologic assessment tools gives the nurse the ability to perform a standardized neurologic assessment that can be compared with the patient's previous assessments and easily communicated to other healthcare professionals. These tools can be used preoperatively to establish a baseline assessment. Postoperatively, they can be used to establish a return to baseline and to assess postoperative neurologic stability. The postoperative condition of a neurosurgical patient can quickly deteriorate, so an adequate baseline assessment is essential (Rapid Response Team box). The Glasgow Coma Scale is commonly used to assess patients with brain injury (Table 20-3). Three indicators of cerebral function—eye opening, verbal communication, and motor response to verbal and noxious stimuli—are assessed; and the appropriate number of points for each is assigned and totaled. The best possible score is 15, and the worst possible score is 3. The Medical Research Council (MRC) Scale for Muscle Strength Grading can be used to assess muscle strength in the upper and lower extremities of spinal cord injury patients or patients who are having spine surgery (Table 20-4).

Preparation for Surgery. Communication among the perioperative team is essential for planning care for the neurosurgical patient in the OR. Information the perioperative nurse needs before the arrival of the patient in the OR includes the following:

- The patient's age, height, weight, level of consciousness, physical disabilities resulting from neuropathologic or other conditions, stability of spine, and communication barriers
- Diagnosis, allergies, medical clearance for surgery, and nothing-by-mouth (NPO) status
- Planned and possible surgical procedures
- Surgical and anesthesia consent signed by the patient or person with power of attorney for medical decisions (if the patient is unable to provide consent)
- Surgical site marked by the surgeon or a representative to designate correct side of head, level of spine, or other surgical site
- Diagnostic and lab studies done and reports needed at the time of operation
- Specific surgical approach and position to be used
- Need for any special equipment, instruments, and supplies

RAPID RESPONSE TEAM

A patient with a neurologic diagnosis may experience irreversible neurologic damage if complications relating to the diagnosis or surgical procedure are not recognized in a timely manner to permit early intervention. In 2008 The Joint Commission established the 16th National Patient Safety Goal; its purpose was to improve the early recognition and response to negative changes in a patient's condition. By January of 2009 all institutions were required to develop and implement a rapid medical response team within their facility (TJC, 2008). Rapid response teams (RRTs) are especially critical for neurosurgical patients because of the rapidity of changes that can occur in the postoperative period. Rapid response teams consist of highly trained personnel that function together to create a pre–code team (Richmond, 2008). The personnel include an ICU nurse, respiratory therapist, medical resident, anesthesia care provider, and sometimes a surgical resident. The RRT can be activated by any bedside clinician, such as registered nurses, residents, and attending physicians, at the earliest sign of patient deterioration. Most criteria for initiating a RRT call are institution specific, but some examples of the criteria include the following:

- Blood pressure: systolic BP below 90 mm Hg or above 180 mm Hg
- Heart rate: below 45 beats/min or above 125 beats/min
- Respiratory rate: below 8/min or above 24/min
- Oxygen saturation: below 90% or increasing oxygen requirements
- Acute change in mental status
- New onset of chest pain
- Staff member concerned about patient and needs a second opinion
- Patient not responding to treatment already underway for recent change in status (Richmond, 2008)

The RRT arrives at the patient's bedside within minutes to plan and implement interventions to stabilize the patient. While stabilization is occurring, the members of the RRT are communicating to the house staff and bedside clinicians the current and future needs of the patient. The RRT can determine if the patient's needs warrant a transfer to an increased level of monitoring such as an ICU. The main objective of the RRT is to provide early detection and treatment for unstable patients thereby avoiding cardiac or respiratory arrest in non-ICU settings (Winters et al, 2006).

RRT EXAMPLE

Mrs. Jones is post-op day 2 from an L4-S1 decompression and fusion for lumbar spinal stenosis. The previous nurse's report states that there were no complications during the procedure and the patient has been hemodynamically stable and neurologically intact postoperatively. The previous nurse's assessment of Mrs. Jones states that she was alert and oriented times 3, she moved all extremities without difficulty and against resistance, and her speech was clear and appropriate. The report also stated that as the day progressed, Mrs. Jones became increasingly drowsy but it was attributed to the patient-controlled analgesia (PCA) pump filled with morphine. The current nurse's assessment determines that Mrs. Jones is difficult to arouse, uncooperative, and having difficulty speaking; she is also not oriented to place or time. All of the current findings contradict the previous nurse's assessment, and the current nurse knows that the patient's health status is rapidly declining. The nurse immediately pages the facility's rapid response team (RRT), who arrives at the patient's bedside within minutes. The RRT performs an assessment and begins immediate interventions to stabilize Mrs. Jones. She is taken for a stat CT scan of the head, which shows cerebral edema. Mrs. Jones did not return to the nursing unit after the CT scan; she was intubated and transferred to an ICU. It was later determined that Mrs. Jones suffered bilateral symmetric cerebellar hemorrhages from a CSF leak that occurred during the initial spinal surgery.

- Amount of blood and blood products (fresh frozen plasma, platelets) ordered and available
- Need for radiologic support, neuromonitoring, intraoperative blood salvage unit, and image guidance
- Planned preliminary procedures, such as carotid ligation, lumbar puncture, placement of lines (IV, central venous, arterial), and Foley catheter insertion
- Verification that all necessary personnel, equipment, and supplies are available
- A focused preoperative neurologic examination should be done as a baseline for postoperative assessment; depending on the pathology and surgery, this may include the following:
  - Mental status (level of consciousness, orientation, behavior, ability to follow commands)
  - Vision, pupil response, extraocular eye movements (EOMs), and hearing
  - Examination of sensation and motor strength of extremities
  - Area and intensity of pain

This information allows the perioperative nurse to properly plan and prepare for the surgery and to ensure the well-being of the patient.

Diagnostic Procedures. Most patients will have undergone diagnostic procedures before arriving in the OR. Radiologic and other diagnostic studies are of great significance to the surgical team. The nurse should ensure that any pertinent radiographic images are available in the OR before the procedure begins. The surgeon can refer to these images to locate the pathologic condition, verify the correct surgical site, and plan the appropriate surgical approach and procedure. Diagnostic studies include the following:

1. *Plain x-rays.* X-rays of the spine can be used initially to identify injury to the spinal column. They are referred to intraoperatively to verify that surgery to the spine is being done at the correct level (Figure 20-33).
2. *CT scan.* A CT scan uses x-ray studies, with or without instilled contrast medium, and computer technology to produce a sequential series of positive images of transverse sections of the brain and spinal cord in which differences in tissue density can be detected and deviations from normal identified. This study remains the criterion standard for evaluation of acute head injury and is considered the first-line screening study.

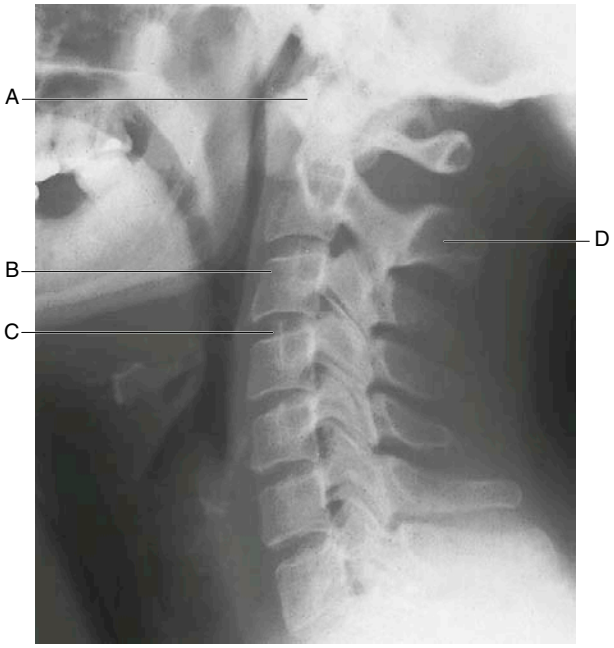

FIGURE 20-33 Lateral x-ray of the cervical spine. **A**, Anterior tubercle of the atlas (C1). **B**, Cervical body. **C**, Intervertebral disk. **D**, Spinous process of the axis (C2).

3. *MRI.* Use of radiofrequency pulses in a powerful magnetic field yields high-resolution images of the human body with no known risk to patients and involves no radiation. Advances in MRI scanning provide enhancement of the scan with the use of gadolinium (contrast medium). A typical MRI study produces views of the brain featured as contiguous slices in three different planes. Axial cuts are from top to bottom. Coronal cuts are from front to back. Sagittal cuts are from side to side. The MRI is the gold standard for the diagnosis of tumors, abscesses, tissue/ligamentous injury, and disk herniation (Figures 20-34 and 20-35).
4. *Stereotactic MRI or CT scan.* Placement of a stereotactic head frame (frame-based system) or fiducials (frameless system) before receiving a CT scan or MRI produces information that is registered into a computer. The goal of stereotactic surgery is to target a point or volume in space precisely by means of a predefined minimally invasive trajectory (Zonenshayn and Rezai, 2005). The frameless system allows the neurosurgeon to see beyond the actual operative field by using an optical tracking device. This handheld device depicts in three planes on a computer screen where the surgeon is working in the brain relative to deeper structures beyond view.
5. *Magnetic resonance angiography (MRA).* MRA is a noninvasive means of studying the cerebral vasculature. An MRA study is capable of detecting carotid stenosis, posttraumatic carotid artery dissection, AVMs, and aneurysms.
6. *Angiography (arteriography).* Injection of contrast medium into the brachial, carotid, vertebral, or femoral arteries is used to study the intracranial blood vessels for size, location, and configuration and to allow diagnosis of space-occupying lesions and vascular abnormalities.
7. *Digital subtraction angiography (DSA).* DSA is a computerized radiologic procedure. An IV rather than arterial injection is required; a contrast medium injection allows examination of selected arterial circulation. By using computer technology DSA provides an alternative to cerebral angiography for high-risk patients.
8. *Three-dimensional CT angiography.* Contrast-enhanced CT brain scan data are used to generate a three-dimensional image of the intracranial vasculature with minimal risk to the patient.
9. *Stereoscopic display of MRA.* Recent advances in MRI permit high-resolution imaging of blood flow. Projection angiograms can be produced to overcome the tomographic nature of conventional MRI scans. These angiograms are similar to plain x-ray films or digital subtraction angiograms in the demonstration of blood vessels, but the three-dimensional information inherent in them is partially lost in single projections. Stereoscopic image pairs allow the clinician to perceive the relative distance of vessels to one another. MRA permits perception of vascular anatomy in three dimensions.

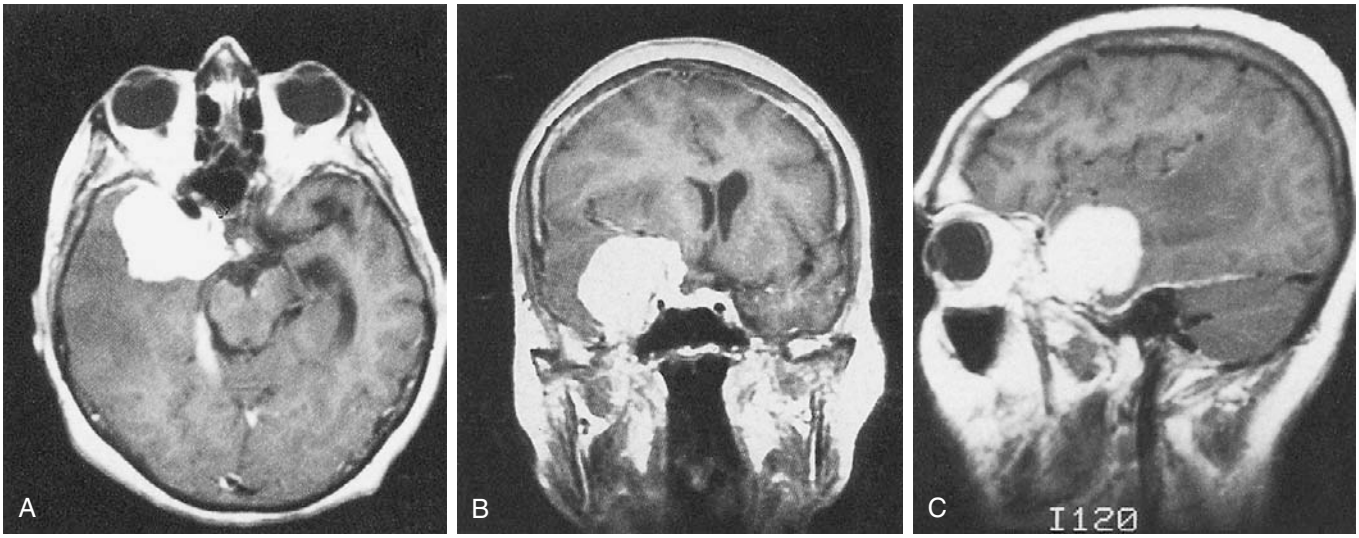

FIGURE 20-34 Gadolinium-enhanced magnetic resonance image (MRI) of a medial sphenoid wing meningioma in (**A**) axial, (**B**) coronal, and (**C**) sagittal planes.

10. *Myelography.* Contrast medium is injected into the spinal subarachnoid space and fluoroscopy is used to view the spinal cord, nerve roots, and spinal column and to demonstrate a defect involving theseareas.
11. *Ultrasound.* Ultrasound is a noninvasive technique that uses high-frequency sound waves and a computer to create images of blood vessels, tissues, and organs. It is often used to assess the blood flow in the carotid artery. This procedure can be done in or out of the surgical suite. It can be used intraoperatively to localize intradural spinal cord tumors.
12. *Electroencephalogram (EEG).* An EEG is a procedure that records the brain's continuous electrical activity by means of electrodes placed on the scalp or intraoperatively on the brain.
13. *Evoked potentials (EPs).* Evoked potentials are procedures that record the brain's electrical response to visual, auditory, and sensory stimuli.
14. *Wada's test (intracarotid amobarbital [Amytal] test).* Wada's test can be used before brain surgery to lateralize language, memory, and the dominant hemisphere. It can help in lateralization of seizure focus and assess the ability of the hemisphere with the lesion to maintain memory when isolated.
15. *Lumbar puncture.* A spinal needle is used to gain access to CSF in the subarachnoid space. Opening and closing pressures are measured to determine if there is increased pressure surrounding the brain and spinal cord. This can help diagnose hydrocephalus or a spinal tumor. CSF is sent to the lab to evaluate for blood, infection, malignancy, and other neurologic diseases. LP is contraindicated when an intracranial mass is known or suspected because it can cause herniation of the brain in the presence of increased ICP.

Nursing Diagnosis

Nursing diagnoses are developed from interpreting and analyzing patient information to determine whether there are specific (actual) or potential (risk for) problems that the perioperative nurse needs to consider in the plan of care. Nursing diagnoses are the basis on which nursing interventions are selected for patients. Neurosurgery patients share common problems that the perioperative nurse should address. Nursing diagnoses

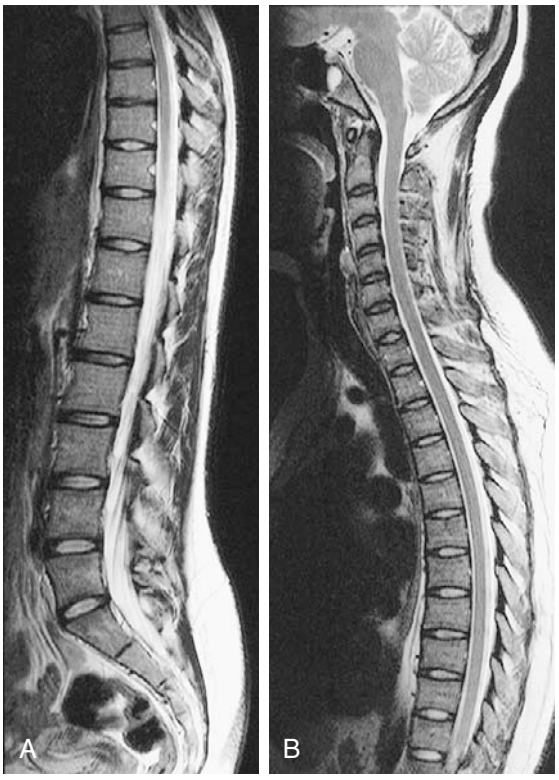

FIGURE 20-35 Sagittal magnetic resonance image (MRI) of (**A**) thoracolumbar spine and (**B**) cervicothoracic spine.

related to the care of patients undergoing neurosurgery might include the following:

- Anxiety related to surgery or surgical outcome
- Deficient Knowledge related to diagnostic tests and surgical procedures
- Risk for Ineffective Breathing Pattern related to location of tumor, surgical position, or effects of general anesthesia
- Risk for Hypothermia
- Risk for Perioperative Positioning Injury

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Anxiety related to surgery or surgical outcome

OUTCOME
The patient's anxiety will be reduced or controlled.

INTERVENTIONS
- Broadly classify intensity of patient's anxiety.
- Determine patient's coping skills.
- Provide listening, reassurance, and information.
- Provide ongoing opportunity for questions or expression of concerns or fears.
- Involve other support systems (e.g., family, friends, social worker, chaplain).
- Assist the patient to use personally effective coping skills.
- Use touch (if welcomed by the patient) and eye contact during communication.

NURSING DIAGNOSIS
Deficient Knowledge related to diagnostic tests and surgical procedures

OUTCOME
The patient and family will verbalize an understanding of the surgical procedure and postoperative plan of care.

INTERVENTIONS
- Determine knowledge level and desire for knowledge.
- Correct misinformation.
- Identify readiness and motivation to learn.
- Provide information regarding tests or surgery.
- Explain perioperative routine, postoperative recovery, and discharge plans.
- Base interventions on patient's needs.

NURSING DIAGNOSIS
Risk for Ineffective Breathing Pattern related to location of tumor, surgical position, or effects of general anesthesia

OUTCOME
The patient will maintain effective breathing patterns.

INTERVENTIONS
- Provide appropriate positioning accessories, and assist in their placement.
- Collaborate with anesthesia provider and surgeon during positioning activities relevant to respiratory effectiveness.
- Determine patient's comfort on OR bed; provide comfort measures as appropriate.
- Maintain open suction line.
- Observe respiratory rate, depth, and character.
- Encourage deep breaths and coughs.
- Communicate with postanesthesia care unit (PACU) regarding respiratory needs.
- Check airway patency frequently during transport to PACU.

NURSING DIAGNOSIS
Risk for Hypothermia

OUTCOME
The patient will remain normothermic.

INTERVENTIONS
- Provide warm ambient OR temperature during surgical intervention.
- Provide warmed intravenous (IV) fluids and blood products.
- Provide body-warming system (e.g., forced warm air) during surgery.
- Keep head covered or wrapped when possible.
- Monitor temperature with anesthesia provider.
- Cover the patient with warm blankets at end of the surgical intervention for transport to PACU.

NURSING DIAGNOSIS
Risk for Perioperative Positioning Injury

OUTCOME
The patient will be free from signs and symptoms of positioning injury.

INTERVENTIONS
- Assess patient's physical limitations before positioning; make accommodations.
- Carefully pad and protect all prominences and sites that are vulnerable to neurovascular injury.
- Check all positioning devices for cleanliness, working order, and freedom from sharp edges.
- Collaborate with OR team in placing positioning devices to maintain patient safety.
- Assess patient at completion of surgery for areas of redness, blanching, or bruising.
- Communicate any findings to PACU nursing staff.
- Document findings and follow-up with patient, as applicable.

Outcome Identification

Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient's anxiety will be reduced or controlled.
- The patient or family will verbalize an understanding of the surgical procedure and postoperative plan of care.
- The patient will maintain effective breathing patterns.
- The patient will remain normothermic.
- The patient will be free from signs and symptoms of positioning injury.

Planning

Preparation can significantly reduce anesthesia time and intraoperative time for the patient, as well as physical and psychologic stress for the patient, surgeon, and perioperative nurse. Planning for the patient's care in the OR is based on the results of nursing assessment and the identification of relevant nursing diagnoses. The plan of care then identifies desired outcomes derived from the nursing diagnoses; priorities are set and nursing interventions are designed to assist the patient to reach the desired outcomes. Nursing interventions identified for the patient's plan of care may include reassessment, teaching, counseling, referrals, and specific interventions to assist the patient achieve patient care outcomes. A Sample Plan of Care for a patient undergoing a neurosurgical procedure is given above.

Implementation

The perioperative nurse must determine that all personnel, equipment, instrumentation, and supplies necessary for a successful surgery are available. The nurse uses the information obtained through assessment of the patient and communication with the surgical team to provide individualized patient care. Neurosurgical patients vary in age from the very young

to the very old. They often have special needs because of conditions such as mental status changes, spinal instability, spinal cord injuries, paralysis, other traumatic injuries, and pain. These conditions need to be considered at all times. Neurosurgery patients who seem to be unconscious may actually be aware of their environment and unable to voice their concerns. The perioperative nurse should always talk to the patient and explain what is happening. Showing compassion and attempting to relieve the fears of the patient and his or her family are essential.

Equipment. Neurosurgical procedures require an extensive amount of equipment. The nurse must analyze the arrangement of the equipment in the OR to ensure that the sterile field is not compromised. Electrical equipment should be placed in proximity to electrical outlets, so that cords are out of high-traffic areas. Monitors should be in comfortable view of the surgeon. A microscope needs a clear path to the surgical field. The surgeon and surgical assistants may require specialized surgical chairs or sitting or standing stools to comfortably perform the surgery.

OR BED AND ATTACHMENTS. The nurse uses information about the proposed surgical procedure and desired surgical position to gather the proper OR bed, attachments, and positioning devices before the patient arrives in the OR suite. Perioperative nurses must anticipate needs that may arise during the surgery and prepare for them, considering questions such as the following: Is this the right OR bed in the right position with the right attachments? If fluoroscopy will be used, is the base of the OR bed in a position that will accommodate the C-arm? A specialized OR bed, such as a Jackson table or Andrews table or frame, may be required for posterior spine surgery. Skull clamps, skull pins, and tongs are commonly used for craniotomies and posterior cervical spine surgeries to stabilize the head and neck (Figure 20-36). Occasionally, a patient may come to the OR in a halo that was placed for preoperative stabilization of the cervical spine. At least part of the halo will need to be removed so the surgical site can be accessed. Compatible wrenches must be available to accomplish this.

BASIC EQUIPMENT. Neurosurgical procedures typically require one special neurosurgical overhead instrument table, such as the Mayfield table (Figure 20-37), or two large Mayo trays along with one back table. Other basic equipment includes the following: a sequential compression device, a cooling-heating unit, one or two monopolar electrosurgical units (ESUs), a bipolar ESU, and a wall supply or tank of nitrogen with a special pressure gauge for operating air-powered instruments. Usually two suction units are required. Intraoperative blood salvage is used for most spine surgeries, unless infection or malignancy is suspected.

Neurosurgeons usually wear surgical loupes and a fiberoptic headlight, requiring a light source.

OPERATING MICROSCOPE. An operating microscope may be required for surgery on certain areas of the brain, spinal cord, and peripheral nerves. The operating microscope has revolutionized neurosurgery by providing intense light and up to a 12-fold magnification to areas that previously may have been inoperable or inaccessible. Microsurgery allows for greater surgical precision when operating in close proximity to vital structures and has better surgical results. The perioperative nurse must be able to prepare the microscope for use in neurosurgery, and the surgeon must check it for focal length and focus before scrubbing. Disposable sterile drapes are available for the microscope, as are assistant and observer lenses. Cameras and closed-circuit television monitors are also available for use with the operating microscope.

ENDOSCOPES. Surgeons use endoscopes to perform minimally invasive neurosurgery, such as endoscopic biopsy. The endoscope provides illumination and magnification of structures and an extended viewing angle. Perioperative nurses must be prepared to convert from a neuroendovascular procedure to

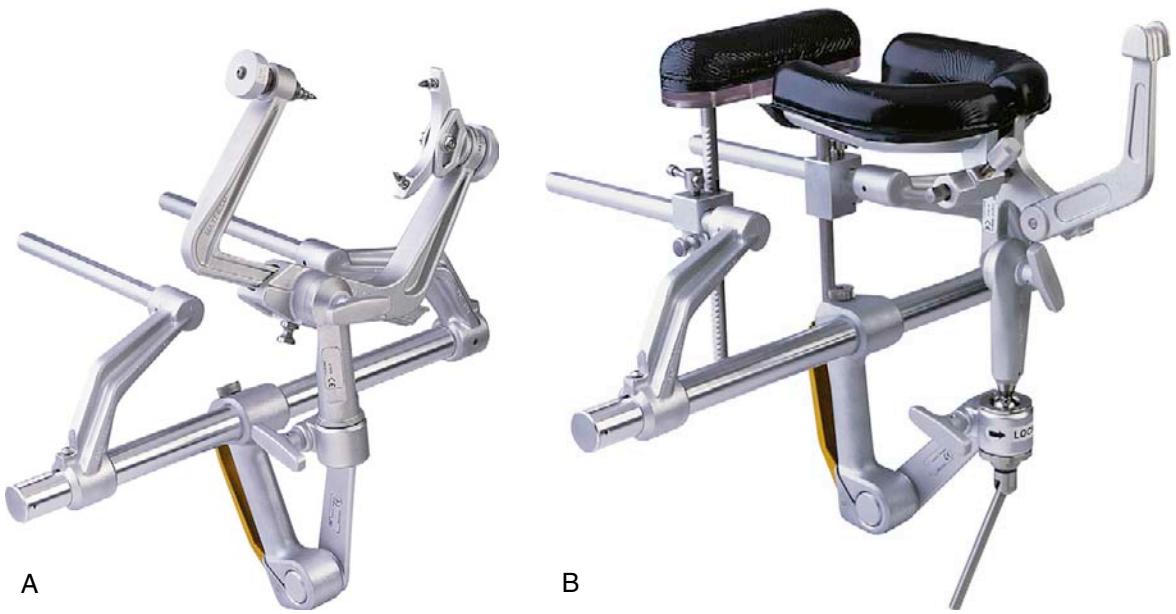

FIGURE 20-36 **A**, Three-pin fixation skull clamp (Mayfield) for stabilizing head during neurosurgical procedures. **B**, Mayfield horseshoe headrest.

an open procedure if it is determined that the surgery cannot be successfully completed endoscopically. An additional use for endoscopes is in open procedures to see areas that are otherwise visually inaccessible.

RADIOLOGIC INTERVENTION. Radiology is commonly used intraoperatively for spine surgery. Typically, a radiology technician will operate the equipment. Lead aprons and thyroid shields must be worn or protective shields must be used by all staff in the OR to protect themselves from radiation exposure. X-rays can be taken to check for proper positioning of the spine and to help the surgeon identify a specific level of the spine. This may be done before incision or after partial exposure of the spinous processes and laminae. In both cases an instrument or needle is used to mark a position on the spine, and an x-ray of the spine is taken. The x-ray enables the surgeon to identify the level of the spine that is marked. The surgeon uses that information to identify the correct surgical level. A postoperative x-ray is also taken to verify that the surgery was done to the correct level of the spine.

With fluoroscopy, also called direct image intensification, a C-arm (covered with a sterile drape) is used to take a continuous x-ray that is portrayed on a monitor. This gives the surgeon the ability to view the spine and to directly view screws as they are being placed during an instrumented fusion. This ensures that spinal instrumentation for fusion is properly positioned in the correct levels. Fluoroscopy is also used for placement of nerve-stimulator electrodes in brain or spinal areas and stereotactic procedures.

STEREOTACTIC AND IMAGE-GUIDED EQUIPMENT. Stereotactic and image-guided equipment is commonly employed for neurosurgery. Either a frame-based (requiring a head-frame skull attachment, see Figure 20-38) or a frameless system (using fiducials) can be used. Both systems use a computer to register points, based on information obtained from a stereotactic MRI or CT scan done preoperatively, to determine the least traumatic approach to the target (tumor, lesion, ventricle). Both systems have accompanying attachments and instruments that must be available. The frameless image-guided system requires a monitor to display views of the brain or spine in three different planes: axial, coronal, and sagittal (Figure 20-39).

FIGURE 20-37 Mayfield overhead instrument table.

ULTRASONIC ASPIRATOR. An ultrasonic aspirator (Cavitron Ultrasonic Surgical Aspirator, CUSA) may be used to emulsify and debulk a tumor with high-frequency sound waves. Various settings allow the surgeon to adjust the instrument to remove firm or calcified lesions, or soft masses. The ultrasonic aspirator provides hemostasis and spares adjacent nerves and vessels as it removes the tumor.

AUDIOVISUAL EQUIPMENT. The use of video cameras, recorders, and television monitors is invaluable to teach staff and enhance understanding of the surgical procedure by perioperative personnel who are otherwise unable to visualize the surgeon's actions directly. By viewing the operative field through the monitor, the experienced scrub person will be able to anticipate the neurosurgeon's next move and will therefore provide better assistance.

INTRAOPERATIVE MONITORING EQUIPMENT. Equipment for intraoperative monitoring, such as EEG, evoked potentials (EPs), ICP, and Dopplers, may also be required.

Instrumentation, Implants, and Supplies. Typically, instrumentation commonly used in neurosurgery is added to basic surgical instrumentation to make neurosurgical-specific trays, such as a basic craniotomy tray or a laminectomy tray. Specialized trays, instruments, or implants can be added based on the surgical procedure.

Powered surgical instruments are commonly used in neurosurgery. Multiple drills, drill bits, and accessories are available. These tools may be powered by air, battery, or electricity and are operated by a hand control or foot pedal. All drills have a safety control that should be engaged at all times the instrument is not in use. The perioperative nurse should monitor the sterile field to ensure that drills and other powered equipment are not left lying on the patient. The use of drills makes bone work easier and reduces operating time. Irrigating the tip of the drill while it is in use prevents overheating of the tissue. By changing drill bits and attachments, different drills can be used to make burr holes, craniotomies, craniectomies, and holes for dural tack-up sutures. They can be used to thin bone for a decompression, to perform decortication for spinal fusion, to harvest hip graft, to shape bone grafts, and to make holes for plating and fixation systems. Examples of specific drills that may be used follow.

The Hall Surgairtome 200 (Figure 20-40) can be used for precision cutting, shaping, and repair of bone. Compressed nitrogen is the power source, as with other air-powered equipment. The Hall Surgairtome 200 can be used to widen the graft area in anterior fusions and to unroof the auditory canal in eighth cranial nerve surgery. For use in less accessible areas, such as the sphenoidal sinus, pituitary fossa, and vertebral bodies, attachments with 20- and 90-degree angles are available. A range of burrs and guards is available.

The craniotome offers a perforator drive for drilling burr holes. Both 12-mm and 7-mm perforators are available in disposable and reusable forms. The perforator driver attachment can be removed and a saw blade and dura guard attached to adapt the instrument for cutting a craniotomy bone flap. A cranioplasty burr and a skull contour burr as well as guards for each type of burr are available.

Another versatile pneumatic tool is the Midas Rex instrument (Figure 20-41). The variety of disposable cutting tools of this foot pedal–controlled instrument and its attachments

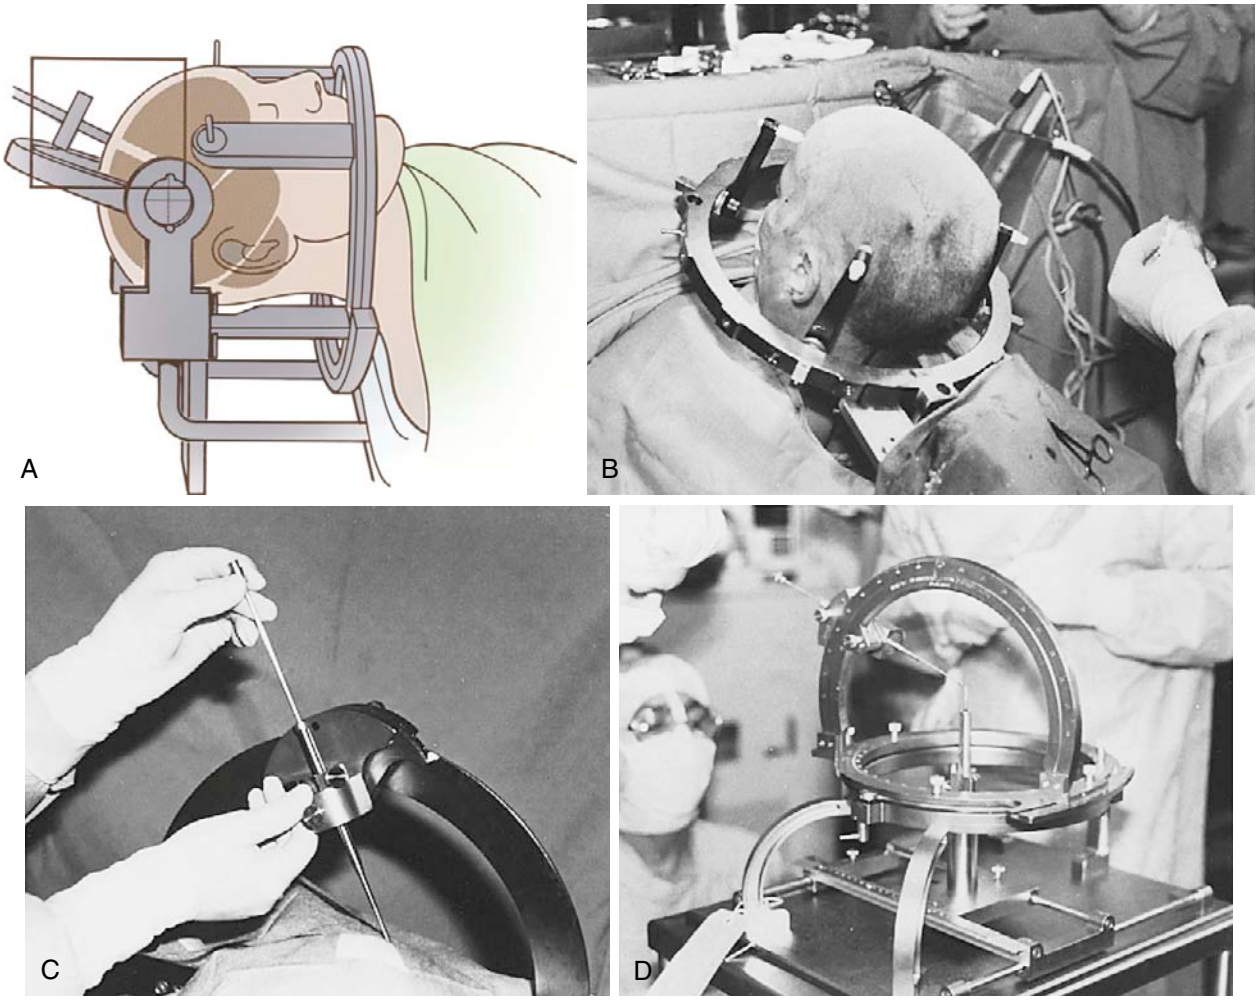

FIGURE 20-38 Stereotactic procedure. Obtaining a biopsy for stereotactic surgery. **A**, Patient fitted with head frame before computed tomography (CT) or magnetic resonance imaging (MRI) scanning. **B**, Awake patient in the sitting position for application of the BRW frame for stereotactic brain biopsy. **C**, Stereotactic surgical procedure with needle insertion for biopsy. **D**, Stereotactic surgical procedure with arc system placed on phantom base to demonstrate and check accuracy of biopsy needle with *xyz* coordinates for precise depth and angle.

provides the neurosurgeon with a versatile bone dissector capable of cutting bone by sawing through it or drilling it away. In addition, large craniotomy flaps can be turned with only a single burr hole. Manufacturers' precautions and instructions must be followed for all powered instruments.

A variety of suction tips, retractors, and retractor systems are required for visualization. A transsphenoidal tray and instruments are required for that specialized approach. Microneurosurgical instruments may be needed for delicate brain or spinal cord surgery. Dural grafts and substitutes may be required to repair the dura. Aneurysm instruments, aneurysm clips, or hemostatic clips may be needed for neurovascular surgery. Titanium plates or wire is used to replace a bone plate after a craniotomy. Spinal instrumentation (plating and fixation systems) may be implanted, and bone grafts and substitutes may be used to promote spinal fusion.

Specific surgeries may require shunts or CSF reservoirs, implantable stimulators or pumps, endoscopes and endoscopic instruments, endovascular instruments, catheters, and coils. These supplies must be available if they are to be placed or implanted during surgery.

The surgical nurse needs to assemble instrumentation with consideration for each individual surgery and according to each individual surgeon's preferences. The instrument list for each procedure and neurosurgeon should be documented, referenced, and frequently updated in collaboration with the surgeon. Specific instruments are mentioned in the surgical procedure descriptions that follow.

Preliminary Procedures. A number of procedures or therapeutic measures are performed before the primary surgery begins. It is important that the perioperative nurse anticipate these procedures, understand why they are done, and be prepared to facilitate them.

ANESTHESIA CONCERNS. The anesthesia provider collaborates with the surgeon and nurses to provide appropriate care to the patient. The anesthesia provider must be aware of and plan for situations in which the neurosurgery patient may

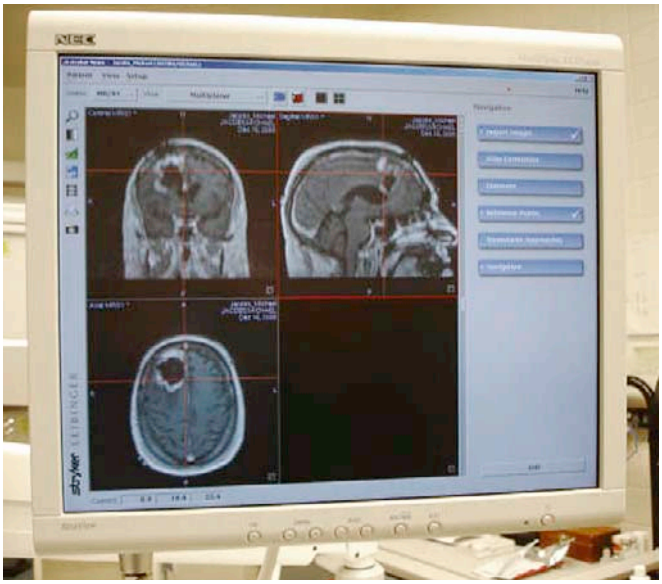

FIGURE 20-39 Frameless stereotactic image-guided navigation monitor showing the brain with tumor in three planes: coronal *(upper left)*, sagittal *(upper right)*, and axial *(lower left)*.

FIGURE 20-40 Hall Surgairtome 200 with attachments.

need to be awake during the surgery for intraoperative assessment. Anesthesia agents must be adjusted if intraoperative monitoring of EPs is to be done. If the cervical spine is unstable or unable to extend, endotracheal intubation may need to be done while the patient is awake. The position of the bed in the OR should be communicated to the anesthesia provider. For

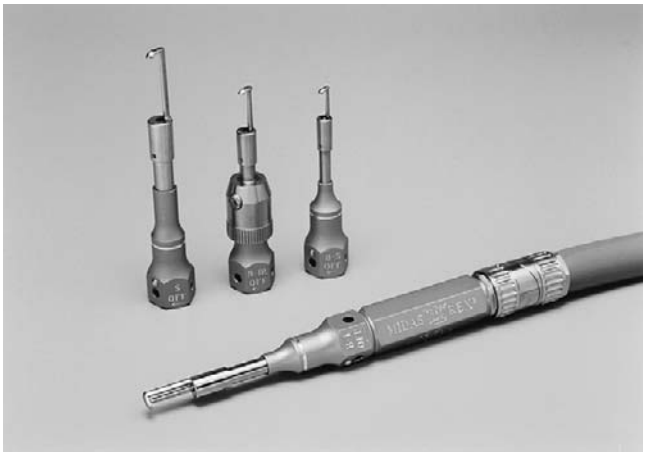

FIGURE 20-41 Midas Rex drill with attachments.

surgery of the head, the bed may be turned 90 or 180 degrees away from the anesthesia machine to provide comfortable access to the surgical site. Anesthesia providers can prepare by having enough length on their tubing to make the turn while maintaining control of the patient's airway.

Anesthesia for neurosurgery requires sufficient IV access. The anesthesia provider may place a central line if peripheral IV lines are insufficient, or if the procedure requires the patient to be positioned in the sitting position. Increased risk of an air embolism during surgery exists when the patient is in a sitting position and when a venous sinus may be breeched. A precordial Doppler ultrasound or a pulmonary artery catheter may be placed to monitor for an air embolus. A catheter in the right atrium can be used to remove an air embolus in the heart. An arterial line may be placed for continuous monitoring of blood pressure and for drawing samples for arterial blood gas (ABG) analysis.

Antibiotic prophylaxis is administered within 30 minutes of incision time and continued at the appropriate dose schedule for at least 24 hours. The preoperative antibiotic dose is the most important dose in the prevention of postoperative infection. Generally, a broad-spectrum cephalosporin is the antibiotic drug of choice, but this depends on the needs of the individual patient. In addition, antibiotics such as bacitracin can be added to the irrigation fluid. Preoperative steroids may be given to minimize inflammation and edema when surgery is done involving the brain or spinal cord. Diuretics may be added for brain relaxation during surgery and to decrease ICP. To prevent seizures antiepileptic drugs are typically given when the cerebral cortex is manipulated. Coagulopathies must be identified and corrected preoperatively.

For all but minor surgeries, a Foley catheter is inserted into the bladder to monitor urinary output during the procedure. It is essential when procedures are expected to be prolonged, when excessive bleeding is anticipated, or when diuretics are to be given intravenously, so that the bladder does not become distended. A Foley catheter is needed by trauma patients for continuous assessment of kidney function.

STEREOTACTIC IMAGE-GUIDED NAVIGATION. To prepare for surgery on the brain, fiducials are placed on bony landmarks or points around the skull before a preoperative MRI or CT scan. Afterward, the fiducials are left in place for entry into the OR. After the patient is anesthetized and positioned,

a skull clamp is placed and an image-guided navigation arm is attached to the skull clamp. This provides a fixed point of reference. The arm should be out of the way of the surgical team to ensure that it will not be inadvertently bumped and moved from its fixed point during surgery, thus disrupting the navigation system and potentially making it useless. The location of the fiducials is registered into the computer, allowing the computer to align the preoperative images (of the CT scan or MRI) to the patient's head. The monitor then shows the location of the navigation probe (which is maneuvered by the surgeon) and its trajectory on all three planes (axial, coronal, and sagittal) of the CT or MRI (see Figure 20-39). This enables the neurosurgeon to plan the approach to the target area and to navigate the surgical area using the navigation probe. After the registration process is complete, the fiducials can be removed so that the area can be prepped for surgery. A sterile sleeve is placed over the navigation arm when draping. The navigation system is used to find the target (tumor, lesion, ventricle) using the least traumatic trajectory. It also helps to ensure that the desired amount of tissue is removed. The image-guided navigation system can also be used for spine surgery.

NEUROMONITORING. An EEG can be used intraoperatively to view and record electrical activity by way of electrodes placed on the scalp or directly on the brain. It can be used to identify the location of seizure foci on the brain for possible resection (Research Highlight). Nonconvulsive use of EEG monitors is employed to monitor for burst suppression during carotid endarterectomy. Burst suppression refers to a decrease in brain activity on the EEG monitor and may be related to hypoxemia-related hypoperfusion.

EPs record the brain's electrical response to visual, auditory, and sensory stimuli. They may be used intraoperatively to monitor hearing during resection of acoustic neuromas or to monitor SSEPs (somatosensory evoked potentials) during some spine surgery. SSEPs may also be used to localize the primary sensory cortex in anesthetized patients. SSEPs involve placing needles in significant muscles of the patient and recording a baseline reading before the surgical incision. A significant change in EPs can indicate surgical invasion of the spinal cord, peripheral nerves, brainstem, or midbrain. To avoid permanent injury to the patient, the patient's position may need to be adjusted, or the surgeon may need to adjust retractors or instrumentation, alter a surgical approach, or decide that a subtotal tumor resection is necessary.

Transcranial Doppler (TCD) ultrasound may be used during carotid endarterectomy surgery. TCD provides information relevant to the major causes of perioperative cerebrovascular morbidity, including intraoperative and postoperative emboli, hypoperfusion during cross-clamping, intraoperative or postoperative thrombosis, and postoperative hyperperfusion syndrome. Using information received from TCD, the surgeon can alter the surgical or treatment plan in an attempt to avoid these complications (Whiten and Gunning, 2009).

LUMBAR AND VENTRICULAR DRAINS. The neurosurgeon may place a lumbar drain in the subarachnoid space of the lumbar spine to allow for CSF removal and intraoperative brain relaxation during aneurysm or tumor exposure. It may also be placed to prevent (or postoperatively, to treat) a CSF leak, which is most likely to occur after posterior fossa or transsphenoidal procedures. Alternatively, surgeons may place a ventricular catheter through a burr hole into a ventricle of the brain. In addition to providing the ability to drain CSF, a ventriculostomy provides the most accurate method of monitoring ICP. A transducer-tipped catheter system is a less accurate but less invasive method for monitoring. It does not allow for CSF drainage. With both the lumbar drain and the ventricular catheter, the nurse must ensure that stopcocks and clamps are properly positioned to avoid overdrainage of CSF, which could result in brain herniation. A separate surgical prep and setup are required for placement of these ICP devices.

Positioning. Many of the basic body positions described in Chapter 5 and their modifications are used in neurosurgery. The perioperative nurse must collaborate with the surgeon before

RESEARCH HIGHLIGHT

Results of Surgical Interventions for Epilepsy

This study sought to evaluate the success of epilepsy surgery in patients who required placement of invasive intracranial (IE) electrodes to localize the seizure source. This is a subset of overall patients who might undergo epilepsy surgery, since many patients can have their seizure source localized from surface electroencephalographic monitoring in conjunction with other standard testing (including magnetic resonance imaging and neuropsychologic evaluation).

A retrospective review was undertaken of all patients at one institution who had IE monitoring over a 5-year period. The IE electrodes were placed through skull burr holes. Resective surgery was offered to the patient if a localizable and resectable source for the seizures was clearly identified. Univariate and multivariate analyses were performed to determine those variables that might predispose the patient to being seizure-free and off medication 1 year after the surgery.

In the 172 patients with placement of IE electrodes, 130 elected to have resective surgery. Reasons for not having surgery were multifocal sources for seizures, unlocalizable source, patient decision, and unresectable source. Surgical procedures performed were temporal lobectomy (47%), focal cortical resection (40%), and supplementary motor area (SMA) resection (10%). At 1 year 47% of patients were seizure free, and at 4 years 44% continued to be seizure free. In the univariate analysis, temporal resections were more likely to be seizure free (53%) compared to non–temporal resections (41%). In addition, seizure-free patients were more likely to be younger (21% of patients over 40 years of age were seizure free whereas 58% of patients under 40 were seizure free). The multivariate analysis suggested that temporal lobectomy, SMA resection, and younger age lead to a higher chance of being seizure free.

IE monitoring is not required for all patients with epilepsy being considered for surgical resection. This study suggests that there are certain patient factors and surgical choices that can predict a more successful outcome when IE monitoring is performed.

From MacDougall KW et al: Outcome of epilepsy surgery in patients investigated with subdural electrodes, *Epilepsy Res,* 2009, doi:10.1016/j.eplepsyres.2009.03.014.

the procedure to ensure the appropriate OR bed, attachments, and supportive positioning devices are available. Positioning devices that may be needed include a headrest, pillows, blankets, gel pads, a safety belt, tape, a shoulder roll (supine), an axillary roll (lateral), a beanbag (lateral), and chest rolls (prone).

Specialized neurosurgical headrests and skull clamps are commonly used for craniotomies and posterior cervical spine surgeries to support and stabilize the head and neck. They can be used with any body position. The basic unit of the neurosurgical headrest attaches to the frame of the OR bed after the standard OR bed headpiece has been removed. An articulated arm allows fine adjustments to the position of the head. A horseshoe-shaped headrest may be used. Alternatively, head clamps, skull pins, and tongs that are attached to the neurosurgical headrest bed attachment and provide maximum stability may be required (see Figure 20-36).

Most skull clamps have three sterile pins that are placed in the skull clamp and covered with antibiotic or povidone-iodine ointment. The surgeon or surgeon's assistant places the skull clamps on the patient's head after anesthetic is administered. The surgeon must place the skull clamp strategically in the skull to provide access to the surgical site and to avoid the frontal sinuses, the superficial temporal arteries, and the eyes. The pins on the clamp partially penetrate the outer table of the skull. If the prone position is used, the surgeon will place the skull clamp while the patient is supine. The surgeon supports the patient's head during the position change and adjusts the final head position after the patient is placed prone (Patient Safety).

After positional adjustments to the patient's body are complete, the skull clamp (and patient's head) is locked into the articulating arm of the headrest by someone other than the person who is supporting the head. The apparatus is tightened from distal to proximal and double-checked for security. Once the patient's head is locked into place, no positional adjustments can be made to the patient's body without first releasing the head. Not doing so could cause injury to the patient's cervical spine. If necessary, an image-guided navigation arm can be attached to certain skull clamps, and the positions of the fiducials are registered into the system before the patient is prepped.

The skull clamp is detached from the basic headrest by loosening the arm from distal to proximal. Finally, while the head is being supported by another person, the skull clamp is loosened, allowing the pins to be released from the skull. Ointment can be applied to the pin sites. Bleeding may occur at the pin sites after the skull clamp is removed. It usually stops with digital pressure, but occasionally a stitch may be required.

The position of the patient's arms must also be considered. For cranial surgery, usually at least one arm is tucked so that

PATIENT SAFETY

Preventing Injury When Using an Intraoperative Head Fixation System

Specialized bed attachments in conjunction with a skull clamp create a mechanical support system that is often used in head and neck surgery when rigid cranial stabilization is desired. Features of this device include the base unit (which attaches to the OR bed), cross bars, a swivel adaptor (reticulating arm), and the skull clamp. Only properly trained OR staff should be permitted to operate these devices. Mounting instructions for the bed attachment vary by OR bed. The nurse must verify that the bed attachment is properly secured before the start of patient positioning.

SAFE APPLICATION OF THE SKULL CLAMP

Once the anesthesia provider has determined that the patient is ready for positioning, the designated member of the OR team will pin the patient's head with the skull clamp. The clamp consists of two skull pins in the rocker arm and one skull pin in the extension arm. When properly placed, the pins in the rocker arm are equidistant from the centerline of the patient's head and the single pin in the extension arm is exactly at the centerline. Improper positioning of the skull pins may cause serious injury to the patient. Special attention should be paid to avoiding the areas of the frontal sinus, temporal fossa, blood vessels, and nerves. The person securing the skull clamp must ensure that the pins are at an angle of 90 degrees, the necessary pounds of clamping force are applied, and the rocker arm is in the "CLOSED" position.

SAFE POSITIONING

After the head is safely pinned, the patient can be positioned for surgery. It is important that open communication exists between all members in the OR suite. Every member of the OR team plays a key role in the positioning process, and without good communication critical steps may be missed. Airway management is vital, and the anesthesia provider must have control of the patient's airway at all times. All movements of the patient's head and body must first be cleared by the anesthesia provider. There must be at least three people responsible for positioning the head. One member of the anesthesia team monitors the airway, one member of the surgical team holds the patient's head within the skull clamp, and one member secures the reticulating arm of the bed attachment to the skull clamp. All the components of the bed attachment have a starburst locking mechanism, and it is critical all teeth are engaged and locked securely. It is the responsibility of the team member holding the patient's head to do the final check to ensure all locking mechanisms are engaged properly. There should be no movement detected in any component of the system if secured properly. If even one component of the system is not properly engaged, the patient could possibly be injured.

POSTOPERATIVE MONITORING

Once the procedure is complete and it is time to remove the patient from the fixation system, the same safety measures go into effect. The anesthesia provider maintains control of the patient's airway while one member of the surgical team holds the patient's head within the skull clamp, and a second member of the surgical team releases all the locking mechanisms of the reticulating arm. At this time either the standard headpiece of the OR bed can be reattached or the patient can be moved to the postoperative bed or stretcher. When the skull clamp is released, the surgeon confirms that all three pins are extracted from the patient's head and secured. If bleeding is observed from the pin site, the surgeon may apply pressure to control the oozing, or may use a monofilament suture to close the hole.

the Mayo stand can be positioned over the patient. For cervical spine surgery, both arms are tucked so that the surgical site can be accessed from both sides of the table. When the arms are tucked, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail.

For thoracic and lumbar spine surgery, armboards can usually be placed out of the way of the surgeon and radiology equipment. Armboards are maintained at less than a 90-degree angle to prevent brachial plexus stretch.

As always, the nurse identifies any potential hazards and takes precautions to prevent them. Sequential compression devices are applied before induction of anesthesia to prevent deep vein thrombosis (DVT) unless they are contraindicated because of a known DVT. Pressure points must be identified and relieved. Joints must be maintained in functional alignment with no pressure or tension on superficial nerves and vessels. A warming/cooling blanket is applied for temperature control. An occlusive dressing applied over the eyes protects them from chemical burns and corneal abrasions that may occur from solutions used to prep the head. Keeping the head positioned above the heart minimizes bleeding when operating on the head.

Supine position or some modification of it can be used for approaches to the frontal, parietal, and temporal lobes; the anterior cervical spine; and the anterior lumbar spine. Lateral position can be used for an approach to the cerebellopontine angle in the posterior fossa, for anterior thoracic and lumbar spine surgery, and for posterior spine surgery. It can be used for lumbar sympathectomies and for placements of nerve stimulators and pumps.

Prone position and modifications of it can be used for access to the posterior spine and for suboccipital and posterior fossa craniotomies. A laminectomy frame or chest rolls are commonly used for prone position. The Jackson table permits access of the C-arm for intraoperative fluoroscopy of the spine. The Andrews table or frame can be used for a modified knee-chest position, which is useful for posterior lumbar spine surgery. The patient's hips and knees are flexed so that the lower body is supported primarily by the knees. The Hicks spinal surgery frame may be used to support this position and allow the abdomen to hang free. The chest is supported on a chest roll. Advantages of this position include decreased bleeding because of the collapse of epidural veins, better exposure resulting from hyperflexion of the spine, absence of pressure on the vena cava, and increased ease of ventilation. Operating time is usually reduced when this position is used. Disadvantages of the knee-chest position include the difficulty of maintaining physical stability on the OR bed, the increased possibility of patient hypotension, and the pooling of blood in the lower extremities.

Fowler's (sitting) position is used for some craniotomies involving a posterior or occipital approach. Advantages of this position include optimum visibility of the operative field and decreased blood loss because of the lowered arterial and venous pressures. Disadvantages are the potential for orthostatic hypotension and air embolism. In the sitting position the venous pressure in the head and neck may be negative, predisposing the patient to air embolism (Risk Reduction Strategies). Other potential problems with this position include neck flexion with airway compromise and difficulty in achieving and maintaining functional alignment. Please refer to Chapter 5 for more information on the previously mentioned positions.

Skin Preparation. Prevention of infection is a primary concern in neurosurgery. An antiseptic skin prep is performed by the perioperative nurse, surgeon, resident, or surgical assistant. General principles and precautions cited in Chapter 3 apply to neurosurgical preps. Although studies have shown that shaving the surgical site can contribute to the possibility of infection, usually some hair removal is necessary when operating on the head and posterior cervical spine.

Hair removal from the head causes a disturbance in body image and can be upsetting to patients. A discussion and often a compromise regarding hair removal should take place between the surgeon and patient before the surgery, and an understanding should be reached as to how much hair will be removed. Hair that is removed is the property of the patient. It should be placed in a container, labeled with the patient's name, and kept with the patient after surgery.

Hair removal should be done as close to the time of skin incision as possible to decrease the possibility of surgical site infection. Whenever possible, minimal hair removal is recommended. It is possible to shave a 1- to 2-cm wide area along the length of some craniotomy incisions after the hair is parted at the incision site. After the minimal shave, the hair can be combed away from the incision and held back with prepping solution or antimicrobial ointment. However, other craniotomies require more extensive hair removal. Electric hair clippers are preferred to razors because they are less irritating and less likely to nick the skin, which would predispose the area to infection. After hair removal, the nurse should inspect the patient's skin carefully for any signs of inflammation or infection. If any such signs are noted, they should be reported to the surgeon immediately. The head and hair surrounding the planned incision can be prepped, even though the hair will be draped out of the operative field.

For surgery on the cervical spine it is possible to secure long hair on top of the head and remove neck hair with clippers to a level even with the top of the ears or to the occipital protuberance. Postoperatively, patients with long hair can comb it down over the shaved area until the hair regrows. Patients undergoing thoracic or lumbar spine surgery may not need to be shaved. If a bone graft from the hip will be taken for spinal fusion, that area must be prepped as well as the spinal incision area.

Many neurosurgeons mark the incision line with a marking pen or a marking solution and wooden stick. If a marking solution is used, indigo carmine, gentian violet, or brilliant green is recommended. Methylene blue should never be found in a neurosurgical OR because it produces an inflammatory reaction in CNS tissue. Because the markings tend to wash off during the prep, some surgeons may scratch the scalp along the planned incision with a sharp sterile needle. This increases the risk of infection and should only be done if there is danger of harming the patient by varying from the planned line of incision.

Draping. According to the recommendations of The Joint Commission, the surgical team takes a "time out" during the prepping and draping procedures to be sure that everyone is in agreement that the correct surgery is being done to the correct patient in the correct location. The surgical consent is read aloud by the circulating nurse. In neurosurgical procedures, the right or left side of the head and the level of the spine must be specified. The

RISK REDUCTION STRATEGIES

Preventing and Managing Venous Air Embolism in the Sitting Position

The use of the sitting position is more common in neurosurgical procedures than in other specialties because of its excellent surgical access, improved ventilation, and improved drainage of blood and cerebrospinal fluid from the head and neck, thereby decreasing intracranial pressure. However, patients undergoing posterior fossa, cervical, or supratentorial procedures in the sitting position are at risk for venous air embolism (VAE). VAE is a potentially serious intraoperative condition that may result in significant morbidity and mortality. The incidence of VAE in neurologic procedures performed in the sitting position is 10% to 80% and has a mortality of approximately 1%.

The perioperative nurse partners with the anesthesia provider, neurosurgeon, and scrub person to provide safety for patients during seated neurosurgical procedures. The nurse must be knowledgeable about the factors that contribute to VAE to plan effective and safe patient care.

Common sources of VAE are the major cerebral venous sinuses, in particular, the transverse, the sigmoid, and the posterior half of the sagittal sinus, all of which may be noncollapsible because of their dural attachments. Air may also enter through the emissary veins, particularly from the suboccipital musculature, the diploic space of the skull, and the cervical epidural veins. VAE is possible any time there is a negative pressure gradient between the operative site and the right atrial pressure.

PREVENTIVE MEASURES

The nurse should anticipate assisting the anesthesia provider with the placement of a pulmonary artery pressure (PAP) catheter, precordial Doppler, and a multiorifice central venous line. The pulmonary artery catheter allows the anesthesia care provider to monitor heart pressures. The right atrial central venous catheter is used to measure right arterial pressure, administer vasoactive medication if needed, and provide a route to aspirate air from the right atrium. Depending on availability, transesophageal echocardiography (TEE) may be used to detect VAE. The nurse should collaborate with the anesthesia provider and neurosurgeon to configure the OR to accommodate the TEE equipment. According to the surgeon's preference, the nurse should ensure the patient is wearing compression stockings, sequential compression devices, or elastic Ace bandage wraps on the lower extremities to promote venous return and prevent venous stasis. With the help of the anesthesia care provider, the nurse can place the patient in an antishock suit with separate inflatable chambers for the legs and abdomen, which may not be inflated until a venous air embolism has been detected.

DETECTION OF VENOUS AIR EMBOLISM

The anesthesia provider will monitor the PAP, Doppler, end-tidal CO_2 levels and TEE (if used). Generally, transient decreases in arterial pressure and end-tidal CO_2 levels, which are not otherwise related to anesthetic administration or surgical condition, indicate the presence of VAE. The audible tone of the precordial Doppler changes, and turbulence, or "washing-machine" sounds, may indicate early VAE. If VAE is detected or suspected, the nurse must be prepared to assist the surgeon and anesthesia provider to rapidly treat the patient.

MANAGING VENOUS AIR EMBOLISM

Once VAE has been diagnosed, a critical component of treatment is to prevent further air entrainment. The nurse should ensure saline-soaked dressings are available on the sterile field so the surgeon can immediately cover the surgical site. The surgeon should then assess and eliminate any entry site to prevent additional air entry. The anesthesia provider is responsible for attempting to aspirate the air by way of the multiorifice right atrial catheter and may administer ephedrine, dobutamine, or norepinephrine to provide inotropic support to the right ventricle. A repositioning to the left lateral decubitus position (right side up) may be indicated to prevent the air in the atrium from moving to the ventricle and causing an air lock. If the patient's position cannot be changed because of the positioning apparatus, the tilt of the OR bed can be adjusted to lower the source of air entry and decrease the negative air pressure gradient. The antishock suit may be inflated, thus increasing right atrial pressure and decreasing the pressure gradient between the right atrium and an entraining vein.

In Winn RH, editor: *Youman's neurological surgery,* vol 1, ed 6, Philadelphia, 2009, Saunders; Mirski MA et al: Diagnosis and treatment of vascular air embolism, *Anesthesiology* 106(1):164-177, 2007; Leslie K et al: Venous air embolism and the sitting position: a case series, *J Clin Neurosci* 13(4):419-422, 2006; St-Arnaud D, Paquin MJ: Safe positioning for neurosurgical patients, *AORN J* 87(6):1156-1172, 2008.

surgical team should also check that the marking (initials) made to the surgical site in the holding area are in the operative field.

Draping for some neurosurgery procedures is complex and requires the cooperation of the surgeon, assistant, and scrub nurse. Four or more towels are placed around the operative site. They may be secured by disposable skin staples, small towel clips, or silk sutures on a cutting needle.

Draping for a craniotomy is challenging. If a minimal shave was done, an adhesive drape with staples placed around the shaved area near the incision can help to keep hair out of the incision. Towels can be contoured to the prepped area of the head and held in place with staples, leaving the operative site exposed. A craniotomy drape can then be placed over the towels. A sterile drainage bag below the incision will help to catch irrigation and blood and drain it into a suction canister. If a stereotactic head frame is used, be sure that the drapes do not interfere with the head frame attachments.

Prepping a hip graft incision site may need to be done with spinal fusion surgery. Two areas may need to be prepped and squared off with towels, which can be held in place with an adhesive drape. A partially unfolded three-fourths drape can be placed between the two planned incision sites before the universal or laparotomy drape is placed. A clamp can be placed over the prepped hip area to positively identify it. The drape can be cut over the prepped area, being sure not to cut an area of the drape that covers a nonsterile area. A second adhesive drape can hold the cut drape in place. Please refer to Chapter 3 for general draping procedures.

Hemostasis and Visualization. A few minutes before making the incision, the surgeon may inject the incision site with a local anesthetic agent, such as lidocaine or bupivacaine. Lidocaine has a more rapid onset and shorter duration of action than bupivacaine. Along with decreasing the effect of the stimulus of

the skin incision, infiltration of the solution will apply pressure within the tissues and decrease bleeding at the time of incision. Using a local anesthetic that also contains epinephrine will constrict blood vessels to further minimize bleeding.

Meticulous hemostasis is particularly important in neurosurgery. Many methods are incorporated to limit blood loss. A major consideration is control of hemorrhage from the highly vascular scalp. Skin edges along the wound are compressed with gauze sponges and fingers during the initial incision. Usually, this is followed by application of disposable scalp clips (Figure 20-42). An automatic clip gun may be used to apply clips to include the galea and skin edge. The clips limit bleeding by applying pressure to the scalp edges. They remain in place until closure. Placement of self-retaining retractors also helps to control bleeding of the scalp.
