Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Author assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

About the Author

JANE C. ROTHROCK, PhD, RN, CNOR, FAAN

To Alan,
partner and good friend,
for whom I have much love and gratitude.
Thank you seems so inadequate,
but I'll say it anyway:
thank you, thank you, thank you
for your love, support,
encouragement, and patience.
I'm so grateful for the affection, respect,
loyalty, and sense of humor we share.
May Mary-Mom smile down
on us as we grow even closer
over the coming years.

Dr. Jane Rothrock has practiced and taught perioperative nursing since 1969. In 1979 she joined the faculty of Delaware County Community College, where she is now Professor and Director of Perioperative Programs. Her responsibilities include entry-level, postbasic RN education for perioperative nursing and advanced skill preparation for RN first assistants. These courses are offered both in Pennsylvania and at various sites nationally, within host institutions. During her 30-year tenure at the college, Jane has helped to educate more than 3600 registered nurses in the professional practice of perioperative patient care.

Jane's decades of experience include not only as a faculty member but also as an author and speaker. She has taught at the University of Pennsylvania, been an OR Director, and served as the preceptor for many graduate students. She has authored 5 perioperative nursing textbooks, published more than 50 articles, and presented a host of topics to nursing audiences across the United States and internationally. Jane is an AORN past president, served in 1996-1997 as the Chair of the AORN Project Team on Professional Practice Issues, chaired the AORN Project Team on a Professional Practice Model for Perioperative Nursing in 1998-1999, and chaired the Perioperative Academic Curriculum Task Force in 2006. She has received a number of distinguished awards, and is very active in both nursing and community organizations. Jane is a past vice chair of NOLF, a past member of the ANCC Magnet Commission, a past president of the ASPAN Foundation, and a past president of the AORN Foundation Board of Trustees. She served on ASPAN's first National Clinical Guideline Panel to develop a Guideline on Prevention of Unplanned Hypothermia in Adult Surgical Patients. In 2000 Jane became a Fellow of the American Academy of Nursing (FAAN). She currently serves as an "Ask the Expert" for Medscape Nursing, and is a co-editor of *Tea & Toast for the Perioperative Nurse's Spirit*, a book of inspirational stories published in 2006.

Jane began her nursing education with a diploma from Bryn Mawr School of Nursing. She received her BSN and MSN from the University of Pennsylvania and was the first recipient of a doctoral degree from Widener University in suburban Philadelphia, earning her PhD in nursing in 1987.

Preface

The fourteenth edition of *Alexander's Care of the Patient in Surgery* has been updated to reflect new concepts in perioperative nursing practice and increased sophistication and complexity of surgical procedures. The multimedia resource, first introduced in the thirteenth edition, enhances the elemental goal of this textbook: to provide a comprehensive basic reference that will assist perioperative practitioners to meet the needs of the patients they care for safely, cost-effectively, and efficiently during surgical interventions.

The standard in perioperative nursing for more than 50 years, *Alexander's Care of the Patient in Surgery* is written primarily for professional perioperative nurses, but it is also useful for nursing students, surgical technologists, healthcare industry representatives, medical students, interns, residents, and government officials concerned with healthcare issues. Perioperative nurses, RN first assistants, clinical nurse specialists, nurse practitioners, surgeons, surgical technologists, and educators from many geographic areas of the United States have served as contributors and reviewers for this text, providing a vast range of perioperative nursing knowledge and procedural information.

This thoroughly revised edition highlights current techniques and innovations in surgery. Hundreds of illustrations, including many new photographs and drawings, help familiarize the reader with new procedures, methods, and equipment. Classic illustrations, particularly of surgical anatomy, have been preserved to enhance the text. New to this edition, clinical chapters now include Ambulatory Surgical Considerations, Risk Reduction Strategies, and Rapid Response Team applications. Best Practices, featured in previous editions, have been updated, and retitled Evidence for Practice.

As with previous editions, there are updated Research Highlights, Sample Plans of Care, Patient and Family Education features, Surgical Pharmacology features, Patient Safety features, and History boxes in each clinical chapter, so that readers can look back, as well as forward, as they explore perioperative patient care.

Enhanced in the fourteenth edition is the *Evolve web site*. With its learner resources, readers are now able to access content updates, surgical instrumentation photos, printable surgical pharmacology tables, printable patient and family education materials, resources for surgical technology students, and web links to surgical procedure videos.

Also improved in the fourteenth edition are resources for instructors and clinical educators. In addition to the learner resources listed previously, there are instructor resources containing a lesson plan for each chapter with the following elements: a pretest, suggested background assessment of learners, critical thinking questions, learning objectives, suggested content for lectures and class activities, PowerPoint lecture slides, an image collection of more than 950 images, and animations to use in teaching. Instructors and clinical educators will also find a test bank with 800 questions as well as more than 50 competency assessments for use in clinical settings or simulation laboratories as learners practice new perioperative nursing skills and techniques. Overall, this textbook imparts state-of-the-art information and resources that reflect contemporary practice and promotes the delivery of comprehensive perioperative patient care.

Unit I, *Foundations for Practice*, provides information on basic principles and patient care requisites deemed essential to the care of all recipients of perioperative patient care. The nursing process, a model for developing therapeutic nursing interventional knowledge, reflects a six-step process that includes the identification of desired patient outcomes. Interest in patient outcomes and their improvement continues to be an essential element of nursing. The collection of health data requires clear identification of contributions to patient outcomes and quantification of these contributions. Perioperative nurses must continue to link their interventions to outcomes. This relationship is presented in Chapter 1 and explicated in each Sample Plan of Care throughout the text. Research Highlights continue to be included in every chapter, reflecting the steady increase in the amount and quality of research relevant to perioperative patient care. As current findings of new research are important to use in clinical practice, the editors and authors of *Alexander's Care of the Patient in Surgery* are committed to supporting this research-practice relationship. The Research Highlights will help perioperative nurses implement research findings in their practice and patient care activities. Chapter 1 also sets the stage for an emphasis on patient and family education and discharge planning throughout the text. Chapters in Units II and III address specific patient and family education and discharge planning relevant for patients undergoing one or more of the respective specialty surgical procedures. As the responsibilities of perioperative nurses become greater with regard to those important care components, it is imperative that we effectively educate patients and families. With the length of stay in healthcare facilities continuing to decrease, patients and families must be informed and prepared to deal appropriately with postoperative needs after discharge. Pain management, addressed in Chapter 9, is also reflected in many of the chapters on surgical specialties, as all perioperative nurses recognize its importance in patient discharge planning.

Chapter 2 has been refocused on both patient safety and risk management. New chapters have been added on interventional radiology and workplace safety. As perioperative nurses and surgical technologists face increasing workloads and workplace stress, this fourteenth edition emphasizes the need for workplace safety. When pressure in the surgical suite mounts, nurses and surgical technologists may feel the need to work faster, even if it means taking shortcuts. The chapter on workplace safety stresses the need for personal safety at work.

The chapters within Unit II, *Surgical Interventions*, include more than 400 contemporary and traditional specialty surgical interventions, with descriptions of both minimally invasive surgical procedures and robotic-assisted surgery. Each chapter provides a helpful review of pertinent anatomy and details the steps of surgical procedures. Perioperative nursing considerations are again presented within the nursing process framework. Current NANDA International–approved nursing diagnoses and Sample Plans of Care for each surgical specialty aim to help perioperative nurses plan, implement, and evaluate individualized perioperative patient care. Each of these chapters also provides an example of Evidence for Practice related to the surgical specialty. In 2010 and beyond, perioperative nurses can expect to find a continuing emphasis on evidence-based nursing as a means to provide care that is effective and yields improved outcomes. The integration of evidence-based practice with the perioperative nurse's individual clinical expertise leads to optimal care provision, the foundation of perioperative patient care. Improving the quality of patient care and effecting safe outcomes are at the heart of all of our efforts to achieve excellence in whatever setting we encounter the patient undergoing an operative or other invasive procedure.

Incorporation of Surgical Pharmacology in the fourteenth edition continues to reflect the ongoing emphasis on medication safety in the United States. *Alexander's Care of the Patient in Surgery* joins the nationwide health professional education campaign aimed at reducing the number of common but preventable sources of medication errors. Providing information about select medications used in surgical specialties, the Surgical Pharmacology features are intended to promote safe medication practices among perioperative practitioners to help avoid serious, even potentially fatal, consequences of medication errors. Medication errors can occur anywhere in the medication-use system, from prescribing to administering a drug. Other areas covered in the Surgical Pharmacology feature address the use of written medication orders, recommendations for read-back and repeat-back reports, and suggestions for proper labeling of medications on and off the sterile field, as well as uses, dosages, and other information regarding perioperative medications.

To further facilitate the perioperative nurse's focus on safe patient care, Patient Safety features in each chapter succinctly review a practice to assist perioperative practitioners in developing a core body of knowledge about safe patient care. We intend this feature not only to raise awareness about patient safety applications but also simultaneously to foster communication and ongoing dialogue in perioperative practice settings regarding application of recommended patient safety strategies and use of robust process improvement initiatives, all to improve quality and safety.

The unique needs of pediatric, geriatric, and trauma surgery patients are presented in Unit III, *Special Considerations*. The chapter *Integrated Health Practices: Complementary and Alternative Therapies* was introduced in the twelfth edition. Perioperative nurses frequently encounter patients who use such therapies, some of which are nonpharmacologic and some of which involve medications. This chapter explores alternative medical systems, mind-body interventions, biologically based therapies, manipulative and body-based methods, and energy therapies. Numerous treatments and systems within each category are discussed.

Many expert perioperative practitioners, RN first assistants, clinical nurse specialists, and educators have contributed to this fourteenth edition, and I owe a debt of gratitude to all of them for sharing their expertise in the development of this text. I give special thanks to my partner, Alan Zulick, for his help during copy-edits and page proofs. I also acknowledge the valuable assistance of editors, reviewers, photographers, and illustrators who have contributed their time and expertise to the revision of this text. The team I had the privilege of working with at Elsevier is talented and eager to support perioperative practitioners in their commitment to excellence in patient care.

Alexander's Care of the Patient in Surgery is written by and for perioperative nurses. Its premise is underscored by the clear understanding that perioperative nursing is a caring and intellectual endeavor, requiring critical thinking, technical acumen, and clinical decision-making to improving patient outcomes. With the multimedia package accompanying this fourteenth edition, *Alexander's Care of the Patient in Surgery* invites you to walk with us as we meet the challenges and opportunities of perioperative nursing in this new decade of the twenty-first century.

Jane C. Rothrock

Contents

Unit I: Foundations for Practice

1 Concepts Basic to Perioperative Nursing, 1

Overview of Perioperative Nursing Practice, 1
Standards of Perioperative Nursing Practice, 3
Evidence-Based Practice, 12
Performance Improvement, 13
Perioperative Nursing Roles, 15

2 Patient Safety and Risk Management, 18

Safety As an Individual Responsibility, 18
Concentrated Emphasis on Systems, 18
Major Association Safety Activities, 19
Perioperative Nursing Safety Issues, 23
Patient Rights, 45

3 Infection Prevention and Control in the Perioperative Setting, 48

Causes of Infection, 48
Controlling Infection, 57
Aseptic Practices to Control Infection, 85

4 Anesthesia, 111

History of Anesthesia, 111
Anesthesia Providers, 111

UNIT I FOUNDATIONS FOR PRACTICE

CHAPTER 1

Concepts Basic to Perioperative Nursing

VICTORIA M. STEELMAN

OVERVIEW OF PERIOPERATIVE NURSING PRACTICE

Perioperative nursing is the nursing care provided to patients before, during, and after surgical and invasive procedures. Nurses practice this specialty in surgical suites, ambulatory surgery centers, endoscopy suites, laser centers, interventional radiology departments, mobile surgical units, and physicians' offices across the United States and the world. Perioperative nursing includes a broad array of cutting-edge innovations, such as remote surgery, virtual endoscopy, robotics, computerized navigation systems for neurosurgery, electronic medical records (EMR), transplanted tissue and organs, biologic materials that are absorbed to replace worn-out body parts, and radiofrequency identification (RFID). In this high-tech era, perioperative patient care is very different than it was in the past.

In the past, the term *operating room (OR)* nursing was used to describe the care of patients in the immediate preoperative, intraoperative, and postoperative phases of the surgical experience (Figure 1-1). This term implied that nursing care activities were circumscribed to the physical confines of the surgical suite. The term may have contributed to stereotypic images of the OR nurse who took care of the operating room and its equipment, but who had little if any interaction or nursing responsibility for medicated and anesthetized patients in the surgical suite. With such an image, nurses practicing outside the OR had difficulty crediting important elements of the nursing process and patient care accountability to the nurse who practiced "behind the double doors" of the surgical suite. Today, perioperative nursing implies the delivery of comprehensive patient care within the preoperative, intraoperative, and postoperative periods of the patient's experience during operative and other invasive procedures, using the framework of the nursing process. In doing so the perioperative nurse assesses the patient—collects, organizes, and prioritizes patient data; establishes nursing diagnoses; identifies desired patient outcomes; develops and implements a plan of nursing care; and evaluates that care in terms of outcomes achieved by and for the patient (Figure 1-2). Throughout, the perioperative nurse functions both independently and interdependently. Like nurses in other specialties, the perioperative nurse collaborates with other healthcare professionals, makes appropriate nursing referrals, and delegates and supervises other personnel in providing safe and efficient patient care (Patient Safety).

When nurses practice perioperative nursing in its broadest scope, care may begin in the patient's home, a clinic, a physician's office, the patient care unit, the presurgical care unit, or the holding area. After the surgical or invasive procedure, care may continue in the perianesthesia care unit (PACU) and evaluation of patient outcomes may extend onto the patient care unit, in the physician's office, in the patient's home, in a clinic, or through written or telephone patient surveys.

When nurses practice perioperative nursing in its most limited sense, patient care activities may be confined to the common areas of the surgical suite. Assessment and data collection may take place in the holding area while evaluation may take place on discharge from the OR. Regardless of the way nurses practice perioperative nursing in a healthcare setting, it remains founded on the nursing process and professional nursing practice.

The perioperative nurse also functions as a patient advocate during times of vulnerability. This specialty requires a broad knowledge base, instant recall of nursing science, the intuitive ability to be guided by nursing experience, and diversity of thought and action, as well as both great stamina and flexibility. Whether a generalist or a specialist, the perioperative nurse depends on knowledge of surgical anatomy, physiologic alterations and their consequences for the patient, intraoperative risk factors, potentials for and prevention of patient injury, and psychosocial implications of surgery for the patient and family. This knowledge enables the perioperative nurse to anticipate needs of the patient and surgical team and to initiate safe and appropriate nursing interventions rapidly. This too is part of patient advocacy—that is, doing for the patient what needs to be done to provide a safe and caring environment. The Association of periOperative Registered Nurses (AORN, 2006) has asserted the significance of such safety by affirming that staffing of healthcare personnel must ensure that patients undergoing surgical and invasive procedures have a perioperative nurse as circulator in the OR, and also that the core activities of perioperative nursing care (assessment, diagnosis, outcome identification, planning, and evaluation) be completed by a perioperative nurse.

A significant part of perioperative nursing is the delivery of scientifically based care. Such care implies understanding the rationale for certain activities and interventions, knowledge of how and when to implement them, and the skills to evaluate safety, cost-effectiveness, and outcomes of the care delivered. Knowledge of anatomy, surgical procedures, instruments, and

PATIENT SAFETY

Never Events

The term "never event" was first introduced in 2001 by Ken Kizer, MD, former CEO of the National Quality Forum (NQF), to describe tragic medical errors, such as wrong-site surgery, that should never occur. The NQF initially defined 27 of these events. Over time, the list has been expanded to describe adverse events that are clearly identifiable and measurable, result in death or significant disability, and are usually preventable.

Healthcare facilities are under increasing pressure to eliminate these preventable medical errors completely. In August 2007 the Centers for Medicare & Medicaid Services (CMS) announced that Medicare would no longer pay for the treatment of *never events*. Many states have now mandated reporting of these events when they occur, and additional states mandate reporting of serious adverse events, including many of the NQF *never events*. Healthcare facilities are accountable for investigating and correcting the system problems that contribute to these events. Some states require that a review called a "root cause analysis" be performed after an event and results reported.

Perioperative nurses play a key role in prevention of many *never events*, including:

- Surgery performed on the wrong body part
- Surgery performed on the wrong patient
- Wrong surgical procedure performed on a patient
- Unintended retention of a foreign object in a patient after surgery or other procedure
- Intraoperative or immediately postoperative death in an American Society of Anesthesiologists Class I patient
- Patient death or serious disability associated with the use of contaminated drugs, devices, or biologics provided by the healthcare facility
- Patient death or serious disability associated with the use or function of a device in patient care, in which the device is used for functions other than as intended
- Patient death or serious disability associated with intravascular air embolism that occurs while receiving care in a healthcare facility
- Patient death or serious disability associated with a medication error (e.g., errors involving the wrong drug, wrong dose, wrong patient, wrong time, wrong rate, wrong preparation, or wrong route of administration)
- Patient death or serious disability associated with a hemolytic reaction attributable to the administration of ABO/HLA-incompatible blood or blood products
- Stage 3 or 4 pressure ulcers acquired after admission to a healthcare facility
- Any incident in which a line designated for oxygen or other gas to be delivered to a patient contains the wrong gas or is contaminated by toxic substances
- Patient death or serious disability associated with a burn incurred from any source while receiving care in a healthcare facility
- Patient death or serious disability associated with a fall while receiving care in a healthcare facility

Accessed March 5, 2009.

FIGURE 1-1 Thomas Eakins, *The Agnew Clinic,* 1889. In this painting, reforms and advancements in surgical techniques and procedures are apparent. Surgeons wear gowns, instruments are sterilized, ether is used, and the patient is covered. An OR nurse is a prominent member of the team.

equipment is essential when implementing nursing care. This knowledge empowers the perioperative nurse to anticipate and prepare for the next steps of the surgical procedure and understand their concomitant implications for the patient and for the surgical team. Scientific nursing interventions and caring, comforting behaviors are at the heart of perioperative nursing. Unit II focuses on surgical procedures common to inpatient and ambulatory settings. Each chapter in Unit II contains a *Sample Plan of Care* with suggested nursing interventions. A fundamental assumption throughout this textbook is that perioperative nursing is a blend of technical and behavioral care and that critical thinking is the underpinning for doing and caring for patients professionally. Good clinical judgment derives from critical thinking (Fesler-Birch, 2005). Critical thinking requires purposeful, outcomes-directed thought and is driven by patient need. It is based on the nursing process and nursing science. Further, critical thinking requires knowledge, skills, and experience, guided by professional standards and ethics and grounded in constant reevaluation, self-correction, and continual striving to improve.

Perioperative Patient Focused Model

The AORN has developed a model to describe the important relationship between the patient and the perioperative nursing care provided. The *Perioperative Patient Focused Model* (AORN, 2009a) (Figure 1-3) consists of domains or areas of nursing

Assessment…	Review medical record, validate important findings, corroborate with patient. Analyze, interpret, and prioritize information.
Nursing Diagnosis…	Synthesize data collected; then label clinical judgment about the patient as a nursing diagnosis. Can be actual or risk for. Based on patient assessment and perioperative nurse's clinical judgment.
Outcome Identification…	Because perioperative nursing is largely preventive, generic outcomes have been identified that apply to all patients undergoing an operative or other invasive procedure. Additional outcomes are identified based on individual patient assessment and nursing diagnosis. Some outcomes are mutually formulated by the nurse and patient. Guide implementation of nursing interventions. Should be specific, realistic, and measurable.
Planning…	Incorporate information into a plan for the patient's care. Identify nursing interventions to achieve identified outcomes.
Implementation…	Carry out nursing plan of care. Gather equipment and supplies; participate in/guide/supervise patient preparation, transfer to OR bed, anesthesia induction, antimicrobial skin preparation, draping, patient positioning, monitoring of physiologic alterations during surgery, and patient discharge (transfer from OR bed, discharge to postanesthesia or postoperative unit).
Evaluation…	Determine whether outcomes were met; use outcome statements. Incorporate outcomes that have been met and those that are pending in report to nurse in postanesthesia care unit/ discharge area.

FIGURE 1-2 The steps of the nursing process are interrelated, forming a continuous cycle of thought and action.

concern: nursing diagnoses, nursing interventions, and patient outcomes. These domains are in continuous interaction with the health system that encircles the focus of perioperative nursing practice—the patient (AORN, 2007a).

Three of these domains—behavioral responses, patient safety, and physiologic responses—reflect phenomena of concern to perioperative nurses and comprise the nursing diagnoses, interventions, and outcomes that surgical patients or their families experience. The fourth domain, the health system, comprises the structural data elements and focuses on clinical processes and outcomes. When looking at the model, note the heavy line that indicates a differentiation between the health system and the patient.

The model as a whole illustrates the dynamic nature of the perioperative patient experience and the nursing presence throughout that process. Working in a collaborative manner with other members of the healthcare team and the patient, the nurse establishes outcomes, identifies nursing diagnoses, and provides nursing care. The nurse intervenes within the context of the healthcare system to help the patient achieve the highest attainable health outcomes (physiologic, behavioral, and safety) throughout the perioperative experience.

The *Perioperative Patient Focused Model* (AORN, 2009a) emphasizes the outcomes-driven nature of perioperative patient care. Perioperative nurses possess a unique understanding of desired outcomes that apply to all patients. In contrast to some nursing specialties in which nursing diagnoses are derived from signs and symptoms of a condition, much of perioperative nursing care is preventive in nature, based upon knowledge of inherent risks to patients undergoing surgical and invasive procedures. Perioperative nurses identify these risks and potential problems in advance and direct nursing interventions toward prevention of undesirable outcomes, such as injury and infection. Based upon an individual patient assessment, the nurse identifies relevant nursing diagnoses. This information guides the nursing interventions for each patient. From admission through discharge and home follow-up, the perioperative nurse plays a major role in managing the patient's care. Research based upon the *Perioperative Patient Focused Model* (AORN, 2009a) continues to test and validate the contributions of perioperative nurses to patient outcomes in the variety of settings in which the specialty is practiced.

STANDARDS OF PERIOPERATIVE NURSING PRACTICE

Perioperative nursing is a systematic, planned process—a series of integrated steps. For professional nursing, national standards establish the full expectations of the professional role within which the nurse practices. In the 1960s the American Nurses Association (ANA) engaged in standards development. First published in 1973, these standards have helped to shape nursing practice. Specialty nursing organizations, including the AORN, have worked with the ANA to develop their own standards and guidelines using the ANA framework. This collaboration has resulted in the use of common language and a consistent format for the profession.

Perioperative Nursing Practice Standards

The AORN (2009b) has developed a set of standards for perioperative nursing care (Box 1-1). These standards are authoritative statements that describe the responsibilities for which perioperative nurses are accountable. The standards represent a comprehensive approach to meeting the healthcare needs of surgical patients.

AORN's nursing standards are categorized within three overarching elements: structure, process, and outcome. The AORN (2009b) *Standards of Perioperative Administrative Practice* are *structure* standards that describe organizational characteristics, administrative and fiscal accountabilities, personnel qualifications, and facilities and environmental requirements. These standards provide authoritative guidance for professionals in

administrative roles and provide the structure within which perioperative patient care should be provided.

Process standards relate to nursing activities, interventions, and interactions. They are used to explicate clinical, professional, and quality objectives in perioperative nursing. The AORN (2009b) process standards are the *Standards of Perioperative Clinical Practice, Standards of Perioperative Professional Practice,* and *Quality and Performance Improvement Standards for Perioperative Nursing.*

Standards of Perioperative Clinical Practice comprise the standards of care and professional performance (AORN, 2009b). The standards of care are based on and describe the application of the nursing process in perioperative nursing. The standards include the collection and analysis of health data, identification of expected outcomes, the planning and implementation of patient care, and evaluation of the effect of this care on patient outcomes.

The AORN (2009b) *Standards of Professional Practice* mandate, in part, that the perioperative nurse evaluate the effectiveness of nursing practice and the quality of that practice. Professional practice standards also require that perioperative nurses evaluate their own practice in relation to AORN's professional practice standards. Achieving certification (Certified Nurse, Operating Room [CNOR]), pursuing lifelong learning, and maintaining competency and current knowledge in perioperative nursing are the hallmarks of the professional. One of the standards focuses on the importance of evidence-based practice and participation in the generation of new knowledge through research. The pace and complexity of advances in surgical procedures, minimally invasive surgery, new technologies, professional nursing issues, ongoing healthcare reform measures, continuing changes in recommended practices, and the burgeoning body of nursing research and best practice guidelines demand constant professional education and development. Perioperative professionals must continue to research patient outcomes tenaciously, to link nursing interventions to outcomes, and to determine methods that conserve resources when implementing interventions. Other

standards of professional practice address ethics, collaboration, and collegiality.

The third set of *process* standards, The AORN (2009b) *Quality and Performance Improvement Standards for Perioperative Nursing,* delineate perioperative nurses' responsibilities to evaluate the patient care provided and make improvement to optimize patient outcomes. This standard underscores the importance of using data to improve patient care.

Outcome standards identify desirable and measurable physiologic and psychologic responses of patients to nursing interventions. Patient outcomes are an essential indicator of the quality of care. The AORN (2009b) *Perioperative Patient Outcomes* provide outcome statements, interpretations, and criteria guidelines for measuring patient responses. The common goal of standards is quality care for the surgical patient.

Nursing Process

Looking at nursing as a process can bring it into perspective as a system of critical thinking that provides the foundation for nursing actions. The focus of the nursing process is the patient, and prescribed nursing interventions are those that meet patient needs. Given the setting and the nature of the work, perioperative nursing is particularly vulnerable to being seen as only an accumulation of mechanical techniques and the execution of surgeon orders. By using the nursing process, however, perioperative nurses can focus on the patient and, at the same time, use skills and knowledge to care for patients and to make independent judgments and clinical decisions. Use of the nursing process, nursing plans of care, clinical pathways, and best practices (discussed later in this chapter) has become an integral part of patient care.

In its simplest form, the nursing process defined by the ANA consists of the following six steps: assessment, nursing diagnosis, outcome identification, planning, implementation, and evaluation (see Figure 1-2). The process is dynamic and continuous. Also, in all areas of nursing practice, certain responsibilities are inherent in the nursing process: (1) providing culturally and ethnically sensitive, age-appropriate care; (2) maintaining a safe environment; (3) educating patients and their families; (4) ensuring continuity and coordination of care through discharge planning and referrals; and (5) communicating information.

Assessment. *Assessment* is the collection of relevant health data about the patient. Sources of data may be a preoperative interview (History box) with the patient and the patient's family; review of the planned surgical or invasive procedure; review of the patient's medical record; examination of the results of diagnostic tests; and consultation with the surgeon and anesthesia provider, unit nurses, or other personnel. Data collection focuses on these major elements: (1) the patient's current diagnosis, physical status, and psychosocial status (including literacy, language skills, and spiritual, ethnic, cultural, and lifestyle information relevant to the delivery of patient-specific care); (2) previous hospitalizations or surgical interventions, and serious illnesses; and (3) the planned surgical or invasive procedure and the patient's understanding of this plan. Implementing patient-centered care requires the perioperative nurse to encourage the patient's active involvement in his or her care as part of patient safety (The Joint Commission [TJC], 2009b). Of primary importance are the patient's and family's understanding of the scheduled procedure and the patient's participation in activities such as marking the surgical site (Patient Safety) (the Universal Protocol for correct site surgery is discussed in Chapter 2) (TJC, 2009b). The perioperative nurse also assesses risk factors that may contribute to negative outcomes (Evidence for Practice). Communication with other members of the healthcare team is essential. The perioperative nurse proactively reports any concerns (e.g., abnormal laboratory values, or issues related to the patient's lack of understanding of the planned procedure) to the surgeon. The nurse should document all data collected and note any referrals that he or she makes.

The assessment format varies from institution to institution but always includes the physiologic and psychosocial aspects of the patient. In some settings, the assessment is done in stages by one or more perioperative nurses. A perioperative nurse may perform an assessment in the presurgical care unit or by telephone before the day of surgical admission. In such cases, the nurse in the OR may verify parts of the assessment previously done and complete the remainder. For a perioperative nurse caring for a healthy patient, assessment may mean only a thoughtful, brief review of the assessments previously done, a short patient interview, review of the medical record

HISTORY

Nurses' Responsibilities to Their Patients

Although theoretic perspectives regarding patient outcomes have been described by nursing scholars, a recognition and appreciation of the contributions and legacy of the past should not be disregarded. Early in our nursing history, the foundation was clearly laid for nurses' responsibility and accountability to their patients.

- The Order of St. John (1000s) had as its mission the relief of sickness, suffering, distress, and danger.
- Florence Nightingale (1800s) analyzed healthcare conditions and patient outcomes related to morbidity and mortality in the Crimean War.
- Clara Weeks-Shaw (1900s) described in some detail the measures perioperative nurses should take when surgery was being done in the patient's home, noting actions to alleviate anxiety and provide for patient comfort.
- Dorothy Johnson (1950s) introduced the concepts of internal and interpersonal equilibrium to relieve discomfort and tension in patients.
- Virginia Henderson (1970s) described nursing as a substitute for self-care, assisting in the outcome of bringing the patient toward independence.
- Dorothy Orem (1970s) identified self-care needs of patients and nursing measures to support them: partially compensatory, wholly compensatory, and supportive-educative. Perioperative nurses act therapeutically in all three ways with their surgical patients.
- Imogene King (1980s) noted the interconnections between nurse and patient, identifying goal-related decisions to attain, maintain, or restore health or to die with dignity.
- Jean Watson (1980s) introduced the science of caring, wherein nurses applied caring factors to promote health, prevent illness, care for the sick, and restore health.
- Patricia Benner and Judith Wrubel (1980s) suggested that caring is central to the essence of nursing, enabling connection and concern.

PATIENT SAFETY

Involving Patients in Marking the Surgical Site

Perioperative nurses collectively value patient safety. One way to facilitate this goal is to improve involvement by patients in their care through information and education. The Joint Commission (TJC) Speak Up™ campaigns are safety initiatives that encourage patients to take an active role in their healthcare. *Help Avoid Mistakes in Your Surgery* offers a patient the following information about marking the surgical site and the time-out:

- A healthcare professional will mark the spot on your body where the surgeon will operate. Make sure that only the correct part and nowhere else is marked. This helps avoid mistakes.
- Marking usually happens when you are awake. Sometimes you cannot be awake for the marking. If this happens, a family member or friend or another healthcare worker can watch the marking. They can make sure that your correct body part is marked.
- Your neck, upper back, or lower back will be marked if you are having spine surgery. The surgeon will check the exact place on your spine in the OR after you are asleep.
- Ask your surgeon if they will take a "time out" just before your surgery. This is done to make sure they are doing the right surgery on the right body part on the right person.

TJC also offers surgery patients these "tips" to further encourage their active involvement:

- You and your surgeon should agree on exactly what will be done during the operation.
- Ask to have the surgical site marked with a permanent marker and to be involved in marking the site. This means that the site cannot be easily overlooked or confused (for example, surgery on the right knee instead of the left knee).
- Ask questions. You should speak up if you have concerns. It is okay to ask questions and expect answers that you understand.
- Think of yourself as an active participant in the safety and quality of your healthcare. Studies show that patients who are actively involved in making decisions about their care are more likely to have good outcomes.

EVIDENCE FOR PRACTICE

The Risk of Hypothermia

Unplanned hypothermia (core temperature less than 36° C) is among the most common complications of surgery. It results from impaired thermoregulation caused by anesthesia and heat lost into the surgical environment. Shortly after induction of anesthesia, body heat rapidly shifts from the body's core to its periphery. This redistribution results in a core temperature drop of about 1.6° C (2.7° F) during the first hour after induction of anesthesia (Matsukawa et al, 1995a, 1995b). This initial temperature drop is followed by a slow, linear decrease during the second hour of anesthesia, in which heat loss exceeds the body's ability to metabolically produce heat. After 3 to 5 hours of anesthesia, the patient's core temperature usually plateaus and is characterized by a constant core body temperature (Kurz, 2008). All anesthetized surgical patients are at risk of hypothermia, and the risk increases as the anesthesia duration increases (Matsukawa et al, 1995a, 1995b; Sessler, 2000; Kurz et al, 1993). The risk of hypothermia is greater in some patients, including neonates (Tander et al, 2005), trauma patients, and patients with extensive burns (Caldwell et al, 1994).

Mild hypothermia increases the risk of negative patient outcomes. Kurz and colleagues (1996) studied 200 patients undergoing colon surgery. Subjects were randomly assigned to either standard care (resulting in hypothermia) or intraoperative warming (resulting in normothermia). Surgical site infection occurred in 19% of subjects who received no warming compared to only 6% of those who received warming. Sutures were removed 1 day later in the patients assigned to standard care and hospitalization was prolonged by 2.6 days more than the normothermia group.

Frank and colleagues (1993) studied 100 patients undergoing lower extremity vascular reconstruction. These researchers found that patients with postoperative temperatures less than 35° C experienced a higher rate of myocardial ischemia, angina, and lower oxygen saturation during the early postoperative period.

When patients become hypothermic, platelet activation is inhibited, resulting in increased blood loss (Michelson et al, 1994). Mild hypothermia also alters medication metabolism and increases the duration of muscle relaxant action, which results in an extended postanesthesia recovery time and may prolong hospitalization. Based upon these and similar studies, warming patients using both active and passive methods in the OR has become a standard, evidence-based practice.

and surgical procedure, and a mental rehearsal of the resources and knowledge necessary to guide the patient successfully through an operative course. At other times, the perioperative nurse must assess all aspects of the patient and the patient's condition thoroughly, along with preoperative and postoperative reviews.

When developing guidelines for preoperative assessment, patient and family education, and discharge planning, the perioperative nurse should consider the following:

- Is relevant, concise patient information already available to the perioperative nursing staff?
- Is enough information available to allow perioperative nurses to consider patient care needs when setting up the room (e.g., special equipment, accessory items, instruments, sutures)?
- Is sufficient time available to initiate a meaningful perioperative nurse-patient interaction?
- Are surgical patients satisfied with their perioperative nursing care (do they express feelings of comfort and satisfaction regarding their care in the surgical setting) and do they have knowledge of the perioperative nurse's role?
- Is there continuity of care between the perioperative unit and other nursing care units?

Being able to exchange information about their patients in face-to-face meetings, by telephone, or by written messages is helpful for unit and perioperative nurses. A thorough assessment made and recorded by the preoperative nurse can accompany patients to the OR and serve as a guide for the perioperative nurse, who then completes a more focused preoperative patient assessment. With the burgeoning number of ambulatory surgery procedures, preoperative assessment is often integrated in preadmission testing. Some institutions hold group preoperative sessions. These not only help nurses get to know the patients, but also permit nurses to impart information on common routines, reactions, sensations, and nursing procedures that will take place preoperatively, intraoperatively, and postoperatively. The perioperative setting determines the type of interaction that may occur. The use of preoperative phone calls and on-line questionnaires has also gained wide acceptance. Soliciting information before the patient's arrival in the perioperative setting can affect patient outcomes. The important point is that some form of assessment, patient and family education, and discharge planning must be done. The particular facility and nursing staff determine how to accomplish it.

Assessment is knowing and understanding the patient as a feeling, thinking, and responsible individual who is a candidate for a surgical or invasive procedure. Data identified through assessment help the perioperative nurse meet unique patient needs throughout the surgical intervention. Based on the data collected, recorded, and interpreted during patient assessment, the perioperative nurse then formulates a nursing diagnosis.

Nursing Diagnosis. *Nursing diagnosis* is the process of identifying and classifying data collected in the assessment in a way that provides a focus to plan nursing care. Nursing diagnoses have evolved since they were first introduced in the 1950s. Today, they are identified, named, and classified according to human response patterns and functional health patterns. The organization responsible for delineating the accepted list of nursing diagnoses is the North American Nursing Diagnosis Association International (NANDA-I) (Box 1-2). Each NANDA-I–approved nursing diagnosis has a set of components, as follows: a definition (i.e., the meaning of the diagnostic term); its defining characteristics (i.e., the requisite pattern of signs and symptoms or cues that make the meaning of the diagnosis clear); and its related or risk factors (i.e., causative or contributing factors that are useful in determining whether the diagnosis applies to a particular patient). For perioperative patients, many nursing diagnoses are "risk" diagnoses, meaning that they are not evidenced by signs or symptoms because the problem has yet to occur and nursing interventions are directed at prevention.

BOX 1-2

Selected Perioperative Nursing Diagnoses

Ineffective **A**irway clearance
Anxiety
Risk for **A**spiration
Risk for imbalanced **B**ody temperature
Readiness for enhanced **C**omfort
Ineffective **C**oping
Risk for imbalanced **F**luid volume
Impaired **G**as exchange
Hyperthermia
Hypothermia
Risk for **I**nfection
Risk for **I**njury
Risk for perioperative positioning **I**njury
Deficient **K**nowledge
Acute **P**ain
Risk for impaired **S**kin integrity
Delayed **S**urgical recovery
Ineffective **T**issue perfusion
Impaired **U**rinary elimination

NANDA International: *NANDA nursing diagnoses: definition and classification 2009-2011,* Philadelphia, 2009, Author.

Not all patient problems encountered in the perioperative setting can be described by the list of accepted NANDA-I nursing diagnoses. Perioperative nurses must participate in describing and naming new nursing diagnoses that characterize unique perioperative patient problems. NANDA-I has established a "to be developed" category to designate nursing diagnoses that are partially developed and deemed useful to the nursing profession; perioperative nurses may develop unique diagnostic labels and definitions and work to develop and validate them further through this process. This constructive process becomes even more important as healthcare moves toward the use of information systems to document nursing practice.

Outcome Identification. *Outcome identification* describes the desired or favorable patient condition that can be achieved through nursing interventions (Box 1-3). The study of patient outcomes is not new (see History box). To be useful for assessing the effectiveness of nursing care, patient outcomes should be "nursing-sensitive"; that is, they should be influenced by nursing and describe a patient state that can be measured and quantified. Nursing-sensitive patient outcomes derive from nursing diagnoses and direct the interventions that resolve the nursing diagnoses. They are the standards or criteria by which

BOX 1-3

Selected PNDS Desired Patient Outcomes

- 2 The patient is free from signs and symptoms of injury caused by extraneous objects.
- 3 The patient is free from signs and symptoms of chemical injury.
- 4 The patient is free from signs and symptoms of electrical injury.
- 5 The patient is free from signs and symptoms of injury related to positioning.
- 8 The patient is free from signs and symptoms of injury related to transfer/transport.
- 9 The patient receives appropriate medication(s), safely administered during the perioperative period.
- 10 The patient is free from signs and symptoms of infection.
- 11 The patient has wound/tissue perfusion consistent with or improved from baseline levels established preoperatively.
- 12 The patient is at or returning to normothermia at the conclusion of the procedure.
- 13 The patient's fluid, electrolyte, and acid-base balance is consistent with or improved from baseline levels established preoperatively.
- 14 The patient's respiratory status is consistent with or improved from baseline levels established preoperatively.
- 15 The patient's cardiac function is consistent with or improved from baseline levels established preoperatively.
- 16 The patient demonstrates knowledge of the physiologic responses to the operative or other invasive procedure.
- 17 The patient demonstrates knowledge of the psychologic responses to the operative or other invasive procedure.
- 23 The patient participates in decisions affecting his or her perioperative plan of care.
- 24 The patient's care is consistent with the perioperative plan of care.
- 25 The patient's right to privacy is maintained.
- 28 The patient's value system, lifestyle, ethnicity, and culture are considered, respected, and incorporated in the perioperative plan of care as appropriate. The plan of care reflects the patient's level of function and ability during the perioperative period.

Association of periOperative Registered Nurses: *PNDS—Perioperative nursing data set,* ed 2, Denver, 2007a, The Association.

the effectiveness of interventions is measured. Outcomes are stated in terms of expected or desired patient behavior and must be specific and measurable. The appropriate time to measure perioperative nursing-sensitive outcomes varies.

Some outcomes from intraoperative nursing interventions can be evaluated immediately. Others occur over a longer period. In this textbook, the use of "the patient will" indicates an outcome that is expected to occur over time. Identification of expected and desired outcomes unique to the surgical patient provides the opportunity to prioritize care, becomes a basis for continuity of care, and directs evaluation (outcomes research). In this type of research, the relationship between patient characteristics, the processes of care (i.e., what the perioperative nurse does, described under Implementation), and the outcomes of that care are studied, enhancing the perioperative nurse's ability to improve care. In many instances, outcomes research results in the identification of a "best practice" to improve patient care (Whittemore, 2005).

Planning. After collecting and interpreting patient data, identifying appropriate nursing diagnoses, and establishing desired outcomes, the perioperative nurse begins *planning* the nursing care for the patient. Planning requires use of nursing knowledge and information about the patient and the intended surgical or invasive procedure in order to prepare the surgical environment and to plan patient care. Perioperative nurses check equipment for proper functioning, have requisite supplies and positioning devices available, and use their knowledge of anatomy to have proper instruments and sutures on hand for the procedure to be performed. They also modify routines based upon unique patient information, such as allergies, transmissible infections, and risk of hypothermia, deep vein thrombosis (Risk Reduction Strategies), infection, or pressure injury. They know the sequence of steps in the operative or other invasive procedure and use surgeons' preference cards, nursing care guides, and other resources such as computerized data sheets to prepare the room and equipment for the patient.

RISK REDUCTION STRATEGIES

Preventing Deep Vein Thrombosis (DVT)

In August 2008 the Centers for Medicare & Medicaid Services (CMS) added DVT and pulmonary embolism to its list of hospital-associated conditions of *never events* when either occurs following total knee arthroplasty or total hip arthroplasty. DVT is considered a preventable condition, and perioperative nurses can take the following measures to reduce its risk of occurrence:

- Review the medical record for risk factors that predispose the patient to developing DVT. These include age older than 50; history of varicose veins, myocardial infarction, cancer, atrial fibrillation, ischemic stroke, or previous DVT; obesity; paralysis; inhibitor deficiency state; or diabetes mellitus (Dipaola, 2008).
- As part of the plan of care for the patient with DVT risk, implement use of mechanical prophylaxis such as sequential compression devices (SCDs), graduated compression stockings, or foot pumps.
- When graduated compression stockings are used, ensure that they are applied properly (smoothly, no wrinkles, heel in pocket) and are the correct size (Patterson, 2009).
- Use safe medication practices if administering pharmacologic prophylaxis (low-molecular-weight heparin, fondaparinux, or warfarin) (Streiff and Haut, 2009).

Adapted from Dipaola CA: Preventing deep vein thrombosis: a perioperative nursing imperative, *AORN J* 88(2):283-285, 2008; Patterson P: Are staff using compression hose correctly? *OR Manager* 25(3):16-17, 2009; Streiff MB, Haut ER: The CMS ruling on venous thromboembolism after total knee or hip arthroplasty, *JAMA* 301(10):1063-1065, 2009.

Planning is preparing in advance for what will or may happen and determining the priorities for care. Planning based on patient assessment results in knowing the patient and the patient's unique needs so that alterations in events such as positioning requirements or the surgical process are anticipated and readily accommodated. Planning also requires knowledge of the patient's psychosocial state and feelings about the proposed operation so that the perioperative nurse can provide explanation, comfort, or emotional support.

BOX 1-4

Selected PNDS Perioperative Nursing Interventions

- I26 Confirms identity before the operative or invasive procedure.
- I143 Verifies operative procedure, surgical site, and laterality.
- I76 Implements protective measures to prevent skin or tissue injury caused by thermal sources.
- I93 Performs required counts.
- I84 Manages specimen handling and disposition.
- I11 Applies safety devices.
- I96 Positions the patient.
- I38 Evaluates for signs and symptoms of injury as a result of positioning.
- I118 Transports according to individual needs.
- I8 Administers prescribed medications and solutions.
- I51 Evaluates response to medications.
- I70 Implements aseptic technique.
- I98 Protects from cross-contamination.
- I94 Performs skin preparation.
- I131 Assesses risk for inadvertent hypothermia.
- I78 Implements thermoregulation measures.
- I86 Monitors body temperature.
- I55 Evaluates response to thermoregulation measures.
- I97 Preserves and protects the patient's autonomy, dignity, and human rights.
- I109 Provides status reports.

Association of periOperative Registered Nurses: *PNDS—Perioperative nursing data set,* ed 2, Denver, 2007a, The Association.

Implementation. *Implementation* is performing the nursing care activities and interventions that were planned and responding with critical thinking and orderly action as changes in the surgical procedure or patient's condition or emergencies occur (Box 1-4). Implementation employs established standards of nursing care, recommended practices, and clinical practice guidelines and best practices, developed and maintained by the nursing profession. During this phase of the nursing process, the perioperative nurse continues to assess the patient to determine the appropriateness of selected interventions and to alter the intervention as necessary to achieve desired outcomes of care. Nursing interventions are the "work of nursing." The study of nursing interventions links nursing diagnoses with interventions and outcomes and leads to the validation of selected interventions or the development of new ones. Likewise, clinical practice, decision making, and evidence-based practice are enhanced by their study. Finally, the study of nursing interventions also assists in the delivery of cost-effective care by quantifying resource allocation.

Implementation also means being the patient's advocate by recognizing and acknowledging the patient's concerns or unmet needs. Advocacy is part of nurse-caring and it encompasses caring behaviors that promote emotional and physical comfort. Caring behaviors include establishing a "connection" with the patient, responding to each patient's individuality, and meeting patient and family expectations (Research Highlight). The role of patient advocate is especially important in surgical settings when patients are sedated or unconscious and unable to speak for themselves. Perioperative nurses as caring patient advocates advance the best interests of their patients (Beyea, 2005).

RESEARCH HIGHLIGHT

Clinical Decision Making: Caring and Advocacy

Clinical judgment and decision making are hallmarks of professional nursing. In one qualitative study, Parker and colleagues asked the question, "What are the processes used by expert perioperative nurses in clinical decision making?" A structured interview guide was used with six perioperative nurses who had a minimum of 5 years of experience and considered themselves expert circulating nurses. After in-depth interviews, four levels of data analysis were used to sort and interpret findings. The single, overriding pattern for these expert nurses was captured as *seeing the big picture: engendered through caring*. Three themes emerged as essential to the expert decision making of the study participants: (1) connecting with patients (subthemes were the use of touch, conducting a perioperative interview, and humanizing the patient's care), (2) advocating for patients, and (3) embodied knowing (knowing through personal experience and through the experience of similar situations).

Another study by Boyle explored perioperative nurses' definition of, role in, and personal experiences with advocacy. A sample of 33 perioperative nurses participated in tape-recorded interviews. Four overarching themes of advocating for surgical patients emerged: protection, communication/giving voice, doing, and comfort and caring.

Seeing the big picture through connecting to and advocating for the patient and depending on one's own experience embody essential elements of critical thinking. Expert perioperative nurses actively and skillfully conceptualize, analyze, synthesize, and evaluate information gathered from and generated by observation, experience, reflection, and intellectual reasoning as a guide to their belief about their practice and the actions they take with patients. Advocacy, as reflected in both of these studies, underscores the perioperative nurse's acts in informing and supporting patients they care for and taking action to achieve goals on behalf of those patients. The pattern, themes, and subthemes identified in these studies support the cognitive, psychomotor, and affective skills used by perioperative nurses as they make decisions about patient care.

Modified from Parker CB et al: Clinical decision-making processes in perioperative nursing, *AORN J* 70(1):45-62, 1999; Boyle HJ: Patient advocacy in the perioperative setting, *AORN J* 82(2):250-262, 2005.

DELEGATION. A team delivers perioperative patient care and different categories of personnel assist in various direct and indirect patient care activities. The surgical team usually consists of a surgeon and assistants (e.g., residents, interns, physician assistant [PA], RN first assistant [RNFA], nurse practitioner [NP], or certified first assistant [CFA]), an anesthesia provider, a circulating nurse, and a scrub person, who may be either a surgical technologist or an RN. Other members of the healthcare team, such as nursing assistants, orderlies, environmental services, and patient care technicians, support the surgical team. During the implementation of patient care, the perioperative nurse may delegate certain nursing activities to these personnel, often called *unlicensed assistive personnel (UAP)*. These healthcare workers emerged during the nursing shortages of World War I and World War II and became part of a team model of delivering patient care. In the 1980s delivery models shifted the skill mix away from assistive personnel; RNs were the principal caregivers in primary nursing models. During

the fiscally constrained 1990s, however, healthcare facilities began to reintroduce assistive personnel, who have less training and receive lower salaries than nurses. Instead of using UAP in narrowly defined job categories (e.g., clerical, housekeeping, orderly, patient transport), the trend in the late 1990s was to create a set of multiskilled assistive personnel who could assist nurses in multiple activities rather than in just a single area.

As the use of UAP quickly grew in the 1990s, questions and concerns arose about the proper scope of delegated activities that nurses had formerly performed. Each state's board of nursing defines the scope of practice for registered nurses, based on the nursing process. Further, each state's nurse practice act—a state law that protects the health and safety of the public—establishes legal qualifications for who can practice nursing. Implementation of the plan of care and the interventions to accomplish it is part of the nursing process. Therefore guidelines for proper delegation of some of these interventions became necessary. Delegation transfers to a competent person the authority to perform a selected nursing task in a selected situation according to the five "rights" of delegation (Box 1-5). When the perioperative nurse delegates a task, he or she retains accountability for that delegation. Nursing functions of performing assessments, determining nursing diagnoses, establishing patient outcomes, developing the plan of care, and evaluating patient outcomes as well as nursing interventions that require independent nursing knowledge, skills, or judgment cannot be delegated (Cherry and Jacob, 2005). Perioperative nurses need to understand that institutional policy cannot contradict the nurse practice act of their state. Although tasks and procedures may be delegated to unlicensed members of the surgical team, the perioperative nurse is responsible for supervising care; supervision cannot be delegated. The perioperative nurse must assess the patient and the competency level of personnel to determine which team member has the skill to provide the necessary care. Using unlicensed personnel appropriately assists the profession of perioperative nursing to be better prepared for the challenge of maintaining high quality in patient care services even when nurse shortages occur.

DOCUMENTING INTERVENTIONS. Accurate documentation of nursing care is an integral part of all phases of the nursing process, especially implementation of the plan of care. A description of the patient, nursing diagnoses and desired patient outcomes, nursing care given, and the patient's response to care (outcomes) should be included in the patient's record (Chapter 2 has a more comprehensive review of documentation). Documentation of the nursing care given should include more than the technical aspects of care, such as the sponge count or the application of the electrosurgical dispersive pad. Nursing care documentation should be associated with the assessment and nursing diagnoses, with preestablished outcomes against which the appropriateness and effectiveness of care may be judged. The form for this documentation may include standardized protocols and interventions as noted on clinical pathways; space should be provided to write in interventions that are unique to individual patients or to describe variances in care. Documentation should require little time to complete, be specific to the perioperative setting, and provide continuity across the various areas in surgery, from presurgical holding areas to the PACU. Many facilities have incorporated computerized documentation systems to allow the data entered to be more readily retrievable. This trend and the need for electronic data are rapidly escalating, with federal requirements for electronic records by 2014 (Gunn, 2008).

BOX 1-5

The Five Rights of Delegation

1. **The Right task.** The perioperative nurse determines that this task is one that is delegable for a specific patient, taking into consideration such factors as potential for harm, the complexity of the task, necessary problem solving, and the predictability of the outcome. Routine tasks that are performed according to a standardized procedure and that have predictable outcomes are the safest to delegate.
2. **The Right circumstances.** The perioperative nurse considers the patient care setting, the resources available, and other relevant factors. Tasks delegated must be ones that do not require independent nursing judgment.
3. **The Right person.** The perioperative nurse is the right person to delegate the right task to the right person to be performed on the right patient. The perioperative nurse must be familiar with the job description of the UAP along with the person's capabilities, knowledge and skill level, and learning needs to ensure that safe, quality patient care is provided. In this way, the nurse matches tasks to the UAP's skills, qualifications, and competence.
4. **The Right communication and direction.** The perioperative nurse provides a clear, specific, and concise description of the task, with key information relating to its objectives, rationale, limits, and expectations. There should be an opportunity for questions and clarifying instructions. Information the perioperative nurse needs to know from the person performing the task must be identified. Communication should be direct and not provided through others.
5. **The Right supervision and evaluation.** The perioperative nurse appropriately monitors the task or person performing it, evaluates the results or patient outcomes or both, intervenes if necessary, and provides feedback. Providing immediate feedback or identifying a problem with performance as it occurs is essential to upholding standards of care and performance expectations.

Perioperative nurses must be involved actively in providing the assessment, evaluation, and judgment needed to coordinate and supervise perioperative patient care. When delegating care activities, the perioperative nurse retains accountability for analyzing and evaluating the outcome of the delegated task. Activities that rely on the nursing process, such as performing assessments, making nursing diagnoses, establishing plans of care, providing extensive patient and family education, and planning for patient discharge, cannot be delegated.

Modified from the National Council of State Boards of Nursing Response to the PEW Taskforce Principles and Vision for Health Care Workforce Regulation, Chicago, 1996, The Council, pp 4-5; Cherry B, Jacob SR: *Contemporary nursing: issues, trends and management,* St Louis, 2005, Mosby; Standing TS, Anthony, MK: Delegation: what it means to acute care nurses, *Appl Nurs Res* 21:8-14, 2008.

PERIOPERATIVE NURSING DATA SET. In 1993 the AORN recognized the need to describe and define the unique contributions of perioperative nurses to patient outcomes. After 6 years of research and validation, the Perioperative Nursing Data Set (PNDS) was recognized as a specialty nursing language, providing a uniform and systematic method to collect and document the basic elements of perioperative nursing care. Similar to the *Perioperative Patient Focused Model* (AORN, 2009a), the PNDS begins with patient outcomes (Figure 1-4). Each outcome is defined and interpreted, and presents criteria by which to measure

Patient outcome. →

OUTCOME 0.110
Patient is free from signs and symptoms of radiation injury.

Definition provides further explanation of the outcome. →

OUTCOME DEFINITION
Patient is free from observable signs or reportable symptoms of radiation injury.

Interpretive statement describes the scope of the current problem or need. →

INTERPRETIVE STATEMENT
Prevention of radiation injury requires the application of principles of physics and radiologic safety standards. Policies addressing education, credentialing, and radiologic safety and maintenance must be in accordance with national regulatory standards and manufacturers' documented instructions. Preexisting patient conditions (e.g., length of and/or previous exposure) can influence the patient's susceptibility to radiologic injury. Radiation exposure is limited to the target site.

Outcome indicators are derived from assessment data and provide a framework for evaluating the patient's progress or a clinical standard. *(This is not intended to be an all-inclusive list.)* →

OUTCOME INDICATORS
- Skin condition (general): smooth, intact, and free from unexplained edema, redness, blistering, or tenderness in nontargeted areas.
- Cognition: responds appropriately to questioning; memory intact.

Examples of interim outcome statements provide outcomes that reflect a patient or patient's family member's* status at a specific point and time across the surgical continuum. *(This is not intended to be an all-inclusive list.)* →

EXAMPLES OF INTERIM OUTCOME STATEMENTS
- The patient's skin remains smooth, intact, free from unexplained redness, blistering, or tenderness in targeted areas between admission and discharge from the perioperative setting.

Nursing diagnoses are linked to each outcome and provide possible human responses linked with surgical experiences. *(This is not intended to be an all-inclusive list.)* →

POTENTIALLY APPLICABLE NURSING DIAGNOSES
- Risk of impaired skin integrity (00047)
- Impaired skin integrity (00046)
- Acute confusion (00128)

Nursing interventions include assessments, implementations, and evaluation statements and are in bold print; each has a definition and a unique identifier. →

Assesses history of previous radiation exposure (A.240.1)
- Ensures that premenopausal women are aware of radiation risks associated with pregnancy.
- Delays, if possible, surgical procedure for 24 hours after radioactive diagnostic studies.
- Recognizes risk of compromised wound healing in patients who have received radiation in large doses preoperatively.

Activity statements are the bulleted points under interventions. Activities support interventions, but do not necessarily need to be documented. *(This is not intended to be an all-inclusive list.)*

Implements protective measures to prevent injury due to radiation sources. (Im.110)
- Assembles proper protective equipment.
- Limits exposure to radiation to therapeutic levels (e.g., fluoroscope is off when not in use, radioactive elements remain in lead-lined containers until ready for implantation).
- Implements measures to protect the patient from direct and scatter radiation.
- Provides shields to protect body areas from scatter radiation or focused beam whenever possible (e.g., fetus/gonadal shields).

Evaluates for signs and symptoms of physical injury to skin and tissue (E.10)
- Assesses the patient's skin and adjacent tissue for discoloration and reddened, raised, or painful areas around the surgical site and compares to preoperative skin assessment and medical record review.
- Assesses for complaints of pain or discomfort in areas other than surgical incision.

* Family member—AORN defines *family* as the person or people that the patient identifies as his or her family or designated support person.

FIGURE 1-4 An explanation of the layout of the Perioperative Nursing Data Set (PNDS).

outcome achievement. Subsequently, nursing interventions to achieve the desired patient outcomes are noted, along with suggested nursing activities to support the interventions. Of special import is the opportunity for perioperative nurses to use the PNDS to support standardized documentation. When this is accomplished, databases enable streamlined comparison of clinical outcomes from large patient populations within an institution and even across institutions. The databases can be used to guide research, develop best practices and practice guidelines, and support the work of evidence-based practice (EBP).

Performance improvement activities, notably by monitoring important aspects of care, problem identification, problem solving, and peer review, may be part of overall system evaluation. Often referred to as *quality improvement (QI) programs,* interdisciplinary teams address areas for improvement in patient care, identify problems, propose solutions, and monitor and evaluate the effectiveness of improvements. This topic is discussed in more detail later.

Evaluation. *Evaluation* is checking, observing, and appraising the results of what was done. Although evaluation is traditionally listed as the last phase of the nursing process, it is an integral, systematic, and ongoing component of providing safe, effective—and good—perioperative patient care. Evaluation focuses on the patient's progress in attaining identified outcomes. When feasible and appropriate, the patient and family should participate in the evaluation process. The attainment of outcomes, any revisions to nursing diagnoses or desired outcomes, and the plan of care are documented. Because perioperative patient care processes and interventions often are interdisciplinary, healthcare facilities may need to use additional evaluation methods.

Institutional Standards of Care

Healthcare facilities have developed additional standards to communicate expectations of performance. Perioperative departments have responsibility, delegated through the administrative governance of the institution, to develop policies and procedures, often called *surgical services standards of care.* Policies are written statements that outline responsibilities and appropriate actions in specific circumstances. To be effective, a policy should be consistent with national and state practice standards, be realistic and achievable, be consistently followed except where prior approval has been obtained, be based on evidence and reasoned and rational thinking, and be related to the long-term intent of the surgical services department.

Procedures are guides to implementing policies. They describe detailed chronologic sequences of activities as they relate to particular policies. Policies and procedures are usually combined into a manual that is kept readily available as a perioperative care resource in departments where operative or other invasive procedures are performed. Many facilities have moved to an on-line manual as well, to provide easy access in multiple patient care locations. Participation of staff members in policy and procedure development increases their knowledge of the subject matter and generates a sense of ownership. This results in meaningful and authoritative interpretation of approved policy and procedure to peers and furthers successful implementation.

Clinical Pathways. Another expectation in the AORN *Standards of Perioperative Nursing Practice* (2009b) is that the nurse will use the best available evidence, preferably research data, in planning patient care and will participate in research activities. Clinical pathways (also referred to as *care maps* or *care protocols*) lead to improvement in patient care because they are based on research and outcomes. In general, clinical pathways are interdisciplinary practice guidelines that allow one to recommend key resources and activities within targeted time frames during all phases of a patient's care. Their intent is to improve quality of care, enhance patient and family satisfaction, and reduce or control costs.

EVIDENCE-BASED PRACTICE

Perioperative nursing has been built upon a strong foundation of traditions designed to provide excellent patient care. These traditions include many aspects of direct patient care as well as control of the environment in which the care is provided. Perioperative nurses have an ethical responsibility to review practices and to modify them, based upon the best available scientific evidence. Using research and other forms of evidence to guide practice is called evidence-based practice (EBP). This process can be used proactively to evaluate alternative ways of providing care, such as using different patient positioning surfaces or developing patient education materials. It can also be used for problem solving, as when investigating a serious adverse event or other clinical problem, such as hypothermia, a pressure injury, or a retained surgical sponge. Regardless of the issue, the underlying evidence should always be examined and used to guide decision making to improve perioperative patient care (Steelman, 2006).

Evidence-based practice is a systematic, thorough process by which to identify an issue, to collect and evaluate the best evidence to design and implement a practice change, and to evaluate the process (Carey et al, 2009). The change may be how patients are assessed for risk (Research Highlight), an intervention, staff education, or a change in supplies or equipment. Some changes that have been implemented through this process are double-gloving to reduce sharps injuries (Stebral and Steelman, 2006), having patients shower preoperatively twice with chlorhexidine gluconate showers (Pottinger et al, 2006), administering antibiotics within 60 minutes before the surgical incision (Spalter and Wyatt, 2006), and using forced-air warming devices to prevent perioperative hypothermia (Wagner, 2006). When there is not enough evidence to guide practice, perioperative nurses should collaborate with a nurse researcher in a research study to address the clinical issue. For example, such collaboration was done to evaluate the best patient positioning surface in one hospital (King and Bridges, 2006). One model used in many healthcare facilities is the Iowa Model of Evidence-Based Practice to Promote Quality Patient Care (Figure 1-5).

Evidence-based practice has become an integral part of many national quality initiatives. One such initiative, the Surgical Care Improvement Project (SCIP), is a national quality partnership endorsed by many organizations and focused on improving care of surgical patients by using EBP to significantly reduce surgical complications. Endorsing organizations include the American College of Surgeons (ACS), American Society of Anesthesiologists (ASA), AORN, Centers for Disease Control and Prevention (CDC), and The Joint Commission (TJC, 2009a). The goal of SCIP is to reduce surgical complications nationally by 25% by 2010. Some core measures of SCIP address prophylactic antibiotics, normothermia, prevention of deep vein thrombosis (DVT), and blood glucose control (TJC,

RESEARCH HIGHLIGHT

Development of a Surgical Apgar Score

Surgical teams lack routine, objective criteria to evaluate a patient's condition after surgery to guide prognosis and clinical communication. This can be of significance in the hand-off report provided to the PACU, ICU, or another area where the patient is being transferred. In this study, researchers at Harvard, Brigham and Women's Hospital and at the Massachusetts General Hospital, Boston, developed a 10-point Surgical Apgar Score based on information routinely available during surgery—estimated blood loss (EBL), lowest recorded intraoperative heart rate (HR), and lowest recorded intraoperative mean arterial pressure (MAP)—to rate outcomes in surgery patients. Next, the Surgical Apgar Score was validated with 4119 general and vascular surgery patients. The main outcome measure examined was incidence of major postoperative complications and/or death within 30 days of surgery. The analysis showed a consistent trend toward worse outcomes with lower scores. Patients with scores of 9 or 10 had only a 5.0% incidence of major complications and a 0.1% incidence of death. On the other hand, patients with scores of 4 or less had a 56.3% incidence of major complications and a 19.5% incidence of death.

Based on these findings, the researchers concluded that the 10-point Surgical Apgar Score successfully identifies patients at higher-than-average and lower-than-average risk of major complications and death after surgery. Based on this research, the three areas of EBL, HR, and MAP may become important elements included in postsurgical hand-off reports.

Adapted from Regenbogen SE et al: Utility of the surgical Apgar score: validation in 4119 patients, *Arch Surg* 144(1):30-36, 2009.

2008). The Centers for Medicare & Medicaid Services (CMS) now require that healthcare facilities receiving reimbursement by Medicare report their level of compliance with these core measures (U.S. Department of Health and Human Services, CMS, 2008). In the future, CMS plans to reduce reimbursement for noncompliance with these core measures.

PERFORMANCE IMPROVEMENT

Recent and continuing trends in healthcare have seen increased control of costs, more efficient use of resources and supplies, decreased length of stay for surgical patients, and a shift of many surgical procedures from inpatient to ambulatory care settings (Ambulatory Surgery Considerations). Concomitantly, there is a keen awareness of the need for continued improvement in the provision of perioperative patient care. TJC has taken a strong position on the need for continuously monitoring and evaluating the quality and appropriateness of care delivery to resolve any identified problems, while striving constantly to improve delivery systems and processes. In 1994 TJC instituted performance assessment, measurement, and improvement as the core of its standards. This represented an evolution from quality assurance, to continuous quality improvement, and finally to performance improvement (PI). Such a transition was underscored by the belief that measuring outcomes and improving care are the essential purposes of healthcare delivery. Performance improvement efforts encompass improvements in quality and effectiveness, based on ethical and economic perspectives.

AMBULATORY SURGERY CONSIDERATIONS

The Functional Recovery Index (FRI) for Ambulatory Surgery Patients

Ambulatory surgery centers perform complex procedures on higher risk patients. It becomes important not only to determine patients' readiness for discharge from the ambulatory surgery center but also to determine how well patients fare in their recovery and rehabilitation after their discharge. Researchers in Toronto developed a research tool to evaluate recovery after ambulatory surgery, focusing on functional abilities after discharge. The research instrument, called the Functional Recovery Index (FRI), takes about 4 to 5 minutes to complete. There are 14 items that are answered on a scale of 0 (no difficulty with activity) to 10 (extreme difficulty with activity). The items are grouped according to important recovery activities such as pain, social activity, lower limb activity, and general physical activity. The responses are summed, and the lower the score, the more superior the patient's recovery. The summation of the items can be adjusted if there is an item that is not applicable or that the patient did not answer. As is usual during development of a research tool, tests were undertaken for validity and reliability. In the Functional Recovery Index, internal consistency for the three factors was Cronbach α = 0.90, 0.89, and 0.86, respectively. Interrater reliability as assessed in 264 patients was 0.99, indicating high reliability. Convergent validity testing for FRI compared to a verbal rating scale pain score was 0.76. Discriminant validity testing showed that the type of surgery was significant and that both intermediate surgery and major surgery were associated with higher FRI scores than minor surgery, not an unusual finding. The tool developers concluded that the FRI has excellent reliability, good validity, responsiveness, and acceptability.

Data from Wong J et al: Development of the Functional Recovery Index for ambulatory surgery and anesthesia, *Anesthesiology* 110(3):596-602, 2009.

A surgical services PI program should be based on established standards of care. The intent of each standard should be reflected in realistic and measurable outcomes. A plan to measure and improve care, including the scope of care and important aspects of that care, should be in place. Specific quality indicators should be identified that reflect all important aspects of care. Thresholds that identify the level of acceptable variance for each indicator are then established. Measurement methods include retrospective or concurrent review of medical records, review of adverse event reports, utilization review, patient surveys and interviews, and peer review. Emphasis has evolved from process auditing to the current emphasis on structure, process, and outcome indicators. Some facilities have implemented programs used in industry, such as Six Sigma and Lean Sigma, to assess and refine processes to improve efficiency. These efforts underscore nursing's commitment to improving processes and outcomes of care.

A performance measurement and improvement approach facilitates the delivery of safe, high-quality perioperative patient care. When processes are understood, they can be improved through a systematic plan of action. Involvement on teams that perform surgical services performance assessments and create improvement plans can strengthen the staff's commitment to meet standards and enhance program effectiveness. TJC supports the evolution to an information technology infrastructure

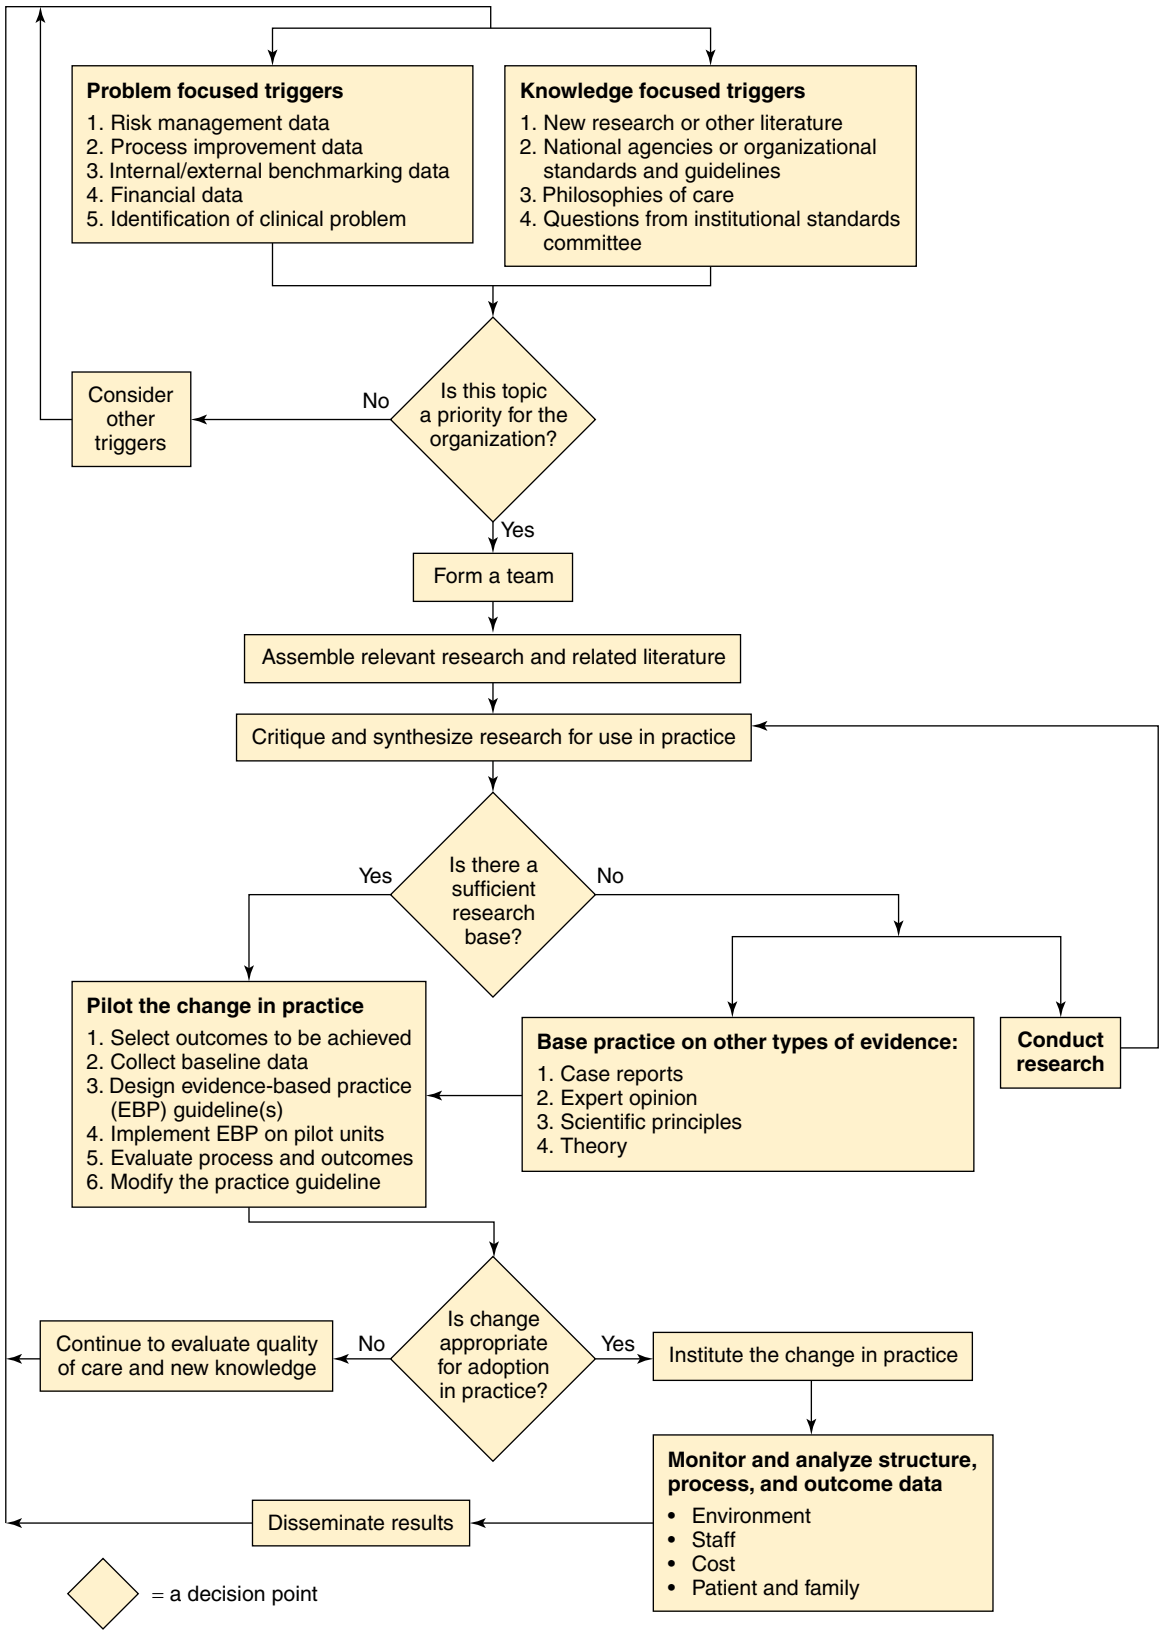

FIGURE 1-5 The Iowa Model of Evidence-Based Practice to Promote Quality Patient Care is one model used in some healthcare settings to identify opportunities to improve care, evaluate the evidence, and design, implement, and evaluate evidence-based practice changes.

(i.e., electronic health records [EHR]) in which performance measurement becomes a natural part of the care delivery process. As current uses of data expand and improve, objectives still will include the use of data for research activities directed at improving the quality of care and identifying and disseminating evidence-based practices. Perioperative nurses can anticipate that measurement requirements and performance expectations will change over time to reflect new technologies and care practices as they affect the quality and safety of care. TJC also is expected to add measurement of patient perception of care to its required set of core measures over the next several years. The objectives of future TJC activities are likely to focus on the following:

- Continuing expansion and coordination of nationally standardized core measurement capabilities
- Increasing the use of measurement data for quality improvement, benchmarking, accountability, decision making, accreditation, and research

PERIOPERATIVE NURSING ROLES

The nursing profession and the healthcare culture in the United States continue to change rapidly in response to many elements. An aging population, with the over-65 population already topping 40 million, will continue to create a significant increase in demand for health services. As baby boomers turn 65, the over-85 segment of the population is projected to triple by 2050. Referred to as the "longevity revolution," in 2030 it is anticipated that one in five residents in the United States will be over 85. New ambulatory settings for the delivery of health services, including operative and other invasive procedures, will continue to develop, as will community-based clinics, school-linked clinics, mobile clinics, and drive-in health centers. Healthcare organizations that are able to respond quickly to change will have an edge in the healthcare industry of the future. Perioperative nurses who understand the need for clinical and service quality, cost-effectiveness, information management, coordinated patient-centered care, efficiency, special needs of an aging surgical population, and the importance of patient satisfaction will be able to anticipate and position themselves for this future. Roles in case management, care coordination, informatics, the healthcare industry, consulting, management, advanced practice nursing, and research are all possibilities for perioperative nurses.

Traditional Perioperative Roles

There are two traditional perioperative nursing roles: the circulating nurse and the scrub nurse. The circulating nurse remains "non-scrubbed" and uses the nursing process to assess the patient, identify desired outcomes, formulate nursing diagnoses, implement interventions, and evaluate the outcome of the care provided. Among many other responsibilities, the circulating nurse manages patient positioning, antimicrobial skin preparation, medications, implants, specimens, warming devices, and the surgical count. The AORN (2006) has published a position statement advocating the requirement that there be a registered nurse circulator for every patient undergoing surgery or an invasive procedure, and that this person manage the care of only one patient at a time.

The scrub person assembles needed instruments and supplies in a manner to maximize safety and efficiency. This role requires an in-depth knowledge of each step of the surgical procedure, and the certain ability to anticipate each and every instrument and supply that will be needed. Many instruments are complex and require assembly. Instruments are positioned on the sterile table so that the scrub person can prepare each instrument as it will be used and quickly transfer it to the surgeon, often without being asked. This role is highly technical and either a registered nurse or a surgical technologist (ST) may assume it. The ST who functions as the scrub person may be certified (CST). The certifying agency for STs is the National Board of Surgical Technology and Surgical Assisting (the NBSTSA, formerly the LCC-ST). Surgical technology students who graduate from an accredited surgical technology program are eligible to take the certification exam. Many of these programs result in an associate degree. The ST and circulating nurse form an important partnership in ensuring patient safety. They work closely and effectively together throughout the procedure. Close teamwork keeps communication open, minimizes the risk of errors, and promotes the cost-effective utilization of supplies. Based upon mutual respect, teamwork enhances quality in the workplace. It is so essential that the National Quality Forum (NQF) has identified the establishment of team-based care and team-led performance improvements as a "safe practice for better health care" to reduce preventable patient harm (NQF, 2009).

Certification in perioperative nursing (CNOR) is available to perioperative nurses who function in traditional or nontraditional roles. This credential represents demonstrated knowledge of clinical practices and standards as well as a marked level of professional achievement. It also demonstrates proficiency in support of quality patient care and sets a standard of commitment to the profession of OR nursing (Competency and Credentialing Institute, 2009).

Registered Nurse First Assistant

The role of the perioperative registered nurse first assistant (RNFA) in surgery is an expanded perioperative nursing role that requires formal academic education (Welter, 2007). In 1984 the AORN approved an official statement on the RNFA and has revised the statement regularly to reflect changes in the RNFA's role. The RNFA works collaboratively with the surgeon (and the patient and surgical team) by handling and cutting tissue, using instruments and medical devices, providing exposure and hemostasis, and suturing, all as components of assisting-at-surgery behaviors. The AORN has developed standards for RNFA educational programs (AORN, 2009c) and certification is available for this role (CRNFA) (Competency and Credentialing Institute, 2009). Many experienced perioperative nurses have prepared for this role by obtaining this education. Performing as an RNFA allows an experienced perioperative nurse to expand clinical knowledge and skills and to assume additional responsibility for preoperative and postoperative patient management, while still remaining directly involved with intraoperative patient care. The RNFA has gained wide acceptance as a highly skilled member of the surgical team and is only one way perioperative nurses can develop professionally to meet the changing needs of healthcare delivery.

Advanced Practice Nurse

Advanced practice nurses (APNs) include nurse practitioners (NPs), certified registered nurse anesthetists (CRNAs), and clinical nurse specialists (CNSs); they are valuable members of

the perioperative team in many healthcare settings (Steelman, 2009). The AORN (2007b) has identified six facets of the advanced perioperative practice role: clinical practice, education, consultation, leadership, management, and research. NPs and CRNAs usually focus on clinical practice, providing licensed independent care to individual patients, one at a time.

Acute-care NPs have begun to fill the gap in providing care for patients who are more acutely ill and whose medical-surgical problems are more complex. NPs are now employed in acute care hospitals and ambulatory surgery centers across the country (Watson, 2007). Some NPs have focused primarily on the preoperative phase of patient care, using their advanced knowledge to assess patients and order preoperative medications and treatment. Other NPs have combined this role with that of the RNFA, to allow them to utilize their advanced practice skills throughout the perioperative care continuum. Some CNSs also provide licensed independent care to individual patients. However, the traditional role of the CNS involves primarily indirect care within the perioperative leadership team. As part of the management team, the CNS provides support for the care of groups of patients through leadership, education, consultation, management, and research. CNSs have assumed a significant leadership role in the implementation of evidence-based practice changes in healthcare settings (Steelman, 2009).

APNs must have graduate nursing education (at least a master's degree). In 2004, however, the American Association of Colleges of Nursing (AACN) published a position statement advocating for the Doctor of Nursing Practice degree as the minimum educational preparation for APNs. These educational programs are now available across the country and have a standardized core curriculum.

As a result of the Balanced Budget Act of 1997, APNs receive Medicare reimbursement in a variety of settings. This legislation provides for Medicare reimbursement for the NP or CNS who also functions as an RNFA.

Emerging Roles

As the needs of patients change and technology advances, new perioperative nursing roles develop to meet these needs. Some of these roles include care coordinator, family liaison, robotics coordinator, and informatics specialist. Some healthcare organizations have established the role of care coordinator in specific programs such as trauma, bariatrics, cardiac care, and organ transplant to meet the unique challenges and complexities of these patient populations. The role of care coordinator provides an opportunity for the perioperative nurse to develop more in-depth skills to meet the needs of a specific population of surgical patients.

In the late 1990s the perioperative nursing role of family or surgical liaison evolved to serve as a communication link between the OR and the family during surgery. The liaison translates information from the surgical team to the family, often serving to clarify issues and answer questions that require an understanding of events in the OR. Some hospitals and ambulatory surgery centers have implemented this perioperative nursing role with the goal of enhanced patient and family satisfaction.

Another emerging role in perioperative nursing is that of robotics coordinator. Both the number and the types of procedures performed with surgical robots have increased dramatically. Robots are now commonly used for general, cardiovascular, pediatric, and urologic surgery. The complexity of the equipment and troubleshooting require additional skills. The evolution of robotic technology and rapid expansion of its use have created many challenges for the perioperative team. Some healthcare facilities have developed a new role, the robotics coordinator, to coordinate this technology, provide complex troubleshooting, and train personnel (Francis, 2006). The robotics coordinator may also serve as a liaison to the public by providing marketing and public educational opportunities about the robotics surgery program.

Informatics is another specialty in which some perioperative nurses are focusing. Pressures for more efficient management of fiscal, material, and human resources have stimulated the development of electronic information systems for diverse functions in perioperative patient care settings (Roeder, 2009). A well-designed information system can synthesize large volumes of data efficiently into meaningful reports to support decision making. Newer nursing applications include point-of-care clinical systems, electronic health and medical records, internet-based patient education, research, and telemedicine and telenursing. The growing field of nursing informatics is an interaction of cognitive science, computer science, and informatics, all of which are based on a foundation of nursing science (Ozbolt and Saba, 2008). Perioperative nurse informatics specialists have the opportunity to develop clinical nursing systems that incorporate nursing care protocols, critical paths, best practices, the PNDS, and patient education materials that track patients over time. Such systems allow sharing information across wide networks as patients access healthcare at different points and times over a continuum of care. Future technology systems may include interactive computer/television, by which perioperative nurses can communicate with their patients over phone or a cable line, allowing the perioperative nurse to "view" the patient's wound or "discuss" recovery and rehabilitation from surgery.

Perioperative nursing is an exciting, ever-changing specialty. The opportunities for continuous learning and challenges are endless. As we move into the future, these opportunities will continue to grow and evolve. Perioperative nurses need to identify their professional goals and develop strategic plans to accomplish these goals, including enhancing their skill sets and education. This strategy will position the perioperative nurse well for exciting roles in the future.

CHAPTER 2

Patient Safety and Risk Management

ELLEN K. MURPHY

Patient safety is and has long been a primary concern of members of the surgical team. "Primum non nocere" or "First, do no harm," is an imperative for physicians and nurses. As early as 1924, an OR nursing textbook included counting sponges among nursing duties (Smith, 1924). Perioperative nursing textbooks and curricula continued to include substantial content on infection control, positioning, safe medication practices, and counts through World War II. The first edition of this very textbook by Edythe Alexander (1943) included content on asepsis, the importance of correct side surgery, proper blood handling, and proper tourniquet application. Alexander (1943, p. 7) did not use the word "safety," but she described the purpose of "perfecting every detail…to insure that patients…have every chance to overcome the disease or injury with which they are afflicted."

Nursing publications accelerated their patient safety content after World War II. The American Nurses Association (ANA) published the *Code for Nurses,* which included provisions on patient safety and privacy, and the Association of Operating Room Nurses (now called the Association of periOperative Registered Nurses [AORN]) began organizing in the early 1950s. AORN's conferences and publications were replete with patient safety information. Its first conference in 1954 included programs on methods improvement, explosion prevention, bacteria destruction, the surgeon-nurse relationship, and positioning (Glass and Murphy, 2002). AORN published its first *"Standards of Operating Room Practice"* in 1974. *"Technical Standards"* soon followed, and by the 1980s AORN published and regularly updated its *Recommended Practices* (RPs) (Glass and Murphy, 2002, p. 116).

SAFETY AS AN INDIVIDUAL RESPONSIBILITY

Through the 1980s, healthcare professionals' errors and their effects on patient safety continued to be seen primarily as the individual practitioner's responsibility. This attitude was reinforced by the legal and professional licensure systems; the finding of negligence required that at least one individual failed to do what a similarly situated, reasonable, and prudent professional would have done under similar circumstances.

In 1991 authors such as Brennan, Leape, and others proposed that despite individual best efforts by professionals, mistakes continued and were, in fact, more common than previously thought (Brennan et al, 1991). Their findings, combined with James Reason's influential 1990 book *Human Error*, spawned a plethora of research and literature based on the role of systems and their relationship to human error in healthcare (Reason, 1990). Human error leading to patient injuries began to be recognized not so much as an individual's shortcoming, deserving of blame or punishment, but more as a result of failures of systems in patient care areas such as the OR. Leape (1994), Cook and Woods (1994), and others urged that the legal and professional licensure systems' continued focus on individual error was misplaced if adverse patient events were to be prevented. They urged an emphasis on transparent systems that required open reporting, investigation, innovation, and dissemination. The aviation and nuclear systems' parallel examination of human factors served as models for ideas that led to relative success in preventing injury attributable to human error.

In 1943 Edythe Alexander also noted "to get the best result from a surgical operation, the surgeon and his assistants, the operating room nurse and the entire staff must work as a team" (Alexander, 1943, p. 8). Despite AORN and its partner professional association's emphasis on safety and teamwork, patient injuries caused by human error in perioperative settings continue (Pronovost and Colantuoni, 2009).

CONCENTRATED EMPHASIS ON SYSTEMS

In 1999 the landmark Institute of Medicine (IOM) report spurred major additional safety initiatives when it reported that at least 44,000, and perhaps as many as 98,000, patients died in U.S. hospitals every year as a result of preventable adverse events (IOM, 1999). Even the lower figure exceeded the number of deaths resulting from motor vehicle accidents, breast cancer, or AIDS. The IOM report did not focus solely on perioperative errors. However, it did note James Reason's theory that complex, tightly coupled systems are most prone to accidents, and specified the surgical suite, along with emergency departments and intensive care units, as examples of complex, tightly coupled systems (Reason, 1990). Moreover, when one considers highly invasive surgical procedures juxtaposed with anesthetized patients who are unable to detect pain or otherwise defend themselves, patient vulnerability and the consequent need for protection by all team members is strikingly apparent.

Brennan and colleagues (1991) studied 30,121 randomly selected hospital records, found adverse events occurred in 3.7% of hospitalizations, and concluded that substantial

numbers of patient injuries resulted from substandard care. In Part II of that study, Leape and collegues (1991) found that nearly half (48%) of adverse events were associated with an operation. Their results were consistent with those of earlier investigators who found half of all hospital-based potentially compensable events (i.e., injuries from substandard care) arose from treatment in the OR. The Joint Commission's (TJC, 2005) collected findings from sentinel event reports over the last 2 decades are consistent with those findings, demonstrating that individual efforts of the best nurses, surgeons and anesthesia providers, combined with a recognized need for teamwork, are not sufficient—and especially not sufficient in the perioperative setting.

MAJOR ASSOCIATION SAFETY ACTIVITIES

The Joint Commission (TJC)

Like individual surgical team members, TJC has long been involved with quality and safety. TJC began in 1951 as the Joint Commission for the Accreditation of Hospitals. It sharpened its systems-based safety focus in the mid-1990s when it established its Sentinel Event Policy. That policy first encouraged and then required self-reporting of medical errors and root cause analysis of the error. Based on cumulative data, TJC published its first *National Patient Safety Goals* (NPSGs) in 2003; recognized the need for standardized methods of patient identification; and established the Universal Protocol (discussed later in this chapter) in 2004. By 2005, the World Health Organization formed the Collaborative Centre for Patient Safety Solutions, which is comprised of TJC and TJC-International.

Sentinel Events. Sentinel events are unexpected occurrences involving death or risk of serious physical or psychologic injuries. TJC chose the word "sentinel" to indicate that these events signal the need for immediate investigation and response through root cause analysis.

ROOT CAUSE ANALYSIS. Root cause analysis is a systematized process to identify variations in performance that cause or could cause a sentinel event. Suggested steps in such an analysis are briefly summarized in the Patient Safety box.

TJC has categorized errors reported to it and published their frequencies. Examples of perioperative care errors are those that are: related to anesthesia; caused by medical equipment; result in infection, fires, and transfusion reactions; are operative or postoperative; or give rise to unintended retention of foreign objects (RFOs) or wrong site surgery.

National Patient Safety Goals (NPSGs). NPSGs for hospitals and office-based surgery, derived from reported sentinel events, evolve and are reviewed, updated, or retired each year. The Patient Safety boxes on pp. 20 and 21 present the 2009 NPSGs for hospitals and office-based surgery.

Goals for patients in both settings are quite similar. Even though patients in office-based surgery settings are of healthier American Society of Anesthesiologists (ASA) physical status classification (see Chapter 4), one could argue that error prevention procedures in office-based surgery facilities must be even more rigorous than in inpatient settings because the array of emergency or corrective equipment and personnel is likely less available in these facilities. In addition, office-based and ambulatory perioperative staff provide most patient and family discharge education and preparation, unlike inpatient care settings (Ambulatory Surgery Considerations).

PATIENT SAFETY

Root Cause Analysis

Root cause analysis typically asks the following questions:

1. What happened?
2. Why did that happen?
   - What systems and processes underlie the proximate factors?
     - Information and management issues
     - Environmental issues
     - Leadership issues
     - Uncontrollable factors
3. What are the most proximate factors?
   - Human
   - Equipment
   - Controllable environmental
   - Uncontrollable external factors
4. What other factors are involved?
   - Are there other factors that directly influenced the outcome?
   - What other areas or services are impacted?

The next phase of root cause analysis moves to "what can be done to prevent this" questions that flow from the "why" questions, and ultimately result in an action plan. Root cause analysis concentrates on systems and processes, not individuals.

Modified from *Frameworks for conducting a root cause analysis and action plan*, available at www.jointcommission.org/NR/rdonlyres/C8CE68F6-85D7-4EA4-B3E0-895FC1075EE6/0/rcawordframework.doc. Accessed September 20, 2009.

Universal Protocol. A required safety practice of TJC is the Universal Protocol. Key features of the Universal Protocol for perioperative patient care are performing a preoperative verification process, marking the operative site, and conducting a "time out" immediately before starting the procedure. A properly performed "time out" includes information about the patient and procedure (Dillon, 2008). This is discussed in more detail later in the chapter.

Rapid Response Teams (RRTs). When a patient exhibits signs of clinical deterioration, a rapid response team (RRT) may be called to the bedside immediately to assess and treat the patient. The creation of such teams was initially included in the Institute of Healthcare Improvement's "100,000 Lives Campaign" in 2005 (Wachter and Pronovost, 2006). By 2008 TJC required accredited hospitals to have a mechanism for requesting additional assistance when a patient's condition appeared to worsen. That led to widespread implementation of RRTs. In some instances, such teams arise following a sentinel event. The Rapid Response Team box presents the implementation of a RRT in one OR following a sentinel event and root cause analysis. Many of the chapters in the remainder of this book have RRT scenarios/information.

Centers for Medicare & Medicaid Services (CMS)

CMS, formerly the Healthcare Financing Administration (HCFA), is the federal agency charged with administration (including regulations for payment) of the Medicare, Medicaid, and State Children's Health Insurance Programs. It also administers the Health Insurance Portability and Accountability

PATIENT SAFETY

Hospital-Based Surgery National Patient Safety Goals

Identify patients correctly.
- Use at least two ways to identify patients. For example, use the patient's name and date of birth.

Make sure that the correct patient gets the correct blood type when receiving a blood transfusion.
- Improve staff communication.
- Read back spoken (verbal) or phone orders to the person who gave the order.
- Create a list of abbreviations and symbols that are not to be used.
- Quickly hand-off important test results to the right staff person.
- Create steps for staff to follow during patient hand-off. Make sure there is time to ask and answer questions. Eliminate distractions during hand-off reports.

Use medicines safely.
- Create a list of medicines with names that look alike or sound alike. Update the list every year.
- Label all medicines that are not already labeled (e.g., medicines in syringes, cups, and basins, both on and off the sterile field).
- Take extra care with patients who take anticoagulants.

Prevent infection (refers to reducing the risk of healthcare-associated infections).
- Use the hand cleaning guidelines from the World Health Organization or Centers for Disease Control and Prevention (CDC).
- Report patient death or injury from infections acquired in hospitals.
- Use proven guidelines to prevent infections that are difficult to treat.
- Use proven guidelines to prevent infection of the blood.
- Use safe practices to treat the part of the body where surgery was performed.

Check patient medicines.
- Find out what medicines each patient is taking. Make sure that it is acceptable for the patient to take any new medicines with the patient's current medicines.
- Give a list of the patient's medicines to the patient's next caregiver or to the primary care physician before the patient is discharged home (medication reconciliation) to prevent discharge medicine discrepancies.
- Give a list of the patient's medicines to the patient and the patient's family before the patient is discharged home. Explain the list. Have the patient or family member repeat back or teach back important considerations in taking these medicines. Document education provided about discharge medicines.

Prevent patients from falling.
- Find out which patients are most likely to fall. For example, is the patient taking any medicines that might make the patient weak, dizzy, or sleepy? Take action to prevent falls for these patients.

Help patients to be involved in their care.
- Educate patients and family members about treatment, services, safety issues, and concerns about care.
- Tell each patient and their family members how to report their complaints about safety.
- Educate patients about hand hygiene, respiratory hygiene practices, and contact precautions (according to patient condition).
- Provide information about the hospital's measures to prevent adverse events.

Identify patient safety risks.
- Find out which patients are most likely to attempt to commit suicide.
- Watch patients closely for changes in their health and respond quickly if they need help.
- Create ways to obtain help from specially trained staff when a patient's health appears to deteriorate (e.g., rapid response teams [RRTs] or clinical triggers [Moldenhauer et al, 2009]).

Prevent errors in surgery.
- Create steps for staff to follow so that all documents needed for surgery are on hand before surgery starts.
- Mark the part of the body where the surgery will be done. Involve the patient in this step.

Adapted from *2009 Hospital National Patient Safety Goals,* available at www.jointcommission.org/NR/rdonlyres/40A7233C-C4F7-4680-9861-80CDFD5F62C6/0/09_NPSG_HAP_gp.pdf. Accessed July 15, 2009; Watson DS: National patient safety goals and implementation, *AORN J* 90(1):123-127, 2009; Wong JD et al: Medication reconciliation at hospital discharge: evaluating discrepancies, *Ann Pharmacother* 42(10):1373-1379, 2008.

Act (HIPAA) (discussed later) and several other health-related federal programs. A brief review of the hundreds of FAQs on its website provides an idea of the breadth and specificity of its activities. Significant to patient safety is the decision by CMS to impose financial disincentives for selected unsafe patient care outcomes by refusing to pay for the extra cost of treating those outcomes. Conversely stated, the agency responsible for paying Medicare claims now provides a financial incentive for safe patient care.

The original list of no longer reimbursable facility-acquired claims includes the following:
- Pressure ulcer stages III and IV
- Falls and trauma
- Surgical site infection after bariatric surgery for obesity, certain orthopedic procedures, and coronary artery bypass surgery (mediastinitis)
- Vascular catheter-associated infection
- Catheter-associated urinary tract infection
- Administration of incompatible blood
- Air embolism
- Foreign object unintentionally retained after surgery (RFO)
- Wrong site surgery
- Deep vein thrombosis (DVT)
- Pulmonary emboli associated with knee and hip replacements
- Certain manifestations of poor glycemic control

CMS cautions that no inference may be drawn that it considers these listed patient safety concerns more important than others. Rather, it has chosen them to emphasize that the financial cost of insufficient patient safety controls will be directly borne by facilities deemed responsible. Furthermore, CMS regulations prohibit as a matter of law passing these costs on to patients. Most private insurance companies have adopted similar provisions. Thus, from a purely risk management standpoint, in addition to potential indirect costs arising from negligence awards and settlements, facilities now incur direct costs to remedy the listed conditions.

PATIENT SAFETY

Office-Based Surgery National Patient Safety Goals

Identify patients correctly.
- Use at least two ways to identify patients. For example, use the patient's name and date of birth.

Make sure that the correct patient gets the correct blood type when receiving a blood transfusion.
- Improve staff communication.
- Read back spoken (verbal) or phone orders to the person who gave the order.
- Create a list of abbreviations and symbols that are not to be used.
- Quickly hand-off important test results to the right staff person.
- Create steps for staff to follow during hand-offs. Make sure there is time to ask and answer questions. Eliminate distractions during hand-off reports.

Use medicines safely.
- Create a list of medicines with names that look alike or sound alike. Update the list every year.
- Label all medicines that are not already labeled (e.g., medicines in syringes, cups, and basins, both on and off the sterile field).

Prevent infection.
- Use the hand cleaning guidelines from the World Health Organization or Centers for Disease Control and Prevention (CDC).
- Report patient death or injury from infections acquired in the facility.
- Use safe practices to treat the part of the body where surgery was performed.

Check patient medicines.
- Find out what medicines each patient is taking. Make sure that the patient is allowed to take any new medicines with current medicines.
- Give a list of the patient's medicines to the patient's next caregiver. Give the list to the patient's primary care physician before the patient is discharged home (medication reconciliation).
- Give a list of the patient's medicines to the patient and the patient's family before the patient is discharged home. Explain the list. Have the patient or the family member repeat back or teach back important considerations in taking these medications.

Prevent fires during surgery.
- Remind staff about the dangers of fire during surgery.
- Fire can be caused by lasers and other heated equipment.
- Some fluids and gases can catch fire. Ask staff to use less oxygen under sheets and blankets around the patient. Use appropriate patient skin preparation practices.

Help patients to be involved in their care.
- Tell each patient and the patient's family how to report complaints about safety.

AMBULATORY SURGERY CONSIDERATIONS

Postoperative Telephone Calls

Office-based and ambulatory perioperative staff provide most patient and family discharge education and preparation, unlike inpatient care settings. Commonly, they also contact patients postoperatively to determine whether there are any problems or concerns. In reviewing the timing for such postoperative phone calls, Flanagan's research explored themes of postoperative patient calls at different time periods and discovered the following:
- At 12 hours postoperatively, patients expressed relief that their procedure was completed. Their primary symptom was nausea.
- At 24 hours postoperatively, patients expressed feelings of being unprepared and unable to manage by themselves. They needed resources to help with their care; they had symptoms of pain, nausea, and fatigue and reported decreased mobility.
- By 72 hours postoperatively, patients were more able to function on their own and continued to experience fatigue, but felt "abandoned." They did not yet feel "back to normal" and had concerns about missing work and their inability to manage other role functions and activities. However, they were now able to ask more questions and felt more comfortable expressing their concerns over the phone.

Patient and family education and preparation for discharge are critical to the well-being of surgery patients. Each of the chapters in this book that reviews a surgical specialty has a discussion of this critical aspect of perioperative nursing care in order to assist both the nurse and the patient in discussing and anticipating what will be needed during the postoperative recovery and convalescence period.

Modified from Flanagan J: Postoperative telephone calls: timing is everything, *AORN J* 90(1):41-51, 2009.

The World Health Organization (WHO)

WHO was created by and functions within the United Nations (UN) as the directing and coordinating authority for health throughout UN member nations. In October 2004 WHO launched the World Alliance on Patient Safety, which began to examine patient safety in acute as well as primary care settings relevant to all WHO member nations. Its action initiatives include "Clean Care is Safer Care" and "Safe Surgery Saves Lives." The focus of the "Clean Care" campaign is hand hygiene (also referenced in TJC's NPSGs), which resulted in release of a 2009 WHO guideline for surgical hand preparation (Evidence for Practice, p. 23). Salient points in "Surgical Hand Preparation" include discussion of the length of preoperative hand antisepsis, encouragement of brushless hand scrubs, and review of hand scrub preparations.

The "Safe Surgery Saves Lives" initiative published its Surgical Safety Checklist (Evidence for Practice, p. 24) in June 2008. Similar in content to TJC's Universal Protocol, it added a third phase following the time-out. The WHO checklist adds a "Sign Out" phase that includes team reviews of outcomes and concerns to be included in the handover (international term for "hand-off") to postanesthesia recovery caregivers. Haynes and colleagues (2009) hypothesized that implementation of the *WHO Surgical Safety Checklist* would reduce complications and deaths associated with surgery. They compared outcomes of surgical patients in eight countries representing widely diverse economic circumstances and patient populations, and found a 1.5% pre-checklist rate of death declined to 0.8% ($p = 0.003$) with use of the checklist. They also found inpatient complications occurred in 11% of patients before the checklist was

EVIDENCE FOR PRACTICE

WHO Guidelines on Surgical Hand Preparation

Steps before starting surgical hand scrubs:

KEY STEPS

- Keep nails short and pay attention to them when washing your hands—most microbes on hands come from beneath the fingernails.
- Do not wear artificial nails or nail polish.
- Remove all jewelry (rings, watches, bracelets) before entering the OR.
- Wash hands and arms with a nonmedicated soap before entering the OR and/or if hands are visibly soiled.
- Clean under the nails with a nail file. Nail brushes should not be used as they may damage the skin and encourage shedding of cells. If used, nail brushes must be sterile and used once only (single use). Reusable nail brushes are available that may be resterilized for each use.

PROCEDURAL STEPS

- Start timing. Scrub each side of each finger, between the fingers, and the back and front of the hand for 2 minutes.
- Proceed to scrub the arms, keeping the hand higher than the arm at all times. This helps to avoid recontamination of the hands by water from the elbows and prevents bacteria-laden soap and water from contaminating the hands.
- Wash each side of the arm from wrist to elbow for 1 minute.
- Repeat the process on the other hand and arm, keeping hands above elbows at all times. If the hand touches anything at any time, the scrub must be lengthened by 1 minute for the area that has been contaminated.
- Rinse hands and arms by passing them through the water in one direction only, from fingertips to elbow. Do not move the arm back and forth through the water.
- Proceed to the OR holding hands above elbows.
- At all times during the scrub procedure, care should be taken not to splash water onto surgical attire.
- Once in the OR, hands and arms should be dried using a sterile towel and aseptic technique before donning gown and gloves.

Modified from *WHO guidelines on hand hygiene in health care,* available at http://whqlibdoc.who.int/publications/2009/9789241597906_eng.pdf. Accessed July 15, 2009.

implemented and in 7.0% after introduction of the checklist. Thus tangible improvements in safety outcomes were confirmed following implementation of the checklist. Notable about WHO's entry into surgical patient safety is recognition that perioperative adverse events causing complications before, during, and after surgery is a public health problem.

The Association of periOperative Registered Nurses (AORN)

AORN has a nearly 60-year history of addressing perioperative patient safety issues. It represents perioperative patients and perioperative nurses in multiple policy settings, participating with TJC, WHO, other nursing associations and surgical alliances, and many safety coalitions to formulate safety statements that impact perioperative patient care. AORN provides an array of standards, RPs, guidelines, publications, videos and toolkits specifically addressing patient safety from the perioperative team's point of view. Toolkit subjects include fire safety, correct site surgery, safe medication administration, hand-off communication, and culture and human factors. RPs and toolkits are evidence-based to the extent possible. These AORN undertakings aim to distill, review, and suggest strategies for implementing perioperative patient care practices. Along with TJC and WHO recommendations, AORN recommendations should be reflected and adopted within institutional policies and procedures and educational curricula for perioperative nursing to the extent possible.

Other Patient Safety Groups/Coalitions/Companies

Major professional associations that represent other perioperative team members (e.g., American College of Surgeons [ACS], American Society of Anesthesiologists [ASA], American Association of Nurse Anesthetists [AANA], Association of Surgical Technologists [AST]) have also issued position statements and clinical recommendations related to patient safety. Additionally, many coalitions with similar patient safety interests have emerged as not-for-profit entities to gather and disseminate data, guidelines, protocols, and goals, for example. For-profit groups are also included in what may fairly be called a "patient safety industry." A partial listing of these groups is found in Box 2-1.

PERIOPERATIVE NURSING SAFETY ISSUES

Communication

Communication underpins many patient safety issues (Research Highlight). Implementation of both the Universal Protocol and the WHO checklist requires enhanced communication. More recent initiatives such as hand-off/handover protocols have joined the traditional clinical written documentation record to further improve communication in perioperative settings.

Ultimately, improved communication is imbedded in human factors, culture, and social systems, all of which are more complex than checklists, mnemonics, and acronyms (Leape and Berwick, 2005; Leonard et al, 2004; Moorman, 2007; Mills et al, 2008).

Clinical Documentation

The historical mainstay of communicating perioperative patient information is the written clinical record. Evidence suggests that a written record is inadequate as the sole perioperative communication tool. More recent enhanced communication initiatives such as preoperative briefings have augmented the written record. Nonetheless, whether written or documented electronically, the clinical record remains a key component in assuring a safer patient experience in all perioperative communication systems.

Institutions in which operative and other invasive procedures are performed maintain records of each operation, including preoperative diagnosis, surgery performed, a description of findings, specimens removed, postoperative diagnosis, and names of all individuals participating in intraoperative care. A sample intraoperative record may be found in Figure 2-1. This operative record is a permanent part of the patient's medical record. AORN's *Recommended Practice for Documentation of Perioperative Nursing* (AORN, 2009) suggests that the intraoperative patient care record should include information listed in Box 2-2. Notice that nearly all key components of perioperative clinical documentation relate to actions taken to enhance safety and prevent patient injuries.

Permanent documentation of perioperative patient care in the clinical record also serves risk management functions.

Surgical Safety Checklist

World Health Organization | Patient Safety
A World Alliance for Safer Health Care

Before induction of anaesthesia

(with at least nurse and anaesthetist)

Has the patient confirmed his/her identity, site, procedure, and consent?
- ☐ Yes

Is the site marked?
- ☐ Yes
- ☐ Not applicable

Is the anaesthesia machine and medication check complete?
- ☐ Yes

Is the pulse oximeter on the patient and functioning?
- ☐ Yes

Does the patient have a:

Known allergy?
- ☐ No
- ☐ Yes

Difficult airway or aspiration risk?
- ☐ No
- ☐ Yes, and equipment/assistance available

Risk of >500ml blood loss (7ml/kg in children)?
- ☐ No
- ☐ Yes, and two IVs/central access and fluids planned

Before skin incision

(with nurse, anaesthetist and surgeon)

- ☐ **Confirm all team members have introduced themselves by name and role.**
- ☐ **Confirm the patient's name, procedure, and where the incision will be made.**

Has antibiotic prophylaxis been given within the last 60 minutes?
- ☐ Yes
- ☐ Not applicable

Anticipated Critical Events

To Surgeon:
- ☐ What are the critical or non-routine steps?
- ☐ How long will the case take?
- ☐ What is the anticipated blood loss?

To Anaesthetist:
- ☐ Are there any patient-specific concerns?

To Nursing Team:
- ☐ Has sterility (including indicator results) been confirmed?
- ☐ Are there equipment issues or any concerns?

Is essential imaging displayed?
- ☐ Yes
- ☐ Not applicable

Before patient leaves operating room

(with nurse, anaesthetist and surgeon)

Nurse Verbally Confirms:
- ☐ The name of the procedure
- ☐ Completion of instrument, sponge and needle counts
- ☐ Specimen labeling (read specimen labels aloud, including patient name)
- ☐ Whether there are any equipment problems to be addressed

To Surgeon, Anaesthetist and Nurse:
- ☐ What are the key concerns for recovery and management of this patient?

This checklist is not intended to be comprehensive. Additions and modifications to fit local practice are encouraged.

BOX 2-1

Perioperative Safety-Related Entities

AHRQ: The federal Agency for Healthcare Research and Quality's mission is to improve the quality, safety, efficiency, and effectiveness of healthcare for all Americans. It has extensive evidence-based resources for nurses and other providers related to patient safety. www.ahrq.gov/.

CSPS: The Council on Surgical and Perioperative Safety is a multidisciplinary coalition of professional organizations whose members are directly involved in immediate perioperative care, including AORN, AST, ACS, ASA, AANA, AASPA, and ASPAN. Its mission is to promote excellence in patient safety in the surgical and perioperative environment. www.cspsteam.org/.

ECRI: ECRI Institute is a nonprofit organization dedicated to using the discipline of applied scientific research to discover which medical procedures, devices, drugs, and processes best improve patient care. www.ecri.org/Pages/default.aspx.

HealthGrades: HealthGrades is a public for-profit healthcare ratings organization. It provides ratings and profiles of hospitals, nursing homes, and physicians to consumers, corporations, health plans, and hospitals. www.healthgrades.com.

HIMSS: The Healthcare Information and Management Systems Society is the healthcare industry's member organization exclusively focused on providing leadership for optimal use of healthcare information technology (IT) and management systems to better healthcare. www.himss.org/.

IOM: The Institute of Medicine was chartered in 1970 as a component of the National Academy of Sciences. The Institute works outside the framework of government to ensure scientifically informed analysis and independent guidance. The IOM's mission is to serve as adviser to the nation to improve health, providing unbiased, evidence-based, and authoritative information and advice on health and science policy. www.iom.edu.

ISMP: The Institute for Safe Medication Practices is the nation's only nonprofit organization devoted entirely to medication error prevention and safe medication use. ISMP focuses on helping healthcare practitioners keep patients safe and leading efforts to improve the medication use process. www.ismp.org.

NHQA (National Hospital Quality Alliance): In 2002 the American Hospital Association (AHA), Federation of American Hospitals (FAH), and Association of American Medical Colleges (AAMC) launched the Hospital Quality Alliance (HQA), a national public-private collaboration to encourage hospitals to voluntarily collect and report hospital quality performance information. This effort is intended to make important information about hospital performance accessible to the public and to inform and invigorate efforts to improve quality. CMS and TJC participate in the HQA, along with the AHA, FAH, AAMC, AHRQ, American Medical Association (AMA), American Nurses Association (ANA), National Association of Children's Hospitals and Related Organizations, American Association of Retired People (AARP), American Federation of Labor and Council of Industrial Organizations, Consumer-Purchaser Disclosure Project, National Quality Forum (NQF), Blue Cross and Blue Shield Association, National Business Coalition on Health, General Electric, and U.S. Chamber of Commerce. www.qualidigm.org/Professionals/Setting/Hospital/NQAProject.aspx.

NQF: The National Quality Forum is a public-private partnership created to develop and implement a national strategy for healthcare quality measurement and reporting. www.qualityforum.org.

NSQIP: National Surgical Quality Improvement Program originated in the Veteran's Administration in 1991 and is now affiliated with the American College of Surgeons and available to the private sector. It prompts the surgical community to place patient safety in surgery within a large conceptual framework and provides a quantitative metric for the assessment of patient safety initiatives. www.acsnsqip.org/.

SCIP: The Surgical Care Improvement Project is a national quality partnership interested in improving surgical care by significantly reducing surgical complications. It is a part of the Medicare Quality Improvement Community (MedQIC) that was established by CMS to provide healthcare quality improvement news, resources, and data reporting tools and applications. SCIP created an original goal of reducing by 25% the national incidence of three types of surgical complications by 2010 (surgical site infections, perioperative MI, and DVT/PE). New SCIP measures have been added and are among measures that acute care hospitals must disclose to receive full annual payment updates from Medicare (Patterson, 2009). www.qualitynet.org/dcs/ContentServer?pagename=Medqic/MQPage/Homepage.

The Leapfrog Group: The Leapfrog Group is a voluntary program aimed at mobilizing employer purchasing power to alert America's health industry that "big leaps" in healthcare safety, quality, and customer value will be recognized and rewarded. It reports comparison data on providers. www.leapfroggroup.org/.

In addition, many states have state-based coalitions that encourage cost-effective, safe, quality healthcare.

Documentation requirements serve as reminders of actions needed to provide safe care, thus prompting risk reduction strategies and preventing injury. Information in the clinical record enhances continuity of care. If a patient injury occurs, documentation that preventive measures or other actions to mitigate risks were taken lessen the likelihood of a successful lawsuit.

Perioperative nursing documentation needs to describe the assessment, planning, and implementation of perioperative patient care that reflects individualization of care and evaluation of patient outcomes. Any unusual or significant incidents/events/occurrences pertinent to patient outcomes should be documented as well as their remediation as related to this patient's care.

Thought should be given to the design of perioperative nursing documentation tools that include identified elements in a format that minimizes time needed for the documentation process (e.g., checklists). Ideally, collaboration with preoperative, PACU, and postoperative nursing units will produce one documentation tool used across all areas, avoiding duplication of patient data by different nursing staff. Increasingly, settings where operative and other invasive procedures are performed use electronic records to enter and track patient care information. Such point-of-care technology can help to streamline workflow and reduce documentation errors.

Hand-offs/Handovers

As noted previously, written documentation alone, however crucial, is insufficient to assure patient safety as care responsibility passes from one team or individual caregiver to another. As they reviewed the evidence related to hand-offs, Friesen

and colleagues (2008) defined the transfer of information and responsibility for care of the patient from one provider to another as a "hand-off" or (internationally) "handover." The IOM, in its 2001 publication *Crossing the Quality Chasm*, identified patient hand-off as an opportunity for error. In 2006 TJC required healthcare organizations to implement a standardized approach to hand-off communication to reduce the risk for error.

TJC, AORN, and WHO all recommend that both "time-outs" (non-handoff/handover communication) and pre- and postoperative hand-off/handover be formalized. In healthcare settings, processes for transfer of care such as hand-offs include nursing shift changes, temporary relief or coverage, nursing and physician hand-offs from one department to another, various other transfers of information in inpatient settings, and interhospital transfers. The purpose of hand-off communication and reports is to provide essential, up-to-date, and specific information about the patient. Standardized hand-off communication must include an opportunity to ask and respond to questions. Strategies to assist in effective and efficient hand-off communication and reports are listed in the Patient Safety box.

RESEARCH HIGHLIGHT

The Importance of OR Briefings

In this study, researchers used real-time observations during cardiovascular surgery to measure the effect of preoperative briefings on specific disruptions, classified as patient-related issues, equipment or resource issues, procedural knowledge issues, and miscommunication events (Henrickson et al, 2009). The format for the briefings was developed following analysis of questionnaires and focus group results. Briefings, which lasted from 1 to 8 minutes, were conducted in the OR immediately before the patient's arrival. Each team member discussed his or her role in the procedure and any concerns specific to the patient. The briefings were then evaluated by monitoring surgical flow disruptions, circulating nurse trips to the sterile core for additional supplies, time spent in the sterile core, and cost-waste reports before and after implementation of the briefings.

Implementation of the briefings led to reductions in surgical flow disruptions, procedural knowledge disruptions, and miscommunication events. There was no significant reduction in disruptions caused by equipment preparation or patient-related issues. The researchers concluded that surgical teams that use specialty-specific preoperative briefings can decrease surgical flow disruptions and improve patient safety. Although they did not correlate circulating nurse trips to the sterile core for additional supplies with issues such as door openings and disruptions in environmental controls, another study (Lynch et al, 2009) found that the circulating nurse and core staff generated 37% to 51% of door openings, compromising the sterile environment of the OR. Future research might focus on the relationship of preoperative briefings to infection control measures.

Finally, the implications of improved communication from preoperative briefings have significant potential for decreasing adverse events such as wrong person, wrong procedure, or wrong site surgery. In a review conducted by the Patient Safety Committee of the American Academy of Orthopaedic Surgeons, the second most frequent source of errors was related to communication problems (24.7%) (Wong et al, 2009). Medication errors (9.7%) and wrong site surgery (5.6%) had the most serious potential for harm. Wrong site surgery involved the wrong side in 59%, another wrong site in 23%, wrong procedure in 14%, and the wrong patient in 5%. Clearly, the benefits of a preoperative briefing that focuses on team communication can significantly impact patient safety.

Modified from Henrickson SE et al: Development and pilot evaluation of a preoperative briefing protocol for cardiovascular surgery, *J Am Coll Surg* 208:1115-1123, 2009; Lynch RJ et al: Measurement of foot traffic in the operating room: implications for infection control, *Am J Med Qual* 24:45-45, Jan/Feb 2009; Wong DA et al: Medical errors in orthopaedics: results of an AAOS member survey, *J Bone Joint Surg Am* 91:547-557, 2009.

PATIENT SAFETY

Strategies to Assist in Effective Hand-Off Communication

1. *Use clear language.* Avoid unclear or potentially confusing terms. When appropriate, define the terms you are using. Use only approved abbreviations and avoid jargon that could be misinterpreted.
2. *Incorporate effective communication techniques* such as the SBAR technique (situation, background, assessment, and recommendations), MAPS (medications, allergies, procedure/pertinent information, special needs), or other mnemonic or acronym to facilitate sequence and type of information. Limit interruptions and distractions, focus on information being exchanged, and allocate sufficient time to this important task. Keep the report patient-centered, and avoid irrelevant details. Use read-back, report-back, or check-back techniques to ensure there is a common understanding about information exchanged. There must be an opportunity for each caregiver to ask and respond to questions.
3. *Standardize shift-to-shift and caregiver-to-caregiver (relief) reporting.* A consistent format increases the information staff members accurately record and improves their ability to plan patient care. Keep reports concise and accurate.
4. *Standardize perioperative nursing reports to the PACU or postoperative ambulatory surgery units.* Consider essential information such as reporting the procedure done, duration (and whether longer or shorter than expected), complexity of the procedure (greater than, less than, or as expected), whether there were events or deviations from the expected course, implants, medications administered, current status of vital signs (including temperature and warming methods used), pulses, incision/dressings/drains, blood/fluids administered, and urinary output.
5. *Use technology.* Communication systems that transmit information across settings and providers improve consistency and coordination. Automated electronic perioperative records can facilitate transitions by providing consistent, accessible information about surgical patients and their care in the OR. Staff members should be able to access readily essential components of care, such as whether a newly ordered medication was administered, whether laboratory studies were done, or if a do-not-resuscitate (DNR) order is in place.

BOX 2-2

Key Components in Perioperative Patient Care Documentation*

1. Evidence of patient assessment on arrival in the OR, which includes assessment of the patient's skin condition immediately before and after the procedure.
2. Confirmation that members of the surgical team took a "time-out" before starting surgery, verifying and agreeing on the correct patient, surgical site/side, and procedure; that equipment and special needs such as implants or imaging studies were available; and that the patient was in the proper surgical position. The surgical site mark must be clearly visible.
3. Evidence of a plan of care, individualized for the patient and that considers the patient's base-line psychosocial, physical, emotional, and religious or cultural status/preferences. The plan of care, with identified outcomes, might include data elements and nursing interventions based on AORN's Perioperative Nursing Data Set (PNDS) (see Chapter 1).
4. Any sensory aids or prosthetic devices worn by the patient on admission to the OR and their subsequent disposition.
5. Patient position, including supports or restraints/immobilizing/safety devices used.
6. Location of electrosurgical unit (ESU) dispersive electrode/pad placement, identification of ESU and settings used.
7. Use of temperature-regulating device, its placement, identification of unit used, and recording of time and temperature, on admission and discharge from the OR.
8. Type and placement of monitoring electrodes (noninvasive and invasive).
9. Medications administered or dispensed by the perioperative nurse, complying with the institution's "Do No Use" list for abbreviations (Table 2-1).
10. Presence of catheters, drains, packing, tubes, other devices, and dressings.
11. Type of tourniquet, location of cuff placement, identification of unit, pressure setting, and inflation and deflation times.
12. Blood products administered and fluid output, including estimated blood loss (EBL), as appropriate. Unused blood returned to the blood bank or taken with the patient to the postanesthesia care unit (PACU) should be noted.
13. Implant type, size, expiration date (if applicable); name of manufacturer or distributor; and identification information used by manufacturer (e.g., lot, batch, model, serial number). A separate implant logbook entry also should be completed with FDA-required information, noting name and address of facility where surgery took place; identification information used by the manufacturer; patient's name, address, and social security number (unless the patient refuses permission to use this information); and name, address, and telephone number of implanting surgeon.
14. Skin preparation solutions used, areas prepared, precautions taken (such as to prevent chemical injury or fire), and any reactions to prep solution.
15. Known patient allergies to medications, prep solutions, tape, latex, dyes, and other substances.
16. Sponge, sharp, and instrument counts taken and results obtained.
17. Wound classification (see Chapter 8) and anesthesia physical status classification (see Chapter 4).
18. Time of discharge and disposition of patient from OR, including mode of transfer and patient status.

*This SBAR hand-off communication outline is also applicable for phase I PACU to phase II recovery hand-off communications.
Adapted from AORN Recommended practice for documentation of perioperative nursing care. In *Perioperative standards and recommended practices*, Nursing, Denver, 2009, The Association.

TABLE 2-1

Do Not Use Abbreviations

Use	Do Not Use	Reason
units	U or u	Mistaken as "0", "4," or "cc"
0.1 mg	.1 mg	No leading zero results in easily missed decimal point (i.e., 10 times the dose)
0.1 mg or 1 mg	.10 mg or 1.0 mg	Trailing zero results in easily missed decimal point (i.e., 10-100 times the intended dose)
mcg or micrograms	μg	Mistaken for mg
morphine sulfate	MS	Mistaken for MSO_4 and $MgSO_4$
morphine sulfate	MSO_4	Mistaken for MS and $MgSO_4$
magnesium sulfate	$MgSO_4$	Mistaken for MS and MSO_4
International unit	IU	Mistaken for IV and 10
daily	Q.D.	Mistaken for Q.O.D.; the period after the Q can be mistaken for an "I"
every other day	Q.O.D.	Mistaken for Q.D.; the period after the Q can be mistaken for an "I" and the "O" can be mistaken for "I"
left ear	as	confused with left eye (os)
right ear	ad	confused with right eye (od)

Amato-Vealey and colleagues (2008) identified and further developed elements of effective hand-off communication for use at each perioperative hand-off stage using the SBAR mnemonic. Identifying critical elements for hand-offs from preoperative to intraoperative (Box 2-3), from intraoperative to PACU or other postanesthesia recovery area (Box 2-4), and from PACU or other postanesthesia recovery area to inpatient unit (Box 2-5) can also facilitate development of critical elements for hand-offs from postanesthesia recovery to discharge units in ambulatory surgery.

BOX 2-3

Elements of the Preoperative to Intraoperative Hand-Off Communication

SITUATION
- Name of patient and date of birth
- Name of operative or invasive procedure to be performed, including modifiers and site
- Pertinent documents present and consistent

BACKGROUND
- Elements of patient history pertinent to surgery
- Medical clearance
- Patient allergies and NPO status
- Patient's vital signs and pain level
- Medication profile and medications taken today
- Specific laboratory results
- Code status of patient

ASSESSMENT
- Patient's current level of understanding of the surgery
- Special patient needs or precautions
- Pertinent aspects of the patient's emotional and spiritual status
- Pertinent cultural implications
- Anesthesia requests

RECOMMENDATIONS
- State whether the patient has been seen preoperatively by the surgeon and anesthesia care provider.
- Determine whether the patient is ready for surgery.
- Allow an opportunity for preoperative and intraoperative staff members to ask questions or voice concerns.

From Amato-Vealey EJ et al: Hand-off communication: a requisite for patient safety, *AORN J* 88(5):766, 2008.

BOX 2-4

Elements of the Intraoperative to PACU Hand-Off Communication

SITUATION
- Name of patient and date of birth
- Name of operative or invasive procedure performed, including modifiers and site

BACKGROUND
- Type of anesthesia administered and name of anesthesia care provider
- Intraoperative medications administered, including dose and time
- IV fluids administered
- Estimated blood loss
- Pertinent information related to the surgical site such as dressings, tubes, drains, or packing
- Any significant OR events

ASSESSMENT
- Hemodynamic stability
- Airway and oxygenation status
- Thermal status (e.g., presence of hypothermia or hyperthermia)
- Urine output
- Presence or absence of surgical complications
- Level of pain
- Method of pain management

RECOMMENDATIONS
- Ensure that immediate postoperative orders have been completed.
- Discharge from the PACU when stable.
- Allow opportunity for intraoperative and PACU staff members to ask questions or voice concerns.

From Amato-Vealey EJ et al: Hand-off communication: a requisite for patient safety, *AORN J* 88(5):766, 2008.

Wrong Site, Person, or Procedure Surgery

Surgery that is the wrong procedure or surgery performed on the wrong site or person includes any operative or other invasive procedure performed on the wrong patient, wrong body part, wrong side of the body, or at the wrong level of the otherwise correctly identified anatomic structure, such as in spinal surgery. Evidence shows that wrong site surgery not only can devastate the patient and family but also can impact the perioperative team adversely (Mulloy and Hughes, 2008). All institutions accredited by TJC must follow the Universal Protocol for Preventing Wrong Site, Wrong Procedure, Wrong Person Surgery. Selected components of the Universal Protocol relating to correct site verification include:

- *Preoperative verification process* to ensure that all relevant documents (e.g., the history and physical examination, surgical consent, required laboratory studies) and imaging studies (properly labeled and displayed) are available before the start of the procedure. The surgical team must agree that this is the correct patient and the planned procedure on the specified side and site.
- *Marking the surgical site* must be done so that the intended site of incision or insertion is clear and unambiguous. Procedures that involve left/right distinction, multiple structures, or multiple levels must be marked. The mark also must be unambiguous; initials, a "yes," or a line at or near the incision site may be used. The person performing the procedure who is accountable for it and who will be present when the procedure is performed must do the site marking; in addition, the patient should be involved in the marking. The method of marking should be consistent throughout the institution. The mark must be visible after the patient has been prepped and draped. Institutions should have procedures in place for patients who refuse site marking.
- *Taking the time-out*. The time-out must take place before starting the procedure or making the surgical incision. The surgeon or other physician who is conducting the procedure must be present for the time-out. If there is more than one procedure being performed by separate teams, there needs to be a time-out before each procedure. This does not apply to patients where the same surgical team is performing multiple aspects of a procedure. Specific situations where two time-outs are required are those when hospital policy or law/regulation requires two separate consents (e.g., for a cesarean section followed by a tubal ligation). During the time-out, active involvement and communication among all surgical team members is expected as they confirm and agree that they have the correct patient, correct side and site, and the correct procedure to be performed. It is helpful to also verify that the patient is in the correct position and that any needed equipment, supplies, or implants are available. In some facilities, the presence and review of relevant imaging studies are also confirmed as is the agreement that all prep solutions have dried to minimize surgical fire risks. The Patient Safety box presents an example of a universal protocol and fire risk assessment.

PATIENT SAFETY

Universal Protocol and Fire Risk Assessment

Planned Procedure: _____

_____

_____

_____ Date of procedure

COMPONENT #1 VERIFICATION PROCESS

Mark all that apply ***indicates required field*	Sending Unit	Prep & Holding	Unit Doing Procedure
Name and date of birth confirmed**			
Patient/decision maker verbalizes planned procedure			
Schedule confirms planned procedure			
Consent confirms planned procedure**			
History and physical confirms planned procedure			
Diagnostic study confirms planned procedure			
Progress record/consult confirms planned procedure			
Site marking required (*go to component 2*)			
Site marking not required			
Date/time:			
Initial:			

COMPONENT #3 TIME OUT

The entire procedure team has performed a Time Out and all members have verbally agreed.

Time out included the verification of:	**1st**	**2nd**	**3rd**
Correct patient identity			
Agreement on procedure to be done			
Correct site and side			
Diagnostic study confirmation of site and side			
Availability of implants			
Availability of special equipment			

1st Time out: Time: _____ Initial: _____

2nd Time out: Time: _____ Initial: _____

3rd Time out: Time: _____ Initial: _____

COMPONENT #2 SITE MARKING (if required)

After verification has been completed, the patient if able, will write "**Yes**" with a permanent marker on or as near the site as possible:

☐ Right _____ ☐ Left _____

Side marked by:

☐ Patient ☐ Family member (Relationship): _____ ☐ Healthcare provider

Initial: _____ Time: _____

FIRE RISK ASSESSMENT

Procedure site or incision above the xiphoid	1 (Yes)	0 (No)
Open oxygen source (face mask/nasal cannula)	1 (Yes)	0 (No)
Ignition source (cautery, laser, fiberoptic light source)	1 (Yes)	0 (No)

Score 1 or 2: ☐ Initiate routine protocol

Score 3: ☐ Initiate high risk fire protocol (see side 2 for specifics)

UNIVERSAL PROTOCOL AND FIRE RISK ASSESSMENT
(For Operating Room and Non-Operating Room Settings)

COMPONENT #1 VERIFICATION PROCESS

Purpose: To outline the process for identifying the correct person, correct procedure, and correct site for surgical and invasive procedures with involvement of the patient or decision maker when possible.

A. The caregiver (RN/LPN, anesthesia provider, surgeon, resident, PA) beginning the verification process will initiate the form.
B. When care of the patient is transferred to a new care area, the new caregiver will complete the appropriate columns and initial.
C. Mark (√) only the boxes that indicate the method reviewed to confirm the planned procedure.
D. Resolve discrepancies identified through the verification process prior to moving the patient to the procedure area or prior to the initiation of the bedside procedure/anesthesia regional block.

COMPONENT #2 SITE MARKING

Purpose: To clearly identify the intended site of incision or insertion.

A. Document site marking for patients having surgical/invasive procedures involving laterality or digits. (Patients having surgical/invasive procedures involving level(s) (i.e., spine or ribs) will have level(s) marked by the Licensed Independent Practitioner (LIP) performing the procedure or identified by the LIP using radiographic techniques during the procedure.)

COMPONENT #3 TIME OUT

Purpose: To conduct a final verification of the correct patient, procedure, site and implants, if applicable.

A. Time out is completed prior to the start of the procedure and a designated person (circulating RN, assisting RN or tech) will complete the section and initial.
B. Mark (√) only the boxes that indicate the components confirmed.
C. An additional Time Out is documented for a second procedure.
D. In the event that the physician performing the procedure leaves the patient or repositions the patient after the Time Out process has occurred, the Time Out process is repeated and documented.

FIRE RISK ASSESSMENT

- Routine Protocol
  1. FUEL:
     A. When an alcohol based solution is used, use minimal amount of solution and allow sufficient time for fumes to dissipate before draping. Observe drying time (minimum 3 minutes). Do not drape patient until flammable prep is fully dry.
     B. Do not allow pooling of any prep solution (including under the patient).
     C. Remove bowls of volatile solution from sterile field as soon as possible after use.
     D. Utilize standard draping procedure.
  2. IGNITION SOURCE:
     A. Protect all heat sources when not in use. (Cautery pencil holster, laser in stand by mode etc.)
     B. Activate heat source only when active tip is in line of sight.
     C. De-activate heat sources before tip leaves surgical site.
     D. Check all electrical equipment before use.
- High Risk Protocol (includes all of routine protocol)
  A. Use appropriate draping techniques to minimize O_2 concentration (i.e., tenting, incise drape).
  B. Electrical Surgical Unit (ESU) setting should be minimized.
  C. Encourage use of wet sponges.
  D. Basin of sterile saline and bulb syringe available for suppression purposes only.
  E. Anesthesia Care Provider considerations:
     - A syringe full of saline will be available, in reach of the anesthesia care provider, for procedures within the oral cavity.
     - Documentation of oxygen concentration/flows. Use of “MAC Circuit” for oxygen administration.

BOX 2-5

Elements of the PACU to Inpatient Unit Hand-Off Communication*

SITUATION
- Name of patient and date of birth
- Name of operative or invasive procedure performed, including modifiers and site

BACKGROUND
- Type of anesthesia administered and name of anesthesia care provider
- Medications administered in the OR and PACU, including dose and time
- IV fluids administered in the OR and PACU
- Estimated blood loss
- Pertinent information related to the surgical site such as dressings, tubes, drains, or packing
- Any significant OR events
- Any significant PACU events

ASSESSMENT
- Hemodynamic stability
- Airway and oxygenation status
- Thermal status (e.g., presence of hypothermia or hyperthermia)
- Urine output
- Presence or absence of surgical complications
- Level of pain
- Method of pain management

RECOMMENDATIONS
- Ensure that PACU physician orders have been completed.
- Ensure that the surgeon's plan of care has been implemented.
- Identify patient's and family members' educational needs.
- Provide discharge instructions.
- Discharge after 2 hours or when stable.
- Allow an opportunity for PACU and inpatient unit staff members to ask questions or voice concerns.

*This SBAR hand-off communication outline also is applicable for phase I PACU to phase II recovery hand-off communications.
From Amato-Vealey EJ et al: Hand-off communication: a requisite for patient safety, *AORN J* 88(5):767, 2008.

RESEARCH HIGHLIGHT

Significance of Retained Foreign Objects (RFOs)

Retained foreign objects (RFOs) after surgical procedures can be associated with significant patient morbidity or mortality. They also can have a significant negative impact on the institution's reputation and can result in litigation.

In one quality improvement project (Cima et al, 2009) the OR was averaging a retained foreign object event every 16 days. The project team undertook a defect analysis to identify patterns of failures unique to the OR culture followed by policy review, focusing on increased clarity and consistency in count policies. This was followed by intense staff education. After the intervention, the average interval between RFO events increased to 69 days. This improvement has been sustained for more than 2 years.

There are also new technologies available to reduce or prevent retained surgical sponges. To understand their cost-effectiveness, researchers in another study (Regenbogen et al, 2009) compared standard sponge counting (incidence of retained sponges is approximately 67 per 100,000 procedures) with universal or selective x-ray, bar-coded sponges, and radiofrequency (RFID)-tagged sponges. While standard counting prevented 82% of retained sponges, bar-coded and RFID-tagged sponges prevented about 97.5% of retained sponges. The bar-coded sponges were the most cost-effective. These researchers suggest that, given medical and liability costs of more than $200,000 per incident, sponge-tracking technologies can substantially reduce the incidence of retained surgical sponges at an acceptable cost.

Adapted from Cima RR et al: A multidisciplinary team approach to retained foreign objects, *Jt Comm J Qual Patient Saf* 35:123-132, 2009; Regenbogen SE et al: Prevention of retained surgical sponges: a decision-analytic model predicting relative cost-effectiveness, *Surgery* 145:527-535, 2009.

In addition to designating a universal protocol to prevent wrong site errors, TJC in 2005 identified numerous risk factors that contribute to an increased risk of wrong site surgery, including the following:
- More than one surgeon involved in the procedure (multiple procedures or care of patient transferred to another surgeon)
- Multiple procedures conducted on the same patient
- Unusual time pressures
- Unusual patient characteristics, such as physical deformity or massive obesity

Retained Foreign Objects (RFOs)

Unintentional retained foreign objects (RFOs) are also a concern of TJC, WHO, and all facilities where surgery is performed. While clinically different, wrong site surgery and RFOs are similar from safety and risk management perspectives. They both also share top positions in TJC's top 10 annual sentinel events. The physiologic, financial, and public relations sequelae from both wrong site surgery and RFOs are very serious (Research Highlight). In some ORs, following the Universal Protocol and conducting correct count processes (audible, visual, and concurrent) are considered inviolable rules (Cima et al, 2009). Applying Judge Learned Hand's legal calculation that the burden of precaution (BP) is directly proportionate to the gravity or severity of the injury (S) times the probability (P) of its occurrence (BP = S × P), the consequent severity of an RFO requires intense attention to prevention despite its relative rarity (*U.S. vs. Carroll Towing, 159 F.2d 169 [2d Cir. 1947]*).

Gawande and others (2003) projected the rate of RFOs as 1500 out of 28 million patients, with sponges being the item most frequently retained inadvertently. The actual rate is likely higher because previously facilities were not required to report RFOs. Physiologic consequences of a RFO include possible infection, obstruction, fistula formation, perforation or consequent pain, suffering (and possible death), and the likely need for reoperation. As noted earlier, CMS and many private insurers now refuse payment for remedial treatment such as reoperation to remove a sponge or treat the physiologic consequences of its inadvertent retention. The healthcare facility must absorb the costs of extended hospitalization and corrective treatment required. Additional financial loss can be incurred from malpractice litigation (Legal issues pertaining to retained sponges and towels, presented at AORN, March, 2009), impaired public reputation, and the need to respond to licensing and regulatory body inquiries.

Prevention of RFOs. At a minimum, all facilities should have a "count" policy that reflects AORN's *Recommended Practices for Sponge, Sharp, and Instrument Counts* (AORN, 2009). Key components of that RP are highlighted in the Patient Safety box and a sample count record is presented in Figure 2-2. The

Purpose: To document sponge, sharp and instrument counts for invasive procedures.

Date: _____

COUNTS	BASELINE	CAVITY IN CAVITY	BEFORE WOUND CLOSURE	FINAL - SKIN CLOSURE	PERMANENT RELIEF	TEMPORARY RELIEF
Time:						
Sponges

CORRECT WITH INTENTIONALLY PACKED SPONGES/INSTRUMENTS

Wound was packet with: _____ (number) _____ (name of item)

Packing communication log initiated: ☐ Yes **Purple arm band applied:** ☐ Yes _____(RN initials)

UNRESOLVED COUNT

Name of unresolved item: _____

☐ Physician notified: _____ (name of physician)

X-ray taken: ☐ Yes ☐ No, reason: _____ _____(RN initials)

Initial	Signature/Title	Print Name	Initial	Signature/Title	Print Name

Instructions:

1. To be completed by RN assigned to the procedure.
2. Record sponge, sharps, and miscellaneous items on dry erase board per policy.
3. Instruments are counted and recorded on the inventory list. If baseline instrument count is not indicated per the policy, document N/A (not applicable).
4. Record the time each count is performed in the appropriate column.
5. Initials and signatures are required for the RN and scrub person that performed each count.
6. Permanent relief is an RN and/or scrub person that provides relief for the circulating RN or scrub person for the remainder of the procedure or until the next shift. A complete sponge, sharps, miscellaneous item, and instrument count is required for permanent relief.
7. Temporary relief is an RN and/or scrub person that provides relief for the circulating RN or scrub person for lunch relief/break. A sponge, sharps, and miscellaneous item count is required.
8. RN performing final count will check appropriate boxes:
   - Correct
   - Unresolved
   - N/A when applicable

FIGURE 2-2 Count record.

policy should also incorporate human factors and keep interruptions, distractions, and repetition-induced attention deficits to their minimum. Counting aloud by two persons combined with the surgeon's manual exploration and the scrub person keeping mental track of sponges and other counted objects in the wound (situational awareness) have long been mainstay approaches to preventing RFOs. New sponge-tracking technologies have emerged in the last decade to enhance risk reduction strategies for preventing inadvertent retention of RFOs (Regenbogen et al, 2009). These include sequentially numbered sponges, bar coding, and radiofrequency identification (RFID) products. Typically, sequentially numbered sponge products are prepackaged, presterilized sponges in groups of 5 or 10 in sequentially numbered packages (e.g., 4 × 8's of 1-10, 11-20, 21-30; or laparotomy sponge packs of 1-5, 6-10 (Pelter et al, 2007). With such systems, surgical teams are more likely to detect a missing/retained sponge because they must account for each individual sponge rather than account for their aggregate number. The usual tenets of counting are still used. Counts are performed audibly, concurrently, and visibly. Distractions are minimized; in some institutions, a "pause for the cause" is taken while counts are conducted.

RFID and bar-code technologies are also incorporated into equipment to prevent retained foreign bodies. Bar-code scanning systems require scanning items as the procedure begins and/or as they are put into the body and again as they are removed from the body and/or as the procedure ends. RFID systems tag instruments, sponges, and other items likely to enter the body during a procedure and use a scanning wand through tissue to ascertain the location of these items before the procedure ends.

Other technological approaches will emerge. No matter which "counting" modality a facility adopts, none is a panacea for the risk of foreign object retention. All technologies need to be used precisely, as designed and in accordance with the manufacturer's instructions. As with any new technology or approach, all team members must be alert to possible unintended consequences of its use (e.g., electrical interference with other equipment or overreliance on the additional margin of safety provided by an approach, which may lead to less vigilance).

INCORRECT COUNTS. An "incorrect" or unreconciled count occurs when the number of items on the count record or worksheet fails to match the number of items recovered during a closing count. All incorrect closure counts should be reported immediately, and attempts made to resolve every discrepancy. If the count remains unresolved, the circulating nurse again notifies the surgeon of the unresolved count, and a search is made for the missing item, including the surgical wound, field, floor, linen, and trash (thus, the rationale that linen and trash not leave the OR until the end of the procedure). All personnel direct their immediate attention to locating the missing item. If it is not found, an x-ray film may be taken and read by the radiologist or surgeon as specified in institutional policy. If the x-ray is negative, the count is recorded as incorrect or unreconciled and the x-ray results noted on the patient's intraoperative record. An incident/occurrence/event report should be initiated according to institution policy. Accurate counting and recording of sponges, sharps, and instruments are essential for the protection of the patient, personnel, and the institution, and are integral to effective risk management.

PATIENT SAFETY

Key Components of Sponge, Sharp, and Instrument Counts

Risk reduction strategies include good communication among the surgical team, application of standardized process, counting that includes wound exploration before the closure of the operative site, and use of technology as applicable in the facility. Prevention of retained foreign objects is a crucial part of patient safety, advocacy, and teamwork in perioperative settings.

1. The scrub person and the circulating nurse count all items in unison (concurrently), aloud (audibly), and quietly, as the scrub person touches each item (visibly). This is referred to as the "first" count.
2. Counting should not be interrupted nor should the persons who are counting be distracted.
3. If any uncertainty exists about a count, it should be repeated.
4. The circulating nurse should record the count for each type of item immediately on the count record or worksheet (see Figure 2-2).
5. If additional sponges, instruments, sharps, or other items are dispensed during the procedure, they are similarly counted, and the circulating nurse records the number added.
6. The names of the circulating nurse and the scrub person are recorded as soon as each count is completed.
7. Additional counts should be performed whenever there is a change in personnel or when a cavity is closed within a cavity, such as the uterus or heart being closed. This is sometimes referred to as a "cavity" count.
8. As the first layer of closure begins, the scrub person and circulating nurse count all items consecutively in a standardized routine (e.g., proceeding from the sterile field to the Mayo stand to the back table and then off the field, or vice versa). The count is done audibly, visibly, and concurrently. This is referred to as the "second" count.
9. The circulating nurse informs the surgeon of the results of the count.
10. The count procedure (final count) is repeated as skin closure begins.

Adapted from AORN Recommended practice on sponge, sharp and instruments counts. In *Perioperative standards and recommended practices*, 2009, Denver, The Association.

Care and Handling of Specimens

During the many years perioperative patient care has included safe handling of surgical specimens, laboratory medicine's safety practices focused on the analysis of the surgical specimen. The WHO World Alliance for Patient Safety now recognizes that to further improve patient safety in laboratory medicine, the pre- and postanalytical stages are equally important. They urge requirements for multidisciplinary, multistage, and multisystem approaches (McCoy et al, 2009). Like other areas of patient safety, laboratory labeling errors occur more frequently than commonly believed (Carraro and Plebani, 2007). Makary and colleagues (2007) found specimen labeling errors occur in 4.3 of every 1000 surgical specimens. Errors were slightly more common in outpatient (0.512%) than inpatient ORs (0.346%) and included unlabeled specimens, empty containers, incorrect laterality, incorrect or no identified tissue site, or incorrect or no patient names (Research Highlight).

RESEARCH HIGHLIGHT

Surgical Specimen Errors

It is well-established that communication errors are a major factor in sentinel events in surgical patient care. One type of communication error that poses significant risks to patients is the misidentification of a surgical specimen before its arrival in the pathology lab. This study was designed to quantify the extent to which specimen errors occur. Of 21,351 surgical specimens involved in the research analysis, there were 91 errors—for an annualized rate of 182 specimen errors a year. These errors included:

- 18—specimen not labeled
- 16—empty specimen container
- 16—incorrect laterality
- 14—incorrect tissue site
- 11—incorrect patient
- 9—no patient name
- 7—no tissue site

Procedures involving the breast had the most common specimen errors; nearly 60% of errors were associated with a biopsy procedure. The researchers aptly concluded that specimen errors are common and pose important risks to patients. Quantifying specimen error rates may be an important measure of patient safety and quality in surgical care.

Modified from Makary MA et al: Surgical specimen identification errors: a new measure of quality in surgical care, *Surgery* 141:450-455, 2007.

TJC does not specifically address specimen handling in the *2009 National Patient Safety Goals*. However, under its communication goal it requires action to improve timeliness of reporting critical laboratory results. Accurate and timely communication and delivery of specimens are necessarily implicit in timely reporting of results. The care and handling of specimens raise considerations unique to perioperative settings, and again AORN's *Recommended Practices for Care and Handling of Specimens in the Perioperative Environment* provides the best guidance. The Patient Safety box summarizes key points in safe specimen care and handling.

PATIENT SAFETY

Key Points in Handling Specimens in the Perioperative Environment

1. Assessment of specimen collecting and handling needs begins when the procedure is scheduled.
2. Procedures for correct patient and specimen identification should include consistent and accurate information on labels and forms.
3. Institute methods to prevent contamination of personnel and specimens including the proper use of preservatives.
4. Forensic specimens may require unique handling to preserve the chain of evidence.

Proper care and handling of specimens are critical to the outcome of a patient's surgery. It is the responsibility of the circulating nurse to identify, document, and care properly for specimens collected in the OR. Common specimens include blood, soft tissue, bone, body fluids, and foreign bodies. Complete and accurate identification and labeling of specimens and timely delivery to the proper laboratory for analysis are imperative. A mislabeled specimen may result in misdiagnosis and subsequent inappropriate treatment of the patient. At a minimum, each specimen is labeled with the correct patient name and identification number, specific origin of the specimen, and laterality (e.g., Jane Doe, 100001, right breast biopsy). The surgeon should provide descriptive information about the specimen (e.g., suture tag at 6 o'clock). The nurse should "repeat-back" to the surgeon information being sent to the laboratory (e.g., patient name, type of specimen, source/location, required tests, special handling needs). All specimens and their disposition are documented on the patient's intraoperative record.

Each specimen is handled according to the specific protocol established by the receiving laboratory. Generally, all tissue should be handled to preserve its integrity, kept moist, and transported to the laboratory as soon as possible. Standard transmission-based precautions should be used to protect individuals handling the specimen (see Chapter 3). Labels should identify the need for precautions and the presence of biohazardous material. Formalin, a combination of methanol, water, and formaldehyde, is frequently used to preserve specimens if they are not taken to the laboratory immediately. Formaldehyde is considered a hazardous substance. Formaldehyde fumes can cause watery eyes and respiratory irritation. Direct contact will injure human tissue. Gloves must be worn and adequate ventilation provided in areas where formaldehyde is handled. Institutional policy should describe procedures to follow in case of formaldehyde spills.

Specimens for Frozen Section. When immediate tissue identification or identification of malignancy is needed, specimens are quick-frozen, sliced, stained, and examined in the laboratory under a microscope. This method of tissue examination is called *frozen section*. Specimens for frozen section usually are placed on Telfa or into a dry specimen container. They are *never* placed in saline solution or formalin nor are they ever transported on a counted sponge. The results of frozen-section analysis are communicated to the surgeon intraoperatively. If the hospital has no system for direct pathologist-surgeon communication, the perioperative nurse receives the telephone report of a frozen section. Since this is considered a critical test result, the nurse "reads-back" the test result to the pathologist and surgeon and receives a "repeat-back" from the pathologist and surgeon to verify accurate communication of the results.

Risk for Electrical and Thermal Burns

Electrical hazards in the OR include electric shock, fire, explosions, and burns. Electric shock results from current flowing through the body and can occur from touching a damaged plug or an ungrounded piece of metal equipment. Electrosurgery works by sending a specified current from the electrosurgical unit (ESU) through the pencil or other ESU instrument (active electrode) to create sufficient heat to cut or coagulate the vessel touched by the pencil or other instrument. The current then exits the body through a dispersive electrode (sometimes called the "ground pad") and returns to the ESU. Fires and burns can result from improper use of electrical equipment such as lasers (see Chapter 7) and ESUs, particularly in the presence of an oxygen-enriched atmosphere (OEA) or flammable liquids.

Flammable liquids, such as alcohol and acetone, must be properly stored. These liquids, as well as flammable aerosol sprays, should not be used for cleaning and incidental use in hazardous locations. Key components of preventing electrical injury caused by electrical equipment including the ESU are listed in the Patient Safety box. In addition, when using an ESU, the patient must be properly grounded to prevent current from seeking an unintended path of less resistance back to ground. For example, current may pass through a patient's ring touching the stainless-steel OR bed rail and then to ground rather than through the ESU grounding device (dispersive pad) and back to the ESU ground. The greater concentration of current exiting at the smaller ring site will cause a burn that would not occur if the current had exited via the larger area of the ESU dispersive pad.

PATIENT SAFETY

Key Components to Preventing Electrical Equipment Injuries

1. Prohibit the use of any apparatus or device producing an open flame.
2. Evaluate and test all new equipment to ensure optimal safety and performance.
3. Inspect all electrical equipment, regardless of the source, for safety and proper functioning before use, and label with an inspection sticker according to institutional procedure.
4. The biomedical technician or electrical safety officer should determine whether electrical equipment (including ESUs) is safe for use.
5. Establish inventory control, regular inspection, preventive maintenance, and safety approval systems.
6. Instruct personnel in the safe use of all equipment, and require and document a return demonstration of personnel competency.
7. All personnel must be familiar with the procedure for prompt removal from use and expeditious repair of defective equipment.
8. A qualified electrician should inspect electrical outlets and equipment at designated intervals or as requested and should file written reports with the director of surgical services.
9. A standard procedure for care and use of electrical equipment should include the following:
   - The plug, cord, and connections of electrical equipment must be checked before each use for insulation integrity and secure connections.
   - All electrical cords should be of adequate length and flexibility to reach an outlet without stress and without the use of extension cords. Kinks and curls should be removed from electrical cords before plugs are inserted into wall outlets.
   - The plug, not the cord, should be handled when electrical cords are plugged into or removed from an outlet. Pulling on the cord may cause it to break at the point where it is attached to the plug.
   - Cords should not be wrapped tightly around equipment; doing so causes the protective covering to wear and breaks the wires inside the covering over time.
   - Cords always should be removed from traffic pathways before equipment such as a bed or a machine is moved. If the position of electrical equipment necessitates cords lying on the floor where people will be walking during surgery, cords should be taped down to prevent tripping.

Risk for Chemical Burns

Perioperative chemical burns most commonly occur during or after surgical site skin preparation (prepping). Skin preparation solutions should be applied with care to prevent pooling, which can lead to chemical burns. Towels should be tucked under the patient along the area to be prepped to catch any dripping solution and removed as soon as the skin prep is completed (these are sometimes referred to as "drip" towels). In addition to being a chemical irritant, prep solution may be ignited by a spark from an active electrode of the ESU or even from a charge of static electricity. Ignition of vapors can also occur as solution evaporates. Solutions used for skin preparation must be permitted to dry before application of the surgical drapes.

Pressure Injuries

Perioperative pressure injuries include nerve compression (peroneal and ulnar nerves are particularly susceptible); nerve stretching (e.g., brachial plexus extension); and pressure ulcers (especially on the coccyx, heels, or back of head in supine position). Pressure or the lack thereof also may cause vessel stasis and DVT. Each surgical position has its own predictable pressure risks and methods of prevention (see Chapter 5). As a general rule, however, the surgical team should remember that increasing the area of contact or reducing the force pushing on that area will decrease pressure. An easy to remember formula is pressure equals force divided by area ($P = F/A$). This formula explains why both thin and obese patients are at risk for pressure injuries during surgery. Thin patients tend to have a smaller area (e.g., the coccyx) directly in contact with the OR bed or a positioning device. Obese patients, on the other hand, have more force from their increased weight and body mass. Thus both situations can result in increased pressure. Padding typically reduces pressure by increasing the area over which the force is applied. Reminding scrubbed personnel not to lean on the patient reduces force applied to an area, thus also reducing pressure. Both increasing area and decreasing force combine to reduce pressure and the likelihood of pressure injury.

Medication Administration

While Hughes and Blegen (2008) report that current evidence suggests there is an adequate mechanism for medication error reporting, the knowledge base to build safer medication administration interventions in this error-prone process remains weak. Medication administration in the OR/invasive procedure room is further complicated compared to that found in other nursing care areas in that the OR often requires that the circulating nurse and scrub person jointly prepare a medication that is being administered by a third person, usually the surgeon. Vigilance in following established safe medication practices is crucial. Perioperative personnel must pay particular attention to acknowledging medication concentrations, labeling solutions in syringes and containers on and off the sterile field, and performing read backs/repeat backs. Safe medication administration practices in perioperative patient care settings are highlighted in the Risk Reduction Strategies box.

Policies and procedures should be strictly followed to check the medication or solution before it is dispensed to the sterile field. Medications and medication containers (e.g., syringes, cups, basins) both on and off the sterile field must be labeled

RISK REDUCTION STRATEGIES

Medication Safety Practices

- Follow the seven rights (7 R's) of medication delivery: right patient, medication, dose, route, time, technique, documentation.
- Use at least two patient identifiers when administering medications. Identifiers include the patient's name, assigned identification number, or bar coding in a patient ID bracelet that includes two or more specific patient identifiers.
- Identify/verify any patient allergies and sensitivities (e.g., medications, latex, foods, adhesives, chemicals).
- Review patient's medication history (including herbal remedies, over-the-counter [OTC] drugs); identify possible medication interactions or contraindications.
- When receiving a verbal or telephone order for a medication, write the complete order or enter it into the computer; then "read back" the medication order, receiving confirmation from the person who gave the order that it is correct.
- When writing the complete order or entering it into the computer, comply with the institution's "Do not use" list and list of look-alike/sound-alike drugs. Look-alike and sound-alike drugs should be stored separately.
- The circulating nurse and scrub person should audibly review and confirm the medication ordered before transfer to the sterile field. Medication verification should include drug/solution/agent name, strength, dosage, and expiration date. The medication order is sometimes part of a standing protocol on the preference card/pick list.
- Label all medications and containers with solutions (e.g., syringes, medicine cups, basins) on and off the sterile field, even if there is only one medication being used.
- Verify any medication listed on the physician's preference card/pick list with the physician before delivery to the field, labeling, or administration.
- Label any medication or solution when it is transferred from its original package to another container.
- Label each medication or solution one at a time. Verify name and concentration, complete preparation for administration, deliver to the sterile field, and label on the field before another medication/solution is prepared.
- Use medication vial transfer devices to dispense medications onto the sterile field without contaminating the medication during dispensing.
- Keep original packages from medications or solutions available for reference in the OR/procedure room until the surgery/procedure ends.
- Labels should contain the drug name, strength, amount (if not apparent from the container), expiration date when not used within 24 hours, and expiration time when expiration occurs in less than 24 hours.
- Differentiate look-alike and sound-alike products by using "tall man" lettering on products or highlighting/circling the distinguishing information to prevent errors.
- Verify all labels verbally and visually by two qualified individuals.
- Discard any unlabeled medication or solution immediately.
- The scrub person should actively communicate medication/solution name, amount, and dose when transferring it to the surgeon.
- At shift change or when personnel are relieved ("hand-off"), all medications and solutions on and off the sterile field and their labels should be reviewed by entering and exiting staff.
- Document all medications administered on the perioperative nursing record.
- Monitor patients for adverse medication reactions, and document interventions to treat adverse reactions.
- Discard all labeled containers used during the surgical procedure at the procedure's end.
- Follow procedures for reporting and responding to medication errors (adverse drug events [ADEs]), including near-misses.

Modified from AORN Guidance Statement: Safe medication practices in perioperative practice settings, *Perioperative standards and recommended practices,* Denver, 2009, The Association; Beyea SC: *Perioperative nursing data set,* ed 2, Denver, 2007, The Association; Cole LM: Documentation to reduce medication errors, *OR Nurse* 2(7):17-19, 2008; Giarrizzo-Wilson S: Clinical issues—medication practices, *AORN J* 81(6):1326-1329, 2005; Improving the OR's medication safety, *OR Manager* 23(1):17-18, 2007; ISMP Medication Safety Alert: *NurseAdvise-ERR; positive identification—not just for patients, but for drugs and solutions,* 3(8), 2005; JCAHO: *What every health care organization should know about sentinel events,* Chicago, 2005, The Association.

and processes established to verify labels. Scrub persons should identify medications by announcing the name of the medication being passed to the surgeon along with its strength. A repeat-back confirmation from the surgeon ensures that the correct dose of medication or solution is used. The institution's "Do not use" list must be applied to all medication orders and medication-related documentation that are handwritten or on preprinted forms (see Table 2-1).

TJC's list of look-alike/sound-alike drugs, based on findings from the Institute for Safe Medication Practices (ISMP), should be available to all perioperative personnel. The table lists potentially problematic drug names, potential errors and consequences, and specific safety strategies. Drugs listed, particularly relevant to perioperative settings, include ephedrine and epinephrine; hydromorphone and morphine; concentrated morphine and liquid morphine; hydroxyzine and hydralazine; various insulin brand names (e.g., Humulin and Humalog); and oxycodone and OxyContin.

Federal agencies, TJC, and individual institutions increasingly look to bar-code medication administration (BCMA) systems to reduce medication errors. Empirical studies have found a reduction in errors after BCMA implementation. However, precursors to errors, such as workarounds, interruptions, and patient and technology characteristics, continue (Carayon et al, 2007). As is the case for any new approach, the perioperative nurse must nevertheless remain vigilant for possibly unintended consequences.

Risk for Fluid or Electrolyte Imbalance

Blood Loss. Measuring blood loss is a vital procedure in the surgical management of critically ill or elderly patients, patients undergoing complex procedures, trauma and organ transplant patients, patients with abnormal bleeding or clotting time or with extensive renal/liver disease, and infants. Some anesthesia providers prefer to estimate blood loss via visual inspection of drapes, suction canisters, and used sponges. When blood loss estimates must be more accurate, weighing sponges provides a reliable means of judging the amount of blood lost and of gauging the need for transfusion. The weight of dry, unused sponges and the weight of the plastic bag for soiled

sponges must first be determined and then excluded from the weight tally. Grams (g) measured are converted to milliliters (ml) on a 1:1 basis, and blood loss estimates are reported to the anesthesia provider. The setup to weigh sponges requires a gram scale and plastic bags to hold soiled sponges. Box 2-6 details the procedure. The estimated blood loss may be part of the hand-off report in ORs that use a surgical Apgar score (Research Highlight).

BOX 2-6

Procedure to Measure Blood Loss by Weighing Sponges

1. Weigh a dry sponge in a plastic bag, and adjust the scale to register zero.
2. Place used, bagged sponges on the scale.
3. Record the scale reading: 1 g equals 1 ml of blood loss.
4. Note the blood loss on the record.
5. Add subsequent weight to the preceding weight each time sponges are weighed so that a running total blood loss, calculated from sponges, is available.
6. Measure blood in the suction canister(s) at regular intervals, subtracting the amount of any irrigating solution used.
7. Add the amount of blood loss calculated from suction canisters to the total recorded from sponges to obtain accurate blood loss estimates.

RESEARCH HIGHLIGHT

The Surgical Apgar Score

In 1953, Virginia Apgar introduced a 10-point scoring system to evaluate the condition of a newborn. The Apgar score revolutionized obstetric care. About 20 years later, interest in a similar scoring system has led to the development and testing of a surgical Apgar score to provide a routine, reliable scoring method to measure a patient's condition and the chances of major complications or death at the end of surgery. Researchers from Harvard and Brigham and Women's Hospital, Boston, developed a 10-point score, similar to an Apgar score, based on a patient's estimated amount of blood loss (EBL), lowest heart rate, and lowest mean arterial pressure during general or vascular surgery. They validated the surgical Apgar score on 4119 general and vascular surgery patients, finding a consistent trend toward worse outcomes with lower scores. Patients with scores of 9 or 10 had only a 5.0% incidence of major complications and a 0.1% incidence of death. On the other hand, patients with scores of 4 or less had a 56.3% incidence of major complications and a 19.5% incidence of death. The researchers concluded that the simple 10-point surgical Apgar score can successfully identify patients at higher and lower than average risk of major complications and death after surgery.

Perioperative nurses frequently accompany surgical patients to PACU and participate in the hand-off report. One of the intraoperative measures they often track and report or record is EBL. This measure may become a routine category in hand-off reports as the anesthesia provider and perioperative nurse collaborate to report measures used in assigning surgical Apgar scores.

Adapted from Gawande AA et al: An Apgar score for surgery, *J Am Coll Surg* 204:201-208, 2007; Regenbogen SE et al: Utility of the surgical Apgar score: validation in 4,119 patients, *Arch Surg* 144:30-36, 2009.

Blood and Blood Products. Maintenance of circulating blood volume is crucial during surgical procedures; this is accomplished with administration of whole blood or blood components (History box). Whole blood is rarely administered unless the patient has an acute, massive loss (often empirically determined as a loss that exceeds one third of the circulating volume, or approximately 1500 ml for an adult). Instead, packed red blood cells (PRBCs) that improve oxygen-carrying capacity and oxygen transport to tissues, with or without crystalloid or colloid solutions, are administered to maintain intravascular blood volume. Crystalloid solutions include normal saline and lactated Ringer's solution; colloid solutions include albumin, purified protein factors, dextran, and hydroxyethyl starch (hetastarch). If coagulopathy is an issue, fresh frozen plasma (FFP) platelets and cryoprecipitate sould be considered. When blood or any blood products must be given, appropriate precautions are necessary to reduce the hazards of its administration.

Elective surgery patients who may need blood products during surgery have a pretransfusion sample taken 1 to 7 days (facility policy and patient history dependent) before surgery to ensure compatibility and to avoid antibodies that may emerge in response to exposure through blood transfusions, pregnancy, or environmental factors or as a consequence of the

HISTORY

Blood Transfusion

The safe transfusion of blood and blood products is commonplace in surgery. It is a relatively recent advance, however, compared with other surgical milestones. Bloodletting and phlebotomy, described in many historical references, were recommended for many ailments, including insanity. Transfusions were attempted several hundred years ago to change the nature of an individual; for example, they were used for individuals accused of being witches, to infuse them with the proper sprits. In 1825 Dr. Philip Syng Physick of Philadelphia administered what might have been the first successful transfusion of human blood. In the 1900s the A, B, AB, and O blood types were discovered, and by the 1940s techniques for cross-matching, anticoagulation, storage of blood, and blood banks made routine blood transfusion possible. A 1942 nursing textbook noted, "blood transfusion is a procedure employed in the treatment of severe shock, especially when accompanied by hemorrhage, whether due to injury or some such emergency…." The textbook showed a procedure for "taking blood," wherein a cuff was applied to the arm to distend the veins, a venesection needle with rubber tubing attached was inserted, and the blood was drained by gravity into a glass bottle that was rotated by an assistant to ensure that it mixed properly with the citrate solution already in it. A second assistant was shown who "may suck the air out of the bottle and so hasten the flow of blood" during the "taking blood" procedure. After the blood was taken, the glass bottle had beads added to it to prevent clots from passing out, glass tubing was placed in the rubber tubing so that the flow of blood could be observed, and a flattened end was placed at the administration part of the tubing so that blood (but not the beads) could pass into the patient. It was noted that a syringe could be used to blow air into the bottle if blood was running too slowly.

Modified from Fakhry SM et al: Hematologic principles in surgery. In Townsend CM, editor: *Sabiston textbook of surgery,* ed 16, Philadelphia, 2001, Saunders; Houghton M: *Aids to tray and trolley setting,* ed 2, London, 1942, Bailliere, Tindall & Cox.

patient's disease process. *Type* refers to the test to determine the ABO and Rh blood type. Screen refers to the test for unexpected antibodies. *Crossmatching* refers to the test for the compatibility of the recipient's serum and the donor's red blood cells. It is crucial to identify the patient correctly before the pretransfusion blood sample is drawn and then to ensure that the sample is properly labeled (Hendler, 2008). Improperly identified pretransfusion blood samples can result in acute hemolytic transfusion reactions at the time of transfusion.

A patient having an elective surgical procedure for which blood has been requested should not be anesthetized without verification that the requested blood products are typed, crossmatched, and available and that informed consent to receive blood products has been documented. This should be part of the preoperative verification process and then reverified during the time-out. An institutional blood requisition form, with complete and accurate patient identification information, should be sent to the blood bank when blood or blood products are being requested. Included on or with this requisition should be the number of units desired. Many institutions have computerized ordering and the same information is required.

If the patient is sent to the OR directly from the emergency department or trauma admitting area without a chart, all patient identification information must be printed plainly on a piece of paper. The perioperative nurse should contact the blood bank to explain the emergency situation and facilitate release of the needed blood products.

Storage of blood products is important to ensure patient safety and to avoid wasting improperly stored products. Whole blood and blood products must be stored under continuously monitored conditions, in accordance with the American Association of Blood Banks (AABB) rules and FDA regulations. Temperatures must be documented and all storage equipment for blood products must be properly maintained and tested, including function checks on alarms. When blood components have been out of monitored refrigeration for more than 30 minutes, they cannot be returned to the blood bank for reissue. Always follow facility policy for return of unused blood products and be aware each component has specific requirements.

Before administration of any blood product, the circulating nurse and anesthesia provider (or a second licensed individual) must confirm the following:

- The unit number on the blood product corresponds with the unit number on the blood requisition. Facilities using electronic records will return a "transfusion card" or "crossmatch card" as verification that this unit can be given to this patient in lieu of the requisition.
- The name, birth date, and number on the patient's identification band agree with the name, birth date, and number on the blood product.
- The patient's name on the blood product corresponds with the name on the requisition.
- The blood group indicated on the blood product corresponds with that of the patient.
- The date and time of expiration has not been reached.
- The blood product bag is free of leaks, damage, or signs of possible bacterial contamination (e.g., presence of fine gas bubbles, discoloration, clots or excessive air in the bag).

Both individuals who verify this information must sign the slip that comes with the blood product. If a discrepancy arises with any of these checks, the blood product must not be infused until and unless the discrepancy is resolved.

When it becomes apparent that additional blood products will be needed than originally anticipated, the perioperative nurse should request the blood bank prepare a specified number of units in advance of the actual need to transfuse. This procedure allows the blood bank time to crossmatch the units carefully, without rushing and jeopardizing patient safety. Crossmatch requisitions should be sent for any additional units requested. If a significant amount of blood product has been required, a new, properly labeled sample with a blood grouping requisition may be needed to have adequate serum for crossmatching or to ensure antibody compatibility although blood banks prefer using the original undiluted sample when possible.

Rapid blood transfusion requires warming of blood product to prevent hypothermia, which may induce cardiac arrest. Blood product should be warmed during its passage through the transfusion set. The warming device must incorporate a temperature monitor and, ideally, an audible warning system. The probability of a transfusion reaction increases in direct proportion to the number of units transfused. The circulating nurse should be alert to any signs of reaction, including the following:

- Hyperthermia
- Increased intraoperative bleeding
- Weak pulse
- Hypotension
- Visible hemoglobinuria
- Vasomotor instability
- Greatly decreased or no urinary output

If any such suspicious signs of reaction occur, the circulating nurse should assist the anesthesia provider to do the following:

1. Stop the transfusion. The tubing is disconnected and a new infusion of fluid such as 0.9% sodium chloride is begun to maintain venous access.
2. Report the reaction to the surgeon and blood bank immediately.
3. Anticipate possible order for stat antihistamines.
4. Return the unused portion of the blood product, the IV tubing used during the transfusion, and a sample of the patient's blood to the blood bank.
5. Send a urine sample to the laboratory if requested.
6. Monitor the patient's reaction carefully.
7. Complete an incident/occurrence/event report covering the details of the suspected reaction. These might include time and date of reaction, type and amount of blood/blood product infused, and times transfusion started and stopped. Signs and symptoms, in the order of occurrence, along with the patient's vital signs, any urine or blood samples sent to the laboratory for analysis, any treatment given, and the patient's response should all be noted. A suspected transfusion reaction report must be sent to the blood bank.

Any unused blood product should be returned to the blood bank as soon as the patient leaves the OR. Returned blood can be reissued if it has not been allowed to warm to a temperature greater than 10° C or been out of monitored refrigeration for more than 30 minutes. New external blood bag thermometers (e.g., HemoTemp II), similar to a skin contact tape thermometer, are being used on blood product bags by many blood banks to quickly identify blood that has exceeded safe storage temperatures.

Autotransfusion—the reinfusion of a patient's own blood—is being used with increasing frequency. In autologous blood donations, the blood is predonated typically 3 to 5 weeks before surgery for use in the patient's own planned surgery. During intraoperative autotransfusion (cell salvage), blood is collected as it is lost during the surgical procedure and reinfused to the patient after it is filtered or washed. This technique can be lifesaving in emergency situations, as with major trauma, or in procedures with major blood loss, as in liver transplantation. It is also used for patients who refuse blood based on religious beliefs.

Maintaining Fluid and Electrolyte Balance

Fluid and electrolyte balances are important to the health and safety of the patient in surgery. The body's fluids and electrolytes play a key role in maintaining homeostasis, transporting necessary oxygen and nourishment to the cells, removing waste products of cellular metabolism, and helping to maintain body temperature. Electrolytes are also essential to transmission of nerve impulses, regulation of water distribution, contraction of muscles, generation of adenosine triphosphate (ATP, needed for cellular energy), regulation of acid-base balance, and hemostasis (clotting blood). The intake, distribution, and output of water and electrolytes, regulated by the renal and pulmonary systems, normally maintain fluid and electrolyte balance.

Fluid and electrolyte imbalances may occur rapidly in the surgical patient, and can be caused by numerous factors, including preoperative fluid and food restrictions, intraoperative fluid loss, or the stress of surgery. The surgical patient is unable to regulate body fluid and electrolyte requirements by normal activities of drinking, eating, excreting, and breathing unaided. It is therefore imperative that the perioperative nurse monitor and collaborate in controlling the fluid and electrolyte status of the patient intraoperatively.

Body Fluids. The adult human body is approximately 60% water, although water content varies by age, gender, and body mass. In the elderly, body water content averages 45% to 55% of body weight, whereas it ranges from 70% to 80% in infants. Older adults are at higher risk for fluid balance problems because they have less fluid reserve, while the very young are at risk for fluid problems because a greater percentage of their body weight is water. Both age groups have a decreased ability to compensate for fluid loss. Muscular tissue contains more water than the same amount of adipose tissue; men generally have higher water content because they usually have more lean muscle mass than women.

Body fluids are distributed in two main functional compartments—intracellular and extracellular. *Intracellular fluids (ICFs)* are liquids within cell membranes that contain dissolved substances essential to fluid and electrolyte balance and metabolism. Intracellular fluids constitute approximately 70% of the body's fluid. Consequently, anything that affects water loss at the intracellular level has significant implications for the entire body. *Extracellular fluids (ECFs)* (30% of the body's fluid) are fluids in compartments outside the cells of the body, including plasma, intravascular fluids, fluids in the gastrointestinal (GI) tract, and cerebrospinal fluid (CSF).

Fluid spacing is a term used to classify distribution of body water. *First spacing* is the normal distribution of fluid in extracellular and intracellular compartments. *Second spacing* refers to excess accumulation of interstitial fluid (edema), while *third spacing* occurs when fluid accumulates in areas that normally have no fluid or only a minimal amount of fluid. This fluid accumulation occurs with burns, ascites, peritonitis, or small-bowel obstruction. Third spacing traps fluid away from normal fluid compartments and results in a deficit in extracellular fluid volume.

Electrolytes. Electrolytes (Table 2-2) are found in both intracellular fluids (ICFs) and extracellular fluids (ECFs). When dissolved in water, electrolytes dissociate into ions and are able to carry an electric current. Positively charged ions are cations, and negatively charged ions are anions. The electrolytes found in the ICF and ECF are essentially the same, but their concentrations in each compartment differ. The primary intracellular cation is potassium, and the primary extracellular cation is sodium. The primary intracellular anion is phosphate, and the primary extracellular anion is chloride. Fluids and electrolytes move between the intracellular and extracellular spaces to facilitate body processes, such as acid-base balance, tissue oxygenation, response to drug therapies, and response to illness. Diffusion, active transport, and osmosis control this movement.

Diffusion, Active Transport, and Osmosis. *Diffusion* is the movement of molecules from an area of high concentration to one of low concentration. When diffusion occurs across a membrane, movement continues until there is an equal concentration of molecules on both sides of the membrane.

Active transport is a process by which molecules are moved across a cell membrane against a concentration gradient (i.e., from an area of low concentration to an area of high concentration) with the use of external energy. The sodium-potassium pump moves sodium out of the cell and potassium into the cell to maintain the intracellular and extracellular concentration differences of sodium and potassium. ATP is the energy source for the sodium-potassium pump.

Osmosis is the movement of a fluid through a semipermeable membrane from a solution that has a lower solute concentration to one that has a higher solute concentration (Figure 2-3). The semipermeable membrane prevents movement of solute particles. The number of particles is measured in a unit called the osmole *(osm)*. *Osmolality* is the term used to express the concentration of a solution in milliosmoles per kilogram (mOsm/kg) of water. A solution with the same osmolality as blood plasma is called *isotonic*. Isotonic solutions, such as 0.9% normal saline or lactated Ringer's solution administered intravenously (IV), prevent the shift of fluid and electrolytes from intracellular compartments. A hypotonic IV solution (0.45% saline or 2.5% dextrose) has a lower concentration of solutes than that found in plasma and moves water into the cells. Administration of a hypertonic IV solution (5% dextrose in normal saline or 5% dextrose in lactated Ringer's solution) with a greater concentration of solutes than that of plasma moves water out of the cells.

Preoperative Considerations. A crucial part of assisting the surgical patient to maintain fluid and electrolyte balances is preoperative assessment and identification of risk factors for fluid and electrolyte imbalances. Preoperative laboratory analysis of electrolyte levels should be checked and abnormalities

TABLE 2-2

Electrolyte Functions and Regulators

Electrolyte	Reference Range	Functions	Regulation
Sodium (Na^+)	135–145 mEq/L	Maintains blood volume Controls water shifting between compartments Major cation involved in sodium-potassium pump necessary for nerve impulse conduction Interacts with calcium to maintain muscle contraction Major cation in bicarbonate and phosphate acid-base buffer system	Renin-angiotensin-aldosterone system ◆ Retains sodium and water is passively absorbed
Potassium (K^+)	3.5–5 mEq/L	Affects osmolality Major cation involved in sodium-potassium pump necessary for nerve impulse conduction Promotes nerve impulse conduction, especially in heart and skeletal muscles Assists in conversion of carbohydrates to energy and of amino acids to protein Promotes glycogen storage in liver Assists maintenance of acid-base balance through cellular exchange with hydrogen	Renin-angiotensin-aldosterone system ◆ Kidneys excrete potassium in exchange for sodium
Calcium (Ca^{2+})	4.5–5.5 mEq/L (or 9-11 mg/ml)	Nonionized form promotes strong teeth and bones Promotes blood coagulation Promotes nerve impulse conduction; decreases neuromuscular irritability Strengthens and thickens cell membrane Assists in absorption and utilization of vitamin B_{12} Activates enzymes for many chemical reactions Inhibits cell membrane permeability to sodium Activates actin-myosin muscle contraction	Parathyroid hormone, calcitonin, and vitamin D ◆ Increases calcium reabsorption from bone ◆ Increases calcium reabsorption by inhibiting phosphate reabsorption from kidney tubules ◆ Increases calcium absorption from gastrointestinal tract
Chloride (Cl^-)	98–106 mEq/L	Inhibits smooth muscle contraction Regulates extracellular fluid volume Promotes acid-base balance through exchange with bicarbonate in red blood cells (chloride shift) Promotes protein digestion through hydrochloric acid; acid pH required for activation of protease	Renin-angiotensin-aldosterone system ◆ Kidneys excrete chloride if body fluids are acidic and reabsorb it if body fluids are alkalotic
Magnesium (Mg^{2+})	1.5–2.5 mEq/L	Promotes metabolism of carbohydrates, fats, and proteins Activates many enzymes (B_{12} metabolism) Promotes regulation of Ca^{2+}, PO_4^{2-}, K^+ Promotes nerve impulse conduction, muscle contraction, and heart function Powers sodium-potassium pump Promotes conversion of adenosine triphosphate to adenosine diphosphate for energy release	Kidneys ◆ Increases or decreases magnesium reabsorption in kidney tubules according to need
Phosphate (HPO_4^-)	1.2–3 mEq/L (or 2.5–4.5 mg/ml)	Nonionized form promotes bone and teeth rigidity Promotes acid-base balance through phosphate buffer system Necessary for adenosine triphosphate production	Parathyroid hormone, calcitonin, and vitamin D ◆ Increases phosphate resorption from bone ◆ Inhibits phosphate reabsorption in kidney tubules ◆ Increases phosphate absorption in gastrointestinal tract as needed

From Harkreader H et al: *Fundamentals of nursing: caring and clinical judgment,* ed 3, St Louis, 2007, Saunders.

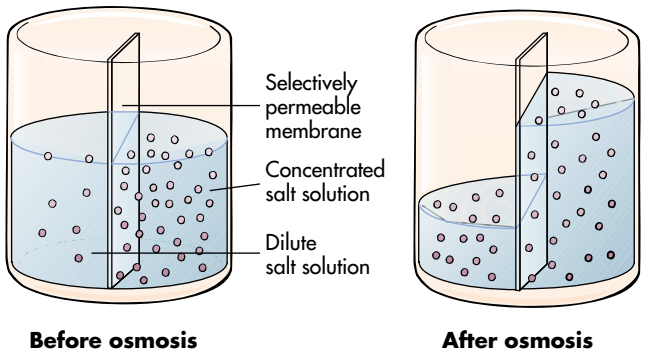

FIGURE 2-3 Osmosis is the movement of solvent molecules across a membrane to an area of higher solute concentration. The solvent moves because the solute cannot pass through the membrane. The result of osmosis is two solutions, separated by a selectively permeable membrane, that are equal in concentration.

corrected to within normal limits before any surgical procedure, unless the surgery is needed to correct a life-threatening problem. Preexisting conditions, such as diabetes mellitus, liver disease, or renal insufficiency, may be aggravated by surgical stress, increasing a patient's risk of fluid and electrolyte imbalances. Diagnostic procedures that require the administration of IV dyes may produce osmotic diuresis, with resulting urinary excretion of water and electrolytes. Preoperative steroids or diuretics affect the excretion of water and electrolytes; diuretics, used in the management of hypertension, cause the loss of potassium. Preoperative surgical regimens, such as bowel cleansing routines, may act to increase fluid loss from the GI tract. Medical management of preexisting conditions, such as gastric suction, can also affect fluid and electrolyte balance in the surgical patient, as can preoperative fluid restriction.

Preoperative fluid restrictions are used to reduce nausea, vomiting, and aspiration risk in the surgical patient. This practice is being modified in many healthcare settings because newer anesthetic agents cause less nausea and vomiting than in the past. Prolonged fluid restrictions may not be necessary in healthy patients before surgery (Anderson and Comrie, 2009); black coffee or pulp-free juice may be ingested 2 to 3 hours before surgery safely, without an increase in gastric volume (see Chapter 4).

Deficient Fluid Volume. The most common patient problems associated with fluid and electrolyte balance during surgery include deficient fluid volume (DFV), water imbalances, and potassium imbalances. DFV is an imbalance in isotonic body fluids related to decreased intravascular, interstitial, or intracellular fluid. Very young and very old surgical patients are affected most rapidly by fluid losses from bleeding; inadequate intake because of previous nothing-per-mouth (NPO) status; inadequate IV fluid replacement; excessive cutaneous losses from fever and sweating; third-space fluid losses attributable to bowel obstructions, ascites, or peritonitis; excessive GI losses resulting from diarrhea, vomiting, GI suctioning, or fistulas; evaporation of fluid from the exposed peritoneum during abdominal surgery; shifting of intravascular fluid into the surgical site (third-space edema); and inhalation of dry gases. Third-space fluid losses cannot be measured directly, but can be considerable after extensive dissection of tissue. Intraoperative use of an electrolyte solution, such as lactated Ringer's solution, for fluid replacement can help correct intraoperative third-space fluid losses.

The effect of fluid loss on the surgical patient depends on the amount of fluid lost and the speed at which the fluid is lost. A patient who loses a large amount of fluid (>500 ml) or loses fluid rapidly exhibits symptoms of shock; immediate fluid replacement therapy is required. A slow loss of fluid may be compensated through albumin synthesis and erythropoiesis.

Sodium and Water Imbalances. Sodium is a cation in ECF; sodium plays a major role in maintaining the osmolality and water balance of the extracellular fluid. Because cell membranes are permeable to water, it also affects ICF volume. Sodium also helps maintain acid-base balance in the body. The sodium-potassium pump plays a vital role in neuromuscular activity.

Hyponatremia (serum sodium level <135 mEq/L) can be caused by increased excretion of sodium with diuretic therapy and the abnormal loss of sodium through nasogastric (NG) suctioning and third spacing. Patients undergoing procedures such as transurethral resection of the prostate (TURP) or uterine endoscopic laser surgery are at risk for dilutional hyponatremia and volume overload, caused by absorption of the irrigation solution used. Because saline is a good conductor of electrical current, fluids that contain no electrolytes, such as glycine, sorbitol, and mannitol, must be used to irrigate in the presence of the electrical current used in tissue dissection during these procedures.

Potassium Imbalances. Potassium is the major intracellular cation and is necessary for contraction of skeletal muscle and smooth muscle. It is necessary for cardiac contractions and for peristaltic movements of the GI tract. It also plays a major role in the transmission of nerve impulses by regulating neuromuscular excitability and in the formation of muscle protein by transporting glucose into the cells with insulin. Potassium also is involved in the maintenance of acid-base balance and intracellular osmotic pressures.

Hypokalemia (serum potassium concentration <3.5 mEq/L) can occur intraoperatively as a result of the suctioning of large amounts of body fluids or using diuretic therapy and other drugs (e.g., mannitol) that increase renal flow. Signs and symptoms of hypokalemia include cardiac effects, such as ectopy, dysrhythmias, conduction abnormalities, and altered sensitivity to digitalis. The neuromuscular effects of hypokalemia include muscle weakness; smooth muscle effects include gastric distention, paralytic ileus, and urinary retention.

Treatment of hypokalemia includes IV replacement when the deficit is severe, as in the development of cardiovascular or other serious symptoms. Potassium irritates veins on infusion; the infusion site should be monitored for redness, heat, swelling, or site pain—all signs of chemical phlebitis. Overcorrection and subsequent hyperkalemia must be avoided by monitoring serum potassium levels at frequent intervals (often every 2 to 4 hours).

Hyperkalemia, a serum potassium level of more than 5 mEq/L, can be caused during surgery by massive transfusions of stored blood; decreased excretion of potassium caused by hypovolemia or renal failure; and shifting of potassium from the cells into the ECF caused by acidosis, tissue breakdown from surgery, crush injuries, or burns. Drugs infused during

surgery can also induce hyperkalemia; such drugs include anti-inflammatory agents, β-adrenergic receptor blockers, digitalis, succinylcholine, heparin, and the penicillins.

Signs and symptoms of hyperkalemia include neuromuscular symptoms, such as weakness and paresthesias in the arms and legs. Smooth muscle symptoms include diarrhea and abdominal distention. Excess potassium can cause serious cardiac symptoms, including ventricular dysrhythmias, heart block, and asystole. Cardiac side effects of hyperkalemia are treated by calcium gluconate. Sodium bicarbonate or insulin-glucose infusions can be given to shift extracellular potassium into the cells, reducing the level of potassium in the plasma.

PATIENT RIGHTS

Protection of a patient's personal, ethical, and legal rights underlies patient safety and risk management. Even if injury occurs, patients who feel they have been treated with respect and dignity are more likely to accept sometimes less than perfect results, are less inclined to litigate, and are more likely to cooperate with postinjury treatment, regardless of fault.

Privacy

In addition to the patchwork of state statutes that protect confidentiality and patient access to their healthcare records and privacy of healthcare data, federal law provides that patients must consent for their health information to be used for treatment, payment, or business purposes. HIPAA limits use or disclosure of protected health information to ensure patient privacy rights with respect to this information, and healthcare facilities must have administrative procedures to protect the privacy and confidentiality of all patient information. Facility policies should include protocols specific to perioperative settings, such as the presence of healthcare industry representatives in the OR.

Perioperative nurses must protect patient privacy even if HIPAA, state law or facility protocol does not specifically address a privacy issue. Care is taken to protect patient's bodies from any more exposure than is required by a procedure. Likewise, comments made in or out of patient care areas about the patient's appearance, lifestyle, or social status, for example, are never appropriate unless required for the safe care of that patient.

Autonomy

Legal cases have long recognized that every adult has the right to determine what happens to his or her body (e.g., *Schloendorff v. Society of New York Hospitals,* 105 N.E.92 [N.Y., 1914]). This legal right is also an ethical right recognized under the ethical principle of respect for persons as autonomous beings (Beauchamp and Childress, 2008). In perioperative practice settings, these rights are protected via informed consent processes for the procedure itself and/or for any research interventions, and via patient wishes expressed in advance directives for healthcare.

Informed Consent

Except in emergencies, surgical procedures should not be performed without documentation of the patient's consent on the chart (Figure 2-4). How this "informed consent" is documented should be described in facility policy, but it is typically accomplished by means of a signed consent form and/or the primary surgeon's entry into the progress notes, which may or may not also be signed by the patient. The surgeon or practitioner performing the procedure is responsible to inform the patient about the proposed operation or other invasive procedure and its inherent risks, benefits, alternatives, and complications before obtaining the patient's oral and written consent. The patient must receive this information in terms that he or she can understand. The patient also must be informed who will perform the procedure and when practitioners other than the primary surgeon will perform important parts of the procedure, even when under the primary surgeon's supervision. Consent documentation must be complete before administration of preoperative medications. On the patient's arrival in the OR, the circulating nurse and anesthesia provider are responsible to verify that documentation of the consent is in the chart and is correct, properly signed, and witnessed before the administration of anesthesia. Typically, the consent process documentation encompasses the following:

- The patient's name (and legal guardian, if applicable)
- Name of facility where the procedure is being performed
- Specific name of the surgical procedure (or when multiple procedures are being done, the names of those procedures) in terms the patient understands
- Site/side of the planned procedure
- Name of the practitioner or practitioners performing the procedure or important aspects of it
- Risks of the procedure
- Alternative procedures, treatments, or therapies
- Signature of the patient (or legal guardian, if applicable)
- Date and time consent is obtained
- Statement that procedure was explained to the patient (or legal guardian or both if applicable)
- Name and signature of person who explained the procedure
- Signature of person witnessing the consent

Nurses who are involved as witnesses to the signing of the consent form attest only to the validity of the patient signature, time, and date. By signing as a witness, they do not assure the adequacy of the patient's understanding, as that assurance remains the duty of the surgeon.

Advance Directives and DNR Orders

Many individual states had statutes to allow patients to make their wishes regarding their future known in a legally recognized fashion if they were unable to do so when a life-threatening situation arose. Then, in the wake of the first U.S. Supreme Court case to deal with the issue, *Cruzan v. Director, Missouri Department of Health,* 497 U.S. 261 (1990), the U.S. Congress in 1991 passed the Patient Self-Determination Act (PSDA) to extend legal protection to all U.S. citizens and residents. Under the Act, patients have the legal right to accept or refuse medical treatment, including resuscitation, even if refusal will likely result in death. The PSDA also provided that all patients admitted to Medicare and Medicaid recipient providers be asked whether they have executed, or wish to be given information about, such an advance healthcare directive, and that information must be included in the patient's medical record. If a patient arrives in a preoperative area with such a directive, the perioperative nurse should immediately clarify with the surgeon and/or anesthesia provider if there has been a presedation discussion with the patient as to the effect the directive should have in the immediate perioperative period.

Date of procedure: _____

Patient name:

Date of birth:

I, _____ (Type or print patient name), request and give consent to _____ (Type or print doctor or practitioner name(s))

to perform the following procedure(s) _____ (Please list site and side if appropriate)

_____

The benefits, risks, complications, and alternatives to the above procedure(s) have been explained to me.

I understand that the procedure(s) will be performed at Christiana Care by and under supervision of my doctor or practitioner. My doctor or practitioner may use the services of other doctors or practitioners, or members of the resident staff as he or she deems necessary or advisable.

I authorize my doctor or practitioner and his or her associates and assistants to perform such additional procedures, which in their judgment are necessary and appropriate to carry out my diagnosis or treatment.

I authorize the hospital to retain, preserve and use for scientific, teaching purposes, or to make other dispositions of, at their convenience, any specimens, tissues, or parts taken from my body during the course of this operation.

I consent to observers in the procedure area in accordance with hospital policy. I consent to a healthcare industry representative being present during the procedure, if necessary, to provide technical assistance or to perform calibration of equipment. I consent to photography or video taping of my surgical procedure for educational purposes, provided my identity remains anonymous and confidential.

I agree to being given blood or blood products as deemed advisable during the course of my procedure. The risks, benefits, and alternatives to receiving blood or blood products have been explained to me.

I consent to the administration of sedation or analgesia during my procedure. The risks, benefits, and alternatives to receiving sedation or analgesia have been explained to me.

If anesthesia is required, I consent to the administration of anesthesia by members of the Department of Anesthesiology. I also consent to the use of non-invasive and invasive monitoring techniques as deemed necessary. I understand that anesthesia involves risks that are in addition to those resulting from the operation itself including, but not limited to, dental injury, hoarseness, vocal cord injury, infection, nerve injury, corneal abrasion, seizures, heart attack, stroke and even death.

If applicable, I consent to the use of fluoroscopy. I understand that prolonged exposure to fluoroscopy may result in skin reactions, such as redness, irritation or a burn.

Please initial one of the following statements (females and those within child bearing years only):

_____To the best of my knowledge I am not pregnant. _____I believe I am not pregnant.

I certify that I have read and understand the above consent statements. In addition, I have been offered the opportunity to ask my doctor or practitioner any questions I have regarding the procedure(s) to be performed and they have been answered to my satisfaction. I acknowledge that I have been given no guarantee or assurance as to the results that may be obtained from the procedure(s).

Signature of patient or decision maker	Date	Time	Doctor or practitioner signature/title	Date	Time
Relationship to patient if decision maker			Doctor ID # or print name		
Witness signature	Date	Time	Practitioner print name		
Witness print name					

Telephone Consent:

Name of person consent obtained from			Relationship to patient if decision maker		
Witness signature	Date	Time	Witness signature	Date	Time
Witness print name			Witness print name		

FIGURE 2-4 Consent for procedure.

The PSDA does not address this issue, but an automatic suspension or continuation of advance directives or DNR orders is not justified under either a legal or an ethical analysis. Again, facility policy should describe a procedure that preserves the patient's right to legal and ethical self-determination.

Veracity and Fidelity

Veracity includes providing accurate information. Fidelity or loyalty carries with it an implicit promise of truth telling. Both principles relate to respect for persons and autonomy—that patients are entitled to the respect of full and accurate information and disclosure. These principles relate most directly to the patient's right to informed consent. Within the patient safety and risk management context, however, veracity and loyalty also demand transparency in disclosure of adverse events to the patient/family. Some states (e.g., Pennsylvania, Florida, and Utah) legally require patient notification when an error occurs (Griffin, 2008, citing Liebman and Hyman, 2004).

Griffin (2008) reviewed data that demonstrated transparency and disclosure after an error has occurred can minimize the consequences of litigation. In fact, articles encouraging full disclosure do so more as a risk management issue than as an issue concerning patient rights (Wojcieszak et al, 2006). In any event, one consequence of the renewed emphasis on patient safety and patient rights has been to merge the heretofore separate systems of perioperative care provision, risk management, and quality improvement (ECRI Institute, 2009) under a patient safety rubric that has enhanced the effectiveness of each.

CHAPTER 3

Infection Prevention and Control in the Perioperative Setting

LILLIAN H. NICOLETTE

Advancements in surgical interventions and the science of infection prevention and control continue to evolve and have become increasingly complex. The complexity is derived from the changes in the healthcare environment, the advancements in minimally invasive and advanced surgical procedures, and the development of new, highly technical instrumentation and equipment. This chapter will provide an overview of the etiology of infection, including emerging drug-resistant bacteria, and will identify various methods to control infection in the perioperative environment. Use of Standard Precautions along with engineering and work-practice controls assists perioperative practitioners in reducing the transmission of pathogenic organisms. Perioperative patient care is based on surgical aseptic principles. Careful adherence to these principles supports infection prevention and control, ultimately improving surgical patient safety and outcomes. Each member of the surgical team must demonstrate the highest integrity in the application of this knowledge. Finally, in today's world, the potential for bioterrorism has forced the United States along with the rest of the world to strengthen security and emergency readiness. If a bioterrorism attack resulted in massive exposure or illness, perioperative personnel could and would be mobilized to serve in a variety of locations, such as in the New York World Trade Center attacks of 2001 and the London tube attacks in July 2005. These attacks redefined the meaning of disaster preparedness for all practitioners. Perioperative personnel need to be familiar with the most likely biologic weapons and the levels of precautions required for patient and personnel safety.

CAUSES OF INFECTION

The human body has three lines of defense to combat infection. The first line of defense consists of *external barriers,* such as the skin and mucous membranes, which are usually impervious to most pathogenic organisms. The second line of defense is the *inflammatory response,* which prevents an invading pathogen from reproducing and possibly involving other tissue. The third line of defense, the *immune response,* is triggered after the inflammatory response. When there is a break in this defense mechanism, the possibility for infection increases (see Box 3-1 for definitions of terms).

Microorganisms that Cause Infection

Microorganisms are living organisms that are too small to be seen with the naked eye. These organisms include bacteria, fungi, protozoa, algae, and viruses. Microorganisms are classified to determine appropriate treatment for an infection. Each organism is assigned two names; the genus is the first name, and the specific epithet (species) is the second. Bacteria are further described by shape, motility, growth in aerobic or anaerobic environments, and reaction to staining processes (Figure 3-1). Scientific names can be assigned to organisms in various ways. *Staphylococcus aureus* is a microorganism commonly found on the skin. *Staphylo* describes the clustered arrangement of the cells; *coccus* (Greek *kokkos,* "berry") indicates that they are shaped like spheres. The species *aureus* is Latin for "golden," the color of the colonies of the bacterium. Bacteria cause most surgical site infections (SSIs). Gram-positive cocci, as a group, are the most common cause of SSIs. The organisms most commonly found in postoperative SSIs include staphylococcal, enterococcal, pseudomonal, and streptococcal species. *S. aureus* is the most frequently identified organism.

Staphylococci. Staphylococci are gram-positive cocci. They are facultative anaerobes but grow best under aerobic conditions. Staphylococci can be found in the indigenous flora of the skin and mucous membranes of the nasopharynx, urethra, and vagina. They are resistant to drying, heat, and high salt concentrations.

The two recognized species of staphylococci are *S. aureus* and *S. epidermidis.* Staphylococci are called *coagulase positive* when they are capable of clotting plasma and *coagulase negative* when the plasma clumps them. Coagulase-positive staphylococci are more virulent or pathogenic than coagulase-negative staphylococci. *S. aureus* is hemolytic, parasitic, pathogenic, and coagulase positive. *S. epidermidis* is parasitic, less pathogenic, and coagulase negative. *S. aureus* is a long-recognized cause of surgical site infections. More recently, *S. epidermidis* has been implicated in infections of prosthetic devices (CDC, 2008a).

The skin surface is the most common site of *S. epidermidis.* Approximately 30% to 70% of individuals carry staphylococci on their skin. This can lead to contamination of clothing and dispersal of the microorganisms. For no known reason, individuals who are skin carriers of staphylococci differ in the rate at which they shed the microorganisms. There is no obvious difference in hygiene and skin condition between light and heavy shedders and no other contributing factor is apparent. Heavy shedders seem to be in normal good health.

S. aureus infections in hospitals can lead to prolonged hospital stays and may result in death. *S. aureus* has been found in the nasal passages of 25% to 35% of the adult population

BOX 3-1

Definition of Terms

Aeration Method by which absorbed ethylene oxide (EO) is removed from EO-sterilized items.

Aerobes Microorganisms unable to live and reproduce without access to free atmospheric oxygen, such as *Mycobacterium tuberculosis*.

Anaerobes Bacteria able to survive only in the absence of molecular oxygen, such as *Clostridium perfringens*.

Bioburden Amount of microbial load and organic debris on an item before sterilization.

Biofilm A thin coating containing biologically active organisms that have the ability to grow in water, solutions, or in vivo and coat the surface of structures or devices. Biofilms may contain viable and nonviable microorganisms that may adhere to a surface and are trapped within organic matter.

Biological indicator A sterilization process–monitoring device commercially prepared with a known population of highly resistant spores to test the effectiveness of the sterilization process being used.

Carrier Person who harbors one or more specific pathogens in the absence of discernible clinical disease.

Cohorting The practice of grouping patients who are colonized or infected with the same pathogen.

Contamination Presence of pathogenic microorganisms on or in animate or inanimate objects. This term generally is used in reference to a specific object, substance, or tissue that contains microorganisms, especially disease-producing microorganisms.

Deep incisional SSI Infection involving deep soft tissue, fascia, and muscle.

Dynamic air removal Mechanically assisted air removal from a sterilizer's chamber. This includes prevacuum and steam flush, pressure pulsed steam sterilizers.

Facultative bacteria Bacteria with enzyme systems that permit them to live and reproduce with or without free oxygen.

Flash sterilization An abbreviated cycle; a sterilization process that is designed for immediate patient use employing the steam sterilization method.

Gram stain A procedure for staining bacteria that is the first step in classifying and differentiating them into two large groups (gram-positive and gram-negative) based on the chemical and physical properties of their cell walls.

Immunity Resistance to infection.

Infection Invasion and multiplication of microorganisms in body tissues, causing cellular injury attributable to competitive metabolism, toxins, intracellular replication, or antigen-antibody response.

Infectious agent Parasite (bacterium, spirochete, fungus, virus, or any other type of organism) that is capable of producing infection.

Healthcare-associated infections (HAIs) Infections acquired by patients during hospitalization, with confirmation of diagnosis by clinical or laboratory evidence. The infective agents may originate from endogenous sources, as from one tissue to another within the patient (self-infection), or from exogenous sources, as acquired from objects or other patients within the hospital (cross-infection). Healthcare-associated infections, which are often referred to as hospital-acquired or nosocomial infections, may not become apparent until after the patient has left the hospital.

Opportunists Microorganisms of low virulence and requiring large numbers to produce infection.

Organ or space SSI Infection involving any part of the anatomy other than the incision.

Parasites Microorganisms that reside on or within the bodies of living organisms called hosts to find the environment and food they require for life and reproduction. Some microorganisms are obligatory parasites, meaning that they depend on their hosts for survival and reproduction. Other microorganisms are facultative parasites, meaning that they normally reside on dead matter, but may receive nourishment from living matter. All disease-producing microorganisms are parasites; however, not all parasites are disease-producing.

Pathogen Any disease-producing agent or microorganism.

Primary pathogens Highly virulent organisms that are capable of producing disease in low numbers.

Resident microorganisms Organisms that habitually live in the epidermis, deep in the crevices and folds of the skin.

Reuse The repeated or multiple uses of any medical device whether marketed as a reusable or single-use device. Repeated/multiple uses may be on the same patient or on a different patient with applicable reprocessing of the device between each use.

Source Object, substance, or individual from which an infectious agent passes to a host. In some cases, transfer is direct from the reservoir, or source, to the host.

Spore Dormant stage of some bacteria that is reversible under favorable conditions. Common spore-forming bacteria include *Clostridium perfringens, Clostridium botulinum, Clostridium tetani,* and *Bacillus anthracis*.

Sterilization process–monitoring device A device used to monitor specific sterilization processes. These devices can be biologic, physical or chemical.

Superficial SSI: Infection involving skin and subcutaneous tissue as opposed to deep tissue.

Surgical site (incisional) infection (SSI) Infection involving body-wall layers that have been incised.

Toxins Protein molecules released by bacteria to affect host cells at a distant site.

Transient microorganisms Organisms with a very short life span, such as the normal flora present on the skin surface of humans. Gram-negative bacteria are transient on the hands of hospital personnel and account for 60% of infections.

Virulence The potency of a pathogen measured in the numbers required to kill the host.

Virus Ultramicroscopic infectious agent that replicates itself only within cells of living hosts.

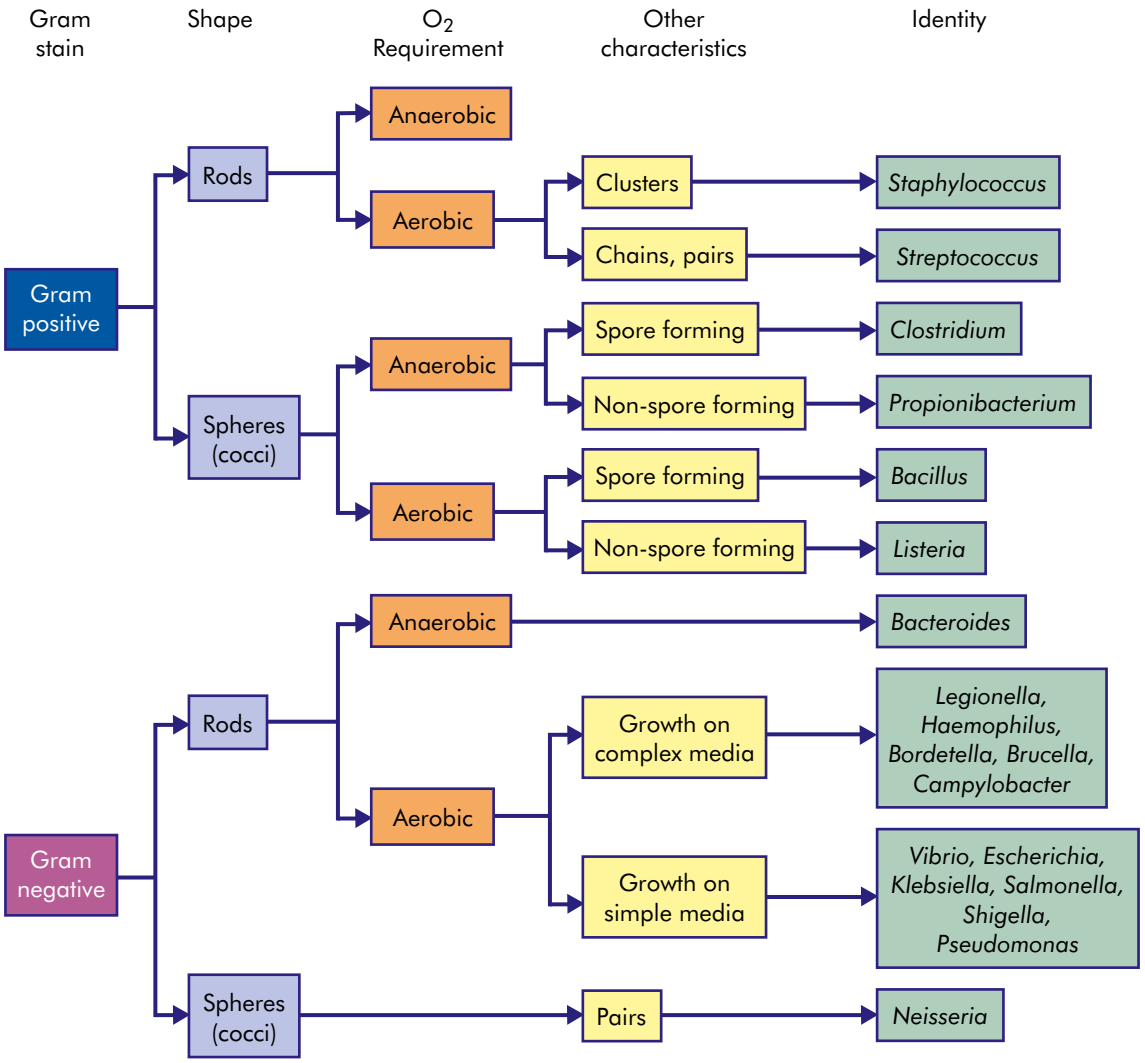

FIGURE 3-1 Types of gram-positive and gram-negative bacteria.

(CDC, 2005a). Human nasal and throat cavities are the most important reservoirs that continually replenish the external environment. Among perioperative personnel, *S. aureus* has been found most commonly in the respiratory passages. The potential for patient infection increases greatly as the personnel carrier rate increases. Nasal carriers also may be skin carriers. Carriers usually harbor either coagulase-positive (pathogenic) or coagulase-negative (nonpathogenic) staphylococci; seldom are there both types and rarely more than one strain is identified. Because an individual may be a carrier of staphylococci one day and a noncarrier the next, frequent swab testing of the nose as an infection control measure is impractical. Staphylococci survive for long periods in the air, dust, debris, bedding, and clothing. Pathogenic staphylococci grow in the sweat, urine, and tissue and on the skin of humans. They are more difficult to destroy than many other non–spore-forming organisms. Cleanliness of the environment; proper handling and, when appropriate, sterilization of linens and equipment; and adherence to adequate hand hygiene practices are important controls to prevent transmission of infection (AORN, 2009a).

Enterococci. Enterococci are gram-positive organisms that are found in the normal flora of the gastrointestinal and female genital tracts. These organisms are responsible for many serious healthcare-associated infections, including surgical site infections, bacterial endocarditis, septicemia, and urinary tract infections (UTIs). This organism also has been implicated in polymicrobial wound infections (CDC, 2007a). Enterococcal infections are most often healthcare-associated and seen in patients with co-morbid conditions.

Pseudomonads. The most common aerobic species of pseudomonads pathogenic to humans is *Pseudomonas aeruginosa.* It thrives in moist environments and is found frequently in soil, water, sewage, debris, and air. It also can be found in the normal flora of the skin and intestines. *P. aeruginosa* was considered a microorganism of slight pathogenic power but is now known to be associated with many infections in humans, including surgical site infections. *P. aeruginosa* seems to be pathogenic only when it is introduced into areas where normal defenses are absent, when it is superimposed on staphylococcal infection, or when it is present in a mixed infection. It may attack

a debilitated patient who has extensive burns or major trauma. The organism is often seen in critical care and burn units. *P. aeruginosa* is resistant to most antimicrobial agents. Other species of pseudomonads have been associated with infections caused by contaminated intravascular cannulae (as from the use of pressure transducers) or by the lumens of equipment (such as endoscopes used in gastrointestinal [GI] studies). An important preventive measure is proper environmental sanitation and strict adherence to aseptic technique.

Streptococci. Most streptococci are gram-positive, non–spore-forming, facultative microorganisms. They are normally found in the indigenous flora of the upper respiratory, genitourinary, and gastrointestinal tracts. Streptococci are classified as alpha, beta, or gamma according to chemical factors, biochemical tests, and their action on red blood cells.

Group A streptococci account for most streptococcal infections in humans. Known as the *flesh-eating bacteria* because of their ability to cause necrotizing fasciitis, group A streptococci are of concern because of the sporadic and deadly outbreaks of community-acquired and healthcare-associated infection (CDC, 2006a). An example is *Streptococcus pyogenes,* which is responsible for most soft tissue infections, otitis media, pharyngitis, impetigo, septicemia, and surgical site infections. Virulent streptococci are more serious invaders than staphylococci. Streptococci tend to involve wide areas of tissue and cause necrosis without localization. Streptococci are usually sensitive to penicillin, whereas staphylococci may not be. Streptococci also occur in mixed infections with other pathogens.

In surgical wounds, streptococci can be introduced into the incision and spread via the lymph vessels and nodes. This distribution can result in inflammation and cellulitis. Streptococcal transmission occurs by droplet transmission and by contamination of the environment. Inhalation of infectious droplets expelled from the nose and mouth of an infected individual is considered direct contact. Indirect contact occurs when infected air and dust from the environment enter a susceptible host. Group A streptococcus can be carried in the nasal passages, anus, or vagina. The upper respiratory tract is not a significant reservoir for microorganisms that cause surgical site infections except in the presence of an acute upper respiratory tract infection. In several randomized, controlled studies, it was found that surgical wound infection rates are unaffected by the use or nonuse of surgical masks by noninfected individuals during the operative procedure. It is not always possible to know who might be infected, and the use of masks during operative procedures continues to be strongly recommended in the prevention of SSIs. Most bacteria in the OR environment are shed from the skin of perioperative personnel (AORN, 2009b).

Clostridia. The clostridia bacteria are spore-forming, anaerobic, gram-positive bacilli that produce virulent toxins. *Clostridium difficile* is a bacterium in the *Clostridium* genus, which also includes *C. perfringens* (gas gangrene), *C. tetani* (tetanus), and *C. botulinum* (botulism). *C. difficile* is an anaerobic, gram-positive, spore-forming bacillus. *C. difficile* is an overgrowth in the colon that can manifest symptoms of diarrhea, colitis, toxic megacolon, dehydration, colonic perforation, and death. The overgrowth of *C. difficile* in the colon usually results from alterations in the normal flora of the colon that are associated with the use of antibiotics (CDC, 2006a). For this organism to cause disease, *C. difficile* must already be in the gastrointestinal system. Subsequently, there must be a change in the normal flora of the colon to allow the organism to grow and produce toxins. The two toxins produced are toxin A, which is an enterotoxin causing excretion of large amounts of fluid from the bowel, and toxin B, which is cytotoxic. Toxin B attacks and disintegrates cells of the intestines. Additionally, *C. difficile* produces tissue-degrading enzymes, which produce an inflammatory response within the colon that can result in a spectrum of disease entities (Matthews, 2008).

In its spore form, *C. difficile* can withstand drying and heat and may be resistant to many disinfectants. The spores can survive up to 5 months in the environment. *C. difficile* can be transmitted between individuals and by touching objects contaminated with the organism. In the healthcare environment, *C. difficile* has been cultured in rooms of infected individuals 40 days after discharge. *C. difficile* also has been cultured from healthcare workers' shoes, fingernails, fingertips, and the underside of rings (Rauscher, 2008; Mitchum, 2009).

Several interventions can assist in the prevention of *C. difficile* transmission in the healthcare environment, including following Contact Precautions, handwashing with antimicrobial soap and water, using personal protective equipment (PPE), cleaning and disinfecting all surfaces and equipment, and cleaning and disinfecting reusable devices in the perioperative suite. The use of disposable equipment only is recommended for infected patients (*Patient Safety Authority* [PSRS], 2005; CDC, 2006a).

Mycobacterium Tuberculosis. *Mycobacterium tuberculosis* is a non–spore-forming, nonmotile, aerobic bacillus. These bacilli can infect almost any tissue—including skin, bones, kidney, lymph nodes, intestinal tract, and fallopian tubes—and cause tuberculosis (TB). Tubercle bacilli spread in the host through the lymphatic channels and bloodstream and by way of the alveoli and gastrointestinal tract. Tuberculosis is responsible for more than 3 million deaths a year and is the most opportunistic infection associated with human immunodeficiency virus (HIV) (Neil, 2008).

Tubercle bacilli are transmitted directly by means of discharge from the respiratory tract (e.g., by inhalation of droplets expelled during coughing or kissing) and, less frequently, through the digestive tract. *M. tuberculosis* is carried via airborne droplet nuclei when infected persons sneeze, cough, or speak. These nuclei particles are less than 5 micrometers in size and contain up to three bacteria, allowing them to be kept airborne for a prolonged period (CDC, 2006a). Infection occurs when individuals inhale these infected droplet nuclei. The droplet nuclei travel through the nasal passages, upper respiratory tract, and bronchi to reach the lung alveoli, where they are engulfed by macrophages and spread throughout the body. Symptoms of TB are dependent on the part of the body infected, but may be vague at the onset and include fever, fatigue, loss of appetite, cough, fever, and night sweats.

Generally 2 to 10 weeks after initial infection, an immune response limits additional multiplication and spread of the bacilli. Some of the bacilli can remain dormant for many years, however, a condition referred to as *latent tuberculosis infection*. Individuals with latent TB usually have positive purified protein derivative (PPD) results, but they exhibit none of the symptoms of active TB and are considered noninfectious. The probability that a person who is exposed to *M. tuberculosis* will

become *infected* depends on the concentration of infectious droplet nuclei and the duration of exposure. When infected, an individual has approximately a 10% risk of developing active TB in his or her lifetime. The risk is greatest during the first 2 years after initial exposure. In individuals with compromised immune systems, there is a higher risk that latent TB will progress into active TB (CDC, 2006a). While the annual rate of TB has declined since the 1980s, the decrease is slowing. Latent TB is treated with isoniazid or rifampin. Active TB is treated with a combination of medications (e.g., isoniazid, rifampin, ethambutol, pyrazinamide) (Neil, 2008).

Viruses. Viruses are classified as small particles, rather than living cells, because viruses have no metabolic activity and must receive all sustenance for survival from a host cell. Viral pathogens are transmitted via the oral and respiratory tracts (e.g., poxvirus, rhinovirus), the intestinal and urinary tracts (e.g., poliovirus, hepatitis A virus [HAV], hepatitis E virus [HEV]), and the genital tract (e.g., herpes simplex 2, human immunodeficiency virus [HIV]) and through blood and some blood products (e.g., HIV, hepatitis B virus [HBV], hepatitis C virus [HCV], hepatitis D virus [HDV], and others). Some viruses have multiple routes of transmission.

When a virus invades a host cell, it combines with the host cell's nucleic acid (deoxyribonucleic acid [DNA] or ribonucleic acid [RNA]) and reprograms the host cell metabolism to accommodate virus replication. Virus replication stimulates the antibody defense in the host. The presence of viruses may be detected by identifying the virus-specific antibodies that are produced by the infected individual's immune system, by detecting the antigens elaborated by the virus and present in the blood, or by growing a culture of the virus itself. Detection of virus-specific antibodies or antigens is termed *seropositivity,* or *seroconversion*. Viruses are susceptible to destruction by high-level disinfection—a process that destroys most disease-producing microorganisms.

HEPATITIS. Hepatitis is defined as a widespread inflammation of the liver, often caused by a virus. It can be acute or chronic. Symptoms include hepatomegaly, right upper quadrant abdominal pain, and jaundice. Hepatitis is a frequently reported viral disease in the United States, with six identified strains (A through E and G).

Hepatitis A virus (HAV) is the causative agent of what is referred to as *infectious hepatitis*. HAV is spread through the fecal-oral route and can be prevented by proper hand hygiene. It is very common in underdeveloped countries with poor sanitation practices. HAV constitutes slightly less than half of all hepatitis cases reported in the United States and usually has an uneventful course and recovery. Immunization against HAV is available and has helped decrease the incidence of this strain of hepatitis.

Hepatitis B virus (HBV) is the causative agent for what is sometimes referred to as *serum hepatitis*. This worldwide virus has reached near-epidemic levels but is preventable via vaccination and the strict use of Universal Precautions. HBV can be transmitted by blood or body fluids, such as serum, saliva, semen, and vaginal fluids. It has an incubation period of 6 weeks to 4 months, depending on the type and amount of exposure. Almost 30% of infected individuals are asymptomatic; individuals with symptoms experience fatigue, abdominal pain, nausea, vomiting, and jaundice. Chronic hepatitis infection leads to progressive liver disease and possible death and is a leading cause of liver transplants. Most adults with HBV recover without incidence and develop immunity, but a small percentage may not develop immunity and will become carriers of the virus. HBV vaccine is recommended, by government regulation, for healthcare workers who may be exposed to blood and body fluids. Postexposure prophylaxis for percutaneous or permucosal exposure to HBV depends on the vaccination status of the healthcare worker. The risk of a susceptible person developing clinical HBV ranges from 1% to 31%, depending on the source person's HBV status (Davenport and Myers, 2009). The Occupational Safety and Health Administration (OSHA) mandates that all healthcare workers report blood and body fluid exposures, and perioperative personnel should follow the institutional protocol for exposure reporting.

Hepatitis C virus (HCV) transmission is most often associated with direct exposure to blood (e.g., via intravenous or subcutaneous routes) or other infectious materials. The average incubation period is 7 weeks. Currently there is no vaccine for the prevention of HCV. Individuals who contract HCV infection are prone to develop chronic infection. A high proportion of this population is asymptomatic and develops chronic liver disease, such as cirrhosis, hepatocellular carcinoma, and portal hypertension. As with HBV, a small proportion of individuals infected with HCV die. Prevention of HCV requires strict use of Universal Precautions, implementation of and adherence to sharps safety programs, compliance with exposure reporting protocols, and completion of a postexposure treatment plan. It is crucial that all perioperative personnel be educated regarding the risk for and prevention of all bloodborne infections, including HCV. These education programs should be conducted routinely and updated for accurate information inclusive of the CDC guidelines. The risk of HCV transmission after percutaneous exposure is about 1.8% (Davenport and Myers, 2009).

Hepatitis D virus (HDV) requires the co-infection of HBV. HDV is transmitted by blood and body fluids. The incubation period is generally 14 to 56 days. Individuals immunized against HBV have protection against contracting HDV. HDV is suspected when individuals present with HBV superinfection. Treatment is supportive for acute infections. With chronic HDV infections, antiviral therapies and liver transplants may be required.

Hepatitis E virus (HEV) is spread by the fecal-oral route. HEV is similar to HAV in the transmission and disease process. Most outbreaks have occurred in developing countries, where fecally contaminated water is found to be the source. The incubation period is 15 to 64 days. No vaccine is available for the prevention of HEV. Prevention is similar to that for HAV, with the use of proper hand hygiene. Treatment for HEV is supportive and the infection generally resolves on its own. The prevalence of HEV in the United States is low.

Hepatitis G virus is a bloodborne pathogen, with a comparable rate of infection as that of HCV in units of banked blood. It is spread in a manner similar to HBV and HCV dissemination, by percutaneous or permucosal exposure. There is no vaccine to prevent hepatitis G virus infection. Similar to HBV and HCV, prudent and consistent use of barrier protection (e.g., Standard Precautions) is recommended. There are no concrete data at present on the chronic nature of this viral disease (CDC, 2006a).

HUMAN IMMUNODEFICIENCY VIRUS. Human immunodeficiency virus (HIV) is a retrovirus (e.g., a virus that carries genetic information in the RNA instead of the DNA) that attacks the immune system by destroying T-helper lymphocytes.

Healthy individuals generally have 800 to 1000 T-helper cells/mm^3 in their blood. Infection with the HIV virus reduces these numbers, and when a person is HIV positive and his or her T-cell count falls below 200 cells/mm^3 (or the person is HIV positive and is diagnosed with an atypical or opportunistic infection and/or cancer) a diagnosis of acquired immunodeficiency syndrome (AIDS) is made (Sampson and Workman, 2010). The period from HIV exposure to actual development of AIDS has been reported to be 12 years or longer. During this time, the individual is a carrier of the virus. HIV has been isolated from all body fluids (e.g., blood, semen, vaginal secretions, saliva, tears, breast milk, cerebrospinal fluid, amniotic fluid, and urine) of infected individuals. Symptoms that result from HIV infection may be attributed to other causes and include fever, night sweats, chills, muscle aches, and headache.

Occupational exposure to HIV can occur by percutaneous injury (e.g., a needle stick or cut with a sharp instrument) or by mucous membrane or nonintact skin (e.g., exposed skin that is abraded) exposure to blood, tissue, or other body fluids that are potentially infectious. The Centers for Disease Control and Prevention (CDC) estimates that there is an average transmission rate of 0.3% per sharps injury (CDC, 2006b). Mucous membrane exposure is associated with a 0.09% transmission risk and exposure through nonintact skin is probably lower (Davenport and Myers, 2009). If an exposure incident occurs, appropriate postexposure management should take place as a part of the workplace safety program. The source patient should be informed of the incident. Serology testing should be done according to institutional policy and governmental requirements. Policies should be established for instances in which source patient consent cannot be obtained. The healthcare worker should be counseled about the risk of infection, and he or she should be evaluated clinically and serologically for evidence of HIV infection as soon as possible after exposure. Postexposure prophylaxis (PEP) regimens (Table 3-1) should be supervised by an expert in the management of exposures; follow-up should be provided for adherence to PEP; and adverse events, including seroconversion, should be monitored. Timely postexposure management and administration is important, and an exposure incident should be treated as an urgent medical condition.

Multidrug-Resistant Organism Infections: Emerging and Resurging Organisms

Historical Perspective. The first antibiotics, sulfonamides, were introduced in 1935 to treat staphylococcal and streptococcal infections. Penicillin was introduced in the 1940s during World War II, followed by the discovery of streptomycin in the mid to late 1940s. While the introduction of these medications was viewed as miraculous and did save many lives, in the mid-1940s strains of previously susceptible microorganisms began showing resistance to some of these medications. During the 1960s, cephalosporin and semisynthetic penicillins were developed, and it was believed that the problem of healthcare-associated infections was solved. Many gram-negative bacteria were found to be susceptible to these new drugs. By the late 1970s, however, strains of *S. aureus* resistant to penicillin, methicillin, cephalosporins, aminoglycosides,

TABLE 3-1

Postexposure Prophylaxis (PEP) for Occupational HIV Exposure*

Basic PEP	Expanded PEP
Basic PEP = two drugs: zidovudine plus lamivudine or emtricitabine; or stavudine plus lamivudine or emtricitabine; or lopinavir/ritonavir	Extended PEP = three or more drugs: zidovudine plus lamivudine or emtricitabine plus lopinavir/ritonavir; or stavudine plus lamivudine or emtricitabine plus lopinavir/ritonavir; or tenofovir plus lamivudine or emtricitabine plus lopinavir/ritonavir
Small-volume (few drops) exposure to mucous membranes or nonintact skin Source patient is HIV positive, asymptomatic with known low viral load Source patient is HIV positive, symptomatic or AIDS with high viral load	Large-volume (major splash) exposure to mucous membranes or nonintact skin Source patient is HIV positive, symptomatic or AIDS with high viral load
Large-volume (major splash) exposure to mucous membranes or nonintact skin Source patient is HIV positive, asymptomatic with known low viral load Optional when source patient is unknown or known with HIV factors	Less severe percutaneous injury (solid needle or superficial injury) Source patient is HIV positive, symptomatic or AIDS with high viral load
Less severe percutaneous injury (solid needle or superficial injury) Source patient is HIV positive, asymptomatic with known low viral load Optional when source patient is unknown or known with HIV factors	More severe percutaneous injury (large-bore hollow needle, deep punctures, visible blood on device, needle was in patient's artery or vein) Source patient is HIV positive, asymptomatic with known low viral load Source patient is HIV positive, symptomatic or AIDS with high viral load

*When PEP therapy is initiated, the recommended course is 28 days.

Modified from Sampson JG, Workman ML: Care of patients with HIV disease and other immune deficiencies. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, St Louis, 2010, Saunders.

clindamycin, erythromycin, and other antibiotics were isolated in hospital outbreaks of infection. This situation led to the development of new antibiotics, including carbapenems, cephamycins, and fluoroquinolones. These broad-spectrum antimicrobials were bactericidal at low concentrations and led to a false sense of euphoria during the 1980s, when it was believed that, at last, resistance to these antimicrobials would be impossible (Sandlin, 2008).

In the 1990s it became evident that the potential for resistance to any and all antimicrobials existed as healthcare-associated outbreaks of multidrug-resistant tuberculosis (MDR-TB) began to occur. Significant outbreaks of methicillin-resistant *S. aureus* (MRSA) (Surgical Pharmacology) and vancomycin-resistant *Enterococcus faecalis* (VRE) also occurred in the 1990s. In some cases, organisms seemed to acquire resistance almost immediately on exposure to the particular antibiotic. As fewer new antimicrobial drugs are being developed by the pharmaceutical industry, many consider the 1990s to be the beginning of the postantibiotic era (Sandlin, 2008).

Mechanisms of Resistance. Similar to their unwilling human hosts, pathogenic bacteria have an instinct to survive. When faced with an antimicrobial attack, they assemble their defensive resources. These microorganisms have the remarkable capability to incapacitate the threatening antibiotic and to mutate and outwit the most lethal clinical weapons. Although carrying only a single chromosome, bacteria by nature have extra minichromosomes called *plasmids*. These plasmids are hearty, and some may survive even the most aggressive antibiotic attack. Surviving plasmids are resistant and reproduce in kind, creating dominant organisms within the host. In addition, incompletely or ineffectively treated infections create the potential for reinfection with resistant organisms (CDC, 2006a).

Microbial resistance can be divided into three categories: (1) presence of a naturally resistant strain of an organism before any drugs are administered, (2) acquisition of a drug-resistant strain from an external source, and (3) drug resistance from treatment-related causes. Occurrence of naturally resistant strains of organisms without any exposure to drugs can occur

SURGICAL PHARMACOLOGY

Treating Methicillin-Resistant *Staphylococcus Aureus* (MRSA)

In the past, vancomycin was the only alternative for treating methicillin-resistant *Staphylococcus aureus* (MRSA). With the increased use of vancomycin, however, strains of *S. aureus* with reduced susceptibility to vancomycin began to appear. Newer antibiotics include daptomycin, linezolid, teicoplanin, and quinupristin-dalfopristin. Of these, linezolid has excellent activity against vancomycin-intermediate and vancomycin-resistant *Staphylococcus* and is approved for skin and soft tissue infection and for pneumonia caused by MRSA.

LINEZOLID (ZYVOX): NURSING CONSIDERATIONS

Assessment

- Assess central nervous system symptoms: headache, dizziness.
- Monitor liver function studies: aspartate aminotransferase (AST), alanine aminotransferase (ALT).
- Monitor allergic reactions: fever, flushing, rash, urticaria, pruritus.
- Assess for pseudomembranous colitis: severe diarrhea, cramping.
- Monitor complete blood count (CBC) weekly, assess for myelosuppression (anemia, leukopenia, pancytopenia, thrombocytopenia).

Nursing Diagnoses

Risk for Infection (uses)
Deficient Knowledge (teaching)
Risk for Impaired Skin Integrity

Implementation

PO route: Store reconstituted oral suspension at room temperature; use within 3 weeks.
IV route: Give over 30 to 120 minutes; do not use intravenous infusion bag in series connections; do not use with additives in solution; do not use with another drug; administer separately.

Patient-Family Education

- Advise patient if dizziness occurs to ambulate and perform activities with assistance.
- Advise patient to complete full course of drug therapy.
- Advise patient to contact prescriber if adverse reaction occurs.
- Advise patient to avoid large amounts of tyramine-containing foods (give list).

SUMMARY

In the early part of 2009 telavancin was approved for specific indications; it is a rapidly bactericidal lipoglycopeptide that operates through mechanisms involving interference with the functions of the cell membrane. This drug has showed promising data in the treatment of methicillin-resistant *S. aureus* (MRSA) and is in the Phase III trial phase. The published Phase 2 randomized trial data have shown that the drug is well tolerated and is at least as effective as vancomycin for complicated skin and skin structure infections. With this and other new promising drugs on the horizon, the perioperative nurse should constantly stay apprised of new and improved therapies for MRSA.

Modified from Skidmore-Roth L: *Mosby's drug guide for nurses with 2010 update,* ed 8, St Louis, 2010, Mosby; Stevens DL: Infections due to gram-positive cocci, *What's New ACP Med* 27(9), Sept 2004, available at www.acpmedicine.com. Accessed July 1, 2009; Gotfried et al: Intrapulmonary distribution of intravenous telavancin in healthy subjects and the effect of pulmonary surfactant on in vitro activities of telavancin and other antibiotics, *Antimicrob Agents Chemother* 52(1):92-97, 2008.

by intrinsic resistance, genetic mutation, or transfer of genetic material. Some microorganisms possess genes that make them resistant to an antibiotic. These genes may always be present in the microorganism but remain in an inactive stage until challenged by an antibiotic. Genetic mutation can occur spontaneously in the course of rapid multiplication of the microbe. These antibiotic-resistant mutants reproduce within the host. New genetic material also can be transferred into bacteria by means of free DNA that contains resistant genes (CDC, 2006a).

Introduction of drug-resistant microorganisms can occur through a person or an inanimate object. Bacteria become mobile and accessible to humans on the hands or clothing of care providers, through instruments and procedures, or through food. Resistant microorganisms may travel from distant parts of the world by means of infected travelers. Surgical instruments that have been ineffectively cleaned and processed can contribute to the spread of resistant organisms. Use of antibiotics in agriculture and in animal feed products also has contributed to the development of resistant organisms. When the food is ingested, resistant genes may be spread to humans (CDC, 2006a).

Drug resistance from treatment-related causes is often the result of misuse (e.g., incorrect use, overuse, or underuse) of antibiotics. It is believed that 50% of all antibiotic use in the United States can be characterized by misuse in one form or another, and efforts to reduce surgical site infections include appropriate prophylactic antibiotic use in surgical patients (Evidence for Practice). It is estimated that half of all antibiotic prescriptions written are not warranted. During antibiotic therapy, the patient may have had a few resistant organisms. By natural selection, as the susceptible organisms are killed, the resistant organisms multiply and become predominant. Inadequate drug therapy may contribute to the phenomenon and may be the fault of the patient, the provider, or both. Failure to perform sensitivity testing along with inappropriate dosing can contribute to resistance. If the patient is noncompliant with the

EVIDENCE FOR PRACTICE

Prevention of Surgical Site Infections: Surgical Care Improvement Project

Surgical site infections (SSIs) occur in 2% to 5% of clean, nonabdominal surgical procedures and in 20% of intraabdominal procedures. Many studies show higher infection rates, suggesting that SSIs account for 14% to 16% of all hospital-acquired infections and are among the most common complications of surgical patient care. SSIs increase morbidity and consume additional resources. Reimbursement for patients without complications exceeded hospital costs, generating a low margin of profitability. Infectious complications result in an increased median hospital stay of 2.8 days and an increased cost to Medicare and private payers. Medicare spent an estimated $326.7 billion on hospital-acquired infections in 2005.

SSIs include superficial incisions, deep incisional, and organ/space infections. These have been defined in the Centers for Disease Control and Prevention (CDC) National Nosocomial Infections Surveillance (NNIS) System and are recognized worldwide. Surgical patients often receive some form of antibiotic prophylaxis. The Surgical Care Improvement Project (SCIP) is a national partnership of organizations committed to improving the safety of surgical care through the reduction of postoperative complications. In 2005 the SCIP launched a multiyear campaign to reduce surgical complications by 25% by 2010. One of the targeted areas is SSIs.

EVIDENCE FOR PRACTICE IDENTIFIED BY SURGICAL CARE IMPROVEMENT PROJECT TO REDUCE SURGICAL SITE INFECTIONS

Although some surgical complications are unavoidable, surgical care can be improved through decisions and subsequent care focusing on evidence-based practice recommendations. Research shows that delivering antibiotics to a patient within 1 hour of beginning surgery can dramatically decrease SSI rates, yet this practice is not followed in all situations.

Numerous more recent, successful projects have shown that institutional implementation of evidence-based practices can have a significant impact on surgical complications.

- Application of the National Surgical Quality Improvement Program (NSQIP) within the Veterans Health Administration resulted in a 27% reduction in mortality related to surgery.
- Hospitals participating in the CDC and NNIS have shown reductions of 44% in device-associated infection rates and SSI rates.
- The national network of Medicare quality improvement organizations (QIOs), working under contract with the Centers for Medicare & Medicaid Services (CMS), conducted a surgical infection prevention collaborative that effectively reduced SSI by 27% at 56 centers across the United States.

Postoperative complications impose a substantial mortality and morbidity ratio on patients. The cost to the healthcare community is overwhelming. One approach to improving outcomes from surgery is to promote adherence to process of care measures such as administering prophylactic antibiotics. The purpose of antibiotic prophylaxis is to reduce intraoperative microbial contamination sufficiently to preclude microbial presence to reduce infection. The antimicrobial used should be safe, inexpensive, and bactericidal against a broad spectrum of the most probable contaminants for the intervention. Key measures identified in the SCIP to reduce surgical site infections and affect outcomes are the following:

- A prophylactic antibiotic should be administered within 1 hour before surgical intervention.
- The appropriate prophylactic antibiotic should be selected for surgical patients.
- Prophylactic antibiotics should be discontinued within 24 hours after surgery.
- Patients undergoing cardiac surgery should have their 6 AM postoperative glucose level controlled.
- Hair of surgical patients should be removed using the appropriate method.
- Patients undergoing colorectal surgery should reach immediate postoperative normothermia.
- Surgery patients should reach immediate postoperative normothermia.

prescribed regimen or discontinues the drug prematurely, he or she may also be contributing to drug resistance (CDC, 2005a).

Perioperative Considerations

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* (MRSA). MRSA infections, which occur in almost 130,000 cases in hospitals each year, lead to 5000 deaths annually (Ignatavicius, 2010). Common sites in which MRSA can be found include wounds (e.g., burns, surgical incisions, abrasions), chest tubes, intravenous catheter tips, intraabdominal abscesses, nasal passages, and the groin. *S. aureus* is one of the most frequently isolated organisms in postoperative surgical site infections. Surgical patients at risk for the development of MRSA infection include high-risk patients with underlying disease, patients who have a prolonged hospitalization, patients who have had previous antimicrobial therapy, patients who receive care in an intensive care unit, and patients who have been in proximity to another patient colonized with MRSA (CDC, 2005a). Patients may present with unrecognized colonization or become infected by caregivers who carry MRSA in their nose or on their skin. The ambient environment is rarely a source of MRSA except for some reported cases in burn units.

The primary mode of transmission for MRSA is most likely direct contact transmission from the hands of healthcare personnel. The organism has been recovered from the hands of personnel after they touched contaminated material and before they washed their hands. It also has been shown that MRSA can be carried in the nares of personnel and transferred to patients by hand contact. The importance of hand hygiene cannot be overemphasized (CDC, 2008a; AORN, 2009a).

Because MRSA is transmitted by contact, perioperative protocols should be used when caring for these patients. They should include the following:

- Segregate the patient, using Contact Precaution guidelines.
- Wear a gown and gloves whenever there is potential for contact with contaminated fluids or materials.
- Implement strict hand hygiene practices.
- Limit patient transportation to essential movement only.
- Clean and disinfect patient care equipment as close as possible to the time of use (AORN, 2009c).

In healthcare facilities, MRSA causes serious and sometimes fatal infections, including necrotizing fasciitis. MRSA resists almost every antibiotic except intravenous vancomycin. In 2005 the U.S. Food and Drug Administration (FDA) approved a new treatment for hospital patients with serious bacterial infections, including infections caused by MRSA. The drug tigecycline (Tygacil) is an antibiotic related to the tetracycline family that was first used in 2005. This drug is formulated to retain activity against some bacteria that are resistant to tetracyclines and provides an expanded broad spectrum of activity for patients with complicated SSIs. Minocycline and doxycycline are also used in the treatment of MRSA.

VANCOMYCIN-RESISTANT ENTEROCOCCI. Enterococci are intrinsically resistant to cephalosporins, semisynthetic penicillins, and clindamycin. Some strains also have acquired resistance to erythromycin, chloramphenicol, tetracycline, fluoroquinolones, and vancomycin (CDC, 2006c). The incidence of vancomycin-resistant enterococci (VRE) infections in the United States has increased rapidly in recent years and now is difficult or impossible to treat. Patients at the greatest risk of VRE infection are patients with a prolonged stay in the critical care unit, intraabdominal or cardiothoracic surgical procedures, presence of indwelling central venous catheters, presence of urinary catheters, extended hospital stays, multiple antimicrobial therapies, and proximity to infected individuals. Because the enterococcal plasmid carrying the resistant gene can be transferred to organisms such as *S. aureus,* VRE infections are of serious concern (Droboni et al, 2009; CDC, 2006c).

The CDC has issued recommendations regarding the use of vancomycin, including identifying situations in which vancomycin should and should not be used; establishing education programs for practitioners, susceptibility testing, isolation procedures, and dedication of equipment and devices; verifying procedures for cleaning and disinfecting the environment; and minimizing movement of personnel between patients with and without VRE (Droboni et al, 2009; CDC, 2006c).

VRE can be transmitted directly from patient to patient, through the hands of healthcare providers, or through contact with contaminated environmental surfaces and equipment used for patient care. As with MRSA, Contact Precautions should be followed when caring for patients infected with VRE. Perioperative protocols are similar to protocols for MRSA patients and should include the following:

- Segregate patients, using Contact Precaution guidelines.
- Wear a gown and gloves when in contact with contaminated materials.
- Implement strict hand hygiene practices.
- Limit patient transportation to essential movement only.
- Clean and disinfect patient care equipment as close as possible to the time of use (AORN, 2009c; CDC, 2007a).

Germicides commonly used for cleaning and disinfecting in hospitals are effective against VRE. Isopropyl alcohol and sodium hypochlorite (bleach) are highly effective. With a 10-minute exposure time, some phenolic and some quaternary ammonium compounds also are effective. These are less effective at shorter exposure times. Hydrogen peroxide has been found to be ineffective. No relationship seems to exist between microbial resistance to antibiotics and increased resistance to germicides (CDC, 2007a). Perioperative personnel should routinely consult the manufacturer's written instructions and follow Environmental Protection Agency (EPA) recommendations when selecting germicides for surface cleaning (AORN, 2009d).

VANCOMYCIN INTERMEDIATE–RESISTANT *STAPHYLOCOCCUS AUREUS*. In 1996 the first known incidence of vancomycin intermediate–resistant *S. aureus* (VISA) occurred in Japan when the organism was isolated from a surgical site infection and undrained abscess. The first occurrence of the organism in the United States was seen 1 year later. A patient that had been treated with vancomycin for multiple episodes of peritoneal MRSA developed bacterial strains moderately resistant to vancomycin, which was the treatment of choice for MRSA. Although the organism showed only intermediate levels of resistance, the CDC viewed this occurrence as an early warning that strains of *S. aureus* with full resistance to vancomycin may emerge (CDC, 2006c). Vancomycin is ineffective for the treatment of VRSA and VISA.

MULTIDRUG-RESISTANT *MYCOBACTERIUM TUBERCULOSIS* (MDR-TB). Outbreaks of TB have heightened concern about healthcare-associated transmission of this disease. The incidence of MDR-TB is increasing in the United States. Transmission is most likely to occur from patients with unrecognized pulmonary or laryngeal tuberculosis and those who do not take their TB medication regularly. Populations at greatest risk of

developing TB or MDR-TB are the elderly, indigent, minorities, immigrants from countries where TB and MDR-TB are prevalent, and HIV-infected individuals (CDC, 2006b). Transmission also occurs as a result of procedures such as bronchoscopy, endotracheal intubation, endotracheal suctioning, and open abscess irrigation, inclusive of inadequate equipment disinfection. Extensively drug-resistant TB (XDR-TB) is now a threat in many Asian countries and the former Soviet Union. This strain of TB is very difficult to treat because of its resistance to the primary medications used to treat TB (e.g., isoniazid and rifampin) as well as many of the secondary medications used (e.g., fluoroquinolone, amikacin, kanamycin, and capreomycin) (Neil, 2008).

The CDC's Guidelines for Preventing the Transmission *of Mycobacterium Tuberculosis in Health-Care Settings* emphasize the following:

- Importance of control measures, including engineering controls and personal respiratory protection, including fit-tested, personal respirators when indicated
- Use of risk assessment to develop a tuberculosis-control plan
- Early detection and treatment of patients with tuberculosis
- Screening programs for healthcare workers
- Training and education for healthcare workers
- Evaluation of the tuberculosis-control program (CDC, 2005b)

CREUTZFELDT-JAKOB DISEASE. Creutzfeldt-Jakob disease (CJD) is an infectious, human prion disease that is a fatal neurodegenerative disease of the central nervous system. CJD is one of a group of encephalopathies known as *transmissible spongiform encephalopathies (TSEs)*. Other human forms of TSE are Gerstmann-Sträussler-Scheinker syndrome and *new variant CJD (nvCJD)* or *variant CJD (vCJD)* (CDC, 2008b).

CJD is considered a slower viral infection caused by a self-replicating prion. Prions are a unique class of organisms that have no detectable DNA or RNA. These small, proteinaceous agents are abnormal isoforms of normal cellular proteins. The incubation period for CJD varies from months to years to decades. Symptoms include rapidly progressing dementia, memory loss, rapid physical and mental deterioration, and a distinctive electroencephalogram reading. Positive diagnosis can be made only by direct examination of affected brain tissue. Most cases occur randomly and for unknown reasons when the patient is between 50 and 75 years old. The average duration of illness after the patient becomes symptomatic is 6 months, always ending in death. In contrast, vCJD has an earlier onset (between 18 and 41 years of age). Patients exhibit initial psychiatric symptoms and then neurologic symptoms differing from those of CJD, and the course of illness averages 14 months. The disease is always fatal (CDC, 2008b). According to the CDC, there is strong epidemiologic and laboratory evidence to support a causal association between vCJD and bovine spongiform encephalopathy (also known as *mad cow disease*).

CJD can be familial (i.e., inherited in the form of a mutant gene) or sporadic (no family history and no known source of transmission). Approximately 90% of cases are sporadic. Only about 1% of cases result from person-to-person transmission, and those are primarily the result of iatrogenic (medically related) exposure. Exposures have occurred via transplantation of contaminated central nervous system tissue, such as dura mater or corneas; from injections of pituitary hormone extracts; and by use of contaminated surgical instruments or stereotactic depth electrodes (CDC, 2008b).

CJD and other TSEs are unusually resistant to conventional chemical and physical decontamination methods. The causative prions are resistant to steam autoclaving, dry heat, ethylene oxide gas, and chemical disinfection with formaldehyde or glutaraldehyde as normally used in the healthcare environment (AORN, 2009e). Glutaraldehyde and formaldehyde act as fixatives, causing the prions to become more stable and less susceptible to normal sterilization/disinfection protocols. Special protocols for instrument care after exposure to prions should be followed (AAMI, 2009a). Some institutions use disposable instrument sets for diagnostic brain biopsies to rule out CJD or TSE. A process using radiofrequency (RF) gas plasma to eliminate prions that cause CJD from surgical instruments has been developed. The technique removed contamination to levels 1000 times lower than that achieved by existing decontamination methods (AAMI, 2009a). Other processes being investigated include the use of an alkaline cleaning agent before sterilization and vaporized hydrogen peroxide (VHP) sterilization. Protocols for handling CJD are evolving as researchers learn more about prions and their destruction. Table 3-2 lists options from which an acceptable protocol for care of instruments and equipment exposed to the CJD prion can be developed.

CONTROLLING INFECTION

Asepsis

The term *asepsis* means the absence of infectious organisms. Asepsis is directed at cleanliness and the elimination of all infectious agents. Surgical asepsis is designed to exclude all microbes, whereas medical asepsis is designed to exclude microbes associated with communicable diseases. Practices that restrict microorganisms in the environment and on equipment and supplies and that prevent normal body flora from contaminating the surgical wound are termed *aseptic techniques*. The goal of each aseptic practice is to optimize primary wound healing, prevent surgical infection, and minimize the length of recovery from surgery (History box). For perioperative practitioners, surgical aseptic principles and practices are the foundation for infection control efforts in the perioperative arena.

Infection control practices should primarily focus on prevention. Transmission of infection involves a chain of events, including the presence of a pathogenic agent, reservoir, portal of exit, transmission, portal of entry, and host susceptibility. Prevention occurs when there is a break in the chain of transmission. Infection control practices involve personal and administrative measures. Personal measures should include fitness for work and application of aseptic principles. Administrative measures should include provision of adequate physical facilities, appropriate surgical supplies, and operational controls in the perioperative area.

As new organisms have emerged, and known organisms become more resistant, the importance of patient education as a risk reduction strategy cannot be minimized. In addition to practicing sound infection control practices, nurses partner with the patient through effective education about infection control measures to maximize the potential for perioperative safe care (Patient and Family Education).

Universal, Standard, and Transmission-Based Precautions

Universal Precautions. In 1985, in response to the growing number of individuals testing positive for HIV, the CDC published recommendations for the use of Universal Precautions

HISTORY

Influences on Infection Control through the Ages

FIRST CENTURY BC
It was believed that swampy land contained minute animals not visible to the naked eye. These invisible animals were thought to become airborne, enter humans through the mouth, and cause disease.

450 BC
Hippocrates, the father of surgery, used wine or boiled water to irrigate wounds, laying the foundation for the rudiments of aseptic technique and infection control.

SECOND CENTURY
Galen, a Roman, is reported to have boiled his instruments before use.

MIDDLE AGES
The practices of segregating lepers, avoiding areas of pestilence, and isolating the severely ill indicated an awareness that diseases were transmissible.

SIXTEENTH CENTURY
Thomas Moffett identified and described lice, fleas, and mites.

SEVENTEENTH CENTURY
Antony van Leeuwenhoek, inventor of the microscope, discovered previously unseen creatures in his microscopic observations.

EIGHTEENTH CENTURY
Agostino Bassi linked a disease of the silkworm with a fungal parasite; he then suggested that many contagious diseases, such as smallpox, typhus, and cholera, were the result of live organisms.

1850s
Louis Pasteur, founder of the science of microbiology, theorized that fermentation was caused by particles of living matter so small that they could not be seen but could be carried freely in the air. He referred to these microorganisms as germs and found that heat killed them. The relationship between the fermentation process and the putrefaction of tissue was not understood at that time.

1860s
Joseph Lister learned about Pasteur's work, recognized the analogous relationship between the two processes, and began to investigate the relationship of the germ theory to the process of infection. By 1867 Lister was advocating carbolic acid soaks and sprays for hands, wounds, dressings, sutures, and the OR itself. Although Lister's antiseptic methods and principles were crude and undeveloped, their use resulted in a decrease in surgical mortality from 45% to 15%.

Ignaz Semmelweis made a simple but momentous contribution to infection control by advocating that hands be washed between examinations of patients and that a clean gown be worn for each patient.

Florence Nightingale instigated radical changes in sanitation, resulting in reductions in mortality from contagious diseases.

1880-1890s
In 1889 Halstead, at the Johns Hopkins Hospital, asked the Goodyear Rubber Company to make rubber gloves for his scrub nurse because she was allergic to the corrosive hand rinse being used. Gradually the idea of wearing gloves to protect the patient emerged. White aprons and gowns replaced the usual morning coat worn by surgeons. Masks were added in 1897 as microbiologists measured the microbial shed that occurred during conversation. Before the use of masks, many procedures were performed in total silence to decrease the probability of surgical wound infection. Sterilizers completed the transition to a truly aseptic approach to surgery, with all items coming into contact with the patient being sterile.

Modified from Foster LG: *Robert Wood Johnson, the gentleman rebel,* State College, Pa, 1999, Lillian Press; Foster LG: *A company that cares—100 year illustrated history of Johnson and Johnson,* New Brunswick, NJ, 1999.

(CDC, 2006b). Reports of hospital personnel becoming infected with HIV after a needle stick or skin exposure to a patient's blood created an urgent need for new and better measures to protect personnel from patient transmission of infection. With knowledge that many patients with bloodborne infections are undiagnosed, Universal Precautions, for the first time, placed emphasis on applying Blood and Body Fluid Precautions (previously a category in the 1993 *Guidelines for Isolation Precautions in Hospitals*) universally to all individuals regardless of their presumed infection status. Universal Precautions expanded the Blood and Body Fluid Precautions by recommending masks and eye protection to prevent mucous membrane exposures in addition to the routine use of barrier protection, such as gowns and gloves. Universal Precautions also emphasized the prevention of needle-stick injuries and the use of ventilation devices when resuscitation was performed. The CDC continued to recommend the use of Universal Precautions until 1987, when a new system of isolation called *Body Substance Isolation* (BSI) was proposed. BSI directed isolation of *all* moist and potentially infectious body substances (e.g., blood, feces, urine, sputum, saliva, wound drainage, other body fluids) for all individuals regardless of their infection status. This was accomplished primarily with the use of gowns and gloves. Because of the similarities yet differences between Universal Precautions and BSI, confusion reigned. In 2007 the CDC further expanded the *Guidelines for Isolation Precautions*.

The Occupational Safety and Health Administration (OSHA) issued a rule for *Occupational Exposure to Bloodborne Pathogens* to address workplace safety. This document was based on the concept of Universal Precautions. OSHA subsequently revised its final rule to include a special focus on needle-stick and other percutaneous exposures to bloodborne pathogens (OSHA, 1991). The revised rule addressed "sharps with engineered sharps injury protections" (nonneedle devices or needle devices with built-in safety features to reduce the potential for injury) and "needleless systems" (alternative delivery devices using blunt cannulae, catheter ports or connectors, or other nonneedle devices). Other revisions focused on the review and updating of exposure control plans, solicitation of employee input, and improved record keeping. The

PATIENT AND FAMILY EDUCATION

Patient Education for SSI Prevention

The Joint Commission has established several National Safety Patient Goals (NPSGs) to provide organizational guidance for key patient safety issues. One of these goals, NPSG 7, focuses on how organizations reduce the patient's risk for developing a healthcare-associated infection (HAI). In addition to implementing hand hygiene measures and other evidence-based practices to prevent HAIs and surgical site infections (SSIs), organizations are also required to provide adequate education about SSI prevention to both patients having surgical procedures and also their families. Education can be provided by any means the organization chooses (e.g., printed materials, verbal teaching, classes), but there must be some documentation within the patient record that the education occurred. Items that might be included in a patient handout are included below.

Millions of people have surgery each year. Every surgery has risks, but we know there are some that can be prevented. One way you can help lower your risk for problems from your surgery is to learn about some of the things that can cause infection and talk with a member of your surgical care team before surgery about the type of care you should receive. Here are some questions that patients often ask about surgical site infections, which are also called SSIs.

What is a Surgical Site Infection (SSI)?

A surgical site infection is an infection that occurs after surgery in the part of the body where the surgery took place. Most patients who have surgery do not develop an infection. However, infections develop in about 1 to 3 out of every 100 patients who have surgery. The following are some of the common symptoms of a surgical site infection:

- Redness and pain around the area where you had surgery
- Drainage of cloudy fluid from your surgical wound
- Fever

Can SSIs be Treated?

Yes. Most surgical site infections can be treated with antibiotics. The antibiotic given to you depends on the bacteria (germs) causing the infection. Sometimes patients with SSIs also need another surgery to treat the infection.

What are Some of the Practices Performed by Hospitals to Prevent SSIs?

To prevent SSIs, doctors, nurses, and other healthcare providers:

- Clean their hands and arms up to their elbows with an antiseptic agent just before the surgery.
- Clean their hands with soap and water or an alcohol-based hand rub before and after caring for each patient.
- May remove some of your hair immediately before your surgery using electric clippers if the hair is in the same area where the procedure will occur. They should not shave you with a razor. Using a razor to remove hair before surgery can cause infections because of the risk of leaving small cuts on the skin.
- Wear special hair covers, masks, gowns, and gloves during surgery to keep the surgery area clean.
- Give you antibiotics before your surgery starts. In most cases, you should get antibiotics within 60 minutes before the surgery starts and the antibiotics should be stopped within 24 hours after surgery. Given properly, antibiotics can greatly lower your chances of getting an infection after surgery.
- Clean the skin at the site of your surgery with a special soap that kills germs.

What Can I Do to Help Prevent SSIs?

Before your surgery*:*

- Tell your doctor about other medical problems you may have. Health problems such as allergies, diabetes, and obesity could affect your surgery and your treatment.
- Quit smoking. Patients who smoke get more infections. Talk to your doctor about how you can quit before your surgery.
- Do not shave near where you will have surgery. Shaving with a razor can irritate your skin and make it easier to develop an infection.

At the time of your surgery:

- Speak up if someone tries to shave you with a razor before surgery. Ask why you need to be shaved and talk with your surgeon if you have any concerns.
- Ask if you will get antibiotics before surgery.

After your surgery:

- Make sure that your healthcare providers clean their hands before examining you, either with soap and water or with an alcohol-based hand rub. *If you do not see your providers clean their hands, please ask them to do so.*
- Family and friends who visit you should not touch the surgical wound or dressings.
- Family and friends should clean their hands with soap and water or an alcohol-based hand rub before and after visiting you. If you do not see them clean their hands, ask them to do so.

What Do I Need to do When I Go Home from the Hospital?

- Before you go home, your doctor or nurse should explain everything you need to know about taking care of your wound. Make sure you understand how to care for your wound before you leave the hospital.
- Always clean your hands before and after caring for your wound.
- Before you go home, make sure you know who to contact if you have questions or problems after you get home.
- If you have any symptoms of an infection, such as redness and pain at the surgery site, drainage, or fever, call your doctor immediately.

If you have additional questions, please ask your doctor or nurse.

TABLE 3-2

Care of Items Exposed to the Creutzfeldt-Jakob Disease Prion

Tissue Infectivity	Item/Device (Using Spaulding Classification System)	Cleanable	Heat/ Moisture Stable	Disposition
High infectivity	Critical/semicritical instruments/ devices	If easily cleaned	If yes	1. Thoroughly clean with detergent germicide 2. Autoclave at 134° C (272° F) immersed in water in prevacuum sterilizer for 18 min (extended cycle) *or* 3. Autoclave instruments immersed in water at 121° C (250° F) in gravity sterilizer for 20 min; 60 min if not immersed in water *or* 4. Immerse in 1N NaOH (1 normal sodium hydroxide) for 60 min at room temperature. After 60 min, remove items from NaOH, rinse, and steam sterilize at 121° C (250° F) in gravity sterilizer for 30 min 5. After processing according to one of above options, prepare instruments in usual fashion and sterilize for future use
			If no	Discard
	Critical/semicritical instruments/ devices	If difficult to clean	If yes	1. Discard *or* 2. Decontaminate initially by: a. Autoclave at 134° C (272° F) in prevacuum sterilizer for 18 min *or* b. Autoclave at 121° C (250° F) in gravity sterilizer for 60 min *or* c. Immerse in 1N NaOH for 60 min at room temperature. After 60 min, remove items from NaOH, rinse, and steam sterilize at 121° C (250° F) in gravity sterilizer for 30 min 3. After initial decontamination as explained above, thoroughly clean, wrap, and sterilize by conventional methods for future use
			If no	Discard
	Critical/semicritical instruments/ devices	If impossible to clean	NA	Discard
	Noncritical instruments/ devices	If cleanable	NA	1. Clean according to routine procedures 2. Disinfect with a 1:10 dilution of sodium hypochlorite (bleach) or 1N NaOH, choosing solution that would be least damaging to items 3. Continue processing according to routine procedures
		Noncleanable	NA	Discard
	Environmental surfaces	NA	NA	1. Cover surface with disposable, impermeable material 2. Incinerate material after use 3. Disinfect surface with 1:10 dilution of sodium hypochlorite (bleach) 4. Wipe entire surface using routine facility decontamination procedures for surface decontamination
Medium/ low/no infectivity	Critical/semicritical/ noncritical instruments/ devices	Cleanable	NA	1. Clean, disinfect, or sterilize according to routine procedures
		Noncleanable	NA	Discard

TABLE 3-2

Care of Items Exposed to the Creutzfeldt-Jakob Disease Prion—cont'd

Tissue Infectivity	Item/Device (Using Spaulding Classification System)	Cleanable	Heat/ Moisture Stable	Disposition
Medium/ low/no infectivity, cont'd	Environmental surfaces	NA	NA	1. Cover surface with disposable, impermeable material 2. Dispose of material according to facility policy 3. Disinfect surface with OSHA-recommended agent for decontamination of blood-contaminated surfaces (e.g., 1:10 or 1:100 dilution of sodium hypochlorite [bleach])

following is a summary of the requirements of the *Final Rule: Occupational Exposure to Bloodborne Pathogens* (OSHA, 2001):

1. Each facility must develop and implement an exposure control plan that defines exposure and implements the requirements of the final rule. This plan is to be reviewed and revised annually with information provided to all employees. The plan must reflect changes in available technology to reduce exposure to bloodborne pathogens and implementation of appropriate technology to that end. Nonmanagerial employee input must be solicited in selecting technology to be implemented in the practice setting.
2. Engineering and work-practice controls must be used to eliminate or minimize employee exposure. Examples follow:
   a. The employer must provide everything necessary for proper hand hygiene.
   b. Contaminated needles must not be recapped or removed unless such action is required by a specific medical procedure. Such recapping or removal must be accomplished by the use of a mechanical device or one-handed technique.
   c. A clamp or other mechanical device should be used to disassemble a knife blade and handle.
   d. Sharps are to be placed in labeled or color-coded, puncture-resistant, leak-proof containers for disposal.
   e. Specimens of blood or body fluids must be placed in containers that prevent leakage and are labeled or color-coded. Warning labels must be affixed to containers of regulated waste, refrigerators and freezers containing blood or potentially infectious materials, and other containers used to transport blood or potentially infectious materials (Figure 3-2). The labels must be fluorescent orange or orange-red.
   f. Food and drink are not to be kept in the same storage area where blood or other potentially infectious materials are present.
   g. PPE must be provided by the employer at no cost to the employee. Appropriate PPE shall include but is not limited to gloves, gowns, face shields or masks, and eye protection. Protective eyewear must have solid side shields. Gloves are to be worn when contact with blood or body fluids is anticipated. Disposable gloves are to be replaced as soon as possible after contamination occurs. Disposable gloves are not to be washed or decontaminated for reuse. Some facilities may have educational signs posted to assist employees in recognition of appropriate PPE (Figure 3-3).
   h. Signs must be posted at the entrance to work areas of potential contamination. These signs are to bear the biohazard legend with the following information: name of infectious agent, special requirements for entering the area, and name and telephone number of the responsible individual.
   i. Housekeeping provisions are to ensure that the workplace is maintained in a clean and sanitary condition. A written schedule for cleaning and a method of decontamination must be established. All equipment and working surfaces must be cleaned and decontaminated after contact with blood or other potentially infectious materials.

FIGURE 3-2 Biohazard label.

FIGURE 3-3 Example of universal symbols for blood and body fluid protection.

j. Contaminated laundry must be placed in a labeled or color-coded container that is recognized by all employees.
k. All employees are to receive education and training about safe handling of hazardous substances and materials. Information must be provided to all occupationally exposed employees at no cost to them. Individuals must receive training at the time of employment and annually thereafter. Individual employee training records are to be maintained by the employer for the duration of employment plus 30 years. The healthcare worker is highly encouraged to receive the HBV vaccine after obtaining the required information about the risk of exposure and about the vaccine. If the employee chooses not to accept the vaccination, the employer must have the employee sign a letter of declination.
l. Employees should report all exposures to blood and body fluids for postexposure evaluation.
m. Employers who are required to maintain a log of occupational injuries and illnesses must maintain a sharps injury log that acts as a tool for identifying high-risk practice areas and for evaluating various devices in use. This log must protect the confidentiality of the injured employee. Log information should include the type and brand of the device, the practice area in which the injury occurred, and an explanation of how the incident occurred.

The bloodborne pathogen regulation is enforceable by OSHA at the federal and state levels. This regulation is based on the concept of Universal Precautions to serve and protect healthcare providers and to minimize the transfer of pathogens from one patient to another. Surveyors for OSHA may engage in on-site visits to healthcare facilities. Unannounced visits may occur at any site where an employee exposure occurs. The visit may be a result of a verbal or written employee concern, referral from another regulatory agency, or random inspections of facilities.

Standard Precautions. By the early 1990s the controversy regarding Universal Precautions and Body Substance Isolation (BSI) had escalated. There was considerable confusion about which body fluids required special care under either Universal Precautions or BSI. There were also concerns about the need for additional precautions to prevent airborne, droplet, and contact transmission of other infectious agents. With this need in mind, the CDC developed a single set of precautions incorporating the major features of Universal Precautions and BSI (CDC, 2007b). These precautions are called *Standard Precautions,* and they are designed to reduce the transmission risk of bloodborne and other pathogens. Additional precautions based on routes of transmission for patients known or suspected to be infected or colonized with highly transmissible or epidemiologically significant pathogens are included in the document.

Standard Precautions are intended to reduce the transmission of microorganisms from recognized and unrecognized sources of infection. Standard Precautions should be applied to all patients receiving care regardless of their diagnosis or presumed infection status. They are considered the first, and most important, tier of precautions and as such are a primary strategy for successful infection prevention and control. Standard Precautions apply to (1) blood, (2) all body fluids and secretions and excretions (except sweat) regardless of whether they contain visible blood, (3) mucous membranes, and (4) nonintact skin. Standard Precautions include the following:

1. *Hand hygiene.* Hand hygiene is the most important factor in preventing the spread of infection. Hands are to be washed whenever they are in contact with blood, body fluids, secretions, excretions, and contaminated items, whether or not gloves are worn. Hands are washed immediately after gloves are removed, between patient contacts, and when otherwise indicated to avoid transfer of microorganisms to other patients or environments. Sometimes it is necessary to wash hands between tasks and procedures on the same patient to prevent cross-contamination of different body sites. A plain (nonantimicrobial) soap should be used for routine handwashing. When special circumstances such as hyperendemic conditions occur, an antimicrobial soap or an antiseptic hand rub (waterless antiseptic agent) should be used. The hand rub antiseptic agent is most effective if the hands are clean before the antimicrobial agent is applied. For effectiveness,

RESEARCH HIGHLIGHT

Handwashing Compared with Alcohol-Based Hand Rubs

Hand hygiene is recognized as a primary method of decreasing healthcare-associated infections. Prevention of infection is a priority for all healthcare providers inclusive of the perioperative team. Compliance with handwashing has been less than 50% in numerous studies. The introduction of waterless alcohol-based hand products increased compliance with hand hygiene, and in 2005 JCAHO (now named TJC) required healthcare organizations to comply with the CDC Category I recommendations for hand hygiene. Alcohol-based hand rubs are easy to use and fast-acting, and provide activity against most bacteria, viruses, and fungi. These recommendations require monitoring healthcare workers' compliance with recommended hand hygiene practices, making hand hygiene an institutional priority, and providing easier methods for hand hygiene, such as alcohol-based hand rubs.

One of the objectives of this study was to evaluate the comparative microbial efficacy of handwashing with an unmedicated soap to hand rubbing. Before and after handwashing or hand rubs, imprints of the participants' palms and fingertips were taken, and then colony counts and identification of transient flora were determined. Handwashing was considered to be satisfactory if both hands were washed together for 30 seconds (±5 seconds), rinsed under running water, and dried with a paper towel. Hand rubs were considered satisfactory if 2 to 3 ml of the alcohol-based agent was applied to both hands, and all surfaces of the hands were rubbed together until the alcohol was dry. Observation was used for this part of the study.

Before hand hygiene procedures, the mean colony counts were 87 ppm for the palms and 85 ppm for the fingertips. During the study, it was observed that hand rubbing was performed more vigorously than handwashing. Transient flora levels were 4% after handwashing and 0% after hand rubbing. The results of this study support the CDC Category I recommendations, indicating that hand rubbing with a waterless, alcohol-based hand hygiene product is more effective than handwashing with an unmedicated soap.

Modified from Kac G et al: Microbial evaluation of two hand hygiene procedures achieved by health care workers during routine patient care: a randomized study, *J Hosp Infect* 60:32-39, 2005; Gupta C et al: Comparison of two alcohol-based surgical scrub solutions with an iodine-based scrub brush for presurgical antiseptic effectiveness in a community hospital, *J Hosp Infect* 65(1):277-278, 2007.

a sufficient amount of the agent must be used for the hand rub. Manufacturers' written instructions should be followed. An additional amount of hand rub agent may be necessary (Research Highlight).

2. *Gloves.* Clean, nonsterile gloves should be worn when touching blood, body fluids, secretions, excretions, and contaminated items. Freshly donned gloves should be worn when touching mucous membranes and nonintact skin. Gloves should be changed between tasks and patient procedures and after contact with material that may contain high concentrations of organisms. Gloves should be removed immediately after use and hands washed before engaging in another task or giving care to another patient.
3. *Masks, eye protection, face shields.* A mask and eye protection or a face shield is to be worn at any time patient care activities are likely to generate sprays or splashes of blood or body fluids, secretions, and excretions. These protective devices help protect the mucous membranes of the nose, mouth, and eyes.
4. *Gowns.* Clean, nonsterile gowns are to be worn at any time patient care activities are likely to generate sprays or splashes of blood or body fluids, secretions, and excretions. Gowns help protect the skin and prevent soiling of clothing. The activity to be performed and the amount and type of fluid likely to be encountered dictate the degree of protective barrier necessary in the gown. Gowns should be removed immediately after use and hands washed before engaging in other activities or giving care to another patient.
5. *Sharps.* Needles, scalpels, and other sharps should be handled in a manner to avoid injury. Needles should never be recapped using any technique that directs the point of the needle toward any body part. If recapping is necessary, it should be done using a mechanical device or a one-handed scoop technique. Used needles should not be removed from disposable syringes, and they should not be bent, broken, or otherwise manipulated by hand. Used disposable sharps should be placed in puncture-resistant containers located as close as possible to the point-of-sharps use. Reusable sharps should be contained in a puncture-resistant container for transport to the point of decontamination.
6. *Patient care equipment.* Single-use items should be discarded after use. Reusable equipment must be cleaned and reprocessed to ensure safe use for another patient. Equipment soiled with blood, body fluids, secretions, and excretions should be handled carefully to prevent exposure of skin and mucous membranes, contamination of clothing, and transfer of organisms to patients, personnel, and the environment.
7. *Linens.* Linens soiled with blood, body fluids, secretions, or excretions should be handled in a manner to avoid skin and mucous membrane exposure, clothing contamination, and transfer of microorganisms to other patients, personnel, and the environment.
8. *Environmental control.* Adequate procedures for routine care and cleaning of environmental surfaces, beds, and associated equipment are to be developed, and the use of these procedures is monitored on a regular basis.
9. *Patient placement.* Patients who contaminate the environment or who are unable to maintain appropriate hygiene or environmental control are to be housed in a private room with appropriate air handling and ventilation. If a private room is unavailable, the infection-control professional may determine a method for cohorting patients with similar infectious organisms (CDC, 2007b).

Transmission-Based Precautions. Transmission-based precautions are the second tier of infection prevention, designed for patients known or suspected to be infected by epidemiologically important pathogens spread by airborne or droplet transmission or by contact with dry skin or contaminated surfaces. They may be used singly or in combination with one another if the patient has a disease that has multiple routes of transmission and are to be used in addition to Standard Precautions.

AIRBORNE PRECAUTIONS. Airborne transmission occurs by dissemination of droplet nuclei from evaporated droplets that can remain suspended in the air for long periods or by dissemination of dust particles that contain the infectious agent.

Droplet nuclei are particles 5 μm or smaller in size. Airborne microorganisms can be dispersed widely depending on air currents and can be inhaled by or deposited on a susceptible host. In addition to Standard Precautions, Airborne Precautions include the following:

1. Patients are to be placed in private, negative-pressure rooms. The air exchange should be at a rate of 6 to 12 exchanges per hour with air discharged to the outdoors or circulated through high-efficiency particulate-arresting (HEPA) filters before being circulated to other areas of the facility.
2. Caregivers must wear OSHA-specified respiratory protection when caring for patients with known or suspected tuberculosis. If susceptible personnel care for patients with rubeola (measles) or varicella (chickenpox), respiratory protection should be worn. If the caregiver is immune to rubeola and varicella, respiratory protection is unnecessary.
3. All precautions for preventing transmission of tuberculosis should be implemented if the patient is known or suspected to have tuberculosis.
4. A surgical mask should be placed over the patient's nose and mouth for Airborne Infection Isolation Precautions when the patient must be transported from one location to another. Patient transport should be limited to essential purposes only.

DROPLET PRECAUTIONS. Droplet Precautions are used for patients known or suspected to be infected with microorganisms that are transmitted by large droplets (>5 μm). These droplets can be generated when the patient sneezes, coughs, or talks. Droplet Precautions are used in addition to Standard Precautions. Droplet Precautions include the following:

1. Patients are to be placed in private rooms when available. If this is not possible, the patient should be placed in a room with another patient who is infected with the same organism and with no other infection. If this is not possible, a 3-foot spatial separation should be maintained between the infected patient and other patients in the same room. For Droplet Precautions, no special air handling is required.
2. Caregivers should wear a mask when working within 3 feet of the patient.
3. Patients should be transported only for essential purposes. When transport is necessary, a mask should be placed over the patient's nose and mouth to minimize dispersal of droplets (CDC, 2007b).

CONTACT PRECAUTIONS. In addition to Standard Precautions, Contact Precautions should be used for patients known or suspected to be infected or colonized with epidemiologically important organisms that can be transmitted by (1) direct contact, as occurs when the caregiver touches the patient's skin, or (2) indirect contact, as occurs when the caregiver touches patient care equipment or environmental surfaces in the patient's room. Contact Precautions include the following:

1. Patients should be placed in a private room. If this is not possible, the patient should be placed in a room with another patient who is infected with the same organism and with no other infection. If this is not possible, patient placement must be determined on an individual basis, depending on the organism involved.
2. Gloves should be worn on entering the patient's room. Gloves should be changed after handling infective material that might contain a high concentration of microorganisms. When patient care activities have been completed, gloves should be removed before leaving the patient's room. Hands should be washed after glove removal. To avoid transferring microorganisms to others, no environmental surfaces in the patient's environment should be touched after the hands have been washed.
3. Gowns should be worn on entering the patient's room if there is a probability that the caregiver's clothing will be in contact with the patient or the environmental surfaces or if the patient is incontinent, has diarrhea, or has an ileostomy or colostomy. The gown should be removed before leaving the patient's room, and care should be exercised to avoid contact with environmental surfaces.
4. Patient transportation should be limited to essential transport only and Contact Precautions maintained to avoid contamination of personnel, visitors, or the environment.
5. Patient care equipment should be dedicated to a single patient and not be shared between patients. If this is impossible, equipment must be cleaned and disinfected thoroughly before being used for another patient (CDC, 2007b).

PROTECTIVE ENVIRONMENT. The purpose of creating a protective environment for allogeneic HSCT (hematopoietic stem cell transplantation) patients is to minimize fungal spore counts in the environment. These immunocompromised patients are highly susceptible to environmental fungi, and such an infection can cause morbidity. Implementation of the following helps create a protective environment:

- Place patients in specifically designated private rooms.
- Filter incoming air using HEPA filters.
- Maintain a positive air-pressure gradient in relation to surrounding areas. Rooms should be well sealed to prevent air leakage into rooms.
- Maintain unidirectional airflow with air entry on one side of the room, across the patient, and exit on the opposite side of the room.
- Maintain more than 12 air exchanges per hour.
- Lower dust levels by using smooth, washable surfaces as opposed to textured surfaces.
- Prohibit dried or fresh flowers and potted plants.
- Place N95 respirators on patients during transport.

Perioperative staff members traditionally have relied on numerous types of precautions to protect themselves and others from bloodborne pathogens and other infectious diseases. Implementing these precautions within the surgical environment requires critical thinking skills and sound nursing judgment. Consistent application of these precautions by all members of the perioperative team serves to protect the healthcare provider and to minimize cross-infection of pathogens among patients (AORN, 2009f).

Infection Control and Bioterrorism. The potential for bioterrorism is a reality in today's world. The CDC has identified agents that may pose a risk to the national security because of their (1) easy dissemination or transmission from person to person, (2) potential to cause high mortality and have a major public health impact, (3) potential to cause public panic and social disruption, and (4) necessity for special action for public health preparedness (CDC, 2009) (Table 3-3). Other emerging infections have been identified as problematic (Box 3-2). Although it is unlikely that patients with these infectious diseases would be among the surgical population except in an

TABLE 3-3

Bioterrorism Agents*

Agent	Transmission	Incubation	Symptoms	Management
Anthrax *(B. anthracis)*	Cutaneous: direct contact Inhalation: droplet, aerosolization	Cutaneous: 1-7 days Inhalation: 1-6 days on average, may be as late as 43 days	Cutaneous: Itching, progressing to papular and vesicular lesions, eschar, edema, ulceration, and sloughing. If untreated may spread to lymph nodes and bloodstream. Fatality: 5%-20%. Inhalation: Influenza-like with progression to high fever, dyspnea, stridor, cyanosis, and shock. Chest wall edema and hemorrhagic meningitis may be present. Death is universal in untreated cases and may occur in 95% of cases not treated in first 48 hr.	Standard Precautions. Special attention should be given to protection and containment of any draining wounds, inclusive of cutaneous lesions.
Smallpox (variola major/ variola minor viruses)	Inhalation of droplets, droplet nuclei, aerosols, and direct or indirect contact	Typically 12-14 days	High fever, malaise, abdominal pains, and, in some cases, delirium. Rash develops over face and spreads to extremities. Rash soon becomes vesicular and then pustular. All lesions progress at same rate. Fever continues throughout course of disease, and growing and expanding pustules are very painful. In 5%-10% of patients, a rapidly progressive disease develops, which is almost always fatal within 5-7 days.	Standard, Droplet, Airborne, and Contact Precautions for patients with vesicular rash pending diagnosis. Avoid contact with organism while handling contaminated bedding. Wear protective attire to include gloves, gown, and N95 respirator. Vaccine does not give reliable lifelong immunity. Previously vaccinated persons are considered susceptible. After exposure, initiate Airborne Precautions and observe for unprotected contact (from days 10-17). Vaccinate within 2-3 days of exposure. One case is a public health emergency because of highly communicable nature of this disease. Consult CDC and local health agencies at earliest opportunity.
Plague *(Y. pestis)*	Pneumonic plague: aerosolized bacteria carried on respiratory droplets from infected person Bubonic plague: bites from fleas or infected rodent	Pneumonic plague: 1-3 days Bubonic plague: 2-8 days	Pneumonic: Fever, headache, and weakness, with rapid progression to pneumonia with dyspnea, chest pain, cough, and bloody or watery sputum. Respiratory failure and shock may follow within 2-4 days. Bubonic: Symptoms include swollen, tender lymph nodes (buboes), fever, headache, chills, and weakness.	Standard and Droplet Precautions. Patients should be placed in private rooms or cohorted with "like" patients. Transport should be limited to essential movement only, and patient should wear mask during transport. Contact Precautions until decontamination is complete.
Tularemia *(F. tularensis)*	Bites of ticks, deerflies, and other arthropods that have eaten infected animal tissue; by handling infected animal carcasses; by eating or drinking contaminated food or water; or by inhaling infected aerosols	1-14 days (average 3-5 days)	Depending on route of exposure, skin ulcers, inflamed eyes, sore throat, oral ulcers, swollen and painful lymph nodes, and pneumonia. When bacteria are inhaled, symptoms include sudden fever, chills, headache, muscle aches, joint pain, cough, and progressive weakness. Symptoms may progress to chest pain, dyspnea, bloody sputum, and respiratory failure.	Standard Precautions

Continued

TABLE 3-3

Bioterrorism Agents—cont'd

Agent	Transmission	Incubation	Symptoms	Management
Botulism *(C. botulinum)*	Foodborne: ingestion of preformed toxin Wound: when wounds are infected with *C. botulinum* that secretes toxin; injection drug users are at risk for wound botulism	Foodborne: within hours of ingesting food, but can occur up to 8 days later	Early symptoms of botulism include gastrointestinal distress, nausea, and vomiting. Symptoms progress to diplopia, blurred vision, drooping eyelids, slurred speech, difficulty swallowing, dry mouth, and muscle weakness. If not treated, the disease progresses to respiratory paralysis and paralysis of arms and legs. Botulinum toxin is most poisonous substance known.	Standard Precautions

*The information about bioterrorism and the identified biologic weapons presented in this table represents current knowledge at the time of publication. The CDC is updating their website with the most current information from throughout the world. Practitioners are encouraged to update their knowledge continually by consulting the CDC website (www.cdc.gov) and other experts in the field. The Health Alert Network (HAN) is the CDC's surveillance system. It connects local, state, and national public agencies with high-speed and satellite Internet access. The extent of precautions necessary can be quickly determined by using this system.

extreme circumstance, it is likely that, given a national crisis or epidemic, perioperative personnel could and would be mobilized to serve in a variety of locations and roles as part of the national, state, and local emergency preparedness plan. Perioperative personnel should have a basic knowledge and understanding of the agents most likely to be encountered and the levels of precautions required for patient and personnel safety. Communication, collaboration, and coordination are required in the face of any bioterrorist event or natural disaster. Communities need emergency plans for such matters, such as guarding patient data and protecting information systems, linking quickly and easily with state and federal resources, ensuring culturally competent communication and care, accessing mental health resources, and identifying agencies that can partner with one another to provide services. Each institution must be compliant with The Joint Commission's requirements for periodic testing of emergency management systems and their associated plans.

Engineering Practices to Control Infection

Environment of Care. The surgical suite should be designed in such a way as to minimize and control the spread of infectious organisms. Either a central-core, race track, or a single-corridor design may be used. With the central-core design, sterile equipment and supplies should be contained within the central-core area, which is surrounded by ORs and a peripheral corridor. The single-corridor design places the ORs on either side of a single corridor, with separate storage rooms, usually along the corridor, to house sterile equipment and supplies. If a single-corridor design is used, sterile and contaminated items must be separated by either space or time. That is, sterile, wrapped, or containerized items can pass contaminated items in the corridor when the contaminated items are covered or otherwise contained (Figure 3-4).

Floors in the ORs should be hard, seamless, easily cleaned, and contiguous with the walls. This design eliminates the sharp angle where the floor and walls meet, where bacteria can become lodged and proliferate. If floors must be seamed, all seams should be heat-sealed. Walls may be constructed of any hard surface that is easily cleaned and hard enough to withstand the impact of surgical equipment that may accidentally be pushed into the wall during transport. If ceramic tile is used, smooth-surface grouting mortar should be used. This grout provides a surface nearly as smooth as the tile itself, eliminating concerns that surface roughness may attract and retain bacteria. Painted walls are less desirable because the paint flakes and peels, particularly in areas of higher humidity.

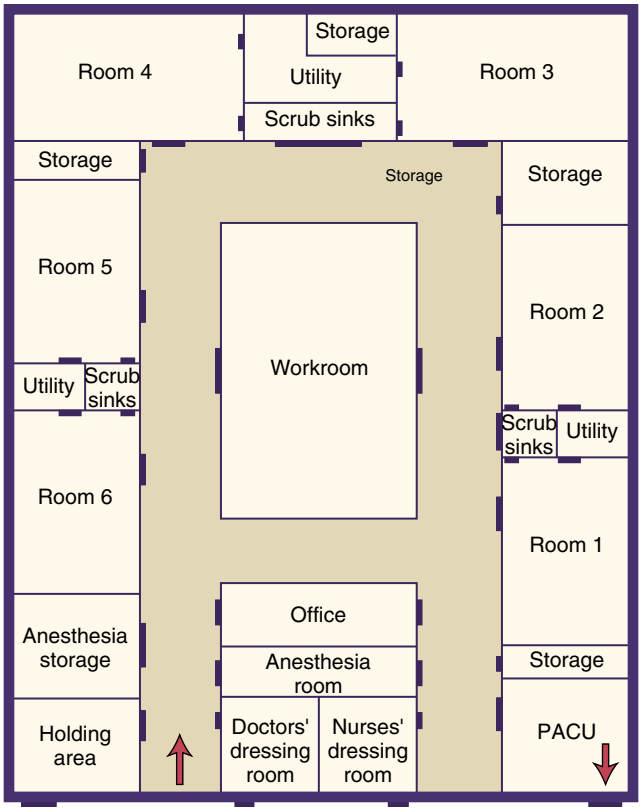

FIGURE 3-4 Racetrack floorplan.

If a hard-finish, epoxy paint is used, it is only as good as the surface beneath it. Equipment banged into a wall may cause damage and expose construction material to the environment. A soft-colored, matte-finished wall may be preferred to reduce reflectance and glare (AIA, 2006).

Doors in the ORs may swing or slide. If sliding doors are used, they should not recess into the wall but should slide over the adjoining wall to facilitate housekeeping. Cabinets should be recessed into the wall if possible. This configuration allows for maximum use of open floor space in ORs. Size and configuration of ORs are discussed in detail by the American Institute of Architects Academy of Architecture (AIA) for Health. Stainless-steel cabinets are preferred because the surfaces remain smooth and are easily cleaned. Wooden cabinets quickly become damaged with cracks and crevices where bacteria can collect and proliferate. Wooden cabinets are difficult to clean and disinfect and should be avoided in ORs. Cabinet doors may be of either the swinging or the sliding type. A cleaning protocol should be established for the tracts if sliding doors are used. For noncabinet shelving, open wire shelves are preferred because dust and bacteria do not accumulate, and air can circulate freely around shelf contents (AIA, 2006).

Scrub sinks should be located adjacent to each OR, with a single area serving two ORs if possible. Ideally, scrub sinks are located in a room or alcove adjacent to the peripheral or single corridor of the OR. Scrub sinks should not be within the central-core area because aerosolization and splashing may occur where sterile items are stored, contaminating the environment.

Each surgical suite must contain an enclosed soiled workroom exclusive for its own use. The workroom should contain a flushing hopper, receptacles for waste and soiled linen, a handwashing sink, and a work counter. If the area is used as a holding area as part of a larger system for collection and disposal of soiled materials, the flushing hopper is not required (AIA, 2006).

Heating, Ventilation, Air Conditioning. To control bioparticulate matter in the OR environment, ventilating air should be delivered to the room at the ceiling and exhausted near the floor and on walls opposite to those containing inlet vents. Airflow should be in a downward directional flow, moving down and through the location with a minimum of draft, to the floor and exhaust portals (AIA, 2006).

Air pressure in the OR should be greater than that in the surrounding corridor; this is called "positive pressure" in relation to corridors and adjacent areas. This positive pressure helps maintain the unidirectional airflow in the room and minimizes the amount of corridor air (less clean area) entering the OR (more clean area). Each OR should have a minimum of 15 total air exchanges per hour, with the equivalent of at least 3 replacements being of outside air to satisfy exhaust needs of the system. No recirculating devices, such as cooling fans or room humidifiers or dehumidifiers, are to be used. These units create a turbulent airflow and may recirculate settled bacteria. Doors to ORs should be kept closed to maintain correct ventilation, airflow, and air pressure. To minimize static electricity and to reduce the potential for bacterial growth, relative humidity in the OR should be maintained between 30% and 60%. A lower relative humidity may support accumulation of static electricity, whereas the presence of a higher humidity may cause condensation of ambient moisture, which may result in damp materials and supplies. This dampness supports bacterial growth. Temperatures in ORs should be maintained at 68° F (20° C) to 73° F (23° C) (AIA, 2006).

Practices to Prevent Infection

Sterilization. *Sterilization* is defined as the complete elimination or destruction of all forms of microbial life. The concept of what constitutes "sterile" is measured as the *probability* of sterility for each item to be sterilized. This probability is known as the *sterility assurance level* (SAL). For terminal steam sterilization processes, 10^{-6} is the recommended probability of survival for microorganisms on a sterilized device. A probability of microorganism survival of 10^{-6} means that there is less than or equal to a 1 in 1 million chance that an item is contaminated or unsterile. The SAL of 10^{-6} is considered appropriate for items to be used on compromised body tissue. For items not intended to come into contact with compromised tissue, an SAL of 10^{-3} is sometimes accepted. An SAL of 10^{-3} represents a 1 in 1000 chance of a surviving microorganism (AAMI, 2009a).

STEAM STERILIZATION. Steam sterilization is the oldest, safest, most economical, and best understood method of sterilization available in healthcare. It is the preferred method of sterilization for items that are heat and moisture sensitive. The efficacy of steam sterilization depends on lowering and limiting the bioburden on the item to be sterilized, using effective sterilization cycles, and preventing recontamination of sterile items before delivery to the point of use (AAMI, 2009b).

Theory of Microbial Destruction. Microorganisms are believed to be destroyed by moist heat through a process of denaturation and coagulation of the enzyme-protein system

within the bacterial cell. Microorganisms are killed at a lower temperature when moist heat is used as opposed to when dry heat is used. This fact is based on the theory that all chemical reactions, including coagulation of proteins, are catalyzed by the presence of water.

Principles and Mechanisms. At standard atmospheric pressure (sea level) when water is heated, the water temperature increases as heat energy is added. After the boiling point of 100° C (212° F) is reached, additional heat energy evaporates the water to form steam. At this point, the steam and the water are at the same temperature, but the steam has more energy than the water. This difference in energy is known as the *latent heat of vaporization*. When a cold item is introduced into the steam, some of the steam releases its latent energy to the object and changes back to liquid water. This phenomenon allows items to be heated much more rapidly in steam than in dry heat. The phenomenon of steam changing to liquid water is called *condensation,* and the steam and the liquid water are at a temperature of 100° C (212° F) when this occurs. At this point, the steam is said to be saturated. This 100° C (212° F) temperature is insufficient to kill microorganisms, however. To achieve a saturation temperature sufficient to kill microorganisms (250° F [121° C]), it is necessary to have a sealed container. When water is boiled in a vessel from which the steam cannot escape, a higher temperature is reached. As more steam is generated with no escape route, pressure in the vessel increases. The higher the steam pressure, the higher the temperature. The steam is the sterilizing agent. Any compressed air remaining in the vessel mixes with the steam and lowers the steam temperature. This reduced-temperature steam is incapable of sterilization. Air acts as a barrier to steam sterilization (AAMI, 2009c).

Steam entering the sterilizer chamber should contain little or no entrapped liquid water. The term *steam quality* describes the amount of steam vapor and liquid water in the mixture. A steam quality of 100% indicates that no liquid water is present in the steam. A steam quality of 97% or greater (i.e., <3% of the mixture is liquid water) is recommended to achieve an efficient sterilization process. Causes of low steam quality include improper boiler operation and inadequate or poorly maintained steam distribution lines to the sterilizer (AAMI, 2009c; AORN, 2009g).

Presterilization Preparation. The efficacy of the sterilization process depends in part on lowering or limiting the amount of bioburden present on the item to be sterilized. Items to be sterilized should be precleaned to lower the bioburden to the lowest possible level.

To prevent infection, all items that come into contact with the patient or sterile field should be systematically decontaminated after a surgical procedure. Handling, transport, and cleaning methods must be selected to prevent cross-contamination to other patients, exposure of personnel to bloodborne pathogens, and damage to instruments. The cleaning and decontamination methods chosen should be economic and of demonstrated effectiveness. Items may be cleaned by hand, by mechanical means, or by a combination of the two (AAMI, 2009a). Increased productivity, greater cleaning effectiveness, and increased employee safety may result from use of mechanical cleaning methods. Some mechanical cleaning equipment is designed to remove microorganisms through a cleaning and rinsing action, whereas others destroy specific types of microorganisms by thermal or chemical means. Types of mechanical cleaning equipment include washer-sterilizers, washer-disinfectors/washer-decontaminators, or washer-sanitizers; ultrasonic cleaners; utensil washers; and cart washers.

All workers handling soiled surgical instruments, whether in the OR, the substerile room, or a central decontamination area, must wear PPE sufficient to prevent contact with any blood or other body fluid. This generally means scrub attire covered with a liquid-proof gown, coverall, or sleeved apron; hair covering; surgical face mask; eye protection; and gloves suitable to the task. In the event that fluids may pool on the floor, liquid-proof boots or shoe covers are recommended.

Instruments should be kept as free as possible from gross soil and other debris during the surgical procedure. Throughout the surgical procedure, the scrub person should wipe used instruments with sponges moistened with sterile water. When blood is allowed to dry on the instrument, it may cause pitting, rusting, or corrosion. Sterile water is preferred to saline solution, which can cause pitting and damage to instrument surfaces. Initial decontamination should begin immediately on completion of the surgical procedure (AAMI, 2009c; AORN, 2009e). All instruments that can be immersed are disassembled, and box locks are opened to allow solution to contact all soiled surfaces. These instruments should be placed in a basin, solid-bottom container system, or bin with a lid. Scissors and lightweight instruments should be placed on top. Heavy retractors should be placed in a separate tray. An enzyme solution, foam, or spray can be added to the instruments to begin the process of breaking down any proteinaceous materials that may remain on the instruments.

Some instruments have sharp or pointed edges, such as scissors, forceps with teeth, perforating towel clamps, curettes, and rongeurs. These items can penetrate the gloves and skin, creating a portal of entry for infectious organisms. A different process is used for these instruments. Sharp instruments must not be placed in a basin or tray in such a way that a worker would have to reach into the container to retrieve the instrument, risking injury. Instead, they are placed with points down in a basin small enough that the handles are outside the basin, allowing individual instruments to be grasped. An alternative is to place all instruments together and not handle them until after they have been through an automated cleaning process.

Soiled instruments should be within leak-proof containers or trays inside plastic bags when they are transported from the OR for cleaning and decontamination. If sharps are being transported, the container should be puncture-resistant. Means of containing instruments include plastic, rubber, or metal bins with lids; solid-bottom sterilization container systems with the lids in place and filters in place; or simply placement of the instrument tray in a plastic bag. All soiled containment packages should be labeled with the biohazard symbol to warn handlers as to the nature of the contents. Transporting instruments while they are soaking is discouraged because of the possibility of a liquid spill and its associated clean-up problems as well as the difficulty of safely disposing the contaminated liquid unless a flushing hopper is available (AAMI, 2009a).

In the decontamination area, an initial cold water rinse with tap water or a soak in cool water with a protein-dissolving and blood-dissolving enzyme helps remove blood, tissue, and gross debris from device lumens, joints, and serrations. After completion of this pretreatment, the instruments should be

processed in an automated device, and washed by hand if an automated device is not available (AAMI, 2009a).

Automated processing is completed with the use of washer-sanitizers or washer-decontaminators. In most facilities, these units have replaced manual washing of instruments and the use of washer-sterilizers. They may have a single chamber where several phases of a rinsing, cleaning, rinsing, and drying process occur. Alternatively, they may have multiple chambers, each specialized for a specific function in the cleaning process, including initial cool water rinse to remove protein debris, enzymatic-solution soak, washing with detergent, ultrasonic cleaning, sustained hot water (80° C to 95° C) rinse, perhaps a liquid chemical germicide rinse (e.g., sodium hypochlorite solution), a lubrication cycle, and drying. Soiled utensils such as basins and trays similarly should pass through a utensil washer, a washer-disinfector-sanitizer, or a washer-sterilizer. When laparoscopic items or other items with a lumen are cleaned, a cleaning apparatus for these items can be attached to the newer washer-sanitizers/decontaminators (AAMI, 2009a; CDC, 2008a).

If instruments are manually cleaned, they should be submerged in warm water with an appropriate detergent and then cleaned and rinsed while submerged. Cleaning in this fashion helps protect personnel from aerosolization or splashing of infectious material and from injury caused by sharp objects. Harsh abrasives should not be used for manual cleaning because they damage the protective surfaces of instruments, contribute to corrosion, and impede sterilization (AORN, 2009e).

If a washer-sterilizer is to be used, gross debris should be removed with a cold water rinse before the instruments are placed in the washer-sterilizer, with care used to minimize splashing during rinsing. Instruments are placed in perforated or meshed-bottom trays or baskets and positioned so that the cleaning portion of the washer-sterilizer cycle can reach all parts of the instrument. The two types of washer-sterilizers are (1) those configured like a tunnel, with doors at each end and rotating spray arms on the sides, top, and bottom of the chamber; and (2) those that cover the instruments with water and blow steam and air through the water to cause agitation that produces the cleaning effect (Figure 3-5). The former machines are generally found in central decontamination areas and may be connected to an automatic or manual conveyer. The second type of machine is generally small (about 16 to 20 inches in diameter) and located in the instrument-processing room of the surgery suite (AAMI, 2009c).

After the instruments are cleaned with detergent and water and rinsed, the washer-sterilizer begins a steam sterilization cycle. The exposure time for this cycle depends on the temperature at which the cycle is run. Some washer-sterilizers of the tunnel type operate at 285° F (140° C) for less than 1 minute. Others, including all of the second type of washer-sterilizers, operate at 270° F (132° C) for 10 minutes. All rely on gravity displacement to remove air from the chamber. Debris remaining on the instruments because of possible inefficiencies of the cleaning process is baked on by the sterilization portion of the process and may be difficult to remove. Instruments processed through a single cycle of a washer-sterilizer are safe to handle and may be sterile, depending on presterilization bioburden. They are not suitable, however, for immediate use in another surgical procedure. They must be inspected, arranged in a manner convenient for the surgical team to use, and steam-sterilized again (AAMI, 2009c).

Not all instruments tolerate this process, and not all hospitals have access to mechanical washers that incorporate hot water or chemical decontamination as part of the cleaning cycle. Some instruments do not tolerate immersion in water or cannot tolerate the heat or pressures involved in mechanical processes. These items must be handwashed using an appropriate detergent for the type of material and the type of soil on the item. If protein or other organic soil is present, the detergent should have an alkaline pH (>7). If inorganic soil is present, the detergent should have an acid pH (<7). The degree of alkalinity or acidity should be selected so that the instrument or item itself is not damaged in the cleaning process. Stainless-steel instruments with organic soil are best cleaned by alkaline detergents with a pH range of 7 to 10, according to most U.S. surgical instrument manufacturers. Using acidic or harshly alkaline solutions can remove the protective passivation layer from the instrument, resulting in irreparable pitting and other corrosive activity. This advice regarding detergent selection applies to mechanical washing also. Although a neutral pH detergent is often selected for the foregoing reasons, written instructions from the instrument manufacturer should be consulted to determine appropriate cleaning products and procedures (AAMI, 2009c).

Items that were soiled with blood or body fluids and that have been cleaned only may not have been sufficiently decontaminated to allow handling by workers not wearing protective attire. If such an item tolerates steam sterilization, it can be decontaminated further by processing through an unwrapped steam-sterilization cycle (flash sterilized). It is then safe to handle. The item also can be soaked in a liquid chemical germicide, such as 2% alkaline glutaraldehyde or ortho-phthalaldehyde (OPA) to disinfect it; the manufacturer's written recommendations for immersion time must be followed. If none of these methods is suitable for the item, because of damage to the item, cost, or unavailability, workers in the preparation area should wear protective gloves when handling, inspecting, assembling, and packaging these items for sterilization.

The ultrasonic cleaning process is designed to remove fine soil from crevices and box-lock areas of instrumentation. It should be used only after instruments have had gross debris removed. Ultrasonic energy occurs in waveforms and is generated by transducers on the sides or bottom of a specially constructed chamber that is filled with water or a water and detergent solution. The ultrasonic waves pass through the water, creating tiny bubbles that collapse or implode. This creates a negative pressure, which pulls debris away from surfaces. This process is known as *cavitation*. Ultrasonic cleaning is not biocidal, and after the cleaning process is done, the instruments should be rinsed to remove the loose debris. Some ultrasonic consoles have chambers for rinsing and drying instruments.

Not all items tolerate the energy waves of the ultrasonic process. Chromium-plated instruments should not be cleaned ultrasonically because the energy waves can loosen the chromium from the base metal underneath. Dissimilar metals, such as stainless steel, titanium, copper, and lead, should not be ultrasonically processed at the same time. The energy waves, combined with the heat and detergent solution, can cause electrolysis to occur, plating one metal onto others, potentially ruining the instruments. Some manufacturers recommend that microsurgery instruments not be placed in the ultrasonic cleaner because of their delicate design and the fact that they

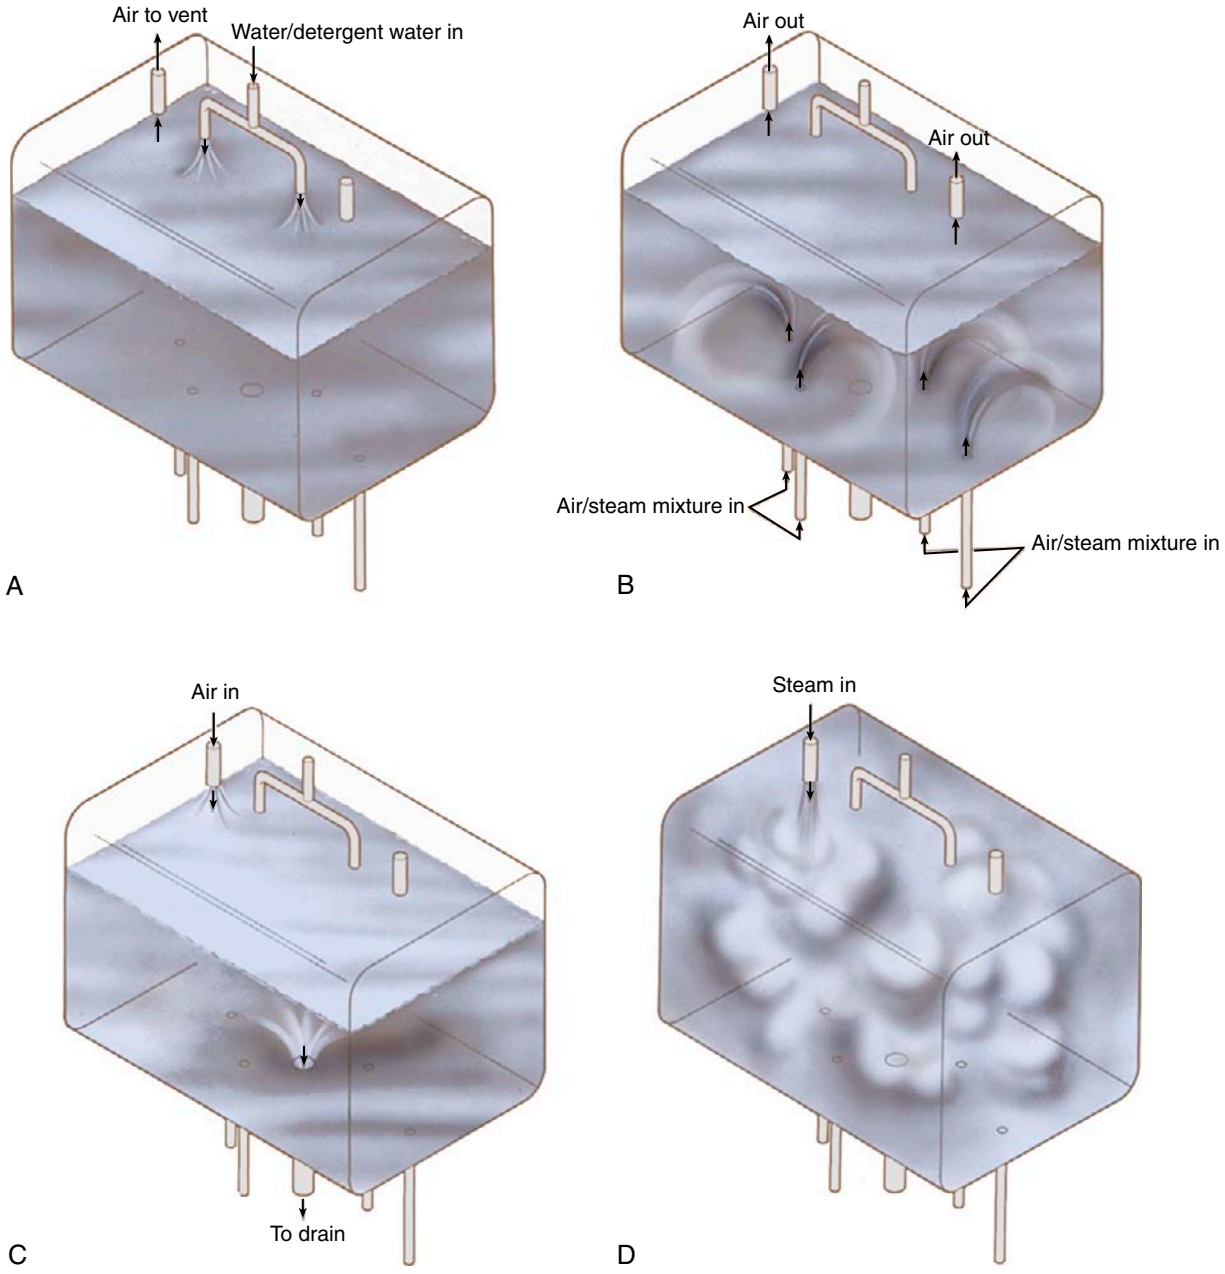

FIGURE 3-5 Automatic washer-sterilizer. **A**, The cycle in this machine begins with a cold water rinse entering through the top of the chamber to loosen and remove gross soil, such as blood and tissue, without coagulating proteinaceous material, which would cause it to adhere to instruments. Then warm water and detergent enter the chamber to a level to cover the instruments. **B**, Next, jets of steam and air are injected into the filled chamber through ports in the floor of the chamber. Violent turbulence in the detergent-water solution removes any debris remaining on the instruments after the initial rinse. **C**, At the conclusion of the wash time, the water drains out of the chamber. Newer models of washer-sterilizers may have microprocessor controls that allow the user to set the duration of wash time based on the nature of soil on the instruments. A final rinse coming in through the top of the chamber carries any detergent residues and soil away from the instruments and out the drain. **D**, Finally, saturated steam begins to fill the chamber. Air in the chamber and load is heavier than the steam and, because of gravity, is displaced downward and out the drain. As pressure builds in the chamber from the incoming steam, the temperature rises to 132° C (270° F), the chamber drain closes, and the temperature is held for the duration of the sterilization exposure time selected by the user. Then steam is exhausted through the automatic condenser exhaust. Some machines have the capability of selecting drying times for the instruments. At the conclusion of the cycle, an audible signal indicates that the unit is ready for unloading. Instruments and the inside of the sterilizer are very hot, and if no dry time was used, the instruments and trays are also wet. Use extreme caution in handling.

may contain several types of metal. The detergent or enzyme cleaner used in the ultrasonic machine should be selected carefully. The corrosiveness and overall effectiveness of some solutions can be dramatically affected by the combination of heat and ultrasonic energy in such a machine.

The final step before sterilization for reuse includes instrument preparation and packaging. These activities occur in a clean area, separate from the area where decontamination occurred. Instruments are inspected carefully for cleanliness and functionality. Soiled instruments are returned for further cleaning. Instruments with movable parts are treated with a water-soluble lubricant solution that contains an antimicrobial agent to retard growth in the lubricant solution. Broken or worn instruments are set aside for repair. Instruments are assembled into sets according to set content lists prepared by perioperative nursing staff.

Packaging and Sterilizer Loading. Packaging of surgical supplies and their arrangement in loads in the sterilizer are factors that govern the effectiveness of steam sterilization. The prime function of a package containing a surgical item is to permit sterilization of the contents and to ensure the sterility of the contents up to the time the package is opened. Provision must be made for the contents to be removed without contamination. To be effective, packaging material should have the following characteristics:

- Allows for adequate air removal and steam penetration
- Provides an adequate microbial barrier
- Resists tearing or punctures
- Has proven seal integrity (i.e., does not delaminate when opened and does not allow a reseal after opening)
- Allows for aseptic delivery of package contents
- Is free of toxic ingredients and nonfast dyes
- Is low-linting
- Is cost-effective by cost and value analysis (AORN, 2009h)

Sterilization container systems are one method of packaging instrumentation. Rigid packaging systems can be sterilized, stacked, and stored and offer a simple, effective packaging method. Because of the rigid material of the container, they cannot be punctured, abraded, or easily contaminated by environmental microbes. Properly initiated, container systems are a cost-effective packaging method. Recommendations and written instructions for sterilizing should be obtained from the container manufacturer. Performance testing should be carried out in the sterile processing department of the healthcare facility to ensure that all conditions essential for sterilization and drying are effectively achieved. Before opening a container, the perioperative nurse should check for evidence of integrity and sterility, and the lid should be carefully removed. The perioperative nurse should examine the contents to verify that the indicator or integrator has changed and that steam or ethylene oxide has reached the interior. When the scrub person removes the inner basket, he or she should ensure that the inner basket does not touch the outer container (AORN, 2009h).

If textile wrappers are used, they must be laundered between sterilization exposures to ensure sufficient moisture content of the fibers. This prevents superheating and absorption of the sterilizing agent. Rehydrated materials also deteriorate at a slower rate. All wrappers must be checked for holes or tears before use. Many in-hospital packaging materials—woven and nonwoven, reusable and disposable—are marketed today. Materials should be evaluated carefully before a product is chosen.

The size and density of woven textile packs must be restricted to ensure uniform steam penetration. The pack should not exceed 12 × 12 × 20 inches (30 × 30 × 50 cm) and should not weigh more than 12 lb (5.4 kg). When the items in the pack are being assembled, the lighter materials should be placed near the center of the pack. Each succeeding layer of dry goods should be placed crosswise on the layer below to promote free circulation of steam and removal of air. Pack density should not exceed 7.2 lb per cubic foot. A chemical indicator or integrator that accurately reflects one or more of the physical parameters of sterilization should be inserted into the center of each pack. These parameters are time, temperature, and steam saturation.

The pack should be wrapped sequentially in two barrier-type wrappers, which may be disposable or reusable. A single-textile reusable wrapper is defined as one layer of 270- to 280-thread count woven fabric. Cross-stitching and raw edges are unacceptable. Sequential double-wrapping creates a package within a package, providing for ease in presenting the wrapped item to the sterile field. Wrappers are made in suitable dimensions for the various items that must be packaged. The familiar envelope wrap is made by placement of the article diagonally in the center of the wrapper. The near corner, which should point toward the worker, is brought over the item, and the triangular tip is folded back to form a cuff. The two side flaps are folded to the center in like manner. The far corner of the wrapper is then folded on top of the other three. The process is repeated with the second wrapper, and the package is secured with autoclave indicator tape.

When the pack is opened for use, the flaps at the corners are used to form a protective cuff over the person's hands during dispensing of the sterile contents. When the items are wrapped, the wrappers should be folded securely about the contents. The package should be firm and sealed securely to prevent contamination in handling and storage. Single, disposable, nonwoven wrappers composed of fused material layers are available and widely used to wrap surgical supplies. These single wrappers provide a bacterial barrier at least equivalent to the sequential double wrap and allow for safe and easy presentation of the package contents to the sterile field, providing an alternative to the sequential double-wrapping procedure. Careful wrapping to prevent tenting and gapping of the package is essential (Figure 3-6). Nonwoven, single-use wrappers should not be reused (AAMI, 2009a).

Sterilization process (chemical) indicator tape should be used to hold wrappers in place on packages and to indicate that the packages have been exposed to the physical conditions of a sterilization cycle. When packages are opened, these tapes should be first torn so that the package cannot be retaped and then removed from reusable wrappers because they create laundry problems, such as occluding screens and filters. In some cases, the tapes leave a dye on the wrappers that may cause deterioration of the material. Tapes also may leave an adhesive residue that can interfere with future sterilizations of the fabric.

Sterilization pouches, commonly manufactured from a combination of paper and plastic films, provide an option for the packaging of single (or small groups) or lightweight instruments or other objects (e.g., medicine cups) for steam or gas sterilization. Double pouching is generally used with this method. A chemical indicator appropriate to the sterilization method is placed in the pouch and the pouch is sealed either with heat lamination or with a self-adhesive strip (Figure 3-7).

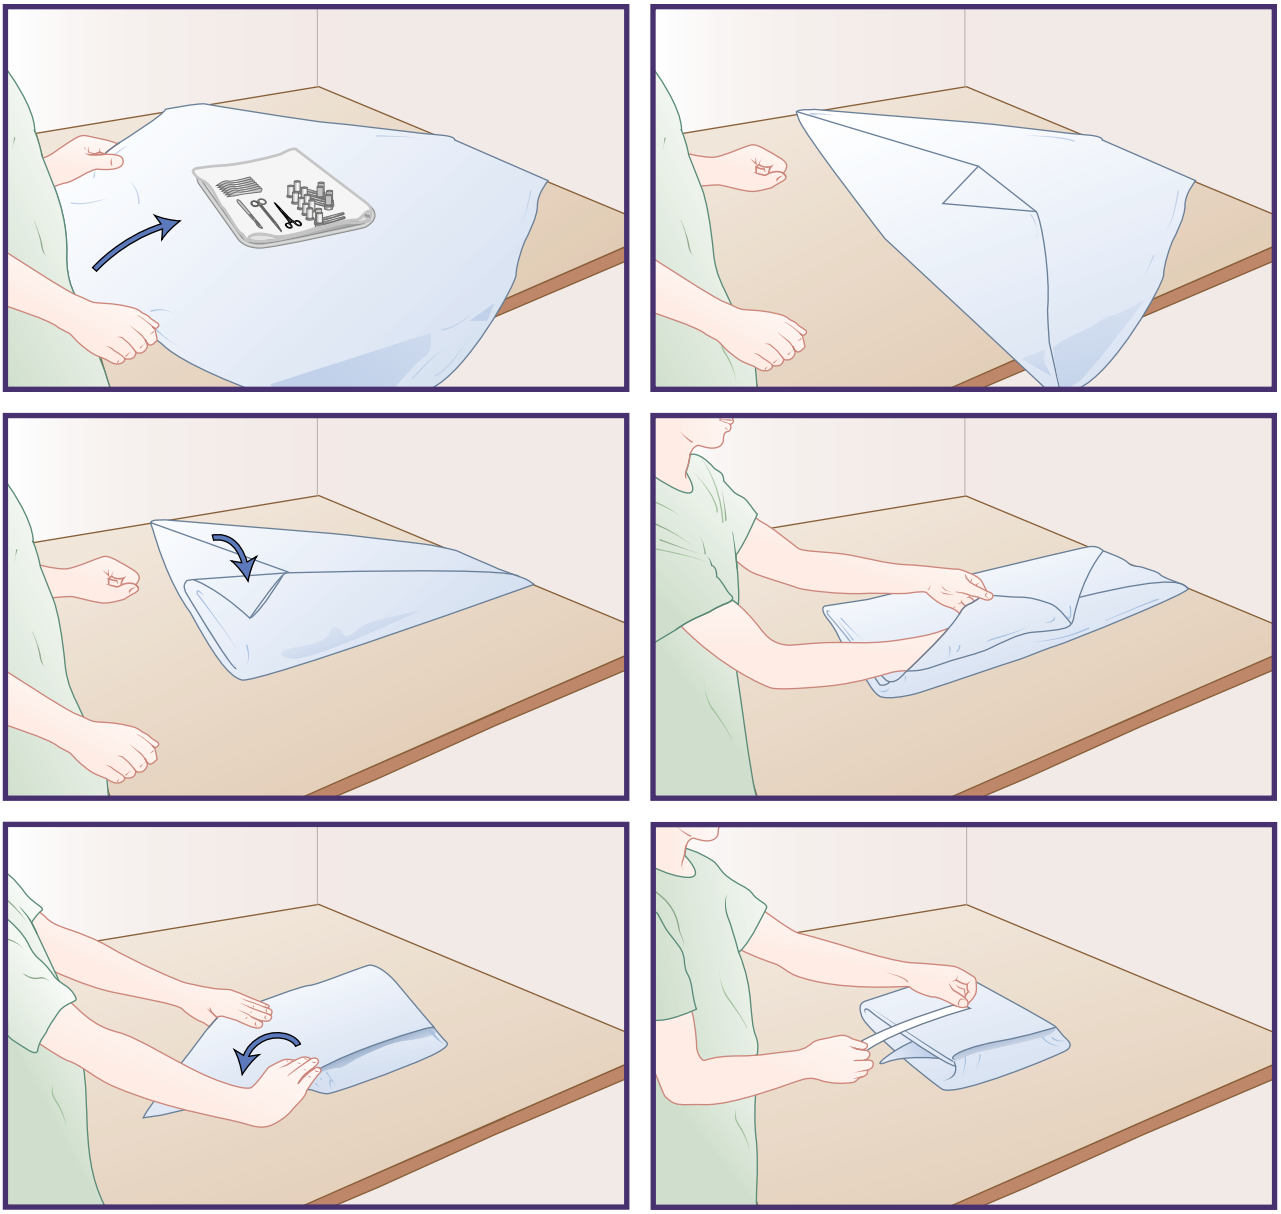

FIGURE 3-6 Envelope style wrapping.

Every package intended for sterile use should be imprinted or labeled with a load-control number that identifies the date of sterilization, the sterilizer used, and the cycle or load number. Load-control numbers facilitate identification and retrieval of supplies, inventory control, and appropriate rotation to ensure that dated packages are used first (AAMI, 2009a). Additional information to be noted on the label includes the initials of the person who prepared the item(s) and the package contents.

Some instruments or packaging systems may present challenges to the sterilization process. Special preparation or loading procedures may be necessary to meet these challenges. Hinged instruments must be arranged so that the steam can contact all surfaces of the instrument, including the tips, hinged surfaces, and ratchets. To accomplish this, these instruments must be sterilized in the open position. If the instruments have ringed handles for the fingers, the instruments may be placed on a "stringer," which is a U-shaped metal rod made especially for this purpose. When using closed container systems for sterilization, basket attachments may be used to immobilize instruments in the proper position for sterilization. Tubular instruments with lumens can trap air, which interferes with the sterilization process. To avoid this problem, lumens should be moistened with water immediately before sterilization. As the instrument is heated, the water turns to steam and forces the air out of the lumen. Instruments with concave or other surfaces that can hold water must be carefully placed on-edge to facilitate removal of air, which may become trapped in the concave surface. Placing the instrument on-edge also facilitates drainage of condensate. Items such as basins, which may be stacked for sterilization, should be stacked with sufficient space between all surfaces so that steam can contact all surfaces (AAMI, 2009a; CDC, 2008a).

When packaging is complete and the sterilizer chamber is loaded, the bundles and packages should be arranged to minimize resistance to steam, which must pass through the load

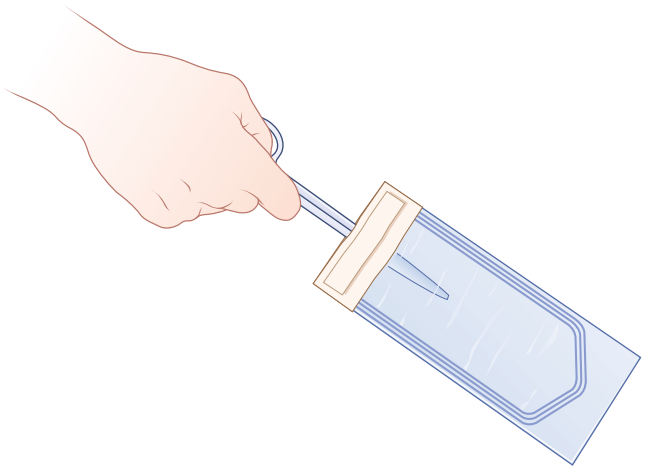

FIGURE 3-7 Sterilization pouch.

from the top of the chamber toward the bottom of the sterilizer. All packages should be placed on a vertical edge in the sterilizer in a loose-contact position. This allows free circulation and penetration of steam, enhances air elimination, prevents entrapment of air or water, and precludes excessive condensation. A second or upper layer may be placed crosswise on the first or lower layer. All jars, tubes, canisters, and other nonporous objects should be arranged on their sides with their covers or lids removed to provide a horizontal path for the escape of air and the free flow of steam and heat. To guard against superheating, surgical packs and supplies should not be subjected to preheating in the sterilizer with steam in the jacket before sterilization.

Rigid container systems should be placed flat on the sterilizer shelf. These containers should not be stacked during sterilization unless the manufacturer specifically recommends this practice. Containers should be stacked only in the manner recommended by the manufacturer's written instructions. Stacking may interfere with air removal and steam penetration. In addition, condensation from upper containers may drip down and contaminate lower containers when the sterilizer door is opened and the cooler room air contacts the containers (AAMI, 2009a; CDC, 2008a).

Sterilizing. When steam enters the autoclave, it is at the same pressure as the atmosphere. As the valves and doors to the outside close, steam pressure rises inside the chamber, increasing the temperature of the steam. Evacuation of air from the sterilizer is necessary to permit proper permeation of steam. If a sterilizer is improperly loaded, mixing of air with steam acts as a barrier to steam penetration and prevents attainment of the sterilization temperature.

The three factors necessary to achieve steam sterilization are *time, temperature,* and *moisture.* The microbial destruction period is based on the known time and temperature necessary to accomplish sterilization in saturated steam. Authorities have shown that definite laws determine the order of death in a given bacterial population subjected to a sterilizing process. If the temperature is increased, the time may be decreased.

To provide a safety margin, the minimum estimated exposure is extended to cover the lag between the attainment of the selected temperature in the chamber and the temperature of the load. The length of exposure varies with the type of sterilizer, cycle design, altitude, bioburden, packaging, and size and composition of items to be sterilized. Written instructions for sterilization parameters should be obtained from the sterilizer manufacturer. If a closed container system is used as packaging for items to be sterilized, the container manufacturer's written instructions for exposure times should be consulted and reconciled with those of the sterilizer manufacturer (AAMI, 2009a).

Sterilizers vary in design and performance characteristics. Use of rigid container systems may alter the come-up and exposure times in steam sterilizers. The configuration of some instruments or medical devices may hinder air removal and steam penetration, making sterilization more difficult. In such circumstances, the device manufacturer must be able to specify the necessary parameters to achieve steam sterilization. Typical minimum cycle times for gravity-displacement steam sterilization and typical minimum cycle times for dynamic air-removal steam sterilization are provided in Table 3-4. Certain instruments and implants require extended time cycles, however. The manufacturer's written instructions for extended time cycles must be followed.

The recording thermometer, not the pressure gauge, is the important guide to the sterilizing phase. The recording clock on the sterilizer gives information about the run of the load and to what temperature the goods were exposed and the exposure time. The temperature inside the chamber must be maintained throughout the determined time of exposure. The sterilization printout documents the come-up time, exposure time, and exhaust time (AAMI, 2009a).

Drying, Cooling, and Storing. On completion of the sterilization cycle, the steam inside the chamber is removed immediately so that it does not condense and produce wet packs. To assist in the drying process, the jacket pressure should be maintained to keep the walls of the chamber hot as the steam from the chamber is exhausted. When the chamber pressure has been exhausted, the door may be opened slightly to permit vapor to escape. Another method is to introduce clean, filtered air by means of a vacuum dryer (ejector) device in conjunction with the operating valve on the sterilizer. The minimum drying time for all methods is approximately 15 to 20 minutes.

After removal from the sterilizer, freshly sterilized packs should be left untouched on the loading carriage until they have cooled to room temperature. This is usually accomplished in 30 to 60 minutes, depending on the load contents. If freshly sterilized packages are placed on cool surfaces such as metal tabletops, vapor still inside the essentially dry package may condense to water. This water may dampen the package from the inside to the outside. When the outside is wet, bacteria may follow the moist tract into the contents of the package. Because bacteria are capable of passing through layers of wet material, any packages that are wet must be considered unsterile.

A written record of existing conditions during each sterilization cycle should be maintained. It should include the sterilizer number, the cycle or load number, the time and temperature of the cycle, the date of sterilization, the contents of the load, and the initials of the operator. These records should be retained for the length of time designated by the statute of limitations in each state.

Sterile packages must be handled carefully and only as necessary. They should be stored in clean, dry, limited-access areas that are well ventilated and have controlled temperature and humidity. Closed cabinets are preferred to open shelves for sterile storage. If open shelves must be used, the lowest shelf should be 8 to 10 inches from the floor to avoid floor contamination.

TABLE 3-4

Common Time-Temperature Parameters for Steam Sterilization

Type of Sterilizer	Load Configuration	Temperature, in °C (°F)	Time, in Minutes
Gravity displacement	Porous or nonporous	121-123 (250-254)	15-30
		132-135 (270-275)	10-25
Prevacuum	Porous or nonporous	132-135 (270-275)	3-4 or manufacturer's instructions
Steam flush/pressure pulse	Porous or nonporous	121-123 (250-254)	20
		132-135 (270-275)	3-4

The highest shelf should be at least 18 inches from the ceiling to allow for circulation around the stored items. All shelves should be at least 2 inches from outside walls to facilitate air circulation and avoid any condensation that might accumulate on the walls during periods of severe temperature change. Shelving should be smooth and well spaced, with no projections or sharp corners that might damage the wrappers. Sterilized packs should never be stacked in close contact with each other. Their arrangement on the shelves should provide for air circulation on all sides of each package. Excessive handling, crowding, dropping, and stacking of sterile packs tend to force particles through the mesh or matrix of the wrapping material, which might contaminate the contents. Sterile items should not be stored near or under sinks or in any area where they can become wet.

Shelf life refers to the length of time a pack may be considered sterile. Loss of package sterility is event-related as opposed to time-related; that is, what happens to the package after sterilization determines its continued sterility—not the length of time the package remains on the shelf ready for use. Variables that must be considered in determining shelf life are the type and number of layers of packaging material used, the presence or absence of impervious protective covers, the number of times a package is handled before use, and the conditions of storage. Impervious protective covers known as *dust covers* may extend shelf life by protecting the sterile package from a contaminating event. When used to protect sterilized items, impervious covers should be designated as such to prevent their being mistaken for a sterile wrap. They should be applied only to thoroughly cooled, dry packs at the time of removal from the sterilizer cart, after the required cooling period (AORN, 2009h).

Supply standards should be planned to maintain adequate stock with prompt turnover. Appropriate volume and proper rotation of supplies reduce the need for concern about shelf life. The longer an item is stored, the greater the chances of contamination. For proper rotation, the most recently dated sterile packages should be placed behind those already on the shelves.

Quality Control Practices: Physical Monitoring. Physical monitoring includes checking items such as time, temperature, and pressure recorders; digital printouts; and gauges. All mechanical parts of sterilizers, including gauges, steam lines, and drains, should be checked periodically by the engineering department within the facility. The individual responsible for the sterilizers should keep reports of these inspections. Temperature, humidity, and vacuum should be measured with control equipment, independently of the fixed gauges. There are several methods of keeping a constant check on the proper functioning of a sterilizer and ensuring the efficiency of the sterilizing process. *Mechanical, chemical,* and *biologic* controls assist in identifying and preventing sterilizer malfunction and operational errors made by personnel (Table 3-5). Automatic controls are a type of mechanical control that, by a predetermined program, controls all phases of the sterilizing process. The controls allow the steam to enter, monitor the time of the sterilizing cycle, exhaust the steam, and initiate drying. Some lock the door so that it cannot be opened until the cycle is complete.

On older sterilizers, recording thermometers (a dial on the front of the sterilizer) were the mechanical control that indicated and recorded the temperature throughout the sterilizing cycle. Sterilizers today provide a digital readout as opposed to a graphic depicter of the sterilizing cycle. The digital readout records a decrease in temperature when and if it occurs; this can warn of sterilizer failure. The digital readout records the time the sterilizer reaches the desired temperature and the duration of each exposure. It can be determined if a decrease in temperature occurred, warning of sterilizer failure. These recordings are proof that the exposure time of loads has been correct and proper temperature limits have been maintained. The daily record should show the number of the sterilizer, the number of cycles run, the time, and the date. Mechanical monitoring devices provide real-time assessment of sterilizer-cycle conditions and permanent records by means of either chart recordings or computer printouts. This evidence can be used for detection of malfunctions as soon as possible so that alternative procedures can be implemented while the cause of the malfunction is identified and corrective action is taken. Recordings cannot detect air pockets within the load or pack, however. Air is a poor conductor of heat; it is one of the most common causes, other than human error, of sterilization failure (AAMI, 2009a).

Chemical controls, also commonly known as *chemical indicators* or *integrators,* include devices such as pellet-containing, sealed glass tubes; sterilizer indicator tapes; color-change cards or strips, which may or may not provide a line of demarcation to indicate use or nonuse of the sterilizer load; and indicators containing color-changing enzymes, which mimic or provide a representation of bacterial kill. Some enzyme indicators contain a biologic component; others do not. Chemical indicators are used to detect failures in packaging, loading, or sterilizer function, such as presence of cool air pockets inside the sterilizing chamber. Chemical indicator cards or strips that are impregnated with a material that changes color or moves up a gauge when steam initiates a chemical reaction are placed in instrument trays or other packages. No chemical monitor verifies that an item is actually sterile. Integrators are so named for their ability to integrate time, temperature, and the presence of steam. They reduce the risk of using an unsterile pack and may be used with numerous types of sterilization processes. Because they vary in color changes for each type of sterilizer

TABLE 3-5

Mechanical, Chemical, and Biologic Sterilization Monitors

Type	Classification	Application
Temperature and pressure recording devices Time recording devices Digital recording devices	Physical monitors	Steam EO Low-temperature: • H_2O_2 plasma • Ozone • Peracetic acid
External strips/tape	Chemical monitors	Used on outside of packages
Bowie-Dick type indicators		Used for dynamic air removal in steam sterilizers
Internal chemical indicator strips (CIs)		Used for: • Steam • EO • Low-temperature H_2O_2 • Ozone
Geobacillus stearothermophilus	Biologic monitors (indicator)	Used for routine load release, efficacy monitoring, qualification testing, product quality assurance, etc. Used for: • Steam • Low-temperature H_2O_2 gas plasma sterilizers • Ozone sterilizers • Liquid peracetic acid sterilizers Should be done weekly, preferably daily, and according to sterilizer manufacturer's written instructions Each load that contains implantable devices should be monitored with a BI; load should be quarantined until BI test results are obtained
Bacillus atrophaeus (formerly *Bacillus subtilis*)	Biologic monitor	Ethylene oxide monitoring devices that should be performed on every load to be sterilized

Modified from Association for the Advancement of Medical Instrumentation (AAMI): *Sterilization in healthcare facilities,* Arlington, VA, 2009, The Association, available at www.aami.org. Accessed July 24, 2009; Association of periOperative Registered Nurses (AORN): Recommended practices for sterilization in the perioperative practice setting. In *Perioperative standards and recommended practices,* Denver, 2009, The Association.
EO, Ethylene oxide.

and because they may have different wording on the integrator to denote that an instrument set or other item is acceptable for use, perioperative nurses and scrub persons should always refer to the manufacturer's written instructions when relying on indicators and integrators (AORN, 2009h).

An external chemical indicator should be used on all packages to be sterilized except those that allow direct visualization into the package, where an internal indicator is used (e.g., paper or plastic pouches). The primary purpose of the external indicator is to differentiate between processed and nonprocessed packages. This indicator should be checked after the sterilization process and before a package is opened to determine that the package has been exposed to a sterilization process.

Each package requiring sterilization should have an internal chemical indicator or integrator placed within the area of the package believed to be least accessible to steam penetration. The indicator or integrator should be located and interpreted by the user at the time the package is opened and before use of the contents (AORN, 2009h).

A biological indicator (BI) is the most accurate method of checking sterilization effectiveness. Commercially prepared biologic indicators should be stored and used according to the manufacturer's written instructions. They contain a known population of *Geobacillus stearothermophilus,* a highly heat-resistant, spore-forming microorganism that does not produce toxins and is nonpathogenic. Rapid-action indicators are available commercially for certain types of sterilizers. These indicators provide a preliminary enzymatic reaction that is highly correlated to biologic kill. Reaction times range from 20 seconds to 3 hours. The length of time necessary for an initial reading depends on the type of sterilizer, type of indicator used, and the cycle used. For a true indication of biologic kill, only indicators having a biologic component should be used, and the indicator should be incubated after the initial reading according to the manufacturer's instructions to ensure accurate results (AAMI, 2009a).

Biologic testing should be done after initial installation of steam sterilizers, after any major repair of the sterilizer, and with all loads of implantable devices. Whenever possible, implantable devices should be quarantined until the results of the biologic testing are available.

Biologic testing for steam sterilizer loads should be conducted weekly and preferably daily on the first run of the day. The BI should be placed in a test pack that is positioned on-edge in the front, bottom section of a routinely loaded steam sterilizer. This area of the sterilizer provides the greatest challenge for the test pack. AAMI (2009a) has defined the contents of the test pack. Commercially prepared test packs are also available.

After the sterilization cycle, the BI is removed from the pack and incubated according to the manufacturer's instructions. Negative reports (failure to recover any spores from the indicators in the test pack) indicate that the sterilizer is functioning properly. Results of these tests should be filed as a permanent record. A positive report does not indicate sterilizer failure

FIGURE 3-8 General-purpose gravity air displacement steam sterilizer. This type of sterilizer can be used to sterilize wrapped or unwrapped instruments and utensils, linen packs, and solutions in specially designed vented flasks. These units are available in several sizes, from the small unit similar in size to the washer-sterilizer described in Figure 3-5 to large, floor-loading units. A medium-size unit is pictured here. Some units have sophisticated microprocessor controls that allow maximum flexibility in selecting sterilization and drying times and help in troubleshooting if a problem occurs during a cycle. Digital readouts and heat-sensitive paper printouts have replaced the round chart and pen found on older models. These changes have helped the operator more easily determine and document that the conditions needed for proper sterilization were met.

because false-positive results sometimes occur. The sterilizer should be retested immediately, however, and taken out of service until it is operationally inspected and the results of retesting are negative. If a sterilizer malfunction is found, all items prepared in the suspect load should be considered unsterile. They should be retrieved if possible and washed, repackaged, and resterilized in another sterilizer. All items in any load processed since the last negative result also should be considered suspect and should similarly be retrieved if possible (AAMI, 2009a)

When a prevacuum sterilizer is used, a test designed to detect residual air in the chamber should be run daily. The test, generally known as a *Bowie-Dick* test, is run with an otherwise empty chamber so that residual air is not forced into other packs or materials, degrading the test results. The Bowie-Dick test determines the efficacy of the vacuum system of the sterilizer. The Bowie-Dick test is *not* a sterility-assurance test.

Types of Steam Sterilizers. For sterilization to occur, steam must contact all surfaces of the item to be sterilized. To accomplish this, the air in the sterilizer chamber must be evacuated. The terms *gravity displacement* and *dynamic air removal* describe the methods by which air leaves the sterilizer chamber. Dynamic air removal sterilizers use preconditioning techniques to remove air from the sterilizing chamber. This may be through a vacuum pump (prevacuum) or by an above atmospheric pressure process, such as the steam-flush pressure-pulse process.

At the beginning of the cycle in a gravity displacement sterilizer, steam begins to enter the chamber after the door is closed and locked (Figures 3-8 and 3-9). An initial burst of steam enters the chamber and forces out much of the free air in the chamber. Air is heavier than steam, and the two do not mix well. As more steam enters the chamber, the air that is held by gravity at the bottom of the chamber exits down the drain, which is at the bottom of the sterilizer—hence the name *gravity displacement sterilizer.*

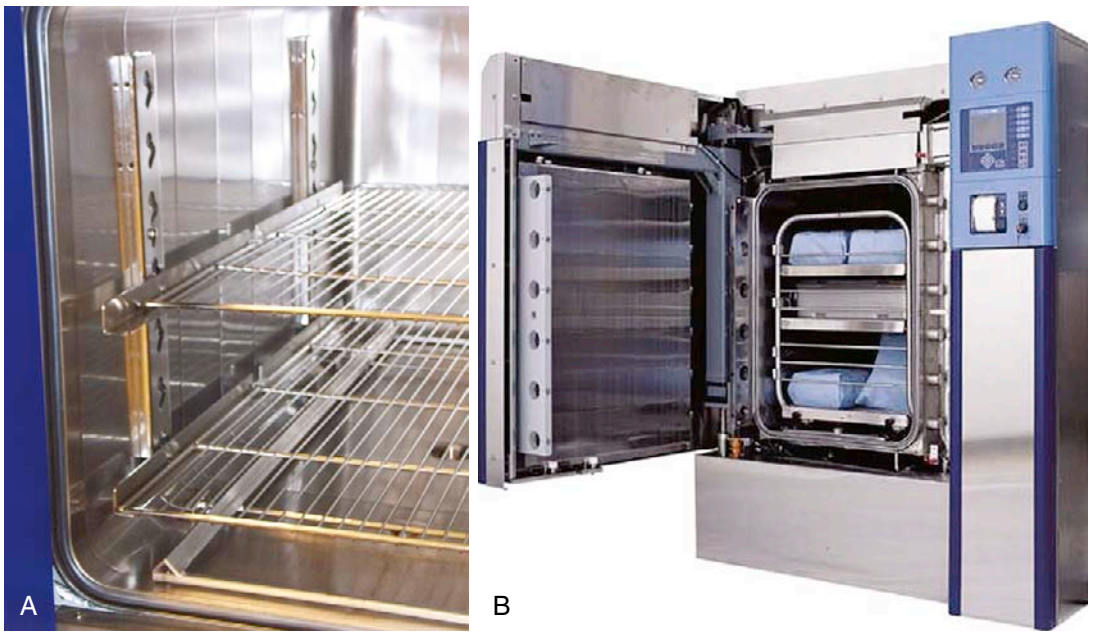

FIGURE 3-9 **A**, Adjustable racks are designed to permit maximum loading efficiency. **B**, Instrument baskets or trays should have either wire-meshed bottoms or a sufficient number of perforations in the sheet metal to allow for air removal and drainage of condensate during the sterilization cycle.

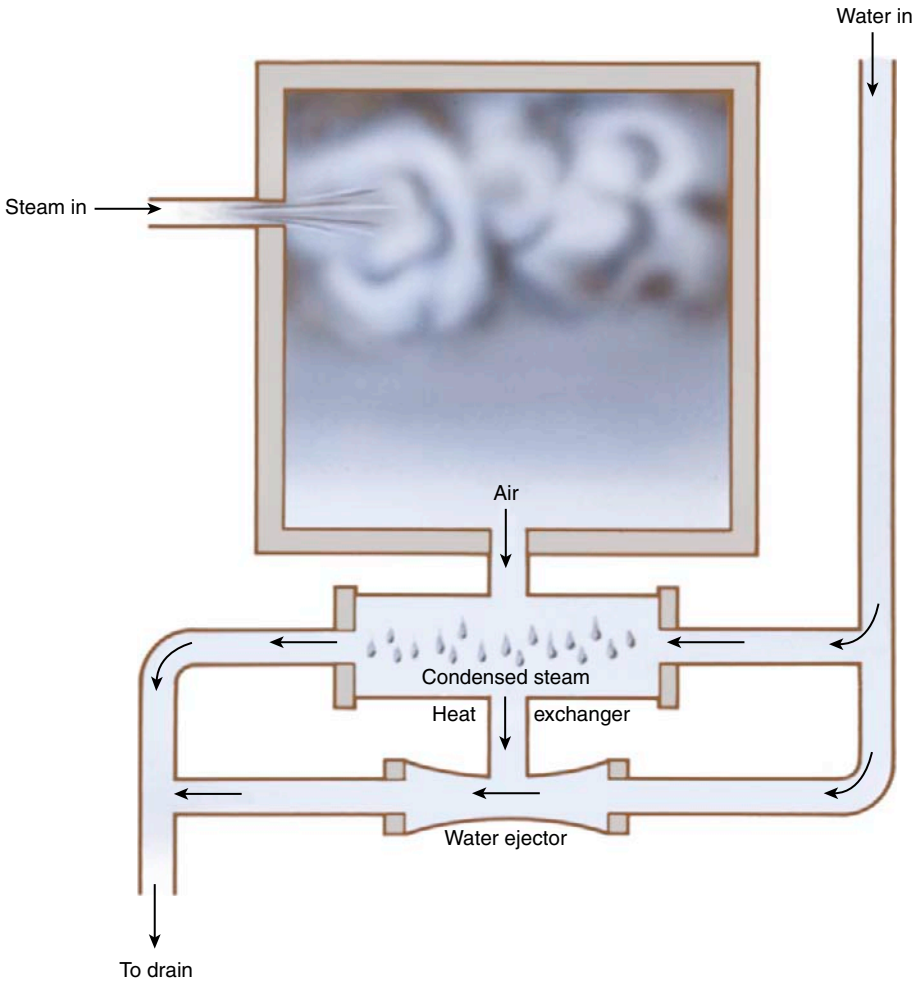

FIGURE 3-10 Prevacuum steam sterilizer. This type of sterilizer features active, aggressive removal of air rather than relying on the passive action of gravity. When the cycle is initiated, steam is injected with force into the chamber. At the same time, the drain at the bottom of the chamber is automatically closed. As more steam enters the chamber, pressure increases and the steam and air form a turbulent mixture. When a specific pressure is reached, the drain opens, and the pressurized steam and air rush from the chamber, aided by a water ejector or a vacuum pump. This sudden rush of gas from the chamber creates a vacuum within the chamber. This process is repeated several times and deepens the level of vacuum drawn with each pulse. The effect of this pulsing cycle is to displace any air in the load and rapidly increase the chamber and load temperatures. At the conclusion of this conditioning phase, steam flows into the chamber and raises the temperature to sterilization levels, usually 132° C (270° F). The temperature is maintained for at least 3 minutes for unwrapped, nonporous materials and 4 minutes for wrapped or porous items. Steam is removed from the chamber to draw a partial vacuum again. Heated, filtered air is introduced into the chamber to dry the load. Drying times are selected and set by the user, depending on the nature of the load. Some units have a special cycle designed for rapid sterilization of an instrument tray in a single wrapper. This express cycle has fewer conditioning pulses, a 4-minute exposure time, and 1 or 2 minutes of dry time, for a total cycle time of approximately 12 minutes. Although the wrapper feels warm and dry to the touch, the contents may not be totally dry. This package should be handled by individuals wearing sterile gloves and using sterile towels for protection from burns. The instruments sterilized in this express cycle must be used immediately. Because the contents are not dry, the package is not suitable for storage

In a prevacuum cycle, rather than passive air removal as is the case with the gravity sterilizer, air is actively removed from the sterilizer (Figure 3-10). When the cycle is initiated, steam is injected with force into the chamber. At the same time, the drain at the bottom of the chamber is automatically closed. As more steam enters the chamber, pressure increases, and the steam and air form a turbulent mixture. When a specific pressure is reached, the drain opens, and the pressurized steam and air rush from the chamber, aided by a water ejector or a vacuum pump. This sudden exit of gas from the chamber creates a vacuum within the chamber. This is the basis for the name *prevacuum sterilizer.* The sterilizer repeats this injection and vacuum process four times in succession in an effort to evacuate all air from the chamber (AAMI, 2009c; CDC, 2008a).

Some prevacuum sterilizers have the capability of providing an *abbreviated prevacuum cycle.* In this cycle, there are two rather than four pulses of the steam injection-vacuum process. This cycle may be used only for simple metal or glass instruments. No instruments with a lumen should be sterilized using this cycle (AAMI, 2009c; CDC, 2008a).

The *high-speed steam sterilizer,* commonly referred to as a *flash sterilizer,* can be adjusted to operate at 132° C (270° F) and 27 psi of pressure for shortened cycles with no accompanying drying cycle. Flash sterilization can be accomplished in either a gravity displacement or a dynamic air-removal sterilizer. Flash sterilization is most frequently used in the OR for sterilizing urgently needed unwrapped instruments. AORN's *Recommended Practices for Sterilization in the Perioperative Practice Setting* recommend that the use of flash sterilization should be kept to a minimum. Flash sterilization should be used only in selected clinical situations and in a controlled manner. This method of sterilization is intended for use with unwrapped items or sterilizing trays or container systems developed specifically for the flash cycle. Flash-sterilized items are to be used immediately after sterilization; they may not be stored for future use. Flash sterilization should not be used for implantable devices except in cases of emergency when no other option is available (AORN, 2009g). In an emergency, when flash sterilization of an implant is unavoidable, a rapid-action BI with a chemical integrating indicator should run with the load (AORN, 2009g). The BI should continue to be incubated for the full time. Documentation should reflect patient follow-up if the final biologic test indicates a failure. Appropriate perioperative planning along with communicating and working with implant manufacturers may help decrease unplanned flash sterilization of implantable devices (AORN, 2009g). Although flash sterilizing is considered a rapid method of sterilization for unwrapped items, some pulsing gravity and the abbreviated prevacuum cycles have been designed with a brief drying cycle intended to dry the single wrapper. Flash sterilization containers should be used, cleaned, and maintained according to the manufacturer's written instructions. Flash sterilization containers should be opened, used immediately, and not stored for later use. Flash sterilization containers should be differentiated from other types of containers (AORN, 2009g). Routine cycle parameters for flash sterilization are shown in Table 3-6. Meticulous recordkeeping must be implemented for flash sterilization. At minimum, facilities should document the patient's name, surgery or procedure performed, item(s) and number flashed, and exposure time and temperature (Stanton, 2008). Additional information to document includes the operator information and reason for flash sterilization. Analysis of the frequency of flash sterilization, the number of objects flashed, and the reason for using flash sterilization can be used as an impetus for process improvements.

CHEMICAL STERILIZATION. Materials that cannot be heat-sterilized are continually being introduced for use in healthcare. These materials require the use of other methods of sterilization. Chemical agents provide an effective alternative to steam sterilization. Chemical sterilization is frequently referred to as *low-temperature sterilization.* This term refers to maximum temperatures of 54° to 60° C (130° to 140° F) for gaseous sterilization compared with temperatures of 121° to 132° C (250° to 270° F) for steam sterilization.

Sterilization can be achieved by many agents when only vegetative cells are present. If the microbial population is unknown, however, a sporicidal agent must be employed to ensure sterilization. An antimicrobial agent must exhibit a wide microbiologic spectrum and sporicidal activity to qualify as a chemosterilant.

Ethylene Oxide. *Ethylene oxide (EO)* is an alkylating agent that results in microbial death under controlled parameters. EO has had application for heat-labile and moisture-sensitive items, such as intricate, delicate surgical instruments; large pieces of equipment; and electrical instruments. EO should be used if alternate methods of sterilization are not available or compatible with the medical devices being processed. EO is colorless at ordinary temperatures, has an odor similar to that of ether, and has inhalation toxicity similar to that of ammonia gas. EO is a known carcinogen and must be used carefully because of its toxicity. It is highly explosive and very flammable in the presence of air. These hazards are greatly reduced by dilution of EO with inert gases such as carbon dioxide and hydrochlorofluorocarbons (HCFCs). Neither of these two inert gases seems to affect the bactericidal activity of EO, serving only as inert diluents that reduce the flammability hazard.

There are several theories on how EO kills bacteria. The killing rate of bacteria is generally believed to be relative to the

TABLE 3-6

Time-Temperature Parameters for Flash Steam Sterilization

Type of Sterilizer	Load Configuration	Temperature, in °C (°F)	Time, in Minutes
High-speed gravity displacement	Metal or nonporous items only (no lumens)	132-135 (270-272)	3 (follow manufacturer's instructions for express cycle)
	Metal items with lumens and porous items (e.g., rubber, plastic), which are sterilized together	132-135 (270-272)	10
Prevacuum (dynamic air removal)	Metal or nonporous items only (no lumens)	132-135 (270-272)	3
	Metal items with lumens and porous items, which are sterilized together	132-135 (270-272)	4 or manufacturer's instructions
Pulsing gravity	All loads	Manufacturer's instructions	Manufacturer's instructions should be followed for time and temperature
Abbreviated prevacuum	All loads	Manufacturer's instructions	Manufacturer's instructions should be followed for time and temperature

rate of diffusion of the gas through the bacterial cell walls and the availability or accessibility of one of the chemical groups in the bacterial cell walls to react with EO. The killing rate also depends on whether the bacterial cell is in a vegetative or spore state. Destruction takes place by alkylation through chemical interference and probably inactivation of the reproductive process of the cell. In the process of alkylation, a hydrogen atom within the microbial cell is replaced with a portion of the EO molecule (e.g., an alkyl group). This process alters the structure of the microbial molecule and renders it nonfunctional. When sufficient molecules within the microbial cell are subjected to this process, the microbial cell is rendered unable to metabolize or produce infection.

Items to be sterilized with EO must be thoroughly cleaned and dried so that no visible droplets remain. Drying inhibits the formation of ethylene glycol during the sterilization cycle. Lumens should be dry and open at both ends. Caps, plugs, valves, and stylets should be removed from instruments or equipment to permit the gas to circulate through the items. The packaging material used should possess the characteristics described previously in this chapter.

Items to be sterilized should be placed in a loose configuration within the confines of metal baskets or sterilizer carts. Packages should not touch the chamber walls when loaded into the sterilizer. An excessively large load or a load that is tightly packed interferes with proper air removal, load humidification, sterilant penetration, and sterilant evacuation at the conclusion of the cycle. Penetration of gas throughout the load is essential. Compression of packages prevents penetration of the gas. If packages are wrapped in plastic, compression hinders evacuation of air and causes packages to open during the decrease in chamber pressure when a vacuum is drawn. Proper loading is essential so that sterilized items do not fall from the container or cart after sterilization, requiring personnel to handle them before aeration. Because metal baskets or carts do not absorb ethylene oxide, they can be handled before aeration. An EO-sensitive chemical indicator should be used with each package to indicate that the package was exposed to the gas. The chemical indicator does not indicate achievement of sterility (AORN, 2009g).

Factors affecting sterilization with EO are time of exposure, gas concentration, temperature, humidity, and penetration. The exposure time required depends on temperature, humidity, gas concentration, the ease of penetrating articles to be sterilized, and the type of microorganisms to be destroyed (Table 3-7). Gas concentration is affected by the temperature and humidity inside the sterilizing chamber. If the concentration of gas is doubled, the exposure time may be shortened. Temperature and humidity have a pronounced influence on the destruction of microorganisms. They are important in gaseous sterilization with EO because they affect penetration of the gas through bacterial cell walls and through wrapping and packaging material.

TABLE 3-7

Common Parameters for Ethylene Oxide Sterilization

Time, in Minutes	Temperature, in °C (°F)	Humidity, in %	Gas Concentration, in mg/L
105-300	37-63 (99-145)	45-75	450-1200

Dry spores are the most difficult to kill, but when such spores are moistened their resistance to gas penetration is lowered. Dehydration makes some microorganisms nearly immune to EO sterilization, whereas droplets of moisture can inhibit the action of the gas by protecting the organism. EO sterilizers with automatic controls provide for moisture injection to increase the relative humidity within the chamber. Manufacturers of gas sterilizers have developed recommended exposure periods for various EO concentrations in relation to the material to be sterilized. Exposure time is set for absolute destruction of the most resistant microorganisms, which is a very slow process.

The adequacy of every EO cycle should be verified by the use of biologic monitors that contain *Bacillus atrophaeus* (*formerly Bacillius subtilis*). AAMI (2009a) has defined two standard test packs for use in monitoring the EO sterilization cycle. The sterilizer manufacturer's written recommendations regarding cycle parameters should be followed.

EO-sterilized items must be aerated to make them safe for personnel handling and patient use. At the conclusion of the sterilization cycle, items may be removed safely from the chamber to a separate aerator. Certain models of sterilizers may have an internal aeration cycle. The sterilizer manufacturer's recommendations relating to opening the sterilizer door after completion of the sterilization cycle and subsequent transferring of items to the aerator must be followed closely. Excessive exposure to EO represents a health hazard to personnel. It is a known carcinogen and has been linked to reproductive problems and other disorders in animals. Inhalation of EO should be avoided or minimized, and direct contact with items sterilized by EO should be avoided during transfer to the aerator. Various safety features, such as a purge system, an audible alarm at the end of the sterilization cycle, and automatic door-locking and door-sealing mechanisms, are used on EO sterilizers to protect personnel. Opening the sterilizer door within the capture zone of the scavenging hood for a period of 5 to 10 minutes can reduce operator exposure to the sterilizing gas. If the sterilizer contents are not removed at that time, they begin to "outgas," resulting in increased EO concentration within the chamber.

Aeration is accomplished in a mechanical aerator. The length of aeration for each item should be based on the manufacturer's written recommendations. Typical aeration times when a mechanical aerator is used are 8 to 12 hours at 50° to 55° C (122° to 131° F) or 12 to 16 hours at 38° C (100.4° F). When moving items from the sterilizer to the aerator, they should be handled minimally. Personnel should not breathe the air that passes over baskets or carts containing EO-sterilized items. To avoid breathing this air, carts should always be pulled as opposed to pushed. Depending on the sterilization-cycle temperature used, items may be warm to the touch at the end of the cycle. Butyl rubber gloves are recommended to protect personnel from contact with liquid EO and from thermal injury (AORN, 2009g).

Because of the highly explosive and flammable nature of EO, the sterilizer and aerator should be installed in a well-ventilated room and should be vented to the outside atmosphere as recommended by the manufacturer and by the requirements of the National Institute for Occupational Safety and Health (NIOSH). Only authorized personnel are allowed access, and hazard signs should be posted. Compliance with other administrative controls to ensure safety is essential.

EO is carcinogenic and carries potential as a reproductive hazard; therefore OSHA has issued standards regulating personnel

exposure to EO. These standards set the permissible exposure level (PEL) (the amount of EO in the air) at 1 part per million (ppm) and the action level (AL) (monitored value at which corrective action should occur) at 0.5 ppm. These are calculated as time-weighted averages (TWAs) over an 8-hour period. OSHA requires that monitoring and surveillance be performed to ensure that exposure levels do not exceed 1 ppm over an 8-hour period (OSHA, 1984). In addition, occupational exposure level to EO may not exceed 15 ppm in any 15-minute period. This is known as the *excursion level* (EL). EO-monitoring badges are available and required. Adherence to these guidelines helps protect patients and personnel from problems associated with EO sterilization (AAMI, 2009c; OSHA, 1984, 1988).

In general, EO sterilization should be used *only* if the materials are heat-sensitive and unable to withstand sterilization by saturated steam under pressure. EO's advantages are that it is easily available; it is effective against all types of microorganisms; it easily penetrates through masses of dry material; it does not require high temperatures, humidity, or pressure; and it is noncorrosive and nondamaging to items. Sterilization with EO also has numerous disadvantages. The long exposure and aeration periods make it a lengthy process. Compared with other methods of sterilization, EO sterilization is expensive. Liquid EO may produce serious burns on exposed skin if not immediately removed; insufficiently aerated materials can cause skin irritation, burns of body tissue, and hemolysis of blood; and diluents used with EO cause damage to some plastics. Human error and mechanical breakdown can enhance these disadvantages (AAMI, 2009c; OSHA, 1984).

Aqueous Glutaraldehyde. When used properly, liquid chemosterilants can destroy all forms of microbial life, including bacterial and fungal spores, tubercle bacilli, and viruses. Although formaldehyde is one of the oldest chemosterilants known to destroy spores, it is rarely used in the United States because it takes 8 to 24 hours to be effective, its pungent odor is objectionable, and it may cause irritant or allergic reactions. Glutaraldehyde works more rapidly and is less irritating than formaldehyde solutions.

Activated aqueous glutaraldehyde 2% is recognized as an effective liquid chemosterilant. It is most useful in the disinfection of lensed instruments, such as cystoscopes and bronchoscopes, because it has minimal deleterious effects on the lens cement and is noncorrosive. Its low surface tension permits easy penetration and rinsing.

Instruments must be free from bioburden and completely immersed in activated aqueous glutaraldehyde solution for 10 hours to achieve sterilization. Any period of immersion less than 10 hours does not kill spores that may be present and must be considered as only a disinfection procedure. During immersion, all surfaces of the instrument must be in contact with the liquid chemosterilant. After immersion, instruments must be rinsed thoroughly with sterile distilled water before being used.

Peracetic Acid. Liquid peroxyacetic (peracetic) acid is a biocidal oxidizing agent. Peracetic acid sterilization is a system that uses a chemical formulation of 35% peracetic acid and water. Peracetic acid is an effective biocide at low temperatures and is effective in the presence of organic material. It has a chemical formula of acetic acid plus an extra oxygen atom. This extra oxygen atom is highly reactive; it reacts with most cellular components and causes cellular death. The ability of peracetic acid to inactivate many different critical cell systems is responsible for its broad-spectrum antimicrobial activity. As peracetic acid is changed to acetic acid and the oxygen decomposes, it is rendered nontoxic and environmentally safe. Because peracetic acid is highly corrosive to instruments, it must be used in combination with anticorrosive additives (AORN, 2009g). Commercially available sterilization systems using peracetic acid have found increasing use in recent years because of their relatively short cycles and subsequent ability to ready items for use quickly. These systems should be maintained and used according to the manufacturer's instructions. Although peracetic acid does not leave toxic residues on items that have been adequately rinsed, the agent may cause serious injury if not handled, neutralized, and rinsed properly. Items processed in peracetic acid systems should be used immediately after processing because the item containers are wet and are not sealed from the environment. Some controversy regarding internal-process monitors has existed with peracetic acid sterilization systems. *Bacillus atrophaeus* indicators should be used on installation of a peracetic acid sterilization unit and after any major repairs. Manufacturer recommendations should be sought and carefully followed for routine sterilizer monitoring.

Low-Temperature Hydrogen Peroxide Gas Plasma Sterilization. Low-temperature hydrogen peroxide gas plasma sterilization should be used for moisture-sensitive and heat-sensitive items and when indicated by the device manufacturer. Plasma is the fourth state of matter, the sequence being solid, liquid, gas, and plasma. Gas plasmas are highly ionized gases composed of ions, electrons, and neutral particles. In this process, microbial life is disrupted when free radicals created from hydrogen peroxide gas plasma interact with microbial cell membranes, enzymes, or nucleic acids (AORN, 2009g). To create gas plasma for sterilization, a precursor solution, such as hydrogen peroxide, is introduced into a closed area in the sterilizer under low-vacuum conditions. In this process, microbial life is disrupted when free radicals created from hydrogen peroxide gas plasma interact with microbial cell membranes, enzymes, or nucleic acids. Hydrogen peroxide vapor is charged with radiofrequency, and plasma is created that removes hydrogen peroxide residuals from the sterilized items. The byproducts of this process are oxygen and water (in the form of humidity). Packages are dry at the end of the cycle (AAMI, 2009c; AORN, 2009g).

Plasma sterilization is displacing ethylene oxide sterilization for most applications. It is designed to provide nontoxic, dry, low-temperature sterilization in a shorter turnaround time than that of ethylene oxide. The hydrogen peroxide gas plasma process rapidly destroys a broad spectrum of microorganisms, including gram-negative and gram-positive vegetative bacteria, *Mycobacterium,* yeasts, fungi, lipophilic and hydrophilic viruses, and highly resistant aerobic and anaerobic bacterial spores. Cycle times for gas plasma sterilization vary depending on the model of sterilizer being used. At the completion of the sterilization process, no toxic residues remain on the sterilized items. No aeration is necessary, making it a safe process for patients and healthcare workers. Preparation of instrumentation for sterilization includes cleaning and decontaminating procedures, drying, reassembly, and wrapping with nonwoven polypropylene wraps or Tyvek/Mylar pouches (Figure 3-11). Cellulosic-based products, such as paper and linen, are not recommended for use with plasma systems because they tend to absorb the vapor and cause the sterilization cycle to abort.

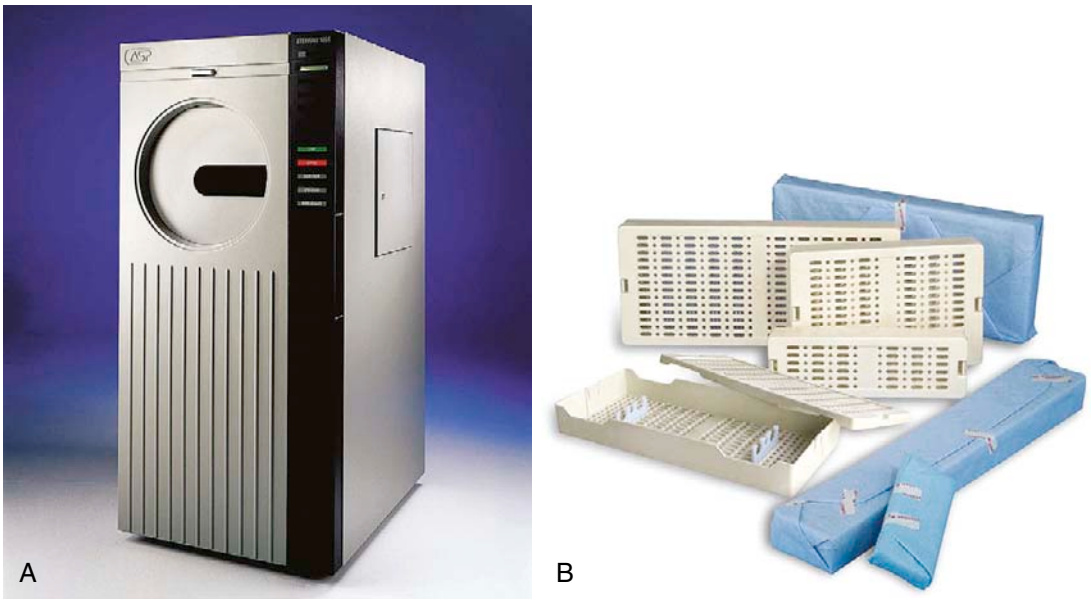

FIGURE 3-11 **A**, Gas plasma sterilizer. **B**, Supplies for use in low-temperature, gas plasma sterilization systems.

Manufacturer's written instructions for use should always be followed (AAMI, 2009c; AORN, 2009g).

Biologic and chemical indicators for process verification are used in the same manner as indicators for steam and ethylene oxide sterilization procedures. Plasma sterilization processes should be tested with biologic indicators at intervals similar to the intervals used for steam and ethylene oxide sterilization. Manufacturer recommendations should be followed in determining the specific monitor to be used. For hydrogen peroxide plasma sterilization systems, *Geobacillus stearothermophilus* spores show the greatest resistance to kill. The importance of consulting the system manufacturer for specific instructions cannot be overemphasized (AAMI, 2009c; AORN, 2009g).

DRY HEAT STERILIZATION. Dry heat sterilization should be used only when the materials cannot be sterilized by other methods, when the moisture of other processes would damage the materials, or when the materials would be impermeable to the process. These materials include grease, anhydrous oils, powders, and some glassware. Dry heat is not a suitable sterilization method for fabrics and rubber goods because the high temperatures necessary for sterilization cause deterioration of these materials. There are two kinds of dry heat (also known as *hot air*) sterilizers—the gravity convection type and the mechanical convection type. Both heat by electricity to achieve accurate and dependable temperature control.

In the *gravity convection sterilizer,* convection is created by the temperature differences within the sterilizing chamber. The heating apparatus present in the bottom of the chamber warms the air within the chamber. The warmed air rises, contacting the items in the chamber to be sterilized. At contact, heat is transferred from the air to the items. With this loss of heat, the cooled air descends toward the bottom of the chamber where it is warmed again by the heating coils.

In the *mechanical convection sterilizer,* the heating apparatus is outside the chamber, in a compartment separated from the chamber by a diffusing wall placed in front of a motor-driven turbine blower. Through an internal process, air is heated and forced into a chamber on the opposite wall. From this chamber, the air is discharged into the chamber uniformly over the vertical plane of the chamber. This system provides for uniform delivery of heated air and equal transfer of heat to all regions of the chamber. This system offers the maximum functional efficiency at a minimum cost and is the system most often used in hospitals (AAMI, 2009c).

Because of the variation in items to be sterilized and packaging methods and materials, parameters for dry heat sterilization vary. Temperature parameters refer to the temperature of the load, not sterilizer chamber temperature.

Spore tests may be used with dry heat sterilization. *Bacillus atrophaeus* is the most commonly used challenge microorganism. The sterilizer manufacturer's instructions should be carefully followed for sterilizer monitoring (AAMI, 2009a).

Disinfection. High-level disinfectants play a key role in the processing of semicritical medical devices. They must be practical, fast, safe, and easy to use. Appropriate cleaning, disinfecting, and sterilizing of reusable devices are crucial to ensure their safe use and to maintain equipment integrity. Advances in instrument processing, specifically in the area of high-level disinfectants, continue to support better patient care in the clinical setting.

Disinfection is defined as the process of eliminating many or all pathogenic organisms, except bacterial spores, from inanimate objects. In healthcare facilities, equipment is usually soaked in liquid chemicals for a specified period to achieve disinfection of the equipment or item. The disinfection process may destroy tubercle bacilli and inactivate hepatitis viruses and enteroviruses but usually does not kill resistant bacterial spores. The term *disinfection* also may refer to treatment of body surfaces that have been contaminated with infectious material. Chemicals used to disinfect inanimate objects are referred to as *disinfectants*. Chemicals used for body surfaces are known as *antiseptics*. The term *germicide* refers to any solution that destroys microorganisms. Some germicides are disinfectants and antiseptics.

Disinfectants are categorized as high-level, intermediate-level, or low-level, depending on their disinfecting capability. High-level disinfectants kill all microorganisms except high numbers of bacterial spores. Intermediate-level disinfectants may kill tubercle bacilli, vegetative bacteria, and most viruses and fungi but not bacterial spores. Low-level disinfectants kill most vegetative bacteria and some viruses and fungi.

As with sterilization, an item must be cleaned properly before it can be disinfected. Thorough cleaning removes all foreign substances, such as soil or organic material, from a device. This is usually accomplished by the use of soap and water or an enzymatic detergent. The term *decontamination* refers to the removal of pathogenic organisms from an object, making the object safe to handle.

Items to be sterilized or disinfected have been classified as critical, semicritical, and noncritical, based on the risk of infection for the patient. This classification system, known as the *Spaulding classification system* and named for its developer, Earle Spaulding (Banerjee et al, 2008), has withstood the passage of time and continues to be used today to determine the correct processing method for preparing instruments and other items for patient use. According to the Spaulding system, the level of disinfection required is based on the nature of the item and the manner in which it is to be used.

Critical items are items that enter sterile tissue or the vascular system. These items should be subjected to a sterilization process and be sterile at the time of use. Many critical items are purchased from the manufacturer as sterile. Unsterile critical items should be steam-sterilized if they are heat-stable and moisture-stable. If the items cannot withstand heat or moisture, they may be sterilized by one of the other methods discussed earlier. Examples of critical items include surgical instruments, needles, implants, and certain types of catheters (Banerjee et al, 2008).

Semicritical items are items that contact nonintact skin and mucous membranes but do not ordinarily penetrate the blood barrier. Examples of semicritical items include anesthesia breathing circuits, fiberoptic endoscopes, and laryngoscopes. Semicritical instruments require high-level disinfection; that is, these items must be free of microorganisms other than bacterial spores. Examples of high-level disinfecting agents include glutaraldehyde, *ortho*-phthalaldehyde, stabilized hydrogen peroxide, peracetic acid, and chlorine or chlorine compounds (Banerjee et al, 2008).

Noncritical items are items that come into contact only with intact skin. Because skin is an effective barrier to most microorganisms, most noncritical, reusable items can be cleaned at the point of use. Intermediate-level or low-level disinfectants may be used to process noncritical items. Examples of noncritical items include blood pressure cuffs, bedpans, linens, utensils, furniture, and floors. Although it is unlikely that infection will be transmitted to patients with intact skin by means of noncritical items, noncritical items can contaminate the hands of healthcare workers or medical equipment that will be used on other patients, which may pose a greater risk for infection. Examples of low-level disinfectants include alcohols, sodium hypochlorite, phenolic solutions, iodophor solutions, and quaternary ammonium solutions (Banerjee et al, 2008).

TYPES OF DISINFECTANTS. Many disinfectants are used alone or in combinations, such as hydrogen peroxide and peracetic acid, in healthcare settings. These include alcohols, chlorine and chlorine compounds, formaldehyde, glutaraldehyde, ortho-phthalaldehyde, hydrogen peroxide, iodophors, peracetic acid, phenolics, and quarternary ammonium compounds. In healthcare the commercial products are considered unique and must be registered with the EPA or cleared by the FDA. In most cases, a given product is designed for a specific purpose and should be used accordingly. Disinfectants are not interchangeable, and incorrect use can cause occupational diseases among personnel who are associated with their use. Written instructions for use should be followed and precautions should be taken to minimize exposure to these products. The following are various types of disinfectants that are used in today's healthcare facilities (CDC, 2008a).

Alcohols. For disinfection in healthcare, the term *alcohol* refers to either 70% or 90% isopropyl alcohol. Both of these compounds are water-soluble and have a high degree of germicidal activity. They are bactericidal as opposed to bacteriostatic against vegetative forms of bacteria. They also are tuberculocidal, fungicidal, and virucidal. Isopropyl alcohol (*n*-propanol) and ethyl alcohol (*n*-ethanol) at concentrations of 60% to 80% are potent virucidal agents that can inactivate lipophilic viruses such as herpes and the influenza virus along with many hydrophilic viruses such as rhinovirus and rotaviruses. Studies have demonstrated the ability of ethyl and isopropyl alcohol to inactivate the hepatitis B virus (HBV) and to inactivate the human immunodeficiency virus (CDC, 2008a). The alcohols do not destroy spores or kill certain hydrophilic viruses. Alcohols are flammable and must be stored in a well-ventilated area. Because they evaporate rapidly, extended contact time is difficult to achieve unless items are immersed. Alcohols lack residual effect and are easily inactivated by protein material. Alcohols tend to damage the coating on lensed instruments and may cause hardening of certain rubber and plastic tubing after repeated exposure to the compound. Alcohols are considered intermediate-level disinfectants. They are often used to disinfect thermometers and rubber stoppers on medication vials. Alcohol also is used in processing flexible endoscopes. After high-level disinfection and a tap water rinse, alcohol is effective in inactivating water contaminants. Its speed of evaporation also assists in rapid drying of the endoscope channels. Guidelines from the Association of Practitioners in Infection Control (APIC) should be followed (AORN, 2009i; CDC, 2008a).

Chlorine Compounds. In healthcare facilities, hypochlorites are the most widely used of the chlorine compounds. Hypochlorites are available in a liquid form (sodium hypochlorite [liquid household bleach]) and in a solid form (calcium hypochlorite). Hypochlorites have a broad-spectrum of antimicrobial activity. They are inexpensive and fast-acting. Low concentrations of free chlorine (50 ppm) are effective against vegetative bacteria and *Mycoplasma*. Free chlorine at 50 ppm inactivates HIV, whereas a 500-ppm concentration is needed to inactivate HBV. Concentrations of 1000 ppm are recommended for inactivation of bacterial spores. Household bleach contains 5.25% sodium hypochlorite. A dilution of 1:1000 provides 50 ppm of available chlorine. A dilution of 1:50 provides 1000 ppm of available chlorine, which is considered adequate to achieve high-level disinfection. The CDC recommends a 1:10 solution, which provides 5000 ppm of available chlorine. Hypochlorite solutions are stable for 30 days in opaque containers. Beyond that time, a new solution should be prepared. Hypochlorites are inactivated in the presence of organic matter. All organic material should be removed before application of the disinfecting solution. Hypochlorites are used sparingly on instruments because of the corrosive action of the compound.

Hypochlorites are most often used for countertops, floors, and other surfaces to be disinfected. Other chlorine compounds that may be used include chlorine dioxide and chloramine-T. Chlorine compounds are the preferred disinfectant in water treatment (CDC, 2008a; AORN, 2009i).

Glutaraldehyde. Glutaraldehyde is a saturated dialdehyde that has gained wide acceptance as an overall effective high-level disinfecting agent and chemical sterilant. Aqueous solutions of glutaraldehyde are acidic and in this state not sporicidal. The solution is said to be "activated" when alkalizing agents are added to make the solution alkaline. Glutaraldehyde has a broad antimicrobial range, being effective against vegetative bacteria, *M. tuberculosis,* fungi, and viruses. Although glutaraldehyde is effective against most bacteria in 10 minutes, some species of mycobacteria require a longer exposure time. To achieve high-level disinfection, a minimum exposure time of 20 to 45 minutes is recommended, based on the manufacturer's written instructions (AORN, 2009g). Glutaraldehyde is noncorrosive to endoscopic equipment, thermometers, rubber, and plastic. Glutaraldehyde phenate is a related compound that has been shown to lose efficacy against certain organisms in the recommended dilution. Another compound, glutaraldehyde with *ortho*-phenylphenol and *para-tert*-amylphenol, provides a wide range of antimicrobial activity similar to that of 2% glutaraldehyde. The compound is odorless and minimizes irritation and allergic reactions in users (AORN, 2009g; CDC, 2008a).

***ortho*-Phthalaldehyde (OPA).** *ortho*-Phthalaldehyde is a 0.55% *ortho*-phthalaldehyde solution in an aqueous buffer with a pH of 7.5 and is considered a high-level disinfectant. Studies have demonstrated excellent microbicidal activity and mycobacterial activity. The solution is bactericidal, virucidal, and fungicidal. It is tuberculocidal at a minimum exposure time of 12 minutes at room temperature. It has several potential advantages over glutaraldehyde. It has excellent stability over a wide pH range and is odorless, and it is not known to irritate the eyes or nasal passages. As with any high-level disinfectant, PPE should be employed when using *ortho*-Phthalaldehyde. *ortho*-Phthalaldehyde can be used for most applications for which glutaraldehyde is used and has broad materials' compatibility. The manufacturer's written instructions should be read before use (AORN, 2009g; CDC, 2008a).

Hydrogen Peroxide. Hydrogen peroxide is active against a wide range of microorganisms, including bacteria, yeasts, fungi, viruses, and spores (CDC, 2008a). Unstable and low concentrations of hydrogen peroxide (<3% solution) may be used as low-level disinfectant for work-surface cleaning and disinfection. Stabilized 6% hydrogen peroxide is sporicidal and can be used as a liquid sterilant with sufficient exposure time. The solution is corrosive, however, to copper, zinc, and brass. It also can damage rubber and plastic. As with other chemicals, dilution of hydrogen peroxide must be monitored by regularly testing the minimum effective concentration. Hydrogen peroxide is not used widely as a disinfectant in today's healthcare environment (AORN, 2009g; CDC, 2008a).

Iodine and Iodophors. Iodine solutions have been used widely by health professionals, primarily as antiseptics on skin or tissue. An iodophor is a water-soluble combination of iodine and a solubilizing agent or carrier that allows for a slow but continuous release of free iodine over time. Iodophors may be used as disinfectants or antiseptics, depending on the concentration of free iodine. The most widely used iodophor is povidone-iodine (Betadine). As disinfectants, iodophors have the advantage of having the germicidal efficacy of iodine without the disadvantages of toxicity and surface irritation. Iodophors are usually nonstaining and effective against vegetative bacteria, *M. tuberculosis,* and most viruses and fungi. Iodophors are not considered suitable for high-level disinfection or for use as hard-surface disinfectants because they have no sporicidal capability (CDC, 2008a).

Phenolics. Phenol (carbolic acid) was first used by Lister in the mid-1800s. Since that time, many phenol derivatives (phenolics) have been developed. Phenolics are assimilated by porous material, making their removal difficult. Residual disinfectant can cause tissue irritation. Most phenolic formulations are tuberculocidal, bactericidal, virucidal, and fungicidal. Certain viruses, including echovirus, are resistant to phenolics. Phenolics are not sporicidal, and they are not considered effective as high-level disinfectants. They are used primarily as intermediate-level and low-level disinfectants for environmental cleaning. They are known to have toxic effects, however, and their use has been associated with depigmentation and hyperbilirubinemia in newborns. Because of this, phenolics are not recommended for cleaning incubators or infant bassinets (CDC, 2008a).

Quaternary Ammonium Compounds. Quaternary ammonium compounds ("Quats") have been used for many years as a result of a reputation for microbicidal activity, good detergent action, and low-level toxicity. In more recent times, it has been noted that environmental factors, such as hard water, soap residues, and protein soils, reduce or nullify the efficacy of these compounds. Quaternary ammonium compounds are ineffective against *M. tuberculosis* and lipophilic viruses. These compounds are not considered to be sporicidal. Quaternary ammonium compounds are not recommended for high-level, intermediate-level, or low-level disinfection. They are good cleaning agents and are used most often for noncritical surfaces such as floors, walls, and furniture (AORN, 2009d; CDC, 2008a).

CLEANING AND PROCESSING ENDOSCOPES AND ACCESSORIES. In today's technologically advanced environment, flexible fiberoptic endoscopes and their associated instrumentation allow for a myriad of minimally invasive surgical procedures. The list of these procedures grows daily. Current technology allows not only for direct visualization of internal structures, but also for diagnostic biopsies and therapeutic procedures to be performed with reduced pain and shorter recovery time and hospital length of stay. Along with advances in technology, complications also have occurred. Some complications, such as bleeding or tissue perforation, are immediately obvious. Infectious complications may be more difficult to identify.

Endogenous and exogenous microorganisms can cause infections related to endoscopic procedures. When an infection occurs from endogenous sources, organisms normally present in the procedure area gain access to the bloodstream. Examples of endogenous infections resulting from endoscopy include localized infections, pneumonia, endocarditis, brain abscess, and subdural empyema. Infections also can be caused by organisms introduced into the patient via the endoscope (exogenous organisms). Organisms commonly associated with exogenous infection include *Pseudomonas, Klebsiella, Enterobacter, Salmonella,* and *M. tuberculosis*. Because HAV, HBV, HCV,

and HIV are inactivated by commonly used chemical germicides, documented endoscopic transmission of these viruses is uncommon. HBV transmission via the endoscope has been reported, as has the transmission of tuberculosis via a contaminated bronchoscope (CDC, 2008a).

For an endoscope to be thoroughly disinfected, the disinfecting agent must contact all internal and external surfaces of the endoscope for the prescribed length of time. Organic soil, such as blood, feces, or respiratory secretions, harbors embedded microorganisms and prevents penetration of the disinfecting agent. Some disinfectants are inactivated by organic material. Rigorous mechanical cleaning is essential to remove soil and debris from the outside of the scope and from the lumens of all accessible channels (CDC, 2008a).

Endoscopes and their accessories should be cleaned immediately after use to prevent drying of secretions or other organic soil. They should be cleaned with a nonabrasive enzymatic detergent as recommended by the endoscope manufacturer (AORN, 2009j; CDC, 2008a). If a powdered detergent is used, all granules must be dissolved completely before washing begins. Undissolved granules can block the internal channels of the instrument. To soften, moisten, and dilute organic debris, endoscope channels should be flushed with copious amounts of water and detergent. The external surfaces of the endoscope should be washed with a detergent solution and rinsed. Internal channels should be brushed to loosen and remove organic matter. The detergent solution should be suctioned or pumped through all channels to remove loosened debris. Special attention should be given to convoluted areas and crevices where contaminated organic material may lodge. The tip of the endoscope should be gently wiped or brushed to remove any debris or tissue that may be lodged around the air and water outlets. Brushes used for cleaning should be disposable or be thoroughly cleaned and sterilized daily. Detachable parts of the endoscope, such as hoods and suction valves, should be removed and soaked in a detergent solution. They should be thoroughly cleaned with a detergent, using a brush to remove any organic material (AORN, 2009j; CDC, 2008a).

Before immersion in any liquid, endoscopes should be pressure tested (leak tested) to determine the integrity of seals and minimize the potential for damage to the head of the scope. If damage is detected, the scope should not be immersed or reused. The endoscope should be removed from service and returned to the manufacturer for repair. An endoscope sent for repair is considered a contaminated item and must be labeled as such for shipping.

Immediately after endoscopes are decontaminated and cleaned, they should be rinsed of residual debris and cleaning agents. After a tap-water rinse, endoscopes should be rinsed with 70% or 90% alcohol and forced–air-dried. Alcohol inactivates organisms normally found in tap water and helps dry the internal channels of the scope. After being cleaned, endoscopes and accessories should be sterilized or high-level disinfected before being stored. Care must be taken to dry internal channels of the scopes after being processed and before being stored. Endoscopes should be stored in a vertical position in an area in which recontamination is unlikely. Endoscopes should be processed immediately before patient use, including first use of the day, to preclude the possibility that the scope may have been recontaminated during storage or handling or both. Endoscopes should be sterilized or high-level disinfected, depending on their intended use (see discussion of the Spaulding classification system earlier in this chapter). Because of pressure and heat sensitivity, for many years the sterilization method of choice for endoscopes was EO. More recently, other technologies and liquid peracetic acid with anticorrosive buffers and Sterrad NX also have been used to process endoscopes. As the utilization of endoscopic surgery expands, and the need for sterile endoscopes increases, additional processing methodologies are expected to become available (AORN, 2009j; CDC, 2008a)

Activated glutaraldehyde was long considered the agent of choice for high-level disinfection of endoscopes. A manual or an automated system may be used. Regardless of whether a manual or automated system is used, meticulous manual cleaning must precede the disinfection process. The solution manufacturer's written instructions should always be followed (CDC, 2008a).

The facility should maintain a log for each procedure with the patient's name, medical record number (if available), and type of procedure being performed; the endoscopy physician's name; and the serial number or other identifier of the scope. If an automatic endoscope reprocessor is used, identification of this device should be included in the record. This documentation assists in the tracking and investigation in the event of an outbreak or safety concern (AORN, 2009g).

PASTEURIZATION. Pasteurization is a process that uses hot water at temperatures between 65.5° C (150° F) and 76.6° C (170° F) for 30 minutes to achieve high-level disinfection. The actual time/temperature relationship depends on the items to be disinfected. Contact time is inversely related to temperature. For equivalent microbial destruction, longer exposure times are required when the temperature is decreased. Controversy exists as to whether pasteurization results in high-level or intermediate-level disinfection. The CDC definition of high-level disinfection requires destruction of all microbial life except for large populations of bacterial spores. Because pasteurization, by definition, does not kill bacterial spores, some would consider the process to result in only intermediate-level disinfection. Some semicritical items, such as respiratory therapy and anesthesia devices, are ready for patient use after cleaning and pasteurization. High numbers of bacterial spores are not found often on these devices after use. Cleaning before pasteurization reduces the bioburden, and the low number of spores that might be present on a properly pasteurized device of this type would not represent an infective dose when contacting intact mucous membranes. Advantages of pasteurization include absence of toxic residues and the associated need for postprocess rinsing. Disadvantages of pasteurization include the lack of sporicidal activity and the potential for splash burns to personnel involved with the process (AAMI, 2009a).

Reprocessing/Reuse of Items Labeled for Single-Use Only. Healthcare trends reflect cost-driven market forces and consumer-driven demands for quality, safety, and effectiveness. Facilities in today's marketplace are reprocessing and reusing devices labeled for single use (Ambulatory Surgery Considerations). The practice of reprocessing and reusing single-use items is controversial and some facilities choose this process as a cost containment effort and to reduce the amount of waste. Each facility must decide whether to reprocess and to what

extent the practice should be instituted. Three basic tenets must be included in any reprocessing/reuse program, as follows:

- If a device cannot be cleaned, it cannot be reprocessed and reused.
- If sterility of a postprocessed device cannot be shown, the device cannot be reprocessed and reused.
- If the integrity and functionality of a reprocessed single-use device cannot be shown and documented, the device cannot be reprocessed and reused (AORN, 2009k).

AMBULATORY SURGERY CONSIDERATIONS

Ambulatory Surgery Centers and the Device Reprocessing Debate

According to the *AORN Guidance Statement: Reuse of Single-Use Devices,* it is noted that this process may realize some operational savings. The authors further elaborate on the fact that a cost-benefit ratio analysis should be completed before any unit or organization enters into this practice.

In the May 2009 issue of *OR Manager,* the author discusses the reprocessing debate as it affects ambulatory surgery centers (ASCs). The three ways to handle used single-use medical and surgical devices are currently identified in the following manner:

- Dispose of them after use.
- Reprocess the device according to the stringent Food and Drug Administration (FDA) guidelines.
- Contract with a reprocessing specialty company to collect, reprocess, and reship the product to the center.

The FDA publishes an extensive listing of single-use devices that have been identified for reprocessing. The FDA has been monitoring this situation since 2001, with vigorous oversight and the development of stringent guidelines and their subsequent enforcement. They have clearly identified those devices that penetrate the mucosa as high risk and do not endorse reprocessing of these devices. The FDA became involved in the debate when they were alerted by the original manufacturers of devices that facilities were reprocessing devices without ensuring the efficacy, effectiveness, and sterility of the original product.

Can Devices be Reprocessed in the Ambulatory Surgery Setting Effectively?
Yes. The ASC needs to engage in a course of identifying the devices based on the FDA listing and requirements along with developing a cost-benefit ratio to determine if the devices meet the needs of their center. The May 2009 *OR Manager* article clearly points out that in some centers this policy works well, some centers have room for improvement, and in other ASCs the practice does not function well for the organization.

SUMMARY
Even with strong oversight by the FDA, the debate will continue as the issues surrounding surgical site infections (SSIs), the economy, and the associated costs remain front and center. The end-users, usually the surgeon and the perioperative nurse, will need to be aware of issues such as cost, efficacy, and associated changes to the FDA's and the manufacturer's recommendations. The issues of universal healthcare coverage and the cost to the public for the plan, along with such issues surrounding documentation from the original manufacturer over concerns of efficacy and sterility after reprocessing by a third party, will expand and need to be monitored.

Modified from Device reprocessing makes inroads in ASCS: *OR Manager* 25(5):28-29, 2009; Association of periOperative Registered Nurses: AORN guidance statement: Reuse of single-use devices. In *Perioperative standards and recommended practices,* Denver, 2009, The Association.

Although some savings may be realized by reusing certain single-use devices, any cost-benefit analysis necessarily would include consideration of the labor costs associated with reprocessing; program costs, including quality systems requirements such as sterility and postprocessing testing, documentation, and record-keeping costs; and the cost of device failure. The results of this cost analysis are helpful when making a decision about reprocessing/reusing single-use devices (Research Highlight).

The FDA views any reprocessor as a manufacturer and subject to federal regulations governing manufacturers. Hospitals and third-party reprocessors are subject to the same regulations as the original equipment manufacturer. These requirements include the following:

- Registration and listing
- Medical device tracking
- Medical device reporting
- Corrections and removals
- Device labeling
- Quality system regulation
- Premarket notification requirements (AORN, 2009k; AAMI, 2009b)

Each requirement has associated resource needs. An in-depth discussion of these requirements is beyond the scope of this textbook. Details of the FDA requirements for reprocessors can be found in the *Code of Federal Regulations*.

If a user facility chooses to engage a third-party reprocessor as opposed to conducting the program at the facility, it is the user facility's responsibility to assess the quality of the services provided under the contractual arrangement with the third-party reprocessor. The user facility must review the processes used by the contracted agency and determine whether correct procedures are being followed (CDC, 2008a; AORN, 2009b).

ASEPTIC PRACTICES TO CONTROL INFECTION

Surgical Aseptic Principles

Asepsis has been defined as the absence of infectious organisms. Surgical aseptic practices are based on the premise that most infections are caused by organisms exogenous to the surgical patient's body. To avoid infection, surgical procedures must be done in a manner that minimizes or eliminates the patient's exposure to exogenous organisms. Opening sterile supplies as close to the time of their use as possible, using sterile drapes to create a sterile field around the incision site, using sterile instruments for the surgical procedure, and placing the operative team in sterile attire after their hands and arms have been cleansed of surface bacteria aid in avoiding infection.

Aseptic technique stems from the principles of asepsis derived over time from microbiologic and epidemiologic concepts. Although some investigators may believe that current aseptic practices and techniques have become too ritualistic or lack scientific research to support their use, present-day infection-control statistics support the application of aseptic principles for safe perioperative nursing practice. Until empiric research shows that a technique is unnecessary or ineffective, the basic aseptic principles should be followed. These principles follow:

1. Only sterile items are used within the sterile field. Individuals dispensing sterile items to the sterile field must look at the sterilization indicator on or visible in the package, check

RESEARCH HIGHLIGHT

Reprocessing Single-Use Devices

The practice of reprocessing single-use, disposable devices has been controversial since the 1970s. Authors favoring the practice cite substantial cost savings and the absence of adverse patient outcomes. Authors who oppose the practice cite concerns about cleaning and sterilizing the devices and concerns about product integrity. Other authors cite the ethical issues of multiple charging for the same device. The purpose of this study was to determine whether reprocessed single-use devices could be sterilized and whether the devices would meet the same standards as a new device.

Single-use and reusable biopsy forceps and papillotomes and a reusable stone-retrieval basket were selected for the study. Eleven instruments, including a sterile control device, were used for the cleaning test. Devices were first contaminated with a radionuclide product and then cleaned under running tap water at 30° to 35° C (86° to 95° F) for 3 minutes. The inner lumens were flushed using a 10-ml syringe filled with enzymatic cleaner. The instrument was submerged in the same enzymatic cleaner for 10 minutes. After the enzymatic soak, the devices were placed in an ultrasonic bath of tap water at 30° to 35° C (86° to 95° F) for 5 minutes. After this ultrasonic treatment, lumens were flushed again by using a syringe, and external surfaces were cleaned under running water at 30° to 35° C (86° to 95° F) for 3 minutes. Lumens were dried by blowing air through them using a dry syringe, and the outer surfaces of the devices were dried. After processing, cleaning results were measured using a gamma camera to determine the distribution and intensity of radioactivity of the radionuclide-contaminating product used before cleaning.

To evaluate disinfection of the devices, channels were filled with 2% glutaraldehyde solution, and the devices were submerged in the glutaraldehyde solution for 20 minutes at a temperature of 20° to 25° C (68° to 77° F). After this treatment, lumens were flushed, using a syringe with tap water; the outside was cleaned under running tap water. Water was blown from the lumens with a dry syringe, and the outer surface of the devices was dried. Disinfection was measured in terms of log reduction factors calculated from the difference in colony-forming units before and after processing.

To evaluate sterilization, devices were placed in appropriate packaging materials and exposed to a half-cycle in either a steam sterilizer or an ethylene oxide sterilizer. After sterilization, devices were placed in appropriate culture media and incubated for the designated length of time. Sterilized devices were evaluated for the presence or absence of bacterial growth. Finally, scanning electron microscopy and x-ray photoelectron spectroscopy were used to evaluate device surfaces and the microstructure of materials after processing.

Results of this study showed that all devices remained contaminated after being cleaned, although the level of contamination differed according to type of device. Testing after disinfection and sterilization indicated that reusable devices were adequately disinfected using the described protocol, but single-use devices were not. Sterilization reduced the number of spores on devices, but spores could not be totally eliminated. Finally, single-use and reusable devices were physically damaged during sterilization. Compared with unused devices, surfaces of soiled and reprocessed devices showed increased concentrations of carbon and nitrogen, which were explained as traces of residual peptides from blood or other body materials.

The authors of this study concluded that when using the described standards for cleaning, disinfection, and sterilization, none of the reprocessed single-use devices in this study were suitable for use with subsequent patients. Disinfection and sterilization of disposable devices could not be accomplished to the required levels, and reprocessing procedures resulted in material changes that added to degradation and reduced functional integrity of the devices.

SUMMARY

According to the AORN (2009) *Guidance Statement: Reuse of Single-Use Devices,* reusing some single-use devices may realize some operational savings. However, it is critical to evaluate the cost-benefit ratio for a specific unit and/or organization. AORN believes that as licensed perioperative practitioners we must demonstrate accountability both to the nursing profession and to patients for ensuring the efficacy of any reprocessing program.

Modified from Heeg P et al: Decontaminated single-use devices: an oxymoron that may be placing patients at risk for cross-contamination, *Infect Control Hosp Epidemiol* 22:539-542, 2001; Association of periOperative Registered Nurses: AORN guidance statement: Reuse of single-use devices. In *Perioperative standards and recommended practices,* Denver, 2009, The Association.

for package integrity, and check for the package expiration date (or appropriate marking for event-related shelf life) before dispensing the item to the field.

2. Items of doubtful sterility must be considered unsterile. Examples include sterile items found in unsterile work areas, sterilized packages wrapped in pervious materials that have become wet, sterilized items without an integrator or other internal indicator, and sterilized packages wrapped in pervious materials that are dropped. If a package wrapped in an impervious material is dropped, and the area of contact is dry, the package may be opened and the contents used. The package should not be returned to sterile storage for future use.
3. Whenever a sterile barrier is permeated, it must be considered contaminated. This principle applies to packaging materials and to draping and gowning materials. Obvious contamination occurs from direct contact between sterile and unsterile objects. Other less apparent modes of contamination are the filtration of airborne microorganisms through materials, passage of liquids through materials, and undetected perforations in materials. Moisture soaking through a drape, gown, or package is considered a strikethrough, and the item must be considered contaminated.
4. Sterile gowns are considered sterile in front from shoulder to level of the sterile field and at the sleeves from 2 inches above the elbow to the cuff. The cuff should be considered unsterile because it tends to collect moisture and is not an effective bacterial barrier. The sleeve cuffs should always be covered by sterile gloves. Other areas of the gown that must be considered unsterile are the neckline, shoulders, axillary area, and back. These areas may become contaminated by perspiration or by collar and shoulder surfaces rubbing together during head and neck movements. Wraparound gowns that completely cover the back may be sterile when first put on.

The back of the gown must not be considered sterile, however, because it cannot be observed and protected from contamination. The sterile area of the front of the gown extends to the level of the sterile field because most scrub personnel work adjacent to a sterile table. For this reason, the scrub person should avoid changing levels, as would occur while moving from footstool to floor. To maintain sterility, scrub persons should not allow their hands or any sterile item to fall below the level of the sterile field. Scrub persons should neither sit nor lean against unsterile surfaces because the threat of contamination is great. The only time scrub persons may be seated is when the entire surgical procedure is performed at that level. Self-gowning and gloving should be done from a sterile surface separate from the sterile field. This method eliminates reaching over the sterile field to retrieve the sterile towel and then the sterile gown. It also eliminates the potential for water to be dripped on sterile items or on any part of the sterile field, preventing inadvertent contamination. When prepared, the scrub person's hands should be kept in sight at or above waist level. Elbows should be kept close to the body, and the hands should be kept away from the face. Hands should not be folded under the arms because axillary perspiration may permeate the bacterial barrier of the gown.

5. Tables are sterile only at table level. Sterile drapes are used to create a sterile field. Only the top surface of a draped table is considered sterile. Although the drape extends over the sides of a table, the sides cannot be considered sterile. Any portion of the drape that falls below the top edge of the table cannot be returned to table level. When placed, a drape should not be shifted or moved. Items should be dispensed to a sterile field by methods that preserve the sterility of the items and the integrity of the sterile field. Good judgment must be used when dispensing items by presenting them to the scrub person or by placing them securely on the sterile field. A sterile field should be created as close as possible to the time of use. Sterile drapes also are used to create a sterile field when placed over the patient and operative bed. Any item that extends beyond the sterile boundary is considered contaminated and cannot be returned to the sterile field. A contaminated item must be lifted clear of the operative field without contacting the sterile surface and must be dropped with minimal handling to a nonscrubbed surgical team member, an unsterile area, or a designated receptacle. Interpretation of sterile areas versus unsterile areas on a draped patient requires astute observation and use of good judgment.
6. The edges of a sterile enclosure are considered unsterile. Items should be dispensed to the field in a manner that preserves the sterility of the item and the integrity of the sterile field. After a sterile package or container is opened, the edges are considered unsterile. Sterile and unsterile boundaries are often intangible. A 1-inch safety margin is usually considered standard on package wrappers, whereas the sterile boundary on a wrapper used to drape a table is at the table edge. When opening a sterile wrapper, the top flap is first opened away from the operator; the side flaps then follow. The inside or proximal flap is opened last. All flaps are secured in the hand by the operator, so as not to dangle and contaminate other items. When removing items from a sterile package, the scrub person should lift it straight up from the package. On peel-pack pouches, the inner edge of the heat seal is the line of demarcation. Peel-pack edges should be pulled back as opposed to being torn. The contents of the package should be flipped on the sterile field by the nonscrubbed person or lifted directly upward by the scrub person. Its contents should not be allowed to slide over the side of the package. Interpreting sterile boundaries requires good judgment based on an understanding of aseptic principles.
7. Sterile individuals touch only sterile items or areas; unsterile individuals touch only unsterile items or areas. All members of the surgical team must understand which areas are considered sterile and which are considered unsterile. All must maintain a continual awareness of these areas. Scrubbed individuals must guard the sterile field to prevent any unsterile item from contaminating the field or the individuals themselves. Unsterile individuals must not touch or reach over a sterile field or allow any unsterile item to contaminate the field. When a perioperative nurse opens a package, hand and arm motions are always from unsterile to sterile objects. The nurse avoids contact with the sterile area by placing the hands under the cuff to provide a protected wide margin of safety between the inside of the pack (sterile) and the hands (unsterile) (Figure 3-12). As the unsterile nurse opens a sterile article that is wrapped sequentially in two wrappers with the corners folded toward the center of the article, the corner farthest from the body is opened first and the corner nearest the body opened last. When a scrub person opens a sterile wrapper, the side nearest the body is opened first. This portion of the wrapper then protects the gown and enables the individual to move closer to the table to open the opposite side (Figure 3-13). If

FIGURE 3-12 The perioperative nurse is shown opening the cover of a pack containing sterile drapes for surgery. The cover is cuffed to provide protection for the sterile contents. The nurse avoids contact with the sterile area by keeping all fingers under the cuff as the cover is drawn back over the table to expose the pack contents.

a solution must be poured into a sterile receptacle on a sterile table, the scrub person holds the receptacle away from the table or sets it near the edge of a waterproof-draped table (Figure 3-14). This procedure eliminates the need for the unsterile nurse to reach over the sterile field. Maintaining a safe margin of space can reduce accidental contamination when items are passed between sterile and unsterile fields. An instrument may be used as an extension of a team member's hands to ensure a safe margin between fields. The use of transfer forceps is unacceptable, however. Maintaining the sterility of these forceps is questionable because of many variables, such as sterilization method, type of container, and type and amount of soaking solution used. Incorrect handling of soaked forceps results in contamination. The preferred procedure is for single use of a packaged, sterile ring forceps, which is discarded into a container for reprocessing.

8. Movement within or around a sterile field must not contaminate the field. The patient is the center of the sterile field during an operative procedure; additional sterile areas are grouped around the patient. If contamination is to be prevented, patterns of movement within or around this sterile grouping must be established and rigidly practiced. Scrub persons stay close to the sterile field. If they change positions, they turn face to face or back to back with another individual while maintaining a safe distance between themselves and other objects. Accidental contamination is a threat to any scrub person who wanders into a traffic pathway or out of the clean area of the OR. Perioperative nurses approach sterile areas facing them and never walk between two sterile fields. Keeping sterile areas in view during movement around the area and maintaining a safe distance from the sterile field assist in preventing accidental contamination. Bacterial fallout from the body or clothing is a source of contamination when an unsterile individual leans over a sterile field. All perioperative personnel must maintain vigilance over sterile areas and identify contamination immediately. Movement within and around a sterile area should be kept to a minimum to avoid contamination of the field or the sterile members of the surgical team (AORN, 2009l).

Close adherence to principles of asepsis and consistent observance of the boundaries established in the principles provide protection against infection. Application of the basic principles of aseptic technique depends primarily on the individual's understanding and conscience. Every person on the surgical team must share the responsibility for monitoring aseptic practice and initiating corrective action when a sterile field is compromised.

Traffic Control

The surgical suite should be designed to minimize the spread of infectious organisms and to facilitate movement of patients and personnel within that framework (AORN, 2009m). Ideally, the suite is divided into three areas, each defined by the

FIGURE 3-13 The scrub person opens the near side of the wrapper first, providing protection for the sterile gown. The scrub person protects his or her gloves with the cuff of the drape as the drape is opened to provide the sterile table cover.

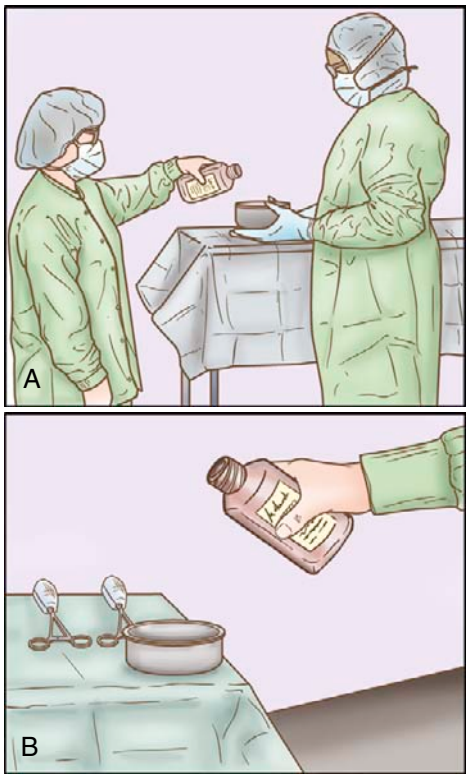

FIGURE 3-14 **A**, When pouring solution into the receptacle held by the scrub person, the perioperative nurse maintains a safe margin of space to avoid contamination of sterile surfaces. **B**, Care must be used when pouring solution into a receptacle on a sterile field to avoid splashing fluids onto the sterile field. Placement of the receptacle near the edge of the table permits the nurse to pour solution without reaching over any portion of the sterile field.

activities occurring within the area. The *unrestricted* area includes areas outside of the surgical suite and a control point to monitor the entrance of patients, personnel, and materials. Street clothes are appropriate attire in this area, and traffic is not limited, but provisions must be made for isolation of patients with communicable conditions (Risk Reduction Strategies). The *semirestricted* area comprises the peripheral support areas within the surgical suite. These may include storage areas, work areas, and corridors leading to restricted areas of the surgical suite. Traffic in the semirestricted area is limited to appropriately attired personnel and patients. Personnel must wear surgical attire and cover all head and facial hair when in this area. Patients should have their hair covered, wear clean hospital attire, and be covered with clean hospital linens. The *restricted* area includes the OR, procedure rooms (if any), the central core, and the scrub sink area. Personnel must wear surgical attire including hair coverings when in the restricted area. Masks are worn where open sterile supplies or scrub persons may be present. Masks are not required for patients because a mask could hinder access to the patient's face and airway and cause additional patient anxiety (AORN, 2009m).

Personnel entering semirestricted or restricted areas of the surgical suite should do so through prescribed routes. These routes contain vestibular areas, which serve as transition zones between the outside and inside of the suite. Offices, holding rooms, and locker rooms act as transition zones. Personnel entering the OR should access the locker room via the unrestricted area. After donning clean, hospital-laundered surgical attire, personnel should exit directly into the OR suite without retracing steps through the unrestricted area.

Air is a potential source of microorganisms that can result in a surgical site infection. Airborne contamination increases with movement of the surgical team. This movement should be kept to a minimum during operative procedures. Each OR door should remain closed except during movement of patients, personnel, supplies, and equipment. The positive-pressure gradient of air in the OR is disrupted if the door remains open. The turbulent flow occurring as the pressure equalizes can increase airborne contamination (Anderson et al, 2008; AORN, 2009m).

Surgical equipment and supplies also are potential sources of contamination. Clean and sterile supplies should be separated from contaminated items by space, time, or traffic

RISK REDUCTION STRATEGIES

H1N1—World Health Organization (WHO) Patient Safety: Clinical Checklist

Influenza A is the most common cause of influenza (flu) in humans. H1N1 is a subtype of influenza A. In June 2009 the World Health Organization (WHO) declared that a new strain of swine-origin H1N1 (commonly called "swine flu" by the public) was responsible for the 2009 flu pandemic. In response to the H1N1 threat, a team from the WHO consisting of experts in the areas of infection control, clinical management of pandemic influenza, and healthcare began developing a patient safety checklist. The checklist was designed to be utilized by healthcare personnel who will care for suspected or confirmed cases of influenza A (H1N1) virus.

Checklists are a practical approach to action and easy to use in the practice setting. They are not meant to be comprehensive documents or to replace routine patient care, but should be flexible on the basis of specific local and institutional needs. The checklist provides guidance regarding the clinical management of the individual patient and infection control measures to minimize and limit the spread of the virus.

The checklist was evaluated for effectiveness by several health centers throughout the world. The utilization of this process will continually need to be evaluated based on the health status of both patients and citizens throughout the world. The checklist does not replace clinical guidance or clinical judgment. Its users should also familiarize themselves with the relevant WHO guidance documents.

How to Use the Checklist

- Staff can use the checklist in a variety of ways. The objective is to ensure that no critical patient care items are missed during or immediately following care. The checklist can do any of the following:
  - It can be used as part of the patient's clinical record.
  - It can be reproduced as wall posters for hospitals or clinics.
  - It can be printed on cards for staff members to carry and use as a reference when treating patients.
- Parts of the checklist can also be extracted for use in any of these formats.

PATIENT CARE CHECKLIST

Upon Arrival to Clinical Setting/Patient Care Area

- Direct patient with flulike symptoms to designated waiting area.
- Provide instruction and materials to patient on respiratory hygiene/cough etiquette.
- Put medical/surgical mask on patient, if available and tolerable to patient.

Before Patient Entry to Designated Area (Isolation Room or Cohort)

- Post restricted entry and infection control signs.
- Provide dedicated patient equipment if available.
- Ensure at least 3 feet between patients in cohort area.
- Ensure local protocol for frequent linen and surface cleaning is in place.

Before Entering Designated Area (Isolation Room or Cohort) (Healthcare Workers and Visitors)

- Put on medical/surgical mask.
- Clean hands (handwashing or alcohol-based hand rub).

Before Every Patient Contact

- Put on medical/surgical mask.
- Clean hands (handwashing or alcohol-based hand rub).
- Put on eye protection, gown, and gloves if there is risk of exposure to body fluids/splashes.
- Clean and disinfect personal/dedicated patient equipment between patients.
- Change gloves (if applicable) and clean hands between patients.

Upon Initial Assessment

- Record respiratory rate over 1 full minute and oxygen saturation if possible.
- If respiratory rate is high (e.g., for the following age groups: <2 months, ≥60/minute; 2-11 months, ≥50/minute; 1-5 years, ≥40/minute; >5-12 years, ≥30/minute; ≥13 years, ≥20/minute) or oxygen saturation is below 90%, alert senior care staff for action.

Continued

RISK REDUCTION STRATEGIES

H1N1—World Health Organization (WHO) Patient Safety: Clinical Checklist—cont'd

- Record history, including flulike symptoms, date of onset, travel, contact with people who have flulike symptoms, co-morbidities.
- Consider specialized diagnostic tests (e.g., reverse transcription polymerase chain reaction [RT-PCR]).
- Use medical/surgical mask, eye protection, gloves when taking respiratory samples.
- Label specimen correctly and send as per local regulations with biohazard precautions.
- Consider alternative or additional diagnoses.
- Report suspected case to local authority.

Initial and Ongoing Patient Management

Supportive therapy for new influenza A (H1N1) patient as for any influenza patient including:

- Give oxygen to maintain oxygen saturation above 90% or if respiratory rate is elevated (when oxygen saturation monitor is not available).
- Give acetaminophen if considering an antipyretic for patients less than 18 years old.
- Give appropriate antibiotic if there is evidence of secondary bacterial infection (e.g., pneumonia).
- Consider alternative or additional diagnoses.
- Decide on need for antivirals* (oseltamivir or zanamivir), considering contraindications and drug interactions.

Before Leaving Designated Area (Isolation Room or Cohort) (Healthcare Workers and Visitors)

- Remove any personal protective equipment (gloves, gown, mask, eye protection).
- Dispose of disposable items as per local protocol.
- Clean hands (handwashing or alcohol-based hand rub).
- Clean and disinfect dedicated patient equipment and personal equipment that has been in contact with patient.
- Dispose of viral-contaminated waste as clinical waste.

Before Patient Transport/Transfer

- Put medical/surgical mask on patient if available and tolerable to patient.

If Performing Aerosol-Generating Procedures (e.g., Intubation, Bronchoscopy, CPR, Suction)

- Allow entry of essential staff only.
- Put on gown.
- Put on particulate respirator (e.g., EU FFP2, U.S. NIOSH-certified N95) if available.
- Put on eye protection, and then put on gloves.
- Perform planned procedure in an adequately ventilated room.

Before Discharge of Confirmed or Suspected Case

- Provide instruction and materials to patient/caregiver on respiratory hygiene/cough etiquette.
- Provide advice on home isolation, infection control, and limiting social contact.
- Record patient address and telephone number.

After Discharge

- Dispose of or clean and disinfect dedicated patient equipment as per local protocol.
- Change and launder linen without shaking.
- Clean surfaces as per local protocol.
- Dispose of viral-contaminated waste as clinical waste.

*Currently there is a lack of data on the clinical effectiveness of antivirals for this disease. Antiviral drugs are to be used according to national pandemic influenza preparedness plans. If antivirals are prescribed, oseltamivir or zanamivir should be used for influenza A (H1N1) patients because of increased risk of resistance with other antivirals. Where antiviral drugs are available for treatment, clinicians should make decisions based on assessment of the individual patient's risk. Risks versus benefits should also be evaluated on a case-by-case basis.

Modified from World Health Organization (2009): *Patient safety, clinical checklist influenza A (H1N1),* available at www.who.int/patientsafety/activities/ah1n1_checklist/en/. Accessed July 28, 2009; *Clinical management of human infection with new influenza A (H1N1) virus* (May 21, 2009), available at www.who.int/entity/csr/resources/publications/swineflu/clinical_managementH1N1_21_May_2009.pdf. Accessed July 30, 2009.

patterns. Clean and sterile items delivered to the surgical suite should be transported in a manner that preserves package integrity and protects the packaged items from contamination along the travel route. Because external shipping containers may collect dust, debris, and insects during shipment, these containers should be removed in the unrestricted area and the contents brought into the surgical suite. Within the suite, supplies should move from the clean core or storage area through the OR to the peripheral or semirestricted corridor. Soiled instruments, supplies, and equipment should not reenter the clean core. Instead, soiled items should be covered or contained in closed carts or containers and transported to an area designated for decontamination. This decontamination area, as well as the soiled linen and trash collection areas, should be separate from personnel and patient traffic areas (AORN, 2009m).

Surgical Attire

Every surgical department should have a written policy and procedure regarding proper attire in the surgical suite. According to OSHA regulations and institutional policy and to prevent transmission of organisms from the patient to personnel, it is required that personnel wear personal protective equipment (PPE) when it can be reasonably anticipated that the individual may come in contact with blood or other potentially infectious materials. PPE—which includes protective eyewear, gloves, and fluid-resistant gowns, aprons, and shoe covers—must be included as part of the surgical attire policy as determined by OSHA regulations (AORN, 2009b; OSHA, 1991).

People are a major source of bacteria in the surgical setting. To reduce bacterial and skin shedding (scurf) and promote environmental control and cleanliness, all persons entering the semirestricted and restricted areas of the surgical suite should wear clean, facility-laundered, surgical attire (Figure 3-15) made of multiuse fabric or limited-use nonwoven material (AORN, 2009b). Home laundering of surgical attire that is not visibly soiled is controversial, and there is no concrete research to support or refute this practice. Surgical attire becomes soiled or contaminated during normal wear. Taking worn, soiled, or contaminated surgical attire into the home can result in the spread of contamination to the home environment (AORN, 2009b). Surgical attire, also known as *scrub attire,* should be constructed of a low-linting material that minimizes bacterial shedding, is comfortable, and provides

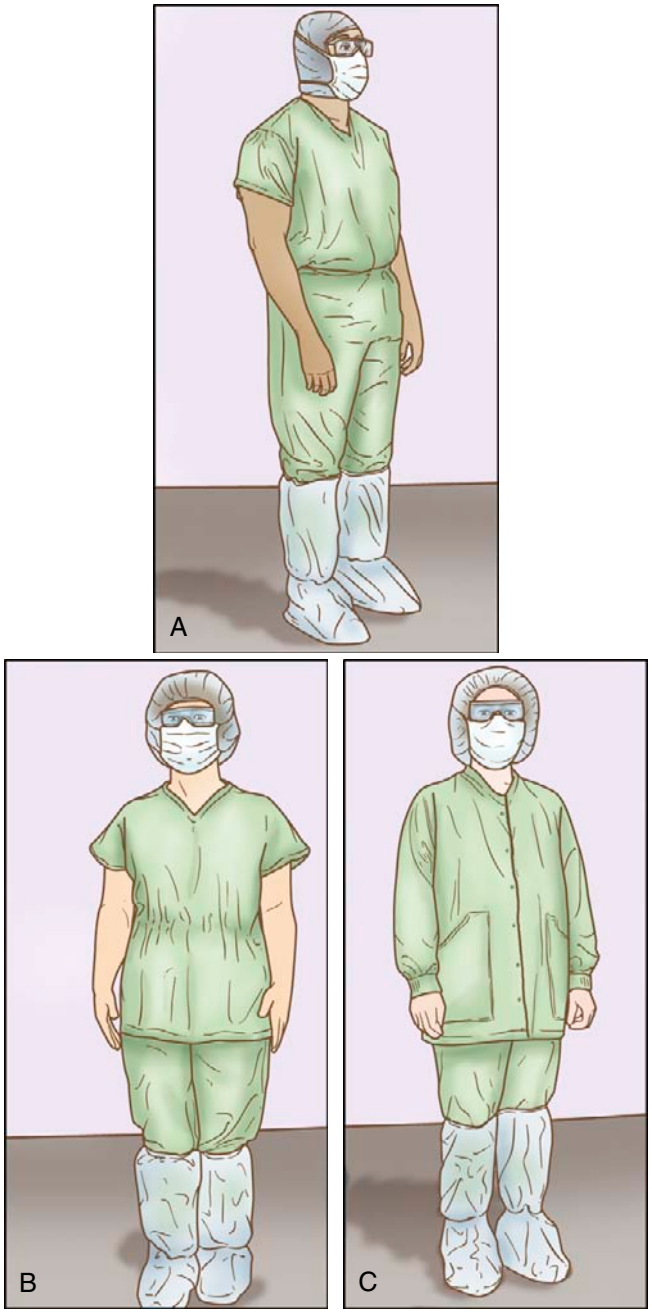

FIGURE 3-15 Proper surgical attire consists of a two-piece pantsuit, a scrub dress, or a one-piece coverall suit. Shoe covers should be worn when it is reasonably anticipated that spills or splashes will occur. If worn, they should be changed whenever they become wet, torn, or soiled. In semirestricted and restricted areas, all head and facial hair should be covered. In restricted areas, all personnel should wear masks. Jewelry should be removed or totally confined. Artificial nails should not be worn. **A**, When a two-piece scrub suit is worn, loose-fitting scrub tops should be tucked into pants. **B**, Tunic tops that fit close to the body may be worn outside of pants. **C**, Nonscrubbed personnel should wear long-sleeved jackets that are buttoned or snapped closed.

a professional appearance. If a two-piece pantsuit is worn, the top of the pantsuit should be tucked into the trousers or fit close to the body. Care should be taken when donning scrub pants to avoid dragging the pant legs on the floor. If nonscrubbed perioperative personnel wear long-sleeved shirts, the sleeves of the warm-up jackets should cover the shirtsleeves. Long sleeves are not appropriate for scrub personnel because the surgical scrub extends beyond the edge of the long sleeves (AORN, 2009b). A head cover, mask, and, if required, shoe covers complete the surgical attire ensemble. Shoe covers are required if there is a risk of blood or body fluid contamination, as described in OSHA regulations (OSHA, 1991). To protect the patient and the healthcare worker, surgical attire must be changed whenever it becomes soiled or wet with blood, any body fluid including perspiration, or food. Nonscrubbed personnel should wear long-sleeved jackets that are buttoned or snapped closed during wear. These jackets help decrease bacterial and skin shedding from bare arms. Closing the jackets helps prevent inadvertent contamination, which can occur if the loose fabric brushes against a sterile area. All jewelry should be confined within scrub attire or removed when personnel enter the semirestricted or restricted areas of the surgical suite. This includes any visible jewelry associated with body piercing. Confinement reduces the possibility of jewelry falling or shedding bacteria into a sterile field or wound. Before handwashing, rings, watches, and bracelets should be removed because organisms can be harbored beneath these pieces of jewelry (AORN, 2009b).

Before scrub attire is donned, the scrub personnel should put on a clean, lint-free surgical hat or hood that completely covers all head and facial hair. Hair acts as a filter when left uncovered and collects bacteria, which are released into the air during activity. Hair attracts, harbors, and sheds bacteria in proportion to its length, curliness, and oiliness. A head cover eliminates the possibility of hair or dandruff being shed on the scrub suit. The design and composition of the hat or hood should minimize dispersal of bacteria, be comfortable to wear, and confine and contain all hair. Head covers should always be worn in areas where equipment and supplies are processed and stored. Disposable bouffant and hood types of head covers are preferred. They are discarded in a designated receptacle immediately after use. Skullcaps that fail to cover the side hair above the ears and hair at the nape of the neck should not be worn in the OR. If reusable hats or hoods are worn, they should be laundered daily. If they become contaminated with blood or body fluids, they must be laundered according to OSHA (1991) regulations.

For personnel safety, shoes that provide protection should be worn. Cloth shoes provide little protection against spilled liquids or sharp items that may be accidentally dropped to the floor. Shoes with enclosed toes and heels help minimize injury. Shoe covers may be worn to help keep shoes clean and may decrease the amount of soil and bacterial tracking throughout the suite. It is easier to change a shoe cover than to stop to clean or change a shoe that has become soiled. If it is reasonably expected that the feet may become contaminated with blood or body fluids, shoe covers are required as part of personal protective attire. Shoe covers should be kept in an area adjacent to the semirestricted area entrance. They should be removed and discarded in the appropriate receptacle when leaving the restricted area (AORN, 2009b). A single surgical mask is worn to reduce the dispersal of microbial droplets expelled from the mouth and nasopharynx of personnel and to protect healthcare workers from aerosolized pathogenic organisms and particles from the surgical environment. Single, high-filtration surgical masks are worn in ORs and other designated areas where open

FIGURE 3-16 Proper handling of a mask. **A**, Edges of a properly worn mask conform to facial contours when the mask is applied and tied correctly. **B** and **C**, Personnel should avoid touching the filter portion of the mask when removing it. **D**, Masks should be discarded on removal.

sterile supplies or scrub persons may be located. A single mask provides a filter; double-masking creates a barrier, causing the exhaled air to be expelled through tents and gaps around the mask. Differences of opinion exist in the literature, with some researchers claiming that oral bacteria expelled by personnel in the OR are of no threat to the surgical patient and surgical masks for nonscrubbed personnel in the OR may not be necessary. OSHA (1991) regulations mandate the use of surgical masks as part of personal protection. Individual practice settings need to develop polices based on OSHA (1991) and state-mandated recommendations on the use of masks. Further research on the topic of surgical masks needs to be established.

Masks with a microbial filtration efficiency of 95% or greater should be selected. Aerosol particles generated by the surgical team, sometimes visible to the naked eye, are most likely 10 μm or larger. The plume of lasers or the electrosurgical unit has been found to contain particles with a mass of 0.31 μm, smaller than that expelled by the surgical staff. The filtration efficiency of masks should ensure protection against aerosol particles that are 0.1 μm or larger (AORN, 2009f). The most effective filter mask is relatively useless if worn incorrectly, however, and can be dangerous if handled improperly. Figure 3-16 illustrates the proper application and removal of a surgical mask.

The mask must cover the mouth and nose entirely and have facial compliance, fitting comfortably around the contours of the nose and cheeks. The mask is tied securely without crossing the strings. Crossing strings allows the sides of the mask to gap (tenting) and consequently permits nonfiltered air to

escape through venting. Air should pass only through the filtering system (the faceplate) of the mask. A pliable metal or adhesive strip in the top hem of some masks provides a firm, contoured fit over the bridge of the nose. This strip may help prevent fogging of protective eyewear. Masks should be either on (properly) or off. They should not be reused for different procedures (e.g., by allowing the mask to hang from the neck or by tucking it into a pocket). Bacteria that have been filtered by the mask become dry and airborne if the mask is worn necklace-fashion. Touching only the strings during removal of the mask reduces contamination of the hands. Masks should be changed between procedures and sometimes during a procedure, depending on the length of the operation and the amount of talking done by the team. The facepiece, which is contaminated with droplet nuclei, should not come into contact with the hands of personnel. Immediately after removal, masks should be discarded directly into a designated covered waste receptacle. After discarding the mask, the wearer must wash and dry the hands thoroughly (AORN, 2009b).

Gloves should be selected according to the task to be completed: sterile gloves for sterile procedures, and medical, unsterile gloves for nonsterile activities. Gloves should be changed between patient contacts and after contact with any infectious material. Hands should be washed thoroughly after gloves are removed. To reduce the risk of mouth, nose, and eye mucous membrane exposure, protective eyewear, masks, or face shields are worn whenever there is opportunity for contamination by splash or aerosols. When the protective devices become contaminated, they should be discarded or decontaminated as soon as possible to prevent contamination to the wearer. Other protective equipment such as liquid-resistant attire, including gowns and shoe covers, should be worn whenever there is a reasonable expectation of exposure to infectious materials (AORN, 2009b).

Surgical Hand Hygiene

Skin is a major source of microbial contamination in the surgical environment. Although members of the surgical team at the sterile field wear sterile gowns and gloves, the skin of their hands and forearms should be cleaned preoperatively to reduce the number of microorganisms in the event of glove failure. The purposes of surgical hand hygiene are as follows: to remove dirt, skin oil, and transient microorganisms from the nails, hands, and forearms; to reduce the resident microbial count to as near zero as possible; and to leave an antimicrobial residue on the skin to prevent regrowth of microbes for several hours (AORN, 2009n). Hand hygiene has been recognized as a primary method of decreasing healthcare-associated infections (Haas et al, 2008). The skin can never be rendered sterile, but it can be made surgically clean by reducing the number of microorganisms present.

The term hand hygiene is currently used to describe measures related to the physical hand condition and decontamination. Decontamination of the hands can be done by a variety of methods:

- Handwashing using soap and water, antiseptic and water, or antiseptic hand rub if visible soil is not present
- Surgical hand scrub using water-aided brushless surgical antiseptics; waterless, brushless surgical antiseptics; or traditional surgical hand scrub using a sponge (WHO, 2009; AORN, 2009n)

A standardized procedure for handwashing should be established and followed within the healthcare setting.

Scrub persons should be in good health and possess healthy, intact skin. Healthcare personnel with cuts, abrasions, weeping dermatitis, or fresh tattoos on exposed skin should not provide direct patient care because of the potential risk for infection (AORN, 2009n). The AORN's *Recommended Practices for Hand Hygiene in the Perioperative Setting* (2009a) provide guidance for healthcare personnel in relation to direct patient care.

Because microorganisms may be protected and harbored by rings, watches, body-piercing jewelry, and bracelets, these items should be removed before scrubbing (AORN, 2009n). Fingernails of scrub persons should be short, clean, and healthy. The subungual region of the nails harbors most microorganisms found on the hands. Soap, running water, and a nail-cleaning device are necessary to clean under the fingernails. Nails that extend beyond the tips of the fingers are more difficult to clean and increase the risk of glove tears. Longer nails also may scratch patients during the positioning or transfer process. Artificial nails or synthetic nails should not be worn by personnel in the perioperative environment. Higher numbers of gram-negative organisms have been cultured, both before and after handwashing, from the nails of individuals wearing artificial nails or nail additives than from individuals with natural nails. Fungal growth also occurs under artificial nails as a result of trapped moisture between the natural and artificial nail. The length of artificial nails may interfere with effective hand scrubs and handwashing. Studies have shown the positive correlation between the number of microorganisms present on healthcare personnel's hands to the number of patients who have surgical site infections (Anderson et al, 2008; AORN, 2009n).

Facility infection control procedures govern the selection of materials and the methods used for surgical hand hygiene. This may be accomplished by a surgical scrub or with the use of an approved hand rub agent.

Surgical Hand Rubs. Alcohol-based hand rubs are easy to use and fast-acting, and they provide activity against most bacteria, viruses, and fungi. All hand rub products that are alcohol-based are not indicated for use in place of the traditional hand scrub. Rubs come in many forms, combinations, and concentrations of alcohols, which may influence the antimicrobial strength and kill factor. Surgical hand hygiene products should be selected following a thorough analysis of each product's efficacy, effectiveness, application processes, cost-benefit ratio analysis, and acceptance by its users. When hand rubs are used for surgical hand antisepsis, the only acceptable products are alcohol-based antiseptic surgical hand rubs with documented persistent and cumulative activity that have met U.S. Food and Drug Administration (FDA) regulatory requirements for surgical hand antisepsis. The manufacturer's written instructions for product use, including time and amount, should be followed. The basic steps of a surgical rub are as follows:

1. Follow the manufacturer's written directions for use of the product.
2. Use the recommended amount of hand rub product.
3. Rub hands and cover all surfaces, including the backs of hands, fingertips, inner webs, and palms.
4. Rub hands until they are dry.

A sufficient amount of product is required to ensure the antimicrobial effect of the rub (AORN, 2009n).

Surgical Hand Scrub. A surgical hand scrub should be performed by healthcare personnel before donning sterile gloves for surgical or other invasive procedures (AORN, 2009n). For the traditional, standardized surgical scrub, individually packaged disposable brushes and sponges or synthetic sponges without a brush may be used. The use of synthetic sponges in place of brushes has gained wide acceptance, especially where long and repeated scrubbing may be traumatic to the skin. Disposable brushes or sponges are available with a variety of antimicrobial soap or antiseptic solutions impregnated into the sponge. A thorough handwash with an antimicrobial agent may be as effective as the traditional surgical scrub using a brush or sponge (TJC, 2009; AORN, 2009n).

Surgical hand scrub agent selection should be based on the efficacy and effectiveness of the product, application requirements, contact time, and user-friendliness. The antimicrobial soap or detergent used for the surgical hand scrub should have the following attributes:

- Reduce microorganisms on the skin
- Be fast-acting
- Have a broad range of activity
- Not depend on cumulative action
- Have a minimally harsh effect on skin
- Inhibit regrowth of microorganisms

Antimicrobial agents used for surgical hand scrubs include povidone-iodine complex and chlorhexidine gluconate (CHG). These agents are broad-spectrum, rapid-acting antimicrobials that are effective against many gram-positive and gram-negative microorganisms. Individuals who have skin sensitivity to CHG may use another broad-spectrum antimicrobial agent, *para*-chloro-*meta*-xylenol (chloroxylenol, PCMX), as an effective alternative agent for surgical scrubbing. Moisturizing agents are now being incorporated into various surgical scrub agents to reduce the potential of skin irritation resulting from multiple scrubs.

An anatomic scrub, using a prescribed amount of time or number of strokes plus friction, is employed for effective cleansing of the skin. The fingers, hands, and arms should be visualized as having four sides; each side must be scrubbed effectively. Individual attention to detail is essential. The prescribed number of strokes with a brush is usually 30 strokes to the nails and 20 strokes to each area of the skin. When using the timed approach, the institution's policies and procedures should be followed. Surgical hand scrub procedures should be documented and available within the perioperative practice setting.

SCRUB PROCEDURE. Before beginning the surgical hand scrub, members of the surgical team should inspect their hands to ensure that their nails are short, their cuticles are in good condition, and no cuts or skin problems exist. The procedure may include but not be limited to the following:

1. Remove all jewelry, including rings, watches, and bracelets, from the hands and forearms.
2. Cover all head and facial hair. Don a surgical mask. If other personnel are at the scrub sink, a surgical mask should be worn in the presence of hand scrub activity. Protective eyewear, such as goggles with side shields or a full-face shield, should be adjusted to ensure clear vision and to avoid lens fogging. Personnel confirm that the scrub shirt is tucked into the trousers to prevent potential contamination of the scrubbed hands and arms from brushing against loose garments.

The basic steps of the scrub procedure follow:

1. If visibly soiled, wash hands and forearms with soap and running water immediately before beginning the scrub procedure. Bring water to a comfortable temperature. Most scrub sinks have automatic or knee controls for the faucets.
2. Moisten hands and forearms. Using a foot control, dispense the manufacturer's recommended amount of the antimicrobial agent into the palms, adding small amounts of water to create lather if necessary.
3. Wash hands and forearms using the antimicrobial soap or detergent. Rinse before beginning the surgical hand scrub. The amount of time needed varies with the amount of soil and the effectiveness of the cleansing agent.
4. Open the scrub brush/sponge package, remove the brush and nail cleaner, and discard the package. Hold the brush in one hand; clean the subungual areas of both hands under running water and then complete the nails on the other hand (Figure 3-17).
5. Rinse the hands and arms thoroughly, exercising care to hold the hands higher than the elbows. Avoid splashing water onto the surgical attire because this moisture may cause subsequent contamination of the sterile gown.
6. Moisten the brush or sponge (if the brush or sponge is impregnated with antimicrobial soap) and begin scrubbing. If the brush or sponge is not impregnated with soap, apply antimicrobial soap or detergent solution to hands according to the manufacturer's written instructions. Starting at the fingertips, scrub the nails vigorously, holding the brush perpendicular to the nails. Scrub all sides of each digit, including the connecting webbed spaces. Next scrub the palm and back of the hand. Repeat on the other hand and arm.
7. Scrub each side of the forearm with a circular motion (see Figure 3-17) up to the elbows.
8. Hold the hands and arms away from the body, with the hands above the level of the elbows while scrubbing, allowing the water and detritus to flow away from the first-scrubbed and cleanest area. Add small amounts of water during the scrub to develop suds and remove any excess debris.
9. Rinse the hands and arms thoroughly.
10. Turn off the faucet by using the knee control or by using the edge of the brush on a hand control. Discard the brush or sponge.
11. Hold the hands and arms up in front of the body with elbows slightly flexed and enter the OR.

If the timed method is used, the policies and procedures of the facility should be followed.

Drying the Scrubbed Area. Moisture remaining on the cleansed skin after the scrub procedure should be dried with a sterile towel before donning sterile gown and gloves. The gown and gloves should be opened on a flat surface before the surgical scrub is completed. A small sterile field is created by the gown wrapper, which is opened over the flat surface. The gown and gloves should not be opened on the sterile back table because of the increased chance of contamination to the field. The towel must be used with care to avoid contaminating the clean skin. The folded towel is grasped firmly near the open corner and lifted straight up and away from the sterile field without dripping contaminated water from the skin onto the sterile field. The person steps away from the sterile field and bends forward slightly from the waist, holding the hands

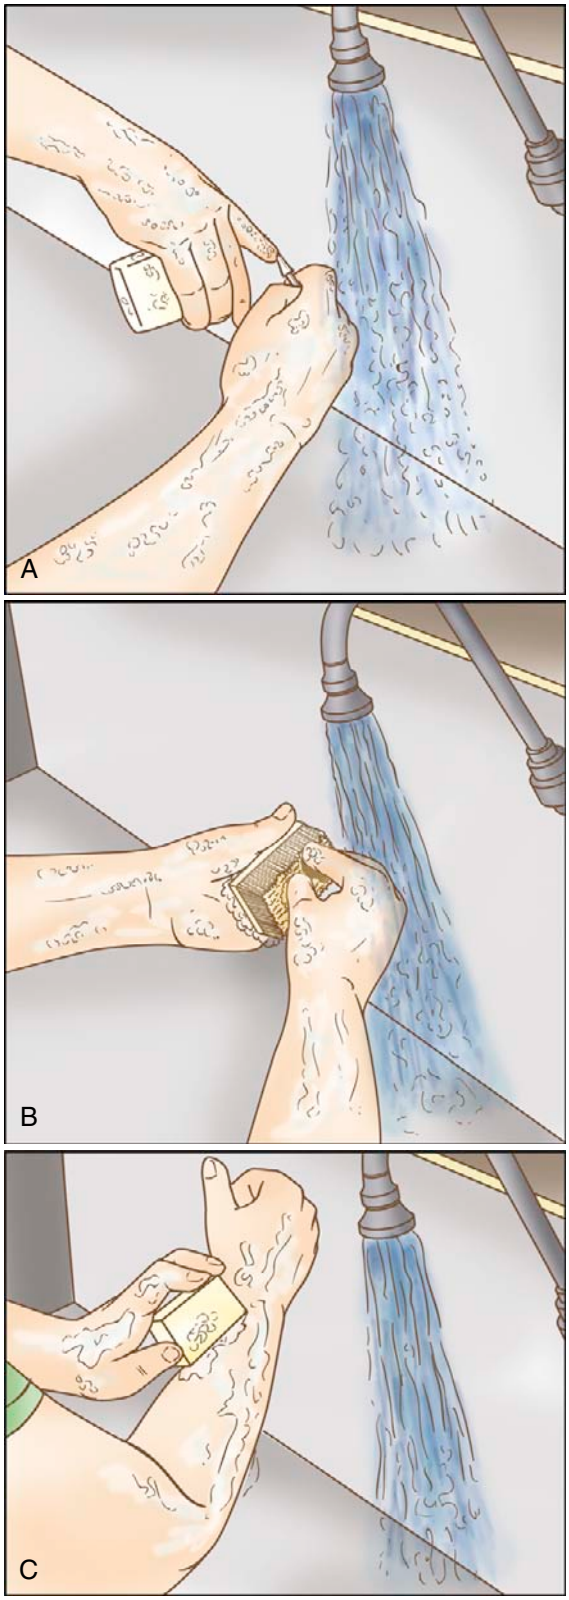

FIGURE 3-17 Traditional surgical scrub technique. **A**, Cleaning nails with plastic nail cleaner. **B**, Holding brush/sponge perpendicular to nails facilitates thorough scrubbing of underside of nails. **C**, Holding brush/sponge lengthwise along arm covers maximum area with each stroke.

FIGURE 3-18 Drying hands and forearms. Fingers and hand are dried thoroughly before forearm is dried. Extending arms reduces possibility of contaminating towel or hands.

and elbows above the waist and away from the body. The towel is allowed to unfold downward to its full length and width (Figure 3-18).

The top half of the towel is held securely with one hand and the opposite fingers and hand are blotted dry, ensuring that they are thoroughly dry before moving to the forearm. To avoid contamination, use a rotating motion while moving up the arm and do not retrace an area. The lower end of the towel is grasped with the dried hand, and the same procedure is used for drying the second hand and forearm. Care must be taken to prevent contamination of towel and hands. On completion, discard the towel without dropping the hands below waist level.

Gowning

Before scrub personnel touch sterile equipment or the sterile field, they must put on sterile gowns and surgical gloves to prevent microorganisms on their hands and clothing from being transferred to the patient's wound during surgery. The sterile gowns and gloves also protect the hands and clothing of personnel from microorganisms present in the patient or in the atmosphere.

The surgical gown should be made of a combustion-resistant material that establishes an effective barrier to minimize the passage of microorganisms, particulate matter, and fluids between unsterile and sterile areas. Reusable fabrics must allow complete penetration of steam during the sterilization process and should withstand multiple launderings and other processing. Tests indicate that 280-thread count, water repellent–treated materials lose their barrier quality when subjected to multiple laundering, and sterilizations, usually at about 75 to 100 cycles. The manufacturer must provide the facility with instructions for testing the material at periodic intervals during the life cycle of the product to ensure continued barrier quality. The particular item should be removed from circulation when the maximum number of

processing cycles have been reached. If possible, the item may be used in circumstances where surgical-barrier quality is not needed. With each processing, reusable materials also must be examined for worn areas, holes, or fraying. If these occur, the material should be removed from use. To reduce particle dissemination into the wound and the environment, materials used for surgical gowns and drapes should be resistant to penetration by blood and other body fluids as necessitated by their use (AORN, 2009o). Regardless of the gown material, the shape and size should fit personnel and allow freedom of movement. To provide extra protection, the gown's front from the waist upward and the forearms of the sleeves can be reinforced with additional or different water-repellent material. Each sleeve should be finished with a tight-fitting cuff that prevents the inner side of the sleeve from slipping down onto the outer side of the sterile glove. Cotton tapes, snaps, or Velcro fasteners are attached to the back of the gown to hold it closed. A wraparound gown may be used to achieve better coverage of the back. Once donned, however, the back of the gown is never considered sterile.

Because the outer side of the front and sleeves of the gown come into contact with the sterile field during surgery, the gown must be folded so that the scrub person can put it on without touching the outer side with bare hands. For in-house wrapping and sterilization, the gown is folded with the inner side out and the back edges together. The sleeves are not turned inside out; consequently, they remain within the folded gown. The side folds of the gown are folded lengthwise toward the center back opening, overlapping slightly at the center. With the open edges of the gown remaining on the inside, the bottom third of the gown is folded upward and the top third of the gown is folded over the bottom portion. The gown is then folded in half widthwise so that the inside front neckline of the gown is visible on top. Gowns with wraparound backs are prepared in the same manner, with care taken to tie the tape securely on the wraparound back flap to the external side tie of the gown before initial folding. A folded hand towel with its free corners facing up is usually placed on top of the folded gown before the gown is wrapped and sterilized. Surgical gowns should be selected for use according to the barrier quality of the item and the wearers' anticipated exposure to blood and body fluids in accordance with OSHA's guidelines for the use of PPE (OSHA, 2001).

Self-Gowning Procedure. The procedure for donning a wraparound sterile surgical gown is as follows (Figures 3-19 and 3-20). The scrub person should do the following:

1. Grasp the sterile gown at the neckline with both hands and lift from the wrapper. Step into an area where the gown may be opened without risk of contamination.
2. Hold the gown away from the body, and allow it to unfold with the inside toward the wearer.
3. Keep hands on the inside of the gown while it completely unfolds.
4. Slip both hands into the open armholes, keeping the hands at shoulder level and away from the body.
5. Push the hands and forearms into the sleeves of the gown, advancing the hands only to the proximal edge of the cuff.

The perioperative nurse should then do the following:

1. Pull the gown over the scrub person's shoulders, touching only the inner shoulder and side seams.

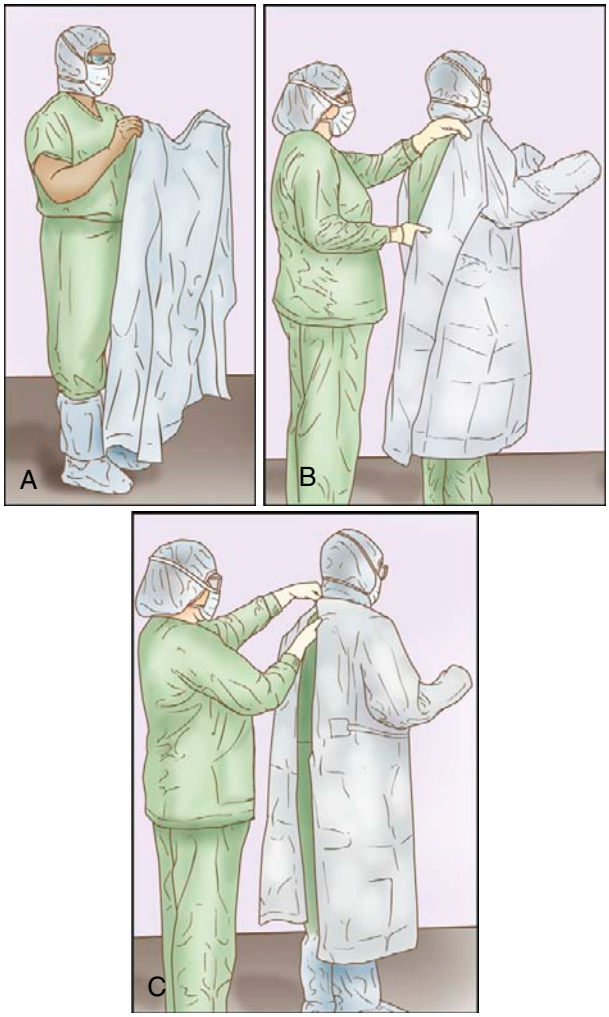

FIGURE 3-19 Gowning procedure. **A**, Scrub person keeps hands on inside of gown while unfolding it at arm's length. **B**, Circulating nurse reaches under flap of gown to pull sleeves on scrub person. **C**, Circulating nurse snaps neckline of gown, touching only snap section of neckline.

2. Tie or clasp the neckline and tie the inner waist ties of the gown, touching only the inner aspect of the gown. The gown should be completely fastened by the perioperative nurse before the scrub person dons gloves, to prevent contamination from flapping of the gown.

To secure the gown, the scrub person and the perioperative nurse do the following:

1. Take the tab (which is attached to the back tie of the gown) from the gloved scrub person. The scrub person then makes a three-fourths turn to the left while the perioperative nurse extends the back tie to its full length. This action effectively wraps the back panel of the gown around the scrub person and covers the previously tied inner waist ties. The scrub person retrieves the back tie by carefully pulling it out of the tab held by the nurse and ties it with the other tie, which had been secured to the front top of the gown.

When a reusable gown is used, the absence of a tab on the back tie necessitates use of an alternative procedure for securing the gown (see Figure 3-20, *C, D,* and *E*). If the closed-gloving technique and commercially prepared, double-wrapped gloves

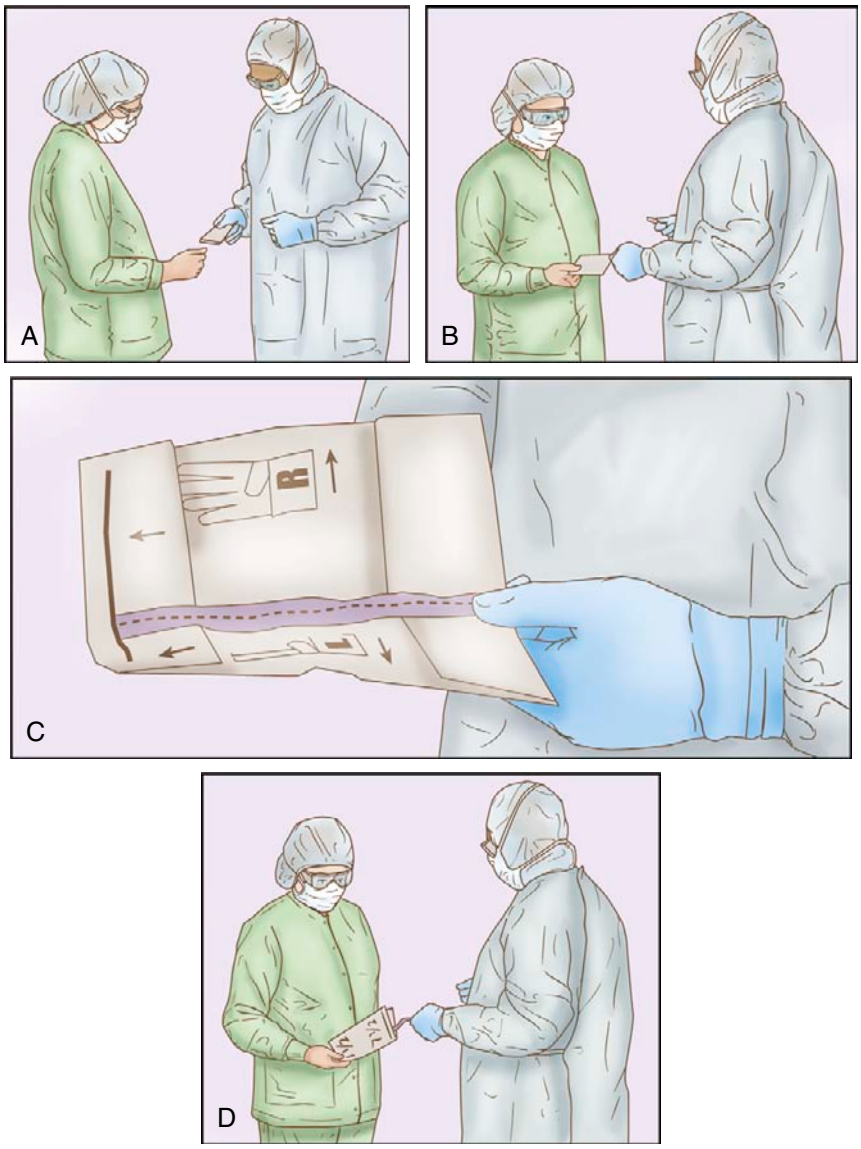

FIGURE 3-20 Methods of tying a wraparound gown. **A**, After handing tab on back tie of gown to perioperative nurse, scrub person makes a three-fourths turn toward the left. **B**, Sterile back panel now covers previously tied unsterile ties; scrub person retrieves back tie by carefully pulling it out of the tab held by the nurse and ties it securely with other tie. **C**, For gowns having no tab on back tie: using sterile inner glove wrapper, scrub person places the end of the back tie in the crease of the wrapper. **D**, After closing the wrapper, scrub person hands tie to the nurse, who grasps it carefully, touching neither the tie nor the gloved hand of the scrub person. The scrub person makes a three-fourths turn to the left, carefully pulls back tie from wrapper and ties it with other tie.

are employed, the inner wrap can be used as a protective extension for the gown tie when the perioperative nurse assists with tying a wraparound gown. After gloving, the scrub person unties the exterior gown ties (which were tied at the front of the gown before it was folded, wrapped, and sterilized) and holds both ties. The end of the back tie is placed in the center crease of the empty glove wrapper, approximately two thirds of the way up to the edge of the opened wrapper. The glove wrapper is then closed so that the tie is concealed. The closed wrapper is handed to the perioperative nurse, who firmly grasps the folded edge of the wrapper without touching the tie. The scrub person pivots in the opposite direction from the nurse, who extends the back tie to its full length. The scrub person grasps the exposed portion of the back tie, pulls it out of the glove wrapper while taking care to avoid touching the glove wrapper or the perioperative nurse, and ties both ties. If a sterile glove wrapper is unavailable, a sterile hemostat or ringed forceps may be clamped to the back tie and used in the same manner as a glove wrapper. After the gowning procedure has been completed, the perioperative nurse retains the instrument in the room to avoid problems with the subsequent instrument count.

If another scrub person is gowned and gloved, that individual, instead of the perioperative nurse, may assist with the wraparound procedure. The assisting individual must extend the back tie to its fullest length before the scrub person turns, to avoid any potential contamination.

FIGURE 3-21 Gowning another person. Gowned and gloved scrub person cuffs neck and shoulder area of gown over gloved hands to prevent contamination as scrub person puts hands and forearms into sleeves.

Assisted-Gowning Procedure. A gowned and gloved individual may assist another individual in donning a sterile gown (Figure 3-21). The gown is opened in the manner previously described. The inner side with the open armholes is turned toward the individual who is to be gowned. A cuff is made of the neck and shoulder area of the gown to protect the gloved hands. The gown is held until the person's hands and forearms are in the sleeves of the gown. The perioperative nurse assists in pulling the gown onto the shoulders, adjusting the back, and tying the tapes. The wraparound back on the gown is fixed into position by the scrub person after gloving is completed.

Gloving

Scrubbed personnel wear sterile surgical gloves to provide a protective barrier between the patient and healthcare personnel to decrease the probability of exposing the patient to exogenous organisms with a resulting surgical site infection. Gloves also decrease the chance of the healthcare provider being exposed to blood or other potentially infectious material. Nonetheless, many surgeons, first assistants, and perioperative scrub personnel have encountered blood on their hands at the conclusion of a surgical procedure without being aware of any breech in the glove barrier (glove puncture, tear, or rip). Increasing evidence supports and recommends the practice of double-gloving to offer a degree of protection from this and other common events (Research Highlight). The evidence for wearing two pairs of gloves during surgical procedures is compelling. According to Copeland (2009), *"Two layers of surgical gloves can reduce the number of breaks to the innermost glove that might allow cross-infection between the surgical team and patient…A second pair of gloves does protect the first set, without apparently lessening surgical skill."* Two gloves are better than one, and although this may be considered optional, all evidence points to double-gloving as being the best practice that can protect both the healthcare provider and the patient (Copeland, 2009). Although a breech may occur in the outer glove, the inner glove remains intact and continues to serve as a barrier. Some surgeons who work in areas where perforation risk is high, such as orthopedics or thoracic surgery, opt to wear double-layer gloves, with the inside glove being a colored glove, which allows the wearer to recognize perforations to the outer glove. In orthopedic surgery, surgeons may wear a glove liner between two layers of gloves to reduce perforations to the inner glove. On completion of the case, both pairs of gloves should be discarded, and hand antisepsis should be performed (Copeland, 2009).

The use of powder as a glove lubricant is not recommended because of three primary hazards: the potential for postoperative complication of powder granulomas; powder fallout from hands and gloves, which provides a convenient vehicle for dissemination of microorganisms throughout the OR; and the ability of powder to carry and disperse latex proteins, contributing to an increased latex sensitivity among healthcare workers and others. Powder-free gloves are widely available. If powdered gloves are chosen, any glove film or powder must be removed. The gloves must be wiped thoroughly after they are put on and before approaching the sterile field.

Latex Allergies and Sensitivities. The increased reporting of latex sensitivity continues to be a concern among perioperative personnel. Individuals can experience three types of reactions to latex. *Irritant contact dermatitis* is the most common type of reaction and is characterized by dry, reddened, itchy, or cracked hands. Irritant contact dermatitis is not a true allergic reaction. *Allergic contact dermatitis* is considered a type IV allergic reaction and is an allergic response caused by chemicals used in the manufacture of gloves. Allergic contact dermatitis is a delayed reaction, usually appearing 6 to 48 hours after exposure. Symptoms are similar to those of irritant contact dermatitis except that the reaction may extend beyond the actual point of contact. *True latex allergies* are classified as type I allergic responses. This is an allergy to water-soluble natural rubber latex (NRL) proteins. True latex allergies are usually seen within minutes of contact with the proteins. Symptoms range from skin redness and itching to hives, dyspnea, gastrointestinal upset, hypotension, tachycardia, and anaphylaxis. Reactions to latex rarely progress to anaphylaxis because the wearer is treated with appropriate drugs to interrupt the allergic response. Appropriate latex-free gloves should be provided for healthcare workers with known latex sensitivity or for procedures in which patients have known sensitivity or allergy. Some personnel claim allergy to the starch powder in latex gloves. Although this is possible, it is more likely that individuals are allergic to the latex proteins that bind with the starch powder and become aerosolized (AORN, 2009p).

RESEARCH HIGHLIGHT

Perioperative Practice of Double-Gloving

The ever-changing healthcare environment challenges perioperative practitioners to become more aware and challenged by their everyday practices. Preventing infections is critical to patient safety and protective barriers must be utilized to reduce the risk of skin exposure to potentially infectious materials. OSHA recommends that personal protective barriers be required when it can reasonably be anticipated that a healthcare worker will be exposed to blood, body fluids, or other infectious materials.

Surgery itself is considered invasive and increases the likelihood of healthcare personnel's exposure to blood and body fluids. Pathogens can be transferred through direct contact from the patient to the surgical team, resulting in infections. Both patients and healthcare providers need to be protected against the risks that exist today. In several studies, it was determined that the risk can be reduced by wearing two pairs of gloves, as opposed to wearing one pair. This provides an additional barrier and further reduces the risk of contamination and subsequent infection.

In reviewing the Cochrane Database, 14 trials of double-gloving (i.e., wearing 2 pairs of surgical gloves) were identified. In each of these trials, it was determined that more perforations were seen to a single glove than to an innermost glove during a double-gloving process. Along with the primary 14 trials, an additional 8 trials were performed using indicator gloves (colored latex gloves worn underneath latex gloves to more rapidly alert the team of perforations). These additional eight trials showed no direct evidence that glove protection worn by the surgical team reduces surgical site infections. The AORN's *Recommended Practices for Prevention of Transmissible Infections in the Perioperative Practice Setting* recommends the double-glove procedure during invasive procedures because of several issues based on a systematic review of the literature:

- Wearing two pairs of gloves significantly reduces the number of perforations to the inner glove.
- Wearing two pairs of gloves does not increase the risk of perforation to the outer glove.
- Wearing one pair of standard gloves on top of a pair of standard colored gloves facilitates rapid recognition of perforations to the outer glove.
- Wearing two layers of colored gloves does not assist in the recognition of a breach of the glove.
- Wearing a glove liner between both layers of gloves does not reduce the risk of perforation to the inner glove.
- Wearing steel-woven outer gloves during orthopedic surgery does not reduce the number of perforations to the inner glove, in comparison to the double-gloving technique.

In conclusion, the Centers for Disease Control and Prevention (CDC), the American College of Surgeons (ACS), and the American Academy of Orthopaedic Surgeons (AAOS) support the double gloving technique during invasive procedures. Although evidence points to double-gloving being a best practice, further research needs to be ongoing to ensure that this process is protecting the healthcare provider and patient and is fiscally responsible.

Closed-Gloving Technique. The closed method of gloving (Figure 3-22) is the technique of choice when initially donning a sterile gown and gloves. Using this technique, the gloves are handled through the fabric of the gown sleeves. The hands are not extended from the sleeves and cuffs when the gown is put on. Instead, the hands are pushed through the cuff openings as the gloves are pulled into place. The woven cuff should remain in the natural wrist area. Because the cuffs of a sterile gown collect moisture, become damp during wearing, and are considered unsterile, the closed-gloving technique can be used only for initial gloving. Cuffs may not be pulled down over the wearer's hand for subsequent gloving. For subsequent gloving, an alternative technique must be used, such as assisted gloving or open gloving.

Open-Gloving Technique. With the open-gloving technique, the everted cuff of each glove permits a gowned individual to touch the glove's inner side with ungloved fingers and to touch the glove's outer side with gloved fingers (Figure 3-23). Keeping the hands in direct view, no lower than waist level, the gowned individual flexes the elbows. Exerting a light, even pull on the glove brings it over the hand, and using a rotating movement brings the cuff over the wristlet. Extreme caution is necessary when using the open method to prevent contamination by the exposed hands. This gloving technique can be used by individuals not wearing a gown.

Assisted-Gloving Technique. A gowned and gloved individual may assist another gowned individual with gloving. To assist another individual, grasp the glove under the everted cuff. Ensure the palm of the glove is turned toward the ungloved individual's hand with the thumb of the glove directly opposed to the thumb of the individual's hand. Using fingers stretch the cuff to open the glove. The ungloved individual can insert his or her hand into the glove. The procedure is repeated for the other hand (Figure 3-24).

Removing Soiled Gown, Gloves, and Mask

To protect the forearms, hands, and clothing from contacting bacteria on the outer side of the used gown and gloves, members of the scrub surgical team should use the following procedure to remove soiled gowns, gloves, and masks (Figure 3-25, p. 103):

- Wipe gloves clean with a wet, sterile towel.
- Untie surgical gown; the perioperative nurse must unfasten back closures.
- Grasp gown at one shoulder seam without touching scrub clothing.

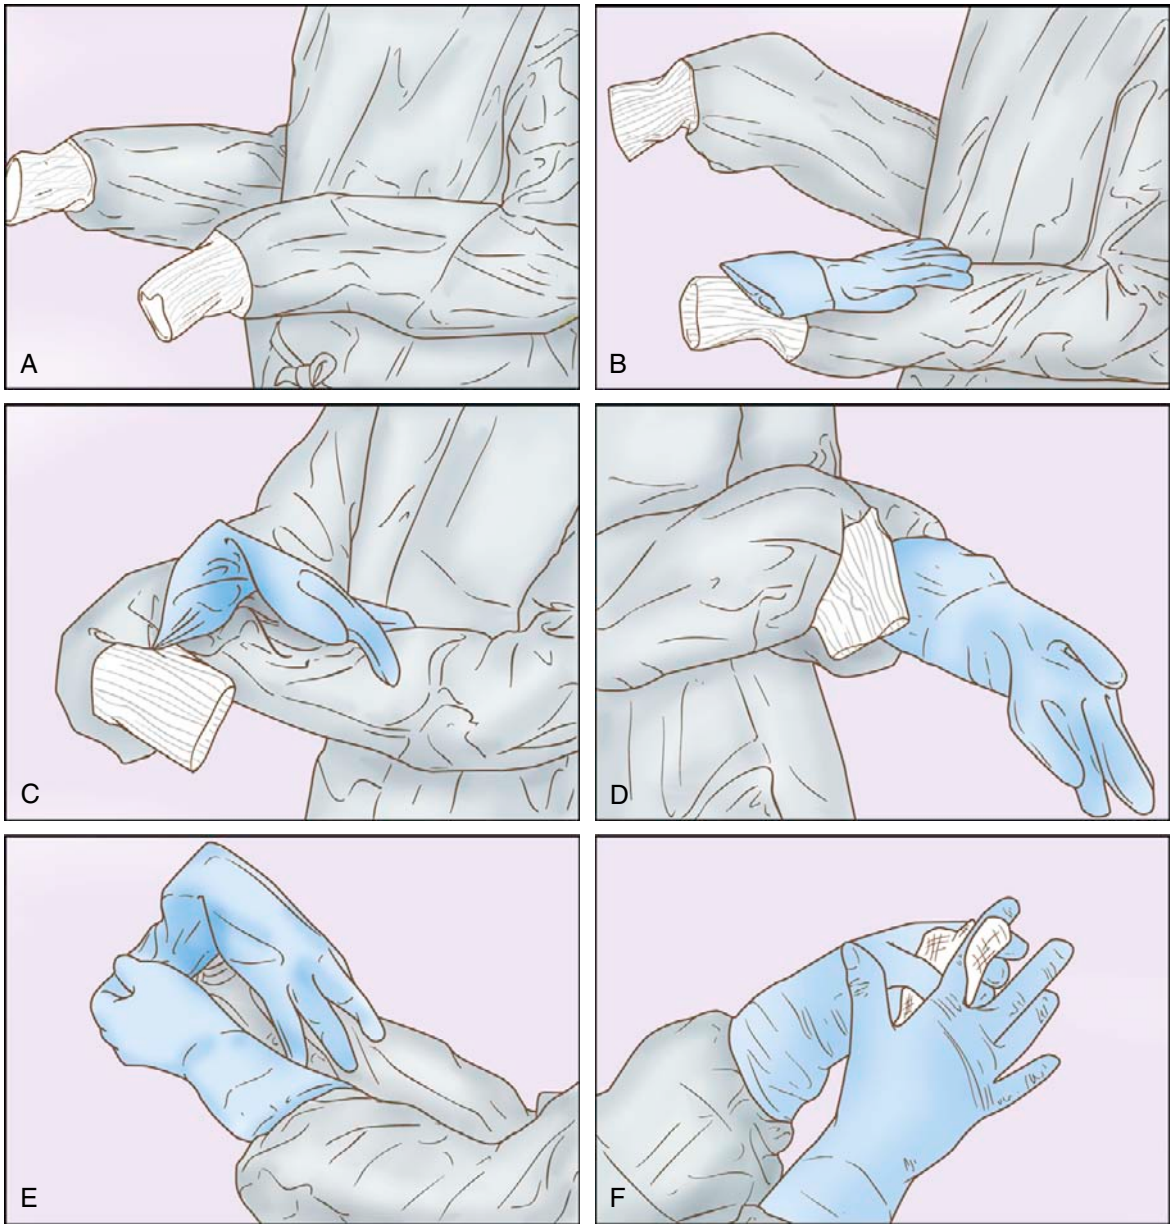

FIGURE 3-22 Closed-gloving procedure. **A**, When donning gown, scrub person does not slip hands through gown cuffs. Hands are not extended from sleeves. **B**, First the glove is lifted by grasping it through the fabric of the sleeve. The glove's cuff facilitates easier handling of the glove. The glove is placed palm down along the forearm of the matching hand, with thumb and fingers pointing toward elbow. Glove cuff lies over gown cuff. If the scrub person is double-gloving, the larger size gloves are donned first. **C**, The glove cuff is held securely by the hand on which it was placed, and with the other hand the cuff is stretched over the opening of the sleeve to cover the gown cuff entirely. **D**, As the cuff is drawn back onto the wrist, fingers are directed into their cots in the glove, and the glove is adjusted to the hand. **E**, Gloved hand is used to position remaining glove on opposite sleeve in the same fashion. Glove cuff is placed around gown cuff. The second glove is drawn onto the hand, and the cuff is pulled into place. **F**, Fingers of gloves are adjusted, and gloves are wiped with wet gauze sponge or commercially prepared sterile, disposable, glove wipe to remove any powder that may be on them.

- Bring the neck and sleeve of the gown forward, over, and off the gloved hand, turning the gown inside out and everting the cuff of the glove.
- Repeat the previous two steps for the other side.
- Keep arms and gown away from body while turning the gown inside out and discarding carefully in the designated receptacle.
- Using the gloved fingers of one hand to secure the everted cuff, remove the glove, turning it inside out. Discard appropriately.
- Using the ungloved hand, grasp the fold of the everted cuff of the other glove and remove the glove, inverting the glove as it is removed. Discard appropriately.
- After leaving the restricted area, remove the mask by touching the ties or elastic only.

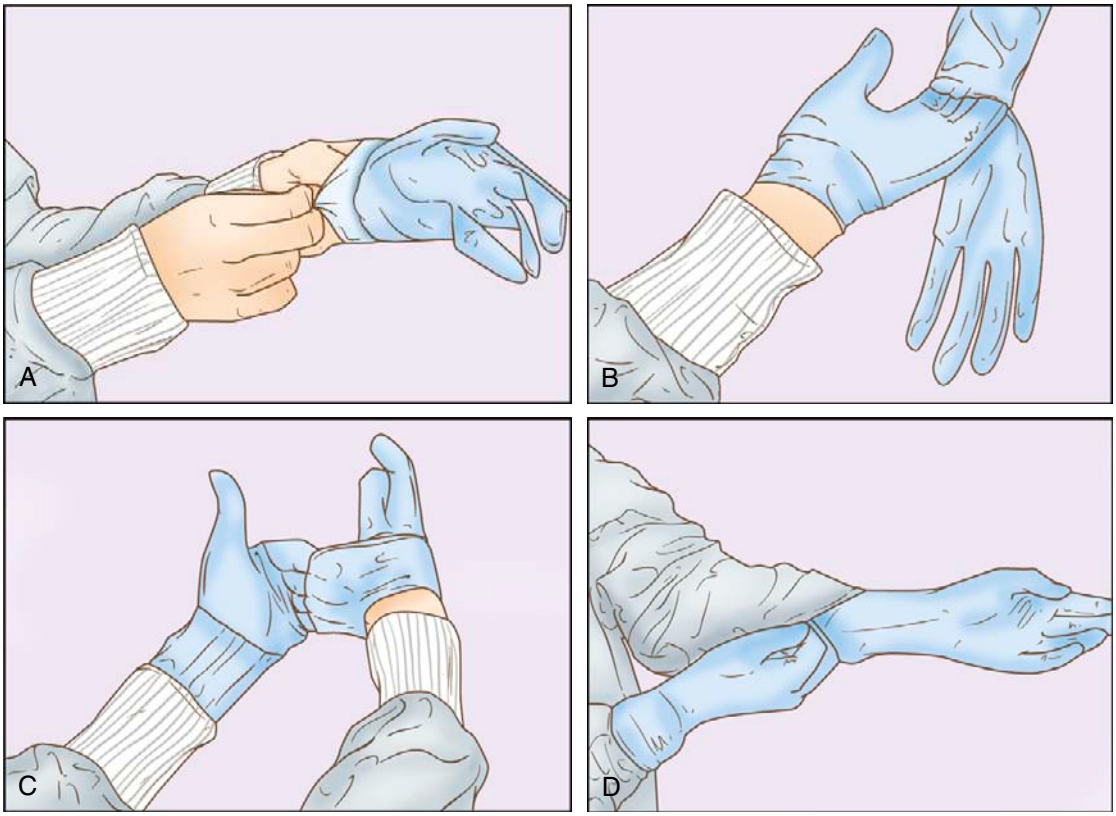

FIGURE 3-23 Open-gloving procedure. **A**, Scrub person takes one glove from the inner glove wrapper by placing the thumb and index finger of the opposite hand on the fold of the everted cuff at a point in line with the glove's palm and then pulls the glove over the hand, leaving the cuff turned back. If the scrub person is double-gloving, the larger size gloves are donned first. **B**, Scrub person takes the second glove from the inner glove wrapper by placing gloved fingers under the everted cuff. **C**, Scrub person, with arms extended and elbows slightly flexed, introduces free hand into glove and draws it over gown cuff by slightly rotating arm externally and internally. **D**, To bring turned-back cuff on other hand over cuff of gown, scrub person repeats step **C**.

FIGURE 3-24 Gloving another person. Gowned and gloved scrub person places fingers of each hand beneath everted cuff, keeping thumbs turned outward and stretching cuff as gowned person slips hand into sterile glove, using firm downward thrust. If other person is double-gloving, the larger size gloves are donned first.

- Discard in the designated receptacle.
- Wash hands and forearms.

Patient Skin Antisepsis

To prevent bacteria on the skin surfaces from entering the surgical wound, the skin area at and around the proposed incision site must be cleaned and disinfected. Skin preparation methods vary, but all are based on the same principles and share the same objectives: to remove dirt and transient microbes from the skin, to reduce the resident microbial count as much as possible in the shortest time and with the least amount of tissue irritation, and to prevent rapid rebound growth of microbes. Factors to be considered in skin disinfection are as follows:

1. Condition of the involved area
2. Number and kinds of contaminants
3. Characteristics of the skin to be disinfected
4. General physical condition of the patient

Many soaps and detergents are available for skin cleansing. Although most of them produce similar results for the immediate removal of soil and microorganisms, certain factors require further consideration in selecting a product for surgical use. Most soaps and detergents emulsify and peptize waste products and oils that are absorbed in surface soil and permit the debris to

RESEARCH HIGHLIGHT

Effects of Chlorhexidine Gluconate (CHG) Showers and Preoperative Shampoos

Patients that are Class 1 surgical interventions/procedures below the chin area should have two preoperative showers with chlorhexidine gluconate (CHG) when this is appropriate to the specific patient. As the epidemiology of infections with methicillin-resistant *S. aureus* (MRSA) changes, accurate information on the scope and magnitude of MRSA infections is needed to provide effective quality care. The incidence and estimated number of invasive MRSA infections and deaths are high. In one study of 8987 observed cases of invasive MRSA, it was noted that most MRSA infections were healthcare-associated: 58.4% (5250) were community-onset infections, 26.6% (2389) were hospital-onset infections, 13.7% (1234) were community-associated infections, and 1.3% (114) could not be classified. In 2005 the standardized incidence rate of invasive MRSA was 31.8 per 100,000. Incidence rates were highest among persons 65 years and older.

Invasive MRSA infection affects certain populations disproportionately. It is a major public health problem related to healthcare in general but no longer is confined to areas such as intensive care units, acute care facilities, or any specific health organization. *S. aureus* is the most common organism that causes surgical site infections (SSIs). The CDC's 1999 *Guideline for Prevention of Surgical Site Infection* recommended requiring patients to shower or bathe with an antiseptic agent at least the night before the operative procedure. Clinical trials have supported the use of preoperative antiseptic showers to reduce organisms on the skin and reduce the subsequent risk of surgical wound infection.

Researchers studied the effects of preoperative showering with a 4% concentration of CHG and povidone-iodine on patients whose skin was colonized with *S. sureus*. Two consecutive showers with 4% CHG the evening before surgery reduced the microbial counts in the incisional areas. Based on the study, povidone-iodine had little effect on colonization and inconsistent results ensued. The critical element is the reduction of the patients own flora with regard to Class 1 surgical wounds. For wounds that are partially or heavily contaminated, other ensuing factors are more likely to cause an SSI. Although there is sufficient evidence to support the effectiveness of two CHG showers in the reduction of microbial counts, additional research needs to be done to link the reduction of SSI rates to this decrease.

Modified from Mangram AJ et al: Guideline for prevention of surgical site infection, *Infect Control Hosp Epidemiol* 20, 1999; Centers for Disease Control and Prevention: *Guideline for prevention of surgical site infection,* 1999, available at www.cdc.gov/ncidod. Accessed April 25, 2009; Klevens RM et al: Invasive methicillin-resistant *Staphylococcus aureus* infections in the United States, *JAMA* 298(15):1763-1771, 2007; Association of periOperative Registered Nurses: Recommended practices for patient skin antisepsis. In *Perioperative standards and recommended practices,* Denver, 2009, The Association.

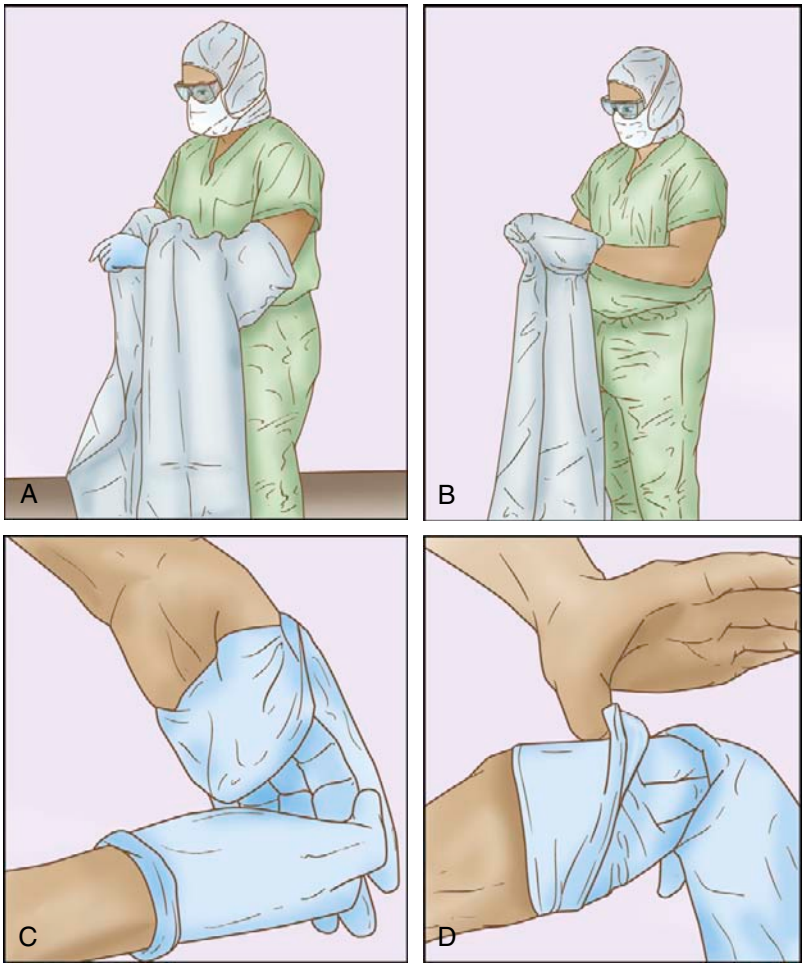

FIGURE 3-25 Removing soiled gown and gloves. **A**, To protect scrub suit and arms from bacteria that are present on outer side of soiled gown, the gown is grasped without touching the scrub clothes. **B**, Scrub person turns outer side of soiled gown away from body, keeping elbows flexed and arms away from body so that soiled gown will not touch arms or scrub suit. **C**, To prevent outer side of soiled gloves from touching skin surfaces of hands, the scrub person places gloved fingers of one hand under everted cuff of other glove and pulls glove off hand and fingers. **D**, To prevent ungloved hand from touching outer side of soiled glove, the scrub person hooks bare thumb on inner side of glove and pulls glove off.

be rinsed off the skin with running water. The product selected should become hydrolyzed in the presence of water and yield a pH that corresponds to that of average, normal skin. An odorless agent that produces a good lather for easy, comfortable use is usually preferred. It should not irritate the skin or in any way interfere with normal functioning. Equally important, an effective antimicrobial agent should be used to achieve appropriate disinfection of skin. The antimicrobial agent employed for disinfection of the skin should be selected according to its ability to decrease the microbial count of the skin rapidly, be applied quickly, and remain effective throughout the operation. The agent should not cause irritation or sensitization or be incompatible with or inactivated by alcohol, organic matter, soap, or detergent (Spry, 2005; AORN, 2009n).

Patients undergoing open Class I surgical interventions below the chin should have two preoperative showers with chlorhexidine gluconate (CHG) before surgery, when it is appropriate (Mangram, 1999). The process of washing and rinsing repeatedly removes microorganisms from the skin. Some organisms may be difficult or virtually impossible to kill with CHG alone. Unless contraindicated, patients should be instructed or assisted to perform two preoperative baths or showers with CHG before surgery to reduce the number of microorganisms on the skin and reduce the risk of subsequent contamination of the surgical wound (AORN, 2009n) (Research Highlight).

Hair should not be removed from the surgical site unless it is required. The necessity for hair removal depends on the amount of hair, the location of the incision, and the type of surgical procedure to be performed. Preoperative shaving of the surgical site increases the risk of surgical site infection (Anderson, 2008; AORN, 2009n). If hair is to be removed, clipping with an electric or battery-operated clipper, not shaving, is recommended. Clipping, immediately before surgery, is the simplest and least irritating method of hair removal. Wound infection rates are considerably higher for patients who are shaved preoperatively than for patients who have no preoperative shave preparation or a small amount of hair clipped or for patients on whom a depilatory is used. Use of a depilatory requires a pretest to ascertain that the patient is not sensitive to the depilatory product. The specific manufacturer's written instructions should be carefully followed. If a shave is desired by the surgeon, some institutions require a written order. The patient should be shaved as close to the time of surgery as is possible. The shave should be performed in an area within the surgical suite that affords privacy and is equipped with good lighting. The amount of time between the preoperative shave and the operation has a direct effect on the surgical site infection rate. Hair removal should be performed by skillful personnel, with great care taken to avoid scratching, nicking, or cutting the skin because cutaneous bacteria proliferate in these areas and increase the chances of infection. The method of hair removal and the condition of the skin before and after removal should be documented.

The surgical principle followed when preparing the patient's skin for surgery ("prepping") is to prepare ("prep") the cleanest area first and then move to the less clean areas (clean to dirty). The skin at the surgical site should be exposed and inspected before beginning the skin prep. Patients should have been instructed to remove any body jewelry before cleansing the site. Jewelry harbors microorganisms and traps these organisms in adjacent skin. Jewelry should also be removed to reduce the risk of injury when positioning the patient or from using electrical devices. Surgical departments often stock snap-ring pliers to remove jewelry from piercings for emergency situations or when a patient has neglected to remove body jewelry. The skin prep usually begins at the point of the incision and continues to the periphery of the area (Figure 3-26). When prepping the surgical site, the nurse dons sterile gloves and applies the antimicrobial agent using commercially prepared devices or applicators that have handles to provide distance between the nurse's hand and the area being prepared. A soiled applicator is never brought back over a previously prepped surface. On completion of the skin prep, the nurse blots the area with dry, sterile sponges or a sterile towel. Depending on the surgeon's preference, a topical antimicrobial solution or "paint" may be carefully applied to the prepped area, using care to avoid any pooling of solution beneath the patient. All wet drapes should be removed from the patient area after the skin preparation is complete (AORN, 2009n).

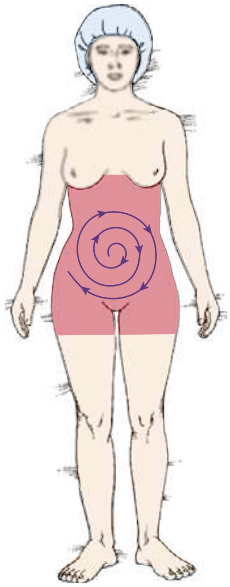

FIGURE 3-26 Principles of starting at the intended incision site and working towards the periphery are illustrated on this example of an abdominal prep. Shaded areas indicate the area to be cleaned with antiseptic; arrows show direction of motion for the prep.

When an intestinal or urinary stoma or other contaminated area is involved within the surgical field and during the prep procedure, a sponge soaked in the antimicrobial agent of choice is placed over the stoma when the prep is initiated. The area should be cleansed separately from the rest of the prepped area. At the completion of the prep, the sponge is discarded. Sponges used to cleanse or disinfect an open wound, sinus, ulcer, intestinal stoma, the vagina, or the anus are applied once to that area and discarded. In contrast to the principle of working from the proposed incision to the periphery, open wounds and body orifices are potentially contaminated areas and as such are prepared after the peripheral intact skin is cleansed. The surgical principle is to work from the cleanest to the least clean area (AORN, 2009n; Spry, 2005).

The nurse should document the area prepped and the antiseptic solution used in the perioperative record. Documentation

is an effective way to promote safe, continuous patient care. Although at times it may seem time-consuming, periodic audits of the documentation of skin preparation help the perioperative nurse assess the effectiveness of the process, while protecting patients from possible surgical site infections (AORN, 2009n; Spry, 2005).

Creating the Sterile Field with Surgical Drapes

To create a sterile field, sterile sheets and towels, known as surgical drapes, are strategically placed to provide a sterile surface on which sterile instruments, supplies, equipment, and gloved hands may rest. The patient and OR bed are covered with sterile drapes in a manner that exposes the prepared incision site and isolates it from surrounding areas. Objects normally draped and composing the sterile field include instrument tables, trays, basins, the Mayo stand, some surgical equipment, and the patient. Within this defined sterile area the actual operative procedure takes place.

Today, reusable and single-use (disposable) drapes are widely used. There are advantages and disadvantages for reusable (fabric) and single-use (disposable, nonwoven) drapes. Regardless of the type of material used, surgical drapes should have the following characteristics (AORN, 2009o):

- Appropriate barrier to microorganisms, particulate matter, and fluids
- Withstand methods of sterilization
- Maintain integrity
- Durable
- Withstand physical conditions
- Resist tears, punctures, fiber strains, and abrasions
- Free of toxic ingredients
- Low linting
- Free of holes or other defects
- Positive cost-to-benefit ratio

In addition to the characteristics just mentioned, draping materials should meet or exceed the current requirements of the National Fire Protection Association (Patient Safety).

Reusable Drapes. Chemically treated cotton or cotton-polyester fabrics provide a barrier to liquids and are abrasion-resistant. Quantitative data verifying the barrier quality of any textile drape must be provided by the manufacturer. Care should be taken with reusable drapes to eliminate pinholes caused by towel clamps, needles, or other sharp objects. Only nonpenetrating towel clamps should be used. Should breaks in the fabric occur, a heat-sealed patch may be used for repair after laundering. An abundance of heat-sealed patches on any surgical drape may interfere with the sterilization process and render the barrier ineffective. Manufacturer's written instructions on the use of patching should be followed. The exact percentage of any item that may be successfully patched is unknown. As with reusable gowns, laundering eventually impairs the barrier

PATIENT SAFETY

Preventing Surgical Fires

According to the ECRI Institute (2009) between 550 and 650 surgical fires occur each year in the United States. The consequences for both patients and the healthcare team are devastating. With appropriate awareness and good practice, all surgical fires can virtually be prevented.

The perioperative environment is a prime target for fires. The fire triad—fuel, ignition source, and oxidizers—is present in all ORs. The use of oxygen, nitrous oxide, medical air, or anesthetizing gases must always be considered as part of the oxygen-enriched environment in the OR. Ignition sources in the form of the electrosurgical units, lasers, fiberoptic lights, drills, or other surgical electrical equipment are also common. The third element—fuel—can be provided in the form of patient skin preparation agents and surgical drapes. Approximately 100 surgical fires occur annually. The Joint Commission (formerly JCAHO) issued a sentinel event alert to prevent surgical fires, and in 2005 it incorporated surgical fire prevention as a National Patient Safety Goal (NPSG). Surgical fires can be prevented if one of the elements of the fire triad is eliminated or reduced.

To reduce the risk of a surgical fire from an agent used to antiseptically prepare the surgical site, the following steps should be taken:

- Use only necessary preparation solutions and in appropriate quantities. Flammable preparation solutions should be packaged to provide for a controlled delivery, such as in unit-dose applicators or swabs.
- Avoid pooling of preparation solution. If linens on the OR bed or the patient become soaked with solution, remove them from the area.
- Allow preparation solution to dry completely (3 to 5 minutes) before surgical drapes are applied. This may be incorporated as a time-out or "all-clear" announcement before proceeding with the draping process.
- Activate an ignition source, such as an electrosurgical unit (ESU), cautery device, or laser, only when vapors from preparation solution have dissipated and areas are completely dry.
- Perform periodic safety hazard assessments for the OR environment.

If a surgical fire occurs, the *RACE* (*R*escue, *A*lert/*A*larm, *C*ontain, and *E*xtinguish) method should be used. Fire policies and fire drills should be readily available and reviewed on a continuous basis. Each member of the perioperative team is responsible for communicating with one another about the risk of surgical fires and for the steps in extinguishing a patient or airway surgical fire. Key concepts in establishing a culture of safety include evaluation, education, standard processes, and tools to foster interdisciplinary communication and collaboration. A culture of safety requires rapid identification of errors and root causes, successful implementation of improvement strategies, strong leadership, critical thinking, and commitment to excellence.

Modified from Cantrell S: Fanning the flames of surgical fire prevention, *Healthcare Purchasing News* 5, 2008; ECRI Institute: Surgical fire safety, *Health Devices* 35, 2006, available at www.hpnonline.com/inside/2008-05-OR-Fire.html. Accessed June 5, 2009; The Joint Commission: *Sentinel event alert: preventing surgical fires,* available at www.jointcommission.org/SentinelEvents/SentinelEventAlert/sea_29.htm. Accessed June 5, 2009; Ball MJ: Culture of safety, *Adv Nurses* 7(23):31-32, 2005; Giarrizzo-Wilson S: Clinical issues—fire protection standards, *AORN J* 82(4):673-674, 2005; Lypson ML et al: Preventing surgical fires: who needs to be educated? *Jt Comm J Qual Patient Saf* 31(9):522-527, 2005.

quality of the drape. Most manufacturers report a loss of barrier quality after 75 to 100 laundry or sterilization cycles. The process of laundering and steam-sterilization swells the fabric fibers, whereas drying and ironing shrink the fibers. Over time, these processes loosen fabric fibers, altering the fabric structure and decreasing the barrier properties and fluid impermeability of the fabric. As with surgical gowns, a system to monitor the number of times an item has been processed is essential for quality control of the barrier and fluid impermeability.

Single-Use (Disposable) Drapes. Many synthetic single-use (disposable) drapes prevent bacterial penetration and fluid breakthrough, also known as *strikethrough*. These versatile materials can be manufactured to meet different specifications in absorbent and nonabsorbent forms. Single-use products are packaged and sterilized by commercial sources. Single-use drapes reduce the hazards of contamination in the presence of known infectious microorganisms from body fluids and excretions and in situations where laundering of grossly contaminated textiles may be problematic. The danger inherent in the use of synthetic drapes is that solvents, volatile liquids, and sharp instruments tend to penetrate the barrier. Loss of effectiveness may be caused by cracking at the folds or by pinholes from the use of regular, perforating towel clamps. Manufacturers are continually improving single-use drapes to permit easy handling and adaptability to the body. When considering the purchase of single-use drapes, the perioperative team must determine whether the drapes will meet the needs of the surgical procedure, be acceptable to the perioperative team, and be cost-effective (versus laundering and processing of reusable drapes). A cost-benefit ratio analysis may warrant their use in the healthcare facility. Availability of items, storage facilities, and disposal methods must be analyzed (AORN, 2009q).

The environmental effect of disposable items can be only roughly estimated. Each facility must carefully evaluate its capabilities and restrictions for handling single-use and reusable supplies and equipment to make an informed decision about the products it will use in the practice setting.

Compactors provide a relatively inexpensive method of discarding disposable drapes. They accept any material and reduce its volume substantially. Storage, collection, and transportation of compacted waste materials can be a problem. Hospital engineers must establish methods of controlling odor and maintaining sanitation in the compactor area. Because a portion of the compacted material may be grossly contaminated, city or county codes may prohibit transporting this potentially infectious material through city streets or dumping it at landfills. Incineration is an alternative method for destroying waste disposables. If incinerators are used, they must be managed properly to prevent environmental contamination. Facilities choosing to incinerate must follow specific state and local guidelines established for medical waste incinerators. Many hospital incinerators do not meet federal pollution standards, and their use is prohibited.

Preassembled, sterile, disposable custom packs are used in many healthcare facilities. Advantages of these packs include reduced setup and room-turnover times, less risk of contaminated waste resulting from fewer individually wrapped items, improved inventory control, and fewer lost charges. Although custom packs may be more expensive than multiple separate items, indirect savings related to increased efficiency can offset those costs. Healthcare facilities choosing to use custom packs should determine and document ownership of liability for the function and integrity of individual items within the packs.

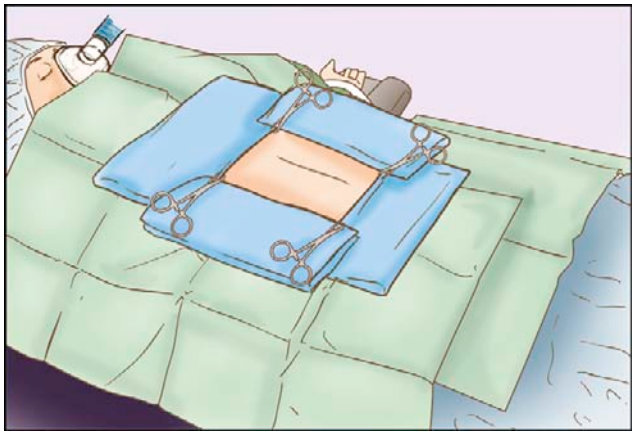

FIGURE 3-27 Abdomen may be draped with four sterile towels, which are secured with nonperforating towel clamps. Standard method of placement of disposable towels is used.

Drape Configurations. Careful planning by perioperative personnel helps determine the desired types and sizes of surgical drapes required for groups or individual surgical procedures. Standardized draping methods provide management control that ensures patient safety, simplifies staff education, and conserves human and material resources.

A whole, or plain, sheet is used to cover instrument tables, operating tables, and body regions. The sheet should be large enough to provide an adequate margin of safety between the surrounding physical environment and the prepared operative field. Surgical towels should be available in several sizes to drape the operative site. Four surgical towels of woven or nonwoven material are usually sufficient (Figure 3-27).

Fenestrated, or slit, sheets are used for draping patients. They leave the operative site exposed. A typical fenestrated (laparotomy) sheet is large enough to cover the patient and operating bed in any position, extend over the anesthesia screen at the head of the bed, and extend over the foot of the bed (Figures 3-28 to 3-30). The typical fenestrated laparotomy sheet can be used for most procedures on the abdomen, chest, flank, and back. Other types of fenestrated sheets with small or split fenestrations may be used for the limbs, head, and neck when the patient is in the supine or prone position. The size of the fenestration is determined by the use for which the sheet is intended. The fenestrated sheet is fan-folded and handled as a typical laparotomy sheet. A perineal drape is needed for procedures on the perineum and genitalia when the patient is in the lithotomy position. A lithotomy drape consists of a fenestrated sheet and two triangular leggings. Although a three-piece drape is less costly and is easier to handle and launder, a single drape with attached leggings may be used.

Several types of impermeable polyvinyl chloride (PVC) sheeting are available in the form of sterile, prepackaged surgical drapes. Plastic incisional drapes are available as a plain impermeable drape or impregnated with iodophor. These plastic drapes are useful adjuncts to the conventional draping procedure. They can be applied after the fabric drape, alleviating

FIGURE 3-28 Placement of laparotomy sheet. Identification of top portion of laparotomy sheet helps the scrub person readily determine correct placement of the drape. After placing the folded laparotomy sheet on the patient, with fenestration of sheet directly over site of incision outlined by sterile towels, the scrub person unfolds drape over sides of patient and bed.

FIGURE 3-29 Laparotomy draping continued. Scrub person protects gloved hands under cuff of fan-folded laparotomy sheet and draws the upper section above fenestration toward the head of the bed, draping it over the anesthesia screen. The bottom portion of the fan-folded sheet is extended over the foot of the bed in a similar manner.

the need for towel clamps. They obviate the need for skin towels and sponges to separate the surgeon's gloves from contact with the patient's skin. Skin color and anatomic landmarks are readily visible, and the incision is made directly through the adherent plastic drape. These materials facilitate draping of irregular body surfaces, such as neck and ear regions, extremities, and joints (Figure 3-31).

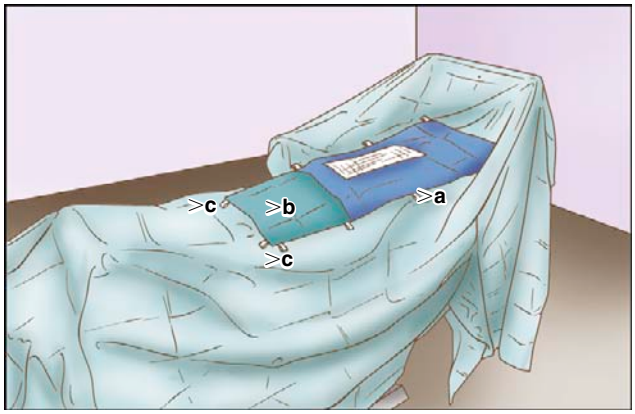

FIGURE 3-30 Laparotomy draping completed. Fenestration provides exposure of prepared operative site. *>a,* Reinforced area around drape fenestration provides greater protection and fluid control. *>b,* Built-in instrument pad prevents instrument slippage. *>c,* Perforated tabs provide means of controlling position of cords and suction tubes.

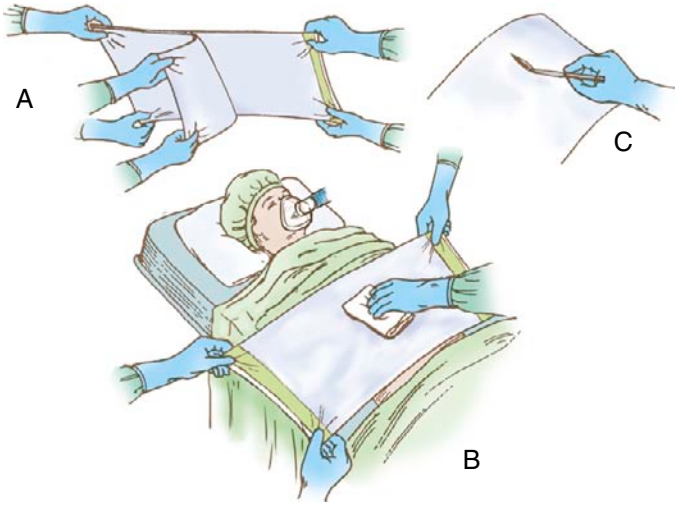

FIGURE 3-31 Sterile, impermeable adhesive drape. For maximum sealing to prevent wound contamination, prepared skin must be dry, and the drape must be applied carefully, preventing wrinkles and air bubbles. **A,** Surgeon and assistant hold plastic drape taut while another assistant peels off back paper. **B,** Surgeon and assistant apply plastic drape to operative site and, using folded towel, apply slight pressure to eliminate air bubbles and wrinkles. **C,** Surgeon makes incision through plastic drape.

Draping Procedure. Drapes should be folded so that the gowned and gloved members of the team can handle them with ease and safety. The larger, regular sheet is usually fan-folded from bottom to top. The bottom folds may be wider than the upper ones. The small sheet is folded in half and quartered, with the top corners of the sheet turned back or marked for easy identification and handling. To provide for safe, easy handling and a wide margin of safety between the unsterile item and the scrub person's gloved hands, the open end of the Mayo stand cover should be cuffed or folded back on itself (Figure 3-32). Most fenestrated sheets are fan-folded to the opening from the top and the bottom, and the folds are rolled or fanned toward the center of the

FIGURE 3-32 Draping Mayo stand. Folded cover is slipped over frame. Scrub person's gloved hands are protected by cuff of drape. Cover is unfolded to extend over upright support of stand.

opening. The edges of the top and bottom folds of the sheet are fanned to provide a cuff under which the perioperative scrub person may place his or her gloved hands. The top and lower sections should be identified by markings to facilitate easy handling.

When applying drapes to create the sterile field, these principles should be followed:

- Allow sufficient time and space to permit careful draping and proper aseptic technique.
- Handle sterile drapes as little as possible. Rapid movement of draping materials creates air currents on which dust, lint, and other particles can migrate (AORN, 2009l).
- Carry the folded drape to the operative site. Carefully unfold the drape, and place it in the proper position. Do not move the drape after it has been placed. Shifting or moving the drape may transport bacteria from an unprepared area of the patient's skin into the surgical field.
- Hold sterile drapes above waist level until properly placed on the patient or device being draped. If the end of a drape falls below waist level, it should not be retrieved because the area below the waist is considered unsterile.
- Immediately discard a drape that becomes contaminated during the draping procedure without contaminating the gloves or other sterile items.
- Protect the gown by distance. During draping, gloved hands should be protected by cuffing the draping material over the gloved hands to reduce potential contamination. Control all parts of the drape at all times during placement, using precise and direct motions.
- Do not flip, fan, or shake drapes. Shaking a drape results in uncontrolled motion ofthe drape, which may cause it to come into contact with an unsterile surface or object. A drape should be carefully unfolded and allowed to fall gently into position by gravity.
- Drape the incisional area first and then the periphery. Always drape from a sterile area to an unsterile area by draping the near side first. Never reach across an unsterile area to drape. When draping the opposite side of the OR bed, go around the bed to drape.
- Use nonperforating towel clamps or devices to secure tubing and other items on the sterile field. The low portion of a sheet that falls below the safe working level should never be raised or lifted back into the sterile area.
- Do not move the portion of the surgical drape that establishes the sterile field after it is positioned.
- Consider the drape contaminated any time the sterility is questionable.

After the patient is positioned, prepared, and draped, a time-out is conducted to verify patient identification, correct position, and correct surgical site (and side if applicable) and that required equipment is available.

Environmental Cleaning

Contamination in the OR can occur from various sources. The patient, healthcare workers, and inanimate objects are all capable of introducing potentially infectious material onto the surgical field. The patient should be provided a clean, safe, environment. Techniques have been established to prevent the transmission of microorganisms into the surgical area, such as wearing proper surgical attire and establishing controlled traffic patterns in the surgical suite. During the surgical procedure, traffic within and through the room should be kept to a minimum to reduce air turbulence and to minimize human shedding. All doors in and out of the OR should be kept closed to decrease air turbulence and the potential for contamination. HEPA filters placed between outside air processing and the OR vents are used in many facilities and are recommended for newly constructed systems/facilities. HEPA filters are capable of screening out particles larger than 0.3 μm (CDC, 2008a; AORN, 2009d). The perioperative registered nurse should assess the perioperative environment frequently for cleanliness and take action to implement cleaning and disinfection procedures if needed (AORN, 2009d; OSHA, 2001).

All surgical patients are potentially infected with bloodborne or other infectious material. For patient and personnel safety, cleaning procedures should be uniform throughout the OR and for all patients. Using a uniform procedure designed to protect persons from visible or invisible contamination eliminates the need for special cleaning procedures for so-called dirty cases. Cleaning procedures should be carried out in a manner that protects patients and personnel from exposure to potentially infectious microorganisms. Cleaning measures are needed before, during, and after surgical procedures and at the end of each day. A safe, clean environment should be reestablished after each surgical or invasive procedure. Overall housekeeping procedures, such as wall and ceiling washing, should be completed on a defined, regular basis and terminal cleaning and disinfection of operating and invasive procedure rooms should be performed when scheduled procedures are completed for the day or each regular 24-hour period (AORN, 2009d).

Transmission-based precautions are designed for patients who have a documented infection or who are suspected to be infected with a highly transmissible pathogen for which

additional precautions are necessary. There are three types of transmission-based precautions: airborne, droplet, and contact. The CDC (2008a) guidelines should be followed when all facility policies and guidelines are developed.

Before beginning the first procedure of the day, horizontal surfaces in the ORs should be dusted with a cloth dampened with a facility-approved disinfecting agent. Dust and lint deposited on horizontal surfaces during the night can become airborne vectors for organisms if not removed. During surgery, efforts should be made to confine contamination to as small an area as possible around the patient. Sponges should be discarded in plastic-lined containers. As they are counted, they should be contained in an impervious receptacle. The perioperative nurse must use protective eyewear and gloves, instruments, or both when collecting and counting sponges or handling contaminated items. Spills should be cleaned immediately, and the cleaned area should be disinfected with a broad-spectrum disinfectant or germicide. Specimens of blood or other potentially infectious tissues or materials should be placed in a container that prevents leakage. The container must be color-coded or labeled using the biohazard symbol (see Figure 3-2). If the outside of the container becomes contaminated, the primary container must be placed within a second container that prevents leakage and is labeled or color-coded. Some facilities use biohazard-labeled impervious bags to transport blood or other potentially infectious material (CDC, 2008a; AORN, 2009d).

On completion of the surgical procedure, soiled linens should be discarded in fluid-impervious bags to eliminate potential contamination from wet linen soaking through to the outside of the bag. Contaminated items should be placed in leak-proof, color-coded, or labeled containers. Sharps (e.g., needles, scalpels, electrosurgical tips) are considered infectious and should be placed in special puncture-resistant containers (OSHA, 2001). Bulk blood or suctioned fluid may be poured carefully down a drain connected to a sanitary sewer unless prohibited by environmental regulations. Local and state environmental regulations may exist and should be consulted before establishing guidelines for waste disposal. Wall suction units should be disconnected to eliminate contamination of the wall outlet. Suction contents should be disposed as soon as possible upon completion of the procedure. Depending on local and state regulations, powder treatments of a chlorine compound are available to solidify liquid material before transport. This chemical also may be tuberculocidal, virucidal, and bactericidal. Suction tubing should be discarded; reusable suction tubing should be avoided because of the difficulty of properly cleaning their lumens. Personnel should remove their gowns and gloves and place them in the proper receptacles before leaving the OR, and then perform handwashing. Instruments and supplies should be contained and taken to the decontamination area, where educated personnel wearing personal protective attire begin the instrument decontamination process. Care should be taken to arrange sharp instruments in such a manner that personnel need not reach into basins where sharp instruments are unexposed and could cause injury. Equipment and furniture in the OR should be cleaned with an EPA-approved hospital disinfectant, and the floor should be cleaned in a 3-foot to 4-foot perimeter around the operating bed and where visibly soiled. A standard practice of cleaning helps prevent surgical site infections and maintains a clean and safe environment (CDC, 2008a; AORN, 2009d).

At the end of each day's operative schedule, all rooms where procedures may be performed should be cleaned by qualified, trained, supervised personnel. Areas to be cleaned include the following:

- Surgical lights and external tracks
- Fixed and ceiling-mounted equipment
- All furniture and equipment including wheels and casters
- Equipment
- Handles of cabinets and push plates
- Ventilation faceplates
- Horizontal surfaces (e.g., countertops, fixed shelving, autoclaves)
- Floor
- Kick buckets
- Scrub sinks

If refillable liquid soap dispensers are used, they should be disassembled and cleaned before being refilled because they can serve as reservoirs for microorganisms. At the conclusion of the housekeeping protocol, cleaning equipment and supplies should be properly cleaned, disinfected, and stored. If a wet vacuum has been used, it should be disassembled and thoroughly washed with a disinfectant before being stored (AORN, 2009d).

CHAPTER 4

Anesthesia

LINDA M. DeLAMAR

Without anesthesia, most modern surgical procedures would not be feasible. As integral members of the patient care team in operative and other invasive procedure settings, perioperative nurses need to be familiar with the principles and practices of anesthesia and the perioperative functions of the anesthesia provider. This chapter presents an overview of the modern practice of anesthesia, the factors involved, and the interrelationship with the perioperative nurse. It discusses major types of anesthesia, introduces the more commonly used drugs, reviews standards of anesthesia care, and summarizes problems that can occur during the perioperative period. The anesthesia machine and monitoring equipment are also described so that perioperative nurses can become familiar with their basic functions as the nurse may use them during local anesthesia or conscious sedation/analgesia procedures.

The sections of this chapter are organized so that they can be referred to independently without reading the entire chapter. Experienced perioperative nurses are familiar with the commonly used abbreviations employed in this chapter. To provide a single reference source for the student or novice perioperative nurse, most abbreviations are defined in Box 4-1.

HISTORY OF ANESTHESIA

The early history of modern anesthesia was fraught with controversy. Surgeons in the early nineteenth century frequently used alcohol or opium to intoxicate the patient for procedures involving intense pain or when muscle relaxation was needed. In some cases, hypnotism also was employed. Successful surgery was related directly to the speed of the surgeon (History box).

In March 1842 a physician in Danielsville, Georgia, named Crawford W. Long, used ether as an anesthetic to remove a cystic tumor from the neck of a patient named James Venable. As confirmed by other physicians in the area, Dr. Long subsequently used ether for other procedures, but did not publish reports of his experiences (Bankert, 2000; Gunn, 2005).

In 1844 Horace Wells, a dentist in Hartford, Connecticut, began to use nitrous oxide (N_2O) for anesthesia and communicated his results to his former partner, William T.G. Morton. After a death with N_2O, however, Wells quit the practice of dentistry and later committed suicide. Morton subsequently studied medicine and learned of the anesthetic effects of chloric ether from his preceptor, Charles T. Jackson, a chemist. In 1846, while employing this new drug, Morton was able to fill a tooth without the patient experiencing pain. He later learned from Jackson that sulfuric ether had similar properties and used it while extracting a deeply rooted bicuspid tooth from another patient (Bankert, 2000; Koch, 2010).

Morton contacted John C. Warren, a surgeon at the Massachusetts General Hospital, and persuaded him to give the new anesthetic a trial during a surgical procedure. With Morton as the anesthetist, this historic operation took place in the amphitheater (subsequently renamed "The Ether Dome") of Massachusetts General Hospital on October 16, 1846. In 5 minutes, Warren operated on an unconscious, quiet patient and dissected "a congenital but superficial vascular tumor just below the jaw on the left side of the neck." As the patient regained consciousness, Warren exclaimed, "Gentlemen, this is no humbug." The next day, Warren, with Morton as the anesthetist, removed a large fatty tumor from the shoulder of another patient (Koch, 2010).

Based on these events, the first medical report of anesthesia was announced to the world on November 18, 1846, by Henry J. Bigelow in the *Boston Medical and Surgical Journal*. An era had ended in which successful surgery was largely predicated on the lightning speed of the surgeon while working on a struggling, distressed patient. Anesthetic techniques gave the surgeon more time to operate and permitted new procedures to be undertaken that would have been impossible before. Many modern surgical techniques have become feasible because of the advances in the art and science of anesthesia.

The word *anesthesia* is derived from the Greek word *anaisthesia,* which literally means "no sensation." Anesthesia was listed in *Bailey's English Dictionary* in 1721. When the effects of ether were discovered, Oliver Wendell Holmes suggested *anesthesia* be used as a name for the new phenomenon. Some believed that he coined this term; others believed that he knew of the Greek word that Plato had employed. In any case, anesthesia was, in the memorable phrase of Werr Mitchell, the "death of pain." From these early beginnings, anesthesia has developed into a sophisticated science and "clinical art" that interfaces with many other medical specialties.

ANESTHESIA PROVIDERS

In the United States, anesthesia care usually is provided by an anesthesiologist, a certified registered nurse anesthetist (CRNA) working in collaboration with or under the direction of an anesthesiologist or a physician, or an anesthesiologist's assistant (AA) working under the direct supervision of an anesthesiologist.

An anesthesiologist is a physician with 4 or more years of specialty training in anesthesiology. Nurse anesthesia programs are a minimum of 2 years in length. They require a

BOX 4-1

Abbreviations Used in This Chapter

AANA—American Association of Nurse Anesthetists
ABG—Arterial blood gas; usually includes pH, Pao_2, $Paco_2$, HCO_3^-, K^+, and ionized Ca^{++}
ACLS—Advanced Cardiac Life Support, a protocol for resuscitation from the American Heart Association
APL—Adjustable pressure-limiting valve; a valve on anesthesia machines that limits the maximum pressure in the patient breathing circuit; frequently referred to as the "pop-off valve"
ASA—American Society of Anesthesiologists
cm—Centimeter; 1×10^{-3} m; 2.54 cm = 1 inch
CRNA—Certified registered nurse anesthetist
CSF—Cerebrospinal fluid; the fluid surrounding the brain and spinal cord; for spinal anesthesia, local anesthetics are injected into the CSF
EGTA—Esophageal (gastric tube) airway; a cuffed tube that is inserted blindly into the esophagus and connected to a mask; this permits ventilation through the mask and gastric suctioning through the cuffed tube
$ETco_2$—End-tidal carbon dioxide reported as a partial pressure; see Capnography section
ETT—Endotracheal tube
Fio_2—Fraction of inspired oxygen; this is a fraction (0.00 to 1.00) that corresponds to the percent (0% to 100%) of inspired oxygen
FO—Fiberoptic
mcg—Microgram
kg—Kilogram; 1 kg = 2.2 lb
LED—Light-emitting diode; an electronic device that emits light at a predetermined frequency
LMA—Laryngeal mask airway or laryngeal airway
MAC—Monitored anesthesia care; see Monitored Anesthesia Care section
mg—Milligram; 1×10^{-3} g
MH—Malignant hyperthermia; see Malignant Hyperthermia section
MHAUS—Malignant Hyperthermia Association of the United States
MMS—Master of medical science degree
MRI—Magnetic resonance imaging
NIOSH—National Institute for Occupational Safety and Health
nm—Nanometer; 1×10^{-9} m
NMS—Neuroleptic malignant syndrome; see Malignant Hyperthermia section
N_2O—Nitrous oxide
NSAID—Nonsteroidal antiinflammatory drug
PA—Pulmonary artery
$Paco_2$—Partial pressure of arterial carbon dioxide; lower case "a" denotes "arterial"; an uppercase "A" denotes "alveolar"
Pao_2—Partial pressure of arterial oxygen; lower case "a" denotes "arterial"; an uppercase "A" denotes "alveolar"
PCA—Patient-controlled analgesia; see Pain Management section
PNB—Peripheral nerve block
ppm—Parts per million; 1 ppm = 1×10^{-6}
psi—Pounds per square inch; a measurement of pressure
QA—Quality assurance; this function also may be identified as quality improvement (QI), continuous quality improvement (CQI), or similar names
RSI—Rapid-sequence induction
Spo_2—Saturation (pulse) of oxygen or in a pulsating vessel, expressed as a percentage; see Pulse Oximetry section
Svo_2—Saturation of mixed venous oxygen in percentage; this measurement is made from a special pulmonary artery catheter
torr—1 mm Hg

HISTORY

A Brief Look at Anesthesia

In *Nursing, The Finest Art,* Donahue notes that "The first nursing specialists have existed since the late nineteenth and early twentieth centuries: the nurse midwife and the nurse anesthetist…The role of the nurse anesthetist developed as part of the increasing sophistication of surgery in the early 1900s, when it was recognized that trained assistants were needed to administer anesthetics. No longer was it safe or satisfactory to have untrained medical students or attendants providing anesthesia. These early specialists were recruited from the available pool of trained nurses to meet very specific societal demands and needs."

Year	Breakthrough
1861-1865	Catherine S. Lawrence and other nurses provided anesthesia for surgeons during the Civil War.
1887	Sister Mary Bernard was the first nurse known to specialize in anesthesia.
1893	Alice Magaw began as a nurse anesthetist for Dr. Mayo, who would later give her the title "The Mother of Anesthesia" for her mastery of open drop ether.
1899	Magaw published the first paper by a nurse anesthetist in the Northwestern *Lancet.*
1909	St. Vincent's Hospital in Springfield, Illinois, began a nurse anesthetist program.
1911	Frances Hoeffer McMelhan began to advocate for physician anesthetists.
1914-1917	Agatha Hodgins and many other nurse anesthetists in volunteer American medical units provided anesthesia to casualties during World War I.
1931	Agatha Hodgins and 47 nurse anesthetists founded the National Association of Nurse Anesthetists (NANA).
1936	The American Society of Anesthesiologists (ASA) was founded.
1939	The NANA became the American Association of Nurse Anesthetists (AANA).
1941-1945	Second Lieutenant Mildred Clark became the first nurse anesthetist to serve as the Chief of the Army Nurse Corps. Nurse anesthetists provided anesthesia to World War II casualties.
1945	AANA administered its first certification examination (CRNA).
1998	A master's degree became mandatory to graduate from nurse anesthesia programs.
2007	AANA announces its support of doctoral education for entry into nurse anesthesia practice by 2025.

Modified from American Association of Nurse Anesthetists: *A brief look at nurse anesthesia history,* available at www.aana.com. Accessed July 1, 2009; American Association of Nurse Anesthetists: *AANA announces support of doctorate for entry into nurse anesthesia practice by 2025,* available at www.aana.com. Accessed July 1, 2009; Bankert M: *Watchful care: a history of America's nurse anesthetists,* New York, 2000, Continuum Publishing; Koch BE: Nurse anesthesia: a history of challenge. bachelor of science (BS) degree in nursing or other appropriate field and a minimum of 1 year of critical care experience before acceptance. All nurse anesthesia programs are at the master's degree level. On program completion, graduates must successfully complete a National Certification Examination. As of 2025 CRNAs will graduate with a Doctorate of Nursing Practice (DNP).

In recent years, AAs also have been trained. These are assistants to anesthesiologists. Acceptance into an AA program requires a BS degree that includes college-level "premed" education. AAs are graduate students within a medical school and typically receive a master of medical science (MMS) degree from the medical school. They also take a national certification examination administered by the National Commission on Certification of Anesthesia Providers' Assistants under the supervision of the National Board of Medical Examiners.

In this chapter, the term *anesthesia provider* denotes the individual *providing* the continuous anesthesia care for the patient. Depending upon the practice in a given hospital, this may be an anesthesiologist, a CRNA, or an AA. In many hospitals, an *anesthesia care team* includes CRNAs, with or without AAs supervised by anesthesiologists. In small rural hospitals in some states, an anesthesiologist may not be present, and a CRNA may be the sole anesthesia provider.

The anesthesia provider is the patient's advocate in the perioperative period; as such, he or she must be concerned with many divergent factors when the patient's own sensory and cerebral functions are obtunded by anesthesia. The field of anesthesia has become so complex that in many large hospitals an anesthesia provider may specialize further in obstetric, neurosurgical, pediatric, cardiovascular, regional, or ambulatory anesthesia. Anesthesiologists also may subspecialize in acute and chronic pain management or in critical care medicine.

PATIENT SAFETY

Patient safety is always a concern during surgery and anesthesia. Approximately 26 million anesthetics are administered each year in the United States. Of these, data from several sources indicate a death rate ranging from 1 per 35,000 to about 1 per 40,000. These rates represent a significant decline during the past 30 years, despite surgical procedures being performed on increasingly higher risk patients than in the past.

The general public still considers anesthesia to be a major risk of surgery. This attitude may be attributable to sensationalized reports in the news media and in magazine articles. In addition, people may have a heightened awareness of anesthesia-related deaths because these often occur acutely in the perioperative period, whereas surgical or medical problems may not result in death until days after the procedure.

ENVIRONMENTAL NOISE

Many studies demonstrate the effects that noise has on humans. Multiple conversations, loud music, and other noises can create or worsen patient anxiety, as well as make communication difficult between team members and between the patient and team members. Noise can also cause distraction, increasing the potential for miscommunication and errors. Patients recovering during the immediate postoperative period have expressed dissatisfaction with high noise levels and overhearing staff member conversations. Improvement in patient satisfaction can be achieved when the noise level is decreased in the postanesthesia care unit (PACU) (Smykowski, 2008). While the patient is in the OR, *especially* during induction and emergence, every effort should be made to maintain a calm, quiet environment. This is especially true when caring for the pediatric patient. Hearing multiple voices can create patient anxiety and confusion. Interventions that may decrease noise are presented in the Risk Reduction Strategies box.

RISK REDUCTION STRATEGIES

Interventions to Reduce Noise

- Increase staff awareness via education and new employee orientation.
- Educate environmental service personnel about noise sources and reduction strategies during cleaning.
- Identify sources of noise to determine whether, how, and if these noises can be lessened.
- Modulate one's own voice tone and volume appropriately.
- Expect every team member to be personally responsible for managing how much noise he or she generates (e.g., minimize or eliminate irrelevant conversation during procedures).
- Limit telephone conversations to brief communications.
- Practice telephone etiquette protocol when answering a call or page.
- Use structured communication methods (e.g., standardized communication templates to disseminate pertinent patient care information).
- Minimize the number of people present during procedures and frequency of door openings.
- Establish times when noise levels routinely should be reduced (e.g., induction, emergence).
- Lower ring-tone volume on telephones and mobile communication devices (use silent mode whenever possible).
- Limit overhead pages with the use of text paging.
- Place pagers on silent mode whenever possible.
- Display "Quiet, Please" posters to remind staff to reduce noise.

Modified from AORN: *Position statement on noise in the perioperative practice setting,* Chicago, Ill, March 2009, AORN, Inc., available at www.aorn.org/PracticeResources/AORNPositionStatements/PositionStatementOnNoise/. Accessed April 11, 2009.

AWARENESS DURING ANESTHESIA

The possibility of being awake during anesthesia is a concern of patients and anesthesia providers (Research Highlight). Some patients are so anxious about being aware of anything during surgery that it may affect their reasoning when discussing the options for anesthesia. Many procedures, such as biopsies, inguinal hernias, or procedures on the lower extremities, can be done under regional anesthesia or monitored anesthesia care (MAC). These patients may want general anesthesia, however, because they do not want to be aware of anything during the procedure. In rare cases during general anesthesia, the patient may be paralyzed but be aware of what is occurring and unable to indicate this to anyone.

Intraoperative awareness (IOA) has been reported with many anesthetic techniques. Several factors may contribute to its occurrence. Overall, 20,000 to 40,000 patients each year experience awareness during general anesthesia (Bazzell et al, 2008). The incidence of awareness may increase to 1% to 1.5% in higher risk patient populations, such as patients requiring anesthesia for obstetrics, major trauma, and cardiac surgery (Lennmarken and Sandin, 2004; Sebel et al, 2004; Ghoneim et al, 2009).

For many years, the electroencephalogram (EEG) has been the standard for assessing a person's hypnotic and sleep state. However, using an EEG for all surgical procedures is unrealistic. In the late 1990s the bispectral index system (BIS) was developed, which analyzes the relationship and frequency of brain signals using an algorithm to generate a composite, numeric value that seems to correlate with the cerebral state. Five electrodes are positioned across the forehead, and the monitor gives an index (0 to 100) of the hypnotic state or sedation level; an index of 40 to 60 is considered optimal anesthesia. The BIS monitors effects of anesthetics and sedatives on the hypnotic status of the brain but is less informative about the level of analgesia. Motion artifacts and mental changes cause erratic changes under lighter levels of sedation commonly used with MAC. Use of the BIS monitor continues to increase. Often patients wake up more quickly and experience less nausea and vomiting because drugs can be titrated using BIS (Lennmarken and Sandin, 2004; Stanski and Shafer, 2005).

PREOPERATIVE PREPARATION

Patient Evaluation

Preoperative evaluation is done in advance of the scheduled surgical procedure, often one or more days before the procedure in a preadmission clinic (sometimes called *preadmission testing, preanesthesia clinic,* or *anesthesia-assessment unit*). Admission data and appropriate consent forms are completed, a preoperative history obtained, a physical examination done, a preanesthesia evaluation and examination completed, and appropriate diagnostic or laboratory tests processed. Numerous studies have shown limited benefits of extensive routine testing (Chung et al, 2009). More extensive testing is indicated for patients who have higher than average risk based on their history. The patient's physical status is assessed, and the most appropriate anesthetic technique selected. The patient's questions and concerns are resolved, and instructions given to expedite admission on the day of surgery.

Before elective surgery, the patient should be in optimal medical condition. Anesthesia, even in healthy patients, presents risks. Inhaled general anesthetics are myocardial depressants; they may lead to dose-dependent decreases in myocardial contractility and blood pressure. This response may be accentuated in patients who are volume depleted, who are overdiuresed, who have poor ventricular function, or who have autonomic neuropathy, such as found in patients with diabetes. If it is determined that the patient's physical status should be improved to reduce the risks involved, this is discussed with the patient's

RESEARCH HIGHLIGHT

Anesthesia Awareness

Intraoperative awareness (IOA) was recognized in 1846 when Morton demonstrated ether anesthesia and the patient later reported that he had been half-awake during the procedure. Although rare with modern anesthetic agents and techniques, IOA does occur. Multiple studies have found IOA to occur in 0.1% to 0.2% of patients undergoing general anesthesia. Of 21 million patients who receive general anesthesia, 20,000 to 40,000 experience awareness each year. Of patients who experienced awareness, 48% reported auditory recollections, 48% reported the sensation of not being able to breathe, and 28% reported feeling pain. Greater than 50% of these patients were reported to experience mental distress, including an indeterminate number with posttraumatic stress syndrome. More recent dramatized accounts in the lay press have caused an increasing number of patients to voice their concern during preoperative interviews. To evaluate this issue, investigators have used a variety of approaches, including the following:

- The effects of intraoperative therapeutic suggestions on the length of postoperative hospitalization or the level of pain
- Positive suggestions during anesthesia for changes in lifestyle (e.g., smoking cessation, weight loss)
- Assessment of inadequate amnesia or recall of intraoperative conversation or events, or both
- Intraoperative memory analyzed by recall of specific words or phrases spoken during anesthesia
- Intraoperative physiologic changes or postoperative recall evaluated under hypnosis when a mock crisis was staged during anesthesia
- Learning of new information during anesthesia

Many of these studies employed changes in the latency and amplitude of middle-latency, auditory-evoked potentials. They found that even under seemingly adequate general anesthesia, implicit memory may be retained along with the ability to process auditory stimuli subconsciously. Based on these studies, it seems prudent to avoid anesthetic techniques that rely solely on receptor-based drugs (i.e., benzodiazepines, opioids, nitrous oxide [N_2O]) and to include volatile anesthetics.

In an effort to reduce the risk of anesthesia awareness, the American Society of Anesthesiologists (ASA) and the American Association of Nurse Anesthetists (AANA) have provided guidelines for administering and monitoring anesthesia.

Studies in the area of patient memory are ongoing. Ghonheim's research suggests that the two most common risk factors are light anesthesia and a history of awareness. While a patient is anesthetized, it is important that all persons in the OR and procedure room conduct themselves in a professional manner. It remains possible that the patient may remember conversations conducted during the anesthesia experience.

Modified from American Society of Anesthesiologists (ASA): Practice advisory for intraoperative awareness and brain function monitoring: a report by the American Society of Anesthesiologists Task Force on Intraoperative Awareness, *Anesthesiology* 104:847-864, 2005; Ghoneim MM et al: Awareness during anesthesia: risk factors, causes and sequelae: a review of reported cases in the literature, *Anesthes Analges* 108:527-535, 2009; Lennmarken C, Sandin R: Neuromonitoring for awareness during surgery, *Lancet* 363:1747-1748, 2004; Sebel PS et al: The incidence of awareness during anesthesia: a multicenter United States study, *Anesth Analg* 99:833-839, 2004; Stanski DR, Shafer SL: Measuring depth of anesthesia. In Miller RD, editor: *Anesthesia,* ed 6, Philadelphia, 2005, Churchill Livingstone.

primary physician or surgeon and, if necessary, elective surgery is deferred until the patient's condition is optimized. In emergent surgery, however, any benefits gained from a delay must be weighed carefully with the hazards of waiting (DeLamar, 2005).

The assignment of a physical status classification is based on the patient's physiologic condition independent of the proposed surgical procedure. The physical status classification was developed by the American Society of Anesthesiologists (ASA) to provide uniform guidelines. It is an evaluation of the severity of systemic diseases, physiologic dysfunction, and anatomic abnormalities. The ASA classification system is widely used to estimate perioperative risk (Table 4-1).

While preadmission clinics are commonly used by many hospitals and ambulatory surgery centers, nurses may conduct preoperative telephone interviews with patients in reasonably good health. Questions are asked relating to pulmonary and cardiac disease; medication (prescription, over-the-counter, herbal, and homeopathic remedies) and alcohol use; medication, latex, or anesthetic allergies; pregnancy; and personal or family history of anesthetic reactions. The preadmission interview, whether by phone or in person, provides an opportunity for patient education as it relates to their procedure (Patient and Family Education). On the day of surgery, patients arrive 1 to 2 hours before the scheduled surgery time to complete other preoperative processes. In some facilities, certain ambulatory patients are evaluated just before surgery. These are usually healthy patients having minor procedures or patients with stable, chronic conditions having a procedure (e.g., cataract removal, skin lesion excision) under MAC. These preadmission processes have reduced costs of healthcare, decreased risk of nosocomial infections associated with longer hospital admissions, increased use and efficiency of healthcare resources, improved patient relations, and enhanced the chances of having a well-informed patient in optimal health status (DeLamar, 2005).

In larger hospitals and ambulatory surgery centers, the individual who evaluates the patient in the preanesthesia clinic is often not the anesthesia provider for the patient's surgical procedure. Immediately before surgery, the anesthesia provider (1) reviews the patient's chart, laboratory data, and diagnostic studies, such as electrocardiogram (ECG) and chest x-ray; (2) confirms that the appropriate consent forms (surgery, anesthesia, use of blood products) have been signed; (3) identifies the patient; (4) verifies the surgical procedure; (5) reviews the choice of anesthesia; (6) examines the patient; and (7) administers preoperative medications if appropriate (DeLamar, 2005; Stoelting and Miller, 2006a). As ambulatory surgery becomes increasingly common, other factors are taken into consideration (Ambulatory Surgery Considerations).

Choice of Anesthesia

The choice of anesthesia for a given surgical procedure is made by the patient, anesthesia provider, and surgeon. Many factors influence this choice, including the following:

1. Patient's wishes and understanding of the types of anesthesia that could be used
2. Patient's physiologic status

PATIENT AND FAMILY EDUCATION

Preanesthesia Preparation

During preoperative assessment, the patient is interviewed and it is important to discuss the following topics:

Preoperative fasting: Explain why it is important (see Research Highlight: Perioperative Nausea and Vomiting).

Medications: Patients should take necessary medications (such as antihypertensive, cardiac, seizure, and asthma medications) with sips of water, preferably before they leave their homes to come to the facility. Patients with diabetes should continue taking oral hypoglycemic agents until the evening before surgery. If the patient takes insulin, it is common to administer a fraction (one fourth to one half) of the usual morning dose. Aspirin and aspirin-containing products should be discontinued 1 week before surgery. Nonsteroidal antiinflammatory drugs should be discontinued 4 days before surgery. If the patient is taking warfarin, it is usually discontinued 3 days before surgery, if appropriate. The prescribing clinician may need to be consulted to ensure it is safe to discontinue these medications or switch to alternative medications, especially if the patient has recently undergone heart valve replacement surgery or other serious conditions that must be taken into consideration.

Herbal supplements: Many herbal supplements can potentially interact with anesthetics. It is important to ask about any supplements the patient is taking (see Chapter 29).

Recent upper respiratory tract infections: A patient with a reactive airway has an increased risk of respiratory complications (e.g., bronchospasm, laryngospasm).

Family-centered preanesthesia preparation for children and their families may include treatment options for anxiety, such as administering sedatives, having a parent present during induction, and providing hospital-based preparation programs (Kain et al, 2007). Preanesthesia patient and family education may also include postoperative care instructions and information about pain control, both nonpharmacologic (e.g., distraction, progressive muscle relaxation, diaphragmatic breathing [Roy-Byrne et al, 2009], ice, elevation) and pharmacologic (e.g., how pain will be assessed, when and how medication will be administered). A study by Kastanias and colleagues (2009) determined that information about pain management strategies and medication side effects was extremely important to patients ready to be discharged. Because patients place such high importance on information about the pain experience, anesthesia providers and perioperative nursing staff need to include discussion of after-discharge pain management plans as part of patient and family education.

An anesthesia provider will also discuss the anesthesia options that are appropriate for that patient/procedure after reviewing pertinent history and physical information that is provided, along with any pertinent diagnostic studies and consultations. The American Society of Anesthesiologists (ASA) has a number of patient education brochures available on their website. These brochures can be printed and offered to patients and their families, or the perioperative nurse can simply direct the patient and family to the appropriate website. One brochure specifically addresses ambulatory surgery anesthesia. These may be accessed at www.asahq.org/patientEducation.htm.

TABLE 4-1

ASA Physical (P) Status Classification

Status*,†	Definition	Description and Examples
P1	Normal healthy patient	No physiologic, psychologic, biochemical, or organic disturbance
P2	Patient with mild systemic disease	Cardiovascular disease with minimal restriction of activity; hypertension, asthma, chronic bronchitis, obesity, diabetes mellitus, or tobacco abuse
P3	Patient with a severe systemic disease that limits activity, but is not incapacitating	Cardiovascular or pulmonary disease that limits activity; severe diabetes with systemic complications; history of myocardial infarction, angina pectoris, poorly controlled hypertension, or morbid obesity
P4	Patient with a severe systemic disease that is a constant threat to life	Severe cardiac, pulmonary, renal, hepatic, or endocrine dysfunction
P5	Moribund patient who is not expected to survive 24 hr with or without operation	Surgery is done as last recourse or resuscitative effort; major multisystem or cerebral trauma, ruptured aneurysm, or large pulmonary embolus
P6	Patient declared brain dead whose organs are being removed for donor purposes	

*In statuses 2, 3, and 4, the systemic disease may or may not be related to the reason for surgery.
†For any patient (P1 through P5) requiring emergency surgery, an E is added to the physical status, such as P1E, P2E. ASA 1 through ASA 6 or I to VI is often used for physical status.
Modified from American Society of Anesthesia (ASA) Providers: *Manual for anesthesia departments,* Park Ridge, Ill, 1997, The Association, available at www.asahq.org/clinical/physicalstatus.htm. Accessed June 28, 2009.

3. Presence and severity of co-existing diseases
4. Patient's mental and psychologic status
5. Postoperative recovery from various kinds of anesthesia
6. Options for management of postoperative pain
7. Type and duration of surgical procedure
8. Patient's position during surgery
9. Particular requirements of the surgeon

Premedications

The primary purpose of premedication before anesthesia is to sedate the patient and reduce anxiety. Medications that may be given preoperatively include sedatives and hypnotics, anxiolytics, amnestics, tranquilizers, narcotics or other analgesics, antiemetics, and anticholinergics. A single drug may possess the properties of several classes. Midazolam (Versed) is administered frequently to relieve apprehension and to provide amnesia. An analgesic or narcotic may be ordered if preoperative discomfort is anticipated during invasive procedures or during the administration of a regional anesthetic. An anticholinergic, such as atropine or glycopyrrolate, may be used to prevent bradycardia in pediatric patients, to control secretions in patients

AMBULATORY SURGERY CONSIDERATIONS

Patient Selection

Ambulatory surgery is increasingly common. Approximately 65% of procedures performed in this country are done on an ambulatory basis. Ambulatory surgery may be done as a "same day" procedure in the hospital, in an office, or in an ambulatory surgery center (ASC). Patients usually enjoy an earlier return to their preoperative physiologic state and experience fewer complications with ambulatory surgery, when compared to surgery performed in the hospital setting. When procedures are performed on an ambulatory basis, there is also a reduced chance of hospital-associated infections (Zoremba et al, 2009).

The list of surgical procedures performed in ambulatory settings continues to grow. However, procedures requiring prolonged immobilization, involving parenteral pain management, and/or having increased incidence of complications are generally performed on an inpatient basis (Marley, 2010).

Patient selection is extremely important in ambulatory settings. The procedure should not have a significant incidence of perioperative or postoperative problems and should not require intensive postoperative management (Marley, 2010). The patient should be in general good health or have well-managed existing illnesses. Patients with a significant history should be interviewed before the day of surgery to determine how well co-existing diseases are controlled and what tests or consultations may be needed before the day of surgery.

The following are some patient conditions for which ambulatory surgery is unacceptable:

- Premature infants (gestational age 37 weeks or less at birth)
- Infants with a history of respiratory difficulties, apneic episodes, feeding difficulties
- Unstable physical status (ASA classification III or IV) (see Table 4-1)
- Active substance or alcohol abuse
- Poorly controlled seizures
- Previously unevaluated and unmanaged obstructive sleep apnea
- Uncontrolled diabetes
- Infectious process requiring isolation
- Anticipation of postoperative pain that will not be controllable with oral analgesics
- Inability to care for self and without access to assistance
- Noncompliance (Marley, 2010)

Anesthetic technique is based upon the surgical procedure, surgeon and patient preference, and skill of the practitioner. Some goals for anesthesia in an ambulatory setting include minimal physiologic changes secondary to the anesthetic, fast induction, rapid emergence while maintaining patient comfort, intraoperative amnesia and analgesia, suitable operating conditions, minimal perioperative side effects, and minimized postoperative side effects, such as nausea (Marley, 2010). Use of an LMA, awareness monitoring, and certain anesthetics (such as propofol, sevoflurane, and desflurane) have contributed to attaining these goals.

undergoing oropharyngeal procedures, or to control cardiac reflex that may cause bradycardia (e.g., during ophthalmic procedures) (Stoelting and Miller, 2006a, 2006b).

To decrease the risk of aspiration, metoclopramide (Reglan) may be given to empty the stomach and to reduce nausea and vomiting (Research Highlight) (see Chapter 9 for a thorough discussion of postoperative nausea and vomiting). In addition, an antacid or an H_2-receptor–blocking drug, such as cimetidine (Tagamet), ranitidine (Zantac), or famotidine (Pepcid), may be included to decrease gastric acid production or the acidity of the gastric contents, or both. Should aspiration occur, a gastric pH greater than 2.5 decreases resultant pulmonary damage (Stoelting and Miller, 2006b).

Before a premedication is given, any last-minute questions from the patient concerning surgery and anesthesia should be answered, and the preoperative verification process should be completed to ensure that all relevant documents (e.g., the history and physical examination, surgical consent) and imaging studies (properly labeled and displayed) are available before the start of the procedure. These must be reviewed and be consistent with the patient's stated expectations (when the patient is awake and aware, the patient should actively participate in the verification process). The surgical team must agree that this is the correct patient and the planned procedure on the specified side and site. Any additional special equipment, supplies, or implants also must be confirmed as being correct and available. Marking the surgical site also must be done before administering premedication (see Chapter 2 for a review of The Joint Commission's [TJC] Universal Protocol for preventing wrong site, wrong procedure, wrong person surgery).

Premedication may be administered intramuscularly (IM), intravenously (IV), intranasally, or orally (PO) with 15 to 30 ml of water. Patients usually prefer oral premedication, and the small amount of water is readily absorbed directly across the gastric mucosa. Premedication may be given 30 to 90 minutes before surgery, via IV in the preoperative holding area, or after the patient arrives in the surgical suite. Except for the small amount of water needed to swallow any medications, adult patients traditionally have been required to maintain nothing by mouth (NPO) status for a minimum of 4 to 6 hours before elective surgery. More recent data indicate, however, that clear liquids may be acceptable up to 2 hours before surgery (DeLamar, 2005) (Table 4-2).

Although premedications commonly are used, studies have shown that visits before surgery by the anesthesia provider and the perioperative nurse are far more important in relieving patient anxiety and concern. Major patient concerns include fear of the unknown, relinquishing control of one's life to someone else, being awake during surgery, and not awakening from anesthesia as well as concerns related to the surgery (e.g., diagnosis, prognosis). Premedication may be unnecessary for older patients because their anxiety levels are lower, their responses to medications are unpredictable, and sedation can be given IV in the OR if required.

RESEARCH HIGHLIGHT

Postoperative Nausea and Vomiting

Despite advances in anesthesia and surgery, postoperative nausea and vomiting (PONV) continues to be a problem for many patients. The estimated incidence is as high as 30% for low-risk patients and 80% for high-risk patients (Murphy et al, 2006). For some patients, this causes more anxiety than the surgery itself. With the increased utilization of ambulatory surgery, patients are discharged and are mobile sooner, before symptoms begin. While nausea is extremely uncomfortable, vomiting can be dangerous and has been associated with major complications such as pulmonary aspiration, dehydration, and electrolyte disturbances; it also can affect healing. Evidence has shown that PONV is more likely to occur after certain procedures such as ophthalmic, breast, ear, nose and throat, gynecologic, gastrointestinal (GI), and laparoscopic surgery. Patient risk factors for PONV include female gender, nonsmoker, history of PONV, history of motion sickness, history of migraines, anxiety, dehydration, and gastroparesis. Anesthetic risk factors include the use of nitrous oxide and/or opioids. The use of Diprivan has also shown to reduce PONV. Movement can also contribute to PONV, such as when patients are moved quickly from the OR bed to the stretcher, or moved quickly down hallways and around corners.

Prevention of PONV should be a high priority. Minimizing risk factors and administering antiemetics are important. Antiemetics have been designed to interact with the four main neurotransmitters that affect PONV: histamine, acetylcholine, serotonin, and dopamine. In higher risk patients, combination therapy of antiemetics has been shown to be more effective than using a single agent. Because of cost and potential side effects, multimodal therapy is generally used with patients at higher risk. Some common antiemetics currently being used are scopolamine (anticholinergic), Compazine and Reglan (antidopaminergics), Decadron (corticosteroid), and 5-HT (5-hydroxytryptamine [serotonin]) receptor antagonists (e.g., odansetron [Zofran], dolasetron [Anzamet], and granisetron [Kytril]). Antihistamines such as diphenhydramine (Benadryl) and dimenhydrinate (Dramamine) have also proven to be effective. As with any medication, one should be familiar with any potential side effects or interactions before administration.

Nonpharmacologic interventions include acupressure, acupuncture, ginger, and aromatherapy. Isopropyl alcohol (usually using an alcohol swab), placed under the nose, has proven effective. Another product, Quease Ease, combines essential oils of peppermint, spearmint, lavender, and ginger. Originally developed for use with sedated patients, it is used by placing under the nose and inhaling. This has also been found to be very effective for nausea, even outside the PACU, and is available on-line. Adequate fasting, IV hydration, antiemetic prophylaxis, selection of induction agents for anesthesia, and avoidance of nitrous oxide may all help to prevent PONV.

Modified from Fetzer S: Putting a stop to postop nausea and vomiting, *Am Nurse Today* 3(8):10-12, 2008; McCaffrey R: Make PONV prevention a priority, *OR Nurse* 1(2):39-45, 2007.

TYPES OF ANESTHESIA CARE

The Joint Commission's *Comprehensive Accreditation Manual for Hospitals* has Anesthesia Care Standards that apply when patients receive, in any setting, moderate or deep sedation or general, spinal, or other major regional anesthesia. Descriptions of frequently used classifications of anesthesia care follow.

General Anesthesia

General anesthesia is a reversible, unconscious state characterized by amnesia (sleep, hypnosis, or basal narcosis), analgesia (freedom from pain), depression of reflexes, muscle relaxation, and homeostasis or specific manipulation of physiologic systems and functions. Most patients think of general anesthesia when they

TABLE 4-2

NPO Fasting Guidelines*

Ingested Material	Minimal Fasting Period (hr)
Clear liquids†	2
Breast milk	4
Infant formula	6
Nonhuman milk	6
Light meal	6

*These guidelines are recommended for healthy patients undergoing elective procedures. They are not intended for women in labor. They do not guarantee complete gastric emptying.
†Clear liquids include water, juice without pulp, black coffee, clear tea, and carbonated beverages. Patients should also be instructed not to chew gum or eat any candies or mints.
Adapted from The American Society of Anesthesiologists: *Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures,* 1999, available at www.asahq.org/publicationsAndServices/NPO.pdf. Accessed May 24, 2009.

are scheduled to have a surgical procedure; that is, they expect to be "put to sleep." As such, they experience a drug-induced loss of consciousness during which they are not arousable. Their ability to maintain ventilatory function is often impaired, requiring assistance maintaining a patent airway. Positive-pressure ventilation may be required because of decreased spontaneous ventilation or drug-induced depression of neuromuscular function.

Regional Anesthesia

Regional anesthesia is defined broadly as a reversible loss of sensation in a specific area or region of the body when a local anesthetic is injected purposefully to block or anesthetize nerve fibers in and around the operative site. Common regional anesthesia techniques include spinals (subarachnoid block [SAB]), epidurals, caudals, and major peripheral nerve blocks. Although ultrasound guidance has been reviewed as a technique to enhance regional anesthesia and analgesia, it may not eliminate complications such as blood vessel puncture or inadvertent intraneural or intravascular injections. Nonetheless, in some healthcare facilities, ultrasound-guided regional anesthesia and analgesia is used to reduce time or number of attempts to perform blocks (Liu et al, 2009).

Monitored Anesthesia Care (MAC)

MAC ("*local standby*" and "*anesthesia standby*" are older, less accurate terms frequently used interchangeably with MAC) is infiltration of the surgical site with a local anesthetic and is performed by the surgeon. The anesthesia provider supplements the local anesthesia with IV drugs that provide sedation and systemic analgesia, monitors the patient's vital functions, and may use additional medication to optimize the patient's physiologic status. MAC is often used for healthy patients undergoing relatively minor surgical procedures. It may also be used for some procedures for critically ill patients who may tolerate a general anesthetic poorly.

Conscious Sedation/Analgesia

Conscious sedation/analgesia is administered for specific short-term surgical, diagnostic, and therapeutic procedures within a hospital or ambulatory center. In the ASA's *Practice Guidelines for Sedation and Analgesia by Non-Anesthesiologists* (Gross and Bailey, 1996), moderate sedation/analgesia (conscious sedation) is defined as "a drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation." No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained. Patients whose only response is reflex withdrawal from a painful stimulus are sedated to a greater degree than encompassed by conscious sedation/analgesia.

The demand for appropriate providers to administer and monitor the patient receiving conscious sedation/analgesia has grown over the past few years, exceeding the supply of anesthesia providers. This demand has resulted in increased use of nonanesthesia providers (usually professional registered nurses with additional training in administering conscious sedation/analgesia medications and monitoring these patients) for these functions. Various medications and techniques may be used to achieve conscious sedation/analgesia, each with advantages and disadvantages. Competency-based education programs and assessment should be established for nurse-monitored conscious sedation. The Association of periOperative Registered Nurses (AORN) publishes recommendations for managing patients undergoing conscious sedation/analgesia that should be used by healthcare facilities to develop such programs (AORN, 2009b).

Local Anesthesia

Local anesthesia refers to the administration of an anesthetic agent to one part of the body by local infiltration or topical application, usually administered by the surgeon. Local anesthesia is used (1) for minor procedures, (2) if the patient's cooperation is necessary for the procedure, or (3) if the patient's physical condition warrants its use. An anesthesia provider is not involved in the patient's care. A perioperative nurse monitors the patient's vital signs and provides supportive care during the procedure. AORN publishes recommendations for managing patients undergoing local anesthesia and documenting care, which should be used to establish policies and procedures in operative and other invasive settings.

PERIOPERATIVE MONITORING

Significant advances continue in perioperative monitoring. Among medical specialties, anesthesiology has been a pioneer in review and analysis of perioperative mishaps and implementation of improved monitoring techniques and guidelines. These advances have resulted in significant decreases in morbidity and mortality. In several states, malpractice insurance carriers have recognized the significance of these improvements and have decreased premiums if certain monitors are used routinely. These monitors include pulse oximetry, which measures oxygen saturation in a pulsating vessel (Spo_2), and capnography, which measures end-tidal carbon dioxide ($ETco_2$) level (Kossick, 2010).

The ASA has adopted Standards for Basic Anesthetic Monitoring (Patient Safety) as guidelines for patient care. Perioperative nurses should be familiar with these standards and understand their significance in patient safety. If routine or frequent deviations from such standards occur, a performance assessment and improvement (also known as *quality assurance [QA]*) review along with a risk management analysis should be considered to ensure safe and high-quality patient care (ECRI Institute, 2009).

PATIENT SAFETY

Standards for Basic Anesthetic Monitoring

The following standards for basic anesthetic monitoring apply to all anesthesia care, although in emergency circumstances appropriate life-support measures take precedence. These standards may be exceeded at any time based on the judgment of the responsible anesthesia provider. They are intended to encourage quality patient care, but following them cannot guarantee any specific patient outcome. They are subject to revision from time to time, given constant advances in technology and practice. They apply to all general anesthesia, regional anesthesia, and monitored anesthesia care. This set of standards addresses only the issue of basic anesthetic monitoring, which is only one component of anesthesia care. In certain rare or unusual circumstances, some of these methods of monitoring may be clinically impractical and appropriate use of the described monitoring methods may fail to detect untoward clinical developments. Brief interruptions of continual monitoring may be unavoidable. Under extenuating circumstances, the responsible anesthesia provider may waive the requirements marked with an asterisk (*); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient's medical record. These standards are not intended to apply to the care of an obstetric patient in labor or in the conduct of pain management.

STANDARD I
Qualified anesthesia personnel should be present in the patient's room throughout the entirety of all general anesthesia, regional anesthesia, and monitored anesthesia care.

Objective
Because of the rapid changes in patient status during anesthesia, qualified anesthesia personnel should be continuously present to monitor the patient and provide anesthesia care. In the event there is a direct known hazard (e.g., radiation) to the anesthesia personnel that might require intermittent remote observation of the patient, some provision for monitoring the patient must be made. In the event that an emergency requires the temporary absence of the person primarily responsible for the anesthetic, the best judgment of the anesthesia provider will be exercised in comparing the emergency with the anesthetized patient's condition and in the selection of the person responsible for the anesthetic during the temporary absence.

STANDARD II
During the administration of all anesthetics, the patient's oxygenation, ventilation, circulation, and temperature should be continually evaluated.

Oxygenation
Objective
To ensure adequate oxygen concentration in the inspired gas and the blood during all anesthesia

METHODS
1. *Inspired gas:* During every administration of a general anesthetic using an anesthesia machine, the concentration of oxygen in the patient breathing system should be measured by an oxygen analyzer with a low oxygen concentration limit alarm in use.*
2. *Blood oxygenation:* During all anesthesia, a quantitative method of assessing oxygenation, such as pulse oximetry, should be employed.* Adequate illumination and exposure of the patient are necessary to assess color.*

Ventilation
Objective
To ensure adequate ventilation of the patient during all anesthesia

METHODS
1. Every patient receiving a general anesthetic should have the adequacy of ventilation continually evaluated. Although qualitative clinical signs may be useful, such as chest excursion, observation of the reservoir breathing bag, and auscultation of breath sounds, quantitative monitoring of the carbon dioxide content or volume of expired gas (or both) is strongly encouraged.
2. When an endotracheal tube or laryngeal mask is inserted, its correct positioning must be verified by clinical assessment and by identification of carbon dioxide in the expired gas. Continual end-tidal carbon dioxide analysis, in use from the time of endotracheal tube/laryngeal mask placement until extubation/removal or initiating transfer to a postoperative care location, should be performed using a quantitative method, such as capnography, capnometry, or mass spectroscopy.*
3. When ventilation is controlled by a mechanical ventilator, a device that is capable of detecting disconnection of components of the breathing system should be in continuous use. The device must give an audible signal when its alarm threshold is exceeded.
4. During regional anesthesia and monitored anesthesia care, the adequacy of ventilation should be evaluated by continual observation of qualitative clinical signs or monitoring for the presence of exhaled carbon dioxide, or both.

Circulation
Objective
To ensure the adequacy of the patient's circulatory function during all anesthesia

METHODS
1. Every patient receiving anesthetics should have an electrocardiogram continuously displayed from the beginning of anesthesia until preparing to leave the anesthetizing location.*
2. Every patient receiving anesthetics should have arterial blood pressure and heart rate determined and evaluated at least every 5 minutes.*
3. Every patient receiving a general anesthetic should have, in addition to the aforementioned, circulatory function continually evaluated by at least one of the following: palpation of a pulse, auscultation of heart sounds, monitoring of a tracing of intraarterial pressure, ultrasound peripheral pulse monitoring, or pulse plethysmography or oximetry.

Body Temperature
Objective
To aid in the maintenance of appropriate body temperature during all anesthesia

METHODS
Every patient receiving anesthetics should have temperature monitored when clinically significant changes in body temperature are intended, anticipated, or suspected.

*Continual is defined as "repeated regularly and frequently in steady rapid succession," whereas continuous means "prolonged without any interruption at any time."

From the American Society of Anesthesiologists (ASA), Park Ridge, Ill. Approved by ASA House of Delegates on October 21, 1986, and last amended on October 25, 2005.

Monitors and basic anesthetic monitoring include the following:

- Inspired oxygen analyzer (F_{IO_2}), which is calibrated to room air on a daily basis
- Low-pressure disconnect alarm, which senses pressure in the expiratory limb of the patient circuit
- Inspiratory airway pressure
- Respirometer (these first four devices are an integral part of most modern anesthesia machines)
- Electrocardioscope
- Blood pressure (usually measured with a noninvasive automated unit)
- Heart rate
- Precordial or esophageal stethoscope
- Temperature
- Peripheral nerve stimulator if muscle relaxants are used
- Spo_2
- $ETco_2$

Newer models of anesthesia machines have basic monitors integrated into a computerized system. These generally include F_{IO_2}; inspired and expired CO_2; inspired and expired volatile agents; airway pressure and disconnect alarms; tidal volume, respiratory rate, and minute ventilation; noninvasive blood pressure (systolic, diastolic, and mean); Spo_2 and pulse rate; temperature; and an event marker. A sophisticated, prioritized system displays caution or alarm conditions in one location, making it unnecessary to scan numerous individual monitors with a variety of displays when an alarm sounds.

Based on the cardiovascular and pulmonary status of the patient, the surgical procedure, and the chance of significant physiologic changes, additional invasive monitors may be required. These include direct arterial and venous pressure measurements, a pulmonary arterial (PA) catheter, and continuous mixed venous O_2 saturation (Svo_2) measured with a special PA catheter. One type of PA catheter can provide a continuous measurement of cardiac output, employing pulsed thermodilution to provide intermittent heat along a distal segment of the catheter. Small changes in the temperature of the blood are proportional to blood flow (cardiac output). These changes are sensed by a thermistor on the tip of the catheter (Kossick, 2010).

For certain conditions equipment such as transcutaneous O_2 and CO_2 monitors, transesophageal echocardiography (TEE), evoked potentials, EEG, and cerebral or neurologic function monitors may be required. An indwelling urinary catheter is frequently inserted to provide a useful indication of renal function and hemodynamic status.

For procedures posing a risk of venous air embolism, a Doppler probe may be used. A central venous catheter is inserted, and the probe is placed over the right side of the heart, along the right sternal border between the third and sixth intercostal spaces. Positioning is confirmed if there is a change in Doppler signal after a 10-ml bolus of saline is rapidly injected through the catheter. The signal is monitored for the sound of a "millwheel" murmur. TEE is the most sensitive method of detection, but may also be the most expensive (Hamm and Maye, 2010).

Somatosensory evoked potential (SEP) monitoring may be used during some neurosurgery procedures. It is used widely to assess the integrity of the spinal cord during surgery in which the spinal cord is manipulated. Upper and/or lower extremities may be monitored. The electrodes are often placed preoperatively, but occasionally may be placed in the OR, before administration of anesthesia. Ischemia of ascending somatosensory pathways produces a drop in amplitude or loss of waveforms, thus warning the surgeon to take corrective action. Ischemic changes are usually widespread; rarely, however, is motor function lost when somatosensory pathways have not been affected (Chawla and Burneo, 2008).

Despite some controversy, most anesthesia providers believe that the monitoring employed depends on the physiologic status and stability of the patient, the surgical procedure planned and its potential for sudden changes in cardiopulmonary functions, the anticipated blood loss and major fluid shifts, and the anticipated monitoring needs for postoperative management. Although not yet a standard of care, many facilities use the BIS monitor (see Research Highlight: Anesthesia Awareness, p. 114). This monitoring modality is a processed EEG obtained noninvasively from scalp electrodes. It provides a measure of the sedative and hypnotic effects of anesthetic drugs on the central nervous system (CNS). Monitoring of some parameters may be negated by the anesthetic technique selected (Dosch, 2010; Kossick, 2010).

Pulse Oximetry

Pulse oximetry is based on principles of spectrometric oximetry, plethysmography, and the Lambert-Beer law, which relates the concentration of solute in suspension to the intensity of light transmitted through the solution. It gives a continuous noninvasive indication of arterial O_2 saturation of functional hemoglobin and pulse rate, providing an early warning of hypoxemia (Valdez-Lowe et al, 2009).

The O_2-dissociation curve indicates the percentage of totally saturated hemoglobin with O_2. The following values are approximations (the O_2 saturation [Spo_2] values are percentages and the Pao_2 levels are in torr): 98% to 100% (≥95 torr), 90% (60 torr), 75% (39 torr), 50% (26 torr), and 25% (16 torr). Most pulse oximeters are accurate to within ±2% greater than 70% and ±3% from 50% to 70% but correlate poorly at less than 50%. When breathing room air, the Spo_2 for a young, healthy individual should be 98% to 100%; the Spo_2 percentage for an elderly patient may be in the low 90s, whereas the percentage for a heavy smoker or a patient with severe lung disease may be in the 80s. It is wise to note the baseline Spo_2 value of a patient before any O_2, medications, or stimulation is introduced. Maintenance of Spo_2 levels greater than 90% corresponds to a Pao_2 value of 60 torr or greater (Moon and Camporesi, 2005).

The sensor combines two low-intensity, light-emitting diodes (LEDs) as light sources and a photodiode as a receiver or light detector. One LED emits red light (approximately 660 nm), and the other emits infrared light (approximately 940 nm). These light sources alternate about 480 times a second. When the two frequencies of light are transmitted through blood and tissue, they are absorbed differently by tissue components and by reduced hemoglobin and oxyhemoglobin. Because absorption by other tissue components is essentially constant, the major variable is saturation of hemoglobin with O_2. An internal microprocessor analyzes variations in absorption of light emitted from both LEDs and provides a readout of the percent saturation of hemoglobin with O_2. Pulse rate also is given. Many units also display a waveform that correlates with arterial pulsations (Kossick, 2010; Moon and Camporesi, 2005).

The pulse oximeter reading (often referred to as "pulse ox") can be adversely affected by any event that significantly

reduces vascular pulsations, such as hypoperfusion, hypotension, hypovolemia, vasoconstriction, or hypothermia. Electrosurgery, motion, or ambient light also may artifactually decrease the readout. Carboxyhemoglobin (carbon monoxide bound to hemoglobin) falsely elevates indicated Spo_2 saturation, while methemoglobin (hemoglobin that has an oxidized iron molecule and cannot reversibly combine with O_2) falsely lowers Spo_2 measurements. Intravenous dyes affect the pulse oximeter. Methylene blue may cause a drop to 65% for 1 to 2 minutes; indigo carmine, a very slight decrease; and indocyanine green, a slightly greater decrease. Nail polish also can decrease Spo_2 values. Blue, black, or green polish significantly decreases the Spo_2 value, whereas red polish has only a slight effect. Opaque, acrylic nail coverings may block the light beam. If nail polish or coverings seem to cause problems, the sensor can be turned sideways so that the fingernail is parallel to the light path.

The sensor usually is placed on a finger or a toe. Some manufacturers have sensors for the earlobe and the bridge of the nose, as well as smaller ones for soles and palms of infants and children. The pulse oximeter does not require user calibration. Care must be taken to prevent localized neurovascular or ischemic damage. For example, a hard-cased sensor placed on a finger may cause ischemia when the arms are tightly secured at the patient's side during a long procedure.

If trouble with the pulse oximeter is encountered when a local anesthetic is being used, the perioperative nurse should evaluate the patient's ventilatory status, verify proper placement of the sensor, and rule out the factors just listed that may adversely affect operation of the unit. Pulsatile blood flow in the extremity may be inadequate because of hypovolemia, decreased cardiac output, malpositioning, constriction by the blood pressure cuff, or hypothermia. As a final step, the nurse can place the sensor on his or her own finger to verify satisfactory function of the pulse oximetry unit, cable, and sensor.

Capnography

A capnometer measures CO_2 concentration, and a capnograph displays the CO_2 waveform. For patients with normal circulation and pulmonary function, capnography is an excellent method to evaluate alveolar ventilation because the gradient between arterial and alveolar CO_2 is small. With forced expiration, the $ETco_2$ level provides a close approximation of arterial CO_2 pressure ($Paco_2$). During general anesthesia, expiration is passive, and the point of measurement is near the connection between the patient's circuit and the endotracheal tube (ETT), laryngeal mask airway (LMA), or mask. The $ETco_2$ value is 5 to 10 torr lower than the $Paco_2$ value measured in arterial blood (Moon and Camporesi, 2005). During other types of anesthesia, in which oxygen may be administered via a nasal cannula, there is a small-bore tube connected to the cannula, which can be attached to the anesthesia machine so that $ETco_2$ levels can be measured.

$ETco_2$ can be measured by a mass spectrometer, a Raman spectrometer, or an infrared analyzer. Compact units that provide a continuous indication of the $ETco_2$ level are the most widely used. These units measure the amount of infrared light absorbed by CO_2 in the sample of gas. Two types of monitors are in use. In the *mainstream* unit, all respired gas passes through the detector, whereas with the *sidestream* unit, a portion of the gas is aspirated at a constant rate (50 to 250 ml/min) through small-bore tubing into the unit. Each design has advantages. Most units display a waveform of expiratory CO_2 partial pressure relative to time after a short sampling and processing delay. The waveform is important for correctly interpreting output data. Digital readouts usually give $ETco_2$ and respiratory rate. Daily user calibration is rarely required with newer units. Clinically, the units confirm proper endotracheal intubation and are useful to detect anesthesia circuit disconnection, alveolar ventilation, early return of respiratory function after muscle relaxants are used, and acute alterations in metabolic functions, such as malignant hyperthermia (MH) or thyrotoxicosis (Dosch, 2010; Moon and Camporesi, 2005).

ANESTHESIA MACHINES AND ANESTHETIC GASES

The first apparatus resembling an anesthesia machine was used in 1905. Since then, innumerable changes and improvements have been made. Anesthesia machines look complicated, but the basic functions are similar and simple to understand. Perioperative nurses should be familiar with the basic function of anesthesia machines (Figure 4-1) because they may need to

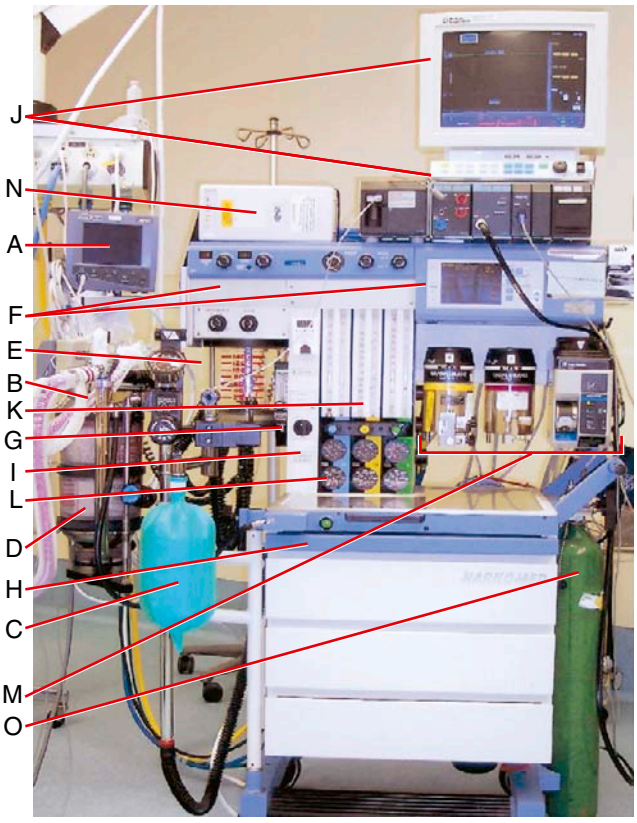

FIGURE 4-1 Modern anesthesia machine. **A**, BIS monitor display. **B**, Patient breathing circuit. **C**, Reservoir ("breathing") bag. **D**, CO_2 absorber. **E**, Ventilator. **F**, Integrated ventilator controls, monitor, and displays. **G**, O_2 flowmeter for nasal cannula. **H**, O_2 flush valve. **I**, On/off switch. **J**, Monitor display and controls for ECG, temperature, blood pressure, pulse oximetry, and end-tidal CO_2. Other modules can be inserted for additional pressures, cardiac output, and BIS. **K**, Flowmeters for air, N_2O, and O_2. **L**, Gauges for pipeline and E-tank pressures (air, N_2O, and O_2). **M**, Flow-through vaporizers (desflurane, isoflurane, and sevoflurane). **N**, Power surge protector for anesthesia machine. **O**, E-cylinder with O_2.

administer O_2 during procedures with local anesthesia or conscious sedation/analgesia.

Oxygen, N_2O, and air usually are supplied from facility pipelines to the anesthesia machine at pressures of 50 to 55 pounds per square inch (psi). Gas hoses connected to the machine are color-coded: green (O_2); blue (N_2O); and yellow (air). Connectors are specific for each gas so that they cannot be inadvertently cross-connected. If a central gas supply is not available or the hospital piping system fails, machines are equipped with E-size cylinders of O_2 and N_2O. One or two cylinders of each gas are connected to yokes on the machine. These yokes are pin-indexed so that only the correct gas can be connected in that position. In the pin-indexing safety system, two steel pins are in a unique location on the yoke assembly. The mating gas cylinder (e.g., the O_2 tank) has two matching holes in the same locations so that cylinders cannot be mounted in the wrong place (Dosch, 2010).

In cylinders, O_2 is stored as a compressed gas. A full E-size cylinder contains about 660 L of O_2 at approximately 2000 psi. As the O_2 is used, the pressure decreases in direct proportion to the remaining volume. Because the E-size cylinder is used to provide O_2 while patients are being transported, one should know how much O_2 is left in a partially used tank; 1000 psi indicates 330 L remaining, and 500 psi indicates 165 L remaining or sufficient O_2 at 5 L/min flow for approximately 30 minutes. When the pressure has decreased to about 250 psi, the cylinder should not be used because it no longer has an adequate reserve (Dosch, 2010).

N_2O is stored as a liquid in cylinders, and the pressure above the liquid is 745 psi. A full E-size cylinder contains about 1600 L of N_2O. As the N_2O is used, the pressure above the liquid remains constant. Only when the liquid has been completely vaporized does pressure begin to decrease. The N_2O cylinder can be nearly empty but still show the same pressure. In contrast to O_2, the amount remaining in the tank cannot be readily determined (Dosch, 2010).

Gases in the cylinders flow through regulators that reduce pressure to about 45 psi as gas enters the machine. Hoses from the hospital gas sources are connected to the machine at the outlet of these regulators. In machines sold after January 1, 1984, a safety interlock device either shuts off the N_2O flow if O_2 pressure is not present or proportionately lowers the O_2 and N_2O flow rates to maintain 30% O_2. The gases flow through individual flowmeters (or rotameters) on the front of the machine so that gas flows and the ratio of O_2 to N_2O or air can be selected by the anesthesia provider. From the top of the flowmeters, the gases are mixed and then flow through a vaporizer in which the inhalational anesthetic of choice is vaporized and added to the gas mixture. The total gas flow is delivered from the machine to the patient. With a flow-through vaporizer, all the fresh gas moving from the anesthesia machine to the patient flows through the vaporizer. The control dials usually are located on top of these vaporizers and are calibrated in percentages. The filling ports on the vaporizers are usually key-indexed so that only the appropriate volatile agent can be used. Newer vaporizers are flow and temperature compensated, meaning that they are reasonably accurate at all flow rates and temperatures (Dosch, 2010).

Desflurane (Suprane) is a unique inhalational anesthetic because it boils at 22.8° C, near room temperature, and its vapor pressure (669 mm Hg) approximates atmospheric pressure (760 mm Hg). The vaporizer for desflurane is pressurized and contains an electric heater. Desflurane also has several other unique characteristics: (1) its solubility in blood (blood-gas partition coefficient) is lower (0.42) than those of N_2O (0.47), sevoflurane (0.63 to 0.69), isoflurane (1.41), and halothane (2.30), which means that it has a faster "wash-in" (induction) and "wash-out" (emergence) than the other agents; (2) metabolism is far less (0.02%) than that of isoflurane (0.2%), sevoflurane (5%), and halothane (15 to 20%); (3) emergence and recovery from general anesthesia and discharge from PACU are significantly faster than when thiopental is used; (4) the cardiovascular effects are similar to those of isoflurane; and (5) muscle relaxation is similar to that which occurs with other inhalational agents. The pungency of desflurane precludes its use as an induction agent (Stoelting and Hillier, 2005b).

Sevoflurane (Ultane) is the newest volatile agent available in the United States. Its pleasant odor and low solubility in blood make it a popular volatile agent for inhalational induction in pediatric patients. In contrast to any of the other volatile agents, it also can provide a rapid, pleasant mask induction in adults.

Another important feature of the anesthesia machine is the O_2 flush valve. Pushing the O_2 flush valve allows 100% O_2 from the 50 psi line to flow directly to the *fresh gas outlet* on the machine and to the patient. This O_2 flow completely bypasses flowmeters and vaporizers. *Caution must be exercised because the pressure is 35 to 50 psi, and the flow rate is 35 to 75 L/min.*

In most hospitals and ambulatory surgery centers in the United States, a semiclosed-circle system (circle system) is used to deliver fresh gas flow (including anesthetic gases) to patients. The circle system is composed of a container filled with a CO_2-absorbing material (e.g., soda lime or Baralyme), two one-way (unidirectional) valves, an adjustable pressure-limiting (APL) valve, a reservoir bag, an inlet connection for fresh gas flow, and two connections to the patient through corrugated breathing (or anesthesia circuit) tubing. As the patient inspires, gases are drawn through the CO_2 absorber and from the fresh gas supply through the inspiratory limb of the corrugated tubing. As the patient exhales, the one-way valve on the inspiratory limb prevents backflow, and the exhaled gases flow into the expiratory limb and through the expiratory one-way valve. The expiratory limb and valve are easily identified by the condensation of water vapor along this portion of the circuit. The reservoir bag absorbs the peak flow of expired gases and allows the anesthesia provider to force gas through the CO_2 absorber, along the inspiratory limb of the circuit, and to ventilate the patient. The expired gases flow through the CO_2 absorber where CO_2 is removed. Substances used in the CO_2 absorbent include an indicator that changes color as the soda lime or Baralyme is exhausted. The soda lime may turn from white to blue, indicating that the absorbent material must be changed to prevent a buildup of CO_2 in the patient. Any excess gas vents through the APL valve into the gas-scavenging system. The APL valve usually is mounted just ahead of the CO_2 absorber (Dosch, 2010).

The F_{IO_2} sensor usually is mounted in the inspiratory limb just after the one-way valve. It measures the fraction of inspired O_2 (F_{IO_2}) and can be set to alarm if a low concentration is detected. A low-pressure sensor usually is mounted in the expiratory limb near the one-way valve to detect a ventilator malfunction or a circuit disconnection.

On newer machines, volumeters are mounted in the inspired and expired limbs where the patient breathing circuit is connected. When the ventilator is used, the electronic circuitry measures the inspiratory and expiratory volumes to ensure that they correspond with the tidal volume and respiratory rate selected. With a cuffed ETT, the ventilator compensates for changes in fresh gas flow or small leaks in the breathing circuit and alarms if a disconnect or inadequate flow occurs (Dosch, 2010).

The advantage of the circle system is that much lower flows of O_2, N_2O, and anesthetic gases can be used; this conserves the patient's body heat and respiratory moisture and reduces the cost of expensive, volatile agents. A *semiclosed-circle system* typically is used when fresh gas flows into the system (flow rate ranges from 0.5 to 6 L/min). During exhalation, some of the expired gases are recycled through the CO_2 absorber, and excess gas is scavenged or eliminated. With a *closed-circle system,* all of the CO_2 is absorbed. No gas is vented from the system, and only enough O_2 is added to meet the basal requirements of the patient (approximately 3.5 ml/kg/min). In a *semiopen circuit* (e.g., Ayres T-piece, Magill, Bain circuits), a relatively high flow of fresh gas is used and most exhaled gas is vented from the circuit. The fresh gas flow rate per minute varies from approximately two thirds of the patient's minute volume with the Magill circuit to at least 100 ml/kg with the Bain T-piece circuit. The semiopen circuit system is commonly used for neonates, infants, and small children (Dosch, 2010). With all these circuits, the final connection to the patient is by a mask, ETT, or LMA.

GENERAL ANESTHESIA

Mechanism of Action

Numerous proposed theories explain the action of general anesthetics. Recent investigations have involved inhalation anesthetics. (The terms *volatile anesthetic, potent agent,* and *inhaled* or *inhalational anesthetic* are synonymous with *inhalation anesthetic.*) Evidence suggests that synaptic transmission of nerve impulses is reversibly inhibited in several areas of the CNS. The extent of inhibition and consequent progressive depression of function are correlated with the partial pressure of the inhaled anesthetic at various sites. The inhibition is believed to occur at a lipophilic site on the biologic membrane of synapses and possibly on small, unmyelinated nerve fibers. Suppression of spinal reflex activity is believed to produce some relaxation of skeletal muscles. Although no single theory explains all phenomena, a few theories explain many of the actions (Stoelting and Hillier, 2005b). The following theories are some of those more widely accepted.

Protein Receptor Theory. This theory proposes that hydrophobic areas of specific proteins in the CNS act as receptor sites. The steep, dose-response curve of inhaled anesthetics seems to support this theory by suggesting that a critical number of receptor sites must be occupied before patient movement in response to noxious stimuli is obtunded (Stoelting and Hillier, 2005b).

Meyer-Overton Theory. This theory is also called the *critical volume hypothesis*. It explains the correlation between lipid solubility (oil-to-gas partition coefficient) and anesthetic potency. It proposes that when enough anesthetic molecules dissolve (i.e., a critical volume is reached) at a crucial hydrophobic site, such as the lipid cellular membrane, anesthesia is achieved. As the cell membrane expands in response to dissolved anesthetic molecules, changes in ionic channels occur and alter the sodium flux involved in cellular depolarization. Because some lipid-soluble compounds are not anesthetics, this theory does not completely explain anesthetic action (Stoelting and Hillier, 2005b).

Endogenous Endorphins. Endogenous endorphins, or opiate-like substances, suppress various pain pathways. Several classes of endorphins have been identified. The action of β-endorphins is antagonized by naloxone or nalmefene, specific narcotic antagonists, but the relative potency of inhaled anesthetics is not altered. Although some degree of analgesia may be explained by this mechanism, it does not correlate well with the level of anesthesia achieved by inhaled anesthetics.

Intravenous anesthetics also may function by some of the mechanisms proposed for inhaled anesthetics. Factors involved in the pharmacokinetics of IV anesthetics include the volume of distribution, biotransformation, and clearance of the drug by metabolism, excretion, or elimination of the drug and its metabolites (Stoelting and Hillier, 2005b).

No single theory for the mechanism of action explains all of the effects observed with anesthetic agents. The range of anesthetic activity varies with different anesthetics; the effects on the CNS and skeletal muscles are similar but not identical; structural and spatial differences exist among agents; changes at the membrane and cellular levels occur; and optical isomers produce different responses. Although similar in many respects, anesthetic agents are individually unique and probably work through numerous mechanisms and at multiple sites to produce their effects.

Levels of General Anesthesia

Guedel integrated the signs and stages of ether anesthesia into a system that was used clinically for more than 60 years. This system applied only to unpremedicated patients breathing spontaneously during ether anesthesia, a technique that is rarely used today except in developing countries. By evaluating physiologic changes and reflex responses, one can estimate the depth of anesthesia. Stage 1 is from the initial administration of anesthetic agents to loss of consciousness. Stage 2 is from loss of consciousness to the onset of regular breathing and loss of the eyelid reflex. Stage 2 also is called the *delirium* or *excitement* stage, and thrashing movements may occur. No auditory or physical stimulation should occur during this stage, especially in children. Stage 3, which begins with the onset of a regular breathing pattern and lasts until cessation of respiration, is divided into four planes and is the stage of surgical anesthesia. Stage 4 is from cessation of respiration to circulatory failure that leads to death (Nagelhout and Plaus, 2010).

Although Guedel's system gives us an appreciation for the interrelationships of numerous signs during anesthesia, the variety of drugs and anesthetic techniques used today do not provide uniform responses suitable to estimate the exact depth of anesthesia. Narcotics and anticholinergic drugs given as premedicants alter pupillary responses. Evaluation of respiratory responses and muscle tone is not valid when controlled ventilation and muscle relaxants are used. Today, general anesthesia usually is induced with IV injection of a rapid-acting drug, such

as thiopental or propofol (Diprivan), which takes the patient rapidly to stage 3 and eliminates the untoward responses often seen during stage 2.

For optimal anesthesia and good surgical conditions, several different but interrelated factors are evident. These include hypnosis (sleep), analgesia (freedom from pain), amnesia (lack of recall or awareness), appropriate surgical conditions including muscle relaxation and positioning of the patient, and continued homeostasis of the patient's vital functions. Different drugs and anesthetic agents possess various properties that facilitate these factors. Combinations of drugs are used to obtain the desired effects. Hypotensive or hypertensive drugs and cardioactive agents also may be used to achieve optimal depth of anesthesia while affecting physiologic homeostasis as little as possible. Drugs commonly used in anesthesia are briefly described in the Surgical Pharmacology box.

Phases of General Anesthesia

General anesthesia is divided into three phases: *induction*, *maintenance*, and *emergence*. *Induction* begins with administration of anesthetic agents and continues until the patient is ready for positioning or surgical prepping (surgical prep), surgical manipulation, or incision. The surgical prep is often started after the induction drugs are given. This end point of induction may vary with the surgical procedure. The *maintenance* phase continues from this point until near completion of the procedure and is accomplished with inhalation agents or with IV drugs given in titrated doses or by continuous infusions. *Emergence* varies in length and depends on the patient's state and the depth and duration of anesthesia. Emergence starts as the patient begins to "emerge" from anesthesia and usually ends when the patient is ready to leave the OR. Intubation occurs during the induction phase, and extubation usually

SURGICAL PHARMACOLOGY

Commonly Used Anesthetic Gases and Drugs

	Common Usage	Advantages	Disadvantages	Comments
INHALATION GASES				
Air	Maintenance with O_2; laser surgery near airway	Less support of combustion than N_2O	No anesthetic qualities	Possibly less nausea than N_2O (Stoelting, Hillier, 2005b)
Oxygen (O_2)	Essential for life	Can slightly ↑ O_2 available to tissues in low cardiac output states	Can cause retinopathy in premature infants	High concentrations hazardous with lasers in surgery of head, neck, and pulmonary areas (Stoelting, Hillier, 2005b)
Nitrous oxide (N_2O)	Maintenance; frequently for induction	Rapid induction and recovery; additive effects to other anesthetics	No relaxation; can depress myocardium	Hypoxia if overdose given; ↑ uptake of other volatile agents (Stoelting, Hillier, 2005b)
Enflurane (Ethrane)	Maintenance; occasionally for induction	Good relaxation; allows more epinephrine to be used than does halothane; 2.4% metabolized	Can cause ↑ HR and ↓ BP; lowers seizure threshold; slightly irritating odor	Abnormal EEG at high concentrations; used less often today (Stoelting, Hillier, 2005b)
Desflurane (Suprane)	Maintenance in short cases	Rapid emergence; good relaxation; 0.02% metabolized	May cause transient ↑ HR and ↓ BP; airway irritation; requires heated vaporizer	Rapid recovery phase; can use for emergence after maintenance with another volatile agent (Stoelting, Hillier, 2005b)
Halothane (Fluothane)	Maintenance; frequently for induction in pediatric patients	Rapid induction and recovery; pleasant, nonirritating odor; fair relaxation	May cause ↓ HR and ↓ BP; PVC and ventricular fibrillation may occur with epinephrine	Narrow margin of safety; sensitizes myocardium to epinephrine; rare cause of liver damage; 15-20% metabolized (Stoelting, Hillier, 2005b)
Isoflurane (Forane)	Maintenance	Good relaxation; allows more epinephrine to be used than does halothane; maintains cardiac output; 0.2% metabolized	↑ HR; slightly irritating odor	Isomer of enflurane; commonly used agent (Stoelting, Hillier, 2005b)
Sevoflurane (Ultane)	Induction and maintenance	Rapid induction and emergence; good relaxation; ≈5% metabolized	Metabolite (compound A) is nephrotoxic in rats; effect in humans unknown	Rapid and smooth mask induction in children and adults (Stoelting, Hillier, 2005b)

SURGICAL PHARMACOLOGY

Commonly Used Anesthetic Gases and Drugs—cont'd

	Common Usage	Advantages	Disadvantages	Comments
OPIOID ANALGESICS				
Morphine sulfate	Perioperative pain; premedication	Inexpensive; duration of action 4-5 hr; euphoria; good cardiovascular stability	Nausea and vomiting; histamine release; postural ↓ BP (↓ SVR); high first-pass effect with PO administration	Used intrathecally and epidurally for postoperative pain; elimination half-life 3 hr (Faut-Callahan, Hand, 2010)
Alfentanil (Alfenta)	Surgical analgesia in ambulatory patients	Duration of action 0.5 hr; used as bolus or infusion	—	Potency: 750 mcg = 10 mg morphine sulfate; elimination half-life 1.6 hr (Faut-Callahan, Hand, 2010)
Fentanyl (Sublimaze)	Surgical analgesia; epidural infusion for postoperative analgesia; add to SAB	Good cardiovascular stability; duration of action 0.5 hr	—	Most commonly used opioid; potency: 100 mcg = 10 mg morphine sulfate; elimination half-life 3.6 hr (Faut-Callahan, Hand, 2010)
Remifentanil (Ultiva)	0.25-1 mcg/kg/min infusion for surgical analgesia; small boluses for brief, intense pain	Easily titratable; metabolized by blood and tissue esterases; short duration; good cardiovascular stability	Expensive; requires mixing	Potency: 25 mcg = 10 mg morphine sulfate; 20-30× potency of alfentanil; elimination half-life 3-10 min (Faut-Callahan, Hand, 2010)
Sufentanil (Sufenta)	Surgical analgesia	Good cardiovascular stability; duration of action 0.5 hr; prolonged analgesia	Prolonged respiratory depression	Potency: 15 mcg = 10 mg morphine sulfate; elimination half-life 2.7 hr (Faut-Callahan, Hand, 2010)
DepoDur (morphine liposomal)	For epidural use only	Single dose provides analgesia for up to 48 hr Decreased requirements for supplemental opioids	Potential for respiratory depression Avoid other epidural drugs ≈48 hr	10-15 mg epidural, 1 dose (Hartrick et al, 2006)
DEPOLARIZING MUSCLE RELAXANTS				
Succinylcholine (Anectine, Quelicin)	Intubation; short cases	Rapid onset; short duration	Requires refrigeration; may cause fasciculations, postoperative myalgias, and dysrhythmias; ↑ serum K^+ with burns, tissue trauma, paralysis, and muscle diseases; slight histamine release	Prolonged muscle relaxation with serum cholinesterase deficiency and certain antibiotics; trigger agent for MH (Nagelhout, 2010)
NONDEPOLARIZING MUSCLE RELAXANTS—INTERMEDIATE ONSET AND DURATION				
Atracurium (Tracrium)	Intubation; maintenance of relaxation	No significant cardiovascular or cumulative effects; good with renal failure	Requires refrigeration; slight histamine release	Breakdown by Hofmann elimination and ester hydrolysis (Nagelhout, 2010)
Cisatracurium (Nimbex)	Intubation; maintenance of relaxation	Similar to atracurium	No histamine release	Similar to atracurium (Nagelhout, 2010)
Mivacurium (Mivacron)	Intubation; maintenance of relaxation	Short-acting; rapid metabolism by plasma cholinesterase; used as bolus or infusion	Expensive in long cases	Rarely need to reverse; prolonged effect with plasma cholinesterase deficiency (Nagelhout, 2010)

SURGICAL PHARMACOLOGY

Commonly Used Anesthetic Gases and Drugs—cont'd

	Common Usage	Advantages	Disadvantages	Comments
Rocuronium (Zemuron)	Intubation; maintenance of relaxation	Rapid onset (dose-dependent); elimination via kidney and liver	Vagolytic; may increase HR	Duration similar to atracurium and vecuronium (Nagelhout, 2010)
Vecuronium (Norcuron)	Intubation; maintenance of relaxation	No significant cardiovascular or cumulative effects; no histamine release	Requires mixing	Mostly eliminated in bile, some in urine (Nagelhout, 2010)
NONDEPOLARIZING MUSCLE RELAXANTS—LONGER ONSET AND DURATION				
Tubocurarine	Maintenance of relaxation	—	May cause histamine release and transient ganglionic blockade	Mostly used for pretreatment with succinylcholine
Pancuronium (Pavulon)	Maintenance of relaxation	—	May cause ↑ HR and ↑ BP	Mostly renal elimination (Nagelhout, 2010)
INTRAVENOUS ANESTHETICS				
Etomidate (Amidate)	Induction	Good cardiovascular stability; fast, smooth induction and recovery	May cause pain with injection and myotonic movements	—
Diazepam (Valium, Dizac)	Amnesia; hypnotic; preoperative medication	Good sedation	Prolonged duration	Residual effects for 20-90 hr; increased effect with alcohol (Stoelting, Hillier, 2005b)
Ketamine (Ketalar)	Induction, occasional maintenance (IV or IM)	Short-acting; patient maintains airway; good in small children and burn patients	Large doses may cause hallucinations and respiratory depression	Need darkened, quiet room for recovery; often used in trauma cases (Stoelting, Hillier, 2005b)
Midazolam (Versed)	Hypnotic; anxiolytic; sedation; often used as adjunct to induction	Excellent amnestic; water-soluble (no pain with IV injection); short-acting	Slower induction than thiopental	Often used for amnesia with insertion of invasive monitors or regional anesthesia (Stoelting, Hillier, 2005b)
Propofol (Diprivan)	Induction and maintenance; sedation with regional anesthesia or MAC	Rapid onset; awakening in 4-8 min	May cause pain when injected	Short elimination half-life (34-64 min) (Stoelting, Hillier, 2005b)
Sodium methohexital (Brevital sodium)	Induction	Ultrashort-acting barbiturate	May cause hiccups	Can be given rectally (Stoelting, Hillier, 2005b)
Thiopental sodium (Pentothal)	Induction	Induction	May cause laryngospasm; can be given rectally (Stoelting, Hillier, 2005b)	Large doses may cause apnea and cardiovascular depression
LOCAL ANESTHETICS				
Bupivacaine (Marcaine, Sensorcaine)	Epidural, spinal, or local infiltration	Good relaxation; long-acting	Overdose can cause cardiac collapse	Epidural or caudal: 2.5 mg/kg Duration: 120-240 min (Faut-Callahan, Hand, 2010)
Chloroprocaine (Nesacaine)	Epidural anesthesia	Ultrashort-acting; good relaxation	May cause neurotoxicity if injected into CSF	Maximum dose 600 mg; duration 30-45 min
Lidocaine (Xylocaine)	Epidural, spinal, peripheral, IV anesthesia, and local infiltration	Short-acting; good relaxation; low toxicity	Overdose can cause convulsions; possible transient neurologic changes with spinal anesthesia	Also used for ventricular dysrhythmias; maximum dose 7 mg/kg and 5 mg/kg with and without epinephrine; duration 60-120 min (Faut-Callahan, Hand, 2010)

SURGICAL PHARMACOLOGY

Commonly Used Anesthetic Gases and Drugs—cont'd

	Common Usage	Advantages	Disadvantages	Comments
Ropivacaine (Naropin)	Local infiltration, peripheral nerve block Epidural	Fast Slow Moderate	≈30-40% less cardiotoxic than bupivacaine (Salinas et al, 2004)	5-8 hr (max single dose 250 mg) 2-6 hr (max single dose 200 mg) (Salinas et al, 2004)
Tetracaine (Pontocaine)	Spinal anesthesia	Long-acting; good relaxation	—	Maximum dose 1–1.5 mg/kg (epinephrine rarely used); duration 60-180 min (Stoelting, Hillier, 2005a)
ANTICHOLINERGICS				
Atropine	Blocks effects of acetylcholine; ↓ vagal tone; reverse muscle relaxants; treat sinus bradycardia	↑ HR; suppresses salivation, bronchial and gastric secretions	Depresses sweating; may cause dry mouth, flushing, dizziness, CNS symptoms	Quite selective at muscarinic receptors in smooth and cardiac muscle and exocrine glands (Nagelhout, 2010)
Glycopyrrolate (Robinul)	Similar to atropine	Slightly ↑ HR; does not cross blood-brain barrier; can increase gastric pH more than atropine	Prolonged duration of effects	Lower incidence of dysrhythmias than atropine (Nagelhout, 2010)
CHOLINERGIC AGENT				
Neostigmine (Prostigmine)	Reverses effects of nondepolarizing neuromuscular blocking agents	Prevents breakdown of acetylcholine by inhibiting acetylcholinesterase	—	Given with either atropine or glycopyrrolate (Nagelhout, 2010)
OTHER				
Dexmedetomidine (Precedex)	Selective α_2-agonist	Produces centrally mediated sympatholytic, sedative, and analgesic effects	Provides hemodynamic stability, potentiates intraop anesthetics, reduces anesthetic requirements, less respiratory depression than opioids (Haselman, 2008)	Intraop 0.2–0.7 mcg/kg/hr (Haselman, 2008)

BP, Blood pressure; *CNS,* central nervous system; *CSF,* cerebrospinal fluid; *EEG,* electroencephalogram; *HR,* heart rate; *IM,* intramuscular; *IV,* intravenous; *MAC,* monitored anesthesia care; *MH,* malignant hyperthermia; *PO,* oral; *PVC,* premature ventricular contractions; *SAB,* subarachnoid block; *SVR,* systemic vascular resistance.

is performed during emergence. Recovery from anesthesia can be considered a fourth phase of general anesthesia.

Types of General Anesthesia

The type of general anesthesia employed often is described as IV technique, inhalation technique (with a volatile anesthetic agent), or a combination of IV and inhalation techniques. An IV technique traditionally includes (1) an induction agent such as thiopental, combined with 30% to 40% O_2 and N_2O; (2) an amnestic/anxiolytic, such as midazolam or diazepam; (3) an analgesic such as fentanyl or morphine sulfate; and (4) a muscle relaxant.

In contrast, an inhalation technique may use thiopental or propofol to facilitate a rapid induction, or patients may "breathe themselves down" with a potent agent, such as sevoflurane or halothane, plus N_2O and O_2. An inhalation induction is often used with children to avoid inserting an IV catheter while they are awake. Depending on the kind of surgical procedure, maintenance of anesthesia may be accomplished with only inhalation agents and spontaneous, assisted, or controlled ventilation. Effects of volatile agents are dose related and they provide differing levels of anesthesia, amnesia, analgesia, muscle relaxation, and hemodynamic responses. If supplemental muscle relaxation is needed, the relaxant dose required is significantly less than the dose necessary during IV anesthesia.

In the past, the term *balanced anesthesia* was used when various combinations of IV drugs were "balanced" to provide complete anesthesia. Today, the term is often used to describe a combination of IV drugs and inhalation agents employed to obtain specific effects for each patient and procedure.

Anesthesia providers also use *total IV anesthesia (TIVA)*. This technique may be used in the OR but is commonly employed for pediatric, uncooperative, or trauma patients in remote locations, such as in the magnetic resonance imaging (MRI), radiology, or surgical laser suite where a waste-gas evacuation system

is not available. TIVA also is used in the expanding area of office-based surgical procedures. With TIVA, short-acting drugs such as propofol with remifentanil or alfentanil are used for induction. These drugs may be administered by continuous infusion. Anesthesia is maintained by an infusion plus O_2 alone or with N_2O. An intermediate-acting muscle relaxant (mivacurium, cisatracurium, atracurium, rocuronium, or vecuronium) may also be given. As surgery nears completion, the maintenance drugs are titrated off, and emergence from anesthesia occurs.

Muscle Relaxants

Muscle relaxants (also referred to as neuromuscular blocking drugs [NMBDs]) are used to facilitate intubation and to provide good operating conditions at lighter planes of general anesthesia. These drugs may be used elsewhere for emergency intubation or, less frequently, when a patient is being mechanically ventilated. Muscle relaxants affect skeletal muscle and have little effect on cardiac or smooth muscle. Although not always dose dependent, many of these drugs have adverse side effects. The route of metabolism and elimination varies, and this may be important for patients with hepatic or renal disease. Muscle relaxants are classified as *depolarizing* or *nondepolarizing*.

Succinylcholine (Anectine) is the only *depolarizing* muscle relaxant used clinically. Its action is similar to that of acetylcholine, and at the neuromuscular junction it causes depolarization of the postjunctional membrane (Stoelting and Hillier, 2005b). Generalized skeletal muscle contractions known as *fasciculations* result from simultaneous depolarization of all the muscle fibers. To prevent these fasciculations and associated postoperative myalgias, a dose of a nondepolarizing relaxant (such as tubocurarine 0.04 mg/kg) is given 3 to 5 minutes before administration of the intubating dose of succinylcholine. Onset of paralysis (30 to 90 seconds) is faster and duration of action (5 to 10 minutes) is shorter than with other relaxants. The speed of onset makes it a preferred drug for rapid-sequence inductions. Adverse side effects associated with use of succinylcholine include cardiac dysrhythmias, hyperkalemia, myalgias (particularly in young and muscular patients), and increases in intraocular, intracranial, and intragastric pressures. It also can trigger malignant hyperthermia (MH) in susceptible patients. It can be infused for longer procedures, but an excessive dose may cause prolonged relaxation (known as *phase II blockade*). Succinylcholine is hydrolyzed by plasma cholinesterase, and the rare patient with an abnormal or absent enzyme (plasma cholinesterase) has prolonged muscle paralysis (Stoelting and Hillier, 2005b).

Nondepolarizing muscle relaxants competitively block the depolarizing action of acetylcholine at the neuromuscular junction, which results in skeletal muscle paralysis. Fasciculations do not occur. These drugs can be subdivided by duration of action into intermediate-acting (mivacurium, atracurium, cisatracurium, rocuronium, and vecuronium) and long-acting (tubocurarine, metocurine, pancuronium, pipecuronium, and doxacurium) (Lynn, 2009). The potency, duration (metabolism and elimination), and side effects of these drugs vary and may be individually altered in patients with hepatic or renal dysfunction, electrolyte imbalance, or hypothermia or when used in combination with other perioperative drugs (inhalation and local anesthetics, aminoglycoside antibiotics, calcium-entry blockers, magnesium, and cardiac antidysrhythmics). Generally, nondepolarizing relaxants can be used for patients with MH or plasma cholinesterase deficiencies (except for mivacurium). Side effects vary with individual drugs, are dose dependent, and include alterations in blood pressure (BP) and heart rate. The neuromuscular blockade of muscle relaxants can be monitored with a peripheral nerve stimulator. Paralysis caused by nondepolarizing relaxants may be antagonized (reversed) by IV anticholinesterases, such as edrophonium, neostigmine, or pyridostigmine. Antagonists allow acetylcholine to accumulate and compete for receptor sites at the neuromuscular junction and may be associated with bradycardia, for which atropine or glycopyrrolate is routinely given (Stoelting and Hillier, 2005b).

Typical Sequence of General Anesthesia

After arriving in the preoperative area or the OR suite, the anesthesia provider again identifies the patient; verifies consent or an operative permit is signed; reviews current laboratory tests, diagnostic studies, and pertinent medical history; and confirms there have been no interval changes in the patient's status. Depending on the practice of the anesthesia department and institutional policy, an IV infusion may be started in the preoperative area or after the patient is transferred to the OR, as nearly all anesthesia-related drugs are given IV except the inhalation agents. After the patient arrives in the OR and is transferred to the OR bed, monitors are connected.

Before induction, the patient usually is preoxygenated (i.e., denitrogenated) using a mask with 100% O_2 for 3 to 5 minutes. This practice permits washout of most gaseous nitrogen from the body and provides a large reserve supply of O_2 in the lungs. Opioids and benzodiazepines usually are administered at this time. A test dose of the induction agent (e.g., 50 mg of thiopental) often is given to check for any unusual or exaggerated response. If succinylcholine is to be used for intubation, a small pretreatment dose of a nondepolarizing muscle relaxant (e.g., 3 mg of tubocurarine, 0.5 to 1 mg of pancuronium or vecuronium, or 5 mg of rocuronium) usually is given. If the patient can be safely ventilated with a mask, many anesthesia providers avoid the adverse effects of succinylcholine and use one of the nondepolarizing muscle relaxants for intubation (Naguib and Lien, 2005).

To induce anesthesia, a short-acting barbiturate, such as thiopental (2 to 6 mg/kg) or propofol (1.5 to 2.5 mg/kg), is given. When the patient becomes apneic and the eyelash reflex is absent, the airway is checked for patency by ventilating the patient with a mask. Depending on several factors, such as the airway and the type and duration of surgery, O_2 and anesthetic gases may be delivered to a spontaneously breathing patient through a mask held in place with a head strap. Positioning of the head or insertion of an oral or nasal airway may be used to maintain a patent airway. If spontaneous or assisted ventilation is planned, an LMA may be inserted without a muscle relaxant. A mask or LMA may be used for a patient with a good airway who is at minimal risk of aspiration and is undergoing a relatively short procedure, and when the surgical site is not located in the head or neck area.

If mask anesthesia or an LMA is inappropriate, an ETT may be used to facilitate ventilation and to prevent aspiration. Typical equipment used for intubation and airway control and monitoring is shown in Figure 4-2. An intubating dose of a muscle relaxant is administered, resulting in temporary paralysis. When the patient is paralyzed, ventilation is controlled during the procedure.

To facilitate intubation, the patient's head is placed in a "sniffing" position. The laryngoscope is held in the left hand. The laryngoscope blade is inserted into the right side of the mouth and moved to the midline, "sweeping" the tongue to

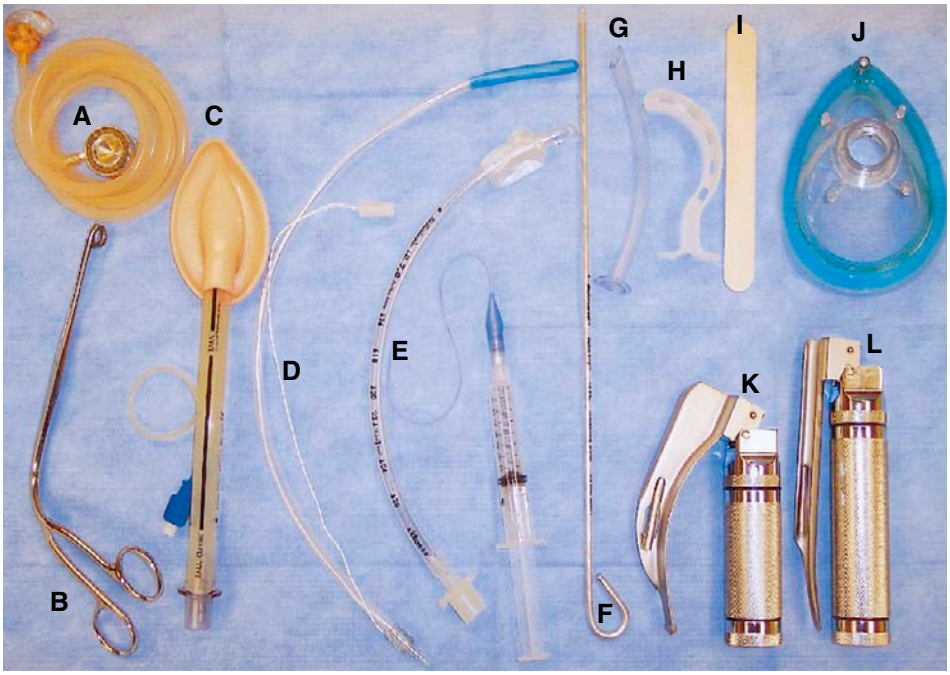

FIGURE 4-2 Commonly used anesthesia equipment. **A**, Precordial stethoscope. **B**, McGill forceps. **C**, Laryngeal mask airway (LMA). **D**, Esophageal stethoscope with esophageal temperature monitor. **E**, Endotracheal tube (ETT). **F**, Intubating stylet for endotracheal tube. **G**, Nasal airway. **H**, Oral airway. **I**, Tongue blade. **J**, Mask. **K**, "Stubby" laryngoscope handle with MacIntosh (curved) fiberoptic laryngoscope blade. **L**, Miller (straight) fiberoptic laryngoscope blade and handle.

the left. The ETT is introduced on the right side of the mouth and gently inserted into the trachea so that the cuff is approximately 1 cm below the vocal cords. The cuff is inflated just enough to occlude any air passage with the peak pressures used for ventilation. Location of the ETT in the trachea is verified by an appropriate level and waveform of $ETCO_2$, bilaterally equal breath sounds and absence of sounds over the stomach (determined using a stethoscope), symmetric movement of the thorax with positive-pressure ventilation, and condensation of moisture from expired air in the ETT and breathing circuit. Proper placement of the ETT is shown in Figure 4-3. While the vocal cords are the narrowest portion of an adult trachea, the smallest portion of a child's airway is below the vocal cords at the cricoid cartilage. Uncuffed ETTs usually are selected for children. After initial paralysis from the muscle relaxant has worn off, the patient may be allowed to breathe spontaneously with intermittent assistance, or additional muscle relaxant is given and ventilation controlled mechanically.

If the procedure is emergent or the patient is at risk for aspiration (as in cases of a full stomach, intestinal obstruction, hiatal hernia, or significant esophageal reflux) (Research Highlight), a rapid-sequence induction or an "awake" fiberoptic intubation may be planned. In these instances and in routine intubation, the perioperative nurse must be ready to assist by applying cricoid pressure (Figure 4-4). The nurse exerts downward pressure on the cricoid cartilage with the thumb and index finger of one hand (Sellick maneuver). The cricoid cartilage is the only complete ring in the trachea. Correctly applied downward pressure occludes the esophagus, which lies immediately posterior (or dorsal) to the trachea, enhancing the view required for intubation (Patten, 2007). The pressure

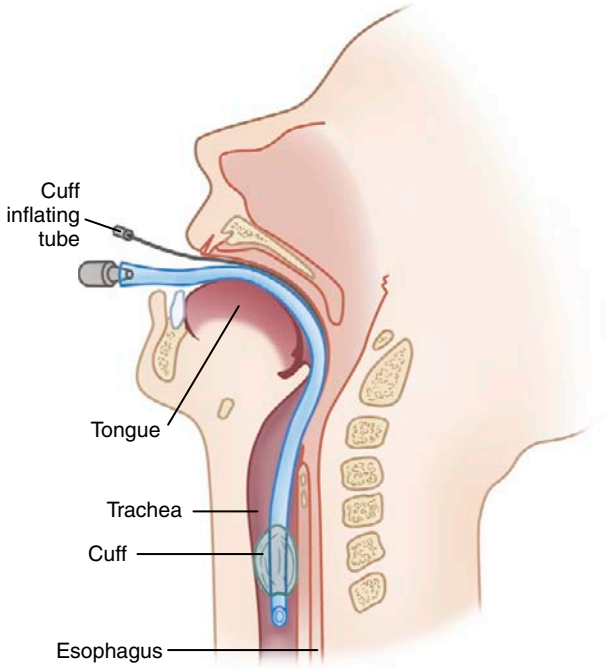

FIGURE 4-3 ETT in position.

should not be released until proper placement of the ETT has been confirmed and the cuff inflated. This procedure has been widely accepted among anesthesia providers. Research suggests that this maneuver is difficult to do correctly and effectively (Beavers et al, 2009).

RESEARCH HIGHLIGHT

Perioperative Pulmonary Aspiration

Pulmonary aspiration is an infrequent event, occurring in about 1 in 3000 patients undergoing general anesthesia. Sicker patients undergoing emergency procedures are at the greatest risk and have the highest incidence. Complications of aspiration have been reported to cause 10% to 30% of anesthesia-related deaths. Approximately 25% of patients who aspirate gastric contents develop significant complications. About 10% of patients who aspirate require mechanical ventilation support for more than 24 hours.

Induced unconsciousness interferes with multiple biologic mechanisms that normally guard the airway against aspiration. Aspiration may occur at any time, but it is most common during tracheal intubation and extubation. A common factor during intubation is inadequate muscle relaxation, which may cause gagging and vomiting. During extubation, aspiration may occur because the patient is weak or unresponsive. Consequences include aspiration pneumonia, acute respiratory distress syndrome, and pulmonary edema as well as long-term complications such as laryngotracheal damage and decreased lung compliance.

The perioperative nurse assists the anesthesia provider in emergent procedures and when a surgical patient is at risk for aspiration (as in cases of a full stomach, intestinal obstruction, hiatal hernia, or significant esophageal reflux). For these patients, a rapid-sequence induction (RSI) or an "awake" fiberoptic intubation may be planned. The perioperative nurse must be ready to assist by applying cricoid pressure—exerting downward pressure on the cricoid cartilage with the thumb and index finger of one hand (Sellick maneuver). When cricoid pressure is used to prevent aspiration, it should not be released until intubation is accomplished (or the anesthesia provider directs release, as in when and if a patient vomits), the cuff on the ETT inflated, the ETT secured, and proper placement of ETT verified by the anesthesia provider.

Modified from Patten SP: Apply cricoid pressure correctly, *OR Nurse* 1(3):72, 2007; Pisegna JR, Martindale RG: Acid suppression in the perioperative period, *J Clin Gastroenterol* 39(1):10-16, 2005; Pousman RM: *Rapid sequence induction for prehospital providers,* 2008, available at www.uam.es/departamentos/medicina/anesnet/journals/ijeicm/vol4n1/rapid.htm#V.%20Rapid%20Sequence%20Induction. Accessed June 3, 2009; Warner MA: Is pulmonary aspiration still an important problem in anesthesia? *Curr Opin Anesthesiol* 13:215-218, 2000.

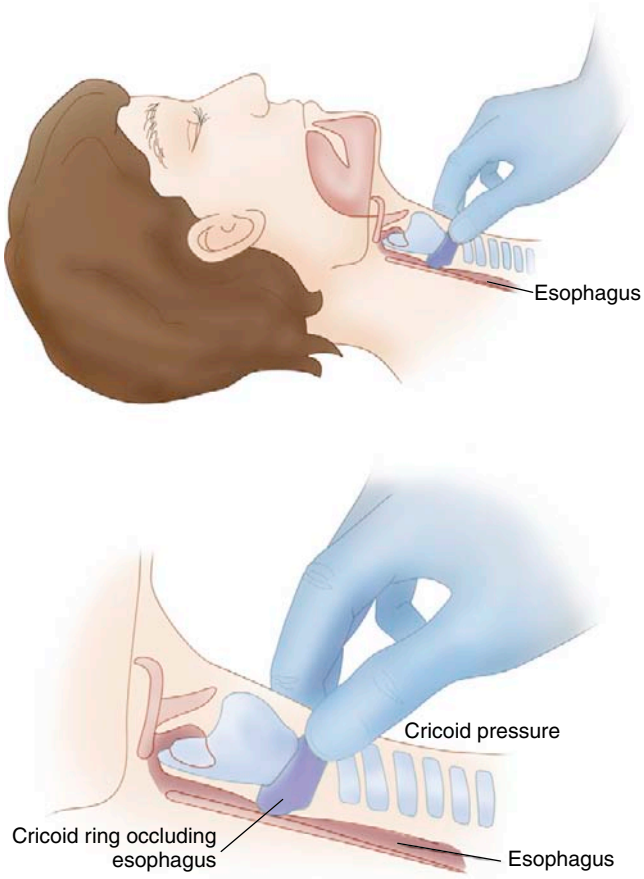

FIGURE 4-4 Applying cricoid pressure.

The perioperative nurse may provide additional assistance if an unexpected difficult intubation occurs or the patient cannot be ventilated adequately via mask. Emergency airway equipment should be brought into the room immediately. The perioperative nurse should be familiar with the location of the various pieces of equipment, know how to assemble the equipment for use, and should assist the anesthesia provider in securing the airway. Securing the airway in an emergency situation requires an intense team effort. The contents of a typical difficult-airway cart are listed in Box 4-2. If invasive monitors (e.g., an arterial line) are to be placed after induction, the perioperative nurse may assist by properly positioning the patient or extremity; prepping the area or areas; and assisting with placement, connection, and calibration of the monitors. If the procedure is emergent, the perioperative nurse also may assist by obtaining additional IV access, connecting fluid-warming or patient-warming units, double-checking blood products, and "pumping" IV fluids as needed. In situations in which the anesthesia provider is involved with a critical procedure, such as a difficult-airway/airway emergency, the perioperative nurse can perform a valuable service by ensuring 100% O_2, having suction available, observing the monitors, recording data (Spo_2 and $ETco_2$ values), and communicating significant changes to the anesthesia provider (Evidence for Practice).

The LMA is a major advancement in airway management. Placement is relatively simple and does not require laryngoscopy or muscle relaxation. When comparing ease of use, invasiveness, and airway protection, the LMA ranks between the facemask and an ETT. It is ideal for a supine patient under general anesthesia with spontaneous ventilation. The LMA also may be useful in a difficult-airway situation in which tracheal intubation cannot be achieved. It is available in six sizes, can be autoclaved, and is reusable. A disposable LMA also is available.

Before insertion, the LMA must be deflated carefully so that there are no wrinkles in the cuff. The recommended technique for insertion of the LMA is shown in Figure 4-5, and correct placement is shown in Figure 4-6. For adults, it is recommended that a 2.5- to 3-cm diameter roll of gauze sponges be used as a "bite block" and inserted beside the LMA tube (*LMA airway instruction manual,* 2004). The LMA and gauze roll can be secured with tape.

Maintenance of anesthesia can be accomplished with IV or inhalational anesthetic techniques or a combination of both,

EVIDENCE FOR PRACTICE

Difficult-Airway Management

Best practices, clinical guidelines, and evidence-based patient care are all forms of systematically developed recommendations that assist practitioners in making decisions about treatments and interventions. Although they are not standards or absolute requirements, they are utilitarian for the clinical situation they represent. In 1992 the ASA developed *Practice Guidelines for Management of the Difficult Airway.* Airway emergencies can occur at any time during the perioperative period. Serious airway problems can result in adverse outcomes, including death, brain injury, myocardial injury, and airway trauma. The ASA difficult-airway algorithm has recommended sequences of activity for recognized and unrecognized difficult airways as well as primary and alternative strategies for awake intubation and intubation attempts after induction of general anesthesia. Although patient management remains the responsibility of the anesthesia team, all perioperative nurses should know about necessary equipment, including location, setup, and function. Most institutions have a difficult-airway cart (see Box 4-2), centralizing items and supplies necessary to manage airway emergencies. The ASA *Practice Guidelines* suggest contents for this cart, but anesthesia providers may add or modify preference items.

The anesthesia provider assesses the likelihood and clinical impact of potential airway problems by evaluating the patient's airway. Questions related to congenital, acquired, and traumatic disease states are posed to detect factors that might indicate the presence of a difficult airway. The patient is examined to detect physical characteristics that may make intubation or mask ventilation difficult. The pharyngeal structures may be assessed, the distance from the mandible to the hyoid noted, and the ability to extend the neck determined. An obese patient is more likely to require a shoulder roll to align the three axes of the airway (oral, pharyngeal, and laryngeal). With a shoulder roll, the scapulae, shoulders, and nape of the neck are supported, resulting in an improved sniff position. Anticipatory action on the part of the perioperative nurse in assisting with shoulder roll placement is an example of the hallmark teamwork and collaboration that characterize good patient care. The perioperative nurse also should anticipate equipment and assistance required should an awake intubation be necessary or if the emergency pathway must be followed. Finally, patients who experience a difficult-airway may be recommended to wear a Medic-Alert bracelet. The National Medic Alert Registry for Difficult Airway/Intubation can be contacted. Information regarding why it was difficult to secure an airway and what technique finally worked is recorded in the Registry's data bank and can be accessed by future anesthesia providers.

Modified from American Society of Anesthesiologists: Practice guidelines for management of the difficult airway, *Anesthesiology* 98:1269-1277, 2003.

Typical Contents of a Difficult-Airway Cart

FIBEROPTIC (FO) EQUIPMENT
Flexible FO bronchoscopes (adult and pediatric); FO light source; Bullard scope (FO); and siliconized spray

LARYNGOSCOPE EQUIPMENT
Assorted pediatric and adult laryngoscope handles and blades; extra alkaline batteries; and video laryngoscope

ENDOTRACHEAL TUBES (ETT)
Regular ETT: uncuffed, 2.5-6 mm; regular ETT: cuffed, 5-9 mm; oral RAE ETT: uncuffed, 3-7 mm; oral RAE ETT: cuffed, 6-8 mm; nasal RAE ETT: uncuffed, 3-7 mm; nasal RAE ETT: cuffed, 6-8 mm; reinforced ETT: cuffed, 7-8 mm; controllable-tip ETT (Endotrol); Combitube

AIRWAYS
Regular oral: assorted pediatric and adult; regular nasal: assorted adult; intubating airways: assorted (e.g., Ovassapian, Williams); nasopharyngeal airway with inflatable introducer; assorted sizes of LMAs; tongue blades; and water-soluble lubricant (K-Y)

INTUBATING EQUIPMENT
Intubating stylets; McGill forceps: pediatric and adult; esophageal (gastric tube) airway (EGTA); hollow ETT changers with removable Luer-Lok connectors for O_2 insufflation

SUCTION EQUIPMENT
Assorted flexible suction catheters to fit ETT and LMA as well as stiff suction catheters (Yankauer)

TOPICAL ANESTHESIA EQUIPMENT
Atomizers and pressurized topical anesthetic spray; long Q-tips; lidocaine 4%; lidocaine 4% with phenylephrine; lidocaine 2%—viscous; lidocaine 5%—ointment; lidocaine 10%; tetracaine 1%

TRANSTRACHEAL AIRWAY EQUIPMENT
Transtracheal O_2 jet ventilator with pressure regulator, manual control valve, and Luer-Lok male connector; assorted large IV catheters; and assorted long guidewires, epidural needles, and epidural catheters (for retrograde intubation)

MISCELLANEOUS
Safety glasses; heat-moisture exchanger (Humidivent); assorted facemasks with port for FO scope; right-angled connector (for facemasks) with port for FO scope; $ETco_2$ chemical indicators (Easy Cap); twill tape (to secure ETT); skin adhesive (Mastisol)

with or without additional muscle relaxation. The anesthesia provider considers a variety of factors when selecting the anesthesia technique for each patient.

Whichever technique is selected for general anesthesia (or for any other anesthesia types discussed subsequently), the entire surgical team participates in a time-out just after the patient is positioned, prepped, and draped and before starting the surgical procedure. The patient's identity is rechecked. The procedure to be done, operative side and site, and correct surgical position are verified by the entire surgical team. The patient must be positioned such that the marking of the operative site (e.g., with the word "yes" or the surgeon's initials) is visible on the patient's skin. The availability of implants, special equipment, or other requirements (e.g., blood, if ordered) is verified. When this has been completed, the procedure can begin. The time-out should be documented according to institutional protocol.

Many factors influence emergence. The objective is to move the patient from the OR bed to the PACU bed as soon as the dressing is applied. During emergence, the anesthesia provider suctions the oropharynx before extubation to decrease the risk of aspiration and laryngospasm after extubation, reverses any residual neuromuscular blockade, and allows the washout of N_2O and volatile agents by giving 100% O_2 for several minutes before extubation. After extubation, the patient is transported to the PACU to awaken. In some situations, the patient may be

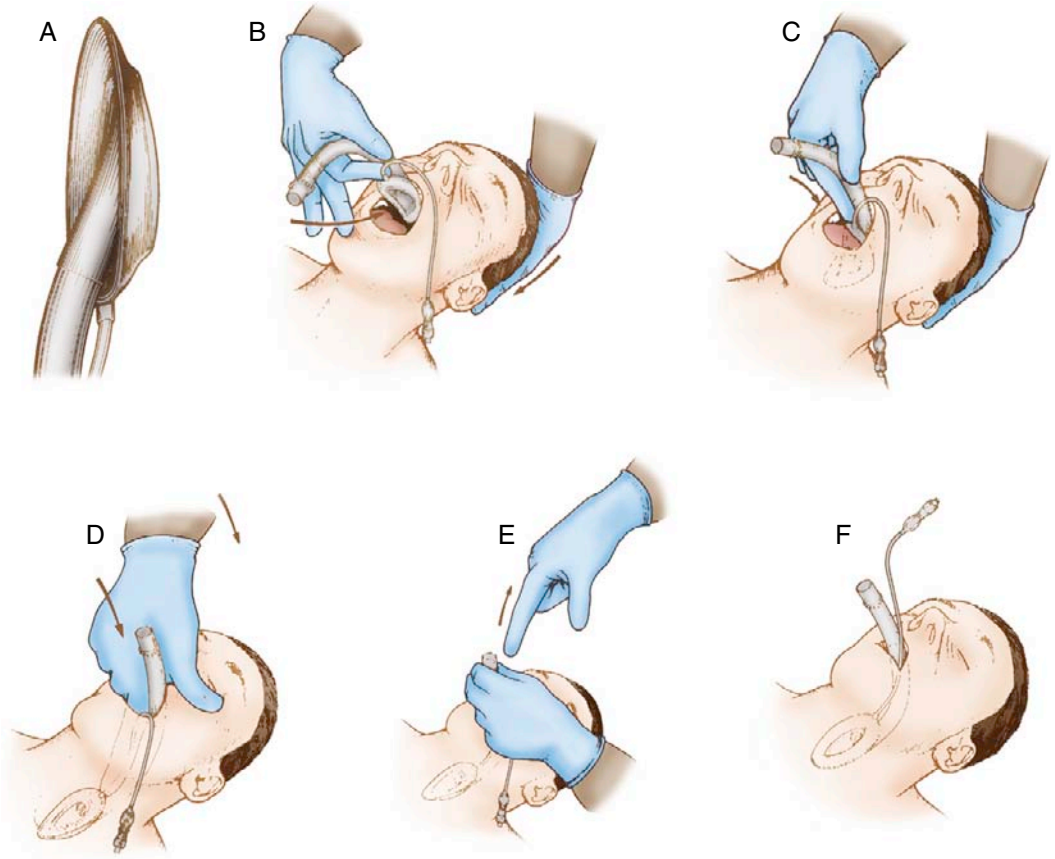

FIGURE 4-5 Insertion of the laryngeal mask airway (LMA). Select the appropriate-size LMA (1, neonates ≤5 kg; 1.5, infants 5 to 10 kg; 2, infants and children 10 to 20 kg; 2½, children 20 to 30 kg; 3, children and small adults >30 kg; 4, normal-size to large adults; 5, large adults). **A,** Carefully deflate the LMA as flat as possible so that the rim faces away from the mask aperture as shown. There should be no folds near the tip. **B,** Under direct vision, press the tip of the LMA cephalad against the hard palate to flatten it out. Using the index finger, continue pressing the LMA against the palate as the LMA is advanced into the pharynx to ensure that the tip remains flattened and avoids the tongue. **C,** Keeping the neck flexed and the head extended, use the index finger to press the LMA into the posterior wall. **D,** Continue pushing with the ball of the index finger, guiding the LMA posteriorly into position. By withdrawing the other fingers and slightly pronating the forearm, it is usually possible to push the LMA fully into position in one fluid movement. **E,** Firmly grasp the tube with the other hand; then withdraw the index finger from the pharynx. Gently press the LMA posteriorly to ensure that it is fully inserted. **F,** Carefully inflate the LMA with the recommended volume of air for size (1, 2 to 4 ml; 2, ≤10 ml; 2½, ≤14 ml; 3, ≤20 ml; 4, ≤30 ml; 5, ≤40 ml). Do not overinflate. Do not touch the LMA tube while inflating, unless it is obviously unstable (as with elderly edentulous patients with loose oropharyngeal tissues). Usually the LMA moves slightly forward out of the hypopharynx as it is inflated. Insert a bite-block (roll of gauze) alongside the LMA tube to minimize occlusion of the tube as the patient is awakening.

transferred to the PACU before extubation and the ETT removed when the patient is fully awake.

Untoward events that can occur with general anesthesia include hypoxia; respiratory, cardiovascular, or renal dysfunction; hypotension; hypertension; fluid or electrolyte imbalance; residual muscle paralysis; dental damage; neurologic problems; hypothermia; and MH. The anesthesia provider usually directs the treatment and management of such events.

REGIONAL ANESTHESIA

Regional anesthesia (also called *conduction anesthesia*) can be accomplished by injecting a local anesthetic anywhere along the pathway of a nerve from the spinal cord. This injection provides anesthesia to a region of the body. Preoperative preparation for regional anesthesia is essentially the same as that for general anesthesia. Preoperative medication frequently is ordered before regional anesthesia to ease any discomfort that may be experienced during placement of the block. The criteria for monitoring during regional anesthesia are similar to those during general anesthesia. Whenever regional anesthesia is performed, resuscitative equipment and drugs must be immediately available. During preparation and placement of the regional anesthetic, the perioperative nurse can provide valuable assistance. This assistance may include placing appropriate monitors, such as pulse oximetry, ECG, and blood pressure; providing supplemental O_2 if indicated; reassuring the patient; administering sedation, such as midazolam, as directed; and properly positioning the patient, which is crucial for a successful block.

Peripheral blocks on the lower or upper extremities or on the head frequently are done in a preoperative holding area to allow adequate time for the local anesthetic to penetrate the peripheral nerve before the patient is transferred to the OR. For peripheral blocks, the perioperative nurse may need to perform aspiration during needle placement (to detect vascular puncture) and inject the local anesthetic while the anesthesia provider stabilizes the needle in the precise location. After an initial period of evaluation by the anesthesia provider, the nurse monitors the patient for any substantial change in vital signs or untoward reactions until the patient is transferred to the OR.

Spinal Anesthesia

A local anesthetic (usually lidocaine, tetracaine, or bupivacaine) injected into the cerebrospinal fluid (CSF) in the subarachnoid space is termed a *spinal anesthetic* or a *subarachnoid block (SAB)*. To provide additional analgesia, fentanyl or preservative-free morphine often is added to the local anesthetic. A spinal needle is inserted into a lower lumbar interspace with the patient either lying on one side or in a sitting position. The local anesthetic generally is mixed with a dextrose solution for a total of 1 to 4 ml to make a *hyperbaric* (heavier than the CSF) solution. These hyperbaric mixtures settle in a gravity-dependent manner after injection into the CSF. By changing the patient's position, the block can be directed up, down, or to one side of the spinal cord. With prostate surgery, the patient may remain in the sitting position for about 1 minute after the local anesthetic is injected to achieve a bilateral block of the S1-S5 dermatomes.

For surgery in the upper abdomen, the patient may be placed in a slight 5- to 10-degree head-down position to allow the anesthetic to move cephalad while the anesthesia provider carefully checks the level of sensory block. When an adequate level is obtained, the bed is leveled to minimize further extension of the sensory block. After 10 to 15 minutes, the block is usually "set" and does not extend farther. The sympathetic nervous system usually is blocked two dermatomes higher and the neuromuscular system two dermatomes lower than the sensory block. The patient is then positioned as necessary for surgery.

If the local anesthetic is mixed with a larger volume of sterile water, the solution is *hypobaric,* and the drug moves to the nondependent area. Hypobaric spinal anesthesia usually is done after the patient is positioned and the surgical site exposed (with the site of injection above the surgical site, as in perianal surgery in the prone position).

By mixing the local anesthetic with some CSF withdrawn from the subarachnoid space, the solution becomes *isobaric.* Distribution of this solution is minimally affected by gravity.

Spinal anesthesia may cause several physiologic responses that can result in major problems if not properly managed. A description of these follows.

Hypotension. Hypotension may occur rapidly after an SAB. It is caused by vasodilation because the sympathetic nerves that control vasomotor tone are blocked. Peripheral pooling of blood occurs, resulting in reduced venous return to the heart and decreased cardiac output. A hypotensive response usually can be avoided by infusing 750 to 1500 ml of balanced salt solution immediately before the block and placing the patient in a 5-degree head-down position to improve venous return to the heart. A vasopressor, such as ephedrine, also may be administered.

Total Spinal Anesthesia. Total spinal anesthesia (or an inadvertently high block) may cause paralysis of the respiratory muscles and necessitate immediate intubation and ventilation. Any sign or symptom of respiratory distress occurring shortly after instituting spinal anesthesia should alert the anesthesia provider to the possibility of a high spinal block.

Positioning Problems. Positioning problems can occur because pain and sensory inputs to a portion of the patient's body are blocked. Care must be taken in positioning the patient intraoperatively to avoid neurologic damage, burns, loss of skin integrity, or other trauma. Positioning the surgical patient is a collaborative effort among the anesthesia provider, the surgeon, the assistant, and the perioperative nurse (see Chapter 5 for a comprehensive discussion of surgical positioning).

Postdural Puncture Headache. Postdural puncture headache (PDPH) (also called *postspinal cephalgia* or *spinal headache*) is a frequent postoperative complaint after spinal anesthesia. It occurs more commonly in young parturients or other patients younger than 40 years. The incidence is about 1% when a 25- or 27-gauge blunt-bevel needle is used. It is unrelated to how soon the patient ambulates postoperatively. The headache is believed to result from leakage of CSF through the hole in the dura and typically occurs when the patient assumes an upright position. The incidence, severity, and duration of the headache appear to correlate with the size of the hole left in the dura. The headache usually occurs in the occipital area and generally resolves over 1 to 3 days but may last 2 weeks. Several treatments

have been used to relieve the headache: strict bed rest for 24 to 48 hours, vigorous hydration, abdominal binders, epidural infusion of saline, oral (PO) or IV caffeine, and injection of 5 to 20 ml of autologous blood into the epidural space at the puncture site ("blood patch") (Burkard and Vacchiano, 2010).

Many anesthesia providers use different spinal needles that have a tip shaped like a sharpened wood pencil with the hole on the side of the needle. These 24- to 26-gauge spinal needles (e.g., Whitacre, Sprotte, Gertie Marx) presumably separate or go between the dural fibers as opposed to cutting the fibers, which may occur when a blunt-bevel spinal needle is used. With these "pencil-point" needles, the incidence and severity of PDPH are substantially lower (Burkard and Vacchiano, 2010).

Epidural and Caudal Anesthesia

The epidural space is located between the ligamentum flavum and the dura and extends from the foramen magnum to the sacrococcygeal membrane. It is filled with epidural veins, fat, and loose areolar tissue. For *epidural* anesthesia, the local anesthetic usually is injected through the intervertebral spaces in the lumbar region (lumbar epidural), although it also can be injected into the cervical or thoracic regions. The anesthetic spreads cephalad and caudad from the site of injection. A comparative location of the needle points and injected anesthetic is shown in Figure 4-7.

For *caudal* anesthesia, the local anesthetic also is injected into the epidural space, but the approach is through the caudal canal in the sacrum. Compared with a lumbar epidural, this approach requires a greater volume of anesthetic to fill the epidural space. Caudal anesthesia has a 5% to 10% technical failure rate. Given its ease of administration, however, it is often employed for perineal procedures or pediatric surgery on the lower extremities (Tobias and Litman, 2004).

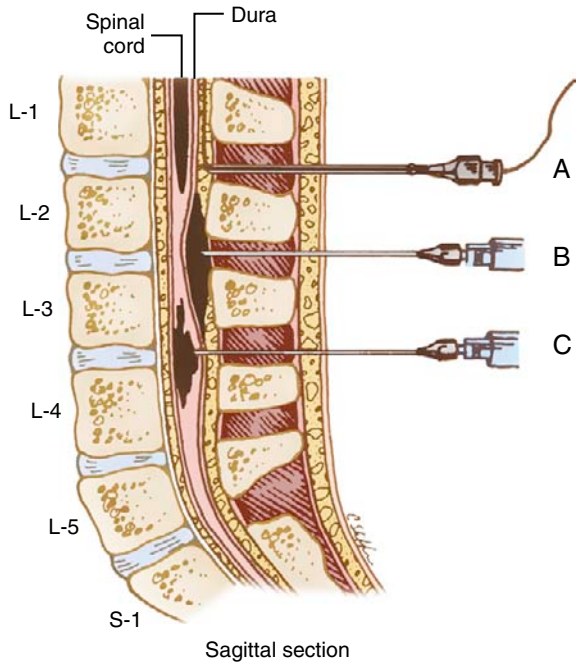

FIGURE 4-7 Location of needle point and injected anesthetic relative to dura. **A**, Epidural catheter. **B**, Single injection epidural. **C**, Spinal anesthesia. (Interspaces most commonly used are L4-L5, L3-L4, and L2-L3.)

Several techniques may be used for epidural or caudal anesthesia. A "single-shot epidural" involves administration of a local anesthetic through the needle before its removal. For intermittent injections or continuous infusions, a small catheter is inserted into the epidural space for administration of local anesthetic.

For combined spinal and epidural anesthesia, the epidural needle is inserted into the epidural space, and a special, long 26-gauge spinal needle is inserted through the epidural needle into the CSF. A small amount of fentanyl or preservative-free morphine may be injected and provides good analgesia for several hours. The spinal needle is removed, and an epidural catheter is inserted. This technique is especially useful for obstetric anesthesia (Burkard and Vacchiano, 2010).

Techniques used to identify the epidural space include the "hanging drop" and the "loss of resistance" to injection of either air or liquid (saline or local anesthetic) as the needle is advanced slowly through the ligamentum flavum. With the hanging-drop technique, the needle is filled with liquid to form a meniscus at the needle hub. As the needle is slowly advanced into the epidural space, negative (less than atmospheric) pressure draws the liquid inward toward the epidural space. Location of the needle tip within the epidural space is verified by injection of an additional 1 to 2 ml of air or saline.

When local anesthetics are injected into the epidural space, the major sites of action are the nerve roots as they leave the spinal cord and proceed out the intervertebral foramina beyond the meningeal sheath. Some of the anesthetic diffuses into the subarachnoid space, however, to the spinal cord. As local anesthetics diffuse away from the site of injection, segmental anesthesia may be possible in specific areas. In contrast to spinal anesthesia, much larger volumes of local anesthetic are needed with epidural anesthesia; the head-up, head-down, or lateral position of the patient does not affect the level of the epidural anesthetic as much, and the onset of anesthesia is much slower with epidural anesthesia. As with spinal anesthesia, hypotension can occur with epidural anesthesia, but the onset is much slower and usually can be managed with rapid IV infusion of balanced salt solution or repositioning of the patient (Burkard and Vacchiano, 2010; Stoelting and Hillier, 2005a).

The local anesthetics most frequently used for epidural anesthesia are lidocaine, bupivacaine, and chloroprocaine. Ropivacaine and levobupivacaine are newer local anesthetics that may prove to be less cardiotoxic than bupivacaine and possess a larger therapeutic ratio. Although much of their pharmacologic profile is similar to that of bupivacaine, levobupivacaine and ropivacaine seem to possess more selective action for neural blockade (Burkard and Vacchiano, 2010; Stoelting and Hillier, 2005a). Depending on the concentration of anesthetic agent, effects can range from loss of sensory input to complete motor blockade. To verify that the anesthetic is not being injected into the subarachnoid space or into an epidural vein, a test dose of 3 to 5 ml of lidocaine with a 1:200,000 concentration of epinephrine is frequently used. Injected intravascularly, this test dose causes a transient tachycardia. If injected into the subarachnoid space, it produces a low level of spinal anesthesia. Complications associated with the use of local anesthetics in the epidural and subarachnoid spaces are unique to the agent used. Permanent neurologic sequelae have been reported when chloroprocaine

with a preservative was injected into the subarachnoid space. Bupivacaine is associated with pronounced cardiac toxicity if injected intravascularly (Burkard and Vacchiano, 2010; Stoelting and Hillier, 2005a). With epidural anesthesia, several complications can occur, including inadvertent dural puncture, subarachnoid injection, and vascular injection.

Inadvertent Dural Puncture. Inadvertent dural puncture with the epidural needle (a wet tap) can cause a PDPH. This headache is significant in about 50% of patients, and the intensity can be incapacitating. Treatment is essentially the same as that discussed under Spinal Anesthesia earlier in this chapter.

Subarachnoid Injection. Subarachnoid injection occurs if the needle or catheter is unintentionally inserted into the subarachnoid space. If a large volume of local anesthetic is injected as a bolus, it causes "total spinal" anesthesia. This condition is associated with a rapid onset of hypotension caused by vasodilation and profound bradycardia as the sympathetic nerves to the heart are blocked, causing a totally paralyzed patient. Treatment includes intubation, control of ventilation, support of blood pressure and the cardiovascular system, and administration of amnestic drugs until the block resolves. If properly managed, this problem is not life-threatening, but use of the test dose described previously and injection of only 3 to 5 ml at a time usually avert this problem. With patient movement over time, the epidural catheter may migrate through the dura. Therefore a small test dose should be given each time additional local anesthetic is injected through the catheter. In addition, each subsequent dose should be injected in increments of 3 to 5 ml each.

Vascular Injection. Injection of local anesthetic into an epidural vein may occur inadvertently with the initial dose or with subsequent injections. Intravenously injected bupivacaine is associated with cardiac arrest. Toxicity from other local anesthetics can cause sudden and profound hypotension, convulsions from effects on the CNS, and tachycardia if the solution contains epinephrine. Convulsions usually dissipate rapidly as local anesthetic redistributes throughout the body. Intravenous thiopental or a benzodiazepine may be given to reduce these effects. A vasopressor (e.g., ephedrine or phenylephrine) can be used to restore blood pressure. If the patient becomes paralyzed, intubation and ventilation may be required until the toxic effects are gone. Use of a test dose with each injection usually prevents these problems.

Peripheral Nerve Blocks

Peripheral nerves can be blocked effectively by injecting local anesthetic around them to provide adequate surgical anesthesia. Onset and duration of the block depend on the drug used and its concentration and volume, addition of epinephrine, and site of injection. Complications usually are caused by an inadvertent intravascular injection or an overdose of the local anesthetic. Rarely, nerve damage occurs from trauma caused by the needle or compression from the volume of local anesthetic injected.

Peripheral nerve blocks (PNBs) are an effective method to deliver analgesia and anesthesia, and have been used by surgeons and anesthesia providers since the late 1800s. However, in the twentieth century, PNBs were replaced with general anesthetics for their desired effect of total body anesthesia and analgesia. Ironically, the advent of ambulatory surgery created renewed interest in the use of PNBs.

With the exponential growth of ambulatory surgery and the demand for time and cost consciousness, the benefits of PNBs are many. Local anesthetics have quick onset of action, provide prolonged analgesia, and often do not require administration of powerful anesthetics that have undesired side effects. Patients are often discharged with less pain and less nausea and vomiting, report greater satisfaction with the quality of care received, and are spared the undesirable side effects of excessive opioids. PNBs are considered an essential aspect of contemporary multi-modal anesthesia.

Peripheral Nerve Anatomy and Physiology. The peripheral nervous system consists of 31 pairs of spinal nerves that exit between the vertebrae on each side of the body. These spinal nerves traverse the torso and innervate specific regions in order to coordinate within the CNS our ability to perceive cutaneous sensation and respond with synchronized motor reflexes. Peripheral sensory nerve impulses are initiated by noxious stimuli, such as a surgical incision. This stimulus creates an "action potential" that changes the electrical voltage traveling across the axonal membrane of the nerve by allowing influx of sodium ions (referred to as cellular depolarization). This creates a propagating electrical wave that conducts the sensory nerve impulse to the brain where it is then interpreted as pain. Local anesthetics work by blocking the opening of these sodium ion channels so that the nerve impulse does not travel back to the CNS and the patient does not perceive pain (Cousins and Bridenbaigh, 2009).

Common Peripheral Nerve Blocks

UPPER EXTREMITY—THE BRACHIAL PLEXUS. Spinal nerves leaving the cervical vertebrae, C5-T1, converge to form a bundle of nerves known as the brachial plexus. Each bundle of nerves innervates the right and left side of the neck and axilla. The brachial plexus divides further into branches that eventually terminate in the radial, ulnar, and median nerves. For example, the median nerve is released from impingement when a carpal tunnel procedure is performed.

PNBs of the brachial plexus are therefore performed for surgery of the shoulder, forearm, or hand. The different anatomic landmarks anesthesia practitioners use to perform a brachial plexus nerve block are the interscalene, supraclavicular, infraclavicular, or axillary sites. The choice of anatomic site for PNB depends on (1) the area of the arm undergoing surgery and (2) the surgical procedure being performed. As an example, for shoulder arthroscopy, an interscalene brachial plexus block is appropriate, whereas for carpal tunnel surgery an infraclavicular or axillary block suffices.

LOWER EXTREMITY. Lumbar and sacral spinal nerves, also exiting through each side of the vertebrae, eventually separate into the sciatic, femoral, popliteal, and tibial nerve roots that innervate the lower extremities. PNBs for the lower extremity are often performed for knee and foot procedures. For example, a femoral nerve block can be used for a knee arthroscopy while an ankle block (essentially a block of the deep and superficial peroneal, tibial, and sural nerves branches of the sciatic nerve) can be used for podiatric procedures (Hadzic and Vlodka, 2004).

PNB Equipment. To identify the correct injection site for the PNB, the anesthesia provider typically uses a nerve stimulator, sometimes with ultrasound guidance. The nerve stimulator creates an electrical current. The goal is to elicit a motor response from the nerve while applying the correct amount of voltage. Once the anesthesia provider isolates the desired nerves to be "blocked," the appropriate local anesthetic is carefully injected into tissue close to the nerve. The local anesthetic then inhibits the propagation of the nerve impulses to the CNS by blocking sodium ion channels. Depending on the desired site of action, PNBs can take from a few minutes to as long as 1 hour to achieve complete effect. The duration of the nerve block depends on the local anesthetic used.

Important Nursing Considerations

EXPECTED SIDE EFFECTS AND SPECIAL CARE CONCERNS. PNBs often have side effects. For example, with an interscalene block, patients may experience Horner syndrome (miosis, ptosis, and increased salivation) and may also have a unilateral phrenic nerve paralysis that causes breathing difficulty. These side effects may need special anesthesia attention depending upon their severity. All perioperative staff must be mindful of the fact that the patient with a PNB has lost the protective reflex of pain sensation. Therefore special care is required with patient positioning and padding pressure points, as is postoperative patient education regarding the risk of burns or falls, for example.

PREPARATION FOR ADVERSE EVENTS. PNBs are a safe method of anesthesia and analgesia delivery. There are, however, serious potential complications that all perioperative staff should understand and anticipate in the event of an emergency.

Local anesthetic toxicity results when an unsafe amount of a local anesthetic has been absorbed into the patient's bloodstream. This can occur either slowly from systemic absorption of a local anesthetic that is correctly injected into the tissue or immediately and catastrophically if the anesthetic is accidentally injected directly into a blood vessel. Signs of systemic local anesthetic toxicity often progress in a stepwise manner. Patients may initially report perioral numbness, a metallic taste in the mouth, ringing in the ears, visual disturbances, and/or dizziness. If toxicity progresses, or is immediate, the patient will likely have seizures, respiratory arrest, and/or cardiac arrest.

PNBs should only be performed in areas that are well equipped to handle emergencies—that is, areas having access to an external oxygen source, vacuum suction, ventilation bag and mask, laryngoscope, ETT tubes, monitoring equipment, and resuscitation drugs to treat hypotension, bradycardia, and seizures. Along with increased use of PNBs have come increased reports of cardiac arrest from accidental intravascular injection. There are new potentially lifesaving treatments that all perioperative staff must know (Research Highlight).

RESEARCH HIGHLIGHT

Lipid Infusion for Local Anesthetic Toxicity and Cardiac Resuscitation

IV local anesthetics work by blocking voltage-gated sodium ion channels that are essential for normal nerve impulse conduction. The result impedes transmission of painful stimuli. There are, however, voltage-gated sodium ion channels found in cardiac nerve cells. Bupivacaine, a commonly used local anesthetic agent, has been implicated as the causative agent for patients experiencing cardiac arrest following an accidental intravascular injection during a PNB. Recent research findings and more than 25 case reports between 2006 and 2008 suggest an effective adjunct to standard cardiac resuscitation procedures for bupivacaine toxicity. An infusion or bolus of a 20% lipid emulsion, such as 20% Intralipid (Baxter Pharmaceuticals), has been shown to help with successful cardiac resuscitation and returning patients to a normal cardiac rhythm. While the exact mechanism of action remains unknown, experts have suggested that lipids simply bind-up and provide a reservoir for bupivacaine, thus allowing the cardiac sodium ion channels to become "unblocked" (Sirianni et al, 2008). Warren and colleagues (2008) discuss a case report of a 60-year-old patient who was successfully resuscitated with IV lipid infusion following cardiovascular collapse after a supraclavicular brachial plexus block with bupivacaine and mepivacaine. After analysis and a literature review, they recommend "lipid rescue for presumed local anesthetic toxicity should be considered during resuscitative efforts in prolonged CPR refractory to standard ACLS protocols." They further recommend availability of 20% lipid emulsion in any site where local anesthetics are administered.

Modified from Sirianni et al: Use of lipid emulsion in the resuscitation of a patient with prolonged cardiovascular collapse after overdose of bupropion and lamotrigine, *Ann Emerg Med* 51(4):412-415, 2008; Warren JA et al: Intravenous lipid infusion in the successful resuscitation of local anesthetic-induced cardiovascular collapse after supraclavicular brachial plexus block, *Anesth Analg* 106(5):1578-1580, 2008.

Intravenous Regional Anesthesia

IV regional anesthesia was first described by Bier in 1908 and is frequently called a *Bier block*. Although it can be used on a lower extremity, it is used more often on the upper extremities. It is highly reliable and easy to accomplish.

A small IV catheter is inserted as distal as feasible, and a single-cuffed or double-cuffed pneumatic tourniquet is placed around the limb proximal to the surgical site. The limb is raised and exsanguinated by wrapping it with an Esmarch bandage. The tourniquet is inflated to approximately 100 mm Hg above the patient's systolic blood pressure, and the Esmarch bandage removed. Approximately 50 ml of 0.5% lidocaine is injected through the catheter. Onset of anesthesia is rapid and lasts until the tourniquet is deflated.

When a double-cuffed pneumatic tourniquet is used, the proximal cuff is initially inflated. When the patient experiences discomfort from the cuff pressure (usually about 35 to 40 minutes after cuff inflation), the distal cuff, which is located over an anesthetized area, is inflated and the proximal cuff deflated. The proximal cuff remains inflated until the distal cuff has been inflated to prevent loss of the IV anesthetic from the limb. Two single-cuffed tourniquets can be used instead of a double-cuffed tourniquet. If the patient experiences pain from the tourniquet, an IV analgesic or sedative can be used to supplement the block (Stoelting and Hillier, 2005a).

Although problems can occur from an overdose or toxic reaction to lidocaine, these are rare if the tourniquet has been inflated more than 20 minutes. The risk is minimized by intermittently deflating the cuff for a few seconds at a time for several cycles when the surgical procedure concludes. This

reduces the transient peak blood level of local anesthetic in the CNS and heart. Loss of pneumatic pressure in the tourniquet can cause a toxic reaction and loss of anesthesia.

MONITORED ANESTHESIA CARE (MAC)

Surgeons can safely accomplish minor and even some major procedures with a peripheral nerve block or when the surgical site is infiltrated with a local anesthetic. These techniques can be employed for normal, healthy individuals as well as for sicker, unstable patients who otherwise would require extensive invasive monitoring and pharmacologic management if general anesthesia were employed. For sicker, unstable patients, relative risks and benefits of MAC versus general anesthesia must be weighed.

During MAC, the anesthesia provider may supplement the local anesthetic with an IV analgesic (e.g., fentanyl) and with sedative and amnestic drugs (e.g., midazolam or propofol). In addition, the anesthesia provider carefully monitors vital signs, respiratory and cardiovascular status, and positioning, and may give supplemental low-flow O_2. Depending on the clinical situation, the anesthesia provider may have to induce general anesthesia or use one of the regional techniques described previously if a greater degree of anesthesia becomes necessary.

CONSCIOUS SEDATION/ANALGESIA

Conscious sedation/analgesia refers to IV administration of certain sedatives and analgesics that produces a condition in which the patient exhibits a depressed level of consciousness but retains the ability to independently maintain a patent airway and respond appropriately to verbal commands or physical stimulation. The anesthesia provider is not involved in the patient's care. Perioperative nurses who have additional training and demonstrated competencies in (1) administering medications to achieve conscious sedation/analgesia and (2) patient monitoring (AORN, 2009b) perform these functions. Objectives for a patient receiving conscious sedation/analgesia include alteration of mood, maintenance of consciousness, enhanced cooperation, elevation of pain threshold, minimal variation of vital signs, some degree of amnesia, and rapid and safe return to activities of daily living.

Selection of patients for conscious sedation/analgesia should be based on established criteria developed by an interdisciplinary team. Patients must be thoroughly assessed physiologically and psychologically before the procedure. Assessment should include a review of physical exam findings; current medications; existing allergies; current medical problems; history of smoking, hazardous alcohol intake, or substance abuse (Tonnesen et al, 2009); current chief complaint; baseline vital signs, height, and weight; age; emotional state; any communication deficits; and the patient's perceptions of conscious sedation/analgesia. Monitoring methods for patients receiving conscious sedation, medications administered, and interventions initiated must be within the scope of nursing practice as defined by the respective state board of nursing. If the nurse does not feel comfortable managing the care and monitoring of a particular patient, the attending physician and an anesthesia provider should be consulted. During the past few years administration of propofol by nurses has been advocated. The FDA continues to include a "black box" warning that it should only be administered by trained anesthesia providers. The AANA and the ASA continue to support the FDA view for patient safety reasons. Even in the hands of a trained anesthesia provider, propofol can affect respirations, possibly requiring advanced airway management.

When monitoring a patient receiving conscious sedation/analgesia, the nurse should have no other responsibilities that would leave the patient unattended or compromise continuous patient monitoring. The nurse must be clinically competent in the use of monitoring equipment and oxygen-delivery devices, medications used for conscious sedation/analgesia and resuscitation, and airway management. Advanced cardiac life support (ACLS) certification of nurses responsible for monitoring patients receiving conscious sedation/analgesia may be required by some healthcare institutions. If not, healthcare professionals with ACLS skills should be readily available to render support if needed in an emergency situation (AORN, 2009b).

The nurse who administers conscious sedation/analgesia medications should know usual dosages, contraindications, interactions with other medications, onset and duration of action and desired effects, adverse reactions, and emergency management techniques. Benzodiazepines (e.g., diazepam, midazolam) and opioids (e.g., fentanyl, meperidine hydrochloride) are used for conscious sedation/analgesia (AORN, 2009b). Equipment that should be ready for use in the room where conscious sedation/analgesia is administered includes a noninvasive blood pressure device, an ECG, a pulse oximeter, oxygen-delivery devices, and suction. An emergency cart with appropriate resuscitative medications and equipment (e.g., a defibrillator) should be immediately available.

An IV access line is established to administer conscious sedation/analgesia medications and emergency medications and fluids if needed. Parameters monitored during conscious sedation/analgesia are respiratory rate, cardiac rate and rhythm, blood pressure, oxygen saturation, level of consciousness, and skin condition.

Nursing documentation should include preprocedure assessment; dosage, route, time, and effects of all medications administered; type and amount of fluids administered; physiologic data from continuous monitoring at 5- to 15-minute intervals and on significant events; level of consciousness; nursing interventions initiated and the patient's responses; and any untoward significant patient reactions and their resolution (AORN, 2009b).

Postprocedure monitoring should be provided until the patient has returned to preprocedure baseline parameters. Patients and family members or significant others should receive appropriate oral and written discharge instructions and be able to verbalize understanding (teach back in their own words). It is helpful if discharge instructions are given after the procedure because conscious sedation/analgesia medications may cause amnesia.

Discharge criteria should be established by an interdisciplinary team and should include adequate respiratory function, stable vital signs, return to preprocedure level of consciousness, intact motor reflexes, return of motor and sensory control, absence of protracted nausea, acceptable skin color and condition, absence of significant pain, and satisfactory surgical

site and dressing condition (when present). A responsible adult must accompany and drive the patient home.

LOCAL ANESTHESIA

The terms *local anesthesia, local,* and *straight local* are used interchangeably to describe the administration of an anesthetic agent to a specific area of the body by topical application, local infiltration, regional nerve block, or "field" block. Local anesthetics are administered by the surgeon. In addition, other physicians, such as cardiologists, pulmonologists, proctologists, and gastroenterologists, may perform local procedures in the OR suite. No anesthesia provider is involved.

Hospitals and ambulatory surgery centers establish interdisciplinary guidelines for selecting patients who are appropriate for local anesthesia procedures and for patient monitoring criteria. Decisions to monitor the patient receiving local anesthesia, parameters that need to be monitored, and the frequency of observation and monitoring are tailored to the patient, the surgical procedure, and medications used. Patients receiving local anesthetics are assessed preoperatively and monitored continually by the perioperative nurse during the procedure.

Local anesthesia usually is employed for minor, short-term surgical, diagnostic, or therapeutic procedures. As the patient does not lose consciousness, local anesthesia is frequently preferred when the patient's cooperation is necessary for the procedure. Local anesthesia is economical and eliminates the undesirable effects of general anesthesia. Adverse reactions, however, may occur from large doses of local agents. If the agent enters the bloodstream directly, convulsions, circulatory and respiratory distress, cardiovascular collapse, or even death can result.

The surgeon chooses local anesthetics based on desired duration of action, surgery site, potency potential, and the patient's physical status. Topical agents, such as cocaine hydrochloride, tetracaine, or lidocaine, may be applied to mucous membranes of the nose, throat, trachea, and urethra. Lidocaine 0.5% to 2%, with or without epinephrine, is the drug most commonly used for local anesthesia, although bupivacaine (Marcaine) may also be selected. Epinephrine may be added to the local anesthetic agent for vasoconstricting properties in the area injected, slower rate of absorption of the local anesthetic agent, and lower incidence of toxicity. Adding epinephrine allows longer duration of action for the local agent by reducing blood flow to the area injected. Epinephrine is used with caution in patients with hypertension, diabetes, or heart disease. A general recommendation for a local anesthetic such as lidocaine is that no more than 50 ml of a 1% solution, or 100 ml of a 0.5% solution, be injected per hour. For maximum adult dosages, see the Surgical Pharmacology box, pp. 124-127. All local anesthetic containers or syringes should be clearly labeled when on and off the sterile field.

Preoperatively, the perioperative nurse reviews the patient's history, physical examination findings, and results of any ordered laboratory or other diagnostic tests. Patients are assessed carefully to determine their physiologic baseline, any allergies (to medications, latex, adhesive tape, or other substances), and emotional status. An IV infusion is started before the procedure because adequate venous access can be crucial in life-threatening situations when resuscitative drugs must be given immediately.

The perioperative nurse must be clinically competent in using monitoring equipment, placing equipment connections, and interpreting data. Most often, intraoperative monitoring minimally includes heart rate and regularity, respiratory rate, and mental status. Additional monitoring parameters are based on the patient's condition and include blood pressure, skin condition, and oxygen saturation status (AORN, 2009b). Any changes in the patient's condition should be communicated immediately to the surgeon.

The perioperative nurse must also be familiar with the drugs administered during the procedure, usual dosages, limits on rate of injection and maximum dosage (usually stated on a per-kilogram basis), duration of action, physiologic and psychologic changes expected, normal and abnormal reactions, and appropriate action to take if untoward reactions occur. The nurse should document dosage, route, and time of administration of all local anesthetics administered. The patient is observed for side effects, such as CNS disturbances, cardiovascular problems, hypersensitivity to medication, and toxic reaction resulting from high levels of the local anesthetic. Emergency drugs, suction apparatus, and resuscitation equipment should be readily available. Symptoms of adverse drug reactions include restlessness, unexplained anxiety or fearfulness, diaphoresis, nausea, palpitations, disturbed respiration, pallor or flushing, syncope, and convulsive movements. Signs and symptoms of allergic reaction include urticaria, tachycardia, laryngeal edema resulting in breathing difficulties, nausea, vomiting, and elevated temperature. In some instances, anaphylactoid symptoms, including severe hypotension, can occur. If any significant change occurs in the patient's physiologic or psychologic status, the nurse should notify the physician immediately. Good communication is essential for optimal patient care (National Quality Forum, 2009). As the patient is awake during the procedure, extraneous or irrelevant conversation and noise are kept to a minimum.

Documentation of care provided to a patient receiving a local anesthetic should be consistent with the AORN's *Recommended Practices for Documentation of Perioperative Nursing Care* (AORN, 2009a). This includes all medications administered, including their dosages, routes, and times of administration; patient monitoring performed; and results of patient care procedures.

After the procedure, the patient's postoperative status is assessed carefully. This evaluation and any special patient needs are documented on the chart, and a report is conveyed to the receiving unit before the patient's transfer (if the patient is going to a recovery area). The hand-off report should include type and amount of drugs given and any adverse reaction noted, site and condition of the IV infusion (if applicable), type and amount of solution infused in the OR, range of intraoperative vital signs, surgical procedure performed, and condition of the dressing. Any special postoperative orders, allergies, and a general statement of the patient's tolerance of the procedure are included. The patient may be transferred to the day-surgery and discharge area or returned directly to a hospital room. Local anesthesia patients are rarely transferred to the PACU for recovery or observation.

PAIN MANAGEMENT

Many anesthesia providers have applied their expertise in analgesia and regional anesthesia to the management of acute and chronic pain. Chronic pain is often multifactorial and may occur after a discrete injury (or trauma), amputation, laminectomy, or

other surgical procedure. It also may result from prolonged repetitive stress, such as "low back pain." Chronic pain frequently has complex psychologic components unrecognized by patients or by individuals closely associated with patients. Diagnosis and treatment of such chronic pain problems usually involve multiple medical disciplines and prolonged management.

Acute perioperative pain is a different problem. Traditionally, postoperative pain has been treated with intramuscular (IM) narcotics every 3 to 6 hours as needed. This treatment is often associated with undesirable side effects, including oversedation, respiratory depression, deep vein thrombosis (DVT) secondary to decreased mobility, and variable degrees of pain relief. Other pain-management modalities are now used successfully. Patient-controlled analgesia (PCA) uses a programmable electronic pump that can continuously infuse a small amount of IV narcotic (at a basal rate); in addition, the patient can administer a predetermined bolus "on demand." Safety interlocks limit the frequency of boluses and total dose per hour (Faut-Callahan and Hand, 2010).

When spinal or epidural anesthesia is employed for a surgical procedure, a small amount of preservative-free narcotic, such as fentanyl, sufentanil, or morphine, may be added to the local anesthetic mixture. The narcotic acts via central opiate receptors and provides analgesia for 24 to 36 hours.

Continuous epidural analgesia also may be used for prolonged postoperative pain management. This technique is employed for extensive procedures, including total hip or knee replacements; knee reconstruction; and major abdominal, thoracic, or gynecologic operations. In addition, it can be used for acute trauma, such as multiple rib fractures.

Typically, a lumbar or thoracic epidural catheter is inserted before surgery, covered with a transparent occlusive dressing, and injected with local anesthetic. Given the duration, manipulation, or positioning required for the operative procedure, general anesthesia is often used for patient comfort. The epidural greatly reduces the analgesic requirements of general anesthesia. For postoperative pain control, the epidural infusion of local anesthetic is usually one eighth to one sixteenth of the concentration used for surgical anesthesia (Faut-Callahan and Hand, 2010). A small dose of preservative-free narcotic, such as fentanyl, sufentanil, or morphine, is usually added to enhance analgesia. After surgery, the infusion rate is adjusted to provide analgesia during early recovery. As the level of pain decreases over time, the infusion rate is reduced. The catheter is removed after 2 to 5 days to minimize the risk of infection. Benefits of epidural analgesia for acute postoperative pain include good analgesia with minimal sedation, early ambulation and physical therapy, and excellent patient satisfaction. Possible side effects include nausea, pruritus, and areas of slight numbness. These are controlled by using drugs such as diphenhydramine (Benadryl) or naloxone (Narcan) and by adjusting the infusion rate. A nonsteroidal antiinflammatory drug (NSAID), such as ketorolac (Toradol), is given for any "breakthrough pain" instead of increasing the epidural infusion.

A single caudal injection is often used in pediatric patients having surgery of the lower abdomen, pelvis, or lower extremities. It usually is administered after induction of general anesthesia, and a long-acting local anesthetic, such as bupivacaine with epinephrine, typically is used. This injection provides good analgesia for 8 to 24 hours postoperatively and greatly decreases intraoperative requirements for general anesthesia. If the procedure requires prolonged recovery, a lumbar epidural catheter can be placed intraoperatively. Postoperatively, management is similar to that for adult patients, although for younger patients the level of analgesia and the presence of side effects must be assessed by someone other than the patient (Faut-Callahan and Hand, 2010; Tobias and Litman, 2004).

Epidural infusions also have been used for patients experiencing the intense pain of terminal malignancies. These patients may experience pain that is so severe that parenteral analgesics provide inadequate pain relief and produce deep respiratory depression. Epidural infusions for prolonged periods have been used in these patients. Transdermal fentanyl patches also may be used for these patients and for patients experiencing chronic pain.

TEMPERATURE CONTROL

Monitoring temperature is an important part of anesthesia monitoring. Temperature monitoring was not routinely practiced until malignant hyperthermia (MH) was described in the 1960s. This complication eventually led to routine monitoring of body temperature in the OR (Kossick, 2010). Increased attention has been directed toward intraoperative maintenance of normal temperature ranges (normothermia) for pediatric and adult patients. Hypothermia is the most common disorder of temperature homeostasis. It may be intentional or unintentional. Unintentional hypothermia can cause patient discomfort, untoward cardiac events, adrenergic stimulation, impaired platelet function, altered drug metabolism, delayed emergence from anesthesia, and impaired wound healing (Burns et al, 2009).

Risk factors for developing inadvertent hypothermia include age extremes (elderly and pediatric patients), co-morbidity, length of surgical procedure, cachexia, fluid shifts, cold irrigating fluids, and general and regional anesthesia. Agents such as skeletal muscle relaxants interfere with shivering mechanisms. Agents that depress the CNS decrease autonomic reflexes that ordinarily autoregulate body temperature. Vasodilation, which accompanies various anesthetic agents, including inhalation agents, enhances heat transfer from the core to the periphery, where it is lost to the atmosphere. Cold, unhumidified inhalation gases further promote hypothermia through convection and evaporation.

Room temperature can be increased and infrared warming lamps used for pediatric patients. Fresh-gas flow rates of cool, dry anesthetic gases can be lowered. A heat and moisture exchanger (e.g., Humidivent) helps to maintain the heat and moisture of inspired gases. A variety of IV fluid warmers are available to warm crystalloid solutions or refrigerated blood products. Some of these units, originally designed for major trauma procedures, warm fluids at flow rates of 500 ml/min. Units that blow heated air onto the upper or lower body surface also are available. These units are effective in maintaining body temperature even during a long abdominal procedure and can be used subsequently in the PACU. Forced-air warming units must be used according to manufacturers' instructions. They must be used with the appropriate disposable patient warming blankets and should *not* have the hose inserted under surgical drapes to warm the patient (this directs the heat on the patient, with the risk of a burn, rather than filtering it through the blanket). The blanket air temperature is typically a couple of degrees lower than that coming directly from the hose because heat is dissipated as it moves through the blanket (Research Highlight).

RESEARCH HIGHLIGHT

Preventing Perioperative Hypothermia

Current evidence-based clinical practice guidelines detail numerous benefits of maintaining a patient's normal body temperature (normothermia) during delivery and recovery from anesthesia. Benefits identified include increased patient satisfaction, decreased surgical site infections, decreased coagulopathies, improved circulation, and normalization of drug metabolism and clearance. As a result of these benefits, the American Society of PeriAnesthesia Nurses (ASPAN), the Association of periOperative Registered Nurses (AORN), and the American College of Cardiology (ACC) have recommendations for maintaining normothermia.

Researchers today focus on new questions that seek to optimize thermal management of perioperative patients. Sessler (2008) reviewed different modalities for temperature monitoring and suggested methods to improve accurate and consistent measurements of a patient's core temperature. Wadhwa and colleagues (2007) reviewed the efficacy of traditional forced-air warming devices compared to circulating water devices on patient rewarming after general anesthesia. A novel research question posed by Andrzejowski and colleagues (2008) asked: "Will pre-warming a patient prior to surgery in the preoperative holding area actually help in preventing the occurrence of inadvertent perioperative hypothermia?" They implemented a prospective randomized trial that assigned patients to one of two cohorts: patients prewarmed using a forced-air warming blanket designed to be worn as a gown by the patient, or patients who received the current standard of care (i.e., no prewarming in the preoperative area).

The study by Andrzejowski and colleagues (2008) suggested that prewarming a patient before surgery with a forced-air warming device was statistically significant in reducing the incidence of inadvertent perioperative hypothermia after induction of general anesthesia at the 60- and 80-minute postinduction marks (p-value <0.05). The authors suggest that prewarming surgical patients may improve vascular circulation and tissue oxygenation, which may reduce rates of postoperative infections. The benefits of prewarming, however, remain to be validated in multiple studies and are considerations for future research.

MALIGNANT HYPERTHERMIA (MH)

First identified in the late 1960s, MH is a rare, life-threatening complication that may be triggered by drugs commonly used in anesthesia. Inhalational anesthetics and succinylcholine are the most frequently implicated triggering agents. Trauma, strenuous exercise, or emotional stress also may induce MH. It is multifactorial and genetically transmitted as an autosomal dominant trait with variable expression in affected individuals (Hernandez et al, 2009). The incidence of MH is increased in patients with central core disease (a congenital myopathy) and some muscular dystrophies (Karlet, 2010; Malignant Hyperthermia Association of the United States [MHAUS], 2005; Theroux, 2004).

The syndrome begins with a hypermetabolic condition in skeletal muscle cells that involves altered mechanisms of calcium function at the cellular level. Characteristics include cellular hypermetabolism resulting in hypercarbia, tachypnea, tachycardia, hypoxia, metabolic and respiratory acidosis, cardiac dysrhythmias, and elevation of body temperature at a rate of 1° to 2° C every 5 minutes. Increase in body temperature is a late manifestation of MH. These signs may occur during induction or maintenance of anesthesia, although MH can occur postoperatively or even after repeated exposures to anesthesia. It is seen most frequently in children and adolescents (Karlet, 2010; MHAUS, 2005; Theroux, 2004). The signs and symptoms associated with MH are listed in Box 4-3.

It is important to remember that MH is a rare, multifaceted syndrome and can have variable clinical presentations. Many of the signs and symptoms associated with MH can have other causes. Other disorders, such as neuroleptic malignant syndrome (NMS), may have similar presentations. NMS occurs after use of neuroleptic drugs, such as haloperidol, and is characterized by muscular rigidity, akinesia, hyperthermia, and autonomic dysfunction. As MH is such a life-threatening disorder, many anesthesia providers initiate a treatment protocol when some of these early signs and symptoms occur that cannot otherwise be readily explained.

Time is crucial when MH is diagnosed. All OR and anesthesia personnel should be familiar with the protocol for its management. In the past, mortality ranged up to 80%, but the immediate infusion of dantrolene (Dantrium) and

BOX 4-3

Signs and Symptoms Often Seen with Malignant Hyperthermia

- Hypercarbia
- Tachycardia
- Tachypnea (may not be seen in a paralyzed patient)
- Muscle stiffness or rigidity
- Hypoxia and dark (desaturated) blood in operative field
- Unstable or elevated blood pressure
- Cardiac dysrhythmias
- Changes in CO_2 absorbent (temperature, color)
- Metabolic and respiratory acidosis
- Peripheral mottling, cyanosis, or sweating
- Rising body temperature (1° to 2° C every 5 minutes)
- Myoglobinuria
- Hyperkalemia, hypercalcemia, lactic acidemia
- Pronounced elevation in creatine kinase level

proper treatment have reduced the mortality to about 7%. Dantrolene is a hydantoin skeletal muscle relaxant that also has effects on vascular and heart muscle. In addition to dantrolene, the major modalities of treatment include cooling the patient with ice packs and cold IV solutions, administering diuretics, treating cardiac dysrhythmias, correcting acid-base and electrolyte imbalances, and monitoring fluid intake and output and the body temperature. Many hospitals maintain an emergency MH kit or cart that contains the drugs, laboratory tubes, other supplies, and instructions to treat MH in the OR area. The location of the iced or cold saline and other equipment also should be listed with the emergency kit. Chilled saline is often kept in the refrigeration unit for blood products (Karlet, 2010; MHAUS, 2005). The Rapid Response Team box presents an outline for emergency treatment of MH. The Malignant Hyperthermia Association of the United States (MHAUS) has names of on-call physicians available for consultation in MH emergencies at 1-800-MH-HYPER (1-800-644-9737). For patient-referral or nonemergency calls, 1-607-674-7910 should be used.

Patients known or suspected to have MH can be anesthetized with minimal risk if appropriate precautions are taken. If the syndrome is suspected, a muscle biopsy specimen should be obtained to make a diagnosis before the patient is electively anesthetized (Dixon and O'Donnell, 2006). For their own safety, relatives of persons with MH should be evaluated for the presence of the syndrome (MHAUS, 2005). A molecular genetic diagnostic test determines risk by means of a DNA analysis obtained from a blood sample (Litman and Rosenberg, 2005). It does not, however, replace muscle biopsy.

PERIOPERATIVE NURSING CONSIDERATIONS

Care of the surgical patient is a cooperative effort, and perioperative personnel should function as a smooth, well-coordinated team. As part of conducting the preoperative patient assessment and developing the plan of care, the perioperative nurse participates with the anesthesia provider in the preoperative verification process. As part of this process, the nurse checks the chart to verify the patient's identity, the surgeon,

RAPID RESPONSE TEAM

Rapid response teams (RRTs) are ordinarily called by the bedside nurse or other clinician when the patient's condition begins to deteriorate or there is an emergent crisis. In OR settings, there are occasions when the perioperative nurse or anesthesia provider triggers the RRT call to summon assistance in stabilizing an at-risk patient, such as the one in MH crisis. The RRT and surgical team members will follow the lead of the anesthesia provider in facilitating the following:

1. Immediately discontinue all triggering agents (inhalational anesthetics and succinylcholine).
2. Terminate surgery if possible, or continue with safe anesthetic drugs.
3. Hyperventilate with 100% O_2 at highest flow rate. It is not necessary to change any anesthesia equipment.
4. Immediately give dantrolene sodium (Dantrium) 2.5 mg/kg rapidly through large-bore IV, if possible. Repeat until the signs of malignant hyperthermia (MH) are controlled. Sometimes more than 10 mg/kg (up to 30 mg/kg) is necessary.
5. Give sodium bicarbonate IV to correct the metabolic acidosis. Refer to arterial blood gas (ABG) values to determine dosage. If ABG results are not available, consider administering 1 to 2 mEq/kg IV.
6. If the patient is hyperthermic (>39° C), begin active cooling.
   a. Infuse cold saline IV.
   b. Lavage the stomach, bladder, rectum, and open body cavities as feasible.
   c. Cool the body surface with a hypothermia blanket. Rub with cold, wet towels or ice.
   d. Monitor the temperature to avoid hypothermia. Stop cooling when temperature is 38° C.
7. Cardiac dysrhythmias usually resolve with correction of acidosis and hyperkalemia. If not, antidysrhythmic agents, such as procainamide 3 mg/kg (maximum 15 mg/kg), may be used. Avoid calcium-entry blockers because they may cause hyperkalemia and cardiovascular collapse.
8. Closely monitor temperature, $ETCO_2$, arterial or central venous blood gases, urine output, K^+, Ca^{++}, and coagulation studies. Insert a urinary catheter. Consider inserting an arterial line and a central venous or pulmonary arterial (PA) catheter.
9. Hyperkalemia is common. Treat with hyperventilation, sodium bicarbonate, or 10 units of regular insulin in 50 ml of 50% dextrose (D_{50}) IV titrated to K^+ level, or regular insulin 0.15 unit/kg in D_{50} 1 ml/kg. Life-threatening hyperkalemia also may be treated with calcium (e.g., 2.5 mg/kg $CaCl_2$).
10. Maintain urine output >2 mg/kg/hr. Consider volume of urine output to determine need for mannitol or furosemide administration.
11. Children <10 to 12 years old who have sudden cardiac arrest without hypoxia after succinylcholine is given may have subclinical muscular dystrophy. Treat for acute hyperkalemia first. Give $CaCl_2$ concomitant with other treatments listed in step 9.
12. Transfer patient to intensive care unit (ICU) when stable. Monitor at least 24 hours for recurrence of MH and for late complications.
13. Administer dantrolene 1 mg/kg IV every 6 hours for 24 to 48 hours; then dantrolene 1 mg/kg every 6 hours for 24 hours may be given orally as necessary.
14. Monitor core body temperature (continuously), ABG, K^+, Ca^{++}, creatine kinase (CK), serum and urine myoglobin, and coagulation studies until values return to normal.
15. Counsel the patient and family about MH and further precautions. Refer the patient to MHAUS, and submit an Adverse Metabolic Reaction to Anesthesia (AMRA) report to the North American Malignant Hyperthermia Registry at 1-888-274-7899.

Modified from Cherry K et al: Developing and evaluating a trigger response system, *Jt Commiss J Qual Patient Safety* 35(6):331-338, 2009; Malignant Hyperthermia Association of the United States: *Emergency therapy for malignant hyperthermia, May 2008*, available at www.mhaus.org. Accessed May 25, 2009. and the scheduled procedure; confirms that the operative and anesthesia permits are properly signed; identifies and communicates any patient allergies; ensures that the surgical site is marked; and ensures that current reports of laboratory tests and diagnostic studies are complete and in the chart.

In many OR suites, a preoperative preparation or *holding area* is used for insertion of arterial, central venous, or pulmonary arterial catheters and placement of epidural catheters or peripheral nerve blocks. Nursing personnel from the OR, PACU, or anesthesiology department may staff this area. The purpose of this area is to improve patient care delivery, optimize flow of patients, and provide supportive patient care.

A patient should never be left alone in the OR suite. When an anesthetized patient is in the OR, a perioperative nurse should always be immediately available to provide assistance if needed. During the insertion of IV, arterial, central venous, or pulmonary arterial catheters, the nurse assists as required.

During induction of anesthesia, particularly with urgent and emergency surgical procedures, the patient is presumed to have a "full stomach." The perioperative nurse should be ready to apply cricoid pressure to prevent regurgitation of stomach contents and assist the anesthesia provider in visualizing the vocal cords. When cricoid pressure is used to prevent aspiration, it should not be released until the intubation is accomplished, the cuff on the ETT is inflated, and proper placement of the ETT has been verified. When two anesthesia providers are present, one of them usually provides this support.

OR personnel should never move an unconscious patient without first coordinating the positioning or move with the anesthesia provider. When the patient is positioned for surgery, the perioperative nurse collaborates with the anesthesia provider in checking the arms and legs to ensure that no pressure points exist and that the extremities are appropriately positioned and padded (see Chapter 5). After positioning, prepping, and draping, the time-out is conducted and documented.

Before transporting the patient from the OR to the PACU, the circulating nurse, in most institutions, calls the PACU to give a preliminary status report of the patient's condition. This report includes the surgical procedure performed, type of anesthesia care provided, information specific to the patient's preoperative diagnosis and subsequent outcome related to intraoperative intervention, and any special equipment required (e.g., ventilator, T-piece, arterial pressure monitor). Postanesthesia recovery care and functions are described in Chapter 9.

CHAPTER 5

Positioning the Patient for Surgery

PAULINE ANNE HEIZENROTH

OVERVIEW

Proper patient positioning is essential for safe, successful surgical procedures. Many institutions require confirmation of the correct patient position during the time-out. An essential surgical team role, among others, is to ensure uncompromised and physiologically safe patient positioning. To do so, the team must understand the systems affected by positioning and their associated risks. Surgery is performed on all anatomic areas and the body may be positioned in multiple and sometimes unnatural configurations to expose a surgical site. Positioning, combined with anesthesia and its physiologic effects, can result in patient harm if safety factors are not paramount. This chapter discusses risks and prevention strategies associated with standard surgical positions.

The goals of surgical positioning include providing optimal exposure and access to the surgical site, maintaining body alignment, supporting circulatory and respiratory function, protecting neuromuscular and skin integrity, and allowing access to intravenous sites and anesthesia support devices. Meeting these goals while maintaining the patient's comfort and safety is the responsibility of every member of the surgical team.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

The perioperative nurse must understand thoroughly the anatomic and physiologic changes associated with positioning the patient. Numerous factors affect these changes: the particular surgical position; the length of time the patient is in that position; the OR bed, padding, and positioning devices used; the anesthesia given; and the operative procedure. These changes most frequently involve (1) the skin and underlying tissue, (2) the musculoskeletal system, (3) the nervous system, (4) the cardiovascular system, (5) the respiratory system, and (6) other vulnerable areas, such as the eyes, breasts, perineum, and fingers.

Skin and Underlying Tissue

The physical forces used to establish and maintain a surgical position can injure the skin and underlying tissue. These forces include *pressure, shear,* and *friction*. Additionally, OR conditions such as moisture, heat, cold, and negativity further increase the vulnerability of the skin and underlying tissues to injury.

- *Pressure* is the force placed on underlying tissue. Pressure can occur from the weight of the body as gravity presses it downward toward the surface of the bed. Pressure also results from the weight of equipment resting on or against the patient, such as drills, Mayo stands, surgical instruments, rigid edges of the OR bed or its attachments, or vertical posts for self-retaining retractors. Positioning devices, such as stirrup bars, leg or arm holders, and edges of laminectomy frames, can rest against the patient under tension. Surgical team members as well can lean on the patient and cause various degrees of pressure.
- *Shear* is the folding of underlying tissue when the skeletal structure moves while the skin remains stationary. A parallel force creates shear, unlike the perpendicular force created by pressure. This can occur when the head of the bed is raised or lowered and when the patient is placed in Trendelenburg's (head-down, supine) or reverse Trendelenburg's (head-up, supine) position. As gravity pulls the skeleton down, any stretching, folding, and tearing of the underlying tissues as they slide with the skeleton can occlude vascular perfusion, which can lead to tissue ischemia.
- *Friction* is the force of two surfaces rubbing against one another. Friction on the patient's skin can occur when the body is dragged across bed linen instead of being lifted. Friction can denude the epidermis and make the skin more susceptible to higher stage pressure ulcer formation, pain, and infection.
- *Moisture,* in excess, can worsen the effects of pressure, shear, and friction. Maceration occurs when prolonged moisture on the skin saturates the epidermis to the point that connective tissue fibers dissolve and can be easily torn apart. The skin becomes weakened and more vulnerable to the detrimental effects of external forces. In surgery, maceration can occur by the patient perspiring or lying in a pool of prep solution, blood, irrigation solution, urine, or feces. If this moisture also is located in an area of high pressure, the risk of pressure ulcer expansion into higher stages increases. If friction occurs on macerated skin, it becomes more vulnerable to denuding into the dermal layer. Every effort should be made to avoid pooling of prep solution. Prolonged exposure to the chemicals in the skin prep under the pressure area also can increase the likelihood of chemically induced contact dermatitis.
- *Heat* on the body surface can increase the metabolism of the tissue, and increase oxygen and nutritional demands. With every 1° C rise in skin temperature, there is a corresponding 10% rise in tissue metabolism (Aronovitch, 2007). If the tissue is also under pressure, constriction of vessels may impede blood flow enough that those demands are not met. Preexisting vascular impairment and the hypotensive effects of anesthesia may lead to further cellular tissue damage. This is especially true when the heated surface is under the

weight of the body. Excessive heat can cause thermal damage as well, resulting in burns.

- *Cold* environmental conditions, such as those found in the OR, can lead to hypothermia. Major surgery can cool the patient further by exposing the core of the body to cold air. A cold core temperature can lessen peripheral circulation, reducing oxygen delivery to the skin and underlying tissue.
- *Negativity* occurs when layers of materials, such as extra sheets or blankets, are placed over the OR mattress or padding. Extra linen can add rigidity and diminish the pressure-reducing properties of the mattress or padding. It is absorbent and abrasive and can produce high and inconsistent pressure. Eliminating extra layers of material between the patient and the OR bed mattress can reduce sacral pressure readings.

Pressure Ulcers. The National Pressure Ulcer Advisory Panel (NPUAP) defines a pressure ulcer as localized injury to the skin and/or underlying tissue, usually over a bony prominence, as a result of pressure or pressure in combination with shear and/or friction (NPUAP, 2007). A number of contributing or confounding factors also are associated with pressure ulcers; the significance of these factors is yet to be elucidated.

Pressure ulcers (also referred to as "pressure sores," "bed sores," and "decubitus ulcers") have been recognized and studied since the 1800s and possibly much earlier (History box). The impact that pressure ulcers have on patients and healthcare institutions is enormous. Patients often endure needless pain, suffering, and lost productivity. Despite all our advances in knowledge and technology to prevent pressure ulcers, their prevalence seems to be on the rise.

In October 2008, the Centers for Medicare & Medicaid Services (CMS) decided to halt reimbursing hospitals for many preventable hospital-acquired conditions which they called "never events." Among those conditions were stage III and IV pressure ulcers that develop after admission (CMS, 2008).

As it costs more to treat pressure ulcers than to prevent them, much research has focused on trying to determine the causes of pressure ulcer development and effective strategies to prevent them. Both *extrinsic* and *intrinsic* factors interact to contribute to the overall risk of developing pressure sores. Extrinsic factors are the physical forces and conditions to which the patient is subjected during surgery. These include pressure, including its intensity and duration; the anesthesia given and its effects; the particular surgery; the position itself; and safety measures used. *Intrinsic* factors are the health and the body structure of

HISTORY

Pressure Ulcers through the Centuries

One of the most emphasized aspects of surgical positioning has been that of maintaining tissue integrity by preventing pressure ulcers. In the past, terms for this condition included *decubitus ulcers* and *bedsores.* The early term, *decubitus,* is a Latin derivative of the word *cumbere,* which means "to lie down." In 1749 a Frenchman, Quesnay, coined the term *bedsores* to distinguish between sores caused by lying down and sores caused by other diseases. *Decubitus ulcer* and *bedsore* both implied that recumbency was the primary reason for this condition. The true source of the injury, *pressure,* can be achieved, however, through other means (e.g., sitting in a wheelchair; unrelieved pressure from a rigid surface, such as an appliance or cast). *Pressure sore* and *pressure ulcer* became the more accurate terms used to describe this condition.

Pressure ulcers are known to have been a problem as far back as the time of the pharaohs. Pressure ulcers were discovered on the mummy of an Egyptian princess. The earliest known documentation was from Hippocrates, about 400 BC, who described debridement of ulcers and healing by secondary intention. Much ahead of his time, Ambrose Paré, a sixteenth century French surgeon, documented how he successfully cured a pressure ulcer by encouraging and feeding his patient, providing pain relief and sleep medications, debriding the wound, and using pillows for pressure relief. In the 1800s Brown-Séquard identified pressure and moisture as causing ulceration of the skin, and Paget described these ulcers as the sloughing and death of a part resulting from pressure. In 1930 Lanis determined that 32 mm Hg is the average capillary pressure at arterial inflow. This value is still accepted as the threshold beyond which tissue trauma occurs. In 1946 Guttman appreciated the importance of relieving pressure in the bedridden patient by initiating a lifting and turning team on a spinal cord injury unit in England. In 1953 Husian showed that there was an inverse relationship between pressure and time for development of pressure ulcers. In studies using rats, he found that low pressures maintained for long periods produced more tissue damage than high pressures for short periods. He also found that the smaller the surface area over which the compressive force was applied, the greater was the damage to tissue. In 1959 Kosiak experimented with dogs and found that their tissue, when subjected to 60 to 70 mm Hg pressure for an average of 2 hours, began to show microscopic damage. Two-hour turning schedules were used to reduce pressure ulcer development in bedridden patients. In the late 1950s, a British nurse, Doreen Norton, developed and tested the first pressure ulcer assessment tool, the Norton scale. After she presented her study findings at a conference in 1962, the tool was widely disseminated and is still used today.

The findings of these early studies laid the foundation for many of the pressure ulcer definitions, descriptions, and prevention strategies practiced today. Continued research and technologic advances in support materials have focused on reducing the incidence of pressure ulcers originating in all settings, including the OR.

Modified from Allman RM: Pressure sores among the elderly, *New Engl J Med* 320:850-853, 1989; Black J et al: National Pressure Ulcer Advisory Panel's updated pressure ulcer staging system, *Dermatol Nurs* 19(4):343-349, 2007; Copeland-Fields LD, Hoshiko BR: Clinical validation of Braden and Bergstrom's conceptual schema of pressure sore risk factors, *Rehab Nurs* 14(5):257-260, 1989; Dealey C: *The care of wounds: a guide for nurses,* Ames, IA, 2005, Blackwell Publishing; Goodman T et al: Skin ulcers: overview and nursing implications, *AORN J* 50(1):24-37, 1990; Levine JM: Historical notes on pressure ulcers: the cure of Ambrose Paré, *Decubitus* 5(2):23-24, 26, 1992; Makleburst J: Pressure ulcers: etiology and prevention, *Nurs Clin N Am* 22(2):359-375, 1987; Melner SE, Lueckenotte AG: *Gerontologic nursing,* ed 3, St Louis, 2006, Mosby; Narcete TA et al: Pressure sores, *Am Fam Phys* 28(3):135-139, 1983; Souther SG et al: Pressure, tissue ischemia, and operating room pads, *Arch Surg* 107(10):544-547, 1973; Torrance C: *Pressure sores: aetiology, treatment, and prevention,* London, 1983, Croom Helm.

the patient. These compose an individual's risk and tolerance for the negative effects of pressure during surgery.

EXTRINSIC FACTORS. Pressure is the physical force responsible for pressure ulcer formation. Its intensity and duration affect the ultimate outcome of the tissue's integrity. An inverse relationship exists between pressure and time. The greater the pressure, the shorter the amount of time it takes to cause ischemic changes. Pressures greater than 32 mm Hg (capillary interface pressure) can occlude the flow of the arterioles, which nourish and oxygenate the tissue at the capillary level. An individual can endure relatively substantial pressure for a short time or lighter pressure for a longer time without sustaining tissue damage. A point will be reached, however, when tissue no longer can withstand the pressure (especially if it is >32 mm Hg), and cells die from lack of oxygen and nutrients. Such prolonged pressure can result in tissue ischemia manifested as a pressure ulcer.

The intensity of pressure depends on the surface area being compressed. The smaller the surface area to which pressure is applied, the greater the intensity of force (pressure per surface area). For example, compression of tissue between an external surface and a bony prominence of the body tends to create high forces of pressure in the local tissue surrounding that bony prominence. Pressure ulcers are most likely to develop around such protruding bony prominences as the heels, elbows, and sacrum in the supine position. Often the tissue injury is highest in the deep areas immediately adjacent to the bone. Deeper ischemia progresses outward toward the skin and, therefore, damage may not appear for several days. If pressure can be distributed more evenly over other surfaces of the body, the force of the pressure in those more vulnerable areas can be reduced. This theory encourages manufacturers to create OR mattresses, overlays, and padding materials that are designed to distribute the forces of pressure more evenly (see OR Beds later in this chapter for a more detailed discussion).

The longer a patient is on the OR bed, the greater is the risk of an OR-acquired pressure ulcer (Scott and Buckland, 2005; Schultz, 2005; Sewchuk et al, 2006; Aronovitch, 2007; Nixon et al, 2007; Walton-Geer, 2009). Duration on the OR bed is considered more a causative factor than is intensity of the pressure. Healthy individuals may tolerate high external pressures (e.g., 100 mm Hg) over bony prominences for short periods, but long, constant, and unrelieved pressure is most responsible for microscopic necrosis. Reduced pressures over extended periods still may cause tissue damage, particularly if tissue tolerance is diminished. Thus frequent repositioning of an immobilized patient can protect against the adverse effects of pressure. Repositioning a patient every 2 hours has long been the standard to diminish the negative effects of pressure in the immobile patent.

Patients in the OR, however, cannot be repositioned easily without jeopardizing access to the operative site and the integrity of the sterile field. Case-based exceptions to this would include limited repositioning of extremities and/or the head when such changes would not interfere with the procedure or sterile field. The perioperative nurse should anticipate such circumstances and ensure that preventive measures are taken to reduce pressure ulcer risks to the extent possible. Pressure-relieving OR mattresses or overlays may reduce pressure in dependent areas. Applying padding around rigid surfaces in contact with the patient and suspending vulnerable areas off the bed surfaces can reduce localized pressure. Because heels have been known to develop pressure ulcers even on pressure-relieving devices, the current Agency for Healthcare Research and Quality (AHRQ) *Clinical Practice Guidelines* recommend suspending the heels by placing a pillow under the length of the lower legs to raise the heels off the bed (AHRQ, 2009).

Patients undergoing regional or general anesthesia are at increased risk because normal muscle tone and pain sensations that enable the body to adjust itself in response to excess pressure are disabled. Patients often are placed in positions that they would not be able to tolerate comfortably if they were awake or even asleep, without the presence of anesthetics. Anesthesia also alters blood pressure, tissue perfusion, and oxygen and carbon dioxide exchange. All these anesthetic side effects can worsen the impact of pressure forces, particularly if other co-morbid conditions are present.

As noted, the hypotensive effects of anesthetic agents reduce tissue perfusion and thus reduce the exchange of oxygen and carbon dioxide. Aronovitch (2007) cites research in which diastolic pressures in surgical patients of less than 60 mm Hg have been associated with pressure ulcer development.

Hypothermia is the frequent result of the cool OR environment, exposure of external and internal body surfaces, and infusion and irrigation with unwarmed solutions. This causes peripheral vessels to constrict to conserve core temperature and increases the patient's heat metabolism. This heightened metabolism leads to increased tissue needs for oxygen, nutrients, and metabolic waste removal. When tissue is under pressure, these needs are not easily met. If a warming blanket is used under the patient in the area where pressures are greatest, tissue requirements become even more intense, and the impact of tissue ischemia may be more profound. Research has shown that the use of a warming blanket under the patient can be the greatest predictor of pressure ulcer development (Scott et al, 2001; Scott and Buckland, 2005; Aronovitch, 2007). Once the hypothermic patient emerges from general anesthesia and starts to shiver, oxygen requirements can rise 200% to 500%, increasing risk of myocardial infarction (Dunn, 2005).

Minimizing intraoperative hypothermia is clearly imperative. Ways to offset hypothermia in the OR and reduce its detrimental effects include using forced-air warming therapy over the patient to minimize unnecessary skin exposure and warming irrigation fluids, especially those used deep inside the body cavity. Intravenous fluids can be warmed by inserting a fluid warming coil or by placing most of the IV fluid tubing under the forced-air warming device (O'Connell, 2006).

The surgery being performed may itself have an impact on pressure ulcer development. Procedures that involve significant blood loss, extracorporeal circulation, and clamping of major vessels can contribute to the lack of blood flow to tissue under pressure. Patients who have cardiac surgery face a high risk for pressure ulcers. This is attributed to the diagnostic procedures these patients undergo, relatively long surgical times, and potential for restricted movement postoperatively (Sewchuk et al, 2006).

The positioning devices used also can increase pressure ulcer development. Rigid, unpadded objects that press against a body surface, such as stirrup bars, compressed beanbags, or rolled sheets, can cause tissue injury if the pressure is not relieved periodically.

Negativity, as noted earlier, can override the pressure-relieving capabilities of mattresses and padding (Schultz, 2005; Sewchuk et al, 2006; Aronovitch, 2007; Walton-Geer, 2009). Placing a warm blanket under a patient may be soothing initially, but if a surgical procedure is long, pressure to the bony prominences resting on the blanket will be higher than if only a sheet and draw sheet are used. Additionally, wrinkles and folds can cause further pressure points.

When a patient is placed in a shear-producing position (e.g., semi-Fowler) before being prepped and draped, measures should be taken to reduce shear forces. One technique is to lift the patient slightly, momentarily, to allow skin to realign with its surrounding skeletal structures. When the patient is placed in these positions *during* a surgical procedure, however, interventions to reduce shearing are limited. Reducing the time that shearing forces are in place is the best countermeasure to reduce tissue injury.

INTRINSIC FACTORS. Intrinsic factors can lower a patient's tissue tolerance to pressure and decrease the time and pressure required for tissue breakdown. Certain preexisting conditions are regarded as intrinsic risk factors for OR-induced pressure ulcer development. These conditions include respiratory and circulatory disorders, diabetes mellitus, anemia, malnutrition (serum albumin levels 3.5 g/dl or less), advanced age, body size (obesity; thin, frail build), body temperature (hypothermia), impaired mobility, and smoking (Scott and Buckland, 2005; Schultz, 2005; Sewchuk et al, 2006; Aronovitch, 2007; Nixon et al, 2007; Walton-Geer, 2009).

Various scales exist to determine pressure ulcer risk. One that is widely used is the Braden scale (Table 5-1). This scale scores a patient's potential to develop pressure ulcers based on various intrinsic factors. A scale such as the Braden scale can be used during the preoperative assessment to guide perioperative nursing interventions. The Evidence for Practice box explains how to interpret the Braden scale score and use the score to plan perioperative interventions. The Braden scale has been tested for reliability and validity. It cannot be shortened or altered without possibly lessening its reliability or accuracy. Copyright restrictions also prohibit alterations (Braden and Maklebust, 2005).

Assessment for pressure ulcer risk factors and development occurs during three periods: *preoperative, intraoperative,* and *postoperative*. Preoperative assessment for intrinsic risk factors using a scale such as the Braden scale can help to determine if the patient may be at higher risk for tissue breakdown and thus guide the nurse in the degree of padding and thermoregulation required. Consideration of expected OR events must be included in such assessments. Research indicates that *all* surgical patients should be considered at some risk because of variables inherent to the OR experience that often cannot be controlled. The most obvious variable is that the main method used for pressure ulcer prevention, changing the position of the patient, is often not an option in the OR. Other variables include the need for vasoactive medications, the patient's hemodynamic state, and the length of the procedure. The intraoperative assessment can include variables that occur during surgery that may have an impact on tissue perfusion, such as length of surgery, rigidity of positioning devices and length of time used, amount of blood loss, hypothermia, and anesthetic events such as ongoing diminished blood pressure. This information should be communicated in the hand-off report to the nurse in the postanesthesia care unit (PACU) or ambulatory recovery. Included in postoperative assessment would be inspections for altered tissue integrity. These inspections continue until discharge.

EVIDENCE FOR PRACTICE

Braden Scale Assessment of Pressure Ulcer Risk: Perioperative Implications

When using the Braden scale (see Table 5-1) to assess pressure ulcer risk, the tool should not be altered. Because the tool has been tested for reliability and validity in its complete form, minor changes to shorten or otherwise alter it may affect the accuracy of results. The lower the score, the greater the risk of developing pressure ulcers. The levels of risk according to scores are as follows (Braden and Maklebust, 2005):

- 19-23, not at risk
- 15-18, mild risk
- 13-14, moderate risk
- 10-12, high risk
- ≤9, very high risk

All surgical patients should be considered at risk for pressure ulcer development. If during the preoperative assessment a patient's score is 18 or lower, the patient is at an increased risk for skin breakdown. The perioperative nurse should do the following with *all* surgical patients:

1. Before positioning, assess skin for evidence of diminished tissue integrity, particularly in areas over bony prominences.
2. Pad and protect any fragile skin areas, and limit the amount of time these areas are under pressure to the extent possible.
3. Pad under or around all areas in contact with a firm surface.
4. For immobile patients, perform passive range-of-motion exercises every 1½ to 2 hours to any accessible limbs and slightly reposition the head if this does not interfere with the surgical procedure or the sterile drapes.
5. Reassess skin postoperatively, document findings, and communicate any changes to appropriate personnel.

During preoperative assessment, if the patient has a score of 18 or lower and an existing pressure ulcer (any grade/stage), has areas of skin breakdown over bony prominences, or has had muscle flap surgery, the perioperative nurse *additionally* should do the following:

1. Support and protect all existing wound dressings.
2. Arrange for the patient to be placed on a specialty bed designed for extreme pressure reduction postoperatively (e.g., alternating air mattress, flotation support bed).

STAGING. The NPUAP (2007) recently revised its guidelines for identification and staging of pressure ulcers:

- *Suspected deep tissue injury:* Deep tissue injury (DTI) may be characterized by a purple or maroon localized area of discolored intact skin or a blood-filled blister attributable to damage of underlying soft tissue from pressure and/or shear. Presentation may be preceded by tissue that is painful, firm, mushy, boggy, and warmer or cooler as compared to adjacent tissue.

  Further description. Deep tissue injury may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may evolve further and become covered by thin eschar. Evolution may be rapid, exposing additional layers of tissue even with optimal treatment.

TABLE 5-1

Braden Scale for Predicting Pressure Sore Risk

Category	1 Point per Square	2 Points per Square	3 Points per Square	4 Points per Square	Scores*
SENSORY PERCEPTION Ability to respond meaningfully to pressure-related discomfort	**COMPLETELY LIMITED** Unresponsive (does not moan, flinch, or grasp) to painful stimuli, owing to diminished level of consciousness or sedation, *or* limited ability to feel pain over most of body surface	**VERY LIMITED** Responds only to painful stimuli. Cannot communicate discomfort except by moaning or restlessness, *or* has a sensory impairment that limits ability to feel pain or discomfort over half of body	**SLIGHTLY LIMITED** Responds to verbal commands but cannot always communicate discomfort or need to be turned, *or* has some sensory impairment that limits ability to feel pain or discomfort in one or two extremities	**NO IMPAIRMENT** Responds to verbal commands. Has no sensory deficit that would limit ability to feel or voice pain or discomfort	**SCORE** _____
MOISTURE Degree to which skin is exposed to moisture	**CONSTANTLY MOIST** Skin is kept moist almost constantly by perspiration or urine. Dampness is detected every time patient is moved or turned	**MOIST** Skin is often but not always moist. Linen must be changed at least once a shift	**OCCASIONALLY MOIST** Skin is occasionally moist, requiring an extra linen change approximately once a day	**RARELY MOIST** Skin is usually dry. Linen requires changing only at routine intervals	**SCORE** _____
ACTIVITY Degree of physical activity	**BEDFAST** Confined to bed	**CHAIRFAST** Ability to walk severely limited or nonexistent. Cannot bear own weight or must be assisted into chair or wheelchair	**WALKS OCCASIONALLY** Walks occasionally during day but for very short distances, with or without assistance. Spends most of each shift in bed or chair	**WALKS FREQUENTLY** Walks outside room at least twice a day and inside room at least once every 2 hr during waking hours	**SCORE** _____
MOBILITY Ability to change and control body position	**COMPLETELY IMMOBILE** Does not make even slight changes in body or extremity position without assistance	**VERY LIMITED** Makes occasional slight changes in body or extremity position but unable to make frequent or significant changes independently	**SLIGHTLY LIMITED** Makes frequent, although slight changes in body or extremity position independently	**NO LIMITATIONS** Makes major and frequent changes in position without assistance	**SCORE** _____
NUTRITION Usual food intake pattern	**VERY POOR** Never eats a complete meal. Rarely eats more than one third of any food offered. Eats ≤2 servings of protein (meat or dairy products) per day. Takes fluids poorly. Does not take a liquid dietary supplement, *or* is NPO or maintained on clear liquids or IV for >5 days	**PROBABLY INADEQUATE** Rarely eats a complete meal and generally eats only about half of any food offered. Protein intake includes only 3 servings of meat or dairy products per day. Occasionally takes a dietary supplement, *or* receives less than optimum amount of liquid diet or tube feeding	**ADEQUATE** Eats more than half of most meals. Eats a total of 4 servings of protein (meat, dairy products) each day. Occasionally refuses a meal, but usually takes a supplement if offered, *or* is on a tube-feeding or total parenteral nutrition (TPN) regimen, which probably meets most nutritional needs	**EXCELLENT** Eats most of every meal. Never refuses a meal. Usually eats a total of ≥4 servings of meat and dairy products. Occasionally eats between meals. Does not require supplementation	**SCORE** _____
FRICTION AND SHEAR	**PROBLEM** Requires moderate to maximum assistance in moving. Complete lifting without sliding against sheets is impossible. Frequently slides down in bed or chair, requiring frequent repositioning with maximum assistance. Spasticity, contractures, or agitation leads to almost constant friction	**POTENTIAL PROBLEM** Moves feebly or requires minimum assistance. During a move, skin probably slides to some extent against sheets, chair, restraints, or other devices. Maintains relatively good position in chair or bed most of time but occasionally slides down	**NO APPARENT PROBLEM** Moves in bed and in chair independently and has sufficient muscle strength to lift up completely during move. Maintains good position in bed or chair at all times		**SCORE** _____
				Total Score	_____

*See Evidence for Practice box on page 147 for scoring implications.

- *Stage I:* A stage I pressure ulcer presents as intact skin with nonblanchable redness of a localized area, usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from that of the surrounding area.
  Further description. When a grading system is used, stage I is graded as a partial-thickness injury pressure ulcer. The area may be painful, firm, soft, and warmer or cooler compared to adjacent tissue. Stage I ulcers may be difficult to detect in individuals with dark skin tones and may indicate "at risk" persons (a heralding sign of risk).
- *Stage II:* A stage II pressure ulcer is characterized by partial-thickness loss of dermis presenting as a shallow open ulcer with a red-pink wound bed without slough. It also may first appear as an intact or open/ruptured serum-filled blister.
  Further description. A stage II ulcer also may present as a shiny or dry shallow ulcer without slough or bruising.* This stage should not be used to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation. When a grading system is used, stage II is graded as a partial-thickness injury pressure ulcer.
- *Stage III:* A stage III pressure ulcer is characterized by full-thickness tissue loss. Subcutaneous fat may be visible but bone, tendon, or muscle is not exposed. Slough may be present but does not obscure the depth of tissue loss. Stage III ulcers may include undermining and tunneling.
  Further description. The depth of a stage III pressure ulcer varies by anatomic location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue; stage III ulcers in these locations can be shallow. In contrast, areas of significant adiposity can develop extremely deep stage III pressure ulcers. Bone/tendon is not visible or directly palpable. When a grading system is used, stage III is graded as a full-thickness injury pressure ulcer.
- *Stage IV:* A stage IV pressure ulcer presents with full-thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. These ulcers often include undermining and tunneling.
  Further description. The depth of a stage IV pressure ulcer varies by anatomic location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue; stage IV ulcers in these locations can be shallow. Stage IV ulcers can extend into muscle and/or supporting structures (e.g., fascia, tendon, or joint capsule); osteomyelitis is possible. Exposed bone/tendon is visible or directly palpable. When a grading system is used, stage IV is graded as a full-thickness injury pressure ulcer.
- *Unstageable:* Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed may render a wound unstageable.
  Further description. Until enough slough and/or eschar is removed to expose the base of the wound, the true depth (and therefore the stage) cannot be determined. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as "the body's natural (biological) cover" and should not be removed. When a grading system is used, an unstageable wound is graded as a full-thickness injury pressure ulcer.

*Bruising indicates suspected deep tissue injury.

Stage I or stage II pressure ulcers may be evident immediately after surgery. These areas must be kept free from additional pressure for healing to occur and to keep them from advancing to higher stages. They are sometimes misidentified and treated inappropriately. Stage I pressure ulcers can resemble normal reactive hyperemia (excessive redness) that generally fades on its own in one half to three fourths of the time that the area was under pressure, with little or no permanent tissue damage. Reactive hyperemia must be distinguished from a stage I pressure ulcer. In reactive hyperemia, the healthy tissue blanches when compressed. As the compression is released, the blood rushes back to the area, causing it to become erythematous again. Stage I pressure ulcers do not blanch when compressed. This is a serious sign, indicating that the compromised tissue is not receiving adequate oxygen and nutrients. The blistering that sometimes occurs in stage II pressure ulcers is often misidentified as a chemical or thermal burn. The lack of contact with a chemical or thermal agent in that area and its location under a bony prominence or near where a hard surface had been during surgery can help distinguish it as a pressure ulcer. A study by Nixon and colleagues (2007) found that nonblanching erythema in the postoperative patient significantly increased the odds of developing a pressure ulcer of stage II or higher.

Full manifestation of pressure ulcers may be delayed from hours to days after the triggering injurious event. Given this delayed manifestation, the connection that the surgical experience was the triggering event may be overlooked. Lack of awareness of an early pressure injury can lead to a delay of pressure relief and treatment. Inappropriate treatment can contribute to advancing the stage of the pressure ulcer.

In many pressure ulcers, deep tissue damage begins at the bony prominence and progresses to the skin. When the deeper necrosis finally erupts at skin level, what first appeared to be a stage I pressure ulcer or intact, but bruised skin may actually be a suspected DTI. As Black and colleagues (2007) describe, NPUAP added this new category to identify a form of pressure ulcer in which deeper tissues (the muscle and deep tissue adjoining the bony prominence that was under pressure) die first. Sloughing follows into the fat and when it finally includes the skin, the underlying tissue is empty, exposing the bone. What appeared as a closed-pressure ulcer exposes itself as a full-thickness stage IV pressure ulcer. Not all DTIs, however, evolve into stage IV pressure ulcers. If these DTIs are identified early enough and relieved of additional pressure, some of the injured tissue may be salvaged.

When a pressure ulcer has reached its highest stage, that stage does not reverse as it heals. In other words, as a stage III pressure ulcer epithelializes, it does not sequentially revert from stage III to stage II, stage I, and stage 0. When it is a stage III, it could worsen to a stage IV, but it can never reverse to a lower stage. The process of healing can be documented only by the improved characteristics of the healing wound (i.e., depth, width, presence of granulation tissue, "closed" versus "open").

Pressure alopecia (pressure-induced hair loss of the scalp) can result from prolonged local pressure to the scalp during and after surgery. Symptoms can occur between postoperative days 3 and 28 (Warner and Martin, 2006). Occipital scalp pain, swelling, exudate, crusting, or focal ulceration may precede actual loss of hair. Pressure alopecia is most commonly reported in cases that require prolonged intubation and head immobilization. In cardiac surgery, anesthesia induction-to-extubation time may extend more than 24 hours. The longer

the surgical time, the greater the risks are that alopecia will be permanent. Repositioning the patient's head every 30 minutes and using soft, contoured head padding can reduce the potential for pressure-induced local alopecia.

Musculoskeletal System

The patient's musculoskeletal system may be subjected to unusual stress during operative positioning. Normal range of motion is maintained in an alert patient by pain and pressure receptors that warn against overstretching and twisting of ligaments, tendons, and muscles. The tone of opposing muscle groups also acts to prevent stress and strain to the muscle fibers. When pharmacologic agents such as anesthetics and muscle relaxants depress pain as well as pressure receptors and muscle tone, the normal defense mechanisms cannot guard against joint damage or muscle stretch and strain. A positioning safety goal is to keep the body as naturally aligned as possible, while providing adequate access to the surgical site. The perioperative team needs to be aware of resistance to range of motion and not extend a joint beyond what is absolutely necessary.

Every time a patient is transferred to or from the OR bed, the alignment of the body needs to be maintained. This is especially true when the transfer involves moving the patient from a supine position to lateral or prone. Quick, jerky movements of unsupported limbs can cause strain to the muscles and ligaments and should be avoided.

Nervous System

Nervous system depression accompanies the administration of anesthetic agents and other drugs. The degree of depression depends on the type of regional anesthesia or the level of general anesthesia. Pain and pressure receptors may be affected regionally or systemically. Most important for the perioperative nurse to remember is that when nervous system depression occurs, the body's communication and command system becomes totally or partially ineffective. Compensatory reactions to changes in physical status no longer naturally occur. Lifesaving physiologic adaptive mechanisms are altered. The stresses of operative positioning are not automatically compensated.

Peripheral Neuropathies. Peripheral nerves can be injured during positioning, resulting in impaired sensory function or motor function, or both. The basic injuries to peripheral nerves in clinical practice are stretch-related injuries, compression, and lacerations (Burnett and Zager, 2004). Stretching and compression tend to be principle factors in position-induced nerve injuries. Prolonged stretching from hyperabduction of an extremity or compression results in ischemia, which can progress to necrosis. In addition, collateral damage to the surrounding tissue and capillaries can affect circulation and nourishment to the nerves. These pathologic forces combine to cause structural or functional damage to the nerves. Depending on the degree of damage, subsequent injuries may be temporary or permanent.

During surgery, all patients are at risk for nerve injury if sustained compression is placed on nerves. Numerous patient characteristics have been identified, however, as potentially increasing the risk for intraoperatively acquired neuropathies. These include diabetes mellitus, peripheral vascular disease, alcoholism, smoking, malnutrition, pernicious anemia, previous nerve injuries or neuropathies (e.g., carpal tunnel syndrome, thoracic outlet syndrome), arthritis, obesity, thin body habitus, and male gender (for ulnar nerve injuries) (Goodkin and Mesiwala, 2005; Tuncali et al, 2005; Faust et al, 2005; Winfree and Kline, 2005; Barnett et al, 2007; Edgecombe et al, 2008). Possible associated risk factors include lengthy surgical procedures, the use of abdominal-pelvic self-retaining retractors, long duration in the lithotomy position, sternal retraction from a median sternotomy, surgical procedures in which shoulder braces are used for support while the patient is in steep Trendelenburg's position, prolonged hospitalization, hypotension, hypothermia, and prolonged bed rest postoperatively (Goodkin and Mesiwala, 2004; Faust et al, 2005; Warner and Martin, 2006; Barnett et al, 2007; Rozet and Vavilala, 2007). Damage usually is not discovered until the patient reaches the PACU. Sometimes there is a delayed onset of symptoms in which the injury does not appear until days or weeks after the suspected insult. This delay can lead to some confusion as to whether the injury occurred during surgery or convalescence. The most commonly reported OR-related nerve injuries involve the upper extremities (primarily the ulnar nerve and the brachial plexus) and the lower extremities (primarily the common peroneal, sciatic, and femoral nerves).

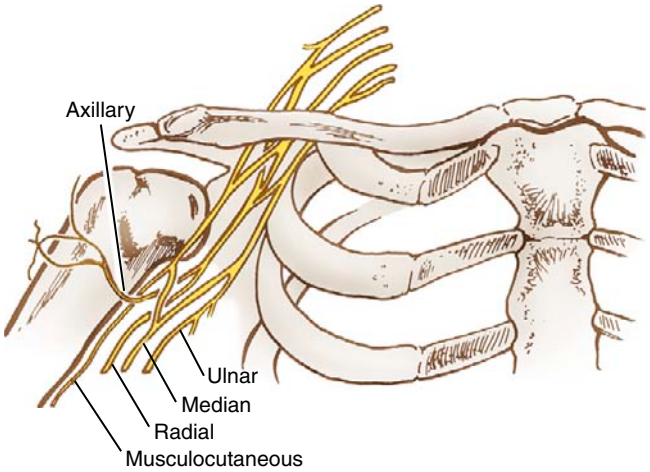

FIGURE 5-1 Brachial plexus on the right with associated bone structures and nerve branches that extend down the right arm.

UPPER EXTREMITY NEUROPATHIES. Upper extremity neuropathies arise from lesions to the brachial plexus and the nerves that emerge from it. The brachial plexus consists of a bundle of nerve cords that traverse the shoulder and innervate the lower shoulder, arm, and hand (Figure 5-1). This bundle originates from cervical spinal nerves C5-C8. The nerve cords emerge to form peripheral nerves. The axillary nerve innervates the deltoid muscle. The musculocutaneous nerve innervates the biceps muscle. Three main peripheral nerves traverse down the arm to the fingers: median, radial, and ulnar (Figure 5-2).

The *median nerve* passes through the antecubital space to the fingers and provides sensory and motor ability to the distal and palmar surfaces of the thumb and adjacent two fingers. A normally perceived pinprick to the palmar surface of the distal index finger generally would show that the median nerve was intact (Figure 5-3).

The *radial nerve* loops around the posterior humerus before it passes through the antecubital space to the fingers. It provides motor and sensory function to the triceps and the

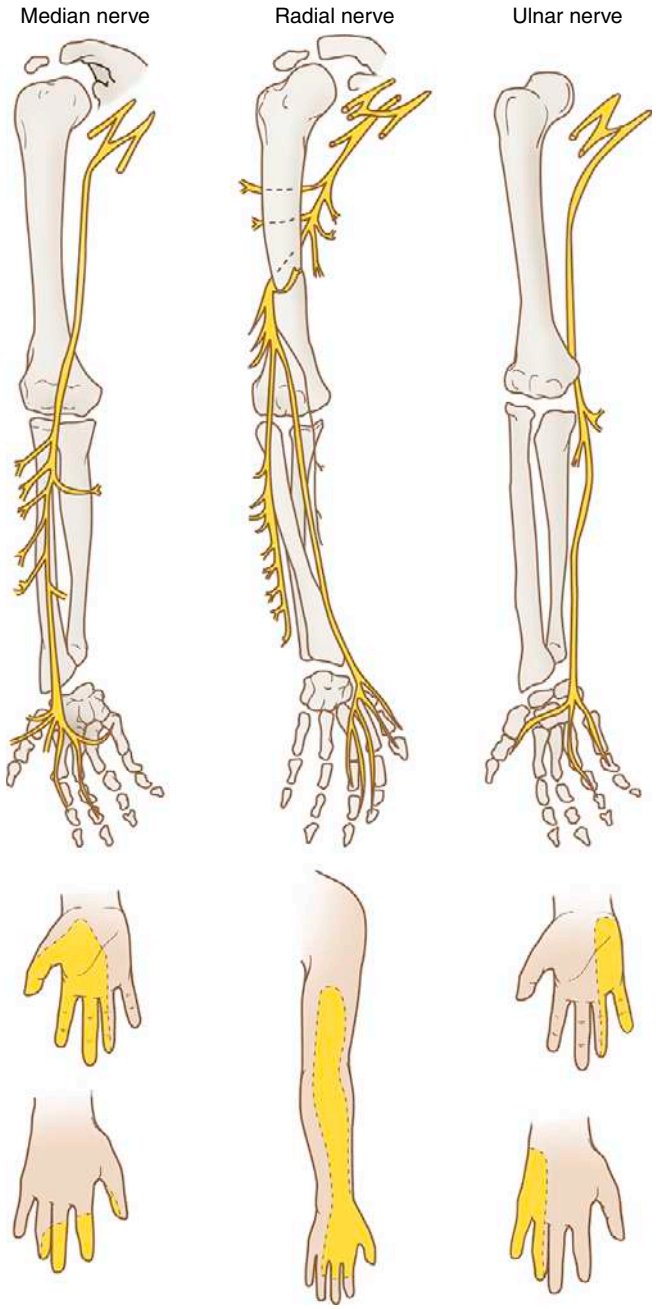

FIGURE 5-2 Median, radial, and ulnar nerves and nerves of the right arm with areas of sensory distribution shaded.

muscles of the posterior forearm and hand. Injury to this area can cause difficulty extending the wrist and thumb. If the distal thumb can be actively extended, this generally indicates an intact radial nerve (see Figure 5-3).

The *ulnar nerve* traverses behind the elbow and innervates the third, fourth, and fifth fingers and the muscles of the medial forearm. It is responsible for wrist flexion and, along with the radial nerve, enables the thumb to oppose the other four fingers. A normally perceived pinprick over the plantar surface of the distal fifth finger generally indicates an intact ulnar nerve (see Figure 5-3).

Injury to any of these nerves along their course can result in sensory or motor defects in areas they innervate. In surgical

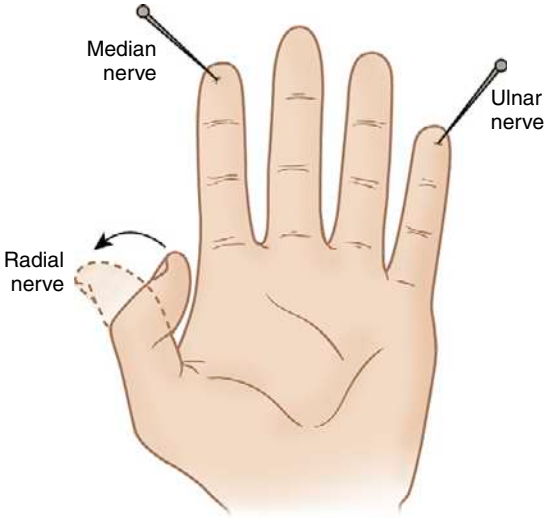

FIGURE 5-3 A quick way to check for injuries to the major peripheral nerves of the upper extremity. The ability to actively extend the thumb indicates an intact radial nerve. A normally perceived pinprick to the distal palmar surface of the index finger indicates an intact median nerve. A normally perceived pinprick to the distal palmar surface of the fifth finger indicates an intact ulnar nerve.

positioning, the most common areas of injury are the brachial plexus and the ulnar nerve (Faust et al, 2005). The major reason for this is that the brachial plexus resides in the shoulder, which is subject to abduction, manipulation, and sometimes pressure, depending on the position. As the ulnar nerve circles behind the elbow, it lies superficially in the shallow cubital tunnel of the humerus, where it is subject to pressure, and to stretching from flexion of the elbow.

The following improper positioning techniques can place the brachial plexus at risk for injury:

- Placing the arms on armboards that extend beyond a 90-degree angle to the body
- Using an armboard that is at a higher or lower level than the OR bed
- Surgical team members leaning against the shoulder or the arm while it is tucked against the body
- Shoulder braces used to support the patient in steep Trendelenburg's position, which can place pressure on the brachial plexus if the braces are medial or lateral to the acromioclavicular joint
- If, in lateral position, the dependent shoulder and arm are compressed under the rib cage
- Extreme lateral rotation of the patient's head, which can pull and compress the brachial plexus at its cervical origin

The brachial plexus also can be injured by the separation of the sternum during cardiac procedures that require median sternotomy. When the sternum is split, a retractor is used to separate it, allowing access to the heart. This separation forces the ribs to move laterally. If internal mammary artery dissection is done as part of the procedure, there is additional asymmetric retraction of the rib cage. The first rib compresses the brachial plexus nerve bundles and, in particular, the nerve cord that emerges into the ulnar nerve. When brachial plexus and ulnar neuropathies develop as a result, they generally are not preventable by proper positioning of the patient's arm (Warner and Martin, 2006).

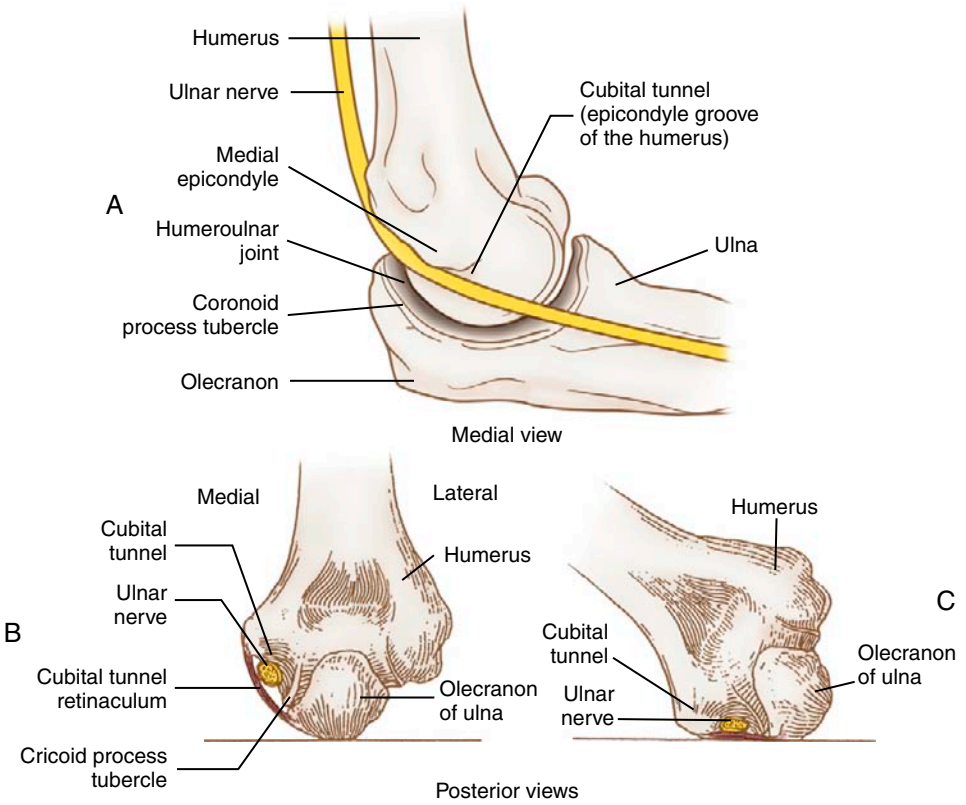

FIGURE 5-4 The ulnar nerve at the cubital tunnel. **A**, Medial view. **B**, Posterior view. Note cubital tunnel retinaculum over the ulnar nerve in the cubital tunnel. **C**, Posterior view with elbow tilted on medial side. Note the ulnar nerve compressed.

Isolated ulnar nerve injuries occur primarily from pressure on the vulnerable location of that nerve at the elbow. The ulnar nerve becomes quite superficial as it passes behind the elbow, nesting in the epicondyle groove of the humerus that makes up the cubital tunnel. There is a 2:1 predominance of ulnar nerve injuries in male versus female patients. Warner and Martin (2006) offer three anatomic differences between the elbows of men and women that probably contribute to this statistic:

1. The tubercle of the coronoid process is larger in men than in women, creating a smaller cubital tunnel around the ulnar nerve (Figure 5-4).
2. Men have less adipose tissue over the medial aspect of the elbow compared with women with similar body fat composition; this provides less natural padding to that area.
3. Men have a thicker, more developed cubital tunnel reticulum, which can further reduce the space for the ulnar nerve in the cubital tunnel. This becomes a greater risk when the elbow is flexed.

The main goal in protecting the ulnar nerve is to eliminate pressure on it. As Figure 5-4, *C* illustrates, pressure on the medial aspect of the elbow can compress the ulnar nerve. Figure 5-5 illustrates ways to prevent this pressure. Position the patient's arm on the armboard with the palms up (supinated) and the fingers extended (Figure 5-5, *A*). This places the olecranon of the elbow on the flat surface of the armboard instead of on the cubital tunnel, which contains the ulnar nerve. When the arm of a supine patient rests on the trunk, direct trauma can occur to the ulnar nerve as the weight of the arm presses the flexed elbow against the surface of the bed. Placing padding under the upper arm, proximal to the elbow (Figure 5-5, *B*), leaves a free space under the elbow, eliminating pressure on the nerve. When a patient is prone with arms pronated on armboards, the ulnar nerve is vulnerable to pressure from the elbow. Placing padding proximal and distal to the elbow (Figure 5-5, *C*) frees the nerve from pressure. If the patient has a history of thoracic outlet syndrome or pain when lifting the arms overhead, the arms should not be pronated, but rather restrained and tucked alongside the trunk.

Ulnar neuropathies may manifest symptoms in the immediate postoperative period. Sometimes symptoms fail to appear until 2 to 7 days after surgery, however, which makes it difficult to isolate an exact event that triggered the complication. The postoperative course cannot be completely ruled out as a causative or contributing factor. Some patients are forced to lie on their backs for prolonged periods postoperatively because of devices such as endotracheal tubes and abdominal drains. Often they rest with their elbows flexed and their hands on their chest. This places pressure on that superficial section of the ulnar nerve under the elbow, which may cause or contribute to nerve injury during the postoperative period.

Many OR-induced peripheral upper extremity nerve injuries can be avoided by properly securing the arms if there are procedure-related reasons to tuck them at the patient's side (Denholm, 2009). The arms should be tucked in such a way as to prevent them from sliding down the side of the OR bed and contacting the bed edge or rigid bed attachments. An effective technique to prevent arm slippage during surgery is to wrap the draw sheet smoothly around the arm, extending to above the

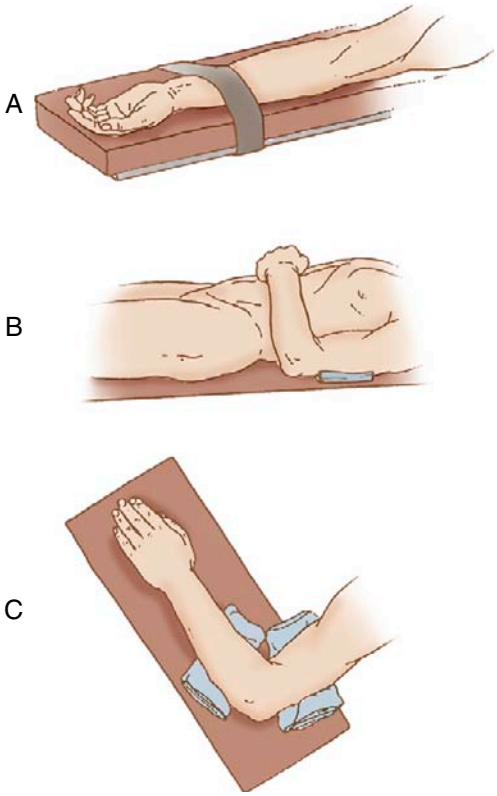

FIGURE 5-5 Three ways to protect the ulnar nerve. **A**, Arm of supine patient on armboard with palm up. **B**, Elbow lifted free from bed surface by padding upper arm when arm is resting on trunk. **C**, Arm of prone patient pronated on armboard. Padding above and below elbow frees the ulnar nerve from the pressure of the armboard surface.

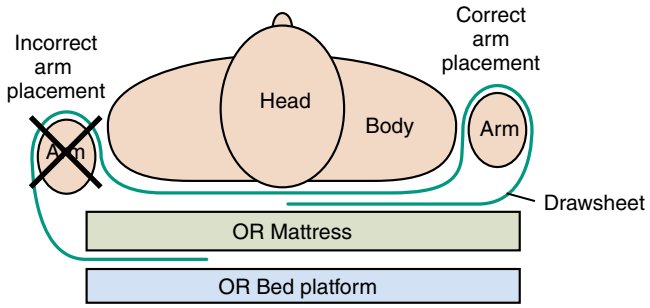

FIGURE 5-6 Correct method for tucking arms in at the patient's side.

elbow, and then tuck the draw sheet under the patient's body instead of under the mattress (Figure 5-6). Tucking the draw sheet is best accomplished with an assistant on the other side of the OR bed to roll the patient's body over enough to tuck the draw sheet underneath it. The elbows are slightly flexed, the palms facing inward, and the wrists in a neutral position. Care should be taken to ensure that the draw sheet is not tucked so tightly as to cause pressure to the arms. A tight fold pressing on the elbow could cause an isolated ulnar nerve injury.

Complete and thorough documentation of intraoperative measures taken to protect vulnerable nerves should include the following details:

- How the arms were secured and by whom
- The location of padding
- The angle of armboards (approximate degree of extension from body), the position of the palms, and the location of arm straps
- Times and type of repositioning or passive range of motion done
- Presence of distal pulses, color, and temperature of arms and hands when procedure is long or extremity is compressed, or both

Upper extremities should be evaluated postoperatively and any changes from the preoperative condition reported and documented.

LOWER EXTREMITY NEUROPATHIES. These neuropathies result most frequently from prolonged lithotomy positioning and tend to manifest symptoms within hours after surgery. The common peroneal, sciatic, and femoral nerves are most frequently implicated.

Intraoperative risk factors include the length of time the patient is in the lithotomy position (including high or exaggerated lithotomy) and the degree the extremities are positioned beyond their comfortable range of motion when the patient is awake. Different types of stirrups vary in the degree to which they control hip flexion (see Lithotomy section later for further discussion). Hip extension should be limited to only the amount required for adequate access to the operative area.

The *common peroneal nerve* branches from the sciatic nerve behind the knee and becomes superficial as it wraps around the lateral head of the fibula (Figures 5-7, 5-8, and 5-9). At this level, it is quite vulnerable to direct compression by stirrup bars. This risk increases in extremely thin patients who have minimal overlying tissue in this area. It is important to ensure that the lateral head of the fibula does not rest against stirrup bars or any other rigid surface. Compressive leg wraps (i.e., pneumatic compressive devices, elastic wrappings, or stockings) also can apply pressure on this nerve if the wrapping is too tight in this area. In addition, pressure behind the knee can compress the common peroneal and tibial nerves where they pass through the popliteal fossa; therefore only *soft* padding or pillows should be used for knee support. The ability to dorsiflex the great toe (point it upward) generally indicates that the common peroneal nerve is intact.

The *sciatic nerve* originates from the L4-S3 spinal nerve roots and travels down the buttock and posterior thigh before it divides into the common peroneal and tibial nerves (see Figure 5-7). It may be injured by the stretching that occurs during hyperflexion of the hip. A patient who has undergone total hip replacement surgery may have some preexisting sciatic nerve damage as a result of excessive rotation of the femur during the operative procedure. Additionally, patients with a history of hip trauma who have had surgery such as open reduction and internal fixation may be at increased risk for sciatic neuropathy because of the potential presence of scar tissue around the nerve area. The branches of the sciatic nerve travel from the thigh to the hamstring; the ability to flex the thigh generally indicates an intact sciatic nerve.

The *femoral nerve* arises from the L2-L4 spinal nerve roots and passes through the medial thigh. Injury to the deep femoral nerve may occur more as a result of inappropriate placement of abdominal-pelvic retractors and vaginal retractors in the pelvic cavity than inappropriate positioning (Irvin et al, 2004). The femoral nerve and obturator nerve can be subjected

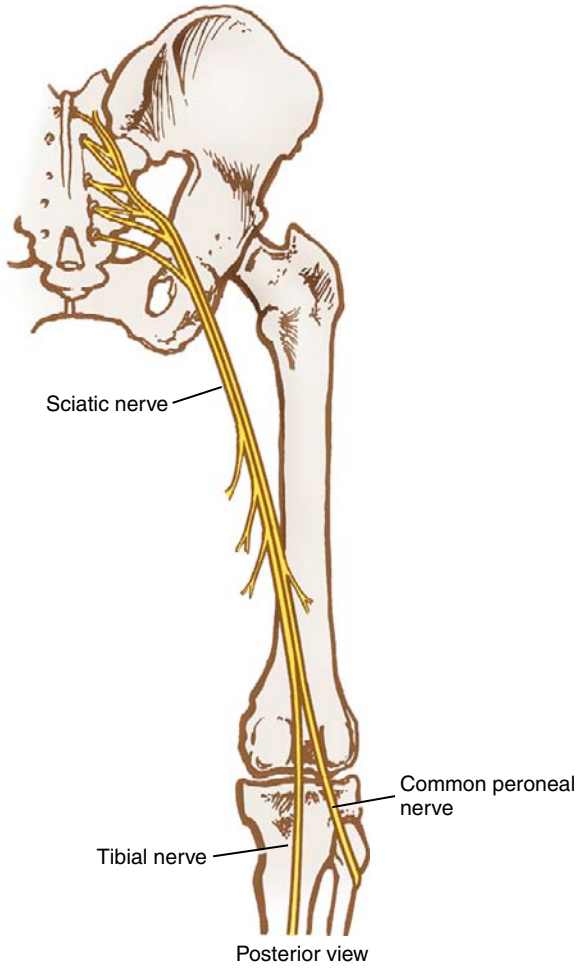

FIGURE 5-7 Posterior view of right sciatic nerve and right thigh and upper leg. Note the division of the sciatic nerve into the tibial and common peroneal nerves.

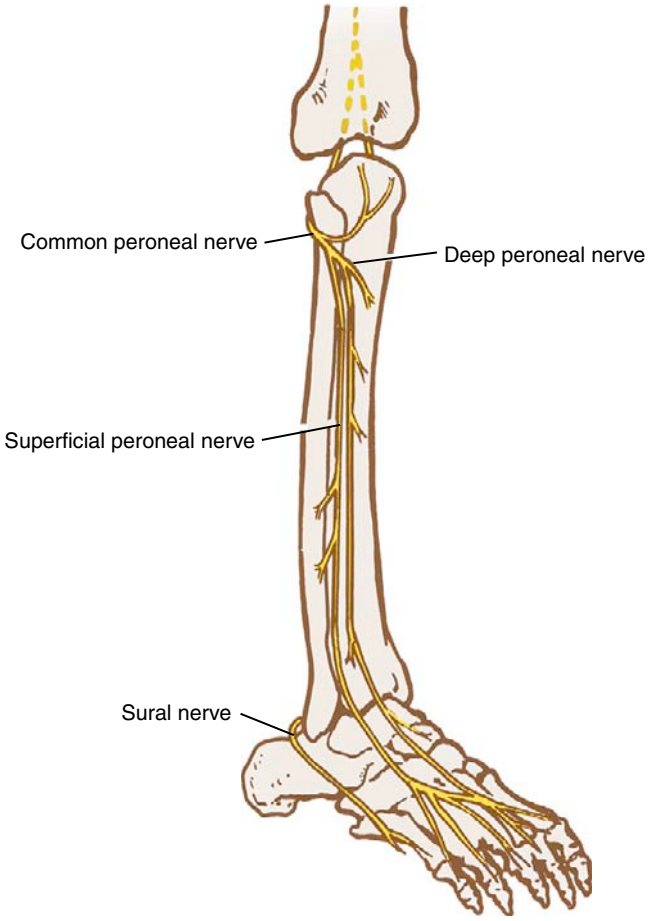

FIGURE 5-8 Lateral view of right leg. Note the common peroneal nerve pathway around the lateral fibular head. This nerve is susceptible to injury when the patient is in lateral position. Also note the sural nerve in the heel area. This nerve is susceptible to injury from stirrup straps.

to excessive stretching and injury, however, as a result of inappropriate lithotomy positioning (see Figure 5-9). The ability to flex the thigh to the trunk generally indicates an intact femoral nerve.

The *obturator nerve* originates from the L2-L4 nerve roots. It passes through the obturator foramen of the ischium to innervate the adductor group of muscles in the inner thigh. It can be subjected to excessive stretching when the patient is in lithotomy position. Scrubbed personnel may lean against the inner thigh while holding vaginal or anal retractors, causing additional stretching and compression of the nerve. The ability to adduct the leg generally indicates an intact obturator nerve.

The *tibial nerve* branches from the sciatic nerve behind the knee and traverses along the posterior tibia to the foot. There it bifurcates into the medial and lateral plantar nerves. Normal sensation to the plantar surface of the foot and the ability to curl the toes downward generally indicate an intact tibial nerve.

The perioperative nurse should document measures taken to protect the lower extremities from injury, such as the following:

- Location and type of padding used (i.e., pillow to support knees or calves, padding under heels)
- Type of stirrups used, names of persons placing legs in stirrups
- Type of lithotomy position (low, standard, high, or exaggerated)
- Presence of distal pulses, color, and temperature of legs and feet
- Use of sequential compressive devices (SCDs) or antiembolic compression stockings

The lower extremities should be evaluated postoperatively. Any changes from the preoperative condition should be reported and documented.

The use of intraoperative neurophysiologic monitoring is a method of preventing peripheral nerve injuries in the upper and lower extremities during procedures in which there is a high risk of such injuries. One type of monitoring used in the OR is somatosensory evoked potential (SSEP). The goal is to establish a baseline of the patient's normal nerve function along selected pathways and then to monitor them at continuous intervals during the procedure. Any emerging insult to these nerve structures or pathways can then be identified and corrective measures taken before permanent nerve injury occurs (Research Highlight) (Labrom et al, 2005; Devlin and Schwartz, 2007).

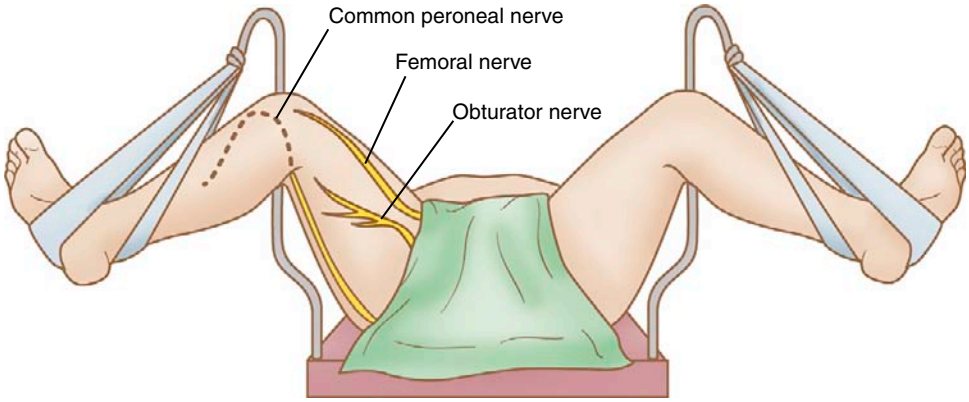

FIGURE 5-9 Nerves of the inner thigh. The femoral and obturator nerves can be overstretched by hyperextending the hips or by staff leaning against the thighs. If the lateral knee rests against a stirrup bar, the common peroneal nerve can be compressed.

RESEARCH HIGHLIGHT

SSEP Monitoring as a Tool to Prevent Intraoperative Peripheral Nerve Injuries

Studies over the past 25 years have demonstrated the benefits of using somatosensory evoked potentials (SSEPs) as an intraoperative tool to prevent peripheral nerve injuries, primarily to the ulnar nerve and the brachial plexus. SSEP monitoring provides early detection of impending neuropathies, allowing enough time for corrective interventions. Three recent studies further corroborate such findings.

Chung et al (2008) studied 230 patients undergoing lumbosacral spinal surgeries in prone position on the Andrews or Jackson spinal bed. Fourteen significant SSEP-negative changes were detected in the upper extremities that immediately returned to normal with repositioning of the arms. There was no documented position-related neuropathy in any of the 230 patients studied. In a study done by Kamel et al (2006) of 929 patients undergoing spinal surgery, upper extremity SSEP monitoring was performed about every 30 minutes. Position-related upper extremity SSEP-negative changes occurred in 68 patients (6.1%), whose average length of time in position ranged from about 4¾ to 9 hours. The SSEP changes were reversed by modifying arm positions. None of these patients developed a new postoperative deficit in the affected arm. Schwartz et al (2006) conducted a retrospective review of 3806 patients who underwent anterior cervical spine surgery in supine position. Neurophysiologic monitoring was done throughout the procedures as well as before and after each of the following maneuvers: neck extension for intubation, shoulder taping, neck extension for surgical exposure, and arm traction. Sixty-nine of these patients exhibited significant neurosurgical changes suggesting impending nerve injuries. Interventional strategies included releasing shoulder countertraction, loosening drapes used to tuck the arms at the side, repositioning the arms, limiting shoulder abduction, flexing the neck, and padding the shoulders, arms, and wrists as appropriate. None of those 69 patients incurred a postoperative position-related neurologic deficit.

Modified from Chung I et al: Upper-limb somatosensory evoked potential monitoring in lumbosacral spine surgery: a prognostic marker for position-related ulnar nerve injury, *Spine J,* 9(4): 287-295, 2009; Kamel IR et al: The use of somatosensory evoked potentials to determine the relationship between patient positioning and impending upper extremity nerve injury during spine surgery: a retrospective analysis, *Anesth Analg* 102:1538-1542, 2006; Schwartz DM et al: Neurophysiological identification of position-induced neurologic injury during anterior cervical spine surgery, *J Clin Monit Comput* 20:437-444, 2006.

Vascular System

Anesthesia and changes in position both affect the vascular system. These effects become more dramatic in patients with cardiovascular disease, hypovolemia, or obesity.

General anesthesia causes peripheral vessels to dilate by depressing the sympathetic nervous system. This dilation causes an overall decrease in blood pressure as blood pools in dependent areas of the body. In general anesthesia, these effects are systemic, whereas in regional anesthesia, such as spinal and epidural, effects are more limited to the areas anesthetized.

Position changes affect where the pooling of blood occurs. Muscle tone and peripheral vascular resistance are no longer effective to counteract the force of gravity on blood pooling. Blood pooling shifts to whatever part of the body is lowest.

The anesthesia provider can treat some of the hypotensive effects of positioning with pharmacologic agents and increased intravenous infusion. Vital signs, intravenous intake, and urinary output need to be monitored closely. Position changes may need to be delayed until blood pressure stabilizes.

Venous thromboembolism (VTE) is a serious complication of surgical positioning. Compression to deep and peripheral vessels (i.e., tight safety strap or wrist straps) can predispose the patient to VTE. When the legs are in a dependent position (i.e., legs lowered during knee arthroscopy, sitting position), venous return slows, and thrombosis can occur. SCDs or compressive antiembolic stockings can reduce this risk. Thrombosis also can occur as a result of hyperabduction of the arms beyond 90 degrees. Subclavian and axillary vessels pass through the brachial plexus; vessel constriction can occur by compression between the clavicle and the first rib. Radial pulses therefore need to be checked whenever arms are extended to ensure that the pulse is not obliterated.

The vascular status of upper and lower extremities should be assessed preoperatively. Measures taken to reduce assessed risks should be documented. Vascular status should be evaluated

intraoperatively and postoperatively. Any changes from the preoperative condition should be reported and documented.

Respiratory System

The respiratory system can be compromised during positioning. In almost all positions, except semi-Fowler, sitting, and reverse Trendelenburg's, the abdominal viscera are shifted upward toward the diaphragm. Consequently, the diaphragm shifts upward and outward such that it contributes only about two thirds of the ventilatory force and significantly reduces tidal volume (the volume of air inhaled or exhaled) (Faust et al, 2005). Patients who are obese or pregnant or have pulmonary disease have additional respiratory compromise in these positions. Any patient who experiences dyspnea should have the head of the bed elevated during transport and during local, regional, or spinal anesthesia if this does not interfere with surgical access. During general anesthesia, the anesthesia provider generally ventilates these patients mechanically.

External chest movement during surgery needs to be as unrestricted as possible to avoid even further reduction in tidal volume. The placement of arms across the chest should be avoided or very time-limited. Arms resting on the chest not only restrict chest expansion but also place pressure on the ulnar nerve at the elbow area. Some positions (i.e., lateral, fracture bed) require the placement of tape or straps around the chest area to secure the patient to the OR bed. In such cases, the perioperative nurse must ensure that tape or straps is not excessively tight. Anesthesia personnel closely monitor the respiratory status of these patients.

The portions of the lung that are perfused with blood also are affected by position. As blood is pumped into the lungs, the areas that are most dependent have a greater pulmonary arterial pressure. The greater the pressure, the greater is perfusion. The alveoli in the bases of the lungs are more compliant and ventilation is generally highest in those areas. An even distribution of ventilation and perfusion (ventilation-perfusion ratio) is needed for efficient gas exchange. If the position causes a pathologically compromised area of the lung to be dominant and most perfused, the balance between perfusion and ventilation may be disrupted and respiratory status diminished. The rest of the lung fields may or may not have the capacity to compensate. Oxygen therapy or mechanical ventilation can help to compensate, but the amount of time a patient can tolerate a certain position and maintain adequate gas exchange may be limited.

Monitoring respiratory status should always include pulse oximetry. In some cases, intraoperative arterial blood gas monitoring is necessary.

Other Vulnerable Areas

Other body structures, including the eyes, breasts, genitalia, and fingers, are placed at risk during positioning and warrant special discussion.

Eyes. Eye injuries during positioning can range from corneal abrasions to blindness. The eyes do not always close during anesthesia, so they are vulnerable to abrasion from the movement of the face on the sheets, pillows, or drapes in certain positions and from being brushed by intravenous lines, masks, fingers, or the clothes of personnel. When the patient is unconscious, the eyelids should be taped shut to reduce this risk. Eye patches or shields can provide additional protection.

Eyes should be checked to ensure that they are not under pressure when the prone or lateral position requires the face to be in a dependent position. Direct pressure on the globe of the eye may displace the intraocular lens in a patient who has had cataract surgery. Direct pressure on the eye, coupled with systemic hypotension, can cause central retinal artery occlusion, which can result in temporary or permanent blindness. The prone position itself, even without pressure on the eyes, can increase intraocular pressure, which in turn can lead to ischemic optic neuropathy, particularly when prone Trendelenburg's position is maintained for a prolonged period (Research Highlight) (Walick et al, 2007).

RESEARCH HIGHLIGHT

Vision Loss Associated with Prone Positioning

Perioperative vision loss (PVL) is a rare, but devastating complication sometimes seen after prone positioning. The American Society of Anesthesiologists Task Force on Perioperative Blindness reported in 2006 that central retinal artery occlusion (CRAO) and posterior or anterior ischemic optic neuropathy (ION) occur in 0.2% of spinal surgeries performed in prone position. According to the Task Force, studies and case reports suggest higher risk factors for these complications are found in patients with co-morbidities of diabetes, carotid artery disease, glaucoma, hypertension, and preoperative anemia. The literature suggests that prolonged procedures, substantial blood loss, or both are also associated with perioperative visual loss. Walick et al (2007) studied the impact of the prone position on intraocular pressure (IOP). They found that the flat prone position increased IOP and tilting the head down to a Trendelenburg's prone position increased ION significantly more. They determined that the longer the subject was in these positions, the higher was the IOP, which can in turn decrease perfusion pressure to the optic nerve. Lee et al (2006) found that some patients who underwent surgery in prone position with Mayfield pins supporting the head (eyes were free of pressure) also acquired PVL, demonstrating that ION can occur even in the absence of pressure on the globe of the eye. These studies suggest that the prone position itself is a factor in ION and that additional pressure to the globe of the eye can also cause CRAO, two position-related complications that may lead to postoperative blindness.

Modified from American Society of Anesthesiologists Task Force on Perioperative Blindness: Practice advisory for perioperative visual loss associated with spine surgery, *Anesthesiology* 104(6):1319-1328, 2006; Lee LA et al: The American Society of Anesthesiologists postoperative visual loss registry, *Anesthesiology* 105(4):652-659, 2006; Walick et al: Changes in intraocular pressure due to surgical positioning, *Spine* 32(23):2591-2595, 2007.

To minimize the risk of postoperative blindness, the American Society of Anesthesiologists Task Force on Perioperative Blindness (2006) recommends avoiding direct pressure on the eyes and face. With the patient in prone position, the head should be in a neutral forward position, higher than the heart when possible, and significant neck flexion, extension, or rotation is avoided.

Breasts. In the prone position, female breasts are compressed between the weight of the body and the bed or ventral chest supports. If the breasts are displaced laterally, their medial

FIGURE 5-10 This figure illustrates "ramping" the obese patient's torso to facilitate optimal airway alignment. An imaginary horizontal line between the earlobe and the sternum *(dashed line)* references the proper position. Distortion of the upper arm *(solid lines)* precludes standard placement of blood pressure cuff.

borders can be stretched and injured. If the patient has a mammary prosthesis, direct pressure can rupture the implant. Soft ventral supports on the lateral sides of the breasts, diverting the breasts toward the midline, are generally better tolerated (Faust et al, 2005; Warner and Martin, 2006).

Genitalia. Crush injuries can occur to genitalia in certain positions. With male patients, prone position on a laminectomy frame can compress genitalia between the pelvis and the frame. Patients positioned supine on the fracture bed have the pelvis stabilized by a vertical post placed close to the perineum. This post should be placed between the genitalia and the uninjured leg so that pressure is not directly on the genitalia. If the post is not well padded, intense pressure placed on the pelvis during traction of the injured leg can crush and severely injure the genitalia and pudendal nerve. Loss of penile sensation has been reported after improper positioning on the fracture bed (Warner and Martin, 2006).

Fingers. Fingers are vulnerable to injury during surgical positioning. If the arms are tucked at the patient's side, the fingers should be straightened with palms toward the patient's body. Curled fingers can put pressure on the finger joints.

Risk for finger injury can also occur during lithotomy positioning. If the fingers hang over the edge after the leg section of the OR bed is lowered, there is a risk for fingers to be caught in the joint of the bed as the leg section is raised at the end of the procedure. This could result in a crushing injury or even amputation of the fingers. To prevent this, the leg section should only be raised with the fingers visualized and secured away from the OR bed leg section hinge.

Obesity

Obesity is an important consideration in positioning. Degree of obesity is based on the body mass index (BMI). The body mass index is determined by dividing the weight (in kilograms) by the height (in square meters). Obesity and morbid obesity are considered to be BMI >30 and 40 kg, respectively (Ogunnaike and Whitten, 2006). Morbid obesity is associated

PATIENT SAFETY

Key Considerations in Positioning Morbidly Obese Patients

The following complications may occur more frequently in this population:

- Deep vein thrombosis (DVT) and pulmonary embolism
- Ventilation impairment with diminished pulmonary functional residual capacity in all surgical positions except sitting
- Higher rates of perioperative ulnar nerve palsies, brachial plexus neuropathies, and pressure ulcers
- Lower limbs falling off bed, causing lateral femoral cutaneous nerve injuries
- Sciatic nerve palsies from tilting the bed sideways
- Postoperative back pain from buttocks acting as a fulcrum for legs, extending the lumbar spine

The following interventions can enhance the morbidly obese patient's safety:

- Provide OR bed made to accommodate patient's size and weight or secure two OR beds together adjacently.
- Use transfer aids such as rollers or backboards. Have numerous staff members available to assist during transfer and positioning maneuvers.
- Use two safety straps if patient size exceeds the limit for regular-sized safety strap. Place one safety strap across the thighs and the other over the lower legs.
- Elevate the head, upper body, and shoulders to facilitate the airway when supine.
- Pad armboards to match the higher elevation of the shoulders to avoid stretching the brachial plexus.
- Support the knees with pillows to reduce strain on back.
- Use SCDs or antiembolism stockings on lower extremities.

Modified from Denholm B: Tucking patient's arm and general positioning, *AORN J* 89(4):755-757, 2009; Guss D, Bhattacharyya T: Perioperative management of the obese orthopaedic patient, *J Am Acad Orthop Surg* 14(6):425-432, 2006; Helgeson LE: Obesity and nutritional disorders. In Fleisher LA, editor: *Anesthesia and uncommon diseases,* ed 5, Philadelphia, 2006, Saunders; Ogunnaike BO, Whitten CW: Anesthesia and obesity. In Barash PG et al, editors: *Clinical anesthesia,* ed 5, Philadelphia, 2006, Lippincott Williams & Wilkins.

with considerable perioperative risks (Patient Safety). Given fat distribution around the morbidly obese patient's back and shoulders, positioning interventions are necessary to gain control of the supine patient's airway. This is done by what has been called "ramping," which is building a ramp of cushioning materials (e.g., pillows, linen, foam wedge) to elevate the head, neck, and shoulders above the chest and into alignment with the airway. To create the correct plane, an imaginary horizontal line can be drawn between the earlobe and the sternum, as noted in Figure 5-10. Alignment in the correct plane enables the anesthesia provider to gain control of the airway by aligning the oral, laryngeal, and pharyngeal axes, as illustrated in Figure 5-11 (Fleisher, 2006). This position is sometimes referred to as the "head-elevated laryngoscopy position" (HELP) as it facilitates laryngoscopy and intubation (Ogunnaike and Whitten, 2006). (See Chapter 11 for a discussion of other special considerations in positioning bariatric patients.)

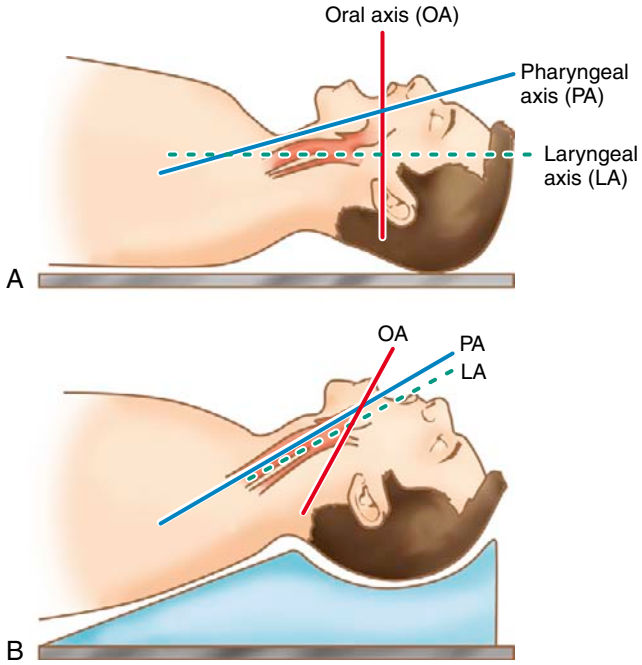

FIGURE 5-11 Head position for endotracheal intubation in an obese patient. **A**, When the head is flat, there is no alignment of the oral, pharyngeal, and laryngeal axes, making exposure of the glottis opening difficult for direct laryngoscopy. **B**, With ramping, the three axes align, forming the shortest distance and straightest line from the incisor teeth to the glottis opening.

Perioperative Nursing Considerations

Assessment

Assessment for positioning needs should be done before the patient is transferred to the OR bed (AORN, 2009). The perioperative nursing assessment includes a patient interview, physical examination, and review of medical records. Key points of assessment related to surgical positioning include age, height and weight, skin condition, nutritional status, preexisting conditions (e.g., conditions of the vascular, endocrine, respiratory, circulatory, neurologic, or immune system), and physical/mobility limits (e.g., prostheses, implants, range of motion). It also should be determined if there are any particular areas of discomfort that may be affected by a particular position and what interventions might avoid or reduce that discomfort.

Assessment will also highlight special patient needs and accommodations for vulnerable patients, including the following:

1. Geriatric patients, whose thin skin layer and increased arteriosclerosis make them more prone to skin breakdown caused by pressure
2. Pediatric patients, whose size and weight must be considered when selecting positioning aids
3. Patients with respiratory and circulatory disorders, diabetes mellitus, malnutrition, advanced age, and anemia because they are more prone to skin breakdown caused by pressure
4. Patients with mobility limitations caused by congenital anomalies, preexisting injuries, arthritis, or prosthetic implants
5. Patients with edema, infection, cancer, conditions of lowered cardiac or respiratory reserves, or who are morbidly obese or have poor general health
6. Patients with demineralizing bone conditions, such as malignant metastasis or osteoporosis, which places them at higher risk for skeletal fractures
7. Patients who will be subjected to the following:
   - Lengthy surgical procedures (≥2 hours), because of the increased risk of pressure-related injuries
   - Lengthy time in the lithotomy position, because of the increased risk of lower extremity nerve injury
   - Vascular surgery, because optimal blood perfusion already may be compromised as a result of the patient's disease process
   - Excessive sustained pressure to certain body areas, because of the surgical procedure or retraction
   - Cool environment or exposure of large body surfaces or both, because of the risk of hypothermia and its related complications

Nursing Diagnosis

The encompassing nursing diagnosis related to the care of the patient during surgical positioning is the risk for perioperative positioning injury. Other applicable nursing diagnoses may include the following:

- Impaired Comfort
- Impaired Transfer Ability
- Risk for Falls
- Risk for Impaired Skin Integrity
- Impaired Tissue Integrity
- Hypothermia
- Impaired Spontaneous Ventilation
- Impaired Physical Mobility
- Risk for Peripheral Neurovascular Dysfunction

Outcome Identification

The outcome identified for safe surgical positioning may be stated as "the patient is free from signs and symptoms of perioperative-positioning injury." To achieve this outcome, the perioperative nurse implements actions to ensure that the patient will:

- Experience a safe transfer to and from the OR.
- Be warm and comfortable.

- Not experience tingling, numbness, or pain unrelated to the surgical procedure.
- Maintain skin and tissue integrity consistent with preoperative status.
- Maintain a respiratory status consistent with preoperative status.
- Regain normal physical mobility postoperatively.
- Maintain normal peripheral neurovascular function.

Planning

The perioperative nurse plans activities to protect the patient from injury and provide physiologic support and comfort, while still allowing for optimal exposure and access to the surgical site. Although carrying out safe surgical positioning involves all members of the surgical team, the nurse plans and coordinates this teamwork. Knowledge of any preexisting risk factors that may affect positioning strategies (e.g., obesity, diabetes, paralysis, advanced age) should be considered when planning for additional assistance and support devices or padding.

The exact location of the operative site must be identified so that access to that site remains unobstructed. If a secondary surgical procedure is involved, such as a graft donor site, that area needs to be exposed and accessible as well. There are times, however, when the incision site cannot be exposed during initial positioning. In those cases, plans are made to reposition the anesthetized patient quickly and smoothly.

Planning for the patient's comfort involves communicating with the patient regarding potential areas for discomfort and possible remedies. An awake patient receiving a local anesthetic can communicate comfort of the position before, during, and immediately after the procedure. In some cases, all or part of the positioning for a patient who is to be anesthetized can be done before induction if it does not interfere with the anesthesia process. A patient might be placed in the lithotomy position before induction if he or she has a history of discomfort with leg abduction or lower back pain. If this is done, privacy must be ensured by covering the patient with a sheet or blanket and covering or pulling the blinds on room windows. A Sample Plan of Care for patient positioning is below.

Implementation

Nursing actions in positioning should reflect an individualized plan of care designed to ensure injury prevention, while maintaining optimal surgical access, patient comfort, and physiologic support. Patient comfort measures include physical

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Risk for Perioperative Positioning Injury

OUTCOME
The patient will be free from injury related to perioperative positioning.

INTERVENTIONS
- Verify surgical site and planned surgical position. Confirm correct patient position during the time-out.
- Identify and document risk factors that may predispose the patient to position-related injuries. Communicate these during the preop briefing.
- Identify areas of potential discomfort/limitations in mobility and possible remedies. Note condition of patient's skin and presence of peripheral pulses, as applicable.
- Check OR bed for proper functioning and availability of all needed attachments.
- Obtain any needed positioning aids and padding materials; verify that these are clean and in working order.
- Ensure a safe transfer between the transport vehicle to OR bed, and document mode of transfer.
- Safely secure the patient to the OR bed without compromising circulation underneath restraining straps.
- Provide warmth, privacy, and reassurance.
- If the patient is repositioned after being anesthetized, support all body parts, and maintain body alignment throughout the move.
- Use slow, smooth movements in making all position changes.
- Avoid pulling or dragging the patient; use lifting techniques instead.
- Pad or suspend bony prominences and all pressure-prone areas.
- Protect the eyes and anatomic areas containing superficial vessels and nerves.
- Secure the patient to the OR bed to prevent falls or slippage of extremities over the OR bed's edge.
- Monitor physiologic effects of position changes and be prepared to intervene when necessary.
- Ensure access to airway, intravenous catheters, and monitoring devices.
- Prevent pooling of fluids under dependent areas or any area under pressure.
- During long procedures, periodically do passive range of motion on accessible extremities if it does not interfere with the surgical procedure or sterile drapes.
- Maintain normothermia.
- Ensure that no equipment or personnel create pressure on the patient during the procedure.
- Periodically recheck position, straps, and padding to ensure that nothing has slipped or moved.
- At the end of the procedure, reposition slowly for patient's hemodynamic accommodation.
- Secure patient and remain at patient's side when emerging from anesthesia.
- Document patient position and pressure and injury prevention interventions including the following:
  - Position of extremities
  - Type and location of safety straps, positioning aids, and padding materials
  - Frequency of passive range of motion and other injury prevention interventions
  - Use and location of warming or cooling blankets or devices
  - Positional changes made during procedure (e.g., supine to lithotomy to supine)
  - Adverse physiologic responses to positions, and interventions taken
- Transfer patient using a team approach and a secured transfer vehicle.
- Reassess tissue integrity; document and verbally communicate any changes during hand-off report.

and emotional aspects. Direct communication with the patient regarding his or her positioning concerns helps to reassure the patient and provides the nurse with possible comfort strategies. Providing warmth and privacy help the patient feel protected.

Assemble all necessary positioning aids, such as padding, pillows, bed accessories, and stirrups, before the patient's induction as positioning takes place immediately after the anesthetic is administered. All positioning devices must be clean and working properly (AORN, 2009). Additional personnel should be available if needed for lifting or turning the patient.

When the patient enters the OR, the circulating nurse uses two patient identifiers and verifies correct person, procedure, and operative site. Institutional procedures for preventing wrong site, wrong procedure, and wrong person surgery must be followed. The patient is then prepared for transfer onto the OR bed. During transfer, the OR bed and transport vehicle should be next to each other and locked. At least one individual stands on either side to assist the patient during transfer. If the patient is unable to assist in the transfer, a lifting device is used or a four-person lift is done, using a draw sheet and supporting the head and feet.

Falls are a risk during all stages of patient transfer and positioning. Prevention of falls is a National Patient Safety Goal (Beyea, 2005). Falls can occur easily during transfers if the transport vehicle and OR bed are not locked. Falls also can occur while the patient is on the OR bed, whether awake or anesthetized. An awake patient may not fully appreciate the narrowness of the OR bed and can continue to move beyond the bed edges. A team member must stand on either side of the patient until the safety strap is applied. Falls also are a risk during induction and emergence from anesthesia. Lighter stages of anesthesia can result in patient movement. Often the movement is strong enough that safety straps alone do not offer adequate security. The nurse remains at the patient's side during both induction and emergence as a fall-prevention strategy and to assist the anesthesia provider in other activities. Infants and toddlers are particularly at risk because standard safety straps frequently are not used given their small stature. Other means to secure a pediatric patient are employed, depending on the area needed for surgical access.

When the patient is on the OR bed, the safety strap is placed about 2 inches above the knees. The strap should be snug, but not so tight as to place pressure on nerves or restrict venous return. One should be able to slide a flat hand or two fingers comfortably beneath the strap. The patient's ankles must not be crossed because vessel and nerve constriction and skin pressure may result. The patient should be reminded of this because many patients automatically cross their ankles while lying down. The nurse should verify that the ankles are not crossed after anesthesia is administered.

If the patient is repositioned, movement is slow and smooth, ensuring that the whole body is supported. Quick, jerky movements can cause musculoskeletal injury and put the patient at risk for bruises, pinches, abrasions, fractures, or falls. Any lateral, anterior, or posterior movement of the patient on the OR bed is done by lifting the patient with the draw sheet rather than by pulling or dragging the patient. Vulnerable areas, such as eyes, breasts, perineum, and fingers, are protected during all movements (see Other Vulnerable Areas section earlier in this chapter).

When the desired position is obtained, the patient is again secured so that movement off the OR bed cannot occur. Safety straps and other support accessories are rechecked. Padding or adjustment is done at this point, the last opportunity to do so before prepping and draping. Review how the position may cause certain body parts to sustain more gravitational weight. If a pillow elevates the knees, for example, the heels bear additional weight from the calves. Heel padding may be needed to relieve this additional pressure. Alternatively, placing the pillow under the calves elevates the knees and lifts the heels off the surface of the OR bed at the same time.

During the procedure, the perioperative nurse monitors and assists with any required modification to the position. Periodically, the nurse checks pressure points that are accessible and adjusts the patient or protective padding as needed. Passive range of motion may be done to accessible extremities. This is particularly important during procedures that last 2 or more hours. If the patient needs to be repositioned during the procedure, the circulating nurse and anesthesia provider coordinate the change and protect the patient from injury. The position, any repositioning, all padding, positioning devices, and methods used to secure the patient to the OR bed are documented.

Evaluation

After the surgical procedure is completed, all pressure sites, especially those under bony prominences, are checked before transfer to PACU. Any changes in the skin integrity are documented and verbally communicated during the hand-off report so that appropriate interventions occur immediately to reduce further injury. The mode of transfer, time of discharge, and patient status on discharge are documented. The successful implementation of the plan of care is measured by the positive patient outcomes listed under the Outcome Identification section.

OR BEDS

Modern OR beds are designed to support and accommodate various anatomic configurations required in surgical positioning. Their height can be raised or lowered, they can tilt laterally, and they can be placed in the Trendelenburg's or reverse Trendelenburg's position. Generally, OR beds are electrically or battery operated with a manual mechanical backup. They have roller wheels, which allow them to be moved easily, and lockable brakes.

OR Bed Parts and Accessories

General OR beds have a flat platform divided into three major sections: the head, torso, and leg sections. Each section has a corresponding removable mattress pad, which usually attaches to the main platform with Velcro or straps. The area between each section is called a "break." Raising or lowering sections is called "breaking the OR bed."

Along the edges of the bed are flat metal side rails that separate at each break and run horizontally along both sides of the entire bed. Armboards lock directly onto the side rails at any level of the bed. The side rails also accommodate sockets and clamps that can secure a multitude of attachments, including stirrups, anesthesia screens, armboards, and various retractors. Underneath the bed platform is a tunnel that runs under the entire body and leg sections to support x-ray cassettes. In

newer models, the entire bed platform is radiopaque to accommodate the use of intraoperative fluoroscopy.

The OR bed width is narrow to allow easy access to the operative site. For some patients, this width may not be enough to support their body adequately. All OR beds have weight limitations. Make sure the bed you use will accommodate your patient's weight.

The torso section is attached to the base of the OR bed because this section supports the heaviest parts of the body: the chest, abdomen, and pelvis. This section also has a break in the center at hip level that can be flexed or lowered to allow the head and chest areas to be elevated or lowered. At this central break in the torso section, there is a crossbar, called a *kidney bridge* (body elevator), that can be raised or lowered for kidney or gallbladder exposure. The kidney bridge is concave and can accommodate lateral braces that slide vertically onto the bridge to maintain the patient in a lateral position. The distal portions of the torso section's platform and mattress have a concave perineal cutout to accommodate access to the perineum when the patient is in the lithotomy position. Drainage trays may be inserted into this section for gynecologic, urologic, and proctologic procedures.

The head section of the OR bed can be flexed, lowered, or removed. It is connected to the bed by two horizontal posts that fit into corresponding grooves in the front of the torso section. Special headrests can slide into these grooves for specific procedures.

The leg section of the OR bed can be flexed or lowered. It folds beneath the torso section to allow leg room for a sitting surgeon to gain access to the perineal area when the patient is in lithotomy position. The leg section also has grooves in the distal-most platform to accommodate a foot extension for tall patients. If needed, the foot extension attachment can be flexed upward to provide plantar support. The distal grooves also accommodate the head section in case the patient must be positioned on the OR bed with the head at the typical location of the feet. Because the leg section protrudes farther away from the base than the head section does, such positioning allows for movement of a fluoroscopy *C*-arm around the patient's chest and abdomen. The head section may also be placed at the foot of the OR bed to enable the patient to be positioned with the buttocks in the perineal cutout immediately on transfer to the OR bed; this extends the leg section so that the patient's legs do not hang over the end of the bed and eliminates the need for the patient to be moved down on the bed after induction.

Multiple positioning accessories assist in achieving desired positions and cushioning pressure points. Examples are various headrests, stirrups, arm supports, hand tables, footboards, and foot extensions. Foam and gel pads and overlays are available in various shapes and sizes designed for specific areas of the body.

New state-of-the-art OR beds and accessory devices can accommodate most types of surgical positioning needs, and the need for additional specialty beds has declined. For example, the traditional orthopedic fracture bed has multiple movable and removable parts and suspended frames; special orthopedic extensions and accessories that duplicate functional features of traditional orthopedic fracture beds are now available for some OR beds. Nevertheless, exceptions remain. Although urologic procedures can be performed on a general OR bed set up in the lithotomy position, specialty urology beds are still beneficial to the OR because they have built-in drainage trays and radiologic equipment.

Mattress Materials and Their Pressure-Reducing Properties

OR mattresses must meet certain basic characteristic requirements: durable, versatile, nonflammable, resistant to bacterial growth, radiolucent with low x-ray attenuation, compatible with warming and cooling devices, covered with flexible nonallergic antistatic fabric, have pressure-reduction capabilities, and preferably be constructed without latex.

Durability leads to increased longevity and cost-efficiency. The cover should be made of durable but pliable material that is easily washed, resistant to deterioration from various prep solutions and chemical cleaning agents, resistant to the effects of heat, and can reduce friction and shear. Covers should be waterproof and completely intact. Seams should be heat sealed or bonded instead of stitched to inhibit entry of liquids into the core of the mattress. The mattress core also should be resistant to fungal and bacterial growth.

Versatility of the mattress pad can be evaluated by its ability to flex easily and extend with the OR bed platform. The more lightweight it is, the easier the pad is to remove and reposition. Some pads must be stored horizontally because of gel components.

Pressure reduction and pressure redistribution are prime considerations in OR mattress pads. Neither the position of the patient nor the time spent on the OR bed can be altered easily. Using effective pressure-reducing mattresses and positioning devices along with performing initial and ongoing assessment of the patient's tissue integrity are the most effective methods to prevent pressure ulcers during surgery. With more attention being directed toward optimal pressure relief, manufacturers are improving OR mattresses to be more protective of tissue integrity. However, as Scott and Buckland (2005) point out, the technology for pressure redistribution surfaces in the OR environment has not reached the same levels of sophistication as it has for simple bed mattresses and chair cushions. This is probably because many other restrictive qualities are required for OR bed surfaces, such as stability, infection control, decontamination, radiologic translucency, and the means for resuscitation.

As mentioned earlier, distributing pressure over a larger surface of the body decreases the force of that pressure. Overall interface pressure can be reduced by providing even pressure distribution without "bottoming out" (i.e., flattening or collapsing such that parts of the body actually rest on the underlying surface, which defeats the purpose of the mattress). Generally, the thinner the foam, the easier it is to "bottom out." Mattress materials vary widely in their pressure-reducing characteristics. Some examples of materials currently available follow.

Standard Foam OR Mattress Pads. Standard foam OR mattress pads have greatly improved in quality. They are usually purchased with OR beds, but replacement pads can be purchased. Years ago, these mattresses were about 2 inches thick, made of standard foam, and covered with a relatively rigid vinyl covering. Today's mattresses are often more than 2 inches thick and afford greater protection against the effects of pressure. They have a soft, pliable waterproof cover. The more pliable the cover, the greater the patient benefits from pressure-reducing

properties of the foam or other mattress material. Many pads are made with new advanced foam technology that reduces "bottoming out." These foams have contouring properties, which allow the bony prominences to sink into the surface of the foam so that they no longer are the sole "landing gear." As other body surfaces also are in contact with the resting surface, the overall interface pressures lessen. Pliable pad covers allow body surfaces more contact with the foam and help reduce shear. The many benefits of these pads have caused some manufacturers to use them as their new "standard" for OR pads.

Bariatric OR Bed Pads and Surgical Stretchers. Some bed pads are made specifically for bariatric patients. The pads are about 4 inches thick. Manufacturers claim the foam contours to the patient's body in all areas it contacts, to "immerse" the patient in the foam and thus distribute pressure over more of the body surface. Various products accommodate patients weighing from 400 to 700 pounds.

Gel Products. Gel products, made of dry polymer elastomer gels, generally are used as overlays to mattress segments and positioning devices. Some OR bed mattress pads are made with a layer of gel over the foam and a pliable cover. Gel products seem to reduce shearing because they are more pliable, similar to the qualities of body fat. They support weight while tending to prevent shearing and "bottoming out" (Walton-Geer, 2009). Compared with a standard OR mattress, gel pads do reduce pressure ulcers (Schultz, 2005). Gel pads, however, are expensive, heavy, and slow to adapt to temperature; they therefore are more practical for spot protection and as overlays for smaller positioning devices. Gel products also are available as lightweight foam-shaped pieces for specific positioning needs.

Fluid OR Pad. This OR mattress uses multiple individual, fluid-filled sacs within the pad to conform to body contours and to distribute pressure evenly.

STANDARD SURGICAL POSITIONS

This section discusses standard positions and variations in terms of requirements for certain surgical procedures, unique risks that they present to various body systems, and nursing interventions to diminish risks. The Risk Reduction Strategies box provides an abbreviated summary of standard surgical positions.

Supine

The supine (dorsal recumbent) position is the most common. The patient lies with the back flat on the OR bed. The arms may be tucked at the side or placed on armboards. The supine position is the most natural position of the body at rest and is the position in which the patient is usually anesthetized.

RISK REDUCTION STRATEGIES

Risks and Interventions of Surgical Positions

Position	Risks	Interventions
Supine	1. Pressure to head, shoulders, elbows, back, sacrum, coccyx, and heels	1. Pressure-reducing OR mattress; additional padding as needed
	2. Pressure to peripheral vessels and nerves, primarily brachial plexus and ulnar nerves	2. Armboards level with OR mattress, <90-degrees extension and palms up; ankles uncrossed
Trendelenburg's	*Risks in addition to those for supine:*	
	1. Diminished lung capacity	1. Close respiratory monitoring
	2. Venous pooling shifts toward head	2. Slow, smooth postural transitions to diminish cardiovascular effects
	3. Sliding and shearing	3. Flex knees slightly; limit time in position
Reverse Trendelenburg's	*Risks in addition to those for supine:*	
	1. Deep vein thrombosis (DVT) in lower extremities	1. SCDs or antiembolic stockings
	2. Sliding and shearing	2. Padded footboard
Fracture bed	1. Pressure to foot and ankle in traction	1. Adequate padding; appropriate foot cuff inflation
	2. Pressure to genitalia	2. Properly padded and positioned perineal post
Lithotomy	1. Hip dislocations, fractures, and muscle and nerve injuries	1. Securely fasten stirrups to OR bed; avoid hyperabduction of hips and leaning against inner thighs; avoid candy cane stirrups when possible; avoid leg contact with stirrup bars; limit time in position
	2. Pressure injuries to foot, ankles, and knees	2. Use stirrups that disperse support and pressure over wide areas; check distal pulses before and after positioning
	3. Back strain	3. Buttocks should not hang off edge of torso section of bed
	4. Diminished lung capacity	4. Close respiratory monitoring
	5. Venous pooling shifts toward head	5. Slow, smooth postural transitions to diminish cardiovascular effects
	6. DVT in lower extremities	6. SCDs or antiembolic stockings if in position >2 hr
	7. Crushed fingers	7. Ensure fingers are away from break of bed when leg section is elevated

RISK REDUCTION STRATEGIES

Risks and Interventions of Surgical Positions—cont'd

Position	Risks	Interventions
Fowler's (sitting)	1. Pressure to scapulae, sacrum, coccyx, ischium, back of knees, and heels	1. Pressure-reducing OR mattress; additional padding as needed
	2. Air embolism if venous sinus is opened	2. Doppler probe over chest wall; insert central venous catheter; saline-soaked sponges available
	3. Shearing	3. Momentarily tilt torso slightly away from OR bed to allow skin to realign with skeletal structures
	4. DVT in lower extremities	4. SCDs
	5. Venous pooling shifts toward lower body	5. Slow, smooth postural transitions to diminish cardiovascular effects
Semi-Fowler's (beach chair)	*Risks similar to Fowler's position, but generally not as severe:*	Same interventions
Prone	1. Pressure to cheeks, eyes, ears, breasts, genitalia, patellae, and toes	1. Pressure-reducing OR mattress; additional padding as needed; check ears, cheeks, eyes, and genitalia for pressure; tape eyes closed
	2. Falls and dislodgment of airway and monitoring cords and intravenous lines	2. Lock both beds; use a minimum of 4 people for turning patient; secure airway and all cords and lines
	3. Diminished lung capacity	3. Chest rolls and close respiratory monitoring
	4. Injury to shoulders, arms, and upper extremity nerves	4. Arms never hang off side of OR bed; arms on armboard are flexed and pronated with upper arm <90 degrees to OR bed; pads placed above and below elbow to free ulnar nerve
Prone variations	*Risks in addition to those for prone:*	
Jackknife	1. DVT in lower extremities	1. Check distal pulses before, during, and after positioning; if position maintained for extended time, SCDs or antiembolic stockings
Kneeling and knee-chest	*Risks in addition to those for prone:*	
	1. Extreme pressure on knees and ankles	1. Additional padding to these areas
	2. DVT in lower extremities	2. Check distal pulses before, during, and after positioning; SCDs or antiembolic stockings
Lateral, lateral chest, and lateral kidney	1. Pressure to structures on dependent side: ears, shoulder, ribs, hips, greater femoral head, knees, and ankles	1. Pressure-reducing OR mattress; additional padding as needed; check that earlobes are not folded over; place pillow between knees and under ankles; be sure neck is in alignment
	2. Risk of tilting and falling during procedure	2. Flex dependent leg for support; support abdomen and back to prevent lateral movement; may require additional straps or wide tape to secure patient further in addition to hip area
	3. Brachial plexus injury	3. Place padded roll under lower axilla; position lower shoulder slightly forward; support lower arm on armboard with palm up; support upper arm on elevated armboard or pillow
	4. Venous pooling shifts toward dependent side	4. Slow, smooth postural transitions to diminish cardiovascular effects
	5. Diminished lung capacity of dependent lung	5. Ventilator support provider includes positive end-expiratory pressure (PEEP); anesthesia inserts double-lumen endotracheal tube to ventilate dependent lung if thoracotomy performed
	6. DVT in lower extremities	6. Check distal pulses before, during, and after positioning; SCDs or antiembolic stockings

Supine position allows access to the major body cavities (peritoneal, thoracic, pericardial). It also allows access to the head, neck, and extremities. Vulnerable pressure areas in the supine position are the occiput, scapulae, olecranon, thoracic vertebrae, sacrum, coccyx, and calcaneus (Figure 5-12).

A safety strap is placed approximately 2 inches above the knees. A sheet or blanket is placed between the safety strap and the patient's skin. The strap is applied with enough tension to secure the patient to the OR bed without compromising circulation under the strap. The head generally rests on a small pillow or head cushion to support cervical alignment, reduce occipital pressure, and reduce strain on neck muscles.

When the arms are placed on armboards, the armboards are padded, with the pad level equal to that of the OR bed. Extension should be less than a 90-degree angle to prevent stretching and compression of the brachial plexus. Wrist straps should be

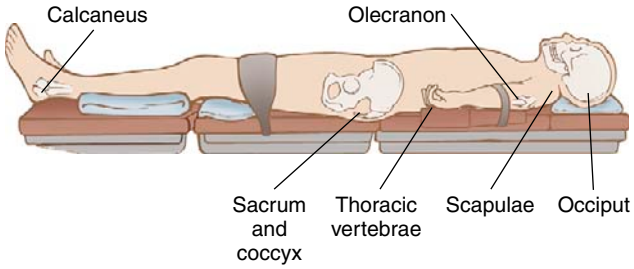

FIGURE 5-12 Potential pressure areas: supine position. A pillow under the calves frees popliteal areas and heels from pressure.

soft and nonocclusive. (See Figure 5-5 and Upper Extremity Neuropathies section for more details.)

Sometimes the patient's legs need to be flexed in a frog-leg fashion to provide access to the groin, perineum, and medial aspects of the lower extremities. To do so, the thighs are externally rotated, and the knees are flexed and supported with a pillow under each leg. Sometimes a special contoured positioning pad is used instead of pillows. This position may be used when access to the genitals is required during abdominal gynecologic and urologic procedures. During coronary artery bypass graft procedures, this position allows access for harvesting the saphenous vein.

In the supine position, blood volume to the heart and lungs increases, compared with the erect position, because venous blood from the lower body flows back to the heart without the counterforce of gravity. This increased blood volume is what increases cardiac output and workload. The weight of the chest in obese patients can cause increased intrathoracic pressure and increase cardiac workload further. If a patient has cardiovascular deficiencies, this position increases the risk for cardiac failure further.

Increased pressure on the inferior vena cava from abdominal viscera, abdominal masses, or a fetus in a pregnant woman may decrease blood return to the heart; if so, blood pressure lowers. The inferior vena cava lies slightly to the right of the vertebral column. Tilting the patient slightly to the left by placing a small roll or wedge under the right flank diverts the weight away from the vena cava. An example is tilting a supine cesarean section patient slightly to the left until the fetus is delivered.

Respiratory function is compromised in supine position because the tidal volume is less than that in the erect posture. The supine position allows more even distribution of ventilation from the apex to the base of the lungs. Anterior and upward excursion of the chest during inspiration is not greatly impeded except in obese patients, whose chest wall weight significantly compresses the rib cage. The abdominal viscera lessen diaphragmatic excursion, particularly when an abdominal retractor is used and packs are placed toward the diaphragm.

Trendelenburg's

Trendelenburg's position is a variation of the supine position in which the upper torso is lowered and the feet are raised. This position enhances visualization of the pelvic organs during open or laparoscopic surgeries in the lower abdomen or pelvis. Trendelenburg's position may also be used to improve circulation to the cerebral cortex and basal ganglia when blood pressure suddenly decreases. In this position, the knees are often bent by flexing the leg section of the bed to keep the patient

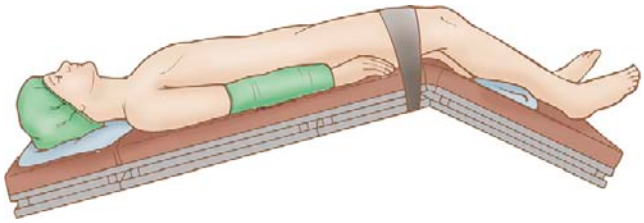

FIGURE 5-13 Trendelenburg's position.

from sliding (Figure 5-13). The patient must have the knees over the break in the bed to maintain safe anatomic positioning. As the lower section of the bed is elevated, the Mayo stand is raised to prevent pressure on the feet.

Shearing is a significant risk in this position. The skeletal structure slides up toward the head of the bed. If the patient is draped, lifting the patient to realign the tissue cannot be done. If necessary, shoulder braces may be used to limit upward sliding; however, they pose their own risk to the brachial plexus (as described in Upper Extremity Neuropathies section earlier) and are used with caution. To protect the brachial plexus from compression injury if shoulder braces must be used, it is important to ensure that braces are well padded and placed above the supraclavicular joint, but not on the soft tissue of the neck. Braces should *not* be used if the arms are extended on armboards.

Any variation of Trendelenburg's position should be maintained only as long as necessary. In this position, blood pools in the upper torso, increasing blood pressure and intracranial pressure. Although the head-down position facilitates drainage of secretions from the bases of the lungs and oropharyngeal passages, the weight of the abdominal viscera further impedes diaphragmatic movement; as the abdominal viscera push the diaphragm up and compress the lung bases, pulmonary compliance and tidal volume diminish. Fluid shifts into the alveoli, causing edema, congestion, and atelectasis. Slow, smooth postural transitions allow sufficient time for the body to adjust to physiologic changes. Hypotension may result if the patient is not returned slowly to supine position.

Reverse Trendelenburg's

Reverse Trendelenburg's position is described as the head-up, feet-down, supine position (Figure 5-14). It is frequently used to provide access to the head and neck and to facilitate gravitational pull on the viscera, away from the diaphragm and toward the feet. When the foot of the bed is tilted toward the floor, a padded footboard supports the patient's body.

For patients having thyroid, neck, or shoulder surgery, a pillow or soft roll is placed horizontally under the shoulders to hyperextend the neck. The knees can be slightly flexed to counteract sliding forward and to minimize shearing. The arms generally are tucked at the side to allow for closer access to the surgical site.

In reverse Trendelenburg's position, respiratory function is similar to that in the erect position. Venous circulation may be compromised by extended time in the legs-downward position. When this is anticipated, superficial venous return can be aided by preoperative application of SCDs, antiembolic stockings, or elastic bandages. If the legs are wrapped, compression of the common peroneal nerve at the head of the fibula must be avoided. Return to the supine position from reverse

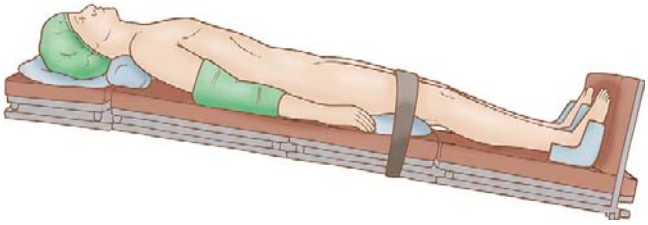

FIGURE 5-14 Reverse Trendelenburg's position with soft roll under shoulder for thyroid, neck, and shoulder procedures.

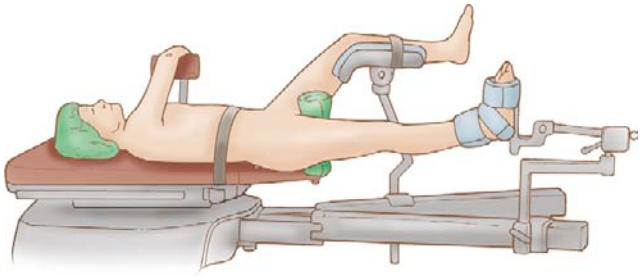

FIGURE 5-15 Fracture bed position. The unaffected leg is raised, abducted, and supported in a padded leg rest.

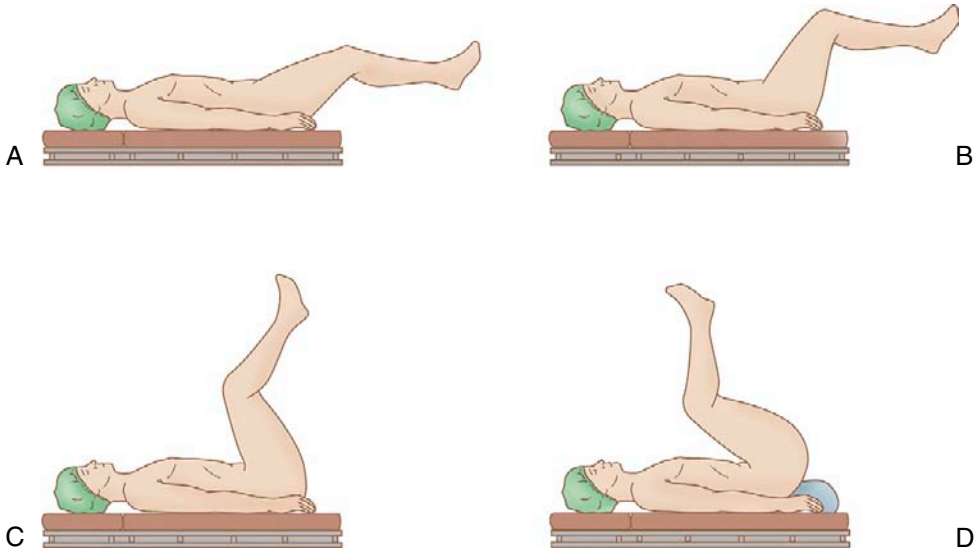

FIGURE 5-16 Four basic types of lithotomy position with progressively increasing leg elevation. **A**, Low. **B**, Standard. **C**, High. **D**, Exaggerated.

Trendelenburg's position should be accomplished slowly and smoothly to avoid overload to the cardiovascular system.

Fracture Bed Position

The orthopedic fracture bed allows the patient to be positioned for hip fracture surgery or closed femoral nailing (Figure 5-15). The patient may be transferred into the OR in the hospital bed with traction applied. The patient is usually anesthetized before transfer to the fracture bed. During transfer, manual traction is often applied to the injured leg. Distal lower extremity pulses should be evaluated before, during, and after positioning on the fracture bed.

The patient is positioned supine with the pelvis stabilized against a well-padded vertical perineal post. Pressure on the genitalia from the perineal post can otherwise injure genital structures. Pressure on the perineal and pudendal nerves can cause fecal incontinence and loss of perineal sensation.

Traction is achieved by restraining the foot of the injured leg in a well-padded, bootlike device that is connected to the traction bar so that the leg may be rotated, pulled into traction, or released, as surgery requires. One method of securing the foot in this device is the use of a boot-shaped cuff that wraps around the entire foot and connects to the traction device. The cuff is inflated with air to secure the foot. Another method is to cushion the foot and secure it to the device with restraining straps, ACE bandages, or a self-adhering wrap. Regardless of the method used, excessive pressure can be placed on the foot and ankle, especially while traction is being applied. Adequate padding must be used. If the boot-shaped cuff is used, care should be taken that it is not inflated beyond the manufacturer's recommendations. The unaffected leg rests on a well-padded, elevated leg holder or is secured in a well-padded, bootlike device. *C*-Arm fluoroscopy examinations can be done during surgery because the unaffected leg is abducted well out of the field.

The arm on the operative side is generally secured over the patient's body in a padded sling or a post-supported arm holder to reduce obstruction of the operative area. Care is taken to avoid pressure on the ulnar nerve. The edges of the sling should not sit on the bend of the elbow. If a post supports the arm holder, the post and arm holder should be distal to the elbow, freeing the cubital tunnel from pressure.

Lithotomy

The lithotomy position is used for gynecologic, rectal, and urologic procedures. With the patient supine, the legs are raised and abducted to expose the perineal region. The legs are placed in stirrups to maintain this position. There are four levels of lithotomy: low, standard, high, and exaggerated (Figure 5-16).

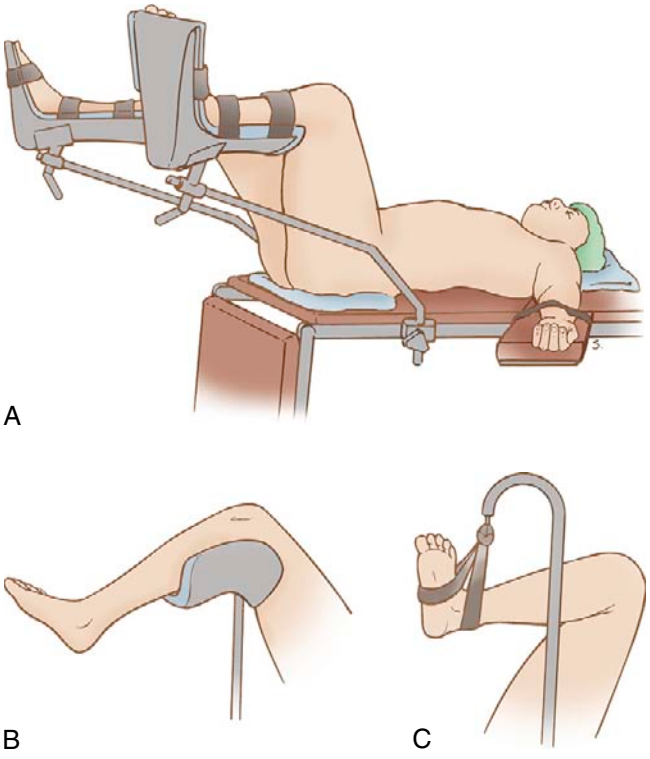

FIGURE 5-17 **A**, Lithotomy position using boot-type stirrups. **B**, Knee-crutch stirrup. **C**, Candy cane stirrup.

Low lithotomy is used for most urologic procedures and for procedures that require access to the perineum and abdomen simultaneously. The thighs are elevated approximately 30 to 45 degrees. *Standard lithotomy* is the most commonly used position for gynecologic procedures. The thighs are flexed approximately 90 degrees from the trunk, and the calves remain horizontal. For improved perineal access, some surgeons prefer a *high lithotomy* position. The thighs are often flexed beyond 90 degrees, and the legs are suspended high toward the ceiling. The *exaggerated lithotomy* position is sometimes used for transperineal access to the retropubic area. This extreme position moves the legs completely out of the way of the surgical field. The thighs are flexed toward the abdomen, the calves are suspended vertically, and the pelvis is flexed vertically at the spine, propped upward on a pillow or pad.

Stirrups are checked before use to ensure they are securely fastened to the side rails of the OR bed. Slippage of the stirrups or dropping of the legs during stirrup adjustments could cause hip dislocation, muscle or nerve injury, or bone fractures. Both stirrups should be at equal height and attached to the OR bed at the same level (Figure 5-17). The legs should be raised simultaneously to prevent strain on the patient's lower back; this requires two people so that both legs are totally supported throughout the move. Each person should grasp the sole of the foot with one hand and support the calf near the knee with the other. The legs are raised and the knees flexed in slow, smooth movements.

When the legs are secured in the stirrups, the mattress of the leg section of the OR bed is removed and the leg section platform is lowered. The buttocks should be even with the edge of the perineal cutout section of the OR bed to reduce the risk of lumbosacral strain.

The arms are supported on armboards (Figure 5-17, *A*), placed across the trunk, or tucked at the patient's side. When the arms are tucked, extreme caution is taken when the leg section of the bed is elevated back to a horizontal position at the conclusion of the procedure. If not, hands and fingers can be caught in the break of the bed and pinched or crushed.

Various types of stirrups are used for lithotomy positioning (Figure 5-17). The most common include posts with knee crutches, candy cane–shaped bars with straps that wrap around the ankles and plantar surface of the foot, and boot-type stirrups that cradle the lower foot and heel, and extend to the midcalf area. The type stirrup used can create unique hazards.

Knee-crutch stirrups (Figure 5-17, *B*), in which the weight of the leg rests solely on knee supports, can cause pressure on the posterior tibial and common peroneal nerves, and the popliteal artery in the popliteal fossa. This pressure predisposes the patient to complications, such as neuropathies and compartment syndrome (Patient Safety).

When using candy cane stirrups (Figure 5-17, *C*), the knees can drop close enough to the vertical stirrup bars that the lateral or medial side of each knee or calf rests against the bars. This can cause pressure on the common peroneal nerve as it curves laterally over the fibula, and this may result in footdrop and a lack of sensation below the knee. If the medial aspect of the knee or calf rests against a stirrup bar, the saphenous branch of the femoral nerve can be compressed against the tibia. Padding the stirrup bars can soften the rigidity of the bars, but does not totally eliminate pressure if the legs rest against the stirrup bars.

The relaxed hips of an anesthetized patient may separate further than they comfortably would if the patient were awake. When the legs hang freely in candy cane stirrups, there is risk of external rotation of the hips and hyperabduction. Hips should not be flexed more than 90 degrees. Exaggerated rotation and flexion can stretch the sciatic and obturator nerves and strain the hip joint and muscles.

When relatively thin ankle straps support the weight of the entire leg, pressure increases on the ankles and distal sural and plantar nerves. Neuropathies of the foot and pressure ulcers at ankle support sites can result. Using wide straps or cradling the feet with gel or foam padding before placing them in the stirrup straps may reduce the localized pressure to the nerves. Heavier leg weight in obese patients adds to the pressure on the ankle supports. Compartment syndrome can be the undesired outcome for a patient kept in high or exaggerated lithotomy position for many hours (Roeder et al, 2005).

Boot-type stirrups (see Figure 5-17, *A*) support the foot and calf, distribute pressure more evenly, and reduce the risk of extreme localized pressure on any one area of the foot or leg. They also allow for controlled and limited abduction.

Special care is needed for the patient who has limited range of motion attributable to a hip prosthesis, cast, amputation, or obesity. Severe hip flexion and abduction of the joint is avoided. The stirrup should be as low as possible and tilted slightly outward. Preexisting lumbar backache can be worsened in this position if the buttocks or lower back is not adequately supported. Several folded towels placed under the lumbar spine before induction of anesthesia can retain lordosis and reduce lower back strain. An exception is the patient with palpable

PATIENT SAFETY

Preventing Compartment Syndrome

Acute compartment syndrome can develop if a surgical position diminishes perfusion to an extremity. This syndrome is characterized by ischemia, hypoxic edema, and elevated tissue pressure within the fascial compartments of the extremity, leading to further damage to muscles and nerves. As this process occurs at a cellular level in tissues, distal pulse rates and capillary refill times may initially appear normal, but then rapidly escalate to a dangerous condition. The syndrome may progress to rhabdomyolysis with resulting renal damage, permanent nerve damage, loss of limb, or even death. The most effective means of terminating this syndrome is a decompressive fasciotomy.

FACTORS THAT CONTRIBUTE TO CAUSING COMPARTMENT SYNDROME

- An armboard strap that is too tight or arms tucked too tightly at the patient's side
- Elevation of an extremity coupled with systemic hypotension
- Compression on an elevated extremity by straps or leg wrappings that are too tight
- Pressure from the weight of an extremity against an edge of a leg-holding device
- Pressure from the arm of a surgical assistant holding an extremity too tightly
- Excessive popliteal pressure from a knee-crutch stirrup
- Prolonged lithotomy position (especially >5 hours)
- Kneeling 90/90 position (prone with hips and knees each flexed at 90 degrees) (Figure 5-23, p. 171)
- Excessive flexion of the knees or hips greater than 90 degrees (knee-chest or "tuck" position; exaggerated lithotomy position)

PREVENTIVE INTERVENTIONS

- Avoid excessively tight straps on extremities.
- Limit time in lithotomy position (especially high or exaggerated lithotomy).
- Place legs in well-padded, adequately supported stirrups, avoiding pressure on calf or popliteal fossa.
- Consider changing from a 90/90 kneeling position to a 45/45 position (Figure 5-24).

Modified from Denholm B: Tucking patient's arm and general positioning, *AORN J* 89(4):755-757, 2009; Edgcombe et al: Anaesthesia in the prone position, *Br J Anaesth* 100(2):165-183, 2008; Leek BT et al: The effect of kneeling during spine surgery on leg intramuscular pressure, *J Bone Jt Surg, Am* 89(9):1941-1947, 2007; Warner MA, Martin JT: Patient positioning. In Barash PG et al, editors: *Clinical anesthesia,* ed 5, Philadelphia, 2006, Lippincott Williams & Wilkins.

tender points in the lumbar region. The pressure of a pad in this area may cause too much distress. Elevating the legs may aggravate the pain of a herniated nucleus pulposus. In each of these situations, the patient may be placed in the lithotomy position before induction to assess areas of discomfort and implement appropriate therapeutic measures before the procedure begins. If the patient will be in this position for longer than 2 hours, SCDs or antiembolic stockings are applied to the patient's legs.

The lithotomy position poses significant risks for respiratory and circulatory compromise. Risks increase as the position is exaggerated for radical surgery of the groin, vulva, or prostate. Extreme flexion of the thighs impairs respiratory function by increasing intraabdominal pressure against the diaphragm, decreasing tidal volume. The elevated legs cause blood to pool in the trunk of the body during the procedure. This effect is greater when hip and knee flexion is extreme, as in high or exaggerated lithotomy positions. Blood loss during surgery may not be immediately noticed because of this increased trunk volume. However, when the legs are lowered and 500 ml or more of blood is diverted to more total leg circulation, circulating volume is reduced, and blood pressure may decrease. Anesthetics affect the nervous system by depressing normal compensatory mechanisms and hemodynamic adjustment may not be achieved easily.

The arms must not impede chest movement and respiration. The weight of the limbs on the chest, especially in infants and children, may fatigue muscles used in respiration and induce respiratory problems. In addition, elevation of the legs pushes abdominal viscera toward the diaphragm. Lowering the head of the bed can exaggerate this shift further as diaphragmatic excursion is reduced.

Releasing the patient from the position must be done slowly and with adequate assistance. The legs must be taken out of the stirrups and lowered simultaneously, with support given to the joints; this helps prevent the lumbosacral musculature from being stretched and strained, which could cause the pelvis and limbs to become unstable. The legs should be lowered slowly to allow for gradual hemodynamic adjustment as more blood shifts into the lower extremities. Distal lower extremity pulses should be evaluated before, during, and after this position.

Semi-Fowler

Semi-Fowler (lawn chair or beach chair) position may be used for some cranial, shoulder, nasal, abdominoplasty, or breast reconstruction procedures. This position is accomplished first with the patient supine. The upper body section of the bed is flexed 45 degrees, and the leg section is lowered slightly, flexing the knees. The arms may rest on a pillow in the lap or be secured on armboards parallel to the OR bed. A footboard may be attached to act as a footrest and prevent footdrop. The entire OR bed is then tilted.

When this position is used for shoulder surgery, the arm of the affected shoulder is prepped and draped to allow for intraoperative shoulder manipulation. The head and cervical spine are aligned and supported to prevent neuromuscular strain. Rotation of the head in the opposite direction of the shoulder the surgeon is manipulating can cause injury to the brachial plexus. A shoulder chair attachment allows for vertical torso support; it also has drop-away shoulder panels, which can be removed on the affected side during shoulder procedures to allow full access to the shoulder. This attachment also includes a padded head restraint, which secures the head from forward and lateral movement while the patient is in semi-Fowler position, and arm supports (Figure 5-18).

Diaphragmatic excursion improves in this position compared with the supine position. Although pressure points

FIGURE 5-18 Shoulder chair with drop-away shoulder support panels to allow surgical access to shoulder while maintaining torso support. Padded U-shaped head restraint with adjustable Velcro straps holds head secure and reduces undue stress on the neck when the back section is positioned.

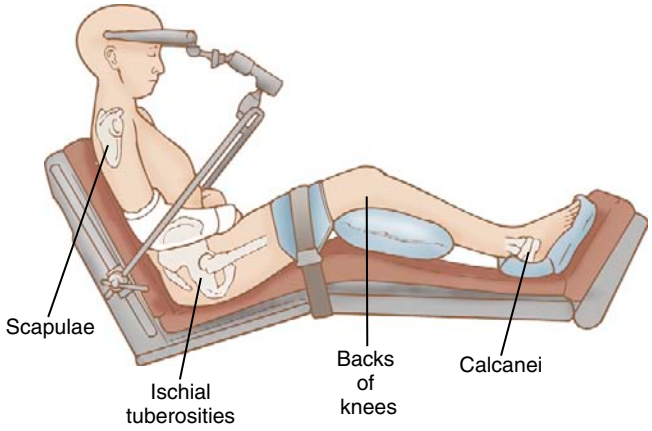

FIGURE 5-19 Potential pressure areas: Fowler's (sitting) position.

remain similar to those of the supine position, additional pressure is placed on the ischial tuberosities, calcanei, and coccyx.

Fowler's

Fowler's (sitting) position is used for some ear and nose procedures and craniotomies involving a posterior or occipital approach (Figure 5-19). This position is accomplished initially with the patient supine. Slowly, the upper body section of the OR bed is raised 90 degrees, while the knees are slightly flexed as the leg section is lowered. A footrest prevents footdrop. The arms either rest in the lap on a pillow with the elbows flexed at 90 degrees or less, or are on padded armboards. The cervical, thoracic, and lumbar sections of the spine are in alignment when the position is established. When this position is used for posterior fossa craniotomy or cranial ventricular procedures, a special craniotomy headrest is used to secure and immobilize the head. (A general discussion of pin fixation of the head is given in the Prone section.)

The main pressure points in Fowler's position include the scapulae, ischial tuberosities, calcanei, and coccyx. Also, pressure increases on the sciatic nerve. Padding is placed at the lumbar area and under the elbows, knees, buttocks, and heels. The popliteal space needs to be checked to ensure that no pressure is sustained from the edge of the mattress at the bottom of the torso section.

This position poses significant circulatory compromises and risks. Blood pooling occurs in the lower torso and legs, which causes significant orthostatic hypotension and diminished perfusion to the brain. Venous return from the lower extremities is impeded and such hindrance causes increased risk of VTE. SCDs or antiembolic stockings are used to support venous return.

With the operative site elevated compared with the heart, gravity causes a negative venous gradient between the operative site and the right atrium; this creates a potential for an air embolism if a venous sinus is opened. During a craniotomy, this potential increases when tissue is dissected free from the cranium, bone removed, the dura tacked up, or a highly vascular tumor bed entered. Additional monitoring for venous air embolism includes insertion of a central venous catheter into the pulmonary artery or right atrium and placement of a Doppler probe over the chest wall. If air embolism is diagnosed, the scrub person irrigates the surgical site quickly with normal saline to prevent further venous aspiration of air into the vein. The exposed area should be packed with saline-soaked sponges or cottonoids. If the air embolism occurred during bone entry, bone wax should be placed immediately over the exposed bone to seal it. The anesthesia provider may aspirate air from the right atrium through the central venous line. The perioperative nurse assists and supports the endeavors of the anesthesia provider and scrub team.

Respirations are probably least impeded in Fowler's position than in any other surgical position. It is important to ensure that if the arms are resting on a pillow in the lap and secured with tape, this position does not restrict chest movement. Flexion of the head and neck is avoided to prevent kinking of the endotracheal tube and subsequent airway obstruction.

When the procedure concludes, repositioning the patient back to supine position is done slowly so that the patient makes hemodynamic adjustments gradually. Distal lower extremity pulses are evaluated before, during, and after this position.

Prone

In the prone position, the patient is lying with the abdomen on the surface of the OR bed mattress (Figure 5-20). Modifications of the position allow approaches to the posterior cranium, posterior spine, rectal area, and dorsal areas of the extremities.

Anesthesia is induced with the patient in supine position, usually on the transport vehicle. Before the patient is turned, the anesthesia provider secures the endotracheal tube with tape, applies eye ointment in each eye, and tapes the eyelids closed to prevent corneal abrasions. The transport vehicle is locked adjacent to the locked OR bed. Four people using the "log-roll" technique can accomplish turning the supine patient to prone position safely, smoothly, and gently. The anesthesia provider supports the head and neck during the turn. A second person stands at the side of the transport vehicle with hands at the patient's shoulders and buttocks to initiate the roll of

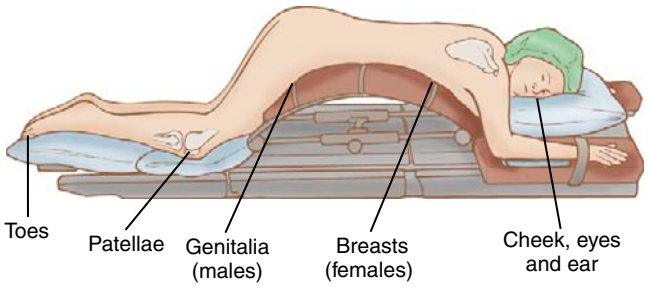

FIGURE 5-20 Wilson frame. Potential pressure areas: prone position using laminectomy frame for spinal procedures.

the patient. A third person stands at the opposite side of the OR bed, with arms extended to support the chest and lower abdomen as the patient is log-rolled laterally onto his or her abdomen. The fourth person stands at the foot of the transport vehicle to support and turn the legs. At the completion of the turn, the transport vehicle is removed.

The perioperative nurse must not allow the patient's arms to hang over the edge of the bed as the radial nerve can be compressed by the weight of the humerus. The arms are placed on armboards or secured at the sides. If the arms are to remain at the patient's side, they should be close to the body and secured with the draw sheet pulled smoothly around the arms and tucked under the patient's body. The elbows face upward in this position, so there is less risk of pressure on the ulnar nerve from the mattress; however, compression still can occur from a draw sheet that is too tight or from scrubbed personnel leaning on the elbow. Padding the elbow minimizes this risk. When the arms are placed on armboards, the arms are brought down and forward slowly, with minimal abduction to prevent shoulder dislocation and brachial plexus injury. Armboards are at the same height as the OR bed or at a lower parallel line to the OR bed, and the arms should rest with elbows flexed and hands pronated. Elbows should not be flexed beyond 90 degrees to avoid stretching the ulnar nerve. Pads should be placed distal and proximal to the elbow so that the ulnar nerve is not in contact with the armboard (see Figure 5-5, *C*). The following pressure points are checked: the cheeks, eyes, ears, female breasts, male genitalia, knees, and toes.

Head Support in Prone Position. Protection of the head and neck while in prone position is extremely important in order to prevent serious complications. Turning the head allows for fair access to the airway and endotracheal tube, and is safe for most patients, provided pressure on the dependent eye is protected (Faust et al, 2005). However, Rozet and Vavilala (2007) note the following concerns with turning the head. Manipulation of the head and neck may lead to mechanical stress on the arteries that supply blood to the brain and spinal cord. The vertebral arteries that pass through the narrow foramina in the transverse processes of the cervical spine can be occluded during extreme head manipulation. Hyperflexion of the head and neck should not exceed a thyromental distance (distance between the thyroid cartilage and chin) of two to three finger-breadths. Head rotation should be limited to a maximum of 45 degrees away from the body. Hyperextension, hyperflexion, lateral flexion, or rotation must be avoided as these can lead to brain stem and cervical spine ischemia, which in turn can result in quadriparesis and quadriplegia. Patients with osteophytes, arthritis, or vascular atherosclerosis are at higher risk of cerebral ischemia from inappropriate head and neck manipulation.

Face pillows and facial helmet devices enable the patient to be positioned with the head facing straight down while the patient is prone, thus in natural spinal alignment. Such devices are either made of foam that is hollowed out to conform somewhat to the contour of the face or are simply foam blocks with cutouts for the eyes, nose, and mouth to prevent pressure to those structures. Openings on the side allow access to the endotracheal tube. Some of these devices are available with mirrors, which enable the anesthesia provider to see the facial structures during the surgery. The weight of the head is supported by the foam at the forehead, cheeks, and chin. These areas must be monitored for signs of pressure. Studies show that interface pressures are lower on devices that contour the face (Atwater et al, 2004; Grisell and Place, 2008).

A horseshoe headrest is another device used to stabilize the head in prone position. This attachment fits onto the OR bed in place of the removable head section. It stabilizes the head by supporting the cheeks and forehead. Its advantage is that the entire head, face, and airway can be accessed and observed by the anesthesia provider without the obstruction of the OR bed. Its disadvantage is that the head is not fixed in place, so that it can move. The head may become unstable during adjustments to the OR bed, which may make it difficult to keep pressure off the eyes (Faust et al, 2005).

Pin fixation of the head (e.g., Mayfield head positioner) is frequently used for craniotomies in prone position (as well as in other positions). The head is supported by three pins that are tightened into the skull. This allows complete stabilization of the head without the risk of pressure to the eyes or other facial structures. However, the tightening of the pins on the scalp has a profound stimulative effect that causes tachycardia and hypertension. Since such a hemodynamic effect could be detrimental, with increased intracranial pressure or cerebral aneurysm, a local anesthetic is injected into the skin before pin fixation (whether the patient is awake or anesthetized). Patients under general anesthesia must have their anesthesia deepened before application of pins (Rozet and Vavilala, 2007). Goodkin and Mesiwala (2004) describe some additional complications. Entering veins within the skull might cause air embolism; therefore the pin sites should be lubricated. Perforation of the skull can occur in patients with thin skulls (especially children) or if the pins are overtightened. Special pins are used for children. Perforation of the skull may injure the middle meningeal artery, causing an epidural hematoma or a middle meningeal arteriovenous fistula. In patients who have had previous cranial surgery or shunts, care is taken not to reenter previous pin or bur hole sites, or craniotomy plates, and not to puncture a shunt valve or tubing.

A risk implicit with both the horseshoe headrest and the pin fixation device is inadvertent dropping of the head before it is stabilized in the device. The head is held by one person until it is secured in the device. The person holding the head should have no other responsibility until it is secured in the positioning device.

The respiratory system is most vulnerable in the prone position because normal anterior lateral respiratory movement is restricted, and the compressed abdominal wall and rib

FIGURE 5-21 Axis Jackson® system uses hinged technology to position the patient in various prone and semikneeling positions for spinal surgery.

cage inhibit normal diaphragmatic movement. This position requires ventilator assistance and chest support.

When placed in prone position, the patient is placed on a laminectomy frame (such as a Wilson frame, pictured in Figure 5-20), on a special prone spinal frame (Figure 5-21), or on chest rolls that extend lengthwise from the acromioclavicular joint to the iliac crest. These positioning devices raise the chest and permit the diaphragm to move more freely so the lungs may expand. They reduce intraabdominal pressure by allowing some open space for the abdomen. Pressure on the inferior vena cava also lessens. This in turn reduces blood loss by decreasing epidural venous pressure. Supports must not press against male genitalia. Female breasts should be angled toward the sternum to reduce stretching or compression. These areas are checked after final positioning to ensure that they are free from pressure. A bolster or pillow under the pelvis can decrease abdominal pressure on the inferior vena cava, especially in obese patients with large abdominal girths. A cushion or pillow is placed under the ankles to prevent pressure on the toes. The safety strap is placed across the dorsal aspects of the thighs so that the patient is secured but superficial venous return is not impaired.

Prone positioning can be initially hazardous when the anesthetized patient is turned from supine to prone position. Endotracheal tubes, intravenous lines, and monitoring devices may dislodge easily. Normal compensatory mechanisms are depressed and the patient cannot readily adjust to imposed hemodynamic changes and the resulting hypotension. Goodkin and Mesiwala (2004) discuss three types of complications associated with prone position. The first is trauma. Crush injuries can occur to the extremities during the roll from supine to prone and back. Pressure necrosis can occur to the skin, peripheral nerves, and brachial plexus. Pressure on the eyes can cause blindness (see Research Highlight: Vision Loss Associated with Prone Positioning). The second is venous air embolism, which can occur when the surgical site is above the level of the heart. The third is associated with anesthesia administration. If an airway problem occurs as a result of a kinked, dislodged, or obstructed endotracheal tube, reintubation and emergency airway management are extremely difficult from this position. Also, the dependent position may cause swelling of the tongue, resulting in macroglossia.

The Wilson frame (pictured in Figure 5-20) is useful during spinal decompression because it can arch the back, reversing the effects of normal lumbar lordosis, and be adjusted to cause the lumbar intralaminal spaces to open. The Jackson spinal surgery bed is also used in many hospitals for posterior spinal surgery when the opposite positioning effect is needed. For example, when screws, plates, or rods are placed in the patient's spine for fusion, a normal physiologic alignment of the spine is required. The torso rests on a chest pad and two hip pads, allowing the abdomen to hang free with the back straight. The legs are either supported on a flat platform or flexed and supported by a sling. A hinged spinal frame (Figure 5-21) can be used, rather than the Wilson or Jackson frames, as it allows the back to be either arched or flat. There are special positioning considerations when using all spinal frames, such as avoiding hyperextension of the shoulders, which can compress the brachial plexus. Manufacturer's guidelines must be followed meticulously.

Returning the patient to supine position onto the PACU stretcher requires a four-person log-roll technique. If a laminectomy frame was used, it can be tilted in the direction of the stretcher to initiate the move. Skin integrity is checked over all pressure point areas. Distal extremity pulses are evaluated before, during, and after prone positioning.

Jackknife

The jackknife or Kraske position is a modification of the prone position often used for hemorrhoidectomy and pilonidal sinus procedures (Figure 5-22). The patient's hips are placed on a bolster or pillow over the break in the lumbar

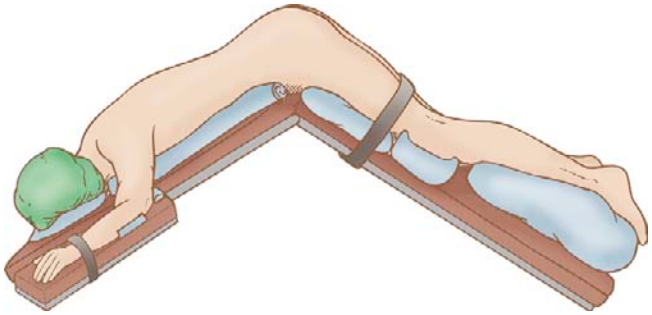

FIGURE 5-22 Jackknife (Kraske) position.

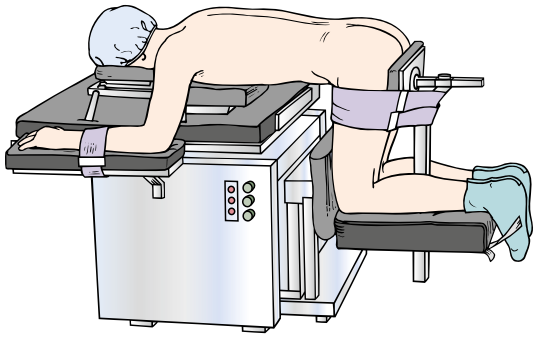

FIGURE 5-23 Frame for supporting patient in 90/90 kneeling position for spinal surgery.

section of the OR bed and the bed is flexed at a 90-degree angle, raising the hips and lowering the head and trunk. The patient's head, chest, and feet need the usual prone supports in this position. Chest rolls placed from under each shoulder to the iliac crest relieve pressure on the brachial plexus from the clavicle. A pillow is placed under the lower legs to prevent pressure on the toes. The safety strap is placed across the posterior thighs.

For anal procedures, the buttocks may be separated with strips of 3-inch tape secured firmly at the level of the anus a few inches from the midline on either side. These strips are pulled tight simultaneously and then fastened to the underside of the bed surface. The strips are released at the end of the procedure to facilitate wound closure.

This position causes circulatory changes because the head and the feet are in dependent positions, causing cephalad and caudad venous pooling. SCDs or antiembolism stockings assist in venous return and decrease the risk of VTE.

Respirations are severely compromised because anterior lateral chest movement is restricted. In addition, pressure is exerted on the diaphragm from the abdominal viscera and that stress worsens with pressure from the flexed OR bed.

When the procedure is completed, the OR bed is straightened very slowly so that the body can adjust hemodynamically. Four people use the log-roll technique to turn the patient supine. Distal lower extremity pulses are evaluated before, during, and after this position.

Kneeling and Knee-Chest

The kneeling and knee-chest ("tuck") positions are used primarily for spinal surgery such as thoracic and lumbar laminectomy and diskectomy (Figure 5-23). The kneeling position requires an extension of the prone position in which the hips and knees are both flexed about 90 degrees. The knee-chest position flexes the hips and knees greater than 90 degrees. The advantage of this position is that it enables the abdomen to hang free, reducing pressure on the abdomen and inferior vena cava. This eases ventilation and reduces bleeding by minimizing pressure on the epidural veins. It also provides good exposure of the posterior spine.

SCDs or antiembolism stockings are placed on the patient, and induction and intubation are performed with the patient supine on the transport vehicle. Transferring the anesthetized patient into kneeling position requires the coordinated effort of at least four people in the manner described for prone position; the knees, however, must be placed gently on a well-padded support platform. A safety strap is placed around the posterior area of the thighs, avoiding compression of the nerves and vessels in the popliteal fossa (St-Arnaud and Paquin, 2008). The knees and chest bear the weight of the body. Various frames are designed to support the patient in this position. Stabilization of the hips and buttocks is provided either by lateral supports on both sides of the hip or by a posterior support at the back of the buttocks. All manufacturers' instructions for safe positioning of the patient in a particular frame are followed to avoid some of the potential complications associated with this position.

Pressure points are a vital consideration for this position. They include the eyes, ears, chin, anterior rib cage, female breasts, anterior iliac crests, male genitalia, anterior tibial aspects of the calves, dorsal feet, toes, and knees. All of these areas need to be well padded and supported. Pedal and radial pulses are assessed before, during, and after positioning to ensure adequate perfusion of all four extremities.

Complications associated with this position are similar to those for prone position, but with added concern for the effects of legs being lower than the body and the weight of the hips and thighs resting on bent knees. The knees are under significantly more pressure than in any other position. Injury to the knee joints and necrosis to the skin and muscles around the knee may result. Hypotension occurs because of the pooling of blood into the lower extremities. This can be somewhat counteracted by the use of SCDs or antiembolism stockings. However, the longer this position is maintained, the higher is the risk for thrombosis and pulmonary embolism. Also, compartment syndrome and rhabdomyolysis (with associated renal damage) have been reported as complications, particularly when the knees are more deeply flexed as in the knee-chest or "tuck" position (see Patient Safety: Preventing Compartment Syndrome). These risks increase in the obese patient (Leek et al, 2007; Edgecombe et al, 2008). A 45/45 suspended position (i.e., hips and knees flexed at 45 degrees and legs suspended in a sling) may mitigate the risk of compartment syndrome for procedures that require a kneeling or knee-chest position (Leek et al, 2007). A modular OR bed system uses a hinged frame to place the patient in a 45/45 suspended prone position (see Figure 5-21), which offers the surgical access benefits of the kneeling position while limiting some of its associated risks. This bed system allows access for C-arm fluoroscopy and can accommodate patients in various other positions as well.

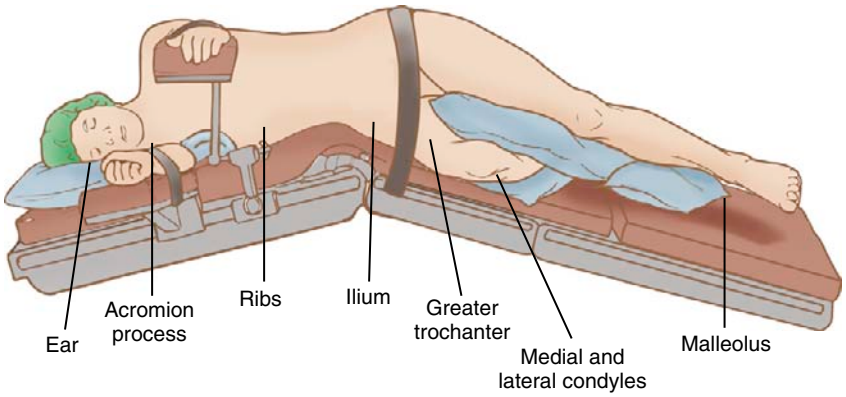

FIGURE 5-24 Potential pressure areas: lateral kidney position.

Lateral

In the lateral (lateral recumbent, lateral decubitus, or Sims) position, the patient lies on the nonoperative side, providing access to the upper chest, kidney (Figure 5-24), or upper section of the ureter. Reference to right or left lateral position relates to the side on which the patient lies. That is, in the right lateral position, the patient lies with the right side down. In left lateral, the patient is positioned with the left side down.

After induction of anesthesia, with the patient supine on the OR bed, the patient is turned to the side. A four-person team uses a draw sheet that is under the patient to facilitate a safe, smooth, gentle turn so that the nonoperative side is down.

A pillow or cushion is placed under the patient's head to maintain good alignment with the cervical spine and the thoracic vertebrae; this alignment also helps to minimize stretching of the dependent brachial plexus. The bottom leg is flexed at the knee and hip to stabilize the patient on the bed. The top leg is straight or slightly flexed. A pillow is placed lengthwise between the patient's legs. The lateral aspect of the bottom knee is padded to prevent pressure on the common peroneal nerve, located superficially at the head of the fibula. A person should remain at the patient's front and back to steady and support the torso during positioning of the lower extremities.

Pillows, rolled blankets, padded kidney braces, or a surgical positioning system (sometimes referred to as a Vac-Pac, or beanbag) support the torso. A beanbag is a soft pad filled with tiny beads. When suction is attached to a port on the pad, it conforms to the shape of whatever it encircles. A valve is closed to maintain the vacuum. It acts as an immobilizer until air is reintroduced, at which time it softens back into its original shape. While it is rigid, it increases the interface pressures of all tissue it contacts and the risk of pressure ulcer development increases. Large gel pads placed between the beanbag and the skin reduce, but do not eliminate, this risk.

The shoulders, hips, and legs may be secured with wide tape fastened to the platform of the OR bed. The upper arm is placed on an elevated armboard or rests on a pillow in front of the patient. The lower arm is flexed and rests on an armboard. The lower shoulder is brought slightly forward and an axillary roll placed under the rib cage, posterior to the axilla. This places the weight of the chest on the rib cage instead of compressing the lower shoulder and axilla, which otherwise may injure the brachial plexus of the dependent arm. Radial pulses and pulse oximetry are monitored to confirm adequate circulation in the dependent hand and arm. The axillary roll is typically made of rolled linen, a cylindrical gel pad, or a 1-L bag of IV fluid wrapped with linen. There have been reports of pressure ulcers occurring on the dependant thorax after the use of wrapped IV fluid as an axillary roll during shoulder surgery (Keyurapan et al, 2007). Speculation suggests that movement of patients during shoulder surgery may have caused friction and shearing forces on the thorax from the wrapped bag of fluid. This may have been further exacerbated by leakage of fluid from the arthroscopy field down onto the nonoperative dependent chest. The authors recommended that a towel or folded sheet be used in place of the bag of fluid and that care be taken to divert any fluid onto the nonoperative site.

Systolic and diastolic pressures decrease in the lateral position because pharmacologic agents and pathophysiologic processes depress normal compensatory mechanisms. The patient may not readily compensate for abrupt postural changes. Respiratory function is also compromised by the weight of the body on the lower chest, limiting its movement. Distal extremity pulses are evaluated before, during, and after this position and its modifications.

Lateral Chest

The lateral chest position allows an operative approach to the uppermost part of the thoracic cavity. The upper arm is flexed slightly at the elbow and raised above the head to elevate the scapula, to provide access to the underlying ribs, and to widen the intercostal spaces. The uppermost arm may be supported on a raised armboard or pillow. Slanting the upper section of the bed downward places the trachea and mouth at a level lower than the lungs—a position that enables bronchial secretions and fluids from the lung bases to drain into the mouth and not pass into the unaffected side of the chest.

A respiratory effect of this position is that the dependent lung is more perfused because gravitational pooling of blood occurs. The nondependent lung is more easily ventilated, however, because it is less compressed. This results in a ventilation-perfusion mismatch. The anesthesia provider applies positive end-expiratory pressure (PEEP) to both lungs to compensate for this decrease in functional lung capacity.

Lateral Kidney

The lateral kidney position (see Figure 5-24) allows approach to the retroperitoneal area of the flank. While being turned from supine to lateral position, the anesthetized patient is positioned so that the lower iliac crest is just below the lumbar break where the kidney bridge is located. To render the kidney region readily accessible, the kidney bridge is raised, and the bed flexed so that the area between the twelfth rib and the iliac crest is elevated. Raising the kidney bridge depends on the cardiovascular response of the body to increased pressure. The bridge must be raised slowly and blood pressure monitored frequently by the anesthesia provider. The bed is flexed to lower the patient's head and legs. The patient's affected side presents a straight horizontal line from shoulder to hip. In this position, the gravitational force on the head and torso opposes that on the extended limb to facilitate operative exposure.

Diaphragmatic movement is limited by increased intraabdominal pressure from the kidney bridge and by flexion of the lower limbs toward the abdomen. Both the acute angulations of the body in the lateral kidney position and gravity may decrease blood return to the right side of the heart.

To stabilize the torso, well-padded kidney braces may be used. The longer brace is placed anteriorly, against the iliac crest. The shorter one is placed against the back. Wide adhesive tape is placed across the hips and secured to the undersides of the OR bed. Before wound closure, the adhesive strap is released, the kidney bridge lowered, and the bed straightened to facilitate approximation of wound edges.

CHAPTER 6

Sutures, Needles, and Instruments

CHARLOTTE GUGLIELMI and SHEILA HUNTER

SUTURE MATERIALS

The development of surgical sutures has been closely associated with the development of the art of surgery. Medical writings of ancient Egyptian and Assyrian cultures dating back to 2000 BC mention the various materials used, to a limited extent, for suturing and ligating. The concept of suturing and ligating also is recorded in the writings of the father of medicine, Hippocrates (born 460 BC). Gut of sheep intestines was first mentioned as suture material by the ancient Greek physician Galen. The Persian physician and philosopher Rhazes is credited with employing surgical gut, or catgut, in AD 900 for suturing abdominal wounds. However, the word *catgut* is a misnomer, and its use is inappropriate. According to the *Oxford English Dictionary,* it refers to the Dutch word *kattedarm,* "cat-intestine." Use of the term *catgut* was adopted by the English around 1560 to 1600 under obscure conditions, possibly connected humorously with caterwauling (History box).

Suture is a generic term for all materials used to sew severed body tissues together and to hold these tissues in their normal position until healing takes place; to *suture* is to stitch together cut or torn edges of tissue (*Mosby's Medical Dictionary,* 2008). A *ligature* is a strand of suture material used to tie off (seal) blood vessels for the prevention of minor bleeding, or to isolate a mass of tissue for excision (cut out). A variety of suture materials are available for ligating, suturing, and closing the wound. The choice of suture takes into consideration several characteristics, such as the following: absorbable versus nonabsorbable, tensile strength, monofilament or multifilament, ease of knot-tying, and reactivity with tissue. An understanding of the characteristics of suture materials, knowledge of the risk factors of wound healing, and awareness of the interactions between tissues and suture materials are essential for proper wound healing. This is important information for all members of the perioperative team.

Characteristics of Suture Material

Key features used to evaluate the general properties of suture material are (1) physical characteristics, (2) handling characteristics, and (3) tissue-reaction characteristics (Box 6-1). The ideal suture material is one that causes minimal inflammation and tissue reaction while providing maximal strength during the lag phase of wound healing (see Chapter 8). Although the ideal suture has not yet been discovered, perioperative nurses should both evaluate the characteristics of suture to determine the ideal choice for surgical patient care and incorporate research findings into their clinical practice.

Physical Characteristics. Physical characteristics of sutures are defined and described by the *United States Pharmacopeia (USP),* which is the official compendium for suture manufacture. Characteristics can be measured or visually determined and include the following properties:

- *Physical configuration:* Suture material can be single-stranded (monofilament) or multi stranded (multifilament), containing numerous fibers rendered into a single thread by twisting or braiding (Figure 6-1).
- *Capillarity:* This is defined as the ability to transmit fluid along the strand.
- *Diameter (size):* Size is measured in millimeters, and expressed in USP sizes with zeroes. That is, the smaller the cross-sectional diameter, the more zeroes; sizes range from #7, the largest, to 11-0, the smallest. Suture sizes 0 to 4-0 are the most commonly used sutures in general surgery. (The surgeon usually selects the finest suture possible for the tissue being closed. The finer diameter [smaller size] provides better handling qualities and small knots. Improved suturing techniques are possible with sutures of finer diameter.)
- *Tensile strength:* This is defined as the amount of weight (breaking load) necessary to break a suture (breaking strength); it varies according to the type of suture material (Table 6-1).
- *Knot strength:* The force necessary to cause a given type of knot to slip, either partially or completely, is the knot strength.
- *Elasticity:* This is defined as the suture's inherent ability to regain original form and length after having been stretched.
- *Memory:* Memory is the capacity of a suture to return to its former shape after being re-formed, as when tied; high memory yields less knot security.

Handling Characteristics. Handling characteristics of suture material are related to pliability (how easily the material bends) and the coefficient of friction (how easily the suture slips through tissue and can be tied). A suture with a high friction coefficient tends to drag through tissue. It is more difficult to tie because its knots do not set easily. Some suture materials are coated to reduce their coefficient of friction. This coating not only improves the way they pull through tissue on insertion but also lessens the force needed to remove the suture after the wound is healed. The coefficient of friction should not be too low, however, because then knots will be loosened too easily.

Tissue-Reaction Characteristics. Because it is a foreign substance, all suture materials cause some tissue reaction. Tissue reaction begins when the suture inflicts injury to the tissue during insertion. In addition, tissue reacts to the suture material itself (Table 6-2). This reaction begins with an infiltration of

HISTORY

The Evolution of Suturing Materials in Surgery

During the sixteenth century, Ambrose Paré reintroduced the use of ligatures to stop hemorrhage and abandoned the use of cauterizing hooks. Subsequently the nurse in the OR became responsible for the time-consuming task of preparing suture material. The following are references to suture and its preparation (or removal from the operative wound) as chronicled in select nursing and medical textbooks.

Year	Breakthrough
1879	Sutures are composed of various materials and are applied in many different ways, according to circumstance. Some surgeons prefer hempen thread or silk; others prefer an animal membrane, such as catgut; and others prefer a fine wire. The advantages claimed for the last-mentioned are that it does not irritate the tissues, and that it does not absorb the secretions.
1890	The method most commonly used by surgeons for the arrest of hemorrhage from an artery of any size is ligation. The artery is picked up by a pair of forceps, and a ligature is tied firmly about it. Ligatures should be about 18 inches long. A ligature is most often made of strong, soft silk, although catgut or wire is sometimes used. Its strength should be tested well, so as to leave no chance of its breaking when strained.
1918	Catgut is wound evenly on glass spools, 1 yard of catgut on each spool, and each spool is placed in a glycerin-jelly jar. Each jar is filled with absolute alcohol; the cap is lightly screwed on; and the jars are placed, cap down, in a 2-quart glass jar and covered with absolute alcohol. The glass jar is placed in a water bath on a gas stove…at a distance from the flame…. The catgut is boiled in alcohol three successive times for 1 hour at intervals of 24 hours.
1961	Skin sutures (black silk thread, fine wire, or metal skin clips) are removed from abdominal wounds on about postoperative day 7, from head and neck wounds on about postoperative day 3 to 5, and from wounds of the extremities on postoperative day 8 to 10. Retention sutures composed of heavy wire and passed deep into muscle tissue usually are not removed until postoperative day 14 to 21. Most patients are apprehensive when they know the sutures are to be removed.
1961	The ligatures used in a surgical operation are of two main kinds: absorbable and nonabsorbable. Absorbable sutures are made of catgut, which is prepared from the muscle coat in the wall of the sheep's intestine. Catgut is now provided already sterilized in ampoules that are stored in antiseptic solution and have to be broken open at the time they are required. When the ampoule is opened, the catgut must be rinsed in warm sterile saline or water to remove the fluid in which it is preserved. This fluid has a penetrating odor because of the cresol in it.
1971	Skin stitches, Mersilene or nylon, are removed when the wound has healed, usually on postoperative day 8 to 10. It is advisable to remove alternate stitches on one day and the remainder the next day if the wound is sound.
1972	The word *catgut* is a misnomer. The Arabic word *kit* means a "dancing master's fiddle," but the word *catgut* has no relation to a cat.

Types of Suture Material

Suture materials are classified into two broad groups: *absorbable* and *nonabsorbable*.

Absorbable Sutures. The USP defines an absorbable surgical suture as follows: …sterile, flexible strand prepared from collagen derived from healthy mammals, or from a synthetic polymer…. It is capable of being absorbed by living mammalian tissue but may be treated to modify its resistance to absorption…. It may be modified with respect to body or texture. It may be impregnated with a suitable coating, softening, or antimicrobial agent. It may be colored by a color additive approved by the federal Food and Drug Administration.

Absorbable sutures can be digested (by enzyme activity) or hydrolyzed (broken down by reaction with water in tissue fluids) and assimilated by the tissues during the healing process. Absorbable sutures vary in treatment, color, size, packaging, and resistance to absorption, according to their purpose. Types of absorbable suture include plain or chromic surgical gut, collagen, and glycolic acid polymers (Table 6-3).

SURGICAL GUT. Surgical gut is obtained from the collagen of the submucosal layer of the small intestine of sheep or the intestinal serosa of cattle or hogs. The processed strands or ribbons of collagen are either untreated (plain, type A) or treated with chromium salts (chromic, type C).

Chromatization delays absorption of the suture in living mammalian tissue. The strength of the chromium salt content and the duration of the chromatizing process are accurately controlled and tested. Proper chromatizing of gut ensures the integrity of the suture and maintenance of its strength during the early stages of wound healing. It enables a wound with slow healing power to heal sufficiently before the suture is entirely absorbed.

The elaborate processes of mechanical and chemical cleaning of the raw gut are followed by sterilization, usually with ionizing radiation, and storage in hermetically sealed packages. Modern manufacturing processes also ensure tensile strength, more controlled absorption, and more predictable results.

Absorption occurs by digestion of the gut by tissue enzymes. The absorption rate of surgical gut is influenced by the type of body tissue it contacts and, to some extent, by the patient's general physical condition. Studies also show that surgical gut is absorbed faster in serous or mucous membranes than in muscular tissues. When fine chromic gut is properly buried in successive layers of the gastrointestinal tract, it retains its strength long enough for primary union to take place.

Degradation	Tissue Reactivity	Handling	Knot Security	Contraindications
Proteolytic	Moderate	Fair	Poor	Not used where extended approximation of tissue under stress is required. Not used in patients with known allergies or sensitivities to collagen or chromium
Proteolytic	Moderate	Fair	Fair	Not used where extended approximation of tissue under stress is required. Not used in patients with known allergies or sensitivities to collagen or chromium
Hydrolytic	Minimal	Excellent	Good	Not used where extended approximation of tissue under stress is required or where wound support beyond 7 days is required
Hydrolytic	Minimal	Excellent	Excellent	Not used where extended approximation of tissue is required. Not for use in cardiovascular surgery, neurologic surgery, microsurgery, or ophthalmic surgery
Hydrolytic	Minimal	Excellent	Good	Not used where extended approximation of tissue is required. Undyed not indicated for use in fascia
Hydrolytic	Minimal	Good	Good	Not used where extended approximation of tissue is required. Not for use in cardiovascular or neural tissues
Hydrolytic	Minimal	Excellent	Excellent	Not used where extended approximation of tissue is required. Not for use in cardiovascular or neural tissues
Hydrolytic	Minimal	Good	Good	Not used where extended approximation of tissue is required. Not for use in cardiovascular or neural tissues
Hydrolytic	Minimal	Excellent	Excellent	Not used where extended approximation of tissue is required. Not for use in cardiovascular or neural tissues
Hydrolytic	Minimal	Good	Good	Not used where extended approximation of tissue is required. Undyed not indicated for use in fascia
Hydrolytic	Slight	Good	Good	Not used where extended approximation of tissue is required. Not used with prosthetic devices, such as heart valves or synthetic grafts
Hydrolytic	Minimal	Good	Good	Not used where extended approximation of tissue is required. Not for use in cardiovascular surgery, neurologic surgery, microsurgery, or ophthalmic surgery

TABLE 6-4

Comparison of Nonabsorbable Sutures

Ethicon	Syneture (U.S. Surgical)	Package Color	Configuration	Tensile Strength	Absorption Rate
Perma-Hand (silk)	Sofsilk	Light blue	Braided; Sofsilk is available with wax coating	Progressive degradation with gradual loss over time	Hydrolysis leads to gradual encapsulation by fibrous connective tissue
Ethilon (nylon)		Light green	Monofilament	Progressive degradation with gradual loss over time	Hydrolysis leads to gradual encapsulation by fibrous connective tissue
Nurolon (nylon)	Dermalon, Surgilon, Monosof (nylon)	Light green	Braided; Dermalon, Surgilon, Monosof silicone coated	Progressive degradation with gradual loss over time	Hydrolysis leads to gradual encapsulation by fibrous connective tissue
Mersilene (polyester)	Surgidac (polyester)	Turquoise, orange (Surgidac)	Braided or monofilament	No significant loss in vivo	Gradual encapsulation by fibrous connective tissue
Ethibond (polyester)	Ti-Cron (polyester)	Orange, orange stripe (Ti-Cron)	Braided; uncoated or coated with silicone	No significant loss in vivo	Gradual encapsulation by fibrous connective tissue
Prolene, Pronova (polypropylene)	Surgipro, Surgipro II (polypropylene)	Deep blue	Monofilament	Not subject to degradation or weakness by hydrolysis	Nonabsorbable
	Novofil (polybutester)	Blue green	Monofilament	Not subject to degradation or weakness by hydrolysis	Nonabsorbable
Stainless steel	Stainless steel	Mustard	Monofilament, twisted, or braided	Indefinite	Nonabsorbable

Modified from *Ethicon wound closure manual,* Sommerville, NJ, 2004, Ethicon, available at www.jnjgateway.com. Accessed July 12, 2009; *Syneture nonabsorbable suture,* available at www.syneture.com/syneture/pagebuilder.aspx?topicID=319&;xsl=xsl/absorptionPage.xsl. Accessed July 12, 2009.

Surgical gut suture is wet-packaged in an alcohol solution to provide maximal pliability and should be used immediately after removal from the packet. When a gut suture is removed from its packet and is not used at once, the alcohol evaporates, which causes the strand to lose its pliability. If required, the strand's pliability may be restored just before use by immersing it in sterile water or normal saline solution, preferably at body temperature, for only a few seconds. This immersion is recommended only for eye sutures; in other areas, tissue fluids moisten the gut sufficiently as it passes through the tissue when the surgeon sews. Excessive moisture reduces tensile strength.

COLLAGEN SUTURES. Collagen sutures are derived from the tendons of cattle. They are chemically treated to remove noncollagenous material, purified, and processed into strands that have physical properties superior to those of surgical gut. Collagen suture is used most often as a fine suture material for the eye.

SYNTHETIC ABSORBABLE SUTURES. To produce synthetic absorbable sutures, specific polymers are extruded into suture strands. The base material for synthetic absorbable sutures is a combination of lactic acid and glycolic acid polymers (Vicryl, Dexon, and Polysorb). The molecular structure of these products has a tensile strength sufficient for approximation of tissues for 2 to 3 weeks, followed by rapid absorption.

Other synthetic polymers (PDS, Maxon, and Monocryl) provide wound support for longer periods (3 months). They are used when prolonged support for wound healing is desired, as with fascial closure or for elderly or oncology patients. They combine the desirable qualities of extended wound support and eventual absorbability.

A new synthetic absorbable suture has recently been approved by the Food and Drug Administration (FDA). Recombinant DNA technology is used to produce poly-4-hydroxybutyrate (TephaFLEX) suture. This suture has a high degree of flexibility and maneuverability, but may have limitations for use in patients who are allergic to the cells or the growth medium used for its production. The suture is not indicated for use in cardiovascular or neurologic tissues or for microsurgery or ophthalmic surgery (FDA, 2007).

Synthetic absorbable sutures are absorbed by slow hydrolysis in the presence of tissue fluids. Hydrolysis is the chemical process whereby the polymer reacts with water to cause an alteration of breakdown of the molecular structure. These sutures are degraded in tissue by this process at a more predictable rate than surgical gut (or collagen) and with less tissue

Degradation	Tissue Reactivity	Handling	Knot Security	Contraindications
Progressive	Acute inflammatory reaction	Good	Good	Not used in patients with known sensitivities or allergies to silk. Not used in contaminated or potentially contaminated wounds. Not used where permanent retention of tensile strength required
Progressive	Minimal	Poor	Poor	Not used where permanent retention of tensile strength required
Progressive	Minimal	Fair; Syneture products coated for better handling	Fair; Syneture products coated for increased knot security	Not used where permanent retention of tensile strength required
None	Minimal	Good	Good	None known
None	Minimal	Good	Good	None known
None	Minimal	Poor	Poor	None known
None	Minimal	Fair	Poor	Not used in patients with known sensitivities or allergies to its components. Not used in microsurgery or neurologic surgery
None	Minimal	Poor	Good	Not used in patients with known sensitivities or allergies to steel or its principal metallic components, chromium and nickel

reaction. These sutures are dry-packaged in sizes 10-0 to #3. They should not be dipped in solutions because moisture reduces their tensile strength. Some polymers have additional coatings to reduce drag in tissue.

Nonabsorbable Sutures. Nonabsorbable sutures are strands of material that effectively resist enzymatic digestion in living animal tissue. The USP classifies nonabsorbable surgical suture as follows:

- Class I suture is composed of silk or synthetic fibers of monofilament, with a twisted or braided construction.
- Class II suture is composed of cotton or linen fibers or coated natural or synthetic fibers, in which the coating significantly affects thickness but does not contribute significantly to strength.
- Class III suture is composed of monofilament or multifilament metal wire.

The strand of suture material may be uncoated or coated with a substance to reduce capillarity and friction when passing through the tissue. Several products are used for coating, including silicone, polytef (Teflon), and various polymers. Fibers may be uncolored, naturally colored, or impregnated with a suitable dye.

Nonabsorbable suture material is encapsulated or walled off by the tissues around it during the process of wound healing. Skin sutures, for which nonabsorbable materials are often the choice, are removed before healing is complete. The most common nonabsorbable suture materials are silk, nylon, polyester fiber, polypropylene, and stainless-steel wire (Table 6-4).

SILK. Silk is prepared from thread spun by the silkworm larva while making its cocoon. Top-grade raw silk is (1) processed to remove natural waxes and gum, (2) manufactured into threads, and (3) colored with a vegetable dye. The strands of silk are twisted or braided to form the suture, which gives it high tensile strength and better handling qualities. Silk handles well, is soft, and forms secure knots.

Because of the capillarity of untreated silk, body fluid may transmit infection along the length of the suture strand. For this reason, surgical silk is treated to eliminate its capillarity properties (able to resist the absorption of body fluids and moisture). It is available in sizes 9-0 to #5, in sterile packets or precut lengths, and with or without attached needles. Silk should be kept dry. Wet silk loses 20% of its original strength. Silk is not a true nonabsorbable material. When buried in tissue, it loses its tensile strength after about 1 year and may disappear after several years.

COTTON. Surgical cotton sutures are made from individual cotton fibers that are combed, aligned, and twisted to form a finished strand. Because new types of fibers have been introduced, cotton suture is rarely used. Some companies no longer manufacture it.

Umbilical tape, although not used for suturing, is produced by suture manufacturers and packaged in the same way as suture. It consists of long woven ribbons of cotton, 1/16 to 1/8 inch wide, and is used for retraction or suspension of small structures and vessels. (Other soft, pliant products, such as vessel loops, are available and more commonly used for this purpose.)

NYLON. Surgical nylon (Dermalon, Ethilon, Surgilon, Nurolon, Bralon, Monosof) is a synthetic polyamide material. It is available in two forms: multifilament (braided) and monofilament strands. Multifilament nylon is relatively inert in tissues and has a high tensile strength. It is used in conditions similar to those in which silk and cotton are used. Monofilament nylon is a smooth material that is particularly well suited for closing skin edges and for tension sutures. Because of its poor knot security, the surgeon usually ties three knots in small sutures and a double square knot in large sutures. It is used frequently in ophthalmology and microsurgery because it can be manufactured in fine sizes. Size 11-0 nylon is one of the smallest suture materials available.

POLYESTER FIBER. Surgical polyester fiber (Ti-Cron, Dacron, Mersilene, Tevdek, Polydek, Ethibond, Surgidac) is available in two forms: a nontreated polyester fiber suture and a polyester fiber suture that has been specifically coated or impregnated with a lubricant to allow smooth passage through the tissue. Polyester fiber is available in fine filaments that can be braided into various suture sizes to provide good handling properties.

Polybutester (Novafil) is a special type of polyester suture that possesses many of the advantages of polyester and polypropylene. Because it is a monofilament, it induces little tissue reaction.

Polyester material has many advantages over other braided, nonabsorbable sutures. It has greater tensile strength, minimal tissue reaction, and maximal visibility and does not absorb tissue fluids. It is used frequently as a general-closure fascia suture and in cardiovascular surgery for valve replacements, graft-to-tissue anastomoses, and revascularization procedures.

POLYPROPYLENE. Polypropylene is a clear or pigmented polymer. This monofilament suture material (Prolene, Surgilene, Surgipro, Dermalene) is used for cardiovascular, general, and plastic surgery. Because polypropylene is a monofilament and is extremely inert in tissue, it may be used in the presence of infection. It has high tensile strength and causes minimal tissue reaction. Sizes range from 10-0 to #2.

STAINLESS STEEL. Surgical stainless steel is formulated to be compatible with stainless-steel implants and prostheses. This formula, 316L (L for "low carbon"), ensures absence of toxic elements, optimal strength, flexibility, and uniform size. Monofilament and multifilament surgical stainless-steel sutures are known for their strength, inert properties, and low tissue reaction. Stainless steel–suturing technique is very exacting, however. Steel can pull or tear out of tissue, and necrosis can result from a suture that is too tight. Barbs on the end of steel can traumatize surrounding tissue or tear gloves. Torn or cut gloves fail to provide an adequate and effective barrier for the patient or the surgeon and assistant and can remain undetected. Kinks in the wire can render it practically useless. For this reason, packaging has played an important part in the development of surgical stainless-steel sutures. Surgical stainless steel is available in packets on spools or in packages of straight, precut, sterile lengths, with or without attached needles. This packaging affords protection to the strands and delivery in straight, unkinked lengths.

TABLE 6-5

Steel Suture Comparison

Size (USP)	B&S Gauge	Size (USP)	B&S Gauge
6-0	40	0	26
6-0	38	1	25
5-0	35	2	24
4-0	34	3	23
4-0	32	4	22
000	30	5	20
00	28	7	18

B&S, Brown and Sharp; *USP,* United States Pharmacopeia.

Before surgical stainless steel was available from suture manufacturers, it was purchased by weight with the Brown and Sharp (B&S) scale for diameter variations. Today the B&S gauge, along with USP size classifications, is used to distinguish diameter ranges. Table 6-5 compares steel suture sizes.

BARBED SUTURE. Barbed suture is a lesser known suture type, marketed as the Quill Self-Retaining System. This is a self-anchoring suture that does not require knots or slack management for wound closure. A polydioxanone suture, it is available in 0 and 2-0 sizes on both straight and curved needles, and it is absorbed in 26 weeks. Murtha and colleagues (2006) report comparable results with conventional would closure techniques in patients undergoing cesarean section. This suture, also used in cosmetic surgery, avoids the drawbacks inherent to suture knots in some patients.

SURGICAL NEEDLES

Surgical needles vary in shape, size, point design, and wire diameter (Figure 6-2). The appropriate needle is selected depending on the type and location of tissue being sutured. Surgical needles are made from stainless steel or carbon steel. Various metal alloys used in manufacturing surgical needles determine their basic characteristics. They must be strong, ductile, and able to withstand the stress imposed by tough tissue. Stainless steel is the most popular, not only because it provides these physical characteristics but also because it is noncorrosive. The three basic parts of a surgical needle are the *eye,* the *body,* and the *point* or *tip*.

Eye

The eye of the surgical needle falls into the following three general categories:

1. Eyed needles, in which the needle must be threaded with the suture strand, and two strands of suture must be pulled through the tissue (Figure 6-3, *A*)
2. Spring, or French, eyed needles, in which the suture is placed or snapped through the spring (Figure 6-3, *B*)
3. Eyeless needles, a needle-suture combination in which a needle is swaged (permanently attached) onto one or both ends of the suture material (Figure 6-3, *C*)

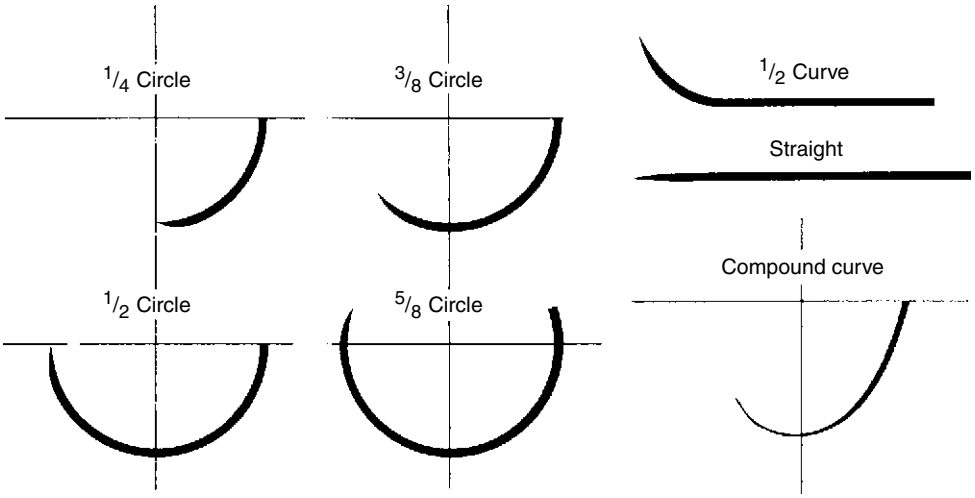

FIGURE 6-2 Surgical needles vary in shape, size, type of point and body, and how the suture is attached.

The swaged needle is the most universally used needle type, eliminating threading eyed needles before and during surgery. A single strand of suture material is drawn through the tissue, and tissue damage is minimized (atraumatic). The swaged needle may need to be cut off with suture scissors or swaged for controlled release of the suture (semiswaged). With semiswaged suture, the needle remains attached until the surgeon releases it with a straight tug of the needle holder.

Body

The body, or shaft, of the needle may be round, triangular, or flattened. Surgical needles also may be straight or curved; the curve is described as part of an imaginary circle (see Figure 6-2). As the radius of the imaginary circle increases, the size of the needle also increases. The body of a round needle gradually tapers to a point.

Point

Choice of needle point relates to the density of the tissue to be penetrated. Delicate tissue, such as bowel or kidney, requires a taper or blunted point, whereas skin, which is dense in structure, requires a cutting edge. Taper points tend to tear tissue less than cutting needles do and leave a smaller hole in the tissue. Recently introduced blunt protect-point needles are being recommended as an alternative to taper point needles. Interest in blunt needles has evolved because of the risk of bloodborne exposure from percutaneous injuries (PIs). Approximately 77% of sharps injuries result from suture needle sticks (Berguer and Heller, 2005). Such injuries have been reported to occur in an estimated 1% to 15% of surgical procedures—mostly associated with suturing. Some studies have been conducted to evaluate the effectiveness of blunt needles in preventing PIs and to assess their clinical acceptability by surgeons. The use of blunt needles represents a key strategy to reduce risk to the surgical team (Risk Reduction Strategies). Blunt needles are associated with a statistically significant reduction in PIs and can be substituted for conventional curved needles in a variety of surgical procedures. Table 6-6 illustrates the type of points available for various tissues. Interestingly, recent research has been conducted to evaluate the relationship between glove perforations and the risk of surgical site infections (Research Highlight).

RISK REDUCTION STRATEGIES

Using Blunt Needles to Avoid Needle-Stick Injuries

Analysis of percutaneous injuries shows that essentially most injury rates have decreased in many device categories. Suture needles have failed to show a major decline in sharps injury rates, however. Of the top six devices responsible for 80% of all injuries, suture needles ranked second, accounting for 19% of needle sticks. A safer alternative to sharp-tip suture needles is the blunt-tip suture needle. These needles are sharp enough to pierce internal tissue, but not sharp enough to penetrate the skin. They are now available in a range of bluntness. In the past, a challenge for perioperative nurses was their inability to persuade a surgeon to use a safer device, such as a blunt-tip needle, because the surgeon chose which devices to use. In 2007 the American College of Surgeons (ACS) replaced the 2005 *Statement on Blunt Suture Needles* with a more comprehensive document entitled *Statement on Sharps Safety*. This document outlines a comprehensive strategy that includes the use of blunt needles, implementation of a neutral zone, use of engineering controls, and implementation of workplace practices such as wearing double gloves.

Modified from Cowles L: The point of the matter, *Adv Nurs* 6(17):43-44, 2004; Perry J, Jagger J: Sharps safety update—are we there yet? *Nursing 2005* 35(6):17, 2007; American College of Surgeons: *Statement on sharps safety,* available at www.facs.org/fellows_info/statements/st-58.html. Accessed July 8, 2009.

Triangular needles have cutting edges along three sides. The cutting action may be conventional or reverse. The cutting edge of the conventional cutting needle is directed along the inner curve of the needle, facing the wound edge when suturing is performed.

The reverse cutting needle is preferred for cutaneous suturing. When it transects the skin lateral to the wound, the outside cutting edge is pointed away from the wound edge, and the inside flat edge is parallel to the edge of the wound. This cutting action reduces the tendency for suture to tear through tissue.

For certain types of delicate surgery, needles with exceptionally sharp points and cutting edges are used. Microsurgery, ophthalmic surgery, and plastic surgery require needles of this type; special honing wheels provide needles of precision-point

RESEARCH HIGHLIGHT

Surgical Glove Perforation and the Risk of Surgical Site Infection

There is an ongoing debate among perioperative personnel about the risk of infection in patients when gloves of operative personnel have been perforated during the course of a surgical procedure. The literature is weak in providing evidence to determine best practices. The hypothesis of this study was, "Clinically apparent surgical gloves perforation increases the risk of surgical site infection (SSI)." Conducted over a 12-month period in a university-based facility with a surgical case volume of 28,000 surgical interventions annually, a consecutive series of 4147 surgical procedures were included. Initial observations were gathered in the OR and follow-up data were gathered through direct chart review, from physician feedback, and with follow-up phone calls. A total of 188 SSIs were detected in the 4147 procedures studied. Asepsis was compromised by glove leakage in 677 (16.3%) of the cases. The study also considered SSIs in procedures that lasted >2 hours without glove perforation. Analysis revealed that the risk of SSIs was higher in those cases in which the patient did not receive antibiotic prophylaxis. The authors contend that the risk of developing SSIs is significantly higher in surgical procedures in which gloves are perforated and no antimicrobial prophylaxis is administered. This was the first study to explore the correlation of these two variables on the risk of SSIs. Other considerations noted in the study were the role of double-gloving, the type of glove worn (latex vs. other), and the duration that the gloves were worn. The authors report some limitations in the study; however, they conclude that the clinical consequences of glove perforation in terms of SSIs have been neglected. They also acknowledge that there is opportunity for greater research in this area. Perioperative nurses have long recognized the importance of the role of vigilance of aseptic practices during a surgical procedure. As members of the team, they need to aggressively declare breeches in technique as well as accurately classify those surgical procedures in which glove perforations occur so that, based on each patient's unique situation, a decision can be made about the risks and benefits of antimicrobial administration in patients who have increased risk.

Modified from Misteli H et al: Surgical glove perforation and the risk of surgical site infection, *Arch Surg* 144(6):553-558, 2009.

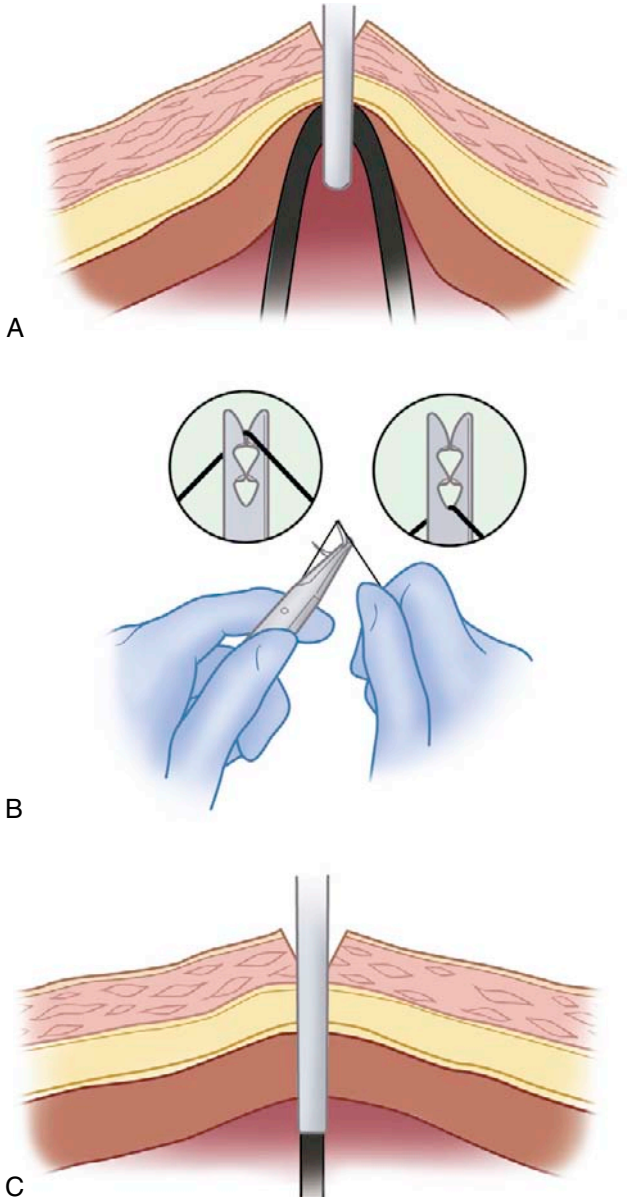

FIGURE 6-3 Types of needles. **A**, Eyed needle. Greater tissue trauma is caused by the double suture strand threaded through eyed needles. **B**, Spring eye. Holding suture strand taut with left hand, bring strand down over top and spring into eye. **C**, Atraumatic (eyeless) needle causes minimal tissue trauma by eliminating the double suture strand.

quality for surgery in these specialties. In some instances, the application of a microthin layer of plastic to the needle surface provides for easier penetration and reduces drag of the needle through tissue.

Most surgical services departments have instituted standardization programs to control the variety of needle-suture combinations available for surgical procedures.

PACKAGING, STORAGE, AND SELECTION OF SUTURES

Types of Packaging

For packaging, the suture material is sealed in a primary inner packet, which may or may not contain fluid; placed inside a dry, outer, peel-back packet; and sterilized. This method permits easy dispensing onto the sterile field. Various forms of foil, plastic, and special paper are used for the inner and outer packets.

Each primary suture packet is self-contained, and its sterility for each patient is ensured as long as the integrity of the packet is maintained. Some suture packets have expiration dates that relate to stability and sterility. Packages should be stored in moisture-proof and dust-proof containers in units of one size and type.

Suture packets may contain single or multiple strands, with or without a needle attached to the strand. The needle may be swaged to the suture and may need to be cut off for removal, or it may be designed to separate easily from the suture with a quick tug of the needle holder (Controlled Release, D-Tach, Pop-off). Some sutures may be double-armed, with a needle at each end of the strand.

TABLE 6-6

Atraumatic Needles

Needle Type	Description of Body	Use
Taper point	Round shaft, straight or curved, taper point, no cutting edge	Soft tissue closure, such as gastrointestinal, fascial, vascular, and most soft tissues below skin surface
Penetrating point	Taper body with finely sharpened point; optimal penetration with less tissue wound	Ligaments, tendons, and calcified, fibrous, and cuticular tissue; mostly used for vascular, thoracic, plastic, obstetrics/gynecology, and orthopedic surgery; excellent penetration through synthetic grafts and scar tissue during repeat surgeries
Blunt point	Taper body with rounded point, no cutting edge	Friable tissue, fascia, liver, intestine, kidney, muscle, uterine cervix (note recommendations regarding use of blunt needles, p. 181)
Protect-point	Taper body with blunted point, no cutting edge	Primarily in fascia and mass closure to minimize potential of needle sticks
Reverse cutting	Triangular point with cutting edge on outer curvature	Skin closure; retention sutures; subcutaneous, ligamentous, or fibrous tissues
Cutting taper	Reverse-cutting tip with taper shaft	In microsurgery for excellent penetration through tough tissue, such as vasovasostomy, tuboplasty
Hand-honed reverse cutting	Same as reverse cutting but hand-honed for added sharpness	Primarily in plastic surgery for delicate work and where good cosmetic result is priority
Spatula side cutting	Two cutting edges in horizontal plane	Ophthalmic surgery for muscle and retinal repair; also for delicate eyelid or plastic surgery; cutting edges "ride" along scleral layers
Regular cutting	Triangular point with cutting edge on inner curvature	General skin closure, subcutaneous tissue; sometimes for ophthalmic surgery, plastic, or reconstructive surgery
Lancet, inverted lancet	Spatula needle with cutting edge (lancet) or outer (inverted lancet) curvature	Ophthalmic surgery and microsurgery

Modified from *Ethicon wound closure manual,* Sommerville, NJ, 2004, Ethicon, available at www.jnjgateway.com. Accessed July 12, 2009.

Color Codes. Color-coded packaging based on suture fiber is used by most companies to make identification quicker and easier. Each individual packet is color-coded, as is the dispenser box. Although most color codes are universal across companies, there are some exceptions. Ethibond, a coated polyester, is coded orange, whereas most polyesters are coded in shades of green. Dexon, a glycolic acid polymer, is gold, whereas Vicryl, a comparable polymer, is violet.

Selection of Suture

The choice of suture material, size, needle, and type depends on the procedure, the tissue being sutured and type of reapproximation required by the general condition of the patient, and the surgeon's preferences. A surgical services committee or project team may be responsible for establishing standard suture uses for various operations. Current guides published by suture manufacturers should be consulted. These guides list the specific suture materials recommended for various wounds and are based on current clinical practice and research. Although the perioperative nurse is not responsible for choosing the suture material used, he or she must be knowledgeable of the suture properties to ensure the best possible outcome for the surgical patient.

SUTURING TECHNIQUES/WOUND CLOSURES

Surgeons may use suture or other devices to accomplish wound closure. The *primary suture line* refers to sutures that obliterate dead space, prevent serum from accumulating in the wound, and hold the wound edges in approximation until healing takes place (Figure 6-4). The *secondary suture line* refers to sutures that supplement the primary suture line. They are placed on each side of the primary suture line, passing through several layers of tissue at once. A secondary suture line helps eliminate tension on the primary sutures and reduces the risk of evisceration or dehiscence. Retention sutures are a type of secondary suture line.

An *interrupted suture* is inserted into tissues or vessels in such a way that each stitch is placed and tied individually. This type of suture is widely used and generally considered the strongest and most secure (Figure 6-5, *A*). Various techniques used for the insertion of interrupted sutures in the tissue are designed to alter the angle of pull and the relationship of the wound's edges to each other. Such maneuvers cause the edges of the wound to invert or to evert and aid in wound healing because fewer sutures are used. The interrupted technique may be used for anastomotic repairs (e.g., bowel anastomosis), in fascial closure, or on the skin.

A *continuous suture* consists of a series of stitches, of which only the first and last are tied (Figure 6-5, *B*). With this type of suture, a break at any point may mean a disruption of the entire suture line. It is used to close tissue layers where there is little tension but tight closure is required, such as the peritoneum, to prevent the intestinal loops from protruding, or on blood vessels to prevent leakage.

Retention (or *stay*) sutures are placed at a distance from the primary suture line to provide a secondary suture line (Figure 6-5, *C*), relieve undue strain, and help obliterate dead space.

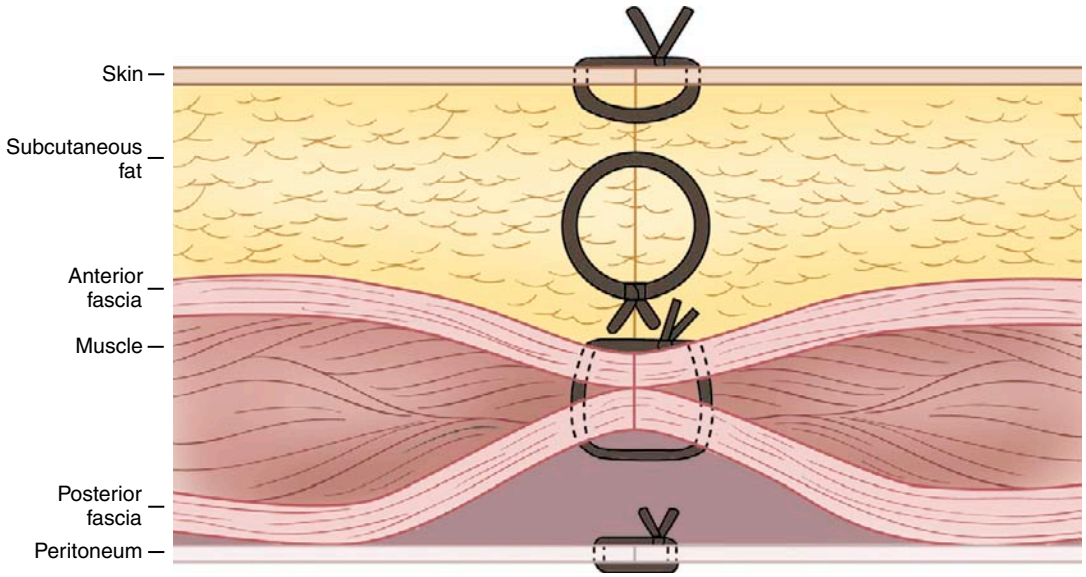

FIGURE 6-4 Primary suture line on the abdominal wall, midline incision.

These sutures are placed in such a way that they include most if not all layers of the wound. A simple interrupted or figure-of-eight stitch is used. Usually heavy, nonabsorbable suture materials, such as silk, nylon, polyester fiber, or wire, are used to close long, vertical abdominal wounds and lacerated or infected wounds. To prevent the suture from cutting into the skin surface, a small piece of rubber tubing (bumper, bolster, bootie) or other type of device (bridge, button) is passed over or through the exposed portion of the suture. The bridge device allows the surgeon to adjust tension over the wound postoperatively.

Subcuticular sutures, sometimes referred to as *buried,* are sutures placed completely under the epidermal layer of the skin (Figure 6-5, *D*). This technique is often used to achieve a cosmetic closure.

A *purse-string suture* is a continuous circular suture placed to surround an opening in a structure and cause it to close (Figure 6-5, *E*). This type of suture may be placed around the appendix before its removal, or it may be used in an organ such as the cecum, gallbladder, or urinary bladder before it is opened so that a drainage tube can be inserted; then the purse-string suture is tightened around the tube.

The Nursing Interventions Classification (NIC) lists suturing as a nursing intervention, defined as "approximating edges of a wound using sterile suture material and a needle" (Bulechek et al, 2008). The NIC was developed to classify nursing interventions so that the work of nursing could be documented and nursing knowledge improved through the evaluation of patient outcomes. In perioperative nursing practice, the act of suturing is considered part of the education and subsequent role of the registered nurse first assistant (AORN, 2009a).

Knot-Tying Techniques

The successful use of the many varieties of suture materials depends, in final analysis, on the skill with which the surgeon or first assistant ties the knot. The completed knot should be firm to prevent slipping and should be small, with ends cut short, to minimize the bulk of suture material in the wound. The suture may be weakened by inappropriate handling. One should avoid excessive tension, sawing, friction between the strands, and inadvertent crushing with clamps or hemostats.

Endoscopic Suturing/Knot Tying

Suturing through an endoscope is a learned skill, not an innate talent. The ports must be placed and used to maximize the precision and efficiency of the suturing motions. An array of needles and suture materials is available for endoscopic suturing so that the surgeon is not disadvantaged by a lack of choice. Research and development of technique, instrumentation, needles, and suture materials are ongoing as the types of procedures done endoscopically increase and methods are perfected. Knot tying is one of the most challenging aspects of endoscopic surgery. Preformed ligature loops are used in ligating the appendix or blood vessels. Extracorporeal knots are tied outside the abdomen and slid into the abdomen using a knot pusher. They can be tied rapidly and securely; the square knot is normally used as the locking loop knot. Intracorporeal knotting is done completely within the abdominal cavity whenever fine sutures are being placed in tissues for reconstruction purposes. All suturing and knot-tying techniques performed through the endoscope require excellent hand-eye coordination, practice, and the ability to perform these techniques while the operative site is being viewed on a television monitor.

Skin Staples

Skin staples are one of the most frequently chosen methods of skin closure. They can be used on many types of surgical incisions. The staple appliers are easy to use. They reduce operating time and tissue trauma, allowing uniform tension along the suture line and less distortion from the stress of individual suture points. When properly applied (Figure 6-6), they provide excellent cosmetic results. Some staplers use bioabsorbable staples that are placed under the skin and then absorbed similar to suture. Others use stainless-steel staples. With these, the length of time the staples stay in place depends on the part

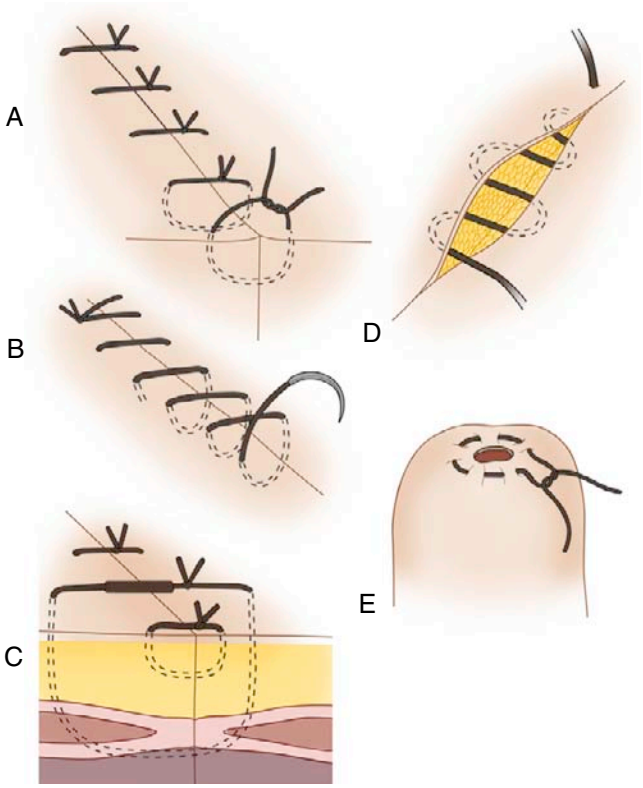

FIGURE 6-5 Types of stitches. **A**, Interrupted. Each stitch is made with a separate piece of suture material, which is tied separately. **B**, Continuous or "running." A stitch is made with one uninterrupted length of suture material. **C**, Retention. Stitches are used to reinforce the primary suture line; heavy, strong suture material is used. **D**, Subcuticular. Stitch is placed completely under the epidermal layer of the skin. **E**, Purse-string. A stitch runs parallel to the edge and encircles a circular wound.

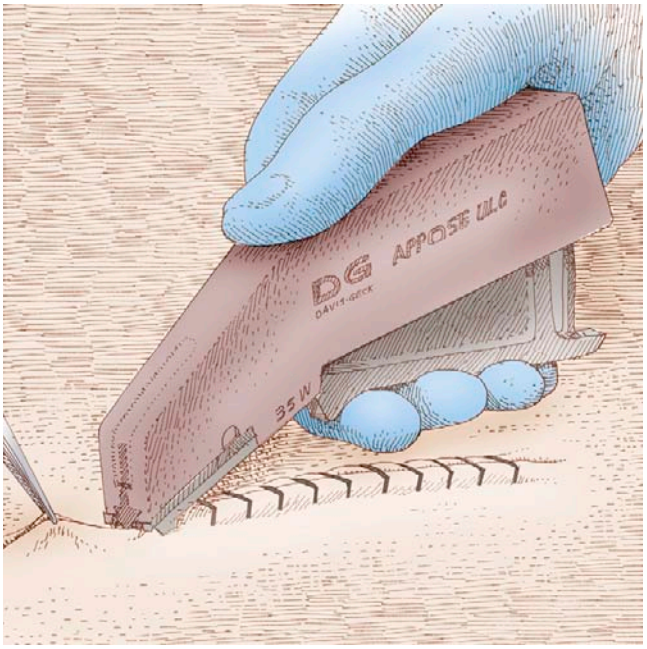

FIGURE 6-6 Application of skin staples. The stapler is lightly positioned over everted skin edges. It is not necessary to press the staple, or stapler anvil, into the skin to get a proper "bite" (just "kiss" the skin). Center the staples over the incision line, using the locating arrow or guideline, and place staples approximately ¼ inch apart.

of the body affected; they are usually removed within 5 to 7 days. An extractor is required for their removal.

Most staplers employ a similar anvil-type mechanism for forming the staple, but the application device varies from company to company. Device choice usually is determined by the weight, handling characteristics, ease of application, and unobstructed view of the site during application. Staplers are packaged in various assortments of numbers and types of staples, depending on the length of the incision and the type of tissue encountered.

Wound Closure Strips

Wounds that are subjected to minimal static and dynamic tension are easily approximated with skin tape. The selection of surgical tape for skin closure is based on the tape's adhesive ability, tensile strength, and porosity. The tape must provide a firm tape-to-skin bond to keep the wound edges closely adhered. The tensile strength must be sufficient to maintain wound approximation. A tape that is too occlusive limits moisture or vapor transmission; fluid may accumulate under the tape and lead to maceration and bacterial growth. Microporous tapes prevent this problem. The surgeon must apply the tape to dry skin; an adhesive adjunct (e.g., tincture of benzoin or Mastisol liquid adhesive) may be applied in a thin film to the skin at the wound edges before tape application. If an alcohol-based adhesive adjunct is used, care must be taken to prevent inadvertent surgical fires (e.g., electrocautery unit must be shut off before the agent is delivered to the field by the perioperative nurse). Edema at the surgical site may cause taped wound edges to invert; supplemental skin sutures may be used to enhance closure. Tapes may be cut to accommodate smaller incisions. Tapes are applied perpendicularly to the wound edge, first on one side and then the other, so that the edges can be pulled together (Figure 6-7).

Surgical Adhesives

Tissue adhesives may be applied topically to intact skin at the wound edges to hold surfaces together. Care must be taken to avoid any contact with the open wound; adhesive in the wound creates a barrier to wound healing. When used in areas that are not subject to stress (e.g., areas that penetrate the fascia) or movement (e.g., on the hands or joints, where there is repetitive movement), tissue adhesives provide for fast closure and less pain for the patient (Neumayer and Vargo, 2008).

HEMOSTASIS

Hemostasis is an ongoing process during surgery. In addition to the damaging physiologic effects of blood loss for the patient, bleeding from cut vessels obscures visualization of the operative site for the surgeon and must be controlled. Hemostasis may be accomplished from direct pressure applied with a surgical sponge (Box 6-2) or by the use of suture materials, electrosurgical devices, lasers, and chemical agents. Before wound closure, the surgeon carefully checks the operative site to ensure that all active bleeding has been stopped.

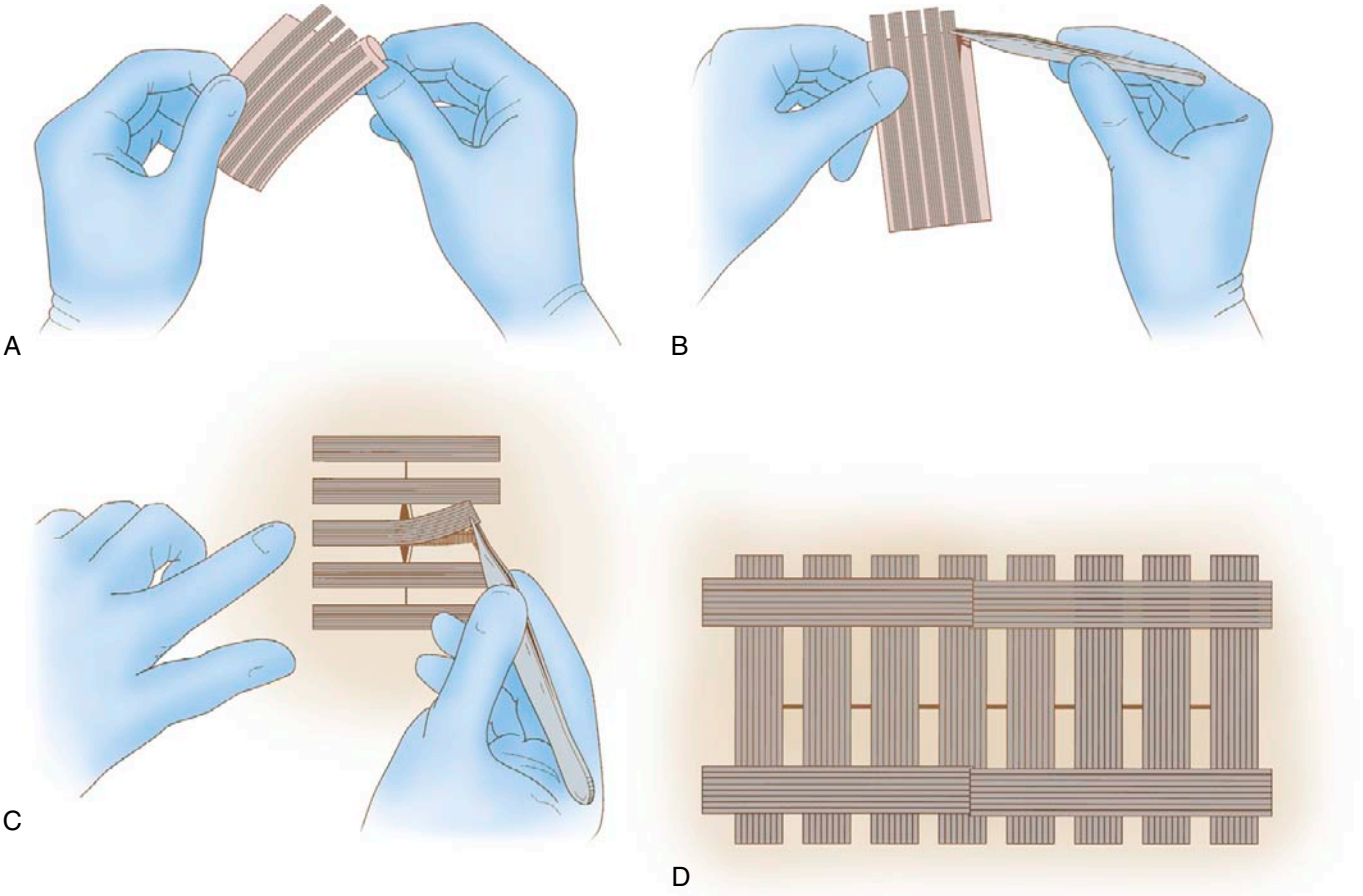

FIGURE 6-7 Application of skin tapes. **A**, Perforated tab is bent and removed. **B**, Tape is peeled from the card. **C**, Tape is applied to wound. **D**, Additional tape is placed parallel to wound to limit shear stress on the skin.

Methods of Ligating Vessels

A ligature is a strand of suture material used to encircle and obstruct the lumen of a vessel to affect hemostasis, block a structure, or prevent leakage of materials. Ties may be on a reel (i.e., a spool or disk containing a long length of suture) that the surgeon may use to ligate several superficial vessels, or they may be free ties (i.e., precut lengths of suture) handed to the surgeon one at a time, usually for bleeders in deeper tissues.

Following are several techniques used to secure a ligature in deep tissues:

- A hemostat is placed on the end of the structure; the ligature is then placed around the vessel. The knot is tied and tightened with the surgeon's fingers or with the aid of forceps.
- A slipknot is made, and its loop is placed over the involved structure by means of a forceps or clamp.
- In deeper cavities, ties are often placed on clamps with the long end extending from the tip. These are sometimes called *ties on a pass* or *bow ties*. The extending long end is held tightly against the rings by the surgeon (creating the bow), who then passes the tip of the clamp under the vessel or duct to be ligated. The first assistant grasps the extending tie with a forceps, the surgeon releases it, and the tie is pulled under and up to the wound surface and tied.
- A forceps or a clamp is applied to the structure, and transfixion sutures are applied and tied. A *suture ligature, stick tie,* or *transfixion ligature* is a strand of suture material threaded or swaged on a needle. This is usually placed through the vessel and around it to prevent the ligature from slipping off the end.

When two ligatures are used to ligate a large vessel, usually a free ligature is placed on the vessel and a suture ligature is placed distal to the first ligature. To ligate a blood vessel situated in deep tissues, the strand must be of sufficient strength and length to allow the surgeon to tighten the first knot. See the discussion of preparation of ligatures and suture ligatures in Perioperative Nursing Considerations later in this chapter.

Ligating Clips

Ligating clips are small, V-shaped, staplelike devices that are placed around the lumen of a vessel or structure to close it. They may be made of one of several metals, such as stainless steel, tantalum, or titanium. Stainless-steel clips are the most economical to use. Although more expensive, titanium clips are used frequently in specific surgical procedures because the starburst reflection on postoperative radiographs is less with titanium than with other metals. Absorbable clips made of synthetic absorbable suture material also are available.

BOX 6-2

Surgical Sponges

Surgical sponges are used to affect hemostasis via direct pressure, absorb intraoperative blood loss and drainage, act as aids to blunt dissection, pack the viscera from the field, and keep areas of the wound moist. Surgeons may also use sponges as a filter between a suction tip and delicate tissue. A variety of surgical sponges are available commercially packed in increments of 5 or 10. Any sponge used during a surgical procedure must contain an x-ray–detectable element to facilitate location of the item if a count discrepancy occurs.

The following is a list of the types of surgical sponges:

- *Radiopaque 4 × 4's:* Commonly referred to as a Ray-Tec or 4 × 4, this sponge is composed of loosely woven gauze folded into a 4-inch square. A radiopaque thread, which may change to a darker color when exposed to fluid, is integrated into the sponge. This type of sponge is useful for superficial small incisions, and may be folded into thirds and mounted onto a sponge stick for use in deeper incisions.
- *Laparotomy sponges:* Also referred to as "laps," "lap pads," or "tapes," these sponges are either square or oblong and have a loop of colored twill tape with a radiopaque marker sewn to one corner. Used for major surgical procedures with large incisions, laparotomy sponges are presented to the surgeon either moist or dry.
- *Dissectors:* Dissecting sponges have the radiopaque element incorporated into the weave of the material and are generally composed of very tightly rolled cloth tape. They may be referred to as "peanuts," "pushers," or "kitners." Dissecting sponges are *always* presented to the surgeon mounted on a clamp because of their small size.
- *Round sponges:* Often known as "tonsil" or "cherry" sponges, round sponges are gauze-covered cotton balls with strings attached. The radiopaque element is woven into the gauze covering. These sponges are often used in the oropharynx and are presented on the tip of a clamp or sponge stick.
- *Flat neurosurgical patties:* Flat sponges are composed of soft compressed cotton or rayon with an embedded radiopaque element and string attached. Often used in neurosurgical procedures, these sponges are available in a multitude of sizes and widths. They may be used as a filter for a suction tip to prevent damage to the underlying tissue, or as a vehicle for the application of topical anesthetic to the nasal mucosa.

Ligating clips are available in several sizes. These clips are available in individual sizes that must be loaded by the scrub person or as preloaded, disposable, prepackaged units. (NOTE: The scrub person may be a surgical technologist or registered nurse. He or she is referred to in this chapter as "scrub person.") There are multiple sizes and lengths of clips that can be used in both open and endoscopic procedures. Ligating clips afford a rapid and secure method of achieving hemostasis when arteries, veins, nerves, and other small structures are ligated. Since the introduction of minimally invasive endoscopic surgery, the need for ligating clips that can be applied through a trocar has emerged. These clips are changing frequently and no one standard has emerged. Regardless of the type of clip, the surgeon applies them similarly. The surgeon often follows the application of a clip with a request for scissors (Figure 6-8).

Metal cushing or Frazier clips are made of small-diameter pieces of stainless steel or silver wire and are heat sterilized.

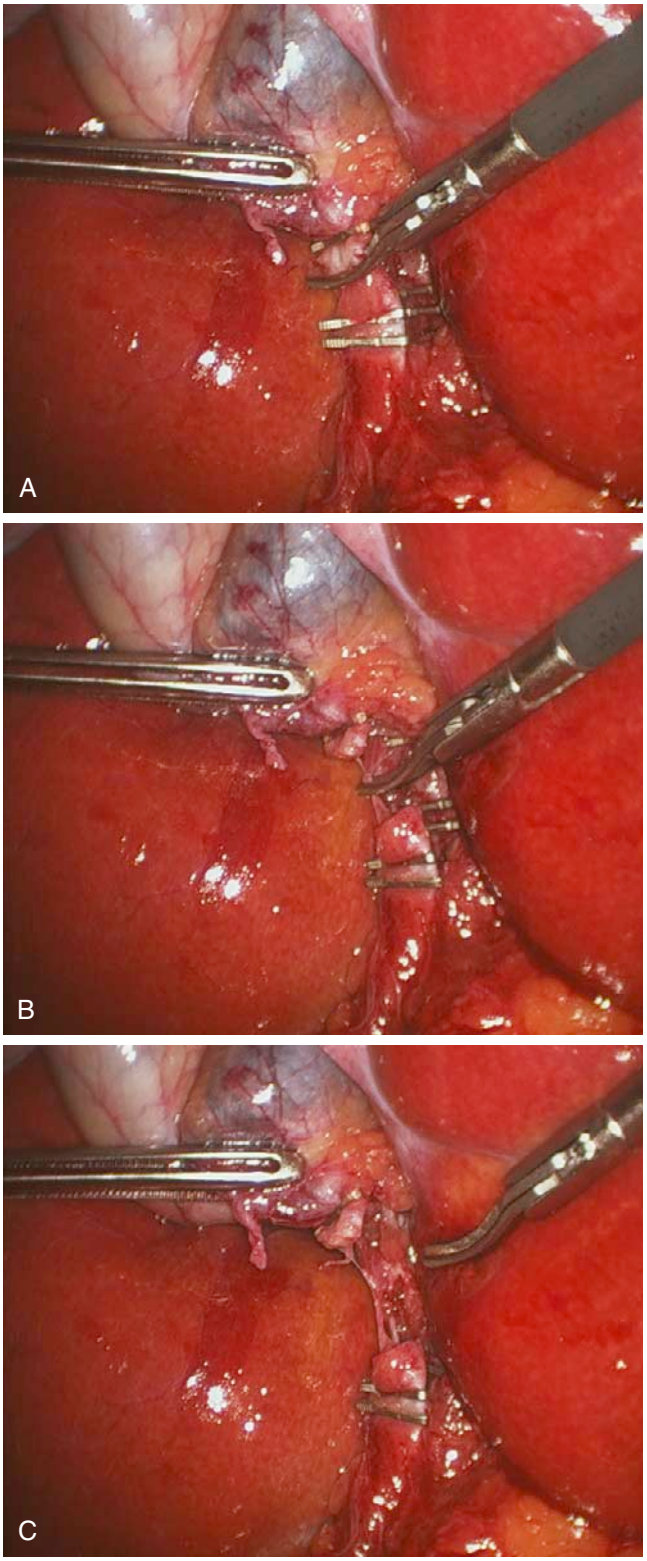

FIGURE 6-8 Laparoscopic instrumentation. **A**, Endo Clip being applied to proximal end of gallbladder duct. **B**, Gallbladder duct being cut with Endo Scissor. **C**, View of severed duct with artery behind it.

They must be hand-loaded onto special rack dispensers. Frazier clips are applied to the ends of severed nerves and blood vessels by means of a forceps designed for this purpose. Formerly widely used in neurosurgery and orthopedic procedures, the use of these clips has diminished since the introduction of prepared ligating clips.

PERIOPERATIVE NURSING CONSIDERATIONS

General Considerations

In the preparation and use of sutures in surgery, every precaution must be taken to keep the sutures sterile, to prevent prolonged exposure and unnecessary handling, and to avoid waste. Before perioperative personnel prepare any suture materials, they should review the sutures listed on the physician's preference card or in the computerized intraoperative record. Care should be taken to ensure fiscal responsibility by minimizing the number of sutures on the field when the initial count is performed. The perioperative nurse should have an adequate supply of sutures available for immediate dispensing to the sterile instrument table as needed throughout the procedure.

Customized suture kits that contain a designated number and variety of sutures for particular procedures, surgeons, or both are available for use when suture preferences are consistently the same. These kits may be more economical than individually packaged sutures because of reduced packaging costs, decreased gathering and dispensing times, and less capital outlay for inventory.

Opening Primary Packets

The scrub person tears the foil packet across the notch near the hermetically sealed edge and removes the suture. Some sutures may be packaged for delivery to the field in their inner folders, ready to load, with no foil wrapper.

Handling Suture Materials

To remove suture strands to be used for ties when they are not on a reel or disk, the user pulls the loose end out with one hand while grasping the folder with the other hand. To straighten a long suture, the free end is grasped (using the thumb and forefinger of the free hand) and the kinks, caused by package memory, are removed by gentle pulling with the free ends secured, one in each hand, and then the arms are slowly abducted to straighten the strands (Figure 6-9).

The scrub person should never remove kinks from suture by running gloved fingers over the strand because this action causes fraying. The tensile strength of a gut suture should not be tested before it is handed to the surgeon. Sudden pulls or jerks may damage the suture so that it will break when in use.

To remove a suture-needle combination from the package, the scrub person grasps the needle with a needle holder and gently pulls (Figure 6-10). To straighten the suture in a suture-needle combination, the scrub person grasps the suture 1 to 2 inches distal to the needle and pulls gently on the other end of the strand with the other hand to remove kinks. The jaws of the needle holder grasp the flattened surface of the needle to prevent breakage and bending. To facilitate suturing, the needle is secured about ⅛ inch distal from the tip of the needle holder (Figure 6-11). The holder is placed on the needle about one third of the distance distal from the eye or swaged end.

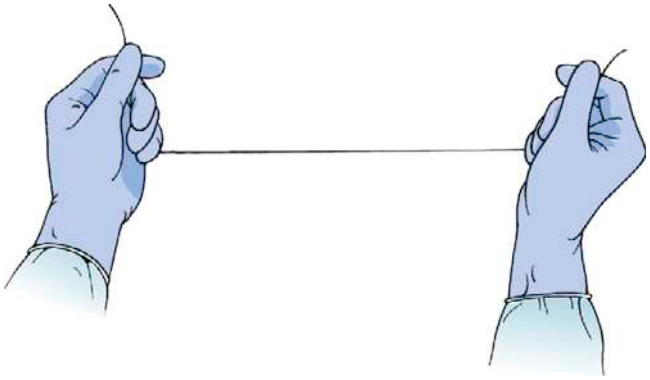

FIGURE 6-9 Straightening suture material.

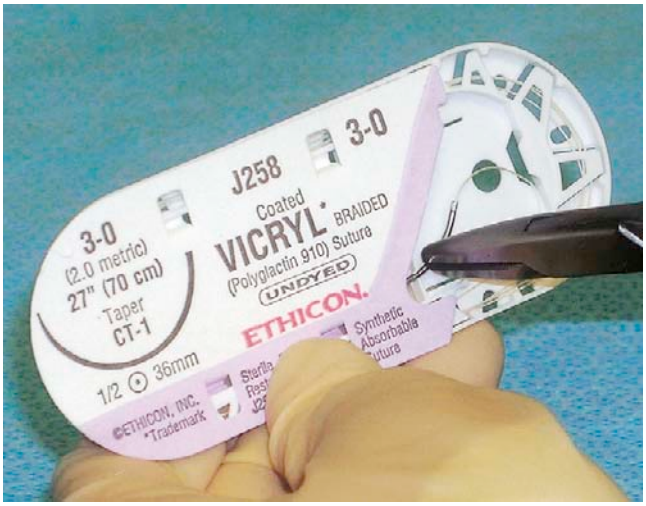

FIGURE 6-10 Loading a suture directly from packet.

FIGURE 6-11 Loading a needle holder. Clamp needle holder approximately one third the distance from the swage or eye to point of needle.

A suture or free ligature should not be too long or too short. A long suture is difficult to handle and increases the possibility of contamination because it may be dragged across the sterile field or fall below it. A short suture makes tying difficult; if threaded on a needle, it may slip out of the eye. The depth and distance to the site of tying or suturing guide the scrub person in preparing ties or sutures of the correct length.

For general surgery, a continuous suture threaded on a needle is usually about 24 inches long, and its short end is 3 to 4 inches long (half-lengths). An interrupted suture is 12 to 14 inches long, with 2 or 3 inches threaded through the needle

(quarter-lengths). To ligate a vessel in the epidermal and subcutaneous layers, the ligature may be quarter-lengths. Vessels or structures deep in the wound are ligated with a suture or ligature that is 24 to 30 inches long (third-lengths to half-lengths). Sutures also are provided in 12- to 60-inch precut lengths by the manufacturer. Also supplied are the more commonly used 54-inch lengths on reels or disks and labyrinth packs, where precut strands may be removed one at a time from the package rather than all at once.

Threading Surgical Needles

Free needles, which are packaged separately from the suture, must be threaded by the scrub person for the surgeon. A curved needle is threaded from within its curvature so that the short end falls away from the outside curvature (Figure 6-12). This practice helps to prevent accidental pullout. The scrub person pulls the suture about 4 inches through the eye of the needle to prevent the suture from being pulled out of the eye during suturing.

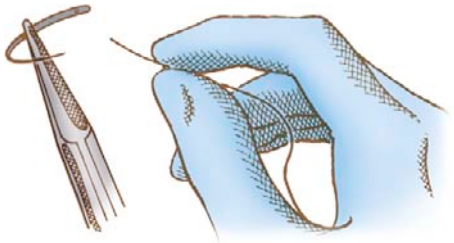

FIGURE 6-12 Eyed needle is threaded from inside curvature. Take care to avoid pricking glove on sharp needle point.

Counting Needles

One of the patient outcomes identified in the Perioperative Nursing Data Set (PNDS) is that "the patient is free from signs and symptoms of injury due to extraneous objects" (Peterson, 2007). One of the many perioperative nursing activities undertaken to achieve this patient outcome is the performance of counts to ensure that the patient is free from injury related to retained sponges, sharps, or instruments (Patient Safety). Institutions vary in their policies regarding needle and sharps counts during operative procedures, but most follow established procedures based on the Association of periOperative Registered Nurses (AORN) *Recommended Practices for Sponge, Sharp and Instrument Counts* (AORN, 2009b). Initial counts before the start of the procedure provide the basis for subsequent counts.

The documentation of counts should include the items on the instrument table at the beginning of the procedure as well as those added during the procedure. The count should be performed audibly and with each sharp visualized by both the scrub person and the perioperative nurse. The number of needles should be recorded.

During the procedure, the scrub person should be aware of the location of sharps on the sterile field. Needles should be accounted for by the scrub person as they are placed in the neutral zone on a one-for-one exchange basis when possible. Subsequent counts should be performed by the scrub person and perioperative nurse before closure of a body cavity or deep, large incision; after closure of a body cavity; and at skin closure. Additional counts should be an element of the hand-off process when either the scrub person or the perioperative nurse is permanently relieved by other personnel. In situations in which personnel may be relieved on a temporary basis, the verbal hand-off should include a discussion about counted items. In all situations it is imperative that two individuals be involved in the count—one counting and the other witnessing that the count is correct. All sharps are retained in the OR during the surgical procedure. Many institutions have printed forms to keep track of routinely counted items (Figure 6-13). Others use erasable count boards visible to all personnel. Recording the count is the responsibility of the perioperative nurse. Depending on institutional policy and practices, the count sheet may become part of the patient's record. To facilitate counting, needles are counted according to the number indicated on the package; the scrub person verifies this number with the perioperative nurse when the package is opened. Used needles should be kept on a needle pad or counter on the scrub person's table. Broken or missing needles must be reported to the surgeon and accounted for in their entirety. Each institution should have established policies for dealing with incorrect counts. Unintentional retention of objects during surgery has been identified as a "Never Event"; institutions need to adopt a comprehensive strategy to manage the complexity of this issue. Strategies include several elements, such as emphasizing forced communication, standard processes, and checklists (Figure 6-14). In general, the surgeon is immediately notified of an incorrect count; a recount is initiated. Sterile team members and the perioperative nurse initiate a search of the sterile and unsterile fields. If the missing item is not revealed after a recount and search, the surgeon is asked to explore the wound. If the missing item is still not found, agency policy may dictate that an x-ray film be taken. Documentation of these activities should be completed according to institutional policy and procedure.

Sharps No-Touch Technique

Because sharp instruments used in surgery are a frequent cause of injury, recommendations for eliminating hand-to-hand passing have been established and numerous engineering controls, such as safety scalpels and blunt suture needles, have been developed (Evidence for Practice, p. 193).

Based on Occupational Safety and Health Administration (OSHA) regulations and the Standard Precautions of the Centers for Disease Control and Prevention (CDC), institutions should have written policies regarding the handling of sharp instruments and needles at the surgical field. In a no-touch technique, sharps are placed in a predesignated basin, tray collection device, or safe "neutral" zone on the field, from which the surgeon can retrieve the sharps. After use, the item is placed back in the neutral zone, and the scrub person retrieves it. This technique eliminates hand-to-hand passing of sharps between the surgeon and the scrub person, such that no two individuals touch the same sharp at the same time, reducing the chance of accidental needle punctures and cuts. All sharps should be accounted for and properly disposed before the room is prepared for the next patient.

The Needlestick Safety and Prevention Act was signed into law November 6, 2000, and changes to OSHA's Bloodborne Pathogens Standards mandated by this Act took effect in April 2001. In fact, OSHA has also reported that the OR is a more

PATIENT SAFETY

Prevention of Unintentionally Retained Objects

Counts are performed to account for items and to ensure that the patient is not injured as a result of a retained foreign body. Implementation of accurate count procedures and clear communication between the members of the surgical team help to promote an optimal perioperative patient outcome. Many institutions have developed strategies to reduce the risk to the patient of negative outcomes resulting from inadvertent retention of foreign bodies, including worksheets (Figure 6-13), checklists (Figure 6-14), guidelines, and policies.* The following are examples of policy statements:

- *Purpose:* Counts are performed to account for items and to ensure that the patient is not injured as a result of a retained foreign body. Implementation of accurate count procedures and clear communication between members of the surgical team help promote an optimal perioperative patient outcome.†
- Sponge, instrument, needle, and miscellaneous item counts should be performed for all procedures in which the possibility exists that a foreign body could be retained. The counting procedure must be followed unless an exception exists or the surgeon or anesthesiologist determines that the patient is medically unstable and there is no time to perform counts. In this circumstance, an x-ray will be ordered by the surgeon to be taken before the patient leaves the OR at a time when the patient is deemed medically stable.‡
- Active communication between all members of the surgical team must be employed in the count process, which includes verbal notification of the status of all counts when executed.
- To ensure patient safety, distractions must be avoided during the count process.
- An exploration of the operative site should be performed by the surgeon before the closure.
- An x-ray must be taken in the OR before the emergence from anesthesia in all cases in which a count is deemed incorrect, unless the surgeon or anesthesiologist determines that the patient is medically unstable and there is no time to perform counts.

EXCEPTIONS TO COUNTS ARE PERMITTED IN THE FOLLOWING LIMITED CIRCUMSTANCES:

- *Emergent procedures:* A count may be deferred in a procedure that is performed emergently in a medically unstable patient for whom there is no time to perform counts (e.g., cardiac bring-back, abdominal aortic aneurysm [AAA], multiple trauma, converting from laparoscopy to laparotomy).
- *Hips and shoulder arthroplasties (total and partial)*
  1. An instrument count may be deferred when an x-ray is taken immediately post-procedure in the PACU.
  2. Sponges, sharps, and miscellaneous items must be counted according to policy.
- *Total knee*
  1. An instrument count is not required for total knee arthroplasties.
  2. An x-ray is not required.
- *Medical implant procedures:* Instrument counts may be deferred during procedures in which there are numerous items of hardware (such as spinal surgery) and an x-ray is taken before the conclusion of the procedure. Sponges, sharps, and miscellaneous items must be counted according to policy.
- *Needles:* When it is identified that the missing needle is 9.5 mm or smaller, an x-ray does not have to be obtained for an incorrect count.
- *Complex, multi-setup procedures*
  1. Counting instruments detracts from, and may be detrimental to, the care of the patient during highly complex procedures that require more than one setup and/or excessive instrumentation.
  2. Certain procedures may be predetermined to meet these criteria (e.g., deep inferior epigastric perforator (DIEP) flaps, transverse rectus abdominus myocutaneose (TRAM) flaps, abdominoplasty).
  3. In circumstances as described in III.5.a above, the circulating nurse and the surgeon may collaborate during the briefing before the beginning of the procedure to set the framework for the day.
  4. A determination may be made that the instrument count be deferred and replaced with an x-ray at closure.
- Any other exception to this policy needs to be approved by the Chief of Surgery (or designee) or the Chief of Anesthesia (or designee) before the patient's emergence from anesthesia.
- If a count is not completed under one of the permitted exceptions and a possibility exists that a sponge/sharp/instrument/miscellaneous item could be retained, *an x-ray of the entire operative area must be taken before the patient leaves the OR,* if the patient's condition permits. If the patient is medically unstable, an x-ray will be ordered by the surgeon before the patient leaves the OR and taken in the ICU when the patient is deemed medically stable by the surgeon.
- The **ONLY** exception to getting an **x-ray** under this policy is if a count is incorrect **solely** on the basis that a sponge, instrument, or miscellaneous item is intentionally retained with the patient, thereby making the count technically incorrect. The retained items(s) must be documented in the intraoperative documentation record and the surgical procedure note.

†Documentation of this process will be done utilizing *Part A of the Count Safety Checklist* (see Figure 6-14).
‡The information will be communicated by the circulating nurse to subsequent circulating nurses during all hand-off reports.
*Sponges, sharps, and miscellaneous items must be counted according to policy.
Policy statements used with permission Beth Israel Deaconess Medical Center, Boston, Mass.

hazardous work environment than a construction site (Taylor, 2006). Considerations for the perioperative healthcare team include the following:

- Blunt needles, stapling devices, adhesive strips (skin tapes), and tissue adhesives are used whenever clinically feasible to reduce the use of sharp suture needles.
- Scalpel blades with safety features are used.
- Alternative cutting methods are used when appropriate.
- Manual tissue retraction is avoided by using mechanical (self-retaining) retraction devices.
- All equipment that is unnecessarily sharp is eliminated.
- Double-gloving is employed.
- Eye protection and face shields are used by all healthcare team members.
- Appropriate use and disposal of all sharps is mandated (Box 6-3).

FIGURE 6-13 Example of a count sheet.

1. Embed forced, "structured" communication between members of the team when resolving counts
   - ✓ Mandating Attending-to-Attending communication in "real-time"
   - ✓ Mandating a scripted discussion that all cavities that could harbor a retained object have been searched
   - ✓ Clarify "Hand-off" content — No staff changes during resolution process
   - ✓ Create clear expectations of how to elevate discrepancies
2. Standardize the mechanism to respond to incorrect counts
   - ✓ Count process including documentation
   - ✓ Response to incorrect counts in a structured manner prescribing roles of all team members
   - ✓ Embed response by radiology to include concurrent visualization of all x-rays by entire team, inclusion of a "like-object" with the film
   - ✓ Document the steps of the room search
   - ✓ Create pathway for managing intentionally retained objects
   - ✓ Create a pathway for managing intentionally not retrieved objects
3. Establish clear resolution process for the resolution of incorrect counts
   - ✓ Count Safety Checklist forces a standard approach to resolution
   - ✓ Implement a "No Hand-off Zone" during incorrct count resolution
   - ✓ Develop a digital library to enhance radiology recognition

EVIDENCE FOR PRACTICE

Preventing Sharps Injuries

The Exposure Prevention Information Network (EPINet) is a voluntary surveillance system used to track needle-stick injuries. During the period from 1993 to 2001, 29% of OR injuries occurred between steps in the procedure, such as when passing sharp devices. Another 29% of injuries occurred after the device was used, but before it was disposed—that is, while disassembling the device. Suture needles caused 34% of injuries to perioperative nurses, whereas scalpels were responsible for 19% of injuries.

Although 2002 data revealed that the number of injuries from reusable scalpels had declined, the proportion of injuries to perioperative nurses from suture needles increased. Perioperative nurses should use the following best practices for handling sharps:

- Double-glove; inspect gloves for punctures frequently.
- Use standardized sterile field setups.
- Keep all sharps on instrument tables or trays with the points away from staff members.
- Use a neutral zone or hands-free method for passing sharps. Establish the neutral zone before the initial surgical incision (a magnetic pad or basin may be used to create the neutral zone; if a basin is used, it should be placed on the field and not held by the scrub person).
- Dedicate the neutral zone for sharps only (these include suture and hypodermic needles, scalpels, and other sharp instruments). Include identification of the neutral zone during hand-off communications to relief scrub persons.
- Only one sharp at a time should be in the neutral zone.
- Avoid handling suture needles manually whenever possible. Instead, use a needle holder, forceps, or suturing assist device.
- Do not hold a sharp and any other instrument simultaneously.
- Announce the transfer of a sharp before placing it in the neutral zone. After the announcement, orient the sharp in the correct position in the neutral zone. The scrub person and surgeon or assistants should communicate about the best placement of sharps in the neutral zone.
- Do not use fingers to touch tissue being cut or sutured.
- Know where all sharps are located throughout the procedure.
- Confine and contain all sharps in a disposable, puncture-resistant needle container.
- Pass sharp, long laparoscopic instruments handle first, keeping the tip down.
- At the conclusion of the procedure, verify that the container holding sharps is securely closed.

Modified from AORN guidance statement: Sharps injury prevention in the perioperative setting. In *Perioperative standards and recommended practices*, Denver, 2009, The Association; Perry J, Jagger J: Exposure safety—pass with care in the OR, *Nursing 2005* 35(2):70, 2005.

BOX 6-3

Sharps Disposal Containers

- Durable, closable, leakproof, and puncture resistant
- Appropriate size for user and type of sharps
- Lids allow sharps to enter by gravity without need for additional manipulation
- Within horizontal reach of healthcare team members (close to the point of use) who dispose of sharps
- Container, level of fullness (full line), proper warning labels (biohazard labels), and color coding (orange, orange-red) must remain visible to healthcare team members
- Self-closing lids to prevent overfill if container is not "see-through" to observe fill line
- Ease of assembly and operation, including one-handed disposal

Modified from AORN guidance statement: Sharps injury prevention in the perioperative setting. In *Perioperative standards and recommended practices,* Denver, 2009, The Association; Davis MS: *Advanced precautions for today's O.R.,* ed 2, Atlanta, 2001, Sweinbinder.

The risk of transmission after a needle-stick or sharps injury is estimated to be 6 to 30 out of every 100 people for hepatitis B virus (HBV), 3 to 10 out of every 1000 people for hepatitis C virus (HCV), and 1 out of every 300 people for human immunodeficiency virus (HIV). If an occupational exposure or injury occurs that could result in a bloodborne pathogen exposure, the injured person should do the following (Kenny, 2005):

- Immediately flood the exposed area with water.
- Clean the wound with an antimicrobial skin disinfectant or soap and water.
- Alert the nurse manager or other appropriate person.
- Identify the source patient.
- Immediately report to employee health department (or the appropriate institutional department).

An immediate evaluation and risk assessment are done. A postexposure treatment plan is initiated with counseling, education, and follow-up testing 1 year after exposure.

All OR personnel should work collaboratively to select the least dangerous device that would accomplish the intended function (e.g., cutting, providing hemostasis, retracting, suturing) efficiently and effectively. By doing so, perioperative personnel may significantly reduce the rates of injuries in the OR and exposures to blood and bloodborne pathogens.

INSTRUMENTS

Historical Perspective

The history of surgical instruments dates back to 2500 BC. The first instruments were sharpened flints and fine animal teeth. Ancient Greek, Egyptian, and Hindu instruments are amazing in their resemblance to contemporary instruments.

To be equipped for the practice of surgery in the late 1700s, the surgeon had to employ various skilled artisans, such as coppersmiths; steelworkers; needle grinders; turners of wood, bone, and ivory; and silk and hemp spinners. The surgeon had to explain the mechanisms of the instruments and supervise their manufacture. The resulting instruments were crude, expensive, and time-consuming to make. Each artisan used hand labor exclusively and devoted time to making only one type of instrument, thus gaining proficiency in the manufacture of a certain kind of instrument. For example, a cutter would keep a small supply of surgical knives. Thus began physicians' supply houses and surgical instrument making.

In the mid-1800s, physicians' principal tools were their eyes and ears. Official records show that amputation, the trademark of the Civil War, was the result in three of four operations. Surgeons were scarce, and medical instruments were almost nonexistent. Kitchen knives and penknives, carpenter saws, and table forks did the job. After the Civil War, the advent of the administration of ether and chloroform brought a demand for new ideas and methods in surgery and instruments. The division of general surgery into specialties occurred in the late 1800s and early 1900s. Delicate instruments were seen as more useful than the force of crude and heavy instruments. So that instruments could withstand repeated sterilization, handles of wood, ivory, and rubber were discontinued.

The development of stainless steel in Germany ensured a better material for surgical instruments and other equipment. Today, surgeons and perioperative nurses assist manufacturers in research, design, and development of new and better instrumentation. Most instrument companies design an instrument to a physician's specifications. Advancement in endoscopic surgery continually requires the development of instrumentation specifically designed for this type of surgery.

Throughout the history of surgery, the tools of the surgeon and the manual aspects of the surgical technique have influenced the evolution of practice. Along with innovative wound closure materials and tools in recent decades, there have been unprecedented developments of new and improved instrumentation. The benefits of minimally invasive surgery are well documented, especially in surgical procedures that typically required lengthy hospital stays, required long and sometimes difficult postoperative recovery or rehabilitation, and exposed the patient to increased risk of surgical infection.

Composition of Surgical Instruments

Successful management of instrumentation requires a continual partnership between surgeons, perioperative nurses, surgical technologists, and central processing personnel, each of whom shares responsibility for the use, handling, and care of surgical instruments. A basic knowledge of how these instruments are manufactured can help in their selection and maintenance. Surgical instruments are expensive and represent a major investment for every institution.

Instruments used today are made in the United States, Germany, France, and Pakistan. The United States does not have an agency that reviews or sets standards for surgical instruments. The quality is set by the individual manufacturer. A reputable company endorses its product. An instrument that receives proper care should last 10 years or more.

Most instruments are manufactured from stainless steel. Stainless steel is a compound of iron, carbon, and chromium, which means that stainless steel can have varying qualities. These qualities are designated by grading the steel into series by the American Iron and Steel Institute (AISI). The 400 series stainless steel has some noncorrosive characteristics and good tensile strength. It resists rust, produces a fine point, and retains a keen edge. Handheld ringed instruments, such as scissors and clamps, should be 400 series stainless steel.

For ringed instruments, the raw steel is converted into instrument blanks by a machinist making an impression of the piece in a stainless-steel blank. These blanks are die-forged into specific pieces—male and female halves. The excess metal is trimmed away, and the instrument parts are ready for the final steps.

The two halves are milled to prepare the box lock fittings, jaw serrations, and ratchets, and the jaws and shanks are properly aligned. After this is completed, the halves are assembled by hand. A hole is drilled through the box lock, and a pin or rivet is inserted through the hole. Final grinding and hardening, accomplished by heat-treating, permit the object to attain proper size, weight, spring temper, and balance.

The last part of the process is called *passivation*. The instruments are submerged into nitric acid to remove any residue of carbon steel. The nitric acid also produces a surface coating of chromium oxide. Chromium oxide is important because it produces a resistance to corrosion in the stainless-steel instrument. The instrument is then polished.

There are three types of instrument finishes. The first is the bright, highly polished mirror finish, which tends to reflect light and may interfere with the vision of the surgeon. The second is the satin or dull finish, which tends to eliminate glare and lessen eyestrain for the surgeon. The third finish is ebonized, which produces a black finish. Ebonized instruments are used during laser surgery to prevent deflection of the laser beam.

The final inspection and testing are for hardness, proper jaw closure, and smooth lock-and-ratchet action. The instrument is then ready for sale.

Instrument Categories

Although there is no standard nomenclature for specific instruments, there are four main categories: *cutting instruments* (also called *dissectors*), *clamps, retractors,* and *accessory* or *ancillary* instruments.

Cutting Instruments (Dissectors). Dissectors, which may be sharp or blunt, are instruments used to cut or separate tissue. The largest categories of sharp dissecting instruments are scalpels and scissors. Scalpels are probably the oldest of all surgical instruments (Figure 6-15). Most scalpels are handles (knife handle) with one end suited to the attachment of disposable blades (Figure 6-16). Safety scalpels have been modified to provide an engineering control in sharps injury prevention strategies. During an operation, the blades may be conveniently changed by the scrub person as often as necessary. The blades are available prepackaged and sterile and are passed onto the sterile field as needed by the perioperative nurse. Careful handling of blades during the procedure and disposal of blades at the end of a procedure are important in the implementation of Standard Precautions.

Scissors are designed in various shapes and sizes for different purposes in cutting body tissues and surgical materials. The basic design consists of two blades, each having a chisel-shaped edge with the bevel consistent with the structure or material it has to cut. Scissor tips may be blunt or sharp, and the blades may be straight or curved. Conventional scissors require two movements in use: one to open and another to close the jaws. Other scissors may have a spring action in the body design that holds the jaws in an open position. A single movement pressing the spring together closes the jaws to cut. Scissors designed for delicate plastic and eye surgery are often of the latter type. A basic instrument set usually includes a curved Mayo scissors for dissection of heavy tissues, a Metzenbaum scissors for dissection of delicate tissues, and a straight scissors for cutting suture. For surgery in deep areas of the body, scissors with long handles and short blades are used for better control and easier use.

Other sharp dissectors include drills, saws, osteotomes, rongeurs, and other instruments such as adenotomes and dermatomes. Some instruments in the dissecting category are produced in sharp or blunt form, such as curettes and periosteal elevators. Instruments or devices used for blunt dissection include gauze dissectors (e.g., peanuts, pushers, kitners), a sponge on a stick, the back of a knife handle, and the surgeon's finger or hand.

Clamps. Clamps are instruments specifically designed for holding tissue or other materials, and most have an easily recognizable design. They have finger rings, for ease of holding;

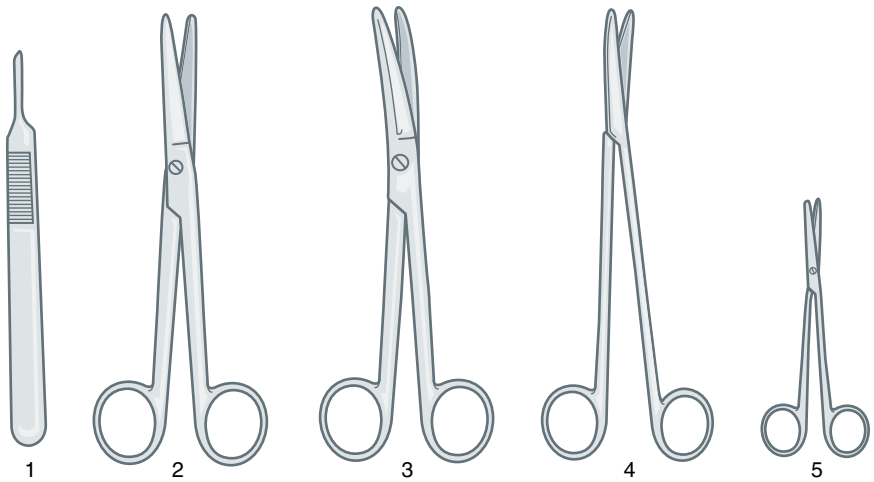

FIGURE 6-15 Basic cutting instruments. *1,* Knife handle; *2,* Mayo scissors, straight; *3,* Mayo scissors, curved; *4,* Metzenbaum scissors, curved; *5,* suture scissors, straight.

shanks, whose length is appropriate to the wound depth; ratchets on the shanks near the rings, which allow for the distal tip to be locked on the tissue or object grasped; a joint, usually a box lock (described later), which joins the two halves of the instrument and allows opening and closing of the instrument; and a jaw, which is the working portion of the instrument and defines its use (Figure 6-17). Clamps are divided into the following categories.

Hemostats are used to close the severed ends of a vessel with a minimal amount of tissue damage (Figure 6-18). They prevent the excessive loss of blood in the course of dissection. The jaws have deep transverse cuts so that the bleeding vessels may be compressed with sufficient force to stop bleeding. The serrations must be cleanly cut and perfectly meshed to prevent the tissue from slipping free from the jaws of the clamp.

Occluding clamps usually have vertical serrations or special jaws that have finely meshed, multiple rows of longitudinally arranged teeth to prevent leakage and to minimize trauma when clamping bowel, vessels, or ducts that are to be reanastomosed.

Graspers and *holders* are used for tissue retraction and generally have jaws of specific design based on their use (Figure 6-19).

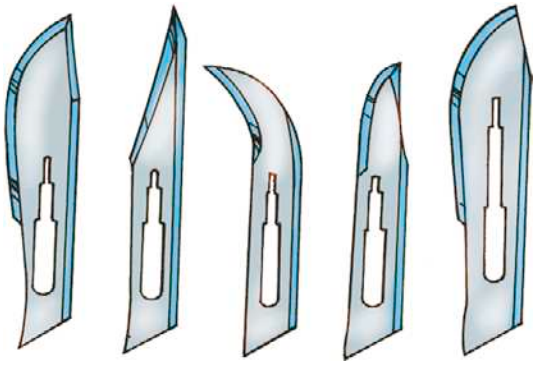

FIGURE 6-16 Scalpel/knife blades. From left to right: blade sizes 10, 11, 12, 15, and 20, respectively (actual size).

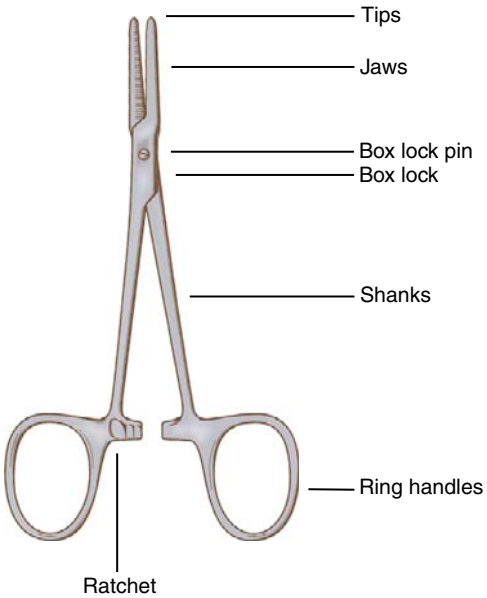

FIGURE 6-17 Anatomy of a clamp.

The Kocher (also referred to as an Ochsner) clamp has transverse serrations and large teeth (1 × 2) at its tip to grasp tightly on tough, slippery tissue such as fascia. The Allis clamp has multiple, interdigitating short teeth on the tip, minimizing crushing or damaging tissue. The Babcock clamp has broad, flared ends with smooth tips, and it atraumatically grips or encloses delicate structures, such as bowel, ureters, or fallopian tubes. Other holding forceps have handles like clamps with specialized tips or jaws, which may be triangular, straight, angular, or T-shaped.

Nonclamp graspers and holders are known as *forceps* or *pickups* because they are used to lift and hold tissue (see Figure 6-19). Often, while the surgeon is cutting with scissors or sewing with a needle, forceps are used in the other hand. Forceps are held like a pencil. The most common kinds are the various two-arm spring forceps. Forceps resemble tweezers, vary in length and thickness, and are available with and without teeth. Nontoothed forceps create minimal damage and hold delicate, thin tissues. Toothed forceps hold thick or slippery tissues that need extra grip. Toothed forceps ("rat tooth") have interdigitating teeth that hold tissue without slipping; these are used to hold skin or dense tissue. Adson tissue forceps have small, serrated teeth on the edge of the tips; these are designed for light, careful handling of tissue and are commonly used during skin closure.

Grasper and holder clamps may hold objects as well. Sponge-holding forceps with ring-shaped jaws (see Figure 6-19) are available in 7- and 9-inch lengths. They can be used to grasp or handle tissue but are commonly used as sponge holders. A gauze sponge is folded and placed in the jaws and is used to retract tissue, to absorb blood in the field, and occasionally to perform blunt dissection.

Needle holders (Figure 6-20), because they must grasp metal rather than soft tissues, are subject to greater damage. As a result, needle holders must be repaired and replaced regularly. For maximal usage, needle holders must retain a firm grip on the needle. Many types of jaws have been designed to meet this need. The so-called *diamond jaw* needle holder has a tungsten carbide insert designed to prevent rotation of the needle. In needle holders of standard design, a longitudinal groove or pit in the jaw releases tension, prevents flattening of the needle, and holds the needle firmly. Needle holders may have a ratchet similar to that of a hemostat, or they may have a spring action that may or may not lock.

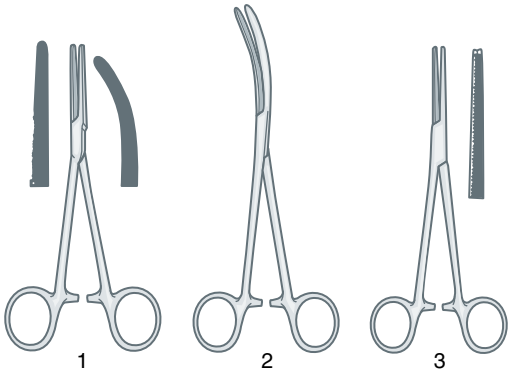

FIGURE 6-18 Basic clamping instruments. *1,* Crile hemostatic forceps; *2,* Rochester-Péan forceps; *3,* Ochsner or Kocher hemostatic forceps.

Towel clamps also are considered holding instruments. Of the two basic types, one is a non-penetrating towel clamp used for holding draping materials in place. The other has sharp tips used to penetrate drapes and tissues, and it is damaging to both. The use of sharp towel clamps to secure drapes is highly discouraged because they penetrate the sterile field.

INSPECTION AND CARE. The apposition of the instrument's tips is necessary for its functioning and must be periodically checked. When a hemostat is held up to the light and the handles are fully closed, no light should be visible between the jaws. These instruments, if used for purposes other than those for which they are intended, can be damaged and need

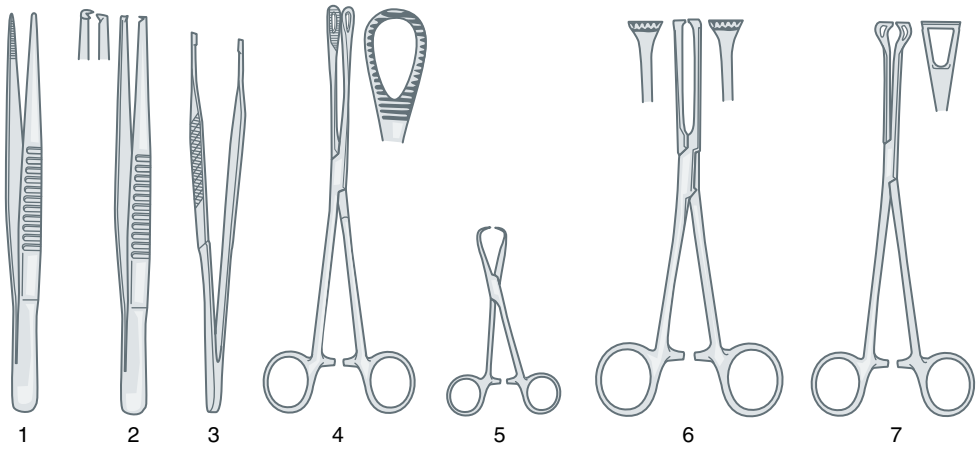

FIGURE 6-19 Basic holding instruments. *1,* Tissue forceps, smooth; *2,* tissue forceps with teeth; *3,* Adson tissue forceps; *4,* Sponge-holding forceps; *5,* towel clamp; *6,* Allis forceps; *7,* Babcock intestinal forceps.

FIGURE 6-20 **A**, Needle holders. **B**, Fine. **C**, Regular. **D**, Heavy.

to be repaired. The instrument's joint also must be checked. Instruments made up of two halves have one of three types of joints.

- The most common joint is the box lock, where one arm has been passed through a slot in the other arm and is riveted or pinned. This joint is needed where accurate approximation of the tips is necessary, and it is basic to most ringed instruments.
- The second type is the screw joint. The two halves are aligned and placed on top of each other, connected only by a screw. The joint must be checked and tightened periodically because the screw may become loose. Screw-joint instruments are easy to make and comparatively inexpensive.
- The final and least common type is the semibox, or aseptic, joint. It has the advantage that the two halves can be separated for easy cleaning.

All types of joints must be cleaned regularly. Protein deposits or rust collecting at the site must be removed to ensure proper functioning.

Retractors. Retractors are used to hold back the wound edges, structures, or tissues to provide exposure of the operative site. A surgeon needs the best exposure possible that inflicts a minimal degree of trauma to the surrounding tissue. Retractors are self-retaining (Figure 6-21) or manually held in place by a member of the surgical team. The two types of self-retaining retractors are (1) retractors with frames to which various blades may be attached, and (2) retractors with two blades held apart with a ratchet. An example of the latter is a Weitlaner retractor. Other very large self-retaining retractors, such as the Omni or Bookwalter, are equipped with multiple blades and attachments of varying lengths and sizes. With handheld retractors, the handles may be notched, hook-shaped, or ring-shaped to give the holder a firm

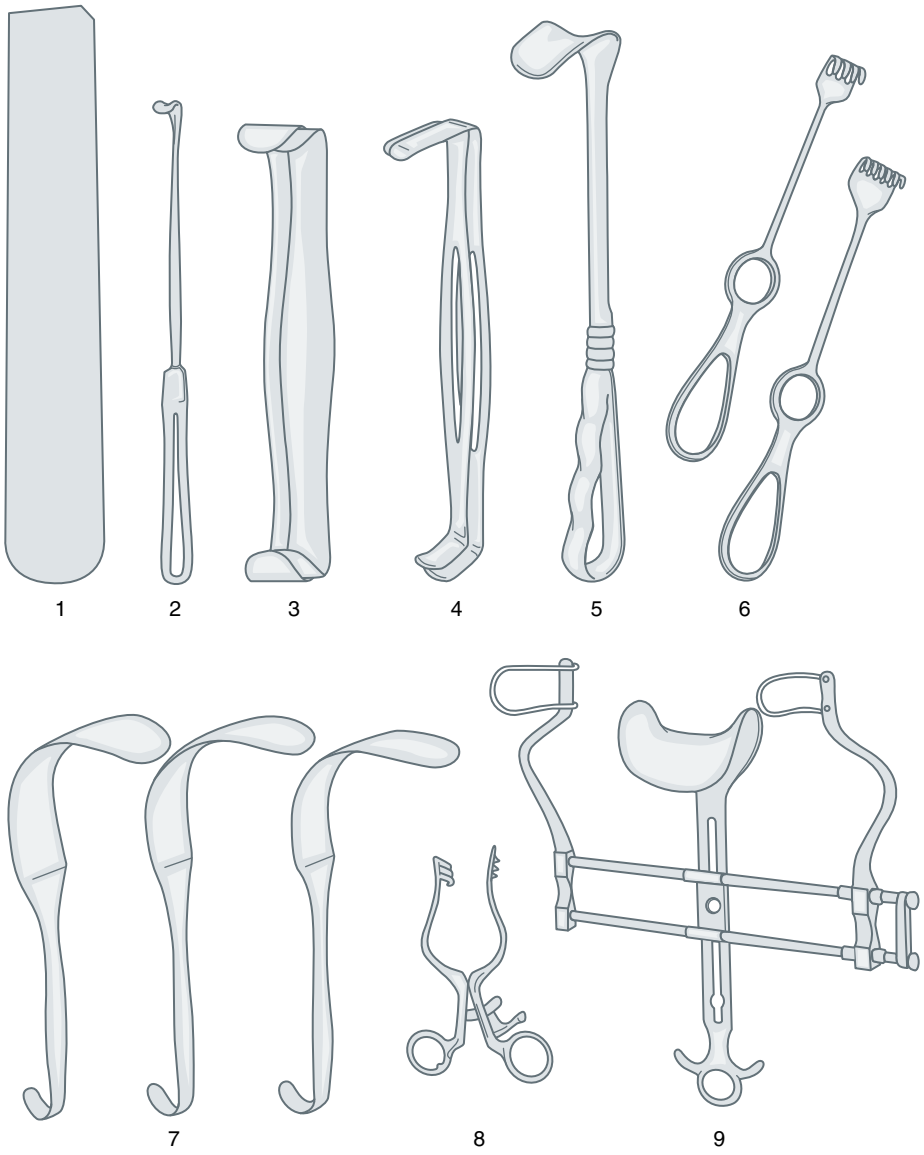

FIGURE 6-21 Basic retractors. *1,* Malleable retractor; *2,* vein retractor; *3,* Parker retractor; *4,* Army-Navy retractor; *5,* Richardson retractor; *6,* Volkmann rake retractors; *7,* Deaver retractors; *8,* Weitlaner retractor; *9,* Balfour retractor with blades.

grip without tiring. The blade is usually at a right angle to the shaft and may be a smooth blade, rake, or hook. A malleable (ribbon) retractor is a flat metal ribbon that may be shaped at the field.

Accessory and Ancillary Instruments. Accessory and ancillary instruments are designed to enhance the use of basic instrumentation or to facilitate the procedure (Figure 6-22). These include suction tips and tubing; irrigators-aspirators; electrosurgical devices; and special-use devices, such as probes, dilators, mallets, and screwdrivers.

Many miscellaneous instruments or specialty items are particular to a certain specialty but generally fall into one of the categories just mentioned. Microsurgical instruments are delicate and expensive. They are extremely fine and should be handled separately from other instruments. Instruments used in specialty surgery are discussed in each of the chapters under Surgical Interventions.

When nursing team members can analyze the planned surgical procedure and approach and identify each instrument and its specific function, they are able to select instrument sets without omitting necessary items and without including items that will not be used. This intelligent, planned approach ensures economy of time and motion, protects instruments from misuse, and prevents unnecessary handling. During the operation, the informed scrub person who anticipates instrument needs becomes a more valuable member of the surgical team.

Endoscopic Instrumentation

Laparoscopy has introduced new equipment and instrumentation to the surgical suite (see Chapter 7 for a full discussion of laparoscopic equipment). In addition to insufflation equipment, an optical system, and a documentation system, perioperative personnel must be familiar with the instrumentation used by the surgeon when performing a surgical procedure through the endoscope. Basic instrumentation, which may be disposable or reusable, includes trocars, forceps or graspers, clip appliers, stapling devices, scissors, needle holders, and aspiration-irrigation systems.

Verres needles and trocars provide access to the peritoneal cavity. A retractable safety shield protects abdominal structures from being inadvertently punctured during insertion. Forceps or graspers are available in 3-mm, 5-mm, and 10-mm sizes. Atraumatic graspers provide appropriate retraction and little risk to tissues. Bipolar coagulation forceps are used to control bleeding. The forceps are available with different tips, including ring, paddle, dolphin nose, claw, spoon, DeBakey, Allis, Pollack, Pennington, Glassman, Maryland, Reddick-Saye, Duval, and Babcock. Some dissectors are available with coagulation capability. Scissors also come with different tips: hook, straight and microtipped, serrated, and curved. Also, several disposable instruments coagulate and cut the tissue. One such instrument is the Harmonic Scalpel (discussed in Chapter 7).

Needle holders have a hinged-jaw tip to allow easy positioning of the needle before intracorporeal suturing and using the sliding sheath. The sliding sheath holds the needle in a distal notch and inner spring-loading mechanism. To aid with extracorporeal knot tying, the surgeon may use a knot pusher (e.g., a Clarke-Reich) to deliver tied knots into the abdomen. A slide and cinch pusher (Gazayerli) also is used to deliver and secure the preformed knot. Intraabdominal stapling devices have been modified to fit and function through the endoscope.

Stapling Instruments

Instrumentation for internal stapling, first introduced in 1908, has been refined and is now widely used (Figure 6-23). Various instruments to suture tissue mechanically are used for ligation and division, resection, anastomoses, and skin and fascia closure. In general, these instruments may be classified as follows (Neumayer and Vargo, 2008):

- Ligating and dividing staplers (LDSs)
- Gastrointestinal anastomosis (GIA) staplers (Figure 6-24)
- Thoracoabdominal (TA) staplers
- End-to-end anastomosis (EEA) staplers
- Laparoscopic hernia mesh staplers
- Open hernia mesh staplers
- Endo-GIA devices

Employed in many surgical specialties, the mechanical application of these instruments reduces tissue manipulation and handling. The edema and inflammation that usually accompany anastomoses are minimized because the noncrushing B shape of the staples allows nutrients to pass through the staple line to the cut edge of the tissue.

Mechanical staplers (both nondisposable and disposable) use cartridges of tiny stainless-steel staples or absorbable, nonmetallic staples that are commercially preloaded, prepackaged, and presterilized. The staples are essentially nonreactive; metal

staples remain permanently in the tissue. The staplers may fire individually or lay down multiple rows in a straight or circular pattern. Devices to cut or anastomose bowel and other structures are available for open-wound use or through endoscopic cannulae. The use of staplers significantly decreases operating time and may shorten postoperative stays.

Selecting and Preparing Instruments for Patient Use

Designated OR or central supply personnel arrange the various instruments into trays or sets. The trays are named according to their functions. Tray/set names and instrument composition will vary by institution, but three basic OR instrument sets are the minor/plastic, the basic laparotomy, and the dilation and curettage (D&C). A minor (or plastic surgery) set includes instruments needed for simple superficial incision, excision, and suturing. A basic laparotomy set includes instruments to open and close the abdominal cavity and repair any gross defects in the major body musculature. A D&C set, in addition to its use for dilation and curettage, is often used as the basic instrumentation for vaginal surgery.

According to each procedure's needs, more individualized instruments or specialty sets, such as an intestinal set or a vascular set, may be added. In the same way, basic instrument sets may be selected for opening other body cavities, such as the skull, chest, and pelvis.

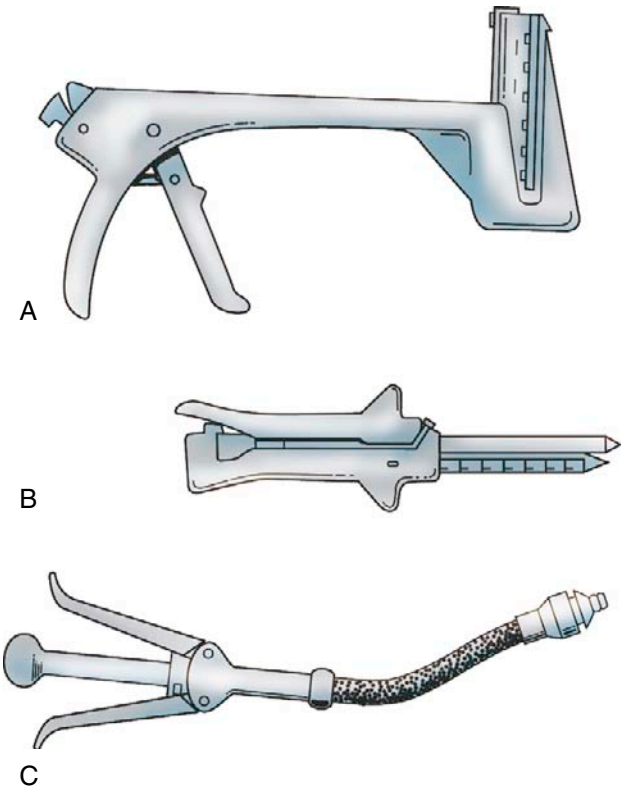

FIGURE 6-23 Internal staplers. **A**, Terminal end stapler, designed for closing the end of a hollow organ, such as the stomach, with a double staggered line of staples. **B**, Internal anastomosis stapler, designed to connect hollow organ segments to fashion a larger pouch or reservoir. **C**, End-to-end stapler, designed to staple two hollow, tubelike organs, such as bowel, to create a continuous circuit.

Instruments are selected according to the size of the patient's body structures and the nature of the organs involved. Proper selection requires a general understanding of surgical procedures and approaches and knowledge of anatomy, possible pathologic conditions, and the design and purpose of instruments.

Basic Table Setups

In most ORs, the instruments are set up on Mayo stands and back tables in a planned, standardized, organized, functional manner to maintain continuity when the original scrub person is replaced by another. Care is taken on all sterile fields to ensure that all solutions, syringes, and medication cups are clearly labeled to guarantee patient and staff safety. Each facility should create tools as a part of a comprehensive orientation process to ensure standardization of setups.

A proficient scrub person must know the instrument inventory of the department; the instruments routinely needed for each type of operation; the individual surgeon's preferences; and the correct use and handling, method of preparation, and postoperative care of the instruments. A file of preference cards or computerized data/preference sheets usually lists the procedures each physician performs, the physician's glove size, the preferred skin prep solution, specific draping instructions, and instruments required for the procedure.

Before an operative procedure, the scrub person may assist the perioperative nurse in gathering the needed supplies, equipment, and sutures. The scrub person scrubs; dons gown and gloves (see Chapter 3); and begins to set up the sterile tables with drapes, instruments, supplies, and sutures. Instruments are arranged with those most frequently used on the Mayo stand. When the patient is on the OR bed and is draped, the Mayo stand, set up for instrument use at the immediate operative site, is brought across the lower part of the patient's legs (Figure 6-25).

One or two back tables, according to the number of instruments and supplies, also are set up. The scrub person prepares the sutures and ligatures and places the knife blades on the handles. Other supplies needed are suction tubing and tips, electrosurgical cord and tip, drains, basins, gowns, gloves, drapes, sponges, and needles, all of which are sterile and set up on the back table according to standardized institutional policy

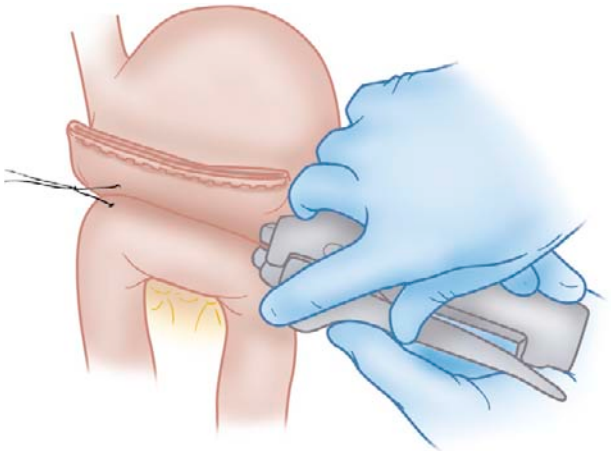

FIGURE 6-24 Using the GIA stapler to staple and join stomach and jejunum. At the same time, the blade in the GIA cuts between double staple lines, creating a stoma for a gastrojejunostomy.

FIGURE 6-25 Mayo stand, with instruments required for start of surgical procedure, is moved into place across the lower part of the draped patient.

(Figure 6-26). During the "Final Time-out" before incision, the scrub person has the responsibility to articulate instrument and equipment readiness to the team to enhance a safe, seamless procedure.

The scrub person must be attentive to the sterile field to anticipate the surgeon's needs. Instruments should be passed in a positive and decisive manner. Each instrument is placed or slapped firmly into the surgeon's palm in such a manner that it is ready for immediate use with no wasted motion. When a curved instrument is passed to the surgeon, the curve should be pointing in the direction of intended use; there should be no need for readjustment. It is necessary to know if a surgeon or assistant is left-handed or right-handed to pass instruments efficiently and in the correct position.

Often the surgeon or assistant uses hand signals for the type of instrument desired, to eliminate unnecessary talking. Scrub persons should become familiar with the basic signals for knife, scissors, suture, forceps, and clamp.

Care and Handling of Instruments

An instrument should be used only for the purpose for which it is designed. Proper use and reasonable care prolong its life and protect its quality. Scissors and clamps, which are most frequently misused, can be forced out of alignment, cracked, or broken when used improperly. Tissue scissors should not be used to cut suture or gauze dressings. Hemostatic clamps should not be used as towel clamps or to clamp suction tubing.

Instruments must be handled gently. Bouncing, dropping, and setting heavy equipment on top of them must be avoided. During the procedure, the scrub person should wipe the used instruments with a damp sponge or place them in a basin of sterile distilled water to prevent blood from drying on the surfaces and in the box locks. Saline solution should never be used on instruments because the salt content is corrosive and accelerates rusting or deterioration of the metal. As time allows during the procedure, the scrub person should rinse and dry the used instruments and replace them on the back table to facilitate closing counts.

At the end of a procedure, during the table breakdown process, the scrub person must handle the instruments in a logical organized fashion, either individually or in small groups. Sharp and delicate instruments should be set aside for individual handling and cleaning to avoid damage and accidental injury. Surgeon-specific instrumentation should be isolated to prevent loss or damage in the cleaning and reassembly process. Standard Precautions should be applied as dictated by institutional policy. All instruments set up for the procedure should be terminally sterilized or disinfected before reassembly. Instruments must be completely clean to ensure effective sterilization.

Each instrument should be inspected before and after each use to detect imperfections. An instrument should function perfectly to prevent needlessly endangering a patient's safety and increasing operative time because of instrument failure.

Forceps, clamps, and other hinged instruments must be inspected for alignment of jaws and teeth. Instrument jaws and teeth should meet perfectly so that blood flow is occluded without damaging the vein or artery. Ratchets should hold firmly yet release easily. Instrument joints should work smoothly.

The edges of scissors should be tested for sharpness by cutting smoothly through four layers of gauze. All instruments

FIGURE 6-26 **A,** Back table setup. **B,** Labeled medications and sharps on table setup.

should be checked for worn spots, chips, dents, cracks, or sharp edges.

Damaged instruments should be set aside and sent for repair or replacement. An instrument repair service should be selected carefully and used for regular maintenance, such as sharpening and realignment.

With today's focus on cost containment, perioperative nurses must assess the care and handling of instrumentation carefully. Instrument sets can be monitored for use, and instruments that are used infrequently can be removed and packaged separately to prevent continued wear from unnecessary resterilization.

Instrument Counts

Instrument counts are standard practice. Establishing standardized instrument sets with the minimal numbers and types of instruments in them facilitates instrument counts and reduces the amount of time and space required for a setup. Initial counts should be carried out concurrently by the perioperative nurse and scrub person before the procedure, with each person simultaneously viewing the instrument and audibly counting it. This is the baseline count. To facilitate the baseline count, the scrub person needs to be in the OR or other invasive procedure room in a timely manner to complete the instrument setup. Items added

during the procedure are counted and immediately recorded. Subsequent counts should be taken before closure of a cavity or large, deep incision; when the scrub person or perioperative nurse is relieved by other personnel; and at the completion of the procedure. The method of counting should be consistent for every procedure, beginning at the surgical site and immediate surrounding area and moving to the Mayo stand, the back table, and then to items discarded from the field. Rushing at the end of a surgical procedure can result in incorrect or incomplete counts. When the scrub person and perioperative nurse are rushed, it may be necessary to call for a "pause for the count," enabling counts to be carried out in an orderly manner. Many institutions have implemented engineering controls to assist in the prevention of the unintentional retention of instruments and other surgical items. These controls do come at some expense. The literature is beginning to demonstrate models for predicting the cost-effectiveness of this new technology (Research Highlight).

Instruments that break during the procedure or are disassembled (e.g., certain retractor systems) must be accounted for in their entirety. The nurse documents all counts on the appropriate record.

RESEARCH HIGHLIGHT

Prevention of Retained Surgical Sponges: A Decision-Analytic Model Predicting Relative Cost-Effectiveness

In a very tight economy, it becomes increasingly difficult for perioperative leaders to prepare a business proposal for safety when considering the introduction of new technology. This study provides decision makers with critical quantitative data about new options available to assist in the prevention of unintentionally retained surgical sponges (RSS). An empirically calibrated decision-analytic model comparing standard counting against alternative strategies—universal or selective x-ray, bar-coded sponges (BCS), and radiofrequency-tagged (RF) sponges—was developed and tested. The study used standard decision trees to model the predicted incidence of RSS and the incremental costs for each prevention strategy. The base case was established by estimating model probabilities on a per-operation basis for an average inpatient population. Estimates of the likelihood of discrepancies and reconciliation were derived from field observations. The following treatment strategies were employed: no sponge tracking, standard counting protocol, universal radiography without counting, universal radiography added to standard counting, selective mandatory radiography for high-risk operations, BCS system, RF-tagged sponge system, and RFID system. Cost estimates were determined and cost-effectiveness and sensitivity analyses were completed. It was determined that standard counting protocols already detected >80% of RSS; however, sponges were still unintentionally retained in 12 of 100,000 operations. Through decision-analytic modeling, the authors illustrated that in order for a sponge-tracking strategy to be cost-effective, it must be able to nearly eliminate RSS while controlling the costs. The BCS strategy was found to be the most cost-effective adjunct of the methods reviewed.

Modified from Regenbogen SE et al: Prevention of retained surgical sponges: a decision-analytic model predicting relative cost effectiveness, *Surgery* 145(5):527-535, 2009.

Patient Safety

In 2002 the AORN initiated its *Patient Safety First Program* and has continued to assist perioperative nurses in maintaining a safe environment for surgical patients. Retained foreign bodies after surgery are a complication with serious potential consequences for the people involved. Several steps are taken to ensure that needles, sponges, and instruments are not retained in the patient, as follows:

- Identification and counting of instrumentation in instrument sets before sterilization
- Initial counting of all items at table setup, before the surgical procedure (baseline count)
- Counting of items added during the procedure
- Counting of items as the wound closure is initiated
- Final counting of items as wound closure is completed

Despite these efforts, items still may be retained in the patient after surgery. The Agency for Healthcare Research and Quality (AHRQ) has established quality indicators based on literature review, expert input, and empiric evaluation. Patient Safety Indicators (PSIs) constitute a set of measures that can be used to screen for problems that patients experience. One of these is "Foreign body left during procedure" (Elixhauser et al, 2005). In 2005 the American College of Surgeons issued a patient safety statement regarding the prevention of retained foreign bodies after surgery. Paramount to preventing retained foreign bodies are good communication, consistent practices, and wound exploration before closure of the surgical site (ACS, 2005).

Storing Instruments

Instruments should be stored in a manner that keeps them safe and supports the maintenance of the container's integrity. Cabinet shelving should be adjustable and properly spaced for storage of various sizes and types of instruments. Most institutions store instruments in presterilized trays or containers. Attached labels and diagrams in cabinets assist personnel. An inventory of all instruments should be taken at periodic intervals.

CHAPTER 7

Surgical Modalities

KAY A. BALL

Surgery continues to evolve as less invasive procedures and instrumentation are adopted. Modalities have been developed that enhance and advance surgical procedures. This chapter provides information about the evolution of some widely used surgical modalities, including laparoscopy (sometimes referred to as endoscopy), video technology, and energies used during surgical intervention.

MINIMALLY INVASIVE SURGERY OVERVIEW

In the late 1980s, the "laparoscopy revolution" began in the United States (History box). General surgeons developed techniques to perform procedures using the laparoscope, eliminating the need for a large incision. As surgeons and perioperative nurses accessed evolving knowledge and information, the surgical industry worked to accommodate a rapid change from open surgical procedures to newer techniques of minimally invasive surgery (MIS). Perioperative nurses and surgical technologists experienced a marked opportunity to acquire new competencies. Since the 1990s, equipment, instrumentation, surgical skills, and perioperative nursing knowledge have markedly expanded as MIS has become a safe approach for many surgical interventions. Ongoing changes in surgery that aim to incorporate MIS procedures continue to present complex challenges for the surgical team while offering patients potentially shorter hospital stays (Sajid et al, 2009), reduced postoperative pain, lower rates of surgical site infections (Poon et al, 2009), and faster recuperation (Schmock, 2009) (Table 7-1). A keen understanding of the goals of endoscopic MIS, clinical competence, and preoperative patient assessment establish the basis for the perioperative plan of care.

Endoscopes

An endoscope is a tube inserted into a natural body orifice or through a small incision to access internal organs or structures. Endoscopes are flexible, rigid, or semirigid. Flexible endoscopes include angioscopes, bronchoscopes, choledochoscopes, colonoscopes (Figure 7-1), cystonephroscopes, hysteroscopes, mediastinoscopes, ureteroscopes, and ureteropyeloscopes. Rigid endoscopes include cystoscopes, laparoscopes, sinuscopes, arthroscopes, bronchoscopes, laryngoscopes, and hysteroscopes (Figure 7-2). Some endoscopes are manufactured in flexible and rigid forms. A semirigid endoscope, such as the deflectable tip video laparoscope, allows movement through a deflectable tip to provide a complete field of view from different angles (Figure 7-3).

Endoscopes are diagnostic or operative. *Diagnostic* scopes are for observation only and have no operating channels. The system is sealed at both ends. A diagnostic scope can be used, however, when multiple access sites are planned for the introduction of other instrumentation to perform a surgical procedure. *Operative* endoscopes are channeled to irrigate, suction, insert, and connect accessory instrumentation (Figure 7-4). For example, when a potassium titanyl phosphate (KTP) laser is used, the laser fiber is inserted into the operating port of the laparoscope. Advanced laparoscopic techniques may include the use of a flexible endoscope to check for anastomotic leaks, identify bleeding sites, or detect other problems before, during, or immediately after the laparoscopic procedure.

Endoscopes are available in various diameters and lengths, depending on access to the area being visualized and the requirements of the procedure. Optical capability through a rigid scope is controlled by a lens system and can be direct (0-degree angle) or angled (e.g., 30, 70, 120 degrees) (Figure 7-5). Some rigid endoscopes integrate a distally mounted camera chip inside the scope with a rotation dial for proper orientation of the target site. Because flexible scopes are able to be angulated, they allow for a more panoramic view.

There are two types of flexible endoscopes: fiberoptic endoscopes and videoscopes. Fiberoptic endoscopes have an eyepiece with a lens for visualization; the image is carried through the endoscope via a bundle of tiny glass fibers. Videoscopes have, at their distal end, a video chip that provides an image that is directly viewed on a monitor; a videoscope does not have an eyepiece for direct viewing.

Flexible endoscopes have four distinct components:

1. Control body (e.g., angulation knobs, air-water channels, biopsy port, eyepiece for fiberoptic endoscopes)
2. Insertion tube (e.g., flexible tube containing channels for suction, biopsy, irrigation, air and water, image bundles for the fiberscope, light bundles)
3. Bending section at distal tip (e.g., bending rubber, lenses, air-water nozzle, C-cover, charge-coupled device [CCD] chip for videoscopes)
4. Light-guide connector unit (e.g., suction, air-water channel)

Flexible endoscopes also have three different systems that include some of the various components within the endoscope:

1. Mechanical system (provides ports to introduce accessories to perform treatments and procedures)
2. Angulation system (allows the endoscope's distal tip to be moved in different directions)
3. Illumination system (provides light to view internal structures)

Rigid endoscopes also have four distinct components:

1. Eyepiece (e.g., ocular lenses; rigid videoscopes are offered today without an eyepiece)
2. Body (e.g., light-guide connector, valves)

HISTORY

Evolution of Endoscopic Minimally Invasive Surgery

Endoscopy, the examination of body organs or cavities by means of an endoscope, has been used for several centuries. Although primitive, the first use of reflected light for inspection of the vagina and uterine cervix is credited to Abul Kasim (936-1013), an Arabian physician. From this new conquest instrumentation was developed to examine the nasal sinuses and urinary bladder. Of primary concern during this initial era of endoscopy was thermal tissue injury caused by the intense heat emitted by the light sources used. Incandescent lighting was eventually incorporated into the tips of certain endoscopes (e.g., cystoscopes, ureteroscopes) that could be cooled by continuous irrigation. Modifications permitted examination of the nasal sinuses, larynx, bronchus, and sigmoid colon. Procedures were restricted, however, to endoscope placement in external body orifices.

In 1910 Jacobaeus, a Swedish physician, first reported using a cystoscope to examine the peritoneal cavity. He was only able to diagnose conditions because the ability to create a pneumoperitoneum (the introduction of a gas into the peritoneum to increase visualization and operative exposure) was yet to be developed. Numerous complications were associated with these brave attempts to perform this rudimentary form of laparoscopy. During these pioneering procedures, common injuries occurred to bowel and vascular structures—complications that today, although not unknown, are rare.

In an attempt to reduce morbidity, gynecologists introduced the cul-de-sac approach to pelvic endoscopy (culdoscopy). Instead of inserting the scope through the abdomen, they did so through the cul-de-sac. During this era, the importance of introducing air into the abdomen was recognized. Air was introduced through the use of a syringe and needle. Knee-chest and Trendelenburg positions were used to facilitate this procedure.

In 1964 the German surgeon Semm developed an automatic insufflation device. Laparoscopy was still considered to be "blind" surgery and did not gain rapid popularity in North America or Europe. During the 1960s two other developments enhanced the endoscopic revolution. In 1966 the rod-lens system designed by the British optical physicist Hopkins improved brightness and clarity. Fiberoptic (cold) light sources also were introduced that further reduced the risk of visceral and bowel burns.

In the late 1970s to early 1980s, endoscopic surgery transitioned from diagnostic to operative. Semm termed his pioneering work *pelviscopy.* His work led to many technologic advances in instrumentation, equipment, and practice. Diagnostic and operative laparoscopies were becoming techniques of choice for gynecologists throughout the world. Flexible and rigid endoscopic procedures also were increasing for urologists, internists, and otorhinolaryngologists. In the 1970s orthopedic surgeons began to develop their skills in the art of arthroscopy.

In the 1980s the laparoscope was introduced in general surgery. General surgeons were familiar with laparoscopy because many were consulted to assist gynecologists evaluating right lower quadrant pain in young women. That experience enabled surgeons to adopt laparoscopic procedures to diagnose acute appendicitis, presaging its wide use in general surgery today.

Modified from Ball KA: *Endoscopic surgery,* St Louis, 1997, Mosby; White RA, Klein SR: *Endoscopic surgery,* St Louis, 1991, Mosby; Semm K: Advances in pelviscopic surgery, *Prog Clin Biol Res* 112(Pt B):127-129, 1982; Zucker KA: *Surgical laparoscopy,* St Louis, 1991, Quality Medical Publishing.

TABLE 7-1

Advantages of Minimally Invasive Surgery Over Open Surgery

Minimally Invasive	Open
Ambulatory or short hospital stay	Hospital admission
Short postoperative recuperation	4- to 6-wk recuperation
Reduced postoperative pain; reduced need for pain medications	Postoperative pain related to surgical site; more analgesics required
Earlier return to normal lifestyle	Return to normal lifestyle varies with recuperation period

FIGURE 7-1 Flexible colonoscope.

3. Shaft (e.g., rod lenses, spacers)
4. Distal end (e.g., objective lens, negative lens)

Understanding the anatomy of an endoscope can help to assess technical problems that can occur during any endoscopic procedure. Internal components are complex, sophisticated, and sometimes delicate (Figure 7-6) and the endoscope must be treated with care.

Light Sources and Fiberoptic Cables

Endoscopic light is often referred to as *cold light*, meaning that the heat from the light source is not transmitted through the length of the scope. Therefore tissue damage from heat at the distal tip of the endoscope is minimized. When the ends of the fiberoptic cables are disconnected from the scope, however, they may be very hot. The surgical team must use extreme caution to ensure the ends of the cables do not contact the patient's skin and any flammable materials or liquids. If the fiberoptic cable is disconnected from the endoscope during surgery, the scrub person must ensure that the cable end is held away from drapes or placed on a moist towel to prevent burns and fires. Ideally the light should be turned off whenever disconnected from the endoscope. ECRI Institute (formerly, the Emergency Care Research Institute) recommends labeling all fiberoptic light sources to prevent fires from the hot light source energy.

According to ECRI, high-intensity fiberoptic light sources and cables can ignite drapes and other materials. To prevent a fire, all cable connections must be completed before activating the light source. The light source must be placed on standby when the cables are disconnected.

Light sources should have adjustable manual and automatic brightness modes. The automatic mode adjusts brightness according to the video image. If the light source is set in this mode, the circulating nurse need not make adjustments constantly.

When selecting a light source, certain options should be considered. A light source that can adapt to several rigid endoscopic systems is desirable, such as one with a universal light cable adapter, which enhances flexibility and usage (Figure 7-7). If a previously purchased unit does not provide this feature, universal light cables with connectors to an interchangeable light source and endoscope adapters are available (Figure 7-8). A generic cord can be used with most scopes and light sources, but some light cables can only be used with specific sizes of endoscopes. For example, a 2.5-mm cable should be used with a scope less than 4 mm while a 4.5-mm cable can be used with a 10-mm scope. Using the incorrect light cable with an endoscope may overheat or damage the optics. Color-coding different cable sizes helps in their differentiation. Light sources also must have connection capability with different camera units.

Fiberoptic light cables must be handled with extreme care. They consist of hundreds of glass fibers that transmit light (Figure 7-9) and the tiny fibers can be broken easily if kinked or dropped. Cables must be loosely coiled, never bent, when not in use. After multiple uses, fibers can break. Cables must therefore be checked after each use. To do this, hold one end of the cable pointing toward a bright light while the opposite end is observed for light transmission (Figure 7-10). Do not test the cable by looking into the end while it is attached to the light source. The visible light and ultraviolet light produced by the light source may harm the eye if directly viewed for extended periods. "Peppering" on the light cable end indicates broken fibers. When approximately 20% of the fibers are broken, the cable is replaced because adequate light for visualization cannot be transmitted through fractured fibers.

Bulbs within the light source usually are easy to replace. Extra bulbs are stored in lamp-assembly drawers, which are readily accessible. The bulb itself must not be touched because (1) it may be very hot and (2) the oils on an individual's hands and fingers can adhere to the bulb, causing the bulb to burn out more quickly. Nonmetal handles usually are built into the light source for bulb removal and replacement.

Three popular types of light sources are available today: xenon, metal halide, and halogen. Advantages and disadvantages are associated with each. Xenon bulbs are more expensive, but last longer. Xenon light is better for smaller diameter endoscopes (≤2 mm) because the light can be focused to a smaller spot size. Xenon light also is a preferred light for video or picture taking. Metal halide bulbs have a shorter life span (about 250 hours) and are less expensive. These bulbs are easier than others to handle and replace, and do not require large fans for cooling. Halogen light sources are used for office and some hospital applications. They do not, however, offer the light intensity required for many endoscopic and video applications. Personal preference and conditions for use are two key factors in choosing an appropriate light source for endoscopy. A light source that incorporates a lamp-life status–testing mode is desirable so that bulb replacement can be anticipated.

Given that light sources produce different colors of light whenever a camera is used, *white balancing* must be performed during each procedure. White balancing adjusts the camera to all other optical components (endocoupler, light cable, laparoscope). This method enables the camera to reference white so that it can identify all primary colors properly. White balancing should be performed only when the scope and light cable are connected, the light source is turned on, and the lens is held close to a white gauze or white drape (for white color referencing).

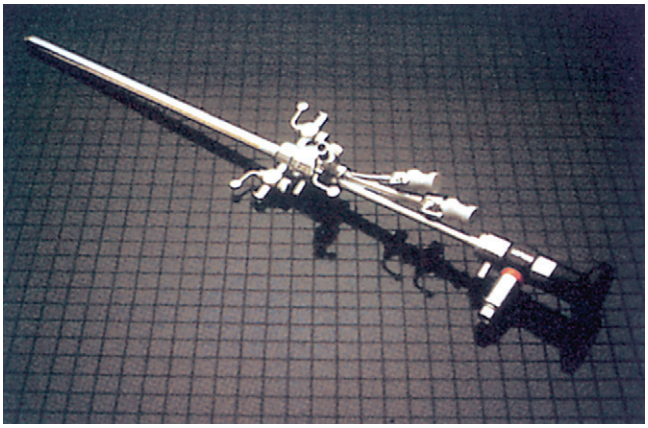

FIGURE 7-2 Rigid endoscope.

Endoscopic MIS Instrumentation

Endoscopic MIS instrumentation has been designed to correspond with the surgical site and the technique used while functioning as an extension of the surgeon's hand. The length and working end of the instrument must be adequate to perform surgery at the target site. The hand control is ergonomically designed for the operator's maximum comfort and reduced fatigue. Graspers and other instrumentation used by the assistant in surgery often are built for a shorter hand span because many women function in this role.

FIGURE 7-10 The light cable can be checked for broken fibers by holding one end toward a bright light while looking at the other end.

FIGURE 7-11 Disposable endoscopic instruments are designed to meet procedural needs during endoscopic surgery.

As endoscopic MIS approaches differ from the traditional open equivalents, modifications of existing instruments have been made. Some basic patterns have been used for years and continue to be popular, whereas others have been designed to accommodate newer MIS approaches. The full effect of this new era in surgery was realized in the 1990s and some instrument designs are in their sixth and seventh generations. As surgery becomes evermore sophisticated, so do the instruments required for successful, less invasive techniques (Figure 7-11).

Trocar System. When a natural orifice does not exist for diagnostic or operative procedures, one or several orifices can be created. To do so, a trocar system is necessary, and consists of an obturator and a sleeve (also known as a cannula or sheath). The trocar system provides a mechanism to insert and remove instruments while MIS is performed. The obturator and sleeve are inserted to access the operative site. When the port of entry has been made, the obturator is removed, and the sleeve is left in place. More complex laparoscopic procedures usually require a greater number of trocar systems and puncture sites. The Research Highlight box describes a magnetically controlled system that has the potential to reduce the number of entry points for laparoscopic instruments.

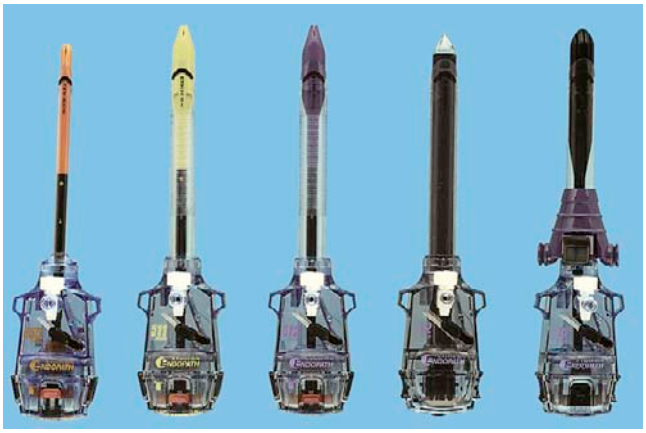

FIGURE 7-12 Disposable trocars and cannulae.

RESEARCH HIGHLIGHT

Trocar-less Instrumentation for Laparoscopy

This study was performed to determine the feasibility of a unique laparoscopic system with instruments that are positioned and locked into place using external magnets placed on the abdomen. The system minimizes the number of trocar sites needed during laparoscopic procedures as only one 12-mm diameter trocar is used. A transabdominal magnetic anchor and guidance platform, designed to integrate instruments, retractors, and a camera, provides movement and stability of the instruments. Results suggest that trocar-less laparoscopy can be performed using magnetically anchored instruments with expanded intracorporeal manipulation capabilities. This decreases the number of trocars and puncture sites needed for laparoscopic surgery, which has the potential to further advance laparoscopic practices.

Modified from Park S et al: Trocar-less instrumentation for laparoscopy: magnetic positioning of intra-abdominal camera and retractor, *Ann Surg* 245(3):379-384, 2007.

If a reusable trocar system is used, the obturator tip must be sharpened routinely. The stopcock and trumpet valves must be inspected before and after each use to ensure proper functioning. Internal gaskets may need occasional replacement. The obturator and sleeve must fit properly and may not always be interchangeable. Component parts must be kept together, but they must be disassembled completely for cleaning and sterilization.

Disposable trocar systems offer several advantages (Figure 7-12). One is that the obturator is always sharp. When multiple ports of the same size are used, the same obturator can be reused on the same patient. Some manufacturers also package one obturator and two or more sleeves of the same size. The same obturator is used to establish multiple access ports. Disposable units also may provide siliconized obturator tips and safety features when entry has been made. Systems are available that both engage a safety shield to advance automatically over the obturator tip (Figure 7-13) and provide retraction of the obturator tip when entry is made.

Many disposable sleeves have gripping devices that can reduce the risk of accidental sleeve removal during repeated advancement and withdrawal of the instruments. Grippers are

FIGURE 7-13 A close-up view of the trocar safety shield in place.

FIGURE 7-14 Blunt-tipped trocars can be used to minimize injuries during insertion.

incorporated into the sleeve or as separate entities. Grippers can be used with reusable sleeves as long as the fit is appropriate.

Disposable sleeves have a stopcock assembly for insufflation gas, similar to the reusable system. One-way flapper valves in disposables provide leakproof protection and operate automatically for instrument insertion, specimen removal, or rapid desufflation. As instrument diameters vary with design and use, various sizes of obturator and sleeve units may be required for one procedure. Reusable and disposable trocar systems are available in a variety of diameters and lengths. To increase flexibility, converters and reducers are used to adapt the size of the instrument. Converters can be separate or built into the sleeve as a diaphragm seal. Both systems are designed to reduce the chance of CO_2 leaks so that the pneumoperitoneum can be maintained. Radiolucent disposable sleeves offer the ability to visualize tissue and lesions without obstruction. This feature may be crucial during an endoscopic cholangiogram to avoid obstructing the view during fluoroscopy. During other procedures, this design may not be necessary.

Radially expanding dilator systems, consisting of a cannula with blunt obturator and an insufflation/access needle with a radially expandable sleeve, have been shown to cause less traumatic abdominal wall entry. Intraabdominal entry is accomplished using an access needle with a radially expandable sleeve. When insufflation is achieved, the needle is withdrawn, leaving the expandable sleeve in place. While the sleeve and tissue are expanded, a tapered, blunt-tipped dilator is inserted, providing a large working channel for an access port. As a sharp-tipped obturator is not used, the muscles are spread, not cut, and the risk of abdominal wall or vascular damage is minimized. Bladeless obturators, which separate tissue in a sequential fashion rather than cut or stretch tissue, also are available in an optical version that allows the surgeon to visualize all tissue layers being separated.

Occasionally a procedure is scheduled as an *open laparoscopy*. Patients who have had multiple surgeries, patients who have developed adhesions, and pediatric patients can present an added risk and may be candidates for open laparoscopy. A small paraumbilical incision is made and tissues dissected. The peritoneum is opened and a large, blunt-tipped obturator-sleeve assembly is inserted (Figure 7-14). The sleeve is designed to fit snugly against the peritoneum from underneath

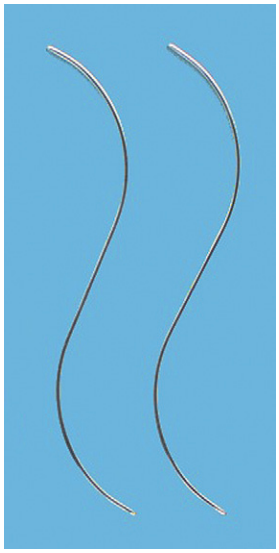

FIGURE 7-15 S-type retractors.

and against the skin from above. Stay sutures are used to close any excess incision. Wafer seals (similar to colostomy wafers) reduce further loss of carbon dioxide (CO_2) gas. Pneumoperitoneum is then created and maintained. If a reusable system is used, stay sutures also are used to stabilize the system. S-type retractors usually are needed for both (Figure 7-15). Sealed system devices have also been developed to introduce not only instrumentation, but the surgeon's hand when direct surgical approaches are necessary during laparoscopy.

When extracorporeal surgery must be performed during laparoscopy (i.e., when tissue undergoing surgery is brought outside the body through a small hole), an even larger diameter port is used. During certain bowel resections, loops of bowel are brought through a larger port to be resected or sutured. When the chest is entered, shorter blunt obturators are used with grippers that provide stabilization while in the pleural cavity. This type of obturator does not have insufflation ports (Figure 7-16). If insufflation is required to assist the anesthesia provider in collapsing the lung, regular obturators with insufflation ports are used.

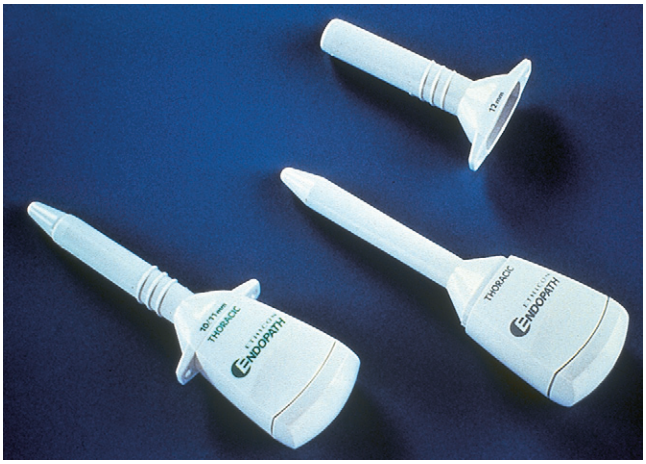

FIGURE 7-16 Thoracic blunt trocar and gripper assembly. Notice absence of stopcock insufflation capability.

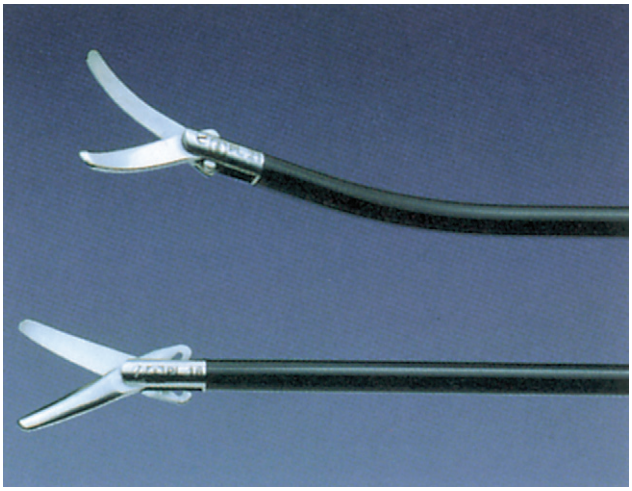

FIGURE 7-17 Straight and curved endoscopic scissors.

Dissecting Instruments. Dissecting instruments are used to cut, divide, or separate tissue. Scissors and dissectors that are similar to their open-procedure counterparts have been designed for use in MIS procedures.

Scissors are available for blunt or sharp dissection. They can be straight or curved (including hook scissors), depending on the location of the target tissue and technique used (Figure 7-17). Scissors usually have a rounded tip when closed so that they also can be used to manipulate tissue without trauma. When open, both jaws of the scissors should be visualized to prevent inadvertent injury. Some scissors are designed to be connected to an electrosurgical energy source so that coagulation can be provided during cutting.

Dissectors are used to separate or divide tissue. Many different tip shapes are available to dissect, spread, divide, grasp, retract, and coagulate structures (Figure 7-18). Other dissecting instruments, such as balloon dissectors, have been developed for blunt dissection or creation of a space so that surgery can be performed. A balloon dissector may be used to create a preperitoneal space during laparoscopic herniorrhaphy (Figure 7-19).

FIGURE 7-19 Balloon dissecting instrument.

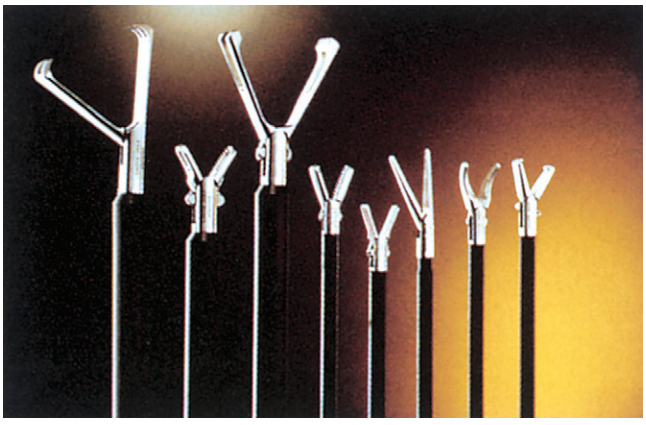

FIGURE 7-20 Endoscopic grasping instruments.

Clamping Instruments. Clamping instruments are used to grasp and hold tissue or other materials. Ratchets are used in the instrument design to allow the distal tip to be locked onto the tissue or whatever is being grasped. Graspers, forceps, and biopsy forceps are classified as clamping instruments.

Graspers and forceps can be (1) traumatic, with sharp teeth, or (2) atraumatic, with a smooth, serrated jaw surface (Figure 7-20). Traumatic graspers and forceps customarily are used to hold tissue that will be excised, whereas the atraumatic

versions are used to gently hold structures, such as the bowel or liver. Some clamping instruments are insulated so that electrosurgical energy can be transmitted to provide coagulation.

Suturing and Stapling Instruments. Suturing or stapling instruments deliver sutures, staples, or clips to join, hold, and secure tissue. Needle holders, clip appliers, and staplers are in this category.

Needle holders have been designed to deliver and place sutures within body cavities during MIS procedures. Tungsten carbide jaw inserts on the needle holders are often used to prevent rotation of the suture needle. These inserts often can be replaced when they become worn. Some needle holders have been designed to transfer the needle from one jaw to the other during suturing (Figure 7-21). Suture passers and curved needle holders also are available.

A clip applier is used to provide hemostasis and tissue security. Its use represents the safest, easiest, and quickest way to occlude small vessels and structures. Reusable appliers exist, but many must be removed from the cannula each time to be reloaded. This process adds time, contributes to loss of pneumoperitoneum (if used), and causes frustration when the clip is dislodged on reinsertion. For this reason, the automatic-feed, reloadable, disposable version is more desirable (Figure 7-22).

Rights were not granted to include this figure in electronic media.
Please refer to the printed publication.

FIGURE 7-21 Endoscopic needle holder that transfers the needle from one prong of the jaw to the other.

Staplers provide cutting and stapling during MIS resections (Figures 7-23 and 7-24). Certain structures can be easily resected intracorporeally (i.e., within the abdominal cavity), such as the ovary or appendix. Others may necessitate extracorporeal resection (outside the body) or reanastomosis; if this is necessary, traditional stapling devices are used.

The evolution of more complex MIS techniques has challenged traditional suturing and ligation methods. As a result, several devices and techniques have been developed for laparoscopic tissue suturing. When surgical clips and staples cannot be used, a laparoscopic suture may be substituted. Conditions that preclude the use of clips include large arteries and edematous or inflamed ducts. Most general surgeons prefer to use nonabsorbable sutures and ligation materials to prevent rapid absorption. Three basic types of laparoscopic suturing materials are *loop ligatures, extracorporeal sutures,* and *intracorporeal sutures.*

LOOP LIGATURES. Preknotted suture loops (loop ligatures) are used to ligate pedicle tissues. The suture loop is packaged with an introducer sleeve, which is inserted through one of the obturator sheaths. The loop is passed over the target tissue or pedicle using a grasping forceps to assist. When the loop is in position, the existing suture knot is pushed down the introducer sleeve until it is cinched tightly around the tissue. The suture is cut with endoscopic scissors (Figure 7-25).

EXTRACORPOREAL SUTURES. Tissue can be approximated intraabdominally when the knot is tied extracorporeally (i.e., outside the body). To accomplish this, endoscopic swaged sutures are used. The suture is grasped proximally to the needle, and both are inserted through one of the obturator sleeves into the abdomen. The needle is held with the grasper or laparoscopic needle holder and driven through the desired tissue. A second grasper or needle holder inserted through a second obturator sleeve is used to assist. The needled end of the suture is pulled through the tissue and out through the sleeve. The needle is removed, and a knot tied extracorporeally. The knot is advanced down the sleeve and onto the tissue. The suture is cut with laparoscopic scissors (Figure 7-26). The three types of knots tied extracorporeally are the *slip knot,* the *fisherman's knot,* and the *surgeon's knot.*

INTRACORPOREAL SUTURES. A suture ligature also can be passed through the obturator sleeve to be tied while it is inside the body. The tissue is approximated in the same fashion but tied intracorporeally (i.e., inside the abdomen) using grasping forceps or laparoscopic needle holders.

Retractors and Accessory Instruments. Retractors are used to hold tissue and expose the operative target site (Figure 7-27). Retractors can be traumatic to some structures, such as the bowel and liver, and must be used with caution. Miniretractors and balloon retractors have been designed for use on delicate

structures. A miniature version of a surgical clamp with blades that splay the incision open beneath the tissue is available. Other accessory instruments have been designed to enhance the use of basic MIS instruments, provide exposure, and facilitate the procedure. Probes used to manipulate tissue should be blunt to minimize tissue trauma. Some probes have centimeter gradations to measure structures within the body. Irrigation-aspirator probes enhance visualization of internal structures, and electrosurgical probes provide hemostasis. Endoscopic specimen bags contain specimens in order to minimize cross-contamination. Special accessory instruments are being designed continually to enhance MIS procedures.

Care and Handling of Endoscopes and Instrumentation. Endoscopes and instruments must be clean and free from all bioburden (contaminating organisms) before sterilization or high-level disinfection. During routine use, bioburden accumulates in channels, ports, crevices, and other movable parts of scopes and instruments. Periodically throughout the procedure, gross blood and bioburden should be removed

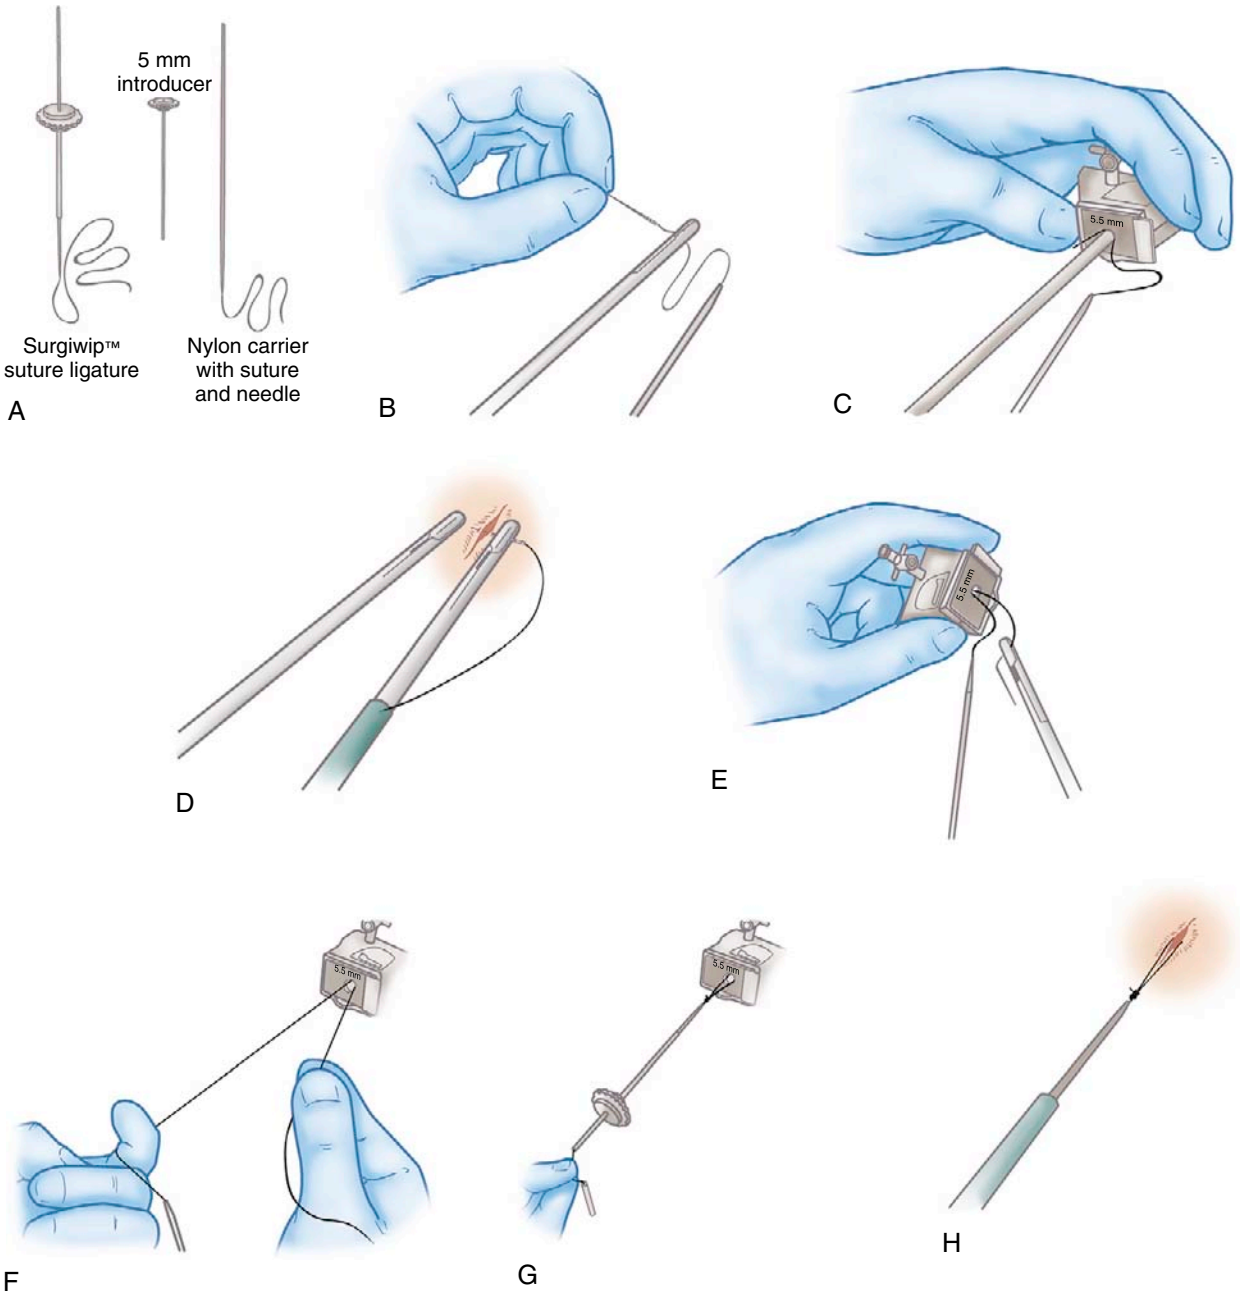

FIGURE 7-26 Surgiwip suture ligature application for approximating tissue intraabdominally by extracorporeal knot-tying (outside body). **A**, Component pieces. **B**, Grasp suture behind swage of needle with tissue grasper or needle holder. **C**, Introduce grasper or needle holder and suture through trocar into abdomen. **D**, Drive needle through tissue to be approximated. Place instrument close to center of needle for control. by flushing the channels and wiping the surfaces with sterile water. Saline should never be used routinely to remove gross debris during the procedure because this salt solution can leave mineral deposits on or in the device. Keeping instruments and endoscopes relatively clean during the procedure helps to prevent debris from drying, thus facilitating the cleaning process and protecting the instrument (Making your GI unit more effective, 2009).

After each procedure, all instruments and devices must be decontaminated thoroughly. Immersible equipment is cleaned or flushed with an enzymatic or other appropriate detergent solution; this loosens organic material and makes it easier to remove. Instruments that can withstand cavitation or ultrasonic cleaning (processes whereby high-frequency energy causes microscopic bubbles to assist with debris removal) can be placed in an ultrasonic device. Fiberoptics and endoscopes

Rights were not granted to include this figure in electronic media.

FIGURE 7-27 Endoscopic fan retractor with five fingers.

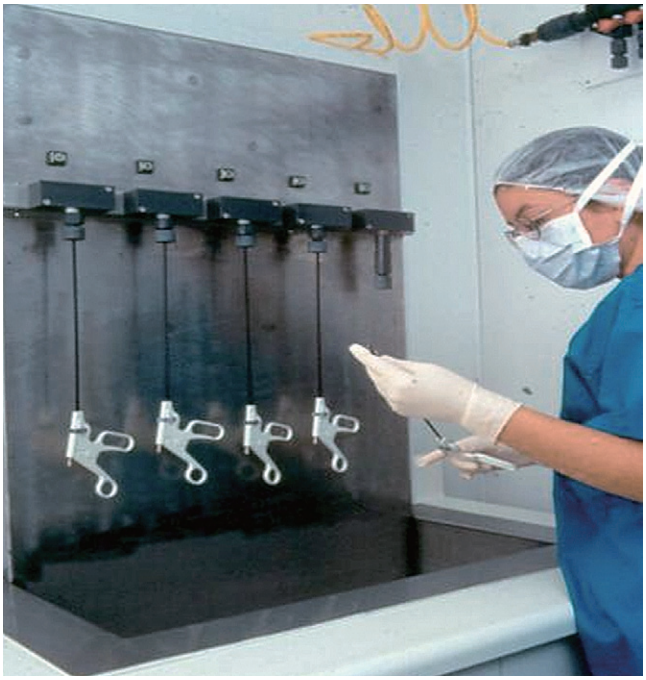

FIGURE 7-28 Commercial endoscopic instrument cleaner used by a reprocessing company.

usually cannot be placed in an ultrasonic machine because the vibratory motion can damage tiny fiberoptic bundles.

Selection of appropriate cleaning solution or detergent is critical. Detergents consist of various formulations that may include pH builders, buffers, surfactants, and chelants that provide the chemical compositions that clean devices. The amount of cleaning power within a solution is determined by the pH of the formulation. The "potential for hydrogen" is the meaning of pH, which represents the degree of acidity (more hydrogen ions present), neutrality (equal hydrogen and hydroxyl ions), and alkalinity (more hydroxyl ions present). A detergent with a very low pH can cause staining and pitting on the surfaces of stainless-steel instruments since they are more susceptible to damage during prolonged exposure of acidic solutions. When detergents are combined with the mechanical or automatic force of a cleaning spray, removal of bioburden is easier.

A low sudsing detergent is recommended so that the detergent can be completely removed. Cleaning solutions with surfactant are less desirable because they are more difficult to rinse. If surfactant is left on the surface, the device may feel sticky or gummy, which could affect the electrical conductivity of the instrument. Careful attention must be paid to the solution used as well as the type of device being cleaned. Certain detergents are not appropriate for cleaning both endoscopes and endoscopic instruments.

Careful rinsing and flushing with copious amounts of water follows the cleaning process. Often deionized or demineralized water is recommended for the final rinse to minimize mineral buildup from tap water. The manufacturer's written recommendations for cleaning and processing always should be followed. After final rinse, instruments must be dried before disinfection or sterilization.

Automatic cleaning devices that flush the ports of instruments provide an economic and effective way to clean reusable channeled instruments (Figure 7-28). Although instruments have flush ports, debris can become lodged distally. Some automatic systems provide a means to flush in a retrograde fashion, forcing debris from the larger proximal port. Sealed instruments also can be tested for seal integrity using this system.

After the device has been thoroughly cleaned, rinsed, and dried, its integrity and functionality must be assessed. Personnel involved with reprocessing MIS devices must be aware of instrument composition, design, and use. Any device with electrosurgical capabilities must be checked to ensure the length of the insulation sheath has not been compromised. Equipment is available that scans these instruments for electrical leakage through breaks in insulation.

Often new MIS accessories are purchased and used without educating the staff responsible for their reprocessing. Staff members cannot understand design and use of a device without proper instruction. The FDA requires that any device purchased as reusable must have written instructions for reprocessing. Staff must understand how the instrument works to ensure that functionality of the device has not changed during reprocessing. Compliance with federal, professional, and regional standards for reprocessing is mandatory.

Instruments and devices that contact sterile tissues and the vascular system must be sterile. Instruments contacting intact mucous membranes can be processed using high-level disinfection (Figure 7-29). This means that sterility is required for all laparoscopy, angioscopy, thoracoscopy, and arthroscopy procedures. High-level (cold-soak) disinfection may be acceptable for colonoscopy, laryngoscopy, bronchoscopy, cystoscopy, and other diagnostic procedures in which surgical devices touch intact mucous membranes. Invasive procedures that access the vascular system (biopsies) are performed during many endoscopy procedures. The adequacy of high-level disinfection must be evaluated for these procedures. Viruses and microorganisms, such as human immunodeficiency virus (HIV), hepatitis B and C viruses, *Mycobacterium* (tuberculosis bacteria), and antibiotic-resistant organisms, are not easily destroyed during high-level disinfection. Even though high-level disinfection has been the accepted primary standard of reprocessing for some endoscopic instrumentation, the concern over viruses and microorganisms has caused debate about the adequacy of using high-level disinfection. Therefore sterilization is quickly becoming the standard for reprocessing endoscopes and endoscopic instruments.

Thermal pasteurization, using a washer/pasteurizer, may be selected for thermal high-level disinfection. An FDA-approved chemical germicide should be selected for chemical high-level disinfection. Glutaraldehyde, used for many years, has hazards for staff that must be considered when this agent is selected for high-level disinfection. The maximum recommended exposure level of glutaraldehyde determined by the Occupational Safety and Health Administration (OSHA) is 0.2 ppm. When solution is being poured after mixing or when devices are being submerged, the level rises to approximately 0.4 ppm, which is double the recommended maximum exposure level. The odor of glutaraldehyde becomes an irritant at 0.3 ppm, causing tearing, nausea, and other effects. Hooded systems to house glutaraldehyde solutions have been designed to remove odor and fumes. When using this or any other chemical germicide, the device must be totally immersed and soaked for the specified contact time, following the manufacturer's recommendations for cleaning protocols, preparing the solution, maintaining contact time, and calculating expiration dates. Other solutions are available for high-level disinfection without the hazards that glutaraldehyde presents.

Institutional policy sets the guidelines from which practitioners work. Insight and coordination are required to provide comparable levels of care when there are too few instruments for the number of scheduled procedures. If sterile instruments are required for a particular procedure, sterile instruments should be used for all patients undergoing that procedure. Sufficient instruments, accessory items, and equipment must be purchased to accommodate patient volume, or other reprocessing measures must be implemented.

When sterile devices and instruments are needed, multiple options provide sterilization today, including steam, ethylene oxide, gas-plasma, and ozone sterilization methods (AORN, 2009). Often, steam cannot be used on delicate endoscopes, but accessory instruments may withstand the heat produced during steam sterilization. Some arthroscopes and laparoscopes have been designed to withstand high temperatures of steam sterilization. For items that cannot withstand high temperatures, options include the following:

- *Ethylene oxide sterilization*—This process has been used for many years to sterilize endoscopes and instruments. Past decisions to eliminate agents that were combined with ethylene oxide to decrease flammability, such as chlorofluorocarbon (CFC) and halogenated CFC (HCFC), have led to the use of 100% ethylene oxide for safe and effective sterilization. Limitations of ethylene oxide sterilization are the prolonged time needed for aeration of ethylene oxide and the installation and monitoring requirements for this type of sterilizer.
- *Plasma sterilization system*—This system uses hydrogen peroxide gas plasma, which sterilizes within 50 to 75 minutes and dissociates into nontoxic by-products. Understanding the advantages and limitations (e.g., lumen restrictions) of this system is important when determining if it would meet the needs of endoscope or instrument sterilization. Generally, flexible endoscopes cannot be sterilized in this system.
- *Ozone sterilizer*—Oxygen is used in a natural process to produce ozone. When oxygen is exposed to an intense electrical field, the oxygen molecule separates into atomic oxygen (O). Atomic oxygen combines with other oxygen molecules (O_2) to create triatomic oxygen (O_3), which is ozone. Ozone reverts quickly back to its oxygen state while producing no toxic residuals. Ozone is a powerful sterilizing agent because it oxidizes organic matter (fungi, bacterial spores, viruses). Key features of ozone sterilization include ease of use, low-temperature sterilization, cost-effectiveness, and compatibility with anodized aluminum containers. The manufacturer's instructions must be followed regarding operation of the sterilizer, instrument and device preparation, and device limitations.

FIGURE 7-29 High level disinfection reprocessor that handles two scopes at one time.

Single-Use Versus Reusable Instrumentation. Many facilities use a combination of reusable and single-use laparoscopic instruments. Advantages of single-use items include sharpness, reliability related to function, guaranteed sterility, and safety. Indirect advantages include no reprocessing, no repair costs, and comparable levels of patient care. Upgraded designs are more easily accepted when the device is labeled for single use. Disadvantages include the need for increased storage space, budgetary implications, and environmental concerns related to disposal of biohazardous waste.

Advantages of reusable instruments include less storage space, reduced costs (except for initial purchase and repair), and minimal waste. With reusable instruments, decontamination and reprocessing systems must be reliable, compatible with the devices being processed, and monitored for effectiveness.

Above all, safe and effective patient outcomes should be the major criteria considered when comparing single-use with reusable instrumentation. Advantages and disadvantages of reusable versus single-use devices must be explored, using a risk-to-benefit analysis, before purchasing decisions can be made. Institutional policy may dictate whether reusable or single-use items are chosen. The choice between single-use and reusable instrumentation and equipment must be evaluated thoroughly in each individual practice setting and justified accordingly.

Reprocessing Single-Use Devices (SUDs). Reprocessing single-use devices is a practice that has grown in acceptance. In the United States, the practice of reprocessing single-use devices is highly regulated by the FDA. The first guidance document was published in 2000, entitled *Enforcement Priorities for Single-use Devices Reprocessed by Third parties and Hospitals* (FDA, 2000). A more recent document to address this practice was published in 2006, entitled *Guidance for Industry and FDA Staff: Medical Device User Fee and Modernization Act of 2002, Validation Data in Premarket Notification Submissions (510(k)s) for Reprocessed Single-use Medical Devices* (FDA, 2006). These documents outline regulatory requirements, enforceable by the FDA, for reprocessing previously used single-use medical devices. The FDA continues to provide prescriptive guidelines to control this industry. In 2006 Dr. Daniel Schultz, addressing the House of Representatives Committee on Governmental Reform, stated that the FDA "will continue to provide, reasonable assurance of safety and effectiveness of reprocessed SUDs for patients."

The FDA defines a "reprocessor" as a third-party reprocessing company or hospital that reprocesses single-use devices. Hospitals rarely pursue the challenges of becoming listed as a reprocessor, given the expense involved with this activity. Reprocessing organizations are considered manufacturers, are subject to the same regulatory requirements as the original device manufacturer, and must comply with the original document guidelines (FDA, 2000):

1. *Registration and listing with the FDA*—Any organization reprocessing single-use devices must register with the FDA and provide a comprehensive list of all single-use medical devices that it reprocesses.
2. *Medical device reporting (MDR)*—Any organization reprocessing single-use devices must comply with the FDA's manufacturer reporting requirements and report not only all patient injuries from device malfunctions or failures but also any event that potentially could have led to patient injury or death.
3. *Device tracking*—The FDA can issue a tracking order for any specific device, if applicable. These devices are typically high-risk, Class III medical devices, such as implants. Reprocessing companies usually refrain from reprocessing Class III devices.
4. *Corrections and removals*—Every reprocessor must have a formal procedure in place to recall or correct affected devices.
5. *Quality System Regulation (QSR)*—Every reprocessor must develop and maintain comprehensive quality system controls that comply with the FDA's requirements for all aspects of their reprocessing operation.
6. *Labeling requirements*—Every reprocessor must provide instructions-for-use documents (IFUs) with reprocessed medical devices and must comply with specific requirements for what appears on the device label. Any reprocessed single-use device must be labeled, "prominently and conspicuously," with the following statement: "Reprocessed device for single use. Reprocessed by (name of manufacturer that reprocessed the device)."
7. *FDA premarket submission of a premarket notification (510[k]) or premarket approval (PMA)*—Every reprocessor is required to register each device to be reprocessed by submitting a 510(k) or PMA. The specific FDA requirements for the regulation of devices are based on the criticality (critical, semicritical, or noncritical) and the risk category/class of the device.

FIGURE 7-30 Single-use device is carefully sharpened during reprocessing at a third-party company.

Reprocessors also repackage and resterilize items with an expired shelf life date or when sterility of the outer packaging has been compromised. Single-use devices that are reprocessed are segregated into two categories for reprocessing: *open/not used* and *open/used* devices. The devices that have been used are grossly decontaminated before they are sent for reprocessing. If devices are not grossly decontaminated, they are collected in approved containers and transported by a licensed biohazardous material hauler using appropriate packaging materials and labeling.

Liability is an important concern for those engaged in reprocessing single-use items. A hospital or surgery center may be liable if reprocessing occurs within the confines of the facility. If a third-party company provides this service, it may likewise be liable and must document liability insurance coverage for this service. Although the original manufacturer of a device warrants a disposable product for one use, a reprocessing company also warrants the reprocessed device for one additional use.

Questions to ask when determining whether to reprocess single-use items include the following:

- Can the disposable device be adequately cleaned?
- Can the device withstand disinfection or sterilization? Can the item be adequately aerated if ethylene oxide sterilization is used?
- Is the device tested and checked for proper form and function after cleaning has been completed?
- Has device integrity been destroyed during reprocessing or is equipment available to test the integrity of the device? How is the integrity of insulation checked on an electrosurgical instrument?
- Can the device be returned to its original intended use (Figure 7-30)?
- Will cost savings be passed on to the patient, if appropriate?
- What is the maximum number of safe reuses, as determined through comprehensive testing? How is the number of reuses indicated on the device?

- Should the patient be informed that a reprocessed device may be used? The FDA does not require informed consent for the use of reprocessed single-use devices. Many providers contend that because reprocessing is so highly regulated and the risk of using a reprocessed device is the same as using the device for the first time, there is no need to seek informed consent.

No matter where reprocessing is performed, appropriate equipment must be available to ensure that the form and function of the device have not been compromised. Customers should inquire about reprocessing and quality assurance practices if dealing with a third-party reprocessor. Usually these companies have appropriate equipment to perform comprehensive device and validation testing. They must register with the FDA and comply with the Quality System Regulations (QSR) (FDA, 2000). Reprocessors should provide documentation of FDA registration, any reports of FDA inspection, such as an Establishment Inspection Report (EIR), FDA warning letters, all-important 510(k) or PMA documentation, and the limited number of uses for each specific device.

The practice of reprocessing single-use devices continues to grow in popularity as significant cost savings are realized by all sizes and types of healthcare facilities. Surgical team members must work closely with their purchasing agent, infection control officer, financial administrator, and others to decide if reprocessing single-use devices is an appropriate option for their facility.

VIDEO TECHNOLOGY

Evolution of Video Technology

A basic standard medical video system includes the scope, light cable, light source, camera head, camera cord, camera-scope coupler, camera control unit, and video monitor. Additional peripheral equipment is necessary for specific surgical procedures and is discussed later. Given the complexity of video technology, a glossary of terms is provided in Box 7-1.

Setting up a video system in surgery begins with the image source—the camera. A camera control unit (CCU) is needed to convert the image signal from the camera into viewable format. The monitor is then connected as the display device that shows the image signal. Options can be added to this setup to record the surgical procedure or to take still images. The image recorder and/or printer is positioned before the display device.

BOX 7-1

Video Glossary

Autoexposure—An electronic circuit built into cameras to eliminate electronically (within the camera) excess light from the picture; sometimes referred to as electronic shutter.
Automatic gain control—Ability to increase or decrease video output levels depending on the average light level of the viewed object.
Blooming—A glaring effect on the monitor caused by excessive light.
Boost—The ability to increase the signal strength of the camera. When used under low light conditions, boost provides increased sensitivity.
CCD—Charge-coupled device.
CCU—Camera control unit.
Chroma—Saturation of a color.
Chromiance—Defines the video camera's ability to handle the color red, the most difficult color to reproduce. The more accurate the color reproduction, the higher the chromiance.
C-mount—Standard thread size and diameter for a standard video camera lens.
Color bars—A test pattern used to adjust controls on the monitor for color, brightness, and contrast.
Color reproduction—Ability of an imaging device to reproduce colors exactly as the human eye perceives them.
Composite video output—Most commonly used video signal; the typical television video signal.
DICOM—Digital Imaging and Communications in Medicine; format for images in healthcare.
DVI—Digital Visual Interface, a popular system for medical imaging.
Electronic shutter—Ability of a camera to freeze image information within fractions of a second (1/60, 1/125, 1/1000, 1/10,000).
Foot-candle—Standard measure of luminance; the amount of light emitted by a standard candle at a distance of 1 foot from the flame; 10 luxes equals 1 foot-candle.
HD-SDI—High-Definition Serial Digital Interface; a popular medical imaging system.
High-definition television (HDTV)—A digital broadcasting system with higher resolution capabilities than traditional television systems, such as standard-definition TV (SDTV). Less bandwidth is needed for transmission because of digital video compression.
Light gain—Another circuit within the camera that amplifies the picture electronically to show a brighter image; sometimes referred to as automatic gain control (AGC), or boost circuit.
Luminance—Intensity or effectiveness of a given light on the eye.
NTSC—National Television Standards Committee; also a designation for a television signal used in the United States.
Orientation—A mark or ridge on the camera head to orient the top portion of the video monitor.
PACS—Picture Archiving Communication System.
Pixel—A signal-sensor element on a solid-state video chip; most solid-state chips used in medical videography have about 400,000 pixels on their surface. Each pixel is light-sensitive and sees its own small part of the total picture.
Resolution—An optical device's ability to separate fine detail; usually expressed in TV lines. Resolution traditionally is measured by aiming the camera at a target chart with squares of fine lines. The maximum resolution of the optical device is determined at the point where it begins to blur the lines together. If a box showing 400 lines per inch is still clear with spaces between the lines, the optical device has at least 400 lines-per-inch resolution.
Sensitivity—The response to low light levels by a video system.
S-Video—Super-Video, used to designate analog video signals.
S-VHS output—Super Video Home System (Japan Victor Co.), a signal from the camera that splits the chroma and luminance, allowing for a richer resolution recording.
White balance—Different light sources produce different temperatures of light and different colors of light. White balancing is an adjustment of the camera for various sources of light.

Video systems use light energy from a source, convert it into electrical energy, and then convert it back into light energy to provide pictures. The camera head contains a sensor, which is light sensitive. The sensor may be a solid-state unit or chip, called a *charge-coupled device (CCD),* which produces the unprocessed video signal, or the sensor may be a high-definition (HD) system.

The CCD is composed of small picture elements called *pixels,* which in the presence of light are conductive and in the absence of light remain nonconductive. Each pixel can sense red, blue, or green light. The picture is transformed into a matrix made up of the conductive and nonconductive pixels. This matrix will scan at an extremely rapid rate that generates the signal frequency.

The National Television Standards Committee (NTSC) sets the standard analog video format in the United States, Canada, Japan, and most of South America and Asia. It was established for broadcast purposes. Even though the NTSC format has been used for more than 50 years, most transmissions in the United States were replaced with the ATSC (Advanced Television Systems Committee) format in 2009, and by August 31, 2011, the ATSC format will also be used in Canada.

The three most commonly used video formats are S-Video, HD-SDI, and DVI. S-Video is short for Super-Video and is a technology used for analog video signals. The information of S-Video is divided into two separate signals, one for color (chroma) and one for luminance (brightness), and carries standard definition video. Standard definition displays 720 lines vertically (side to side) and 480 lines horizontally (from top to bottom). This is usually designated as 720×480 resolution, which produces 345,600 pixels. An S-Video cable is needed to support this transmission.

For medical imaging, the two most widely used systems are HD-SDI (High-Definition Serial Digital Interface) and DVI (digital visual interface). The HD-SDI system was engineered for the highest picture quality (and is most widely used for endoscopic systems) while DVI was engineered for copy-protected distribution.

High-definition (HD) systems that produce ultrasharp images with increased levels of contrast are replacing many standard analog video systems. HD systems are often described as offering picture quality equivalent to what one experiences with the naked eye.

An HD video system refers to a system that has higher resolution (greater numbers of lines of resolution) than with the standard-definition analog systems. The HD visual image is much sharper because gaps between the scan lines are either narrower or invisible to the naked eye. This improvement is most evident with larger screens, but on smaller screens there is no noticeable improvement in picture quality. The number of lines of resolution in the vertical display for HD systems is 1080 or 720 lines. Display resolution for HD is usually 1280 ×720 or 1920×1080 (horizontal × vertical pixels). With this higher number of pixels, as compared to the old standard analog video signal, a much clearer picture results, with higher quality and greater detail.

The vertical lines are also described with a lower-case "i," meaning interlaced, or lower-case "p," meaning progressive (which also describes the picture refreshment rate). An interlaced scanning format divides the 1080 lines of resolution into pairs, with the first 540 alternate lines on one frame and then another 540 lines on a second frame. The progressive scanning method displays all 1080 lines simultaneously on every frame, which then requires a greater bandwidth. Today's highest achievable resolution is 1920×1080p. HD video systems that use 1080i resolution are very appropriate for endoscopy because this procedure targets small areas and uses slow-moving videos.

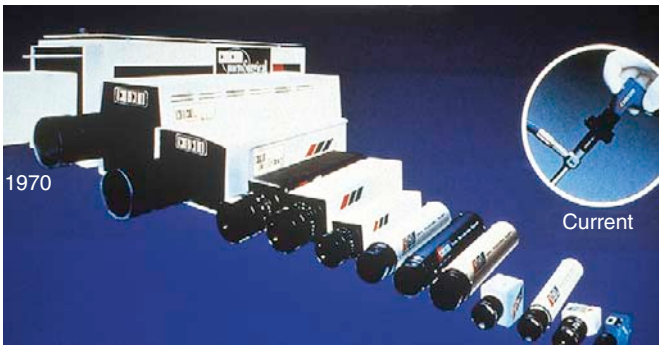

FIGURE 7-31 Evolution of medical video cameras.

Visualization Systems

Endoscopes are used to offer visualization only to the operating physician. The introduction of the teaching arm provided direct visualization not only for the physician, but also for the assistant, perioperative nurse, and other surgical team members. Often, however, images seen through the teaching arm were not identical to the images seen through the primary optics. The inability to interact effectively with the physician or to anticipate surgical needs was frustrating and time-consuming.

In the late 1960s and early 1970s, medical video and still cameras were continually being introduced to the marketplace; this allowed for still photography and video documentation of select surgical procedures. Tube style cameras were large, bulky, and heavy—inadequately meeting the video needs of surgery. Video technology rapidly changed with the introduction of the chip TV camera. Its lightweight, low-profile design triggered the era of video-guided surgery. Cameras that previously weighed several pounds now weigh only a few ounces (Figure 7-31).

Rapid developments in video imaging resulted in higher resolution monitors. Today's integrated video systems provide increased visual capabilities. This leads to enhanced participation by assistants and promotes accurate assessment and planning by perioperative staff. Video technology has evolved to the point of being almost mandatory during MIS procedures. All surgical disciplines have been enhanced by the availability and capability of video systems.

Camera, Cable, and Control Unit. The video camera represents the beginning of the optical-electronic chain of the video system. The camera cable transfers the signal frequency from the camera to a camera control unit (processor), which modifies the signal and then transmits the image to a video monitor, recorder, or hard copy picture, or all three. The camera, being the first in the video chain, is the most important component of the video system. Camera options vary widely according to available technology, specialty, and personal preference.

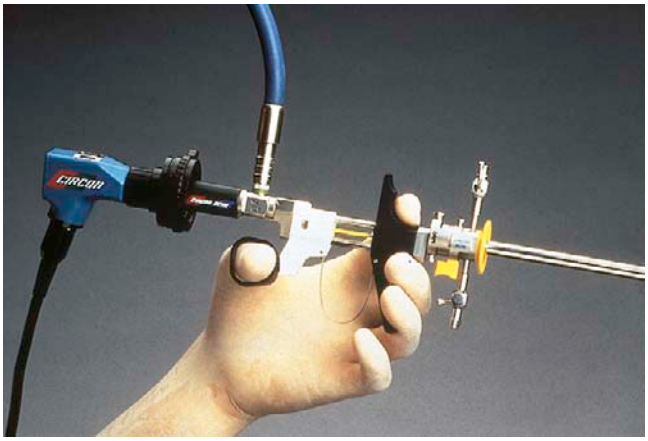

FIGURE 7-32 Microdigital I RGB color video camera with fingertip control.

Cameras have either one or three CCD chips. Three-chip cameras provide enhanced color and image quality, but are larger, can cost three times that of a single-chip camera, and are not as light sensitive. Color and the resulting image are enhanced because each chip is dedicated to one of the primary colors—red, green, or blue. For this reason, three-chip cameras are often used with microscopes when higher magnification requires increased resolution.

Newer single-chip cameras are available with digital processing in their control units, which boosts resolution. In essence, this technology incorporates three-chip quality in a single chip. Although signal processing in the control unit may be digital, the video output from most cameras is still an analog signal.

Digital processing refers to the way information is delivered through the various components of the control unit. This processing format allows for image enhancement and manipulation of the video image. It also allows multiple video signals to be shown on one monitor and has electronic zoom capability. Digital processing also provides the user with freeze-frame capability when using video printers and when using picture-in-picture systems.

Most cameras also feature the ability to adjust to changes in light intensity while in use. This adjustment is done by an automatic shutter (iris), which measures the availability of light and adjusts accordingly. Automatic shutter activation also helps reduce glare from light reflected off instruments and moist viscera. The ability for continuous variable shutter speeds (rather than discrete speeds) allows for instruments to be brought into the field without glare, while still maintaining adequate illumination of background objects. The shutter's response should be rapid, without perceptible stepping of image intensity.

Camera heads have buttons to control certain functions, such as white balancing, light-sensitivity boosting (ability to provide a brighter picture when the image requires more light, especially when a scope less than 3 mm is used during sinusoscopy), starting and stopping the recorder, and taking hard copy prints. The surgeon controls these functions at the camera head instead of requesting the circulating nurse to do so each time at the recording device or with a remote; therefore the surgeon also has the ability to capture events exactly as and when they occur (Figure 7-32).

FIGURE 7-33 Camera control unit.

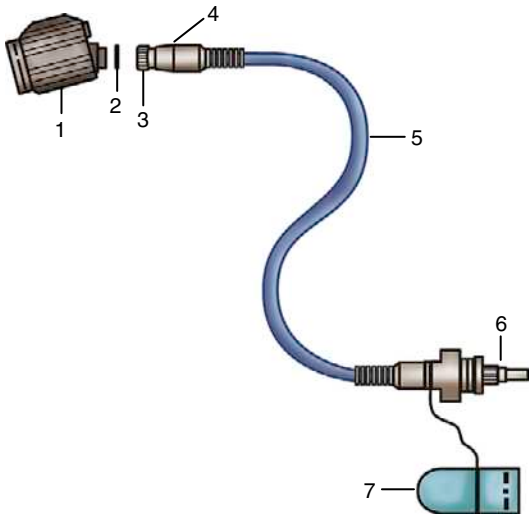

FIGURE 7-34 Camera and field-replaceable cable. *1*, Camera head; *2*, O-ring; *3*, knurled ring; *4*, cable connector; *5*, replaceable cable; *6*, camera connector; *7*, soak cap.

White balancing is performed by turning on the light source, holding the camera about 2 inches away from a white surface, and pressing the white balance button, usually found on the camera head or camera control unit. By sensing pure white, the primary colors of red, green, and blue are controlled so that a white image is created without a visible tint or color cast.

All cameras have focusing capability at the camera-coupler interface. Some also have zoom capability, allowing for closer visualization of specific structures or pathologic conditions. A camera cable connects the camera head to the camera control unit (Figure 7-33). Most camera malfunctions are cable-related, not camera-related. For this reason, a system that provides field-replaceable cables is optimum (Figure 7-34). If wires in the cable break, a new cable can be quickly exchanged, reducing downtime from having to ship the camera and cable for repair. Because wires in the flexible cable can break, the cable must be handled with care. Cables should never be twisted, crimped, or kinked. They also must be long enough to allow sufficient space between the sterile field and the visualization system.

Couplers (Adapters). Endocouplers are optical coupling devices used to connect cameras to various endoscopes. They are usually available in 28-mm and 35-mm focal lengths, with different optical magnifications.

The specific coupler required depends on the surgery or diagnostic procedure to be performed and endoscope to be

FIGURE 7-35 This camera adapter provides a direct link from the camera to the monitor when eyepiece viewing is not desired.

FIGURE 7-37 The camera adapter with a beam splitter allows the physician to look through the eyepiece while others view the procedure on the monitor.

FIGURE 7-36 This camera can be directly attached to the endoscope for viewing on the monitor.

FIGURE 7-38 A one-piece design with a camera incorporated into the endoscope provides consistent, superior image quality.

used. When the surgeon will view only on a monitor, a direct-link coupler between the telescope and camera head is required (Figures 7-35 and 7-36). For the surgeon to look directly through the endoscope and have monitor-viewing capability, a beam-splitter coupler is necessary (Figure 7-37). Beam splitters often are used with flexible endoscopes. There are rotating beam splitters designed for the surgeon who operates in a sitting position. Zoom couplers provide variable focal lengths, usually from 22.5 to 50 mm.

A videoscope is a camera-to-scope connection designed without using a coupler (Figure 7-38). As a coupler adds one more link to the chain, coupler connections can cause loss of light and lens fogging. Connecting the camera and scope with a screw-in design instead of a coupler clamp achieves a tighter fit. This design, however, requires that the camera and scope be purchased as a unit; there is no interchangeability between systems. It also does not allow for sterile bagging of the camera because the camera is part of the endoscope.

Lens fogging can be frustrating. It occurs because a cool metal scope is introduced into a warm body. There are several ways to address this phenomenon. Elimination of a coupler has been discussed. Sterile defogging solutions are available to apply to the endoscope and coupler lenses (Figure 7-39). These provide a coating and reduce the incidence of fogging. Other options on the market include O-ring seals at connections, sapphire lenses,

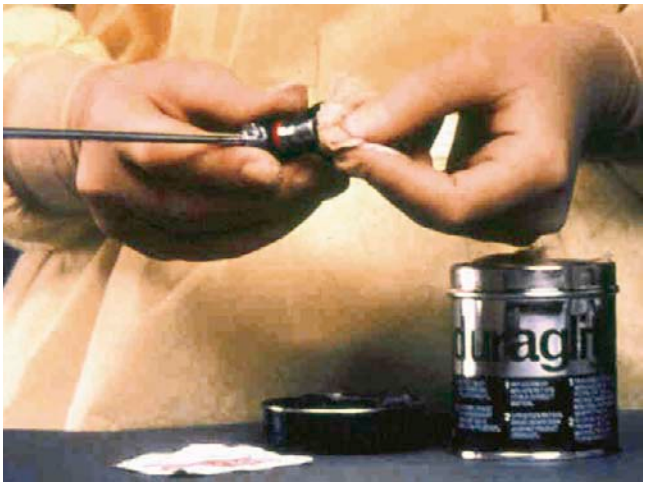

FIGURE 7-39 Sterile defogging solutions are available for endoscopic procedures.

and various water seals. Warming the endoscope before insertion also may reduce fogging. The endoscope can be warmed by wrapping it with lap sponges that have been soaked in warm, sterile water. Also available are scope warmers, such as thermos jugs that warm the scope while maintaining sterility.

Another method is to use a CO_2 insufflator, which warms the gas (if used) before it enters the body. It may be sufficient to change the insufflation site to a secondary port, after the initial pneumoperitoneum has been achieved. The surgeon also may opt to warm the lens of the endoscope by gently touching an intraabdominal structure that requires visualization, obviating the need to withdraw the scope to wipe or defog the outer lens.

An advanced video system has been developed that uses the "chip on a tip" technology. This innovative digital imaging system positions a video chip at the distal tip of the endoscope so that the target is clearly and consistently visualized. The seamless one-piece design eliminates couplers that join together the camera head, telescope, and light cable. The distal end can have either a rigid or flexible tip to access hard-to-reach areas. This unique videoscope minimizes problems encountered by other video systems, such as fogging and faulty connections.

Video Monitor. High-resolution video monitors are the end of the chain in video endoscopy. They have become the "windows of observation" during minimally invasive surgery (MIS). Monitors should match closely the resolution quality of the camera used. A high-resolution monitor that meets or exceeds the horizontal resolution of the camera is required for optimum visualization. By definition, the camera-monitor system will always have the resolution of the least-detailed element. Determining picture quality of monitors is difficult unless the monitors are side by side. Picture-tube design is the component that alters a monitor's picture quality. Monitors must be able to handle the camera/recorder format (standard analog or HD).

Many operative procedures require two video monitors, one placed on each side of the patient so that the primary surgeon and assistant can view the screen simultaneously. The second monitor is called the *slave monitor*. Abdominal and thoracic procedures are performed in this manner. Certain procedures can be performed with only one monitor. Whenever the monitor can be placed comfortably in a position of visibility to both the surgeon and assistant, only one is necessary. This is usually the method of choice for urologists, endoscopists, gynecologists, and otorhinolaryngologists. Most general surgeons require only one monitor whenever they perform surgery with the endoscope directed toward the patient's feet (as in laparoscopic herniorrhaphy).

Monitors should be at least 19 inches (diagonal measurement of screen) for adequate visualization. When the endoscopic revolution began, most institutions purchased 19-inch or 20-inch main monitors and 13-inch slave monitors. Today many institutions purchase mainly 24-inch to 32-inch monitors. This size increases flexibility in usage and provides excellent visibility from most observational angles and distances.

When only one monitor and a composite signal are used, the 75-ohm termination on-off switch must be in the *on* position. When multiple monitors are used, the switch on the last monitor in line to receive the video signal should be in the *on* position, and all others should be in the *off* position to enhance picture quality. Some monitors are self-terminating and do not have termination switches (Figure 7-40), an electronic wiring design known as a "daisy chain."

Recording Systems. Some recording devices allow for archiving the surgical procedure or selected portions of it. The most commonly used is the video printer (Figure 7-41), similar

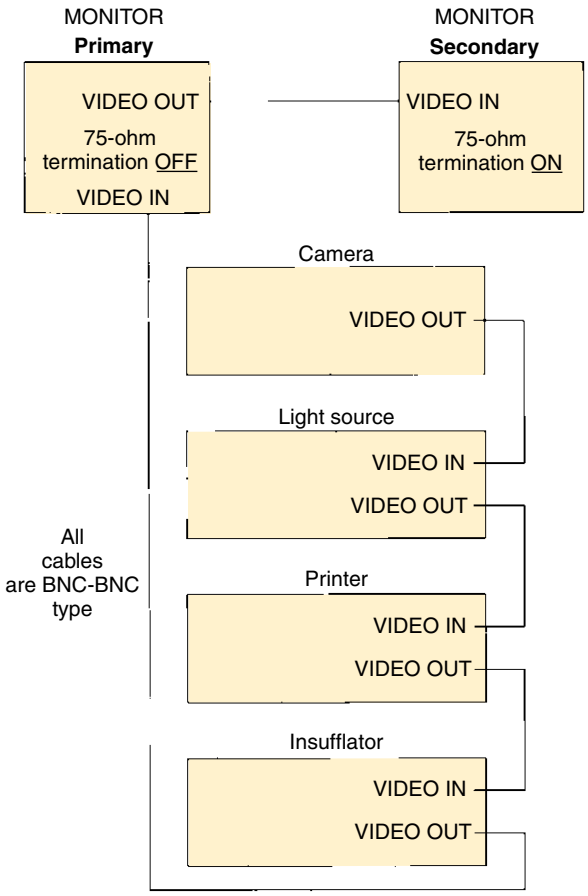

FIGURE 7-40 Basic wiring configuration.

FIGURE 7-41 Video printer producing a picture of the endoscopic image.

to a Polaroid camera in that it takes still pictures instantly. The printer stores the selected image and prints it onto special paper. Many units can be programmed to print 1, 4, 9, or 25 pictures on one piece of 5½ × 8 inch paper in split-screen fashion. Comparisons can then be made as the pathologic condition changes. Information such as patient name, date, time, and operating surgeon usually can be superimposed on top of the print. These prints can be used both for teaching purposes and

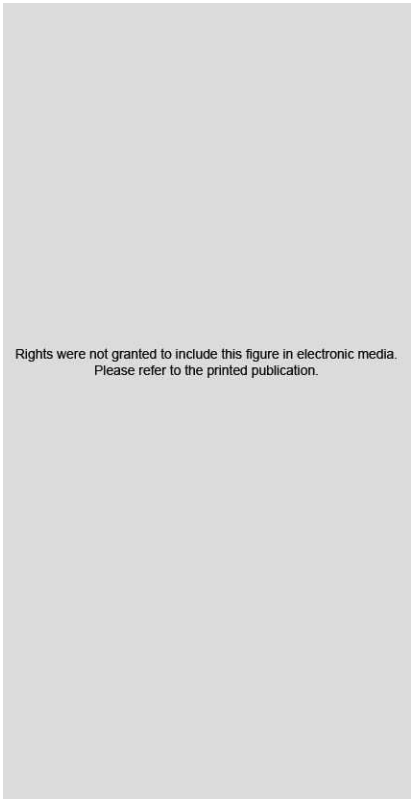

FIGURE 7-42 Video laparoscopy cart.

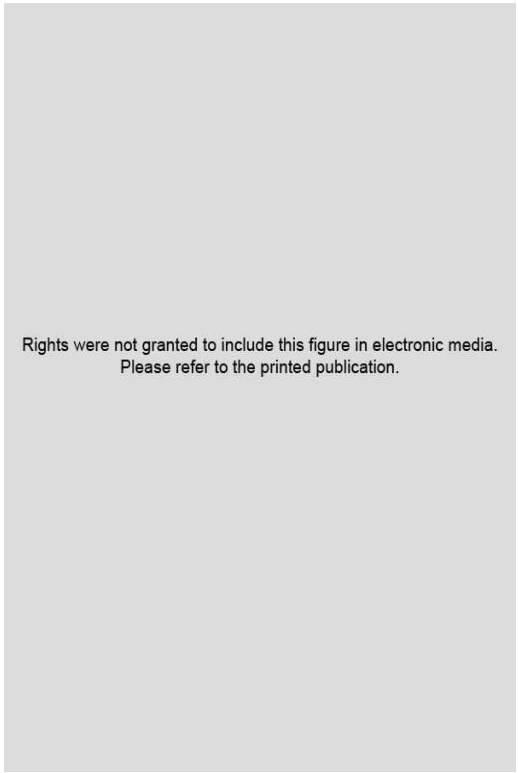

FIGURE 7-43 Video storage cart with swivel monitor arm and lockable door.

as part of the permanent record. Some patients are interested in seeing prints of "before and after" images of their condition.

Video disc recorders store and permit easy access to video information. Video disc recorders have become the documentation format of the future. To use a video disc recorder, one also must use a video printer because the images stored are limited to video. HD recorders with touchscreen monitors are also available; they record on an internal hard drive (usually 250 gigabytes). The images and videos can then be exported via a USB port, burned on a DVD, or sent to the hospital's server. The optical disc standard, known as Blu-ray, can provide digital storage for up to 10 hours of HD, depending on the encoder settings used.

If a picture or video is sent to the hospital's server, HIPAA (Health Insurance Portability and Accountability Act) regulations must be met. The digital images must be saved in a DICOM (Digital Imaging and Communications in Medicine) format as opposed to JPG or MPG formats used in the consumer market. The digital images are exported from the camera to the hospital's server system, called PACS (Picture Archiving Communication System).

Storage Systems. Space, storage capability, security, and required components determine the type and size of video storage carts needed. Purchasing a cart that can house multiple components of the video system is optimum (Figure 7-42). Such carts eliminate the clutter of multiple smaller carts and tables. They also eliminate the number of cord connections to wall outlets because most carts have power strips incorporated in their electrical setup. If a cart has a power strip, an on-off main switch usually is located near its base. The power switch must be in the *on* position for the equipment that is plugged into the strip to work. Given the location of the switch, it can be turned off easily during transport and cleaning. Time and embarrassment can be avoided if this switch position is routinely checked before each use.

Articulating arms can be used as monitor mounts. Surgeon preference and room space determine if this option is necessary or possible. If a surgical or treatment room has been designated for endoscopy, the monitor can be suspended from the ceiling on a swivel mount. The mount should be placed in a location where the monitor can be easily and comfortably viewed and cleaned. Care must be taken to ensure the swivel mount can support the weight of the monitor and other equipment.

Carts have either a locked (Figure 7-43) or an open (Figure 7-44) shelf design. Institutional security determines this configuration. Storage, tampering, and key availability are important issues. A locked drawer may be ideal to store HD recording devices, printing paper, and other valuable video supplies. Carts also should be selected for ease of movement, component accessibility, and cleaning. Carts may also include an optional storage bracket for E-cylinders when insufflation is required. Secondary (slave) monitor carts usually do not contain multiple shelving and cabinet components.

Robotics

Robotic devices to assist with holding and maneuvering a laparoscope free team members to perform other roles and attend to other duties. The robotic arm minimizes shaky video images and reduces miscommunications between surgeon and assistant. The robot's movement is controlled directly by foot pedals, handheld control panels, and voice activation (Figure 7-45).

FIGURE 7-44 Open shelf design video cart.

Advances in laparoscope stabilization and movement facilitate the procedure, promote safety, and sometimes minimize the time to perform the procedure.

The robotic arm chassis houses the power system and the computerized control unit. An electromechanical positioner bar attaches to the surgical bed and connects to the laparoscope with a magnetic coupling device. A sterile drape covers this arm to maintain a sterile field. The robotic arm maintains the laparoscope in proper orientation—the lack of which was a problem experienced with manual scope maneuvering.

Advantages of a robotic device for laparoscope positioning are as follows (Phillips, 2008):

- Minimizes fatigue associated with holding and moving the scope
- Returns scope control to the physician
- Accommodates quick scope movements through a computerized memory
- Shortens the procedure time by minimizing scope-positioning time
- Provides a steady image that enhances video quality
- Ensures consistent scope positioning and movement, not always possible with human assistants
- Frees the surgeon's hands to perform other tasks

In September 2001, an internet news source reported that surgeons at Mount Sinai Hospital in New York used a remote-controlled robot to operate successfully on a patient in France. The American surgeons removed the gallbladder of a 68-year-old French woman at the European Institute for Tele-Surgery in Strasbourg, France, more than 4000 miles from the surgeons. Physicians viewed this as a defining moment in medical history that advanced remote telepresence surgery to a new level (Scheeres, 2001). Research and experimentation continue to determine if robotics can assist with more delicate and precise procedures, such as during laparoscopic surgeries.

FIGURE 7-45 By being able to command the movement of the robotic arm, the surgeon has complete control over laparoscopic positioning.

Computer-assisted surgery (CAS) (also called image-guided surgery, surgical navigation, and three-dimensional [3-D] computer surgery) has also grown rapidly. This surgery is any computer-based surgery that uses high technology, such as 3-D computer imaging and real-time sensing, in planning, implementing, and following up on surgical procedures. CAS provides enhanced visualization and site targeting along with improved diagnostic capabilities.

Videoconferencing

Videoconferencing is a method to reach distant sites through two-way interactive communications using live audio and video signals. Communications between two or more sites may be live, or one site may play a videotape for the other sites connecting to the videoconference. This technology requires basic videoconferencing equipment and a network mode to transmit the communication signal to multiple sites. The higher the network bandwidth used by the participating sites, the better are audio and video motion-handling capabilities, and the resolution of the video signal that can be transmitted to each. A videoconference can be held between two sites or dozens of sites simultaneously. Videoconferencing applications in healthcare include education, remote assessments and consultation, administrative meetings, and product development.

Formal education and continuing education are the foundations of quality healthcare, and providing education to and from distant sites has gained tremendous popularity. Healthcare workers practicing in remote areas do not feel as isolated because educational videoconferencing is now widely available. Distant preceptorships also have been offered as one physician monitors and oversees another physician learning a new surgical technique or using advanced surgical instruments.

Remote consultation to evaluate patients at remote sites has been used as assessment technology has been introduced and accepted. A physician or nurse practitioner (depending on state regulations) can assess heart sounds of a patient located at a distant location through the use of a telemedicine stethoscope. The retina of a diabetic patient can be viewed from afar by use of a special remote-assessment ophthalmoscope. A perioperative nurse practitioner located in a rural area can consult with a specialty physician located in a large urban teaching institution regarding treatment of a patient (Figure 7-46).

FIGURE 7-46 A nurse practitioner can consult with a physician at a remote location about a patient's treatment.

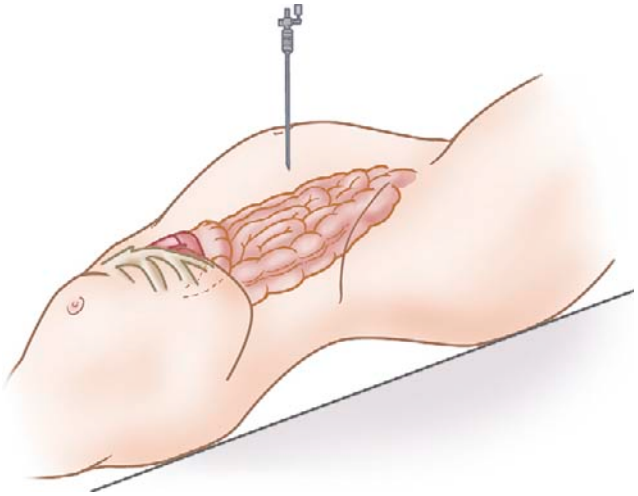

FIGURE 7-47 Verres needle insertion into abdomen.

Videoconferencing can also be conducted for administrative and other meetings to minimize travel expenses and time away from work. Product development also can be enhanced using videoconferencing. A company that manufactures surgical devices can communicate on a regular basis with key customers who are conducting trials of its devices. Device malfunctions and limitations can be assessed easily through real-time audio and video communication.

Some issues remain as videoconferencing becomes accepted. Standardization must be followed so that videoconferencing equipment can communicate and be compatible with each other. Some governmental and professional organization recommendations and mandates have guided manufacturers to meet approved criteria so that global interconnectivity can occur more easily. Confidentiality is another concern as the popularity of this technology increases. Patient information, assessment data, and treatment results are being shared among providers by means of videoconferencing today. Patient confidentiality and privacy must be maintained. HIPAA compliance is vital when transmitting patient records. Private networks, advanced coding systems, and other technology can help address this issue. Practicing across state lines also has become a concern as videoconferencing in healthcare evolves (Cohen, 2009). State boards of nursing, medicine, pharmacy, and other professions are addressing this situation and proposing methods to facilitate licensing so that providers can practice across state boundaries. Finally, reimbursement for remote consultation and assessment is being analyzed by many insurance carriers. Pilot project sites have been established by the Centers for Medicare & Medicaid Services (CMS, formerly the Health Care Financing Administration) to study this question. When reimbursement can be consistently provided, more healthcare providers and facilities will embrace videoconferencing.

PRACTICES AND POTENTIAL RISKS DURING MIS

Insufflation

To help visualize abdominal structures and to enhance safety during laparoscopic procedures, a pneumoperitoneum is created. The surgeon makes a paraumbilical incision and inserts an insufflation (Verres) needle into the abdomen (Figure 7-47). Trendelenburg's position is used to reduce the risk of visceral perforation. Appropriate positioning devices should be used (see Chapter 5). As the surgeon inserts the needle, he or she lifts up the patient's abdomen by grasping and lifting a fold of tissue on either side of the umbilicus. Preoperative patient education should include the possibility of finger-pinched bruising at the site where the abdominal tissue is grasped.

The needle safely enters the peritoneum positioned at a 45-degree angle. Placement is confirmed by negative bowel and blood return on aspiration and by saline instillation that meets no resistance. This is a relatively blind procedure because no scope can be introduced until pneumoperitoneum is established. A new laparoscopic trocar system has been introduced in which the obturator tip, instead of a needle, is inserted with minimal penetration into the peritoneum, then rapid insufflation is provided.

After needle confirmation, insufflation tubing is connected and the process begun. CO_2 gas is used to insufflate because it does not support combustion, can be absorbed at large volumes per minute without serious side effects, and is fairly inexpensive. The peritoneal cavity is filled, first at a low flow rate that is increased to a high flow rate of at least 9 L/min ideally. Flow rate refers only to how quickly a predetermined intraabdominal pressure can be reached. Intraabdominal pressure is the actual measure that must be closely monitored and should be maintained between 14 and 16 mm Hg. High flow rates are important because during the procedure, the insufflation CO_2 gas can escape through smoke evacuation, instrument changes, and other practices. The more quickly the gas can be replaced, the less time is spent waiting for the abdomen to be redistended. Perioperative nurses must demonstrate competence in insufflation, and understand and manage its potential risks.

Insufflator control panels should monitor and display the following variables:

- Rate of flow
- Volume delivered
- Intraabdominal pressure

Selection of an insufflator that accommodates a high flow rate is important. Insufflators delivering 15 to 20 L/min are much more effective than those delivering gas at slower

FIGURE 7-48 A smoke evacuator that can manually remove the insufflation gas using a closed system.

FIGURE 7-50 Computerized high-flow insufflator with CO_2 warmer.

rates. The insufflator must monitor insufflation pressure continuously, stop the insufflation process when the predetermined set pressure has been reached, and release pressure if there is an inadvertent pressure increase (called "taking a breath"). Intraabdominal pressure can be increased for reasons other than CO_2 insufflation; leaning on the abdomen and additional gas introduction from other sources, such as an argon-beam coagulator or a CO_2 laser with a purge gas system, can inadvertently increase intraabdominal pressure.

Overpressurization can be extremely hazardous to the patient. Excess pressure can force CO_2 to diffuse into the blood, resulting in hypercarbia. End-tidal CO_2 monitoring becomes a crucial assessment parameter to detect increased CO_2 absorption. Excess pressure also increases diaphragmatic pressure, which can cause gastric regurgitation and aspiration of stomach contents. It also can reduce intrathoracic space, resulting in decreased respiratory effort and cardiac output. The phrenic nerve innervates the diaphragm and is responsible for some motor activity associated with respiration. CO_2 gas can irritate this nerve, causing postoperative pain in the shoulder and neck. Excessive pressure could cause tremendous postoperative discomfort and severe nerve damage. The surgeon or assistant should press on the patient's abdomen to release as much residual CO_2 gas as possible before removal of the last trocar sheath when the procedure is completed. Insufflators that automatically vent excess CO_2 gas into the air ensure that many potential complications can be avoided. A special smoke evacuator provides a safe and quick method to manually remove the insufflated gas using a closed system so that no gas escapes into the environment when the surgeon is releasing the insufflated gas (Figure 7-48). This minimizes contaminated air that could possibly be inhaled by the surgical team.

A two-way, single-use disposable filter should be incorporated into the insufflation tubing (Figure 7-49). This hydrophobic filter provides patient protection from harmful gas-tank contamination, such as chromium particles. It also provides protection from the colonization of organisms in the insufflator itself. Without a filter, when the insufflator is turned on, organisms such as *Klebsiella, Pseudomonas,* and *Staphylococcus aureus* can be blown into the patient. This contamination could be deadly for a very ill, elderly, or immunocompromised patient. The manufacturer's written instructions must be followed when implementing CO_2 insufflation. Perioperative nurses should consider the following steps to reduce cross-contamination of the patient and insufflator during CO_2 insufflation:

1. *Before* the procedure, verify that the cylinder is medical-grade CO_2; note the level of gas in the cylinder.
2. Flush insufflator and tubing with CO_2 gas before attaching to patient.
3. Use a disposable hydrophobic filter on insufflation tubing. Discard after procedure.
4. *During* the procedure, monitor level of CO_2 remaining in cylinder; have second cylinder readily available.
5. Keep insufflator elevated above the patient to prevent fluid backflow.
6. At end of procedure, disconnect tubing from insufflator before turning off.

An insufflator capable of warning the team of insufflation problems throughout the procedure is vital. Alarms that sound when there is a deviation from predetermined parameters call attention to the need for immediate intervention, such as an alarm ringing and a monitor blinking "Gas supply low." An alarm sounding when overpressurization occurs from a secondary source (e.g., by leaning on the abdomen) also alerts the team to take corrective action.

Insufflators are also available with CO_2 warming devices (Figure 7-50). Cylinder CO_2 is a liquid, and as it is released, it expands into a gas. During conversion from liquid to gas, energy is lost, and the gas becomes colder. The higher the flow, the colder the gas. Some warming occurs as the gas travels through insufflation tubing. Use of cold CO_2 can cause a decrease in patient temperature, especially with prolonged laparoscopy. Many factors contribute to reduced body temperature during laparoscopic procedures (e.g., cold irrigation,

room temperature, surface exposure, length of the procedure, patient's age and medical history, anesthetic choice); cold CO_2 represents an additional one. The best way to reduce patient heat loss and the risk for hypothermia is to address all variables and intervene wherever possible.

Complications and Anesthetic Considerations During MIS

Although anesthetic technique and delivery are the responsibility of the anesthesia provider, perioperative nurses must anticipate and respond appropriately to associated risks during MIS procedures. Many formerly performed open surgical procedures are now performed as MIS procedures in ambulatory surgery. With this change, anesthetic technique also has changed. Today there is an emphasis on minimal anesthesia during surgery. Short-acting drugs are used so that the patient awakens quickly and experiences far fewer side effects (see Chapter 4).

The three major goals of the anesthesia provider during MIS procedures remain the same: *respiratory stability, appropriate muscle relaxation,* and *hemodynamic stability.* In addition, during many laparoscopic and pelviscopic procedures, it is necessary to control diaphragmatic excursion. Patient monitoring includes an electrocardiogram (ECG) and assessment of end-tidal CO_2, blood pressure, oxygen saturation, and temperature.

When Trendelenburg's position is used, intraabdominal pressure increases, and this can cause respiratory complications, including hypoxia. CO_2 absorption from the peritoneal cavity can aggravate this situation. Reverse Trendelenburg's position, on the other hand, can cause decreased venous return, reduced cardiac output, and hypotension. CO_2 insufflation in this position can also cause an increase in total peripheral resistance, especially if intraabdominal pressure is high and the aorta compressed. The perioperative nurse must be prepared to quickly change the position of the OR bed, decrease the CO_2 flow rate of the insufflator, and assist the anesthesia provider with medications and extra supplies.

CO_2, highly soluble in blood, generally is not hazardous when used during laparoscopic insufflation as it is rapidly absorbed in the splanchnic vascular region. Excessive intraabdominal pressure or any anesthetic technique that reduces splanchnic blood flow, however, could increase the potential for CO_2 gas emboli. That in turn could lead to circulatory collapse. CO_2 also could advance from the heart to pulmonary circulation, causing acute pulmonary hypertension with right-sided heart failure. If these effects are undetected and CO_2 insufflation continues, cardiac arrest and death may occur. If there are signs of CO_2 embolus, and there is not sufficient assistance, it may be necessary to call a rapid response team (Rapid Response Team box).

Intraoperative hypotension can result from excessive bleeding, excessive intraabdominal pressure, and hypoxia. CO_2 insufflation rates may need to be reduced. Extra intravenous fluids may be needed. Likewise, intraoperative hypertension can result from increased intraabdominal pressure, and increased CO_2 gas absorption also may be evident. Increased bleeding may result. The perioperative nurse may need to decrease CO_2 insufflation flow rates. Additional hemostatic agents and endoscopic clips may be required.

Gastric reflux may occur if the patient is obese, a hiatal hernia is present, or excessive pneumoperitoneum occurs. A nasogastric or orogastric tube may be inserted after general anesthesia is induced. Postoperative discomfort is less if an orogastric tube is used. During epidural and regional anesthesia, patients are usually awake, and insertion of a gastric tube may be poorly tolerated. For this reason, the tube is not inserted unless gastric distention occurs. The perioperative nurse must be quick to respond if assistance is required during gastric tube insertion. Intercostal nerve blocks offer surgical pain relief and abdominal muscle relaxation when the patient is awake during surgery. The perioperative nurse's role during intercostal nerve block induction is to remain at the patient's side and help reduce anxiety. Other risks during MIS procedures include hypercarbia, subcutaneous emphysema, and pneumoscrotum.

ENERGIES USED DURING SURGERY

Laser

A healthcare revolution occurred with the birth and evolution of the laser (Box 7-2). Perioperative nurses must be accordingly aware of expanded responsibilities associated with laser applications. The laser has significantly impacted surgery by making possible less invasive procedures, decreasing inpatient hospitalization, diminishing postoperative complications, and saving healthcare dollars.

Laser Biophysics

PRINCIPLES OF LIGHT. *LASER* is an acronym that describes a process in which light energy is produced—*l*ight *a*mplification by stimulated *e*mission of *r*adiation. The term also refers to the device that generates laser energy.

Light is a form of electromagnetic energy that can be graphically illustrated on a continuum known as the electromagnetic spectrum (Figure 7-51). The unit of measurement for this

RAPID RESPONSE TEAM

Most often, the OR has sufficient personnel available to respond to critical situations with patients, such as CO_2 embolus and the risk of cardiac arrest. However, on occasions when there is no additional staff to assist with a suspicion of CO_2 embolus, a Rapid Response Team (RRT) should be called. Signs of CO_2 embolus (pulmonary embolism) include sudden decrease in blood pressure, dysrhythmia, heart murmur, cyanosis, pulmonary edema, and an abrupt increase in end-tidal CO_2 level. If an embolus is suspected, continuous monitoring of heart sounds, blood pressure, and end-tidal CO_2 level assists the anesthesia provider in making a rapid diagnosis. Immediate deflation of pneumoperitoneum is necessary. Treatment may include immediate placement of the patient in a left lateral position and aspiration of the CO_2 gas through a central venous catheter. The perioperative nurse should assist in patient repositioning while maintaining the sterility of the equipment and the surgical field wherever possible. Assistance may be required during central venous catheter placement. Debilitated patients may require preoperative invasive monitoring.

BOX 7-2

History of Laser Technology

During the early 1900s Einstein first described a theory that involved the stimulation of matter to cause the release of energy. In 1957 Gould developed the principle of LASER, derived from the acronym, light amplification by stimulated emission of radiation. In 1958 Schawlow and Townes investigated this concept of stimulated atoms and the creation of photons. They suggested that mirrors be used to amplify the stimulated emission of radiation to multiply photons at an accelerated rate.

In 1960 Maiman developed the first laser for medicine and surgery using a ruby crystal. The ruby laser was used for dermatologic applications and for retinal photocoagulation in patients with diabetic retinopathy, but it was not very efficient. Many other lasers—such as the argon, CO_2, Nd:YAG, KTP, holmium, erbium, excimer, and diode lasers—have been developed and are now used in multiple surgical disciplines. Advancements in laser technology provide surgeons with a precision tool for cutting, coagulating, vaporizing, and welding tissue during surgery.

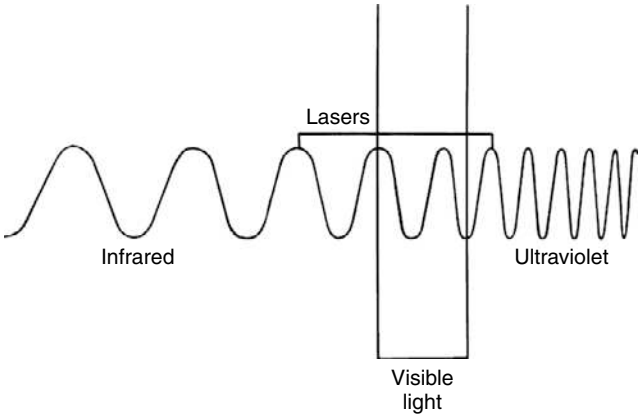

FIGURE 7-51 Electromagnetic spectrum.

continuum is called a wavelength, the distance between two successive peaks of a wave. Wavelength determines color and usually is measured in nanometers (10^{-9} m) or micrometers (1000 nm). Various wavelengths of light extend from the shorter waves in the ultraviolet area to the longer waves in the infrared region (Table 7-2). Visible laser wavelengths occupy only a small portion of this continuum. Radiation used in laser technology in healthcare is nonionizing in that it does not present the hazard of cellular DNA disruption with continual tissue exposure. Pregnant women, for example, can work with lasers because laser energy produces no harmful ionizing radiation.

Briefly, the laser functions in the following way. A negatively charged electron orbits a positively charged nucleus while the atom is in its ground or resting state, its lowest energy level. An outside source of energy (e.g., electricity, flash lamps, other lasers) can excite the atom and cause an electron to jump to a higher, less stable orbit. The electron almost immediately returns to its stable orbit, and the atom resumes its normal resting state. As the unstable electron returns to its ground state, it spontaneously releases a tiny packet of light energy known

TABLE 7-2

Electromagnetic Spectrum Wavelengths

Type of Light	Wavelength (nm)
Ultraviolet (UV)	100-400
Visible	400-750
Near-infrared (NIR)	750-3000
Mid-infrared (MIR)	3000-30,000
Far-infrared (FIR)	30,000 nm-1 mm

as a photon, which travels away from the source in the form of waves. If the photon is close to another similar atom while it is still in the excited state, it interacts with this atom. The photon triggers the excited second atom to return to its resting state, and in this process another photon of laser light is emitted. These two photons of identical energy travel together. The process of stimulated emission has occurred, and laser energy initiated (Figure 7-52). This process repeats itself over and over again, creating more photons of laser energy.

This activity occurs in the resonating chamber of the laser, where the lasing medium is contained. The name of the laser usually is derived from the actual medium that causes the lasing action. The photons generated during the stimulated emission process are reflected back and forth between mirrors at each end of the resonating chamber as the process is amplified, until the number of excited atoms surpasses the number of resting atoms. This is known as population inversion. One of the mirrors in the chamber is partially reflective and, when activated, allows a stream of laser photons to escape the unit. These photons are introduced to the target area by means of a specific delivery system.

CHARACTERISTICS OF LASER LIGHT. Three distinct characteristics distinguish laser light from ordinary light. Laser light is monochromatic, collimated, and coherent.

1. *Monochromatic light* is composed of photons of the same wavelength or color. In contrast, ordinary light consists of many different colors or wavelengths. When white light is passed through a prism, an array of different colors is displayed. White light is the presence of all colors, whereas laser light consists of one color or wavelength.
2. A *collimated* laser beam consists of waves parallel to each other that do not diverge significantly, minimizing any loss of power. When a collimated beam is passed through a lens, the light pattern is changed, allowing the light to be focused into a tiny spot that highly concentrates the energy. In comparison, the light waves from a flashlight are not parallel and lose intensity as they travel away from the source. A lens cannot easily focus these noncollimated waves to concentrate the light into a small area.
3. Laser light is *coherent*—all the waves are orderly and in phase with each other as they travel in the same direction. All peaks and troughs of the waves are opposite each other in time and space. This property provides an additive effect that gives the laser beam power. Ordinary light is incoherent because the waves radiate away from the source without being in phase or in an orderly pattern.

LASER POWER. The power, or energy, of a laser beam is measured in watts. An important factor in laser applications is the concept of power density, or irradiance of the beam. *Power*

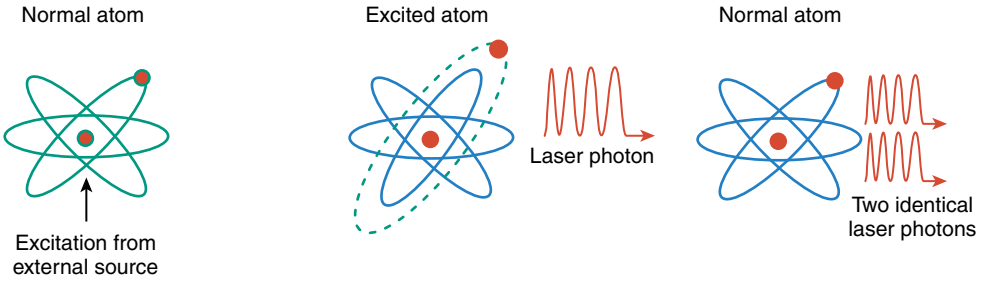

FIGURE 7-52 Laser energy is produced when an external source excites the atom to emit a photon spontaneously. This photon can "stimulate" the emission of two identical photons.

density is the amount of power that is concentrated within an area and is described by the following formula:

$$\text{Power density} = \text{watts/spot size (cm}^2\text{)}$$

The spot size of the laser beam can be controlled when the beam is passed through a special lens that causes the beam to converge. The focal configuration of the lens determines at what distance from the lens the beam would be most intense; this is called the *focal point*. If the beam is defocused into a larger spot size, the laser energy is spread over a greater area, decreasing the intensity or power density of the beam. In contrast, a small spot size of the beam concentrates the laser energy into a smaller area, increasing the intensity or power density of the beam. When power density is increased, the beam has a greater depth of penetration into the tissue.

A *joule* is the unit of measure used to describe total energy used. A joule is expressed by the power multiplied by the time duration of the beam exposure (expressed in the equation joule = watts × time). Often the laser energy used during ophthalmic procedures is expressed in millijoules.

Fluence is a term that expresses the power and duration of exposure of the beam and measures the specific amount of energy delivered to tissue. Fluence is also known as energy density or radiant exposure. The following equation calculates fluence:

$$\text{Fluence} = \text{watts} \times \text{duration time/spot size (cm}^2\text{)}$$

TISSUE INTERACTION. When laser energy is delivered to a target site, four different interactions can occur: reflection, scattering, transmission, or absorption (Figure 7-53). The extent of reaction of the beam on the target depends on laser wavelength, power settings, spot size, length of contact time with target tissue, and tissue characteristics.

Reflection of the laser beam occurs when the direction of the beam is changed after it contacts an area. Specular reflection occurs when the angle of the incoming light is equal to the angle of the reflected light. Laser light can be intentionally reflected in this manner off a reflective mirror to contact hard-to-reach areas. Such reflection also can pose safety problems by inadvertently striking untargeted areas if it is not controlled at all times. The CO_2 laser beam can be reflected off of the surface of a shiny instrument and impact a surgery team member's mask, causing it to ignite. Accordingly, eye and fire safety measures are mandatory when the potential for laser beam reflection is high.

Scattering of laser light occurs when the beam spreads over a large area as tissue causes the beam to disperse. The intensity of the beam decreases as the waves travel in different directions. The Nd:YAG laser beam can backscatter up an endoscope and possibly cause damage to the end of the scope, the optics, or the operator's eye. The noncontact Nd:YAG beam also can scatter through tissue, causing penetration of 3 to 5 mm.

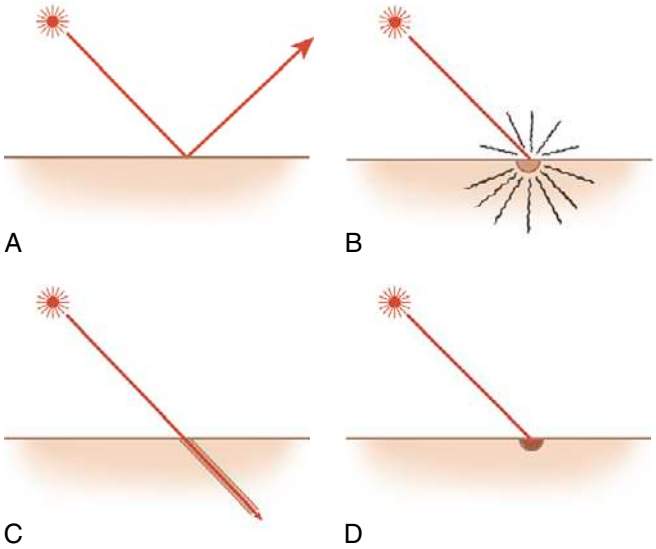

FIGURE 7-53 Laser-tissue interaction. **A**, Reflection. **B**, Scattering. **C**, Transmission. **D**, Absorption.

Transmission of the laser beam occurs when the beam passes through fluids or tissue without thermally affecting the area. The argon beam can be transmitted through clear fluids and structures of the front part of the eye and the vitreous to cause thermal photocoagulation on the retina, while the cornea, lens, and vitreous are unaffected by transmission of this beam.

Absorption of laser light results when tissue is altered from the absorption of the beam. As the amount of energy delivered to tissue (fluence) increases, different tissue effects can be produced. The lowest level of energy produces a photochemical reaction. Then as fluence increases, a photothermal reaction occurs. With the highest level of fluence, a photoacoustic effect occurs. Reactions from the lowest to highest level of energy occur as follows:

- *Photochemical effect*— laser energy is selectively absorbed by tissue containing a light-sensitive dye, leading to a chemical change that produces singlet oxygen, which ultimately causes tissue destruction.
- *Photothermal effect*—laser energy is absorbed by tissue, heating it.
- *Photoacoustic effect*—laser energy is absorbed, creating kinetic energy that produces a snapping sound, disrupting the tissue without significant thermal effect.

TABLE 7-3

Tissue Changes with Temperature Increases

Temperature (°C)	Visual Change	Biologic Change
37-60	No visual change	Warming, welding
60-65	Blanching	Coagulation
65-90	White/gray	Protein denaturization
90-100	Puckering	Drying
>100	Smoke plume	Vaporization, carbonization

Consistency, color, and water content of the target tissue often determine the rate of absorption of laser energy. Laser wavelength also affects absorption of the beam. Certain laser light, such as that from the argon laser, is highly absorbed by pigmented tissues. The CO_2 laser, however, is independent of color-selective absorption. CO_2 laser light is absorbed superficially by tissue to a shallow depth of approximately 0.1 to 0.2 mm, whereas the holmium laser beam is absorbed to about 0.4 to 0.6 mm. Argon laser light is readily absorbed by pigmented tissue to a depth of approximately 1 to 2 mm, whereas that of the noncontact Nd:YAG laser beam is more readily absorbed by darkened tissue to a depth of 3 to 5 mm.

Photothermal tissue reaction becomes more pronounced as the temperature of the target area increases during absorption of the laser beam (Table 7-3). As laser energy is absorbed, the water within each cell is heated. As temperature increases, intracellular protein is destroyed and water inside the cell turns to steam. Eventually, the cellular membrane ruptures from increased pressure, spewing cellular debris and plume (smoke) from the tissue. The surrounding tissue also is heated through conduction because it borders the impingement site. The degree of adjacent tissue damage depends on the duration of laser-beam exposure that causes the intended thermal destruction of target tissue.

Laser Systems. New laser systems are being introduced into healthcare regularly. Constant efforts by researchers and physicians to explore the use of different wavelengths frequently change surgical approaches in a variety of specialties. Table 7-4 describes popular lasers used in medicine and surgery today.

LASER SYSTEM COMPONENTS. Five major components of a laser system are the laser head, excitation source, ancillary components, control panel, and delivery system (Ball, 2004). When a laser malfunctions, an organized investigation of each of these parts (Figure 7-54) usually can determine the source of the problem.

The *laser head,* or resonating chamber, is the component in which laser energy is generated and amplified. The laser head contains the active medium or substance that actually produces the photons that generate laser light. The active medium can be a gas (CO_2 or argon), a solid crystal (Nd:YAG), a liquid (tunable dye), or a semiconductor crystal (diode).

The *excitation source* supplies the energy to excite the active medium in the laser head. Different sources include flash lamps, electricity, radio waves, batteries, chemicals, and other laser systems. The CO_2 laser gas mixture is excited by electrical current or radio waves, and the Nd:YAG laser crystal is excited by flash lamps. Diode lasers, such as the gallium arsenide laser, are solid-state lasers that are excited by electrical energy.

Ancillary components are other laser parts needed to help produce laser energy. A cooling system maintains the appropriate temperature of the laser head and keeps the unit from overheating. Usually lasers are air cooled or water cooled. A vacuum pump may be required in a CO_2 free-flowing laser to pull the gas mixture from an external cylinder into the laser head for laser light production. Current sealed-tube CO_2 lasers do not require a vacuum pump because the laser gas mixture is catalyzed to regenerate itself for the lasing action to continue, using the same gas mixture over and over again.

The *control panel* consists of a board that regulates delivery of laser energy. Various power settings, modes, durations, and other parameters can be selected. Most laser panels are computerized, allowing the laser to be controlled quickly and accurately. Wireless control modules can be placed into a sterile plastic bag so that the surgical team can control the laser from the sterile operating field.

The *delivery system* is the device or accessory that conducts laser energy from the laser head to the target area. CO_2 laser energy usually is delivered to tissue through an articulated arm with a series of special mirrors at each joint. The commonly used argon, KTP, Nd:YAG, and holmium lasers deliver energy through a fiber system. Advancements in laser technology are refining delivery systems to make them more adaptable, convenient, and user-friendly. Various lasers are described in the next

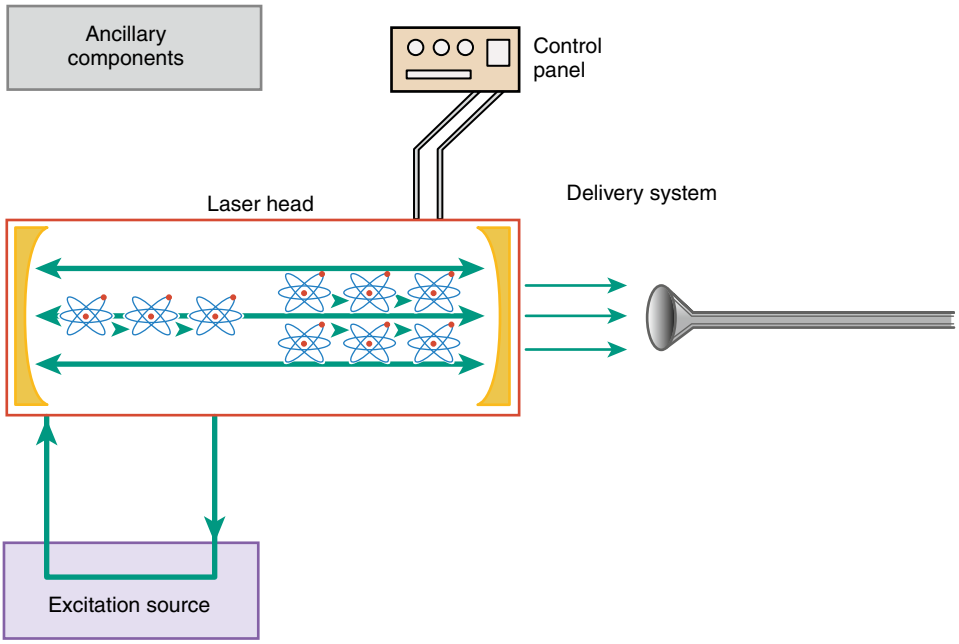

FIGURE 7-54 Parts of a laser system.

section, beginning with lasers in the infrared region with long wavelengths, through visible wavelengths, and finally to short ultraviolet wavelengths.

CO_2 LASER. The CO_2 laser is versatile and widely used. Its wavelength of 10,600 nm is located in the infrared electromagnetic spectrum. As this light is invisible, a visible helium-neon laser beam is transmitted co-axially with the CO_2 laser energy to serve as an aiming beam.

The CO_2 laser is characterized by its superficial tissue interaction (0.1 to 0.2 mm) because the beam is highly absorbed by water. The degree of tissue response is related to the photothermal effect (the amount of heat buildup) from absorption of the CO_2 laser beam. The longer the CO_2 beam is in contact with tissue, as with other laser wavelengths, the more destruction occurs. With the CO_2 beam a greater depth of penetration can be achieved. Tissue reaction is visible and has been described as "what you see is what you get." The CO_2 beam is independent of color selectivity, meaning that lighter tissue absorbs the beam as readily as darker tissue.

There are two types of CO_2 lasers that use electricity or radio waves as the excitation source:

1. *Free-flowing CO_2 laser system*—This is an older system that requires an external cylinder of a special laser gas mixture of CO_2, helium, and nitrogen. The concentrations of these gases must be specific to the particular laser unit so that the laser operates properly. The gas is pulled into the laser head by a vacuum pump, laser energy is generated, and harmless disassociated by-products are discharged from the unit. The laser gas cylinder is replaced when empty.
2. *Sealed-tube CO_2 system*—This system contains a special mixture of CO_2, helium, and nitrogen within a sealed tube. A catalyst is added to the tube to cause regeneration of the mixture so that lasing action can be produced again. The shelf life (functional period) of this tube is usually 1 to 5 years or more. The tube can then be serviced by the manufacturer to replace the special gas and catalyst mixture.

The CO_2 laser beam is delivered to the target site through a hollow tube called an articulated arm. Mirrors are positioned within the arm to reflect the laser energy forward. Care must be taken when moving the laser so that mirrors are not jarred out of alignment.

The articulated arm can be attached to a microscope, a special handpiece, or a scanner for the most precise energy delivery. A lens system within these attachments causes the beam to converge at the focal point. A special coating on the lens maintains the beam's integrity and intensity, and must be carefully maintained, following manufacturer's instructions, so that the coating is not disrupted. The articulated arm is connected to a microscope through the use of a microslad (or micromanipulator). Laser energy is conducted through the articulated arm to a mirror within the microslad that directly reflects the beam to tissue. The position of the beam is controlled by moving a joystick.

As noted previously, the focal length of the lens is the distance from the lens to the focal point where the beam converges and is most concentrated and intense within a small spot. The size of the spot can be changed by focusing or defocusing the lens to allow the spot to become larger or smaller. When the CO_2 handpiece is moved toward and then away from the tissue, the spot size changes.

Sometimes tubing is connected to the handpiece or microscope adapter to conduct a gas purge using compressed air that blows the laser smoke away, keeping the lens cool and free from debris. If this tubing is unavailable, a smoke evacuator can be used to prevent plume from flowing back into the handpiece and coating the focusing lens.

The CO_2 laser beam also can be conducted through a narrow wave guide, which consists of a hollow, semiflexible tube that allows energy to "wiggle" down its path by being reflected off the surface of the inner lumen. With this reflection, some beam power is lost as it exits the delivery device. Solid fibers that will conduct the CO_2 wavelength to target sites are being developed.

The CO_2 laser energy can be delivered to tissue in several modes. *Continuous mode* allows laser energy to be delivered continuously as long as a foot pedal is depressed. *Timed pulsed mode* delivers energy one pulse at a time or in a repetitive manner that specifically controls the duration of exposure. *Superpulse* or *ultrapulse mode* delivers energy in an extremely quick sequence of interrupted pulses that may appear to be continuous. Energy may peak 5 to 10 times higher than the desired wattage, but the duration of exposure is extremely limited, providing greater precision. This type of interaction allows adjacent tissue to cool, minimizing tissue destruction from thermal buildup.

ERBIUM:YAG LASER. One of the newer YAG lasers in healthcare is the erbium:YAG solid crystal laser, generating a wavelength of approximately 2940 nm. Laser energy is usually delivered in a pulsed mode. The erbium laser beam is highly absorbed by water, allowing a shallow penetration of energy into tissue. The erbium is frequently used in dermatology for skin resurfacing and ablation.

HOLMIUM:YAG LASER. The holmium:YAG laser crystal is doped with holmium, a rare earth element. This laser produces a wavelength of 2140 nm and is delivered to tissue in a quick, pulsed mode. The holmium wavelength is absorbed intensely by water, so depth of penetration is limited to approximately 0.4 to 0.6 mm. Like the CO_2 laser, it can ablate tissue precisely. The difference is that it can be conducted to the target through a flexible fiber. This wavelength can be delivered to tissues in a fluid environment because it produces a vapor bubble that transmits laser energy within a short distance. If the fiber is held almost in contact or directly in contact with the tissue, cutting occurs. If sculpting or ablating is needed, the fiber is held at a distance of approximately 2 mm from the target. Adjacent tissue is left significantly unharmed, enhancing precision. If the fiber is held 5 mm from the target, no tissue response is noted. The holmium:YAG laser also is used to produce a photoacoustical effect to fragment urinary stones and gallstones.

ND:YAG LASER. The Nd:YAG laser wavelength is in the near-infrared region of the electromagnetic spectrum at approximately 1064 nm. This invisible wavelength usually is accompanied by a visible helium-neon beam or other colored light, such as white light, to provide an aiming source. The Nd:YAG laser consists of a solid crystal of YAG that is doped with neodymium, which then produces lasing energy when exposed to bright flash lamps.

The Nd:YAG energy is delivered to tissue through a fiber system. The core fiber, usually made of quartz, is surrounded by a polytetrafluoroethylene (Teflon) silicone coating or cladding that retains the light. This is known as a bare fiber. If the bare fiber is encased by a catheter sheath, a purge gas, air, or fluid can be conducted down the length of the fiber. This purge is used to cool the fiber tip and keep debris from accumulating.

The Nd:YAG laser wavelength can be delivered to the tissue in a *noncontact mode,* meaning that the fiber does not touch the tissue. If the noncontact fiber contacts the tissue, any debris on the end of the fiber can cause the fiber to heat to the point of destroying the tip. Noncontact Nd:YAG wavelength is transmitted through clear fluids and structures and is more highly absorbed by darker tissue. This laser light tends to scatter within the tissue and cause thermal damage from a range of 3 to 5 mm. Tissue absorption produces a homogeneous coagulative effect as tissue is heated to the point of coagulation without vaporization occurring. A noncontact Nd:YAG beam can backscatter, posing an eye safety risk when used through an endoscope.

Nd:YAG laser energy also can be delivered to the tissue using the *contact method*. A synthetic sapphire contact probe or scalpel is attached to the end of a fiber with a special connector to deliver the Nd:YAG laser energy directly to the tissue in a more concentrated manner. The depth of penetration from the laser energy is limited to less than 1 mm. These contact tips are available in a variety of configurations. Depending on the desired tissue effects, the appropriate contact tip is chosen. A scalpel is used to cut while a rounded probe is used to vaporize. A flat probe may be used to coagulate tissue.

The end of the quartz fiber also may be sculpted into a configuration that can be used in direct contact with the tissue. Contact technology provides precision because the power output of the beam is confined to a small area and less wattage is needed. It causes less thermal buildup, so adjacent tissue is relatively unaffected. The beam does not scatter as readily as the noncontact Nd:YAG laser fiber energy, and less plume is generated.

Besides the continuous-mode Nd:YAG laser, a special *pulsed-mode Nd:YAG laser* for ophthalmic applications (Class 3B laser) delivers energy to tissue in extremely short pulsations of nanoseconds. This laser works with an acoustic effect instead of a thermal effect. A clouded membrane behind an artificial lens implant can be ruptured quickly and painlessly with this ophthalmic Nd:YAG laser beam through production of an acoustic effect at the target site.

KTP LASER. The frequency-doubled YAG (KTP) laser is often utilized for the ablation of hypertrophied prostatic tissue. An Nd:YAG beam of 1064 nm is passed through a potassium titanyl phosphate (KTP) crystal to produce an intense green laser light of 532 nm. Delivering the Nd:YAG incident beam of 1064 nm through the KTP crystal shortens the wavelength by half, to 532 nm, while doubling the beam's frequency. The emergent beam then is visible. If the original Nd:YAG beam is again desired, the crystal is rotated out of the way when a button is pressed on the control panel (if this feature is available). The aiming system of the KTP laser can be a low-power KTP laser beam or a helium-neon beam.

The 532-nm wavelength responds to tissue in the same manner as the argon beam. It is color selective and highly absorbed by hemoglobin, melanin, and other similar pigmentation. The beam is conducted to tissue through a fiber, and this wavelength can be transmitted through clear solutions and structures. The depth of penetration is approximately 1 to 2 mm.

ARGON LASER. The argon laser is a widely accepted visible laser beam system used for ophthalmology, dermatology, and general applications. This laser produces an intense, visible, blue-green light of approximately 488 nm and 514.5 nm (or 457 nm and 528 nm). In clinical applications, this combination of light wavelengths allows for more complete tissue absorption. Depth of penetration is usually 1 to 2 mm. The aiming system can be a low-power argon laser beam or a helium-neon beam.

Argon energy is highly absorbed by hemoglobin, melanin, and other similar pigmentation and is less absorbed by lighter tissue. Absorbed laser energy is converted to heat to cause coagulation or vaporization. As a result of the high color selectivity

of the beam, adjacent tissue injury is reduced significantly when the laser is being used on a localized pigmented area.

The argon wavelength, similar to that of the Nd:YAG laser, is transmitted through clear fluids and structures while being delivered to the target site through a fiber. The fiber can be attached to a slit lamp, microscope, or handpiece, depending on surgical approach. As with other fiber-directed lasers, the argon light diverges 10 to 14 degrees when leaving the fiber. The size of the spot can be altered by changing the distance of the fiber tip from the tissue. Special handpieces that contain an internal lens can be adjusted to change the spot size of the beam for dermatology and other procedures.

TUNABLE DYE LASER. This laser allows the operator to dial in the desired wavelength within a limited range of visible light (i.e., 400 to 1000 nm). By changing dyes or other parameters, the wavelength can be altered. Tunable dye lasers produce a range of colors by exposing a liquid dye to an intense light source, such as an argon laser beam. The dye then absorbs the laser light and fluoresces over a broad spectrum of colors. By using special crystal prisms, diffraction gratings, or birefringent filters within the laser, a specific wavelength can be produced.

Flash lamp pulsed dye lasers are used in treating pigmented dermatologic conditions. A yellow laser beam can be generated at 585 nm, which is readily absorbed by hemoglobin and less absorbed by the epidermal melanin, resulting in less scarring. These tunable dye lasers have been refined to provide quick pulsations in milliseconds that allow increased power. Automatic scanners attached to the delivery system have been perfected for this quick pulsation while moving the beam over the target area. Less adjacent tissue damage occurs with shorter durations of exposure, and there is greater tissue response through the increased wattage used. Advancements to produce an array of different wavelengths with a variety of pulsation modes continue to be developed to treat dermatologic conditions and to fracture urinary stones and gallstones.

DIODE LASER. Extremely compact and reliable, diode lasers are used in many consumer products, such as video disc players and computers. This technology also is being used in surgical lasers with low wattage and an output in the 532- to 908-nm range. Given the efficiency, small size, and reliability of these systems, medical applications have been introduced. With the advent of high-power semiconductor diode lasers in the gallium arsenide family (840 to 910 nm), smaller laser photocoagulators for ophthalmic, urologic, and other applications have been developed. This laser energy can be delivered directly to the tissue through a fiber or can be attached to an existing slit lamp microscope for ophthalmic applications. Other clinical applications that allow this laser to be used in place of other wavelengths, such as the Nd:YAG or argon lasers, are available.

EXCIMER LASER. Invisible excimer laser wavelengths are located in the ultraviolet area (short wavelengths) of the electromagnetic spectrum. The excimer laser derives its name from use of an active medium, an excited dimer. This laser also is known as a rare gas-*n*-halide laser in that it combines a rare gas with a halide, usually a halide-oxide or a halide-halide dimer. The dimeric media are excited to emit laser energy. Depending on the chemical composition of the active medium, various short ultraviolet wavelengths can be produced. Four of the most popular wavelengths are argon fluoride (ArF) at 193 nm, krypton fluoride (KrF) at 248 nm, xenon chloride (XeCl) at 308 nm, and xenon fluoride (XeF) at 351 nm. One hazard of the excimer laser is that its gases are extremely toxic; appropriate protective laser housings have been manufactured to minimize this risk.

Excimer lasers are chosen for their effective ablative capabilities. The beam penetrates less than 1 mm into tissue and disassociates the molecular bonds of cells. Adjacent tissue is not significantly damaged because the beam provides a sharp, clean-cutting action at the target site without significant thermal damage. This laser has been used successfully to sculpt corneas for refractive purposes and to ablate plaque in arteries. Excimer lasers producing wavelengths from 308 to 311 nm are used to treat psoriasis and vitiligo. Other applications continue to be researched for FDA approval.

FUTURE LASERS. As technology continues to advance, laser wavelengths are being combined into a single unit so that a selection of wavelengths, such as the Nd:YAG, erbium:YAG, or holmium:YAG, can be offered easily during a procedure. Delivery systems must be compatible for this setup. A variety of wavelengths are being developed as other active media are also being explored. New delivery systems are being perfected as well that more efficiently conduct the laser energy to the tissue.

Benefits of Laser Technology. Laser technology evolves as more surgical applications are explored and introduced. As physicians become more adept in laser applications, use continues to grow. The laser has fostered the development of new minimally invasive procedures and endoscopic techniques along with ophthalmic and dermatologic applications. The true potential of the laser has yet to be realized as healthcare practitioners explore different procedures that can benefit from its use. Following are some advantages that have been associated with laser technology, depending on the procedure performed:

- Seals small blood vessels (less intraoperative and postoperative blood loss)
- Seals lymphatics (decreases postoperative edema and potential spread of malignant cells in the lymphatic system)
- Seals nerve endings (on selective procedures, decreases postoperative pain)
- Sterilizes tissue (from the heat generated at the laser-tissue impact site)
- Decreases postoperative stenosis (by decreasing the amount of scarring that could lead to stenosis)
- Produces minimal tissue damage (from precision of the laser beam)
- Reduces operative and anesthesia time
- Allows a shift to more ambulatory surgery procedures
- Allows more use of local anesthetics instead of general anesthetics
- Provides quicker recovery and return to daily activities

Laser Safety. As laser systems are capable of concentrating high amounts of energy within very small areas, they present hazards. Safe and appropriate use of lasers is the responsibility of the entire healthcare team. Each member must be acutely aware of the many controls needed to prevent accidental injury. Often the laser team member is given responsibility and authority to shut down the laser system if safety policies are not being followed.

The laser is a class III medical device that is subdivided into four subclasses. Lasers designated as subclasses 3 and 4 have the potential to cause injury. Some ophthalmic Nd:YAG lasers that cause a photoacoustic, instead of a photothermal reaction, are classified in the subclass 3B category and can cause injury with sustained interaction. Most of the lasers used in surgical applications are subclass 4 lasers and can cause photothermal reactions that may lead to fire, skin burns, and optical damage by either direct or scattered radiation. Specific safety precautions must be followed to prevent injury from these lasers.

Many agencies regulate laser safety. Healthcare facilities must develop safety protocols in anticipation of mandates by these regulatory agencies as technology advances and grows.

The American National Standards Institute (ANSI), a nongovernmental organization of experts, first published standards (Z136.1) in 1973 as safety guidelines for laser use in warfare, industry, and healthcare. Standards were expanded to provide specific recommendations for laser use in healthcare environments (ANSI Z136.3) (ANSI, 2005). The appendix of ANSI Z136.3 (revised and published in 2005) discusses a consensus on laser safety in each of the special areas of medicine and surgery. These standards are reviewed periodically and revised as surgical trends change. It is recommended that the most current versions of both ANSI standards be acquired for reference because the Z136.3 document often refers to the Z136.1 publication.

Other guidelines have been suggested by the Center for Devices and Radiological Health (CDRH), Association of periOperative Registered Nurses (AORN), American Society for Laser Medicine and Surgery (ASLMS), Laser Institute of America (LIA), FDA, OSHA, and individual state and local regulatory bodies.

Hospitals and other healthcare delivery facilities need to create laser safety policies and procedures using these expert references as resources. In developing safety guidelines for a facility, protocols should address various situations while being neither too general nor too specific. A policy or procedure must be general enough to address the need, but not so detailed that the surgical team cannot follow it. Staff must realize that they are accountable for following their own safety policies and procedures. Basic education on written laser policies and procedures for all personnel in the surgical environment (including orderlies, aides, and housekeeping personnel) should be mandatory. Topics for policy and procedure development for laser safety should include the following areas, each of which is addressed below:

- Eye protection
- Controlled access
- Fire safety
- Smoke (plume) evacuation
- Documentation
- Laser team responsibilities
- Skin/tissue protection
- Electrical safety
- Education/training
- Credentialing

EYE PROTECTION. The eye is extremely sensitive to laser radiation and great care must be taken to protect eyes during laser intervention. Even low levels of laser radiation can lead to permanent optical damage. Possible ophthalmologic injuries depend on laser wavelength. The CO_2 laser can damage the cornea because this beam is absorbed readily by water within surface cells, causing a burn. Immediate pain is associated with this corneal injury. The argon and Nd:YAG laser beams, in contrast, are transmitted through clear optical structures and fluids and can be refocused by the lens of the eye. The intensity of the beam after refocusing can permanently damage the retina. No pain may be felt during this injury (Figure 7-55).

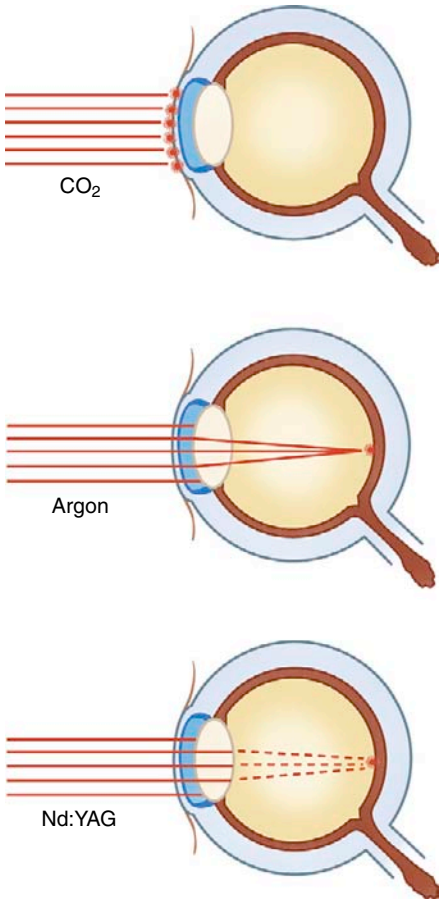

FIGURE 7-55 The CO_2 laser beam can damage the cornea; the argon and Nd:YAG beams can injure the retina.

Adequate eye protection requires understanding the two concepts of maximum permissible exposure (MPE) and nominal hazard zone (NHZ). According to the ANSI Z136.3 standards, the MPE is the level of laser radiation to which a person may be exposed without hazardous effects to the eye or skin. MPE levels are determined through consideration of laser wavelength, power, exposure time, and pulse repetition.

The NHZ is the space where the level of direct, reflected, or scattered radiation during normal laser operation exceeds MPE; eye, skin, and fire safety precautions must be followed while one is working within this hazard zone. The NHZ can be calculated mathematically to determine the distance from the laser beam emission in which the beam can cause skin and eye damage. With power, operating modes, and other parameters changing frequently during a procedure, this calculation also changes. The area inside the surgical room usually is considered to be within the NHZ so that consistency and simplicity can be maintained when lasers are used.

FIGURE 7-56 The frame of the protective eyewear displays wavelength and optical density information.

It is recommended that protective goggles and glasses be inscribed with the appropriate filtering capabilities and adequate optical densities for the specific wavelength being used (Figure 7-56). For example, a pair of Nd:YAG goggles may be inscribed "1064 nm, optical density 5." The optical density of the lens is the capability of the lens material to absorb a specific wavelength. Darker lens shades do not indicate higher optical density, nor do they give more protection than lighter ones. There are lighter lens shades with high optical densities that provide adequate safety. Laser team members must ensure that eyewear is properly labeled, handled, and stored so that hazards are minimized, and scratching and damage of the eyewear avoided.

During surgical procedures using multiple wavelengths, protective eyewear must change as wavelengths change. Some eyewear protects against a limited range of wavelengths. If the range is expanded to block a greater variety of wavelengths, the transparency of the eyewear is reduced.

Controversy exists as to the appropriateness of using personal prescription eyeglasses as CO_2 laser eye protection when the wearer is not in the immediate vicinity of the laser beam emission (e.g., the circulating nurse). Prescription eyeglasses do not have wavelength protection inscribed on them and have not been tested to determine the protective ability of the lens; therefore adequate protection cannot be guaranteed. Proponents state that the NHZ is so limited when the CO_2 beam is passed through the focusing lens that individuals who are not close to the laser emission port are not at high risk for eye damage. Facilities must address this controversy and develop a policy for the surgical team. Contact lenses and half glasses do not offer adequate protection against CO_2 laser energy and should not be used.

During a microscopic procedure, the optics of the microscope provide eye protection against CO_2 laser energy. When other wavelengths are used, such as argon or Nd:YAG, an automatic lens shutter can be connected to the microscope head. During laser activation, the shutter allows a lens filter to drop into place to provide a shield from any laser backscatter, protecting the eyes of the laser operator. When this device is attached to the microscope head, any observer tube being used also must be placed above the filter so that all portal optics offer protection. Others involved with the procedure must wear appropriate eyewear.

A lens filter can be placed over the eyepiece of a rigid or flexible endoscope. The lens must offer appropriate protection for the specific laser being used. Guidelines recommend that other surgical team members also wear eye protection, even though laser energy seems confined within an enclosed cavity. Optical injury is always possible if a fiber or articulated arm separates from the endoscope while the laser is activated, or if a fiber fractures and the beam escapes at the fracture site.

For healthcare professionals who routinely work with laser systems, a baseline eye exam is sometimes recommended, including visual acuity and an assessment of retinal health. Another eye exam can be performed after any ophthalmic accident or on termination of employment. The baseline exam provides a foundation for comparison with abnormal findings from subsequent exams. Performing baseline eye exams merely documents the ocular health of laser team members so that it can be used during a potential workers' compensation claim for retinal damage from accidental beam exposure. Some facilities opt not to follow this expensive and difficult-to-monitor guideline of performing baseline eye exams. Instead, they strictly enforce their eye safety policy, minimizing the chance of ophthalmic injury. These facilities state in their eye safety policy that an eye exam will be performed if an ocular accident occurs.

The patient's eyes also must be protected during laser intervention. When general anesthesia is used, patients' eyes are covered with wet gauze, eye pads, or a towel; the eyelids are taped closed. If awake or under local anesthesia, the patient wears appropriate eye protection. Explanations about this should be provided. If the laser is to be used in the immediate vicinity of the eye, such as to lighten a port-wine stain on the eyelid, a special laser eye shield can be placed on the surface of the eye after instillation of a drop of ophthalmic local anesthetic. If the laser eye shields are sterilized with steam, these devices must be cooled completely before being placed on the cornea to prevent burns. The Risk Reduction Strategies box summarizes actions to promote eye safety during laser surgery.

CONTROLLED ACCESS. Inadvertent access to rooms where laser treatments are being performed should be prevented. Laser warning signs must be placed at all entrances to the treatment area so that access is granted only to individuals who have been appropriately educated in laser safety. The word "Danger" and the universally accepted laser symbol should be present on laser warning signs to indicate the possibility of hazards (Figure 7-57). Laser signs should be removed when the procedure has been completed.

Windows and ports into rooms where lasers are used must be covered with appropriate protection for the specific laser being used. The CO_2 laser beam, passed through a lens, and the holmium laser beam, delivered through a fiber, provide a limited NHZ, so window coverage is not required. Argon, Nd:YAG, and certain other laser wavelengths can be transmitted through window glass and have longer NHZs. Windows and ports must be covered with a blocking barrier that stops transmission of specific wavelengths with more extensive NHZs.

The laser key must not be left in the laser during storage. The key should be available only to authorized personnel who

RISK REDUCTION STRATEGIES

Eye Safety During Laser Surgery

- Ensure that everyone in the laser room wears appropriate eye protection with side shields before activating the laser. Inscribed on the eyewear should be the laser wavelength protection and optical density of the lens material.
- Place a special lens cover over the eyepiece of an endoscope to protect the physician's eye from laser backscatter. Remember the physician's other eye is unprotected.
- Ensure everyone in the laser room wears eye protection during laser endoscopic procedures.
- Connect an automatic lens shutter to a microscope head, if needed, to provide eye protection for individuals viewing the procedure through the microscope.
- When general anesthesia is used, cover the patient's closed eyes with moistened gauze pads. When the patient is awake, place appropriate glasses or goggles on the patient. Explain the need for eye protection to the patient.
- During laser surgery near the eye, place a special laser eye shield directly on the anesthetized eye surface.
- Ensure that appropriate protective eyewear is available at all entrances to the laser room for anyone entering the room.
- Cover windows in the laser treatment area appropriately, depending on the wavelength of the laser used.
- To prevent reflection of the laser beam, follow special precautions (e.g., use anodized or ebonized instruments near the laser-tissue impact site and cover large reflective retractors with wet towels or sponges).
- When storing protective eyewear, guard against scratches and mishandling. Scratches may decrease effectiveness. Inspect eyewear regularly to ensure that integrity of lenses has not been compromised.

FIGURE 7-57 Warning signs should be placed at all entrances to the surgical room to notify personnel that a laser is being used, and that appropriate eye protection is needed before entering the room.

have appropriate education and training to operate the laser. Laser keys can be stored in the narcotics cabinet or in a special key lockbox to control access. The Risk Reduction Strategies box summarizes how best to control access to laser rooms and laser equipment.

RISK REDUCTION STRATEGIES

Guide to Controlled Access During Laser Surgery

- Post laser warning signs at all entrances to the laser room to prevent unauthorized individuals from entering. Warning signs should include the word *Danger* along with the universal laser symbol.
- Cover windows or ports with the appropriate protection for the specific laser wavelength being used.
- Do not store the laser key in the laser ignition port; the laser key must be available only to authorized individuals.

FIRE SAFETY. An awareness of laser biophysics and tissue interaction is necessary to understand actions needed to prevent laser fires. A fire can be started by a reflected beam as easily as from direct impact. The laser team responds quickly if a fire occurs. Immediate action is key to minimize injury to the patient and the surgical team. The Patient Safety box provides important detailed measures for fire safety during laser surgery.

Sterile water or saline solution should be readily available to douse a small fire on the patient. A laser-appropriate fire extinguisher should be available to control a fire within the laser system. During surgery, combustibles, such as sponges or towels near the laser target site, should be kept wet to prevent ignition. The surgical team should monitor constantly the moisture level of sponges and other materials to prevent drying, which eventually could support a fire.

A laser beam can ignite flammable draping material easily. Some water-repellent drapes and other laser-safe materials are able to withstand laser impact since the flammability of the material is minimal. If the flammability of draping material or any other supplies is questionable (e.g., plastic tooth protectors), the suspect item can be tested in the manufacturer's or researcher's laboratory.

Instruments used in the immediate vicinity of the laser target site should be nonreflective to decrease the chance of the laser beam bouncing off the surface and accidentally impacting another area. The laser beam can easily be reflected off shiny instrument surfaces and can cause skin or eye injury or ignite flammable materials. To decrease reflectivity, an instrument may be ebonized by coating it with a special substance (usually black). The instrument should be inspected regularly to ensure integrity of the coating. Any scratched surface where ebonization has worn off should be recoated.

Instruments also may be anodized or surfaced with a matte finish to decrease reflectivity. Other coatings and surfaces that cause laser light to scatter and diffuse on impact are being introduced. Large retractors can be covered with wet sponges or towels so that the laser beam cannot accidentally reflect off a shiny surface.

Special instruments have been designed to provide backstops for laser energy to decrease adjacent tissue damage and fire risk. Titanium rods are effective backstops. Quartz rods often are used as backstops for the CO_2 laser beam, but argon and Nd:YAG beams may be transmitted through them. Glass rods are never to be used with a CO_2 laser because glass material heats and shatters after continuous impact by a laser beam. Teflon backstops are not to be used because they can melt when heated and produce toxic fumes. Wet sponges also can be used as backstop material.

PATIENT SAFETY

Fire Safety During Laser Use

- Ensure sterile water or saline is immediately available to douse a small fire near or on the patient.
- Have a laser-appropriate fire extinguisher available in the department in case the laser catches fire. Surgical team members must know how to operate the fire extinguisher.
- Do not place fluids or solutions on the laser unit. The laser system should be protected from spillage or splatter, which could cause short-circuiting and fire.
- Do not place dry combustibles in the vicinity of the laser impact site. Use wet towels, nonflammable drapes, or special laser-retardant materials near the laser target area. Moisten dry drapes and sponges with sterile saline or water to prevent ignition. Monitor the moisture level constantly throughout the procedure. Remoisten as needed.
- Do not use flammable materials near the laser-tissue impact site.
- Use nonreflective instrumentation in or near the laser-tissue impact site to decrease accidental reflection of the laser beam. Cover larger instruments, such as retractors, with wet sponges or towels to protect against reflection.
- Do not use flammable skin preparations, such as alcohol, as prepping solutions.
- Insert a wet pack into the rectum as a tamponade to prevent methane gas from escaping into the surgical area if ordered by the physician. A cleansing bowel prep before surgery also decreases this risk.
- Use appropriate laser-resistant endotracheal tubes during upper airway surgery. Follow directions in product literature and on labels, which typically include information regarding the tube's laser resistance, use of dyes in the cuff to indicate a puncture, use of a saline fill to prevent cuff ignition, and immediate replacement of the tube if the cuff is punctured.
- Protect the endotracheal tube cuff with counted wet gauze sponges.
- Use nonexplosive anesthesia gases during laser procedures.
- Keep oxygen concentrations between 21% and 30% to minimize the possibility of an airway fire during laser procedures of the airway.
- Do not use nitrous oxide as it supports combustion.
- Place the laser in the standby mode when it is not in active use.
- Identify and verify the laser foot pedal with the operating physician to avoid accidental activation. Allow only the individual using the laser to activate it. Only activate the laser when the delivery tip is within the user's direct field of vision.

Special laser mirrors that directly reflect the beam onto a hard-to-reach area are available. Mirrors may be made of rhodium or stainless steel. Glass-surface mirrors do not withstand laser impact and heat and shatter instead. Using a laser mirror requires skill because the beam must be focused on the target area and not on the mirror to deliver the full impact of laser energy. A laser beam that is misdirected off a mirror can easily cause a fire.

Flammable skin preparations should not be used for laser procedures. During skin cleansing, prep solution can pool underneath a patient, and ethanol vapors from alcohol-based preparations can be trapped beneath drapes. The volatility of these vapors increases the risk of a surgical drape fire. Iodophor or any other tinted prep solution should be wiped before argon or Nd:YAG lasers are used because the tint may increase laser absorption by the skin.

FIGURE 7-58 A polyvinyl chloride endotracheal tube can become a blowtorch if ignited by a laser beam.

When a laser is used in the rectal area, a wet pack may be used to tamponade the bowel to prevent the escape of methane gas, which could enter the surgical area from the colon and cause an explosion. Wet sponges used for the pack must be counted so that packing is not inadvertently left in place after surgery. Some practitioners disagree with this practice, stating that wet sponges may stretch the colon walls, increasing peristalsis and the movement of methane gas into the surgical area. Whatever method is chosen, a cleansing bowel prep before surgery also helps decrease this potential hazard.

Airway explosion caused by the laser beam igniting the endotracheal tube (ETT) can cause a potentially lethal accident for the patient. A polyvinyl chloride (PVC) ETT is highly flammable, especially when a high concentration of oxygen flows through it during anesthesia administration (Figure 7-58). Specific laser-retardant ETTs should be used during oral, tracheal, or esophageal laser procedures that require general anesthesia. The laser power limitations of a commercially manufactured ETT must be followed closely to ensure proper protection. The cuff of the ETT should be inflated with sterile saline to provide a heat sink and retard a fire if perforated by the laser beam. Saline may be tinted with methylene blue to note a cuff rupture more quickly as the blue dye escapes. A protocol should be developed to describe the emergency steps needed to control an endotracheal fire. Immediate considerations include the following:

- Stop ventilation (disconnect gas flow).
- Extinguish all flames with saline.
- Remove the ETT, ensuring entire tube is removed.
- Ventilate the patient by mask or reintubate immediately to prevent laryngospasm.
- Examine the airway (mouth, oral cavity, bronchial tree) for burns, foreign bodies, or both.
- Decide on the next course of action (anesthesia provider and surgeon), that is, cancel or continue with procedure.

A nonintubation technique involving jet ventilation also may be used during laser microlaryngoscopy. A jet ventilator is a mechanical ventilation unit that delivers oxygen through

a small metal needle used with a rigid laryngoscope. Under pressurization, the jet ventilator is set to deliver a predetermined amount of oxygen with a set rate, pressure (in pounds per square inch [psi]), and percentage of inspiratory time. The needle is positioned between the vocal cords on the side opposite the lesion. The needle extends into the trachea so that the proper amount of oxygen is easily delivered. After surgery, the patient may be intubated to maintain an open airway if postoperative edema or tracheal spasm is anticipated.

Other nonintubation techniques, such as apneic methods, can be used to avoid intubation. The patient's oxygen saturation must be monitored closely when these techniques are used.

ENDOSCOPE SAFETY. Special precautions should be followed when using the laser during an endoscopic procedure. When a laser fiber is introduced through the biopsy port of a flexible or rigid endoscope, the operator must view at least 1 cm of the tip of the fiber before activating the laser (Figure 7-59). If the end of the fiber is still within the sheath of the endoscope and the laser is fired, the heat from the laser energy quickly damages the optics and channel of the endoscope.

When a "bare" fiber is placed down the biopsy channel of a flexible endoscope, the sharp tip possibly can tear the inside lumen of the channel. A length of medical-grade tubing can be placed over the fiber with the tip recessed within the sheath. The entire unit is then passed through the endoscope. When the end of the tubing is observed, the medical-grade tubing is withdrawn sufficiently to expose the end of the fiber. This procedure effectively protects the inside lumen of the endoscope channel during fiber insertion.

SMOKE EVACUATION. Smoke evacuation and odor control must be adequate whenever a plume is generated, whether it is from the laser, electrosurgical unit (ESU), or other surgical devices being used. When "hot" tools such as these are used to cut, excise, ablate, or coagulate tissue, cells of the target tissue are heated to the point of boiling. This causes cellular membranes to rupture, spewing cell contents into the air and producing surgical smoke. Research and reports about the hazards of surgical smoke are described in Box 7-3.

One of the crucial elements of adequate smoke evacuation is to determine the method of smoke evacuation. The method selected depends on the amount of plume produced.

An *in-line smoke evacuation filter* is appropriate only for small amounts of plume generation, similar to what is produced during microlaryngoscopy vaporization of vocal cord polyps. The in-line filter connects to the existing suction line by positioning it between the wall connection and suction canister (Figure 7-60). If the filter becomes wet, it loses its effectiveness.

If an in-line filter is not used, particulate matter from surgical smoke can occlude and corrode suction pipes and contaminate the building. Also, suction flow may not be forceful enough to capture the plume adequately. Wall suction usually generates 2 cubic feet per minute (cfm) of air movement, whereas an individual smoke evacuator may move air at 35 to 50 cfm. An in-line filter is changed after each procedure (or according to the manufacturer's instructions).

When greater amounts of surgical smoke are generated, an *individual smoke evacuator* is used. Individual smoke evacuators have filtration systems that include a charcoal filter and an ultra–low penetration air (ULPA) filter (Figure 7-61). The charcoal filter removes toxic gases and odor, whereas a ULPA filter removes small particulates with filtration of 0.12-μm size matter at 99.9999% efficiency (Ulmer, 2008).

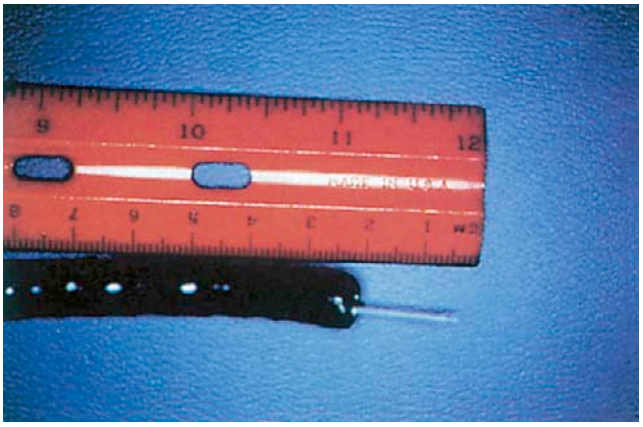

FIGURE 7-59 The laser fiber should extend past the end of the endoscope before the laser is activated.

Maintenance of a smoke evacuator requires changing the filter per the manufacturer's written instructions. Standard Precautions should be used when changing a contaminated filter because this is an occupational hazard (AORN, 2009, pp. 428-429). Usually, the used filter can be placed in a plastic disposal bag and discarded in the general waste receptacle. Some practitioners believe that a contaminated filter need not be treated as infectious or as regulated medical waste (biohazardous) because it is not listed as an environmental hazard. Some manufacturers have provided contaminated filter disposal guidelines, however, that suggest the filter be treated as biohazardous. A contaminated filter is considered an occupational hazard and Standard Precautions should be used when handling it. It is not designated as an environmental hazard, however, and it need not be treated as biohazardous medical waste.

Centralized smoke evacuation systems provide smoke evacuation for several surgical rooms at the same time. The smoke evacuation line needs to be routinely flushed and cleaned to prevent debris buildup and pathogen growth within the system. A central system is convenient because it is always available; however, if it malfunctions, smoke evacuation is not available to multiple surgical areas.

Contamination by surgical plume and tissue splatter is decreased when the surgical team wears gloves, gowns, and masks. The surgical team must ensure that the smoke evacuation wand or suction device is close to the target site so that all plume is evacuated. Devices are available that attach or are built into the ESU or laser delivery system that effectively evacuate surgical smoke as it is generated (Figure 7-62). Using appropriate smoke evacuation methods (Evidence for Practice) to ensure that all plume is eliminated is the only practice that protects the surgical team from exposure to hazardous surgical smoke. The Research Highlight box describes a study performed to identify key indicators of compliance with surgical smoke evacuation recommendations.

Surgical smoke that arises during flexible endoscopic or laparoscopic procedures impairs visibility. Hand control suction devices and valve filters provide gentle movement of plume during laparoscopy without destroying pneumoperitoneum.

BOX 7-3

Research and Reports About Surgical Smoke Hazards: A History

1975
Mihashi and associates vaporized tissue with a CO_2 laser in a laboratory setting to note the size of the particles within the smoke. Their results determined that approximately 77% of the particulate matter in the plume was less than 1.1 μm in size. Note: A regular surgical mask may filter particulate matter that is 5 μm in size; surgical smoke can pass easily through these masks and be deposited in the alveoli of lungs when inhaled. This potentially can cause chronic irritation, bronchitis, or emphysema-like or allergic-like conditions.

1985
The National Institute for Occupational Safety and Health (NIOSH) published and distributed a *Health Hazard Evaluation Report,* which stated there is "potential hazard from exposure to smoke generated by electrosurgery knives."

1988
The NIOSH issued a *Health Hazard Evaluation Report,* which stated "smoke generated during laser surgery presents a potential health hazard."

1988
Baggish and associates compared the effects of unfiltered laser smoke on rat lungs with plume that had been filtered. The rats breathing unfiltered plume developed hypoxia and pulmonary congestion with bronchial hyperplasia and hypertrophy. Rats subjected to plume filtered to 0.1 μm in size (similar to smoke evacuators) developed no lesions and remained identical to control rats.

1988
Garden's research team used the CO_2 laser to vaporize bovine fibropapillomavirus. Intact viral DNA was extracted from the plume emitted. The viral DNA material was reinjected into the cow at another site, and the same papilloma viral lesion grew again. This study demonstrated that viral DNA can cause viral growth in the host if the transmission mode is through injection.

1989
Tomita and associates compared the hazards of cigarette smoke with the hazards associated with laser and electrosurgery smoke. CO_2 laser vaporization generated a plume with the same hazard potential as smoking three unfiltered cigarettes. The ESU created a plume equivalent to smoking six unfiltered cigarettes.

1991
A report described a 44-year-old surgeon in Norway who developed laryngeal papillomatosis, probably at his workplace where he used lasers to vaporize condylomas. The surgeon's own laryngeal biopsy revealed human papillomavirus DNA types consistent with the anogenital condylomas being lased on his patients.

1993
Ott and his team demonstrated that when surgical smoke is not evacuated during a laparoscopic procedure, the patient's methemoglobin and carboxyhemoglobin levels increase, while oxygenation of tissues decreases. The patient usually responds with nausea, vomiting, or headaches.

1995
Hoglan's analysis indicated that more than 600 compounds within surgical smoke have yet to be identified.

2008
AORN ratified a position statement on *Surgical Smoke and Bio-Aerosols*.

2009
AORN introduced its on-line *AORN Surgical Smoke Evacuation Tool Kit* to assist surgical team members in the implementation of smoke evacuation practices for all surgical smoke. This resource contains a sample PowerPoint presentation for educational sessions, a checklist for smoke evacuation practices, and a bibliography of surgical smoke evacuation studies and articles.

There are four issues of concern associated with the hazards of surgical smoke:

1. Odor
2. Size of the particulate matter
3. Viability of the particulate matter
4. Endoscopy concerns

When surgical smoke is generated, a noxious odor is emitted with the smoke. This odor results from tissue destruction that produces chemical by-products and toxins. Some of these chemical by-products already have been identified as toxic carcinogens, such as polycyclic aromatic hydrocarbons, benzene, toluene, formaldehyde, and acrolein. It has not been conclusively proven if particulates within surgical smoke are viable. Further studies are needed to note if inhalation of surgical smoke containing viral DNA can be transmitted and lead to regrowth. Nonetheless, surgical smoke continues to be recognized as hazardous as more research studies are published. The following professional organizations, agencies, and research groups have recommended guidelines and statements regarding these hazards and how to minimize them:

- ANSI Z136.3: *Safe Use of Lasers in Healthcare Facilities,* 2005
- NIOSH: *Control of Smoke From Laser/Electric Surgical Procedures,* March 1998
- AORN: *Recommended Practices for Laser Safety in Practice Settings; Recommended Practices for Electrosurgery; Recommended Practices for Endoscopic Minimally Invasive Surgery; Recommended Practices for Safe Environment of Care,* 2009.
- AORN: *Position Statement on Surgical Smoke and Bio-Aerosols,* 2008
- AORN: *Surgical Smoke Evacuation Tool Kit,* 2009
- ASLMS
- OSHA

FIGURE 7-61 Individual smoke evacuator.

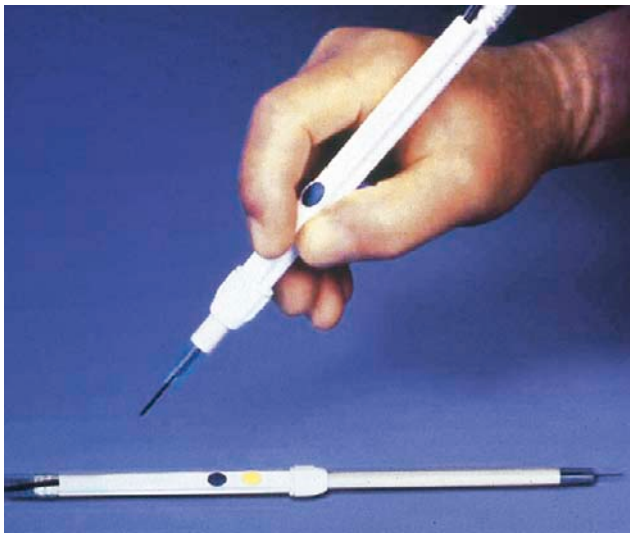

FIGURE 7-62 Electrosurgery pencil with the smoke evacuation system built into the device.

A high-flow insufflator is recommended for continual replacement of CO_2 gas. A special smoke evacuator may be used that automatically provides a slow evacuation of plume without destroying the pneumoperitoneum.

OTHER SAFETY MEASURES. Foot pedals present safety problems if mistakenly activated. Multiple foot pedals placed on the floor can be confusing and lead to accidents. The laser pedal should be identified clearly and used only by the physician delivering laser energy to the target area.

Laser team members must appreciate potential electrical hazards because the laser, similar to the ESU, is high-voltage equipment. Water and other solutions should not be placed on the laser unit, and the components of the laser should be protected against spillage or splatter, which could cause short-circuiting. The outside housing of the laser should never be removed by unauthorized personnel because of the potential for electrical shock or electrocution.

Transportation hazards are always a threat because some laser systems are quite heavy. When these units need to be moved, proper body mechanics must be employed to prevent

EVIDENCE FOR PRACTICE

Smoke Evacuation During Laser Surgery

- Use the appropriate smoke evacuation system, depending on the amount of plume generated. If small amounts of plume are generated and room suction is to be used, an in-line suction filter is positioned between the suction canister and the wall outlet to capture surgical smoke particulate. An individual smoke evacuation system is used if larger amounts of plume are generated.
- Change the smoke evacuation filter or filters according to the manufacturer's written instructions.
- Hold the smoke evacuation suction tube close (<1 inch away) to the tissue interaction site to remove as much plume (odor and particulate matter) as possible.
- Smoke evacuation tubing should have a smooth inner lumen to eliminate any whistling.
- Use a reducer fitting to adapt a large smoke evacuation tube to a smaller suction or evacuation tube.
- The scrub person or first assistant can operate the smoke evacuation foot pedal (if available) to minimize wear and tear on the smoke evacuator motor and to decrease noise. Some smoke evacuators have sensing mechanisms that automatically activate the smoke evacuator when plume is generated.
- Evacuate surgical smoke generated during endoscopic or laparoscopic procedures. Endoscopic smoke evacuation instruments, such as suction tubes, help decrease the presence and retention of plume inside a body cavity or organ. A low-pressure suction valve can be used to remove plume gently during a laparoscopic procedure without destroying pneumoperitoneum. A high-flow insufflator is recommended to replace any lost insufflation gas quickly. A special smoke evacuator that provides automatic plume removal also can be used to evacuate the intraabdominal smoke without destroying pneumoperitoneum.
- Wear a surgical mask that provides adequate filtration (0.1-μm filtration) to protect against residual smoke particulate that has not been evacuated. The high-filtration mask must fit snugly around the face. Wearing a high-filtration mask does not replace the use of a smoke evacuation system to remove surgical smoke from the environment.
- Continuing education helps healthcare personnel to understand the hazards of surgical smoke and encourages the use of appropriate methods for evacuation.

RESEARCH HIGHLIGHT

Compliance with Surgical Smoke Evacuation Recommendations

This study was performed to identify key indicators for compliance with surgical smoke evacuation recommendations. A piloted and validated survey that focused on individual perioperative nurse characteristics, organizational characteristics, and perceptions of the attributes of smoke evacuation recommendations using the Diffusion of Innovations Model by Rogers (2003) was sent to a random sampling of 4000 staff nurse members of AORN. Responses from 777 perioperative nurse participants revealed that the more education a nurse receives about smoke evacuation hazards and the more a nurse is trained on smoke evacuation equipment and devices, the more compliant the nurse will be with smoke evacuation recommendations. Age, level of education, and years of experience do not make a significant difference in compliance. If the smoke evacuation recommendations are perceived to be easy to understand and implement, then compliance is greater. Compliance is also greater within larger urban facilities that offer multiple specialties and have strong leadership support and interconnectedness (collaboration among professionals). Freestanding surgery centers are more apt to have greater compliance with smoke evacuation recommendations than surgical departments within hospitals. Lack of smoke evacuation equipment, resistant physicians, noisy smoke evacuators, and staff complacency are all listed as substantial barriers to implementing smoke evacuation recommendations. Perioperative nurses report a greater incidence of respiratory problems (e.g., allergies, asthma, or nasal polyps) than the general population. Research results can be used to target audiences and develop education and training sessions to improve OR practices regarding evacuation of surgical smoke.

injury to the transporter. The laser unit should be pushed instead of pulled to provide less stress on the transporter's back muscles. The laser should never be bumped against a wall as its internal components can be damaged or become misaligned.

DOCUMENTATION. Closely following written laser safety procedures is crucial for safety and legal reasons, as with any hazardous equipment. Specific notes about laser safety can be written on a laser log form or as part of the intraoperative nursing note. Either record should be placed on the patient's chart so that safety activities can be recorded. Safety measures may not be specifically documented if already described and mandated in the facility's policies and procedures. This is referred to as "documentation by exception."

A special laser log can be designed to be a permanent part of the patient's record and might include information such as the laser used, power, pulse duration, and other laser parameters. The use of smoke evacuation, fibers, and contact tips also may be documented, especially if specific charges for these items are made. A sample laser log is shown in Figure 7-63.

ROLE OF THE LASER TEAM MEMBER. As the use of laser technology grows, the role of the laser team member becomes more important. The backbone of a progressive and successful laser program is the enthusiastic and dedicated laser team. Expanded responsibilities are being assumed by the laser team member to provide consistency and promote a safe environment for the patient and the surgical team. Some roles of the laser team member may include serving as the laser safety officer, serving on the laser committee, becoming actively involved with laser procurement, and promoting the laser program through marketing.

According to ANSI Z136.3 (2005), the definition of the laser safety officer (LSO) is "the person responsible for the laser safety program in the facility…[who] has the training and experience to administer a laser safety program…is authorized by the administration and is responsible for monitoring and overseeing the control of laser hazards (p. 6)." Following are some of the duties of the LSO:

- Labels laser with appropriate hazard classification
- Evaluates potential hazards of the laser
- Serves on laser committee
- Enforces standard operating procedures (e.g., maintenance, service, perioperative checklists, policies)
- Ensures protective equipment and devices are in good working order (e.g., protective eyewear)
- Ensures laser installation and maintenance are carried out by qualified individuals, documented, and performed regularly
- Ensures appropriate training and education on laser safety are conducted and documented
- Documents incidents with lasers that could cause or has caused harm to patients or healthcare providers
- Delegates duties within the laser program as appropriate

Perioperative nurses who are part of the laser team are often involved with patient education. The perioperative nurse reinforces what the physician has described to the patient before a laser procedure. When told that surgery is needed, the patient is often anxious because of the unknown. Anxiety may be compounded because the patient is confronted with two alarming unknowns. Many patients develop uneasiness about laser procedures based on information from science-fiction movies, talk shows, and other such sources. The patient always should have the opportunity to discuss a proposed procedure to allay any worries. The perioperative nurse may provide additional information if the patient has further questions about laser technology. After the physician has explained the procedure, a surgical consent is signed. Sometimes, the consent form reflects that a laser will be used during surgery. Some physicians, however, suggest that a laser is merely a tool used during surgery and do not believe it is necessary to list laser use on the consent form.

Adequate time should be allotted for patient questions before the procedure. If a local anesthetic is used, the patient should understand what to anticipate during surgery, what sounds or odors will arise, why eye protection is needed, and what the patient's role is during the procedure. If the patient understands the application, the role of the laser, and his or her responsibility during and after the procedure, the perioperative nurse can expect better compliance and less anxiety in the patient.

Discharge instructions are required for any ambulatory procedure; laser discharge instructions may be preprinted for each surgical application. These written instructions should be reviewed and given to the patient on discharge. A follow-up phone call helps the perioperative nurse evaluate the care delivered during the laser intervention and the patient's compliance with the postoperative instructions.

Sometimes, the perioperative nurse is placed in a compromising position by being expected to circulate during the surgical procedure and also to operate the laser. This nurse has the tremendous responsibility of being accountable for two crucial roles in the OR; the risk of a laser incident may increase. In the traditional setting, one nurse circulates while another nurse or a technologist, a member of the laser team, operates the laser. The healthcare facility must determine which procedures require more staffing to deliver safe patient care.

Electrosurgery

Electrosurgical units (ESUs) have been used for many years to cut and coagulate tissue (Box 7-4), but ESU use also has been associated with numerous patient injuries and accidents. The same laser safety measures used to prevent surgical fires and to evacuate surgical smoke are also used for electrosurgery. (See the Laser Safety section in this chapter for detailed information.) Education is vital to ensure safe use of electrosurgery by understanding the principles and actions of this surgical energy.

Physics of Electrosurgery. The basic principles of electricity underpin electrosurgery. Electricity involves the motion of subatomic particles that behave in a consistent and predictable manner. Electrons orbit the nucleus of an atom. Once electrons are charged, they jump from one atom to the orbit of another, creating a charged particle or ion, and an electrical current is generated.

BOX 7-4

History of Electrosurgery

Around 1926 Dr. Harvey Cushing, a neurosurgeon, and Dr. William T. Bovie, a biophysical engineer, combined their talents and knowledge to develop electrosurgical technology for use during neurosurgical procedures. In 1928 they published a series of 500 neurosurgical procedures performed using an electrical device developed by Bovie. This primitive electrosurgical tool provided hemostasis for surgery in highly vascular areas. The first commercial ESU was produced in the early 1930s. The unit stood chest high, weighed about 300 lb, and was set in a beautifully crafted wooden cabinet. In the third edition (1958) of *Alexander's Care of the Patient in Surgery* it was noted, "Electrocoagulation has become an essential part of the neurosurgical setup. The nursing personnel must understand the construction of the machine before attempting to regulate it and they must carry out proper safety measures." Electrosurgery began to gain wide acceptance as the benefits of tissue coagulation and a drier surgical field became recognized by many surgical disciplines. Today it remains one of the most important and basic surgical modalities used in operative and other invasive procedures.

Three terms describe the properties of electricity—current, voltage, and impedance. *Current* is the flow of electrons measured in amperes or amps. *Voltage* is the force or push that moves the electrons from one atom to another and is measured in volts. *Impedance* is the opposition to the flow of current (electrons) and is measured in ohms (Ulmer, 2007). As electrons encounter impedance, heat is produced, and a tissue effect results.

Electricity must have a complete circuit or pathway so that electrons can flow. That is, if an electrical current originates from earth, the electricity must be returned to ground to complete the circuit. Two forms of electrical current are used today—direct current (DC) and alternating current (AC). With DC the electrons flow in only one direction, whereas with AC the electrons flow back and forth as polarity changes. During electrosurgery, AC enters the patient's body, causing the patient to become part of the circuit as the energy is returned to the source of the energy.

"Electrocautery" often is misused as a reference for electrosurgery. Electrocautery devices use direct current because electrons flow in one direction through a wire. The wire provides resistance and becomes hot. As the hot wire is held in contact with tissue, coagulation results. Electrocautery units are usually battery-operated, such as the small disposable units used during ophthalmic procedures to coagulate small blood vessels.

Frequency is the number of waves passing through a given point over a specified time. This is measured in hertz (Hz) or cycles per second. Electrosurgical systems operate at frequencies greater than 100,000 Hz, which also is the frequency at which nerve and muscle stimulation ceases. In comparison, the electrical current in a normal household wall outlet in the United States alternates at 60 cycles per second, or 60 Hz. An ESU generator takes the 60-cycle current and increases its frequency to greater than 200,000 Hz so that it can pass through the patient's body without muscle or nerve stimulation and with no risk of electrocution (Figure 7-64).

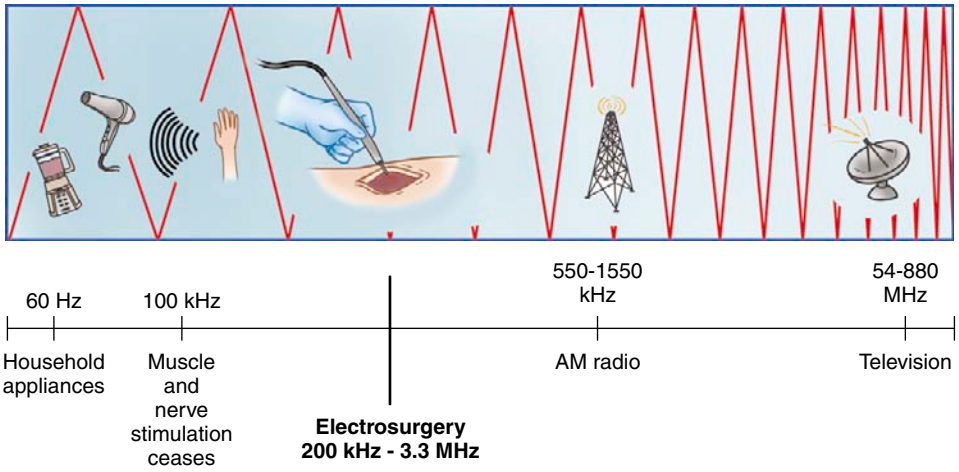

FIGURE 7-64 Frequency spectrum.

Electrosurgical Modes. The two modes used for electrosurgical cutting or coagulation are *monopolar* or *bipolar*. In a monopolar system, electrical energy flows from the generator through an active electrode to the patient (Figure 7-65). If energy is concentrated in a small area, and the tissue provides increased impedance, controlled heat is generated and cutting or coagulation is achieved. Electrical energy passes through the patient to a dispersive electrode (pad) or patient return electrode (PRE) placed on the patient's body. The dispersive electrode surface area is larger so that the energy is not concentrated enough to generate significant heat. Energy is then returned to the generator as the circuit is completed. If the dispersive electrode is tented, or only a small part of the pad is in contact with the patient's body, electrical energy becomes concentrated, and a burn can result. With monopolar electrosurgery, the patient completes the electrical circuit; it is the most common mode of electrosurgery used today.

In a bipolar system, a dispersive electrode is not needed because electrical energy flows from one tine (or prong or blade) of the bipolar instrument to the other tine as it passes through the tissue located between these tines (Figure 7-66). Energy returns directly through the instrument to the generator to complete the circuit, eliminating flow of current through the patient. During bipolar electrosurgery, the flow of electricity stops if a certain impedance level is reached. This is frequently 100 ohms but may differ for various bipolar generators available today. Although the ESU seems to be activated because an audible sound is heard while the pedal is depressed, the flow of current significantly decreases when the specified impedance is met. Impedance meters (or ammeters) are often used to alert the physician when tissue desiccation is occurring or when complete desiccation has occurred.

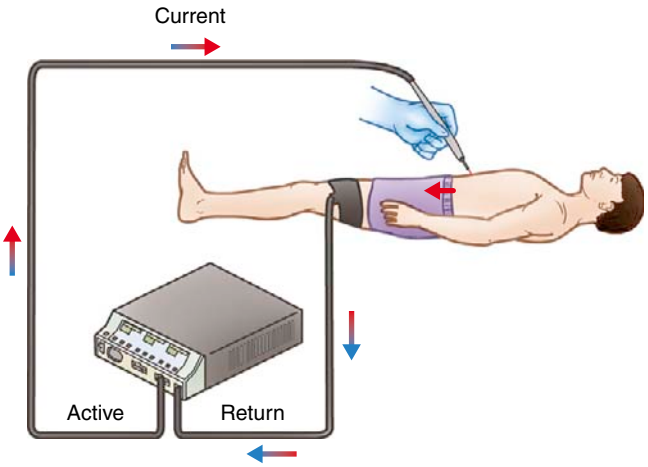

FIGURE 7-65 Monopolar electrosurgical circuit.

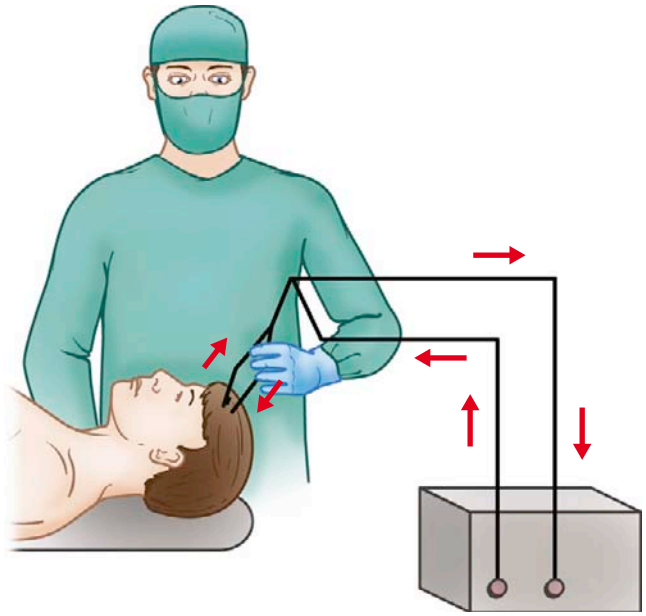

FIGURE 7-66 Bipolar electrosurgical circuit.

Tissue Effects. As electrosurgery variables change, different tissue effects can be achieved. Electrosurgery variables, explained below, include the following:

- Waveform
- Power setting
- Length of exposure
- Active electrode size
- Type of tissue
- Eschar presence

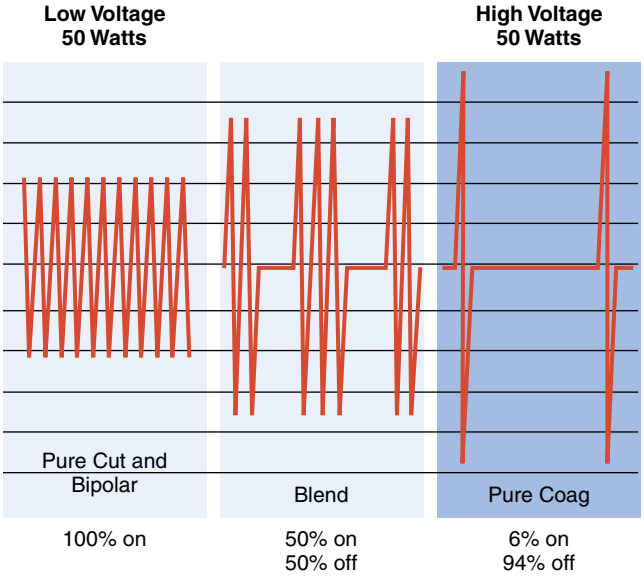

FIGURE 7-67 Electrosurgery waveforms: typical examples.

As waveform changes, so does tissue effect. Waveforms range from pure cut to pure coagulation. To produce a pure-cut mode, the generator must be on a 100% duty cycle, meaning that the electrical flow is continually applied, and heat is quickly generated for cutting and tissue vaporization (Figure 7-67). Current is high, but voltage is low. As less force is used to push the current, the cut mode may be considered safer than other modes. As the cut mode produces a constant bombardment of electrons on the tissue, heat is produced, cells rupture, and the tissue is cut. For maximum activity, the active electrode used to deliver the current should be held slightly above the tissue so that the electrons have to jump through the impedance of the air to reach the target site. This generates even more heat. Most of the heat dissipates as steam as tissue cells vaporize.

In pure coagulation mode, current is decreased, but voltage is increased. The duty cycle is on only about 6% of the time, leaving 94% of the time with no flow of electrons to the surgical site (see Figure 7-67). To compensate for this "off" duty cycle, the voltage, or force of the push, must be increased to produce the desired wattage. During coagulation, this intermittent delivery of electrons causes cells to heat and then cool, producing a coagulative effect. Higher voltage allows the active electrode to be held over the area while a fulguration or spraying effect delivers the electrical energy to coagulate a larger area. The tissue effect is superficial, collapsing the cells and producing a coagulum.

Most ESUs have a blend mode that allows the operator to achieve different levels of simultaneous coagulation in the cut mode. Increasing voltage and decreasing the duty cycle provide increased coagulation effects (see Figure 7-67).

The power setting also influences tissue effect. Higher power settings produce more extensive tissue effects. Long activation of electrical current increases thermal effects in tissue. Thermal energy can spread from the target site, causing damage to adjacent tissue. Smaller active electrodes concentrate electrical energy and require lower power settings; larger electrodes disperse electrical energy and require higher power settings.

Tissue type also influences tissue effect. Tissue that is not well vascularized, such as adipose tissue, offers more impedance. As a result, electrical energy is not conducted as well, and higher power settings may be required. Muscle tissue is well vascularized and requires less power to achieve a tissue effect. Eschar is less conductive and impedes the flow of electrons, requiring more power to be used to achieve the desired tissue effect. Electrosurgical tips on the active electrode must be kept clean and free from debris to function properly. Electrode tips with nonstick coating make removal of eschar easier.

Electrosurgical Units. Four ESU systems have evolved over the years: grounded, isolated, dispersive electrode monitoring, and tissue response monitoring.

GROUNDED ESU. The grounded ESU system was the first ESU introduced to the surgical market during the late 1920s. The grounded ESU delivers electrical energy from the generator to the patient and returns energy to ground, which is intended to be the generator. As electricity takes the path of least resistance, current can flow or divide through any grounded alternative paths, such as an ECG pad or an intravenous pole that touches the patient, as it returns to a grounded site. Patients have sustained burns at these alternative path sites as the electricity searches for the most conductive object or path to return to ground. When an alternate path is chosen, the current may not be dispersed over a large area, so an alternate site burn may result as current concentrates.

ISOLATED ESU. In 1968 the isolated ESU was introduced. An isolated ESU has a transformer that causes current to return only to the generator and not use alternate pathways to return to its source. Current flows through the patient's body and must return to the generator to complete the circuit. If this is not possible, the generator shuts down, adding to the safety of this type of unit. An isolated ESU prevents alternative site burns, but not patient return electrode (PRE) burns. The function of a dispersive electrode is to remove electrical current from the patient safely, but this may not always happen. If the pad is tented, the electrical current arcs from the patient's skin to the pad to complete the circuit. The current concentrates in the reduced pad-patient interface surface area and may cause a burn at this site. With experience, surgical teams became more focused on proper dispersive electrode placement by choosing a well-vascularized site with a secure pad-patient interface. Monitoring pad placement with an isolated ESU is a crucial responsibility of the perioperative nurse.

DISPERSIVE ELECTRODE MONITORING. In the 1980s different dispersive electrode monitoring systems were introduced, using a variety of names: dispersive pad monitoring, REM (return electrode monitoring), RECQMS (return electrode contact quality monitoring system), contact quality monitoring system, and patient safety system. Dispersive monitoring protects the patient from dispersive electrode site burns caused by inadequate contact of the dispersive electrode. The system continually monitors impedance under the split pad as it transmits an interrogation circuit to measure impedance levels. The system deactivates current flow when impedance under the pad increases to an unsafe level, thus preventing a burn.

Placement of a dispersive electrode pad is crucial to prevent patient injuries. The pad should be placed over an area that is well vascularized, such as a muscle mass. Sites with excessive

FIGURE 7-68 Capacitance pad that provides pressure reduction to prevent skin breakdown.

hair, bony prominences, excessively dry skin, or adipose tissue should be avoided. When a patient is repositioned after the pad has been placed, the pad site must be inspected again to ensure proper adherence.

A capacitance pad working on the principle of "bulk resistivity" and "capacitive coupling" is an advanced technology. A capacitor is defined as two conductors separated by an insulator. In an ESU, the patient is one conductor (plate), and the conductive mesh (plate) inside the pad is the other conductor. The ability for current flow to be induced from one plate of the capacitor to the other is affected by three primary variables: (1) frequency of current, (2) size of the plates, and (3) distance between the plates. Higher frequency large plates and less distance between plates lead to better current flow. One small low-frequency plate or a great distance between the plates yields decreased current flow.

The large capacitive pad, approximately 2 feet × 3 to 4 feet, consists of a flexible conductive fabric surrounded by a nonlatex, urethane insulating material. The pressure reduction version of this pad is composed of a dry, viscoelastic polymer, one of the best materials to prevent the formation of decubitus ulcers.

This large reusable pad is placed on the OR bed (Figure 7-68) with a linen sheet and draw sheet placed on top of it. When the patient is lying on the OR bed, the electrode pad forms a large capacitor with the patient that capacitively couples or connects the patient into the ESU circuit. When in place, this dispersive electrode completes the circuit by capacitive reactance, allowing the ESU to function. The amount of current transmitted into the pad is directly proportional to the amount of contact with the pad. The pad serves as the gatekeeper for this current. With too little current, there is very little current flow, too low to cause burns.

The capacitive pad can be used for patients in all types of positions. A positioning chart is available from the manufacturer to assist the surgical team with safe and appropriate positioning. This larger pad is inappropriate for patients weighing less than 25 pounds because adequate contact (weight-bearing area) cannot be achieved. In 2009 a pediatric capacitive pad was introduced for patients between 0.8 and 50 pounds (Figure 7-69).

The large capacitive pad eliminates the need for an individual adhesive dispersive electrode pad, which is problematic if an ESU is used without dispersive electrode monitoring capabilities and the pad tents during a procedure. The bulk resistivity of this unique capacitive pad ensures that current densities are kept to a clinically safe level such that pad site burns rarely occur. Adhesive pads also can irritate sensitive skin, may require a shaved area for placement, or may become a hazard if not placed on the patient appropriately. As surgical teams learn more about the use and safety features of the capacitance pad, its acceptance continues to grow.

TISSUE RESPONSE MONITORING. This system represents a substantial advancement in ESU generator technology. It uses a computer-controlled tissue feedback system that senses impedance of the tissue and automatically adjusts current and voltage output to maintain a constant surgical effect.

FIGURE 7-69 Pediatric capacitive dispersive pad for infants weighing from 0.8 to 50 pounds.

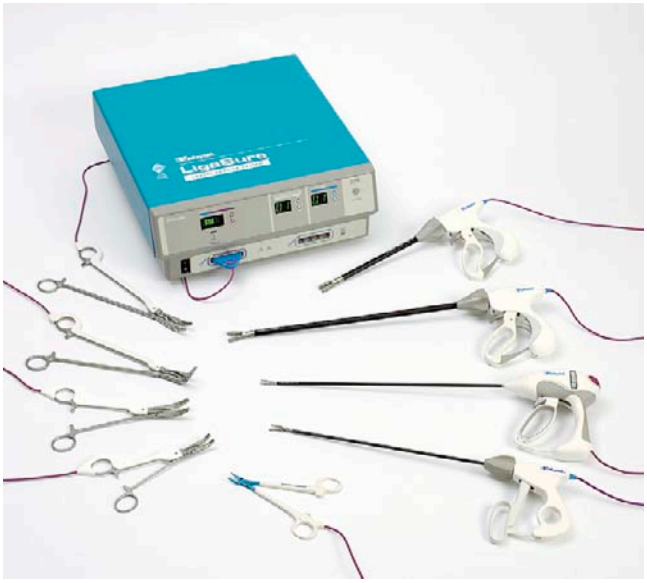

FIGURE 7-70 Vessel-sealing generator with instruments.

This feedback system eliminates the need to adjust power settings for different tissue types. In addition, improved performance at lower power settings and voltages reduces the risk of patient injury.

Another advanced feedback–controlled generator has been combined with a bipolar instrument to seal vessels and tissue bundles reliably for surgical ligation during open and laparoscopic procedures (Figure 7-70). The feedback system helps to achieve a reliable tissue seal in less time, reducing thermal spread compared with traditional bipolar systems. With a single activation, this system provides stable seals on tissue bundles or on vessels up to 7 mm in diameter. The surgeon is able to assess the level of hemostasis at the seal site before cutting. The strength of the seal compares favorably to mechanical ligation methods, such as suture or clips, and is significantly stronger than standard bipolar coagulation. It is important to note that tissue response systems use the cut mode while the new tissue sensing systems give feedback when implementing the coagulation mode of ESU generators.

Special Electrosurgery Considerations During Endoscopic Minimally Invasive Surgery. Three unique problems can occur during MIS procedures involving electrosurgery: direct coupling, insulation failure, and capacitive coupling.

DIRECT COUPLING. Direct coupling occurs when the active electrode accidentally touches a noninsulated metal instrument, allowing the electrical energy to flow from one to the other (metal-to-metal sparking) (Figure 7-71). Direct coupling may also occur if an active electrode is activated while in contact with a clip. When the metal instrument or clip receives electrical energy, a burn can easily result. This coupling is often called "pilot error" because it is within the surgeon's control to avoid. The surgeon should not activate the active electrode until the target site is within the field of vision and the active electrode is in close proximity or direct contact with target tissue and not a metal object.

INSULATION FAILURE. Insulation failure occurs when the insulation coating of an endoscopic instrument has been compromised. If a crack or break occurs in the insulation along

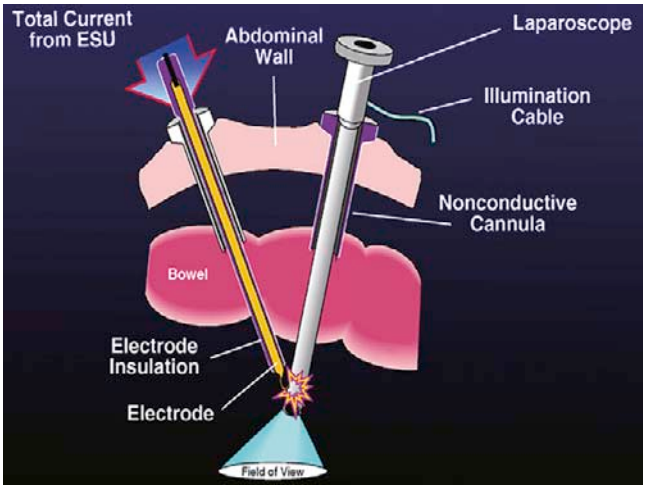

FIGURE 7-71 Direct coupling during laparoscopy.

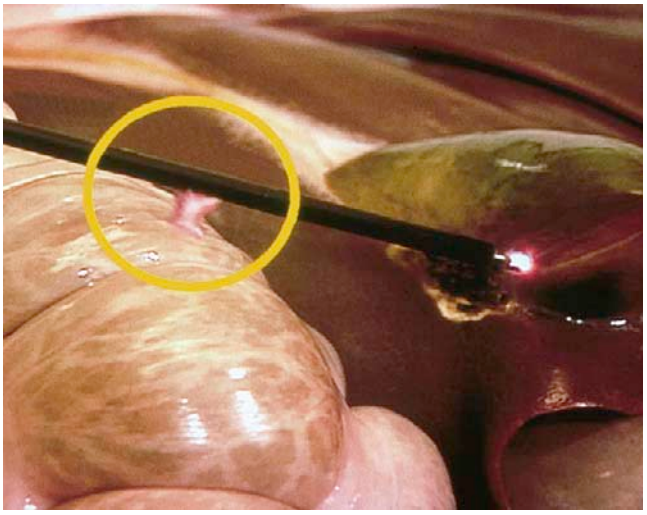

FIGURE 7-72 Insulation failure during laparoscopy.

the shaft of the instrument, electrical energy can escape at the point of the defect and burn untargeted tissue (Figure 7-72). Insulation must be inspected before, during, and after each use of the instrument. A scanning device can be used to ensure that insulation is not compromised during reprocessing. Even an area of insulation that is merely weakened may be penetrated by electrical flow if high voltage, or pure coagulation mode, is being used. Given that the force (or voltage) of electrons is greater in coagulation mode, any weakened area may become an actual break along the insulation sheath. Insulation failure presents the greatest risk to the patient because the full energy output can be delivered to nontargeted tissue. Insulation failure may result in an instantaneous, irreversible death to tissue as a result of the high power density that insulation failure creates on the instrument shaft. The resulting tissue burn may not be observed or realized by the surgeon because it may not be within the field of vision.

Laparoscopic instruments may be purchased with a dual layer of insulation. The outer black insulation layer lies on top of a bright yellow insulation layer. When the top black layer is penetrated, the bright yellow layer can be seen easily and alerts the user that insulation failure may be imminent.

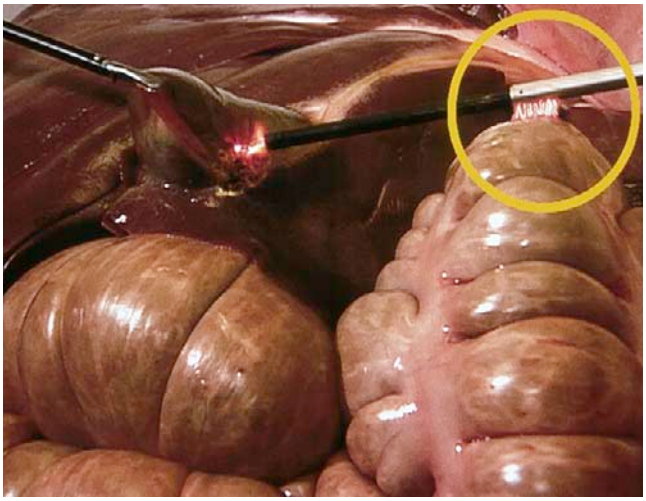

FIGURE 7-73 Capacitive coupling occurs when electrical energy flowing from an instrument charges a nearby metal trocar sheath or laparoscope.

CAPACITIVE COUPLING. Capacitive coupling is a natural RF (electrosurgical energy) phenomenon that occurs when energy is transferred through intact insulation on the laparoscopic instrument shaft to nearby conductive materials (Figure 7-73) (Dennis, 2005). A capacitor consists of *two conductors* separated by an *insulator.* The metal active electrode is one conductor, and an adhesion, an adjacent organ, or a conductive trocar/suction irrigation cannula can act as the second conductor. The primary insulation on the instrument represents the insulator. When an electrode is activated within a narrow suction irrigator, the RF energy can flow from the active electrode through the intact insulation and transfer 20% to 80% of the power displayed on the ESU to the metal suction irrigator. The induced current on the suction irrigator can cause a burn even though the outer insulation on the first instrument has been inspected and determined to be intact.

Monopolar ESU instruments used in concert with metal suction irrigators or shafts increase the risk of visceral burns through capacitive thermal energy. The laparoscope also can cause alternate-site burns if the ESU electrode is used through a narrow-lumen scope. In addition, long and narrow instruments with thin insulation, combined with high voltage, increase the incidence of capacitive coupling.

An electrical charge remains in the second metal instrument until it finds a path to the dispersive electrode to complete the circuit. Usually this energy disperses safely through the large surface of the abdominal wall from the conductive cannula. However, if a nonconductive device, such as a plastic stability collar, is in this path, energy cannot be safely discharged and will burn any tissue touched by the metal instrument. These burns often are undetected by the surgeon, and the problem is not diagnosed until the patient presents with complications after surgery. Accordingly, surgeons avoid hybrid instruments (combination of plastic and metal) during laparoscopy to minimize capacitive coupling.

To eliminate the hazard of capacitive coupling and insulation failure, special instruments that provide active electrode monitoring (AEM) are available to capture stray energy that is transferred from one conductive device to another (Dennis, 2005). AEM laparoscopic instruments are shielded and monitored to detect stray RF current and prevent ESU burns. The protective shield built within an AEM instrument provides the neutral path for capacitive-coupled energy and returns it to the ESU (Figure 7-74). These safety devices also detect insulation failure and provide a path for stray current back to the generator. AEM is the only fail-safe technology currently designed to address insulation failure and capacitive coupling. AEM ensures that 100% of electrosurgical energy is delivered at the intended site.

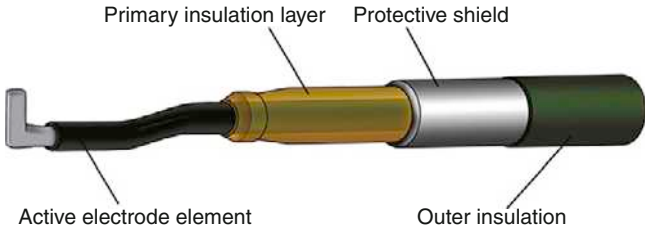

FIGURE 7-74 Cross section of active electrode monitoring instrument.

Many hospitals that have implemented AEM technology require documentation of its use on the patient's perioperative chart for liability and risk management, much like rationales for documenting needle count, sponge count, and pulse oximetry.

Argon-Enhanced Electrosurgery. An argon-enhanced ESU device combines argon gas with electrosurgical energy to improve the effectiveness of the electrosurgical current. As argon gas is heavier than air, inert, and noncombustible, it creates an efficient pathway for electrosurgical energy to travel from electrode to target tissue. The flow of argon gas also clears the surgical site of blood and fluids, allowing for greater visibility of the bleeding site or target area, and disperses oxygen, decreasing the chance of combustion and formation of surgical smoke.

Benefits of argon-enhanced electrosurgery include:

- Rapid coagulation of diffuse bleeding site with reduced blood loss
- Reduced risk of rebleeding
- Noncontact tissue coagulation
- Reduced depth of penetration by electrical energy and less adjacent tissue damage (Dooley and Braghieri, 2008)

When an argon-enhanced ESU is used during laparoscopic procedures, care must be taken not to overinsufflate (or overpressurize) the abdomen because the constant flow of argon gas could cause formation of a gas embolism. Often another port is left open during activation of argon-enhanced ESUs to allow excess gas to escape. An insufflator with an audible alarm indicating overpressurization should be used. The patient should be monitored closely so that early symptoms of an embolism can be detected and treated.

Ultrasonic Device Surgery

Vibrating energy devices provide a safe option for cutting and coagulation. High-frequency sound waves are propagated to a blade tip to produce ultrasonic energy. These ultrasonic waves have a frequency of greater than 20,000 Hz and cannot be sensed by the human ear.

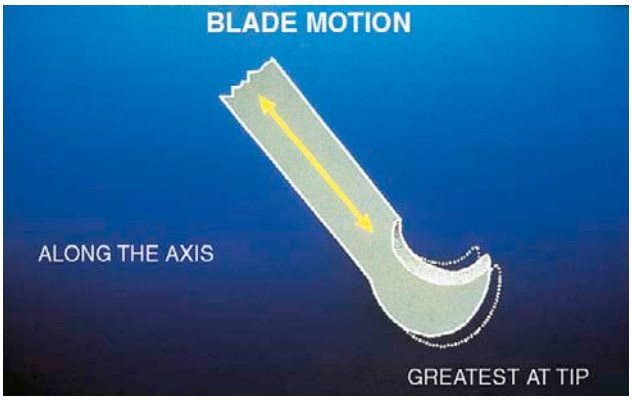

FIGURE 7-75 An ultrasonic blade may move longitudinally more than 55,000 times per second.

Production of ultrasonic energy begins with electrical current that generates an electrical signal sent through a co-axial cable to a transducer in a handpiece. The transducer converts electrical energy to mechanical motion through contraction and expansion of ceramic elements. A longitudinal vibratory response that moves the tip at the end of the handpiece from 23,000 Hz to greater than 55,000 Hz is produced (Figure 7-75). As the power increases, the frequency remains the same, but longitudinal excursion of the tip lengthens.

Because the tip is in contact with tissue, mechanical motion causes tissue protein to denature as hydrogen bonds are broken. As protein molecules become disorganized, a sticky coagulum forms that welds and coagulates smaller bleeding vessels. Aerosolization occurs during cellular destruction, consisting of a small amount of water vapor that usually dissipates quickly. Only a small amount of thermal energy is produced and any adjacent tissue damage is minimal.

Different tip configurations include a blade, ball, and hook. To obtain optimal tissue response, countertraction must be applied to the structure being treated. A shear-grasper to hold the tissue between a blade and tissue pad can be used to eliminate the need for countertraction.

The following are advantages of using an ultrasonic device to cut and coagulate:

- No surgical plume or odor is generated; only a small amount of aerosolization is created.
- Less adjacent tissue is damaged compared with laser and ESU devices.
- Tactile feedback is retained.
- No nerve or muscle stimulation occurs because no electrical current is delivered to the target area.
- No stray electrical or laser energy is produced.
- Precise cutting and control are offered.

Neutral Plasma Coagulation. A neutral plasma coagulator consists of a range of disposable handpieces that are used for coagulation by neutral argon or thermal plasma. In the PlasmaJet system, anode (where current enters) and cathode (where current exits) electrodes generate argon plasma. As the electrodes are contained in the handpiece, no ground plate is used. Risk for the patient is reduced because no electrical current passes through the patient. When the plasma coagulator handpiece reaches bleeding tissue, it releases its kinetic energy as heat and causes coagulation of the bleeding surface.

Microwave Ablation. Microwave ablation is a new technology that ablates tissue. Frictional heat is generated from rotation of water molecules that creates an ablation zone with simultaneous application of one or more antennas. When the antennas are spaced closely to each other (i.e., 1.5 to 2 cm apart), one combined ablation zone is created. No electrical current flows through the patient and no dispersive pad is required. The system automatically shuts off when the set ablation time is achieved. The advantage of microwave ablation is that the desired level of soft tissue coagulation can be reached more quickly compared to other RF ablation devices.

Hydrodissection and Irrigation

Irrigation is essential during most open and endoscopic procedures. Irrigation is accomplished with irrigation probes for open procedures; via irrigating channels built into endoscopes; or by irrigating systems inserted through an operating port, cannula sheath, or operative endoscope.

Irrigating fluid can be introduced manually through an endoscope by a syringe and stopcock attached to irrigation tubing on one end and an irrigation bag and tubing assembly on the other (original intravenous pole, Y-tubing, and irrigation system). Fluid flows by gravity and is manually forced through the distal tubing.

A pressure bag can be used to increase flow, if desired. Irrigation through a flexible endoscope also can be delivered directly by a syringe attached to the irrigation port. Fluid travels through a specific channel built into the scope. Rigid scopes, such as ureteroscopes, cystoscopes, and hysteroscopes, also have this capability, as do operative laparoscopes.

Pumps are utilized when large quantities of fluid are used and manual operation is cumbersome and time-consuming. Pumps are beneficial when irrigation is used for hydrodissection because more fluid can be introduced to the surgical site under pressurization. More force can be exerted over longer periods, and the pressure is adjustable.

A common pump irrigation system includes the irrigation pump (CO_2 or electric), irrigation bottle caps, irrigation probe with dual trumpet valves, and Y-tubing irrigation set. When a CO_2-controlled system is in use, an E-cylinder of CO_2 gas is attached by means of a tank yoke and input hose. A wrench must be available to turn off the tank when not in use. It is important to check tank pressure before and after each use. The pump usually has an adjustable pressure on-off capability and dual irrigation bottle selection. As one bottle empties, a flip of the switch redirects CO_2 flow to the second bottle. Bottles can be replaced as needed. The system operates by displacement of water or saline with CO_2 gas.

When an electric setup is used, a carrier bag with an inflatable bladder surrounds the solution bag (Figure 7-76). When the bladder inflates, adequate pressure can be achieved and controlled to provide irrigation and hydrodissection.

Distal tubing attaches directly to an irrigation probe. The length of time and volume of irrigation are controlled by a trumpet valve (Figure 7-77). Probes are available as reusable, disposable, or a combination of both. All three types incorporate a second trumpet valve for suctioning.

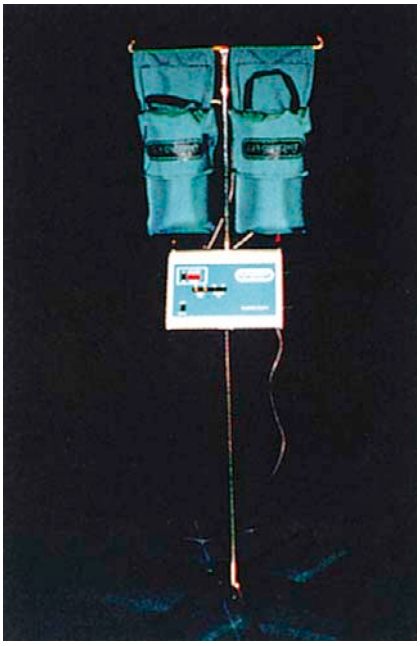

FIGURE 7-76 Hydrodissection system.

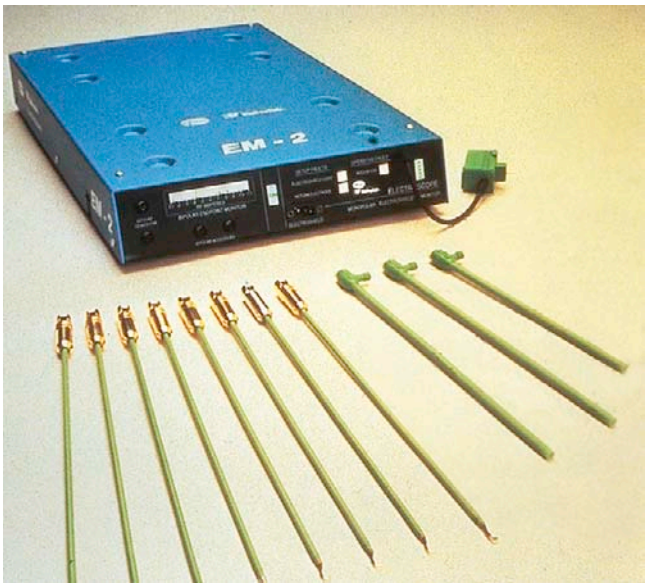

FIGURE 7-78 Disposable laparoscopic system with irrigation, suction, and monopolar electrosurgical capability. Electrosurgical probes are available in a variety of tips.

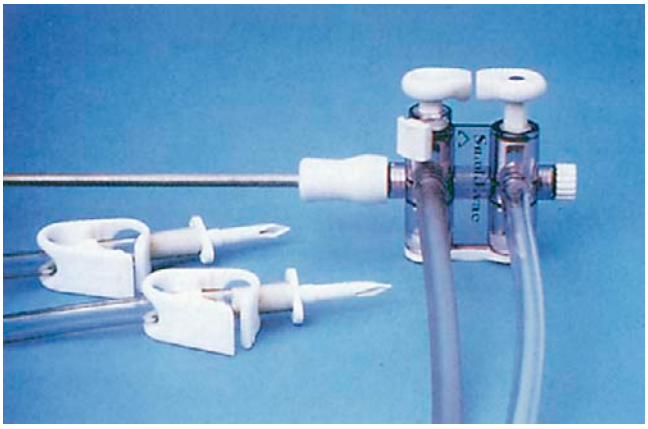

FIGURE 7-77 A trumpet valve controls the flow of irrigant and suction.

If reusable probes are used, they are completely disassembled for cleaning and sterilization or disinfection. Each trumpet valve has a spring mechanism (similar to that of a ballpoint pen). These springs are under pressure when the trumpet valve is inserted. During disassembly, it is important to hold a hand over the valve so that the spring cannot eject, disappear, or cause eye injury. Protective eyewear is worn during disassembly and extra springs should be available.

Completely disposable units are available; other systems incorporate disposable with reusable components. In the latter unit, tubing and pistol-grip handles containing the trumpet valves are disposable, but suction and irrigation probes are reusable. The disposable and disposable-reusable units may also incorporate electrosurgical capability (Figure 7-78), allowing the device to be used for three separate functions.

Choice of irrigation fluid depends on surgeon preference. Traditionally, normal saline has been used. Because saline is a conductive fluid, use of a monopolar ESU presents a safety hazard relating to potential for transfer of heat and current to adjacent tissues. As a result, sterile water or other nonconductive solutions should be considered to prevent ESU energy from transferring to alternative sites when extensive use of a monopolar ESU is anticipated. Sorbitol, also used for irrigation during hysteroscopy, can be absorbed rapidly into the vascular system, especially during excessive venous bleeding. The patient must be monitored carefully because of the potential for congestive heart failure from fluid overload.

Cryosurgery

Cryosurgery has been used in healthcare for many years, even though it may appear to be a space-age surgical technique. Archeological evidence indicates that in 2500 BC, freezing tissue was probably employed as an anesthetic. In the early 1800s, cancer was treated using different freezing techniques. Today, cryosurgery is used to destroy small quantities of unwanted tissue, such as skin tumors, and to ablate larger tissue targets, such as liver tumors, prostatic cancer, and cervical dysplasia. Cryosurgery causes tumor death by freezing. When internal tumors (e.g., liver cancer) are treated, dead tumor cells eventually are absorbed into surrounding tissue. Cryosurgery often involves cycles or steps during the treatment as a tumor is frozen, allowed to thaw, and then refrozen.

To freeze tissue properly, a cooling device or cryosurgical probe must produce an ice ball capable of destroying tissue at approximately –50° C and colder. Some devices produce temperatures as low as –240° C (–400° F). The cooling source is usually gaseous nitrogen or supercooled liquid nitrogen.

For external tumors, liquid nitrogen is applied directly to the dysplastic tissue either with a cotton swab or with a spraying device. For internal tumors, liquid nitrogen is circulated through the length of a cryoprobe with an insulated shaft to confine freezing to the distal tip. Ultrasound imaging often is used to guide the cryoprobe and to monitor tumor freezing. By

localizing the freezing effects, nearby healthy tissue is spared. Smaller cryoprobes are available that can be inserted through small trocar sites.

Cryosurgery may be used to treat early-stage skin cancers (basal and squamous cell carcinomas) and retinoblastoma (a childhood cancer that attacks the retina of the eye). Precancerous lesions, such as actinic keratosis and cervical intraepithelial neoplasia, may also be treated with this therapy. Cryosurgery has been used to treat a variety of cancers, including prostate, liver, breast, bone, brain, spinal, lung, and tracheal. It may be used in combination with other cancer treatments, such as radiation, hormone therapy, chemotherapy, and surgery. Cryosurgery has also been found useful in ophthalmology to reattach detached retinas and to treat other eye problems, such as retinoblastoma.

The primary advantage of cryosurgery over other therapies for cancer treatment is that it is less invasive. Only a small incision is needed to introduce the cryoprobe through the skin, and less bleeding, pain, and other complications occur. Cryosurgery is also less expensive compared with other treatments and often requires shorter hospital stays and recovery time. The main disadvantage of cryosurgery is the uncertainty of its long-term effectiveness because microscopic cancer cells can spread easily if these cells are missed during the freezing application. Cryosurgery continues to evolve as new cryosurgery techniques are explored for treatment and palliative therapy.

CHAPTER 8

Wound Healing, Dressings, and Drains

DONNA R. McEWEN

The ability to heal wounds is one of the most powerful defensive properties humans possess. Wound healing is a complex, highly organized response by an organism to tissue disruption caused by injury. This process is highly reliable in the absence of endogenous and exogenous infections, mechanical interferences, or certain disease processes. Apposition and maintenance of the edges of a cleanly incised wound almost always result in prompt healing. A primary goal of perioperative patient care is the prevention of surgical wound infections. Surgical wound infections are an important cause of illness, death, and excessive healthcare costs. Surgical wound infections have been complicated further by the potential for infection from new strains of antibiotic-resistant bacteria, such as methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci (VRE).

Postoperative surgical site infections (SSIs) are a major source of complications for the millions of individuals undergoing surgery annually in the United States and frequently are related to healthcare-associated infection (HCAI). SSIs are the third most commonly reported HCAI, numbering about 500,000 out of an estimated annual 27 million surgical procedures (Barnett, 2007). Although many surgeries are performed on an outpatient basis and the average number of admissions to hospitals and length of stay have decreased since the 1980s, the incidence of HCAIs has increased. In 2008, as part of the 2005 Deficit Reduction Act, the Centers for Medicare & Medicaid Services (CMS) began withholding reimbursement for eight conditions that have evidence-based prevention guidelines. Examples of these conditions are catheter-related infections and infections associated with coronary artery bypass grafts (Beaver, 2008), certain orthopedic procedures, and certain bariatric surgery procedures. Actions taken by perioperative personnel sometimes can mean the difference between developing an SSI and the normal healing process. A clear understanding of these actions and a solid knowledge of wound healing and factors adversely affecting healing are important for the appropriate management of patients undergoing surgery, not to mention imperative in light of continuing CMS-imposed refusals to reimburse for an expanding array of avoidable conditions that include wound-related infections.

ANATOMY

The skin is the largest organ of the body and acts as the first line of defense against infection. It provides protection and sensation, regulates fluid balance and temperature, and produces vitamins (e.g., vitamin D) and immune system components. The skin of the average adult covers about 3000 square inches, weighs about 6 pounds, and receives one third of the body's circulating blood volume. It varies in thickness from 0.5 mm in the tympanic membrane to 6 mm on the soles of the feet and the palms of the hands. Key structures of the skin are the primary layers of the epidermis, the dermis, and the subcutaneous. The *epidermis* is the outermost layer of the skin, lines the ear canals, and is contiguous with the mucous membranes. The epidermis is composed of several layers consisting of keratin and lipids. Keratin is the primary substance that hardens nails and hair and protects the body from fluid loss and invasion by pathogens. The epidermis is supported by the *dermis,* which is thicker than the epidermis and composed of collagen. The dermis is the largest portion of the skin, providing strength and structure. Contained within the dermis are blood vessels, lymph ducts, hair roots, nerves, and sebaceous and sweat glands. The dermis is vascularized and innervated (Figure 8-1). The innermost *subcutaneous* layer is composed of adipose tissue that merges with the deepest layer of the dermis to provide insulation, shape, and support. Any wound or disruption of the skin can provide a portal for bacteria and possible infection.

ETIOLOGY OF WOUNDS

The causes of wounds can be described as follows:

- *Surgical*—caused by an incision or excision
- *Traumatic*—caused by mechanical, thermal, or chemical destruction
- *Chronic*—caused by underlying pathophysiologic condition (e.g., pressure ulcers or venous leg ulcers) over time

The amount of tissue loss, the existence of contamination or infection, and the degree of damage to tissue are some factors that determine the type of wound closure selected by the surgeon. The healing process is inherently related to whether the wound is closed or left open. This process occurs in one of three ways: primary intention, secondary intention (granulation), and delayed primary closure (tertiary intention).

TYPES OF WOUND CLOSURE

Primary Intention

Healing through primary intention occurs when wounds are created aseptically, with a minimum of tissue destruction and postoperative tissue reaction. Wounds closed with sutures,

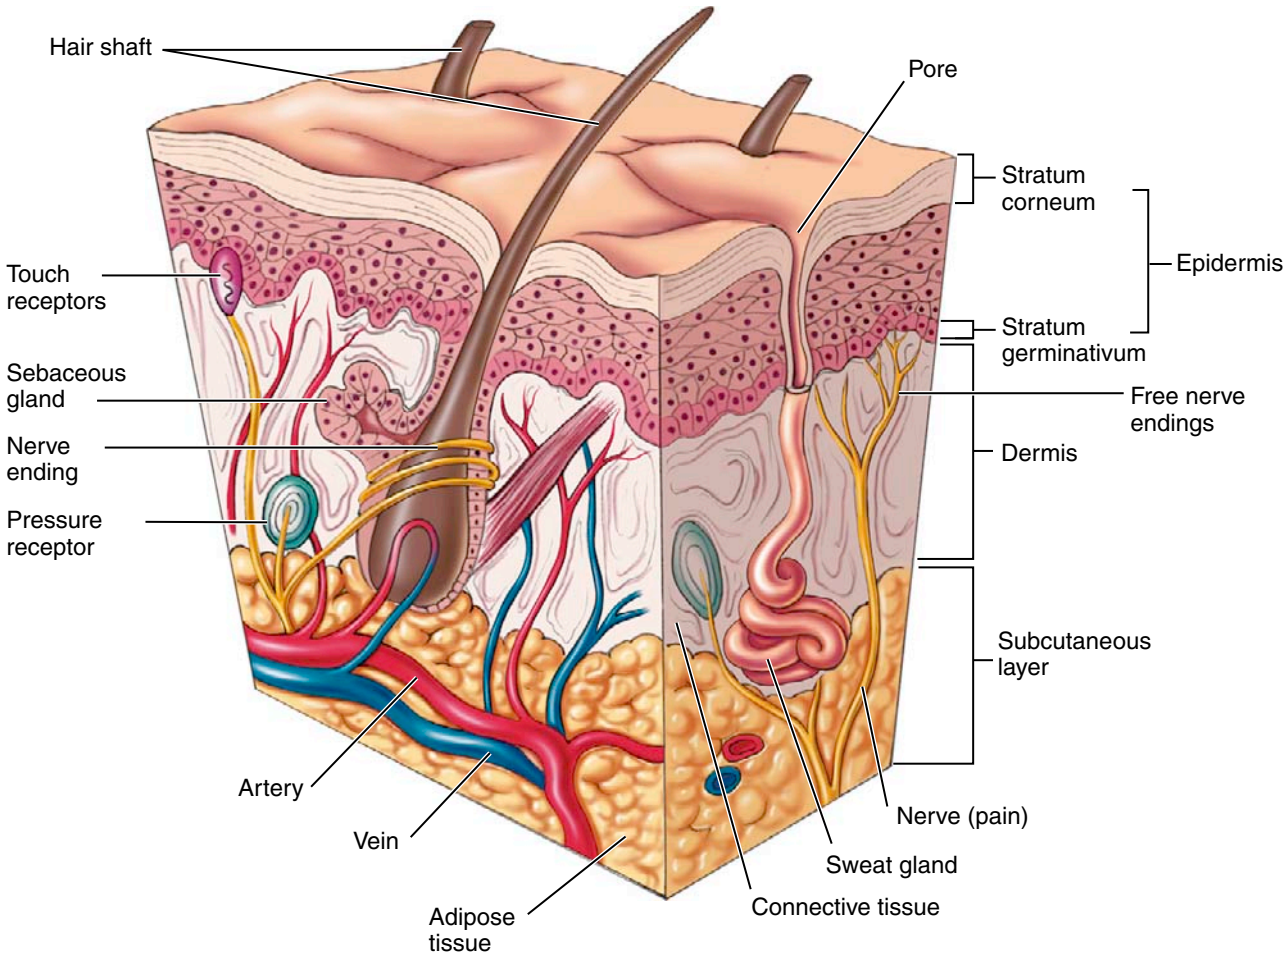

FIGURE 8-1 The skin.

staples, or tape applied as soon after the time of injury as possible fall into this category (Figure 8-2). When wounds are created under sterile conditions, healing is optimized and begins almost immediately. This type of healing is known as primary intention and occurs under the following conditions:

- Edges of an incised wound in a healthy individual are promptly and accurately approximated.
- Contamination is held to a minimum by rigid adherence to aseptic technique.
- Trauma is minimal.
- No tissue loss occurs.
- On completion of closure, no dead space remains to become a potential site of infection.
- Drainage is minimal.

Secondary Intention (Granulation)

When surgical wounds are characterized by tissue loss with an inability to approximate wound edges, healing occurs through secondary intention (see Figure 8-2). This type of wound is usually not closed; instead, it is allowed to heal from the inside toward the outer surface. In infected wounds, this process allows the proper cleansing and dressing of the wound as healthy collagen tissue expands from the inside. The area of tissue loss gradually fills with granulation tissue, comprising fibroblasts and capillaries. Scar tissue is extensive because of the size of the tissue gap that must be closed. The scar is referred to as a *cicatrix*. Contraction of surrounding tissue also occurs. Consequently, this healing process takes longer than primary intention healing. Healing by secondary intention is often seen in chronic wounds, dirty wounds, and traumatic wounds where large areas of tissue are lost.

Delayed Primary Closure or Tertiary Intention

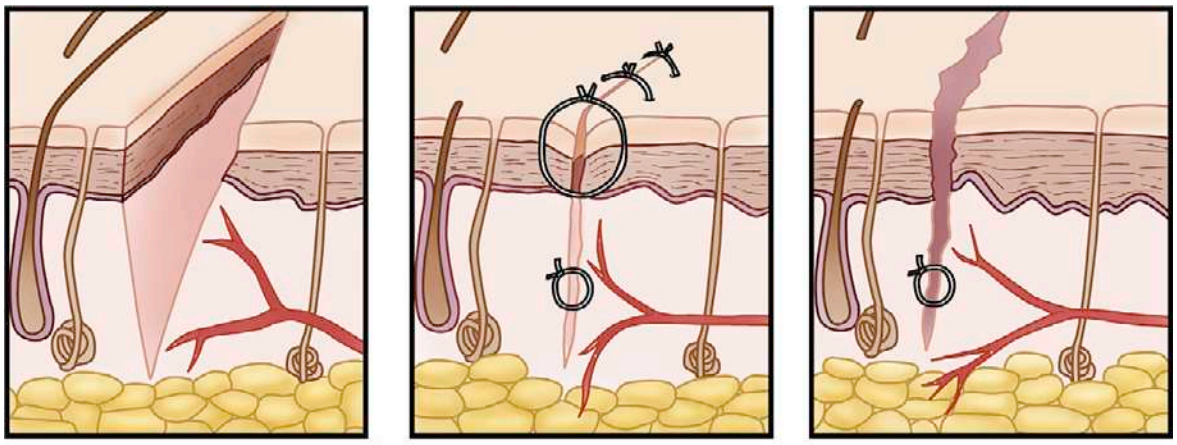
As the name *delayed primary closure* implies, this healing process occurs when approximation of wound edges is intentionally delayed by 3 or more days after injury or surgery (see Figure 8-2). These wounds may require debridement and usually require a primary and secondary suture line, such as when retention sutures are used. The conditions leading to a decision to delay closure are as follows:

- Removal of an inflamed organ
- Heavy contamination of the wound
- The critical nature of the patient's intraoperative condition, such as with hemodynamically unstable trauma patients

PHASES OF HEALING

Clean, full-thickness wound healing is an intricate biologic process that occurs in three overlapping phases: (1) inflammatory (also known as the reactive stage), (2) proliferative

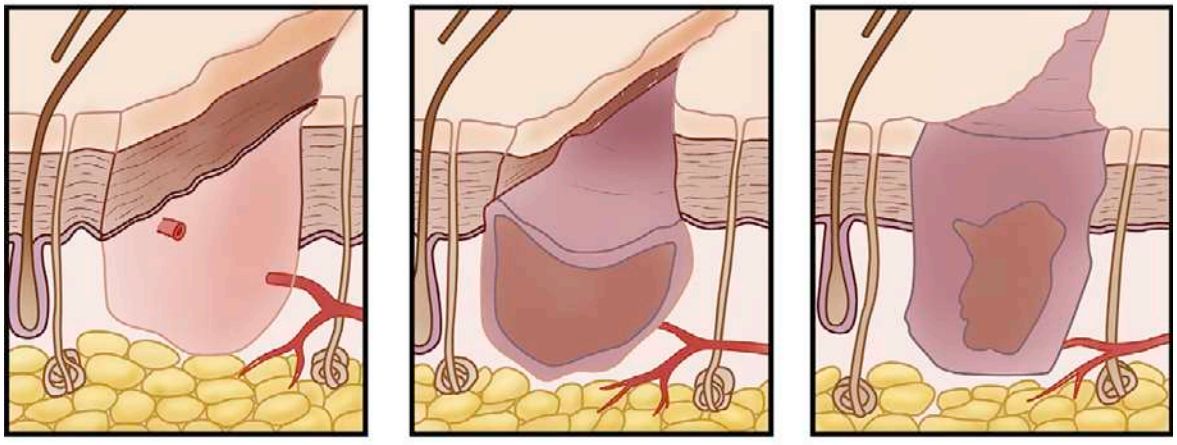
Healing by First Intention



Clean incision | Early suture | "Hairline" scar

An aseptically made wound with minimal tissue destruction and minimal tissue reaction begins to heal as the edges are approximated by close sutures or staples. No open areas or dead spaces are left to serve as potential sites of infection.

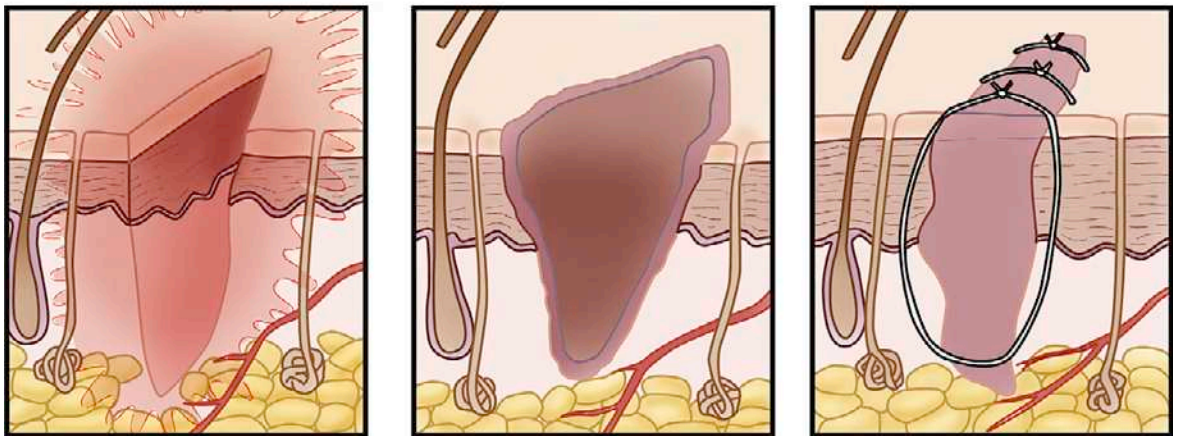
Healing by Second Intention (Granulation) and Contraction



Gaping, irregular wound | Granulation and contraction | Growth of epithelium over scar

An infected or chronic wound or one with tissue damage so extensive that the edges cannot be smoothly approximated is usually left open and allowed to heal from the inside out. The nurse periodically cleans and assesses the wound for healthy tissue production. Scar tissue is extensive, and healing is prolonged.

Healing by Third Intention (Delayed Closure)



Infected wound | Granulation | Closure with wide scar

A potentially infected surgical wound may be left open for several days. If no clinical signs of infection occur, the wound is then closed surgically.

FIGURE 8-2 The process of wound healing.

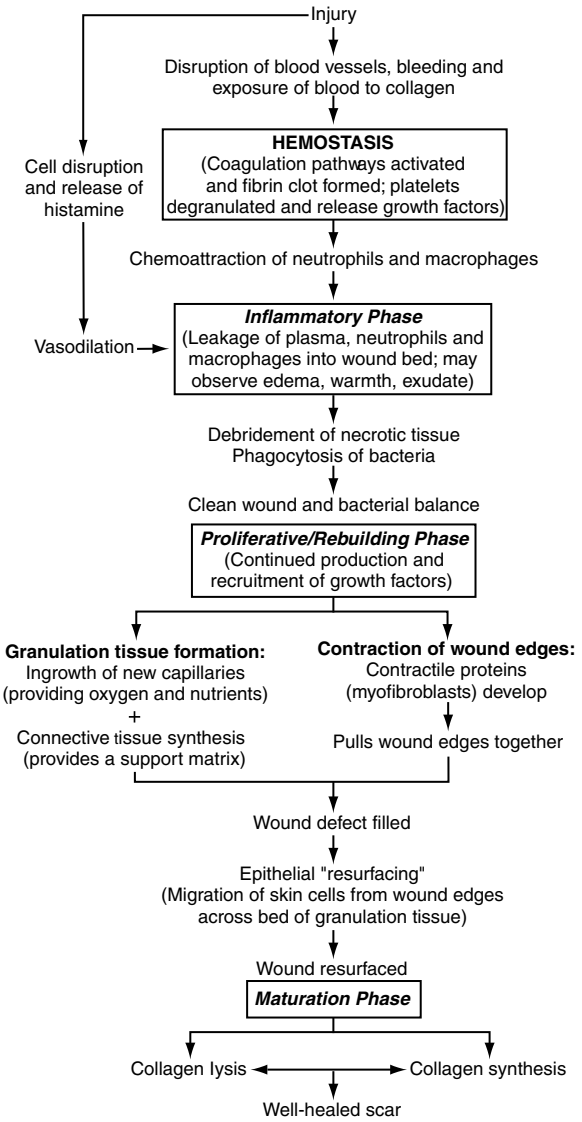


FIGURE 8-3 Cascade of events in wound repair process.

(also known as the regenerative or reparative stage), and (3) remodeling (also known as the maturation stage) (Ethridge et al, 2008) (Figure 8-3).

Inflammatory Phase

In the inflammatory phase, an exudate containing blood, lymph, and fibrin begins to clot and loosely binds the cut edges together. Blood supply to the area increases, and the basic process of inflammation begins. Inflammation is a prerequisite to wound healing and is a vascular and cellular response to dispose of bacteria, foreign material, and dead tissue. Leukocytes increase in number to fight bacteria in the wound area and by phagocytosis help to remove damaged tissues. The severed tissue is quickly glued together by strands of fibrin and a thin layer of clotted blood, forming a scab. Plasma seeps to the surface to form a dry, protective crust. This seal helps to prevent fluid loss and bacterial invasion. During the first few days of wound healing, however, the seal has little tensile strength. The inflammatory phase normally lasts 1 to 4 days. The skin edges may appear mildly swollen and slightly red in this phase as a result of the inflammatory processes at work. Many chronic wounds "stall" at this phase.

Proliferative Phase

The proliferative phase allows new epithelium to cover the wound, beginning the process within hours of the injury. Epithelial cells migrate and proliferate to the wound area, covering the surface of the wound to close the epithelial defect. Epithelialization also provides a protective barrier to prevent fluid and electrolyte loss and to reduce the incidence of infection. While reepithelialization takes place, collagen synthesis and wound contraction are occurring. Contraction begins approximately 5 days after the wound onset and peaks at 2 weeks, gradually shrinking the entire wound. Granulation tissue forms under the edges of the incision and can be palpated as a hard ridge, which eventually resolves during the remodeling phase. Epidermal migration is limited to about 3 cm from the point of origin. Larger wounds may require skin grafting because of this limited epidermal migration. Collagen synthesis produces fiber molecules that crosslink to provide strength to the wound.

Remodeling Phase

The remodeling phase begins after approximately 2 to 4 weeks, depending on the size and nature of the wound. It may last 1 year or longer. During the remodeling phase, scar tissue formed during fibroplasia changes in bulk, form, and strength. Throughout normal wound healing, new collagen is produced while old collagen breaks down in a balanced fashion. This collagen turnover allows randomly deposited connective tissue to be arranged in linear and lateral orientation. As the scar ages, fibers and fiber bundles become more closely packed and form a crisscross pattern, ultimately creating the final shape of the wound. At best, the tensile strength of scar tissue is never more than about 80% of the tensile strength of nonwounded tissue.

FACTORS AFFECTING WOUND HEALING

Patients should be assessed for factors that may impair wound healing. The patient's nutritional status, oxygenation level, and overall recuperative power are important factors in tissue repair and healing. The inflammatory response and oxygen tension both depend on microcirculation to deliver components to the wound. Decreased oxygen tension to the wound area inhibits fibroblast migration and collagen synthesis, resulting in decreased tensile strength of the wound. Nutritional status also has a profound effect on healing because of the need for an adequate supply of protein necessary for the growth of new tissues. Protein also is required for the regulation of the osmotic pressure of blood and other body fluids and the formation of prothrombin, enzymes, hormones, and antibodies. Other nutritional essentials are water; vitamins A, C, B_6, and B_{12}; iron; calcium; zinc; and adequate calories. It is also important to maintain body temperature (normothermia) in the OR as hypothermia contributes to vasoconstriction, which can adversely affect wound healing.

The most common cause of delayed wound healing in a surgical patient is surgical site infection (SSI). Box 8-1 lists types of SSIs and defines criteria for classification. There are many possible causes of SSIs, including patient susceptibility to and severity of illness, microbial contamination by the patient's microflora, and exogenous wound contamination from the OR environment and personnel. Adherence to strict

BOX 8-1

Criteria for Defining a Surgical Site Infection

SUPERFICIAL INCISIONAL SURGICAL SITE INFECTION

- Occurs within 30 days after the operation
- Involves only the skin and subcutaneous tissue of the incision *and* at least one of the following:
  1. Purulent drainage, with or without laboratory confirmation, from the superficial incision
  2. Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision
  3. At least one of the following signs or symptoms of infection—pain or tenderness, localized swelling, redness, or heat—*and* superficial incision is deliberately opened by the surgeon, *unless* the incision is culture-negative
  4. Diagnosis of superficial incisional SSI by the surgeon or attending physician

DEEP INCISIONAL SURGICAL SITE INFECTION

- Infection occurs within 30 days of the operation if no implant is left in place or within 1 year if implant is in place, and the infection seems to be related to the operation, *and* infection involves deep soft tissues (e.g., fascial and muscle layers) of the incision *and* at least *one* of the following:
  1. Purulent drainage from the deep tissue, not from the organ/space component of the surgical site
  2. Deep incision spontaneously dehisces or is deliberately opened by a surgeon when the patient has at least one of the following signs or symptoms—fever (38° C [100.4° F]), localized pain, tenderness—unless site is culture-negative
  3. Abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination
  4. Diagnosis of a deep incisional SSI by a surgeon or attending physician

ORGAN/SPACE SURGICAL SITE INFECTION (AREA CONTIGUOUS WITH ORGAN OR SPACE OF THE OPERATING SITE)

- Infection occurs within 30 days of the operation if no implant is left in place or within 1 year if implant is in place, the infection seems to be related to the operation, *and* infection involves any part of the anatomy (e.g., organs or spaces), other than the incision, that was opened or manipulated during an operation, *and* at least *one* of the following:
  1. Purulent drainage from a drain that is placed through a stab wound into the organ/space
  2. Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space
  3. An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination
  4. Diagnosis of an organ/space SSI by a surgeon or attending physician

Modified from Mangram AJ et al: *Special report: guidelines for prevention of surgical site infection,* 1999, National Centers for Infectious Diseases, Hospital Infections Programs, available at www.cdc.gov/ncidod/dhqp/pdf/guidelines/SSI.pdf. Accessed February 9, 2009; *National Nosocomial Infections Surveillance System,* Centers for Disease Control and Prevention, available at www.cdc.gov/ncidod/dhqp/nnis_pubs.html. Accessed February 9, 2009.

aseptic principles, careful observation of sterile technique, and thorough antimicrobial preparation of the patient and operative site are essential to minimize the risk of postoperative SSI. Perioperative personnel who are not scrubbed at the sterile field must maintain meticulous hand hygiene during the procedure to decrease the transmission of bacteria to the surgical field or the patient (Patient Safety).

Wound healing also can be impaired by poor surgical technique. Rough handling of tissue may cause trauma that can lead to bleeding and other conditions conducive to infection. Examples of surgical technique promoting wound healing include adequate hemostasis, precise cutting and suturing techniques, efficient use of time to minimize wound exposure to air, elimination of dead spaces, and minimal pressure from retractors and other instruments.

Additional factors affecting wound healing are the patient's age, stress level, immunologic status, and smoking history. Preexisting conditions, such as diabetes, anemia, malnutrition, cancer, obesity, certain drug therapies (e.g., steroid therapy), and cardiovascular or respiratory impairments, also contribute to poor wound healing. Additional terms used in connection with wound healing are shown in Box 8-2.

BOX 8-2

Additional Terms Used in Connection with Wound Healing

The following are additional terms used in connection with wound healing:

Adhesions—Adherence of serous membranes to one another, causing fibrous tissue to form; sometimes occur in healing and inflammatory processes; commonly occurs in or around gastrointestinal tract, where adhesions may form bands and cause obstructions and subsequent surgical emergencies

Dead space—Air or empty space between layers of tissue or beneath wound edges that have been approximated

Dehiscence—Separation of layers of surgical wound (Figure 8-4)

Evisceration—Extrusion of internal organs or viscera through gaping wound (see Figure 8-4)

Gangrene—Anaerobic infection process that may occur instead of healing; implies necrosis (death of tissue) and putrefaction (decomposition); usually caused by failure of nutriment or blood to reach a part

Keloid—Dense, unsightly connective tissue or excessive scar formation that is often removed surgically

"Proud flesh"—A mass of excessive granulation formed when a wound shows no other sign of healing or excessive cicatrization

WOUND CLASSIFICATION

The Centers for Disease Control and Prevention (CDC) recommends four surgical wound classifications: clean wounds, clean contaminated wounds, contaminated wounds, and dirty or infected wounds (Mangram et al, 1999). This classification scheme reflects the probability of infection and enables appropriate preventive measures to be taken. The *AORN Recommended Practices for Documentation of Perioperative Nursing Care* note the importance of documenting the wound classification in the patient record (AORN, 2009). Following are descriptions of each classification.

Clean Wounds (Class I)

Clean wounds are uninfected operative wounds in which no inflammation is encountered, and the respiratory, alimentary, and genitourinary tracts are not entered. They are primarily closed and can be drained with a closed wound drainage

PATIENT SAFETY

Perioperative Handwashing

The Joint Commission has made patient safety a priority through annual National Patient Safety Goals (NPSGs). One NPSG is the goal of reducing the risk of healthcare-associated infections. One of the criteria for meeting this goal is for organizations to comply with the current Centers for Disease Control and Prevention (CDC) hand hygiene recommendations. The OR typically is considered a "sterile" environment, but perioperative nurses must be especially vigilant about complying with hand hygiene guidelines. Patients are vulnerable whenever the intact skin barrier is breached. Activities that are not properly conducted in a sterile fashion, such as application of surgical dressings to a fresh incision, provide an opportunity for the establishment of pathogens. Healthcare workers (HCWs) often have a false sense of security about the protection that gloves offer and may think that frequent hand hygiene is unnecessary. The use of gloves cannot replace routine, faithful adherence to effective hand hygiene. Other reasons cited for noncompliance with hand hygiene include the following:

- Too busy
- Dry skin caused by hand hygiene agents
- Forgetfulness
- Denial about risks
- Inadequate time/staff
- Lack of supplies for hand hygiene
- Patient is a higher priority than infections

Effective hand hygiene is the easiest, least expensive, and most effective tool that perioperative nurses have at their disposal when acting in the role of patient advocate. The goal of hand hygiene is a sufficient reduction of microbial counts on the skin to prevent cross-contamination of pathogens. Good hand hygiene practices also provide safety and protection to the HCW.

After extensive research, the CDC published guidelines for hand hygiene. The guidelines are ranked by category ratings, which provide direction to facilities for implementation.

Category I rankings (IA and IB) are applicable to all settings and should be adopted. Subcategories A and B differ only in the strength of supporting research and evidence. Category II rankings are supported by less research and evidence. They may be appropriate for addressing specific situations or patient populations. The Unresolved category offers no recommendation for some practices, either because little research is available to support the effectiveness or because there is no consensus regarding their efficacy. Perioperative nurses must exercise judgment in determining policies and practice interventions based on the Unresolved category.

RANKINGS

Indications for Handwashing and Hand Antisepsis

Category IA

- When hands are visibly dirty or contaminated with proteinaceous material or are visibly soiled with blood or other body fluids, wash hands with a nonantimicrobial soap and water or an antimicrobial soap and water.
- If hands are not visibly soiled, use an alcohol-based hand rub for routinely decontaminating hands in all other clinical situations. Alternately, wash hands with an antimicrobial soap and water.
- Decontaminate hands after contact with body fluids or excretions, mucous membranes, nonintact skin, and wound dressings if hands are not visibly soiled.

Category IB

- Decontaminate hands before having direct contact with patients.
- Decontaminate hands before donning sterile gloves when inserting a central intravascular catheter.
- Decontaminate hands before inserting indwelling urinary catheters, peripheral vascular catheters, or other invasive devices that do not require a surgical procedure.
- Decontaminate hands after contact with a patient's intact skin (e.g., when taking a pulse, measuring blood pressure, and lifting a patient).
- Decontaminate hands after removing gloves.
- Before eating and after using a restroom, wash hands with a nonantimicrobial soap and water or with an antimicrobial soap and water.
- Antimicrobial-impregnated wipes (i.e., towelettes) may be considered as an alternative to washing hands with nonantimicrobial soap and water. Because they are not as effective as alcohol-based hand rubs or washing hands with an antimicrobial soap and water for reducing bacterial counts on the hands of HCWs, wipes are not a substitute for using an alcohol-based hand rub or antimicrobial soap.

Category II

- Decontaminate hands if moving from a contaminated body site to a clean body site during patient care.
- Decontaminate hands after contact with inanimate objects (including medical equipment) in the immediate vicinity of the patient.
- Wash hands with nonantimicrobial soap and water or with antimicrobial soap and water if exposure to *Bacillus anthracis* is suspected or proven. The physical action of washing and rinsing hands under such circumstances is recommended because alcohols, chlorhexidine, iodophors, and other antiseptic agents have poor activity against spores.

Unresolved Issue

- No recommendations can be made regarding the routine use of non–alcohol-based hand rubs for hand hygiene in healthcare settings.

Hand Hygiene Techniques

Category IB

- When decontaminating hands with an alcohol-based hand rub, apply product to palm of one hand, and rub hands together, covering all surfaces of hands and fingers until hands are dry. Follow the manufacturer's recommendations regarding the volume of products to use.
- When washing hands with soap and water, wet hands first with water, apply an amount of product recommended by the manufacturer to hands, and rub hands together vigorously for at least 15 seconds, covering all surfaces of the hands and fingers. Rinse hands with water, and dry thoroughly with a disposable towel. Use towel to turn off faucet. Avoid using hot water because repeated exposure to hot water may increase the risk of dermatitis.

Category II

- Liquid, bar, leaflet, or powdered forms of plain soap are acceptable when washing hands with a nonantimicrobial soap and water. When bar soap is used, soap racks that facilitate drainage and small bars of soap should be used.
- Multiple-use cloth towels of the hanging or roll type are not recommended for use in the healthcare setting.

Continued

PATIENT SAFETY

Perioperative Handwashing—cont'd

Surgical Hand Antisepsis

Category IB

- Surgical hand antisepsis using an antimicrobial soap or an alcohol-based hand rub with persistent activity is recommended before donning sterile gloves when performing surgical procedures.
- When performing surgical hand antisepsis using an antimicrobial soap, scrub hands and forearms for the length of time recommended by the manufacturer, usually 2 to 6 minutes. Long scrub times (e.g., 10 minutes) are unnecessary.
- When using an alcohol-based surgical hand-scrub product with persistent activity, follow the manufacturer's instructions. Before applying the alcohol solution, prewash hands and forearms with a nonantimicrobial soap, and dry hands and forearms completely. After application of the alcohol-based product as recommended, allow hands and forearms to dry thoroughly before donning sterile gloves.

Category II

- Remove rings, watches, and bracelets before beginning the surgical hand scrub.
- Remove debris from underneath fingernails using a nail cleaner under running water.

Selection of Hand Hygiene Agents

Category IA

- Do not add soap to a partially empty soap dispenser. This practice of "topping off" dispensers can lead to bacterial contamination of soap.

Category IB

- Provide personnel with efficacious hand hygiene products that have low irritancy potential, particularly when these products are used multiple times per shift. This recommendation applies to products used for hand antisepsis before and after patient care in clinical areas and to products used for surgical hand antisepsis by surgical personnel.
- To maximize acceptance of hand hygiene products by HCWs, solicit input from these employees regarding the feel, fragrance, and skin tolerance of any products under consideration. The cost of hand hygiene products should not be the primary factor influencing product selection.

Category II

- When selecting nonantimicrobial soaps, antimicrobial soaps, or alcohol-based hand rubs, solicit information from manufacturers regarding any known interactions between products used to clean hands, skin care products, and the types of gloves used in the institution.
- Before making purchasing decisions, evaluate the dispenser systems of various product manufacturers or distributors to ensure that dispensers function adequately and deliver appropriate volume of product.

Skin Care

Category IA

- Provide HCWs with hand lotions or creams to minimize the occurrence of irritant contact dermatitis associated with hand antisepsis or handwashing.

Category IB

- Solicit information from manufacturers regarding any effects that hand lotions, creams, or alcohol-based hand antiseptics may have on the persistent effects of antimicrobial soaps being used in the institution.

Other Aspects of Hand Hygiene

Category IA

- Do not wear artificial fingernails or extenders when having direct contact with patients at high risk (e.g., patients in intensive care units or ORs).

Category IB

- Remove gloves after caring for a patient. Do not wear the same pair of gloves for the care of more than one patient, and do not wash gloves between uses with different patients.

Category IC

- Wear gloves when contact with blood or other potentially infectious materials, mucous membranes, and nonintact skin could occur.

Category II

- Change gloves during patient care if moving from a contaminated body site to a clean body site.

Unresolved Issue

- No recommendation can be made regarding wearing rings in healthcare settings.

Healthcare Worker Educational and Motivational Programs

Category IA

- Monitor HCWs' adherence to recommended hand hygiene practices, and provide personnel with information regarding their performance.

Category II

- As part of an overall program to improve hand hygiene practices of HCWs, educate personnel regarding the types of patient care activities that can result in hand contamination and the advantages and disadvantages of various methods used to clean their hands.
- Encourage patients and their families to remind HCWs to decontaminate their hands.

Administrative Measures

Category IA

- As part of a multidisciplinary program to improve hand hygiene adherence, provide HCWs with a readily accessible, alcohol-based hand rub product.
- To improve hand hygiene adherence among personnel who work in areas in which high workloads and high intensity of patient care are anticipated, make an alcohol-based hand rub available at the entrance to the patient's room or at the bedside, in other convenient locations, and in individual pocket-sized containers to be carried by HCWs.

Category IB

- Make improved hand hygiene adherence an institutional priority, and provide appropriate administrative support and financial resources.

Category IC

- Store supplies of alcohol-based hand rubs in cabinets or areas approved for flammable materials.

PATIENT SAFETY

Perioperative Handwashing—cont'd

Category	Supporting Research and Evidence
IA	Strongly recommended for implementation and supported by well-designed experimental, clinical, or epidemiologic studies
IB	Strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and strong theoretic rationale
IC	Required for implementation, as mandated by federal or state regulation or standard
II	Suggested for implementation and supported by suggestive clinical or epidemiologic studies or theoretic rationale
No recommendation; unresolved issue	Practices for which insufficient evidence or no consensus regarding efficacy exists

Modified from Centers for Disease Control and Prevention: Guideline for hand hygiene in health-care settings: recommendations of the Healthcare Infection Control Practices Advisory Committee and the HICPAC/SHEA/APIC/IDSA Hand Hygiene Task Force, *MMWR* 51(RR-16), 2002, available at www.cdc.gov/Handhygiene/. Accessed January 4, 2009.

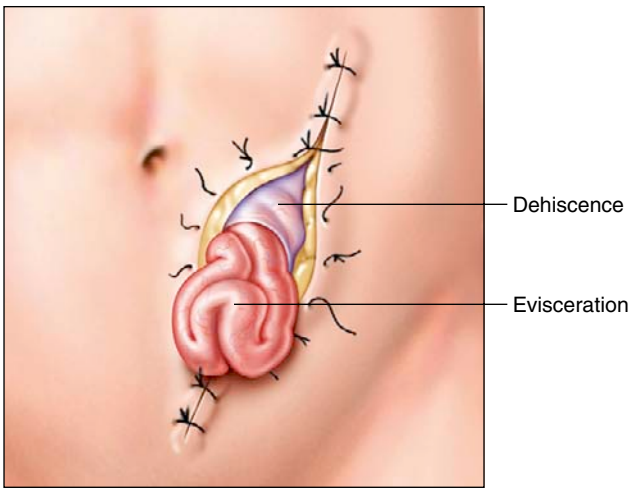

FIGURE 8-4 Complications of wound healing.

system. Clean wounds show no sign of infection. Examples are breast biopsy, total hip replacement, and open heart surgery.

Clean Contaminated Wounds (Class II)

Clean contaminated wounds are operative wounds in which the respiratory, alimentary, or genitourinary tract is entered under controlled conditions. There is no sign of infection and no break in surgical aseptic technique. Examples of clean contaminated wounds are nonperforated appendectomy, hysterectomy, and thoracotomy.

Contaminated Wounds (Class III)

Contaminated wounds are open, fresh, accidental wounds, such as penetrating trauma, open fractures, or operations with major breaks in aseptic technique. Incisions with signs of infection or gross spillage from the gastrointestinal tract also are included. Examples are a penetrating abdominal trauma involving bowel and a gunshot wound to the abdomen.

Dirty or Infected Wounds (Class IV)

Infected wounds include old, physically induced wounds with retained devitalized tissue and wounds that involve an existing clinical infection or perforated viscera. Examples are excision and drainage of abscess and delayed primary closure of a wound after appendectomy for ruptured appendix.

ANTIMICROBIAL PROPHYLAXIS

The most effective course of action in dealing with SSI is prevention. Appropriate antimicrobial prophylaxis (antibiotic administration) also is an important factor in the prevention of SSI (Evidence for Practice). Major considerations in administering prophylactic antimicrobial therapy include selecting the appropriate agent, properly timing the administration of the agent, and limiting the duration of therapy.

Proper selection of the prophylactic antimicrobial agent is based on clinical efficacy, safety, cost, and whether the agent is broad spectrum. The surgeon commonly considers the nature of the surgical procedure, noting the most common pathogens associated with it (e.g., common pathogens of the small bowel in undertaking a small-bowel resection). Cephalosporins often are used for elective clean or clean contaminated surgical procedures. For these procedures, a single dose usually is administered during the immediate preoperative period. It is important to carefully evaluate the need for antibiotics with the emergence of antibiotic-resistant microorganisms (see Chapter 3).

To enhance the effectiveness of prophylactic antimicrobial therapy, it is necessary for the optimal level of the antibiotic to be present in the tissue at the time of the incision. Equally important is the need to maintain circulating blood levels throughout some procedures. The antibiotic of choice should be administered within 1 hour before the skin incision. The anesthesia provider administers the antibiotic intravenously. If the surgical procedure is longer than the half-life of the antibiotic, another dose usually is administered intravenously during the procedure. Antibiotic therapy is usually discontinued within 24 hours; there is little evidence that ongoing administration contributes to decreased SSI rates in clean or clean contaminated procedures.

NURSING DIAGNOSES

The nursing diagnoses—Risk for Infection, Risk for Impaired Skin Integrity, Imbalanced Nutrition, Ineffective Tissue Perfusion, and Hypothermia—point the perioperative nurse toward strategies that can be used to prevent wound infections and promote healing.

EVIDENCE FOR PRACTICE

Antimicrobial Prophylaxis

A best practice based on evidence is important for improving patient outcomes. The long established practice of administering antimicrobials (i.e., antibiotics) prophylactically (antimicrobial prophylaxis [AMP]) in surgical patients is used to enhance the host defense by reducing any microbial burden that may result from surgical intervention. AMP should be viewed as an adjunct to other measures that nurses use to promote successful outcomes for their patients and can never substitute for strict adherence to aseptic technique. Optimizing AMP is a form of patient advocacy and can be maximized by understanding and implementing recommendations from the Centers for Disease Control and Prevention.

CENTERS FOR DISEASE CONTROL AND PREVENTION RECOMMENDATIONS FOR ANTIMICROBIAL PROPHYLAXIS

- Use an AMP agent for all operations or classes of operations in which its use has been shown to reduce surgical site infection (SSI) rates based on evidence from clinical trials (e.g., trauma, thoracic surgery, general surgery, head and neck procedures with incisions through the oropharyngeal mucosa, obstetrics and gynecological procedures) or for operations after which incisional or organ/space SSI would represent a catastrophe (e.g., when intravascular prosthetic materials or a prosthetic joint will be inserted, all cardiac operations including pacemaker insertion, limb revascularization).
- Use an AMP agent that is safe, inexpensive, and bactericidal with an in vitro spectrum that covers the most possible intraoperative contaminants for the operation.
- Time the infusion of the initial dose of antimicrobial agent within 1 hour before the surgery so that a bactericidal concentration of the drug is established in serum and tissues by the time the skin is incised.
- Maintain therapeutic levels of the antimicrobial agent in serum and tissues throughout the operation and until, at most, a few hours after the incision is closed in the OR. Because clotted blood is present in all surgical wounds, therapeutic serum levels of antimicrobial agents are logically important in addition to therapeutic tissue levels. Fibrin-enmeshed bacteria may be resistant to phagocytosis or to contact with antimicrobial agents that diffuse from the wound space.
- Do not use AMP for operations classified as contaminated or dirty. In such operations, patients frequently are receiving therapeutic antimicrobial agents perioperatively for established infections.

From Mangram AJ et al: *Special report: guidelines for prevention of surgical site infection,* 1999, National Centers for Infectious Diseases, Hospital Infections Programs, available at www.cdc.gov/ncidod/dhqp/pdf/guidelines/SSI.pdf. Accessed January 4, 2009.

The CMS and CDC provide SSI prevention guidelines for consideration in planning and implementing nursing interventions to optimize successful patient outcomes (Box 8-3). Attention also should be given to controlling perioperative serum glucose level in major cardiac procedures, to maintaining skin integrity through proper positioning and the use of pressure-reducing mattresses as needed (see Chapter 5), and to employing safe practices during electrosurgery (see Chapter 7). The perioperative nurse plays an essential role in the prevention of adverse events and patient injury by using intellectual and technical knowledge.

PATIENT AND FAMILY EDUCATION AND DISCHARGE PLANNING

Given that more patients are discharged from the acute care setting to the home care setting much earlier in their recovery, more surgical wound care is delivered by patients, their families, and home care providers instead of by the hospital nurse. Early planning and teaching about wound care, Standard Precautions, and medical waste disposal have become a vital part of preparing the patient to continue care after discharge (Patient and Family Education).

WOUND MANAGEMENT

A variety of treatments exist for acute and chronic wound management. Perioperative nurses often care for patients with infected wounds and are familiar with surgical wound debridement and sterile dressing changes performed under anesthesia. Patients also may come to the OR with chronic wounds being managed with a combination of surgical interventions and other treatment modalities. An understanding of adjunct wound therapies is essential to planning perioperative nursing care. These therapies include hyperbaric oxygenation (HBO), negative pressure therapy, hydrotherapy, use of engineered living skin substitutes, and the topical application of growth factors.

Debridement

Debridement is the act of removing dead and devitalized tissue from a wound. It is necessary because dead tissue in the wound provides a nidus for wound infection. Perioperative nurses often care for patients scheduled for surgical wound debridement (i.e., the sharp excision of dead or devitalized tissue). Debridement also can be accomplished through mechanical means (forceful irrigation, wet-to-dry dressings), enzymatic action (application of debriding agents containing papain and collagenase), and biologic methods (sterile maggot debridement therapy) (Ramundo, 2007). There are advantages and disadvantages to each method. Surgical debridement may not always be precise and healthy tissue may be sacrificed. Additionally, the act of surgical debridement may shower organisms into the bloodstream resulting in bacteremia. Mechanical debridement is painful and nonselective in the tissue it removes. Enzymatic debridement may be uncomfortable for the patient and may macerate surrounding tissue. Biologic debridement may not be accepted by most patients. Patients with chronic, nonhealing wounds may become well-known to the perioperative staff as they are scheduled for procedures such as debridement, grafting, flaps, and other wound coverage. Perioperative nurses play a key role in wound care and must be familiar with various wound care treatments in order to support patients throughout the course of their recovery.

Hyperbaric Oxygenation (HBO)

HBO has been used to enhance healing in problem wounds for many years. Although some form of HBO treatment for wounds has been used since 1662, the modern era of HBO use

PATIENT AND FAMILY EDUCATION

Wound Care and Dressing Changes

Although the surgeon may perform the initial dressing change after surgery, patients or their caregivers are often responsible for subsequent dressing changes and wound care. Patient compliance with wound care and dressing change techniques is important to prevent infection.

HOME CARE

Provide *written* and *verbal* instructions to the patient and the caregiver. Patients may be anxious about wound care. Provide reassurance and encouragement to the patient to bolster confidence in implementing this procedure at home. Assess the availability of dressing materials in the home setting and assist the patient with the appropriate referral if necessary to obtain the needed materials.

Warning Signs

Review the signs and symptoms that should be reported to a physician or a nurse:

- Redness, marked swelling (beyond ½ inch from the incision site), tenderness, increased warmth around the wound, or red streaks near the wound
- Temperature greater than 37.7° C (>100° F) or chills
- Purulent drainage or foul odor

Special Instructions

- Advise patients to ask the physician if bathing or showering is allowed.
- Review dressing change and wound care products with the patient and caregiver; explain the procedure and the frequency procedure should be performed.
- Emphasize the need to keep the wound dry and clean.
- Instruct patients not to remove casts and splints unless instructed to do so by the physician.
- Advise patients to assemble all supplies needed for the dressing change before starting. Explain how to maintain sterility of dressing supplies, and provide instruction on disposal of soiled dressings.
- Teach proper handwashing techniques, and instruct the patient to wash hands before changing the dressing.
- Instruct the patient to remove tape gently to avoid traumatizing the skin. Remove the old dressing and discard. Wash hands.
- Advise the patient to inspect the wound, and review the warning signs that should be reported to the physician.
- Describe how to clean the wound as ordered by the physician (i.e., with saline, povidone-iodine [Betadine], or alcohol, using cotton swabs, gauze, or other materials). Discuss how to clean around drain sites if applicable.
- Provide instruction on how to reapply the dressing, with emphasis on the order of materials used (i.e., nonadherent pad, gauze, any packing, top layer of dressing, and tape).
- Instruct the patient to wash hands after completing the dressing change.

Interventions to Reduce Swelling after Extremity Surgery

To avoid venous congestion and to enhance wound healing, advise patients recovering from extremity surgery to elevate the affected limb:

- Hand or arm
  - Sleep—elevate the arm on pillow at side
  - Sitting—place arm on pillow on adjacent table
  - Standing—rest affected hand on opposite shoulder; support elbow with unaffected hand
- Leg or foot
  - Sitting—place a pillow on the facing chair; provide support underneath the knee
  - Lying—place a pillow under affected leg

Wound Care after Suture/Staple Removal

- Remind patient that although the wound appears healed, it still may be tender and will continue to heal and strengthen for several weeks.
- Instruct the patient to keep the suture line clean; do not rub vigorously; pat dry after bathing or showering. Provide education about the appearance of the wound at this stage. Remind the patient that the wound edges still may be red and slightly raised.
- If allowed by the physician, advise the patient to massage around the wound gently using bland baby oil, petroleum, or moisturizing cream twice a day.
- Recommend that the patient report to the physician any swelling, redness, tenderness, or excessive scar thickening that persists beyond 8 weeks.

Modified from Canobbio MM: *Handbook of patient teaching,* ed 3, St Louis, 2006, Mosby.

in wound healing began in 1962 when it was used to treat gas gangrene (Frantz et al, 2007). HBO increases the capacity of blood to carry oxygen to the tissues. The increased oxygenation assists in cellular restoration, is directly bactericidal to anaerobes, and improves leukocyte migration and phagocytosis to the wound bed (Frantz et al, 2007). HBO therapy is administered in a pressurized chamber with the patient breathing 100% oxygen. Chambers may be monoplace to accommodate a single patient or multiplace to allow simultaneous treatment of multiple patients. Patients who undergo HBO therapy may require the insertion of myringotomy tubes to manage pressure changes while in the chamber. Perioperative nurses may be involved in the placement of the tubes and may be involved in wound debridement procedures for these patients.

BOX 8-3

Guidelines for Prevention of Surgical Site Infections

SSIs account for 14% to 16% of all hospital-acquired infections. An understanding of the Centers for Disease Control and Prevention guideline ranking system enables nurses to weigh factors that are viewed as effective in preventing SSIs. Category I rankings (including IA and IB) are applicable to all settings and should be adopted. Subcategories A and B differ only in the strength of supporting research and evidence. Category II rankings are supported by less research and evidence. They may be appropriate for addressing specific situations or patient populations. The Unresolved category offers no recommendation for some practices, either because little research is available to support their effectiveness or because there is no consensus regarding their efficacy. That category is not addressed here.

RANKINGS

Category	Supporting Research and Evidence
IA	Strongly recommended for implementation and supported by well-designed experimental, clinical, or epidemiologic studies
IB	Strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and strong theoretic rationale
II	Suggested for implementation and supported by suggestive clinical or epidemiologic studies or theoretic rationale

RECOMMENDATIONS

Preoperative—partial and modified

PREPARATION OF THE PATIENT

Category IA

- When possible, identify and treat infections remote to the surgical site before elective operation; postpone surgery until resolved. Do not remove hair from operative site unless necessary to facilitate surgery. If hair is removed, do immediately before surgery, preferably with electric clippers.

Category IB

- Adequately control serum blood glucose in diabetics and particularly avoid hyperglycemia perioperatively.
- Encourage cessation of tobacco use (cigarettes, cigars, pipes, chewing/dipping) 30 days before surgery.
- Do not withhold necessary blood products from surgical patients to prevent SSIs.
- Require patients to shower or bathe the night before operative procedure.
- Wash incision site to remove gross contamination before performing antiseptic skin preparation.

Category II

- Prepare skin in concentric circles from incision site.
- Keep preoperative stay in hospital as short as possible.

SURGICAL TEAM MEMBERS

Category 1B

- Keep nails short and do not wear artificial nails.
- Perform a preoperative surgical scrub/surgical hand antisepsis (hands and forearms up to the elbows) for at least 2 to 5 minutes using an appropriate antiseptic. After performing the surgical scrub/surgical hand antisepsis, keep the hands up and away from the body. Dry hands with a sterile towel, and don a sterile gown and gloves.
- Educate and encourage surgical personnel who have signs and symptoms of transmissible infections to report conditions promptly to supervisory personnel.
- Develop well-defined policies concerning patient care responsibilities when personnel have potentially transmissible infectious conditions.
- Do not routinely exclude surgical personnel who are colonized with organisms such as *S. aureus* or group A streptococcus, unless such personnel have been linked epidemiologically to dissemination of the organism in the healthcare setting.

Category II

- Clean underneath each fingernail before performing the first surgical scrub of the day.
- Do not wear hand or arm jewelry.

POSTOPERATIVE INCISION CARE

Category IB

- Protect with a sterile dressing for 24 to 48 hours postoperatively incisions that have been closed primarily.
- Wash hands before and after dressing changes and any contact with the surgical site.

Category II

- When an incision dressing must be changed, use sterile technique.
- Educate the family regarding proper incision care, symptoms of SSI, and the need to report such symptoms.

Modified from Mangram AJ et al: *Special report: guidelines for prevention of surgical site infection,* 1999, National Centers for Infectious Diseases, Hospital Infections Programs, available at www.cdc.gov/ncidod/dhqp/pdf/guidelines/SSI.pdf. Accessed February 9, 2009.

Negative Pressure Wound Therapy

Also known as vacuum-assisted closure (VAC), negative pressure wound therapy (NPWT) is used for difficult-to-manage wounds that do not respond to traditional wound care methods. This treatment may be associated with health cost savings (Research Highlight, p. 261). Negative pressure wound therapy works by using a device to apply constant controlled negative pressure to a wound that is filled with a drainage sponge and sealed with an occlusive dressing. The VAC system has three main mechanisms of action that promote wound healing. First, negative pressure results in mechanical tension on the tissues, causing the development of new blood vessels, mitosis, and dilation of the arterioles; at the same time, pressure produces a centripetal force that helps to pull the wound edges together. Second, VAC therapy promotes evacuation of excess wound fluid, such as the interstitial fluid that accumulates in a wound and prevents the circulatory and lymph systems from delivering nutrients and oxygen. Third, negative pressure reduces bacterial colonization in the wound bed. Stagnant exudates are eliminated, stunting bacterial growth and proliferation (Thompson and Marks, 2007). VAC therapy may be used for acute and traumatic wounds, subacute wounds, pressure ulcers, chronic open wounds, meshed skin grafts, and skin flaps. The therapy is

RESEARCH HIGHLIGHT

Vacuum-Assisted Wound Care and Economics

The cost of managing chronic wounds, particularly wounds resulting from complications related to diabetes, is staggering and remains a challenge for practitioners as they try to balance the patient's needs with available resources and hospital utilization. This randomized study compared wound treatment using either negative pressure wound therapy or moist wound therapy to determine the direct economic costs and resource utilization for patients with diabetic foot wounds.

Patients with partial foot amputation wounds up to the transmetatarsal level were enrolled into this 16-week, multicenter randomized clinical trial. A total of 162 patients participated in the study; 77 were randomized to the group receiving negative pressure wound therapy using a vacuum-assisted closure device and 85 patients received moist wound therapy using alginates, hydrocolloids, foams, or hydrogels. Each group received no less than three dressing changes a week. The wounds were treated until healed or until completion of the study period (112 days).

The researchers calculated resource utilization and direct costs using data from patient records and Milliman's Health Cost Guidelines. Costs included inpatient care, antimicrobial agents, outpatient visits, surgical procedures, and dressing supplies. The average cost of total direct care per patient treated for 8 weeks or longer was $27,270 in the negative pressure wound therapy group and $36,096 in the moist wound therapy group.

The study substantiated the hypothesis that the treatment of complex diabetic foot wounds is a major factor contributing to healthcare costs. Negative pressure wound therapy appears to be a comparatively cost-effective means of managing diabetic foot wounds.

Modified from Apelqvist J et al: Resource utilization and economic costs of care based on a randomized trial of vacuum assisted closure therapy in the treatment of diabetic foot wounds, *Am J Surg* 195:782-788, 2008.

FIGURE 8-5 The VAC pump.

contraindicated if blood vessels, nerves, bones, or organs are exposed and in the presence of necrotic tissue with eschar, a malignancy in the wound edges, untreated osteomyelitis, peripheral vascular disease, or fistulas to organs or body cavities (Bonham, 2009).

The negative pressure unit may be applied in the OR after wound debridement. All nonviable tissue must first be removed to reduce bacterial load in the wound bed. The skin area around the wound is dried and specialized reticulated foam is cut to fit the wound bed, including all tunnels and tracks. The surgeon must be careful not to overfill the wound with the sponge because this could cause further mechanical trauma. When the sponge is in place, the surgeon covers the entire sponge, wound bed, and surrounding skin with a transparent occlusive drape, taking care to seal the edges completely. A 2-cm or greater edge of intact periwound skin must be available to ensure an airtight seal of the dressing. A 2-cm cut is made through the occlusive dressing into the sponge for insertion of the drainage tube, which has side and end ports. The tubing is connected to a VAC pump (Figure 8-5). A portable, battery-operated unit also is available for more ambulatory patients. A canister collects the fluid and exudate. The pump cycle may be used on a continuous or intermittent setting. For best results, the patient must use the unit at least 22 hours a day (Thompson and Marks, 2007).

Hydrotherapy and Hydrosurgery

Traditionally hydrotherapy is undertaken via immersion in a whirlpool tank or tub. The mechanism of agitated water and injected air is thought to dilute bacterial loads and remove debris, while increasing circulation to the area. Because immersion in a tank is not practical from an intraoperative perspective, the hydrotherapy method most frequently used in the OR is pulsatile lavage. Manufacturers provide a variety of systems to deliver pulsatile lavage. Most systems consist of a motor that creates pressure within a tubing set to allow the delivery of fluid at 10 to 15 psi through a handpiece to the wound bed. The handpiece is equipped with a splash shield to help concentrate the spray and minimize droplet aerosolization of the irrigant. While the system is delivering the fluid, it simultaneously suctions it to remove debris and bacteria. Standard Precautions must be observed by all healthcare team members while using pulsatile lavage and the patient should be protected from aerosolization.

Hydrosurgery is a form of wound debridement that utilizes a powered handpiece system with narrow nozzle through which pressurized saline (up to 15,000 pounds psi) is used to excise necrotic tissue. The highly pressurized force creates a suction effect that allows the surgeon to remove devitalized tissue through the handpiece while preserving the healthy tissue (Knox et al, 2007; Stojadinovic et al, 2008) (Research Highlight, p. 262).

Skin Substitutes

A more recent technology for the treatment of wounds is the use of an engineered skin substitute. The skin substitute stimulates wound epithelialization and is capable of producing growth factors. The skin substitute may be used in lieu of a split-thickness skin graft for wound coverage. Skin substitutes are not permanent solutions in most cases, but are a bridge to permanent closure with skin grafts or granulation tissue. Skin substitutes are formed by placing human cells

RESEARCH HIGHLIGHT

Hydrosurgical Wound Debridement

Surgeons use many techniques to manage wounds and to prepare wound beds for healing or closure, including the use of pressurized fluid delivered via a bulb syringe or pulsed lavage. These hydrosurgery methods have limitations in terms of effectiveness of tissue removal and increased exposure of the patient and surgical team to droplet aerosolization or splashing from irrigant use. Newer hydrosurgery technology allows surgeons to remove devitalized tissue via the Versajet™, a commercially available system that pressurizes an irrigant via a disposable handpiece. As the irrigant is forced through the handpiece, a localized vacuum is created and the dissected tissue is suctioned.

Surgeons used the Versajet hydrosurgery system to prepare wound beds in 16 patients ages 35 to 80 years with a variety of wounds (e.g., necrotic, burns, traumatic, diabetic). The authors reported that the system was more selective in tissue removal and allowed them to perform a single wound debridement in many cases instead of multiple debridement sessions using traditional sharp dissection. Although a comparative analysis was not conducted, the authors stated anecdotally that the speed of the system over traditional methods saved operating time, and they estimated the time per debridement procedure was approximately 15 minutes. Other advantages included decreased bleeding (which decreased the need for electrocoagulation and thermal tissue damage), improved wound visibility, decreased tissue edema, removal of tissue in layers, and subjective patient reports of decreased pain. Formalized studies remain necessary to substantiate the authors' findings.

Modified from Pascone M et al: Use of a novel hydrosurgery device in surgical debridement of difficult-to-heal wounds, *Wounds* 20(5):139-146, 2008.

onto matrices that are collagen or synthetic based. As the cells grow and divide, they secrete growth factors and other useful substances to help build a foundation for healing. The substitutes are formed into a variety of shapes and sizes to facilitate wound coverage. They also may be used to cover donor sites from skin graft harvesting. Table 8-1 summarizes the actions and uses for some commonly available commercial skin substitutes. Advantages to using skin substitutes include ready commercial availability, effective wound contracture management, decreased risk of donor area morbidity, provision of long-term coverage of the wound, and compatibility with autologous tissues (Evans, 2007).

Growth Factors

Growth factors are naturally occurring proteins (cytokines and peptides) that are signaling molecules that stimulate cycles of mitosis of fibroblasts and epidermal cells, smooth muscle cells, and vascular endothelial cells. Human or recombinant growth factors may be applied to wounds in the OR, but are more typically administered in the clinic setting. Growth factors initiate wound healing by accelerating the formation of granulation tissue and work most effectively in the proliferative phase of wound healing. They improve the cellular or molecular environment of the wound and signal target cells to begin tissue repair. Growth factors generally are categorized by their source (i.e., if obtained from platelets, they are designated as platelet-derived growth factors [PDGFs]; from the epidermis, epidermal growth factor [EGF]). To obtain PDGFs, typically 50 to 200 ml of venous blood is withdrawn. The platelets are separated and activated with thrombin to make a gel that is applied to a clean wound bed. The wound is covered with a nonadherent gauze dressing that remains in place for 12 hours (Panuncialman and Falanga, 2007).

TABLE 8-1

Skin Substitutes

Name	Description	Use/Application
Biobrane	Porcine collagen-coated nylon mesh is bonded to a silicone rubber membrane.	Donor sites and partial-thickness wounds
Dermagraft	Single layer; contains cultured fibroblasts on cultured synthetic matrix. Provides cells and growth factors to wound.	Approved only for use in diabetic foot ulcers
TransCyte	Two-layer product. Outside layer is semipermeable and synthetic, allowing fluid and gas exchange and promoting a moist healing environment. Inner layer is a bioengineered cell matrix that adheres quickly to wound surfaces.	Superficial to mid–partial-thickness burns, temporary coverage of excised burns
Apligraf	Living, two-layer product. Inside layer combines bovine type I collagen with human fibroblasts to produce matrix proteins. Outside layer stimulates epidermal cells to replicate.	Widely used for wounds of ankle and foot; also used to treat donor sites and surgical excisional wounds
AlloDerm	Cadaver-donated product is processed to remove all epidermal and dermal cells while leaving cellular matrix intact.	Can be used on large areas; comes in large sheets
Oasis	Made from porcine small intestinal submucosa. Consists of naturally occurring growth factors and collagen.	Superficial burns, donor sites
Integra	Two-layer dressing consisting of dermal layer and epidermal layer. Inner, dermal layer is composed of bovine tendon collagen and synthetic chondroitin 6-sulfate. As healing progresses, inner layer degrades. Outer layer is a synthetic material (silicone) that serves to control moisture loss from the wound.	Useful in burn coverage

Modified from www.burnsurgery.org. Accessed January 4, 2009; Tenenhaus M, Rennekampff HO: Burn surgery, *Clin Plast Surg* 34(4):697-715, 2007.

DRESSINGS

Application of surgical dressings is often the responsibility of the perioperative nurse (History box). The dressing may serve one or more of the following purposes:

- Cushioning and protection of the wound from trauma and gross contamination
- Absorption of drainage
- Debridement of the wound
- Support, splinting, or immobilization of the body part and incisional area
- Assistance in hemostasis and minimization of edema and dead space, as in a pressure dressing
- Promotion of the patient's physical comfort and aesthetic appearance
- Maintenance of a moist environment and prevention of cell dehydration
- Application of medications

Dressings are selected based on the characteristics of the surgical site, depth, and area, and the patient's overall condition (Table 8-2). Questions to ask when choosing a dressing are as follows:

- What does the wound need?
- What is the purpose of the product?
- How well does the product function?
- What does the patient need?
- What is available?
- What is practical?

Dressings can be grouped into two main categories: primary and secondary dressings. *Primary* dressings are placed directly over or in the wound. A variety of primary dressing materials are available on the market today. The function of these dressings is to absorb drainage and then wick it away from the wound edge. Cotton gauze or synthetic dressings may be used for this purpose. The layer of primary dressing directly contacting the wound should be nonadherent, unless debridement is desired.

Secondary dressings are placed directly over the primary dressing. These function to absorb excessive drainage, provide hemostasis by compression, and protect the wound from further trauma. These functions usually are accomplished with a bulky dressing, such as an abdominal pad. These pads have a cotton filling that provides extra absorbency.

Dressings may be secured with a variety of products, including tape, Elastoplast®, ACE bandages, or soft roll products. Tape is available with a variety of backing materials (cloth, paper, taffeta, plastic) and with regular or nonallergenic adhesive. The strength and elasticity required, patient allergies, the condition of the patient's skin, and anticipated frequency of dressing change determine which type is selected. When applying tape to the dressing, the perioperative nurse should apply pressure evenly from both sides of the tape and away from the direction of the incision. Applying tape with excessive pressure may result in stretching and trauma to the skin. The tape should cover the edges of the dressing and be placed at right angles to the direction of motion when applied over a joint. When frequent dressing changes are anticipated, Montgomery straps can be selected to secure the dressing (Figure 8-6). When compression of the wound for hemostasis or reduction of edema is desired, a polyurethane dressing, elastic tape, or elastic bandage may be used to secure the secondary dressing.

HISTORY

A Historical Look at Dressing Materials

One of the duties of the perioperative nurse in the early 1900s was to manufacture, sterilize, and maintain bandages and drains. Typical classifications of bandages were roller bandages, compound bandages (e.g., many-tailed bandages and slings), immobilizing bandages (e.g., gauze rolls impregnated with plaster, paraffin, or starch), and pressure bandages.

Roller bandages were made from muslin, crinoline, flannel fabric, or gauze. Pressure and occlusive bandages were made from India-rubber cloth. To make roller bandages from muslin, crinoline, or flannel, the nurse obtained 4 to 6 yards of uncut fabric and washed it first in a hot saline solution. When the fabric dried, it was cut to the desired width and rolled by hand or on a bandage-rolling machine operated by a foot treadle. An expedited method of making multiple roller bandages was to roll the entire length of fabric without cutting it into individual strips and place it into a carpenter's miter box, later cutting the desired width with a bread knife. Roller bandages were steam sterilized and wrapped in paraffin-coated paper. This paper was made by spreading paper over a flat surface, pouring wax on it, and ironing it evenly with a flat iron. Compound dressings (e.g., the scultetus binder) were cut and sewn by hand. The nurse made immobilizing bandages by manually applying plaster of paris to crinoline strips and placing the rolled bandage in an airtight metal container. India-rubber cloth and other rubber goods were maintained in drawers dusted with powdered sulfur. To prepare drains, the nurse obtained the desired length and diameter of tubing from the rubber goods drawer, scrubbed the drain in soap and water, rinsed the drain, and then boiled the drainage tube in a solution of 1% carbonate of soda for 1 hour. The drain was removed and sealed in a jar containing a solution of normal saline and carbolic acid. The solution in the jars was changed once a week. Any fenestrae or other modifications were made at the time of use. Cigarette drains were made by impregnating four 9-inch lengths of lamp wicking with antiseptics, such as iodoform powder, zinc oxide powder, carbolic crystals, resin, or castor oil, and enclosing the bundle in green silk or rubber tissue stitched in place.

To apply muslin bandages, the nurse saturated the bandage in warm water to enhance the patient's comfort and wound the bandage in a circular, figure-of-eight, or spiral fashion to cover the affected area. Muslin roller gauze was used to bandage all parts of the body. When the bandage was complete, the nurse secured it by sewing it closed, fastening it with safety pins, or knotting the tails. Removal of the bandage was accomplished by unrolling the muslin instead of cutting it, to facilitate disinfection and reuse.

Modified from Fowler FS: *The operating room and the patient,* ed 3, Philadelphia, 1913; Saunders, Witkowski JA, Parish LC: Occlusive therapy in historical perspective, *Int J Dermatol* 37:555-558, 1998.

Immobilization is accomplished with the addition of soft padding, elastic bandages, splints, and casting materials (splints and casts are discussed in greater detail in Chapter 19).

In some situations, the wound is not dressed at all. An undressed wound that heals by exposure to air has the following advantages: (1) allows for optimal observation of the incisional area, (2) aids bathing, (3) prevents possible adhesive-tape reactions, (4) increases comfort and maneuverability for many patients, and (5) seems to minimize adverse responses by the patient to the operation.

TABLE 8-2

Comparing Wound Dressings

Products*	Advantages	Disadvantages	Nursing Considerations
COTTON MESH GAUZE	Low cost, readily available	Woven forms may leave lint in wound	Can be used as wet-to-dry dressing for wound debridement and granulation
Woven and nonwoven	Wicks away moisture	May dry out	Frequent dressing changes may be needed if gauze dries out
	Can be used for mechanical debridement	Nonwoven not as effective as woven for debridement	May be used with saline and amorphous gels to keep moist
NONADHERENT DRESSING	Less traumatic for patient	Poor absorption of fluids	*Nonimpregnated* can be used as primary or secondary dressing
Nonimpregnated: Telfa		Impregnated form cannot be used as primary dressing	Useful for donor sites, skin grafts
Impregnated: Adaptic, Scarlet Red, Vaseline Gauze, Xeroform		Impregnated form may cause maceration if left on wound for prolonged period	
TRANSPARENT FILMS	Resistant to shearing and friction	Cannot absorb exudate, which may lead to maceration	May wrinkle on application
Bioclusive, Opsite, Tegaderm	Conform well to irregular surfaces Wound is easily monitored through film May be more cost-effective because of decreased frequency of dressing change	Exudate may leak through seal	Use with caution on fragile skin
HYDROCOLLOID	Insulates and cushions	May melt and leave residue in wound	Should not be used in presence of infection because of occlusive properties
Comfeel, Sorbex, DuoDerm, Tegasorb	Available in a variety of sizes and forms	May bunch or wrinkle at edges	Need 1- to 2-in. border of intact skin beyond wound to seal edge of dressing
	Useful on all stages of wounds	May not adhere well to irregular shapes or contours	Can be used as a primary or secondary dressing
	Adheres in presence of moisture	May be bulky	May react with wound proteins and develop an odor that can be mistaken for infection
HYDROGEL	Can be used to fill shallow wounds and cavities	Excessive application can lead to maceration	Should be applied to wound surface only
Carrasyn, Solosite Gel, Tegagel, Vigilon, Nu-gel, Curagel	Cooling, soothing action may decrease painMay be used to rehydrate wounds	May be difficult to keep in shallow wounds	Viscosity varies among products Compatible with a variety of medications, so can be used as a carrier for antibiotics
ALGINATES	Highly absorbent	May cause burning sensation for patient	Available in pastes, pads, ropes, powders, starches
Algiderm, Algosteril, Curasorb, SeaSorb, Kaltostat, Sorbsan	Useful for increased levels of exudates	Requires secondary dressing	Product swells, so apply lightly in cavities and undermined areas
	Moisture retentive	Easily dislodged by mechanical force	Saturate with saline for removal if dried
FOAM	Highly absorbent	Contraindicated for desiccated wounds	Dressing should be 2-3 cm larger than wound
Lyofoam, Curafoam, Allevyn, Flexzan, BioPatch, VigiFOAM	Helps contain exudates	Leakage may occur if not covered with waterproof protection	Use with packing in undermining, tunneling wounds

TABLE 8-2—cont'd

Comparing Wound Dressings

Products*	Advantages	Disadvantages	Nursing Considerations
FOAM, cont'd	Can be left in place for 7 days Comfort for patient		Available as pads, sheets, or rolls
SILICONE	Easy to apply, reusable	May adhere to itself	May be used to reduce pain when wound vacuum system is used
Cica Care Adhesive Silicone Gel Sheet, Mepiform, Oleeva	Variety of sizes, promotes scar reduction	Can be difficult to apply	Marketed to consumers as a way to reduce scar formation
COLLAGEN	May accelerate wound repair	May have unpleasant odor	Requires a secondary dressing
Fibracol Plus, Promogran Cellerate, Biostep, Catrix, ColActive, Collieva, Biopad	Effective in recalcitrant wounds		Available in gels, pastes, pads, powder Source is equine, bovine, porcine, or avian collagen
COMPOSITES	Thin, nonadherent attached adhesive	Not recommended for heavily draining wounds	May be used as primary or secondary dressing
Alldress, Primapore, OpSite Post-Op, DermaSIL			One-hand application in some cases Use with caution with fragile skin

*NOTE: The products included here are representative of what is available and are not meant to be inclusive.

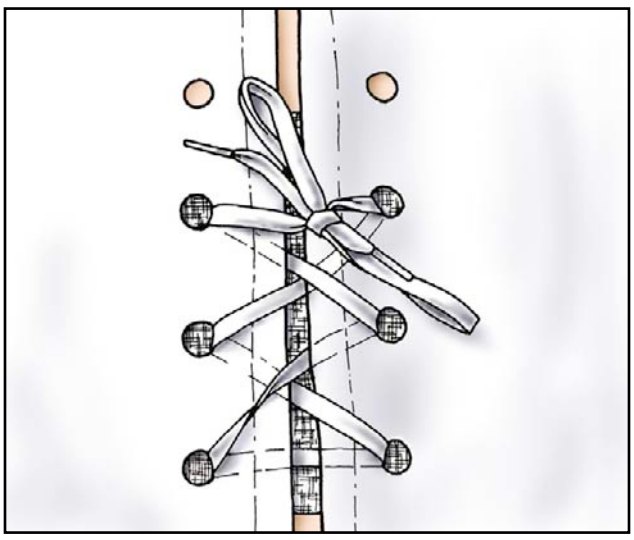

FIGURE 8-6 Montgomery straps.

DRAINS

Drains control ecchymosis and provide exits through which air and fluids, such as serum, blood, lymph, intestinal secretions, bile, and pus, can be evacuated from the operative site. Drains also may be used to prevent the development of deep wound infections. They usually are inserted at the time of surgery, primarily through a separate small incision known as a *stab wound,* close to the operative site. Drains may or may not be sutured to the skin.

In some instances (e.g., chest, common bile duct, bladder), drainage is directly through the lumen of the tube (as with a Foley retention catheter) or via perforations or fenestrations in the tubing into a closed drainage system. In other instances (e.g., peritoneal cavity or skin wound), drainage of pus or blood is primarily along the outside surface of the drain by capillary action and gravity (as with the simple Penrose drain) into a dressing. The selection of a simple versus a closed drainage system depends on the needs of the site to be drained, patient activity, and overall healing capability. Many types of drains are available. The most common are made of latex, polyvinyl chloride (PVC), or silicone (Figure 8-7). Particular care should be taken to ensure that the patient is not allergic to latex when considering any latex drain. For many wounds, a portable, self-contained, closed wound suction unit is selected. These units create a negative pressure in a reservoir attached to the drain. Fluid is gently drawn out of the wound and collected in the reservoir.

The perioperative nurse must document clearly on the operative record the location and type of drain and ensure the drain is working properly before the patient leaves the OR. This information is important to nurses caring for the patient in the postanesthesia and postoperative nursing units. Some wounds yield significant drainage and must be monitored closely during the postoperative course. A disadvantage of wound drains is that they create a portal for entry and exit of infectious microorganisms. Extreme care must be taken in emptying drain reservoirs to avoid contamination. Closed autologous drains allow for collection of blood from a surgical wound and the return of that blood to the patient; this minimizes the need for transfusion of blood from outside donors, reducing the risk of bloodborne pathogen transmission.

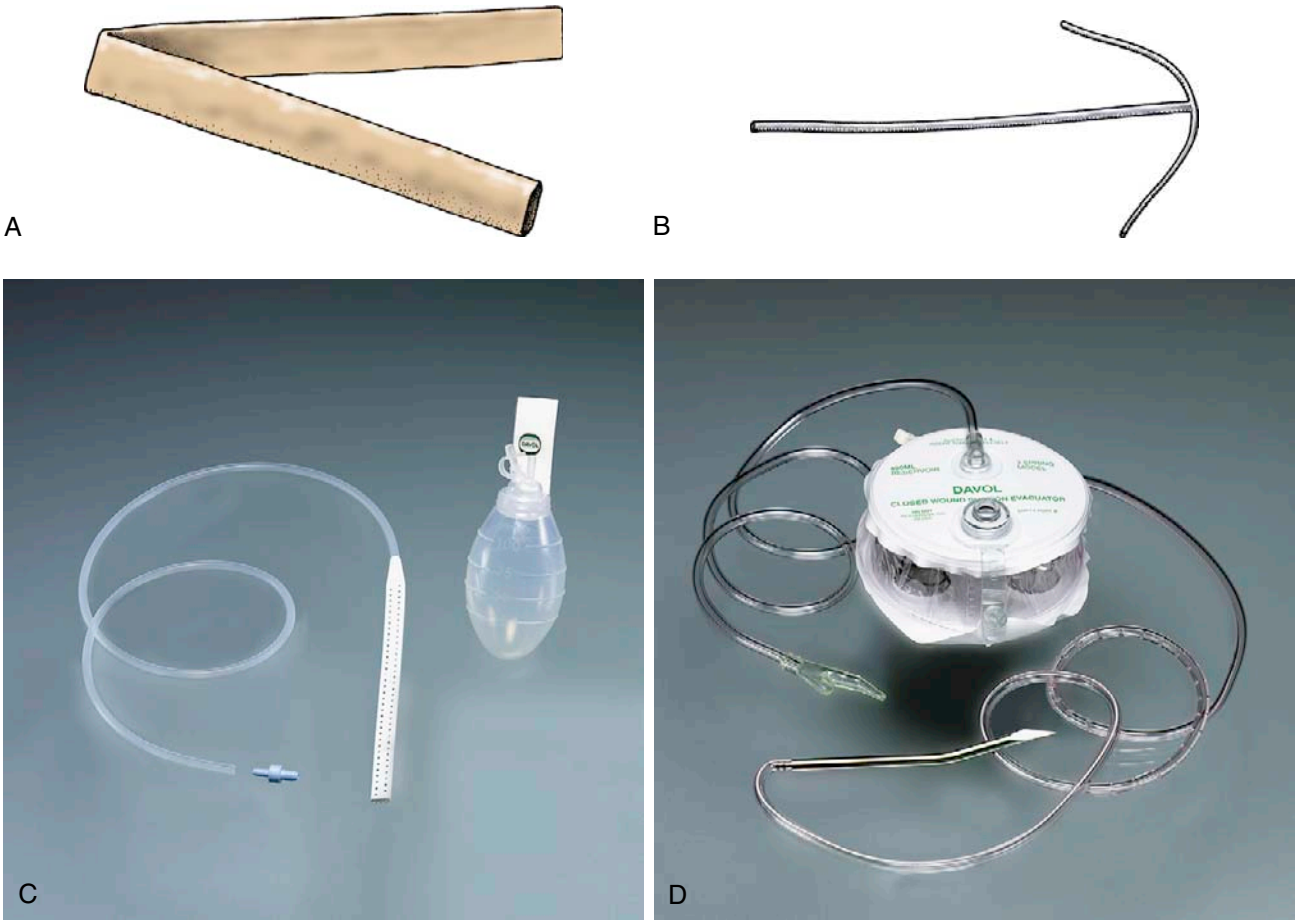

FIGURE 8-7 Drains are available in a variety of styles. Pictured are Penrose (**A**) and T-tube (**B**), which drain by gravity, and Jackson Pratt (**C**) and Hemovac (**D**), which represent closed drainage systems.

CHAPTER 9

Postoperative Patient Care and Pain Management

JAN ODOM-FORREN

The postoperative phase of care begins as soon as the surgical procedure concludes and the patient is transferred to the postanesthesia care unit (PACU). The PACU, in the past, was called the *recovery room* or *postanesthesia room*. In 1863 Florence Nightingale first described a postanesthesia area this way: "It is not uncommon, in small country hospitals, to have a recess or small room leading from the operating theater in which the patients remain until they have recovered, or at least recovered from the immediate effects of the operation" (History box).

An assigned area for the care of the postoperative patient is a relatively recent addition to surgical patient care. Although surgical procedures have been performed for thousands of years, and general anesthesia has been available for almost 150 years, PACUs became common only in the past 30 to 40 years. A few recovery rooms were opened in the 1920s and 1930s. In the 1940s numerous PACUs opened because of the shortage of nurses during the war years and the need to centralize patients, equipment, and personnel for postoperative care. Hospitals soon realized that use of the PACU decreased patient morbidity and mortality and shortened the stays of some patients (Ruth et al, 1947). Many hospitals opened PACUs after this discovery was reported.

PACUs have since flourished. Technologic innovation has profoundly affected PACUs, as in other critical care areas. The complexity of anesthesia management demands specially trained nurses who have expertise in the prompt recognition and management of postoperative complications. Most patients who receive general anesthesia, major regional anesthesia, or monitored anesthesia care are transferred to the PACU. PACU is considered postanesthesia phase I—where the patient transitions to phase II (preparation for discharge home [Ambulatory Surgery Considerations]), an inpatient setting, or a critical care unit (ICU or CCU) (ASPAN, 2009a).

PACUs should be adjacent to the surgical suite with easy access for patient transport. The patient's status should be assessed for needs during transfer (e.g., oxygen, manual positive-pressure ventilation device, a bed instead of a stretcher).

A perioperative nurse accompanies the patient to the PACU with an anesthesia provider and gives a hand-off report on the status of the patient to a perianesthesia nurse. A PACU nurse assumes care of the patient after initial assessment of the patient and report from the transferring team.

PERIANESTHESIA CONSIDERATIONS

Assessment

Admission to the PACU. Initial assessment of the postoperative patient begins with an immediate determination of airway and circulatory adequacy. The airway is assessed for patency, humidified oxygen applied, and respirations counted. Pulse oximetry is initiated on all patients, and the quality of breath sounds determined. The PACU nurse connects the patient to the cardiac monitor, and evaluates rate and rhythm. Blood pressure is measured by means of a manual cuff or an automatic cuff (e.g., a Dinamap). If the patient has an arterial line, the PACU nurse connects it to the monitor.

After the PACU nurse assesses the *ABCs* (*a*irway, *b*reathing, *c*irculation), the perioperative nurse and anesthesia provider give a comprehensive hand-off report. The 2009 Joint Commission (TJC, 2009) *National Patient Safety Goals* (NPSGs) emphasize a standardized approach to hand-off communication that includes the opportunity to ask and respond to questions (Risk Reduction Strategies). Standardization of how information is communicated assures that the information will be accurate and complete. The perioperative nurse should collaborate, adding and verifying important patient information. Box 9-1 includes suggestions on what each surgical team member should report.

The American Society of PeriAnesthesia Nurses (ASPAN) (2009a) recommends that the hand-off report contain the following elements:

- Relevant preoperative information, such as vital signs and temperature; radiologic findings; laboratory values; oxygen saturation; allergies (including latex); medication use/last dose; NPO status; disabilities; substance abuse; mobility limitations; prostheses; sensory limitations (including hearing and visual aids); and, for pediatric patients, birth history, developmental stages, gestational age, and parent/child interactions
- Anesthesia technique and agents administered
- Length of time anesthesia was administered and time reversal agents were given
- Type of operative or other invasive procedures performed
- Estimated fluid or blood loss, and replacement therapy
- Complications occurring during anesthesia, treatment initiated, and patient responses
- Emotional status on arrival in the OR or procedure room
- Pain and comfort management interventions and plans

HISTORY

The Evolution of the PACU

Separate care for postsurgical patients can be dated to 1751, when New Castle Infirmary, in New Castle, England, reserved rooms for dangerously ill or major surgery patients. In 1863 Florence Nightingale suggested separate rooms for patients to recover from the immediate effects of anesthesia. During the twentieth century, the complexity of surgeries increased in direct relation to technical discoveries. The number of recovery units gradually grew, especially after their value became clear. The Anesthesia Study Commission of the Philadelphia County Medical Society reported in 1947 that one third of preventable postsurgical deaths during an 11-year period could have been prevented by improved postoperative nursing care. In 1949 the Operating Room Committee for New York Hospital noted that adequate recovery room service was necessary for any hospital that provided surgical services. By the 1970s "recovery rooms" were managing routine postanesthesia patients as well as critically ill postanesthesia patients receiving respiratory and circulatory support. Today, recovery rooms are known as *postanesthesia care units (PACUs)* and sometimes, because of space constraints and cost containment, PACU nurses also manage the care of overflow intensive care unit/telemetry patients or provide space for procedures such as pain management or insertion of central lines.

Modified from Odom-Forren J, Clifford T: The evolution of perianesthesia nursing. In Schick L, Windle P, editors: *Perianesthesia nursing core curriculum: preoperative, phase I and phase II PACU nursing,* St Louis, 2009, Saunders.

AMBULATORY SURGERY CONSIDERATIONS

Important Education Information for Patients Who Are Discharged from Phase II Recovery to Home

- Anesthesia
  - Advise patient of common side effects: dizziness and drowsiness, have assistance if needed; sore throat; post discharge nausea and vomiting.
  - For the next 24 hours the patient should not drive or operate machinery, drink alcohol, or sign important papers, and a responsible adult should stay with the patient.
- Activity limitations
  - Advise patient to go home and rest for next 24 hours. Inform patient of any limits to activity because of procedure (e.g., no sexual activity for 4 weeks, no lifting of objects that weigh more than 10 pounds).
- Diet
  - Instruct patient how to progress to regular diet, or give instructions to patient detailing specific diet required because of procedure.
- Safety concerns
  - Review preparation of home for patient return (e.g., removal of rugs that increase fall risk, sleeping area close to bathroom).
- Medications
  - Discuss new take-home medications or prescriptions. Document last dose of medication on patient's written instructions if given before discharge.
  - Discuss resumption of home medications. Physician should have noted which home medications the patient is to continue after discharge.
  - Instruct the patient to take the medication with food (unless contraindicated) to decrease stomach irritation.
  - Discuss the use of acetaminophen or ibuprofen if the patient has no pain medication ordered (unless contraindicated).
  - Advise patient not to take acetaminophen if taking pain medications that include acetaminophen as an ingredient.
- Surgical procedure
  - Discuss any information that pertains to specific procedure (e.g., when to remove dressing, when to resume showers or baths, ice at site, weight-bearing restrictions).
- Bowel habits
  - Increase dietary fiber and fluids.
  - Use stool softener if needed.
- When to call the healthcare provider
  - Fever greater than 101° F orally
  - Pain that becomes worse or is not relieved by pain medication
  - Bleeding that is unexpected
  - Warmth, redness, or swelling at the operative site
  - Evidence of pus
  - Unable to eat or drink by day after discharge
  - Persistent nausea and vomiting
  - Unable to void
- Follow-up care
  - Instruct patient about next appointment with physician or ascertain that appointment is already scheduled.
  - Give patient telephone number for physician's office.
  - If applicable, give patient telephone number of ambulatory surgery center.
- Home procedures
  - If patient requires procedures at home such as dressing change or emptying drainage reservoir, ascertain that responsible adult has received instructions and given a return demonstration of action.
- Written instructions
  - All discharge instructions should be in writing and given to the patient, including all the pertinent information included above, specific information about any new medication, and a list of home medications that physician requests be continued or discontinued.

The patient's American Society of Anesthesiologists (ASA) physical classification status (see Chapter 4) also should be provided during the hand-off report. Useful information that the perioperative nurse can also provide includes airway status and presence of tubes, drains, catheters, and intravascular lines. Any postoperative orders to be initiated in the PACU are discussed at this time.

The anesthesia provider should not leave the patient until the PACU nurse accepts responsibility for the patient's care. Standard III-3 of the ASA's *Standards for Postanesthesia Care*

RISK REDUCTION STRATEGIES

Patient Hand-Off

The *2009 National Patient Safety Goals (NPSGs)* from The Joint Commission (TJC) identify "Improve Communication" as Goal 2. The goal addresses specific ways of handling verbal or telephone orders including "reading back" the complete order or test result. Goal 2 also requires that each healthcare facility have in place a standardized list of abbreviations, acronyms, symbols, and dose designations that are not approved for use in the facility. Important to the PACU is that the organization implement a standardization approach to hand-off communications, including an opportunity to ask and respond to questions (TJC, 2009; Saufl, 2009). Ineffective communication is the most frequently cited root cause for sentinel events (TJC, 2009). Communication must be timely, accurate, complete, unambiguous, and understood by the recipient to be effective and reduce risk to the patient.

Any patient hand-off from the surgical team (anesthesia provider, surgeon, perioperative nurse) to the PACU nurse should include the following:

1. Interactive communication that allows the PACU nurse an opportunity to question the person giving the report.
2. Up-to-date information regarding the patient's condition, care, treatment, medications, services, and any recent or anticipated changes.
   a. Consider a policy that specifies information required in each report based on current standards and guidelines.
3. An opportunity for the PACU nurse to review relevant patient historical data, which may include previous care, treatment, and services.
   a. Anesthesia provider is not to leave the bedside until the PACU nurse accepts responsibility for the patient's care.
4. Interruptions during hand-offs are limited to minimize the possibility that information fails to be conveyed or is forgotten.
   a. Surgical team should not answer pagers, telephones, or otherwise cause interruption or distraction during the hand-off.
   b. The PACU nurse will limit interruptions or distractions during hand-off to emergencies.
   c. The PACU environment should be conducive and supportive of uninterrupted time during hand-off.
      (i) Consider adding a signal in the PACU to alert other nurses that a hand-off is in progress.

Adapted from The Joint Commission: *2009 National Patient Safety Goals Hospital Program,* available at www.jointcommission.org/patientsafety/nationalpatientsafetygoals/09_hap_npsgs. Accessed July 9, 2009; Saufl NM: 2009 National Patient Safety Goals, *J Perianesth Nurs* 24:114-118, 2009; Martin LB: Enhanced communication protects patients, *Breathline* 28(1):13, Jan/Feb 2008.

(ASA, 2004) states, "the member of the anesthesia care team shall remain in the PACU until the PACU nurse accepts responsibility for the nursing care of the patient."

Initial Assessment. After the immediate assessment of the ABCs and completion of the hand-off report, the PACU nurse begins a more thorough postanesthesia assessment. The assessment is performed quickly and is specific, in part, to the type of operative procedure. Recommended elements of an initial assessment in the PACU are presented in Box 9-2.

BOX 9-1

Suggestions on Content for Hand-Off Report from Anesthesia Provider and Perioperative Nurse

ANESTHESIA PROVIDER MAY REPORT:

- Patient name, allergies, surgical procedures performed
- Pertinent medical and/or surgical histories
- Current medications
- Anesthetic delivered
- Medications administered
- Regional anesthetic used
- Intraoperative course (anesthesia-related)
- Lines, fluids, losses; the anesthesia provider may include estimated blood loss (EBL) in the hand-off report to the PACU nurse. In some institutions, a surgical Apgar score is calculated at the end of the surgical procedure from the EBL, lowest mean arterial pressure (expressed in mm Hg), and lowest heart rate rhythm recorded on the anesthesia record during the procedure. The score may be used to identify patients with a higher likelihood of developing complications after surgery (Regenbogen et al, 2009).
- Pain management
- PACU orders
- Questions and answers

PERIOPERATIVE NURSE MAY REPORT:

- Identity of patient
- Preoperative diagnosis
- Procedure performed
- Location of incision(s), dressings, drains, catheters, tubes, packing, stomas
- Surgical complications
- Allergies and reactions
- Medications, fluids, irrigations delivered by surgeon or RN
- Positioning during surgery
- Communication of other pertinent issues:
  - Location/presence of family or others
  - Special requests verbalized by the patient preoperatively
  - Special devices
  - Patient deficits
- Questions and answers

Modified from Chard R: Care of postoperative patients. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* St Louis, 2010, Saunders; Sullivan EE: Handoff communication, *J Perianesth Nurs* 22:275-279, 2007; Drain CB, Odom-Forren J: *Perianesthesia nursing: a critical care approach,* St Louis, 2009, Saunders.

Some PACUs use a head-to-toe assessment to organize the data obtained (Figure 9-1). Other PACUs take a major body systems' approach (Figure 9-2). In any case, the PACU nurse assesses admitting vital signs and the ABCs, beginning with the respiratory system. Respiratory assessment comprises rate, rhythm, auscultation of breath sounds for ventilatory adequacy, and oxygen saturation level. Any artificial airway and type of oxygen delivery system are noted.

The PACU nurse next assesses the cardiovascular system by monitoring heart rate and rhythm. The patient's initial blood pressure is compared with one or more preoperative readings. Body temperature is obtained, skin condition examined, and peripheral pulses checked, if indicated. Next, the PACU nurse assesses neurologic function by asking questions such as the following: Has the patient reacted (awakened from anesthesia)? Can the patient follow commands? Is the patient oriented, at least to name and hospital? Can the patient move all extremities

BOX 9-2

Initial Assessment in the PACU

Initial assessment in the PACU includes documentation of the following:

1. Integration of data received at hand-off report for transfer of care
2. Vital signs
   a. Respiratory status—airway patent, breath sounds, type of artificial airway, mechanical ventilator settings, oxygen saturation, and $ETCO_2$ monitoring if indicated
   b. Blood pressure—cuff or arterial line
   c. Pulse—apical, peripheral
   d. Cardiac monitor, rhythm documented
   e. Temperature/route
   f. Hemodynamic pressure reading if indicated (central venous, arterial blood, pulmonary artery wedge, and intracranial pressure)
3. Pain/comfort assessment (including emotional comfort)
4. Neurologic function including level of consciousness
5. Position of patient
6. Condition and color of skin
7. Patient safety needs
8. Neurovascular—peripheral pulses and sensation of extremity or extremities as applicable
9. Condition of dressings or suture line, drains, tubes, receptacles
10. Amount and type of drainage
11. Muscular response and strength/mobility status
12. Pupillary response as indicated
13. Fluid therapy—location of lines, condition of intravenous site, and security and amount of solution infusing (including blood)
14. Postanesthesia scoring system if used
15. Procedure-specific assessment

Modified from American Society of PeriAnesthesia Nurses: *2008-2010 Standards of perianesthesia nursing practice,* Cherry Hill, NJ, 2009, The Society.

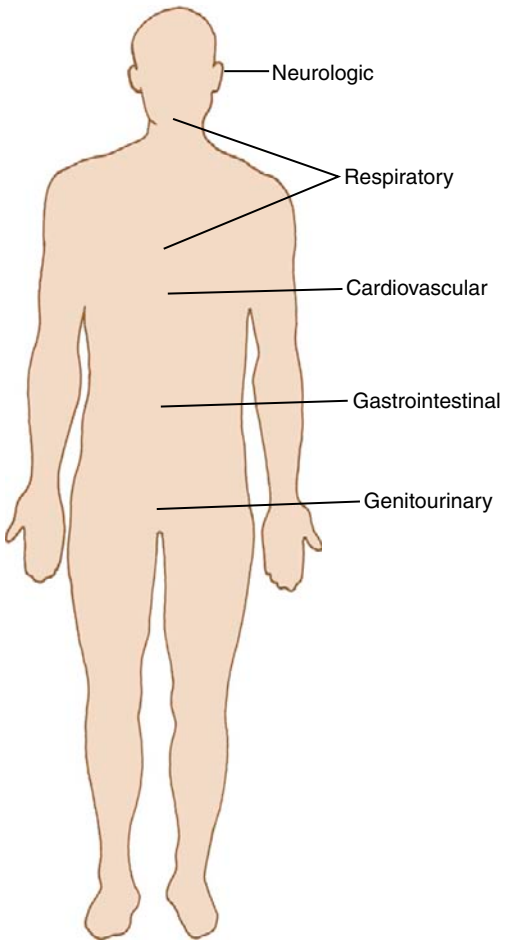

FIGURE 9-1 Head-to-toe assessment.

and lift the head? Are there deviations from preoperative neurologic functioning? Some operative procedures require a more detailed assessment.

To assess renal function, the PACU nurse measures intake and output. Total intraoperative fluid intake and estimated blood loss are reviewed. IV lines, infusions, and irrigation solutions are noted and recorded. Any drains or catheters are listed; their output is noted for color, amount, and consistency.

The surgical site is checked, noting any drainage on the bandage, including amount and color. The area around the incision is inspected so that any future changes may be compared. Patients undergoing vaginal hysterectomy require that the abdomen be assessed for firmness. A rigid abdomen may indicate hemorrhage. Comparing firmness of the abdomen on admission and later findings of a rigid abdomen can lead to important comparisons. The patient is also assessed for signs or symptoms of pain or discomfort and nausea, and medicated appropriately.

Information obtained from the admission assessment is documented in the PACU record (Figure 9-3).

Nursing Diagnosis

Common nursing diagnoses related to the care of postanesthesia patients include the following:

- Ineffective Breathing Pattern
- Decreased Cardiac Output
- Ineffective Thermoregulation
- Acute Pain

Outcome Identification

Outcomes identified for the selected nursing diagnoses can be stated as follows:

- The patient will demonstrate adequate ventilation, perfusion, and expansion of the lungs on discharge from the PACU.
- The patient will achieve and maintain adequate cardiac output on discharge from the PACU.
- The patient will attain a normal body temperature (96.8° to 100.4° F) (36° to 38° C) on discharge from the PACU.
- The patient will demonstrate appropriate cognitive function on discharge from the PACU.
- The patient will exhibit 4 or less on a numeric pain rating scale of 0 to 10 (or a pain/comfort level established by the patient as "acceptable") on discharge from the PACU.

Planning

When nursing diagnoses and desired outcomes are identified for the postoperative patient, a plan of care is designed that considers specific patient needs. Some nursing diagnoses are appropriate for all postanesthesia patients. A Sample Plan of Care for a postanesthesia patient follows on p. 271.

SAMPLE PLAN OF CARE

Immediate Postoperative Patient Care in the PACU

NURSING DIAGNOSIS

Ineffective Breathing Pattern related to medications associated with anesthesia, type of surgical procedure, pain, tracheobronchial obstruction

OUTCOME

The patient will maintain ventilation, perfusion, and adequate expansion of lungs on discharge from the PACU as evidenced by regular respiratory rate and pattern, bilateral breath sounds clear and equal, blood pressure and pulse within preoperative range, oxygen saturation at least 92% or equal to preoperative status, patent airway, and control of pain.

INTERVENTIONS

- Assess respiratory status on admission to the PACU and at intervals until discharge.
- Determine level of consciousness (to assess for need to reverse opioid, benzodiazepine, or muscle relaxant).
- Administer humidified oxygen; assess need for continued oxygen after discharge.
- Elevate head of bed (if not contraindicated).
- Encourage patient to take deep breaths or sustained maximal inspiration.
- Determine need for chin tilt or jaw thrust if patient is nonreactive without patent airway. Insert artificial airway if needed. Call anesthesia provider for further assistance.
- Assess patient for level of comfort. Administer pain medication as needed, per order or protocol.

NURSING DIAGNOSIS

Decreased Cardiac Output related to anesthetic agents and other medications, fluid or blood loss or replacement, peripheral pooling of blood, alteration in preload or afterload, alterations in rate or rhythm

OUTCOME

The patient will maintain adequate cardiac output on discharge from the PACU as evidenced by blood pressure within preoperative range, skin warm and dry, oriented to person and place, and pulse strong and regular.

INTERVENTIONS

- Monitor vital signs, electrocardiogram, and central venous pressure, with or without pulmonary artery catheter.
- Assess level of consciousness to determine effect of medication still in circulation.
- Monitor and record drainage from surgical site.
- Monitor and record intake and output.
- Administer fluid or blood products if indicated.
- If hypotensive, elevate legs unless contraindicated; increase rate of fluid administration.
- Maintain patency of intravenous lines.
- Administer medication if needed to improve depressed myocardial contractility, increase cardiac output, and promote diuresis.
- Administer vasodilators, vasoconstrictors, or antidysrhythmics as ordered.
- Warm patient to temperature 36° C (96.8° F).
- Administer humidified oxygen.

NURSING DIAGNOSIS

Ineffective Thermoregulation related to surgical procedure: anesthetic agents, length of surgery, age of patient, environment, irrigation, type of surgery, or genetic predisposition to malignant hyperthermia

OUTCOME

The patient will maintain normothermia, a core temperature of 36° to 38° C (96.8° to 100.4° F), on discharge from the PACU.

INTERVENTIONS

- Measure body temperature on admission; document temperature and route of measurement.
- Assess peripheral circulation.
- Monitor vital signs and oxygen saturation.
- Observe for shivering.
- Initiate measures to warm patient if hypothermic: place warmed blankets on patient's body and head; use forced-air warming device to rewarm patient.
- Initiate appropriate measures for malignant hyperthermia, if indicated (see Chapter 4).
- Maintain ongoing temperature monitoring until discharge.

NURSING DIAGNOSIS

Acute Pain related to operative or other invasive procedures

OUTCOME

The patient will exhibit a decreased level of pain or pain at a tolerable level on discharge from the PACU.

INTERVENTIONS

- Assess for subjective signs of pain: patient reports to the PACU nurse that he or she is in pain; patient is given a visual analogue or numeric scale to rate pain level.
- Assess for objective signs of pain: protective guarding behavior, moaning, crying, whimpering, restlessness, irritability, diaphoresis, dilated pupils, facial expression of pain, changes in vital signs (blood pressure, respiratory rate, or pulse).
- Refer to agency protocol for assessing and treating pain based on patient's pain rating.
- Monitor for pain relief and adverse reactions (respiratory depression, oversedation), and document.
- Administer pain medication as prescribed: titrate intravenous doses; initiate patient-controlled analgesia or continuous epidural analgesia (this may be patient-controlled epidural analgesia).
- If epidural analgesia is used, assess for numbness, leg weakness, pruritus, and respiratory depression. Document findings and notify physician if findings are positive.
- If patient is intubated but conscious, collaborate in pain rating scale by pointing to a number or face and having patient indicate *yes* or *no.* If patient is unconscious, be especially attentive to signs such as grimacing.
- Initiate alternate methods of pain relief: transcutaneous electrical nerve stimulation (TENS), music, massage, relaxation, guided imagery.
- Reposition patient for comfort if not contraindicated.
- Assess causes of pain (e.g., surgical site versus chest pain).
- Document medications administered, dose, route, time, and effectiveness of pain relief.

Implementation

Dangerous and life-threatening changes can occur rapidly during postanesthesia care. The following complications are pertinent to the care of all patients during the immediate postoperative period. Prompt recognition and immediate intervention are imperative for the well-being of PACU patients.

Postoperative Complications

RESPIRATORY

Airway Obstruction. The first priority in the care of the postanesthesia patient is to establish a patent airway. A common cause of airway obstruction is the tongue, which is relaxed because of anesthetic agents and muscle relaxants used during surgery (Figure 9-4). The patient may present with snoring, little or no air movement on auscultation of the lungs, retraction of intercostal muscles, asynchronous movements of the chest and abdomen, and a decreased oxygen saturation level. The nursing action taken may be simple, such as stimulating the patient to take deep breaths, positioning the patient on the side, or providing supplemental oxygen. If the patient is still unresponsive, the nurse may need to open the airway with a chin tilt or jaw thrust. A chin tilt is accomplished by lifting the chin with one hand while tilting the forehead back with the other. A jaw thrust is accomplished by displacing the temporomandibular joint forward bilaterally. The patient also can be repositioned on the right side. This position is called the recovery position. Placing the patient in this position allows the tongue to move forward and the airway to remain open.

If these actions do not open the airway, an artificial airway may need to be inserted. An oral or nasal airway may be used. An oral airway is indicated for use with an unresponsive patient (Figure 9-5). A nasal airway, better tolerated by an awake patient, is indicated for patients who are arousable.

Hemorrhage after neck surgery or carotid endarterectomy also can cause acute obstruction of the airway. The PACU nurse should assess such patients carefully for bleeding. In situations such as apnea, intubation with ventilation may be required. If intubation is impossible, the patient may require a tracheostomy, although this rarely is needed. The need for airway support is a common complication in the PACU (Tarrac, 2006).

Laryngospasm. A serious PACU complication is laryngospasm, usually the result of an irritable airway. The muscles of the larynx contract and partially or completely obstruct the airway; the patient can become hypoxemic quickly. Nursing actions include removing the irritating stimulus, suctioning secretions that may be triggering a glottic response, hyperextending the patient's neck, oxygenating the patient, and possibly administering an aerosol with racemic (optically inactive) epinephrine. An awake patient experiencing a laryngospasm will be terrified and need reassurance and a calm demeanor from nurses and physicians. Other treatment suggested for the patient includes application of pressure in the depression just posterior to the condyle of the mandible and administration of IV doxapram (Ahmed, 2004). In many cases, positive-pressure ventilation must be delivered by mask and bag. If symptoms last longer than 1 minute and are unrelieved by positive pressure, administration of a muscle relaxant, such as succinylcholine, is required to relax the muscles of the larynx. Reintubation is undesirable and used only as a last resort.

Bronchospasm. Bronchospasm is a lower airway obstruction caused by spasms of the bronchial tubes. These spasms can cause complete airway closure because of lack of cartilaginous support in the bronchioles. The patient presents with wheezing, dyspnea, use of accessory muscles, and tachypnea (Odom-Forren et al, 2010). Bronchospasm can result from aspiration, pharyngeal suctioning, or histamine release secondary to allergic response or related to medication use. Inhaled bronchodilators are the first choice of therapy for these patients, followed by intravenous aminophylline. Both IV and inhaled lidocaine can ease bronchospasm induced by histamine (Benca, 2007). If bronchospasm becomes life-threatening, epinephrine may be administered. Steroids, such as methylprednisolone, also may be administered if the underlying cause is inflammatory disease (e.g., asthma).

When obstruction occurs, the partial pressure of arterial carbon dioxide ($PaCO_2$) increases 6 mm Hg in the first minute of total obstruction and 3 to 4 mm Hg each minute thereafter (Nicholau, 2009). It is imperative that the PACU nurse make a quick assessment, rapidly intervene with airway assistance, and call for help to the anesthesia provider.

CARDIOVASCULAR. Cardiovascular system instability is a frequent finding after surgery because many anesthetic agents exert a depressive effect on the heart and vascular system. Common problems include hypotension, hypertension, and dysrhythmias. In one study of complications in the PACU, 13% were a result of tachycardia, 10.5% a result of hypertension, and 6.5% a result of hypotension (Tarrac, 2006).

Hypotension. Hypotension has been defined as a blood pressure reading that is 20% less than baseline or preoperative blood pressure measurement; it indicates either relative or absolute hypovolemia (O'Brien, 2009). Clinical signs of hypotension include a rapid, thready pulse; disorientation; restlessness; oliguria; and cold, pale skin. As hypovolemia is the most common cause of postoperative hypotension, the initial intervention is to administer IV fluids (physiologic saline or lactated Ringer's solution) at a maximum rate while making a specific diagnosis.

Cardiac output and vascular resistance determine blood pressure. Hypotension may be caused by cardiac dysfunction (such as myocardial infarction, tamponade, embolism, ischemia,

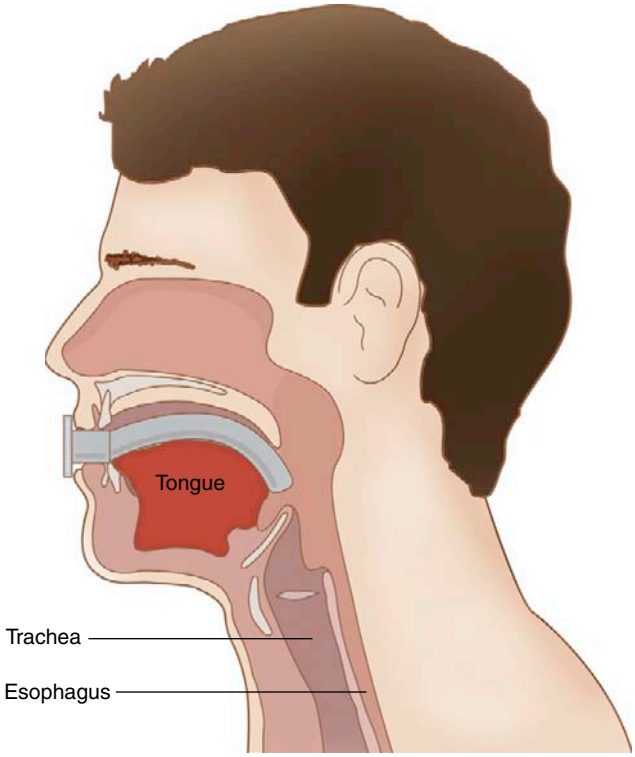

FIGURE 9-5 Oropharyngeal airway in place.

dysrhythmias, congestive heart failure, valvular dysfunction) or by medications (including anesthetic agents). In such cases, the heart no longer pumps effectively. Hemodynamic monitoring, supplemental oxygen, and cardiac stimulants are used as needed.

Hypovolemia. Hypovolemia reduces cardiac output and may be caused by hemorrhage, dehydration (inadequate fluid replacement), or increased positive end-expiratory pressure (PEEP). Fluid or blood replacement is used to treat hypovolemia. If the patient is hemorrhaging at the surgical site, a return to the OR is indicated.

Decreased vascular resistance, which causes relative hypovolemia (interference with venous return to the heart), can be related to medications, general and regional anesthesia, or anaphylaxis (Odom-Forren et al, 2010). Vasodilation can be treated with fluids, vasopressors, or elevation of the patient's legs. Anaphylactic reactions are treated with epinephrine, antihistamines, and additional fluids.

Hypertension. The normal ranges for systolic and diastolic blood pressures are generally accepted as 100 to 140 mm Hg and 60 to 95 mm Hg, respectively, although these ranges vary. Hypertension has been defined as a 20% to 30% increase above baseline blood pressure measurement (O'Brien, 2009; Odom-Forren et al, 2010). Hypertension is among the most common postoperative complications and often occurs early in the recovery phase. Blood pressure must be verified, and rapidity of the change must be noted. Clinical signs and symptoms are the most important indicators of the severity of the hypertension. Headache, mental status changes, and substernal pain are all indicators of end-organ damage. Hypertension may be caused by volume overload or pulmonary edema, which causes an increase in the cardiac output. In this case, the patient is given diuretics, placed on fluid restriction, and hemodynamically monitored. The patient with a history of cardiac disease is more at risk for adverse results.

Asymptomatic hypertension commonly occurs in the PACU and is usually considered harmless. The solution usually is determined by the cause. Pain is one of the most common causes of hypertension. Other causes of hypertension are anxiety, reflex vasoconstriction from hypothermia, hypoxemia, hypercapnia, and viscus distention, all of which cause increased vascular resistance. Patients in pain are medicated, and patients with hypothermia are warmed. Patients are oxygenated and ventilated if necessary to improve hypoxemia or hypercapnia. Patients are encouraged to void or are catheterized to empty a full bladder.

Antihypertensive drugs are used as necessary to control blood pressure. Preexisting hypertension is common in patients who have hypertension immediately after surgery. Patients should resume taking prescribed preoperative antihypertensives as soon as possible after surgery. Ambulatory surgery patients and inpatients usually are directed to take their prescribed antihypertensives on the day of surgery.

Dysrhythmias. Most dysrhythmias seen in the PACU have an underlying cause that is unrelated to myocardial injury (Odom-Forren et al, 2010). A common dysrhythmia after surgery is sinus tachycardia (rate >100 beats/min in an adult). Frequent causes include pain, hypoxemia, hypovolemia, increased temperature, and anxiety. The underlying cause is treated. Propranolol, metoprolol, or esmolol may be given. Sinus bradycardia (heart rate <60 beats/min in an adult) also is a common dysrhythmia in the PACU. Causes include hypoxemia, hypothermia, high spinal anesthesia, vagal stimulation, and some medications commonly given during or after surgery. The underlying cause is treated. Atropine is the drug of choice to increase heart rate, and usually no other treatment is required. Temporary or permanent pacemakers sometimes may be required.

Premature ventricular contractions (PVCs) are represented by wide, bizarre-looking QRS complexes. The most common causes in the postoperative period are hypoxemia and hypokalemia. These underlying conditions should be treated. Often, if cardiac disease or hypotension is not present, PVCs do not require medication. Treatment of dysrhythmias begins with determining and removing any source of the problem. Antidysrhythmic drugs, resuscitation equipment, and monitoring equipment should be immediately available.

THERMOREGULATION AND TEMPERATURE ABNORMALITIES

Hypothermia. Postoperative hypothermia, defined as a temperature less than 36° C (96.8° F) (ASPAN, 2009b), continues to be a widespread PACU problem. Often hypothermia is not life-threatening; it does, however, cause physiologic stress. Hypothermia can prolong recovery time and contribute to postoperative morbidity (Wong et al, 2007). Especially vulnerable to the effects of hypothermia are the elderly and children 2 years old or younger. Macario and Dexter (2002) determined that there are four major risk factors for hypothermia; this includes three patient populations—neonates less than 1 month of age, burn patients, and patients whose surgery included general anesthesia with neuraxial anesthesia—along with the low ambient temperature of the OR. Other risk factors include female gender, extreme age, length and type of surgical procedure, cachexia, significant fluid shift, and use of cold irrigants (Good et al, 2006; Wagner, 2006). The prevention and management of unplanned perioperative hypothermia remain a national priority in the prevention of surgical site infection, and it has been designated as a quality measure by the Surgical Care Improvement Project (SCIP) (ASPAN, 2009b; Langham et al, 2009).

Assessment of the need for prewarming begins preoperatively. Preventive warming measures are begun for normothermic patients and active warming measures instituted for hypothermic patients (ASPAN, 2009b).

Prevention of heat loss continues in the OR. Under general anesthesia, the patient does not produce heat and depends on ambient temperature. Prevention includes increasing the ambient temperature in the OR, providing the patient with warm blankets on arrival in the OR, and using draping techniques that minimize exposure during the procedure. Heated humidifiers and fluid warmers add heat. A common device to prevent hypothermia in the OR is a forced-air warming device (Figure 9-6).

In the PACU, tremendous demands are made on the body when the patient shivers. Shivering can increase the need for oxygen by 300% to 400%. Hypothermic patients should have oxygen therapy initiated immediately on admission. For a patient with a healthy heart, there may be no harmful effects. For a patient with coronary artery disease or cardiomyopathy, however, decompensation can occur. Perioperative normothermia has been associated with reduced incidence of morbid cardiac incidents and ventricular tachycardia in patients with cardiac risk factors (Leslie and Sessler, 2003; Siew-Fong et al, 2003).

Other problems associated with hypothermia include intravascular volume loss attributable to a fluid shift from the extracellular space, probably related to vasoconstriction (Reynolds et al, 2008). As the patient begins to rewarm, vasodilation follows, and the patient can require large amounts of intravenous fluids to avoid hypovolemia. The central nervous system is depressed by hypothermia. A cold postanesthesia patient remains more anesthetized than a warm patient while recovering. Nitrogen loss and hypokalemia can cause a predisposition to wound infection (Doufas, 2003). Impaired wound healing and surgical site infection have been linked to hypothermia (Paulikas, 2008).

Hypothermia slows metabolism and alters the effects of some anesthetic drugs. Of special interest is the prolonged elimination of muscle relaxants in hypothermic patients. Clotting abnormalities can occur. Platelet activity declines, and fibrinolysis increases with hypothermia; both conditions enhance the tendency to bleed (Sessler, 2001).

FIGURE 9-6 Bair Hugger; focused thermal environment.

Rewarming is a priority in the immediate care of the postoperative patient because hypothermia may augment the risk of adverse outcomes (Sessler, 2001). Wet and cold gowns and blankets should be removed, and warm, dry gowns and blankets should be applied to the head and body. Several external rewarming techniques are available. Application of warm cotton blankets has been a PACU tradition. Warm blankets are applied every 5 to 10 minutes until the patient is normothermic. Cotton blankets gradually increase the patient's temperature. They do not actively heat patients, however, and warming can be a slow process. Forced-air warming devices have been effective in rewarming patients. They produce a thermal-focused environment that transfers heat to a patient by blowing warm air through a plastic and tissue paper blanket that covers the patient (Siew-Fong et al, 2003). Forced-air warming devices are standard hypothermia treatment in PACU settings.

Continuous fluid-circulating blankets or warm-water mattresses have shown little value in rewarming patients because the size of the surface area in contact with the heat source is limited. Radiant heat lamps depend on exposure of large areas of body surface and are of limited use to adult patients. Fluid and blood warmers are useful for large volumes of cool fluids, but not to reverse hypothermia.

Studies have explored the best method to obtain accurate temperatures in the PACU when invasive core temperature measures, pulmonary artery, distal esophagus, nasopharynx, and tympanic membrane are unavailable. Both a study comparing eight noninvasive techniques to bladder temperature (Langham et al, 2009) and another systematic review of accuracy of noninvasive core temperature measurement (Hooper and Andrews, 2006), concluded that the most accurate method for routine postoperative temperatures was electronic oral temperatures.

Hyperthermia. Hyperthermia may indicate an infectious process or sepsis, or it may indicate a hypermetabolic process—malignant hyperthermia (MH). MH is a serious emergency

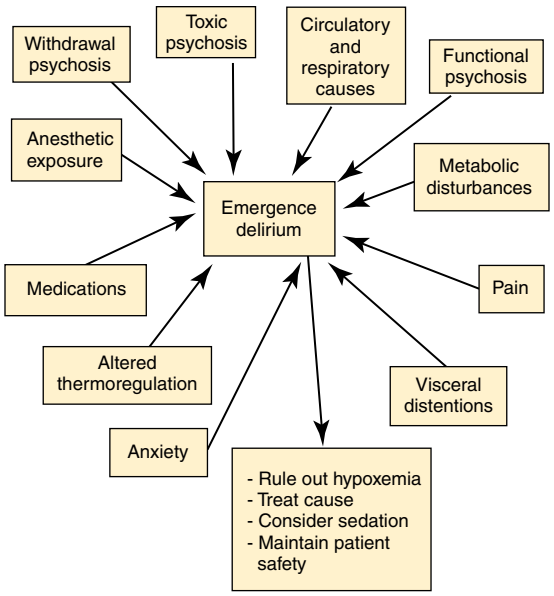

FIGURE 9-7 Emergence delirium in the PACU: contributing factors and treatment.

that is genetic in origin (Rosero et al, 2009). It is triggered by volatile anesthetic agents and the depolarizing muscle relaxant *succinylcholine*. Death may ensue unless MH is immediately recognized and treated (see Chapter 4).

DISTURBANCES IN COGNITIVE FUNCTION. PACU patients may be disoriented, drowsy, confused, or delirious. Attempts have been made to differentiate emergence delirium from agitation, with agitation defined as mild restlessness and mental distress. Delirium can be confused with agitation or the cause of agitation (Moos, 2005; Vlajkovic and Sindjelic, 2007). Causes range from residual effects of anesthetics to pain and anxiety. Hypoxemia always should be ruled out first; it remains the most common cause of postoperative agitation. Chemically dependent patients often awaken in an agitated state. Viscus distention also can contribute to agitation in a drowsy, confused patient. The PACU nurse should identify and eliminate the cause of the agitation or confusion, if possible. The patient can be engaged in short conversations and reoriented to place and person. Baseline preoperative data are important to determine the cause of agitation. Persistent changes from preoperative status require thorough assessment and possible intervention by the physician. See Figure 9-7 for a summary of contributing factors to emergence delirium and treatment options.

NAUSEA AND VOMITING. Postoperative nausea and vomiting (PONV) is a problem that affects approximately 30% of PACU patients (Odom-Forren and Moser, 2005). For patients with four risk factors, the incidence can be 70% to 80% (Apfel et al, 2002). Primary risk factors associated with PONV are female gender, nonsmoker, history of PONV or motion sickness, use of volatile anesthetics, use of nitrous oxide, postoperative use of opioids, duration of surgery, and type of surgery (Murphy et al, 2006; Gan et al, 2007). Management of nausea and vomiting begins preoperatively and continues into the intraoperative period (Evidence for Practice). Preventive therapy for patients at high risk of PONV has been effective in reducing its incidence. There is no single method to prevent or treat PONV. Many causative factors relate to anesthesia and surgery. Risk factors for PONV should be assessed preoperatively and care planned accordingly. Apfel and colleagues (1999) developed a simplified risk assessment tool, widely used today, based on four risk factors: gender, smoking status, history of PONV or motion sickness, and postoperative use of opioids. See Figure 9-8 for guidelines regarding preoperative management and prophylaxis of PONV.

Receptors that can cause nausea and vomiting when triggered are dopamine type-2, serotonin type-3, histamine type-1, muscarinic cholinergic type-1, and neurokinin type-1. Patients at risk for PONV should have either one or a combination of agents that block one or more of these receptor sites. Medications that have proven effective are ondansetron (Zofran), dolasetron (Anzemet), granisetron (Kytril), promethazine (Phenergan), prochlorperazine (Compazine), dexamethasone (Decadron), palonosetron (Aloxi), and transdermal scopolamine. Other medications that can be considered are metoclopramide (Reglan) at a dosage of at least 25 to 50 mg IV, dimenhydrinate (Dramamine), diphenhydramine (Benadryl), or droperidol (Inapsine). Droperidol has a black box warning and the patient must be monitored for QT prolongation/torsades de pointes after administration (Golembiewski and Tokumaru, 2006). If the patient

EVIDENCE FOR PRACTICE

ASPAN's Evidence-Based Clinical Practice Guideline for the Prevention and/or Management of PONV/PDNV

The lack of a multidisciplinary and multimodal treatment approach to PONV and PDNV prompted ASPAN to appoint a Strategic Work Team (SWT) that consisted of 16 multidisciplinary, multispecialty experts who were national and international academic and private practice experts. These experts reviewed and analyzed published evidence and developed a consensus regarding evidence-based, multimodal clinical practice recommendations that addressed prevention or management of PONV and PDNV. The specific aims of this group were to critique and synthesize evidence regarding the prevention and/or management of PONV/PDNV in the adult population, to develop evidence-based recommendations including traditional therapeutic management and complementary modalities, and to identify areas of needed research. The guideline includes separate algorithms for preoperative patient management, postoperative management of PONV, and management of PDNV.

Some of the evidence-based recommendations for postoperative patient management in the phase I and phase II PACU include:

- Assess for PONV on admission, discharge, and more frequently as indicated. If nausea is present, quantify the severity with a verbal descriptor scale (VDS) or visual analogue scale (VAS).
- Implement rescue interventions: verify hydration and blood pressure, select and administer appropriate rescue antiemetic. (Rescue antiemetic should affect a different receptor site than prophylactic agents already administered.)
- Include patient education on management of PDNV in all ambulatory surgery discharge education.
- Include assessment for the presence and severity of PDNV in any ambulatory surgery patient follow-up contact.

Adapted from ASPAN: ASPAN's evidence-based clinical practice guideline for the prevention and/or management of PONV/PDNV, *J Perianesth Nurs* 21:230-250, 2006.

is hypotensive with nausea and vomiting, ephedrine may be administered with additional fluid administration. PONV rescue medication administered in the PACU should be an antiemetic from a different pharmacologic class than medication given for prophylaxis (Golembiewski and Tokumaru, 2006). See Figure 9-9 for postoperative management of the patient with PONV.

Patients may also experience nausea and vomiting after discharge home from ambulatory surgery. Less research is available to direct the care of these patients, but the use of transdermal scopolamine, promethazine (suppositories or oral), or ondansetron dissolving tablets (ODTs) is supported by small studies (Odom-Forren et al, 2006). See Figure 9-10 for management of the patient with postdischarge nausea and vomiting (PDNV) (Research Highlight).

ASPIRATION. Aspiration, the passage of regurgitated material into the lungs, can occur during the perioperative period, with most aspirations occurring during tracheal intubation or extubation (Kalinowski and Kirsch, 2004). The PACU nurse must protect the airway of an unconscious or semiconscious patient to prevent aspiration of gastric contents. Prevention of aspiration postoperatively includes responding quickly to reports of nausea and vomiting, avoiding conversations that could elicit nausea and vomiting, and preventing rapid movement and head elevation of the

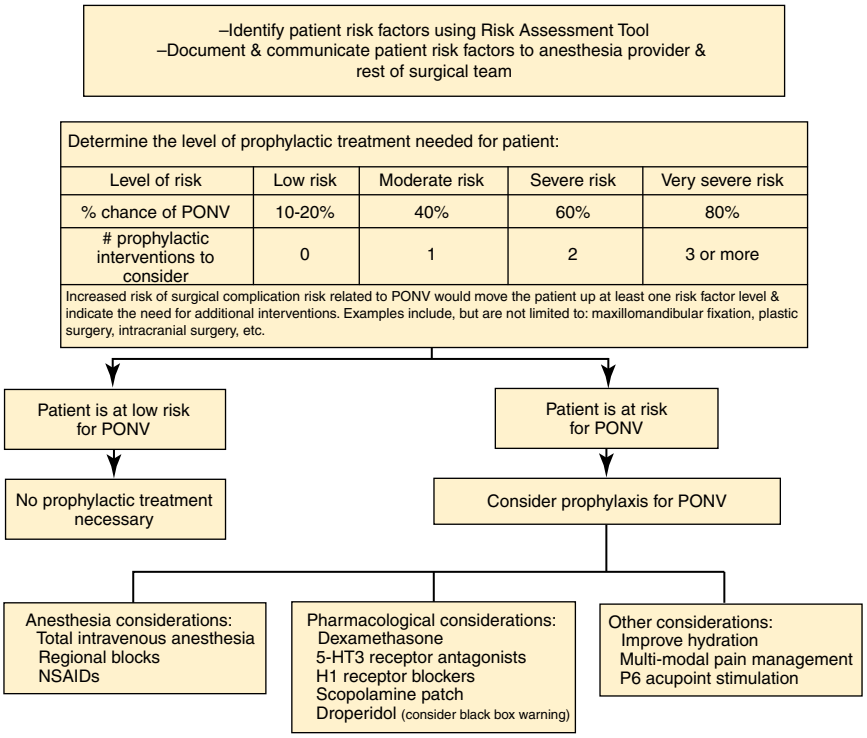

FIGURE 9-8 Preoperative patient management of PONV/PDNV.

RESEARCH HIGHLIGHT

Antiemetic Prophylaxis for Postdischarge Nausea and Vomiting (PDNV) and Impact on Functional Quality of Living during Recovery in Patients with High Emetic Risks

Pan and colleagues conducted a prospective, randomized, double-blind comparison of two prophylactic antiemetic regimens. In a sample of 64 women undergoing gynecologic ambulatory surgery, the study group was given intraoperative IV dexamethasone 8 mg and ondansetron (ODT) 4 mg, followed by a 1-mg oral disintegrating ondansetron tablet taken on discharge and each of the next two mornings. The control group only received the IV ondansetron during surgery. The patients were followed for 5 days after discharge. The reported incidence of postdischarge nausea for the study group was 20%, while it was 57% for the control group. Postdischarge vomiting occurred in 3% of the study group and 20% of the control group. Sixty percent of the control group and 33% of the study group stated that emetic symptoms negatively affected quality of life. It was concluded that the study group had a reduced incidence of PDNV and its negative impact on their quality of life. PDNV incidence is high and affects quality of life for ambulatory surgery patients for up to 5 days after surgery.

Modified from Pan P et al: Antiemetic prophylaxis for postdischarge nausea and vomiting and impact on functional quality of living during recovery in patients with high emetic risks: a prospective, randomized, double-blind comparison of two prophylactic antiemetic regimens, *Anesth Analg* 107:429-438, 2008.

TABLE 9-1

Risk Factors for Pulmonary Aspiration

General Risk Factors	Specific Risk Factors
Age (older > younger)	Emergency
Gender (female > male)	Pregnancy
Co-morbid diseases	Recent oral intake
IDDM	Opioid administration
CNS deficits	Increased gastric residual volume, as with gastrointestinal obstruction or dysfunction
Peripheral vascular disease	Obesity
Hepatobiliary or gastrointestinal diseases	Difficulty in protecting airway, as with depressed level of consciousness
Renal dysfunction	Previous esophageal dysfunction
	Head injury or neurologic dysfunction
	Lack of coordination of swallowing and respiration
	Procedures that increase intraabdominal pressure (e.g., upper abdominal surgery, straining with ETT)
	Difficult intubation/airway

CNS, central nervous system; *ETT,* endotracheal tube; *IDDM,* insulin-dependent diabetes mellitus (type 1).
Modified from Warner M: Risks and outcomes of perioperative pulmonary aspiration, *J Perianesth Nurs* 12(5):355, 1997; Schick L: *Calling 911: management of common PACU emergencies,* presented at 19th Annual ASPAN Conference, Kansas City, Mo, April 19, 2000; Kalinowski CPH, Kirsch JR: Strategies for prophylaxis and treatment for aspiration, *Best Pract Res Clin Anaesthesiol* 18(4):719-737, 2004.

patient. Nonreactive patients can be placed on their sides in the recovery position.

Volume and acidity of the aspirate determine the extent of damage to the lungs. The most severe damage seems to be in cases in which the pH is less than 2.5 or the volume greater than 25 ml (Kalinowski and Kirsch, 2004). Preoperatively, patients may receive clear, nonparticulate antacids, such as Bicitra, to raise the gastric fluid pH. Histamine (H_2)-receptor antagonists, such as cimetidine, ranitidine, or famotidine, decrease gastric acid production. Metoclopramide speeds gastric-emptying time. Aspiration does not occur in patients with normal protective reflexes. Risk factors can be divided into general and specific (Table 9-1).

Signs and symptoms of aspiration include tachypnea and hypoxemia attributable to a decrease in lung compliance. Wheezing, coughing, dyspnea, hypotension, apnea, and bradycardia may occur. Treatment focuses on promoting tissue oxygenation. Supplemental oxygen is given. Positive pressure applied by use of a mask or an endotracheal tube may be needed to maintain arterial oxygenation, and a chest x-ray may be performed. If intubated, the trachea can be suctioned. Bronchoscopy is performed if aspirated particles are large and cause an airway obstruction. Neither steroids nor antibiotics are warranted (Kalinowski and Kirsch, 2004). Tracheal secretions can be cultured, and if the results are positive, an appropriate antibiotic can be started. Bronchodilators are used as required. Recovery of the patient depends on recognition of the problem, quantity and pH of aspirate, physical condition of the patient before the event, and speed with which medical intervention begins (Kalinowski and Kirsch, 2004).

ACUTE PAIN. Pain is a subjective experience and may or may not be verbalized. Often, healthcare providers require objective signs of discomfort in addition to subjective reports of pain from the patient, which can lead to undertreatment of pain. The guiding principle in pain care is that pain is whatever the patient says it is (AHCPR, 1992; Pasero, 2009). The Agency for Health Care Policy and Research (AHCPR, now known as the Agency for Healthcare Research and Quality [AHRQ], 1992) reports that the most reliable indicator of the existence and intensity of pain is the patient's self-report. All patients should be assessed for pain severity using a verbal descriptor rating scale, numeric rating scale, or a visual analogue scale (Flaherty, 2008) (Figures 9-11 and 9-12). Approximately 80% of patients in one study experienced acute postoperative pain, with most patients experiencing moderate, severe, or extreme pain (Apfelbaum et al, 2003).

Pain management is one of the highest priorities of postanesthesia care (Buss and Melderis, 2002). Patients should be assessed for pain on admission to the PACU and at frequent intervals (Box 9-3). It is important to remember that not all patients respond to pain in the same manner, despite comparable surgical procedures. Measures of pain assessment should be correlated with the patient's self-report as the most important measure of intensity. Measures to determine pain intensity in a patient who cannot self-report include exposure to a painful procedure or underlying painful conditions; behavioral signs, such as crying or restlessness; a proxy pain rating by someone who knows the patient well; and physiologic indicators, such as elevated vital signs (Pasero, 2002a, 2009). An analgesic trial can be attempted as a final measure in the hierarchy of importance in assessing the nonverbal patient. Improvement in behaviors after the analgesic trial indicates that pain was the likely underlying cause (Pasero, 2009).

Evidence indicates that early analgesia reduces postoperative problems. Nonsteroidal antiinflammatory drugs (NSAIDs), or cyclooxygenase-type 2 (COX-2) inhibitors for patients who have experienced adverse effects from conventional NSAID use, and opiates are the analgesics of choice. Generally, they are used in combination (multimodal therapy) in the PACU (Surgical Pharmacology, p. 284 and Surgical Pharmacology, p. 285). Using NSAIDs in combination with opiates can reduce opioid requirements by 20% to 40% (Joshi, 2005). COX-2 inhibitors were developed with selective inhibition of the COX enzyme, with resulting analgesia and decreased inflammation without gastrointestinal and bleeding risks (Brophy, 2005). Until more recently, there were three COX-2 inhibitors available: celecoxib, rofecoxib, and valdecoxib. Rofecoxib and valdecoxib have been withdrawn from the U.S. market because they pose an unacceptable cardiovascular risk, leaving celecoxib as the only COX-2 inhibitor currently available in the United States. It is believed that the risk with celecoxib is small and comparable to that for traditional NSAIDs (Brophy, 2005). Parecoxib is another COX-2 inhibitor currently approved for use in Europe, but is not approved by the FDA for use in the United States.

Traditionally, pain was treated with intramuscular (IM) injections of opioids at intervals from 3 to 6 hours as needed. It is now recognized that inadequate pain relief experienced

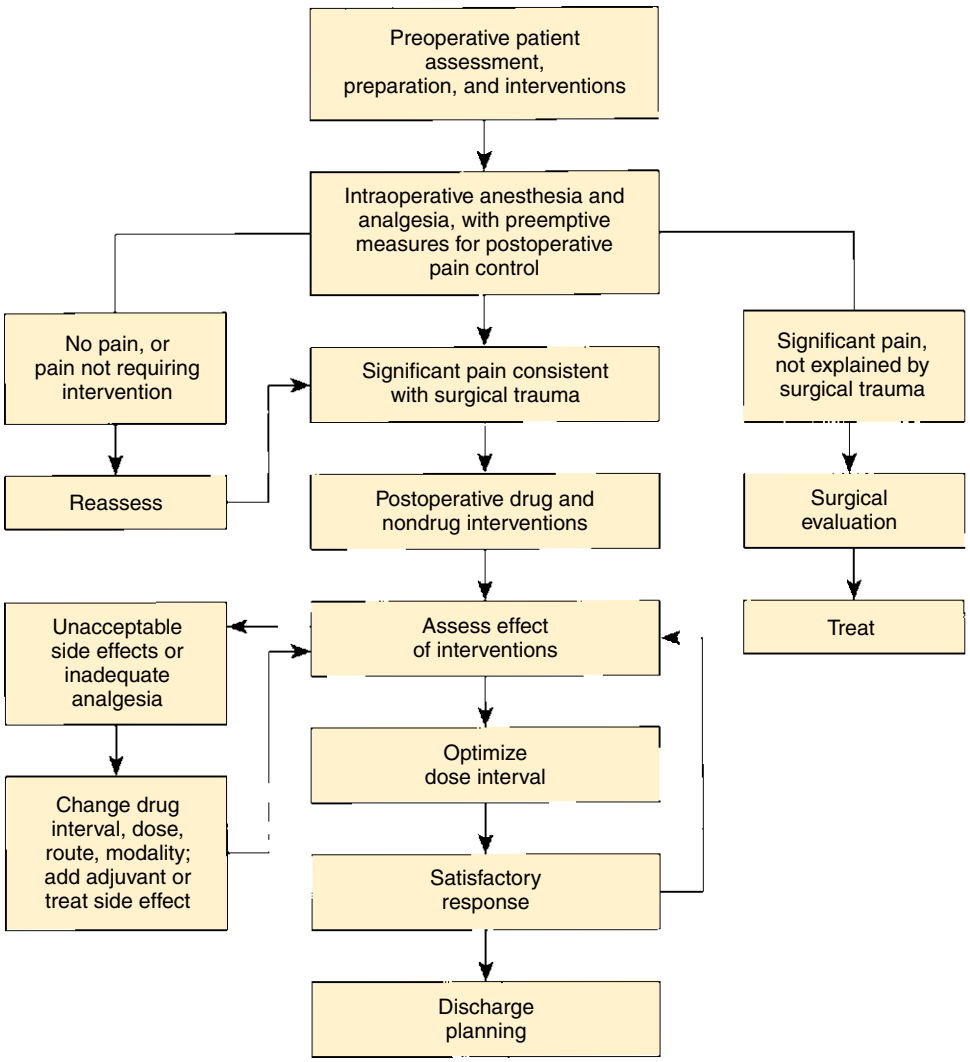

FIGURE 9-11 Acute pain management in adults.

by postoperative patients using IM injections is attributable to varying blood levels. Other methods of pain relief have since become more widespread. A common form of an opioid-delivery system is patient-controlled analgesia (PCA). PCA allows a patient to control analgesic administration. Dosage, time between doses, and the maximum dosage that can be administered are programmed into the machine. This form of analgesia also allows for a basal rate of opioids to infuse continuously, if ordered. The PCA pump also can be set to deliver continuous infusion and patient boluses. This setting allows the patient to use the bolus function to premedicate before an activity or for breakthrough pain. When PCA devices are started in the PACU, delays in preventing pain are avoided, effectiveness of the PCA device can be evaluated, and the patient's understanding and ability to use PCA can be monitored.

Other forms of postoperative pain relief may involve use of spinal analgesia, usually in the form of epidural opioid or local anesthetic administration. Patients who have had extensive procedures, including total hip or knee replacements, knee reconstruction, and major abdominal or thoracic operations, have been shown to profit from this method of pain control. Benefits of epidural analgesia for acute postoperative pain include good analgesia with minimal sedation, early ambulation and physical therapy, and excellent patient satisfaction. The FDA has approved a new extended-release epidural morphine (EREM; DepoDur) that provides pain relief for 48 hours after a single bolus injection (Pasero and McCaffery, 2005). Side effects of intrathecal administration of opioids include nausea, pruritus, urinary retention, areas of slight numbness, and respiratory depression. These side effects can be controlled by adjusting the infusion rate or by adding drugs such as diphenhydramine, ondansetron, or naloxone. Naloxone is the opioid antagonist used most frequently to reduce opioid-induced respiratory depression. It is administered slowly, never as a bolus, while the nurse observes the patient response. The patient should be able to open his or her eyes and talk to the nurse within 1 to 2 minutes of administration; naloxone is discontinued when the patient can take deep breaths on instruction and respond to physical stimulation.

Other techniques that have been shown to reduce the level of pain for the surgical patient include infiltration of the incision site with a local anesthetic in the OR before the initial

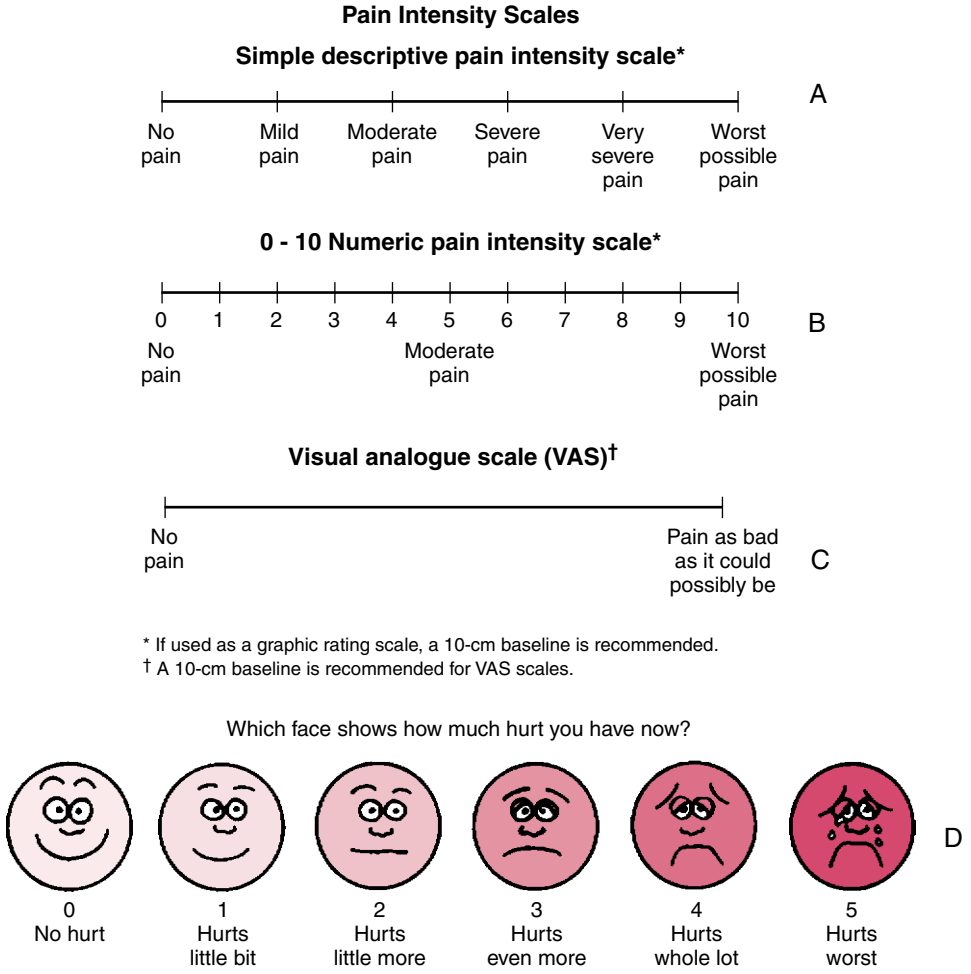

FIGURE 9-12 **A-C**, Examples of pain intensity and pain distress scales. **D**, FACES Pain Rating Scale.

incision and use of a long-acting local anesthetic at the site at the conclusion of the surgical procedure. Local anesthetics as part of a multimodal approach to pain management can contribute to a considerable decrease in opioid dosage with minimal side effects (Pasero, 2002b). One option is perineural local anesthetic infusion, in which a catheter is threaded along or into the wound. A diluted concentration of a long-acting local anesthetic is delivered to the surrounding nerves by a mechanical infusion pump for inpatients or a disposable infusion pump for ambulatory surgery patients (Banks, 2007). Thorough patient education is imperative, including removal of the catheter for patients who will be discharged home with the pump. It also is important to know the type of anesthetic the patient received during surgery and the type of local anesthetic in the pump to prevent overdose of local anesthetic. Multimodal analgesia allows a smaller dose of each component, which helps to minimize adverse effects (Viscusi, 2004).

Nonpharmacologic interventions that may be used to relieve pain include positioning for comfort, verbal reassurance, touch, applications of heat or cold, massage, and transcutaneous electrical nerve stimulation (TENS). If the patient was instructed preoperatively, other techniques that can be used are relaxation, imagery, music (Nillson, 2008), distraction, and biofeedback. Interventions that can be useful for PACU patients are preoperative education, which reduces the fear of the unknown; relaxation with deep breathing; distraction; and therapeutic massage (National Pharmaceutical Council [NPC], 2001). Nonpharmacologic interventions are designed to supplement, not substitute, pharmacologic interventions (AHRQ, 1992).

The physiologic effects of pain can be harmful for the postoperative patient. Such effects include decreased thoracic movement, increased splinting, reduced lung compliance and volume (leading to atelectasis), decreased mobility, increased risk of thromboembolism, exaggerated catecholamine response (which increases cardiac work and myocardial oxygen demand), increased risk for myocardial ischemia, impaired immune system, and delayed return of bowel and gastric function. Physiologic responses to acute pain include increased blood pressure and heart rate, dilated pupils, perspiration, increased respiratory rate, and decreased respiratory excursion (NPC, 2001; Dunwoody et al, 2008). Psychologically, the patient still in pain may display fear, helplessness, anxiety, anger, or frustration (Krenszichek, 2009). There is also an association between poorly controlled postoperative pain and the risk of developing chronic pain, which emphasizes the importance of pain control in the perioperative period (Dunwoody et al, 2008).

BOX 9-3

Pain Assessment and Reassessment

PRINCIPLES

- Pain is multidimensional. Patients experience its aspects in different ways. Comprehensive pain assessment considers the physical, sensory, behavioral, sociocultural, cognitive, affective, and spiritual dimensions of pain.
- Patients who have difficulty communicating their pain require particular attention. This includes patients who are cognitively impaired, psychotic, or severely emotionally disturbed; children; the elderly; patients who do not speak English; and patients whose level of education or cultural background differs significantly from that of the healthcare team.
- Unexpectedly intense pain, particularly if sudden or associated with altered vital signs, such as hypotension, tachycardia, or fever, should be evaluated immediately, and new diagnoses, such as wound dehiscence, infection, or deep venous thrombosis, should be considered.
- Family members should be involved when appropriate.

PAIN ASSESSMENT TOOLS

- The most reliable indicator of the existence and intensity of pain and any resultant distress is the patient's self-report.
- Self-report measurement includes numeric or verbal descriptor ratings and visual analogue scales.
- Tools should be reliable, valid, and easy for the patient and the nurse or physician to use. One may use these tools by showing a diagram to the patient to indicate the appropriate rating. One may also simply ask the patient for a verbal response: "On a scale of 0 to 10 with 0 as no pain and 10 as the worst pain possible, how would you rate your pain?" or "Please describe your pain for me, from no pain to mild, moderate, severe, or pain as bad as it could be."
- Tools must be appropriate for the patient's developmental, physical, emotional, and cognitive status.

PREOPERATIVE PREPARATION

- Discuss the patient's previous experiences with pain and beliefs about and preferences for pain assessment and management.
- Give the patient information about pain management therapies that are available and the rationale underlying their uses.
- Develop with the patient a plan for pain assessment and management.
- Select a pain assessment tool and teach the patient to use it.
- Provide the patient with education and information about pain control, including nonpharmacologic options, such as relaxation, distraction, imagery, and massage.
- Inform patients that it is easier to prevent pain than to attempt to reduce it after it is established, and that communication of unrelieved pain is essential for its relief. Emphasize the importance of a factual report of pain, avoiding stoicism or exaggeration.

POSTOPERATIVE ASSESSMENT

- Assess the patient's perceptions, along with behavioral and psychologic responses. Observations of behavior and vital signs should not be used instead of a self-report, unless the patient is unable to communicate.
- Assess and reassess pain frequently during the immediate postoperative period. Determine frequency of assessment based on the procedure performed and severity of pain. Pain should be assessed every 2 hours during the first postoperative day after major surgical procedures.
- Increase the frequency of assessment and reassessment if the pain is poorly controlled or if interventions are changing.
- Record the pain intensity and response to intervention in an easily visible and accessible place, such as a bedside flow sheet.
- Revise the management plan if the pain is poorly controlled.
- Review with the patient before discharge the interventions used and their efficacy, and provide specific discharge instructions regarding pain and its management. Have patient "teach back" or repeat instructions in his or her own words.

Modified from Acute Pain Management Guideline Panel: *Acute pain management in adults: operative procedures. Quick reference guide for clinicians,* AHCPR pub. no. 92-0019, Rockville, Md, 1992, Agency for Health Care Policy and Research, U.S. Public Health Service, U.S. Department of Health and Human Services; Flaherty E: Using pain-rating scales with older adults, *AJN* 108(6):40-47, 2008; Silkman C: Assessing the seven dimensions of pain, *AJN* 3(1):13-15, 2008.

With the advent of The Joint Commission (TJC) standards for pain management, healthcare providers had to become more knowledgeable about pain assessment and management. An excellent resource is the monograph developed by the National Pharmaceutical Council as part of a collaborative project with TJC (NPC, 2001). Patients of differing cultures respond to and communicate pain differently. A patient may believe that nonverbal communication expresses the pain to the nurse, but the nurse may not recognize the clues. Common misconceptions about pain also abound. These misconceptions must be recognized and corrected. A summary of misconceptions is listed in Table 9-2.

Buss and Melderis (2002) developed a tool to allow perianesthesia nurses to assess cognitively impaired postanesthesia patients to determine the presence of pain. This tool is limited to use in the phase I PACU but adds to the PACU nurse's ability to address acute postoperative pain. The tool, an algorithm, was developed to "assist perianesthesia nurses with the assessment and management of pain during the patient's emergence from anesthesia" (Figure 9-13). ASPAN established the first comprehensive pain and comfort guideline. The guideline addresses assessment, expected outcomes, and appropriate interventions for pain in the preoperative phase, postanesthesia phase I, and postanesthesia phases II and III (ASPAN, 2003).

The available guidelines for pain are very general and do not address procedural pain (Kehlet, 2007). However, that is changing. Procedure-specific and evidence-based pain management guidelines are now available through a web-based program called PROSPECT (Procedure Specific Postoperative Pain Management) (Pasero, 2007; PROSPECT, 2009). These clinical practice guidelines and recommendations were developed after consensus of an international group of surgeons and anesthesia care providers who have reviewed pain research and graded the evidence (Figure 9-14).

SURGICAL PHARMACOLOGY

Dosing Data for Nonopioid Analgesics

Drug	Usual Adult Dose	Usual Pediatric Dose*	Comments
ORAL			
Acetaminophen	650-975 mg q4hr	10-15 mg/kg q4hr	Acetaminophen lacks peripheral antiinflammatory activity of NSAIDs
Aspirin	650-975 mg q4hr	10-15 mg/kg q4hr†	The standard against which other NSAIDs are compared Inhibits platelet aggregation; may cause postoperative bleeding
Choline magnesium trisalicylate (Trilisate)	1000-1500 mg bid	25 mg/kg q12hr	May have minimal antiplatelet activity; also available as oral liquid
Diflunisal (Dolobid)	1000 mg initial dose followed by 500 mg q12hr	—	—
Etodolac (Lodine)	200-400 mg q6hr	—	—
Fenoprofen calcium (Nalfon)	200 mg q4-6hr	—	—
Flurbiprofen	100 mg bid, tid, qid	—	—
Ibuprofen (Motrin, others)	400 mg q4-6hr	10 mg/kg q6-8hr	Available as several brand names and generic forms; also available as oral suspension
Ketoprofen (Orudis)	25-75 mg q6-8hr	—	—
Magnesium salicylate	650 mg q4hr	—	Many brands and generic forms available
Meclofenamate sodium (Meclomen)	50 mg q4-6hr	—	—
Mefenamic acid (Ponstel)	250 mg q6hr	—	—
Naproxen (Naprosyn)	500 mg initial dose followed by 250 mg q6-8hr	5 mg/kg q12hr	Also available as oral liquid
Naproxen sodium (Anaprox)	550 mg initial dose followed by 275 mg q6-8hr	—	—
Oxaprozin	600 mg q24hr	—	Long half-life, so can be given once daily
Salsalate (Disalcid, others)	500 mg q4hr	—	May have minimal antiplatelet activity
Sodium salicylate	325-650 mg q3-4hr	—	Available in generic form from several distributors
SELECTIVE COX-2 INHIBITOR			
Celecoxib (Celebrex)	100-200 mg twice daily	—	Reduces risk of gastrointestinal side effects and renal toxicity No effects on platelet aggregation May have a higher risk of having heart attack or stroke
PARENTERAL NSAID			
Ketorolac	30 or 60 mg IM initial dose followed by 15 or 30 mg q6hr Oral dose after IM dose: 10 mg q6-8hr IV dose: 30 mg for healthy adults and 15 mg for adults >65 years	—	IM dose not to exceed 5 days. IV administration comparable to 10 mg IM morphine

NOTE: Only the above NSAIDs have Food and Drug Administration approval for use as simple analgesics, but clinical experience has been gained with other drugs as well.

*Drug recommendations are limited to NSAIDs for which pediatric dosing experience is available.

COX-2, cyclooxygenase-type 2; *NSAID,* nonsteroidal antiinflammatory drug.

†Contraindicated in presence of fever or other evidence of viral illness.

Modified from Acute Pain Management Guideline Panel: *Acute pain management in adults: operative procedures. Quick reference guide for clinicians,* AHCPR pub. no. 92-0019, Rockville, Md, 1992, Agency for Health Care Policy and Research, U.S. Public Health Service, U.S. Department of Health and Human Services.

Pentazocine (Talwin, others)	150 mg q3-4hr	60 mg q3-4hr	50 mg q4-6hr	NR	NR	NR

**CAUTION:* Doses listed for patients with body weight <50 kg cannot be used as initial starting doses in infants <6 months of age. Consult the AHCPR *Clinical practice guideline for acute pain management: operative or medical procedures and trauma* section on management of pain in neonates for recommendations.
NOTE: Published tables vary in the suggested doses that are equianalgesic to morphine. Clinical response is the criterion that must be applied for each patient; titration to clinical response is necessary. Because there is not complete cross-tolerance among these drugs, it is usually necessary to use a lower equianalgesic dose when changing drugs and to retitrate to response.
CAUTION: Recommended doses do not apply to patients with renal or hepatic insufficiency or other conditions affecting drug metabolism and kinetics.
†For morphine, hydromorphone, and oxymorphone, rectal administration is an alternate route for patients unable to take oral medications, but equianalgesic doses may differ from oral and parenteral doses because of pharmacokinetic differences.
‡*CAUTION:* Codeine doses >65 mg often are inappropriate because of diminishing incremental analgesia with increasing doses but continually increasing constipation and other side effects.
§*CAUTION:* Doses of aspirin and acetaminophen in combination opioid/NSAID preparations also must be adjusted to the patient's body weight.
NA, Not available; *NR,* not recommended.

Accessed December 1, 2009.

TABLE 9-2

Misconceptions about Pain

Misconception	Correction
Best judge of the existence and severity of patient pain is the physician or nurse caring for the patient.	The patient is the authority about his or her pain. The patient's self-report is the most reliable indicator of the existence and intensity of pain.
Clinician must believe what the patient says about pain.	The clinician must accept and respect the patient's self-report of pain and proceed with an appropriate assessment and treatment. The clinician is entitled to a personal opinion but should not allow it to guide practice.
Patients should not receive analgesics until the cause of pain is diagnosed.	Symptomatic relief of pain should be provided while the investigation of cause proceeds.
Visible signs, either physiologic or behavioral, accompany pain and can be used to verify its existence and severity.	Even with severe pain, periods of physiologic and behavioral adaptation occur, leading to periods of minimal or no signs of pain.
Pain never killed anyone.	Unrelieved pain may be dangerous and is unacceptable. Postoperative pain can delay healing and contribute to complications that can be life-threatening. Acute pain warns of actual or potential tissue damage and resolves when healing has occurred. Unrelieved postoperative pain is a complication or risk, not an acceptable consequence of surgery.
If the patient requires higher doses of opioids than other patients, "he's hitting the PCA button too often."	There is no set dose of opioid that is effective for all patients. Even an opioid-naïve patient may require 6× more opioid than another patient. A patient who is opioid-tolerant may require 100× the opioid of an opioid-naïve patient.

Modified from Canobbio MM: *Mosby's handbook of patient teaching,* ed 3, St Louis, 2006, Mosby; McCaffery M, Pasero C: *Pain clinical manual,* ed 2, St Louis, 1999, Mosby; Pasero C: Challenges in pain assessment, *JOPAN* 24(1):50-54, 2009.

Evaluation

The PACU nurse evaluates the patient on outcomes identified as significant after the initial assessment. For the desired outcomes presented previously in this chapter, these might be stated as follows:

- The patient demonstrated adequate ventilation, perfusion, and expansion of lungs on discharge from the PACU. Oxygen saturation was adequate while receiving room air.
- The patient maintained adequate cardiac output; blood pressure and heart rate were within normal range.
- The patient was normothermic in discharge from the PACU.
- The patient had appropriate cognitive function and was oriented to time and person.
- The patient's pain was 4 or less (on a scale of 0 to 10) or at a pain/comfort level established as acceptable by patient. The patient was relaxed and slept at intervals. The patient verbalized satisfactory pain relief.

DISCHARGE FROM THE PACU

The PACU nurse completes a final assessment immediately before the patient's discharge and transfer to the surgical unit. The nurse assesses vital signs, level of consciousness, condition of the operative site, pain and comfort level, intake and output, respiratory function and oxygen saturation, and mobility. If the patient requires ongoing oxygen therapy, a transport oxygen canister is provided, and oxygen supply is prepared in the hospital room.

The patient usually is discharged from the PACU by an anesthesia care provider, who may be present and write a discharge order. Alternatively, a numeric scoring system approved by the department of anesthesia may be used to determine if the patient is ready for discharge. The most common scoring system in use is the Aldrete score. Activity, respiration, circulation, consciousness, and oxygen saturation level are scored from 0 to 2 (see Figure 9-3). A total score of 8 to 10 is generally acceptable for PACU discharge, with exceptions made by physician order.

A hand-off report on the patient's condition is given to the nurse who will assume care for the patient on the surgical or short procedure unit. This report may be given by telephone before the patient leaves the PACU or in person after the patient reaches the unit. The report should include a preoperative history, pertinent information regarding the patient's surgery and recovery, medications the patient was given, physician's orders, and all other appropriate information.

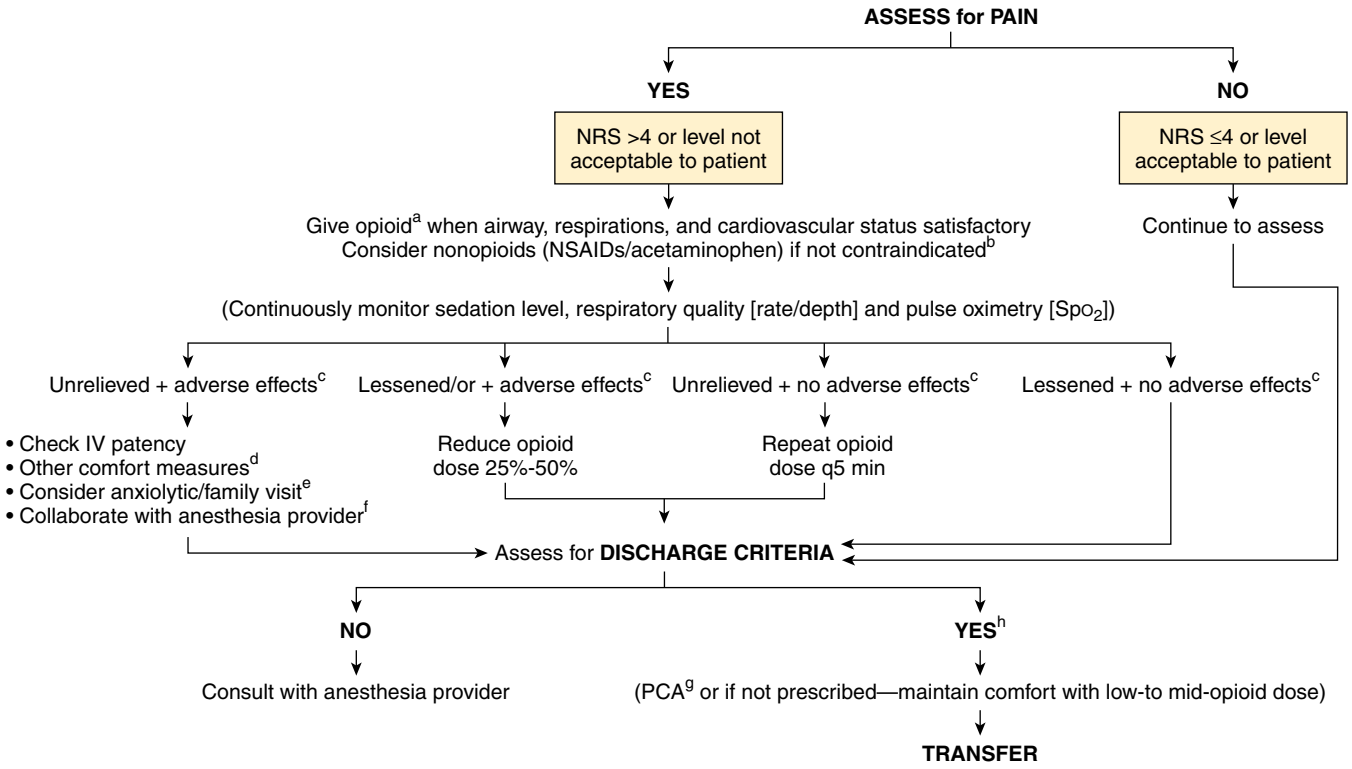
ADMISSION TO THE SURGICAL OR SHORT PROCEDURE UNIT

The patient's room is prepared for admission, and any necessary equipment is obtained. The patient is assisted into the bed. To prevent falls the bed rails should remain raised until the patient is fully awake. The patient is informed to notify the nurse for assistance to ambulate. Family members also are instructed and enlisted to maintain safety for the patient. Equipment and the patient's condition should be explained to family members present. A special concern is the use of PCA. Family members should be instructed that the PCA is for the patient's use only and that pushing the PCA button for the patient can have a detrimental effect on the patient's well-being.

POSTOPERATIVE NURSING CONSIDERATIONS

Assessment

The nurse in the receiving unit makes an immediate assessment as soon as the patient transfers to the bed. The nurse may choose a head-to-toe or systems' assessment. Parameters



Perianesthesia Pain Management Considerations (for Use in Conjunction with PACU Pain Algorithm)

- Using the Sedation Scale, level of sedation (LOS) 3 requires proceeding with opioid cautiously (reduce opioid dose 25%-50%/increase interval between doses). LOS 4 requires holding opioids, and other sedatives, regardless of numeric rating scale (NRS); administer naloxone if physical stimulation fails to reverse respiratory depression and sedation.
- Respiratory function in an emergent tachypneic patient can improve through use of opioids by reducing respiratory rate, the depth increases, and the Spo_2 rises.
- During preadmission testing/preparation, staff should identify candidates for PCA and teach its use. Include in teaching the benefits of effective pain control, use of the pain scale, and the importance of reporting pain early. This information should be reinforced before surgery/procedure and again in the PACU.
- Encourage patients preoperatively to consider and discuss with anesthesia provider the use of local, regional, or epidural anesthesia/analgesia for preemptive analgesia, because the most effective pain control is achieved through multimodal approach (combined use of local anesthesia, opioids, and nonopioids).
- Give nonopioids (acetaminophen, salicylates, NSAIDs) on admission to the PACU when not contraindicated or previously administered. Encourage anesthesia providers to administer intraprocedure for preemptive analgesia.
- Preferred opioids are morphine, fentanyl, and hydromorphone. Avoid meperidine except for treatment of shivering or allergy to other opioids; meperidine metabolite, normeperidine, is toxic to the central nervous system and can cause seizures and death.
- Determine patient's preoperative use of opioids, nonopioids, and substance/alcohol use for possible higher opioid requirements.
- Give feedback to anesthesia provider when a patient has prolonged pain with an NRS higher than 4 for collaborative solutions.
- Avoid sedatives and use of antiemetics that produce sedation. Avoid IM injections.
- Pain goal: Level of comfort should allow patient to deep breathe, cough, turn, and move into/out of bed. Opioid side effects should be minimal.
- Appearing to sleep may not equal comfort. Always ask patients to rate their pain.
- Initiate PCA early when possible for evaluating effectiveness of programmed dose. Opioid loading is indicated first for severe escalating pain with minimal opioids on board.
- This algorithm is a suggested guide. Interventions should be individualized to each patient.

[a]For a numeric rating scale (NRS) of 5 or higher, use the higher opioid dose range; for an NRS lower than 5, use the mid-to-low dose range.
[b]Acetaminophen, salicylates, or NSAIDs (which include ketorolac, ibuprofen, salsalate, nabumetone, choline magnesium trisalicylate, and so on). Rofecoxib (Vioxx) has been withdrawn from the market. Contraindications to NSAIDs are aspirin-sensitive asthma, bleeding, coagulopathy disorders, history of gastrointestinal bleeding, renal compromise, and hypovolemia.
[c]Adverse effects include but are not limited to increasing sedation (LOS 3), respiratory depression, local histamine reaction, and uncontrolled nausea and vomiting.
[d]Comfort measures include the following: reassurance, reposition, warm/cold applications, relaxation measures, and music therapy.
[e]Use anxiolytics for anxiety and muscle spasms only.
[f]Collaborate for other adjuvants or regional block. Consult also with surgeon.
[g]Start PCA early or after opioid loading (PCA pump or syringe) per anesthesia provider orders for rapidly escalating pain higher than an NRS of 4.
[h]Discharge criteria include the following: NRS of pain of 4 or less, LOS of 3 or less, respiratory rate of 10 or higher, Spo_2 of 93% or higher, and minimal other opioid side effects.

FIGURE 9-13 PACU pain algorithm.

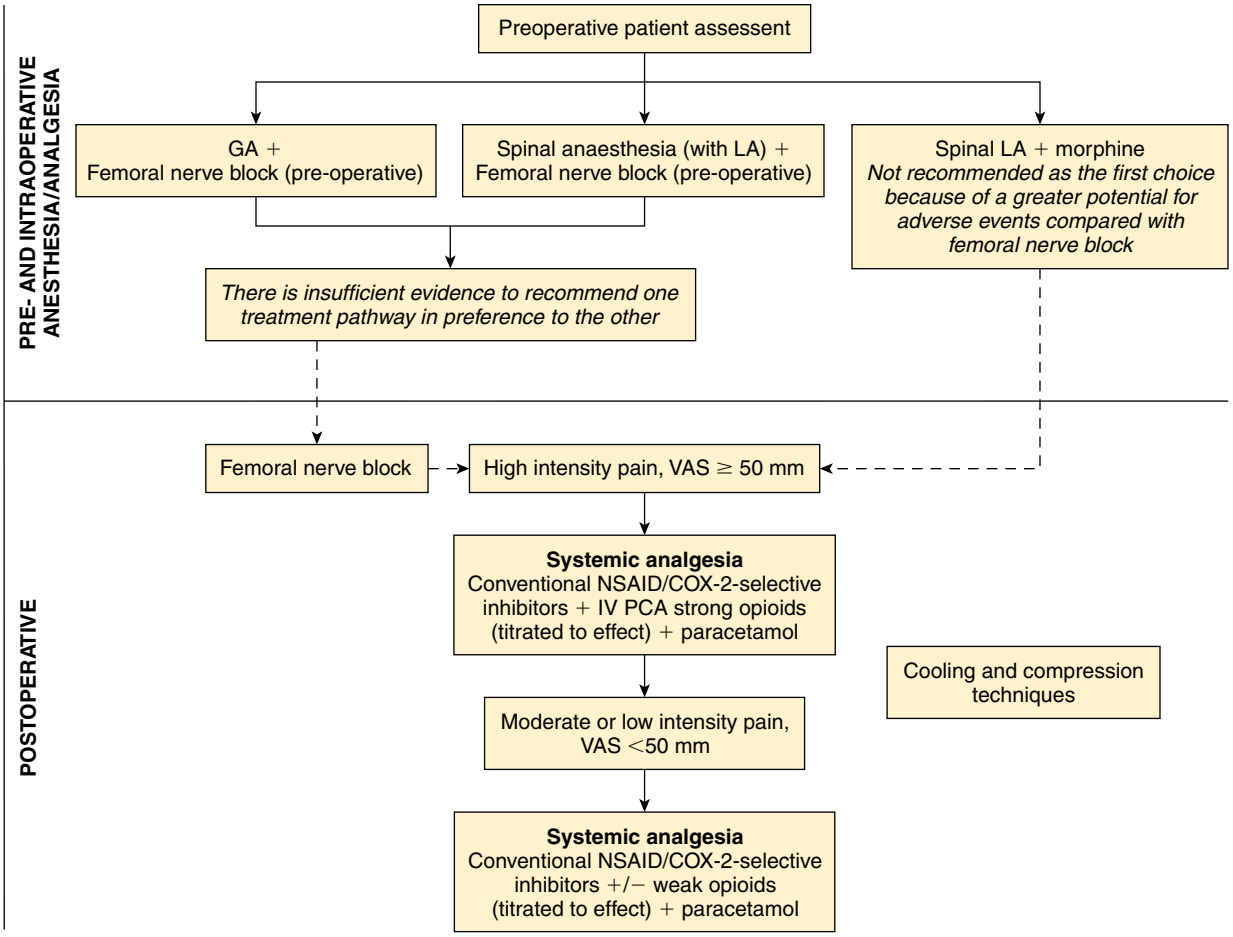


FIGURE 9-14 Algorithm for the management of postoperative pain—total knee arthroplasty (TKA).

include respiratory, cardiovascular, and neurologic status. The condition of the dressing and surgical site and patient comfort and safety also are assessed (Box 9-4).

Nursing Diagnosis

Nursing diagnoses related to the care of the postoperative patient include the following:

- Risk for Infection
- Ineffective Breathing Pattern
- Acute Pain
- Imbalanced Nutrition: Less Than Body Requirements
- Impaired Physical Mobility

Outcome Identification

Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient will be free from infection as indicated by normal vital signs; temperature within normal range; normal white blood cell count; clear breath sounds; clear, yellow urine; warm, dry skin; and adequate nutritional intake.
- The patient's respirations will be easy, unlabored, and adequate.
- The patient will state subjective assertions of comfort: "I am in no pain." "My pain is a 2 on the scale of 0-10." The patient will have no objective signs of discomfort (e.g., grimaces, tachycardia).
- The patient will eat well from prescribed diet; weight loss will be minimal.
- The patient will ambulate at an appropriate level and carry out activities of daily living appropriate for condition.

Planning

Planning for the postoperative patient requires knowledge of surgical procedures and underlying medical conditions. Throughout the patient's stay, planning must always involve the family or significant others, with measurable goals determined by discharge. A Sample Plan of Care for the postoperative patient is on p. 290.

Implementation

Wound Healing. Nursing care of the postoperative patient includes a focus on wound healing. Nursing interventions focus on preventing and monitoring wound complications. The nurse should use strict aseptic technique when placing a new dressing and monitor for signs and symptoms of infection (e.g., elevated body temperature; red, swollen, warm area surrounding the incision; elevated white blood cell count; tachycardia; and purulent drainage from wound) (Smith, 2007). For

BOX 9-4

Patient Assessment on Admission to Postoperative Unit from the PACU

- Respiratory status
  - Patency of airway
  - Respirations—depth, rate, character
  - Breath sounds—presence, character
- Circulatory status
  - Pulse, blood pressure
  - Skin color, temperature
  - Capillary filling
- Neurologic status
  - Level of consciousness
  - Ability to move extremities, peripheral pulses (as applicable)
- Dressing
  - Presence of drainage
  - Presence of tubes to be connected to drainage systems
- Comfort
  - Presence of pain, nausea, vomiting
  - Pain score
  - Patient positioned for comfort and to facilitate ventilation
  - Other comfort measures as determined by patient preference (e.g., warm blanket, music, massage)
- Safety
  - Use of two patient identifiers
  - Necessity for side rails
  - Call cord within reach and instructions on operation reviewed
- Equipment
  - Monitors connected and functioning
  - Intravenous fluids—location of insertion site, type and size of intravenous device, type of infusion, rate, amount in bag, patency of tubing, assessment of site
  - Drainage systems (e.g., nasogastric, chest, urinary)—type, patency of tubing, connection of appropriate container, character and amount of drainage

a detailed discussion of the pathophysiology of wound healing, see Chapter 8.

Adequate Respirations. Postoperative patients are at risk for pulmonary complications because of increased respiratory secretions, decreased lung expansion, depression of the respiratory center, and the possibility of aspiration of gastric contents. These complications can be minimized by appropriate nursing management, including elevating the head of the bed whenever possible; encouraging coughing, turning, and deep breathing every 2 hours; ambulating the patient as soon as possible; and encouraging hydration (Smith, 2007).

Circulation. Venous stasis in the postoperative patient can lead to thrombophlebitis, which is usually a preventable complication. Platelets adhere to the venous wall and form a thrombus, with a resultant potential for deep venous thromboembolism (DVT) or pulmonary embolus.

Prevention often includes administration of prophylactic heparin, aspirin, dextran, or warfarin. Application of an intermittent external pneumatic sequential compression device (SCD) may be ordered, or application of antiembolic (AE) hosiery may be required. Nursing measures that can prevent formation of a thrombus include using the AE hosiery whether the patient is in or out of bed, teaching the patient not to cross the legs, having the patient perform isometric leg exercises, and encouraging early ambulation.

If thrombophlebitis is suspected (pain or tenderness, erythema, localized area of warmth, swelling), the patient should return to bed and the physician notified. Treatment consists of rest, heat, AE hosiery, and anticoagulant therapy.

Urinary Function. One of the priorities during surgery and immediately afterward is to keep the patient well hydrated so that voiding takes place 6 to 8 hours after surgery. Usually intake is greater than output for 48 hours, as the fluid and electrolyte balance returns to normal. Every effort is made to refrain from use of a catheter to avoid the risk of urinary tract infection. Measures to help the patient void include warming the bedpan, letting water run, applying warm water to the perineum, and allowing the patient to go to the bathroom when possible. If discomfort is present and the bladder is palpable, catheterization becomes necessary. In the event several catheterizations are required, an indwelling catheter is inserted. Hydration of the patient becomes a priority. Intake and output are recorded accurately. A urine output of less than 30 ml/hr is reported to the physician.

Bowel Elimination. The postoperative patient who underwent abdominal or pelvic surgery may have decreased peristalsis for at least 24 hours; this may persist for several days for the patient who had gastrointestinal surgery (Smith, 2007). Increased fluid intake and early ambulation promote the return of peristalsis. Bowel sounds should be auscultated with a stethoscope to ensure that peristalsis has returned, and the abdomen should be assessed for distention.

Constipation occurs frequently after surgery because of the effects of the anesthetic agents and narcotics, immobility, and decreased gastrointestinal motility. Fluids, roughage, and bulk laxatives can relieve constipation. Occasionally a suppository or an enema is needed to empty the lower bowel.

Early Ambulation. Early ambulation can expedite recovery and prevent complications. Early ambulation increases muscle tone, improves gastrointestinal and urinary tract function, stimulates circulation, and increases vital capacity (Smith, 2007). Benefits are shown in Figure 9-15. Ambulation usually is postponed if severe infection or thrombophlebitis is present.

Evaluation

Evaluation of the postoperative patient outcomes on the surgical unit might be stated as follows:

- The patient's vital signs and laboratory values were within normal limits; the surgical site showed no signs or symptoms of infection.
- The patient's breathing was easy and unlabored; breath sounds were clear bilaterally.
- The patient verbalized freedom from pain and was free from facial grimaces, moaning, and other evidence of pain or discomfort.
- The patient was eating well; there was no weight loss or complaints of nausea or vomiting.
- The patient ambulated regularly and was assessed as capable of performing appropriate activities of daily living.

SAMPLE PLAN OF CARE

Admission to the Postoperative Patient Care Unit

NURSING DIAGNOSIS

Risk for Infection related to altered skin integrity, compromised aseptic technique, or malnutrition

OUTCOME

The patient will be free from infection, as indicated by normal vital signs; temperature within normal range; normal white blood cell count; clear breath sounds; clear, yellow urine; warm, dry skin; and adequate nutritional intake.

INTERVENTIONS

- Monitor vital signs every 4 hours or as prescribed.
- Monitor temperature every 4 hours as needed; document and report increased temperature.
- Monitor laboratory values for evidence of infection; report variance from normal.
- Encourage patient to take deep breaths or sustained maximal inspiration or use respiratory aids.
- Preserve closed urinary system and provide catheter care. Remove catheter as soon as possible.
- Encourage patient to eat foods high in protein and vitamin C.
- Avoid antiinflammatory drugs such as steroids to facilitate healing.
- Use aseptic technique when changing dressings and change soiled dressings immediately.
- Monitor contents of wound drainage catheters.
- Teach patient and family members how to care for surgical site, what to expect, and when and who to call if drainage at incision or drain sites increases or if other symptoms develop, such as fever, increased pain at site, redness and swelling of incision.

NURSING DIAGNOSIS

Ineffective Breathing Pattern related to postoperative pain, decreased energy, fatigue, decreased lung expansion, surgery

OUTCOME

The patient's respirations will be easy, unlabored, and adequate.

INTERVENTIONS

- Monitor respirations and chest expansion frequently for 24 to 48 hours after the surgical intervention.
- Place the bed in high-Fowler position if possible.
- Auscultate lungs and evaluate productiveness of cough; document any adventitious breath sounds and nature and amount of sputum associated with cough (as appropriate).
- Have patient cough and deep breathe at regular intervals; collaborate with patient to identify cues to remember to undertake these activities or recommend 10 deep breaths each hour.
- Encourage use of respiratory aids (e.g., incentive spirometry, if appropriate).
- Treat underlying conditions, such as pain.
- Demonstrate splinting incisional area with pillow before cough.
- Encourage patient to turn and change positions at least every 2 to 3 hours.
- Encourage early and regular ambulation and explain importance to patient.

NURSING DIAGNOSIS

Acute Pain

OUTCOME

The patient will state subjective assertions of comfort: "I am in no pain." "My pain is a 2 on a scale of 0-10." The patient will have no objective signs of discomfort (e.g., grimaces, tachycardia).

INTERVENTIONS

- Discuss the concept of pain and what it means for patient (e.g., throbbing, aching, stabbing, burning, tight).
- Educate patient and family members on the use of pain rating scale:
  - Show pain rating scale and explain its purpose.
  - Explain the components of the scale (if numeric scale used, explain what the numbers mean).
  - Set realistic comfort goals (pain rating score should be ≤4).
- Encourage patient to report pain, emphasizing that this is an important part of his or her care (Rapid Response Team box).
- Consider personal, cultural, spiritual, and ethnic beliefs in developing a pain management plan with patient.
- Document assessment of pain (intensity, duration, location, frequency) and response to pain management therapies.
- If patient has continuous local anesthetic infusion therapy (also known as *site-specific infusion therapy*) (common with select orthopedic procedures, abdominal hysterectomy, mastectomy, or hernia repair):
  - Assess site to ensure dressing is intact and catheter site is clean and dry.
  - Query patient to determine if symptoms of local anesthetic toxicity are present (dizziness, ringing in the ears, metallic taste, tingling or numbness of lips, slowed speech); contact physician to initiate immediate treatment if assessment is positive.
- If patient is to be discharged with infusion therapy, provide verbal and written instructions.
- Support patient in the use of personally effective nonpharmacologic pain management strategies (e.g., relaxation techniques, distraction, massage, biofeedback, music, guided imagery, meditation).

NURSING DIAGNOSIS

Imbalanced Nutrition: Less Than Body Requirements related to surgery

OUTCOME

The patient will eat well from prescribed diet; weight loss will be minimal.

INTERVENTIONS

- Encourage patient to eat foods high in protein and vitamin C.
- Offer frequent, small amounts of food or high-protein liquids to patient with little or no appetite.
- Encourage ambulation (improves appetite).
- Schedule procedures not to conflict with mealtime.
- Administer medication for pain as needed.
- Determine patient's previous history of nausea and vomiting after surgery; consult with physician regarding preventive measures for discharge if history is positive.
- Refer to nutritional support team if appropriate; dietary consultation may be important for patient with cultural or ethnic food preferences.

NURSING DIAGNOSIS

Impaired Physical Mobility related to surgical procedure or pain

OUTCOME

The patient will ambulate at an appropriate level and carry out activities of daily living appropriate for condition.

INTERVENTIONS

- Encourage muscle-strengthening exercises before ambulation. Encourage ambulation or position changes and extremity exercises at least every 8 hours.
- Encourage leg exercises in bed.
- Before attempting to ambulate, have patient dangle legs over side of bed until pulse rate has stabilized and patient is not dizzy.
- Have two people to help ambulate if patient is weak or obese.
- Encourage patient to walk further with each ambulation.
- Teach proper use of appropriate devices (e.g., crutches, slings, ACE bandages) and observe return demonstration.

RAPID RESPONSE TEAM

Rapid response teams (RRTs) include various responders. When the RRT is activated, as in the following scenario, the nurse also contacts the patient's physician. The nurse stays with the patient and continues to monitor the patient's status. When the RRT arrives, a brief history is provided and RRT members conduct assessments and prescribe interventions.

A postoperative patient who had undergone a vaginal hysterectomy was in the PACU for 1 hour, after which she was discharged to a surgical floor for care. At the time of discharge, vital signs were normal, and self-reported pain level was 3 on a 0 to 10 scale. After 1 hour on the surgical unit, the patient, who had been dozing, rolled over and asked for more pain medicine, saying that her pain was now a 7. The nurse checked vital signs for the hour and noted that the current blood pressure was 90/60 mm Hg while it had been 120/70 to 130/78 mm Hg since before surgery. She checked the vaginal pad, which was dry. Because the nurse had administered a dose of pain medication and because the blood pressure had changed to low-normal from previous measurements, the nurse rechecked the blood pressure in 15 minutes. The pressure was now 85/58 mm Hg. At that point in time, the nurse checked the heart rate, which was 120 beats/min, increased from the 80-89 beats/min range. She noted the vaginal pad was still dry, but checked the abdomen and discovered a hard knot on the left side of the abdomen that had not been present on admission from the PACU. The nurse immediately lowered the head of the bed, increased the intravenous rate of fluid, and called the rapid response ream.

The rapid response team arrived immediately. A stat hematocrit and type and crossmatch were drawn, and a urinary catheter was inserted to ascertain that the knot in the abdomen was not caused by a full bladder. A plasma volume expander, Hespan, was begun immediately and the patient placed in Trendelenburg's position after the BP measurement was determined to be 70/40 mm Hg. The surgeon and anesthesia provider were notified and the patient was immediately taken back to surgery; in the OR the patient was determined to have an arterial bleed, which was resutured, and then the abdomen was reexplored to verify hemostasis. The patient recovered without further incident and was discharged home 2 days later.

Modified from Mattiace R: Preventing hypovolemic shock, *Am Nurse Today* 3(3):28, 2008.

PATIENT SAFETY

Educating Patients about Medications for Pain Management

- Explain the purpose, dosage, schedule, and route of administration of any prescribed drugs and side effects to report to a physician or nurse.
- Give the patient general guidelines for the use of pain medications.
  - Provide information from the Agency for Healthcare Research and Quality Guidelines for patients.
  - Explain that a variety of pain-relief measures may be necessary for some types of pain.
  - Instruct the patient to use pain-relief measures before pain becomes severe. Determine the patient's ability or willingness to participate actively in the use of pain-relief measures, and suggest pain-relief measures the patient believes would be helpful.
  - Rely on patient behavior that indicates pain severity rather than on known physical stimuli.
  - Encourage the patient to try a pain-relief measure at least twice before abandoning it as ineffective. Instruct the patient to keep an open mind as to what may relieve pain.
  - Urge the patient to keep trying to relieve the pain and not to become discouraged.
- Discuss the use of nonopioid analgesics.
  - Inform the patient that nonopioid analgesics include acetaminophen, aspirin, and nonsteroidal antiinflammatory drugs, such as ibuprofen, indomethacin, and naproxen.
  - Explain that these medications are generally well tolerated, but have the potential to cause gastrointestinal ulceration, renal and hepatic toxic effects, and inhibition of platelet aggregation.
  - Tell the patient that if the nonopioid drug does not have a therapeutic effect initially, the dosage should be increased before another type of drug is tried.
- Discuss the use of opioids, which are indicated for severe postoperative pain or intractable pain such as that associated with cancer.
  - Inform the patient that opioids include morphine, hydromorphone, and methadone, and that these may be administered by oral route, intravenous drip, intrathecally, or epidurally to enhance the analgesic effect.
  - Explain that fixed dosage schedules with adequate doses for pain relief provide more constant blood levels and predictable pain relief. Suggest that additional doses may be needed for breakthrough pain.
  - Discuss the side effects of opioid analgesics, including constipation, vomiting, and respiratory and central nervous system depression.
  - Review the use of opioid agonists and antagonists, including nalbuphine (Nubain), butorphanol (Stadol), pentazocine (Talwin), and buprenorphine (Buprenex).
- Explain the use of analgesic potentiators.
  - Inform the patient that these drugs include hydroxyzine (Vistaril), diazepam (Valium), lorazepam (Ativan), diphenhydramine (Benadryl), and phenothiazine derivatives, such as promethazine (Phenergan), prochlorperazine (Compazine), and chlorpromazine (Thorazine).
  - Discuss the use of stimulants.
  - Inform the patient that these drugs include cocaine, methylphenidate (Ritalin), dextroamphetamine, and caffeine.
- Discuss other types of drugs used in pain control, including tricyclic antidepressants, such as amitriptyline (Elavil), imipramine (Tofranil), and doxepin (Sinequan); and butyrophenones, such as droperidol (Inapsine) and haloperidol (Haldol).
- Discuss and demonstrate the use of equipment for administering pain-relief medications.
  - External and implantable pumps for intravenous, epidural, and intrathecal administration of opioid analgesics
  - Patient-controlled analgesia, particularly for the management of acute pain, such as postoperative pain
  - Continuous subcutaneous infusion with an ambulatory infusion pump
  - Transcutaneous electrical nerve stimulation (TENS)
- Discuss the side effects of opioids. For example, constipation requires the use of laxatives and stool softeners (e.g., senna [Senokot]).

RESEARCH HIGHLIGHT

Patient Retention of Discharge Instructions

Lee and Bokovoy conducted a study to describe patient responses to predischarge instructions and teaching. The study sample included patients who had undergone either femoropopliteal bypass or abdominal aortic aneurysm repair. All patients in the study received standardized prewritten discharge instructions and verbal education from a staff nurse on the day of discharge. Items discussed in the discharge instructions included pain control, diet, bowel elimination, medications, activity limitations and progression, driving, sexual activity, bathing, incision care, clothing, foot care, and reasons to contact the surgeon. Three days after discharge, patients were contacted and surveyed to determine their understanding of the education provided.

The overall mean of comprehension was 67% with no significant difference between surgery groups. Further research on patient knowledge retention of preprinted patient education materials needs to be conducted. The authors also request more research to test the association of patient knowledge with objective outcomes, such as wound infection rates. Nurses need to be aware of patients' knowledge of discharge instructions because understanding is vital to the patient's outcome. Strategies such as "teach-back" are part of patient safety. In this type of strategy, the patient and family members, as applicable, or the individuals responsible for providing continuing care should be asked to recount in their own words what they have been told or reviewed as part of discharge education and planning.

Modified from Lee TL, Bokovoy J: Understanding discharge instructions after vascular surgery: an observational study, *J Vasc Nurs* 23(1):25-29, 2005.

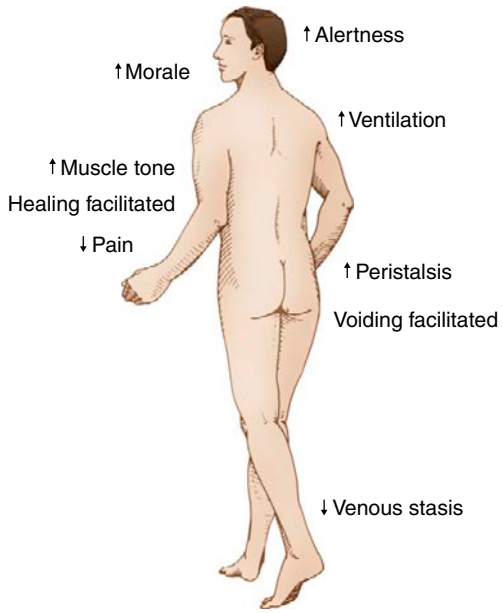

FIGURE 9-15 Benefits from early postoperative ambulation.

PATIENT AND FAMILY EDUCATION AND DISCHARGE PLANNING

Ideally, patient and family education and discharge planning begin before the patient's admission for surgery. The patient and family should be prepared to assume any care that may be needed after discharge. If needed, community resources are used. Home healthcare is a valuable resource for patients with treatment needs after discharge. The nurse responsible for the patient's care in the acute care setting collaborates and communicates with the home health team as soon as the need is identified so that the patient's care will be consistent.

The patient and family members should be instructed in the proper care of the wound or incision and signs and symptoms of a wound infection. They should know how to take a temperature and when the physician should be notified for elevated temperature. They should be knowledgeable about medication that the patient will be using at home, including analgesics (Patient Safety). Appropriate nonpharmacologic methods of pain control, such as imagery, distraction, massage, music therapy, and relaxation, also can be taught. An appointment for a return visit with the surgeon should be scheduled as ordered, and the nurse should emphasize the importance of the return visit. The patient resumes normal activities gradually according to the physician recommendations. The chapters on surgical interventions in Unit II have incorporated important elements for patient and family education and discharge planning. These elements assist the perioperative nurse in identifying and teaching what patients need to know and they facilitate safe self-care during recovery from operative and other invasive procedures (Research Highlight).

CHAPTER 10

Gastrointestinal Surgery

CHRISTINE E. SMITH

Surgery of the gastrointestinal (GI) system may be indicated to establish a diagnosis, to prevent or cure disease, to relieve symptoms or restore function, or to afford palliative measures that provide comfort or nutrition and promote quality of life. Advances in scientific knowledge, research, pharmacology, and technologic developments in the interventional disciplines as well as successful outcomes based on clinical evidence continue to broaden the spectrum of modalities and approaches to managing patients with GI disorders.

GI surgery, a subspecialty within the domain of general surgery, traditionally concerns itself with surgical management of the esophagus, stomach, small intestine, large intestine, and rectum. Gastroenterology is a medical specialty that diagnoses and manages GI disorders and conditions through endoscopic and pharmacologic approaches. Many surgical procedures that once entailed laparotomy and extensive postoperative recovery have been replaced or duplicated by endoscopic access and intervention. Endoscopic examination, enhanced with fluoroscopy, ultrasound, and video magnification in conjunction with interventional radiology, is a critical component of surgical diagnosis and postoperative evaluation. Laparoscopy, a minimally invasive approach to the intraabdominal compartment, has revolutionized GI surgery. Medical and surgical specialties have evolved to embrace and facilitate these advancements. Although clinicians may specialize in the disciplines of laparoscopy, gastroenterology, general surgery, bariatrics, GI surgical oncology, or colorectal surgery, the perioperative nurse and surgical technologist must know the fundamentals of GI surgery, interventional options available to patients, and care requirements common to all GI patients.

Surgical Anatomy

The GI tract, or alimentary canal, is a continuous tubelike structure that extends the entire length of the trunk (Figure 10-1). The tract includes the mouth; pharynx; esophagus; stomach; small intestine, consisting of the duodenum, jejunum, and ileum; and large intestine, which comprises the cecum, ascending colon, transverse colon, descending colon, sigmoid colon, rectum, and anus. The length of the GI tract in a cadaver is about 9 meters, or 30 feet. In a living person it is shorter because of sustained muscle contraction and tone. The six basic functions of the GI tract are ingestion, secretion, mixing and propulsion, digestion, absorption, and defecation.

The esophagus extends from the pharynx, at the level of the sixth cervical vertebra, and passes through the neck, posterior to the trachea and heart, and anterior to the vertebral column. The lower portion of the esophagus passes in front of the aorta and through the diaphragm, slightly to the left of the midline, to join the cardia of the stomach. Blood is supplied to the esophagus from branches of the inferior thyroid arteries, bronchial arteries, thoracic aorta, and branches of the left gastric and inferior phrenic arteries. The nerve supply comes from branches of the vagus and sympathetic nervous system. The length of the esophagus in an adult is about 25 cm, or 10 inches. The esophagus is a collapsible musculomembranous tube that functions primarily to transport ingested material, by peristalsis, from the pharynx to the stomach.

The stomach is an expanded J-shaped organ situated between the esophagus and the duodenum. It lies in the upper left abdominal cavity, slightly to the left of the midline and beneath the diaphragm. The stomach is divided into three parts: the fundus, the body, and the antrum (Figure 10-2). The fundus lies below the left dome of the diaphragm, behind the apex of the heart. The body and antrum lie in an oblique direction within the abdominal cavity. The stomach is stabilized indirectly by the lower portion of the esophagus and directly by its attachment to the duodenum, which is anchored to the posterior parietal peritoneum. The omentum, the peritoneal ligaments, and branches of the celiac vessel provide additional support to the stomach.

The convex, or lower, margin of the stomach is known as the *greater curvature;* the concave, or upper, margin is the *lesser curvature*. Attached to the greater curvature is the greater omentum, which is a double fold of peritoneum containing fat. It covers the intestines loosely and is not to be confused with the mesentery, which connects the intestines with the posterior abdominal wall. The left gastroepiploic branch of the splenic artery and the right gastroepiploic branch of the hepatic artery run through the greater omentum. The lesser omentum, attached to the lesser curvature of the stomach, contains the left gastric artery, a branch of the celiac axis, and the right gastric branch of the hepatic artery.

Stomach functions include acceptance and storage of ingested material; chemical and mechanical digestion through the production of gastric lipase, pepsinogen, hydrochloric acid, gastrin, and intrinsic factor, responsibility for the absorption of vitamin B_{12}; and peristaltic waves, which both mix and propel stomach contents, or chyme, into the duodenum.

The small intestine, the longest part of the digestive tract, begins at the pylorus and ends at the ileocecal valve (Figure 10-3). The small intestine varies in size with the degree of contraction but is usually about 3 meters in length and 2.5 cm in diameter in the adult. It is divided into three parts: the duodenum, about 25 cm long; the jejunum, which is about two

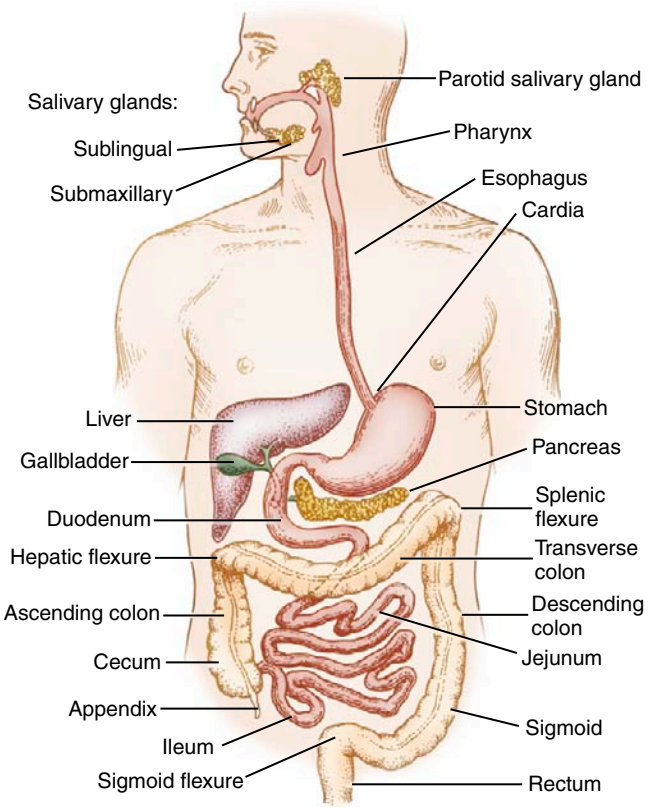

FIGURE 10-1 Alimentary canal and its appendages.

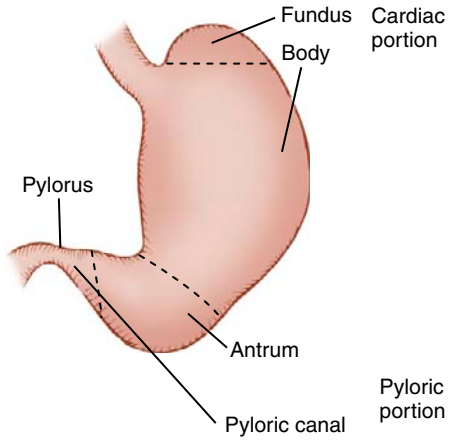

FIGURE 10-2 Regional anatomy of stomach.

fifths of the length of the entire small intestine; and the ileum, which makes up the remaining length in an adult. The duodenum, which is the proximal portion of the small intestine, begins at the pylorus, is contiguous with the jejunum, and is stabilized by a fusion between the pancreas and the posterior parietal peritoneum. The duodenum is divided into four portions: superior (I), descending (II), transverse (III), and ascending (IV) (Figure 10-4). Nearly all of the superior portion mucosa is characterized by the lack of folds; it appears slightly dilated and is referred to as the *duodenal bulb*. The characteristic circular folds of the small intestinal mucosa begin proximal to the end of the superior portion of the duodenum and

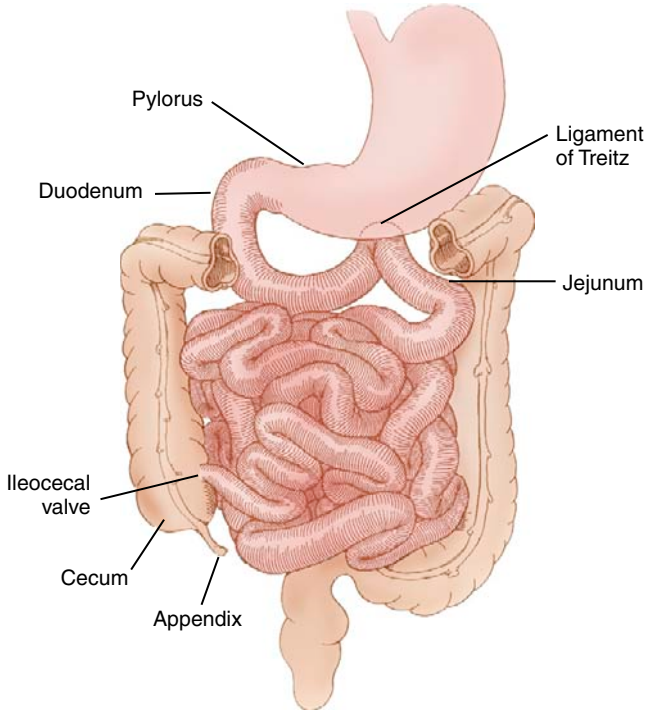

FIGURE 10-3 Illustration of the small bowel; the duodenum originates at the pylorus and flexes at the ligament of Treitz where the jejunum begins. The jejunum extends into the ileum, which terminates at the ileocecal valve at the cecum.

extend through the jejunum. They become less prominent in the ileum. The purpose of the circular mucosal folds, called *plicae circulares of Kerckring* or *valvulae conniventes,* is to provide greater mucosal surface area.

The common bile duct and the main pancreatic duct enter the medial wall of the middle of the second portion of the duodenum at the ampulla of Vater. The first, second, and third portions of the duodenum curve in a C-loop concavity in which the head of the pancreas is located. The fourth portion of the duodenum ascends to the duodenojejunal flexure. The duodenojejunal flexure is stabilized by the ligament of Treitz, which suspends the duodenum from the posterior body wall. The ligament of Treitz serves as a landmark during any abdominal exploration because it provides the surgeon with a reliable orientation of the patient's anatomy.

The blood supply of the duodenum comes from the arterial branches of the celiac axis (Figure 10-5). The gastroduodenal artery branches off the hepatic artery and is located behind the duodenal bulb. At the inferior margin of the bulb, the gastroduodenal artery divides into the right gastroepiploic artery and a superior pancreaticoduodenal branch. The superior pancreaticoduodenal artery supplies blood to the proximal duodenum and head of the pancreas. The inferior pancreaticoduodenal artery branch of the superior mesenteric artery supplies blood to the third and fourth portions of the duodenum as well as to the head and body of the pancreas.

The jejunum, situated in the upper portion of the abdomen, joins with the ileum, situated in the lower portion of the abdominal cavity. The ileum empties into the large intestine through the ileocecal valve. The jejunum and ileum are suspended by the mesentery, which is attached to the posterior

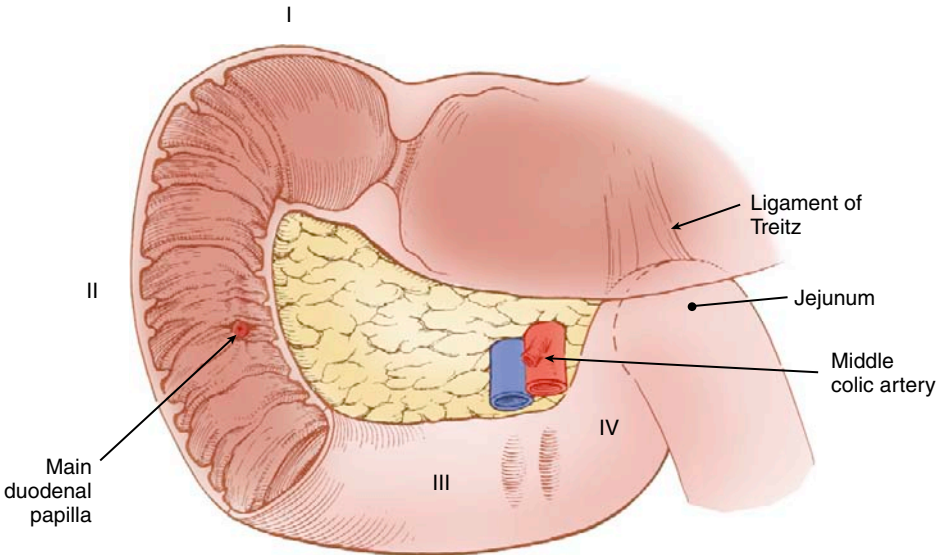

FIGURE 10-4 The duodenum consists of four portions, as illustrated.

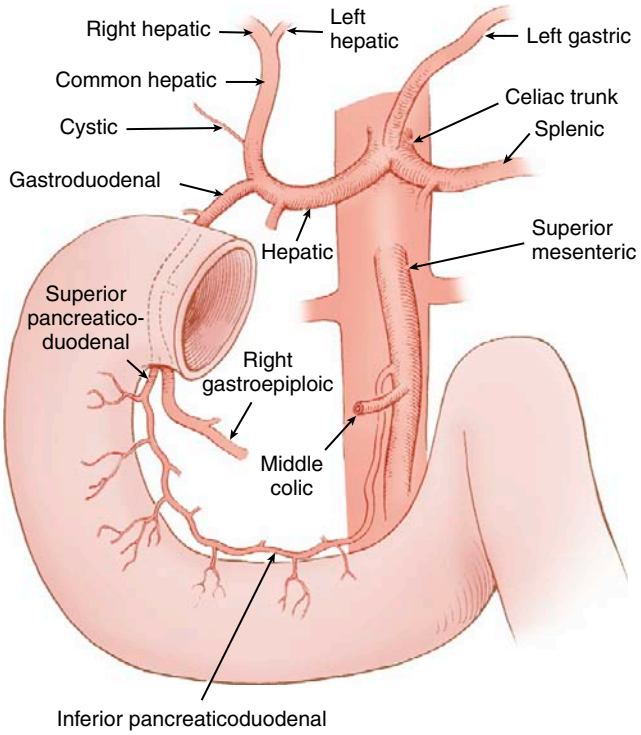

FIGURE 10-5 Blood supply of the duodenum.

abdominal wall. The free border of the mesentery, which is about 5.5 meters (18 feet) long, contains branches of the superior mesenteric artery, many veins, lymph nodes, and nerve fibers. The blood supply to the jejunum and ileum comes entirely from the superior mesenteric artery. The small bowel contains major deposits of lymphatic tissue, known as *Peyer's patches,* in the ileum. The rich lymphatic drainage of the small bowel plays a major role in fat absorption. Lymphatic drainage from the mucosa proceeds through the wall of the small intestine to lymph nodes adjacent to the mesentery. Lymphatic drainage then proceeds to larger lymphatics that communicate with the retroperitoneal cisterna chyli and from there to the thoracic duct. The lymphatics of the intestine play a major role in the body's immune defense as well as in the distribution of cells arising from intestinal neoplasms.

Compared to the ileum, the jejunum has a larger circumference and thickness. The mesenteric vessels usually form only one or two arcades, a series of anastomosing arterial arches, compared with the multiple vascular arcades of the ileum. The jejunal mucosa is thick and has prominent *plicae circulares*. The ileum mucosa is thinner with few plicae.

The small intestine serves two important, but opposite, functions simultaneously. It absorbs essential nutrients at 95% efficiency while it provides an effective barrier from harmful ingested environmental elements. The remarkably large surface area of the combined small and large intestinal mucosa is estimated to be 200 square meters, about the size of a doubles' tennis court.

The large intestine begins at the ileocecal valve and ends at the anus. It is divided into the cecum, colon, and rectum. The cecum attaches to the ileum and extends about 7 cm below it. The cecum in an adult usually adheres to the posterior wall of the peritoneal cavity and has a serosal covering on its anterior wall only. The cecum forms a blind pouch from which the appendix projects.

The colon, about 1.5 meters long, is divided into four parts: the ascending colon, the transverse colon, the descending colon, and the sigmoid colon (Figure 10-6). The *ascending colon* extends upward from the ileocecal valve to the hepatic flexure. The upper portion of the ascending colon lies behind the right lobe of the liver and in front of the anterior surface of the right kidney. The *transverse colon* begins at the hepatic flexure and ends at the splenic flexure. It lies below the stomach and is attached to the transverse mesocolon. The *descending colon* extends downward from the splenic flexure to just below the iliac crest. The iliac portion of the sigmoid colon lies on the inner surface of the left iliac muscle. The remaining portion of the colon passes over the pelvic rim into the pelvic cavity and lies partly in the abdomen and partly in the pelvis. It then forms an S-shaped curve in the pelvis and

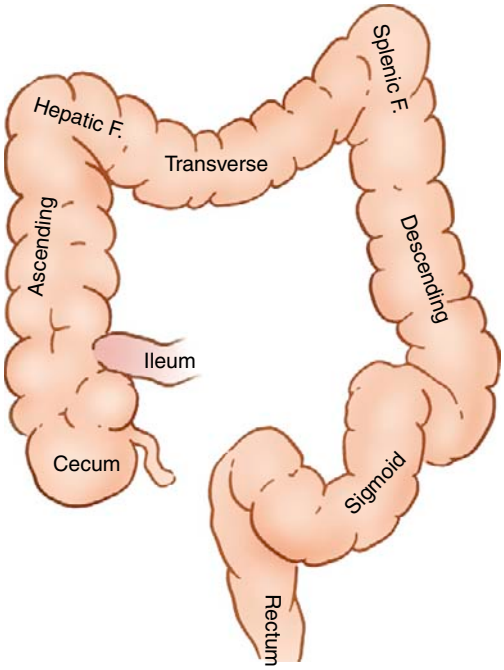

FIGURE 10-6 Anatomic division of large intestine, showing locations of hepatic flexure and splenic flexure. *F,* Flexure.

terminates in the rectum at the level of the third segment of the sacral vertebrae. The blood supply to the ascending colon, hepatic flexure, and transverse colon comes from the superior mesenteric artery, whereas the blood supply to the descending colon and rectum comes from the inferior mesenteric artery (Figure 10-7).

The wall of the colon consists of taeniae coli, epiploic appendices, and haustra. The taeniae coli are three longitudinal, or axial, strips of muscles distributed around the circumference of the colon. They represent the longitudinal muscle layer, which is not complete in the colon (the small intestine and rectum have both circular and complete longitudinal muscle layers). The epiploic appendices are fatty appendages along the bowel that have no particular function. The haustra are sacculations that outpouch from the bowel wall among the taeniae coli. The diameter of the colon varies in size from about 9 cm (3½ inches) in the cecum to an average of about 1.25 cm (½ inch) in the sigmoid colon.

The rectum begins at the sigmoid colon and ends in the anus. This slightly curved passage is surrounded by the pelvic fascia as it lies on the anterior surface of the sacrum and coccyx. In the male, the rectum lies behind the prostate gland, seminal vesicles, and bladder. In the female, the rectum lies behind the uterus and the vagina. A septum rectovesical, also

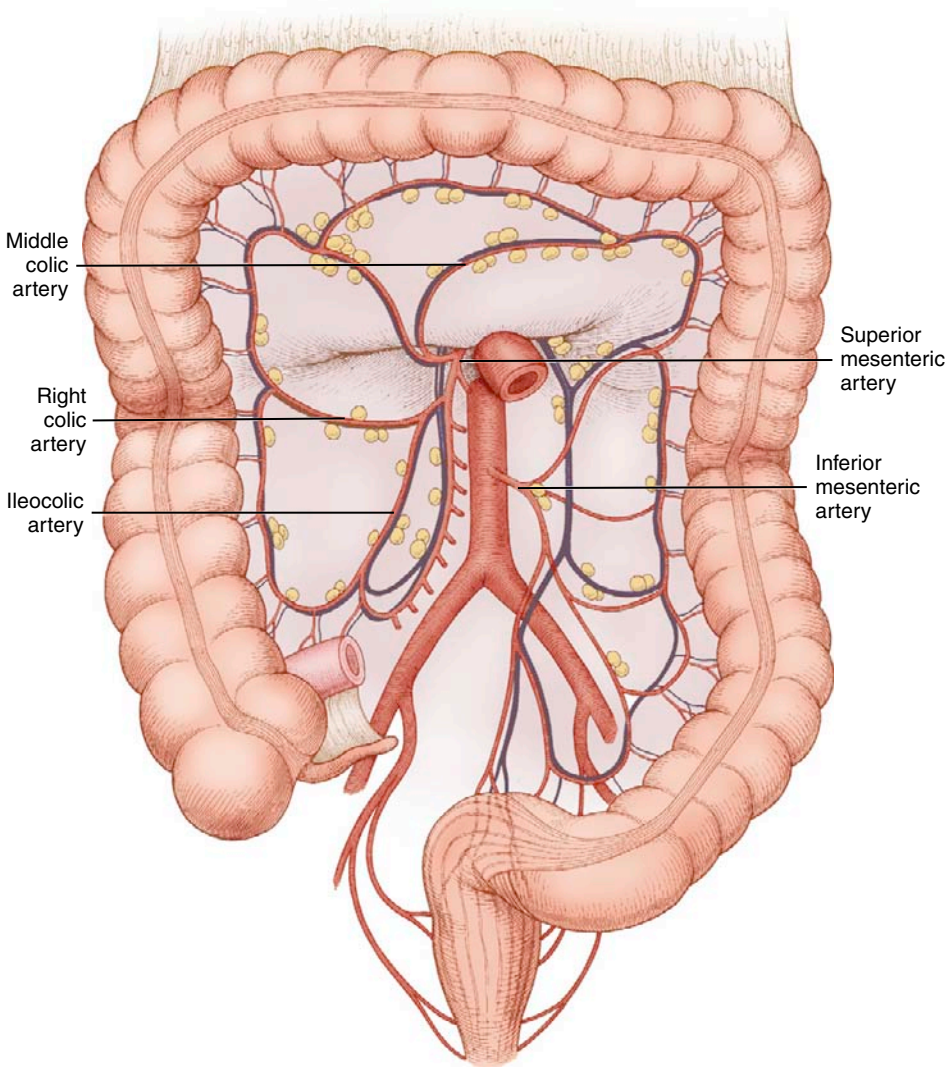

FIGURE 10-7 Blood supply of the colon.

called *Denonvilliers' fascia,* separates the rectum from the urogenital structures. The rectum is suspended in the pelvis by fascia extending from the right and left pelvic sidewalls. Rectosacral fascia extends from the sacrum to the anorectal junction and suspends the rectum posteriorly. The rectum dilates just before it becomes the anal canal. This dilation, or ampulla, presents folds called *Houston's valves*. The wall of the rectum consists of four layers, similar to those of the small intestine.

The anal canal is a narrow passage that passes downward and slightly posteriorly. It is surrounded and controlled by two circular muscle groups, which form the external and internal anal sphincters. The internal sphincter is a continuation of the longitudinal muscle layer.

The primary function of the large intestine is to reabsorb water and electrolytes, to form solid waste into feces, to synthesize vitamin K and B-complex vitamins, and to propel and eliminate solid food residue and waste through defecation.

The GI tract constitutes a complex microbiologic ecosystem that supports and maintains essential digestive and protective functions vital to life, yet it presents significant risks and challenges during diagnostic and surgical interventions. Substantial populations of microorganisms, both obligate anaerobes and facultative bacterial spores, exist in the intestinal lumen. The organisms of the upper tract differ from those of the lower tract, with the highest concentration in the distal bowel. These organisms can contribute to contamination and disease processes within the intestinal tract and throughout the body. Gastric and intestinal pH, while necessary for digestive benefit and protection from selected organisms, can compromise peritoneal tissues and structures when unplanned spillage or leakage occurs. The pH of the stomach ranges from 1.5 to 3, whereas the pH of the intestines can range from 7 to 8.5.

Perioperative Nursing Considerations

GI surgery and endoscopic procedures present special considerations related to the planned procedure, instrumentation, approach, anatomic structures involved, primary and secondary diagnoses, health status of the patient, surgeon and patient preferences, and availability of special institutional resources. Special institutional resources may include a bariatric program, an oncology program with research protocols, a transplant program, a trauma center, or a technologically advanced OR with computer-integrated imaging display and robotics. Optimum care of the patient undergoing GI surgery and other invasive GI procedures relies on sound knowledge and experience, thorough assessment of the patient with identification of care needs, preplanning and preparation, and follow-through with competent care and evaluation of the completed process and its results. The risks for injury or failure to achieve the intended outcome are equally present in GI surgery as in any surgical or invasive procedure. No procedure is routine and unexpected outcomes can occur even when planning and preventive measures have been employed under the most optimal circumstances. Although it is prudent to address and review the vulnerabilities faced by all surgical patients, specific concerns arise for patients undergoing GI surgery and other invasive GI procedures.

Assessment

Patient care begins with assessment. Individualized care that integrates physiologic with psychologic preparation is given to each patient. Patients undergoing GI surgery need to understand why they need preoperative preparation, what the intended surgical intervention will be, and how it will affect them and their family postoperatively. A preoperative nursing assessment of the patient is essential to plan and implement intraoperative nursing care and evaluate patient outcomes. The nurse ensures that the patient understands the nature of the surgery, the expected site of the incision(s), the anticipated outcome(s), and follow-up recovery and care. Turning, coughing, and deep breathing are taught preoperatively and reinforced after surgery. If an ostomy is anticipated, a wound ostomy continence nurse (WOCN, formerly called an *enterostomal therapist*) is consulted to site-mark the abdomen for optimal stoma placement (Box 10-1) and prepare the patient for the postoperative management and care. The WOCN also helps to allay fears and anxieties for the patient and the family (Carmel and Goldberg, 2004).

BOX 10-1

Ostomy Site-Marking

- Determine planned surgical procedure and ostomy (refer to surgeon's notes and preferences).
- Explain procedure to patient, and establish privacy.
- Provide ostomy appliance and literature for patient and family to read and examine.
- Verify patient's knowledge and understanding of surgery and planned ostomy.
- Examine abdominal skin integrity and surface for scars, lesions, bulges, implants, and stomas.
- Locate waistline and patient's preferred beltline. Patient may have to put on pants to illustrate.
- Locate abdominal skinfolds, creases, and bulges as patient lies flat, stands, bends forward, and sits upright.
- Identify the lateral margins of the rectus abdominis muscle. Palpate while patient coughs.
- Select a site within the rectus margin on the crest of the infraumbilical or infraabdominal bulge.
- Place fingertip on proposed site and verify patient can see site when standing or sitting.
- Avoid belt or waistline, bony prominences, scars, excoriated lesions, creases, folds, below pendulous breasts, umbilicus, hernia, or horizontal plane with existing stoma or fistula.
- Position ostomy pouch faceplate on proposed site as template to ensure avoidance of umbilicus, beltline, and waistline. At least 2 inches of smooth skin should surround stoma for good seal. (Patients who wear their pants low below the waistline and have selected a lower quadrant site for the ostomy can wear suspenders or sweat pants postoperatively; this enables the pants to be held loosely above the stoma without irritating the site and surrounding skin.)
- Mark site boldly with indelible or permanent skin marking pen. Cover with clear adhesive dressing to protect from shower or wear.
- Verify site by having patient stand, sit, and twist, noting avoidance of creases and interference. Patient must be able to see site for later self-care.
- Document skin assessment, teaching, patient's understanding and level of acceptance, site selected, and rationale for choice.

Nursing assessment of the patient before GI procedures includes the following information (Box 10-2):

- Demographic data
- Present problems, chief complaint, or symptoms that led the patient to seek medical attention
- Medical history, including nutrition and allergies to foods, drugs, latex, or other substances
- History of chronic disease or other medical conditions
- Surgical history, including prior procedures and anesthesia experiences
- Medications, including use of nonsteroidal antiinflammatory drugs (NSAIDs), antacids, histamine blockers, proton pump inhibitors, steroids, or anticoagulants
- Family history
- Personal and social history, including use of alcohol, nicotine, herbal nutraceuticals, and illicit substances
- Focused GI assessment, including bowel sounds, pain, abdomen appearance, and GI risk factors

BOX 10-2

Assessment Data

GENERAL DATA

Usual height, weight, and body mass index (BMI, measured as weight in kilograms divided by height in meters squared)

Nutrition
- Types of food usually eaten at each meal or snack
- Food likes and dislikes
- Alcohol consumption
- Tobacco use
- Religious, cultural, ethnic, or medically prescribed food restrictions
- Food intolerances or allergies
- Patient's perception and concerns pertaining to diet and weight
- Effects of lifestyle on diet and weight gain or loss
- Vitamins and other nutritional or herbal supplements used

Oral hygiene

Bowel elimination patterns

Use of medications or laxatives
- Stool softeners
- Antiemetics
- Antidiarrheals
- Antacids
- Histamine blockers or proton pump inhibitors
- Frequent or high doses of aspirin, acetaminophen, or ibuprofen

SPECIFIC DATA

Oral lesions

Appetite

Digestion or indigestion

Dysphagia

Nausea

Vomiting

Hematemesis

Change in stool
- Color (clay color, black)
- Contents (undigested food, blood, mucus)

Constipation

Diarrhea

Flatulence

Hemorrhoids

Abdominal pain

Hepatitis

Jaundice

Ulcers

Gallstones

Polyps

Tumors

Anal discomfort

Fecal incontinence

Exposure to infectious disease

Examination of the patient's abdomen includes inspection, palpation, and auscultation of bowel sounds. Systematic investigation, with open-ended questions, addresses descriptions of pain with or without palpation; digestion; presence of nausea, vomiting, diarrhea, or constipation; bleeding; recent trauma; anorexia or bulimia; weight loss or gain programs; and nutrition.

Laboratory studies might include a complete blood count (CBC) with differential, serum electrolytes, platelet count, cholesterol level, vitamin and mineral levels, liver function, serum proteins, coagulation profile, pancreatic function, and indices of nutritional status (Table 10-1).

Diagnostic endoscopic examinations, radiologic studies with or without contrast markers, abdominal ultrasound, endoscopic ultrasound (EUS), magnetic resonance imaging (MRI), positron emission tomography (PET), and computed tomography (CT) imaging scans plus GI secretion studies add further information about the patient's health or disease process to help formulate the surgical plan. Advances in endoscopic technology provide enhanced details of GI anatomy and pathology. EUS combines endoscopy and ultrasound, using sound waves to generate an image of the histologic layers of the esophageal, gastric, and intestinal walls. The frequencies used, higher than those used in traditional ultrasound, provide high-level accuracy of depth of mucosal invasion (Birn, 2005). EUS is of critical importance in staging GI malignancies and determining surgical options and potential for therapeutic resection. Endoscopic image-enhancement techniques include high-resolution endoscopes with narrow-band imaging and magnification to identify mucosal surface details; narrow-band filters to see capillary patterns, pits, and villi; and chromoendoscopy (staining techniques) and fluorescence to differentiate between normal and dysplastic tissue (Kwon et al, 2005).

Capsule endoscopy is an emerging technology and noninvasive diagnostic test that uses a small wireless camera in the shape of a capsule about the size of a large vitamin. It is swallowed with a few sips of water and propelled along the GI tract by normal peristalsis. The capsule glides down the esophagus taking two color digital pictures per second, which are transmitted to a data recording device worn by the patient. This device is suitable for imaging the mucosal surface of the esophagus, stomach, and small intestine. The battery power of the capsule lasts about 8 hours. The capsule is eventually passed naturally within 24 to 72 hours. The wireless capsule has dramatically enhanced the ability to visualize the mucosal surface of the small intestine. The small bowel makes up 90% of the mucosal surface of the entire GI tract and had formerly been constrained by the limits of traditional diagnostic modalities. The only preprocedure preparation is an 8-hour fast. Contraindications to capsule endoscopy include inability to swallow a large capsule; small bowel strictures, narrowing,

TABLE 10-1

Common Serum Studies with Relevance to GI Surgery

Test	Normal Adult Values	Significance of Abnormal Values
COMPLETE BLOOD COUNT WITH DIFFERENTIAL (CBC WITH DIFF)		
Red blood cell count (RBC)	*Men:* 4.7-6.1 million/mm^3 *Women:* 4.2-5.4 million/mm^3	Low value indicates anemia from blood loss, hemolysis, dietary deficiency, drug ingestion, bone marrow failure, or chronic illness. High value indicates compensation for high altitudes, chronic anoxia, or polycythemia vera.
Hemoglobin (Hb) concentration	*Men:* 14-18 g/dl *Women:* 12-16 g/dl	Low and high values tend to be caused by same processes that cause low or high values for RBCs. Artificially high values seen in dehydration.
Hematocrit (Hct)	*Men:* 42%-52% *Women:* 37%-47%	Low and high values are same as above.
Mean corpuscular volume (MCV)	*Adults:* 80-95/mm^3	High values found in megaloblastic anemias (vitamin B_{12} deficiency). Low values seen in iron-deficiency anemia or thalassemia.
Mean corpuscular hemoglobin (MCH)	*Adults:* 27-31 pg	Low and high values tend to be caused by same processes that cause low or high values for MCV.
Mean corpuscular hemoglobin concentration (MCHC)	*Adults:* 32-36 g/dl	Low value indicates hemoglobin deficiency seen in iron-deficiency anemia or thalassemia.
White blood cell count (WBC) differential	*Adults:* 5000-10,000/mm^3	Elevated WBC level indicates infection or leukemia, trauma, or stress. Decreased WBC level may indicate bone marrow failure, overwhelming infection, dietary deficiency, drug toxicity, or autoimmune disease.
Neutrophils	55%-70%	Elevated neutrophil count may indicate acute suppurative infection.
Lymphocytes, monocytes	20%-40%, 2%-8%	Decreased neutrophil count may indicate overwhelming bacterial infection (especially in elderly) or dietary deficiency.
Eosinophils	1%-4%	Elevated lymphocyte count may indicate chronic bacterial or viral infection.
Basophils	0.5%-1%	Decreased lymphocytes may indicate sepsis. Elevated eosinophils may indicate parasitic infestation, allergic reactions, or autoimmune diseases. A "shift to the left" means percentage of neutrophils and immature leukocytes is increased, which occurs with infection.
Platelet count	150,000-400,000/mm^3	Reduced levels of platelets may result from decreased platelet production, increased sequestration (as seen in hypersplenism), increased platelet destruction or consumption (e.g., disseminated intravascular coagulation [DIC]), or loss of platelets through hemorrhage. Elevated levels may indicate severe hemorrhage, polycythemia vera, postsplenectomy syndromes, and some malignant disorders.
SERUM ELECTROLYTES		
Sodium (Na^+)	136-145 mEq/L	Elevated levels may be seen with excessive sweating, extensive burns, osmotic diuresis, and excessive sodium intake or reduced sodium excretion. Reduced levels may be seen with inadequate sodium intake, increased sodium losses (e.g., vomiting, nasogastric suction, diarrhea, renal disease, third-space losses of sodium).
Phosphate (PO_4^{2-})	3-4 mg/dl	Decreased levels seen in long-term antacid ingestion.
Potassium (K^+)	3.5-5 mEq/L	Elevated levels may indicate excessive intake or reduced excretion of potassium (e.g., renal failure). Crush injuries cause release of intracellular potassium, or metabolic acidosis. Reduced levels may indicate inadequate intake or excessive losses (e.g., diarrhea, vomiting, use of diuretics, hyperaldosteronism) or result of metabolic alkalosis or administration of glucose, insulin, or calcium (which causes a shift of potassium from bloodstream into cells).
Chloride (Cl^-)	98-106 mEq/L	Changes in chloride concentration usually parallel changes in sodium concentration. Decreased levels seen in patients who undergo long-term gastric suctioning.
Carbon dioxide (CO_2)	23-30 mEq/L	Elevated levels are seen with acidosis. Reduced levels are seen with alkalosis.

TABLE 10-1

Common Serum Studies with Relevance to GI Surgery—cont'd

Test	Normal Adult Values	Significance of Abnormal Values
ARTERIAL BLOOD GASES		
pH	7.35-7.45	High levels indicate alkalosis. Low levels reflect acidosis.
Partial pressure of carbon dioxide (P_{CO_2})	35-45 mm Hg	High levels indicate carbon dioxide retention caused by respiratory depression or pulmonary disease (respiratory acidosis). Low levels reflect excessive loss of carbon dioxide through hyperventilation (respiratory alkalosis from overventilation or emotional trauma; may also be seen as compensatory response in metabolic acidosis).
Bicarbonate (HCO_3^-)	21-28 mEq/L	Low levels indicate metabolic acidosis caused by excessive acid production, resulting in depletion of HCO_3^- (e.g., diabetic acidosis); failure to eliminate H^+ ions, resulting in depletion of HCO_3^- (e.g., renal failure); or excessive loss of HCO_3^- (e.g., intestinal losses through diarrhea, fistula drainage). Low levels may also be seen with insulin overdose, insulinoma, hypothyroidism, hypopituitarism, Addison's disease, and extensive liver disease. High levels indicate metabolic alkalosis resulting from bicarbonate overdose or excessive gastric losses. May also be seen as compensatory response in patients with prolonged respiratory acidosis, pancreatic disorders (e.g., adenoma, pancreatitis), corticosteroid therapy, diuretics, Cushing's disease, and hyperthyroidism.
COAGULATION STUDIES		
Prothrombin time (PT)	85%-100% or 11-12.5 sec	Elevated times with anticoagulant, acetylsalicylic acid (ASA), and nonsteroidal antiinflammatory drug (NSAID) use. Decreased times may be seen in malignant disease caused by unidentified hypercoagulability factors.
Partial prothrombin time (PTT)	60-70 sec	Increased in acquired or congenital clotting factor deficiencies, cirrhosis, vitamin K deficiency, leukemia, DIC, heparin administration, hypofibrinogenemia, von Willebrand's disease, hemophilia. Decreased in early stages of DIC, extensive cancer.
Activated partial prothrombin time (APTT)	30-40 sec	Same as for PTT.
OTHER SERUM STUDIES		
Albumin	3.5-5.5 mg/day	Decreased levels seen in protein malnutrition and hepatocellular injury.
Alkaline phosphatase (ALP)	30-120 units/L	Slightly elevated in elderly. Elevated in intestinal ischemia. Decreased with excess vitamin B ingestion.
Amylase	60-120 Somogyi units/dl	Increased in penetrating or perforated peptic ulcer, perforated or necrotic bowel, or duodenal obstruction.
Ammonia	10-80 mcg/dl	Increased in gastrointestinal (GI) bleeding, GI obstruction, or liver disease.
Carcinoembryonic antigen (CEA)	<5 ng/ml	Elevated in GI cancer, colitis, diverticulitis, cirrhosis, peptic ulcer, hepatobiliary and pancreatic cancers.
Complement assay (C3 and C4)	C3: 55-120 mg/dl C4: 20-50 mg/dl Total complement: 75-160 mg/dl	Elevated in ulcerative colitis and cancer.
Cortisol (hydrocortisone)	8 AM: 5-23 mcg/dl 4 PM: 3-13 mcg/dl	Elevated in obesity.
C-reactive protein	<1 mg/dl	Elevated in Crohn's disease, postoperative wound infection, malignant disease.
Transferrin (serum)	250-300 mg/dl	Decreased levels may indicate protein malnutrition; transferrin levels may be used to monitor a patient's response to nutritional support therapy since half-life of transferrin is 8-10 days, whereas half-life of albumin is 19-20 days (this means that, compared to albumin levels, transferrin levels reflect changes in patient's visceral protein status much faster).

TABLE 10-1

Common Serum Studies with Relevance to GI Surgery—cont'd

Test	Normal Adult Values	Significance of Abnormal Values
Prealbumin (serum)	15-32 mg/dl	Decreased levels seen in protein malnutrition. Because half-life of prealbumin is 2-3 days, these values, compared to transferrin levels, reflect changes in patient's visceral protein status even faster.
Total lymphocyte count (serum)	>150,000/mm^3	Decreased levels may be seen in protein malnutrition; however, many other conditions affect total lymphocyte count (e.g., infections, conditions affecting WBC production).

Data from Pagana KD, Pagana TJ: *Mosby's diagnostic and laboratory test reference,* ed 9, St Louis, 2009, Mosby.

or fistulas; swallowing disorders; suspected intestinal obstruction; and pacemakers. The patient is instructed not to undergo MRI imaging for at least 30 days to ensure that the capsule has been passed and will not cause internal thermal injury. Reports and images of capsule endoscopy results should be available at the time of surgery.

Nursing Diagnosis

Perioperative nurses often assess, diagnose, and plan care in a short preoperative time frame, often sharing the patient's attention with other members of the surgical team and the patient's family. They must be aware of the care considerations general to all surgical patients plus those implications specific to patients anticipating GI surgery. A focused preoperative assessment provides data to formulate nursing diagnoses, identify desired outcomes, and organize and prioritize the plan for intraoperative care.

Nursing diagnoses related to the care of patients undergoing GI surgery might include the following:

- Anxiety related to perioperative events
- Deficient Knowledge related to impending surgery
- Disturbed Body Image related to intestinal diversion (when diversion possible or planned)
- Risk for Imbalanced Body Temperature
- Risk for Infection at the surgical site
- Risk for Perioperative Positioning Injury
- Impaired Tissue Integrity related to lasers, thermal devices, electrosurgery, radiation, or chemical solutions
- Risk for Injury from retained surgical items, wrong procedure, wrong site, or administration of wrong or incorrect medications
- Risk for Imbalanced Fluid Volume

Outcome Identification

Outcomes identified for selected nursing diagnoses could be stated as follows:

- The patient will demonstrate or verbalize decreased anxiety and ability to cope throughout the perioperative period.
- The patient will verbalize understanding of the surgical procedure and expected responses.
- The patient will demonstrate ability to cope and acceptance of appearance and self-care.
- The patient will be at or returning to normothermia at the conclusion of the immediate postoperative period.
- The patient will be free from signs and symptoms of surgical site infection.
- The patient will be free from perioperative positioning injury.
- The patient will be free of evidence of impaired tissue integrity.
- The patient will be free from injury related to retained surgical items, wrong procedure, wrong site, and medication errors.
- The patient's fluid volume, electrolyte levels, and acid-base balance will be consistent with or improved from preoperative baseline levels (Carpenito-Moyet, 2007).

Rationales guide the interventions aimed at achieving nursing outcomes for the surgical patient. Rationales identified for the selected nursing outcomes are presented in Box 10-3, p. 306.

Planning

The plan of care is designed to guide both the nurse and the surgical technologist in selecting materials and supplies and providing interventions based on evidence, research, and past successful outcomes. Planning and preparation extend beyond the list of items and informational notes on the surgeon's preference card/pick list.

Preoperative assessment enables the perioperative nurse to plan for specific physiologic, psychologic, and technical needs of the patient. For example, patient size influences surgical positioning and may require additional instruments, such as deeper retractors and longer forceps and scissors. A safe, clean, and well-equipped surgical environment requires meticulous planning that integrates standard recommended practices with information specific to the patient with materials typically used during this procedure by this surgical team. The perioperative nurse and surgical technologist proactively organize, prioritize, ensure safety, and expedite all aspects of the surgical experience for the patient.

A Sample Plan of Care for a patient undergoing GI surgery follows on pp. 304-305.

Implementation

Implementation includes activities involved with the preparation of the surgical environment; procurement of the supplies, equipment, materials, and devices; and team communication based on materials and processes typical for this particular procedure and team, along with data gathered from the patient, family, and medical record.

Both open laparotomy and laparoscopic approaches are usually performed with general endotracheal or spinal anesthesia. The choice of anesthetic depends on the patient's health status, planned surgical or laparoscopic approach, length of

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Anxiety related to perioperative events

OUTCOME
The patient will demonstrate or verbalize decreased anxiety and ability to cope throughout the perioperative period.

INTERVENTIONS
- Explain preoperative activities and expectations (e.g., IV lines, skin preparation, positioning), sequence of sensory experiences and activities in the OR, and postoperative expectations (e.g., postanesthesia care unit [PACU], drains, catheters, dressings).
- Provide time for patient and family members to ask questions.
- Determine effective coping strategies used by patient in the past; support these as appropriate.
- Minimize stimuli in the OR that can contribute to anxiety (e.g., high noise levels, excessive talking, music that is not of the patient's preference).
- Remain with the patient during induction; convey caring behaviors (e.g., appropriate touch; a soft, reassuring voice; warm blankets).
- Maintain the patient's dignity and privacy.
- Encourage expression of feelings and concerns.
- Communicate unresolved or excessive anxiety to team members.

NURSING DIAGNOSIS
Deficient Knowledge related to impending surgery

OUTCOME
The patient will verbalize understanding of the surgical procedure and expected responses.

INTERVENTIONS
- Verify information the patient and family need and want to know. Determine current knowledge level and perceptions of surgery. Take into consideration language, culture, hearing or visual impairment, health literacy, cognitive impairments, and any relevant disability.
- Initiate preoperative education and discharge planning early in the perioperative process.
- Assess readiness to learn and patient's preferred learning style.
- Include family or patient's accompanying responsible adult in teaching. Use simple language. Present information in the patient's dominant language (use an interpreter if necessary). Note any sensory impairments and accommodate. When possible, provide written information that replicates verbal education.
- Verify patient's understanding of material presented by having the patient repeat back, in his or her own words, information that has been presented. Correct misunderstandings.
- Communicate patient or family concerns to appropriate surgical team members, or make appropriate referral.

NURSING DIAGNOSIS
Disturbed Body Image related to intestinal diversion (when diversion possible or planned)

OUTCOME
Patient will demonstrate ability to cope and acceptance of appearance and self-care.

INTERVENTIONS
- Encourage verbalization of feelings about anticipated alterations in body function if diversion procedure planned.
- Elicit patient's and family's (if appropriate) perceptions of planned surgical intervention.
- Identify effective sources of support.
- Encourage patient to implement cultural, religious, ethnic, or social customs associated with perceived loss.
- Provide accurate information relevant to patient's postoperative expectations (general principles of ostomy care and solutions to concerns that may be worrying patient).
- Refer patient to wound, ostomy, and continence nurse (WOCN) if this has not already been done.

NURSING DIAGNOSIS
Risk for Imbalanced Body Temperature

OUTCOME
Patient will be at or returning to normothermia at the conclusion of the immediate postoperative period.

INTERVENTIONS
- Determine patient's risk for developing inadvertent hypothermia.
- Regulate ambient room temperature in range between 20° C and 25.6° C (68° F and 78° F) as appropriate.
- Monitor patient temperature during surgery.
- Minimize unnecessary patient exposure. Keep patient covered with warm blankets before induction. Ask patient if he or she is comfortable/warm.
- Use effective skin-surface warming methods (e.g., forced-air warming, circulating water garment, energy transfer pads) preoperatively, intraoperatively, and in PACU as needed.
- Use warmed irrigating solutions and fluid replacement therapy (e.g., IVs) as appropriate. Follow manufacturer's recommendations when using warming equipment.
- Cover patient with a warm blanket before transport to the PACU.

NURSING DIAGNOSIS
Risk for Infection at the surgical site related to operative or other invasive procedure

OUTCOME
Patient will be free from signs and symptoms of surgical site infection.

INTERVENTIONS
- Identify patient-specific risk factors for infection (e.g., altered nutritional status, chronic diseases, preoperative radiation therapy, total parenteral nutrition [TPN]).
- Follow institutional protocol for perioperative skin preparation (patient bath or shower preoperatively with prescribed antimicrobial agent; intraoperative skin preparation with antimicrobial agent).
- Initiate practices required for creating and maintaining a sterile field.
- Protect the patient from cross-contamination—employ bowel/GI technique as appropriate.
- Designate appropriate wound classification (clean, clean-contaminated, contaminated, dirty/infected) at end of procedure.
- Utilize Standard Precautions when handling contaminated instruments, specimens, and cultures.
- Initiate traffic control measures/protocols.
- Administer medication as prescribed (e.g., antibiotic prophylaxis), using safe medication practices and document same.

NURSING DIAGNOSIS
Risk for Perioperative Positioning Injury

OUTCOME
Patient will be free from signs of perioperative positioning injury.

SAMPLE PLAN OF CARE—cont'd

INTERVENTIONS
- Assess patient for physical alteration, prosthetics, or corrective devices requiring modifications to procedure-specific position.
- Position patient in body alignment with attention to possible modifications of surgical position, patient limitations, and safety.
- Use adequate body supports, restraints, and padding of pressure sites specific to planned position and patient body mass. Reassess position status throughout procedure.
- Lift and transport patient carefully with sufficient assistance and lifting aids as needed.
- Reassess patient for signs and symptoms of injury at conclusion of procedure.

NURSING DIAGNOSIS
Risk for Impaired Tissue Integrity related to lasers, thermal devices, electrosurgery, radiation, and chemical solutions

OUTCOME
The patient will be free from evidence of impaired tissue integrity.

INTERVENTIONS
- Inspect skin condition, and determine patient's risk factors related to skin injury.
- If hair must be removed from surgical site, select removal method most likely to preserve skin integrity.
- Protect patient from thermal, electrical, laser, and chemical injury by following institutional practice guidelines. Implement fire precautions with skin prep solution.
- Before applying dressings, clean and dry skin at incision site or sites.
- Prevent stretching of the skin when securing dressings with tape.
- Reassess patient for signs of skin injury at conclusion of procedure and document findings.
- Wash patient of blood and body fluids and cover with clean gown and blankets before transfer to PACU.

NURSING DIAGNOSIS
Risk for Injury from retained surgical items, wrong procedure, wrong site, or medication administration

OUTCOME
The patient will be free from injury related to retained surgical items, wrong procedure, wrong site, and medication errors.

INTERVENTIONS
- Confirm patient identity.
- Initiate preoperative verification process. Verify surgical procedure, and involve patient in marking surgical site.
- Identify any allergies to medications.
- Perform and document required counts. If necessary, take a "pause for the count" to avoid distractions.
- Administer medications and solutions as prescribed. Label all medications and solutions on and off the sterile field.
- Verify and record implants.
- Follow protocols for containing, identifying, labeling, preserving, transferring, and transporting surgical specimens.

NURSING DIAGNOSIS
Risk for Imbalanced Fluid Volume

OUTCOME
The patient's fluid volume, electrolyte, and acid-base balance will be consistent with or improved from preoperative baseline levels.

INTERVENTIONS
- Review baseline laboratory data; confer with surgeon or anesthesia provider regarding deviations from normal.
- Assess nutritional status, skin turgor, renal status, and other conditions or medications affecting fluid, acid-base, and electrolyte balance.
- Collaborate with surgeon and anesthesia provider in accurately estimating fluid and blood loss and maintaining or correcting losses (administration of fluid replacement therapies, electrolytes, or medications).
- Record all solutions administered from the surgical field.
- As appropriate, include estimated blood loss (EBL) in hand-off report to receiving unit. In some institutions, a surgical Apgar score is calculated at the end of the surgical procedure from the EBL, lowest mean arterial pressure (expressed in mm Hg), and the lowest heart rate rhythm recorded on the anesthesia record during the procedure. The score may be used to identify patients with a higher likelihood of developing complications after surgery.

surgery, the patient's preference, and the collaborative judgment of the anesthesia provider and surgeon. Procedures done endoscopically, such as esophagogastroduodenoscopy (EGD) (upper endoscopy) or colonoscopy, typically use intravenous (IV) moderate sedation. Monitoring devices and parameters typical to those anesthesia plans will be used (see Chapter 4). Patients at risk for fluid and electrolyte shifts, or significant blood loss, require arterial monitoring and frequent intraoperative sampling of hemoglobin and hematocrit, arterial blood gases, electrolytes, and coagulation studies. Preoperative fasting and bowel cleansing, combined with alterations in nutrition, may severely deplete fluids and electrolytes. These must be measured, replaced, and balanced throughout and after the procedure. A nasogastric tube may be inserted to decompress the stomach and to suction gastric secretions. A urinary catheter may be inserted to decompress the bladder and provide accurate measurement of urinary output and renal function.

Preoperatively, the physician may order blood for open laparotomy or laparoscopic GI surgery patients whose blood replacement is predictable. Elective surgery patients may choose to donate 1 or 2 units of autologous blood; friends and family may also donate donor-directed blood. Autotransfusion (or cell salvage) of the patient's blood during surgery may not be appropriate, given potential contamination from bowel contents such as organisms or malignant GI neoplasm cells. Blood replacement is augmented, managed, and balanced with IV colloids and crystalloids, albumin, platelets, fresh frozen plasma, and electrolytes.

IV antibiotics are given before the incision is made and throughout the procedure (Surgical Pharmacology). Antibiotic irrigation solutions may be used intraabdominally during the procedure and before closure. Additional intraoperative medications may be indicated per institutional standard or surgeon preference. Hemostatic agents, anticoagulants, steroid preparations, and local anesthetics may be utilized. The best guide is a comprehensive and frequently updated plan of care, pick list, or surgeon/procedure preference sheet.

For laparotomy and laparoscopic approaches, the patient typically is placed in the supine position. Arms are placed on padded armboards with the palms up and fingers extended. Armboards are maintained at less than a 90-degree angle to

BOX 10-3

Rationales for Perioperative Nursing Interventions

- Providing emotional support and sharing may clarify fears. Fears may be based on inaccurate information.
- Anxiety and sensory deficits may impair the patient's readiness to learn or retain new knowledge.
- Patients who are prepared for painful procedures by an explanation of the actual sensory experience have less stress than those with vague information.
- Use of noninvasive pain management measures can enhance comfort and the therapeutic effect of pain medications.
- Pain management should be aggressive and individualized at regular intervals of administration rather than as needed (PRN).
- Divert focus from changes to positive characteristics that reinforce self-concept and control.
- The surgical and anesthesia experience, with exposure of body surfaces, introduction of fluids and instruments, and an open wound, will decrease core body temperature.
- The physiologic stress of surgery may impair normal thermoregulating mechanisms.
- The surgical and anesthesia experience challenges the immune system and poses many risks of introducing endogenous and exogenous microorganisms.
- Hyperextension of limbs, mechanical pressure, and prolonged positioning can cause skin, nerve, vascular, and musculoskeletal compromise.
- Repositioning and transfer can cause shearing force and skin injuries.
- Directed energy modalities such as electrosurgery, lasers, radiation, and fiberoptic light cords can cause tissue burns and fire.
- Antimicrobial prep solutions, chemical sterilants, and alcohol can cause tissue irritation and burns.
- Surgical patients are at risk for wrong procedure and wrong site surgery when patient identification practices are flawed and not repeated at each stage of perioperative care.
- Multiple surgical items, such as instruments, sharps, and sponges, present the risk of retention if counting practices are flawed.
- Anesthetized patients are vulnerable and unable to advocate for themselves.
- The physiologic stressors of surgery and anesthesia can result in fluid shifts from excess to depletion throughout the entire procedure (Carpenito-Moyet, 2007).

Carpenito-Moyet LJ: *Nursing diagnosis: application to practice,* ed 12, Philadelphia, 2007, Lippincott Williams & Wilkins.

SURGICAL PHARMACOLOGY

GI-Specific Prophylactic Systemic Antibiotics

Although prophylactic systemic antibiotics are not indicated for patients undergoing low-risk, "clean" surgical procedures, there are clinical situations where their administration is beneficial. High-risk GI procedures are an example of a situation when prophylactic systemic antibiotics reduce infection and clinically benefit the patient. These procedures include surgery for gastric cancer, ulcer, obstruction, or bleeding. Antibiotics are also useful in patients whose gastric acid secretion has been suppressed and in patients undergoing gastric surgery for morbid obesity. Oral antibiotics before procedures on the colon suppress both aerobic and anaerobic flora (Anaya and Dellinger, 2008).

GASTROINTESTINAL-SPECIFIC ANTIBIOTICS

- Ampicillin—prophylaxis against gram-positive cocci such as *Enterococcus faecalis* and gram-negative bacilli such as *Salmonella* and *Shigella*
- Cephalosporin—prophylaxis against aerobes and anaerobes
- Clindamycin—prophylaxis against aerobes and anaerobes
- Ertapenem—broad-spectrum prophylaxis for colorectal surgery
- Fluoroquinolone—prophylaxis in combination with metronidazole or clindamycin
- Gentamicin—prophylaxis against gram-negative rods and enterococci
- Metronidazole HCl—prophylaxis in Crohn's disease, pseudomembranous colitis
- Tetracycline HCl—prophylaxis against shigellosis, cholera, *Helicobacter pylori*
- Tobramycin—prophylaxis against aerobic gram-negative bacilli, *Pseudomonas aeruginosa*
- Vancomycin—prophylaxis in penicillin allergy, pseudomembranous colitis, staphylococcal enterocolitis

Anaya DA, Dellinger EP et al: Surgical infection and choice of antibiotics. In Townsend CM et al, editors: *Sabiston textbook of surgery,* ed 18, Philadelphia, 2008, Saunders.

prevent brachial plexus stretch. If there are surgical reasons to tuck the arms at the side, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail. Modifications may include flexion of the knees to a modified lithotomy position with the legs in self-balancing stirrups (Allen or Yellofin) for procedures where access to the rectum is necessary. Check for the presence of bilateral posterior popliteal, posterior tibial, and dorsalis pedis pulses, and document. Monitor and document circulation throughout the procedure. Intraoperative access and exposure may require frequent alterations of patient position with side-to-side tilt, elevation of the kidney rest, and shifts to Trendelenburg's or reverse Trendelenburg's position to permit gravity displacement of abdominal organs for surgical exposure. Entry into the thoracic and abdominal space is often approached via thoracoabdominal access; the patient is placed and immobilized in a lateral or side-lying position. EGD is typically done with the patient in slight semi-Fowler position, whereas colonoscopy is accomplished with the patient in left lateral position with the knees flexed.

Morbidly obese patients pose a positioning challenge as to safety, exposure, and access, as well as for the safety of staff that must transfer and position the patient (see Chapter 30 for a discussion of staff safety). These patients require a surgical bed that accommodates their weight and size, protects them from falls, and supports their frame while preventing skin and musculoskeletal injury. More than four staff persons are often needed to transfer and position the patient safely. Transfer aids, such as rollers, sliders, lift sheets, air-filled transfer mattresses, and hydraulic lifts, are used when available. Encourage patients to assist in their transfer. Determine the patient's level of comfort, and make appropriate adjustments before anesthesia induction. Meticulous assessment and continued evaluation of skin and tissue are critical to recognize compromise early and to prevent injury.

GI surgery patients will have a sequential compression device (SCD) ordered for use during surgery. SCDs are applied as soon as possible before anesthesia induction to prevent deep vein thrombosis (DVT) (Hageman et al, 2008). Wrap the sleeves around the legs smoothly, to prevent folds when the legs are positioned in stirrups. The unit is hung on the OR bed or an IV pole or is placed on the floor under the OR bed in an area away from team members' feet and areas that may be wet. The vibration noise can be buffered with a blanket or mat placed under the unit.

Positioning requires attention to body alignment; access and exposure to the intended incision site; positioning of the surgical light and instrument accessories and equipment, which may be attached to the OR bed; and padding and protection of potential pressure sites (see Chapter 5).

The large amount of skin exposure required for either a laparotomy or a laparoscopic approach presents a risk for hypothermia. Prewarming the patient for at least 15 minutes before anesthesia induction is recommended (AORN, 2009a). A forced-air warming blanket may be positioned under the sterile drapes. Temperature settings range from "low" at 32° C (89.6° F) to "high" at 43° C (109.4° F). Keep the ambient room temperature warm (between 20° C [68° F] and 26° C [78° F]) until after the patient is prepped and draped. Keep the patient covered with warm bath blankets until the skin prep is begun. Expose only the areas to be prepped. Warm all irrigation fluids to a temperature not greater than 40.5° C (105° F). Consult with the anesthesia provider for an assessment of the patient's body temperature during the procedure. Raise the room temperature before the conclusion of the procedure. IV fluids and blood products are administered by way of a fluid warming system with blood warmed to 37° C (98.6° F) and IV fluids between 37° C (98.6° F) and 40° C (104° F). Surgical skin prep solutions are not warmed unless recommended. The manufacturer of the prep solution must provide clear directions for solution warming (AORN, 2009b).

If prescribed, hair removal at the operative site is done as close as possible to the time of incision. Hair should be removed according to institutional protocol; many institutions require a physician's order for this procedure. Direct special attention to existing or intended ostomy sites, avoiding further skin injury. Existing ostomy stomas may be covered and protected with an occlusive sterile plastic dressing or a collection appliance, or be isolated with a plastic drape with adhesive strip. Antimicrobial skin preparation follows general protocol for laparotomy, with generous borders in the event that the surgeon extends the incision. Precautions are taken to prevent accumulated fluid at or under the bed line, skin injury, and surgical fires. Sites within the prep area that provide concentrated microorganisms, such as an existing ostomy, draining fistula, or the rectum, are prepped last.

Intraoperative draping follows standard draping for patients undergoing laparotomy or laparoscopy. Extra drapes are needed when the patient is placed in a modified lithotomy position and where bowel isolation precautions are taken. The patient may be redraped or the existing drapes reinforced before incision closure.

All surgical team members pause for a "time out briefing" before the incision is made. Participation is required by all team members, who engage in a comprehensive review and consensus that includes the following: an introduction of all present team members, patient identification, intended surgical procedure or procedures, marked site (and laterality if appropriate, which must be visible when the patient is draped), patient position, pertinent medical conditions or concerns, availability of implants or any special equipment or devices, potential threats to good outcome, fire risk score, and verification that prep solutions have dried.

GI surgery instrumentation, for both the laparotomy and laparoscopic approach, requires a basic laparotomy instrument set. Sharp cutting instruments include #3 and #4 knife handles (#11 or #15 knife handles are required for laparoscopic port stab incisions), curved tissue dissection scissors, and curved and straight utility scissors. Clamps include curved and straight hemostats; Kelly clamps; Kocher, right angle, and Crile (tonsil) hemostats; Babcock and Allis clamps; towel clamps; ring or sponge forceps; and assorted needle holders. Tissue-grasping forceps include short-, medium-, and long-toothed, plain, DeBakey, Adson, and Russian forceps. Handheld retractors include Army-Navy, Richardson, Deaver, malleable, or rake, and selected self-retaining retractors. Accessory instruments may include but are not limited to various grooved and nontraumatic curved, straight, and angled bowel clamps. Suction tips may include Yankauer tonsil suction, Frazier tip, cardiac suction tip, or a Poole, intestinal sump suction. Protective nontraumatic covers or shods may be slipped over the jaws of selected clamps to protect and stabilize tissue during dissection or suturing. Longer versions of many of the basic instruments will be required for low abdominal procedures, obese patients, and thoracoabdominal approaches.

Laparoscopic surgery of the GI tract requires laparoscopic instruments intended for abdominal surgery. These instruments may be disposable, reusable, hybrid "reposables" (reusable instruments with disposable cutting or coagulation tips), or a combination. Laparoscopic instruments have operating tips that function similarly to the basic laparotomy instruments but are designed to fit through a narrow trocar and extend into all quadrants of the abdominal cavity from the skin surface. Several laparoscopic dissectors and scissors have electrosurgical capability. Bipolar or monopolar electrosurgery may be used, with bipolar considered the safer alternative (Risk Reduction Strategies). Accessories for laparoscopic instruments, telescopes, and trocars include a light cord, insufflation tubing, camera and cord, suction-irrigation tubing, ultrasonic dissection handpiece with cord, and thermal plasma coagulation devices. Safe practices when using devices that generate surgical smoke require the use of a smoke evacuation system and accessories in both open and laparoscopic procedures (see Chapter 7). When laparoscopic procedures necessitate extracorporeal (outside the abdomen) assistance for inspection, dissection, anastomosis, or specimen manipulation, a hand-assisted port may be used to offer the surgeon a sterile, protected entry into the abdomen for his or her nondominant hand, while maintaining pneumoperitoneum. Referred to as hand-assisted laparoscopic surgery (HALS), the hand-assisted port is suitable for laparoscopic surgeries that require a minilaparotomy to remove an organ or specimen or for extracorporeal anastomoses. A primary advantage with HALS is tactile sensation. These devices have an adhesive base to attach the sleeve and a protractor to expose the wound and to protect against contamination. Additional small incisions, or port sites, are made to introduce standard laparoscopic instruments.

RISK REDUCTION STRATEGIES

Monitoring Integrity of Laparoscopic Instrument Insulation

Laparoscopic injury can result from electrical and thermal burns when the integrity of an instrument's insulation coating is defective. Electrosurgery has been a standard surgical tool since the 1930s and most laparoscopic procedures employ electrosurgical energy for tissue cutting and coagulation. Minimally invasive surgery provides a moist environment and limited access for visualization. Current leakage while using monopolar laparoscopic electrosurgery can occur within the trocar cannula or outside the trocar cannula, and capacitive leakage can occur from the active electrode shaft to the cannula. Significant injury can result from such stray current. Even a slight tear in the insulation can produce a power density of current and high-voltage waveform to create a larger opening in the insulation. The surgeon may not notice the change in current and the patient may not present with symptoms for several days after the procedure. Perioperative team members must continually monitor the functioning of equipment and instruments to prevent hazards and injury. The following are recommendations for care and handling of laparoscopic instruments and accessories:

- Use active electrode monitoring (AEM) devices with electrosurgery during patient care.
- Use active electrode insulation integrity testing devices before transfer to the surgeon at the sterile field and/or during instrument processing.
- Inspect instruments for small visible breaks in the insulation before use.
- Handle instruments so as to protect them from sharp objects during use, transport, and processing.
- Inspect insulation with a magnifying lens after decontamination.
- Conduct stray leakage testing with an insulation testing device after each decontamination.
- Remove damaged instruments from service for repair or replacement.
- Comply with all manufacturer care and handling instructions.

Modified from Association of PeriOperative Registered Nurses (AORN): Recommended practice for cleaning and care of surgical instruments and powered equipment. In *Perioperative standards and recommended practices,* Denver, 2009, The Association; Dennis A: Laparoscopic electrosurgical complications: stay informed, *Endonurse* 46-56, 2008; ECRI Institute: Safety technologies for laparoscopic monopolar electrosurgery: device for managing burn risks, *Health Devices* 34:259-271, 2005.

Robotic or telerobotic surgical systems have advanced laparoscopic surgery, enhancing the surgeon's performance and precision by promoting an ergonomically comfortable hand position, visualizing a three-dimensional virtual field, replacing the camera holder with a stable platform, and providing unlimited motion of instrumentation (Ewing et al, 2004). Magnification and full-field lighting enhance the surgeon's orientation. Since 1997 robotic systems have been successfully employed in a broad range of GI procedures of the esophagus, stomach, and bowel, including fundoplication and bariatric procedures.

A tall, multishelf video cart, primary tower, or ceiling-mounted boom contains the primary video monitor, light source, video camera, DVD, printer, insufflator, and directed energy generators. The tower may also contain a bipolar electrosurgical unit (ESU), pulsed irrigation system, or ultrasonic dissection unit. A second tower, cart, or boom displays a second monitor, allowing the surgical team on the other side to view the procedure. The surgeon may prefer to use one monitor, placed between the patient's legs, when lithotomy position is used.

Meticulous planning ensures that all equipment is in working order. Equipment may have to be positioned after the patient is transferred to the OR bed; it is done quickly and quietly to expedite the procedure, without provoking anxiety in the patient. Place the insufflator unit on a tower shelf above the level of the patient's abdomen. This precaution prevents backflow of gas, fluid, and organic debris if the unit is turned off before the tubing is disconnected from the patient. Run electrical cords and tubing from all equipment to the nearest outlet, with consideration for staff and patient safety. Avoid areas that may be wet. Secure cords to the floor to prevent falls. Do not overload an outlet with plugs from several units that each draws considerable current, such as units that produce heat. Be prepared to connect all equipment cords and tubing after the patient is draped, and white-balance the camera. Provide a source of light for the anesthesia provider and the scrub person when the overhead room lights are turned off.

It is prudent to have an open laparotomy set with instruments and accessories available, should conversion to an open laparotomy or laparoscopic-assisted procedure be necessary. The laparotomy instruments may be opened and counted on the laparoscopy back table or a separate sterile table as per institutional protocol. All sharps must be counted or inventoried before the incision is made regardless of approach or size of incision (AORN, 2009c).

The surgeon may request ureteral catheters to be placed by a urologist before a GI procedure is begun. The catheters enable the surgeon to see and palpate the ureters during the procedure. A basic cystoscopy setup with sterile ureteral catheters, two of each size, will be needed.

Intraluminal examination of the bowel may be necessary during the procedure. The surgeon may request a sterile colonoscope or sigmoidoscope to insert into an opening made through the bowel wall, after the abdomen is open. Set up the scopes and accessories on a separate sterile table. This table will be considered contaminated after the scope is removed. Team members who have directly participated in the endoscopic procedure must change gown and gloves before proceeding with the remainder of the surgical intervention.

Additional accessory instruments or devices may include a sterile plastic drawstring intestinal bag to confine loops of normal bowel from the operative segment, sterile counted radiopaque surgical towels, combination suction-irrigator, or irrigator-bipolar coagulation. Ultrasound-guided probes and ultrasonic dissection instruments are commonly used in GI surgery. Automatic stapling devices streamline the processes of ligating tissue, cross-clamping, and creating anastomoses and reservoir pouches. These instruments deliver single staples and single or double rows of closely staggered linear and circular rows of inert staples. The staple appliers may be single-fire or accept multiple cartridges for successive use. They may be designed for open laparotomy or endoscopic use. The B-shaped design of the implanted staple does not compromise the vascularity of the approximated tissue edges. These devices are available in reusable and disposable units. Personnel must be

familiar with the types of available stapling equipment, applications, assembly if indicated, and proper loading.

Electrosurgery is critical to achieve and maintain hemostasis. Optimal dispersive pad sites include the thigh, flank, shoulder, upper arm, and buttocks. The pad is placed over a fleshy muscular site as close as possible to the incision, yet out of the prep area. Avoid dependent areas that may have a bony prominence or affinity for pooled solution. Choose power settings that achieve the best tissue response at the lowest setting. The smoke evacuation apparatus should be utilized. Provide long and angled ESU tips. Other hemostatic and dissection equipment and devices may include the argon beam coagulator, ultrasonic tissue dissector, radiofrequency ablation, and laser (see Chapter 7).

Suture materials used on GI tissue were traditionally chromic gut and silk. With the increased number of synthetic absorbable and nonabsorbable suture materials available, surgeons have a variety of materials from which to choose. Polyester fiber sutures and polyglycolic acid sutures are frequently employed on GI tissue. Generally, 3-0 and 4-0 sutures on a semicircular taper needle are used on intestinal tissues. Ligatures for small vessels usually require a 3-0 or 4-0 braided material, whereas 0 or 2-0 braided ligatures are used for larger vessel occlusion. For closure or anastomosis of GI layers, 3-0 or 4-0 synthetic absorbable suture with a curved intestinal needle is commonly used on the mucosa. A 3-0 or 2-0 continuous synthetic absorbable suture and 4-0 or 3-0 nonabsorbable suture with curved or straight intestinal needles may be used for the seromuscular layer. Some surgeons may prefer interrupted silk sutures on intestinal (semicircular taper) needles for anastomosis procedures. For abdominal closure 1 or 0 braided or monofilament suture is commonly used. Retention sutures may be indicated when there is potential for compromised tissue or wound healing. Checking the surgeon's preference/procedure card or pick list for appropriate suture materials not only ensures the availability of necessary supplies but also is cost-effective.

Sponges used in open laparotomy procedures include large packs (18 × 18 inches), large laps (12 × 12 inches), or small elongated tape sponges (4 × 18 inches). Sponges vary in size according to product availability. Gauze dissectors (referred to variously as "Kittners," "peanuts," or "pushers") on a Kelly clamp or right angle clamp may be used for blunt tissue dissection. Meticulous vigilance prevents the incidental misplacement of these items. Larger gauze sponges are not recommended for use in the abdominal cavity. In the case of significant bleeding or isolation of bowel during anastomosis, lint-free radiopaque cloth towels can be used. Towels are counted, as are all sponges.

Bowel technique, also referred to as *contamination* or *isolation* technique, prevents cross-contamination of the wound or abdomen with bowel organisms. This technique is also employed during cancer procedures to prevent mechanical metastasis, or "seeding" of malignant cells throughout the abdomen. Bowel technique begins as soon as the GI tract is clamped and transected, and proceeds through wound irrigation, before wound closure. The wound edges and surrounding drapes are protected with extra drapes, while instruments used for GI tract resection and anastomosis are sequestered and used only for this part of the procedure. The rest of the sterile back table remains untouched throughout the anastomosis. Separate instruments and drapes are used for the closure. Gowns, gloves, and drapes are changed before closure. The contaminated GI tract instruments are handed off or left on a separate Mayo stand. Preplanning during preoperative setup includes extra and separate instruments ready for anastomosis and closure. These must all be included in the instrument count with provision for a closing count of the contaminated set. There is also a provision for containment and display of needles used for the anastomosis. Surgeon preference and institutional protocol determine details of bowel technique.

Specimens are handled carefully and prepared for examination by the pathologist. The specimen may be contaminated with microorganisms or malignant cells and no contamination of the sterile field and instruments can occur. The surgeon usually determines how the specimen is handled before examination. It may be sent to the pathology department fresh, in saline, or in a preservative solution. Tissue also may be sent for frozen-section examination to verify pathologic condition and to determine if tissue margins are free of malignant cells. Specimens may also be entered into research protocols, which will require further special handling, storage, and transport.

The surgical department has procedures for correct patient and specimen identification that are followed each time a specimen is collected. Accuracy is verified with the surgeon by reading back (referred to as "write down, read back") the label and pathology form before removing the specimen from the room or before the surgeon leaves the room, and documented according to institutional protocol.

Drains may be used to evacuate gastric secretions or serosanguineous fluid. A closed suction wound drain may be used. A Malecot, Pezzer, or Foley catheter in desired size may be inserted as a gastrostomy tube for drainage until normal bowel peristalsis returns. A jejunostomy tube may be placed in the jejunum after gastric resection to provide access for enteral nutrition.

Determination and documentation of wound classification are done at the end of the procedure. If the GI tract has been entered or transected, the wound class will be considered "clean-contaminated" as long as no breaks in technique have occurred or signs of infection have been discovered in the surgical wound.

Evaluation

Evaluation of nursing care is ongoing throughout the procedure and before the patient is transported to the postanesthesia care unit (PACU) or a surgical intensive care unit (SICU). The dressing, drains, and any pain management pump tubing are secured so as to avoid damage during transfer to the PACU stretcher or SICU bed. Skin is assessed for reddened or bruised areas; if such areas are present, they are documented and treatment initiated immediately. The ESU dispersive pad is removed, the site inspected, and the condition of the skin documented. Ensure that the patient is covered with a clean, warm blanket before being transported to PACU or SICU. Any variances are reported to the surgeon, documented in the patient's record, and included in the hand-off report given to the nurse in the PACU, SICU, or nursing unit. Patient outcomes, based on the perioperative nursing diagnoses, will be reviewed. Postoperative documentation reflects and measures how each outcome was met and notes significant variations from the desired expectation.

Patient and Family Education and Discharge Planning

Patients undergoing surgical intervention for GI disorders vary greatly in the length of time and complexity of their recovery. Recovery and convalescence depend on the type of procedure, surgical approach, site of surgery, type of anesthesia, pain management, and individual health of the patient. GI structures may have varying degrees of edema, decreased peristalsis, and alterations in tissue oxygenation and lymphatic drainage; these all depend on the amount of manipulation, resection, and trauma suffered by the anatomic structures of the GI tract. The patient usually experiences decreased peristalsis for 3 to 5 days after open laparotomy or laparoscopy. Postoperative ileus, commonly called paralytic ileus, is a condition of delayed GI motility that extends beyond 3 days, causing bloating, pain, nausea, emesis, and general feeling of fullness that could progress to bowel obstruction (Carter, 2006). Causes are varied (Box 10-4) and can arise from neurogenic, inflammatory, hormonal, pharmacologic, or mechanical effects of surgery, including manipulative handling of the intestines during surgery (Kulaylat and Dayton, 2008). In the absence of risk factors for delayed peristalsis, motility of the small intestines returns to normal first, within several hours after surgery. Stomach motility returns to normal within 24 to 48 hours and the large bowel, the final GI segment, returns to normal within 48 to 72 hours (Bisanz et al, 2008). Identifying early bowel sounds through abdominal auscultation may signal return of small intestinal motility while the remaining segments may not be ready for return to regular feedings and full diet. The return of motility of the entire GI tract, or resolution of ileus, is evidenced by the first passage of flatus or stool (Bisanz et al, 2008).

Diet is introduced only after evidence of GI motility returns (Research Highlight). The patient may experience nausea and vomiting if food or drink is introduced too early for the GI system to function with normal absorption and motility. Postoperative outcomes are improved when nutritional status is maximized. When GI motility returns, the patient will receive nutritional support as tolerated: by oral feeding, total enteral nutrition (TEN), or total parenteral nutrition (TPN).

Coughing and deep breathing help the patient to recover from general anesthesia. Splinting of the abdominal muscles and the use of incentive spirometry assist with postoperative coughing and deep breathing and move pooled secretions. Early ambulation aids in regaining overall muscle tone and strength, supports cardiac and pulmonary function, prevents DVT in the lower extremities, and boosts a sense of well-being.

Pain management is critical for the patient's recovery. An epidural catheter may be placed immediately before surgery for postoperative pain control. For most major GI procedures, patient-controlled analgesia (PCA) or patient-controlled epidural analgesia (PCEA) is used for consistent control of pain and discomfort in the first 1 to 3 postoperative days of hospital recovery. Narcotics may increase the time for normal bowel peristalsis to return and require close monitoring after the third postoperative day.

The patient with a new ostomy will need consultation with the WOCN so that both patient and family can learn to care for and manage the ostomy and surrounding skin. Many lifestyle changes occur with an ostomy. The WOCN first teaches the

BOX 10-4

Risk Factors for Postoperative Ileus

- Intraabdominal infection
- Intraabdominal inflammation
- Lengthy surgical procedure
- Prolonged exposure of abdominal organs
- Opioid and psychotropic drugs
- Inhaled anesthetics
- Electrolyte imbalance
- Retroperitoneal hemorrhage
- Pancreatitis

RESEARCH HIGHLIGHT

Early Feeding After Abdominal Surgery

Traditionally, postoperative fluid and food intake was delayed until evidence of bowel function returned; early feeding, however, may stimulate GI activity and return of motility, decreasing length of stay (LOS). Oral intake of nutrition as early as 4 to 12 hours postoperatively may stimulate reflexes that produce coordinated propulsion activity and release of GI hormones (Bisanz, 2008). Several recent studies investigated if a routine of permitting patients to eat normal food after major abdominal surgery would affect the return of GI motility. In one randomized controlled study (N = 447), one group of patients (227) was assigned to "nil per os" (NPO) and enteral tube feeding, while another group (220) was permitted to eat-at-will from their first day after surgery. A total of 76 NPO patients had complications compared with 62 of the eat-at-will group. Return of motility, LOS, total number of complications, and post discharge complications significantly favored the eat-at-will group (Lassen et al, 2008).

A smaller study of 128 patients separated into 2 equal groups compared the traditional progression from clear liquids to full diet over 4 days to early eat-at-will feeding. The endpoint indicators were the need to reinsert an NG tube, LOS, and postoperative complications. This study also included pain scale ratings and several quality of life criteria. There were no differences in outcomes between the two groups, including pain and quality of life indicators (Han-Geurts et al, 2007).

Gum chewing following surgery has been associated with enhanced recovery of GI function. A study of 158 patients who chewed gum had return of motility evidenced by passing of flatus and bowel movement sooner than the average of 1.10 days. It is possible that gum chewing represents a type of sham feeding that stimulates the digestive nerves and GI hormones (Purkayastha et al, 2008).

Early nutrition increases wound healing, enhances return of GI motility, shortens LOS, and decreases some postsurgical complications. For most patients, progressive feeding according to the GI tract's capability to tolerate food immediately after surgery is likely to result in significant positive outcomes.

Modified from Han-Geurts et al: Randomized clinical trial of the impact of early enteral feeding on postoperative ileus and recovery, *Br J Surg* 94: 555-561, 2007; Lassen et al: Allowing normal food at will after major upper gastrointestinal surgery does not increase morbidity: a randomized multicenter trial, *Ann Surg* 247:721-1140, 2008; Purkayastha S et al: Chewing gum associated with enhanced bowel recovery after colon surgery, *Arch Surg* 143(8):788-793, 2008.

patient and family to accept the ostomy. Skin care, appliance application, ostomy irrigation, diet, bowel training, and quality of life strategies are but a few of the topics that must be presented for care and management of an ostomy. Clothing, self-esteem, body image, sex and intimacy, travel, public toileting, and odor control are some of the key issues the WOCN helps the patient and family to face with useful strategies and resources to ensure quality and fulfillment in their lives (Carmel and Goldberg, 2004).

Patients with resected small bowel may require TPN because their ability to absorb nutrients from ingested food is compromised. Referral to home care agencies expert in administering TPN is essential for this patient population.

General discharge instructions for the patient undergoing GI surgery include both verbal and written instructions. They are provided with the name and phone number of the healthcare provider to call if questions or concerns arise (Patient and Family Education). Procedure-specific instructions are necessary to fully assist the patient and caregivers with recovery and rehabilitation at home (Canobbio, 2006).

PATIENT AND FAMILY EDUCATION

General Discharge Instructions for GI Surgery Patients

General discharge instructions for the GI surgery patient should include the following:

- Swelling inside the GI tract may produce a feeling of tightness that should dissipate in 6 to 8 weeks.
- Solid foods should be added to the diet gradually. Chew solid foods well, and avoid gulping, eating fast, or swallowing large bulk portions.
- Avoid carbonated beverages for 3 to 4 weeks to help prevent gas bloating.
- Plan small, frequent meals because a feeling of fullness will occur quickly.
- Keep the incisional area clean and dry. Check the site daily for redness, swelling, bruising, tenderness, and drainage.
- Expect itching and prickly sensations around the incision as these are normal during healing.
- Observe dressing and perform ostomy care as instructed.
- Increase exercise gradually to return to activities of daily living. Exercise regularly.

The perioperative nurse should also review the following with the patient and family. Where appropriate, have the patient repeat back, in his or her own words, information provided. Allow time for questions. Use the patient's preferred language, and consider ramifications of culture, any hearing or visual impairments, health literacy, cognitive impairments, or disability:

- Pain management strategies.
- Reconcile and explain all discharge medications (purpose, dose, schedule, route of administration, side effects to report). The patient should be provided with a copy of these.
- When to make an appointment for follow-up care with the surgeon (provide phone number).
- When to call a physician or nurse practitioner. Generally, this call should be made if any of the following develop: persistent fever (38.4° C [101° F] or higher), bleeding, increased abdominal swelling or pain, persistent nausea or vomiting, chills, persistent cough or shortness of breath, changes in bowel habits, diarrhea, constipation, flatulence.

AMBULATORY SURGERY CONSIDERATIONS

Preprocedural Instructions for Esophagogastroduodenoscopy (EGD) and Colonoscopy

The perioperative nurse caring for patients undergoing esophagogastroduodenoscopy (EGD, upper endoscopy) and colonoscopy may include the following activities as part of preprocedure care:

- Using simple language, review explanation of procedure, postprocedure expectations, and recovery. Use patient's preferred language; obtain services of a translator if necessary.
- Verify written consent; patient should be able to state name of planned surgical procedure. Secure advance directives according to facility policy.
- Discuss oral intake restrictions, including medications to be taken the morning of procedure with sips of water.
- Provide special instructions for patients taking insulin (who may need to consult primary health provider for dosing adjustment).
- Remind patient not to take anticoagulants, herbal supplements, aspirin, or ibuprofen 1 week before procedure (patient may need alternative blood thinners ordered).
- Remind patient not to use bulk-forming agents, iron-containing supplements, or synthetic dietary fat products as they may impair visualization of colonic mucosa.
- Review any skin cleansing recommendations, including showering with an antibacterial soap according to facility policy.
- Describe need to remove all jewelry, including body jewelry, and removable prostheses or devices. Advise patient to wear comfortable loose clothing that is easy to remove and redress.
- Require a responsible adult to accompany the patient to the facility, drive them home, and remain with the patient for 24 hours.
- Review instructions for bowel prep and/or cleansing enema for colonoscopy.
- Review institutional criteria for discharge, including return of gag reflex and oral fluid intake for EGD.
- Provide directions on when and where to report for procedure.
- Review situations for procedure cancellation or delay: failed bowel prep, oral intake, sickness the morning of procedure.
- Give contact information for who and where to call if issues with preprocedure instructions arise or if patient is unable to arrive for procedure.

Modified from Canobbio MM: *Mosby's handbook of patient teaching,* ed 3, St Louis, 2006, Mosby.

Ambulatory procedure considerations are based on patient, procedure, and anesthesia selection. Patient instructions before and at discharge are critical, and depend on the patient's ability, self-efficacy, and family support for home care (Ambulatory Surgery Considerations).

Surgical Interventions

ABDOMINAL INCISIONS

The abdominal cavity is surgically entered more than any other anatomic region. The site of the incision (Figure 10-8) is chosen to gain quick, easy access and exposure to underlying

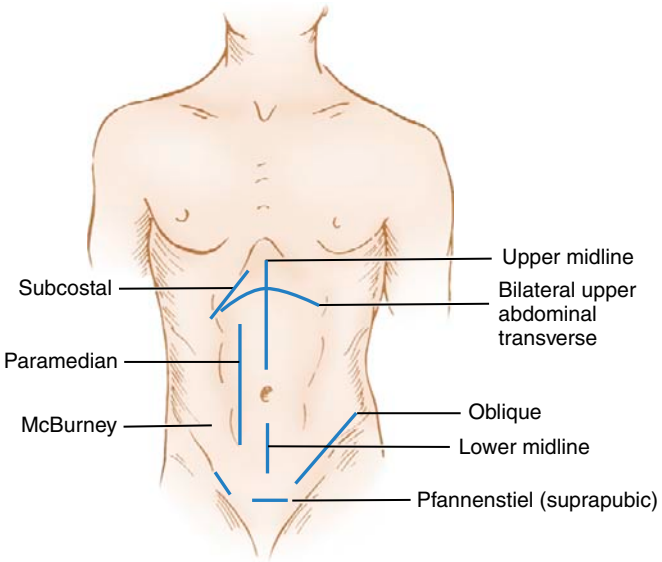

FIGURE 10-8 Incisions made through the abdominal wall.

pathology; to minimize trauma, bleeding, and postoperative discomfort; to maximize wound strength; and to afford ample room to accomplish the surgery. Each incision has advantages and disadvantages as to adequacy of exposure, length of time required for closure, disruption of surrounding blood and nerve supply, underlying muscles that must be cut or split, incidence of postoperative wound hernia, effect on pulmonary function, and cosmesis. Abdominal incisions permanently change the blood supply of the anterior abdominal wall and impact future surgeries and reconstructive options available to the patient. Any compromise of the skin, muscle, or blood supply by prior incision may preclude the use of an otherwise optimal tissue flap for reconstruction after radical thoracic, breast, or GI surgery. Minimally invasive approaches decrease the use and extent of abdominal incisions and preserve the integrity of the abdominal wall.

The abdominal wall consists of various tissue layers (Figure 10-9). Beneath the skin and subcutaneous fat are the fascia, muscles (internal and external oblique, rectus abdominis, transverse abdominis), preperitoneal fat, and peritoneum. The fascia, consisting of bands of tough fibrous connective tissue, surrounds the muscle anteriorly and posteriorly (Figure 10-10). The peritoneum is a serous membrane that lines the abdominal cavity (parietal peritoneum) and surfaces of the abdominal organs (visceral peritoneum).

Vertical Midline Incisions

The vertical midline incision is the simplest abdominal incision to perform. It is an excellent primary incision and offers good exposure to any part of the abdominal cavity. Hemostasis is easily achieved, and fewer layers are traversed. The incision can be extended from just below the sternal notch, distally around the umbilicus (which is avascular, tough connective tissue), back to the midline, and down to the symphysis pubis. The peritoneum is incised, and the round ligament of the liver may be divided. Postoperative hernias are more common above the umbilicus than below it. The midline crossover vasculature is permanently altered with this incision.

The paramedian incision, also called a *rectus* incision, is a vertical incision placed approximately 4 cm (2 inches) lateral to the midline on either side of the upper or lower abdomen. This incision is used infrequently because it adds little to the exposure obtained by way of a midline vertical incision. Paramedian incisions take longer to create and close and are more prone to herniation; this is especially true when they are more lateral.

Closure of the paramedian and midline incisions begins with the peritoneum. The peritoneum and posterior fascia may be sutured as a single layer in a continuous stitch with an absorbable suture material. The suture line may be supported with retention sutures when outward abdominal pressure on the suture line is anticipated, which raises the risk for herniation, dehiscence, or evisceration. Retention sutures are placed through all layers of the wound, using a heavy #2-gauge nylon, polypropylene, or wire suture material. Wound dehiscence, a risk of abdominal surgery, is separation of the unhealed incision. When dehiscence is severe, bowel or other abdominal structures may protrude (evisceration). Dehiscence and evisceration are most common with midline vertical incisions. Risk factors include serious nutritional deficiencies, diabetes, steroid use, obesity, infection, and improper surgical closure.

Anterior fascia, subcutaneous tissue, and skin are closed as separate layers. Anterior fascia and muscle are closed with interrupted nonabsorbable synthetic sutures. The subcutaneous layer may be closed with an absorbable interrupted suture. Skin edges are approximated and secured with interrupted nonabsorbable sutures, skin staples, subcuticular continuous closure with an absorbable suture material, skin-bonding adhesive, or sterile skin tape strips. There are many alternatives and variations to abdominal incision closure, based on the individual patient's need and surgeon preference.

Oblique Incisions

McBurney Incision. The McBurney muscle-splitting incision is commonly used for open appendectomy. It is an 8-cm oblique incision that begins well below the umbilicus, goes through McBurney point (two thirds of the distance from the umbilicus to the anterior iliac spine in the right lower quadrant), and extends upward toward the right flank. The external oblique muscle and fascia are divided bluntly (split in the direction of their fibers) and are retracted. The internal oblique muscle, transverse muscle, and fascia are also split and retracted. When muscles are divided in line with their direction of pull, as is the case with muscle-splitting incisions, there is less chance of postoperative herniation or disruption. The peritoneum is incised transversely. This incision is quick and easy to close and allows a firm wound closure. However, it does not permit good exposure and is difficult to extend. To extend the incision medially, the inferior epigastric vessels are ligated and the rectus sheath incised transversely.

Lower Oblique Inguinal Incision. An oblique right or left inguinal incision extends from the pubic tubercle to the anterior iliac crest, slightly above and parallel to the inguinal crease. This is the standard incision for open inguinal herniorrhaphy. Incision through the external oblique muscle provides access to the cremaster muscle, inguinal canal, and cord structures. This incision does not typically interrupt major abdominal arteries.

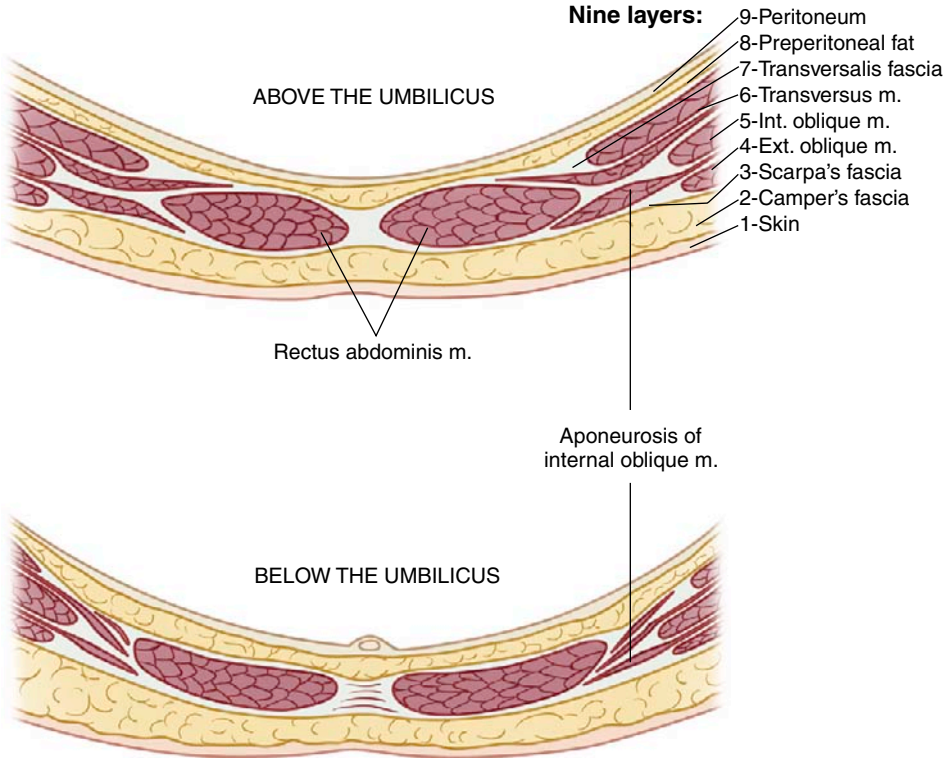

FIGURE 10-9 Horizontal section of abdominal wall. Aponeurosis of internal oblique muscle splits into two sections, one lying anterior and the other posterior to rectus abdominis muscle, thereby forming an encasing sheath around muscle above umbilicus. Below umbilicus, aponeuroses of all muscles pass anterior to rectus. *m.*, Muscle; *Int.*, internal; *Ext.*, external.

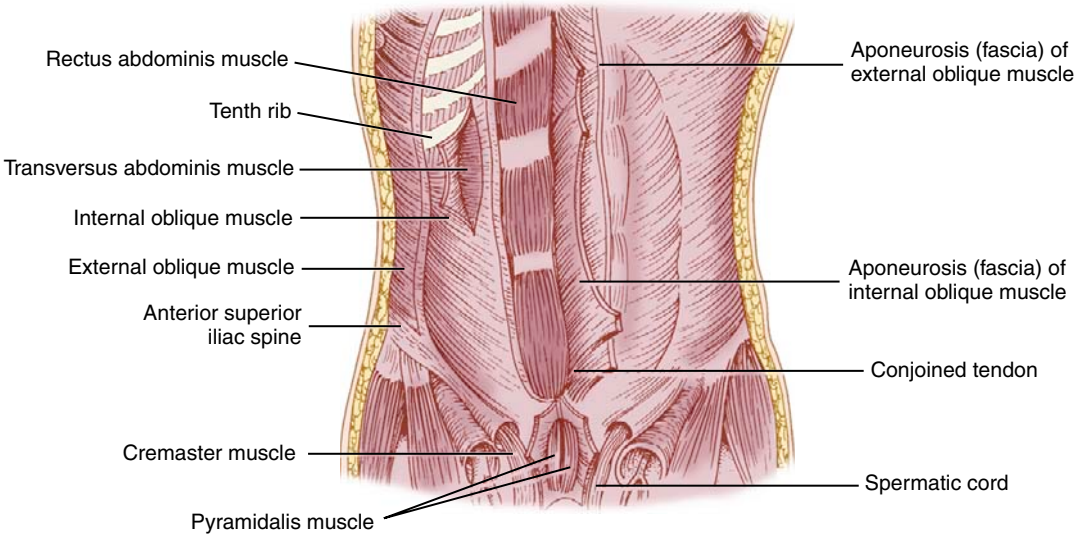

FIGURE 10-10 Superior muscles of abdominal wall.

Long, lower abdominal oblique incisions are used for transplant, urologic, and vascular procedures. These incisions require transection of the abdominal wall and flank musculature. They may require ligation of the deep inferior epigastric artery.

Subcostal Incision. The subcostal incision is made on the right side (Kocher incision) when used for open procedures of the gallbladder, biliary system, and pancreas (Figure 10-11). A left subcostal incision is used for surgery of the spleen. This incision provides limited exposure unless the patient is short with a wide abdomen and wide costal margins. It provides good cosmetic results because it follows the skin lines and nerve damage is minimal. Tension on the skin edges is less than that of a vertical incision, permitting wider retraction and exposure with less respiratory impairment during the procedure.

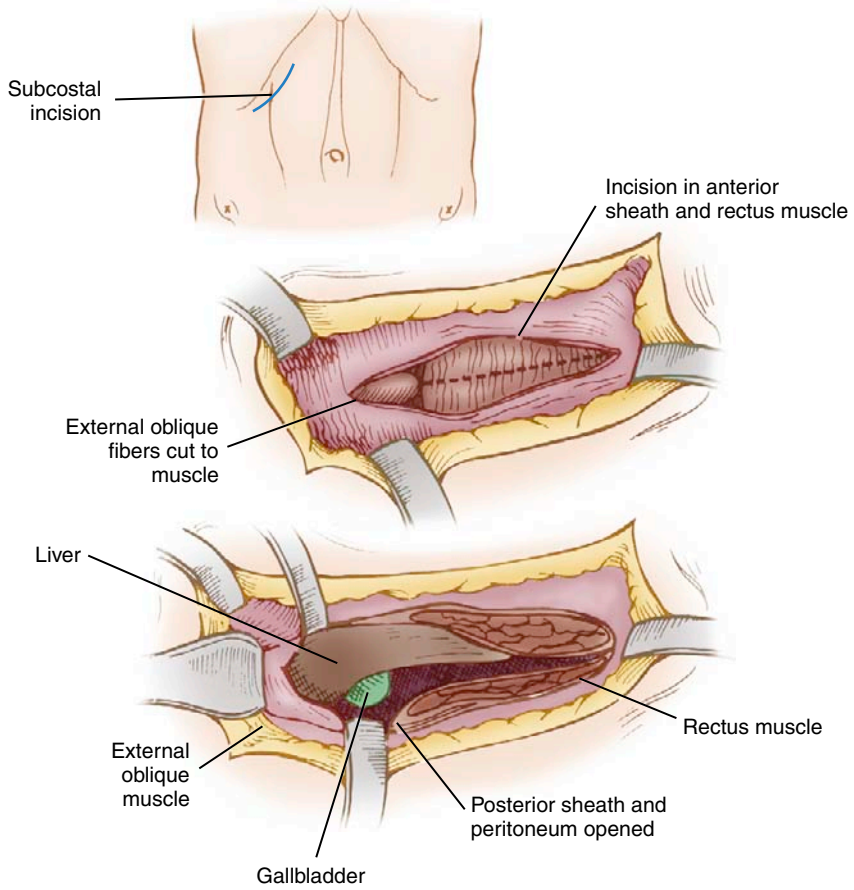

FIGURE 10-11 Subcostal incision in upper right quadrant. Anterior sheath has been divided transversely, and muscle is exposed. Posterior sheath and peritoneum have been opened transversely.

This oblique incision begins in the epigastrium and extends laterally and obliquely downward to just below the costal margin. It continues through the rectus muscle, which is retracted or transversely divided. The superior epigastric artery is occasionally sacrificed. A chevron incision (joined right and left subcostal incisions) provides excellent exposure for gastric, duodenal, pancreatic, and portal system procedures. This incision, however, interrupts lateral blood supply and innervation to the rectus muscle and postoperative muscle atrophy may occur.

Closure of this incision includes approximation of the falciform ligament, peritoneum, posterior rectus sheath, and anterior rectus sheath. Postoperatively, this is a strong but painful incision.

Transverse Incisions

Pfannenstiel Incision. The Pfannenstiel incision is used for pelvic surgery. It is a curved transverse incision across the lower abdomen through the skin, subcutaneous layer, and rectus sheath, approximately 1 cm (½ inch) above the symphysis pubis, usually within the pubic hairline (Figure 10-12). This is the standard incision for open obstetric and gynecologic procedures. The rectus muscles are separated along the midline, and the peritoneum is entered through a midline vertical incision. This incision does not alter vascular supply to the abdominal wall if the deep inferior epigastric artery is left intact. It provides good exposure and a strong postoperative scar that is cosmetically acceptable.

Midabdominal Transverse Incision. The midabdominal transverse incision is used on the right or left for a retroperitoneal approach. The incision begins slightly above or below the umbilicus on either side, extends laterally to the lumbar region at an angle between the ribs and the iliac crest, follows Langer's lines of tension of the abdominal wall, and runs parallel to vessels and nerves, rarely causing permanent damage. It is a standard incision for transverse colectomy or colostomy and choledochojejunostomy. The skin and subcutaneous tissue are incised, the anterior sheath split, the rectus muscle divided, and vessels within the rectus clamped and ligated. The posterior rectus sheath and peritoneum are cut in the direction of the fibers, preserving intercostal nerves. The peritoneum is incised along the midline, and the incision extended laterally to the oblique muscle.

Thoracoabdominal Incision. The thoracoabdominal incision is the standard incision for surgery of the proximal stomach, distal esophagus, and anterior spine. The patient is placed in a lateral position. The incision begins at a midpoint between the xiphoid and umbilicus and extends posteriorly, across the seventh or eighth interspace and the midscapular line into the chest. The rectus, oblique, serratus, and intercostal muscles are

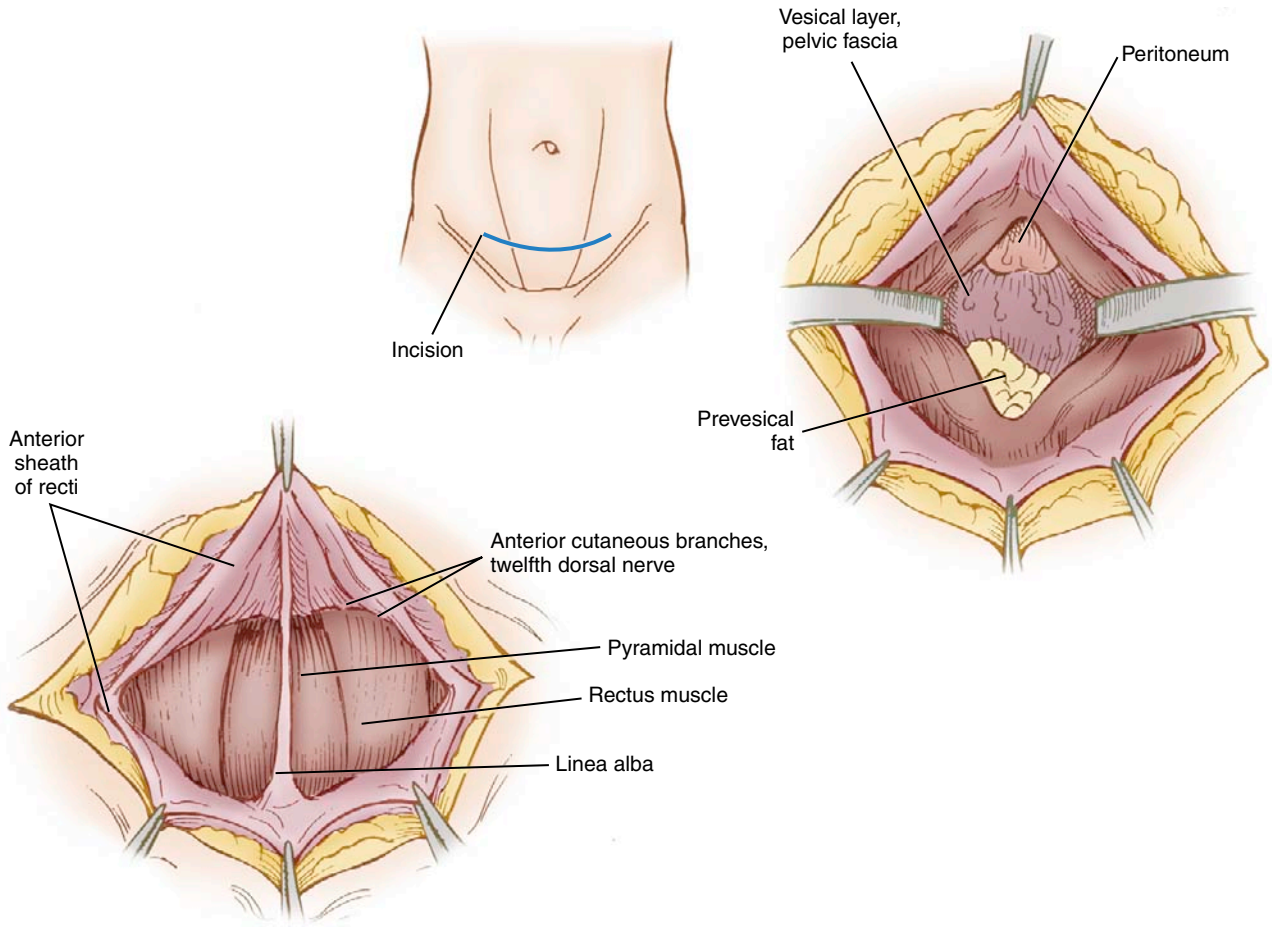

FIGURE 10-12 Pfannenstiel incision (suprapubic).

divided down to peritoneum and pleura. The costal cartilage and diaphragm are then divided (Figure 10-13). This incision sacrifices the superior epigastric artery.

Wound closure occurs in layers with an interrupted suture technique. The peritoneum and pleura may be closed with an absorbable suture material, whereas the muscle and fascia layer may be closed with either an absorbable or a nonabsorbable synthetic suture material. Skin edges are approximated and secured with suture, staples, skin bonding adhesive, or skin tape strips.

LAPAROTOMY

An opening made through the abdominal wall into the peritoneal cavity is called a *laparotomy*. Surgical intervention may be necessary to repair or remove traumatized tissue, to cure disease processes by organ removal, or to examine by biopsy or otherwise visualize internal organs for diagnosis. Surgery may be indicated for diagnostic, therapeutic, palliative, or prophylactic reasons. Most procedures requiring a laparotomy involve the organs of the GI tract.

Procedural Considerations

A basic laparotomy set with long and short soft tissue instruments and various shallow and deep retractors is used. An ESU, smoke evacuator, and suction are basic to performing laparotomy. The patient is positioned supine with arms extended on locked armboards at less than a 90-degree angle. General anesthesia with endotracheal intubation is usual, although spinal or epidural anesthesia may be used. An indwelling urinary catheter may be inserted before the abdominal prep, which extends from above the nipple line to above the symphysis pubis. A forced-air warming blanket may be applied over or under the patient's upper body, arms, and head for thermoregulation. SCDs are applied before induction to prevent deep venous blood pooling in the lower extremities.

In select patients, laparotomy leads to the formation of adhesions and the consequent likelihood of chronic pain, infertility, painful intercourse, and small bowel obstruction. Adhesions are fibrous bands of filamentous protein tissue that form a network of fibers, causing separate tissues and organs to adhere to one another in the abdominal cavity (Porth and Gaspard, 2004; The Surgical and Clinical Adhesions Research [SCAR]-3 study, 2005). Adhesions are caused by a defect in the process of normal tissue healing, prompted by tissue injury, inflammation, infection, or ischemia. The peritoneum is most associated with abdominal and pelvic adhesions. Introduction of microscopic particles, such as glove powder talc or starch, gauze fibers, and suture materials, seems to promote adhesion development.

Surgical separation of individual adhesions, called *adhesiolysis,* is not always effective, with adhesions re-forming, causing a cycle of symptoms and recurrent adhesive disease. Adhesive

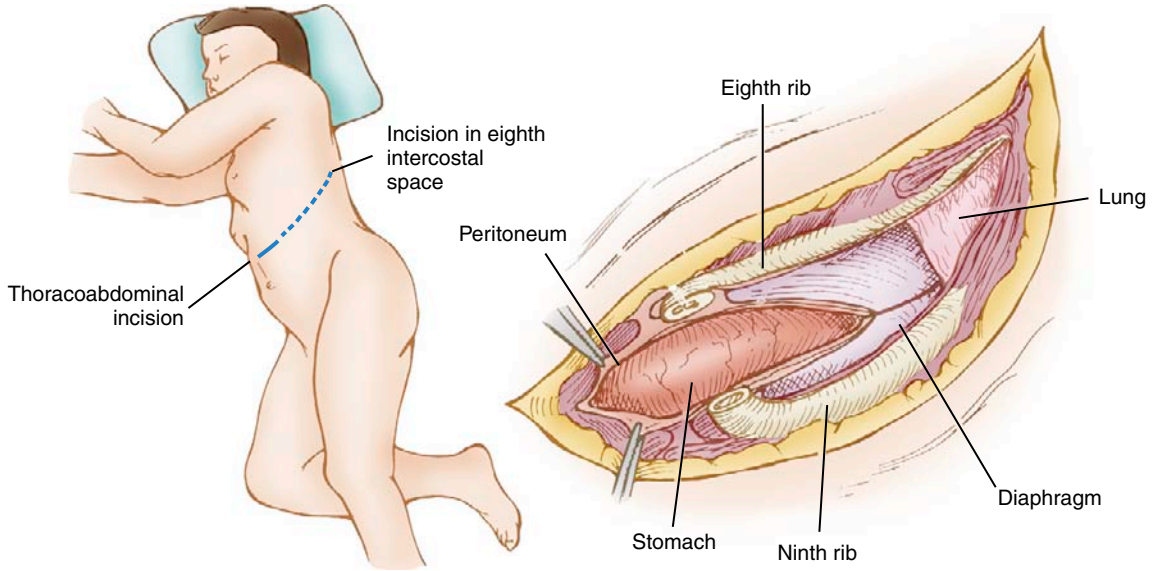

FIGURE 10-13 Thoracoabdominal incision. Patient is placed on unaffected side. Incision is usually made from point midway between xiphoid process and umbilicus to costal margin at site of eighth costal cartilage. Dissection is carried down to peritoneum and pleura. Costal cartilage and diaphragm are divided, and stomach is exposed.

tissues have increased levels of growth factors, which suggest a greater probability of re-formation. Adhesions may also develop as a result of radiation-induced endarteritis, endometriosis, pelvic inflammatory disease (PID), or Crohn's disease.

Adhesion-related disorder (ARD) is a chronic condition of pain, constipation, and cramping. Patients often describe substantial psychologic burdens and disability. Because adhesions are not evident on x-ray unless they present with bowel obstruction, torsion, or volvulus, many patients are misdiagnosed initially.

Pharmacologic agent interventions aimed at treating adhesions are limited. Systemic administration is essentially ineffective since surgical sites typically interrupt blood supply. Further, rapid absorption via the peritoneal membranes removes most of the agent within 24 hours after surgery. Most of the promising lytic-acting agents that interfere with production of hyperplastic adhesive fibrous tissue also interfere with normal wound healing. Historically, surgeons have tried many experimental substances and methods to delay adhesion development, such as mineral oil, animal biomembranes, silk, rubber, Teflon, gold foil, and amniotic membranes. Adhesions are best divided with sharp dissection.

Preventive measures include the following:

- Minimizing tissue trauma and inflammation with meticulous surgical technique
- Utilizing laparoscopic approach when indicated
- Reducing the time that the abdomen is open
- Minimizing use of electrosurgery
- Applying meticulous hemostasis
- Minimizing infection risk
- Avoiding gastrointestinal contamination
- Irrigating the abdomen with copious amounts of warmed solution before closure
- Administering antiinflammatory drugs such as corticosteroids and nonsteroidal antiinflammatory drugs (NSAIDs)
- Limiting suture use and using fine, nonreactive suture materials
- Mechanically separating the organs before closure with physical barriers such as omentum, polytetrafluoroethylene (PTFE), cellulose, sodium hyaluronate membrane, bioresorbable polymer films, gels, and water-soluble glucose polymer or polyethylene glycol (PEG) solution
- Using hydroflotation with saline, lactated Ringer's, or Hartmann's solution
- Using alternative therapies such as deep tissue massage, biofeedback, acupuncture, and hypnosis

Operative Procedure

Laparotomy Opening

1. The skin incision is made and carried to the fascia (Figure 10-14, *A*).
2. Bleeding is controlled with hemostats and vessels ligated with fine nonabsorbable ligatures (ties), or electrocoagulated.
3. The wound edges are retracted with small retractors.
4. With tissue forceps and scalpel, the external fascia is incised (Figure 10-14, *B*).
5. With Metzenbaum, curved Mayo scissors, electrosurgery, or a knife, the external oblique muscle is split the length of the incision. Bleeding vessels are controlled with hemostats, ligating clips, medium or fine ligatures, or electrocoagulating current.
6. The external oblique muscle is retracted.
7. The internal oblique and transverse muscles are split, parallel to the fibers, up to the rectus sheath with a scalpel or scissors. These muscles are then retracted.
8. The peritoneum is exposed, grasped with smooth tissue forceps, and nicked with a #10 blade.
9. Sponges, laparotomy pads, and suction are used as needed. Culture samples may be taken at this time.

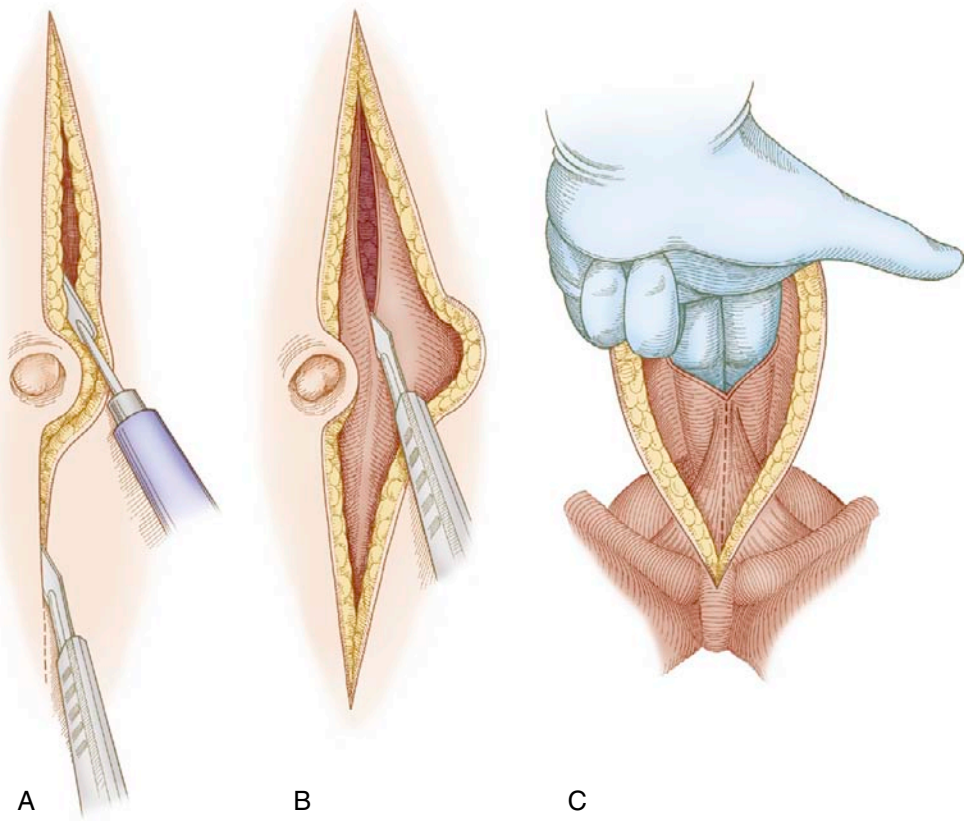

FIGURE 10-14 **A**, Midline laparotomy incision around the umbilicus. **B**, External fascia is incised. **C**, Entry into the peritoneal cavity.

10. The peritoneal incision is extended the length of the wound with Metzenbaum or Mayo scissors (Figure 10-14, *C*).
11. The peritoneum is retracted with large Richardson retractors for initial exploration.
12. Once the affected organs are identified, a self-retaining retractor, such as a Balfour or Bookwalter retractor system, may be used to establish hands-free exposure.

Laparotomy Closure

1. Two tissue forceps or clamps are used to approximate peritoneal edges, and the peritoneum closed with a continuous synthetic absorbable suture or interrupted nonabsorbable sutures. The internal oblique fascia is usually closed with the peritoneum. Muscle tissue is approximated and may or may not be sutured.
2. The external oblique fascia is closed with interrupted sutures, staples, or both. Retraction is necessary as the various layers are closed. Richardson retractors are commonly used.
3. Fine (3-0 or 4-0) absorbable sutures are usually employed to close the subcutaneous or subcuticular tissue. Retraction is provided with laparotomy pads or small retractors.
4. Skin edges are held with Adson, Russian, or medium-toothed forceps and approximated with interrupted 3-0 or 4-0 silk, nylon, or other nonabsorbable sutures on a cutting needle. A cosmetically aesthetic wound closure is achieved in patients with limited tension on the incision by using a subcuticular closure with a 3-0 or 4-0 nonabsorbable suture. Skin staples or clips, sterile adhesive strips, or skin-bonding adhesive is often used to approximate skin edges. Retention sutures of #1 or #2 nonabsorbable suture material may be used. Prepackaged retention bridges or flexible tubing bolsters are used to protect the incision site.

LAPAROSCOPY

Laparoscopy is an approach to abdominal surgery for minimal access into the abdomen to achieve the same surgical result as open laparotomy. Laparoscopic surgery is often referred to as minimally invasive surgery (MIS), wherein the surgery is performed with instruments (rather than the surgeon's hands) inside the body, yet manipulated from outside the body (Box 10-5 describes terms used in laparoscopic gastrointestinal surgery). The first generation of modern laparoscopic surgery began in the early 1970s in the GYN specialty; it was used primarily for diagnostic direct (eye on the telescope eye piece) visualization of endometriosis, ectopic pregnancy, and uterine fibroids, and later, laparoscopic tubal ligation with electrosurgery was performed. These procedures were originally called Band-Aid, keyhole, or belly button procedures.

Traditional laparoscopic port placement, via triangulation, is the fundamental concept of laparoscopic surgery. It places the instruments on planes where they meet to effectively support dissection with adequate visualization and identification of anatomy and pathology. Incorrectly placed ports can cause sword-fighting instruments and indirect access to the operative

TOGA—Trans Oral GAstroplasty

target. Challenges also exist in delivering intact specimens through small ports. The increased intra-abdominal pressure from the insufflation of CO_2 into the peritoneal cavity applies pressure on the diaphragm and femoral vessels. This can compromise patients with cardiac and respiratory disease and cause deep vein thrombosis. The venting of CO_2 at the end of the procedure is believed to have the potential of "blowing" cancer cells into the layers of the port site, causing later cancer recurrence of the skin and subcutaneous layers of the abdomen. This is a very rare event and probably not a concern that should eliminate laparoscopic approaches for cancer patients. Less invasive approaches to surgery are less stressful to the patient. Traditional laparoscopic surgery has many other advantages over traditional open surgical approaches (Box 10-6). These advantages, however, do not exist without technical challenges and cost concerns.

Procedures described as "laparoscopically assisted" combine laparoscopic surgical manipulation of tissue with enlargement of one of the port incisions, permitting the surgeon direct access, or hand contact, on the operative tissue. The surgeon may transfer a portion of the surgical tissue onto the abdominal surface to achieve repair outside the body (*extracorporeal* repair). *Intracorporeal* refers to inside the abdomen. Laparoscopically assisted surgery may also refer to laparoscopic dissection and resection with an open approach to remove the surgical specimen.

Laparoscopy is usually contraindicated in patients with extensive adhesions from prior surgeries. Patients with bleeding disorders or pregnancy also pose a risk. Advanced cardiac or pulmonary disease may preclude the option of a minimal access approach. Potential complications include trocar site bleeding (Patient Safety), vascular injury, hemorrhage, perforation or laceration of organs, infection, anastomotic leaks, ileus, strictures, accidental electrosurgical injury, and pulmonary problems. The surgeon may have to convert to an open procedure in the presence of adhesions, hemorrhage, fixed small bowel, unusual anatomy, unexpected findings, or instrument failure. The potential for conversion to an open approach is discussed with the patient before surgery and documented on the consent form by the surgeon.

Single port access laparoscopy entails entry through the abdominal cavity via one port placed through the umbilicus. This approach is also called "radical endoscopy" or "stealth surgery" (surgery that takes place without leaving a trace that it occurred, since there is no scar). Access is gained through the Hasson cutdown technique with a small scalpel and bladeless dissecting-tip trocar. The port maintains pneumoperitoneum and retracts the incision. Instruments are curved and flexible to accommodate space restrictions and afford range of motion that follows the surgeon's hand movements. Multiple instruments can be used via one port with standard digital technology (video systems and processors).

Single port/puncture laparoscopy offers considerable advantages over traditional laparoscopy. The high-dexterity instrumentation that is used bends and flexes to provide manipulative options not available with traditional laparoscopy. It does so essentially with three or four instruments: a combined telescopic light/camera and two working tools. At the end of the procedure, the port is removed and the umbilicus is gently folded back into its original shape. Many procedures that can be accomplished via laparoscopic access are now approached

PATIENT SAFETY

Perioperative Considerations in Trocar Safety

Trocar and insufflation needle–associated insertion mishaps can result in major vascular injury and death. The aorta and right common iliac artery are the most often injured vessels because of the right handedness of most operators. Trocars may be bladed, bladeless, or blunt-tipped. To gain access to the abdominal cavity, the selected trocar must pass through the abdominal wall layers without injuring blood vessels or internal organs. Although the surgeon has primary responsibility for preventing these and other trocar injuries, the perioperative nurse should understand the risks related to such instrumentation, as well as have a basic understanding of the techniques for trocar insertion. The perioperative nurse's review of the patient's history should focus on previous surgeries that might have contributed to the formation of adhesions, patient weight (in thin patients, the distance between vascular structures and the abdominal wall is comparatively short; in obese patients, more force may be required), and patients with enlarged livers or spleens. Of special concern is any trocar with a shield. With this device, the scrub person and surgeon must ensure that the shield is retracted before insertion and kept retracted. If it is not, too much force is required. Further, the shield itself may lock into place prematurely when pressure is reduced before full penetration into the abdomen.

Another important safety issue with trocars is the distance they extend into the abdomen. Registered nurse first assistants (RNFAs) assisting in access procedures during minimally invasive surgery (MIS) should develop the skill to detect passage of the trocar tip through the peritoneum, but still avoid possible injury to internal organs. When working in the upper abdomen, the RNFA should use maximum countertraction when inserting a trocar toward the diaphragm. This assists in avoiding major blood vessels. Often, aiming the trocar parallel to the spine and off midline helps to avoid vascular injury. Injury prevention will benefit from a systems' approach with a focus on training, technique, and equipment design. Operators must be aware of the spatial relationships within the abdomen and the tactile senses of force and resistance. They must comply with the technical aspects of proper protocol, and pay attention to potential hazards of blind insertion.

In Souba WW et al: *ACS surgery—principles and practice,* New York, 2005, WebMD; Girard NJ: Perioperative grand rounds: procedural mishap: learning curve, *AORN J* 89(2): 468, 333, 2009.

BOX 10-6

Advantages and Disadvantages of Laparoscopic Surgery

BENEFITS FOR THE PATIENT
- Minimal blood loss
- Reduced risk for infection
- Rapid return of GI function
- Less small bowel obstruction
- Less risk for incisional hernia with smaller incisions
- Less immune suppression than open techniques
- Less postoperative pain and reduced analgesia use
- Adjunct to preoperative staging
- Application of chemotherapy and brachytherapy

DRAWBACKS FOR THE PATIENT
- Less capacity for intraabdominal inspection and large specimen removal
- Potential for port-site recurrence
- Potential for DVT
- Decreased venous return
- Decreased vital capacity
- Increased peak airway pressure, cardiac volume, systemic vascular resistance (SVR) (50%), systolic pressure
- Risk for pleural or peritoneal seeding of malignant cells

BENEFITS FOR THE SURGEON
- Enhanced imaging resolution
- Image/video-recording option
- All team members see same image
- Abundant light
- Magnification

DRAWBACKS FOR THE SURGEON
- Ergonomically challenging
- Instruments move in opposition—fulcrum effect
- Loss of haptic sensation and tactile feedback
- Critical moves necessary with nondominant hand
- Sees two dimensionally but must perceive three dimensionally
- Significant learning curve to competence

via single puncture as well. Contraindications include multiple prior abdominal surgeries because of adhesions or altered anatomy, and morbid obesity because of decreased visibility and difficult movement inside the cavity (Curcillo, 2007; Fowler, 2008; Pasricha, 2005).

Because the umbilicus has no muscle or fascia layer, umbilical incisions are safe and less painful than other incision sites. With only one incision site, there is less risk of penetration injuries, infection, and hernia. The growing capabilities of therapeutic flexible endoscopy have ushered in a new era in treatment of GI conditions. Refinements in laparoscopic surgery have progressed to the point that complex surgical procedures, such as gastric bypass, are performed in a minimally invasive fashion.

These trends have set the stage for the development of even less invasive methods to treat conditions both in the gut lumen and in the peritoneal cavity. Major intraperitoneal surgery is being performed without skin incisions. The natural orifices may provide the entry point for surgical interventions in the peritoneal cavity, thereby avoiding abdominal wall incisions. Natural orifice transluminal endoscopic surgery (NOTES) is performed by a team that has the skills of an advanced therapeutic endoscopist and a laparoscopic surgeon. Advantages for the patient include decreased pain, blood loss, and morbidity; absence of a scar; and earlier return to activities of daily living (ADLs). Advantages for the surgeon include increased visibility with light and magnification, larger field of view, flexible tips that eliminate the need to change instruments frequently, and easy transition to traditional laparoscopy (Lucile Packard Children's Hospital, 2008). Operative costs are similar to those for traditional laparoscopy.

While single port laparoscopy was developed from the platform of traditional laparoscopic surgery, new instrumentation is advancing the ergonomics and precision of dissection (Barclay et al, 2008; Cleveland Clinic, 2008; Raman et al, 2008). Laparoscopy offers advantages over the conventional open approach in many GI procedures. Success of surgical repair, postoperative recurrence of disease, and overall survival are similar between open and laparoscopic approaches for the same surgery. Operative times vary according to many variables, including unusual occurrences, the surgeon's skill and technique, and instrumentation. Postoperative analgesia needs are the same or may be less than in the open laparotomy approach. Patients typically report less postoperative discomfort because of the absence of a large abdominal incision. Nonetheless, many do report muscle discomfort in the area of a working-port incision where significant manipulation of instruments occurred. Postoperative flatus and first bowel movement may occur a day sooner than for conventional surgery patients. Resumption of oral intake may also be sooner in this group (see Research Highlight, Early Feeding after Abdominal Surgery, p. 310). Minimal access approaches also result in faster recovery of pulmonary function, fewer postoperative complications, less potential for surgical site infections, improved cosmesis, shorter recovery period, and quicker return to former activities of daily living.

Procedural Considerations

Minimal access surgery requires specially designed instruments, telescopes, trocars with cannulae, suction and irrigation devices, retractors, electrosurgery, CO_2 introduction devices, stapling instruments and appliers, and video image equipment. The video camera, light source, and monitors provide indirect visualization of the surgical site, enhanced with magnification and bright illumination.

Operative Procedure

1. Initial entry is made in the periumbilical region with percutaneous puncture with an insufflation (Veress) needle (closed technique) or a sharp trocar in a sheath (direct technique). A cutdown technique (Hasson technique) may be used with a small incision through to the fascia with a #15 blade. The trocar is then introduced through and into the peritoneal cavity. In the direct technique, an optical trocar is inserted to visualize trocar placement before insufflation.
2. Pneumoperitoneum is established with insufflation of 3 to 4 liters of CO_2 into the peritoneal cavity to achieve an intraabdominal pressure of 12 to 15 mm Hg.
3. The needle is removed and replaced with a 10-mm or 11-mm trocar. The rigid laparoscope, with video camera and cord coupled to the telescope eyepiece end, is inserted into the port for visualization. Two to six more ports may be created to facilitate use of an endoscopic fan retractor; various grasping, dissection, cutting, and electrosurgery instruments;

ultrasonic scalpel dissector; suction-irrigation devices; laser fibers; endoscopic clip and staple appliers; and specimen retrieval graspers. Port sites are selected to permit all instrument tips to converge at the primary surgical work site.

4. Surgical exploration, dissection, resection, anastomosis, inspection, and irrigation then follow.
5. CO_2 is exhausted and ports removed. The umbilical incision is closed with 3-0 or 4-0 nonabsorbable synthetic suture. Remaining port incisions are closed with the same suture, adhesive strips, or skin-bonding adhesive. A small dressing or bandage is applied.

INTRAOPERATIVE INTRAPERITONEAL CHEMOTHERAPY

Patients who undergo abdominal surgery for GI and peritoneal cancers may benefit from intraoperative hyperthermic intraperitoneal chemotherapy (HIPEC) to remove or to reduce the burden of tumor or diseased organs, often called cytoreductive (removing as much tumor tissue as possible) (also referred to as "debulking") surgery. HIPEC may take place while the abdomen is still open or after it is closed (referred to as the "closed" technique). The abdominal cavity is connected to an extracorporeal fluid circuit for instillation and continual perfusion of heated chemotherapeutic agents (Pappas et al, 2008). Access may be created with a peritoneal port such as a Tenckhoff catheter or with separate inflow and outflow catheters. Tissue contact can be maintained with perfusion pump–directed flow or by manually rocking the abdominal cavity (by a sterile team member) to agitate fluid around and about the abdominal organs. The procedure may take up to 2 hours. This therapy allows for a high concentration of chemotherapy to have direct contact with the tumor, surrounding organs, and visceral and parietal peritoneum. Heating the fluid increases topical absorption. Contraindications to intraperitoneal chemotherapy include adhesive disease, hypovolemia, massive ascites, malnutrition, GI dysfunction, or postoperative infection (Marin et al, 2007). Complications may include wound infection, abdominal wound dehiscence, anastomotic leak sepsis, and enterocutaneous fistula (Marin et al, 2007).

Proper personal protective equipment (PPE) must be worn and safe medication handling practices must be employed to protect all team members and the patient from accidental injury from hazardous cytotoxic drugs (Risk Reduction Strategies). HIPEC has been shown to increase survival in select patients when combined with cytoreductive surgery (Pappas et al, 2008).

ENDOSCOPIC PROCEDURES

GI endoscopy has transformed the diagnosis and treatment of patients with GI diseases. Endoscopic procedures permit direct or video visual inspection of the contents and walls of the esophagus, stomach, duodenum, and colon. Endoscopy provides significant tools for routine screening of individuals at risk for GI disease (Ransohoff, 2005), for establishing a diagnosis, for determining preferred treatment of a disease process, and for follow-up after a treatment regimen or surgery. GI endoscopy, enhanced by advances in imaging, instrumentation, and accessory devices, has evolved into an interventional discipline, offering nonsurgical approaches to cure and palliation of symptoms of selected GI diseases and conditions. Common GI endoscopy procedures include esophagogastroduodenoscopy (EGD) (also referred to as gastroscopy or upper endoscopy), small bowel endoscopy (also referred to as push enteroscopy or double-balloon enteroscopy), colonoscopy (also referred to as lower endoscopy), and sigmoidoscopy (also referred to as a "flex sig").

Endoscopic procedures are performed with local anesthetics, IV moderate sedation/analgesia, or general anesthetics, all of which ensure a safe and complete examination. Smaller caliber flexible endoscopes have evolved so that they can be passed easily without the need for sedation (Research Highlight). IV moderate sedation provides a depressed level of consciousness and tolerance of a potentially uncomfortable procedure, yet patients retain their ability to maintain their airway and respond appropriately to physical and verbal stimuli. It is administered by the attending physician/interventionalist, anesthesia provider, or a registered nurse competent to monitor the patient's heart rate and rhythm, oxygen saturation, blood

RISK REDUCTION STRATEGIES

Safe Care and Handling of Cytotoxic Drugs

Safe work practices, engineering controls, and proper use of approved protective equipment can minimize potential health effects from occupational exposure to cytotoxic, antineoplastic drugs, and other hazardous drugs. Cytotoxic drugs are pharmaceutical compounds that are destructive to cells within the body. Antineoplastic agents control or kill cancer cells. They are cytotoxic but generally more damaging to dividing cells than to resting cells. Safe work practices include:

- Personal protective equipment (PPE) must be used whenever there is a risk of exposure to cytotoxic or other hazardous drugs; PPE includes nonpermeable gowns, latex or nitrile chemo gloves changed every 30 minutes or when torn, masks, and eye protection whenever there is risk for splash or eye exposure.
- PPE is worn whenever preparing, transferring, spiking, changing, priming, and disposing of chemotherapeutic agents (chemo).
- Always work below eye level.
- Have a chemo spill kit available wherever chemo is prepared, administered, stored, or disposed.
- Have yellow chemo waste containers available in the work area for contaminated sharps, linen, and trash.
- PPE is worn during chemo spill cleaning and when handling and disposing of patient body fluids. Wear the N95 NIOSH certified respirator mask when cleaning cytotoxic spills.
- Unused medication vials, bags, or syringes must be returned to the pharmacy or placed in chemo waste containers in the work area.
- Place needles, syringes, broken glass, empty vials, and tubing in the sharps containers labeled for chemotherapy waste.
- Place used PPE in yellow chemo waste container. Wash hands.
- If exposed, wash affected area with soap and water for 15 minutes. Flush eyes with normal saline for 15 minutes. Report to employee health or appropriate healthcare provider.

RESEARCH HIGHLIGHT

The Body Pillow as a Tool for Upper Endoscopy

This small study investigated use of a large body pillow as a comfort and positioning tool for unsedated upper endoscopy (EGD); 177 healthy patients who had previously undergone upper endoscopies in a medical facility in Japan were followed. The procedure was performed with the patient positioned on the left side, hugging the pillow to the chest and abdomen with knees flexed. No sedation was given. After the procedure, the patients were interviewed about their current distress levels in comparison with their former procedure without the pillow. A total of 60% stated that the pillow procedure was less stressful than their prior procedure. Another 29% claimed no change. Of the remainder, 8% claimed more distress and 3% had no answer. The researchers concluded that the pillow should be recommended as a tool for upper endoscopy, as it is safer than sedation and contributed to alleviation of patient stress during the procedure.

From Matsuda R et al: Body pillow: an extremely useful tool for an upper endoscopy examination, *Gastroenterol Nurs* 32(1):53-54, 2009.

pressure, respirations, level of consciousness, and comfort during and immediately after the procedure until the patient is stable and ready for discharge or transfer. Preprocedure preparation for elective procedures limits ingestion of solid foods and liquids for a prescribed period. Bowel preparation with diet limitation, bowel cleansing preparations, and sometimes enemas is prescribed before lower endoscopy procedures.

Flexible endoscopes are semicritical patient care devices that must undergo high-level disinfection before each use. They are easily damaged by misuse and should be handled according to the manufacturer's recommendations. They must be leak-tested, decontaminated, reprocessed, and dried after each use. They must be stored in an appropriate secure and ventilated endoscope closet. Endoscopic accessories, such as biopsy forceps, snares, cytology brushes, and fine-needle aspiration (FNA) catheters, must be sterile because they are considered critical devices that invade the mucosal barrier.

Esophagogastroduodenoscopy (EGD) (Upper Endoscopy)

EGD visualizes the esophagus, stomach, and proximal duodenum. It is used for diagnosis, treatment, and documentation of abnormalities with biopsy, brush cytology, polypectomy, electrosurgery, thermal coagulation, laser therapy, dilation, banding or sclerosing of esophageal varices, removal of foreign bodies, insertion of an esophageal prosthesis, and other interventional procedures for gastroesophageal reflux disease (GERD), Barrett's esophagus, and percutaneous endoscopic gastrostomy (PEG) tubes. When an EGD is performed with a local anesthetic or sedation, the patient is usually permitted no solid food for 6 to 8 hours before the procedure but may drink liquids up to 2 hours before the procedure.

Procedural Considerations. The patient's position for EGD depends on the areas to be visualized, but a left lateral supine or low Fowler's position is commonly used. For inspection of lesions in the gastric fundus and cardia, an upright sitting position may be used. A protective bite-block is placed in the patient's mouth to protect the scope and the patient's teeth from injury. Instrumentation includes a gastroscope and video system (optional), biopsy forceps, suction, water-soluble lubricant, saline and water for irrigation, and electrosurgery capability.

A topical local anesthetic (applied to the posterior pharynx) along with IV moderate sedation is the most common technique. A perioperative or endoscopy nurse skilled and credentialed in moderate sedation and advanced cardiac life support (ACLS) or an anesthesia provider monitors the airway, vital signs, and oxygenation.

A light source with air and water infusion capability and a water bottle for irrigation are required. Suction, aspiration tubes, and a cup of saline for the biopsy specimen should be available. Lubricating jelly is placed over the sheath of the gastroscope for ease in placement. An ESU and cord are available for fulgurating a lesion or coagulating a bleeding site.

Operative Procedure

1. The gastroscope tip is completely covered with a thin coat of water-soluble lubricating jelly.
2. During introduction of the gastroscope, the patient's head and neck must remain in the sagittal plane of the spine so that the axis of the mouth is in line with the esophagus.
3. The gastroscope is slowly passed through the nasopharynx into the esophagus, stomach, and duodenum.
4. The mucosal surface is inspected and contents may be aspirated for cytologic analysis. A biopsy may be performed.
5. After the procedure, the patient is monitored and must have a gag reflex before fluids are offered.

Small Bowel Enteroscopy

The small bowel has traditionally been a difficult segment of the GI tract to reach for endoscopic visualization. Enteroscopy can be approached orally or through the anus using an adult or pediatric colonoscope, or a push enteroscope that measures 200 to 250 cm in length. Push enteroscopy advances the scope far into the small bowel. A balloon on the tip of the scope permits it to be held in place. The patient receives IV metoclopramide (Reglan), promoting peristaltic advancement of the scope. The small bowel is examined as the scope is slowly withdrawn. This procedure may take 6 to 8 hours (Society of Gastroenterology Nurses and Associates [SGNA], 2004). Push enteroscopy is useful for examining areas of bleeding and strictures.

Double-balloon enteroscopy employs an enteroscope with a balloon on its end and on the end of the overtube, which creates a traction system that permits the small bowel to pleat itself onto the overtube, and prevents overstretching of the small intestine. This technique also permits visualization and therapeutic measures such as biopsies, coagulation of small bleeders, and lysis of strictures (Lewis, 2005; Sunada et al, 2005).

Colonoscopy and Sigmoidoscopy (Lower Endoscopy)

Colonoscopy is endoscopic examination of the colon from the rectum to the ileocecal valve. The bowel wall is inspected for abnormalities such as bleeding, polyps, inflammation, ulceration, or tumors during both insertion and withdrawal of the colonoscope. Colonoscopy facilitates biopsy, removal of polyps,

electrocoagulation or laser treatment of tumors or bleeders, dilation, decompression, and provision for a video and photographic record of the procedure and findings. Sigmoidoscopy, both flexible and rigid, provides access and visualization of the sigmoid or descending colon to the level of the splenic flexure. Colonoscopy or sigmoidoscopy may be performed before colon or sigmoid resection for surgical localization of the tumor site with india ink tattooing or clip placement. This permits the surgeon to identify the tumor site, viewing the marked site from the serosal side of the colon by laparotomy or laparoscopy access.

Endoscopy can also be performed through an ostomy stoma to inspect an anastomosis site or identify recurrence of disease or bleeding. Reservoir pouches can also be inspected after surgical healing for anastomosis integrity, inflammation, bleeding, and other abnormalities. The patient must receive a clear liquid diet the day before colonoscopy and sigmoidoscopy and may receive bowel-cleansing agents such as citrate of magnesia or a commercial bowel prep solution. Enemas may be necessary before the procedure.

Procedural Considerations. The instruments and equipment that must be available to perform colonoscopy and sigmoidoscopy include a colonoscope or flexible sigmoidoscope, video camera and monitors (optional), a light source, an air-insufflation device with water bottle for irrigation, a biopsy forceps, snares, cytology brush, electrosurgical-fulguration-desiccation unit and appropriate accessories, lubricating jelly, and suction.

Operative Procedure

1. The patient is positioned on the left side with knees bent.
2. The well-lubricated colonoscope is passed slowly into the anal canal and advanced continuously until it reaches the cecum in colonoscopy. The endoscopist or surgeon may ask the nurse or surgical technologist to apply gentle abdominal pressure to assist advancement of the scope around the splenic or hepatic flexures. With sigmoidoscopy, only the left colon is examined. Flexible sigmoidoscopy may be accomplished in a cooperative patient without sedation.
3. After the endoscopic examination, the patient is observed for postprocedural bleeding, pain (Rapid Response Team box), signs of perforation, or reaction to medications.

Procedures for Gastroesophageal Reflux Disease (GERD)

GERD is described as a condition of backflow of gastric or duodenal contents into the distal esophagus, causing pain, heartburn, coughing, and respiratory distress. GERD may also present with incompetence of the distal esophageal valve to the stomach or lower esophageal sphincter (LES). Chronic GERD can lead to erosive esophagitis, asthma, dysphagia, aspiration pneumonia, and Barrett's esophagus. Several innovative, nonsurgical interventional endoscopic techniques now can minimize or prevent the reflux of stomach acid into the esophagus, controlling GERD symptoms by enhancing the competency of the LES. These procedures, accomplished through an EGD, or upper endoscopy, reinforce the LES by plicating and sewing the inner lumen of the esophageal junction to re-fashion the valve, tightening the tissue above the LES to create a stricture, or implanting devices to narrow the LES lumen. The American Gastroenterological Association's guidelines address management and treatment of GERD according to evidence-based medical literature. Recommended practice includes the use of proton pump inhibitor (PPI) medications as the first line of therapy followed by antireflux surgery only when the patient can no longer tolerate acid suppression therapy (Barclay et al, 2008).

Several antireflux procedures can be performed endoscopically in an endoscopy procedure room using moderate sedation or general anesthesia. The Stretta (Curon Medical) procedure is radiofrequency heat energy delivered through an endoscopically-introduced balloon catheter to the distal esophagus, creating thermal lesions that tighten the tissue.

The EndoCinch (Bard Medical) technique dilates the lumen of the esophagus before passing the EndoCinch device through

RAPID RESPONSE TEAM

In phase II PACU, while recovering from colonoscopy under moderate sedation, the patient described vague generalized abdominal pain, increasing in intensity. He had nausea and vomiting, low-grade fever, abdominal tenderness, guarding, and muscle rigidity on palpation. Respirations were shallow and he was tachycardic and anxious. The gastroenterologist had left the building. The nurse, concerned about his increasing distress and delay in normal recovery after colonoscopy, summoned the hospital rapid response team, using the SBAR format in her call for assistance:

Situation—"I have a patient with increasing abdominal distress, tachycardia, and shallow respirations."

Background—"The patient is a 53-year-old normally healthy man post screening colonoscopy. The procedure was unremarkable; however, he has complained of increasing vague abdominal pain, nausea, and vomiting."

Assessment—"He has abdominal tenderness, guarding, and rigidity on palpation. He is tachycardic with shallow respirations and a low-grade fever, which he did not have before the procedure. He states that he has never felt like this before and is afraid something is seriously wrong. His wife is very concerned. He has emerged from the moderate sedation; however, this is not a normal recovery from a routine colonoscopy."

Recommendation—"His condition is deteriorating and he must be seen now. I am concerned he may have a perforation of the colon. He is in Endoscopy recovery bed 4."

The rapid response team consisted of an ICU nurse, respiratory therapist, and critical care hospitalist. They performed a focused assessment and review of the medical record, placed an additional IV line and administered fluids, ordered a stat abdominal CT scan and pain medication, and called the surgeon on-call. The CT revealed free air in the abdomen and perforation at the splenic flexure of the colon. The patient had emergency surgery for repair of the perforation and recovered without incident.

Adapted from O'Brien D: Postanesthesia complications. In Drain CB, Odom-Ferren J, editors: *Perianesthesia nursing: a critical care approach,* ed 5, St Louis, 2009, Saunders.

an EGD scope. The device is a sewing capsule that pinches or pleats mucosal folds and anchors them in place with a suture. Several plications are placed in a circumferential or staggered vertical pattern.

The Wilson-Cook sewing system (Wilson-Cook Medical) is another submucosal plication device that suctions a small fold of tissue into the lumen of the scope accessory, and then plicates, sutures, and knots the tissue pleat.

Procedures for Barrett's Esophagus

Cellular changes, or dysplasia, of the mucosa of the distal esophagus is called Barrett's esophagus, a precursor for cancer of the esophagus. A significant percentage of patients with GERD may develop Barrett's. Patients who show progressive dysplasia in spite of medical therapies, such as histamine blockers and proton pump inhibitors, may be treated with one of several endoscopic techniques targeted to eliminate dysplastic tissue, prevent or eliminate strictures, and promote regrowth of normal esophageal mucosa.

Endoscopic mucosal resection (EMR) is an interventional technique to remove submucosal flat or depressed lesions. EUS is used to determine depth of invasion into the esophageal wall, and the lesion or dysplastic tissue is then injected with isotonic saline, hypertonic saline, or saline with epinephrine to lift the lesion away from the muscle layer, creating a polyp-like lesion. This tissue bulge is then suctioned into a cap secured to the end of the scope, resected with a rigid wire snare, and removed. The saline creates a cushion to protect the muscle wall from perforation and facilitates snare resection. This technique also provides a tissue specimen for histologic examination. Areas of bleeding can be endoscopically electrocoagulated (Ransohoff, 2005).

Photodynamic therapy (PDT) is a technique using laser light ablation. Dysplastic tissue uptakes a photosensitizer drug, Photofrin II (sodium porfimer), which is activated by the laser. The drug is administered 48 hours before the procedure to allow for tissue uptake. Normal tissue excretes the drug sooner than abnormal or dysplastic tissues. The drug is retained in the mucosal layer, which limits the depth of the laser effect. After 48 hours, the patient returns for the endoscopic procedure. The laser fiber is introduced through the scope channel and laser light is directed toward the mucosa, causing tissue destruction and cell death of those areas identified by the uptake of the photosensitizer drug. The patient may continue to be sensitive to light for 60 to 90 days following the injection and must take precautions to prevent cutaneous burns (Wang, 2005). Unlike EMR, PDT does not provide a tissue specimen. PDT is often combined with endoscopic mucosal resection. PDT and EMR can also be used to treat the gastric and colonic mucosa.

Self-Expanding Metal Stents

Self-expanding metal stents (SEMSs) expand within a lumen to maintain patency in an area constrained by stricture or tumor. They are used in the esophagus or colon, advanced across the obstruction, and released to remain in place. They are preloaded in a closed position on a delivery catheter, introduced through an endoscope with fluoroscopy guidance, and deployed, applying radial force that holds them in place. Stents may also be made of silicone. Although initial complications are low, stents may migrate, perforate, become impacted with food, cause bleeding or fistula development, or become obstructed with tumor overgrowth. Stent placement is frequently a palliative procedure.

SURGERY OF THE ESOPHAGUS

Esophagectomy

Esophageal cancer is the sixth most common cancer worldwide and is notorious for aggressive progression of intramural invasion of the esophageal wall and lymphatic metastasis (Edmondson and Schiech, 2008). Esophageal cancer may be adenocarcinoma or squamous cell, each with an equally poor prognosis when treated in late stages. As many as 50% of patients with esophageal cancer are ineligible for surgery because of late-stage diagnosis, debilitating multisystem conditions, infection, or malnutrition.

Esophagectomy can be performed by several different approaches and procedures: transthoracic, transhiatal, video-assisted thoracotomy surgery (VATS), or laparoscopic-assisted approach. A segment of the colon or jejunum may be used as a reconstructive conduit in the patient with prior partial or total gastrectomy.

Procedural Considerations. Instrumentation includes a basic thoracotomy set, basic laparotomy set, vascular instruments, and a GI instrument set. Long versions of basic instruments, deep retractors, linear stapling devices, and vascular ligating clips should also be available. Laparoscopic and thoracoscopic instrumentation and video equipment is used in the VATS approach. The surgeon may perform an EGD before the surgical prep. The patient is positioned and secured in the preferred position for the intended surgical approach after induction of general anesthesia. A double-lumen endotracheal tube is placed in order to deflate the lung for a thoracotomy approach. Critical monitoring devices, such as arterial lines and pulmonary artery catheters, are placed. An indwelling urinary catheter is inserted. Measures are taken to ensure that the patient's body temperature is maintained in normothermia. Any of these procedures may be modified with laparoscopic, thoracoscopic, mini-laparotomy, or mini-thoracotomy access. Postoperative pain management may be augmented with interscalene perineural blockade for shoulder pain. Patients undergoing esophagectomy usually are transferred to the intensive care unit (ICU).

Transhiatal Esophagectomy

1. Transhiatal esophagectomy removes from 67% to 100% of the thoracic esophagus through an upper midline abdominal incision and an incision in the neck above the left clavicle. The abdominal component may be approached laparoscopically. Thoracotomy is avoided.
2. Accessible lymph nodes are removed for staging purposes. Not all lymph nodes can be accessed.
3. The stomach is mobilized and fashioned into a tubular shape at the greater curvature with surgical staples.
4. The tubular stomach segment is tunneled up through the posterior mediastinum to the left cervical incision. This procedure is often called a gastric pull-up.
5. The stomach is reconstructed with the fundus attached to the remaining cervical portion of the proximal esophagus using an end-to-side anastomosis. The fundus is also sutured to the cervical prevertebral fascia.

6. A pyloromyotomy or pyloroplasty then follows to increase stomach emptying. This often results in postoperative "dumping syndrome" and reflux.
7. A jejunostomy tube is placed for postoperative enteral nutrition.
8. Postoperative hoarseness and dysphagia are common because of ipsilateral nerve damage.

Transthoracic Esophagectomy

Transthoracic esophagectomy is indicated for disease of the middle third of the esophagus and high-grade dysplasia in Barrett's esophagus. This approach permits complete lymph node dissection under direct vision and combines a left-sided thoracoabdominal incision or separate right posterior lateral thoracotomy and midline abdominal incision. The latter describes the traditional Ivor Lewis approach. Another variation, sometimes called the "three-hole esophagectomy," combines a cervical, right thoracotomy, and midline laparotomy approach for proximal tumors. The single incision thoracoabdominal incision provides the best exposure for low gastroesophageal junction tumors and is indicated for patients with cardiac and pulmonary disease.

Operative Procedure

1. The skin incision is carried downward, midway between the vertebral border of the scapula and the spinous processes to the eighth rib and then forward along this rib to the costochondral junction. The extent of the vertical portion of the incision depends on the tumor's location.
2. The wound is retracted, and bleeding vessels are ligated or coagulated.
3. The chest cavity is opened, and the rib spreader is placed. Moist packs are placed, and the lung is retracted with a Deaver or Harrington retractor.
4. The mediastinal pleura is incised with long Metzenbaum scissors and long plain forceps in line with the esophagus and the lesion.
5. The esophagus is dissected free from the aorta with dry gauze dissectors.
6. Suture ligatures of 2-0 and 3-0 nonabsorbable material are used to control bleeding vessels.
7. The diaphragm is opened, and a series of traction sutures are placed.
8. The stomach is mobilized by dissection of its ligamental attachment with long scissors and curved thoracic clamps.
9. The left gastric artery is clamped, cut, and doubly ligated with 2-0 nonabsorbable suture and a suture ligature of 3-0 nonabsorbable material. The sterile field is prepared for the open method of anastomosis.
10. The stomach is transected well below the lesion with selected resection instruments.
11. Closure of the stomach is completed with two rows of intestinal sutures of 2-0 synthetic absorbable suture and sometimes with an additional row of 3-0 nonabsorbable sutures for reinforcement. A linear stapling device may be used as well.
12. A separate circular opening is usually made in the upper portion of the stomach for anastomosis to the esophagus.
13. Two Allen clamps or a stapler type of clamp is applied above the stricture, and the freed esophagus is divided.
14. The circular opening in the stomach and the transected end of the esophagus are anastomosed. The mucosal layers are approximated. The muscular layers of the esophagus and stomach are closed by two rows of interrupted sutures. A mechanical end-to-end anastomosing (EEA) surgical stapling device may also be used to accomplish the gastroesophageal anastomosis.
15. The stomach is anchored to the pleura, and the edges of the diaphragm are sutured to the wall of the stomach with interrupted sutures of 3-0 or 2-0 nonabsorbable material.
16. The pleura is cleansed with warm normal saline irrigation, which is then removed by suctioning.
17. A thoracic catheter is inserted for closed drainage. The chest wall is closed as described for thoracotomy.

Video-Assisted Thoracotomy Surgery (VATS)

1. VATS is accomplished in three stages beginning with thoracoscopic dissection and mobilization of the esophagus.
2. The second stage is the laparoscopic dissection, mobilization, and tubular construction of the stomach. Pyloroplasty is also performed laparoscopically.
3. The third stage is the open cervical incision anastomosis.

Excision of Esophageal Diverticulum

Excision of an esophageal diverticulum, sometimes called *Zenker's diverticulum,* is removal of a weakening in the wall of the esophagus that collects small amounts of food and causes a sensation of fullness in the neck. Diverticula usually occur in the cervical portion of the esophagus, and excision usually relieves symptoms completely.

Procedural Considerations. Instrumentation includes a thyroid set with the addition of Pennington clamps, curved mosquito hemostats, 5-inch Adson forceps, and lateral retractors. The patient is positioned supine with a shoulder roll placed to assist with hyperextension of the neck. The head may be turned to the side and supported with a padded headrest. This procedure may be done endoscopically.

Operative Procedure

1. An incision is made over the inner border of the sternocleidomastoid muscle and is extended from the level of the hyoid bone to a point 2 cm above the clavicle.
2. The sac of the diverticulum is freed and ligated.
3. The pharyngeal muscle and surrounding tissues are closed.
4. In conjunction with this procedure, an esophageal myotomy is often performed distal to the diverticulum to minimize likelihood of recurrence.

Esophageal Hiatal Hernia Repair and Antireflux Procedure

Hiatal herniorrhaphy restores the LES to its correct anatomic position in the abdomen, secures it firmly in place, and corrects GERD. A hiatal hernia (also called a *diaphragmatic hernia*) is a defect, either congenital or acquired, in the diaphragm through which a portion of the stomach protrudes up into the thoracic cavity.

Hiatal hernias are usually of two types—paraesophageal and sliding. Symptoms vary from none to severe heartburn, reflux (backward flow), regurgitation, and dysphagia. When symptoms are severe, a repair of the hernia is done, usually through a transabdominal approach. A transthoracic approach is used

for patients with prior left upper quadrant surgery and for those who are extremely obese.

An antireflux procedure, to prevent reflux of gastric juices into the esophagus, is also done when the hernia is repaired. The three most frequently performed antireflux procedures are the Nissen, Hill, and Belsey Mark IV.

Procedural Considerations. The patient is positioned supine but may need to be repositioned to lateral if the gastroesophageal sphincter cannot be accessed through a high midline position. An indwelling urinary catheter is inserted after induction of general anesthesia.

Instrumentation includes a basic laparotomy set, Maloney or Hurst dilators in sizes 32 French (32F) to 42F, a self-retaining retractor system, and a 1-inch Penrose drain. If a transthoracic approach is planned, a basic thoracic set is required.

Operative Procedure

1. Through a transabdominal incision, the hernia is located and a crural repair is done.
2. The fundus of the stomach is wrapped around the lower 4 to 6 cm of the esophagus and is sutured in place (Nissen fundoplication); the upper part of the lesser curvature of the stomach and the cardioesophageal junction are sutured to the median arcuate ligament (Hill procedure); or the stomach is plicated approximately 270 degrees around the esophageal circumference (Belsey Mark IV procedure). The Nissen fundoplication procedure is illustrated in Figure 10-15.
3. Vagotomy, pyloroplasty, or both may be performed at the same time.
4. The wound is closed.

Laparoscopic Nissen Fundoplication

The Nissen-Rossetti fundoplication and several other laparoscopic procedures have been developed for GERD management. Nissen fundoplication is also used in the following ways: to reduce the hernia, to eliminate the hernia sac, and to repair the large defect in the diaphragm hiatus. GERD may also be treated with a silicone prosthetic implant placed around the distal esophagus under the diaphragm and above the stomach. The prosthesis, a small donut-shaped device with an open end that is sutured to be continuous, allows food to pass but prevents the stomach from sliding into the chest cavity. This procedure may also be performed as an open laparotomy.

The patient undergoing a laparoscopic Nissen fundoplication is usually admitted the day of surgery. Surgery is performed through five trocar sites in the abdomen, which greatly reduces postoperative recovery. The patient is typically discharged by the second postoperative day if there are no complications. A postoperative upper GI series verifies functioning of the newly constructed antireflux valve.

Procedural Considerations. Surgery is performed using a general anesthetic to anesthetize the patient. A nasogastric (NG) tube and urinary drainage catheter are placed after induction and intubation. The patient is positioned supine or in the modified lithotomy position.

Instrumentation and supplies include a basic laparotomy set, laparoscope, laparoscopic camera, five trocars (trocar size or sizes depend on the surgeons' preference), a light cord, filtered insufflation tubing, and an ESU cord. Laparoscopic instruments

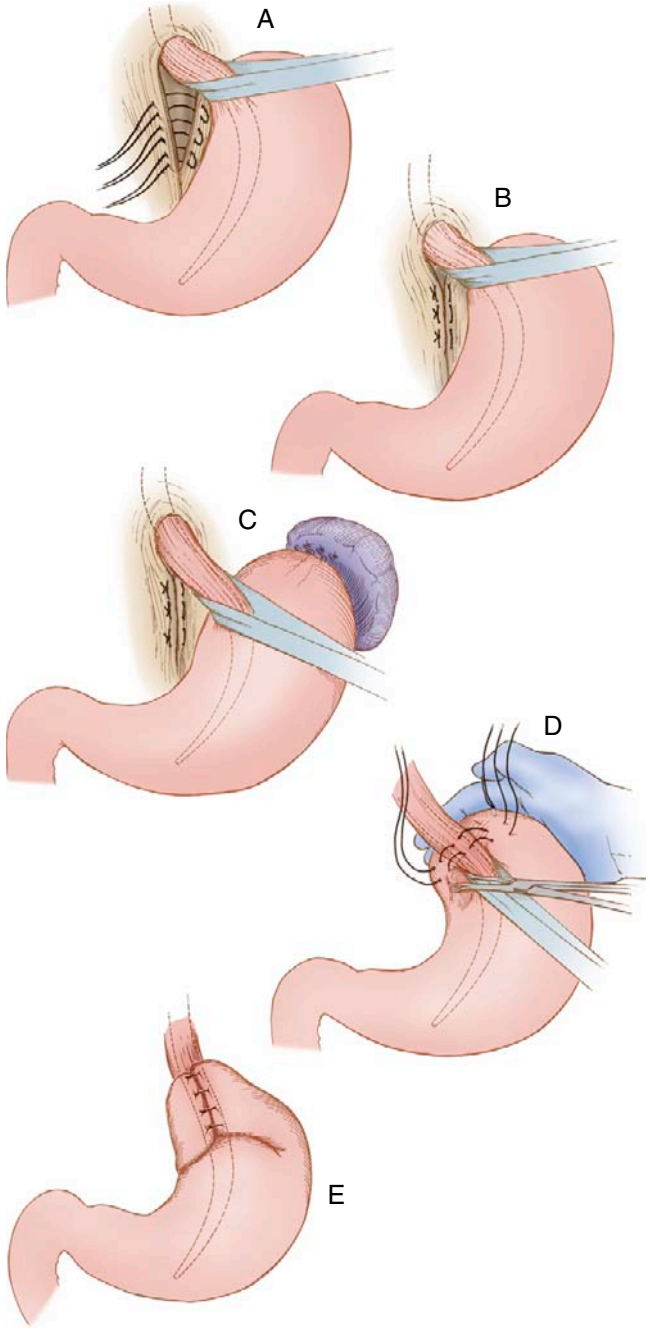

FIGURE 10-15 The Nissen fundoplication procedure begins with oral passage of a Maloney dilator (40F to 48F) into the lumen of the stomach. **A**, The esophagus is then mobilized. A Penrose drain is placed around the gastroesophageal junction to pull the esophagus down and out of the hernia. **B**, Shown are three heavy sutures (#0 braided absorbable) placed to narrow the hiatal aperture but not so tight as to constrict the esophagus, thus the purpose of stenting the esophagus with the Maloney dilator. **C**, Further traction is applied to the distal esophagus while the proximal stomach and fundus are freed from all peritoneal attachments. **D**, The posterior wall of the stomach is relocated around the distal esophagus. **E**, The stomach walls are wrapped and sutured around the intraabdominal esophagus, with the Maloney stent in place.

commonly used include grasping forceps, endoscissors, endo-Babcock forceps, endodissecting forceps, endoclip appliers, an endosuturing device, and endoretractors, such as the fan retractor. Suction and a suction-irrigator are commonly used. A Penrose drain or a 12F red Robinson catheter is used to assist in isolating and retracting the distal esophagus. Bougie dilators (large sizes, such as 40F to 60F) may be used as an esophageal stent by which to secure the fundoplication. A water-based lubricating jelly is used to assist the anesthesia provider in placing the bougie. Equipment needed for the procedure includes an ESU, an insufflation unit with CO_2 gas, and two video monitors (one placed on each side of the patient).

Operative Procedure

1. A stab wound is made with a #11 blade for insertion of the first trocar.
2. The trocar is placed, and insufflation achieved. This may be performed before placing the trocar by inserting a *Veress* needle for insufflation.
3. The laparoscope is placed through the port, and the camera attached to the laparoscope.
4. Two trocars are placed below the xiphoid process, in the right upper quadrant of the abdomen, high in the costal margin, about 5 to 6 mm to the right and left of the midline. Another trocar is placed on the lateral plane to the midline in the left abdomen (left midclavicular). The last trocar is placed in the lateral abdominal wall for use by the assistant.
5. A fan-shaped endoretractor is inserted through the right midclavicular port site and used to retract the left lobe of the liver to expose the gastroesophageal junction.
6. An endo-Babcock forceps is inserted through the left midclavicular port and is used to grasp the upper aspect of the fundus of the stomach. The stomach is retracted laterally and downward. This port site is also used for insertion of a grasper to hold the Penrose drain, clip applier, and ultrasonic coagulating shears.
7. The surgeon mobilizes the distal esophagus by opening the hiatus and employs an endodissector forceps to bluntly dissect the tissue along the right and left crura.
8. Endoclips are used to ligate the most distal portion of the pericardiophrenic vessel before it is divided.
9. The posterior vagus is identified but left intact.
10. Dissection is continued to expose the posterior esophagus.
11. The upper aspect of the greater curvature of the stomach is mobilized, and dissection continues to the posterior esophagus.
12. The Penrose or Robinson catheter is inserted through a sheath and is passed behind the gastroesophageal junction. The ends are united and secured with an endoclamp that is then locked and used as a traction retractor during the procedure.
13. Another grasping forceps is used to grasp the apex of the gastric fundus and retract it downward to expose the short gastric vessels. The vessels are ligated with endoclips and divided with endoscissors.
14. The upper portion of the mobilized greater curvature is grasped and passed through the opening that has been created at the hiatus.
15. Tension and adequate mobilization of the greater curvature of the stomach are assessed. The portion of the greater curvature of the stomach that has been moved around the posterior esophagus at the proximal part of the gastroesophageal junction is then manipulated over the anterior distal esophagus.
16. A nonabsorbable endosuture is passed through a 5-mm port and used to place a row of interrupted sutures to join the aspects of the greater curvature of the stomach in a 2-cm to 3-cm "wrap" around the esophagus.
17. The anesthesia provider passes a large bougie down the lumen of the esophagus. The sutures are secured with the bougie in place.
18. The catheter (or drain) and bougie are removed. The abdomen is deflated.
19. Final inspection is completed, hemostasis obtained, and the instruments and ports removed under direct vision so that any bleeding from the abdominal wall can be readily detected. The trocar sites are then closed and dressings applied.

Esophagomyotomy (Heller Procedure)

Esophagomyotomy (Heller cardiomyotomy) is myotomy of the esophagogastric junction to correct esophageal obstruction resulting from achalasia, a motility disorder of aperistalsis of the esophagus and elevated LES pressure. These patients have dysphagia, esophageal fullness, regurgitation, and weight loss (SGNA, 2004).

Procedural Considerations. Selection of a transthoracic or transabdominal incision depends on the patient's general condition and other existing pathologic factors. The surgeon may elect to perform a pyloroplasty to prevent reflux by promoting stomach emptying. Instrumentation includes a basic laparotomy set and instruments to enter and retract the thorax if necessary. Laparoscopic and VATS approaches are safe and effective alternatives to the open procedure. The laparoscopic approach offers the advantage of adding fundoplication (Lee et al, 2004). Potential postoperative complications include esophageal perforation and reflux.

Operative Procedure

1. A midline abdominal incision is made from the xiphoid process to the umbilicus.
2. After exposure of the esophagogastric junction, a Maloney dilator is inserted through the patient's oral cavity to distend the esophagus.
3. A scalpel with a #15 blade is used to make a longitudinal incision through the muscular wall of the distal esophagus and proximal stomach, leaving the mucosa intact.
4. A small portion of the fundus of the stomach may be plicated to the lateral wall of the esophagus.
5. The wound is closed.
6. VATS is approached with the patient positioned and secured in a right lateral position.
7. A 30-degree thoracoscope is inserted in the left eighth intercostal space along the left posterior axillary line.
8. The lung is retracted through a working port placed in the left anterior axillary line of the fifth space.
9. Dissection is done through a mini-thoracotomy in the left ninth intercostal space to sweep the muscular layer from the mucosa from 6 cm above and 1 cm below the gastroesophageal junction. This dissection is made halfway around the circumference of the esophagus.
10. A chest tube is placed and the incision and port sites closed.

Esophageal Dilation

Esophageal dilation may be indicated in patients who have an esophageal stricture related to past surgery, chemical or thermal injury, or anatomic anomalies. An upper GI series is required before the procedure to locate the stricture.

Procedural Considerations. Esophageal dilation is a clean procedure performed in the OR or endoscopy unit. General anesthesia or moderate sedation is usually indicated. An esophageal perforation is a complication that could require open repair. The patient is positioned supine.

A flexible gastroscope and light source with video camera and monitor, bougie dilators (Hurst or Maloney dilators are commonly used) in graduated sizes, water-soluble lubricant, gauze sponges, and gloves are required to perform the procedure. An esophageal stent that can be inserted through a large-channel gastroscope or along a guidewire may be requested. The surgeon may use fluoroscopy to demonstrate that the dilation site is accurate by combining esophagoscopy with fluoroscopy and marking the site of stricture distally and proximally with radiopaque markers taped to the patient's skin.

Operative Procedure

1. The bougies are arranged in graduated order beginning with the smallest size (24F) and progressing to the largest size (60F).
2. The surgeon may first perform gastroscopy and pass a guidewire through the esophageal stricture.
3. The bougies are then passed one at a time gently but firmly through the stricture in an attempt to dilate the esophageal lumen.
4. Continuation of the dilation to the largest bougie depends on ease of passage and the patient's tolerance.
5. Laser therapy may be indicated for palliation if a tumor mass is causing the stricture. The neodymium:yttrium-aluminum-garnet (Nd:YAG) laser energy may be delivered to the mass or stricture by way of a flexible quartz fiber passed through the operative channel of the gastroscope.
6. An esophageal stent may be placed at the stricture site to decrease the chance of recurrence.

SURGERY OF THE STOMACH

Vagotomy

Truncal vagotomy is identification of the two vagal trunks on the distal esophagus and resection of a segment of each, including any additional nerve fibers running separately from the trunks. By interrupting parasympathetic innervation, this procedure reduces gastric acid secretion in patients with duodenal ulcers. When truncal vagotomy was initially performed alone, a high incidence of gastric stasis resulted from the loss of cholinergic innervation to the smooth muscle of the stomach; thus pyloroplasty or another gastric drainage procedure almost always accompanies truncal vagotomy. Truncal vagotomy deprives not only the stomach but also the liver, gallbladder, bile duct, pancreas, small intestine, and half of the large intestine of parasympathetic nerve supply (Figure 10-16). Truncal vagotomy with antrectomy or a drainage procedure is the most common operation for duodenal ulcers.

Selective vagotomy is transection of each abdominal vagus at a point just beyond its bifurcation into gastric and extragastric divisions. Thus the hepatic branch of the anterior vagus and the celiac branch of the posterior vagus are preserved. Selective vagotomy has theoretical advantages over truncal vagotomy because vagal innervation of the viscera other than the stomach is preserved. However, selective vagotomy also denervates the entire stomach, so that addition of a drainage procedure is still necessary. Selective vagotomy may cause less postvagotomy diarrhea than truncal vagotomy does, but the incidence of dumping syndrome is probably the same or even higher. Both procedures are about equally effective in controlling duodenal ulcers.

Parietal cell vagotomy is the vagal denervation of only the parietal cell area of the stomach. The technique spares the main nerves of Latarjet, but divides all vagal branches that terminate on the proximal two thirds of the stomach. The operation has also been called *proximal gastric vagotomy* (Figure 10-17) and highly selective vagotomy. Because antral innervation is preserved, gastric emptying is unimpaired and a drainage procedure is unnecessary. The incidence of dumping and diarrhea after *parietal cell vagotomy* is much lower than that after truncal or selective vagotomy.

Procedural Considerations. Instrumentation for vagotomy includes a basic thoracotomy set (if a thoracoabdominal incision is to be used), a laparotomy set, a GI instrument set, blunt nerve hooks (Smith-Wick), 10-inch vessel clip appliers with clips, and 10-inch Metzenbaum dissecting scissors. A 1-inch Penrose drain is used to retract the esophagus. After receiving a general anesthetic, the patient is positioned supine. A laparoscopic approach may also be used.

Operative Procedure

1. A midline incision is made, and the esophagus identified and retracted with a 1-inch wide Penrose drain.
2. The vagus nerves or their branches, depending on which type of vagotomy is being done, are identified, clamped with either a ligature or a hemostatic clip, and resected.
3. The wound is closed in layers.

Pyloroplasty (Pyloromyotomy)

Pyloroplasty is the formation of a larger passageway between the prepyloric region of the stomach and the first or second portion of the duodenum. A pyloroplasty may be performed for treatment of a peptic ulcer under selected conditions but is more frequently employed to remove cicatricial bands in the pyloric ring, thus relieving spasm and permitting rapid emptying of the stomach. In adults, a vagotomy is usually performed with a pyloroplasty.

Procedural Considerations. A laparotomy set and GI instrument set are required. The patient is positioned supine, and a general anesthetic is administered. An NG tube is placed and an indwelling urinary catheter inserted.

Operative Procedure

1. The abdominal cavity is opened through a midline incision.
2. The pylorus of the stomach is isolated.
3. An incision is made through the stomach and the duodenum.

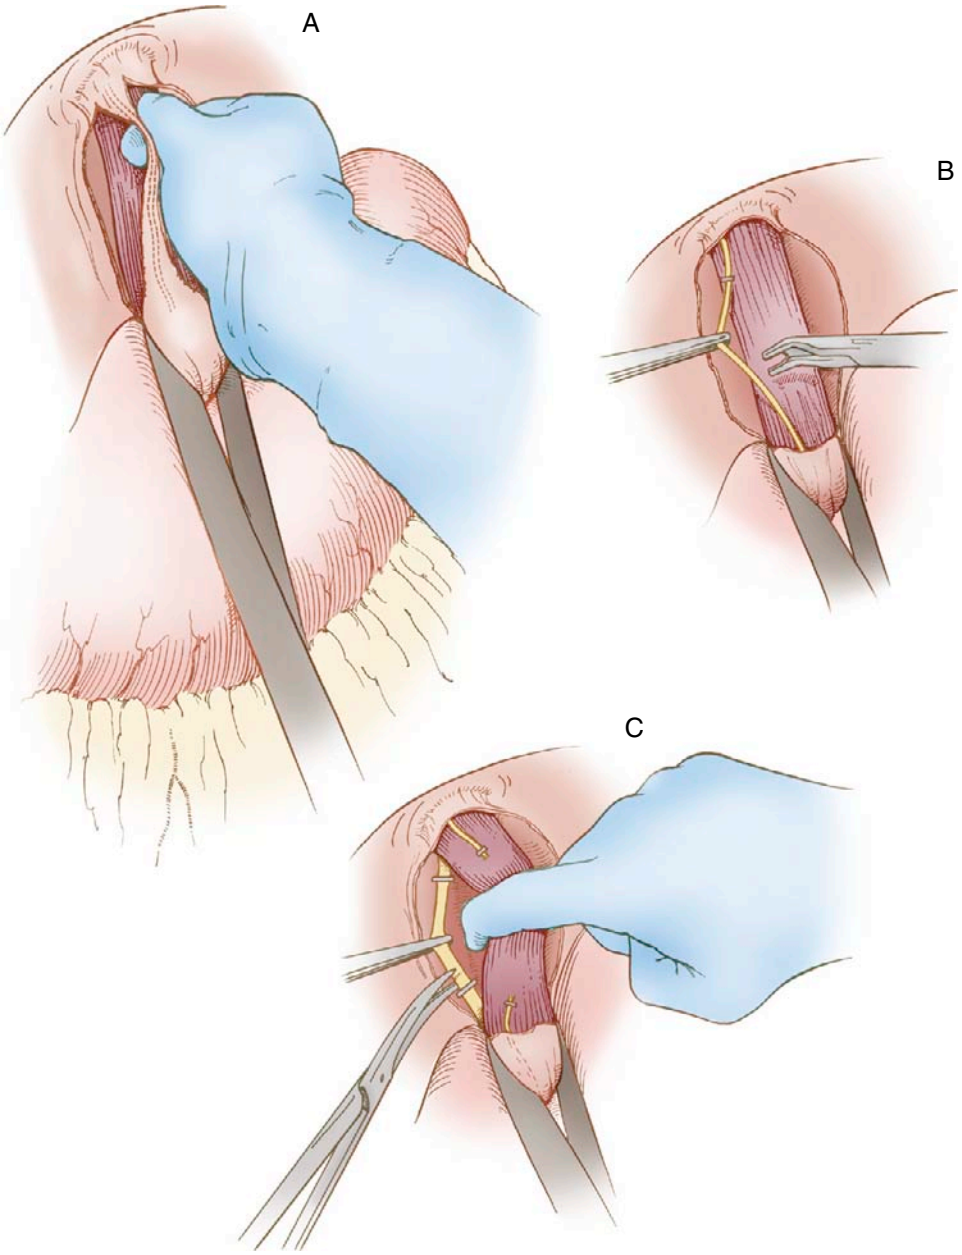

FIGURE 10-16 Truncal vagotomy. **A**, The phrenoesophageal ligament is lifted from the surface of the esophagus, and the vagal trunks are identified. **B**, Ligating clips are applied to the vagus nerve. **C**, Ligating clips have been applied to the larger posterior nerve in preparation for resecting a 2-cm segment between the clips.

4. The pyloroplasty is closed with nonabsorbable or synthetic absorbable intestinal sutures.
5. The abdominal wound is closed in layers, and a dressing is applied.

Percutaneous Endoscopic Gastrostomy (PEG)

PEG is now the most popular gastrostomy tube placement approach. After administration of a local anesthetic or induction of moderate sedation/analgesia, the tube is placed endoscopically. It can be used for gastric decompression and enteral feedings. PEG uses a flexible gastroscope and a uniquely designed gastrostomy tube for placement through the abdominal wall; it requires a push-pull technique to insert. This procedure may be done in the endoscopy suite, in the OR, or at the bedside in a critical care unit if necessary.

Procedural Considerations. A PEG tube kit containing the following is required: a percutaneous needle, a long silk suture with one end strengthened for feeding it down the lumen of the needle, a percutaneous gastrostomy tube, and a bolster. A flexible gastroscopy system is also required as well as snare forceps.

The patient is positioned supine after being anesthetized with IV moderate sedation. A bite-block is inserted into the patient's mouth.

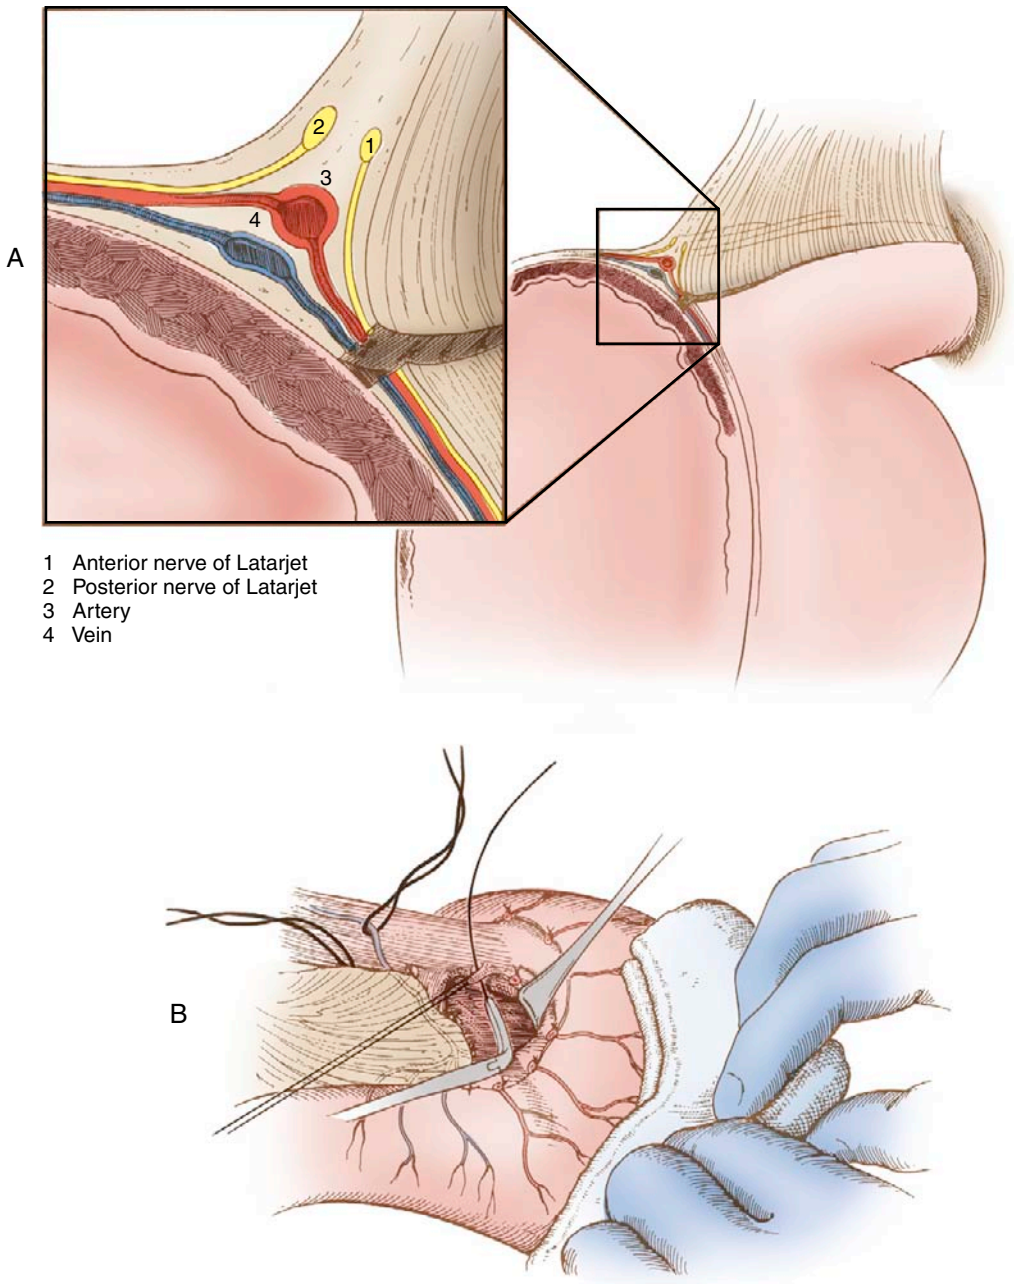

FIGURE 10-17 Selective proximal vagotomy. **A**, Illustrates the junction of the gastrohepatic ligament with the lesser curve of the stomach and demonstrates the anterior (*1*) and posterior (*2*) nerves of Latarjet, along with the artery (*3*) and vein (*4*). **B**, The lesser curve is lifted with a vein retractor to facilitate serial ligation of the intermediate and posterior neurovascular attachments.

Operative Procedure

1. The gastroscope is passed.
2. The end of the scope is angled anteriorly to the left anterolateral wall of the stomach's fundus so that the light from the gastroscope can be seen through the abdominal wall.
3. The stomach is insufflated with air through the gastroscope.
4. A local anesthetic is injected at the site of the intended gastrostomy if the patient is awake.
5. A small stab wound is made with a #11 blade.
6. The percutaneous needle is inserted into the abdominal wall and into the stomach lumen under direct visualization of the gastroscope.
7. The long silk suture is threaded into the lumen of the needle and passed into the stomach, where it is snared with the forceps.
8. A clamp is applied to the exterior distal end of the suture after the needle is removed.
9. The gastroscope is removed, and the suture extends out of the patient's oral cavity.

10. The suture is then attached to the tapered end of the gastrostomy tube.
11. The gastrostomy tube is gently guided into the patient's oral cavity, down the esophagus, and into the lumen of the stomach and pulled through the abdominal wall ("push-pull" technique).
12. The tube is secured with an internal bolster by reinserting the gastroscope and snugging it close to the gastric wall under direct visualization.
13. An external bolster is applied over the tube and snugged to the abdominal wall. Care is taken to ensure the bolsters do not compress the tissues because such compression might compromise tissue integrity and perfusion.
14. The distal end of the tube is cut, and a connector is applied.
15. The patient's stomach is deflated, and the procedure is complete.

Closure of Perforated Gastric or Duodenal Ulcer

Closure of a perforation in the stomach or duodenum is performed through a high right rectus or midline abdominal incision.

Procedural Considerations. A perforated gastric or duodenal ulcer is treated as a surgical emergency, and the operation is performed as soon as the diagnosis is made. The patient is typed and crossmatched so that an adequate supply of blood is available. A gastric lavage is not performed, but continuous suction is used. A laparotomy set and a GI instrument set are required. Linear stapling instruments should be available.

Operative Procedure

1. Through a right rectus or midline abdominal incision, the perforation is located.
2. Suction is used to remove exudate in the peritoneal cavity.
3. The perforation is closed with a purse-string suture by inverting the raw edges and suturing a piece of omentum over the closure.
4. The ulcerated area may be resected using linear stapling devices.
5. The abdomen is copiously irrigated with warm saline, which may contain a broad-spectrum antibiotic.
6. The abdominal wound is closed in layers, and a dressing applied.

Gastrojejunostomy

Gastrojejunostomy establishes a permanent communication between the proximal jejunum and either the anterior or the posterior stomach, without removing any segment of the GI tract (Figure 10-18). It is accomplished through a midline or paramedian abdominal incision.

Gastrojejunostomy is performed to treat a benign obstruction at the pyloric end of the stomach or an inoperable lesion of the pylorus when a partial gastrectomy is not feasible. It also provides a large opening without sphincter obstruction.

Procedural Considerations. Laparotomy and GI instrument sets are required. Linear stapling instruments should be available. The patient is positioned supine after induction of general anesthesia. The anesthesia provider inserts an NG tube after intubation. An indwelling catheter is placed into the urinary bladder before the abdominal skin prep.

Operative Procedure

1. Through an upper midline or paramedian abdominal incision, exploration of the peritoneal cavity is completed, as described for routine laparotomy.
2. The pathologic condition is confirmed.
3. Warm, moist packs are placed, and a self-retaining retractor is positioned.
4. A loop of proximal jejunum is grasped with a Babcock forceps and freed from the mesentery.
5. The loop of jejunum is approximated to either the anterior or the posterior stomach wall several centimeters from the greater curvature of the stomach.
6. Nonabsorbable 2-0 traction sutures are placed through the serosal layers at each end of the selected portion of the jejunum and stomach.
7. Gastroenterostomy clamps may be placed before insertion of the posterior interrupted 3-0 or 2-0 nonabsorbable serosal sutures.
8. The field is draped for open anastomosis (bowel technique).
9. The jejunum and stomach are opened.
10. Bleeding points are clamped with mosquito or Crile hemostats and ligated with 3-0 synthetic absorbable sutures.
11. The inner posterior row of sutures is placed, using atraumatic intestinal needles with 2-0 or 3-0 synthetic absorbable suture, and continued for the first anterior row.
12. The anastomosis is completed with anterior serosal sutures of 3-0 or 2-0 nonabsorbable material.
13. Traction sutures are removed.
14. Interrupted 4-0 nonabsorbable sutures may be used for reinforcement.
15. Contaminated instruments are discarded into a basin.
16. The abdominal wound is closed in layers, and a dressing applied.

Partial Gastrectomy—Billroth I and Billroth II

A Billroth I gastrectomy is resection of a diseased portion of the stomach through a right paramedian or midline abdominal incision and establishment of an anastomosis between the stomach and duodenum. It is performed to remove a benign or malignant lesion located in the pylorus, or upper half of the stomach. One of several techniques may be followed to establish GI continuity, including the Schoemaker, the von Haberer-Finney, and other modifications of the Billroth I procedure (Figure 10-19).

Procedural Considerations. Laparotomy and GI instrument sets are required. Linear stapling instruments should be available. The patient is positioned supine after induction of general anesthesia. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before the abdominal skin prep.

Operative Procedure

1. The abdominal wall is incised, and the peritoneal cavity is opened and explored.
2. Bleeding vessels are clamped and ligated or coagulated.
3. The abdominal wound is retracted, and the surrounding organs are protected with warm, moist packs.
4. The gastrocolic omentum is freed from the colon mesentery to prevent injury to the middle colic artery.

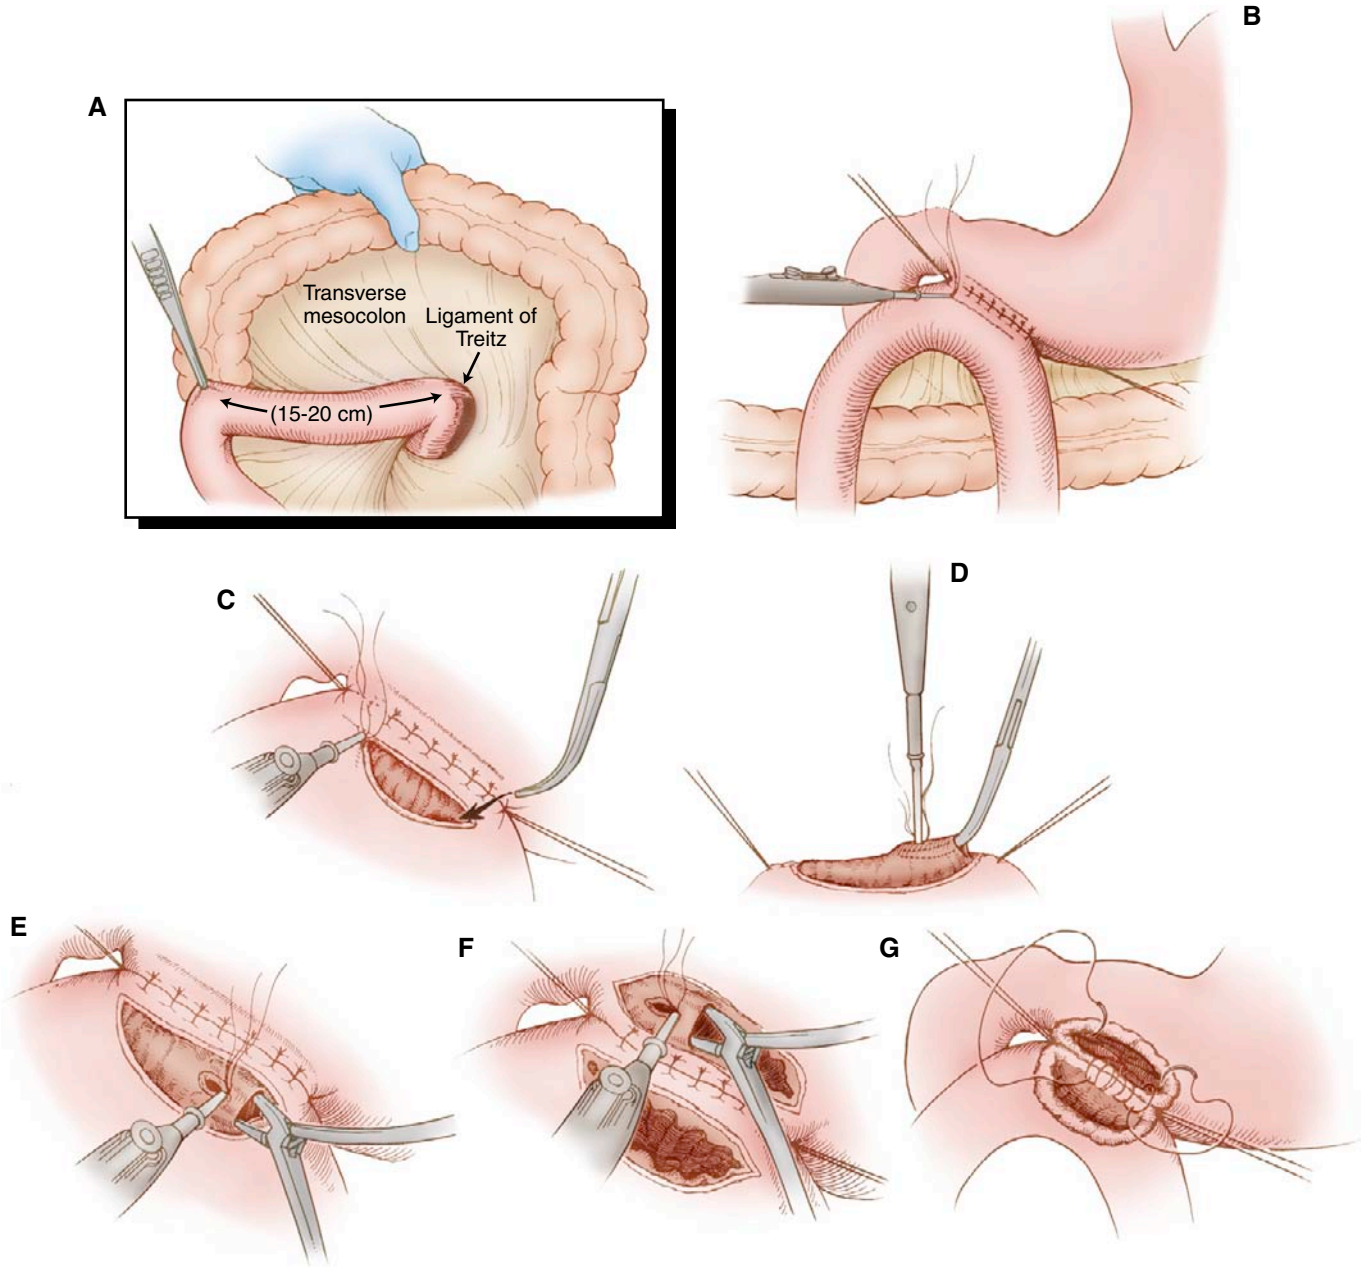

FIGURE 10-18 Gastrojejunostomy. **A**, Illustrates the selection of a segment of jejunum that will be anastomosed to the stomach; the distance between the ligament of Treitz and the anastomosis should not be excessively long or under any tension. **B**, A posterior row of interrupted sutures is placed between the gastric and jejunal serosae, and the sites of the gastric and jejunal stomas are scored with the electrosurgical pencil. **C**, The jejunal stoma is created by dissecting through the serosa and muscularis with the electrosurgical pencil. An opening is made in the mucosa, and a right-angled clamp is inserted into the lumen. **D**, The clamp is opened and elevated. **E**, Electrosurgery is applied between the two jaws of the clamp. **F**, The procedure is repeated for creating the gastric stoma. **G**, Full-thickness anastomosis is begun posteriorly.

5. With hemostats and Metzenbaum scissors, the right and left gastroepiploic arteries and veins are clamped, divided, and ligated with 2-0 nonabsorbable sutures and 2-0 and 3-0 suture ligatures, thereby freeing the greater curvature of the stomach.
6. The gastric vessels are clamped, divided, and ligated to free the diseased portion of the stomach.
7. The operative field is prepared for open anastomosis (bowel technique).
8. After sectioning the stomach from the greater to lesser curvature, two Allen intestinal anastomosis clamps or other suitable clamps, or linear stapling device, are placed on the upper portion of the duodenum just distal to the pylorus.

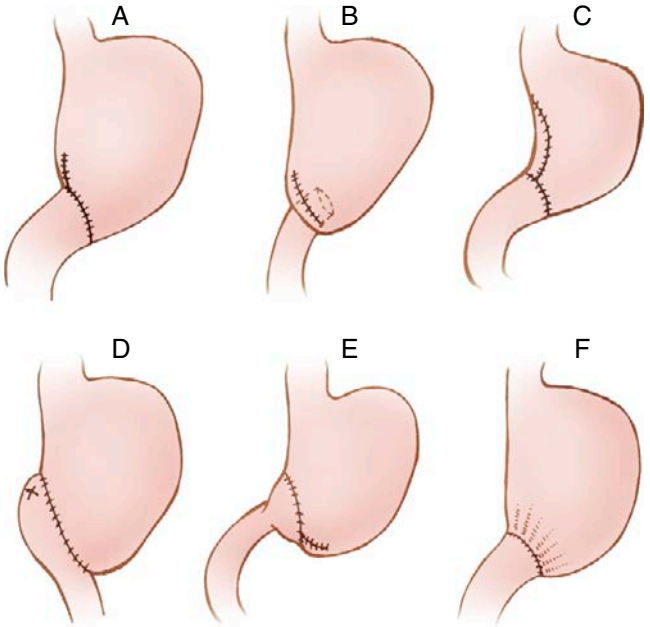

FIGURE 10-19 Diagrams illustrating resections of stomach with anastomosis of stomach and duodenum (gastroduodenal anastomosis). All are modifications of the Billroth I technique, in which the stomach is moved to the duodenum. **A**, Billroth I: after pylorus is removed, lesser curvature is partially closed and duodenum is sutured to open end of stomach at its lower margin. **B**, Kocher: distal end of stomach is closed, and duodenum is transferred up to posterior margin of closed stomach. **C**, Schoemaker: lesser curvature of stomach is sutured closed and and brought down to same size as duodenum, and end-to-end anastomosis is done. **D**, von Haberer-Finney: side of duodenum is transferred up to end of stomach so that entire end of stomach is open for direct anastomosis. **E**, Horsley: lesser curvature end of stomach is used to suture to duodenum and closes greater curvature end. **F**, von Haberer: modification of operation shown in **D**. Stomach is, so to speak, narrowed or puckered so that it fits end of duodenum. Modification of this is done by some surgeons as follows: duodenum is split longitudinally, and its ends are flared open so that opening is large enough to fit open end of stomach.

9. The duodenum is divided by scalpel, electrosurgery, or a linear cutting and stapling device (e.g., gastrointestinal anastomosis [GIA]).
10. Additional moist packs are placed for protection, and two sets of anastomosis clamps are placed across the stomach.
11. Division of the stomach is completed.
12. At the lower margin, the opened stomach is approximated to the duodenum by a series of interrupted sutures placed in the serosal layers. An atraumatic intestinal needle with 3-0 nonabsorbable suture is used. Suture ends are held with hemostats, and the intestinal clamps are removed.
13. Stumps of the stomach and duodenum are cleansed with moist sponges, and bleeding vessels are ligated with fine suture or coagulated.
14. During anastomosis of the stomach and remaining duodenum, the involved segments may be held with rubber-shod clamps. The excess of the lesser curvature of the stomach is closed on completion of the anastomosis.
15. Instruments used in the open portion of the GI tract are discarded into a separate basin.
16. Routine laparotomy closure is completed.

A Billroth II gastrectomy is resection of the distal portion of the stomach through an abdominal incision and establishment of an anastomosis between the stomach and jejunum. It is performed to remove a benign or malignant lesion in the stomach or duodenum. This technique and modifications are selected because the volume of acidic gastric juice will be reduced and the anastomosis can be made along the greater curvature or at any point along the stump of the stomach. Modifications of the Billroth II procedure include the Polya and Hofmeister operations, which also establish GI continuity by duodenal bypass.

After surgery, duodenal and jejunal secretions empty into the remaining gastric pouch.

Procedural Considerations. Laparotomy and GI instrument sets are required. Linear stapling instruments should be available. The patient is positioned supine after induction of general anesthesia. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before the abdominal skin prep.

Operative Procedure

1. The abdominal wall is incised and the peritoneal cavity opened and explored.
2. Bleeding vessels are clamped and ligated or coagulated.
3. The abdominal wound is retracted, and the surrounding organs are protected with warm, moist packs.
4. The gastrocolic omentum is freed from the colon mesentery to prevent injury to the middle colic artery.
5. With hemostats and Metzenbaum scissors, the right and left gastroepiploic arteries and veins are clamped, divided, and ligated with 2-0 nonabsorbable suture and 2-0 and 3-0 suture ligatures, thereby freeing the greater curvature of the stomach.
6. The distal portion of the stomach is isolated.
7. Moist packs are placed for protection of the viscera, and two sets of anastomosis clamps are placed across the distal stomach.
8. The stomach is resected just distal to the pylorus using a scalpel, electrosurgery, or a linear stapling and cutting device (GIA) (Figure 10-20, *A*).
9. A proximal loop of jejunum is positioned for anastomosis to the posterior wall of the remaining stomach.
10. An anastomosis is established between the stomach and jejunum using mechanical linear stapling devices (GIA and thoracoabdominal [TA] instruments) (Figure 10-20, *B, C*).
11. The abdomen is closed.

Total Gastrectomy

Total gastrectomy is complete removal of the stomach and establishment of an anastomosis between the jejunum and esophagus (esophagojejunostomy) (Figure 10-21). It includes an enteroenterostomy if indicated. Total gastrectomy is done with curative intent or as a palliative procedure to remove a malignant lesion of the stomach and metastases in the adjacent lymph nodes.

Procedural Considerations. The incision may be bilateral subcostal, long transrectus, long midline, or thoracoabdominal. Thoracotomy, GI, and laparotomy sets are necessary. Mechanical linear stapling devices should be available. In addition, two

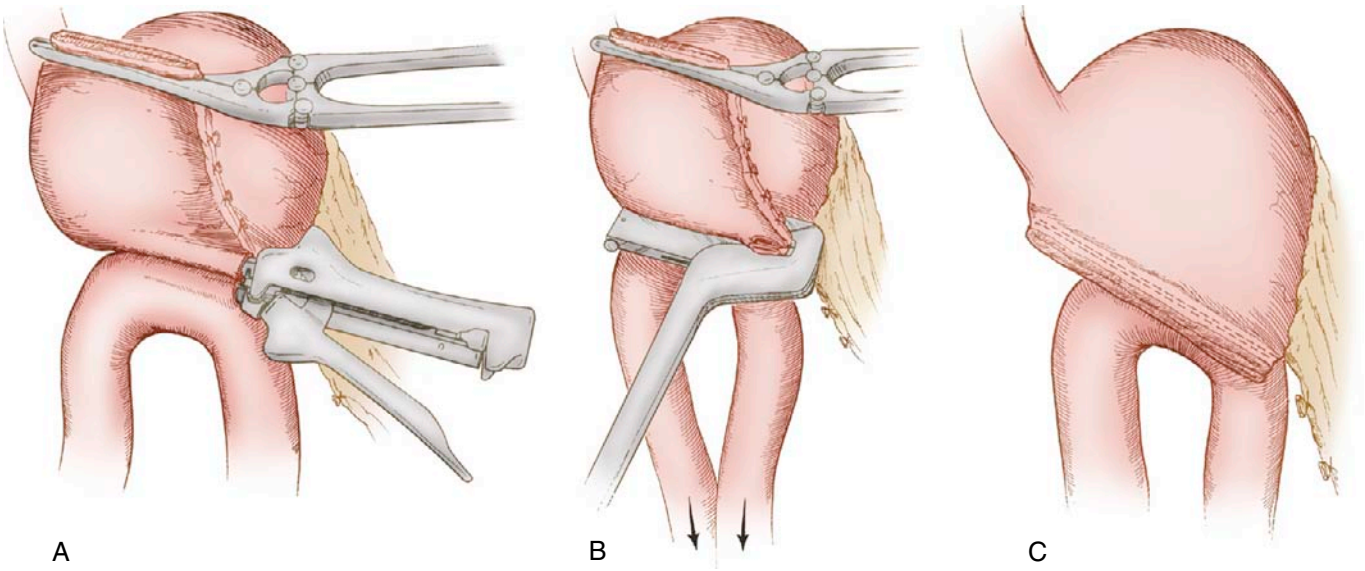

FIGURE 10-20 Subtotal gastrectomy with stapled Billroth II anastomosis. **A**, The distal stomach has been dissected free and resected just distal to the pylorus. A proximal limb of jejunum is transferred up to anastomose to the posterior wall of the stomach with a linear stapling instrument that transects between two parallel staple lines. **B**, The stomach is elevated, and a 90-degree mechanical stapling device is placed across the distal stomach. **C**, Illustration of the completed subtotal gastrectomy with stapled antecolic gastrojejunostomy.

long, blunt nerve hooks and two 10-inch needle holders are required. The patient is positioned supine after induction of general anesthesia. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before the abdominal skin prep.

Operative Procedure

1. The abdomen is opened through an incision of choice.
2. The wound edges are protected and retracted.
3. Complete exploration for metastasis is performed.
4. The omentum is freed from the colon, using sharp dissection; vessels are ligated with 2-0 nonabsorbable suture.
5. The splenic vessels are ligated and transfixed with 2-0 and 3-0 nonabsorbable suture at the tail of the pancreas; the spleen is left attached to the omentum.
6. The duodenum is mobilized, intestinal clamps or linear stapler is applied, and the operative field is protected for transection and closure of the distal duodenum (bowel technique).
7. The right gastric artery is ligated and transfixed with 2-0 and 3-0 nonabsorbable suture, and the gastrohepatic omentum is separated from the liver.
8. After ligation of the left gastric artery, the mobilized stomach, spleen, omentum, and lesser and greater curvature ligamentous attachments are delivered into the wound.
9. The coronary ligament of the left lobe of the liver is divided, exposing the diaphragmatic peritoneum over the esophagogastric junction.
10. The liver is protected by moist packs, and gentle retraction is maintained with a Harrington, Deaver, or malleable retractor.
11. A flap of peritoneum is freed from the diaphragm, and branches of the vagus nerves are divided.
12. A loop of jejunum is selected and delivered antecolic to the esophagogastric junction for anastomosis.
13. Traction is placed on the specimen, and the posterior row of interrupted 3-0 nonabsorbable sutures is placed, or a stapling device is used.
14. As the jejunum and esophagus are incised, mosquito or Crile hemostats and ligatures of 3-0 synthetic absorbable suture control bleeding.
15. The posterior row is reinforced with 3-0 intestinal synthetic absorbable sutures or a linear staple line.
16. Division of the esophagus is completed, and the entire specimen is removed.
17. The mucosal anterior wall of the anastomosis is approximated with 4-0 interrupted synthetic absorbable sutures; an end-to-end anastomosis circular stapling device may be used to anastomose the esophagus and jejunum.
18. A second layer of sutures, 3-0 nonabsorbable or synthetic absorbable, is placed anteriorly in the seromuscular and muscular coat of the intestine.
19. A flap of the peritoneum is attached to the jejunum with interrupted 3-0 nonabsorbable sutures to relieve traction on the anastomosis.
20. A lateral jejunojejunal anastomosis is completed to permit irritating bile and pancreatic fluids to bypass the anastomosis line, thereby preventing esophageal regurgitation.
21. The abdominal wound is closed in layers. If retention sutures are used, they must be placed extraperitoneally because of the absence of omentum to protect the small bowel.

An alternative to using suture materials is the use of mechanical stapling devices. Another method of establishing continuity is a combination of a Roux-en-Y jejunojejunostomy and a jejunoesophagostomy. A Roux-en-Y, also written RNY, is any Y-shaped anastomosis in which small bowel is included.

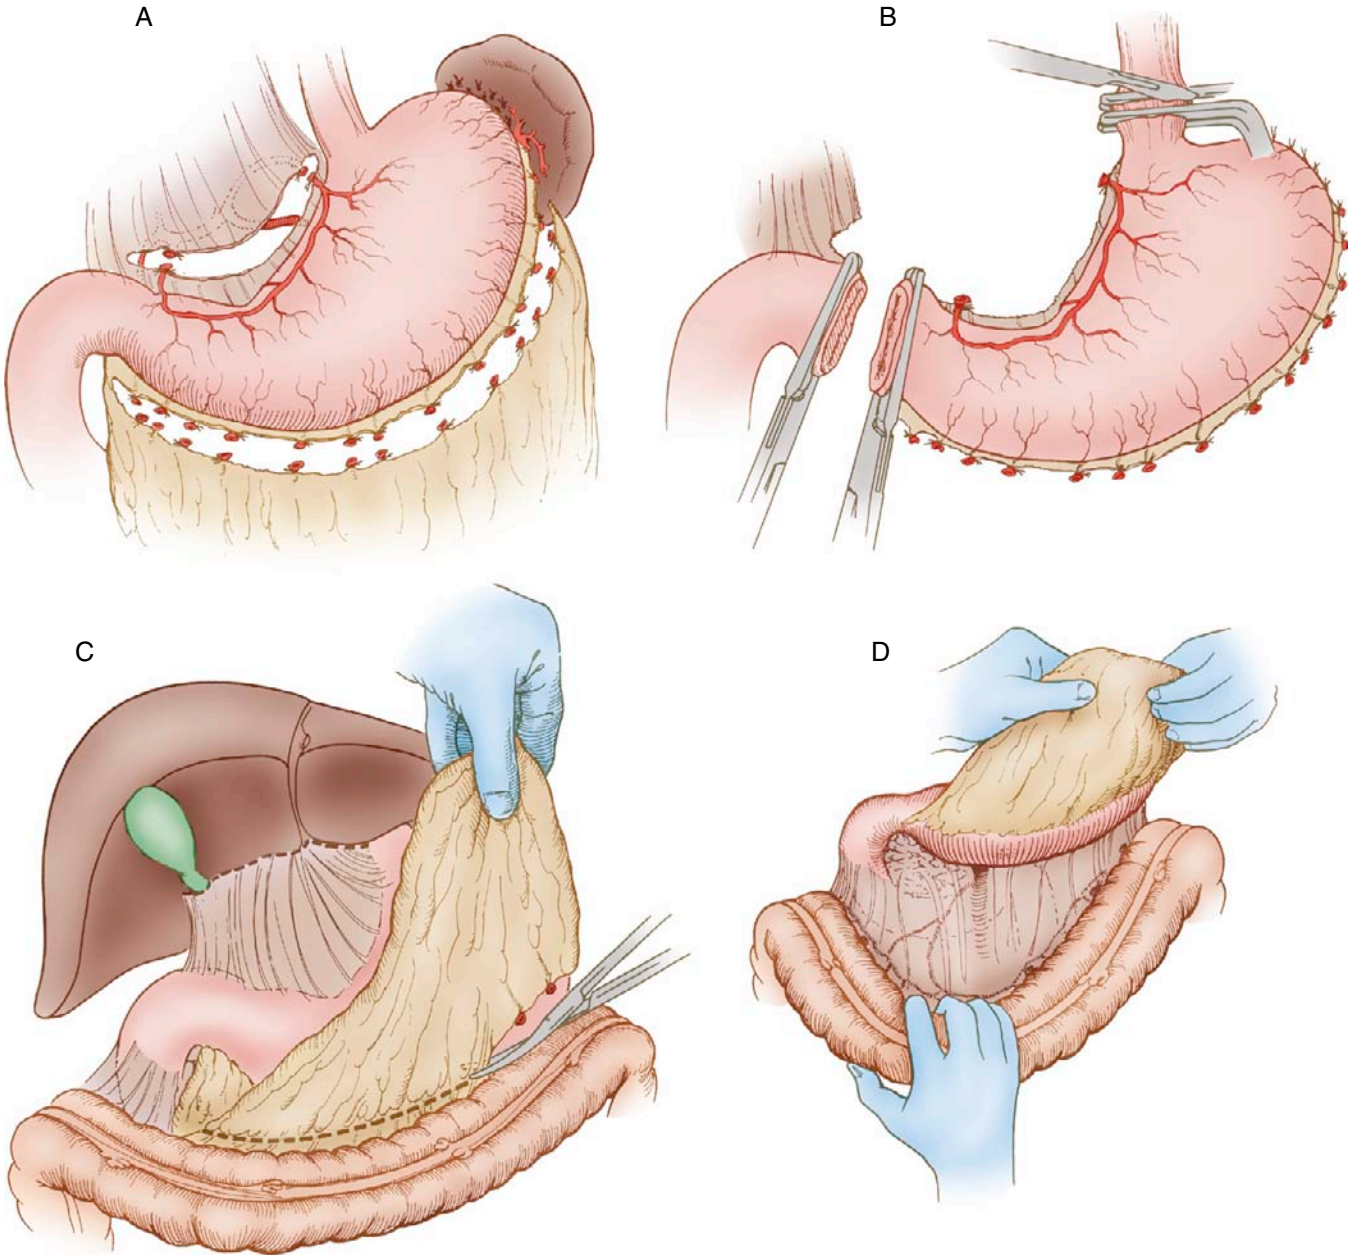

FIGURE 10-21 Total gastrectomy may be performed for benign or malignant disease. **A**, Demonstrates the mobilization of the stomach for benign disease. Serial division of the vessels in the gastrocolic ligament and gastrohepatic ligament is performed to free the greater and lesser omentum. The short gastric vessels connecting the stomach to the spleen are divided, and the spleen is preserved. **B**, The duodenum is divided distally to the pylorus, and the proximal line of division is at the distal intraabdominal esophagus. **C**, For malignancies, the line of resection includes both the lesser and the greater omentum. **D**, The retrogastric area is inspected for tumor involvement. The spleen and tail of the pancreas may be included in the resection.

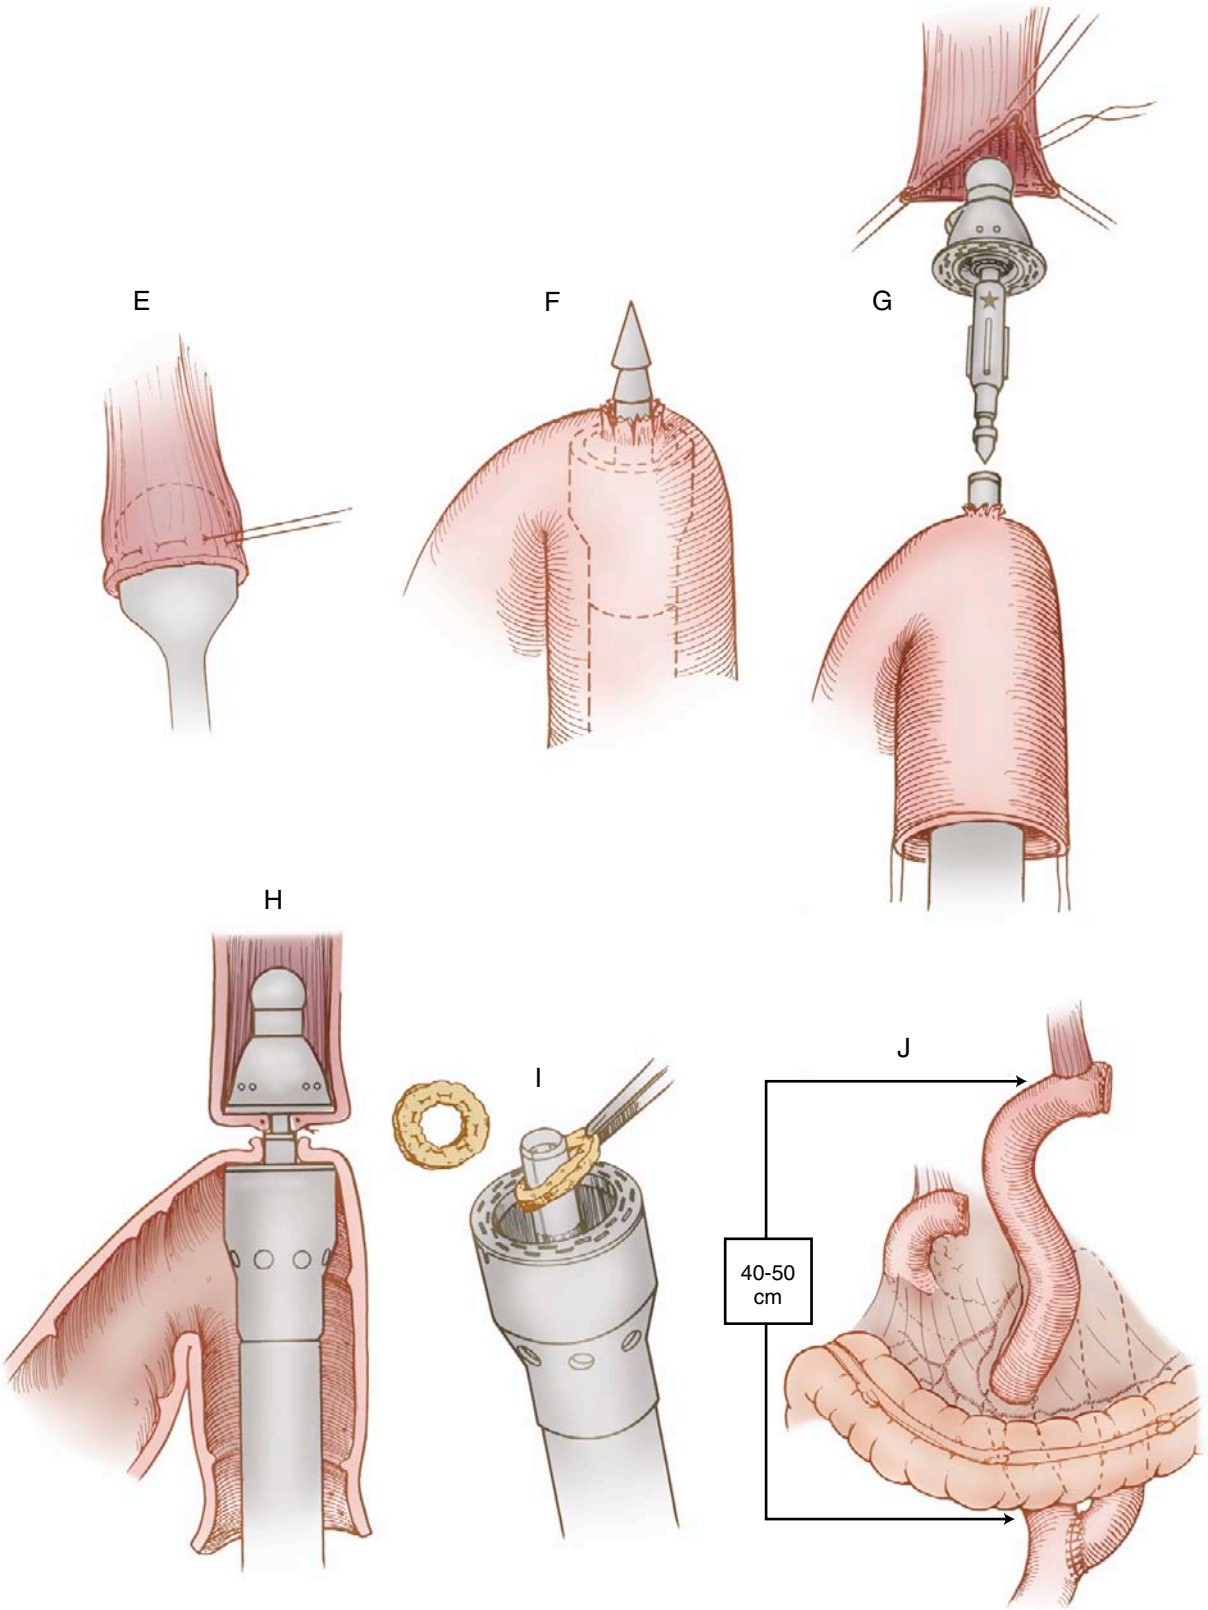

FIGURE 10-21, cont'd **E**, A sizer is inserted into the lumen of the distal esophagus. **F**, The EEA or intraluminal anastomosis (ILA) is inserted into the lumen of the jejunum to facilitate esophagojejunostomy. **G**, The anvil is inserted into the distal esophagus where purse-string sutures will be snugged around the protruding arm of the anvil. **H**, The distal esophagus and the jejunum are united by the mechanism of the stapling device, and the interluminal anastomosis will be performed. **I**, The "donuts," distal esophagus and jejunal tissues, are examined for integrity and completeness. **J**, Illustration of the esophagojejunostomy completed.

BARIATRIC SURGERY

Bariatric surgery, also termed *weight loss or weight reduction surgery,* is surgical treatment of obesity (History box). Morbid obesity is a disease affecting more than 20 million people in the United States. Morbid obesity (also referred to as clinically severe obesity or extreme obesity) is defined as a body mass index (BMI) of 40 kg/m^2 or more, the equivalent of about 45 kg (100 lb) over ideal body weight (AORN, 2009d) (Box 10-7). Obese patients typically present with serious co-existing health conditions, such as diabetes, cardiopulmonary disease, obstructive sleep apnea (OSA), gallstone disease, hypertension, hyperlipidemia, respiratory problems, or joint disease.

Eligibility criteria for patients seeking bariatric surgery include morbid obesity complicated by medical conditions secondary to obesity, history of failed dietary therapy, psychologic stability and motivation, acceptable operative risks, and a patient who is well-informed about the procedure, recovery, and postsurgical lifestyle modifications.

Contraindications are not easily generalized because morbidly obese patients are typically at greater risk for surgery. Patients at greatest risk are those with end-stage heart and lung function, inability to ambulate, weight more than 272 kg (600 lb), age younger than late teens or older than 65 years, and presence of Prader-Willi syndrome (SGNA, 2004).

There are three categories of bariatric procedures: restrictive, malabsorptive, or a combination of both. Restrictive procedures reduce the size of the stomach. When the patient eats, food is digested and absorbed normally, but the smaller capacity of the stomach gives the feeling of fullness, and the patient eats less. In malabsorptive procedures, surgery reduces the absorptive capacity of the small intestine with a bypass of a segment or segments of the proximal small bowel.

Adjustable gastric banding is a restrictive procedure. Adjustable band surgery uses a silicone strip and elastic ring called the adjustable *LAP-BAND* (INAMED Health). The band is placed laparoscopically around the top of the stomach. A fold of stomach is sutured around the band to secure it in place (Figure 10-22). The band has a port that is inflated with saline 4 weeks postoperatively. The constriction created by the inflated band restricts the amount of ingested food that can enter the stomach, preventing overeating. This procedure is adjustable and reversible (laparoscopic adjustable gastric banding, or LAGB) (Research Highlight).

HISTORY

Bariatric Surgery

Year	Breakthrough
1950s	J. Kremen, MD, performs jejunoileal bypass. It is recognized that patients with short-bowel syndrome lose weight because of impaired absorption. Similar procedure is performed in Sweden, excising redundant portion of intestine.
1960s	Ten jejunocolic shunt procedures are reported. Shunts are eventually converted to jejunoileostomies to control diarrhea, electrolyte imbalance, and dehydration. Patients continue to experience postoperative anemia, cholelithiasis, vitamin depletion, and renal and liver disease. E. Mason, MD, performs partial gastrectomy with staples, creating a pouch anastomosed to small intestine. Early complications promote refinement of gastroplasty.
1970s	E. Mason, MD, develops vertical-banded gastroplasty (VBG). L. Wilkinson, MD, uses mesh strip for the band to reduce size of gastric reservoir. Biliopancreatic diversion is developed in Italy.
1980s	Gastric banding is refined to limit food intake. L. Kuzmak, MD, develops first adjustable gastric band and later a hollow band with inflatable ring. American Society for Bariatric Surgery (ASBS) is formed in 1983.
1990s	Laparoscopic access becomes approach of choice. Some procedures move to ambulatory surgery units.
2000s	Bariatric becomes common medical terminology. Many institutions develop interdisciplinary programs specifically for weight loss surgery. Bariatric boutique surgery centers enter surgical market. Long-term studies begin to evaluate surgery results over time. Insurance reimbursement continues to evolve as studies evaluate risks, complications, rehospitalization rates and costs. Laparoscopic-adjustable gastric band (LAGB) approved by the Food and Drug Administration. Sleeve gastrectomy evolves as primary alternative for those not candidates for other procedures. Gastric and vagal pacing developed. Endoscopically accessed interventions evolve with implanted balloon and stapling delivery devices. Bariatric surgery viewed as significant treatment and resolution for type 2 diabetes.

BOX 10-7

Calculating a Patient's Body Mass Index

Obesity is defined in terms of body mass index (BMI), which is a measure of the weight-to-height ratio to gauge total body fat. BMI is expressed as kilograms per square meter and calculated by the following formula: BMI = (weight in pounds ÷ height in inches^2) × 703. Obesity levels are characterized as follows:

- Obese: BMI of 30-39.9 kg/m^2
- Extremely (also referred to as "morbidly") obese: BMI of 40-49 kg/m^2
- Super obese: BMI greater than 50 kg/m^2

Modified from Association of periOperative Registered Nurses: Bariatric surgery guideline. In *Perioperative standards and recommended practices,* Denver, 2009, The Association; Pelczarski KM: Take a proactive approach to bariatric patient needs, *Mater Manag Health Care* 16(6), 2007, available at www.ecri.org/Documents/News/20070601_MaterialsManagementinHealthCare_Bariatric.pdf.

RESEARCH HIGHLIGHT

Bariatric Surgery Outcomes

In this study, researchers from the Department of Health and Human Services' Agency for Healthcare Research and Quality (AHRQ) reviewed insurance claims for 9582 bariatric surgeries at 652 hospitals to determine how 6-month complication rates after bariatric surgery improved between 2001 and 2006. The 6-month complication rate for bariatric surgery in 2001 was 40%. However, surgical advances, including laparoscopic approaches, contributed to a 21% drop in complication rates for bariatric surgery by 2006. Readmissions with complications declined 31%, and surgical infection rates dropped 58%. Improvements in complication rates and readmission rates were associated with increases in surgical volume (within-hospital volume), which accounted for more surgical experience in performing bariatric procedures. Interestingly, the use of laparoscopy reduced costs by 12%, and gastric banding decreased costs by 20%. Although laparoscopy had no impact on readmissions, gastric banding did reduce readmissions.

Modified from Encinosa WE et al: Recent improvements in bariatric surgery outcomes, *Med Care* 47:531-535, 2009.

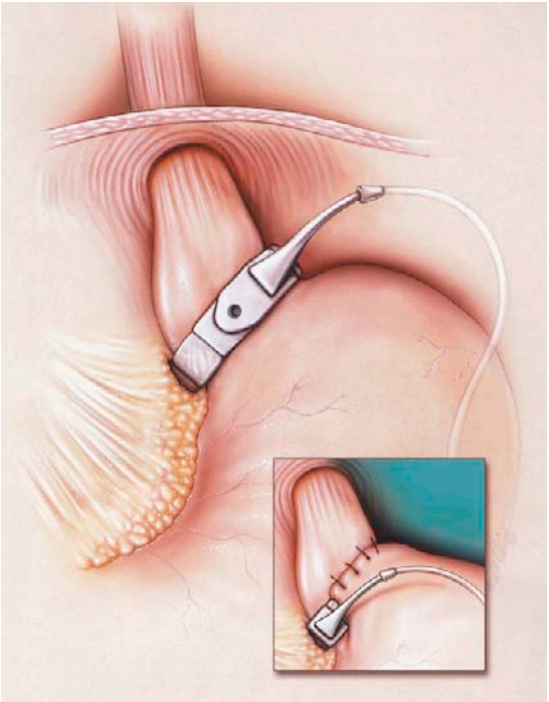

FIGURE 10-22 Proper position of the LAP-BAND. The silicone band around the fundus of the stomach creates a small gastric pouch. The inner lining of the band contains an inflatable balloon that is connected to a subcutaneous port on the patient's abdomen (not shown). The band can be inflated or deflated, adjusting the stomach size as needed.

Bariatric procedures have been shown to improve long-term health, including reducing the risks of cardiovascular disease and type 2 diabetes (Adams et al, 2007; Beauchamp-Johnson, 2007; Hager, 2007).

Laparoscopic Roux-en-Y Gastric Bypass

Roux-en-Y gastric bypass (RYGB) is a largely restrictive and mildly malabsorptive procedure that reroutes the passage of ingested food and fluid from a small pouch created with surgical staples or sutures in the proximal stomach to a segment of the proximal small bowel. The jejunum or ileum is used as described under Gastrojejunosotomy. Laparoscopic RYGB is commonly performed in the United States. Postoperatively, changes in lifestyle are required for fully successful weight loss (Chambers, 2009).

Procedural Considerations. All patients undergoing bariatric surgery need special consideration, because they usually have associated serious co-morbidities that place them at risk during the procedure. A special OR bed is required that can accommodate patients who weigh more than 350 lb (159 kg). In addition to laparoscopic instrumentation and accessory supplies, extralarge blood pressure cuffs and extra-long trocars are required. Positioning requires additional padded safety restraints, pressure-reduction devices to reduce the risk of pressure injury, and properly fitting SCDs. The perioperative nurse should anticipate the potential for anesthesia assistance during intubation and airway management.

Operative Procedure

1. Five trocars are placed above the umbilicus: two on the midline, two in the left upper quadrant, and one in the right upper quadrant; an incision is made for the liver retractor (Figure 10-23).
2. The omentum is mobilized and the ligament of Treitz identified.
3. The jejunum is divided 40 cm distal to the ligament of Treitz with a vascular stapler (Figure 10-24). The proximal jejunum is left to lie in the patient's right side and the Roux limb lifted superiorly and passed through the transverse colon mesentery (Figure 10-25).
4. A gastric pouch is created with several loads of a linear stapler.
5. The Roux limb is anastomosed to the proximal gastric pouch. Methylene blue is used to check for leaks. The gastrojejunostomy may be accomplished with either traditional suturing technique or a circular EEA stapler.
6. Mesenteric defects are closed, the abdomen is inspected, and the port sites are closed.

With RYGB, a critical segment of the calorie- and nutrition-absorbing mucosal surface is avoided. The gastric pouch is generally less than 30 ml in volume. This procedure results in considerable weight loss for the patient. Serious complications may include hemorrhage, anastomotic leaks, pulmonary embolism, pneumonia, infection, small bowel obstructions or stenosis, and incisional hernia. Nutritional deficits, nausea, flatus, diarrhea, and dumping syndrome are other common complications.

Biliopancreatic diversion (Figure 10-26) and duodenal switch (Figure 10-27) procedures are largely malabsorptive and mildly restrictive. In both procedures, both the Roux limb and the biliopancreatic limb are long in length, leaving a shortened common channel where digestion and absorption of proteins, fats, and carbohydrates can occur. These procedures present more risk of complications, nutritional deficiencies, liver abnormalities, anemia, and lactose intolerance.

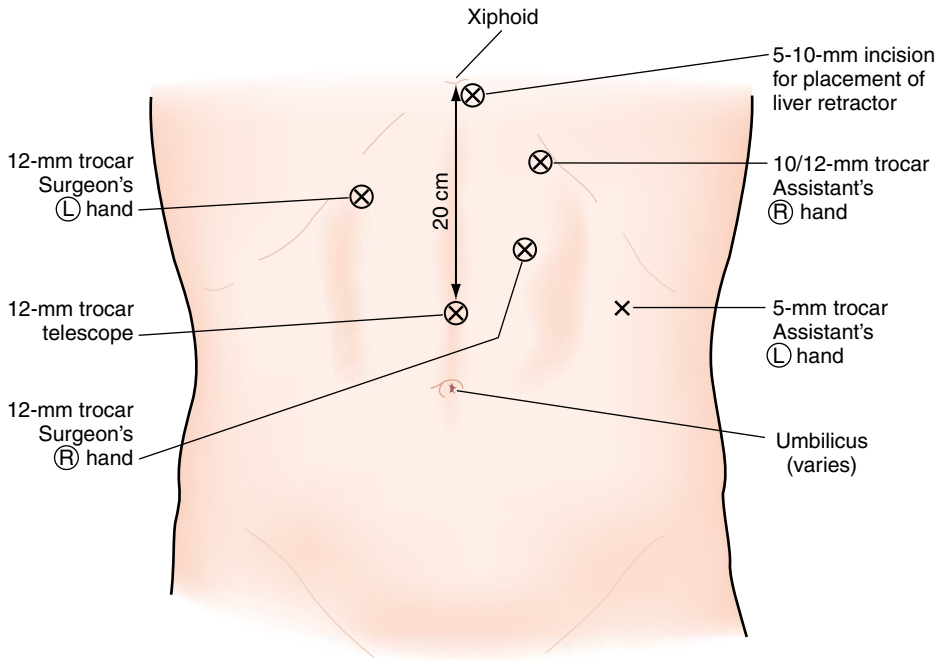

FIGURE 10-23 Trocar configuration for laparoscopic Roux-en-Y gastric bypass.

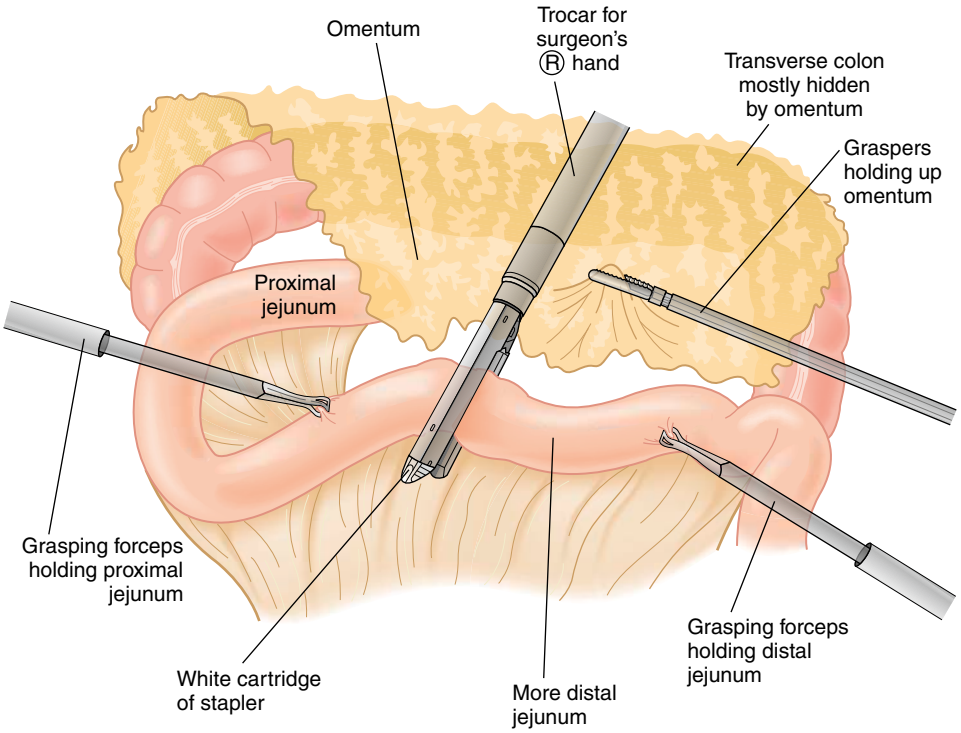

FIGURE 10-24 Placing stapler to divide jejunum to create Roux limb.

SURGERY OF THE SMALL BOWEL

Meckel's Diverticulectomy

Meckel's diverticulum is removed to prevent inflammation and obstruction from intussusception of the diverticulum, which consists of an unobliterated congenital duct at the umbilicus that is attached to the distal ileum. The diverticulum may contain gastric mucosa, which can ulcerate, perforate, or bleed.

Procedural Considerations. Laparotomy and GI sets are required. Linear stapling devices should be available. The patient is positioned supine after induction of general anesthesia. The

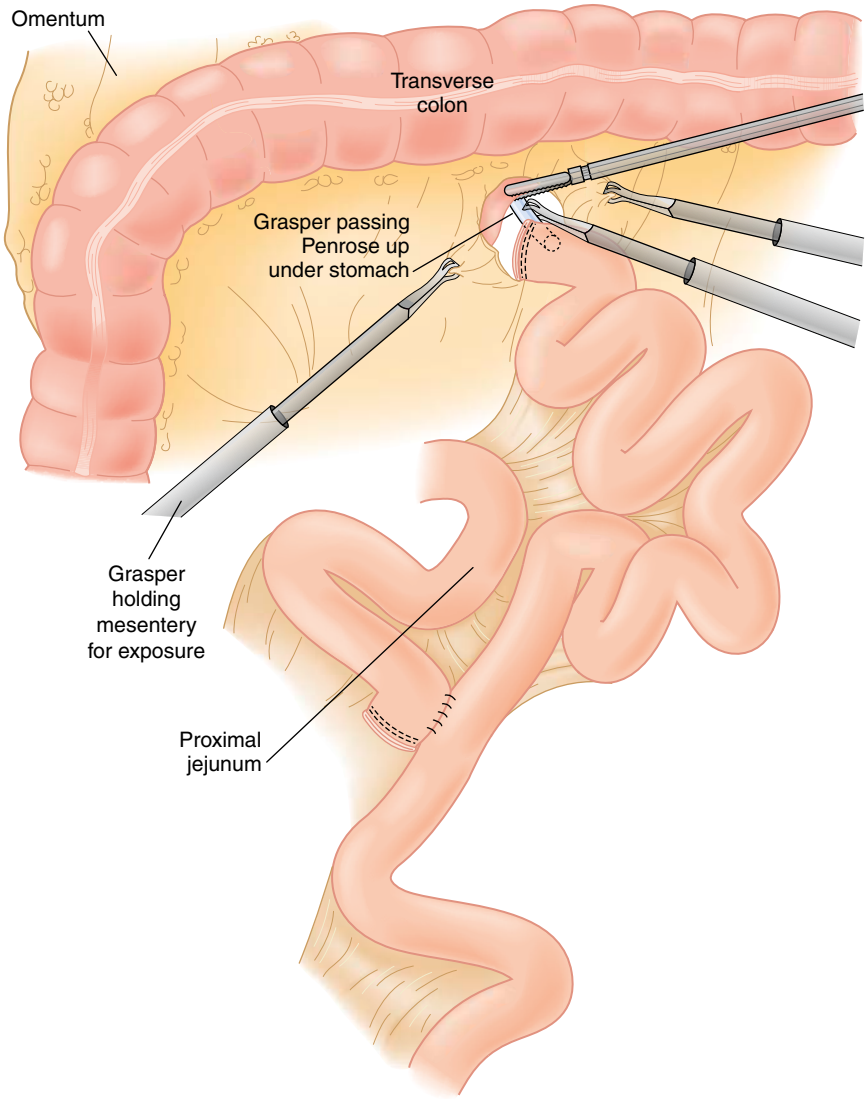

FIGURE 10-25 Passing the Roux limb into a retrocolic and retrogastric position.

anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before the abdominal skin prep.

Operative Procedure

1. The abdomen is opened through a midline incision or laparoscopically accessed, and the diverticulum is identified.
2. If the diverticulum is long and narrow with a narrow base, the procedure is similar to that of an appendectomy (see the following discussion). If the base is broad, the loop of bowel containing the diverticulum is isolated from the mesentery and a limited small bowel resection is performed.
3. An anastomosis of the divided ends is completed with an inner continuous layer of 3-0 synthetic absorbable suture and an interrupted outer layer of 4-0 nonabsorbable sutures.
4. The abdominal wound is closed.

Appendectomy (Open Approach)

Appendectomy is severance and removal of the appendix from its attachment to the cecum through a right lower quadrant muscle-splitting incision (McBurney). This procedure is performed to remove an acutely inflamed appendix, thereby controlling the spread of infection and reducing the danger of peritonitis (Research Highlight).

Procedural Considerations. A basic laparotomy instrument set is used. The patient is positioned supine after induction of general anesthesia. Culture tubes should be available.

Operative Procedure

1. A right lower quadrant muscle-splitting (McBurney) incision is usually made.
2. Muscles are retracted with Richardson or Parker retractors to expose the peritoneum.
3. The peritoneum is grasped with tissue forceps or Allis forceps, and a small incision is made with a #15 blade.
4. A culture sample is taken.
5. The incision is completed with Metzenbaum scissors.
6. The mesoappendix is grasped near the tip with Babcock forceps or a hemostat for gentle traction.
7. The mesoappendix is dissected from the appendiceal wall and ligated with 3-0 nonabsorbable suture. If a suture

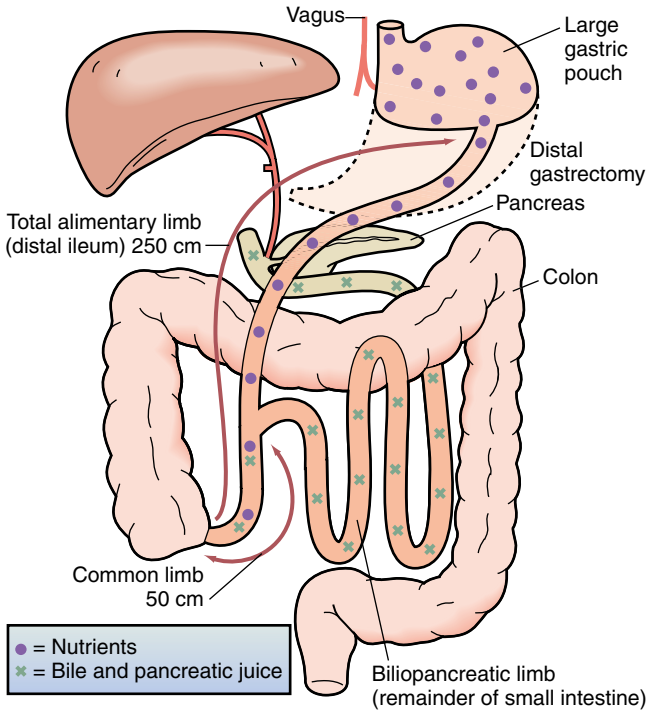

FIGURE 10-26 Configuration of the biliopancreatic diversion (BPD), which is transection of the stomach with anastomosis of the duodenum to the distal ileum. In this malabsorptive procedure, the pancreatic enzymes and bile enter near the ileum, allowing nutrients to pass from the stomach to the distal ileum without being digested. Weight loss occurs because of the partial gastrectomy, which restricts intake, and because of the shortened alimentary canal, which causes malabsorption.

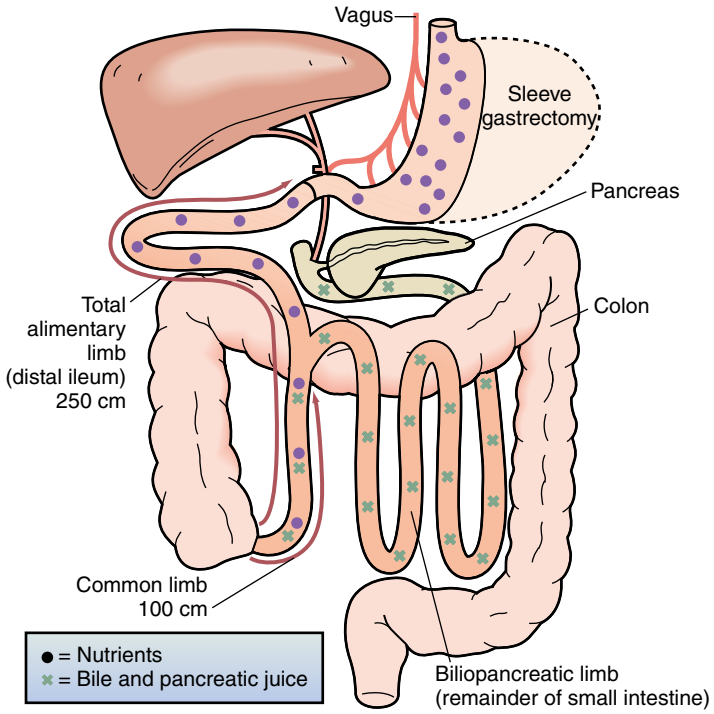

FIGURE 10-27 Configuration of the duodenal switch, which leaves a larger portion of the stomach intact, including the pyloric valve. This helps in alleviating dumping syndrome.

RESEARCH HIGHLIGHT

Antibiotic Therapy versus Appendectomy as Primary Treatment of Acute Appendicitis

Standard treatment for acute appendicitis is appendectomy to avoid perforation. However, appendectomy is associated with postoperative risks, such as small bowel obstruction. Because of such risks, there has been increased interest in antibiotic therapy as primary treatment. This study investigated the feasibility of antibiotic therapy as a first-line treatment for acute appendicitis by assigning patients (N = 369) to antibiotic treatment (n = 202) or surgery (n = 167).

Treatment efficacy was 90.8% for the antibiotic therapy group and 89.2% for the surgery group. Appendicitis recurred in 13.9% of the antibiotic group after a median of 1 year with one third of recurrences within 10 days after discharge. Eleven of the antibiotic group required an appendectomy because of clinical progression within 24 to 36 hours. Although minor complications were similar between groups, major complications were threefold higher in surgery patients.

The researchers concluded that antibiotic treatment appears to be a safe first-line therapy in patients with acute appendicitis.

Modified from Hansson J et al: Randomized clinical trial of antibiotic therapy versus appendectomy as primary treatment of acute appendicitis in unselected patients, *Br J Surg* 96:473-481, 2009.

ligature is required, 2-0 synthetic absorbable suture on an atraumatic GI needle is preferred.

8. The appendix is elevated as a purse-string suture of 2-0 synthetic absorbable suture is placed in the cecal wall at the appendiceal base.
9. The base of the appendix is crushed with a straight hemostat, a 3-0 synthetic absorbable suture tie placed over the crushed area, and a hemostat placed above the ligature.
10. A basin is provided for the specimen and instruments that contact the GI mucosa (bowel technique).
11. Protective gauze sponges are placed over the cecum around the base of the appendix.
12. The appendix is amputated with a scalpel. The stump is often swabbed with alcohol or povidone-iodine (Betadine) solution to reduce bacterial flora.
13. The appendiceal stump is usually inverted into the lumen of the cecum as the purse-string suture is tightened and tied by means of a fine straight hemostat and a small sponge on a holder. Soiled instruments are discarded into the basin.
14. If the appendix has ruptured, copious amounts of warm fluids are used to irrigate the peritoneal cavity. A drain may be inserted in the appendiceal bed to allow continuous drainage. Deeper layers are closed; the subcutaneous tissue and skin may be left open. The wound is then packed with moist fine-mesh gauze to heal by secondary intention. (This method may be used in any case in which bowel contamination or abscess formation is present. It allows clean healing and prevents pocketing of pus.)

Laparoscopic Appendectomy

The laparoscopic approach to appendectomy may be used for uncomplicated appendicitis. In the presence of perforation, conversion to an open procedure may be necessary.

Procedural Considerations. The procedure involves the placement of three trocars with standard laparoscopic instrumentation, equipment, and supplies available. The patient is positioned supine after induction of general anesthesia. An indwelling urinary catheter may be placed before the abdominal skin prep.

Operative Procedure

1. Pneumoperitoneum is obtained by a Veress needle or through the periumbilical trocar.
2. An 11-mm or 12-mm trocar is placed in the umbilicus for insertion of the laparoscope.
3. An 11-mm or 12-mm trocar is placed in the right upper quadrant (RUQ) to serve as the working port.
4. A 5-mm trocar placed in the midline suprapubic site serves as the traction trocar.
5. A laparoscopic Babcock forceps is inserted into the RUQ trocar to grasp the cecum and retract it toward the liver.
6. The appendix is grasped at its tip by a grasping forceps that has been inserted through the suprapubic trocar and is held in an upward position.
7. The Babcock forceps is removed, and a dissecting instrument is inserted through the RUQ trocar to create a mesenteric window in the mesoappendix.
8. Dissection is performed in proximity to the appendix, beginning directly under the base and progressing to a 1-cm to 2-cm length.
9. Depending on surgeon preference, the appendix may be transected in several different ways: (a) with an endoscopic linear stapling instrument, (b) with a ligating loop instrument, or (c) with a suturing instrument.
10. If an endoscopic linear stapling instrument is used, the lower jaw of the stapling device is passed through the mesenteric window previously created by way of the RUQ trocar.
11. The grasping forceps are used to rotate the tip of the appendix so that the stapling device can be snugged to the base of the appendix and closed.
12. The stapling instrument is fired and withdrawn, and the staple line is inspected.
13. The remainder of the mesoappendix is dissected, hemostasis achieved, and the appendix removed through the RUQ port.
14. If the appendix is too thick, a specimen pouch may be necessary for its extraction.
15. The abdomen is irrigated, irrigation fluid is aspirated with a suction and irrigation device, and the abdomen is deflated.
16. Trocar sites are closed and dressed or closed with skin-bonding sealer.

Resection of the Small Intestine

Resection of the small intestine involves excision of diseased intestine through an abdominal incision followed by reanastomosis. It is performed to remove tumors, a gangrenous portion of intestine caused by strangulation from bands of adhesions, intestinal obstruction, areas of ulceration and bleeding as in Crohn's disease, herniation of the intestine, or volvulus.

Procedural Considerations. Laparotomy and GI sets are required. Linear stapling instruments should be available. The patient is positioned supine after induction of general anesthesia. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before the abdominal skin prep. The procedure may be performed laparoscopically.

Operative Procedure

1. The abdominal wall is incised through a midline incision and retracted.
2. The peritoneal cavity is explored and protected with moist, warm saline packs.
3. Intestinal clamps are placed above and below the diseased segment of small bowel and mesentery.
4. The involved area is removed with a linear stapling instrument such as a GIA, an electrosurgical blade, or a scalpel.
5. Continuity of the GI tract is established by an end-to-end, end-to-side, or side-to-side anastomosis.
6. The wound is closed and dressed.

An alternative approach to suture anastomosis is use of a mechanical stapling device to perform an end-to-end, end-to-side, or side-to-side anastomosis. An enterotomy is made close to the anastomosis site. The stapler is inserted, and the distal bowel secured between the anvil and the head of the stapler. The anvil is then inserted into the proximal loop of bowel and secured to the center rod. The gap is closed, and the stapler fired. The stapler is removed through the enterotomy. The integrity of the anastomosis is verified, and the enterotomy closed with sutures.

Ileostomy

Ileostomy is formation of a temporary or permanent opening into the ileum. This procedure is indicated in the presence of an extensive lesion to reduce large bowel activity, often called *bowel rest,* by creating a temporary fecal diversion to the outside of the body, or as permanent fecal diversion in total colectomy. The patient is site-marked before surgery and anesthesia by the WOCN (see Box 10-1).

Procedural Considerations. Laparotomy and GI sets along with linear stapling instruments are required. The patient is positioned supine after induction of general anesthesia. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before the abdominal skin prep. An ostomy appliance for the stoma is available.

Operative Procedure

1. Through a midline incision, the peritoneal cavity is explored and the pathologic condition determined.
2. The ileum is mobilized with Metzenbaum scissors and hemostatic clamps.
3. The mesentery is clamped, divided, and ligated with 3-0 nonabsorbable sutures at the proposed site, usually about 15 cm from the ileocecal junction.
4. Two intestinal clamps are placed on the bowel, and the ileum is divided with a scalpel or linear stapling instrument (GIA) between the two clamps.
5. The distal end of the ileum is closed with 2-0 synthetic absorbable suture on a taper needle if a stapling device has not been used.
6. The proximal end is relocated to the skin through an opening on the right side and is held in place by clamps, making sure that the ileum is not overstretched or its blood supply compromised.

7. The mesentery of the ileum is sutured to the parietal wall to eliminate a potential internal hernia.
8. The abdomen is closed.
9. The stoma is sutured to the skin after the ileum is everted to form a protective cover over the exposed ileal serosa.
10. A disposable ostomy appliance is placed over the stoma to collect small bowel contents.

An alternative to conventional ileostomy for selected patients is the Kock pouch, or continent ileostomy. The internal pouch is created from a segment of small intestine with an outlet to the skin. When functioning properly, the stoma and pouch are continent and do not continually drain stool. A catheter is inserted into the stoma three or four times daily to evacuate the contents, eliminating the need for an external appliance.

Intestinal Transplantation

Small bowel transplantation may be indicated for patients with intestinal failure caused by short-gut syndrome as a result of extensive resections necessitated by Crohn's disease, necrotizing enterocolitis, mesenteric thrombosis, atresias, volvulus, trauma, dysmotility, or congenital enteropathy (Shortridge et al, 2004). Intestinal failure leads to malabsorption and malnutrition, preventing the bowel from meeting the body's nutrient and fluid requirements. Approximately 10 to 20 cm of small intestine with an ileocecal valve, or 40 cm without an ileocecal valve, is minimally required to maintain nutritional status. Patients with short-gut syndrome require TPN to sustain life. A critical indication for intestinal transplant arises when patients can no longer receive TPN because of clotting of major veins, frequent IV line sepsis, episodes of dehydration despite TPN and IV fluids, and TPN-induced liver failure (Markmann et al, 2008). Intestinal transplantation may also include the liver in the presence of impending progressive end-stage liver disease. The perioperative time frame, beginning with immunosuppression, surgery, transition from parenteral to enteral feedings, and the long recovery process, may be 6 months and poses many physical and emotional challenges to the patient and family. Despite these challenges, refinements in surgical technique and patient selection and advances in immunosuppression protocols have contributed to significant improvements in patient survival rates.

Procedural Considerations. The transplant surgeon does the final visual inspection and assessment of the donor organ. The allowable cold ischemic time of the donor intestine (allograft intestine) is approximately 12 hours. The patient is positioned supine and anesthetized with general endotracheal anesthesia. Arterial and multiple venous lines are inserted. An NG tube, urinary catheter, and physiologic monitoring are indicated.

Operative Procedure

1. The incision is made along previous incision lines, or a vertical midline approach is used.
2. The superior mesenteric artery of the donor organ is anastomosed to the recipient's infrarenal aorta.
3. Venous drainage of the donor organ is established by connecting the donor superior mesenteric vein to the recipient portal vein if the patient has no liver disease or signs of portal hypertension.
4. Reperfusion begins with release of venous flow when the clamps are opened.
5. Bleeding sites are identified and ligated or coagulated.
6. The arterial clamp is released.
7. Continuity of the intestine is restored after vascular supply is established.
8. Proximal anastomosis joins the donor jejunum to the recipient stomach, duodenum, or proximal jejunum.
9. The distal ileum is anastomosed side-to-side with the remaining colon.
10. A distal loop ileostomy is created for later endoscopic evaluation and intestinal biopsies.
11. The intact intestine is inspected, hemostasis verified, and the abdomen closed.

SURGERY OF THE COLON

Laparoscopic Colectomy

Resection of a segment of bowel and reanastomosis can be accomplished laparoscopically. Advantages of laparoscopic colectomy include reduction of morbidity associated with open techniques (e.g., postoperative ileus), less postoperative pain, faster return to normal activities, shorter length of stay, and improved cosmesis (Evidence for Practice). Laparoscopic colectomy is indicated for obstruction and benign tumors of the large bowel.

Procedural Considerations. Depending on the intended segment of bowel to be resected, the patient is initially positioned supine or in modified lithotomy for access to the rectum for end-to-end anastomosis. The surgeon may stand on the patient's left or between the patient's legs (modified lithotomy). SCDs are applied to minimize the risk of DVT. The patient is

EVIDENCE FOR PRACTICE

Laparoscopic versus Open Colectomy

Laparoscopic-assisted colectomy is a safe alternative to traditional open colectomy. Recent research comparing open laparotomy for colectomy with laparoscopic-assisted colectomy reveals better outcomes for the laparoscopic approach for both benign and malignant disease of the colon. The laparoscopic approach has also been shown to be equivalent to open colectomy in cancer-related survival for curable cancer. A large prospective, randomized, multi-institution trial compared laparoscopic-assisted to open colectomy for colon cancer. It involved 863 patients, 66 surgeons, and 48 institutions. The primary endpoint was time-to-tumor recurrence; the secondary endpoints were disease-free and overall survival, minimal complications, and increased quality of life. At the median follow-up of 4.5 years, there was no significant difference in oncologic outcome between the two groups. A higher 5-year survival rate for patients with the laparoscopic approach was shown in a retrospective cohort study of 11,038 patients compared with 231,381 patients who had the open approach for nonmetastatic colon cancer between 1998 and 2002. Laparoscopic-assisted colectomy is a technically demanding procedure with a significant learning curve for the surgeon; the advantages for the patient, however, make this approach the treatment of choice.

From Clinical Outcomes of Surgical Therapy Study Group (COST Trial): *NEJM* 350(20):2050-2059, 2004; Hageman D et al: Laparoscopic-assisted colon surgery, *AORN J* 88:403-416, 2008; Bilimoria KY et al: Use and outcomes of laparoscopic-assisted colectomy for cancer in the United States, *Arch Surg* 143(9):832-840, 2008.

secured with restraining straps to support and maintain position during steep position changes. A beanbag device may be used. An NG tube and urinary catheter are inserted before the abdominal skin prep. Laparotomy instrumentation, mechanical stapling devices, and endostapling devices are required. To assist the surgeon in accurately identifying the segment of bowel to be resected, a colonoscope may be used preoperatively or during the laparoscopic procedure to tattoo the lesion with india ink. Right hemicolectomy, described below, is performed to treat disease of the cecum, ascending colon, or hepatic flexure. Extended right hemicolectomy is done to treat tumors located in the transverse colon, particularly those located to the right of the midline (Sonoda and Milsom, 2007).

Operative Procedure (Right Hemicolectomy)

1. Pneumoperitoneum is established at 10 to 12 mm Hg, and the 10-mm umbilical trocar is placed after a supraumbilical cutdown. Alternatively, a 12-mm Hasson trocar may be inserted through the rectus muscle and into the abdominal cavity by way of a small incision in the left upper quadrant, 3 to 4 cm below the costal margin.
2. Additional ports (usually 5 mm) are placed in locations dependent on the anatomic segment of colon to be resected.
3. After the patient is moved into Trendelenburg's position, with right side tilted up, dissecting scissors and a grasper are inserted. The peritoneum along the cecum is incised as are the appendiceal and terminal ileal attachments. The bowel is then bluntly dissected from the retroperitoneum, the ureter identified, and the colon mobilized as necessary for resection of the diseased segment. A mesenteric window is created, and the mesenteric artery and vein and right colic vessels are identified and clipped.
4. A multifire endoscopic linear stapling device (GIA) is positioned over the segment of bowel and fired to both transect and staple the segment.
5. Unless an end-to-end anastomosis can be performed, as in a low sigmoid or rectal resection, a small incision is made over the area of the abdomen that will provide access to the segments for anastomosis.
6. The segment of bowel to be resected is grasped, transferred through the small incision, and transected, and anastomosis is performed in the surgeon's preferred manner (with staples or with sutures).
7. The anastomosed bowel is returned to the peritoneal cavity, and the cavity is irrigated and inspected for hemostasis and drained by suction. The cannulae are removed, port sites closed, and skin closed with subcuticular absorbable suture. Skin tapes (Steri-Strips) are applied.

Colostomy

Colostomy is mobilization of a loop of colon through a right rectus incision to expose the transverse colon. A left rectus incision can also be made to expose the descending sigmoid colon. The layers of the wound beneath or around the colostomy are subsequently closed. Colostomy is performed to treat obstruction in the sigmoid colon resulting from a malignant lesion or advanced inflammation or trauma that has caused distention or obstruction of the proximal portion of the colon. A temporary colostomy is often done to decompress the bowel or to divert bowel contents to promote healing (bowel rest) (Figure 10-28).

Procedural Considerations. Laparotomy and GI sets are required. Linear stapling instruments may be used. Stoma appliances are required. These items may include a colostomy rod, rubber tubing, or a loop ostomy bridge. The patient is site-marked by the WOCN before surgery. The patient is positioned supine after induction of general anesthesia. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before the abdominal skin prep.

Operative Procedure

FIRST-STAGE LOOP COLOSTOMY

1. The abdomen is opened, and the wound edges are protected and retracted.
2. The peritoneal cavity is opened and walled off with moist laparotomy packs, and appropriate retractors are inserted.
3. A small opening is made in the mesentery near the bowel with curved hemostats and Metzenbaum scissors.
4. A piece of tubing or Penrose drain is passed around the colon, and the two ends are held with a hemostat to maintain gentle traction.
5. The loop of colon is moved through an incision made on the left side of the midline. The abdominal incision is closed.
6. A loop ostomy bridge is used to support and retain the loop of colon in position on the abdominal wall.
7. The loop of intestine is dressed with petrolatum gauze.

SECOND-STAGE LOOP COLOSTOMY. After 48 hours the loop of colon is completely opened with the blade tip of an electrosurgical pencil. By this time, if there is no tension, healing has advanced sufficiently to allow protection from feces contamination onto the wound. This procedure is simple and painless and is usually performed in the patient's room or in a treatment room. An ostomy appliance is applied.

TRANSVERSE COLOSTOMY

1. A short transverse or vertical incision is made to reach the transverse colon.
2. A loop of transverse colon, freed of omentum, is withdrawn (Figure 10-29).
3. A loop ostomy bridge is passed through an avascular area of the mesocolon, preventing the loop from returning to the peritoneal cavity.
4. A mushroom catheter, held in place with a purse-string suture, results in immediate decompression.

The bowel is opened 24 to 36 hours later, and the bridge is removed in about 7 to 10 days.

Closure of a Colostomy

Closure of a colostomy reestablishes internal intestinal continuity and repairs the abdominal wall.

Procedural Considerations. When the loop has been completely divided, a closed or open anastomosis may be performed. Laparotomy and GI sets are required. Linear stapling instruments may be used. The patient is positioned supine after induction of general anesthesia. The anesthesia provider inserts a nasogastric tube after intubation. An indwelling urinary catheter is inserted before the abdominal skin prep. Depending on location of the bowel to be reanastomosed, the patient may be placed in low lithotomy position to facilitate transanal access for a circular stapling device. An end-to-end anastomosis of the left colon or ileal pouch to the rectal stump can then be achieved.

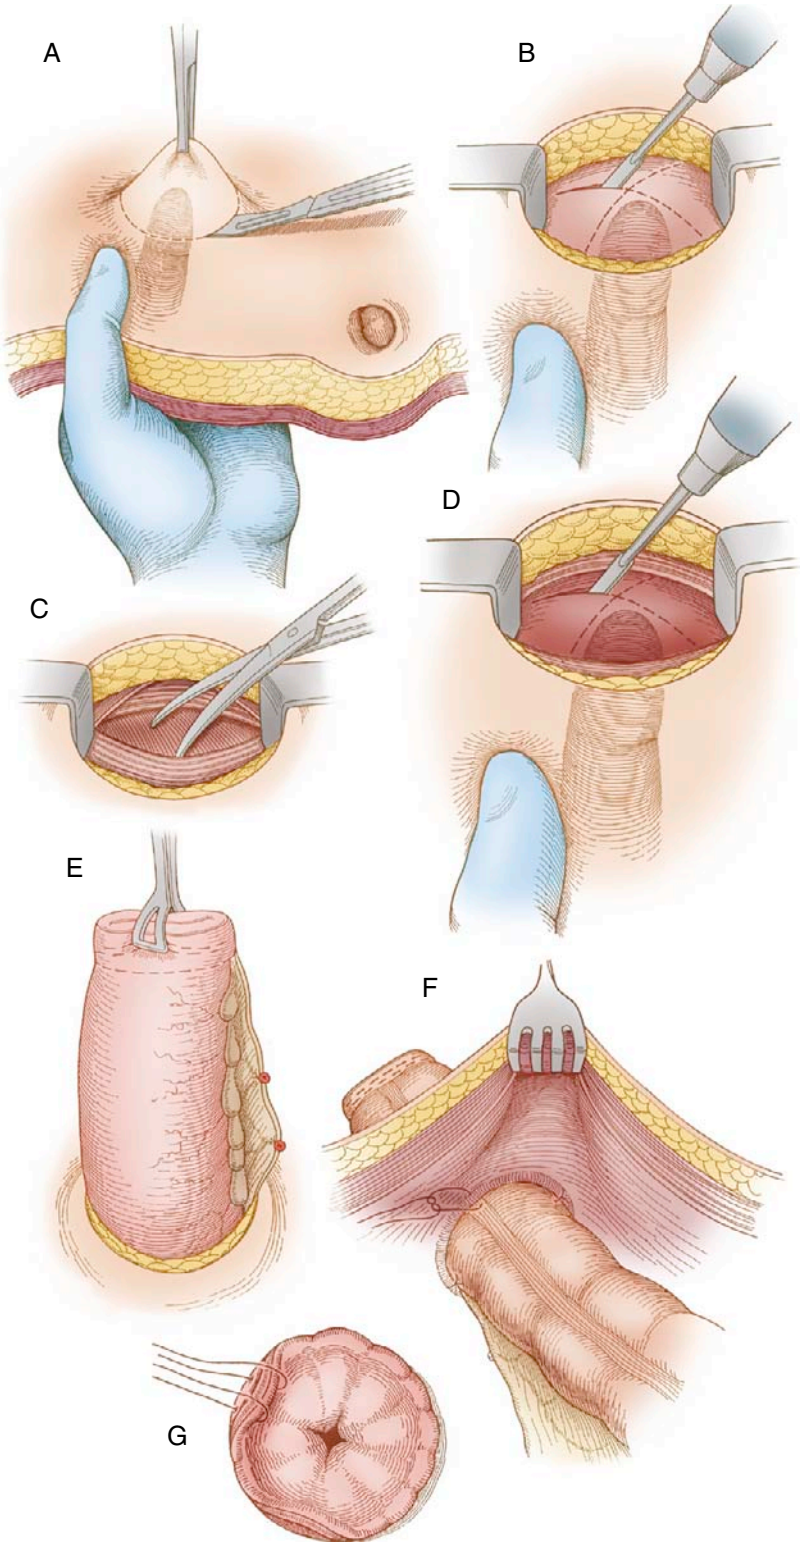

FIGURE 10-28 Construction of a colostomy through the anterior abdominal wall. **A**, A core of subcutaneous tissue is removed after making a circular skin incision with a #10 blade and using an electrosurgical pencil to dissect down to the anterior fascia. **B**, Muscle fibers are split. **C**, Tissues are dissected to the posterior layers, and, **D**, the peritoneum is opened. **E**, The colon is delivered through the abdominal wall so that it extends 2 to 3 cm beyond the skin surface. **F**, The bowel is tacked internally to the peritoneal defect. **G**, Four sutures are placed in each quadrant, incorporating the full-thickness cut end of the colon, the serosal surface approximately 1 to 2 cm below the open end of the colon, and up to the dermis. Additional sutures are used to mature the stoma, which refers to the procedure of everting the mucosa to create a stable opening through which feces can be evacuated.

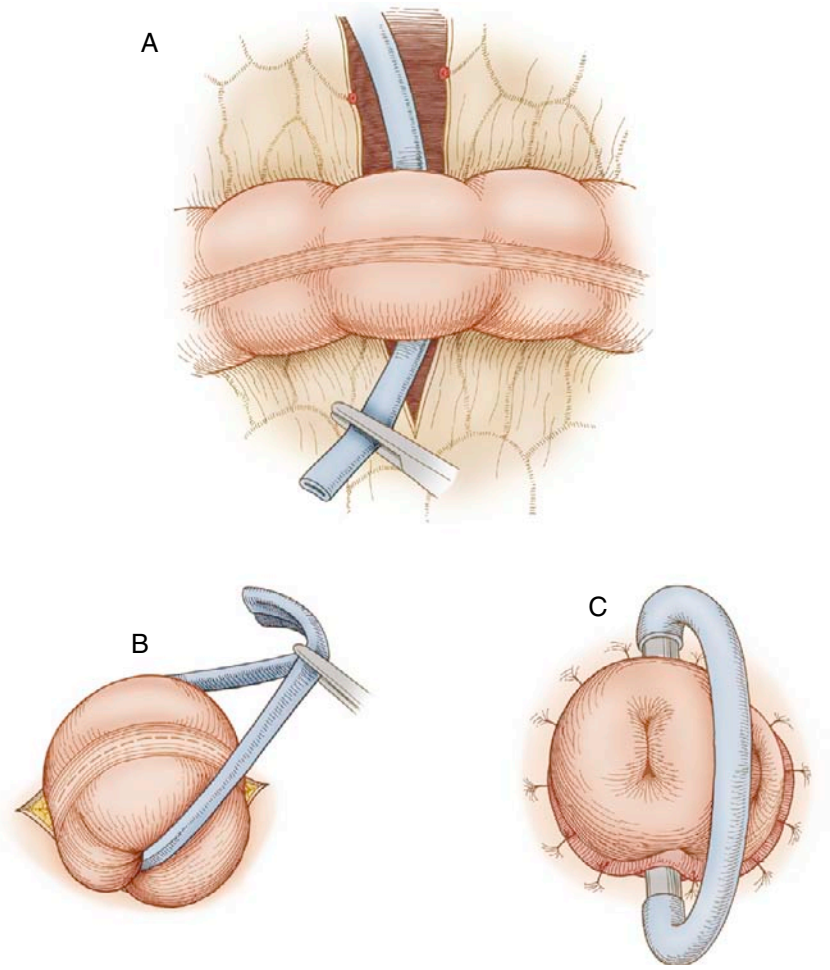

FIGURE 10-29 Transverse loop colostomy. **A**, The mesentery adjacent to the colon is taken down so that a Penrose drain may be passed beneath the colon. **B**, The colon is pulled through the transverse incision and opened longitudinally along the taeniae. **C**, An apparatus or rod is placed underneath the stoma; sutures are used to mature the colostomy. The rod can be removed after the seventh postoperative day.

Operative Procedure

1. A circumferential incision is made around the colostomy to free the skin margin.
2. Moist packs, a scalpel with #10 blade, Metzenbaum scissors, and Crile hemostats are used as layers of the abdominal wall are identified and dissected free.
3. An end-to-end anastomosis is completed in two layers—the inner with 3-0 synthetic absorbable suture and the outer with 3-0 nonabsorbable suture on an intestinal needle, using interrupted sutures. Alternatively, a surgical stapling device may be used.
4. The abdominal wound is closed in layers and a dressing applied.

The surgeon may elect to leave the subcutaneous tissue and skin open. In this instance the wound is packed and permitted to heal by secondary intention.

Right Hemicolectomy and Ileocolostomy

Right hemicolectomy and ileocolostomy involve resection of the right half of the colon—including a portion of the transverse colon, ascending colon, and cecum—and a segment of the terminal ileum and mesentery (Figure 10-30, *A*). An end-to-end, side-to-side, or end-to-side anastomosis is done between the transverse colon and ileum. A right hemicolectomy and ileocolostomy are performed to remove a malignant lesion of the right colon or, in some cases, to remove inflammatory lesions involving the ileum, cecum, or ascending colon.

Procedural Considerations. When a side-to-side anastomosis is carried out, the transected stumps of the ileum and transverse colon are closed before the anastomosis is done. A side-to-side anastomosis can also be performed by inserting the GIA stapler into both colon segments and firing the device. The stumps are then closed using a TA linear stapling device.

When an end-to-end anastomosis is performed, the layers of the transected stumps of the ileum and transverse colon are sutured together. Circular linear stapling devices, such as an EEA, may also be used for anastomosis.

Laparotomy and GI sets are required. The patient is positioned supine after induction of general anesthesia. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before the abdominal skin prep.

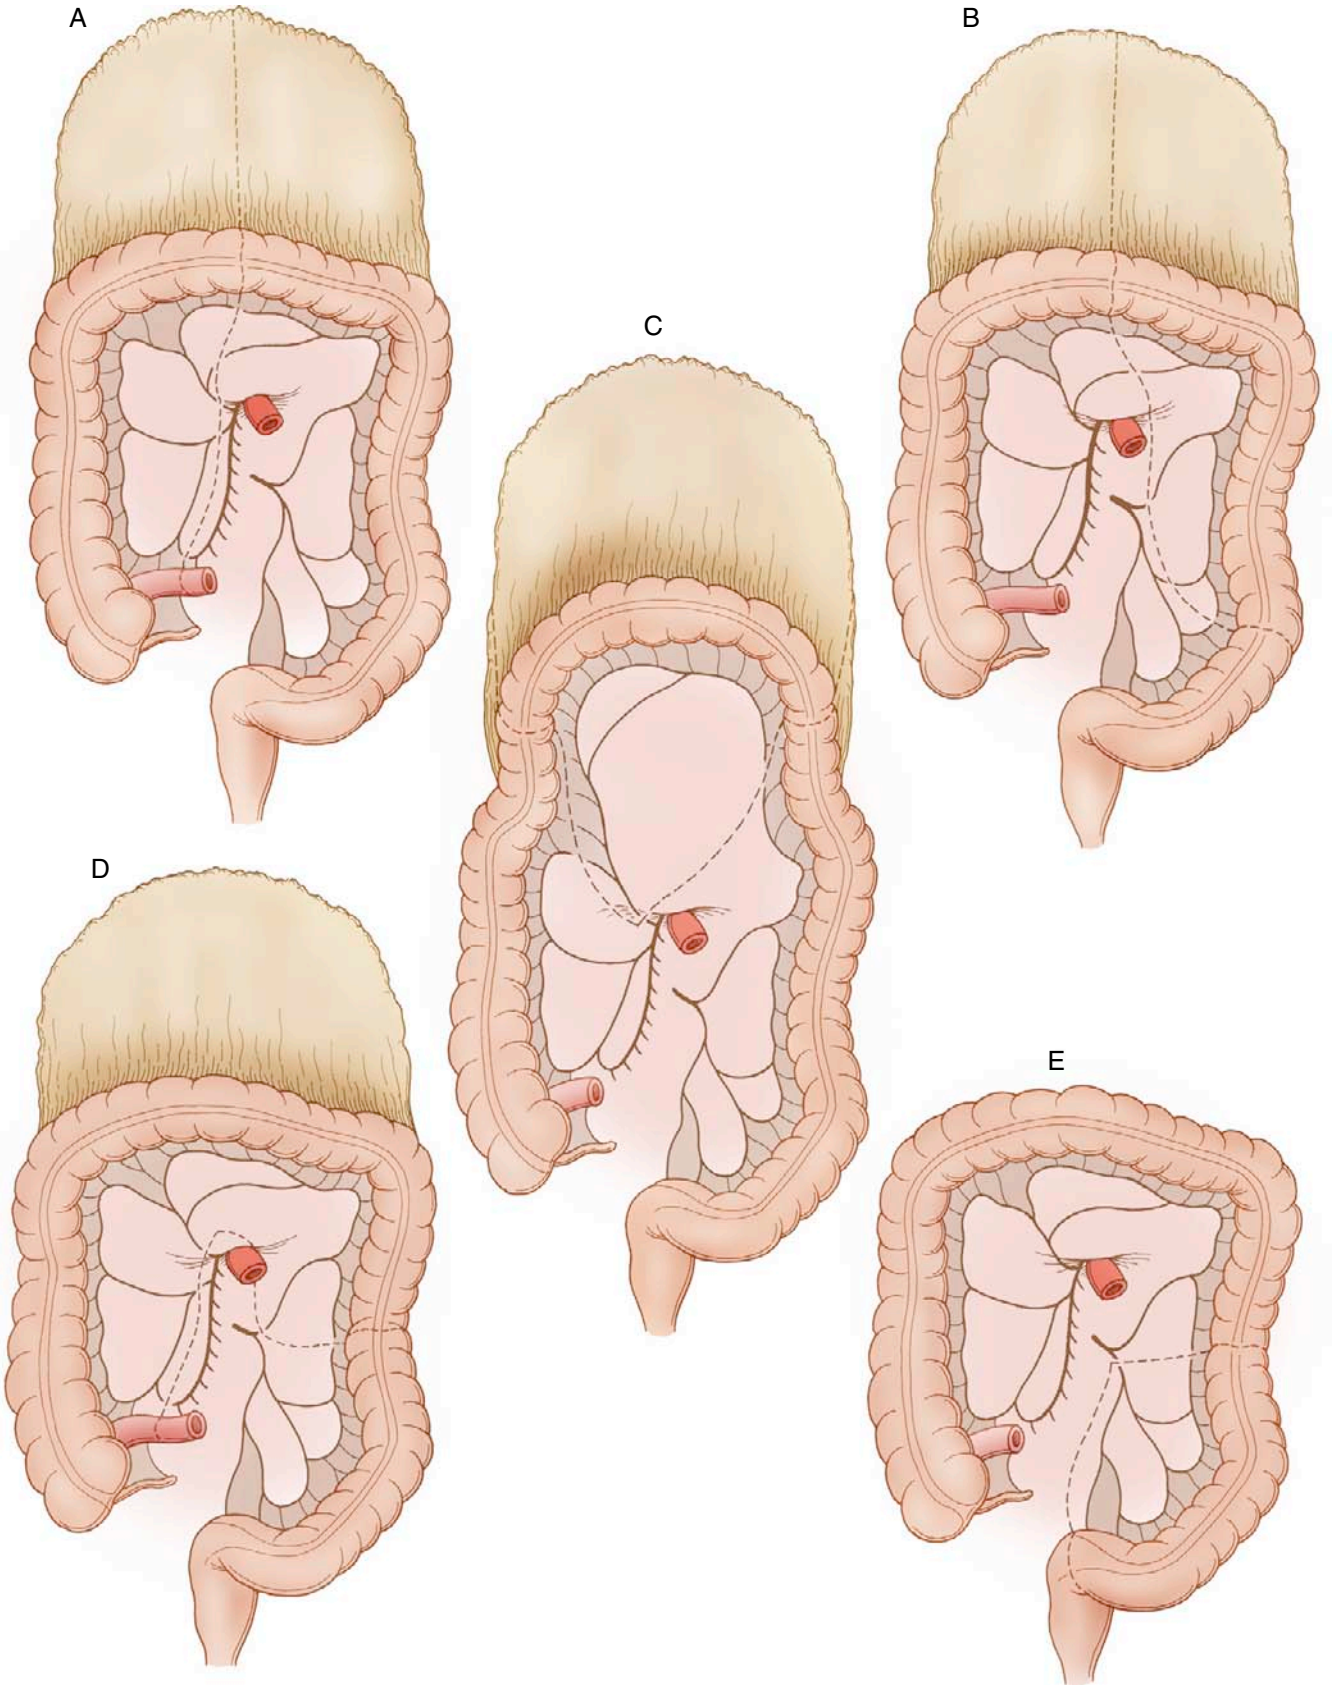

FIGURE 10-30 The resection lines for various types of colon resection. **A**, Right hemicolectomy and ileocolostomy. **B**, Left hemicolectomy. **C** and **D**, Transverse colectomy. **E**, Anterior resection of sigmoid colon and rectosigmoidostomy.

Operative Procedure

1. The abdomen is opened, and the peritoneal cavity retracted and packed with warm, moist sponges.
2. The mesentery of the transverse colon and terminal ileum is incised at the points where the resection is to be done.
3. Moist packs are placed to isolate viscera to be resected. Metzenbaum scissors, hemostats, and 3-0 nonabsorbable ligatures are used to clamp, cut, and ligate mesentery vessels.
4. The lateral peritoneal fold along the lateral side of the right colon is incised, and the right colon is mobilized medially. Metzenbaum scissors, hemostats, and sponges on holders are used.
5. The ureter and duodenum are identified.
6. The same procedure is carried out on the terminal ileum. The mesenteric vessels are clamped and ligated with 2-0 nonabsorbable ligatures.
7. The operative field is prepared for anastomosis (bowel technique).
8. Intestinal clamps are placed on the transverse colon and ileum.
9. Division is completed with a scalpel, and the specimen removed.
10. An end-to-end anastomosis is completed between the severed ends of the terminal ileum and transverse colon.
11. Instruments and supplies that have contacted bowel mucosa are discarded.
12. The mesentery and posterior peritoneum are closed with interrupted 3-0 nonabsorbable sutures.
13. The abdominal wound is closed and a dressing applied.

Transverse Colectomy

Transverse colectomy is excision of the transverse colon through an upper midline or transverse incision (Figure 10-30, *C* and *D*). Bowel integrity is reestablished by an end-to-end anastomosis. Transverse colectomy is performed to remove malignant lesions of the transverse colon. A more radical procedure may be required when the lesion has perforated the greater curvature of the stomach. If the entire lesion is resectable, a partial gastrectomy may also be performed.

Procedural Considerations. Laparotomy and GI sets are required. Linear stapling instruments and a self-retaining retractor system should be available. The patient is positioned supine after induction of general anesthesia. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before the abdominal skin prep.

Operative Procedure

1. The abdomen is opened, and the peritoneal cavity explored to determine the pathologic area.
2. Moist packs are used to wall off surrounding structures to expose the hepatic and splenic flexures of the colon.
3. The colon is mobilized by incising the lateral peritoneum on either side and transecting the transverse mesocolon. Hemostats, Metzenbaum scissors, and 3-0 nonabsorbable ligatures are used.
4. The operative field is prepared for resection by placing towels or laparotomy sponges around the colon to isolate any contamination from the lumen of the bowel.
5. Two intestinal resection clamps are applied.
6. Transection is completed with a scalpel or mechanical linear stapling device.
7. An end-to-end or side-to-side anastomosis is completed.
8. Contaminated articles are isolated (bowel technique).
9. Approximation of mesentery and lateral peritoneum is completed with 3-0 nonabsorbable sutures.
10. The abdominal wound is closed. Retention sutures may be used.
11. The wound is dressed.

Anterior Resection of the Sigmoid Colon and Rectosigmoidostomy

Anterior resection of the sigmoid colon and rectosigmoidostomy involve removal of the lower sigmoid and rectosigmoid portions of the rectum (Figure 10-30, *E*). This is usually done through a laparotomy incision, and an end-to-end anastomosis is completed. This procedure treats lesions in the lower portion of the sigmoid and rectum that can be excised with a wide margin of safety and still retain sufficient tissues with adequate blood supply for a viable rectosigmoid end-to-end anastomosis.

Procedural Considerations. Laparotomy and GI sets are required. Linear stapling instruments as well as the end-to-end curved mechanical stapling instruments (EEA) are used. Long instruments for dissecting into the pelvis may be necessary. A rigid sigmoidoscope is used before patient preparation and after anastomosis. A self-retaining retractor set is required. After induction of general anesthesia, the patient is placed in a modified lithotomy position with legs extended in stirrups. An indwelling urinary catheter is inserted before the abdominal and perineal preps.

If there is an assisting surgeon, a table with a basic minor set and rectal instruments should be available to facilitate end-to-end stapling of the anastomosis. Cross-contamination from the table of instruments used on the patient's rectum to the table with the laparotomy instruments is prevented. A table with laparotomy closure instruments may be the surgeon's preference. In this case, only laparotomy instruments are required.

Identification of the ureters during extensive deep abdominal procedures is achieved by preoperative placement of ureteral catheters by a transurethral approach. If the tumor is believed to involve the ureters, a urologist will place ureteral stents cystoscopically before the abdominal prep begins.

Operative Procedure

1. The abdomen is entered through a laparotomy incision.
2. The peritoneal cavity is explored for metastasis and resectability of the lesion.
3. Before the colon is mobilized, the tumor-bearing segment is isolated by ligatures to the lymphovenous drainage, provided that these structures are accessible.
4. A loop of sigmoid colon is elevated as the small intestines are walled off with moist packs; retractors are placed.
5. The peritoneum on the left side of the colon is incised with a long scalpel, scissors, hemostats, and sponge forceps.
6. Traction sutures (2-0 nonabsorbable) may be used as the peritoneum is reflected.
7. Bleeding vessels are ligated with 2-0 or 3-0 nonabsorbable ligatures.
8. The pelvic peritoneum is exposed and dissected free to form the left side of the reconstructed pelvic floor. Long dissecting instruments are used.

9. Vessels are ligated with 30-inch nonabsorbable ligatures.
10. Extreme care is exercised throughout to protect the ureters from injury.
11. The sigmoid colon is turned leftward; incision and dissection of the peritoneum are then performed on the right side of the pelvis.
12. The two incisions are then curved and joined in front of the rectum.
13. The rectum is freed anteriorly and posteriorly from adjacent structures.
14. The sigmoid colon is clamped with intestinal clamps after mobilization of the proximal portion. A right-angled intestinal clamp or a reticulating linear stapling device may be used to clamp the distal portion of the rectosigmoid colon.
15. As the sigmoid colon is divided distally to the clamp, the transected rectal edges are grasped with Allis or Ochsner forceps and the rectal opening is exposed.
16. The diseased portion is removed, and the soiled instruments are discarded into a separate basin (bowel technique).
17. Continuity is established by an end-to-end anastomosis of the proximal colon and the rectum using a curved mechanical stapling instrument (EEA) (Figure 10-31).
18. "Donuts" of tissue are removed from the EEA stapling device, examined closely for thickness and continuity, and then sent as separate specimens to the pathology laboratory.
19. The assisting surgeon passes a rigid sigmoidoscope into the lumen of the bowel transanally.
20. Warm irrigating solution is poured into the peritoneal cavity, and the lumen of the bowel is insufflated.
21. The surgeon looks for air leaks from the anastomosis and oversews the site if indicated.
22. The pelvic floor is reperitonealized, and drains may be placed.
23. The abdominal wound is closed and a dressing applied.

Abdominoperineal Resection

Abdominoperineal resection (APR), also called *Miles' resection,* is the mobilization and division of a diseased segment of the lower bowel through a midline incision. The proximal end of bowel is exteriorized through a separate stab wound as a colostomy. The distal end is pushed into the hollow of the sacrum and removed through the perineal route (Figure 10-32). APR is performed to remove malignant lesions and to treat inflammatory diseases of the lower sigmoid colon, rectum, and anus that are too low for the use of EEA stapling devices.

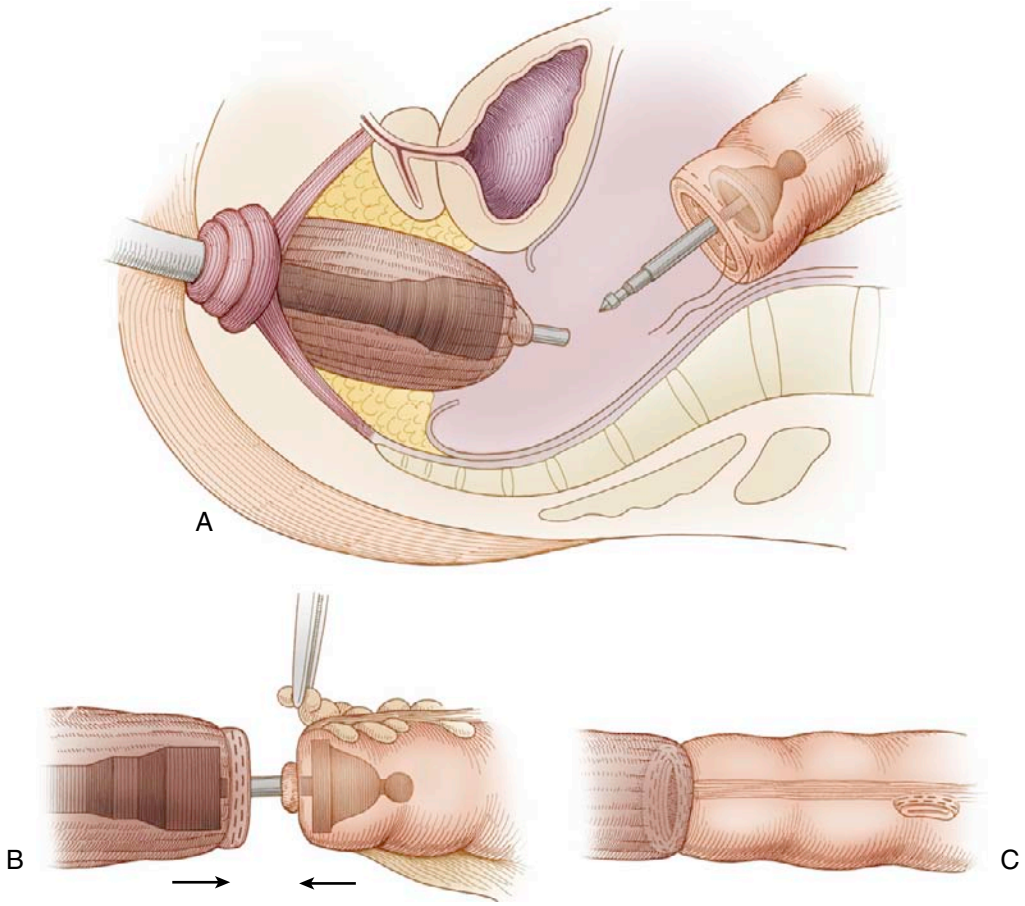

FIGURE 10-31 EEA stapling device, used to perform low anterior anastomosis. **A**, Stapler is introduced into anus, and the anvil is placed into the proximal colon loop. **B**, EEA is advanced to level of the anvil, and the EEA is closed and fired. **C**, Circular double-staggered row of staples joins bowel; simultaneously, circular blade in instrument cuts stoma. Instrument is gently removed. The resulting anastomosis is illustrated with bowel wall transparent to depict reconstruction.

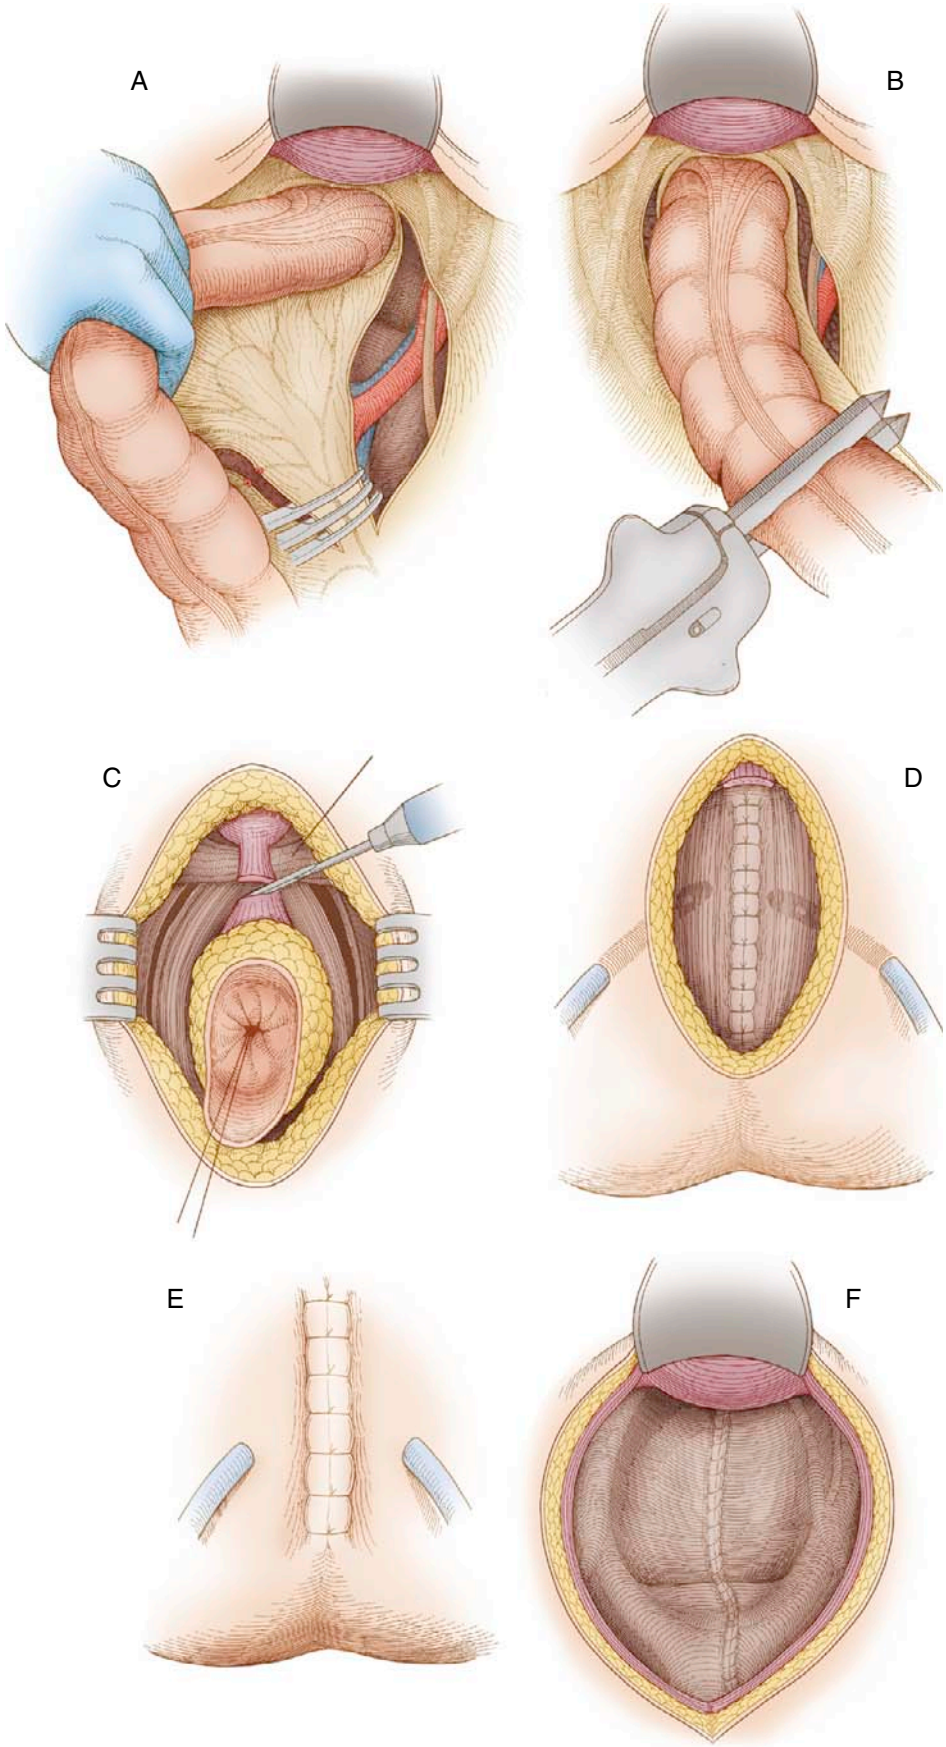

FIGURE 10-32 Abdominoperineal resection for cancer of the rectum. **A**, The sigmoid colon is deflected to the right to complete the rectosigmoid peritoneal detachment. **B**, The distal sigmoid is transected to allow for better access to mobilize the rectum from the sacrum. **C**, The rectal stump is excised from the perineal approach. **D**, Drains are placed and moved through stab wounds; the levator tissues are reapproximated with 2-0 synthetic absorbable sutures. **E**, The perineal skin is closed. **F**, The pelvic peritoneal floor is closed from the abdominal approach.

Procedural Considerations. The choice of patient position depends on the surgeon. Some surgeons prefer to start with the patient in supine position and move the patient into lithotomy for the perineal portion of the operation. Others initially position the patient in modified lithotomy. Thus surgery may be performed simultaneously by two teams, which may require two scrub persons with two different setups. An indwelling catheter is inserted into the urinary bladder after induction of anesthesia. The anesthesia provider inserts an NG tube after intubation. A GI instrument set and an ostomy appliance are required for the abdominal portion of the procedure. A perineal set is used for the rectal portion of the procedure. Identification of the ureters during extensive deep abdominal procedures may be achieved by the preoperative placement of ureteral stents using the transurethral approach.

Operative Procedure

1. A midline incision is made.
2. After thorough exploration of the abdominal cavity and inspection of the colon, the surgeon determines the extent of the lesion and probable surgical outcome. If a resection is indicated, the sigmoid colon is retracted to the right side.
3. The peritoneum on the left of the mesocolon is divided.
4. The incision into the peritoneum is made opposite the main branches of the inferior mesenteric vessels and extended into the pelvis and around, anterior to the rectum.
5. The pelvic peritoneum is mobilized by blunt dissection to form the left side of the new pelvic floor and permit visualization of the left ureter.
6. The peritoneum is incised on the right side until the incision connects with that made on the left.
7. The right ureter is identified and protected.
8. The blood supply of the portion of intestine to be removed is isolated and ligated. Care is taken not to damage the left colic artery, which will supply blood to the colostomy.
9. The mesentery is tied to permit greater exposure in the operative field.
10. The surgeon frees the rectum, usually as low as the sacrococcygeal junction. Care is taken to avoid injury to the presacral nerves, which could result in sexual and bladder dysfunction.
11. After the bowel is freed, the distal segment is transected with a linear stapling instrument (Figure 10-32, *B*).
12. The proximal margin of resection is examined and transected. The bowel and mesentery are removed from the abdominal cavity.
13. The surgeon prepares the permanent colostomy by extending the stump through the abdominal wall. The colostomy will be "matured" (sutured externally to the abdominal wall tissues so that the mucosa is everted into a raised and secured ostomy) after abdominal closure.
14. The combined excision and perineal dissection are initiated when the lesion is determined to be resectable.
15. To prevent contamination, the anus is often closed with a purse-string suture.
16. An incision is made around the anus in an elliptic manner outside the sphincter muscles with a generous margin of perianal skin.
17. The anus is grasped with an Allis or Ochsner forceps and tipped upward to enable its attachment to the coccyx to be severed more readily.
18. Electrodissection is used. The levator ani muscle is exposed; while the finger of the surgeon is held beneath it, it is divided as far from the rectum as possible.
19. All bleeding points are clamped and tied. The Foley catheter allows the surgeon to get as close to the bladder as possible without damaging it.
20. After the anococcygeal raphe is divided, the surgeon's hand is thrust up into the hollow sacrum to free the rectum by blunt dissection, grasp the upper end of the distal fragment, and deliver the stump through the perineum.
21. Drains may be placed into the pelvic cavity and exteriorized through stab wounds in the buttocks (Figure 10-32, *D*).
22. The surgeon is regowned and regloved before returning to the abdominal wound. When all bleeding is controlled, the incision is closed.

If two teams are not available for synchronous excision of the perineum, the perineal portion of the operation is performed after the abdominal resection is complete. In this case, the abdomen is closed and the remaining rectosigmoid stump is excised perineally.

Ileoanal Endorectal Pull-through

Ileoanal endorectal pull-through is removal of the entire colon and the proximal two thirds of the rectum. It includes a mucosectomy of the remaining distal rectum, creation of a pouch from the distal small bowel, and anastomosis of the pouch to the anus. The operation is performed to relieve ulcerative colitis and familial polyposis (e.g., diarrhea, pain, cramping, bleeding) and to prevent colon cancer in high-risk individuals. This procedure is an anal sphincter–saving operation that is done to avoid the need for ileostomy.

Procedural Considerations. The patient is usually positioned in modified lithotomy. Some surgeons prefer to perform the mucosectomy with the patient in jackknife position and then place the patient in modified lithotomy position for the remainder of the procedure. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before the abdominal skin prep.

A GI instrument set, a perineal set, rectal instrumentation, and a self-retaining retractor system are used. Separate instrument tables are prepared for the rectal and abdominal approaches. Additional draping and gowning are needed because redraping and regowning occur after the mucosectomy and after the ileoanal anastomosis. An epinephrine solution should be available for injection into the submucosal tissue, proximal to the anus, to separate the mucosa from the muscularis layer. A proctoscope is available as it may be used at the conclusion of the procedure to check for leaks. Air is pumped into the scope, which is inserted into the anus. The surgeon at the abdominal site looks for air bubbles. If there are none, the anastomosis has no leaks. An ileostomy appliance is applied immediately postoperatively.

Operative Procedure

1. The anal canal is dilated and inspected through an anoscope.
2. Starting at the dentate line (the anorectal junction), epinephrine solution is injected circumferentially, separating the mucosa from the muscularis layer.
3. The mucosectomy is then performed by making a circular incision at the dentate line, cutting only through mucosa.

4. The mucosa is peeled off the muscularis tissue for a distance of 2 to 8 cm and resected.
5. When all bleeding is controlled, the patient is repositioned, if necessary, for the abdominal approach.
6. A midline incision is made, and the abdomen is explored.
7. The entire large intestine from the ileocecal junction through the upper two thirds of the rectum is freed and immobilized. All vessels are ligated.
8. The terminal ileum is separated from the cecum using a mechanical cutting and stapling device (GIA).
9. The mesocolon is ligated using suture ligatures or a ligating, dividing, and stapling (LDS) instrument.
10. The rectum is resected down to the level of the mucosectomy. The colon and resected portion of the rectum are removed en bloc.
11. The pouch is created. Most surgeons use either the J pouch or the S pouch.
12. The J pouch (Figure 10-33) is created at the terminal ileum by folding two adjacent loops of small bowel, approximately 10 to 15 cm each, parallel with each other and anastomosing them using a GIA. An opening is made at the bottom of the pouch, and the pouch is pulled through the rectal stump. The bottom of the pouch is anastomosed to the anus with interrupted absorbable sutures.

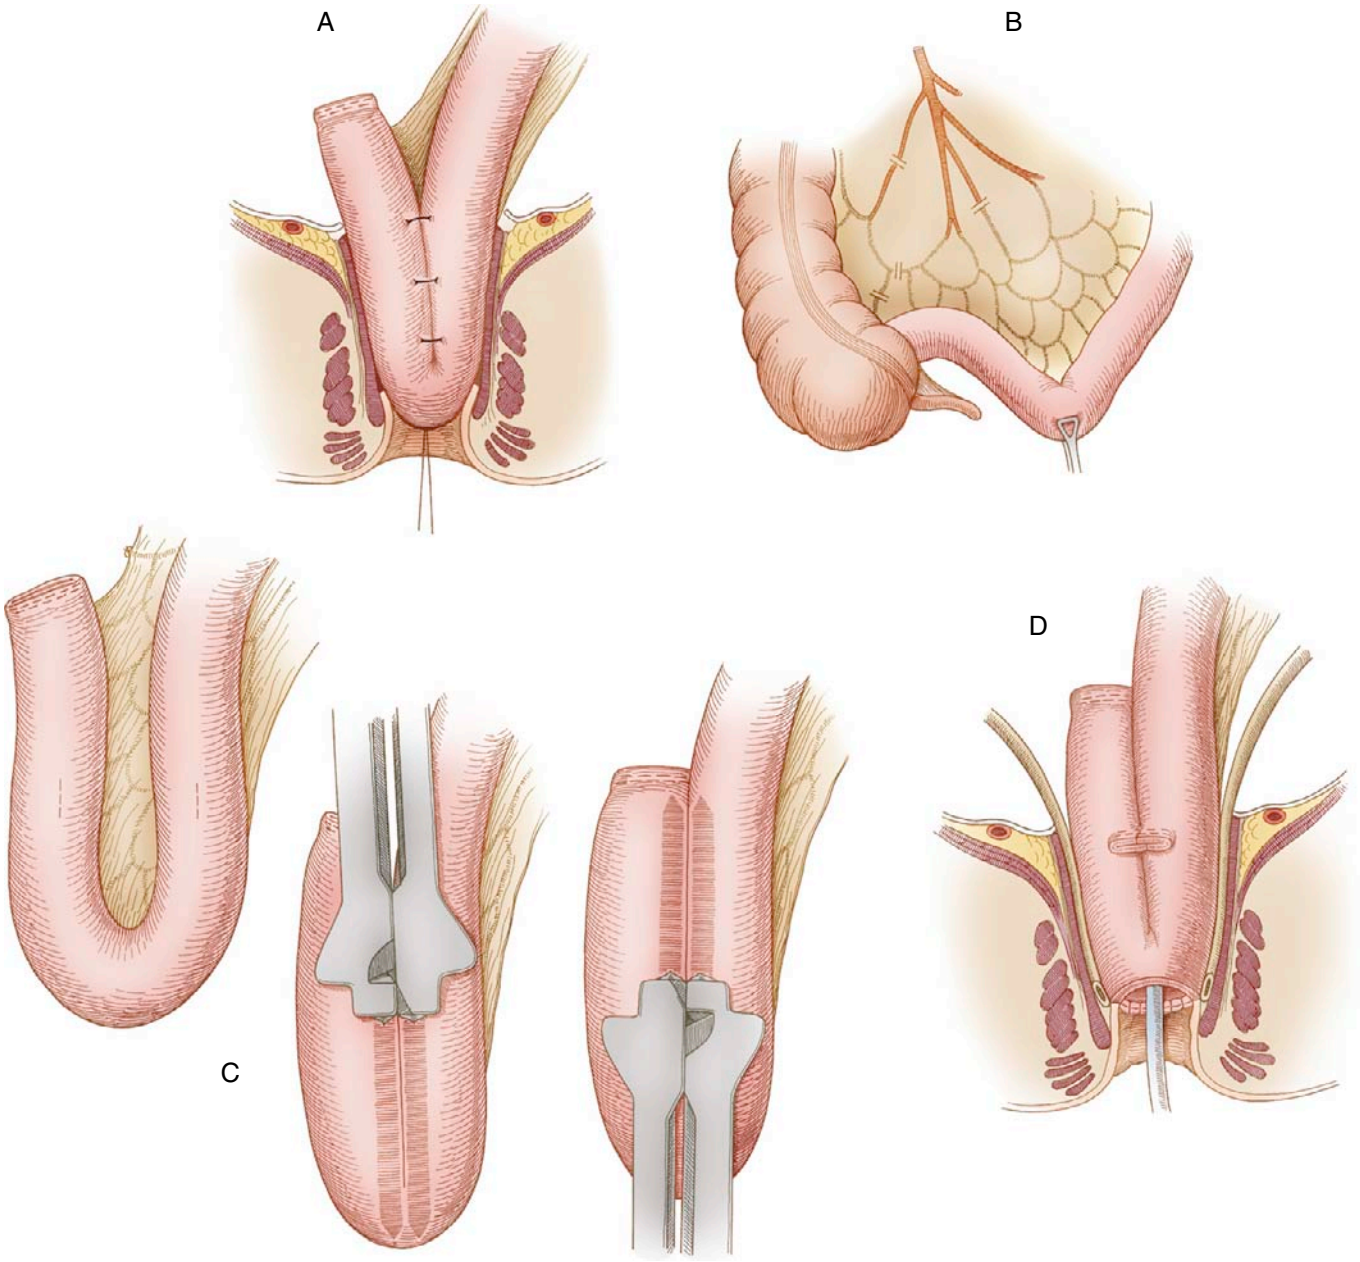

FIGURE 10-33 J pouch for ileoanal endorectal pull-through. **A**, The J pouch is created at terminal ileum by folding two adjacent loops of small bowel, approximately 10 to 15 cm each, parallel to each other. **B**, Mesenteric vascular arcades may need to be divided to provide adequate length for anal anastomosis. **C**, The two loops are anastomosed using a mechanical cutting and stapling device (GIA). **D**, Opening is made at bottom of pouch, and pouch is pulled through rectal stump. Bottom of pouch is anastomosed to anus.

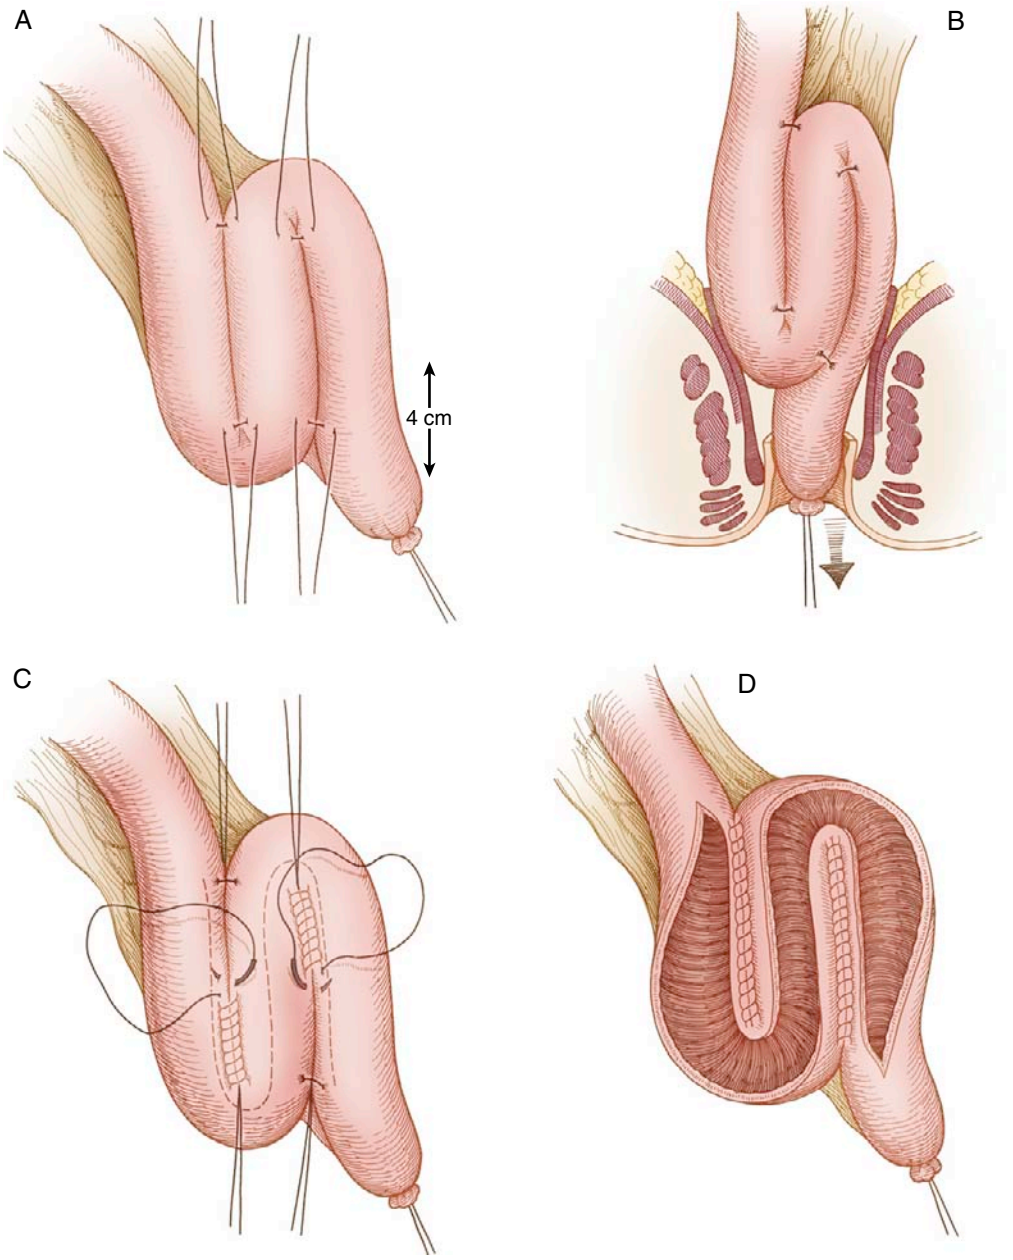

FIGURE 10-34 S pouch for ileoanal endorectal pull-through. **A**, Pouch is created by aligning distal ileum in S configuration with each limb (three in total) approximately 12 cm in length. **B**, The length is measured before anastomosis begins. **C**, Three limbs are incised and anastomosed to create pouch. **D**, Incision is made as illustrated.

13. A Y pouch (Figure 10-34) is created by aligning the distal ileum in an S configuration with each of the three limbs approximately 10 cm in length. The most distal 2 cm of the ileum is not incorporated into the pouch but is preserved for the anastomosis to the anus. The three limbs are manually incised and anastomosed to create a pouch. Mucosal tissue is approximated with absorbable suture; nonabsorbable suture is used for the serosal layer. The preserved distal end of the ileum and the pouch are pulled through the rectal stump and anastomosed to the anus. This completes the anal portion of the procedure.

14. The scrub team changes gowns and gloves, redrapes, and completes the abdominal procedure by creating a loop ileostomy through the abdominal wall, on a previously designated site.

SURGERY OF THE RECTUM

Hemorrhoidectomy

Hemorrhoidectomy is excision and ligation of dilated veins in the anal region to relieve discomfort and to control bleeding. Hemorrhoidectomy is an ambulatory surgery procedure undertaken with the application of sclerotherapy, heater probe coagulation, monopolar or bipolar coagulation, laser, infrared energy coagulation, or

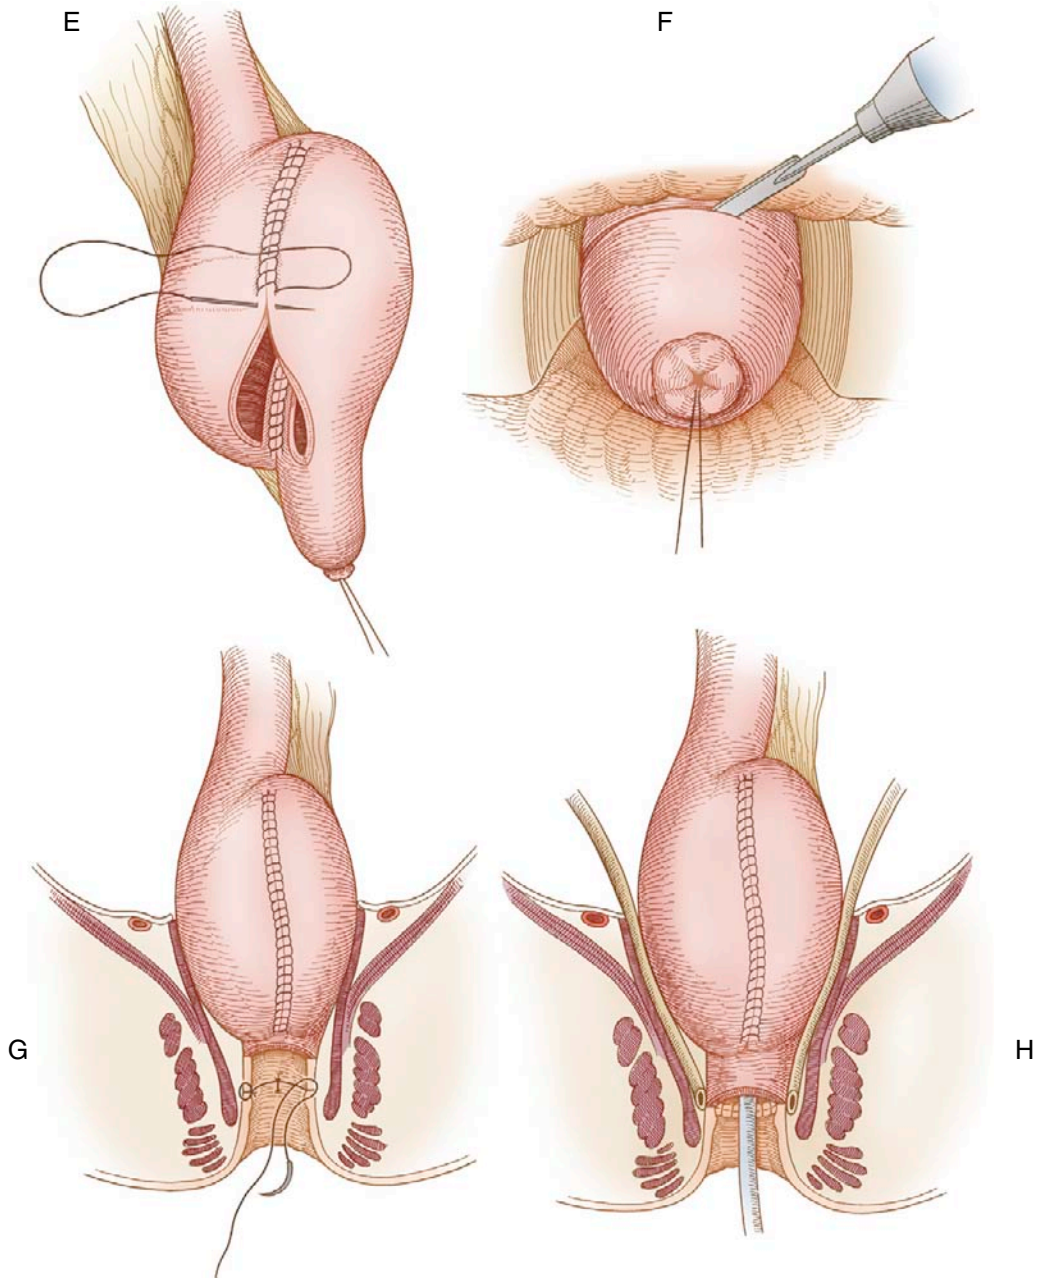

FIGURE 10-34, cont'd **E**, The pouch is closed using suture for the formation of the reservoir. **F**, Distal ends of ileum and pouch are pulled through the rectal stump, and the lower outflow tract is trimmed. **G**, With 3-0 absorbable sutures, the outflow tract is anastomosed to the anus at the dentate line. **H**, Drain in place in the lumen of the newly created ileoanal-rectal canal.

Doppler-guided hemorrhoidal artery ligation (Acheson and Scholefield, 2008). Rubber band ligation is done through an anoscope without sedation in an office or endoscopy setting. Larger symptomatic external and internal hemorrhoids that do not respond to conservative medical treatment are managed with surgery. This patient is at risk for hemorrhoid prolapse, strangulation, thrombosis, and possible ulceration and fistula formation. Surgical treatment aims to coagulate, seal, and excise the hemorrhoid, leaving sufficient anal mucosa surface to minimize pain and prevent stenosis or stricture. Various coagulation, vaporization, and tissue-welding technologies offer successful outcomes. Radiofrequency tissue/fusion energy (LigaSure, Valleylab, Inc.) is a unique form of electrocoagulation that provides hemostasis and sealing by fusing collagen in vessel walls. A specific stapling device may also be used (stapled hemorrhoidectomy; stapled anopexy).

Procedural Considerations. Preoperative anal dilation aids in exposing the vessels and contributes to the patient's comfort in the immediate postoperative period. Many surgeons prefer to precede the operation with a sigmoidoscopy. Spinal, caudal, epidural, or local anesthesia may be used. The patient is usually placed in lithotomy or jackknife position. Postoperative complications include hemorrhage, pain, constipation, fecal impaction, infection, and urinary retention.

Operative Procedure

1. The anal canal is dilated and inspected through an anoscope.
2. Four Allis forceps are applied several centimeters from the anal margin to expose the anus.
3. The base of the hemorrhoid and tissue are grasped with Allis forceps and held.
4. A 2-0 synthetic absorbable intestinal suture is placed and tied at the proximal end of the hemorrhoid, and a Buie Pile forceps is applied across the base and above the proposed incision line.
5. Excision is completed with a scalpel. Coagulation and excision may also be done with monopolar or bipolar electrosurgery, laser vaporization, infrared energy, radiofrequency fusion/ligation, cryotherapy, or even heater probe coagulation. Care is directed toward preserving the rectal sphincter.
6. Loosely placed continuous sutures are placed over the Buie Pile forceps. The suture is tightened as the forceps are removed, and the suture ends are then tied.
7. Traction may be maintained as hemostatic forceps are applied and dissection is completed segmentally.
8. 2-0 synthetic absorbable suture ligatures are used as each hemostat is removed.
9. Remaining hemorrhoids are excised in a similar manner.
10. Petrolatum gauze packing may be placed in the anal canal.

Excision of Pilonidal Cyst and Sinus

Excision of a pilonidal cyst and sinus is removal of the cyst with sinus tracts from the intergluteal fold on the posterior surface of the lower sacrum (Figure 10-35). A pilonidal cyst and sinus, which may be congenital in origin, rarely become

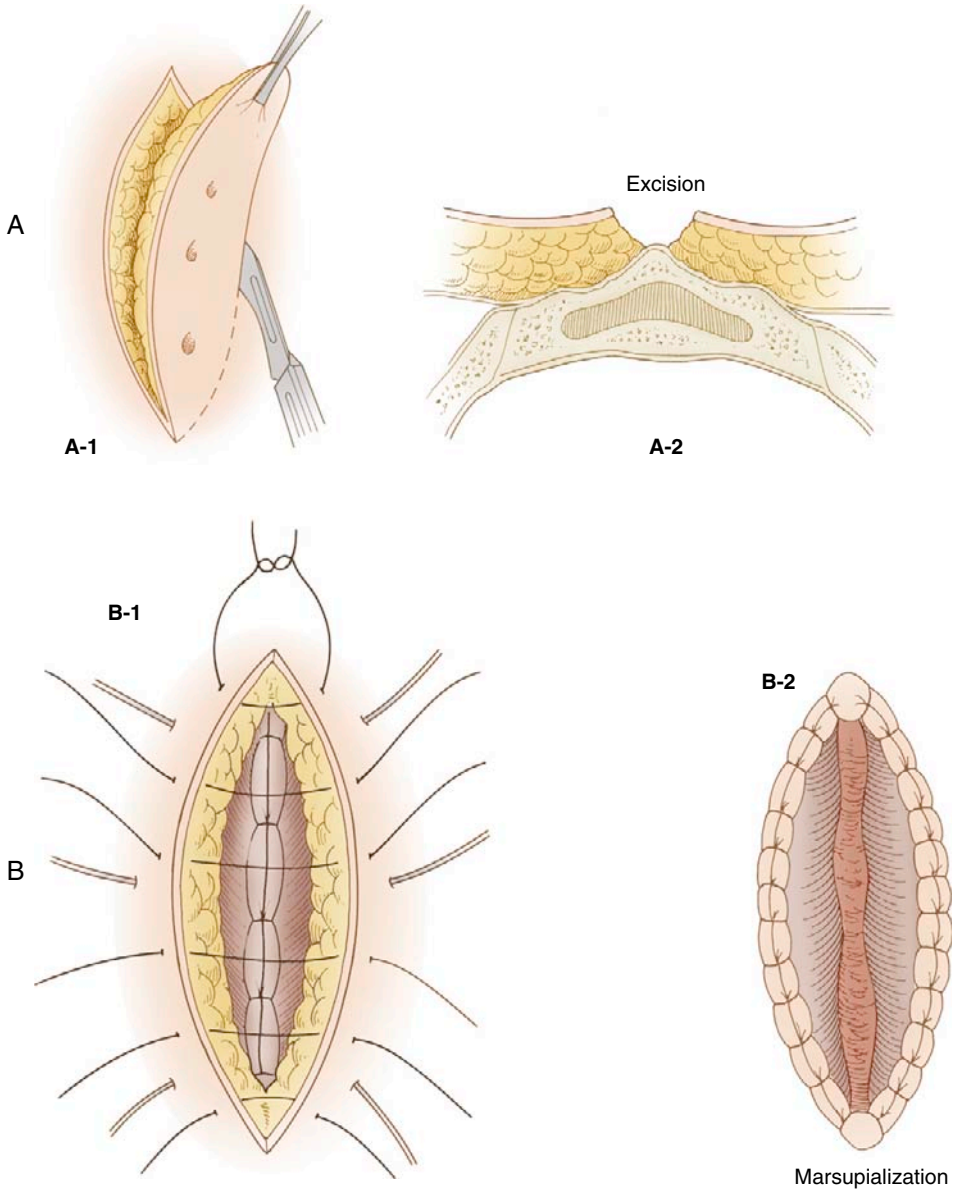

FIGURE 10-35 Pilonidal cyst. The pilonidal sinus tract is identified with injection of methylene blue into the tract. **A**, Wide elliptic incision (*A-1*) is made to include all the subcutaneous tracts and tissue that are part of the fascia overlying the sacrum and coccyx (*A-2*). **B**, Closure of the wound can be primary (*B-1*) or secondary (*B-2*).

symptomatic until the individual reaches adulthood, most commonly in young men. Inflammatory reaction varies from a mild, irritating, draining sinus tract to a painful, acute abscess with secondary recurrences. Treatment consists of drainage in the acute stage and total surgical excision during remission.

Excision of the cyst and sinus tracts must be complete to prevent recurrence. The defect resulting from recurrences may become too large for primary closure. In this case the wound is left open to heal by granulation.

Procedural Considerations. A minor set and rectal instruments are required, as well as methylene blue, a 10- or 20-ml syringe, and a blunt-tipped needle. The patient is placed in jackknife position with the buttocks taped open laterally and secured to the sides of the OR bed.

Operative Procedure

1. The sinus tracts are identified with probes and an incision made over the probe.
2. The tract is marked by injecting methylene blue with a blunt needle.
3. An elliptic incision is made down to the fascia.
4. A curette is used to remove granulation tissue.
5. Excision of cyst and sinus tracts is completed. Bleeding is controlled.
6. If the wound is to be left open, it is packed and a pressure dressing applied.
7. If the wound is closed, 2-0 nonabsorbable sutures are used for stay sutures on the deeper tissue and fine nonabsorbable suture is used on skin.

CHAPTER 11

Surgery of the Liver, Biliary Tract, Pancreas, and Spleen

JANICE A. NEIL

A pathologic condition in the liver, biliary tract, pancreas, or spleen often requires surgical intervention. These organs are highly vascular and control many metabolic and immune functions of the body. Surgical intervention may be indicated for infection, cystic anomalies, congenital anomalies, metabolic diseases, trauma (see Chapter 27), or malignancy. Many new cases of malignancy of the pancreas, gallbladder, or extrahepatic biliary tract are diagnosed each year and the prognosis for these is often poor (Steer, 2008; Chari and Shah, 2008). Pancreatic cancer remains the fourth leading cause of death in the United States (McPhee et al, 2007). In the past decade, surgeries of the liver and biliary tract have become more advanced as research and new technology permit more complete diagnoses of pathologic conditions. A resection of the liver for carcinoma has achieved a recognized role for cure or substantial palliation with safety and low morbidity.

Cholecystectomy is the most common, nonemergency abdominal operation performed. In the United States more than 750,000 cholecystectomies are performed each year. It is one of the most frequently performed inpatient procedures in the United States (Afdhal and Vollmer, 2008; Chari and Shah, 2008). Laparoscopic cholecystectomy has become the gold standard surgical intervention for the treatment of cholecystitis. Since the early 1990s, laparoscopic cholecystectomy, as compared with open-incision cholecystectomy, has resulted in reduced trauma to tissues as well as shorter postoperative recoveries, both distinct advantages. About 94% of cholecystectomies are elective surgeries while the remainder are emergencies (Afdhal and Vollmer, 2008). Laparoscopic cholecystectomies were the precursor to numerous abdominal procedures now performed or assisted with the laparoscope. Current innovations in cholecystectomy are focusing on removal of the gallbladder through a natural orifice (referred to as NOTES, or natural-orifice transluminal endoscopic surgery) (Ramos et al, 2008).

New diagnostic technology and the intraoperative use of ultrasonography, biliary endoscopy, and radiography have enabled surgeons to better treat diseases of the biliary tract. Solid organ transplantation (History box), such as for the liver, pancreas, and kidneys, has become common as a means to treat primary hepatic tumors, end-stage liver disease, and insulin-deficient diabetes. Liver transplant procedures have advanced to include entire organ transplants as well as living-related organ donations.

This chapter explores the most common open and minimally invasive procedures performed on the liver, biliary tract, pancreas, and spleen.

Surgical Anatomy

The liver is in the right upper quadrant of the abdominal cavity, beneath the dome of the diaphragm and directly above the stomach, duodenum, and hepatic flexure of the colon. The external covering, known as *Glisson's capsule,* is composed of dense connective tissue. The visceral peritoneum extends over the entire surface of the liver, except at the point of posterior attachment to the diaphragm. This connective tissue branches at the porta hepatis into a network of septa that extends into an intrahepatic network of support for the more than 1 million hepatic lobules. The porta hepatis is located on the inferior surface of the liver and provides entry and exit for the major vessels, ducts, and nerves. The hepatic artery maintains the arterial blood supply, while venous blood from the stomach, intestines, spleen, and pancreas travels to the liver by the portal vein and its branches (Figure 11-1). The hepatic venous system returns blood to the heart via the inferior vena cava.

Lobules are the functional units of the liver. Each lobule contains a portal triad that consists of a hepatic duct, a hepatic portal vein branch, and a branch of the hepatic artery, nerves, and lymphatics. A central vein is located in the center of each lobule and provides venous drainage into the hepatic veins.

Lobules also contain hepatic cords, hepatic sinusoids, and bile canaliculi. The hepatic cords consist of numerous columns of hepatocytes—the functional cells of the liver. The hepatic sinusoids are the blood channels that communicate among the columns of hepatocytes. The sinusoids have a thin epithelial lining composed primarily of Kupffer cells—phagocytic cells that engulf bacteria and toxins. The sinusoids drain into the central vein.

Bile is manufactured by the hepatocytes. The bile canaliculi are tiny bile capillary vessels that communicate among the columns of hepatocytes. The bile canaliculi collect and transport bile to the bile ducts in the portal triad of each lobule, from which bile then flows into the hepatic ducts at the porta hepatis. These ducts join immediately to form one common hepatic duct that merges with the cystic duct from the gallbladder to form the common bile duct (Figure 11-2). The common bile duct opens into the duodenum in an area called the *ampulla,* or *papilla of Vater,* located about 7.5 cm below the pyloric opening from the stomach.

Bile contains bile salts, which facilitate digestion and absorption, and various waste products. The liver is essential in the metabolism of carbohydrates, proteins, and fats. It metabolizes

HISTORY

Solid Organ Transplant

In the eighteenth century, researchers experimented with solid organ transplants on animals and humans. Transplant science evolved after many trials and failures. Important medical breakthroughs, such as surgical technique, tissue typing, immunology, immunosuppressant drugs, and organ preservation, have permitted more success in the viability of organs and longer survival rates for transplant recipients. The following is a summarized timeline of significant "firsts" and milestones in the evolution of solid organ transplant surgery, an often clinically effective and life-saving strategy for patients with end-stage organ failure.

Year	Breakthrough
1954	The first successful kidney transplant Dr. Joseph E. Murray, Brigham & Women's Hospital, Boston, Massachusetts
1963	The first lung transplant Dr. James Hardy, University of Mississippi, Oxford, Mississippi
1966	The first simultaneous pancreas/kidney transplant Dr. Richard Lillehei, William Kelly, University of Minnesota, Minneapolis, Minnesota
1967	The first successful liver transplant Dr. Thomas Starzl, University of Colorado Health Sciences Center, Denver, Colorado
1968	The first isolated pancreas transplant Dr. Richard Lillehei, University of Minnesota, Minneapolis, Minnesota
1968	The first successful heart transplant in the United States Dr. Norman Shumway, Stanford University Hospital, Stanford, California
1981	The first successful heart/lung transplant Dr. Bruce Reitz, Stanford University Hospital, Stanford, California
1983	The first successful lung transplant Dr. Joel Cooper, Toronto Lung Transplant Group, Toronto General Hospital, Toronto, Canada
1986	The first successful double-lung transplant Dr. Joel Cooper, Toronto Lung Transplant Group, Toronto General Hospital, Toronto, Canada
1989	The first living-related liver transplant Dr. Christoph Broelsch, University of Chicago Medical Center, Chicago, Illinois
1990	The first successful living-related lung transplant Dr. Vaughn A. Starnes, Stanford University Medical Center, Stanford, California
1992	The first baboon-to-human liver transplant The University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
1992	The first pig-to-human liver transplant Cedars-Sinai Medical Center, Los Angeles, California
1993	The first successful living-related lung lobes transplant (one from each of the recipient's parents) University of Southern California, Los Angeles, California
2002	The first uterus transplant took place in Saudi Arabia. The transplanted organ remained viable for 99 days. The intent of the transplant is to make childbirth possible for women who have undergone hysterectomies; the transplant would be temporary—the uterus would be removed once the baby was born to prevent ongoing administration of antirejection drugs
2005	The first partial face transplant, Amiens, France
2008	First partial face transplant in United States, The Cleveland Clinic, Cleveland, Ohio
2009	First simultaneous face-and-hand transplant, Paris, France. The upper half of the face, including the scalp, forehead, nose, ears, and upper and lower eyelids, was transplanted

nutrients into stores of glycogen, used for regulation of blood glucose levels and as energy sources for the brain and body functions.

The liver plays several important roles in the blood-clotting mechanism. It is the organ that synthesizes plasma proteins, excluding gamma globulins but including prothrombin and fibrinogen. Vitamin K, a co-factor to the synthesis of prothrombin, is absorbed by the metabolism of fats in the intestinal tract as a result of bile formation by the liver. Patients with liver disease may have altered blood-coagulation abilities.

The liver also synthesizes lipoproteins and cholesterol. Cholesterol is an essential component of the blood plasma. It serves as a precursor for bile salts, steroid hormones, plasma membranes, and other specialized molecules. A diet high in cholesterol reduces the amount that must be synthesized by the liver. When the diet is deficient in cholesterol, the liver increases synthesis to maintain levels necessary for production of vital chemical molecules.

The liver also serves in the metabolic alteration of foreign molecules or biotransformation of chemicals. The microsomal enzyme system (MES) plays a major role in the body's response to foreign chemicals, such as pollutants, drugs, and alcohol. Patients with liver disease may have an altered response to chemical substances. This consideration is important in the

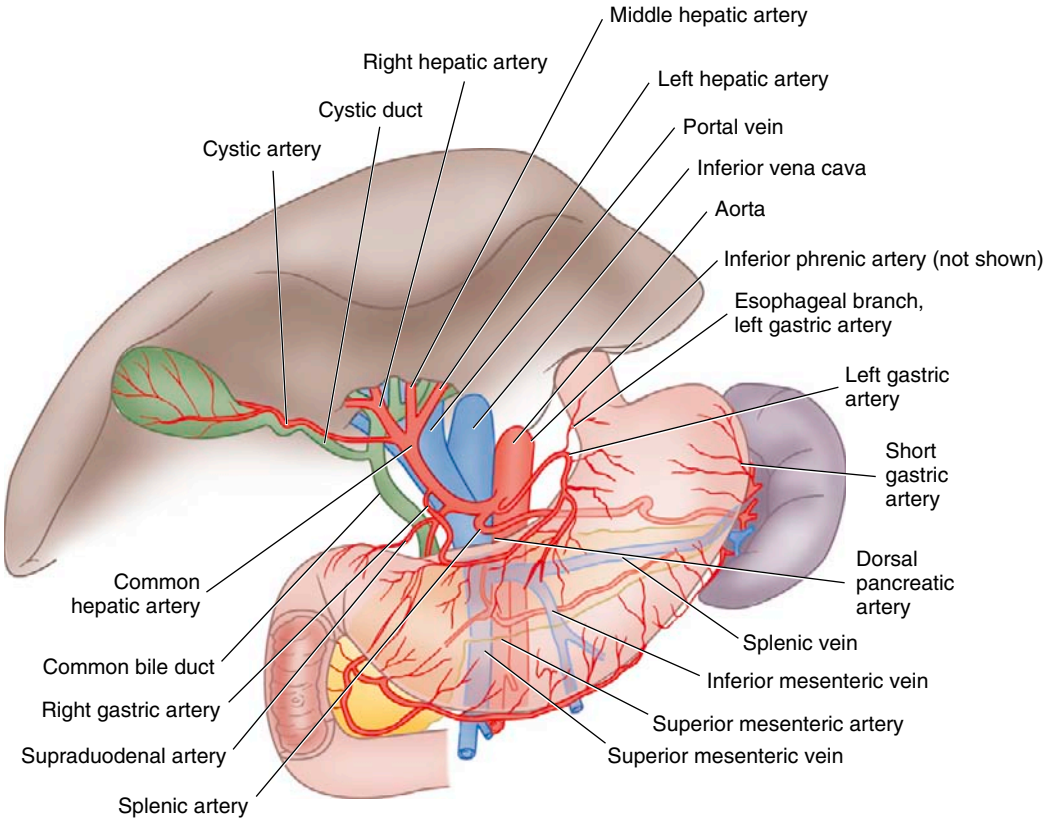

FIGURE 11-1 Intricate relationships of the arterial and venous blood supply of the liver, gallbladder, pancreas, spleen, and the biliary ductal system.

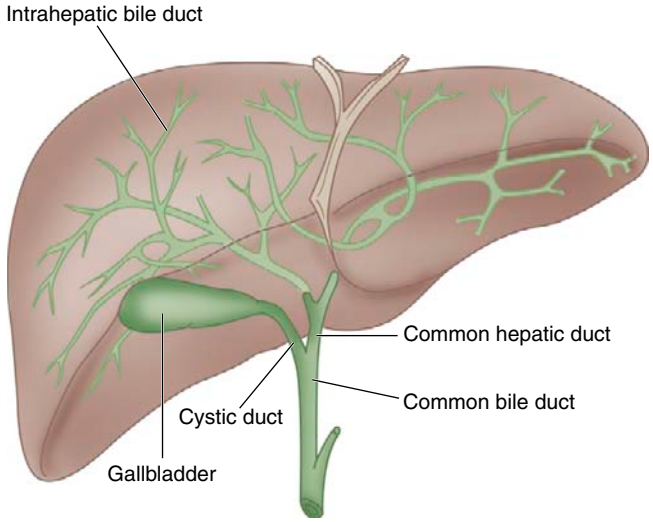

FIGURE 11-2 Biliary system can be divided into three anatomic areas: the intrahepatic bile duct, the extrahepatic bile duct (common hepatic and common bile ducts), and the gallbladder and cystic duct.

induction and management of general anesthesia for patients with liver disorders.

The gallbladder, which lies in a sulcus on the undersurface of the right lobe of the liver, terminates in the cystic duct (Figure 11-3). This ductal system provides a channel for the flow of bile to the gallbladder, where it becomes highly concentrated during storage. The liver produces about 600 to 1000 ml of bile each day. The gallbladder's average storage capacity is 40 to 70 ml. As foods, especially fats, are ingested, the duodenal cells release cholecystokinin. As the musculature of the gallbladder contracts, bile is forced into the cystic duct and through the common duct. As the sphincter of Oddi in the ampulla of Vater relaxes, bile is released, flowing into the duodenum to aid in digestion by emulsification of fats. The gallbladder receives its blood supply from the cystic artery, a branch of the hepatic artery. The triangle of Calot contains the cystic artery (and possibly the right hepatic artery); it is an anatomic landmark in surgical removal of the gallbladder. Its boundaries may be remembered as "the *3 Cs*": *C*ystic duct, *C*ommon hepatic duct, and *C*ystic artery (Chari and Shah, 2008). Innervation for the gallbladder and biliary tree is controlled by the autonomic nervous system. Parasympathetic innervation stimulates contraction, whereas sympathetic innervation inhibits contraction.

The pancreas (see Figure 11-3) is a fixed structure lying transversely behind the stomach in the upper abdomen. The head of the pancreas is fixed to the curve of the duodenum. Blood is supplied to the pancreas and the duodenum from the celiac axis and superior mesenteric artery (Figure 11-4). The body of the pancreas lies across the vertebrae and over the superior mesenteric artery and vein. The tail of the pancreas extends to the hilum of the spleen. In total, the pancreas extends about 25 cm. Pancreatic secretions containing digestive enzymes are collected in the pancreatic duct, or duct of Wirsung, which joins with the common bile duct to enter the

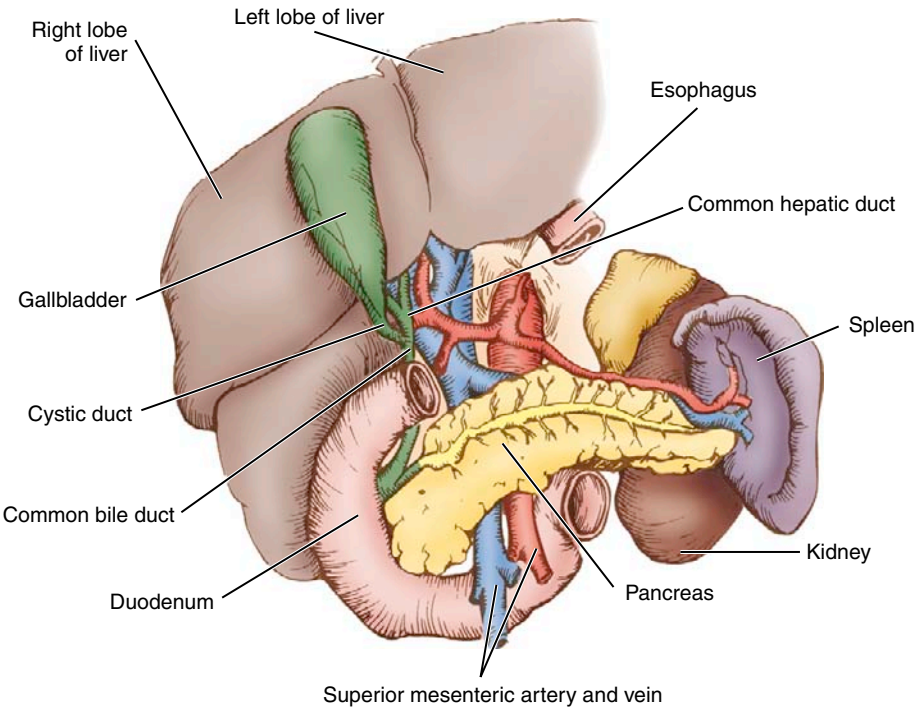

FIGURE 11-3 Gallbladder and surrounding anatomy.

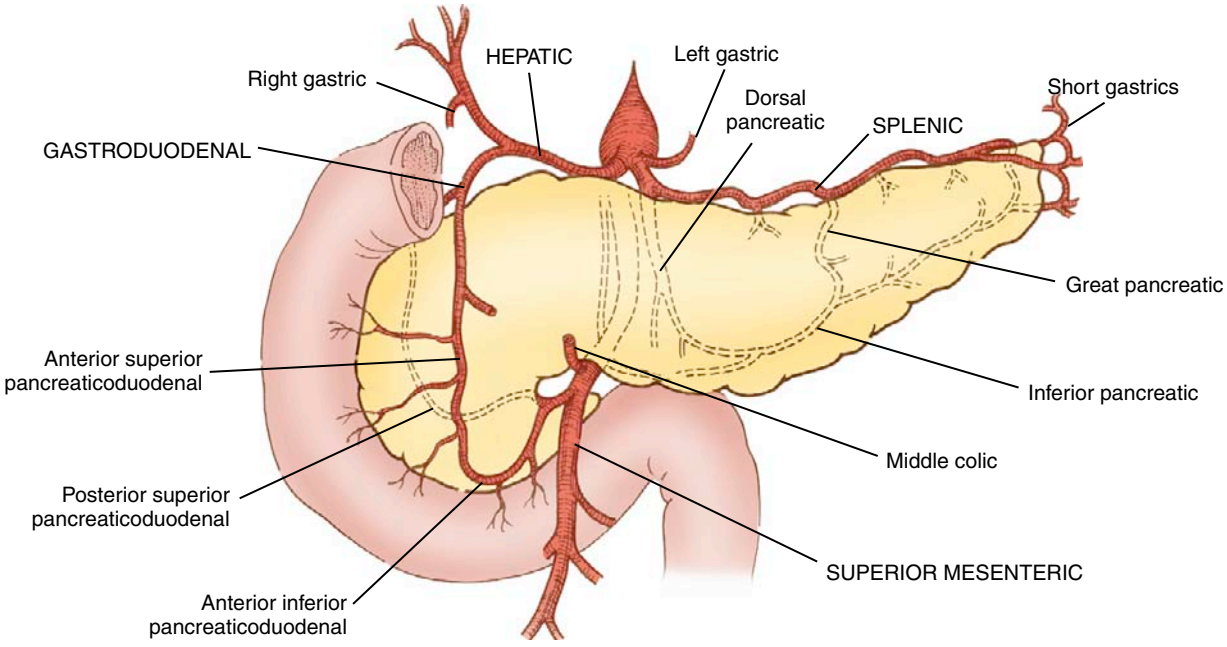

FIGURE 11-4 Arterial supply to the pancreas arises from the celiac axis (hepatic and splenic arteries) and the superior mesenteric artery. The blood supply to the head of the gland is by way of the pancreaticoduodenal (anterior and posterior) arcades, which arise from the gastroduodenal artery (superior) and superior mesenteric arteries (inferior).

duodenum about 7.5 cm below the pylorus. The dilated junction of the two ducts at the point of entry forms the ampulla of Vater.

The pancreas also contains groups of cells, called *islets,* or *islands, of Langerhans,* that secrete hormones into the blood capillaries instead of into the duct. These hormones are insulin and glucagon, and both are involved in carbohydrate metabolism.

The spleen (Figure 11-5) is in the upper left abdominal cavity, with full protection provided by the tenth, eleventh, and

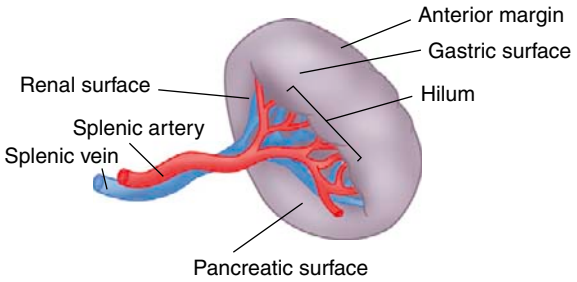

FIGURE 11-5 Spleen.

twelfth ribs; its lateral surface is directly beneath the dome of the diaphragm. The anterior medial surface is in proximity to the cardiac end of the stomach and the splenic flexure of the colon. The spleen is covered with peritoneum that forms supporting ligaments. The splenic artery, a branch of the celiac axis, furnishes the arterial blood supply. The splenic vein drains into the portal system.

The spleen has many functions. Among them are defense of the body by phagocytosis of microorganisms, formation of nongranular leukocytes and plasma cells, and phagocytosis of damaged red blood cells. It also acts as a blood reservoir.

Perioperative Nursing Considerations

Assessment

The patient with hepatobiliary disease may have extreme jaundice, urticaria, petechiae, lethargy, and irritability. Depending on the extent of the disease, bleeding and coagulation times may be increased and the platelet count decreased, contributing to intraoperative concerns with achieving hemostasis. A thorough nursing history is necessary for proper assessment of the health status of patients with dysfunctions of the hepatobiliary system, pancreas, or spleen. Assessment should include data about the patient's history of chronic disease, current medications, perceptions of his or her disease, comfort status, nutritional status, fluid and electrolyte balance, bowel and elimination patterns, energy level and independence, and exposure to toxins. Many industrial compounds are toxic to the liver (Table 11-1).

Establishing an objective database for a person with hepatobiliary or pancreatic dysfunction requires particular attention to characteristic signs of organ dysfunction. Increased abdominal girth and distention, palmar erythema, distended periumbilical veins, hemorrhagic areas, spider nevi, muscle wasting, and dry mucous membranes are some characteristic signs and symptoms. Vascular volume can be assessed by noting vital signs, including any orthostatic changes, skin turgor, temperature, appearance, and weight gain or loss. Physical examination of the patient's abdomen should include palpation and percussion to evaluate tenderness, ascites, and organ enlargement.

Common laboratory tests to assess liver function are those that evaluate fat metabolism, protein metabolism, blood coagulation properties, bilirubin metabolism, and antigens and antibodies of hepatitis (Table 11-2). Common tests of pancreatic function can be found in Table 11-3. Radiographic studies commonly used to evaluate function of the liver, pancreas, and spleen include abdominal examination, upper gastrointestinal (GI) series, ultrasound studies, computerized tomography (CT) scan, radioisotope scanning, nuclear magnetic resonance imaging (MRI), angiography, cholecystography, and cholangiography. State-of-the-art imaging includes contrast-enhanced MRI, MR cholangiopancreatography (MRCP), endoscopic ultrasound (EUS), and high-resolution, thin-section spiral CT for imaging pancreatic and biliary structures. In addition, fluorodeoxyglucose positron emission tomography (FDG-PET) is a whole-body technique that can detect metastases, recognition of which may change surgical management (Chari and Shah, 2008).

Endoscopy and biopsy are more invasive diagnostic procedures that may be used to evaluate the liver, pancreas, and spleen. Endoscopic retrograde cholangiopancreatography (ERCP) (Figure 11-6) allows direct visualization of the biliary tract, injection of radiographic dye into the ductal system, and biopsy when indicated. Percutaneous transhepatic cholangiography (PTC) uses percutaneous insertion of a long flexible needle into a bile duct of the liver. Contrast medium is injected and serial x-ray examination is performed. Arteriography of the liver, biliary tree, pancreas, and spleen requires femoral arteriotomy and placement of a catheter into the celiac branch of the abdominal aorta under fluoroscopic visualization. Contrast medium is then injected and serial x-ray examination allows the vessels to be visualized during the perfusion and drainage phases.

EVIDENCE FOR PRACTICE

Monitoring Mycophenolic Acid: A Method to Detect Rejection in Solid Organ Transplants

Although solid organ transplants are commonly performed, complications occur, the most common and significant being infection and acute graft rejection. In light of the significance of rejection, this review sought evidence for the utility of monitoring concentrations of mycophenolic acid (MPA) in patients who receive solid organ transplants to answer three questions: (1) if such monitoring resulted in a lower incidence of transplant rejections and adverse events versus no monitoring of MPA; (2) whether the incidence of rejection or adverse events differs according to dose, frequency, type of MPA, the form of MPA monitored, the method of MPA monitoring, or sample characteristics; and (3) whether such monitoring is cost-effective. A number of database searches were conducted. Each of the studies selected from the database search was abstracted according to select criteria, two of which were study design (i.e., randomized, controlled trial [RCT], observational study with comparison group, or case series) and patient receipt of allograft solid organ transplant. To be included in the search for evidence, any form of MPA had to be measured in the study at least once (plasma or serum, using any method of measurement). MPA measurement needed to be linked in the study to transplant rejection.

The results were inconclusive in providing evidence for clinical practice. While the state of knowledge about therapeutic drug monitoring of MPA in solid organ transplants remains in its infancy, clinicians are advised to make monitoring decisions on a patient-by-patient basis.

Modified from *Utility of monitoring mycophenolic acid in solid organ transplant patients,* Feb 2008, available at www.ahrq.gov/clinic/tp/mpaorgtp.htm. Accessed April 1, 2009.

TABLE 11-1

Common Hepatotoxic Agents and Type of Liver Damage

Toxic Agent	Source	Liver Damage
Aflatoxin B	Moldy foods, rice, corn, cassava, oil, grain dust (during bin clean out and animal feeding in enclosed buildings)	Jaundice, fatty liver, hepatocellular carcinoma, thromboses
Amanita phalloides	Poisonous mushrooms	Centrilobular and massive necrosis
Benzene	Chemical industry, to make plastics, resins, and nylon and synthetic fibers	Fatty liver, cirrhosis
Beryllium	From x-ray tube and fluorescent lamp manufacture; alloys are used in automobiles, computers, sports equipment (golf clubs and bicycle frames)	Necrosis and granulomas
Boron, cadmium, nickel, chromium, copper	From gold smelting, plating	Liver damage, rise in levels of liver enzymes
Carbon tetrachloride	Propellants for aerosol cans, as a pesticide, cleaning fluid, degreasing agent, fire extinguishers, spot removers (now banned)	Centrilobular necrosis
Kerosene	From fuel handling	Liver damage, rise in levels of liver enzymes
Lead	Environment	Steatosis, hepatitis
Pesticides	Polyvinyl chloride, farming industry	Steatosis, angiosarcoma (liver tumors)
Phosphorus	From poisons and firecrackers	Fatty liver, necrosis, fibrosis
Toluene, xylene	Occurs naturally in crude oil	Fatty liver, fibrosis
Vinyl chloride	Used to make polyvinyl chloride (plastics; also named PVC)	Angiosarcoma (liver tumors), fibrosis

Nursing Diagnosis

After review of the nursing assessment, the perioperative nurse formulates nursing diagnoses. Nursing diagnoses related to the care of patients undergoing surgery of the liver, biliary tract, pancreas, or spleen might include the following:

- Anxiety related to impending surgical procedure, perioperative events, and surgical outcome
- Risk for Imbalanced Fluid Volume
- Hypothermia related to exposure of body surface or abdominal cavity and effects of anesthesia on thermoregulation
- Risk for Infection related to organ systems involved (portions of the GI tract)
- Risk for Perioperative Positioning Injury
- Risk for Impaired Skin Integrity related to invasion of body structures, disruption of skin surface
- Acute Pain related to surgical procedure

Outcome Identification

Statements about desired outcomes reflect nursing diagnoses identified for a patient population. Nursing diagnoses are also individualized according to cultural, ethnic, religious, and spiritual values, as well as an individual patient's status. From these are derived the outcomes the perioperative nurse wishes to achieve. The best outcome statement has specific criteria by which the perioperative nurse intends to measure whether the outcome has been met. These criteria are more meaningful when they are established in partnership with the patient. Not all outcomes will be planned with the patient, but ones relating to nursing diagnoses such as anxiety and coping can and should reflect the patient's participation. Outcomes identified for the selected nursing diagnoses might be stated as follows:

- The patient will verbalize management of anxiety and ability to cope, demonstrate knowledge of his or her psychologic responses to the planned procedure, and show an understanding of the planned sequence of perioperative events.
- The patient will maintain fluid volume equilibrium throughout the operative procedure.
- The patient will evidence an intraoperative core body temperature within the normal range (35.5° to 37.2° C; 96° to 99° F).
- The patient will be free of clinical signs and symptoms of surgical site infection (SSI).
- The patient will maintain baseline neuromuscular function and intact skin at positional pressure sites.
- The patient will demonstrate understanding of the plan to heal the incision site.
- The patient will report that the pain management regimen relieves pain to a satisfactory level (Ackley and Ladwig, 2008).

Planning

Planning for the care of the patient requires knowledge of the anatomy and subsequent physiologic complications that may occur with surgical interruption of tissues. Planning is driven by intended outcomes. The experienced perioperative nurse reflects on those intended outcomes and, using theory, science,

TABLE 11-2

Liver Battery (Liver Function Studies)

Test Name	Normal Values
SERUM ENZYMES	
Alkaline phosphatase (ALP)	30-120 units/L. Elevated levels with biliary obstruction, cholestatic hepatitis, liver disease.
Aspartate aminotransferase (AST; previously SGOT)	0-35 units/L. Elevated levels with hepatocellular injury, necrosis.
Alanine aminotransferase (ALT; previously SGPT)	4-36 units/L. Elevated levels with liver damage, acute hepatitis; AST/ALT ratio usually is higher in liver necrosis and acute hepatitis and lower in cirrhosis, chronic hepatitis, cancer of liver.
Lactate dehydrogenase (LDH)	100-190 units/L (normal value may differ with method). Elevated levels in liver disease, untreated pernicious anemia, acute myocardial infarction, renal disease, muscle disease, malignant tumors.
5-Nucleotidase	0-1.6 units at 37° C. Elevated levels may indicate hepatobiliary disease.
Leucine aminopeptidase (LAP)	Males: 80-200 units/ml. Females: 75-185 units/ml. Elevated in liver necrosis and cancer, extrahepatic biliary obstruction (stones), viral hepatitis.
γ-Glutamyltransferase (GGT), γ-glutamictranspeptidase (GGTP)	Adults ≥45 yr: 8-38 units/L; <45 yr: 5-27 units/L. Newborns: 5× higher than in adults. Elevated levels in cirrhosis, acute and chronic liver necrosis, alcoholism, acute and chronic hepatitis, liver cancer. Enzyme produced by bile ducts. Reflects rare forms of liver disease. Medications commonly cause GGTP level to be elevated. Liver toxins such as alcohol can cause increases in GGTP level.
Alpha fetoprotein	<15 ng/ml. Elevated in cirrhosis, hepatitis. May indicate liver metastases from another cancer source.
Mitochondrial antibodies	Presence of these antibodies can indicate primary biliary cirrhosis, chronic active hepatitis, certain other autoimmune disorders.
BILIRUBIN METABOLISM	
Serum Bilirubin	
Indirect (unconjugated)	0.2-0.8 mg/dl. Elevated levels with hemolysis (lysis of red blood cells) and severe liver damage.
Direct and total (conjugated)	Total: 0.3-1.0 mg/dl. Direct: 0.1-0.3 mg/dl. Newborn: 1.0-12.0 mg/dl. Elevated levels seen with intrahepatic or extrahepatic obstruction.
Urine bilirubin	Negative: 0.02 mg/dl. Bilirubin in urine may be seen with hepatic disease or biliary obstruction; only conjugated bilirubin spills into urine because unconjugated bilirubin is bound to albumin in serum and thus cannot pass glomerular membrane.
Urine urobilinogen	Random: negative or <1.0 Ehrlich unit. 2 hr: 0.3-1.0 Ehrlich unit. 24 hr: 0.5-4.0 Ehrlich units. Increased levels seen with hemolytic processes, shunting of portal blood flow.
Fecal urobilinogen	50-300 mg/24 hr. Reduced levels cause clay-colored stools and are seen in biliary obstruction.
Ammonia	Adults: 10-80 mcg/dl. Elevated levels may be seen with liver dysfunction, hepatic failure, or heart failure.
SERUM PROTEINS	
Albumin	3.5-5.0 g/dl. Decreased levels seen in liver disease.
Globulin	Reduced levels seen with hepatocellular injury test of specific proteins: Serum globulin: 2.3-3.4 g/dl Immunoglobulin M (IgM) component: 75-300 mg/dl IgG component: 650-1850 mg/dl IgA component: 90-350 mg/dl
Total	Albumin + globulin: 6.4-8.3 g/dl. Decreased levels may be seen with hepatocellular injury.
Albumin/globulin (A/G) ratio	>1.0 (albumin ÷ globulin). Low ratio in liver disease.
Transferrin	215-365 mg/dl. Reduced levels may be seen with liver damage; increased levels may be seen with iron deficiency.
BLOOD-CLOTTING FUNCTIONS	
Prothrombin time (PT)	11-12.5 sec, or 90-100% of control. Increased levels may be seen with chronic liver disease (e.g., cirrhosis) or vitamin K deficiency.
Partial thromboplastin time (PTT)	Activated partial thromboplastin time (APTT): 30-40 sec. PTT: 60-70 sec. Increased levels may be seen with severe liver disease or heparin therapy.
International Normalized Ratio (INR)	Oral coagulant therapy: 1.5-3.5 INR. Test used to monitor therapy for patients receiving warfarin sodium (Coumadin) therapy. More consistent measure than PT.

Accessed April 1, 2009; Pagana KD, Pagana TJ: *Mosby's diagnostic and laboratory test reference,* St Louis, 2009, Mosby; *Serum globulin electrophoresis,* 2005, available at www.nlm.nih.gov/medlineplus/ency/article/003544.htm. Accessed April 1, 2009.

TABLE 11-3

Tests of Pancreatic Function

Test Name	Normal Values
Serum amylase	60-120 units/dl (Somogyi method). Elevated levels are seen with acute exacerbation of chronic pancreatitis, ampulla of Vater obstruction, pancreatic duct obstruction, pancreatic cancer, acute pancreatitis, and pancreatic trauma.
Serum lipase	0-160 units/L. Elevated levels are seen with pancreatitis, renal failure, and intestinal infarction or obstruction.
Urine amylase	0-5000 Somogyi units/24 hr; 6.5-48.1 units/hr (SI units). Elevated levels are the same as for serum amylase.
Secretin-pancreozymin test	Volume: 2-4 ml/kg body weight. Assessment of exocrine secretory ability of pancreas for carcinoma, ductal obstruction, or chronic pancreatitis. Low volume may indicate obstruction.

Modified from Pagana KD, Pagana TJ: *Mosby's diagnostic and laboratory test reference,* St Louis, 2009, Mosby.

and what has been learned through experience, identifies actions required for outcome achievement (Benner et al, 2009). Principles of safe surgical positioning, maintenance of asepsis, prevention of biologic and electrical hazards, and provision of proper instrumentation and equipment are a few constituents of the plan of care that are based on theory and science and augmented by nursing experience.

A review of the nursing assessment and a patient interview provide insights as to the specific needs of the patient. The patient's medical and surgical history, as well as age, size, and nutritional status, will assist the perioperative nurse in developing an effective plan of care. A Sample Plan of Care for a patient undergoing surgery of the liver, biliary tract, pancreas, or spleen is shown on p. 365.

Implementation

Patients having surgery of the liver, biliary tract, pancreas, or spleen are usually given a general anesthetic. The following pertinent factors should be considered in caring for these patients.

Universal Protocol. The Joint Commission (TJC) requires that the "wrong site, wrong procedure, wrong person" prevention protocol be carried out before each surgical procedure (TJC, 2009). This protocol involves the following principles:

- Wrong site, wrong procedure, wrong person surgery can and must be prevented.
- Active involvement and effective communication among all members of the surgical team are required.

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Anxiety related to impending surgical procedure, perioperative events, and surgical outcome

OUTCOME
The patient will verbalize management of anxiety and ability to cope, demonstrate knowledge of his or her psychologic responses to the planned procedure, and indicate an understanding of the planned sequence of perioperative events.

INTERVENTIONS
- Greet the patient positively; determine the name he or she prefers to be called.
- Introduce the patient to the OR team.
- Avoid hasty movements or gestures of indecision.
- Speak slowly and clearly when addressing the patient, and use terminology the patient can understand.
- Offer emotional reassurance by using touch, assisting the patient to a position of comfort on the OR bed, and offering warm blankets (thermal comfort).
- Classify the patient's level of anxiety (mild, moderate, severe) by asking the patient and observing signs of anxiety (e.g., clenching/unclenching hands, crying, tremors).
- Determine the patient's personally effective coping mechanisms, and facilitate use of these.
- Identify the patient's special concerns, values, and wishes concerning his or her care.
- Provide explanations of perioperative events; encourage questions.

NURSING DIAGNOSIS
Risk for Imbalanced Fluid Volume

OUTCOME
Patient will maintain fluid volume equilibrium throughout surgical procedure.

INTERVENTIONS
- Review orders for blood/blood products; have these available in easily accessible, refrigerated storage for timely access.
- Communicate availability of blood/blood products during the preop briefing or time-out.
- Measure, communicate, and record estimated or real fluid volume loss throughout surgical procedure.
- Anticipate and communicate to blood bank personnel the potential need for additional blood and blood products.
- Collaborate with anesthesia provider in fluid replacement therapies.
- Check laboratory values intraoperatively; monitor and note deviations in study results.

NURSING DIAGNOSIS
Hypothermia related to exposure of body surface or abdominal cavity and effects of anesthesia on thermoregulation

OUTCOME
The patient will maintain an intraoperative core body temperature of 35.5° to 37.2° C (96° to 99° F).

INTERVENTIONS
- Determine thermal comfort: ask the patient if he or she is cold.
- Adjust room temperature and humidity to accommodate preservation of body temperature.
- Provide warm blankets on transfer to OR bed.
- Expose only that part of the body necessary for the surgical prep; cover all other body surfaces to maintain body heat.
- Provide warm irrigation solutions, first ensuring solution temperature is below 40.5° C (105° F).
- Collaborate with anesthesia provider in warming intravenous (IV) fluids and blood/blood products before infusion.
- Use other active warming measures (such as forced-air warming system) for preventing hypothermia.
- Monitor body temperature to evaluate response to thermoregulation measures.

NURSING DIAGNOSIS
Risk for Infection related to organ systems involved (portions of the gastrointestinal tract)

OUTCOME
The patient will be free of clinical signs and symptoms of surgical site infection.

INTERVENTIONS
- Implement aseptic technique; communicate and correct breaks in asepsis.
- Ensure that preoperative antibiotics are administered as ordered; prophylactic antibiotics should be administered 1 hour before surgical incision is made. Follow guidelines for safe medication practices.
- Contain and confine contaminants appropriately.
- Ensure that all sterilization procedures have been properly observed.
- Ensure that the integrity of sterile supply packaging is intact before dispensing items to the sterile field.
- If ordered, verify that patient has performed preoperative showers.
- Perform intraoperative skin preparation with antimicrobial agent of choice (institutional protocol).
- Implement measures to prevent cross-contamination.
- Initiate traffic control and environmental measures that reduce risk for infection.
- Use aseptic technique in applying dressings to surgical sites.
- Correctly classify wound according to established wound classification system.
- Manage culture specimen collection according to institutional policy and safe practices for specimen management.

NURSING DIAGNOSIS
Risk for Perioperative Positioning Injury

OUTCOME
The patient will maintain baseline neuromuscular function and intact skin at positional pressure sites.

INTERVENTIONS
- Identify any physiologic alterations or mobility limitations that may affect procedure-specific positioning.
- Implement measures to prevent shearing forces during patient transfer to and from OR bed and during positional changes.
- Ensure that all positioning equipment is clean and functioning properly.
- Ensure patient is in optimal anatomic alignment after induction of anesthesia.
- Adequately pad all bony prominences and vulnerable neurovascular areas.
- Secure limbs to ensure position is maintained and to prevent limb from falling from positioning device (as appropriate to procedure-specific position).
- Ensure safe and proper placement of electrosurgical dispersive pad.
- Verify correct position during time-out.

Continued

SAMPLE PLAN OF CARE—cont'd

- Ensure that no weight or stress is placed on body parts and structures during the surgical intervention.
- Check protective padding and safety restraints after all positional changes.

NURSING DIAGNOSIS

Risk for Impaired Skin Integrity related to invasion of body structures, disruption of skin surface

OUTCOME

The patient will regain integrity of skin surface.

INTERVENTIONS (POSTOPERATIVE)

- Monitor incision site for color, redness, swelling, warmth, and pain.
- Avoid positioning patient on incision site.
- Individualize plan according to patient's skin condition, needs, and preferences.
- Monitor incision edges for intactness, bleeding, and drainage.
- Maintain a moist wound healing environment that is balanced with the need to absorb exudate.

NURSING DIAGNOSIS

Acute Pain related to surgical procedure

OUTCOME

The patient will report that the pain management regimen relieves pain to a satisfactory level, using a pain assessment scale.

INTERVENTIONS (POSTOPERATIVE)

- Review use of a pain scale with the patient and family before surgery.
- Identify cultural and value components related to pain.
- Provide patient and family with information on pain management.
- Determine whether the patient is experiencing pain at the time of the initial postoperative assessment.
- Assess and document intensity and location of pain.
- Assume pain is present and treat as ordered.
- Use a preventative approach to keep pain at or below an acceptable level.

- The patient (to the extent possible) should be involved in the process.
- Consistent implementation is necessary.
- The protocol is flexible to allow for implementation with adaptation to patient needs.
- Site marking should focus on operative and other invasive procedures involving right/left distinction (laterality) and multiple structures or multiple levels.
- The protocol is adaptable to all procedures that expose patients to the risk for harm.

Proper implementation of the Universal Protocol should use the following steps:

1. Preoperative verification
   - Relevant documents and studies should be available before the start of the procedure and must be consistent with each other, with the patient's expectations, and with the team's understanding of the intended patient, procedure, and site. As applicable, any implants, special equipment or positioning devices, and availability of ordered blood/blood products must be verified. Missing information or discrepancies must be addressed before starting the procedure. This begins an ongoing process of information gathering, verification, and open team communication.
   - The signed consent should have the correct site and specific procedure documented.
   - The surgical posting should match the procedure.
   - Before receiving sedation the patient (or the patient's representative) should know and be able to state in his or her own words the name of the procedure and the site of surgery.
2. Marking the operative site
   - This is intended to identify unambiguously the intended site of incision/insertion. For procedures with right/left, multiple structures, or multiple levels, the site must show a mark that is visible after the patient has been prepped and draped. Special marking pens are available for this process. Marking pens should only be used for a single patient and then discarded.
   - The surgeon (or another licensed independent practitioner who will be present during the procedure and is ultimately accountable for the procedure) marks the site with "yes" or his or her initials. Check marks or Xs are not appropriate.
3. "Time-out" immediately before starting the procedure (the final verification of the correct patient, procedure, and site).
   - The surgical position, and, if applicable, implants and other required special items may also be verified before the incision is made. At this time, it should also be verified that any flammable prep solutions have dried (see Chapter 2 for a full discussion of fire safety and prep solutions).
   - Active communication among all members of the surgical/procedure team must be consistently initiated by a designated member of the team (usually the registered nurse). This must be conducted in a "fail-safe" mode: that is, the procedure may not be started before any questions or concerns are resolved (this is also referred to as a *hard stop*).
   - Completion of the time-out must be documented on the patient record.

Positioning the Patient. For biliary surgery, the patient is placed in supine position. Arms are placed on padded armboards with the palms up and fingers extended. Armboards are maintained at less than a 90-degree angle to prevent brachial plexus stretch. If there are surgical reasons to tuck the arms at the side, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly, but not tightly, under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail. A small positioning aid may be placed under the lower right side of the thorax to elevate the lower rib cage, providing better exposure and access to the viscera in the right upper quadrant of the abdomen. Alternatively, a lateral tilt of the OR bed may be used in combination with reverse Trendelenburg for procedures such as laparoscopic cholecystectomy.

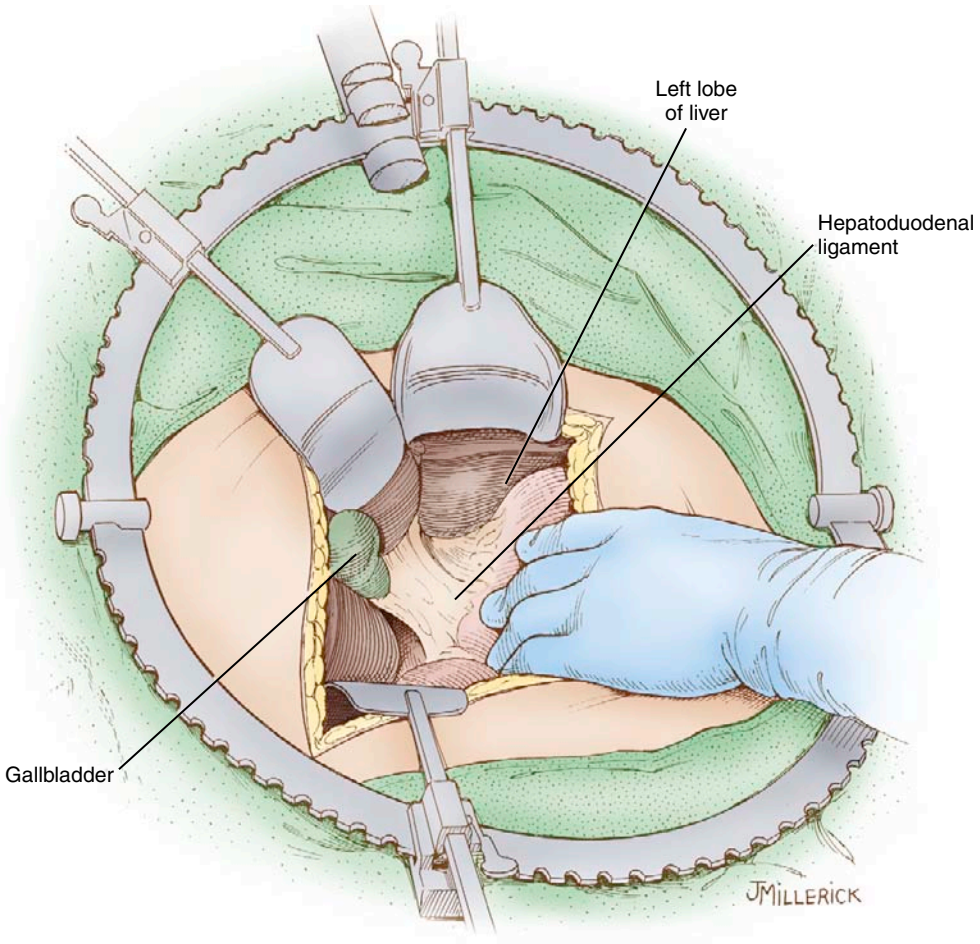

FIGURE 11-7 Bookwalter self-retaining retractor in place to provide optimal exposure to the abdominal viscera.

Positioning for laparoscopic procedures requires the perioperative nurse to exercise caution when applying safety straps. Given that the patient may be placed in a severe side tilt or reverse Trendelenburg position, safety or restraining straps must be placed securely, but not too tightly. Attention is given to proper alignment of the patient's body and extremities, and padded footboards are applied to prevent the patient from slipping. Areas of pressure in the selected surgical position (see Chapter 5) and bony prominences are padded well to prevent interruption of circulation and pressure injury to tissues and neurovascular structures. These precautions are especially important for diabetic, circulatory-impaired, immunocompromised, and elderly patients. Close monitoring of the patient is essential during positional changes, especially in laparoscopic procedures with decreased lighting in the room.

When anticipating an operative cholangiogram, the perioperative nurse must ensure that the OR bed has been equipped and positioned so that C-arm image intensification can be accomplished efficiently. Radiation-protection devices for the surgical team and patient should be available.

Thermoregulation. The risks of intraoperative hypothermia have been well documented (see Chapter 4). When laparotomy is performed, patients are at further risk for hypothermia. To prevent unplanned hypothermia, the perioperative nurse takes affirmative measures to maintain body temperature in the OR (Insler and Sessler, 2006). The environmental temperature and humidity are set to prevent body heat loss caused by evaporation and convection. A forced-air warming blanket placed over the patient's upper body, head, and neck assists in maintenance of body temperature. Minimizing body exposure to ambient air and the use of warm irrigating solutions also support thermoregulation. The temperature of irrigating fluids should be no higher than body temperature (37° C; 98.6° F) (AORN, 2009). A blood- and fluid-warming device may be used by the anesthesia provider to deliver intravenous (IV) fluids at a temperature higher than room air temperature (see Chapter 4). The anesthesia provider commonly monitors the patient's core temperature by use of an esophageal temperature probe when the duration and complexity of the surgical procedure place the patient at risk for hypothermia. Additional comfort measures include using warm blankets before and after surgery.

Application of Sequential Compression Device. Patients undergoing lengthy surgical procedures are at risk for venous dilation and blood pooling in the lower extremities. This may predispose the surgical patient to develop venous thromboembolism (VTE) in the postoperative period. Sequential

SURGICAL PHARMACOLOGY

Chemical Hemostatic Agents

Agent	Chemical Composition	Actions	Perioperative Precautions
Absorbable gelatin: powder or compressed forms (Gelfoam)	Purified porcine gelatin, beaten, dried, and heat sterilized	On areas of capillary bleeding, deposits fibrin, forming a clot. Absorbs 45× its own weight.	Dipped in warm saline or soaked in thrombin. Must be squeezed to remove air.
Absorbable collagen (Collastat, Superstat, Helistat, Lyostypt)	Bovine collagen origin	Collagen activates coagulation mechanism, aggregation of platelets.	Must be kept dry and applied with dry gloves. Do not use in infected areas or in pooled blood.
Microfibrillar collagen (Avitene, INSTAT)	Hydrochloric acid salt of purified bovine corium collagen	Promotes adhesion of platelets and prompt fibrin deposition.	Applied dry. Use firm pressure against bleeding surface.
Oxidized cellulose (Surgicel, Surgicel Nu-Knit)	Absorbable oxidation product of cellulose	On contact with blood, clot forms. Increases in size and forms gel. Absorbs 10× its own weight.	Applied dry. May be sutured in place.
Oxytocin	Synthetic pituitary hormone	Injected directly into uterine muscle during cesarean birth to cause contraction after delivery of baby and placenta. Prevents uterine hemorrhage.	Also may be given intravenously to induce labor.
Phenol and alcohol	Chemical compounds used to electrocoagulate tissue across lumen of appendix	Phenol coagulates proteins, and 95% alcohol neutralizes phenol.	Phenol is caustic and may cause severe burns.
Epinephrine (Adrenalin)	Adrenal hormone	Powerful vasoconstrictor—prolongs action of local anesthetics to decrease bleeding.	Gelatin sponges may be soaked in 1:1000 epinephrine; especially useful in ear and microsurgical procedures.
Tannic acid	Powder from astringent plant	Used on nose and throat mucous membranes to stop capillary bleeding.	Also used in dental procedures.
Silver nitrate	Crystals of silver nitrate compound mixed with silver chloride and molded onto applicator sticks	Astringent and antimicrobial. Seals areas of surgical incisions.	May also be used in treatment of burns.
Thrombin	Enzyme extracted from bovine blood	Accelerates coagulation of blood. Unites rapidly with fibrin to form clot.	May be used topically as a dry powder or as a solution in which gelatin sponges are dipped. May also be sprayed onto site. Topical use only. Loses potency after 3 hr.
Zeolite beads (QuikClot)	Derived from form of volcanic pumice	Beads cause hemostasis by absorbing water from blood.	Used for emergency hemostasis in uncontrollable bleeding or evisceration, especially in trauma. Causes an exothermic reaction. Must be removed, not biodegradable.

Modified from Phillips NF: *Berry and Kohn's operating room technique,* ed 11, St Louis, 2007, Mosby.

compression devices (SCDs) are frequently applied in the OR before commencing lengthy surgical procedures in order to prevent or minimize VTE risks.

Draping the Patient. After the abdominal prep, time must be allowed for the prep solution to dry and vapors to dissipate. This is an essential patient safety precaution when flammable prep solutions are used in conjunction with electrosurgery (or other ignition sources, such as a laser). Sterile towels are then arranged to accommodate the intended incision. A sterile drape sheet may be placed over the patient's lower torso and a laparotomy sheet is then placed to provide a wide sterile field and to cover all exposed body surfaces except the incision site.

Instrumentation. Instrumentation for open (i.e., performed via a laparotomy incision) surgeries of the liver, biliary tract, spleen, and pancreas includes a basic laparotomy set, biliary probes and forceps for dilating and exploring the ducts of the pancreas and biliary tract, vascular clamps, gastrointestinal (GI) clamps, and ligating clips and appliers of all sizes. Linear stapling instruments also should be available. A self-retaining system such as the Bookwalter retractor set (Figure 11-7)

RISK REDUCTION STRATEGIES

Latex Sensitivity and Allergy Guidelines

Natural rubber latex allergy can be a serious and life-threatening condition. Healthcare workers and others who have experienced repeated exposure to latex can develop latex sensitivity or allergy. The following is a list of guidelines that should be instituted in persons with suspected or known latex sensitivity or allergy:

- Identify the patient's risk factors and report them to the OR team. Those at high risk include persons with the following:
  - Myelomeningocele
  - Multiple surgeries, particularly if begun in early infancy
  - A positive serum latex antibody test
  - Occupational exposure to latex products, particularly powdered products
  - Allergy to bananas, kiwi, avocado, stone fruits, raw potato, tomato, papaya, chestnuts
  - History of hives or pruritus after incidental exposure (such as condom use, dental or other procedures)
- Schedule patients with known latex sensitivity as the first procedure of the day if facility is not latex-safe or latex-free.
- Notify the anesthesia department and OR 24 to 48 hours in advance.
- Notify healthcare providers in other perioperative areas of the patient's latex sensitivity status.
- Plan for a latex-safe environment of care:
  - Remove all latex products from the room unless no alternative exists.
  - Obtain a latex-free cart from the designated area.
  - Place a latex precaution card on the OR door.
  - Look for the signs and symptoms of latex reaction: contact rash, wheezing, bronchospasm, chest pain or tightness.

Modified from Association of periOperative Registered Nurses (AORN): *Perioperative standards and recommended practices,* Denver, 2009, The Association; Brown RH et al: The final steps in converting a health care organization to a latex-safe environment, *Jt Comm J Qual Patient Saf* 35(4):224-228, 2009; Phillips N: *Berry and Kohn's operating room technique,* ed 11, St Louis, 2007, Mosby.

provides excellent exposure of the abdominal viscera. In addition, a flexible choledochoscope, Cavitron ultrasound suction aspirator (CUSA), intraoperative ultrasound, laser, argon beam coagulator, harmonic scalpel, and electrosurgical unit (ESU) may be required to perform certain procedures on the hepatobiliary system. Safe practices when using devices that generate surgical smoke require the use of a smoke evacuation system and accessories in both open and laparoscopic procedures (AORN, 2009).

The basic equipment for minimally invasive surgical (MIS) procedures consists of two high-density monitors, an insufflation unit, ESU, light source, camera, and 0-degree and 30-degree telescopes in 10-mm and 5-mm sizes. A printer is optional. An ultrasonic dissecting unit is often used with MIS procedures. Trocars and sleeves are available in reusable, disposable, and resposable designs. Trocars and sleeves are commonly designed to accommodate 10-mm to 5-mm instruments and 12-mm to 5-mm accessories and instruments. MIS instruments include scissors and shears, dissecting forceps, atraumatic grasping forceps, hooks, Babcock clamps, retractors, needles, suturing devices, pouches, suction-irrigating devices, and mechanical stapling devices.

Thrombin, Gelfoam, Surgicel, Avitene, and other chemical hemostatic agents (Surgical Pharmacology) should be available in the OR suite. Radiographic dye, supplies, and radiation-protection devices will be required if intraoperative radiography or angiography is planned as part of the procedure.

Drainage Materials. Tubes and catheters are selected for the areas to be drained. If a defective drain is used, a free fragment may remain in the wound on removal of the tube. Thus the scrub person should note the condition of all drainage materials and should test them for patency before they are placed in the patient.

Soft rubber or latex tissue drains may be used after an open cholecystectomy or a choledochostomy. Verify that the patient has no latex allergy before using these devices and substitute nonlatex drains if necessary (Risk Reduction Strategies). The surgeon will prepare a latex rubber T-tube drain of suitable size after exploring the duct. The center of the crossbar is notched opposite the junction of the vertical limb so that its ends will bend more readily during removal. The ends are beveled and tailored to fit the duct.

Drains are usually exteriorized through separate stab wounds and anchored to skin edges to prevent their retraction. The perioperative nurse should document the types of drains and reservoirs inserted during the procedure. Depending on institutional protocol, these may be identified with an applied label. All drains and their locations should be included in the perioperative nurse's hand-off report to the nursing unit to which the patient is transferred postoperatively.

Aseptic Considerations. When the common duct is opened or an anastomosis is established between a duct and other parts of the alimentary tract, it may be the institution's policy or the surgeon's preference to isolate contaminated instruments and materials from the remainder of the operative field, as described for GI surgery (Chapter 10). The wound is classified according to a standard system: any procedure in which the alimentary tract is entered under controlled conditions and without unusual contamination is considered a *clean contaminated wound;* if there is gross spillage, however, the wound is classified as *contaminated.* Proper wound classification is considered an important predictor of postoperative SSI (Phillips, 2007; Meakins and Masterson, 2007).

Blood Products. During the preoperative verification process, the perioperative nurse should ascertain the type and amount of blood and blood products, both requested and available, as well as ensure the patient has a signed consent for transfusion. Constant, ongoing evaluation of blood loss is communicated to the anesthesia provider and surgical team during the procedure. When additional blood or blood products are required, the perioperative nurse communicates with blood bank personnel so that products are readily available and carries out the required steps to verify blood/blood products with the anesthesia provider before transfusion.

Autologous blood or donor-directed blood products may be used in elective procedures involving the liver, pancreas, spleen, and biliary tract. Cell-saver devices may be used when

AMBULATORY SURGERY CONSIDERATIONS

Same-Day Surgery versus Overnight Stay: Laparoscopic Gallbladder Surgery

Many patients have same-day surgery for elective laparoscopic cholecystectomy. A meta-analysis revealed that 80.5% of the patients were discharged the day of surgery with few untoward effects. The analysis demonstrated no significant differences in morbidity, prolongation of hospital stay, readmission rates, or pain with same-day procedures vs. overnight stays. Quality of life, patient satisfaction, and return to normal activity were also not significantly different in the group that went home the same day versus the group that was discharged the following day (or 24 hours after surgery).

As surgical stays for laparoscopic cholecystectomy become shorter, sometimes with a 4- to 8-hour observation before discharge, patient education and discharge planning become even more critical. Before the patient departs the ambulatory surgery center, the nurse verifies that the patient is hemodynamically stable, oriented, and alert; tolerates oral fluids; has voided; has dressings that are clean and dry; and has resolved or controlled postoperative nausea and vomiting (PONV). Important discharge preparation includes information about early and continuing ambulation to decrease VTE risk, diet, changes in bowel patterns (feces may pass more quickly after cholecystectomy), steps to take if diarrhea is persistent, when to call the surgeon or other healthcare provider (for routine follow-up as well as problems with bleeding, fever, abdominal distention, persistent pain, jaundice, persistent cough, or shortness of breath), and medication management strategies (these are especially important if a bile acid binder has been prescribed). After reviewing these and other important discharge planning information, have the patient and family, if applicable, "teach back" instructions in their own words and allow an opportunity to ask questions.

PATIENT AND FAMILY EDUCATION

General Discharge Instructions for the Patient Undergoing Surgery for Disorders of the Liver, Biliary Tract, Pancreas, or Spleen

- Keep incision area clean and dry.
- Swelling inside the GI tract may produce a feeling of tightness; this should dissipate in 6 to 8 weeks.
- Solid foods should be added to the diet gradually. Chew solid foods well, and avoid gulping or eating fast or swallowing large, bulky portions.
- Avoid carbonated beverages for 3 to 4 weeks to help prevent gas bloating.
- Plan small, frequent meals because the feeling of fullness comes quickly.
- Increase exercise gradually to return to normal activities of daily living. Exercise regularly.
- Make an appointment for follow-up care with the surgeon.

potential contamination of the blood from bile or bowel does not exist.

Evaluation

Evaluation of the patient after surgery includes examination of all skin surfaces and comparison with preoperative assessment data. Abdominal drains, chest drainage systems, urinary drainage systems, and peripheral infusion lines are assessed for patency. Fluid volume use and loss are documented and communicated appropriately. A report of the patient's history, preoperative assessment, intraoperative events, and postoperative evaluation is communicated to the postanesthesia care unit (PACU) or surgical intensive care unit (SICU) nurse during the hand-off report.

Evaluation of patient status can be phrased as outcome statements such as the following:

- The patient verbalized management of anxiety and ability to cope, expressed knowledge of his or her psychologic responses to the planned procedure, and indicated an understanding of the sequence of perioperative events.
- The patient maintained equilibrium in fluid volume; hematocrit remained in the expected range; vital signs were stable.
- The patient's intraoperative core body temperature remained consistently in the 35.5° to 37.2° C (96° to 99° F) range.
- The patient's surgical incision was dressed aseptically and was dry and intact. There will be no clinical signs or symptoms of infection.
- At the conclusion of the surgical procedure, skin surfaces were clean, intact, and free of reddened areas; adequate capillary filling was noted after blanching of tissues. The patient had palpable pulses in all distal extremities and showed no evidence of diminished neuromuscular function.
- The patient will be able to perform activities of recovery with acceptable levels of pain.

Patient and Family Education and Discharge Planning

The length of time and complexity of recovery vary greatly for patients undergoing surgical intervention for disorders of the liver, biliary tract, pancreas, or spleen. Laparoscopic cholecystectomy may be performed on an ambulatory surgery basis with extended recovery and observation of 6 to 8 hours (Ambulatory Surgery Considerations). In contrast, patients undergoing liver transplant or resection may require extensive recovery that includes a stay in the intensive care unit.

Patients undergoing laparotomy for surgical procedures on the liver, biliary tract, pancreas, or spleen may have varying degrees of postoperative edema, decreased GI peristalsis, and alterations in tissue oxygenation and lymphatic drainage, depending on the amount of manipulation, resection, and trauma to the normal anatomic structures of these viscera. General anesthesia is commonly administered. Smooth muscle relaxation is imperative for most major abdominal procedures. The patient usually experiences decreased peristalsis for 2 to 5 days after laparotomy. A nasogastric (NG) tube or gastrostomy tube is inserted during the procedure to evacuate large volumes of gastric juices. Diet is introduced

only after bowel sounds return. The patient may experience nausea and vomiting if food or oral fluid is introduced too early for the GI system to function with normal absorption and motility.

Coughing and deep breathing are important for the patient recovering from general anesthesia and abdominal surgery. Splinting of the abdominal muscles and use of an incentive spirometer assists the patient in postoperative coughing and deep breathing. Early ambulation assists the patient to regain overall muscle tone and prevents VTE in the lower extremities.

Pain management is very important in the patient's recovery and discharge planning. For most patients undergoing abdominal surgery, patient-controlled analgesia (PCA) or epidural analgesia may be used for better and more consistent control of pain and discomfort in the first 1 to 3 postoperative days. Narcotics may, however, add to the length of time for normal bowel peristalsis to return and their use is monitored closely after the third postoperative day.

General discharge instructions for the patient undergoing surgery for disorders of the liver, biliary tract, pancreas, or spleen might include the recommendations found in the Patient and Family Education box. In addition to such general instructions, surgical patients and their family or caregiver should receive surgery-specific special instructions. The nurse should review any medications the patient will be taking after discharge, and should explain the purposes, dosages, schedules, and routes of administration for each, as well as any side effects to be reported. Both verbal and written instructions are provided, with phone numbers of those to call if questions arise (Canobbio, 2006). Patients should "teach back," in their own words, all instructions and should be able to state the name of their surgical procedure. For most patients, a healthcare provider should be notified if any of the following develop:

- Persistent fever (body temperature of 38.3° C [101° F] or higher)
- Bleeding
- Increased abdominal swelling or pain
- Chills
- Persistent cough or shortness of breath
- Persistent pain, redness, swelling, or purulent drainage from incision sites

Follow-up care may also require providing referrals for home care (or other) services.

Surgical Interventions

SURGERY OF THE BILIARY TRACT

Cholecystectomy (Open Approach)

Cholecystectomy is removal of the gallbladder. It is performed for the treatment of diseases such as acute or chronic inflammation (cholecystitis) or stones (cholelithiasis) (Box 11-1). Most of these procedures are done laparoscopically. The few contraindications to the laparoscopic approach include suspected or diagnosed cancer of the gallbladder, third trimester of pregnancy, cirrhosis with portal hypertension, or poor pulmonary or cardiac reserve (Chari and Shah, 2008); these patients may not be able to tolerate the pneumoperitoneum required in laparoscopy. Further, if the surgeon is unable to identify all the anatomic structures during a laparoscopic approach, conversion to an open procedure becomes necessary.

Procedural Considerations. A basic laparotomy set and biliary instruments are used when cholecystectomy is performed through an open abdominal incision. The patient is positioned supine and receives a general anesthetic. After the patient is intubated, the anesthesia provider inserts an NG tube. Antibiotic prophylaxis may be administered. When an operative cholangiogram is anticipated, the perioperative nurse must ensure that the OR bed has been equipped and positioned so that C-arm image intensification can be efficiently accomplished. Radiation-protection devices for the surgical team and patient are used during image intensification.

Operative Procedure

1. The abdominal cavity is opened through a right subcostal or upper midline incision.
2. Hemostasis of capillary vessels is achieved with electrocoagulation. Larger vessels are clamped with hemostats and ligated with suture material.
3. Retractors and laparotomy packs are placed as the abdominal cavity is carefully examined.
4. The common duct is palpated for evidence of stones and pathologic conditions are determined.
5. Harrington, Deaver, or self-retaining retractors, such as an upper-hand or Gomez retractor, are placed to provide exposure. Long tissue forceps and suction are used to manipulate tissues. The surrounding organs are isolated from the gallbladder region by moistened laparotomy packs and deep retractors.
6. To facilitate gentle traction, Péan forceps are usually placed on the body of the gallbladder (Figure 11-8, *A*).
7. The peritoneal fold overlying the junction of the cystic and common duct is incised with a #7 knife handle and a #15 blade, long Metzenbaum scissors, and forceps. Suction is available, and bleeding vessels are clamped and ligated or electrocoagulated.
8. Adhesions are separated by blunt dissection with small, round, dry dissector sponges; sponges on holders; and blunt right-angled clamps.
9. Dissection is continued to expose the neck of the gallbladder, the cystic artery, and the cystic duct. Lateral traction on the gallbladder neck allows incision of the peritoneum overlying the triangle of Calot.
10. Dissection is continued to expose the cystic artery as it enters the wall of the gallbladder.
11. On complete exposure and visualization of the branches, the cystic artery is doubly ligated with silk or clamped with ligating clips and divided (Figure 11-8, *B*).
12. Occasionally a third ligature or clip may be used. If the cystic artery has more than one branch, each is ligated and divided separately.
13. Abnormalities of the arterial and ductal anatomy are common (Figure 11-9), and the surgeon and assistant work with meticulous care to identify these structures.

BOX 11-1

Overview of Cholelithiasis and Cholecystitis

The two most common diseases of the biliary tree are *cholelithiasis* (stone formation in the gallbladder) and *cholecystitis* (inflammation of the gallbladder). These conditions may occur alone but usually occur simultaneously. Gallstones are becoming more common in the United States, affecting an estimated 8% to 10% of adults. Cholecystectomy is one of the most common surgeries performed. Gallstones are usually found in individuals older than 40 years, with a high incidence in people of Pima and Chippewa descent, white women, and African Americans.

Clinical conditions that may predispose one to gallstones include diabetes, obesity, cirrhosis, ileal disease or resection, cancer of the gallbladder, and pancreatitis. Cholecystitis usually results from obstruction of the cystic duct from gallstones (acute calculous cholecystitis); in a few patients, however, it results from stasis, bacteria, or sepsis (acute acalculous cholecystitis).

PATHOPHYSIOLOGY

The pathophysiology of gallstones depends largely on the following factors: the type of stone, the stone's location within the ductal system, and the nature of its occurrence (i.e., acute or chronic). Gallstones are formed as a result of the imbalance of cholesterol, bile salts, and calcium. The metabolism of cholesterol is often altered so that the bile is supersaturated, leading to precipitation and formation of stones. Cholesterol stones are the most common type and occur most often in women. Mixed stones are a combination of pigment and cholesterol stones. The exact cause of gallstone formation is unclear. Contributing factors may include the following:

- *Supersaturation of bile with cholesterol.* Bile is composed mainly of water, with other components including cholesterol, bile salts, and pigments. Cholesterol alone is insoluble in water; it must be combined with other components (e.g., bile salts) to remain in solution. When bile salts are insufficient to maintain cholesterol in solution, cholesterol crystals form.
- *Bile stasis.* This occurs when the gallbladder has not contracted normally in response to a meal and the bile is stagnant and then becomes thick and concentrated. This occurs in patients receiving total parenteral nutrition (TPN) for a prolonged period. Approximately 50% of these patients develop "sludge" (a mucous gel composed of calcium bilirubinate and cholesterol crystals) in the gallbladder by week 6 of TPN therapy. Gallstones frequently occur during periods of fasting or dieting, during which there is a lack of stimulus for the gallbladder to contract.
- *Nucleation.* A nucleus (nidus) is formed of agents such as bacteria, bile, pigments, cellular debris, and calcium salts. Additional substances aggregate around this nucleus, forming a stone.
- *Genetics* may be a factor, as evidenced by increased prevalence in people of Pima and Chippewa descent.

Some stones may form and pass through the ducts without causing clinical manifestations (asymptomatic cholelithiasis). Symptomatic cholelithiasis occurs when stones intermittently become lodged in the cystic duct, causing biliary colic (episodic pain in the right upper quadrant or epigastric area). The pain usually occurs after meals, especially high-fat meals, as a result of increased intraluminal pressure when the gallbladder attempts to contract to release bile (a normal response to food entering the duodenum) against the obstructing stone.

Cholecystitis develops as stones become impacted within the cystic duct, causing unyielding obstruction, edema, distention, and inflammation of the gallbladder. In chronic cholecystitis, gallstones remain, causing recurrent obstructions and producing changes in the gallbladder wall from recurrent edema and inflammation. The muscular coat becomes fibrous, and the gallbladder functions less effectively.

COMPLICATIONS

Edema and distention of the gallbladder walls decrease blood supply, resulting in patchy areas of necrosis and gangrene. Perforation of these areas can then occur. Bile leakage through these perforations into the peritoneum results in peritonitis. Abscess formation may occur if secretions from the ruptured gallbladder are confined by the omentum or other adjacent organs (e.g., colon, stomach, duodenum, pancreas).

Stone migration from the gallbladder to the common bile duct (CBD) may cause cholangitis (acute CBD inflammation). The presence of gallstones in the CBD is called choledocholithiasis. CBD stones are a major source of morbidity in patients with symptomatic gallstone disease. Stone migration to the ampulla of Vater can cause pancreatitis.

From Lewis SL et al, editors: *Medical-surgical nursing: assessment and management of clinical problems,* ed 7, St Louis, 2007, Mosby.

14. The true junction of the cystic duct with the common bile duct is visualized.
15. The cystic duct is identified and carefully dissected down to its junction with the hepatic duct.
16. Any stones in the cystic duct are "milked" back into the gallbladder, and a tie is placed around the proximal part of the cystic duct.
17. If necessary, a cholangiogram is performed at this time (see following procedure: Intraoperative Cholangiogram). If a cholangiogram is not done, the cystic duct is doubly ligated and divided (Figure 11-8, *C*). A fine, absorbable transfixion suture may be used on the stump of the cystic duct near the common bile duct.
18. The gallbladder is then dissected from the liver bed and removed (Figure 11-8, *D*).
19. All bleeding is controlled; reperitonealization of the liver bed, if indicated, is accomplished with interrupted or continuous fine absorbable intestinal sutures.
20. A closed suction drain may be inserted near the cystic duct stump. The free end of the drain is exteriorized through a stab wound in the lateral abdominal wall.
21. The wound is closed in layers and a dressing applied.

Intraoperative Cholangiogram

An intraoperative cholangiogram is usually performed with both open and laparoscopic cholecystectomy to visualize the common bile duct and the hepatic ductal branches, and to assess the patency of the common bile duct.

Procedural Considerations. An intraoperative cholangiogram requires fluoroscopy to visualize the filling of the ducts. Before the patient's arrival in the OR, the perioperative nurse ensures that a radiolucent bed is available or prepares the OR bed with an image-intensification attachment. The perioperative nurse should ensure that the patient has not had previous allergic reactions to the x-ray medium before

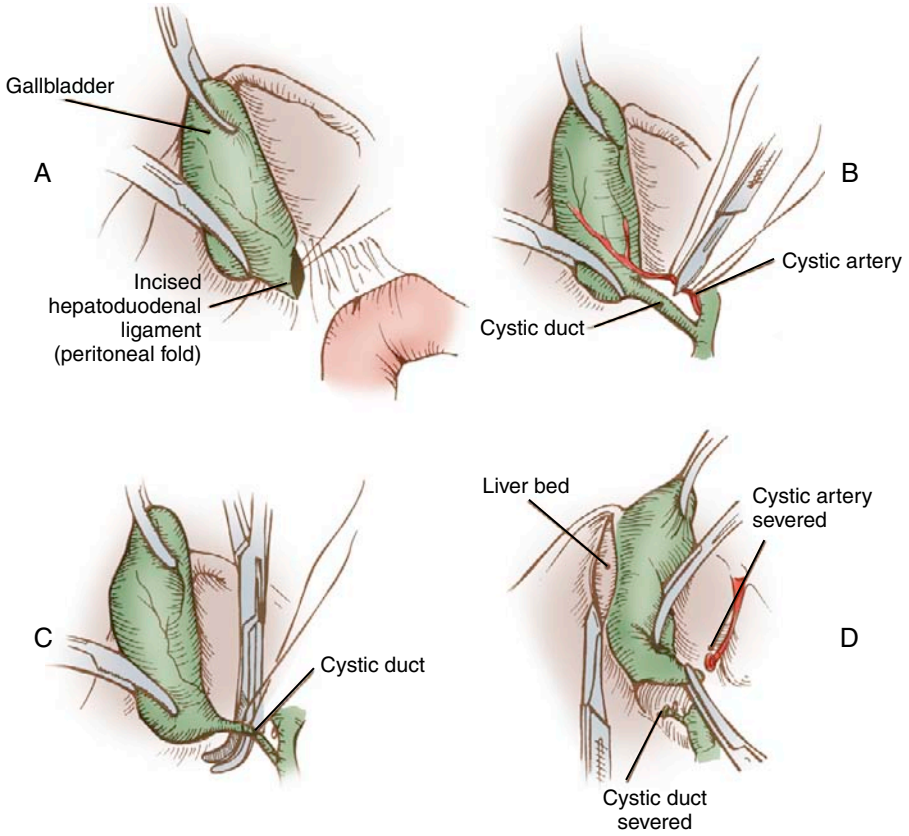

FIGURE 11-8 Cholecystectomy. **A**, With Péan forceps in place, gentle traction is maintained as peritoneum over the triangle of Calot is incised. **B**, Cystic artery is clearly visualized, doubly ligated, and divided. **C**, Cystic duct is carefully dissected and identified before forceps and ligatures are applied. **D**, Dissection of gallbladder from liver bed is completed.

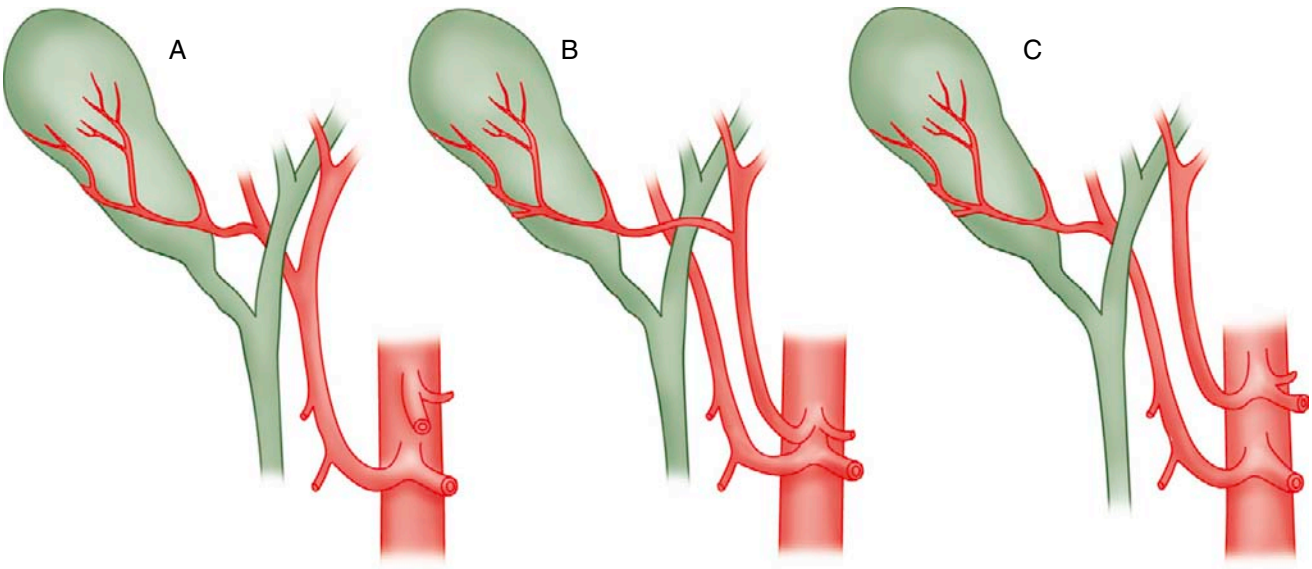

FIGURE 11-9 Arterial blood supply of the liver and biliary system is quite variable. **A**, The most common anatomic arrangement is a cystic artery arising from the right hepatic artery. **B**, A dual hepatic blood supply is found in 15% to 20% of patients, with the right hepatic artery arising from the superior mesenteric artery in a significant number of patients, as in **C**.

dispensing the pharmaceutic agent to the sterile field. Medication safety practices should be followed for labeling and dispensing all medications on and off the sterile field. Protection such as x-ray aprons or leaded shields is used for all members of the surgical team and the patient. As the patient's abdomen remains open while the x-ray equipment is positioned directly over the operative site, appropriate draping to maintain asepsis is necessary. Radiopaque sponges and any unnecessary instrumentation are removed from the abdominal site to avoid obscuring the view of the contrast medium filling the ducts.

The scrub person prepares a cholangiocatheter by attaching a stopcock with a 20-ml syringe of saline and a 20-ml syringe of contrast medium to the Luer-Lok ports. All air bubbles are removed because they might be misinterpreted as gall duct stones on the x-ray film.

Intraoperative Procedure

1. The cholangiocath is irrigated with saline before and during its insertion into the cystic and common bile ducts.
2. The cholangiocath is inserted into the duct using atraumatic grasping forceps. Irrigation during insertion facilitates dilation and reduces trauma to the ductal lumen.
3. The cholangiocath is anchored in the lumen of the common bile duct by the surgeon's preferred method. The more common methods are applying a ligaclip proximal to the insertion site; tying or suturing the catheter in place; or using a ring-jawed holding clamp, such as a Swenson clamp, that has been designed specifically for this purpose.
4. With placement of the cholangiocath confirmed and anchored, all radiopaque sponges, instruments, and obstructing equipment are removed from the field.
5. The surgical field is draped with a sterile drape sheet to maintain asepsis of the wound and field. The image-intensifier equipment (C-arm) is positioned, as the surgeon redirects the stopcock to allow for injection of the contrast medium. If stones are found, the surgeon removes them under fluoroscopic guidance.

Laparoscopic Cholecystectomy

Laparoscopic cholecystectomy is the surgical treatment of choice for patients with gallbladder disease who meet the appropriate criteria for safe laparoscopic intervention. Preoperative evaluation of patients having laparoscopic cholecystectomy differs little from that for patients scheduled for open cholecystectomy. For patients with a history of peptic ulcer disease, a flexible esophagogastroduodenoscopy (EGD) may be performed to rule out existing disease. For patients with suspected ductal stones, a preliminary ERCP or other diagnostic evaluation is often done. A laparoscopic procedure always has the potential to be converted to a laparotomy—a potential the patient should be informed about before the surgical procedure (Research Highlight). Laparotomy instrumentation and supplies should be available in the OR.

RESEARCH HIGHLIGHT

Identifying Risk Factors for Complications of Laparoscopic Cholecystectomy

Even though laparoscopic cholecystectomy (LC) is the treatment of choice for cholecystitis, perioperative nurses anticipate possible conversion to an open procedure and have the necessary equipment and supplies available for a "difficult cholecystectomy." In this study, researchers used a large, prospective database to attempt to accomplish two objectives: (1) identify perioperative risk factors that might be used to predict a difficult cholecystectomy and (2) determine the relationship of the risk factors to perioperative complications for LC. These complications were divided into two categories: (1) local intraoperative and postoperative complications (such as bleeding or bowel injury) and (2) systemic complications (such as myocardial infarction or pulmonary embolism).

There were 22,953 patients in the study database. Their mean age was 54.5 years, there were twice as many males as females, and the majority underwent LC for chronic cholecystitis. While the overall complication rate was 7%, the rate was higher for patients with acute cholecystitis. Using multivariate analysis, the researchers identified the following associated factors for increased local intraoperative complications:

- Male gender
- Duration of the procedure
- Increased body weight
- Surgeon experience

Postoperative local complications were associated with the following factors:

- Male gender
- Patient age
- Intraoperative complication
- ASA class III or IV
- Increased body weight
- Emergency surgery
- Duration of the procedure

Systemic postoperative complications were associated with the following factors:

- Conversion to an open procedure
- ASA class III or IV
- Emergency surgery
- Duration of the procedure

During the OR briefing, perioperative nurses, the anesthesia provider, and the surgeon can use this information to review and communicate possible risks based on assessment findings. Physical characteristics (gender, age, body weight), ASA class, and clinical reason for the procedure (acute or chronic cholecystitis) can be used to estimate the risk of complications. A well-prepared team can mitigate against extending the duration of the surgery by good planning; complication rates in this study were 4 times higher for procedures lasting more than 2 hours.

Adapted from Giger UF et al: Risk factors for perioperative complications in patients undergoing laparoscopic cholecystectomy: analysis of 22,953 consecutive cases from the Swiss Association of Laparoscopic and Thoracoscopic Surgery database, *J Am Coll Surg* 203:723-728, 2006.

Procedural Considerations. Patients are generally admitted to the ambulatory surgery center (ASC) on the morning of surgery and will commonly require less than a 24-hour stay or admission to an extended recovery unit (ERU). A general anesthetic is used, and antibiotic prophylaxis may be administered in the immediate preoperative period. The following instrumentation, supplies, and equipment are required for laparoscopic cholecystectomy: laparoscope, two 5-mm trocars and sheaths, two 10-mm or 11-mm trocars and sheaths (trocar size depends on surgeon preference and may vary), a #7 knife handle with a #11 blade, multiple clip appliers, blunt grasping forceps (an assortment of alligator, Babcock, and

spatula), and laparoscopic scissors. A laparoscopic video unit and secondary "slave" monitor, laparoscopic camera and control unit, light source, CO_2 source and insufflation unit, ESU, suction-irrigator (disposable), filtered insufflation tubing (disposable), and a pressure bag for IV saline 0.9% are commonly used. Instrumentation and supplies for laparoscopic common bile duct exploration should be available in the room. This may include a balloon-tipped Fogarty catheter, wire baskets, dilators, a T-tube, and a small, flexible choledochoscope. The patient is positioned supine with the usual comfort and safety measures observed. A Foley catheter (for bladder decompression) and an NG tube (for decompression of the stomach) will be inserted. Anesthesia is administered, the time-out completed, and the patient then placed in reverse Trendelenburg's position of 10 to 20 degrees.

Pneumoperitoneum may be accomplished using the closed or open technique. In the closed technique, a special hollow insufflation needle (Veress) with a retractable cutting sheath is inserted into the peritoneal cavity through a supraumbilical incision and used for insufflation. In the open technique, sometimes termed the *Hasson technique,* a small incision is made above or below the umbilicus into the peritoneal cavity. A blunt-tipped cannula (Hasson) with a gas-tight sleeve is inserted, and then insufflation takes place. This approach is used for patients who have had a prior abdominal incision near the umbilicus or for those who have the potential for intraperitoneal adhesions. The Hasson technique may also use sutures, placed on either side of the sleeve, to anchor and hold the sleeve in place.

CO_2 is the gas of choice for pneumoperitoneum. Gas flow is initiated at 1 to 2 L/min. Elevated CO_2 levels and respiratory acidosis may occur because CO_2 diffuses into the patient's bloodstream during laparoscopy. Intraabdominal pressure is normally between 8 and 10 mm Hg and is commonly used as an indicator for proper Veress needle placement by the surgeon. If the pressure gauge indicates a higher pressure, the needle may be in a closed space (such as fat), be buried in omentum, or be in the lumen of the intestine. The perioperative nurse should set the insufflation unit to a maximum pressure of 15 mm Hg. When intraabdominal pressure reaches 15 mm Hg, the flow will stop. Pressure higher than 15 mm Hg may result in bradycardia or a change in blood pressure, or may force a gas embolus into an exposed blood vessel during the operative procedure. Most insufflation units are equipped with an alarm mechanism to alert the operative team if the intraabdominal pressure is exceeded. Alarm systems on clinical equipment should be activated and sufficiently audible with respect to competing noise in the OR. The surgeon may frequently ask what the pressure reading is, as may the anesthesia provider.

Operative Procedure

1. A small skin incision is made in the folds of the umbilicus with a #11 blade on a #7 knife handle.
2. Pneumoperitoneum is created using either the open or the closed technique.
3. An 11-mm trocar is inserted through the supraumbilical incision; this becomes the umbilical port.
4. The laparoscope with attached video camera is inserted through the umbilical port and the peritoneal cavity is examined. The surgeon usually stands on the left side of the patient while the first assistant stands on the right. Video monitors are positioned at eye level at both the right and left sides of the operative field. The patient is then placed in a 30-degree reverse Trendelenburg's position and tilted slightly to the left.
5. Three additional trocars are inserted into the peritoneal cavity under direct visualization of the laparoscopic view (Figure 11-10).
6. Blunt grasping forceps are inserted through the medial 5-mm port to grasp the gallbladder.
7. The gallbladder is retracted laterally (Figure 11-11, *A*), exposing the triangle of Calot. The junction of the gallbladder and cystic duct is then identified. The endoscopic dissector, hook, and scissors are used to partially dissect the base of the gallbladder off the liver bed. Electrosurgery is also used. The electrosurgical instrument (active electrode) may have a channel through which suction can be applied to evacuate smoke plume. Some disposable instruments permit suction, electrocoagulation, and irrigation through the same instrument.
8. Hemoclips are placed proximally and distally on the cystic artery and the artery is divided. The use of a disposable, preloaded, multiple-clip applier assists in the placement of ligating clips in a more efficient manner than a singly loaded, reusable applier.
9. An intraoperative cholangiogram may be performed by placing a hemoclip proximally on the cystic duct, incising its anterior surface, and passing the cholangiogram catheter into the duct. Once the cholangiogram is completed, two clips are placed distally on the cystic duct and it is divided (Figure 11-11, *B*). A pretied loop ligature may be used if the duct is large.
10. Attention is then given to dissecting the gallbladder out of its fossa.
11. The surgical site is inspected for hemostasis and the gallbladder dissected off the liver.

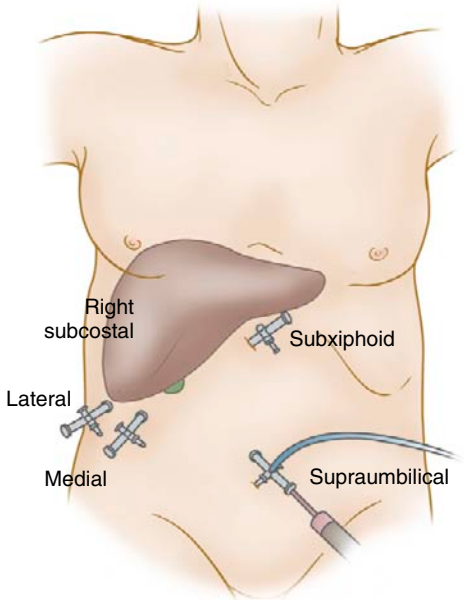

FIGURE 11-10 Trocar placement for laparoscopic cholecystectomy.

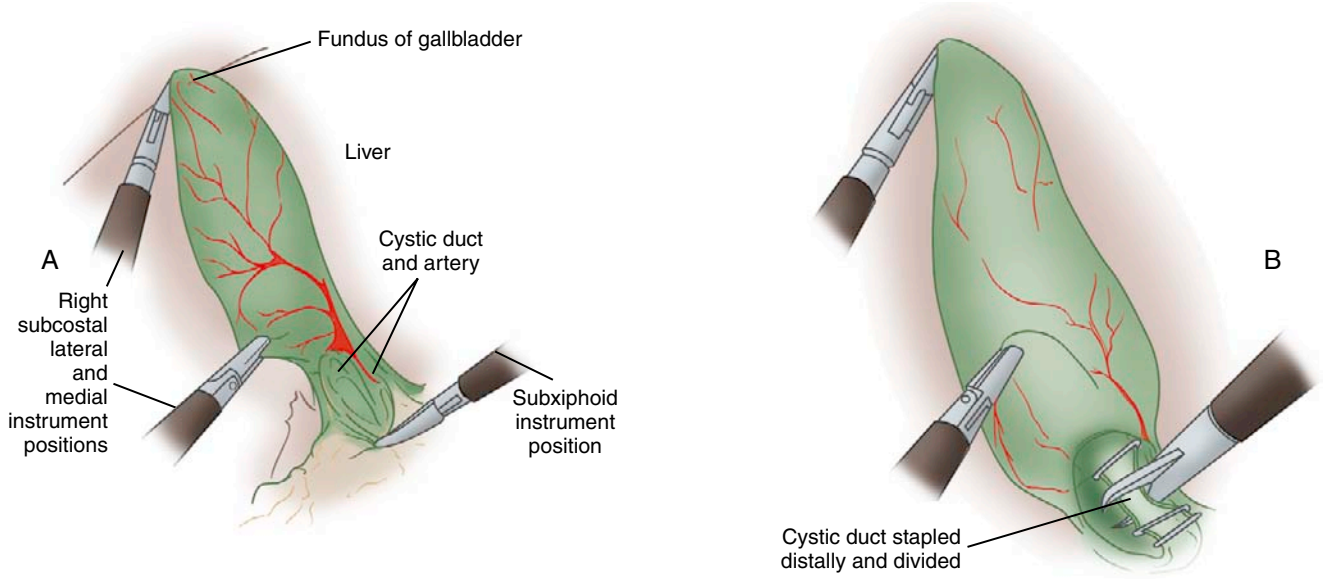

FIGURE 11-11 **A**, The gallbladder is retracted cephalad (using the grasper on the fundus) and laterally at the infundibulum. The peritoneum overlying the gallbladder infundibulum and neck and cystic duct is divided bluntly, exposing the cystic duct. **B**, Once the gallbladder–cystic duct junction has been clearly identified, clips are placed proximally and distally on the duct and it is sharply divided.

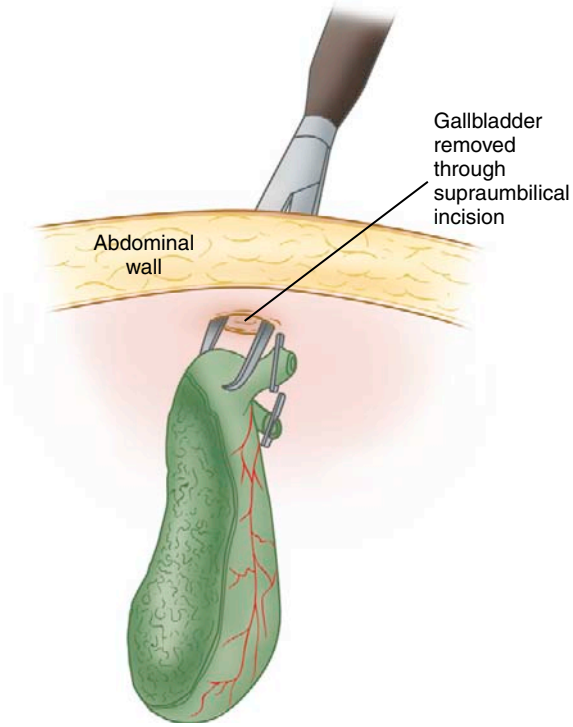

FIGURE 11-12 The gallbladder being removed through the supraumbilical incision.

12. The gallbladder is then removed through the umbilical port (Figure 11-12). An Endo-Bag or similar specimen-retrieval accessory may be used to secure the gallbladder for extraction.
13. The peritoneal cavity is decompressed. The port sites are closed and dressed with Steri-Strips.

Robotic-Assisted Laparoscopic Cholecystectomy

Procedural Considerations. Robotic surgery enables surgeons to perform more advanced and complex procedures. For this surgery, the surgeon controls two robotic arms with laparoscopic instruments and cameras while sitting at a console. Surgical assistants are positioned at the field. Many laparoscopic instruments have been developed to facilitate abdominal procedures. These include a bladeless trocar to minimize injury on entry and the ultrasonic shear to facilitate laparoscopic dissection with hemostasis. An endoscopic stapler and suture device may be used to facilitate intracorporeal anastomosis and knot-tying techniques (Nguyen et al, 2004). Laparoscopic cholecystectomy was one of the first procedures to demonstrate the utility of surgical robots in general surgery (Bodner et al, 2005a) (Research Highlight). For cholecystectomies, robotic operative times may be slightly longer because of equipment setup, but clinical outcomes are equivalent. The view of the ductal anatomy is subjectively superior with robotic surgery because of the magnified three-dimensional picture, which may reduce bile duct injuries (Hanley and Talamini, 2004).

The da Vinci Surgical System (Intuitive Surgical Inc., Sunnyvale, Calif) and the Zeus Robotic Surgical System (Computer Motion, Inc., Goleta, Calif) are two robotic systems used for minimally invasive laparoscopic surgery. The Automated Endoscopic System for Optimal Positioning (AESOP) can be "trained" to recognize the surgeon's voice (Jacobsen et al, 2004). A CT scan can also be imported into the console so that the surgeon can perform preoperative planning and surgical procedure rehearsal (Hanley and Talamini, 2004). It is even possible to perform telesurgery—the complete separation of the surgeon from the operative field. Transcontinental cholecystectomies have occurred successfully between Strasbourg, France, and New York City (Bodner et al, 2005a). For advantages and myths about robotic surgery see Box 11-2 and Table 11-4.

RESEARCH HIGHLIGHT

Robot-Assisted Laparoscopic Cholecystectomy

Laparoscopic cholecystectomy has been the gold standard since 1987. Robots were first used in surgery in the mid-1990s. With current robotic systems, the surgeon sits at an operative console with three-dimensional imaging and handheld controls. Movement of the controls follows the movement of the instrument's tip.

The Mayo Clinic in Scottsdale, Arizona, reviewed all robotically assisted laparoscopic cholecystectomies from October 2002 to July 2003. The Zeus Robotic Surgical System was used to dissect the cystic duct and artery, and the surgical assistant at the OR bed placed the clips on the cystic duct and artery. The robot was used to dissect the gallbladder from the liver. Cholangiocatheters were inserted into the cystic duct with the robotic instruments. Nineteen patients underwent the procedure. Sixteen were completed robotically. Conversions to laparoscopic techniques took place as a result of malfunctioning instruments; however, open procedures were not necessary. The mean setup time was 28.1 minutes (range 7 to 51 minutes). The mean hospital stay was 0.9 day (range: same-day release to 2 days postop). There were no complications or injuries related to use of the robot.

Often cholecystectomy is the initial robotically-assisted procedure to test surgical robots because the operation is technically straightforward and reproducible. Advantages of surgical robots are elimination of the surgeon's tremor, scaling of movements, increased degrees of freedom, three-dimensional visualization, and a comfortable working position for the surgeon, who sits at a console. The scaling of movements makes delicate dissection more exact, and the increased degrees of freedom make dissections simpler. Sitting at the console is ergonomically beneficial. The surgeon does not have to assume awkward positions or reach over assistants.

Telesurgery, the performance of surgery from a distant site using robotics, offers the potential of procedures being performed worldwide from remote sites.

In Townsend CM et al, editors: *Sabiston textbook of surgery,* ed 18, Philadelphia, 2008, Saunders; Miller DW et al: Robot-assisted laparoscopic cholecystectomy: initial Mayo Clinic Scottsdale experience, *Mayo Clin Proc* 79(9):1132-1136, 2004.

BOX 11-2

Advantages of Robot-Assisted Surgery for the Patient and Surgeon

ADVANTAGES FOR THE PATIENT

Smaller incisions
Decreased postoperative pain
Shorter length of hospital stay
Reduced blood loss
Reduced tissue trauma and inflammatory response to surgery
Improved cosmetic result
Faster return to work

ADVANTAGES FOR THE SURGEON

Better visualization (higher magnification)
Hand tremor eliminated, allowing great precision
Three-dimensional video image of the operative field; view of ductal anatomy enhanced
Robotic "wrist" more flexible than human wrist, improving maneuverability around organs and vessels
Movements can be reduced, allowing complex technical tasks
Better ergonomic environment (sitting at a console), better levels of concentration

Modified from Gomez G: Emerging technology in surgery: informatics, electronics, robotics. In Townsend CM et al, editors: *Sabiston textbook of surgery,* ed 18, Philadelphia, 2008, Saunders; Purkayastha S et al: Robotic surgery: a review, *Hosp Med* 65(3):153-159, 2004.

Cholecystostomy (Open Procedure)

Cholecystostomy establishes an opening into the gallbladder to drain the organ and remove stones. The open approach is usually selected for patients with advanced medical problems who cannot tolerate general anesthesia or more extensive surgery. Ultrasound-guided percutaneous cholecystostomy has become an accepted procedure for patients who are not otherwise good candidates for surgery. In the rare situation where interventional radiology is not available, an open procedure may be done, as is described here.

Procedural Considerations. A large Toomey syringe (50 ml) or an Asepto syringe may be needed for irrigation purposes. If a local anesthetic is used, the anesthetic agent, syringes, and needles are assembled. Protocols for safe administration and labeling of all medications/solutions on and off the sterile field must be followed. Specified drainage tubes or catheters should be available. The patient is positioned supine. Although many surgeons prefer a right subcostal incision, when cholecystostomy procedures are performed as emergencies a quicker midline or transverse incision may be used. Instrumentation includes a basic laparotomy set plus a gallbladder set.

Operative Procedure

1. After incision into the abdominal cavity, the gallbladder is isolated by retraction of the surrounding viscera.
2. The fundus of the gallbladder is grasped with an Allis or Babcock forceps and, if needed, the proposed opening is encircled by means of an absorbable purse-string suture, leaving the ends long.
3. If the gallbladder is distended or tense, it may be isolated with moistened laparotomy packs to protect the abdominal cavity from contamination.
4. If decompression of the gallbladder is required, a large-bore needle (e.g., 18 gauge) may be inserted with suction attached. Gallbladder contents are aspirated and the site closed using surgical clips on a clip applier.
5. If a trocar is used within the purse-string suture, suction tubing is attached to the trocar sheath.
6. As the contents are aspirated, culture specimens may be taken. The contaminated trocar and sheath are removed and isolated in a discard basin.
7. The opening into the gallbladder can be enlarged with Metzenbaum scissors. Gallstones are removed with malleable scoops and stone forceps.
8. Irrigating the gallbladder with isotonic saline solution may be necessary to remove small stones, grit, or paste-like material. A syringe with a catheter or an Asepto syringe is sometimes used for irrigation.
9. Remaining contaminated instruments are placed in a discard basin.

TABLE 11-4

Myths about Robotic Surgery

Myth	Reality
Robots do all the work.	The surgeon manages the robot system from a console away from the operative field.
Robotic surgery is better than conventional surgery.	Current surgical outcomes are comparable.
Robotic arms function just like a surgeon's hands.	Robotic arms are better than human hands—steadier and more precise, with no tremor and smaller hand movements, and able to work in a very small space. However, hand dexterity is missing—a human hand can move 20 ways; robotic arm has good but not exactly replicable range of motion.
Robots make surgery simpler, faster, or less expensive.	System setup time can be lengthy. Some surgeries take longer to perform with a robotic system.
Robotic surgery has been a big disappointment.	Robotic surgery is constantly improving. This technology has significant implications for the future of surgery, with its near-perfect visualization and sophisticated camera system that provides a three-dimensional view of the heart.

Modified from 5 Myths about robotic surgery, *Cleveland Clin Heart Advis* 7(5):4-5, 2004; Robotics extend surgeon's reach, *Cleveland Clin Heart Advis* 11(3), 2008, available at www.heart-advisor.com/cgi-bin/texis/scripts/heartadvisor-search/search.html?query=robotic+heart+surgery. Accessed April 1, 2009.

10. A drainage tube is inserted into the gallbladder opening. The purse-string suture is tightened around the catheter, with care taken not to occlude it.
11. The free end of the catheter or tube is exteriorized through a stab wound and then anchored to the skin edges, as described for open cholecystectomy.
12. Drainage of the abdominal cavity is established with the exterior ends of each drain secured.
13. The wound is closed in layers, as described for laparotomy, and dressings applied at the incision and drain sites.

Open Common Bile Duct Exploration

With the advent of endoscopic, percutaneous, and laparoscopic techniques (Figure 11-13), open exploration of the common bile duct is rarely performed. When these newer methods are not available, when they are not possible because of prior surgery, or when an open procedure is otherwise necessary, open common bile duct exploration is performed.

Procedural Considerations. The patient is positioned supine after administration of a general anesthetic. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter may be inserted before the abdominal skin prep. Instrumentation includes a basic laparotomy set with the addition of gallbladder instruments. T-tubes of assorted sizes should be available. Intraoperative cholangiography will most likely be used to confirm that all stones have been removed; radiation-protection devices for the patient and surgical team are required. Culture tubes are needed. Soft rubber catheters for irrigation, balloon-tipped catheters such as the biliary Fogarty catheter, stone baskets, and the surgeon's preferred cholangiocath should be available, as well as both flexible and rigid choledochoscopes. A choledochoscope requires the following:

- Choledochoscope with accessories: biopsy forceps, stone-grasping forceps, and a sheath that can be used to direct other instruments into various portions of the biliary tract
- Video camera and viewing screen
- Light cord
- 0.9% normal saline (1000-ml bag)
- Sterile IV tubing
- Pressure bag
- Light source for the choledochoscope

Distending the common duct is necessary for better visualization and is accomplished by irrigating the duct with copious amounts of sterile saline. A pressure bag is placed around an IV bag of 0.9% saline, and pressure to 300 mm Hg is applied. Sterile tubing is then passed from the sterile field and attached to the saline bag. The scrub person attaches the distal end of the sterile IV tubing directly to the irrigating stopcock on the scope.

Operative Procedure

1. The abdomen is opened through a subcostal incision or midline incision.
2. If the gallbladder has not been previously removed, it is exposed and removed or retracted by means of laparotomy packs and retractors.
3. The common duct may be identified by means of an aspirating syringe and fine-gauge needle to make certain that the suspected duct is not a blood vessel. Culture specimens may be obtained.
4. The common duct region is isolated with moistened laparotomy packs and narrow-blade retractors. A discard basin for contaminated instruments is placed at the lower end of the operative field and suction is prepared for immediate use.
5. Two fine traction sutures are placed in the wall of the duct, below the entrance of the cystic duct. A longitudinal incision is made in the common duct, between the traction sutures, with a long #3 knife handle and #15 or #11 blade, and enlarged with Potts angled or Metzenbaum scissors.
6. Visible stones are removed with gallstone forceps, after which exploration of the duct is begun with small, malleable scoops, proximal and then distal to the opening. Isotonic solution in an Asepto syringe and a soft, small-lumen catheter or a balloon-tipped catheter are used to facilitate the removal of small stones and debris as well as to demonstrate patency of the common bile duct in its entirety to the duodenum.

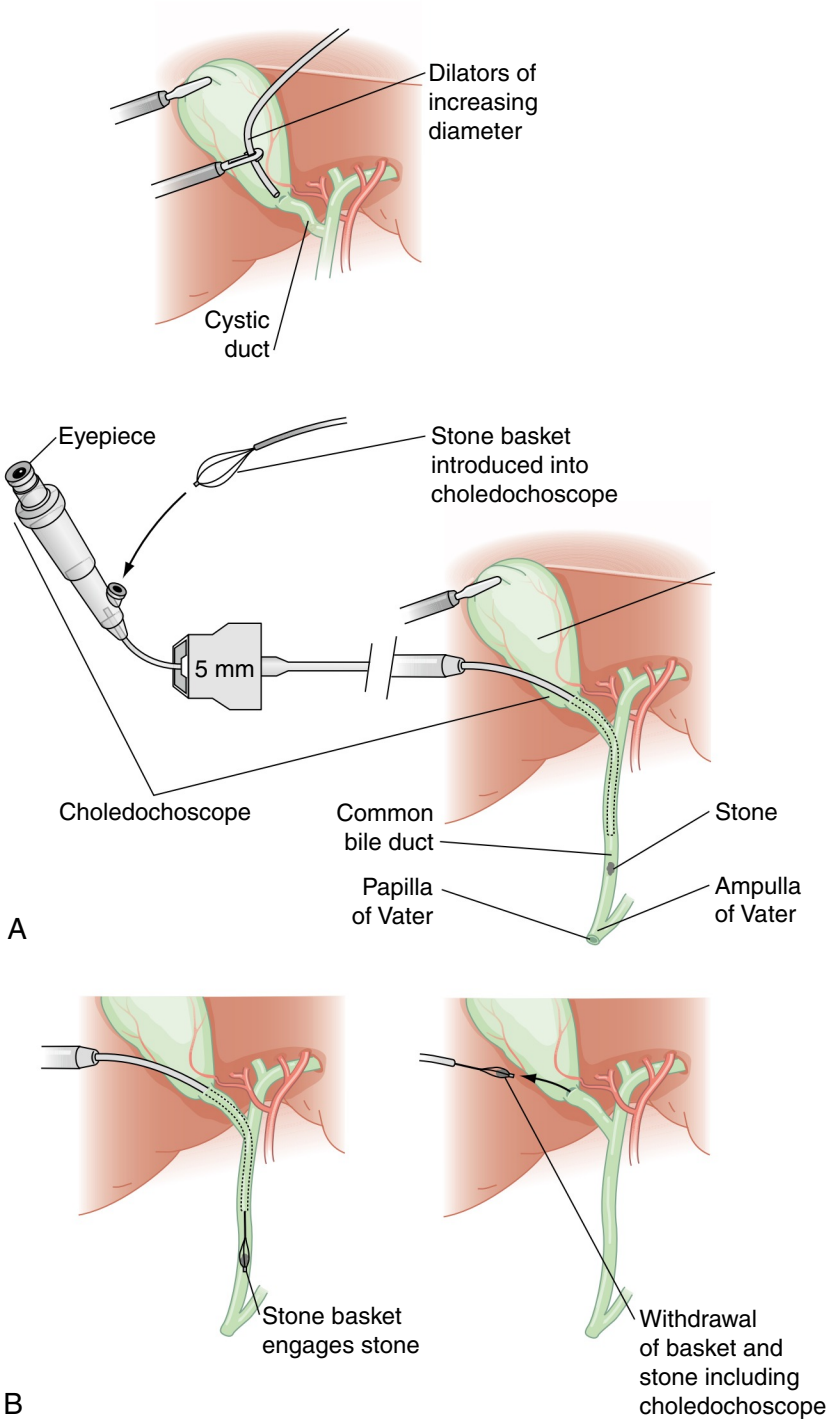

FIGURE 11-13 **A**, Laparoscopic common bile duct exploration. After dilation of the cystic duct, the flexible choledochoscope is inserted into the abdomen through the small trocar and maneuvered into the distal common bile duct. **B**, A stone basket is passed through the working channel of the choledochoscope and is used to snare a common duct stone. The stone basket and choledochoscope are then withdrawn together.

7. The choledochoscope may be used to identify additional stones. The scope is inserted into the common duct, which is then flushed with saline. After visualizing the duct to ensure that no stones remain, a T-tube is placed in the common bile duct and the choledochotomy is closed around the tube. A completion cholangiogram is performed to be certain all stones have been removed. The wound is closed, the T-tube anchored to the skin, and dressings applied. Sterile tubing is used to connect the T-tube to a small drainage container or bag.

Cholecystoduodenostomy and Cholecystojejunostomy

Cholecystoduodenostomy and cholecystojejunostomy create an anastomosis between the gallbladder and duodenum or the gallbladder and jejunum, respectively, to relieve an obstruction in the distal end of the common duct. An obstruction in the biliary system may be caused by a tumor of the ducts involving the head of the pancreas or the ampulla of Vater, an inflammatory lesion, a stricture of the common duct, or the presence of stones.

Procedural Considerations. Instrumentation includes a basic laparotomy set; gallbladder instruments with two curved Doyen intestinal forceps with guards, or similar atraumatic holding forceps; and a self-retaining retractor system. Fluoroscopy should be anticipated and radiation-protection devices for patient and surgical team should be available. The patient is positioned supine after administration of a general anesthetic. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before abdominal skin preparation.

Operative Procedure

1. The abdomen is opened, the gallbladder exposed, the contents aspirated, and the pathologic condition confirmed.
2. The anastomosis site is prepared, posterior serosal silk sutures placed, and open anastomosis performed.
3. Anastomosis of the gallbladder to the duodenum or loop of the jejunum is usually performed as a two-layer anastomosis.
4. The serosa of the duodenum or loop of the jejunum is sutured to the full thickness of the fundus of the gallbladder.
5. A 1-cm to 1.5-cm opening is made into the small bowel and gallbladder in corresponding positions. GI technique (also referred to as bowel technique; see Chapter 10) is instituted.
6. Interrupted fine monofilament (5-0 or 4-0) sutures are then placed around the entire circumference.
7. Contaminated instruments are placed in the discard basin and the operative field is prepared for closure.
8. A drain may be inserted, the wound closed, and dressings applied.

Choledochoduodenostomy and Choledochojejunostomy

Choledochoduodenostomy is anastomosis between the common duct and the duodenum, and choledochojejunostomy is anastomosis between the duct and the jejunum. These procedures (referred to as choledochal drainage procedures) may be necessary in postcholecystectomy patients to circumvent an obstructive lesion and reestablish the flow of bile into the intestinal tract.

Procedural Considerations. Surgical approaches are similar to those for choledochostomy and cholecystojejunostomy. The patient is positioned supine after administration of a general anesthetic. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before abdominal skin preparation.

Instrumentation and supplies necessary for this procedure include a basic laparotomy set with the addition of gallbladder instruments, a self-retaining retractor system, linear stapling devices, and T-tubes in varying sizes; a Silastic biliary stent should be available as should magnifying loupes. Fluoroscopy should be anticipated; radiation-protection devices will then be required for the patient and surgical team.

Operative Procedure

CHOLEDOCHODUODENOSTOMY

1. The abdomen is opened with a midline incision.
2. The common duct and duodenum are exposed.
3. The common duct is identified and dissected free, using forceps and Metzenbaum scissors.
4. The common duct and duodenum are approximated, side-to-side or with the end of the common duct to the side of the duodenum, and an anastomosis is established.
5. An intraluminal catheter is inserted.
6. The wound is closed and dressings applied.

CHOLEDOCHOJEJUNOSTOMY

1. The abdomen is opened with a midline incision.
2. The jejunum is mobilized, the common duct identified and opened, and the jejunum transected (Figure 11-14, *A*).
3. Anastomosis is established between the common duct and the transected jejunum.
4. A catheter is introduced, as described previously for cholecystoduodenostomy.
5. Jejunal continuity is reestablished by jejunojejunostomy (Figure 11-14, *B*).
6. As an alternative, anastomosis may be fashioned from the end of the severed duct to the side of a loop of jejunum, with a side-to-side jejunal anastomosis.
7. Contaminated instruments are removed from the operative field.
8. A drain may be inserted, the wound closed, and dressings applied.

Transduodenal Sphincteroplasty

Transduodenal sphincteroplasty achieves a choledochoduodenostomy between the distal end of the common duct and the side of the duodenum. The sphincters normally affecting the distal common and pancreatic ducts are rendered functionless because the stoma is noncontractile and therefore remains permanently open. An indication for transduodenal sphincteroplasty is sphincter of Oddi dysfunction—a poorly defined clinical syndrome that is characterized by pain characteristic of biliary colic and recurrent acute pancreatitis. There may be a structural or functional abnormality of the sphincter, with or without fibrosis and elevated sphincter pressures. Both endoscopic sphincterotomy and transduodenal sphincteroplasty with transampullary septectomy have been used with similar results. The procedure described has the advantage of including division of the transampullary septum, which promotes pancreatic duct drainage.

Procedural Considerations. Instrumentation is as described for choledochotomy, with the addition of a GI set, since the duodenum is entered. The patient is positioned supine after administration of a general anesthetic. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before abdominal skin preparation. The abdomen is prepped from nipple line to pubis. Supplies for an operative cholangiogram are necessary

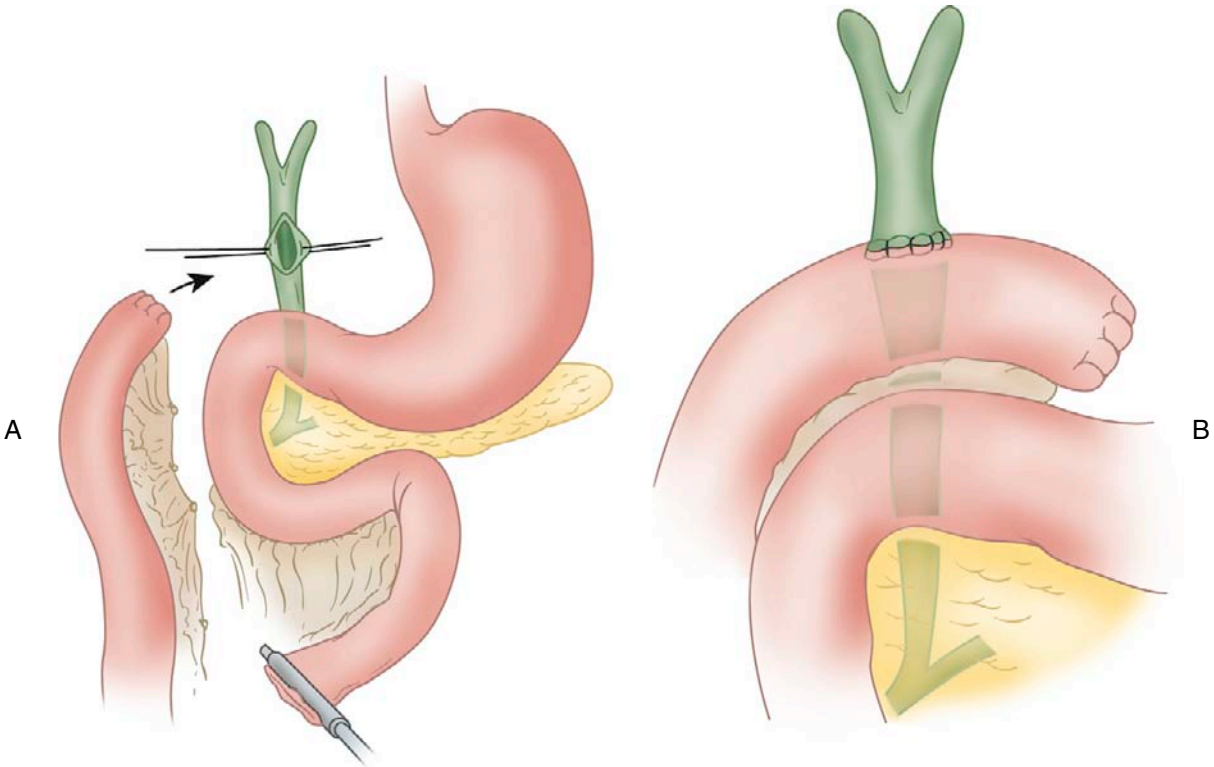

FIGURE 11-14 Choledochojejunostomy. **A**, The divided end of the jejunum is closed, and an end-to-side choledochojejunostomy is made in two layers to the jejunum. **B**, A jejunojejunostomy completes the operative procedure.

as are radiation-protection devices for the patient and surgical team.

Operative Procedure

1. A right subcostal or midline incision is made and the biliary tract exposed.
2. All structures are inspected and the normal configuration established before any structure is tied, clamped, or divided during biliary tract dissection.
3. Operative cholangiography is then performed by placing a cholangiocath through a small incision made with a #11 blade into the cystic duct.
4. If the gallbladder is present, cholecystectomy is performed.
5. The duodenum is mobilized by dividing the peritoneal reflection that covers the lateral portion of the second part of the duodenum and holds it in place.
6. The common duct is incised longitudinally between two stay sutures and explored.
7. Any residual stones are removed. Duodenotomy is performed with a longitudinal incision and the papilla of Vater located (Figure 11-15, *A*).
8. The sphincter of Oddi is divided at the 11 o'clock position with angled Potts scissors, and the ductal mucosa is sutured to the duodenal mucosa with a fine monofilament synthetic absorbable suture on a small needle (Figure 11-15, *B*).
9. The duodenum is then closed in two layers.
10. The common bile duct is joined to the apex of the mobilized duodenum in a two-layer anastomosis.
11. A T-tube may be inserted to splint the anastomosis (Figure 11-15, *C*).
12. The abdominal cavity is closed.

SURGERY OF THE PANCREAS

Drainage or Excision of Pancreatic Cysts (Open Method)

Pancreatic pseudocysts are localized collections of pancreatic secretions in a cystic structure. The preferred operative therapy in patients with uncomplicated pseudocysts is internal drainage by one of three options: cystojejunostomy (use of a defunctionalized Roux-en-Y jejunal limb) (Figure 11-16); cystogastrostomy (drainage into the stomach); or cystoduodenostomy (drainage into the duodenum) (Steer, 2008). Cystogastrostomy is a faster and technically simpler procedure used when the cyst adheres to the posterior wall of the stomach. Cystojejunostomy is the most versatile drainage procedure. Cystoduodenostomy is used in selected cases, depending on cyst location, but has limited utility.

Procedural Considerations. The patient is positioned supine after administration of a general anesthetic. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before abdominal skin preparation. Instrumentation and supplies necessary for this procedure include a basic laparotomy set, gallbladder instruments, a GI set, and a self-retaining retractor system.

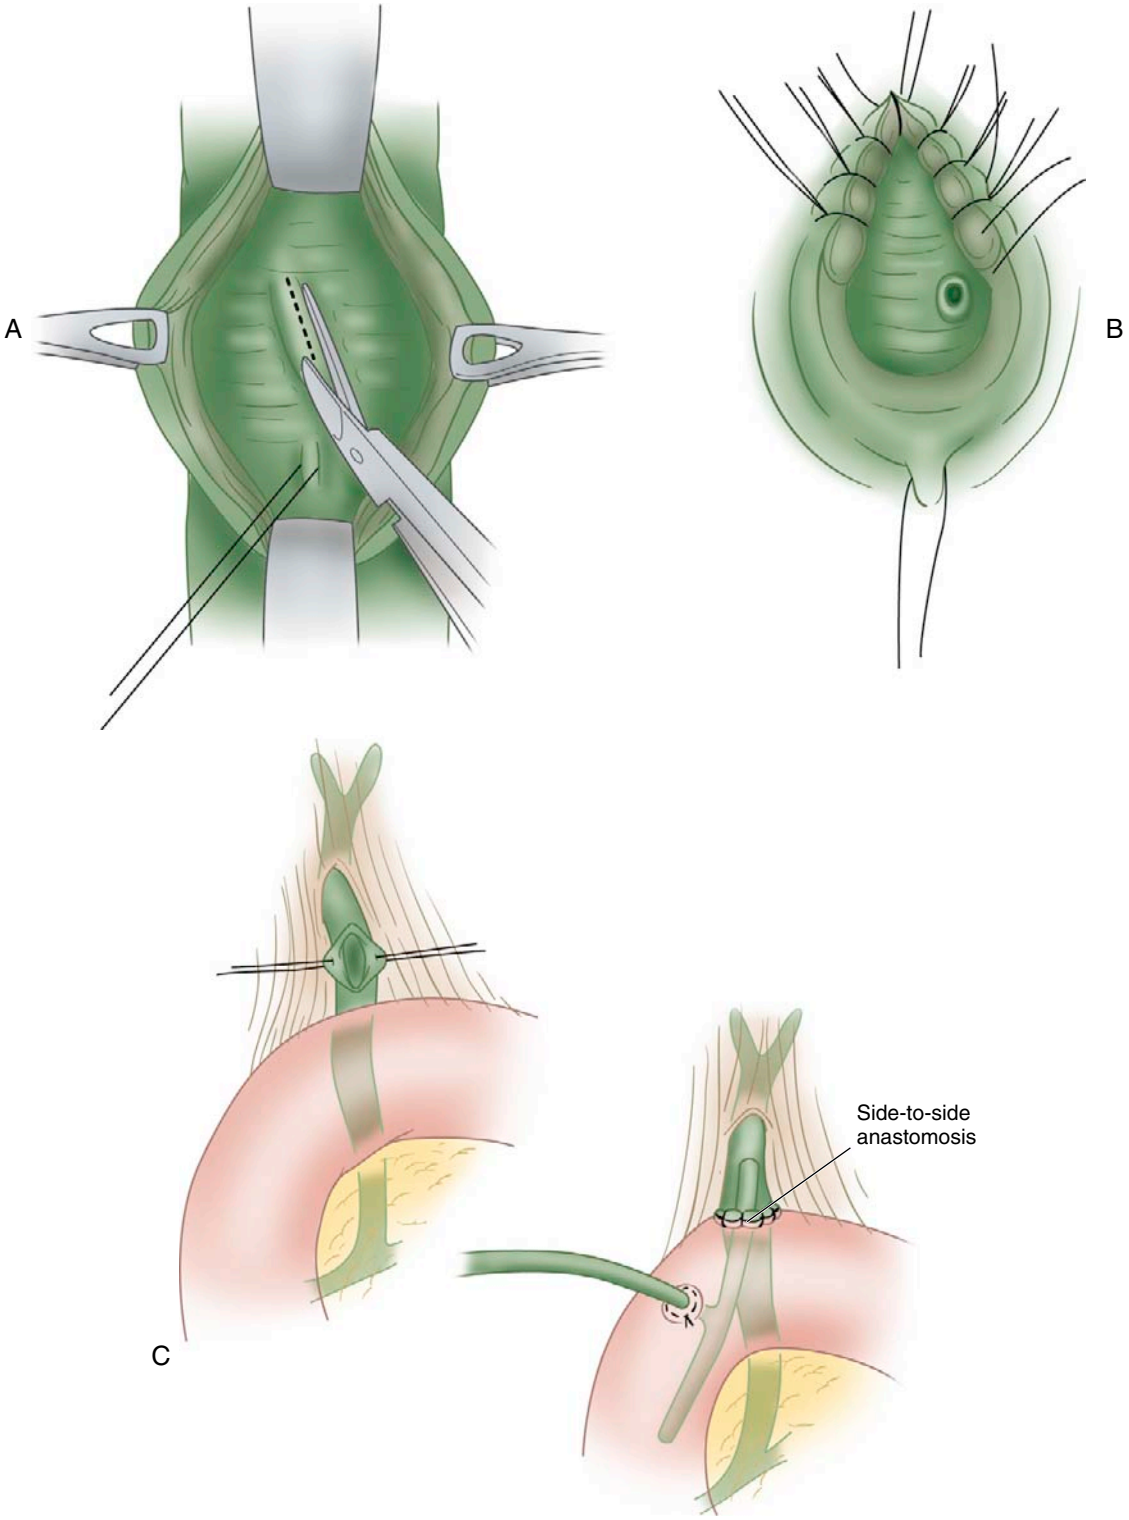

FIGURE 11-15 Transduodenal sphincteroplasty. **A**, The duodenum is opened longitudinally. **B**, The sphincter of Oddi is divided at 11 o'clock with angled Potts scissors, and the ductal mucosa is then sutured to the duodenal mucosa with 4-0 absorbable suture. The duodenum is then closed longitudinally in two layers. **C**, Choledochoduodenostomy. The common bile duct is joined to the apex of the mobilized duodenum in a two-layer anastomosis. A T-tube is placed to stent the anastomosis, with the external stem of the tube passed through the bile duct or through the wall of the duodenum.

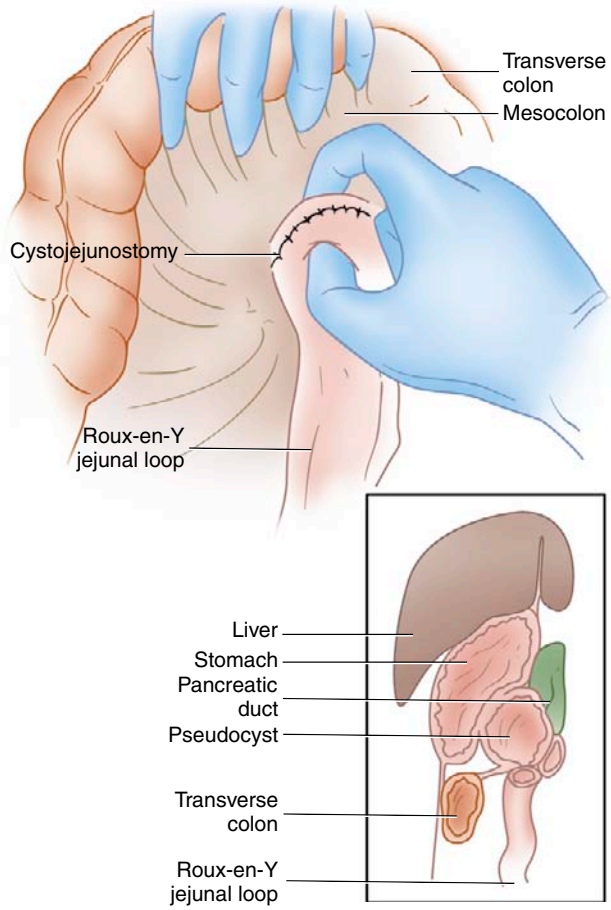

FIGURE 11-16 Internal drainage of a pancreatic pseudocyst by Roux-en-Y cystojejunostomy through the base of the transverse mesocolon.

Operative Procedure

1. A midline incision is made into the abdomen.
2. A self-retaining retractor system is used to expose the pancreatic area.
3. The pancreatic cyst is examined and the area isolated with moist packs.
4. Internal drainage may be accomplished by an incision into the anterior wall of the stomach, directly opposite the cyst if it adheres to the posterior wall, thereby providing drainage through the GI tract.
5. A fistula is established between the anterior wall of the cyst and the posterior wall of the stomach. Many surgeons prefer an anastomosis between the cyst and a Roux-en-Y loop of jejunum (see Figure 11-16) or into the duodenum directly, depending on the location of the cyst.
6. The anterior gastrostomy is closed, and wound closure completed.

Laparoscopic Pancreatic Cyst–Gastrostomy

Laparoscopic techniques may be used for internal drainage procedures for pancreatic pseudocysts. CT imaging is used to diagnose the pancreatic pseudocyst. An EUS may also provide additional information. The location, size, and thickness of the wall of the pseudocyst are all assessed to determine the most appropriate procedure for drainage, either a laparoscopic pancreatic cyst–gastrostomy or a Roux-en-Y pancreatic cystojejunostomy. Endoscopic drainage of pseudocysts may also be done in surgical centers where endoscopists are experienced in percutaneous drainage techniques (Steer, 2008).

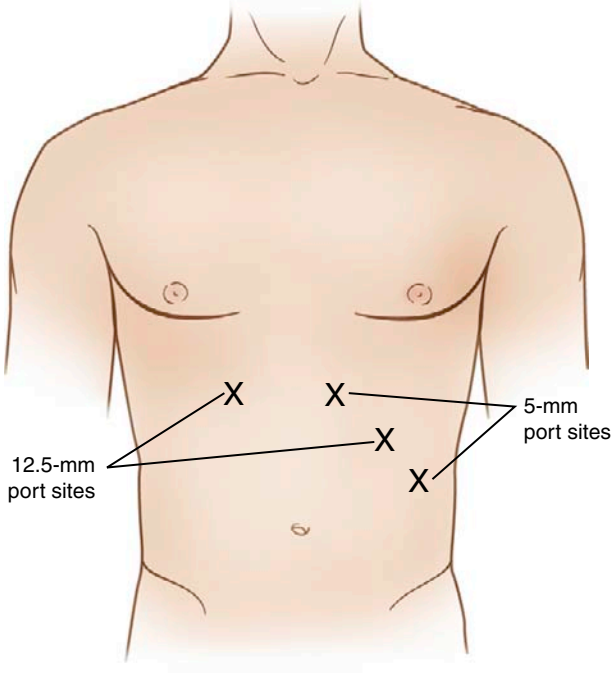

FIGURE 11-17 Port sites for trocar placement in laparoscopic pancreatic cyst–gastrostomy.

Procedural Considerations. General anesthesia is induced and an NG tube inserted. The patient is positioned supine. Equipment and instrumentation are a 30-degree telescope (10 mm or 5 mm); a video camera; two high-density video monitors; a high-flow insufflator with CO_2 tank; an electrosurgical unit; two 12.5-mm trocar ports; two 5-mm trocar ports; an endodissecting instrument (5 mm) or atraumatic grasping forceps (5 mm); endoshears/scissors (5 mm) with electrocoagulation connection; an endo-Babcock instrument; a mechanical stapling device; a 10-mm endoclip applier; a 10-mm endosuturing instrument (optional); 2-0 suture material, 7-inch length (optional); an electrocoagulation hook; a long 5-mm laparoscopic needle; and an endoretractor.

Operative Procedure

1. Pneumoperitoneum is created and the trocars inserted by way of port sites as illustrated in Figure 11-17.
2. The pancreatic pseudocyst is located by entering the lesser sac by way of the greater curvature. Hemostasis is achieved by using the endoclip applier. An endostapling device (GIA type) with vascular cartridges is used to dissect the greater curvature.
3. The surgeon assesses the site for entry into the stomach. An endoretractor may be used to retract the left hepatic lobe.
4. Using electrodissection an incision centered between the lesser and greater curvatures is made on the anterior wall of the stomach and then extended.
5. A long laparoscopic aspiration needle is inserted into the intraabdominal and gastric cavity. The camera is advanced to visualize the posterior wall of the stomach.

6. The needle is inserted into the cyst and its presence is confirmed by aspiration.
7. A small incision is made into the cyst and the pancreatic fluid aspirated.
8. The endostapling device is inserted into the gastric cavity. The smaller jaw of this instrument is inserted into the pseudocyst. The stapling device is closed. It is important that the anastomosis not be under tension. The stapling device is fired and the anastomosis checked for integrity. An endosuturing instrument is used to close any defects in the anastomotic line.
9. An NG tube is directed into the pseudocyst.
10. The two edges of the anterior wall gastrostomy are approximated using endograsping forceps (atraumatic) or an endodissecting instrument. The gastrostomy is then closed using an endostapling device (thoracic-abdominal [TA] type).
11. A drain is placed, the abdomen deflated, trocar ports removed, and trocar sites closed and dressed.

Robotic-Assisted Laparoscopic Pancreatic Procedures

Procedural Considerations. Pancreatic lesions can be resected with robotic-assisted laparoscopy. Pancreaticojejunostomy may be performed following an open pancreaticoduodenectomy (Hanley and Talamini, 2004). Computer-assisted robotic surgery may be used to resect, drain, and reconstruct the pancreatic duct. Precise tissue manipulation and three-dimensional imaging allow better surgical approaches for reconstruction of the pancreatic or common bile ducts than open techniques (Melvin, 2003).

Pancreaticoduodenectomy (Whipple Procedure)

Pancreatic cancer is treated using a multidisciplinary approach that may include surgeons, gastroenterologists, oncologists, radiologists, nurses, and nutritionists (Hines and Reber, 2006). Tumors arise from the exocrine glands (95%) and endocrine glands (5%) in the pancreas. Ductal adenocarcinoma constitutes 80% of all pancreatic tumors. Most tumors begin in the head of the exocrine gland, obstruct the bile duct, and extend to the duodenum, intestines, and spine. Metastasis occurs to regional lymph nodes, and common metastatic sites include the liver and lungs. As symptoms most often occur late in the disease, the prognosis is usually poor (Research Highlight). Pancreaticoduodenectomy (Whipple procedure) is the removal of the head of the pancreas, the entire duodenum, a portion of the jejunum, the distal third of the stomach, and the lower half of the common bile duct, with reestablishment of continuity of the biliary, pancreatic, and GI tract systems.

Procedural Considerations. A basic laparotomy set, a GI instrument set, a self-retaining retractor system (e.g., Bookwalter), linear stapling devices, and appropriate drains and catheters are required. The perioperative nurse should ensure that ordered blood and blood products are available. Pancreaticoduodenectomy may take 5 to 6 hours and require the transfusion of many units of blood or blood products. The patient is positioned supine after administration of a general anesthetic. Attention is paid to padding positional pressure points with gel pads or using a pressure-reducing OR bed mattress. SCDs are applied as well as a forced-air warming device and other active warming measures to prevent hypothermia. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before abdominal preparation. The abdomen is prepped from nipple line to midthigh.

RESEARCH HIGHLIGHT

Pancreatic Cancer Research Matures

Cancer of the pancreas is found in industrialized countries in increasing numbers. Pancreatic cancer research has been slow to progress, making it the fourth leading cause of cancer deaths for men and women. Early detection techniques and effective treatment strategies have evolved slowly, but progress is being made in several areas.

It is now possible to describe the progression of lesions from precancer to full-blown disease. "Candidate genes for diagnosis, screening, and treatment, are being tested in trials. Several new risk factors have been identified. And a whole-genome scan of about 2,000 pancreatic cancer patients revealed new genetic targets and pathways affected by the disease" (Nelson, 2007, p 1432). There are currently more than 200 clinical trials testing combinations of chemotherapeutic agents. Lack of response to chemotherapy has been a problem, but new research shows an understanding of the genetic structure of precancerous pancreatic lesions. Drugs are being developed to inhibit the "hedgehog signaling pathway," a pathway that plays a role in cell differentiation, growth, and proliferation that is particularly active in many pancreatic cancers (Genentech, 2008). In addition, new screening techniques are being investigated in high-risk groups. Chronic alcohol abuse and smoking cause more than one third of all pancreatic cancers (Berger and Rau, 2007). However, other risk factors include persons with a family history of pancreatic cancer, inherited gene mutations, chronic pancreatitis, long-standing diabetes, and cirrhosis of the liver (Spader, 2009). Groups of high-risk individuals are being studied and screened in an attempt to identify pancreatic cancer in its early stages (Nelson, 2007).

Modified from Cell differentiation, growth and proliferation, *Genenetech BioOncology,* available at www.biooncology.com/bioonc/research/hedgehog/index.m?s_cid=0001&;s_src=googleppc&gclid=CPOp5evlwJcCFQNvHgod5X-qSg. Accessed April 1, 2009, Nelson NJ: Pancreatic cancer research matures, *J Natl Cancer Inst* 99(19):1432-1434, 2007; Berger HG, Rau BM: New advances in pancreatic surgery, *Curr Opin Gastroenterol* 23(5):522-534, 2007; Spader C: Pancreatic cancer takes center stage, *Nurs Spect* 18(7):14-16, 2009.

Operative Procedure

1. The abdomen is entered through either an upper transverse, a bilateral subcostal, or a long paramedian incision. Resectability is assessed, exploring for hepatic metastases, serosal implants of tumor, and lymph node metastases. If these are outside the zone of resection, the disease is unresectable.
2. Laparotomy packs and retractors are used to expose the operative site and protect vital structures.
3. The duodenum is mobilized using the Kocher maneuver (incision of peritoneal reflection lateral to the second portion of the duodenum) with Metzenbaum scissors and subsequent blunt dissection of loose areolar tissue.
4. Mobilization of the duodenum continues and bleeding vessels are ligated with silk.
5. The gastrocolic ligament and the gastrohepatic omentum are divided between curved forceps and are ligated or transfixed.

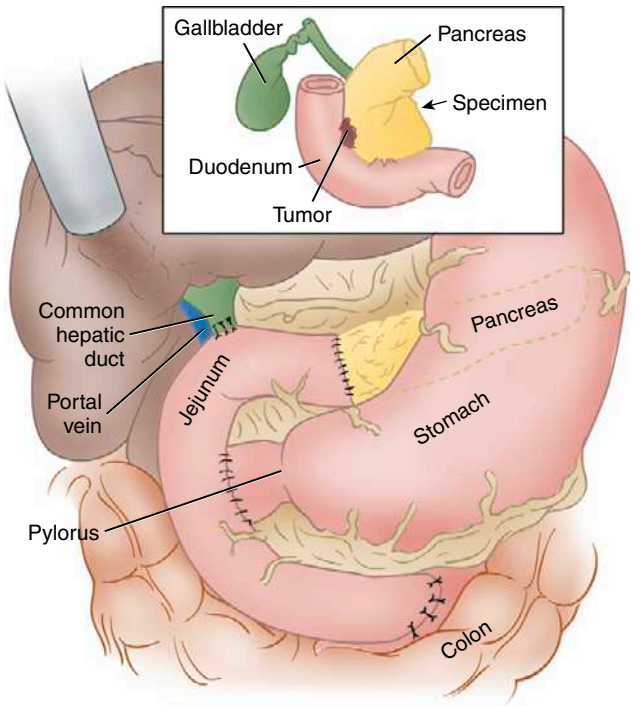

FIGURE 11-18 Illustration of a pylorus-preserving pancreaticoduodenectomy and the subsequent reconstruction. The inset at the top depicts the resected specimen. The jejunal limb is passed through and sutured to the transverse mesocolon.

6. The gastroduodenal and right gastric arteries are clamped, divided, and ligated.
7. The prepyloric area of the stomach is mobilized.
8. The operative field is prepared for open anastomosis by isolating the area with laparotomy sponges.
9. By placing two long Allen or Payr clamps near the midportion of the stomach, the transection is completed.
10. The duodenum is reflected, the common duct is divided, and the hepatic end is marked or tagged for later anastomosis.
11. The jejunum is clamped with two Allen forceps and the duodenojejunal flexure divided.
12. The pancreas is divided and the duct carefully identified.
13. Further mobilization of the duodenum and division of the inferior pancreaticoduodenal artery are done to permit complete removal of the specimen.
14. The most common reconstructive technique anastomoses the pancreas to the jejunum first, followed by the bile duct and the duodenum (Figure 11-18).
15. Drains may be placed, the abdomen closed, and an abdominal dressing applied.

Pancreatic Transplantation

Pancreatic transplantation is the implantation of a pancreas from a donor into a recipient for patients with type 1 (formerly known as juvenile-onset) diabetes. Options for pancreatic transplant include a pancreas transplant alone (PTA), an option chosen for patients with functioning kidneys; a simultaneous pancreas-kidney transplant (SPK), because severe diabetes is often associated with chronic renal failure; or a pancreas transplant after a kidney transplant (PAK), in which the pancreas is transplanted sometime after the kidney transplant. Pancreatic transplantation differs from other organ transplants in that it does not have immediate life-saving results. It is done in the hope of preventing debilitating side effects of diabetes, such as cardiovascular, retinal, and renal disease. For patients, a significant benefit is freedom from dependence on insulin. However, pancreatic transplant in patients with brittle diabetes remains a rare procedure because the trade-off of insulin dependence is lifelong immunosuppression (Gruessner et al, 2008). Transplant is most effective in persons with few or no secondary diabetic complications and it can reverse or stop the progression of these complications.

Procedural Considerations. The majority of pancreas transplants performed in the United States are SPK procedures (Figure 11-19). Instrumentation includes a transplant set as described for kidney transplantation in Chapter 14. In addition to the transplant set, vascular instruments and instruments for resection of the duodenal segment and management of the pancreatic duct are required. A linear stapling device may be used.

The patient is positioned supine after administration of a general anesthetic. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter is inserted before the abdominal skin prep and is attached to a urometer. Like other transplant procedures, these procedures are lengthy, lasting 5 to 7 hours. Positional pressure sites must be padded and a pressure-reducing mattress placed on the OR bed. Given the patient's diabetes, maintaining skin and tissue integrity is paramount. SCDs will likely be used. Careful monitoring of blood glucose level will occur throughout the procedure by the anesthesia provider. Blood and blood products will be ordered and their availability must be verified. Blood-warming devices, a forced-air warming device, warmed irrigating solution (<40.5° C [105° F]), and other measures are used to maintain normothermia. Communication among team members is essential in all transplant surgery. The patient is transferred to the SICU on completion of the procedure. Measures to address and reduce patient and family anxiety are usually part of all transplant programs. At-home rehabilitation is a gradual process and social services and other resources are part of the transplant team. The patient must take immunosuppressive drugs indefinitely. The verification process for organ transplant, established by the United Network for Organ Sharing (UNOS), must be followed to ensure that the organs of the donor and the recipient are compatible (Patient Safety).

Operative Procedure

1. The whole-organ pancreatic transplantation procedure is performed through an oblique incision opposite the side of the renal transplant in the lower abdominal quadrant. A midline incision may also be used for pancreatic transplant.
2. The external iliac artery and vein are skeletonized and lymphatics are tied off with 4-0 nonabsorbable ligatures.
3. The external iliac vein is clamped with noncrushing vascular clamps and a #11 blade used to make a venotomy.
4. The venotomy incision is extended with Potts scissors.
5. An end-to-side anastomosis of the donor portal vein to the recipient's external iliac vein is performed with four double-armed 5-0 polypropylene sutures.
6. The external iliac artery is then clamped and an aortic punch used to make an arteriotomy.

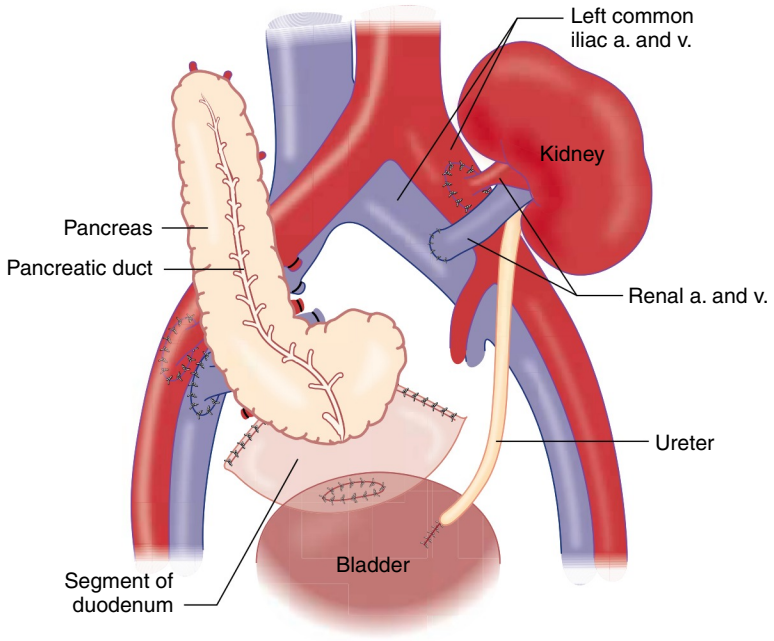

FIGURE 11-19 Transplantation of the pancreas with drainage of the bladder through a pancreaticoduodenocystostomy. A renal transplant is also shown with the common iliac vessels used for vascular anastomoses.

PATIENT SAFETY

Transplant of Donor Organs/Tissues: Example of Procedure for Establishing Identity and Matching Donor with Recipient

Before the transplant surgical procedure, a process of nine checkpoints is implemented to ensure identity and matching between the organs/tissues of the donor and the recipient.

Before the patient enters the OR the following must occur:

1. Once a transplant has been posted, Preliminary Transplant Crossmatch Reports are faxed from the human leukocyte antigen (HLA) lab to the OR where the transplant is to occur. The blood bank will fax ABO reports.
2. The OR charge nurse verifies the posted recipient's Preliminary Transplant Crossmatch Report and the ABO report.
3. The organ arrives at the OR.
4. The circulating nurse applies an addressograph label to the box with the organ.
5. The circulating nurse and another registered nurse together do the following:
   - **a.** Verify the tag on the organ with the Preliminary Transplant Crossmatch Report to ensure the following match:
     - **i.** Recorded ABO type of the recipient is the same or is compatible with the recorded ABO type of the donor.
     - **ii.** The UNOS (United Network for Organ Sharing) number on the organ is the same as the UNOS number on the Preliminary Transplant Crossmatch Report.
   - **b.** Identify the patient using the usual hospital policy.
   - **c.** Sign the Transplant Verification form.

In the OR the following must occur:

6. Preliminary anatomic checks are done by the surgeon. The transplant surgeon verifies that the UNOS number on the Preliminary Transplant Crossmatch Report is the same as the UNOS number on either the organ container or the paperwork provided and verifies the compatibility of the organ and the patient by ABO blood type. The transplant surgeon signs the Transplant Verification form.
7. Once the patient is taken into the OR, a time-out is taken with the OR team according to OR policy and procedure.
8. The Transplant Verification form and Preliminary Transplant Crossmatch Report are a permanent part of the patient's medical record.
9. The Transplant Verification form (deceased donor) is attached to the record.

Modified from *UNOS Policy 3.1.4.1: ABO verification prior to transplant,* 2005, available at www.unos.org/SharedContentDocuments/ABO_Verification_Processes_1_04.pdf. Accessed November 28, 2008.

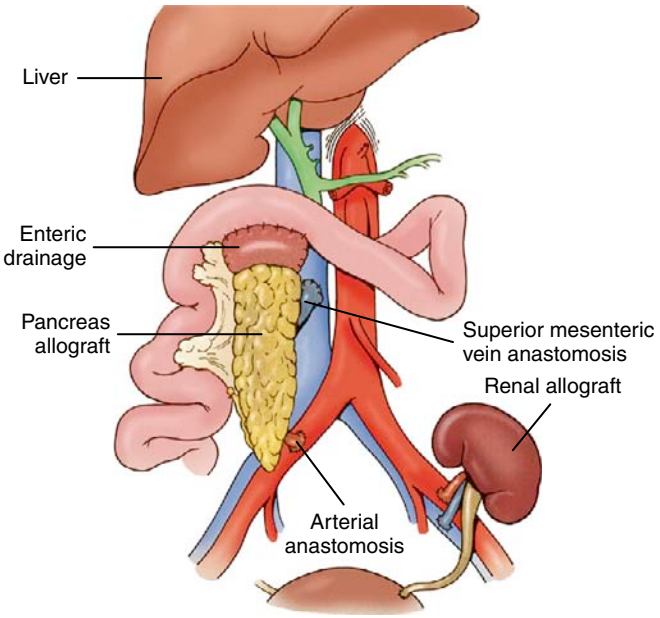

FIGURE 11-20 Pancreas and kidney transplants (PAK or SKP) with the donor pancreas vascularized to facilitate enteric exocrine drainage to a proximal portion of the jejunum (enteric drainage [ED] technique). The donor kidney is implanted in the left iliac fossa anastomosed to the femoral vessels and a ureteroneocystostomy is performed.

7. An end-to-side anastomosis of the recipient's external iliac artery with the donor aortic patch containing the origin of the superior mesenteric artery and the celiac axis is performed with four double-armed 6-0 polypropylene sutures.
8. Management of the pancreatic duct is then performed, according to the type of en bloc procedure performed.
9. Various enteric procedures for drainage of pancreatic duct secretions have been performed with whole-organ transplants en bloc with a segment of duodenum and the spleen. They include cutaneous jejunostomy, drainage into an ileal loop, and duodenojejunostomy with end-to-end or side-to-side anastomosis. Direct grafting of the pancreatic duct into the enteric or urinary system is also performed for management of exocrine secretions. Surgical procedures include pancreaticojejunostomy with an established Roux-en-Y loop of jejunum (Figure 11-20), pancreaticoductoureterostomy, and pancreaticocystostomy. The whole-organ pancreas transplant may also be performed as a pancreaticoduodenal transplantation or a pancreaticoduodenal-splenic transplantation.

SURGERY OF THE LIVER

Drainage of Abscess

Abscesses of the liver occur primarily by spread of bacteria or other organisms through the portal system (a direct route after trauma), the biliary tract, or the hepatic artery (in generalized septicemia); in addition, direct extension from a subdiaphragmatic or subhepatic abscess can lead to a liver abscess. In most instances, percutaneous drainage is effective and safe in the drainage of hepatic abscesses. However, open procedures may be required, often by way of the transperitoneal route. This approach permits inspection of the abdominal cavity for the underlying source of the abscess.

Procedural Considerations. A basic laparotomy set is used. Biliary instrumentation, drainage materials, and aerobic and anaerobic culture tubes are needed. Safe practices for handling specimens such as cultures are initiated. The patient is positioned supine after administration of a general anesthetic. The anesthesia provider inserts an NG tube after intubation. An indwelling urinary catheter may be inserted before the abdominal skin prep.

Operative Procedure

1. The incision preferred by many surgeons is the transperitoneal route; the surgical approach may be modified, however, according to the location of the abscess (e.g., in a high posterior abscess, the transpleural approach may be selected).
2. The abdomen is opened as described for laparotomy and abdominal inspection carried out.
3. The abscess is mobilized and evacuated, and cultures obtained.
4. Surgical drains are placed and the wound closed.

Hepatic Resection

Anatomically, the liver is divided into left and right lobes with the caudate lobe lying in the dorsal segment. Resection of the liver is undertaken for primary tumors, benign conditions (e.g., hepatolithiasis), and metastatic tumors. Hepatic resection is usually approached in one of three ways. The *anatomic* approach is based on the premise that malignant cells distribute along the portal venous segmental supply. In the *enucleation* approach, specific benign lesions with limited chance of local invasion are removed. The third approach, the *nonanatomic,* includes resections appropriate for a pathologic process in which a limited margin is acceptable, such as in tumor debulking.

Procedural Considerations. Instruments used are a laparotomy set, biliary instruments, vascular instruments, noncrushing liver clamps, a self-retaining retractor, and a surgical stapler. Supplies and equipment should be available for thermoregulation, electrosurgery, measurement of portal pressure, and replacement of blood loss. For major liver procedures, intraoperative ultrasound (to guide vessel isolation and minimize vascular occlusion), the argon beam coagulator, and the CUSA are used. Special blunt needles for suturing liver tissue are also necessary.

The patient is placed in supine position. Mild Trendelenburg's position may be requested by the surgeon. The anesthesia provider inserts an NG tube after induction of general anesthesia and intubation. An indwelling urinary catheter is inserted before abdominal skin preparation. The abdomen is prepped from nipple line to midthigh. Surgeons often use a right subcostal incision, with the ability to extend with a left subcostal if necessary. In some instances, a median sternotomy or right thoracotomy incision is required, and chest instruments are then necessary. Liver sutures, absorbable or nonabsorbable according to surgeon's preference, vessel loops, and umbilical tapes should be available on the sterile field.

Hemostatic material, such as Gelfoam, Surgicel, or Avitene, and absorbable collagen sheets should be readily available when the resection begins. The potential for bleeding exists both intraoperatively and postoperatively because of the high vascularity of the liver. If postoperative bleeding and subsequent hypovolemia occur, it may become necessary to call the Rapid Response Team (Rapid Response Team box).

RAPID RESPONSE TEAM

Treatment of nontraumatic shock can be delayed because of inadequate knowledge and/or skills of some clinicians. Some hospitals do not have system-wide resources to handle emergencies such as hypovolemic episodes, and the death rate can be high. Rapid response teams empower clinicians to identify and treat patients in shock using a multidisciplinary team approach. The team may consist of ICU nurses, respiratory therapists, emergency physicians, laboratory personnel, ECG and radiology technicians, pharmacists, and intensivists. These groups use evidence-based practice to promptly evaluate and treat deteriorating patients, which can lead to decreased inpatient cardiac arrests and postoperative morbidity and mortality.

Hypovolemia and sepsis are two typical reasons for team response. Early hemodynamic optimization improves survival in high-risk surgical patients and those with sepsis. Attitudes and behaviors of medical staff must be positive for this program to work effectively. Signs are posted that not only educate staff but also remind healthcare providers to use the team. Nurses are encouraged to call the team whenever something "doesn't feel right" about a patient or the patient is deteriorating rapidly.

In the case of hepatic, biliary, pancreatic, and splenic surgery, potential for bleeding exists postoperatively because of the high vascularity of these areas. When postoperative hypovolemia occurs and it becomes necessary to call the rapid response team, the nurse needs to provide a short, but comprehensive, report on the type of surgery performed. For liver transplant patients, it is paramount that early intervention occurs in patients with hypovolemia or hypotension as renal dysfunction can worsen and renal failure can result.

Modified from Sebat FS et al: Effect of a rapid response system for patients in shock on time to treatment and mortality during 5 years, *Crit Care Med* 35(11):2568-2575, 2007; Biancofiore G, Davis C: Renal dysfunction in the perioperative liver transplant period, *Curr Opin Organ Transplant* 13(3):291-297, 2008.

Surgeons use various methods to remove liver tissue. A CUSA allows the surgeon to dissect tissue using ultrasonic waves incorporated with fluid and suction. The ultrasonic waves cut through liver tissue, emulsifying it and diluting the tissue with fluid so that it can be suctioned. The electrosurgical pencil uses electrical current to cut through and desiccate liver tissue. Finger-fracture of the liver tissue is performed by digital pressure against the parenchyma to fracture the tissue.

Operative Procedure

1. Through a right subcostal incision, the abdominal cavity is opened and examined.
2. Pathologic condition is determined and resectability evaluated.
3. Moist laparotomy packs are inserted and a self-retaining retractor placed.
4. Intraoperative ultrasonography (US) is performed to assess all segments of the liver (Figure 11-21). Ultrasound-guided, digital intraparenchymal isolation of vessels is used during resection.
5. Lymph nodes in the porta hepatis and along the gastrohepatic ligament are then assessed by palpation to determine extrahepatic metastasis.
6. The intended resection line is scored with the blade tip of the electrosurgical pencil, and coagulation is set at the surgeon's selected setting (Figure 11-22).
7. The liver parenchyma is then delicately resected using the CUSA handpiece (Figure 11-23).
8. Once the portion of the liver is resected, the remaining liver resection margins are assessed for bleeding and bile leakage.
9. A laparotomy sponge may be placed against the transected surface for several minutes. The laparotomy sponge is gently rolled from the surface, which is then examined for bile leakage.
10. Areas may then be oversewn with 2-0 or 3-0 absorbable suture or an intended layer of eschar is applied using electrocoagulation or the argon beam coagulator.
11. Abdominal drains may be placed along the liver bed and exteriorized through the abdominal wall through separate stab wounds.
12. The abdominal wound is then closed and dressings applied.

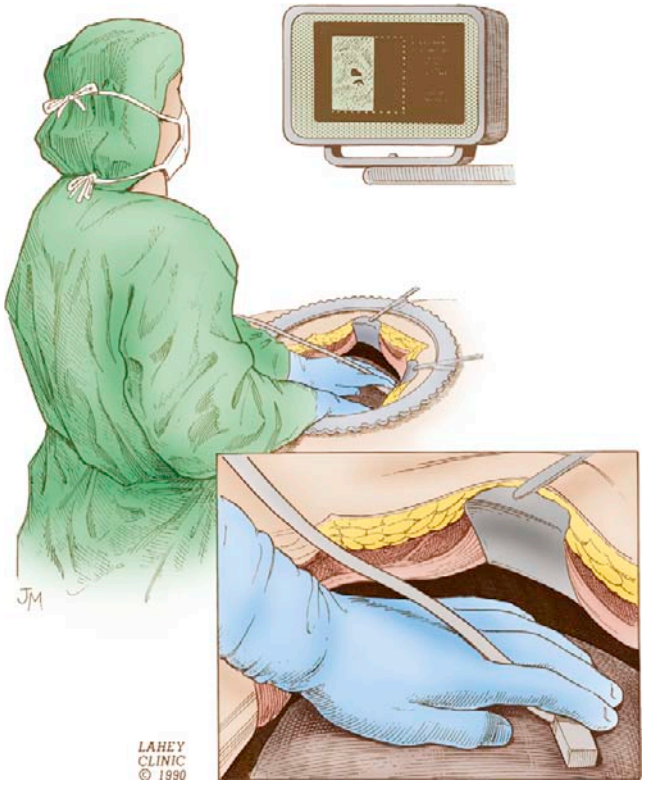

FIGURE 11-21 Use of intraoperative ultrasound using a 7-MHz T-probe to permit assessment of the liver.

Laparoscopic and Robotic-Assisted Laparoscopic Hepatic Surgery

Procedural Considerations. Laparoscopy for liver resection is a highly specialized field. It can present severe technical difficulties such as control of bleeding and risk of gas embolism (Belli et al, 2006; Borzellino et al, 2006). Other limitations relate to inadequate retraction, the inability to assess safe margins of resection with the loss of tactile sense, difficulty with safe parenchymal transection, and the potential for injury of adjacent structures (Poultsides et al, 2007). The use of stapling

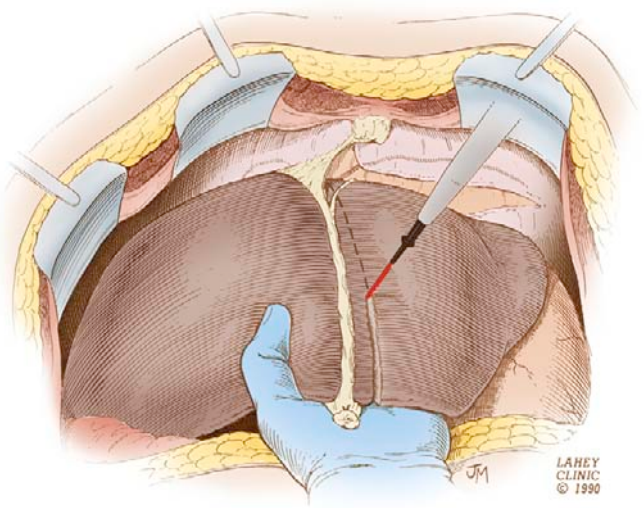

FIGURE 11-22 Use of electrosurgical pencil with blade tip to score the line of resection on the surface of the liver.

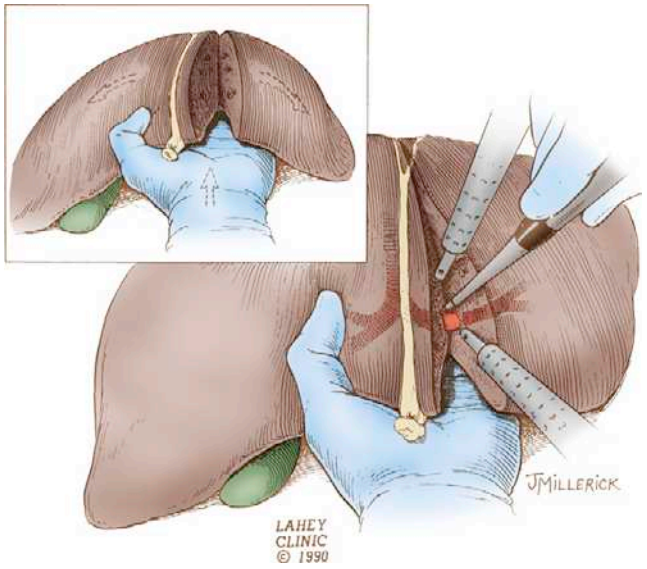

FIGURE 11-23 Use of the Cavitron ultrasonic surgical aspirator (CUSA) handpiece to dissect through the hepatic parenchyma.

devices has made the procedure faster and safer. Results for laparoscopic resections have been similar to those of open surgical technique in carefully selected cases (Borzellino et al, 2006). The benefits associated with robotic technology include less blood loss, faster recovery, less scarring, and reduced postoperative pain. The robot extends the surgeon's skills by providing a 360-degree range of motion not possible with traditional laparoscopic instruments. It also allows access to all the fine structures of the liver and better visualization of delicate blood vessels (First Robotic, 2005). Laparoscopic ultrasound navigation is often an important element in laparoscopic hepatic surgery as well (Kleemann et al, 2006). It enables determination of tumor location and the relationship to adjacent vascular and biliary structures (Santambrogio et al, 2007).

Radioimmunoguided Surgery

Radioimmunoguided surgery (RIGS) is a technique used intraoperatively to detect cancer that may not be readily detected by inspection or palpation. RIGS technique has been useful to determine safe margins of resection for metastatic colon cancer, as well as for extrahepatic disease and occult tumors in patients with rising serum carcinoembryonic antigen (CEA) levels.

About 2 to 3 weeks before surgery, patients receive an IV injection of radiolabeled monoclonal antibody, which binds reactive antigen on or near the surface of tumor cells. The antigen-antibody bond keeps minute amounts of radioactivity, or gamma emissions, localized in tumor tissue. An intraoperatively used, handheld gamma ray–detecting probe connected to a microcomputer emits an audible signal when the radioactive waves hit the crystal in the distal end of the probe. The Neoprobe instrument gives a digital reading as well as an audible pitch that rises or falls when placed on the gamma ray–emitting tissue. This advance in the intraoperative detection of adenocarcinoma and metastases can greatly assist in decision-making and resection of diseased tissue.

Procedural Considerations. Instrumentation includes a basic laparotomy set, biliary instruments, vascular instruments, and additional items such as a sterile marking pen, long clamps and a self-retaining retractor system (e.g., the Bookwalter retractor). Minimal suture (2-0 and 3-0 silk ties, 2-0 suture ligature) is added to the sterile field until the abdomen is explored and the extent of disease is assessed. The patient is positioned supine. The anesthesia provider inserts an NG tube after induction of general anesthesia and intubation. An indwelling urinary catheter is inserted before the abdominal prep. The abdomen is prepped from nipple line to midthigh. A midline abdominal incision provides access to the liver. Vertical abdominal incisions are sometimes used because they can be made and closed more rapidly and permit better exposure of all abdominal organs.

Operative Procedure

1. A midline abdominal incision is made from the xiphoid process to the pubis.
2. Intraoperative scanning of the liver and abdominal viscera is performed using the probe.
3. The digital readings as well as the anatomic structures being scanned are recorded.
4. Great care is taken to scan mesenteric, pelvic, and periaortic lymph nodes individually.
5. The liver is scanned and areas emitting strong-pitched tones are marked with a sterile marking pen. A very distinct change in pitch may be noted on liver tissue within a 2-cm to 3-cm radius of the tumor site.
6. Intraoperative ultrasonography and review of CT and MRI scans of the patient's liver are used to further confirm the liver lesions.
7. Margins for resection are drawn using an ESU tip on blend mode.
8. Resection of the lesion may be segmental, circumferential, or lobar.
9. After each resection, the margins of healthy liver tissue adjacent to the resection site are scanned and readings are recorded. This procedure continues until all tissue emitting high gamma ray waves has been resected.

10. Specimens are sent to the pathology laboratory for further pathologic and histologic analysis. The perioperative nurse supports accurate correlation of pathologic diagnosis with intraoperative RIGS findings by using safe specimen practices. Tissue specimens are verified, and specifically and meticulously identified.
11. The surgeon determines the best plan of treatment for the patient based on the information obtained from intraoperative assessment of the extent of the patient's disease. Resection of RIGS-positive tissue may result in an extensive retroperitoneal lymphadenectomy, liver resection, gastrohepatic ligament lymphadenectomy, or the resection of colon, uterus, or bladder.

Liver Transplantation

Liver transplantation is the implantation of a liver from a donor into a recipient. The total procedure involves retrieving or procuring the liver from a donor, transporting the donor liver to the recipient's hospital, performing a hepatectomy on the recipient, and then implanting the donor liver. Reanastomoses are then undertaken of the suprahepatic vena cava, infrahepatic vena cava, portal vein, and hepatic artery; biliary reconstruction with end-to-end anastomosis of donor and recipient common bile ducts; or Roux-en-Y anastomosis if the recipient's bile duct is absent as a result of biliary atresia.

Liver transplantation is indicated for patients with chronic hepatocellular disease, chronic cholestatic disease, metabolic liver disease, primary hepatic cancer, acute fulminant liver disease, and inborn errors of metabolism. When malignancies are the cause of end-stage liver disease, the right upper quadrant may be radiated intraoperatively—after hepatectomy and before transplantation. The patient undergoes extensive physiologic and psychologic assessment and evaluation by physicians and transplant coordinators before being placed on a national-network waiting list. The potential for postoperative complications (Table 11-5) requires ongoing evaluation.

Procedural Considerations. Successful transplantation requires the cooperative efforts of the organ-procurement agency and the staffs of the donor and recipient hospitals.

TABLE 11-5

Assessment and Prevention of Common Postoperative Complications Associated with Liver Transplants

Assessment	Prevention
ACUTE GRAFT REJECTION	
Occurs from fourth to tenth postoperative day.	Use prophylaxis with immunosuppressant agents, such as cyclosporine, FK-506, CellCept, Prograf, Imuran, sirolimus, and prednisone.
Manifested by tachycardia, fever, right upper quadrant (RUQ) or flank pain, diminished bile drainage or change in bile color, or increased jaundice.	Diagnose early to treat with more potent antirejection drugs, such as muromonab-CD3 (Orthoclone OKT3).
Laboratory changes include increased levels of serum bilirubin, transaminases, and alkaline phosphatase and prolonged prothrombin time.	Use antibiotic prophylaxis.
INFECTION	
Can occur at any time during recovery.	Diagnose early and treat with organism-specific antiinfective agents.
Manifested by fever or excessive, foul-smelling drainage (urine, wound, or bile); other indicators depend on location and type of infection.	Perform frequent cultures of tubes, lines, and drainage. Remove invasive line as early as possible. Use good hand hygiene.
HEPATIC COMPLICATIONS (BILE LEAKAGE, ABSCESS FORMATION, HEPATIC THROMBOSIS)	
Manifested by decreased bile drainage, increased RUQ abdominal pain with distention and guarding, nausea or vomiting, increased jaundice, and clay-colored stools.	Keep T-tube in dependent position and secure to patient; empty frequently, recording quality and quantity of drainage.
Laboratory changes include increased levels of serum bilirubin and transaminases.	Report manifestations to physician immediately. May necessitate surgical intervention.
ACUTE RENAL FAILURE	
Caused by hypotension, antibiotics, cyclosporine, acute liver failure, or hypothermia.	Monitor all drug levels with nephrotoxic side effects. Prevent hypotension.
Indicators of hypothermia include shivering, hyperventilation, increased cardiac output, vasoconstriction, and alkalemia.	Observe for early signs of renal failure and report them immediately to physician.
Early indicators of renal failure include changes in urinary output, increased blood urea nitrogen (BUN) and creatinine levels, and electrolyte imbalance.	

Modified from Ignatavicius DD, Workman ML: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, Philadelphia, 2010, Saunders.

Usually two members of the surgical team from the recipient's hospital travel to the donor's hospital to procure the donated liver. Often, multiple transplant teams may arrive at the donor hospital to procure various organs for transplantation. UNOS policies dictate a detailed system for checking and rechecking organs for transplantation to ensure that organs of the donor and recipient are compatible (see Patient Safety box, p. 386). These policies must be strictly followed before any transplant can take place. Safe practice further requires that hospital policies are consistent with applicable law and organ donation regulations and should address patient and family preferences for organ donation, as well as specify the roles and desired outcomes for every stage of the donation process (NQF, 2009).

PREPARING THE OR FOR THE DONOR. The donor OR is set up for a major laparotomy procedure. Basic instrumentation and equipment include a basic laparotomy set, cardiovascular instruments, power sternal saw, and nephrectomy instruments. A sterile, draped, medium-size instrument table is needed for preparation of the liver away from the main sterile field and instrument tables. The procurement team provides special Collins solution for flushing the organs, sterile plastic containers and ice chests for organs, and in situ flush tubing. The liver is generally placed in two Lahey bags immediately after procurement.

PREPARING THE OR FOR THE RECIPIENT. Each transplant surgeon has preferred instruments, supplies, and sutures. In general, the following are needed in the recipient's OR: a basic laparotomy set, a cardiovascular instrument set, an assortment of T-tubes, a slush unit or means of providing iced lactated Ringer's solution, two ESUs, a forced-air warming device, a temperature probe, IV volumetric pumps on stands, two blood warmers or water baths, an indwelling urinary catheter, an insertion tray, and a urometer. An argon beam coagulator may be used and should be available. A defibrillator is always located in the room with sterile external paddles available.

Large-bore cannulae for IV monitoring and fluid or blood replacement lines are placed in addition to an arterial line and a central venous line.

Two surgeon headlights and light sources will be necessary to augment visualization of the abdominal site. A venovenous bypass system may be used to support peripheral blood flow. Extra drape sheets, table covers, gowns, towels, gloves, sponges, and laparotomy pads; cold IV Ringer's solution; sterile IV administration set for flushing the new liver; umbilical tape; booties; and vessel loops should be available to support the many steps of the transplantation procedure.

A cart containing sutures and the numerous other small items should be arranged and placed in the room for each procedure. This eliminates the need for the circulating nurse to leave the patient and surgical team to obtain extra supplies.

The procedure for liver transplantation is a three-part process: retrieval of the donor organ, hepatectomy, and implantation of the donor liver. It is a lengthy procedure that takes many hours. The following aspects of implementing a plan of care deserve special attention.

Patient Positioning. The patient is placed supine with knees slightly flexed and padded. An indwelling urinary catheter is inserted after induction of anesthesia. Accurate body alignment is essential. A gel pad that is the length of the OR bed or a pressure-reducing OR bed mattress should be used, with attention to all potential pressure areas. Heel protectors are applied and SCDs are placed on the patient's legs. The safety strap is placed over the lower part of the thighs and secured. A forced-air warming device is applied over the upper body, neck, and head to assist in maintaining the patient's temperature. Fluid warmers are used to warm blood products and IV solutions.

Skin Preparation. The patient is prepped from the neck to midthigh, bedline to bedline. Prep solution should not pool at the bedline or wet the sheets on the OR bed. Fire safety precautions for prep solutions must be followed.

Blood Loss and Replacement. Blood loss may be extensive and replacement must be timely. The perioperative nurse should confirm that blood products are available at the beginning of the procedure. These include 10 units each of packed red blood cells (RBCs) and fresh frozen plasma (FFP) and 1 unit of pooled donor platelets. The perioperative nurse should be available to assist the anesthesia provider during the insertion of peripheral and arterial lines. An autologous cell-saver device may be used to assist in blood replacement by way of autotransfusion.

Intraoperative Laboratory Testing. It is possible that as many as 50 blood specimens will be drawn for analysis during the procedure. Safe specimen collection practices are implemented. These specimens must be recorded on the blood-loss record and calculated into replacement needs. Specimens are delivered to the laboratory immediately. A telephone in the OR is useful for receiving and reading back critical test results/reports directly from the laboratory. Safe practices for reporting of critical test results require the perioperative nurse to verify the test result by "reading-back" the result (NQF, 2009). Standard precautions in collection of specimens must be observed.

Length of Procedure. Procedures may last from 6 to 20 hours. Special attention must be paid to maintaining the integrity of the sterile environment, given the length of surgery and number of people entering and exiting the OR.

Communication with Family. Frequent reports to the family are important. Family members often are knowledgeable about liver function tests and laboratory values and want this information in addition to reports on the condition of their loved one. One person should be assigned in advance to make regular contacts with family and support persons. The UNOS team often works closely in communicating with the donor's and recipient's families.

Communication Among Teams. The perioperative nurse ensures that communication occurs among teams. Coordination among the procurement team, anesthesia team, and surgical teams is essential for a successful transplantation procedure. Perioperative nursing responsibilities also include monitoring and communicating blood-loss volume in suction canisters and on sponges, the availability of blood and blood products, laboratory results, time of organ arrival, ischemic time, and other events as they unfold in preparation for and during the transplant procedure.

Operative Procedure

1. Bilateral subcostal incisions are made with a midline incision extended toward the umbilicus. If necessary, the xiphoid is removed. The right side of the chest is entered if additional exposure is needed.
2. Initial dissection of the underlying tissues is achieved with electrosurgery and suture ligatures.

3. Isolation of all hilar structures and dissection to mobilize the lobes of the native liver are performed.
4. The retrohepatic vena cava is skeletonized, as are the hepatic artery, portal vein, common bile duct, and inferior vena cava.
5. The donor liver is examined.
6. Preparations may be made at this time for venovenous bypass using an extracorporeal assist device if the patient is unstable.
7. The infrahepatic vena cava and the suprahepatic vena cava are clamped, as are the portal vein, the hepatic artery, and the common bile duct.
8. Native hepatectomy is then performed.
9. The donor liver is placed in the right upper abdomen, and revascularization of the donor organ begins with end-to-end anastomoses in the vena cava and portal vein, with double-armed fine vascular suture.
10. At this point, the clamps on the portal vein, suprahepatic vena cava, and infrahepatic vena cava are released slowly, and blood flow through the vena cava and portal vein is restored.
11. The anastomosis sites are then checked for leaks.
12. If it was used, venovenous bypass is discontinued, and the cannulation sites are closed.
13. The postrevascularization phase focuses on achieving hemostasis. Complete hemostasis may require extensive time at this point. Bleeding may be exacerbated by a fibrinolytic episode associated with the reperfusion of the donor organ. The liver is monitored for a change in color from dusky to pink. An intraoperative Doppler may be used to confirm patency of the blood supply.
14. The anastomosis of the hepatic artery is then commenced, followed by bile duct reconstruction. This varies with the status of the recipient's biliary tract. If biliary atresia is the cause of the patient's end-stage liver disease, choledochoenterostomy into a Roux-en-Y loop of jejunum is performed (Figure 11-24).
15. The anastomoses are then checked for leaks.
16. Drains are placed behind and in front of the liver and exteriorized. The abdomen is then closed.

Donor Hepatectomy

Donor hepatectomy is performed for procurement of a healthy liver for transplant into a patient who has end-stage liver failure. This procedure occurs only after the donor patient has been determined to be brain dead and family consent for organ donation has been obtained. Donor hepatectomy can be performed at any hospital. Organ procurement agencies arrange contact with transplant centers when a viable organ donor has been identified.

Procedural Considerations. Once the liver transplant candidate has been identified, the procurement team from that transplant center travels to the institution where the organ donor is hospitalized. If multiple organs are being donated, surgeons from several transplant centers may arrive to procure the organs they will be transplanting to their respective centers.

The procedure for procurement of multiple organs will differ according to the transplant centers represented. Most commonly, the systemic cooling of the donor's body temperature is started before the procurement of the heart. Cannulation sites also vary according to which organs are procured.

Perioperative nurses at the donor hospital are responsible for supplying a basic laparotomy setup with instrumentation to open the sternum. Basic vascular clamps are also required to clamp the major vascular structures. Cold lactated Ringer's solution for parenteral infusion and cold Ringer's solution for irrigation are usually used in large amounts.

Operative Procedure

1. The donor patient is positioned supine on the OR bed. The skin area from neck to midthigh is prepped and draped.
2. A midline incision is made from the suprasternal notch to the pubis.
3. A subcostal incision is performed bilaterally on the abdomen for better exposure of the abdominal viscera.

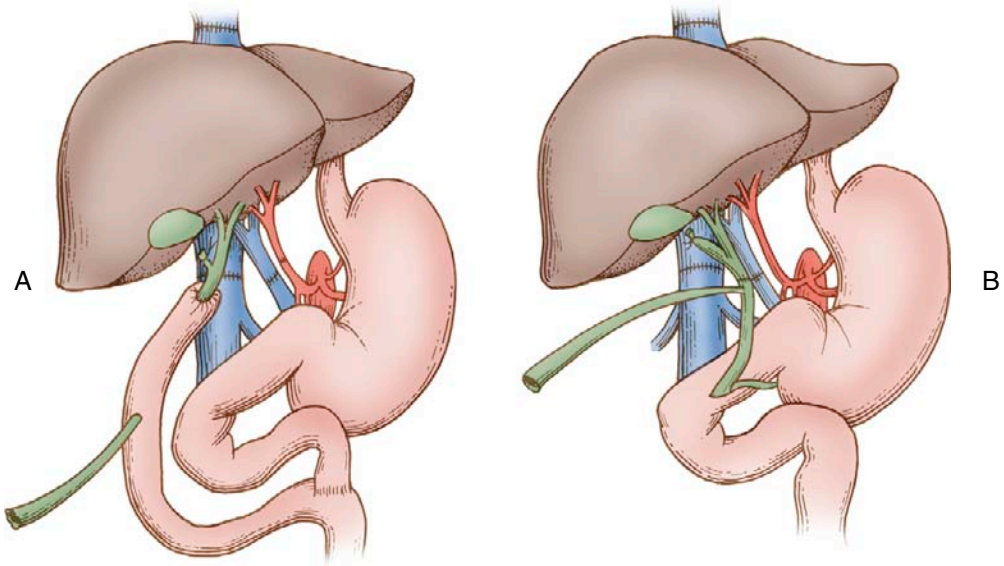

FIGURE 11-24 Completed orthotopic liver transplant with Roux-en-Y biliary reconstruction (**A**) and end-to-end anastomosis of the donor-to-recipient common bile ducts (**B**).

4. Retractors are placed to provide optimal exposure of the organs that will be procured.
5. The aorta and vena cava, superior and inferior to the liver and kidneys, are skeletonized by dissection and ligation of the lymphatics and smaller vasculatures.
6. The porta hepatis is dissected; the superior mesenteric artery and celiac trunk are then dissected and delicately exposed as close to the aorta as is convenient.
7. The superior mesenteric vein is dissected and prepared for cannulation. The donor is heparinized and systemically cooled.
8. If the heart is to be procured, removal takes place at this time.
9. Further cooling and flushing of the pancreas, liver, and kidneys are achieved by cannulation and infusion of cold lactated Ringer's solution through the inferior vena cava just superior to the bifurcation.
10. The liver, pancreas, spleen, and a segment of the duodenum harboring the pancreatic duct are procured en bloc by placing clamps on the suprahepatic and infrahepatic venae cavae.
11. The suprahepatic vena cava is transected with a surrounding cuff of diaphragm intact.
12. The infrahepatic vena cava is transected above the level of the renal veins.
13. The celiac axis is detached from the aorta as an aortic patch or taken with a full aortic circumference.
14. The duodenal segment is procured, using a linear stapling device at opposite ends of the segment.
15. The en bloc organs are taken to a back table for further dissection and ligation to separate the liver from the en bloc pancreas, spleen, and duodenal segment graft. Meanwhile, other members of the procurement team continue working to free the kidneys and ureters if they are to be taken.
16. The liver is placed in a basin of cold Ringer's solution, double-bagged in sterile Lahey bags, and placed in an ice chest for transport to the recipient's hospital.
17. The kidneys are placed in sterile cassettes and mechanically perfused.
18. The pancreatic en bloc graft is also placed in a basin of cold Ringer's solution, bagged, and transported in a thermal chest of ice.
19. The abdomen is closed with a single layer of size 1 or 0 nonabsorbable suture.
20. Drapes are removed, and the donor patient is cleaned and washed. Tubes and infusion lines are tied off or clamped. Sometimes family members of the donor patient request to view the body after organ donation. This factor may be important in helping them face their loss. Before family viewing, the donor's body is covered with a warm blanket. The perioperative nurse assists the family in their grieving process by providing a quiet and private environment in which to say good-bye to their family member. The nurse should stay with family members to support them.
21. The donor patient is then transported by stretcher to the morgue.

Living-Related Liver Transplantation

Just as kidney transplantation has evolved into living-related donor possibilities, so too has liver transplantation. The capacity of the liver to regenerate provided the scientific basis for development of the living-related donor transplantation procedure. Reduced-size and split-liver transplants have been performed successfully. Reduced-size liver transplantation has been performed for infants, children, or very small adults with results comparable to those obtained with whole-organ transplantation. Prospective living donors are thoroughly evaluated with a protocol that includes blood group compatibility, a comprehensive history and physical examination, laboratory studies, psychosocial evaluation, independent advocate opinion, anatomic compatibility, review of candidacy with the donor, and presentation to a selection committee (Patt and Thuluvath, 2003). As cloning, biogenetic engineering, and other technologic advances increase the possibilities for organ transplants, society will need to address ongoing debates of ethical dilemmas surrounding transplantation.

SURGERY OF THE SPLEEN

Splenectomy (Open Approach)

Splenectomy is removal of the spleen. It is performed for multiple reasons: trauma to the spleen; specific malignant conditions (Hodgkin's disease and non-Hodgkin's lymphomas; hairy cell, chronic lymphocytic, and chronic myelogenous leukemias); hemolytic jaundice or splenic anemia; idiopathic thrombocytopenia purpura (ITP); tumors, cysts, or splenomegaly; or accidental injury during vagotomy or other procedures involving mobilization of the splenic flexure of the colon. If accessory spleens are present, they are also removed because they are capable of perpetuating hypersplenic function. In most instances, patients evaluated for elective splenectomy are considered candidates for laparoscopic splenectomy. Contraindications to laparoscopic splenectomy include severe portal hypertension, uncorrectable coagulopathy, severe ascites, extreme splenomegaly, extensive adhesions, and most traumatic injuries to the spleen. For these patients, an open approach is indicated.

Procedural Considerations. Instrumentation is as described for a basic laparotomy, plus two large, right-angled pedicle clamps, long instruments, and hemostatic materials and devices. Abdominal suction apparatus is available and a cell-saver may be requested. The patient is positioned supine. After induction of general anesthesia and intubation, the anesthesia provider inserts an NG tube. An indwelling urinary catheter is inserted before the abdominal prep. The abdomen is prepped from nipple line to midthigh. The OR bed is moved to reverse Trendelenburg's position with a slight tilt to the right. A midline abdominal incision provides access to the spleen and allows maximal exposure of all abdominal organs. Occasionally, a subcostal approach is used for a patient without traumatic injury. Rarely, a thoracoabdominal approach is used.

Operative Procedure

1. The abdomen is opened through the selected incision.
2. Retractors are placed over moistened laparotomy packs and exploration is carried out.
3. The costal margin is retracted upward.
4. The splenorenal, splenocolic, and gastrosplenic ligaments are clamped and divided with long dressing forceps, long hemostats, sponges on holders, and long Metzenbaum or Nelson scissors.

5. Adhesions posterior to the spleen are freed.
6. The spleen is delivered into the wound.
7. The short gastric vessels are now easily identified, clamped, divided, and ligated.
8. The cavity formerly occupied by the spleen is packed with moist laparotomy pads, if necessary.
9. The splenic artery and vein are dissected free with fine dissecting scissors and forceps.
10. The artery is clamped and doubly ligated. The artery is ligated first to permit disengorgement of blood from the spleen and facilitate return of venous blood to the circulatory system.
11. The splenic vein is then clamped, divided, and ligated.
12. The specimen is removed, bleeding vessels controlled, and the wound closed in layers, as described for laparotomy. Dressings are applied.
13. Drainage is usually required only if extensive adhesions to the diaphragm were divided or if significant clotting abnormalities exist.

Laparoscopic Splenectomy

Laparoscopic splenectomy is standard procedure for surgical treatment of benign hematologic disorders (Beauchamp et al, 2008). Indications are the same as with open procedures, with the exception of the contraindications noted previously. Robotic assistance has improved visibility and motion control (Bodner et al, 2005b).

Procedural Considerations. After induction of general anesthesia, an NG tube and indwelling urinary catheter are inserted, and SCDs applied to the lower extremities. The patient is positioned in right lateral position, with the OR bed flexed and kidney rest raised to increase the distance between the lower rib and iliac crest. The anterior abdomen is brought close to the edge of the OR bed. A beanbag device may be used. Safety restraints must be placed, especially in anticipation of a possible slight backward patient tilt. Alternatively, supine or modified lithotomy position may be used. The surgeon stands on the patient's right side, as does the scrub person, and assistants stand to the left.

Instrumentation and equipment include a 30-degree telescope (10-mm or 5-mm); a camera (triple-chip or single-chip); a high-flow insufflator with CO_2 tank; a high-resolution monitor (second monitor optional for assistant); a printer (optional); a Surgineedle or Veress needle; four 12-mm trocars (trocar size depends on surgeon preference—some surgeons substitute one or two of the 12-mm trocars with 5-mm trocars or even 3-mm trocars); endoshears/scissors; ultrasonic endoshears; an endodissecting forceps or endograsper (atraumatic); an endoretractor; an endoclip applier; a linear stapling device (GIA type) with vascular cartridges; an endoretrieval pouch; and a suction-irrigation system. As with other laparoscopic procedures, instruments and supplies are available if it becomes necessary to convert to an open approach.

Operative Procedure

1. Pneumoperitoneum is created and the first trocar placed under direct visualization. Three to five 2- to 12-mm operating ports are used, with the camera port at the umbilicus.
2. The laparoscope is inserted through the port and the camera placed.
3. The stomach is retracted to expose the spleen and a search made for any accessory spleens.
4. Initial dissection is begun by mobilizing the splenic flexure of the colon.
5. The splenocolic ligament is divided using sharp dissection, mobilizing the inferior pole of the spleen. The spleen is now retracted cephalad, taking care not to rupture the splenic capsule during retraction.
6. The lateral peritoneal attachments of the spleen are then incised using either sharp dissection or ultrasonic endoshears.
7. The lesser sac is entered along the medial border of the spleen.
8. With the spleen elevated, the short gastric vessels and main vascular pedicle are visualized. The tail of the pancreas is also visualized and avoided.
9. The short gastric vessels are divided by means of an ultrasonic dissector, endoclips, or an endovascular stapling device.
10. After the short gastric vessels have been divided, the splenic pedicle is carefully dissected from both the medial and lateral aspects.
11. After the artery and vein are dissected, the vessels are divided by application of the endovascular stapler. Multiple vascular branches may be encountered and each is taken individually.
12. The spleen is now devascularized and ready for removal.
13. An Endo-Bag is introduced through one of the trocar sites, usually the left lateral site.
14. The bag is opened and the spleen placed into it. The drawstring is grasped and the bag closed, leaving only the superior pole attachments, which are now divided.
15. The open end of the bag is exteriorized from the abdomen through the supraumbilical port or epigastric trocar site. The spleen is then morcellated and removed in fragments.
16. The laparoscope is reinserted and the splenic bed is assessed for hemostasis.
17. If necessary, a drain is placed in the intraabdominal cavity, the abdomen deflated, and the trocars removed.
18. The trocar sites are then closed.

CHAPTER 12

Repair of Hernias

MAYA CLARK and JANE C. ROTHROCK

A hernia is an abnormal protrusion of a peritoneum-lined sac through the musculoaponeurotic covering of the abdomen. The word *hernia* is a Latin term that means "rupture" of a portion of a structure. Descriptions of hernia reduction date back to Hammurabi of Babylon and the Egyptian papyrus (History box). Weakness of the abdominal wall, congenital or acquired, results in the inability to contain the visceral contents of the abdominal cavity within their normal confines. This defect occurs frequently; hernia repair is the most common operation in general surgery (Menon, 2008). More than 700,000 surgical procedures are performed each year to repair congenital hernia defects; nearly 75% of all acquired hernias occur in the inguinal region. Of these, about 50% of hernias are indirect inguinal hernias and 24% are direct inguinal hernias. Incisional and ventral hernias account for approximately 10% of all hernias; as the frequency and magnitude of abdominal surgeries have increased in recent years, so has the incidence of incisional hernia. Femoral hernias account for 3%, and unusual hernias account for the remaining 5% to 10%.

Hernias occur most often in males. The most common hernia in both males and females is the indirect inguinal hernia. Femoral hernias occur much more frequently in females, and only 2% of females will develop inguinal hernias in their lifetime. Also, hernias occur more commonly on the right side than on the left. Herniorrhaphy is one of the most common operative procedures performed and is the preferred treatment when a defect is detected.

Hernias have a tremendous economic significance in the United States. The number of workdays lost is substantial. The trend toward ambulatory surgery for hernia repair is one of many attempts to provide cost-effective healthcare that also leads to patient satisfaction.

A hernia can occur in several places in the abdominal wall, with protrusion of a portion of the parietal peritoneum and often a part of the intestine. The weak places or intervals in the abdominal aponeurosis are (1) the inguinal canals, (2) the femoral rings, and (3) the umbilicus. Any number of conditions causing increased pressure within the abdomen can contribute to the formation of a hernia. Contributing factors to hernia formation include age, gender, previous surgery, obesity, nutritional status, and pulmonary and cardiac disease. Loss of tissue turgor occurs with aging and in chronic debilitating diseases. Current evidence suggests that adult male inguinal hernias are likely associated with impaired collagen metabolism and weakening of the fibroconnective tissue of the groin (Gilbert et al, 2009). Smoking has also been noted as a contributing factor to hernia formation (Read, 2004). A successful herniorrhaphy is measured by the percentage of recurrence, the number of complications, the total costs, and the ability to return to normal activities of daily living (Research Highlight).

Surgical Anatomy

A hernia is a sac lined by peritoneum that protrudes through a defect in the layers of the abdominal wall. Generally, a hernia mass is composed of covering tissues, a peritoneal sac, and any contained viscera. Hernias may be acquired or congenital.

Depending on their location, hernias are classified as direct inguinal, indirect inguinal, femoral, umbilical, incisional, or epigastric (Figure 12-1). Hernias in any of these groups are either reducible or nonreducible; that is, the contents of the hernia sac either can be returned to the normal intraabdominal position or are trapped in the extraabdominal sac (incarcerated). The conditions preventing the return of the hernia contents to the abdomen can result from (1) adhesions between the contents of the sac and the inner lining of the sac, (2) adhesions among the contents of the sac, or (3) narrowing of the neck of the sac. Patients with incarcerated hernias may have signs of intestinal obstruction, such as vomiting, abdominal pain, and distention. The greatest danger of an incarcerated hernia is that it may become strangulated. In a strangulated hernia, the blood supply of the trapped sac contents becomes compromised and eventually the sac contents necrose. When bowel is strangulated in such a hernia, resection of necrotic bowel, in addition to the repair of the hernia defect, becomes necessary. This is a surgical emergency.

Inguinal Hernias

The anterolateral abdominal wall consists of an arrangement of muscles, fascial layers, and muscular aponeuroses lined interiorly by peritoneum and exteriorly by skin (Figure 12-2). The abdominal wall in the groin area is composed of two groups of these structures: a superficial group (Scarpa's fascia, external and internal oblique muscles, and their aponeuroses) and a deep group (internal oblique muscle, transversalis fascia, and peritoneum).

Essential to an understanding of inguinal hernia repair is an appreciation of the central role of the transversalis fascia as the major supporting structure of the posterior inguinal floor. The inguinal canal, which contains the spermatic cord and associated structures in males and the round ligament in females, is approximately 4 cm long and takes an oblique course parallel to the groin crease. The inguinal canal is covered by the aponeurosis of the external abdominal oblique muscle, which forms a roof (Figure 12-3). A thickened lower border of the

HISTORY

History of Hernia Repairs

Groin hernias were originally documented 3500 years ago, with surgical intervention starting approximately 1500 years after that. Before the intervention of surgical repair of the hernia, external supports called *trusses* were used to contain hernias that protruded from the body. A brief chronology of some of the events that laid the foundation for modern hernia repair is presented below.

Time Period	Breakthrough
2800 BC	Herodotus reported that physicians specialized in treating hernia.
1700 BC	Hammurabi described hernia reduction.
400 BC	Hippocrates described hernia as a tear in the abdomen.
200 BC	Galen described anatomy of the abdominal wall.
AD 100	Celsus described clinical signs to differentiate a hernia from a hydrocele.
1559	Maupassius performed the first surgical intervention to correct a strangulated hernia.
1724	Heister described direct hernias.
1804	Astley Cooper defines a hernia as a protrusion of any viscus from its proper cavity.
1814	Scarpa described sliding hernias.
1881	Lucas-Championniere laid the basis for the most important inguinal hernia repair procedure—reinforcing the posterior wall of the inguinal canal and narrowing the internal inguinal ring.
1887	Bassini introduced his repair technique that involved suturing the conjoined tendon to the inguinal ligament up to the inguinal ring; he is considered the father of modern-day hernia surgery.
1898	Lotheissen modified the Bassini repair, recommending the oblique internus and transversus abdominis muscles be attached to the Cooper ligament. (Cooper was the first to describe the superior pubic ligament, although he never used it to surgically repair a groin hernia.)
1918	Nursing textbook listed instruments for femoral, inguinal, umbilical, and ventral herniorrhaphy.
1940	Shouldice introduced multilayer closure; founded Shouldice Hospital near Toronto. Local anesthetic was used; patients walked to and from the OR.
1942	McVay again described Lotheissen repair; it became known as the *McVay/Cooper repair.*
1958	Usher introduced use of "Marlex" mesh for repair of both primary and recurrent hernias, describing it as "tension-eliminating."
1971	Nursing textbook described the Gallie method, in which fascia lata is removed from the thigh and stitched around the hernial orifice.
1982	Ger performed the first laparoscopic herniorrhaphy.

RESEARCH HIGHLIGHT

Prioritizing General Surgery Procedures for Quality Improvement Efforts

Despite growing reliance on quality improvement measures, there is no established protocol for determining which general surgical procedures should be the focus of these efforts. In this study, researchers sought to prioritize procedures for quality improvement efforts in general surgery in terms of morbidity, mortality, and excess length of stay. Using data from the American College of Surgeons' National Surgery Quality Improvement Program, they identified 129,233 patients who underwent general surgery between 2005 and 2006.

Patients were placed in 36 procedure groups. Of these, 10 groups accounted for 62% of complications and 54% of excess length of stay. Patients undergoing ventral hernia repair accounted for only 5% of complications. In contrast, the colectomy group accounted for the highest number of adverse events (24%), followed by small intestine resection (8%), inpatient cholecystectomy (6%), and pancreatic resection (4%).

In looking at ambulatory surgery, outpatient inguinal hernia repair, cholecystectomy, breast procedures, thyroidectomy, and parathyroidectomy accounted for 34% of procedures but only 6% of complications and less than 1% of excess hospital days.

Based on their analysis, researchers concluded that a relatively small number of general surgery procedures account for a disproportionate share of the morbidity, mortality, and excess hospital days. Therefore focusing quality improvement efforts on those procedures may be an effective strategy for improving care and reducing cost.

Adapted from Schilling PL et al: Prioritizing quality improvement in general surgery, *J Am Coll Surg* 207:698-704, 2008.

external oblique aponeurosis forms the inguinal (Poupart's) ligament, which runs from the anterior superior iliac spine to the pubic tubercle. Structures that traverse the inguinal canal enter it from the abdomen by the internal ring, a natural opening in the transversalis fascia, and exit by the external ring, an opening in the external oblique aponeurosis, to go to either the testis or the labium. If the external oblique aponeurosis is opened and the cord or round ligament is mobilized, the floor of the inguinal canal is exposed. The posterior inguinal floor is the structure that becomes defective and is susceptible to indirect, direct, or femoral hernias.

The key component of the important posterior inguinal floor is the transversalis muscle of the abdomen and its associated aponeurosis and fascia. The posterior inguinal floor can be divided into two areas. The superior lateral area represents the internal ring, whereas the inferior medial area represents the attachment of the transversalis aponeurosis and fascia to the Cooper ligament (iliopectineal line). The Cooper ligament is the
