Retraction is required for visualization. Self-retaining retractors such as cerebellar or Gelpi retractors can be used to retract skin, subcutaneous tissue, muscle, or the scalp. Suture can be used to retract the scalp or the dura of the brain or spinal cord. Blunt, malleable retractors are used on brain tissue. Table-mounted self-retaining retractor systems such as the Greenberg help the surgeon to see deep into the brain and may be used with a microscope.

Electrosurgery is routine for neurosurgical procedures. Perioperative nurses must understand the uses and hazards of the ESU and be familiar with the safety measures. Electrocoagulation current seals the blood vessels. To be effective, the electrocoagulating current must contact the vessel in a dry field. For this reason, suctioning is necessary to remove blood as the contact is made between the instrument carrying the current and the bleeding point. A monopolar current is used to cut and coagulate tissue. It can be applied to forceps, a metal suction tip, or another instrument, which acts as a conducting tool. Monopolar electrosurgery is safe to use on the epidermis, dermis, galea, periosteum, muscle, and bone. It is used extensively for exposure of the posterior spine.

Bipolar ESUs provide a completely isolated output with negligible leakage of current between the tips of the forceps, permitting use of electrocoagulating current in proximity to structures where ordinary monopolar electrocoagulation would be hazardous (Figure 20-43). It is safe to use the bipolar ESU to control bleeding on the dura of the brain and spinal cord and near vital nerves and vessels. It can be used to maintain hemostasis and to dissect tissue in the brain. Lactated Ringer's or normal saline solution irrigation is often used during bipolar electrocoagulation to minimize tissue heating, shrinkage, drying, and adherence to the forceps. Some bipolar units have built-in irrigating systems. The use of the bipolar electrocoagulation technique allows hemostasis of almost any size vessel encountered. Vessels as large as the superficial temporal artery, as well as those too small for suture or clip ligation, may be coagulated with bipolar units.

Suction is necessary to evacuate blood, CSF, and irrigation solution from the surgical site. Metal suction tips in multiple sizes, such as the Sachs, Frazier, and Adson, are used not only because they keep the wound dry but also because they can conduct electrocoagulation current from a monopolar unit to the bleeding point. Suction applied directly on normal neural tissue may be harmful and is avoided. Instead, a cottonoid patty may be placed between the suction tip and neural tissue for protection. Suction can be used to aspirate necrotic or traumatized brain tissue or soft brain tumors after a sample has been obtained for pathologic examination. It is also useful in evacuating abscess cavities, removing fluid from a ventricle or the subarachnoid space, holding a solid tumor during its removal, and applying compression to a bleeding vessel.

Bone wax is a hemostatic material that should be available for all cranial and spinal cord operations. Bone wax may be applied with the surgeon's fingertip or with the tip of an instrument such as a Freer or Penfield elevator. The surgeon firmly rubs or packs the wax into the bleeding surfaces of bone. Bone wax is commonly used in burr holes, along the edges of a craniotomy, and on the cut edges of the spine.

FIGURE 20-42 Automatic clip gun, with disposable scalp clips and cartridge.

FIGURE 20-43 Malis bipolar coagulator and bipolar cutter, with irrigation module.

Gauze sponges are used to control bleeding before the skull or spinal canal is entered; however, they are coarse and can injure fragile tissues such as the brain and spinal cord. Instead, compressed, absorbent patties made of rayon or cotton (cottonoids) are used to control bleeding beneath the skull and around the spinal cord. Patties are also placed over delicate neural tissue for protection. It is far less traumatic to suction on a patty than directly on the tissue. Patties are available in a variety of sizes, both squares and strips, ranging from ¼ inch to 6 inches long and from ¼ inch to 1 inch wide (Figure 20-44). A supply of various sizes is typically moistened with irrigation solution or thrombin and offered to the surgeon on a waterproof surface. Patties have x-ray–detectable markers and strings attached and are included in the standard sponge count.

Cotton balls moistened with irrigation solution or thrombin may be used as a temporary pack or tamponade in a bleeding tumor bed after a tumor has been removed. The gentle pressure of the cotton balls along with time and patience on the part of the surgeon may stop bleeding not controllable by other means. Cotton balls also have x-ray–detectable strings and are included in the sponge count.

A variety of hemostatic clips are available and used by neurosurgeons to occlude both superficial and deep vessels. Unlike clips that were used in the past, hemoclips and Ligaclips are made of an alloy that is compatible with the MRI scanner. The scrub person removes the clips from a special cartridge with the appropriate applicator and passes them to the surgeon for application to a vessel. Such clips enable the surgeon to occlude vessels in areas difficult to reach by other means and to ligate superficial vessels of the brain before cutting them and without destroying any surrounding tissues. Clips are available in a variety of sizes. Numerous types of special clips are used for permanent or temporary occlusion of vessels or an aneurysm neck in the surgical treatment of an intracranial aneurysm (Figure 20-45).

Neurosurgeons almost routinely use certain hemostatic agents in addition to mechanical hemostasis (Surgical Pharmacology). An absorbable gelatin sponge (Gelfoam) can be applied to an oozing surface, either dry or saturated with

SURGICAL PHARMACOLOGY

Hemostatic Agents

Achieving hemostasis in delicate areas can be a challenge for the neurosurgeon. In addition to using meticulous technique to prevent bleeding, topical agents are routinely used as an adjunct to hemostasis. The perioperative nurse must be familiar with the agents used in this setting.

Agent	Dosage Form	Mechanism of Action	Side Effects	Nursing Considerations
Topical thrombin	Powder for reconstitution; packaged with diluent and spray pump, or diluent and spray tip syringe, with diluent only	Catalyzes conversion of fibrinogen to fibrin	May cause fever or allergic-type reactions	Product is for external use only; must be refrigerated.
Gelatin matrix (FloSeal)	Gelatin matrix granules and topical thrombin packaged as a kit with syringes and mixing bowl	Matrix particles form a composite clot that seals bleeding site; thrombin component converts fibrinogen in patient's blood to fibrin	Anemia, atrial fibrillation, infection	Product reaches maximum expansion at approximately 10 min. Excess product should be removed with gentle irrigation.
Absorbable gelatin sponge (Gelfoam)	Film, powder, and topical forms	Absorbs and holds blood and fluid within its interstices; exerts physical hemostatic effect	Local infection and abscess formation	Should not be used in closure of skin incisions because it may interfere with healing of skin edges. Often moistened with saline or topical thrombin before use.
Collagen hemostat (Avitene, Helistat, Instat)	Pads, powder, sheets, sponges	When in contact with a bleeding surface, attracts platelets that aggregate into thrombi, initiating formation of a physiologic platelet plug	Adhesion formation, allergic reaction, foreign-body reaction, inflammation, potentiation of infection	Apply dry. Excess material should be removed.
Oxidized regenerated cellulose (Surgicel)	Fibrous, knitted, or sheer weave fabric	Allows platelets and aggregates of thrombin and particulate blood elements to cling and form a coagulum that can act as a patch	Encapsulation of fluid, foreign-body reactions	Store at room temperature.

FIGURE 20-44 Cottonoid strips and patties.

FIGURE 20-45 Standard aneurysm clips and appliers.

irrigation solution or topical thrombin. Larger pieces can be cut into a variety of sizes of strips and squares. Gelfoam is often followed by a patty, which enables the surgeon to maneuver and compress it once it is in the surgical site. Gelfoam is absorbable and can be left in the body.

Oxidized regenerated cellulose is available in two forms: a rayonlike gauze (Surgicel) and a cottonlike form (Fibrillar). These are also absorbable hemostatic agents that are used to control bleeding from oozing surfaces, vessels, and sinuses in the brain. These hemostatic substances are presented in various sizes and shapes and are offered to the surgeon dry. The hemostatic material adheres to the bleeding area with gentle pressure.

Thrombin is a drug that can be topically applied to bleeding surfaces to achieve hemostasis. Typically, Gelfoam or patties are saturated with thrombin and placed on the oozing surface.

Irrigating the wound helps the surgeon identify active bleeding points and may facilitate hemostasis. A syringe with an angiocatheter tip may be used to deliver irrigation for microsurgery. Many neurosurgeons irrigate surgical wounds with an antibiotic solution before wound closure. The antibiotic is mixed with irrigation solution according to the surgeon's preference so that it is ready for use when needed.

Suture. Required suture will vary according to the surgery, the condition of the wound and patient, and the surgeon's preference. Suture can be used for retraction of the scalp for a craniotomy flap. Dura of the brain and spinal cord may be retracted, tacked up, and closed with braided nylon suture. In general, high tensile strength is needed for closure of the galea of the scalp and the fascia and subcutaneous tissue of the back. Braided, absorbable suture can be used in interrupted stitches to close these layers. Skin may be closed with subcuticular absorbable suture, with either a continuous or an interrupted suturing technique using a monofilament, nonabsorbable suture material such as nylon; alternatively, skin can be closed with staples. Whatever technique is used for skin closure, skin edges should be everted. A drain may be secured to the skin with a nonabsorbable suture such as nylon. In an environment of infection, monofilament, nonabsorbable suture is preferred.

Dressings. Applying dressings to wounds on the head is challenging, especially if a minimal shave was done. For larger incisions in particular, a head wrap can be the best alternative. It keeps a nonadherent dressing in place over the incision site and provides compression to prevent the formation of a postoperative hematoma. A smaller dressing can sometimes be held in place with a transparent dressing or tape. Applying a liquid adhesive, such as Mastisol, to the skin before application of the dressing can help to hold it in place.

Evaluation

After the surgical procedure is completed, the patient is transported to the intensive care unit (ICU) or postanesthesia care unit (PACU). A report along with intraoperative

documentation is given to the nurse receiving the patient. The identified outcomes from the established nursing diagnoses and interventions are evaluated on an ongoing basis throughout the perioperative period, and adjustments to the plan are made as necessary. Before leaving the OR, the nurse assesses the patient's postoperative skin integrity and performs a postoperative neurologic assessment for comparison with the preoperative assessment. In addition, the patient's outcomes from the identified nursing diagnoses are evaluated. If the outcomes were met, they may be communicated as follows:

- The patient expressed feeling less anxious, coped with perioperative routines adequately, and verbalized an understanding of the planned procedure or procedures.
- The patient or family verbalized knowledge of diagnostic and surgical procedures and had realistic expectations of tests, routines, and postoperative care.
- The patient maintained effective breathing patterns; ventilation was maintained, arterial blood gases were within normal limits, and breath sounds were bilateral.
- The patient will continue to maintain a normal body temperature or undergo rewarming.
- The patient exhibited no signs and symptoms of pressure injury; sensation and motion were the same as preoperative functional levels; and respiratory status and blood pressure were maintained within expected parameters.

Patient and Family Education and Discharge Planning

Patient and family education is the key to helping the patient return to his or her optimal quality of life. As soon as the need for surgery is identified, a multidimensional education program should begin and include the patient's family. Teaching should address the psychosocial as well as the physiologic aspects of the patient's life. The plan should offer opportunities for the patient to develop new skills, coping mechanisms, and behaviors to adapt to aspects of temporary or permanent neurologic deficit.

Neurosurgery patients may experience a variety of deficits involving vision, hearing, swallowing, speech, motor, sensation, and mental status. Depending on the patient's pathologic condition and surgery, other physicians may observe the patient postoperatively along with the neurosurgeon. Neurologists, ophthalmologists, endocrinologists, cardiologists, radiologists, oncologists, and infectious disease physicians may be involved with managing the medical care of neurosurgery patients. Rehabilitation, physical, occupational, and speech therapists are instrumental in the recovery of neurosurgery patients. They also teach the patients and their families how to cope with temporary and lifelong deficits and how to improve their quality of life. Some patients may benefit from time spent in a rehabilitation facility before returning home. Patients with severe alterations in neurologic function may require long-term care.

The nurse plays an important role in teaching patients and family members how to look for and recognize potential postoperative complications, such as changes in mental status or behavior, progressive weakness, seizure activity, increasing pain, and signs and symptoms of infection. Routine discharge instructions should include information about newly prescribed medications and their potential side effects in addition to treatment options for postoperative and chronic pain (Patient and Family Education). The nurse should also ensure the patient has instructions for the use of cervical collars, braces for spinal stability, and wound dressing changes when applicable.

PATIENT AND FAMILY EDUCATION

Discharge Planning for Postoperative Posterior Thoracic or Lumbar Spinal Fusion

When discharging patients, ensure that all postoperative instructions are clear and legible, including proper phone numbers for the surgeon and nurse. The nurse should reinforce all written instructions, and ask the patient and caregivers to verbalize and demonstrate a clear understanding of the instructions.

HOME CARE

- Stress the importance of follow-up care. Advise patients when to schedule a follow-up appointment with the surgeon, and when to begin physical therapy.
- Review the signs or symptoms of infection that warrant immediate notification to the surgeon. They include a temperature of 101° F or greater; increased swelling, redness, or tenderness around the incision site; and any drainage originating from the incision.
- Instruct the patient to seek immediate medical attention if they experience the onset of a sudden and/or severe headache, weakness of the extremities, or any changes in bowel or bladder function.

WOUND CARE

- Ensure that patients and caregivers are instructed on proper cleaning, inspecting, and dressing of the wound. Assure them that a small amount of swelling is normal and should continually decrease. Instruct patients to avoid soaking the wound, to shower only when cleared by the surgeon, and to discontinue the use of any lotions or oils on or near the incision site.
- Educate patients on the risk factors that contribute to delayed wound healing such as smoking, obesity, advanced age, diabetes, chronic steroid use, and malnutrition.

ACTIVITY

- Walking and climbing stairs are typically encouraged. Activity tolerance is generally patient specific and should be personalized as necessary.
- Patients will have activity restrictions which typically include the following: prolonged travel or driving; sitting for periods longer than 30 minutes at a time; occupational limitations; strenuous exercise; lifting more than 10 pounds; and bending or twisting at the waist.

PATIENT AND FAMILY EDUCATION

Discharge Planning for Postoperative Posterior Thoracic or Lumbar Spinal Fusion—cont'd

PAIN MANAGEMENT

- Discuss how much pain, soreness, and stiffness are expected and the importance of contacting the surgeon if the pain is excessive. Over several months, back and leg pain should decrease, depending on the severity of pain preoperatively.
- Review all prescriptions and proper dosing. Discuss which over-the-counter medications, such as acetaminophen, are appropriate. Advise patients that the use of aspirin and NSAIDs, such as ibuprofen, may not be indicated for several weeks because they can cause bleeding.
- Offer pain-reducing activities such as exercise, and relaxation techniques.

DIET

- Proper nutrition promotes wound healing.
- Fluids, fruits, and fiber can help prevent constipation.

SPECIAL INSTRUCTIONS AND FOLLOW-UP CARE

- Provide instructions for use of any braces or supports. Generally, a brace should be worn at all times, except when showering and sleeping, until told otherwise by the surgeon.
- Advise patients to resume all preoperative medications unless otherwise noted.
- Provide prescriptions for new x-rays, CT scans, and MRIs according to the physician's orders.
- Discuss smoking cessation when appropriate. Stress the connection between smoking and delayed would healing, and offer resources for smoking cessation.

The entire healthcare team is responsible for planning an easy transition from the acute care center to the patient's home or to a skilled nursing or rehabilitation facility. The patient and family need to be involved in every aspect of the neurosurgery patient's care and should be encouraged to ask questions and voice their concerns and opinions.

Surgical Interventions

MINIMALLY INVASIVE AND SPECIALIZED NEUROSURGERY TECHNIQUES

Microneurosurgery

Adaptation of the operating microscope for neurosurgery has resulted in improvement of many neurosurgical procedures and made new procedures possible. For years, neurosurgeons have worn magnifying loupes to see small structures. Loupes usually have a magnification of 2× or 3.5×. The microscope has a variety of magnifications ranging from 6× to 40×, providing flexibility and precision. The co-axial illumination overcomes the difficulties of lighting neurosurgical wounds (History box).

Use of the microscope restricts the surgeon's field of vision and mobility; therefore the surgical technologist and surgical assistant must be proficient. The operative field, unless video monitoring is available, cannot be seen. Surgical personnel must understand the surgical procedure and the corresponding anatomy, know the names and uses of all microinstruments, and be proficient at passing the instruments to the surgeon without delay that are ready for use. Each time the surgeon must look away and then back to the surgical field, open wound time and anesthesia time are increased while the surgeon becomes reoriented to the field. Therefore the assistance the scrub nurse gives the surgeon saves time and directly benefits the patient.

Microsurgical instruments have been modified and adapted to the requirements of neurosurgery. These instruments often possess the following characteristics: bayonet shape, so that the surgeon's hand remains outside the line of vision and the beam of the microscope light; finely sprung and fluted grip; long length for access to deep structures; and slender and delicate tips that occupy as little space as possible. Microneurosurgical instruments are expensive and delicate. Instructions for handling, cleaning, sterilizing, and storing these instruments should be followed. An instrument that is sprung, bent, dulled, hooked, or in any way damaged must never be handed to a surgeon for use but must be repaired or replaced. Instruments must be kept free from blood and tissue during use because the microscope also magnifies debris on the instruments, occluding the structure the surgeon is about to approach. Very fine microsutures are available.

Microsurgical techniques have been applied to cranial, spinal, and peripheral nerve operations. Some procedures in which microsurgery is of value are explorations of the posterior fossa, especially for tumors of the fourth ventricle or cerebellopontine angle, and removal of small acoustic neuromas, with resulting preservation of the facial nerve. Small-vessel endarterectomy, cerebral arterial bypass, cerebral aneurysm clipping, and excision of AVMs are performed using the microscope for visualization of the surgical site. Microsurgery also has advantages in the treatment of tumors and AVMs of the spinal cord.

Neuroendoscopy

Neuroendoscopy is a rapidly evolving field of minimally invasive surgery. The endoscope provides illumination and magnification of structures and an extended viewing angle. Brain retraction and manipulation are reduced in endoscopic surgery, resulting in decreased tissue damage (Teo and Mobbs, 2005). The surgical team must be prepared to convert from a neuroendovascular procedure to an open procedure if it is determined that the surgery cannot be successfully completed endoscopically.

Indications for neuroendoscopic surgery are many. Endoscopic tumor removal or CSF diversion through endoscopic fenestration, such as a third ventriculostomy, can be done for

HISTORY

Evolution of Surgical Magnification

From 1813 to 1825 English, French, and German opticians attempted to coordinate two monoculars into a single instrument, finally providing the modern binocular, used then as opera glasses. Abbe and Zeiss, circa 1870 to 1880, improved opera glasses with the invention of the binocular roof prism, which enabled greater enlargement of the image without having to deal with the increased length of the optical tube.

In 1886 Westien, a German instrument maker, developed the first surgical loupes for a zoologist interested in performing more accurate dissections. Later, Westien developed binocular loupes for an ophthalmologist. He further adapted magnifying loupes from a stationary device to an instrument to be worn on the head, offering a power of 5× to 6× magnification. These proved impractical because of their weight.

The first teleloupes were developed in 1912. They were the prototype of current surgical loupes, offering a light weight and a magnification of 2×. Their initial popularity was appreciated by ophthalmologists, and in 1948 Riechert, initially an ophthalmologist who later became a neurosurgeon, advocated their use during neurosurgical procedures. It is believed that neurosurgeons' use of surgical loupes was more widespread, but they had not published this fact.

Operating microscopes borrowed the technology of optical systems developed for surgical loupes and underwent further development of their optical and mechanical systems between 1921 and 1952. Monocular scopes, first fixed near the head of the patient, evolved to binocular scopes that attached to the OR bed and later became freestanding floor mounts. The delayed application of the operating microscope in general surgery has been related to the technical deficiencies of the early microscopes, in that they were unstable and immobile and had limited illumination.

In 1952 Littman succeeded in developing a sophisticated, maneuverable microscope for surgical requirements that maintained sharp focus and had a co-axial light system. This prototype was known as the *OPMI 1* and drew the attention of otologic surgeons, ophthalmologic surgeons, and neurosurgeons. The operating microscope has made it possible for neurosurgeons to perform delicate, minimally invasive surgery in anatomic regions requiring magnification and illumination.

Modified from Carl Zeiss: *Technical milestones,* available at www.zeiss.com/C12567A100537AB9/Contents-Frame/63125BAC5434D55DC1256DB900446D61. Accessed June 22, 2009.

the treatment of hydrocephalus and can eliminate the need for a shunt. Interventricular tumors may be removed endoscopically. In addition, the endoscope can be used to assess adequacy of tumor removal and to identify tumor portions left behind or adherent to vital structures. Stereotactic and image-guided surgery is often used with neuroendoscopy successfully. The endoscope is commonly used in the transsphenoidal approach for pituitary and sellar tumor resection (possibly in collaboration with an otolaryngology surgeon), for microvascular decompression, and for endoscopic biopsy of a lesion. The potential rewards of neuroendoscopy include improved postoperative results, shorter hospitalization times, and fewer postoperative complications (Teo and Mobbs, 2005).

Endovascular Procedures

There are several neurovascular disorders that are amenable to an endovascular procedure. This approach is considered minimally invasive, and is therefore a reasonable option for patients who are not candidates for open surgical procedures because of age, health status, medical condition, or location of the lesion. Interventional neuroradiology uses fluoroscopy to gain access to the intracranial circulation by way of a percutaneous transfemoral catheter.

The endovascular approach to the treatment of both ruptured and unruptured cerebral aneurysms is endosaccular occlusion (Evidence for Practice). This is an excellent technique for aneurysms that are complex, have a neck that is too short for clipping, or are difficult to reach via traditional craniotomy. A flexible platinum coil is fed through the transfemoral catheter and is coiled within the body of the aneurysm, conforming to the aneurysm's shape. The coil is then detached from the catheter. The coil blocks blood flow to the site, thereby preventing rupture or rerupture, both of which can be fatal.

Although surgical excision is still the standard treatment for intracranial arteriovenous malformation (AVM), surgical morbidity may be decreased by utilizing endovascular embolization preoperatively in select cases. A specialized microcatheter is guided directly into the AVM via angiography. The abnormal blood vessels in the AVM are occluded from the inside by means of embolization. There are several materials used to cause embolization, including fibered titanium coils, polyvinyl alcohol particles, and fast-drying biologically inert glues. The AVM may effectively be devascularized and reduced in size through endovascular embolization, and when combined with microsurgery or stereotactic radiosurgery, the AVM may be completely eradicated. Endovascular embolization as the sole treatment of intracranial AVMs is unacceptable, because of unknown long-term occlusion rates and low rates of complete occlusion. In the case of dural arteriovenous fistulas, which comprise 10% to 15% of all intracranial AVMs, endovascular techniques may be curative without the need for further intervention.

Endovascular embolization is also advantageous when employed as a preoperative treatment for select intracranial tumor resections. Highly vascular tumors, as well as tumors that are inopportunely positioned, can be devascularized using techniques similar to those used in the treatment of AVMs, thus decreasing blood loss and risk of hemorrhage during resection.

Carotid artery angioplasty and stenting are the endovascular procedures used to treat carotid artery stenosis. A balloon-tipped catheter is advanced to the location of the offending plaque within the carotid artery and is inflated to press against the plaque. Consequently, the plaque is flattened against the vessel lumen and blood flow is reestablished. A metal-mesh tube is then advanced to the same location to act as a scaffold to prevent reocclusion. Stents may be bare metal, or they may be coated with thrombolytic agents.

Intracranial stenosis has been deemed a high-risk disease in need of alternative therapies. Endovascular intracranial angioplasty and stenting are options, although neither has yet to be

EVIDENCE FOR PRACTICE

Surgical/Endovascular Treatment of Ruptured Aneurysms

The Stroke Council of the American Heart Association (AMA) has formulated recommendations for the surgical/endovascular treatment of ruptured aneurysms. These guidelines are intended to serve as a framework for the treatment of ruptured aneurysms.

- Endovascular coil occlusion of the aneurysm is appropriate if the aneurysm is deemed treatable by either endovascular coiling or surgical clipping.
- Reasonable consideration of the individual characteristics of the patient and aneurysm must be used in deciding the best means of repair.
- The patient should be managed in a surgery center offering both techniques.
- Either procedure should be performed to reduce the risk of rebleeding after the initial aneurysmal subarachnoid hemorrhage (SAH).

CLIPPING

The surgeon performs a craniotomy (opening of a portion of the skull) and separates the aneurysm from the surrounding tissue. A small titanium clip, whose features are similar to those of a clothespin, is then placed across the base of the aneurysm. Once the clip is secured, blood can no longer enter or exit the aneurysm sac. By using a needle to drain the remaining blood out of the aneurysm, the sac should empty and eventually collapse. The procedure is ideally performed within 72 hours of diagnosis. It is important to note that following rupture, there is a 40% chance of death and 80% chance of disability. Early detection and treatment offer the best chances of survival.

COILING

Also known as endovascular therapy, coiling is a less invasive treatment option. Especially for those patients who are in poor health, surgical intervention may pose a greater threat than the aneurysm itself. Coiling has proven to be a safe alternative to the traditional treatment of a craniotomy. This procedure does not involve opening of the skull, and is performed from inside the blood vessel. A catheter is inserted into the patient's groin, and is guided up toward the brain under fluoroscopy. A wire is then threaded into the catheter and directed into the aneurysm. Once inside the aneurysm, the wire twists into small coils and continues filling the aneurysm sac until eventually the aneurysm is occluded (Zuccarello and Ringer, 2009).

Previous studies, such as the International Subarachnoid Aneurysm Trial (ISAT) in 2002, found that patients who were initial candidates for both types of procedures had better outcomes 1 year after endovascular coiling as opposed to surgical clipping. Since that time, few studies have emerged to either support these findings or challenge them. It is essential that research continues to determine which course of treatment is the most beneficial.

Modified from Bederson BJ et al: Guidelines for the management of aneurysmal subarachnoid hemorrhage: a statement for healthcare professionals from a special writing group of the Stroke Council, *Stroke* 40:994-1025, 2009; Zuccarello M, Ringer A: Aneurysm clipping, *Mayfield Neuro,* 2009, available at http://mayfieldneuro.com/PE-Clipping.htm. Accessed May 31, 2009.

evaluated in a controlled clinical trial. Successful use of balloon angioplasty has been documented in mostly academic, high-volume centers, performed by highly skilled and experienced physicians. While the results are encouraging, the technically demanding nature of the procedures carries substantial risk. The Wingspan stent has been approved by the U.S. Food and Drug Administration (FDA) to treat symptomatic patients with intracranial stenosis greater than 50% that is refractory to medical therapies. The stent is implanted using the Wingspan technique. Following balloon angioplasty, a self-expanding nitinol stent is placed across the atherosclerotic lesion in the brain. While the Wingspan system appears to be a viable treatment option, a high rate of restenosis has been reported, and its value is not yet firmly established (American Association of Neurological Surgeons [AANS], 2009).

Intraarterial thrombolysis for the treatment of acute ischemic stroke is a consideration for patients who have missed the 3-hour window for therapeutic intravenous thrombolysis. The endovascular route is used to deliver a high concentration of a thrombolytic agent directly to the site of the offending thrombus in combination with mechanical clot extraction. Intraarterial thrombolysis is still being studied for its long-term value. It is currently recommended for selected patients with major ischemic stroke of less than 6-hours duration caused by occlusion to the middle cerebral artery, and who have contraindications to intravenous thrombolysis, such as recent surgery (Doherty and Way, 2006).

Mechanical clot extraction is an endovascular technique that may be used alone or in conjunction with intraarterial thrombolysis. Success rates are improved when both modalities are used. There are several retrieval devices approved by the FDA for extraction of thrombi from occluded intracranial arteries. A typical retrieval device consists of a coil that is delivered to the thrombus site via endovascular microcatheter and screwed into the clot like a corkscrew to extract the clot. The coils are available in different shapes and configurations to accommodate the specific thrombus. Mechanical clot extraction shows its best utility for cerebral arteries demonstrating large or irregularly shaped clot burdens (Meyers et al, 2009).

Stereotactic Radiosurgery

In stereotactic radiosurgery, stereotactic localization is coupled with delivery of ionizing radiation to destroy a lesion in the brain. Radiosurgery is technically noninvasive and has a low associated morbidity. The use of radiosurgery has increased, and success of treatment has improved with advancements in neuroimaging (CT and MRI) and computer technology. The goal of radiosurgery is to obliterate a relatively small intracranial target with a high irradiation dose while sparing adjacent and distant tissues. Stereotactic imaging and target localization using CT, MRI, or angiography must be fully integrated with the radiation delivery device to achieve pinpoint localization of the target (Pollock and Brown, 2005). Radiosurgical instruments include the Gamma Knife, the Novalis, and the CyberKnife.

Radiosurgery can be used to treat AVMs, tumors, and trigeminal neuralgia. Best results are achieved for lesions smaller than 35 mm. Larger lesions or lesions involving or near cranial nerves can be successfully treated with a fractionated approach where the radiation is precisely delivered in small

daily fractions. This technique, called fractionated stereotactic radiotherapy (FSR), has been particularly useful for preserving vision and hearing. Patients with larger lesions often have symptoms of mass effect that are generally not improved with radiosurgery. Radiosurgery and FSR techniques have successfully sterilized a variety of intracranial lesions often with far less morbidity than a surgical approach.

Stereotactic Procedures

The goal of stereotactic surgery is to target a point or volume in space by way of a predefined minimally invasive trajectory (Zonenshayn and Rezai, 2005). This is accomplished with coordinate systems that provide a constant frame of reference. Radiographic modalities (CT, MRI) are used to navigate three dimensionally and locate and destroy target structures. Predetermined anatomic landmarks are used as guides.

Originally, special head-fixation devices were developed for stereotactic brain surgery (see Figure 20-38). Over the past decade frameless systems have surpassed frame-based techniques in popularity and versatility. These systems employ fiducial markers that either affix temporarily to the skin or are implanted into the outer table of the skull, thereby eliminating the need to mount a frame on the patient's head. These markers are visible on the imaging modality being used. By registering the physical location of the fiducials on the patient's skull, the corresponding points on the image can be aligned with the operating space (Zonenshayn and Rezai, 2005).

Both frame-based and frameless stereotactic systems use radiography, fluoroscopy, CT scans, or MRI to permit accurate placement of a probe directed at the target area. The preoperative images are aligned to the patient's head during surgery so that the surgeon has a better idea of the target area.

The many common applications for cranial stereotactic surgery include craniotomies, transsphenoidal approaches, endoscopic surgery, needle biopsies, and therapeutic aspiration. It is also used for catheter placement and third ventriculostomy surgery. Spinal stereotactic surgery is used for screw placement and spinal cord lesions. Common target areas for the stereotactic approach include tumors, infectious lesions, vascular malformations, the basal ganglia, the thalamus, and anterolateral spinal tracts. Target areas can undergo biopsy, be destroyed by chemical or mechanical means, or be electrically stimulated. Stereotactic procedures are also done to place electrodes in various regions of the brain to determine the site of origin of seizures.

Procedural Considerations. As in most image-guided surgery (IGS), carts with a monitor and the computer, along with accessory equipment and supplies, are required. A variety of stereotactic frame systems are available. The nurse must be familiar with the system in place at his or her institution. Frameless stereotactic surgery triggered a new era in surgical navigation and information delivery. This technology provides three-dimensional visualization of anatomic features with real-time localization information (see Figure 20-39).

Operative Procedure

1. The patient's head is placed into a halo head frame with a stereotactic cage before the surgery (framed stereotaxy). Alternatively, fiducials are placed on the patient's skull (frameless stereotaxy).
2. The patient is then taken for a CT or MRI scan of the brain. The target is identified, and computer coordinates are determined and recorded.
3. The nurse brings the patient to the OR with the frame or fiducials left in place. The stereotactic coordinates are registered or entered into the computer, and the procedure is performed through a burr hole. The stereotactic probe is guided by the computer, directing the surgical approach and trajectory (see Figure 20-38).
4. Hollow cannulae, coagulating electrodes, cryosurgical probes, wire loops, and other lesion-producing or biopsy instruments may be introduced for the destruction of areas in the brain. Temporary and permanent nerve-stimulator electrodes are also introduced to augment the pain-control function of the CNS. These instruments are introduced through a burr hole in the skull.

SURGICAL APPROACHES TO THE BRAIN

Burr Holes

A burr hole is the minimum exposure that can be made to gain access to the brain. A small incision is made in the scalp down to the skull. A small self-retaining retractor is placed. The periosteum is retracted using a periosteal elevator. A drill is used to make the appropriate-size burr hole (usually 1 to 2 cm). If necessary, the burr hole can be enlarged using Kerrison rongeurs. The dura is incised, exposing the brain.

Burr holes are necessary for many neurosurgical procedures. They are placed in the skull to remove a localized fluid collection secondary to head trauma that results in an epidural or subdural hematoma. A burr hole can be used to access the intracerebral ventricles for the following reasons: placement of a ventricular catheter to drain obstructed CSF; measurement of ICP; or establishment of a ventricular shunting system. Burr holes are placed for many stereotactic procedures, such as stereotactic biopsy or placement of electrodes. Burr holes are also made before turning the bone flap in preparation for a craniotomy procedure.

Craniotomy

A craniotomy is the removal of a section of the cranium referred to as a bone flap. One or more burr holes are placed, and the dura is dissected away from the cranium. A craniotome with a dura guard attachment is used to excise a section of the cranium, exposing an area of the brain. The surgeon replaces the bone flap to its original location and secures it with wire or titanium plates and screws.

Multiple types of craniotomy incisions are used to expose different parts of the brain. Depending on the location of the pathologic condition, a craniotomy may be frontal, parietal, occipital, temporal, or a combination of two or more of these approaches. The pterional craniotomy is an extremely versatile approach to the anterior and middle fossae. It is useful to access lesions of the frontal or temporal lobes near the sylvian fissure or skull base. A craniotomy may be performed to evacuate intracranial hematomas not accessible through a burr hole, to control bleeding, to debulk or resect tumors, to excise or clip vascular lesions, to aspirate abscess formation, and to decompress cranial nerves.

When turning a scalp flap for a craniotomy, the surgeon may peel the scalp back off the pericranium. The surgeon

elevates the bone flap with the overlying muscles still attached (osteoplastic) or strips the periosteum off the skull before the bone flap (free flap) is turned. The bone plate may be separated from the soft tissues, removed from the skull, and set aside for replacement at the end of the procedure. It is placed in an antibiotic solution and remains on the sterile field. The surgical technologist ensures that the bone flap stays separate from other items on the sterile field and alerts the perioperative nurse and any relief surgical technologists of its location to prevent it from being inadvertently discarded. If the bone is not separated from the soft tissues, it is reflected with the temporal muscle and soft tissues. If intracranial swelling is a major concern or the purpose for the craniotomy, the bone plate may not be replaced. If it is not replaced, it may be frozen in a sterile container according to hospital protocol to be used at a future date.

Craniectomy

Craniectomy is the permanent removal of a section of the cranium using burrs and rongeurs to enlarge one or more burr holes. The surgeon performs a craniectomy to gain access to the underlying structures. This procedure may be required to remove tumors, hematomas, and infection of the bone. A suboccipital craniectomy, done with the patient in prone or lateral position, allows access to the posterior fossa. Titanium mesh may be used to repair the cranial defect. Craniectomy is also indicated as treatment for craniosynostosis in infants and young children. Severe head injury with increased ICP can be treated with a craniectomy to give the brain room to swell.

Transsphenoidal Approach

The transsphenoidal route to the pituitary fossa is a less invasive means of removing tumors than the transcranial route. This can be done with a small incision through the nose or through the gingiva under the upper lip. More recently, an endoscope has been used to assist with access through the sphenoid sinus into the pituitary fossa. Tumors of the parasellar region may also be approached using this technique.

SURGERY OF THE BRAIN AND CRANIUM

Evacuation of Epidural or Subdural Hematoma

After trauma, decompression of the brain, as well as removal and drainage of blood clots and collections of liquefied blood from above or beneath the dura mater, may be required. The need for hematoma evacuation is primarily determined by a declining neurologic status in the patient. Depending on the severity of the injury, evacuation can be accomplished through burr holes or a craniotomy. If elevated ICP is a major concern, the craniotomy plate may be temporarily removed from the skull. This gives the brain more room to swell and may prevent brain herniation and death.

Operative Procedure—Burr Hole Placement for Evacuation of Hematoma

1. A preoperative CT scan is very useful in planning optimal placement of burr holes. The surgeon makes at least two linear or small horseshoe incisions over the site of the lesion. Two or more burr holes are made.
2. If a blood clot or collection of bloody fluid is found outside or beneath the dura mater, the surgeon enlarges the burr hole with a Kerrison rongeur until adequate exposure is obtained.
3. If the hematoma is subdural, the dura is incised.
4. Clot and fluid are evacuated, and hemostasis is accomplished with the ESU or the use of hemostatic clips.
5. The surgeon irrigates through the holes using catheters or bulb syringes. Large amounts of irrigating solution are used until the return appears clear.
6. A drain or catheter may be inserted in the subdural or epidural space for postoperative drainage. Additional burr holes can be made as necessary during the course of the procedure to ensure complete evacuation.

Cranioplasty

Cranioplasty is performed for repair of a skull defect resulting from trauma, malformation, or a surgical procedure. The purpose of cranioplasty is to relieve headache and local tenderness or throbbing, to prevent secondary injury to the underlying brain, and for cosmetic effect.

Procedural Considerations. Repair of a skull defect may be performed acutely in clean cases. In contaminated cases, 6 months should pass before repair is attempted (Connolly et al, 2009). When a bone plate is removed for control of elevated ICP, it can be repaired following resolution of ICP issues. If the patient's bone plate was frozen under sterile conditions, it could be replaced with microplates and screws.

The most common materials used for cranioplasty include titanium mesh and/or methylmethacrylate. Commercially prepared cranioplastic synthetics that supply the needed chemicals and mixing containers have simplified the procedures of shaping and molding the prosthesis. Sometimes heavy wire mesh is cut to the shape of the defect, and the methylmethacrylate is molded over the mesh.

Recent technologic advancements use CT scans to produce a computer-generated duplication of the defect. A properly sized prosthesis can be produced and sterilized before the surgery. After the defect is exposed, minor adjustments in the shape of the prosthesis can be made with a burr to achieve an optimal fit.

Operative Procedure—Cranioplasty Using Computer-Generated Prosthesis

1. Typically, the old incision is reopened.
2. Keeping in mind that there is no bony protection between the scalp and the brain, the surgeon carefully elevates the scalp flap from the underlying scar, dura, and brain.
3. Bone edges are exposed with a curette, and the prosthesis is fitted to the defect using a burr. Debris is irrigated out of the wound.
4. Microplates and screws secure the prosthesis in place.
5. The incision is closed as usual for craniotomy.

Operative Procedure—Cranioplasty Using Cranioplastic Material

1. A scalp flap is turned, and the bony defect is exposed.
2. The edges of the defect are trimmed, and a ledge is formed to seat the prosthesis.
3. After the bone defect has been prepared so that it is slightly saucerized, the methylmethacrylate is mixed by combining one volume of liquid monomer with one volume of the pow-

dered polymer. When this has formed a doughy mass, it is dropped into a sterile polyethylene bag. The soft plastic is then rolled on a flat surface into the desired shape, leaving the thickness to the approximate depth of the skull edges. A sterile test tube, syringe barrel, or other round object can be used, although a stainless-steel roller is preferred because of its weight and ease of use.

4. The soft cranioplastic material in the bag is placed over the skull defect and, through light pressing with the ends of the fingers, is fitted into the missing skull area. Assistants stretch the plastic bag as the surgeon molds the plate into the defect and forms an overlapping bevel edge. This overlapping fringe keeps the plate from falling inside the skull, in the same manner as the skull saucerization.
5. When the heat of the chemical reactions is evident, the surgeon lifts the plate out of the bony wound and removes it from the polyethylene bag. Cool saline should be used on the flap while the exothermic reaction takes place.
6. When the plate is cool enough to handle, the surgeon trims excess material and bone using rongeurs or a saw and places the plate in the cranial defect to check for fit.
7. A craniotome is used to smooth the rough spots and bevel the edges so that the plate will blend gradually with the skull.
8. Mixing and fitting the plate take about 7 minutes, the same time needed for the cranioplastic material to harden. Sutures may be used to hold the plate in place, generally at three or more points.

Ventricular Catheter and Shunt Placement for Hydrocephalus

Hydrocephalus is a condition marked by an excessive accumulation of CSF resulting in dilation of the ventricular system (where CSF is manufactured and circulated) and increased ICP. Conditions that result in the development of hydrocephalus and CSF obstruction in both children and adults include congenital hydrocephalus, spina bifida, tumors, intracranial/intraventricular hemorrhage, aqueductal stenosis, and Chiari's malformations. Hydrocephalus is treated by accessing the lateral ventricles for the insertion of a ventricle shunting system. The most commonly used methods to divert CSF from the ventricles are the externalized ventriculostomy catheter and the internalized VP shunt.

Placement of an externalized ventriculostomy catheter requires that a burr hole be made to access either the right or the left lateral ventricle. The ventricular catheter is passed into the ventricle. Flow of CSF is verified. The distal end of the catheter is tunneled beneath the scalp, posterior to the burr hole, externalized, and secured to the scalp with suture. The externalized end of the catheter is connected to an external drainage system, which allows for controlled CSF drainage and for ICP measurement. This system has allowed for temporary shunting in patients with elevated ICP and hydrocephalus from any cause. It is an invaluable adjunct in the clinical assessment and management of head trauma with increased ICP.

For more permanent control of hydrocephalus, an internalized ventricular shunt is placed. The type of shunt and the site of insertion are determined by the neurosurgeon. Three approaches for ventricular insertion are frontal, parietal, and occipital. Although the most common drainage site for an internalized shunting system is the peritoneum by way of open dissection or percutaneous trocar, there are other options. If drainage in the peritoneum is inappropriate because of infection or adhesions, other possible distal insertion sites include the right atrium, the pleural cavity, and the gallbladder (Wang and Avellino, 2005).

The VP shunt system comprises a ventricular (proximal) catheter, a reservoir, a valve, and a peritoneal (distal) catheter. A unitized shunt has fewer separations and connections. The reservoir, if used, is inserted between the catheter and the valve. Access to the system through the reservoir enables the practitioner to assess the patency of the shunt, to obtain CSF for laboratory analysis, to introduce contrast medium for radiologic studies, and in some specific cases to inject medication into the shunt. The one-way valve system directs flow of CSF out of the ventricular system. Valves are available in a variety of different pressure and flow settings. Nonprogrammable valves and shunts are pressure controlled and open to release flow whenever the actual pressure exceeds the pressure that the valve is designed to open (the opening pressure). Some valves are flow controlled and attempt to maintain a constant flow despite pressure changes. A more recent advance is the programmable valve. Programmable valves and shunts allow adjustments to the opening pressure after the shunt is implanted, avoiding surgical procedures to change valves.

Procedural Considerations—Ventriculoperitoneal Shunt Placement.

The patient is placed in a modified supine position with a shoulder roll. The head is turned to the opposite side and supported on a donut. Hair is removed from the site where the burr hole will be made to behind the ear and down to the neck. The burr hole site must be prepped, along with the neck, chest, and abdomen on the side of the shunt insertion.

The shunt unit should be handled with extreme care. As with all implantable devices, each manufacturer's specific instructions must be followed and care taken to keep the assembly free of lint, powder, or other foreign bodies that could cause a reaction in the patient's tissues. Lubricants are never used. Blood should be kept clear from the lumen of the catheter to prevent clotting and obstruction. The unit is soaked in normal saline and antibiotic solution and primed before implantation. Air trapping in the valve assembly should be avoided. The valve must be properly oriented to facilitate CSF flow from the ventricles to the peritoneum.

The surgeon may use an endoscope or stereotactic image-guided navigation system to locate small ventricles or to fenestrate the septum between ventricles, thus avoiding the necessity to place multiple ventricular catheters. Surgical technique for VP shunt placement is basically the same for adults and children (Figure 20-46).

Operative Procedure—Ventriculoperitoneal Shunt Placement

1. The surgeon makes a horseshoe-shaped incision to the right or left of midline, along the papillary line. Skin and periosteum are elevated.
2. Scalp bleeding is controlled, and the skin flap is retracted.
3. A burr hole is placed, and the dura is coagulated and incised. The surgeon uses the bipolar ESU to electrocoagulate the pia at the catheter insertion site.

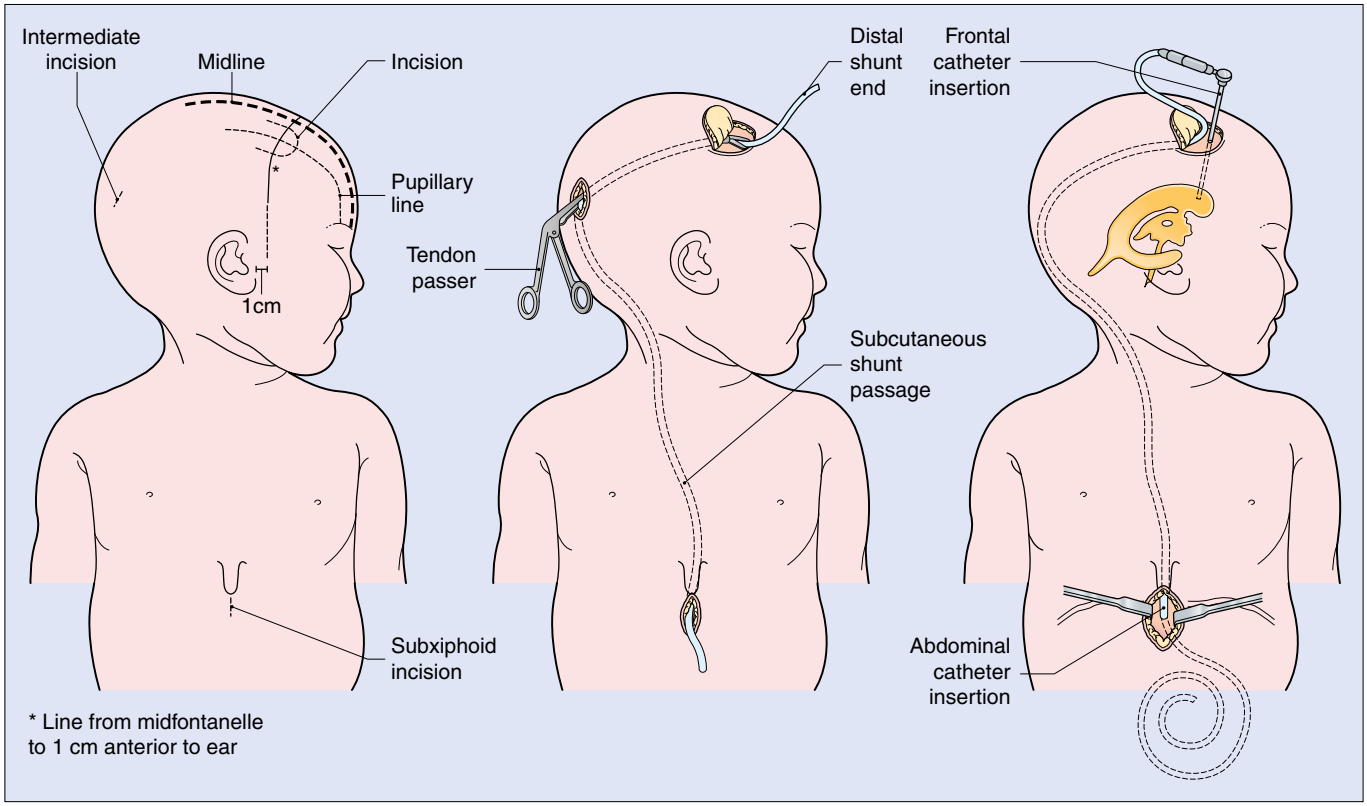

FIGURE 20-46 Placement of a frontal ventriculoperitoneal (VP) shunt. The technique is similar for adult and pediatric patients. The patient is positioned, and coordinates are marked. The shunt is passed subcutaneously. The ventricular catheter and then the peritoneal catheter are inserted.

4. The ventricular catheter with an introducer is inserted perpendicularly into the lateral ventricle approximately 4.5 cm in the infant and 6.5 cm in the adult. When the ventricle is penetrated, the surgeon removes the introducer, verifies the CSF flow, and attaches and secures the reservoir and valve with 2-0 silk ties.
5. A subcutaneous tunnel is created from the burr hole to a neck incision, where the peritoneal catheter is then connected.
6. The surgeon makes a subxiphoid or lateral abdominal incision and exposes the peritoneum.
7. Further tunneling is performed from the neck to the chest and abdomen, avoiding the nipples and umbilicus. The surgeon passes the catheter through the tunneling device to the abdominal incision. After spontaneous distal flow of CSF is verified, the distal end of the peritoneal catheter is passed into the peritoneal cavity, leaving enough length to allow for growth in the child and movement in the adult.
8. The catheter is secured to the peritoneum with a purse-string suture. All incisions are closed, being careful not to puncture the shunt system with a suture needle.

Shunt failure can occur at any time, requiring any single portion of the shunt system or the entire system to be replaced. Obstruction, disconnection, malfunction, and infection are routine causes of shunt failure. Revising a shunt typically involves a troubleshooting process. Therefore it is best to prep and drape the patient to provide access to any and all portions of the shunt system. An infected shunt may be externalized until the infection is treated.

Craniotomy

Procedural Considerations. Craniotomy is a technique for exposure of the brain to surgically treat intracranial disease. There are multiple types of craniotomy incisions. A key element of these operative approaches is patient positioning, which facilitates exposure, allowing complex procedures to be done through small bony windows with limited dural opening and a minimum of cortex exposure. A skull fixation device provides head stability and allows for rotation, flexion, and extension in the final positioning of the head. If frameless stereotactic image-guided navigation is to be used, registration of fiducials must be done. Careful planning of the incision is imperative for adequate exposure. As a rule, flaps that create a vascular pedicle should be avoided and linear or sigmoid (S-shaped) flaps should be used. This is particularly true for patients with malignant brain tumors who will be treated with radiation, steroids, and chemotherapy. A pedicle flap compromises the blood supply to the incision and, with these other treatments, increases the likelihood of wound infection.

Operative Procedure—Craniotomy for Tumor Resection

1. The surgeon infiltrates the incision site using a local anesthetic with epinephrine.
2. The surgeon and the assistant apply digital pressure along the skin edges as the surgeon incises the skin through the galea.

3. Raney scalp clips are applied to skin edges, and/or self-retaining retractors are placed. The ESU is used on the major scalp vessels for hemostasis.
4. The scalp flap is reflected in the subperiosteal plane with periosteal elevators or with the monopolar device to divide muscle attachments. It is retracted up using devices that may include retractors, towel clips, suture, or rubber bands and supported with a scalp roll.
5. Burr holes are placed that expose the dura and are widened using curettes and Kerrison rongeurs. The dura is dissected from the cranium using Woodson, Penfield, or Adson dissectors.
6. The craniotomy is accomplished using a craniotome with footplate attachment as the assistant irrigates to cool the bone. The bone flap is carefully elevated from the dura and placed in irrigating solution on the back table.
7. Bone dust is irrigated away from the wound, and hemostasis is established. Bleeding edges of bone are waxed, and bleeding vessels in the dura are electrocoagulated with the bipolar ESU or occluded with thrombin-soaked Gelfoam and patties. The surgeon places hemostatic agents and patties around the craniotomy edges, and then places dural tacking sutures that will remain permanently to prevent postoperative epidural hematoma formation.
8. After hemostasis is achieved, the surgeon opens the dura with a #11 or #15 blade. A dural suture may be placed in the dura before incising it. This tents the dura, ensuring that the surface of the brain is not inadvertently nicked. A Woodson dissector and blade or Metzenbaum scissors are used to extend the dural incision. Bleeding from transected dural vessels can be prevented by coagulating them with the bipolar ESU before cutting them, or to avoid shrinking of the dura, hemoclips can be placed or vessels can be compressed with a hemostat.
9. A self-retaining retractor system is placed if necessary. Cortical dissection is achieved using the bipolar ESU, microscissors, and suction, and the specific surgical procedure is completed. Samples of tumor are sent for pathologic study if applicable.
10. Hemostasis is established. Irrigation can be used to find bleeding sites in the brain. A resection cavity is lined with Surgicel and filled with irrigation. Valsalva's maneuver can be produced with the ventilator to verify hemostasis.
11. The surgeon closes the dura with a 4-0 suture (braided nylon or silk). Gaps in the dura can be repaired using muscle, pericranium, dural substitute, or pericardium. A central dural tacking suture may be placed, and Gelfoam may be placed over the dura.
12. The bone plate is fitted with titanium plates and screws and reconnected to the cranium, or it may be wired into place depending on the surgeon's preference.
13. Muscle/fascia is reapproximated and galea is closed with interrupted absorbable sutures. Skin is closed with suture or staples.

Operative Procedure—Pterional Craniotomy

1. The skin incision for the pterional craniotomy extends from the zygoma to the midline, curving gently just posterior to the hairline (Figure 20-47).
2. The surgeon and the assistant apply digital pressure over folded sponges on both sides of the incision line. The skin and galea are incised in segments, with the length of each segment being equal to that over which the finger pressure is applied. The tissue edges are held with 6-inch toothed forceps as scalp clips are placed on the flap edges. Any remaining active arterial bleeding is controlled by electrocoagulation. If the incision extends into the temporal area, bleeding in the temporal muscle is managed by electrocoagulation, hemostats, tamponade, or suture ligature. Mayo scissors can be used to incise temporal muscle and fascia.
3. The soft tissue is peeled off the periosteum by sharp or blunt dissection or by electrodissection. The scalp flap is reflected over folded sponges and retracted by use of small towel clips and rubber bands or by muscle hooks on rubber bands. In either case, the traction is maintained by securing the rubber band to the drapes with heavy forceps. The flap may be covered with a moist sponge or Telfa strips and a sterile towel. Bleeding is controlled by electrocoagulation (Figure 20-48).
4. When a free bone flap is planned, the muscle and periosteum are incised. Muscle and periosteum are elevated with the skin-galea flap, reflected, and retracted as a unit, as described previously.
5. The periosteum and muscle are incised with a scalpel or ESU knife except at the inferior margins, which are left intact to preserve the blood supply to the bone flap. The periosteum is stripped from the bone at the incision line with a periosteal elevator. Bone wax is used to control bleeding.
6. The scalp edges and muscle are retracted from the bone incision line by a Sachs or Cushing retractor. Two or more burr holes are made (Figure 20-49). A great deal of heat is generated by the friction of the perforator or burr against the bone. The assistant must irrigate the drilling site to counteract the heat and remove bone dust, which collects as the holes are made. A large-gauge suction tip is used to remove both irrigating solution and debris from the field. As the inner table is perforated and the dura exposed, tamponade

FIGURE 20-47 The skin incision for a pterional craniotomy.

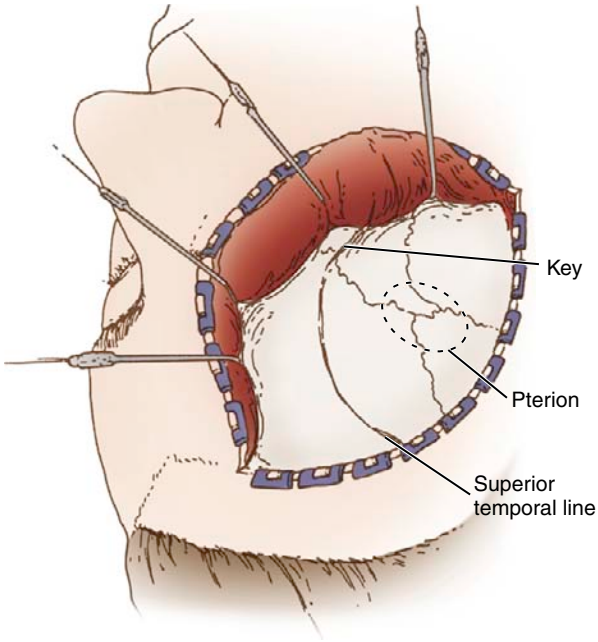

FIGURE 20-48 A commonly employed means of opening the scalp involves incision of the skin, galea, temporalis fascia, and muscle with reflection of the resultant flap in a single layer.

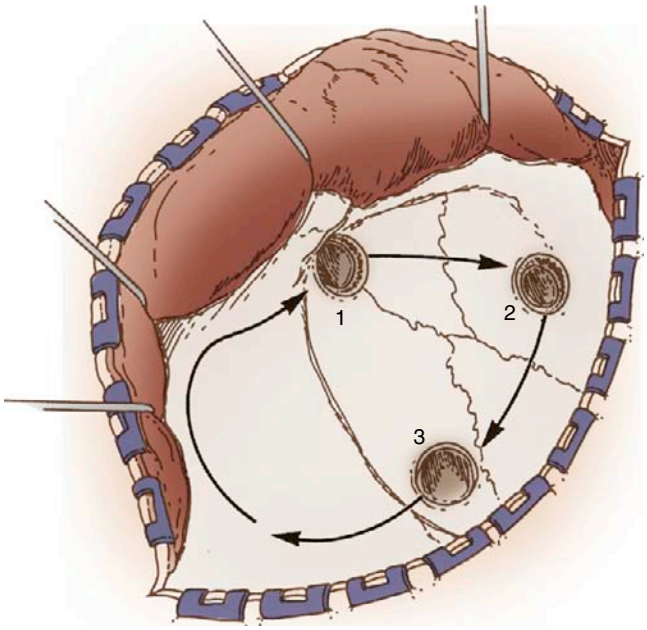

FIGURE 20-49 The pterion craniotomy is performed with power instruments so that three burr holes are placed. The bone is cut as shown, exposing the frontal and temporal dura and the sphenoid ridge.

of the burr hole may be done temporarily with bone wax or a cottonoid strip or patty. Each hole is eventually debrided by a #0 or #00 bone curette or small periosteal elevator. The dura mater is freed at the margins with a #3 Adson elevator, #3 Penfield dissector, or right-angle Frazier elevator or similar instrument. The hole is irrigated and suction applied simultaneously. Active bleeding points in the bone are identified, and bone wax is applied.

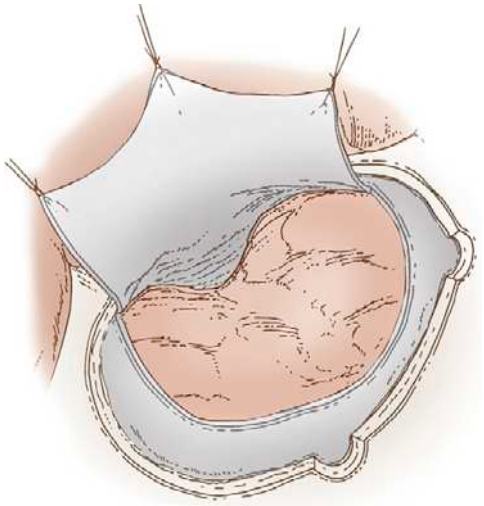

FIGURE 20-50 The dura is opened and reflected back with stay sutures.

7. When all burr holes have been made, the surgeon separates the dura mater from the bone with a dural separator, such as a #3 Penfield dissector. Dural separation is done to prevent tearing of the dura mater, especially over venous sinuses. An air craniotome or Midas Rex drill can be used for cutting the bone flap. Irrigation and suction are required as the bone flap is cut. Soft tissue edges are retracted with Sachs or Cushing retractors.
8. The bone flap with muscle attached is lifted off the dura mater by two periosteal elevators. Bleeding from the bone is controlled with bone wax. The bone flap is covered with a moist sponge, cottonoid material, and then a clean sterile towel and is retracted in the same manner as the scalp flap.
9. The dura mater is irrigated. Moist patties may be inserted between the dura mater and bone and folded back to cover the exposed bone edges. Epidural tack-up sutures are usually placed around the edge of the craniotomy defect to close the epidural dead space. Sterile towels may be placed around the operative site.
10. The surgeon opens the dura (Figure 20-50). A dura hook or a dural stitch may be used to elevate the dura mater from the brain, and a small nick is made in the dura mater with a #15 blade. Alternatively, a small opening may be made in the dura mater without elevating it, after which the dural edges are grasped with two forceps with teeth and are elevated. A narrow, moist cottonoid strip is inserted with smooth forceps (bayonet or Cushing) into the opening to protect the brain as the dura mater is incised and elevated. The dural incision can be made with Metzenbaum scissors, special dura scissors, or a Rayport dura knife. Usually traction sutures are placed at the outer edge of the dura mater and are tagged with small bulldog clamps or mosquito hemostats. Sometimes the tag instruments are attached to the drapes to increase traction and keep tension on them. As the dural veins are approached during dural opening, the surgeon ligates or coagulates them before cutting. Ligation is done with hemostatic clips such as Weck hemoclips, McKenzie clips, or Ligaclips. The brain surface is protected by moist cottonoid strips.

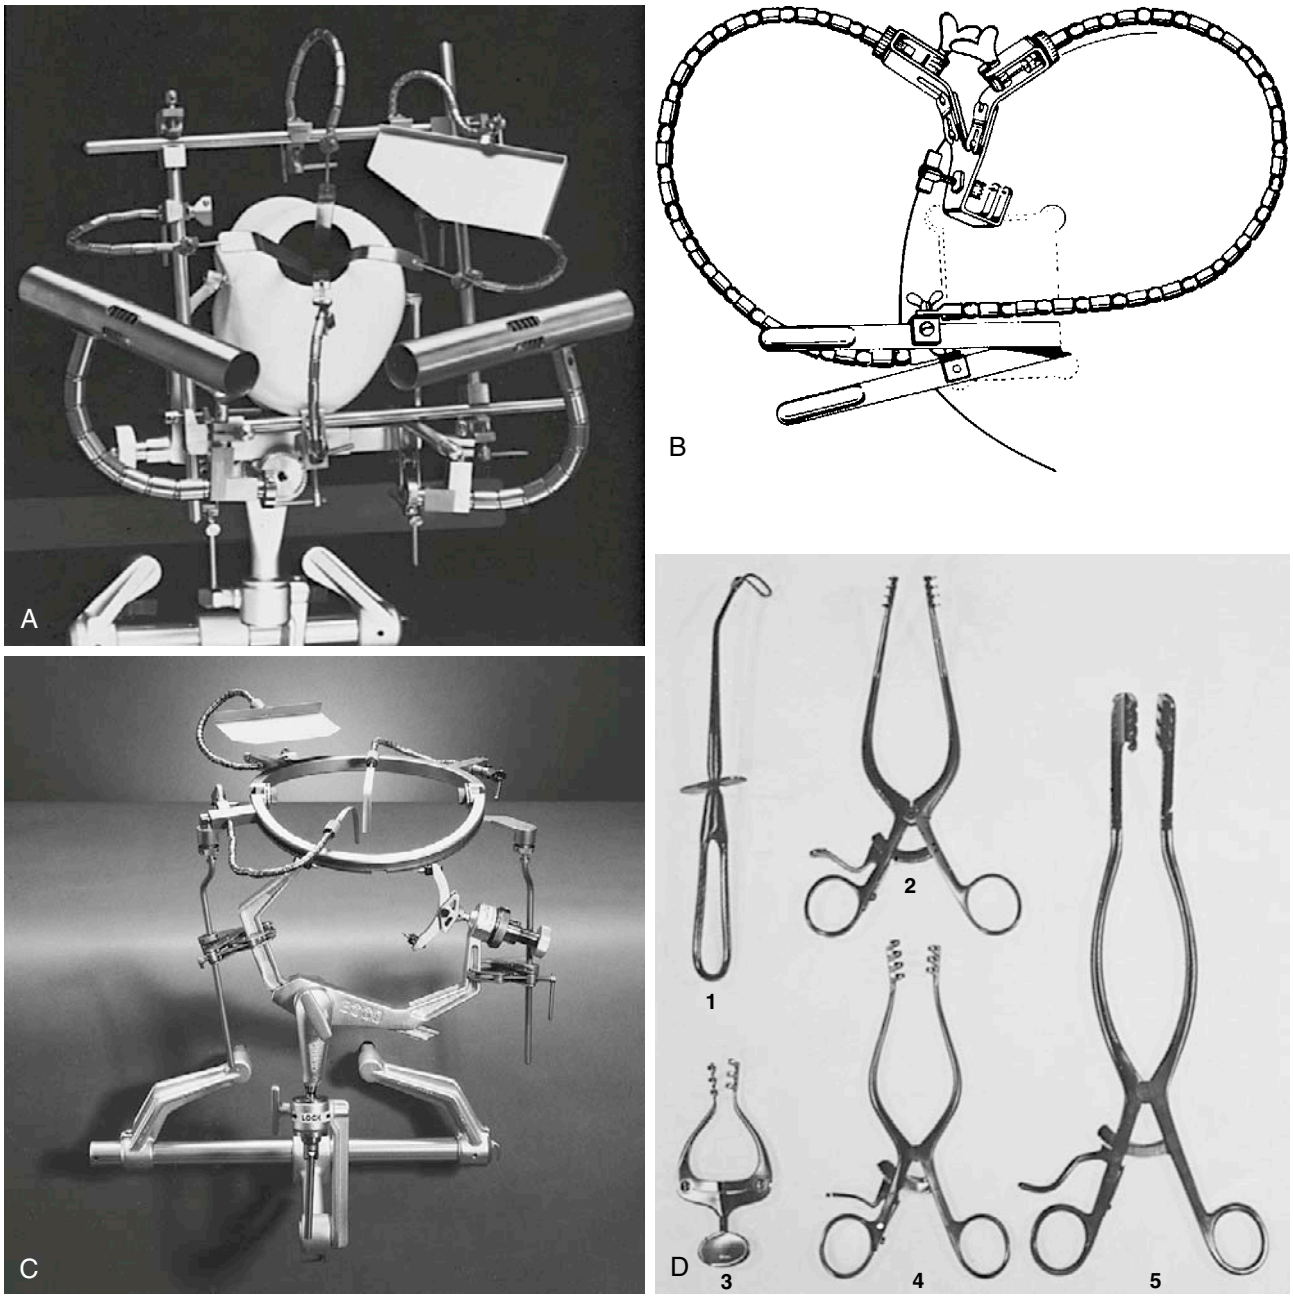

FIGURE 20-51 **A**, Greenberg retractor with blades. **B**, Leyla-Yasargil self-retaining retractor. **C**, Budde halo retractor with attachments. **D**, Retractors: *1*, Cushing subtemporal decompression retractor; *2*, Adson cerebellar retractor; *3*, Jansen mastoid retractor; *4*, Weitlaner retractor; *5*, Beckman laminectomy retractor.

11. The surgeon appropriately places cottonoid strips and brain retractors, both self-retaining (Figure 20-51) and manual, while working toward visualizing the particular pathologic entity.
12. Pituitary rongeurs as well as the CUSA (Cavitron Ultrasonic Surgical Aspirator) may be needed for tumor removal. Also, a selection of dissectors, bayonet and Gerald forceps, and a bipolar ESU are used. Completely filled irrigating syringes and a full range of moist cottonoid patties and strips must be within easy reach of the surgeon and the assistant. After correction of the pathologic condition and control of bleeding, the brain may be irrigated with an antibiotic solution of the surgeon's choice.
13. The dura mater is usually closed by running or interrupted sutures of absorbable suture or black braided nylon. Dural grafts may be used.
14. The bone flap is replaced and fixated with titanium plates and screws.
15. Periosteum and muscle are approximated with 2-0 or 3-0 absorbable suture. The galea is closed with the same sutures. Skin closure can be interrupted or continuous suture or skin staples.

Surgery for Intracranial Aneurysm

An aneurysm is a vascular dilation usually caused by a local defect in the arterial vascular wall, particularly at points of bifurcation. Vessels at risk within the brain involve those of the major circulation within and around the circle of Willis. Aneurysms are believed to arise from a complex set of circumstances involving a congenital anatomic predisposition enhanced by local and systemic factors. Aneurysmal rupture and hemorrhage into the subarachnoid space are frequently the first sign of an aneurysm, resulting in a sudden, severe headache described as "the worst headache ever." Current neurosurgical techniques have made operations on intracranial aneurysms more feasible; however, fewer than 40% of patients with ruptured aneurysm will return to functional life and 30% die before reaching the hospital (Batjer et al, 2005). Hemorrhage and the cascade of ensuing cerebral trauma are the greatest hazard of the condition and of the operation. To minimize this, control of blood pressure as well as vascular supply to the region beyond the limits of the lesion may be required. Occasionally, control of the cerebral circulation at the level of the cervical carotid artery is desired. The artery may be exposed and controlled by means of preplaced ligatures or clamps that can be tightened to occlude the vessel if bleeding occurs at the aneurysm site during the operation. This is a separate preliminary surgical procedure.

Procedural Considerations. Aneurysm clips and appliers of the surgeon's choice must be included with the instrumentation. A variety of aneurysm clips are available, and most are spring loaded. Figure 20-45 illustrates a few of the clips and appliers available. Clips may be classified as temporary or permanent, and both must be available with a minimum of two appliers for each type of clip. Temporary clips are commonly used to control giant aneurysms where it may be necessary to evacuate clot and debris before permanent occlusion can be accomplished (Figure 20-52). Temporary clips may also be used to establish the best position for the permanent clip. Temporary clips should be discarded after use. Permanent clips are used to occlude the neck of the aneurysm. Aneurysm clips should not be compressed between the fingers. Clips should be compressed only by the surgeon when seated in their appliers. Once a clip has been compressed, it should be discarded. Clips that have been compressed may be sprung and may slip, causing complications such as bleeding or compression of another vessel or a nerve.

The full armamentarium of aneurysm-occlusion tools should be available for the surgeon. Besides clips, fast-setting aneuroplastic resinous material, a piece of temporal muscle, ligature carriers, or any other material requested by the surgeon should be in the room and ready to use. Fine silk ligatures and hemostatic clips, with or without bipolar electrocoagulation of the neck of the aneurysm, have also been used successfully.

A basic craniotomy setup is required in addition to the special items mentioned. Supplementary suction must be immediately available on the field to prevent hemorrhage from obscuring the surgeon's vision if the aneurysm dome ruptures during the operation. A blood salvage unit should be available for reprocessing of blood for replacement when significant blood loss is expected.

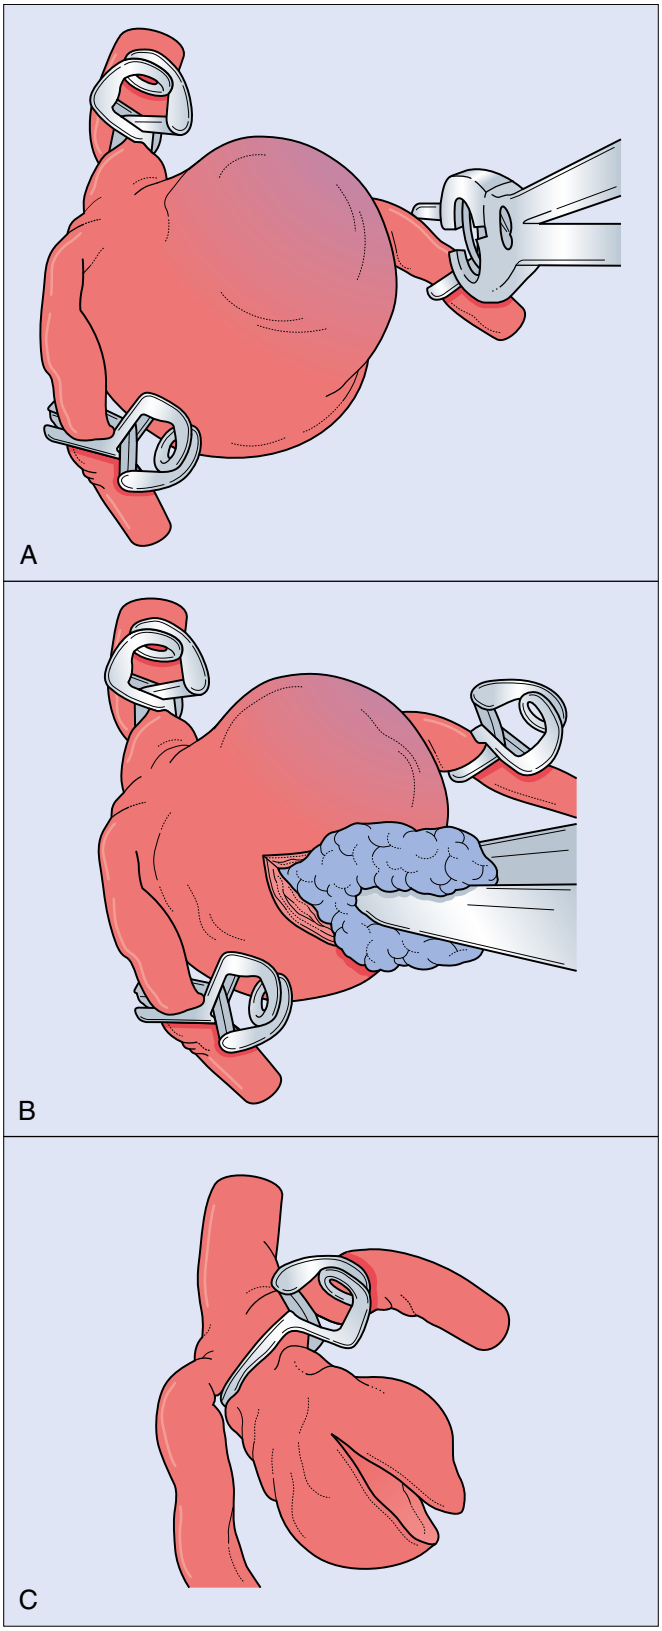

FIGURE 20-52 Temporary arterial occlusion is often necessary in repairing complex large or giant aneurysms. **A**, Temporary clips are placed on the feeder vessels. **B**, The aneurysm sac is opened to allow evacuation of debris and thrombus. **C**, Permanent clip in place.

Interventional radiology now plays an important role in the management of intracranial aneurysms. Intravascular balloon occlusion and coiling of aneurysms by interventional radiologists are now considerations in the treatment of aneurysms that meet the criteria for endoscopic therapy. The coils, composed of a soft platinum alloy, allow conformability to the dome of the aneurysm. A guide catheter is introduced into the femoral artery under fluoroscopy and advanced from the aorta into the vessel specific to the aneurysm. Coils are first introduced to outline the border of the aneurysm, and then smaller coils are added to fill the center of the aneurysm. Gradually, blood flow will be reduced, allowing the aneurysm to thrombose (Khatri et al, 2008). Both the neurosurgeon and the radiologist work closely to diagnose and treat these life-threatening anomalies.

Operative Procedure—Craniotomy for Aneurysm Clipping

1. A frontal, pterional, or bifrontal craniotomy may be done to approach an aneurysm in the area of the circle of Willis. The bifrontal approach requires extra scalp clips and hemostatic forceps. All aneurysm instruments preferred by the surgeon must be included.
2. After the dura mater has been opened, the surgeon places a self-retaining brain retractor and exposes the optic nerve and subarachnoid cisterns. The olfactory nerve may be electrocoagulated and divided with a long scissors for better exposure.
3. The surgical technologist and perioperative nurse position the operating microscope as directed by the surgeon. Microinstruments, including a micropolar bayonet, are used.
4. Bridging veins are coagulated with bipolar electrocoagulating forceps. Irrigation, which may be a part of the bipolar ESU, is necessary during bipolar electrocoagulation.
5. The surgeon uses microdissectors, hooks, elevators, scissors, knives, forceps, a diamond microknife, and an irrigating bipolar ESU to dissect the covering arachnoidal webs.
6. Careful dissection of the arachnoid and clear visualization of the neck of the aneurysm without rupture of the dome are the aims of the surgeon.
7. The surgeon identifies and frees the parent arteries so that they can be occluded with a temporary clip if necessary. Other structures, such as the optic chiasma and optic nerves, are identified.
8. As the surgeon works slowly toward the dome and neck of the aneurysm, the anesthesia provider may lower the patient's blood pressure for easier control of hemorrhage, should the aneurysm rupture. If the neck of the aneurysm can be isolated, the surgeon places a clip across it. Clips such as the Sundt-Kees and Heifetz have Teflon linings and can be used to approach the aneurysm from a 180-degree angle to avoid excessive manipulation and traction of the parent vessel, if the neck is on the underside of the vessel. These clips support the vessel and serve as a clip graft.
9. Following clip placement, the surgeon may check the aneurysm sac by puncturing it with a needle to see if the clip pressure is adequate to stop blood flow to the aneurysm or to aspirate the aneurysmal contents.
10. As soon as the aneurysm has been occluded, the anesthesia provider returns the patient's blood pressure to normal and the surgeon checks the aneurysm site for bleeding. When the surgeon is satisfied that the operative field is dry, wound closure is begun.

Surgery for Arteriovenous Malformation

An AVM consists of thin-walled vascular channels that connect arteries and veins without the usual intervening capillaries. These vascular lesions may be microscopic or massive. AVMs are rare, affecting only about 300,000 people in the United States (National Institute of Neurological Disorders and Stroke [NINDS], 2009). Malformations vary widely in size, area of involvement, and structure. Arteriovenous fistulas may be congenital or may result from trauma or disease. Vascular anomalies may also lead to subarachnoid or intracerebral hemorrhage or may have extensive irritative effects and cause focal or generalized seizures.

Procedural Considerations. AVMs are difficult to treat successfully. Feeding vessels can be clipped with or without partial removal of the lesion. Total removal, when possible, gives best results. Microsurgical techniques have made total removal without devastating injury to surrounding brain tissue and vessels possible in many cases.

Other methods of treating these malformations include stereotactic radiosurgery with the Gamma Knife. Another method is preoperative embolization, which makes dissection much easier. Surgical glue, such as *N*-butyl cyanoacrylate and tantalum powder, is delivered by means of a catheter into the blood vessels before surgery. During the surgery, the glue is removed along with the AVM. Serial embolization may be performed to reduce the size of the AVM and provide symptom relief when the goal of treatment is not complete obliteration (Schumacher and Marshall, 2006).

Operative Procedure—Craniotomy for Arteriovenous Malformation

1. A supratentorial or infratentorial craniotomy is done, depending on the location of the lesion.
2. The surgeon exposes the feeding arteries distant from the malformation, traces toward it, and then occludes the feeders by clipping, electrocoagulation, ligation, or laser beam coagulation.
3. The malformation is dissected out with suction and bayonet forceps. Additional vessels are clipped or coagulated along the way. Usually one or more draining veins are left to be ligated as the last step in the removal. Closure and dressing are as described for craniotomy.

Craniotomy for Suprasellar and Parasellar Tumors (Pituitary Tumor, Craniopharyngioma, Meningioma, Optic Glioma)

Procedural Considerations. The preferred approach for pituitary tumors and some parasellar tumors is the less invasive transsphenoidal approach. However, for large and complex pituitary and parasellar tumors, a craniotomy may be indicated. A craniotomy setup is used with these additional pituitary instruments: Ray curettes (ring, sharp); angulated suction tips, right and left; large and small spinal needles, #22 or #24; curettes, small, #0 through #4-0; and a Luer-Lok syringe, 10 ml.

Operative Procedure—Craniotomy for Pituitary Tumor Resection

1. The surgeon makes either a bifrontal or a unilateral incision into the frontal or frontotemporal region. Most unilateral approaches are carried out from the right side.

2. Wet brain retractors over moist cottonoids are inserted for exposure of the optic chiasma and the pituitary gland. The frontal and often the temporal lobes are retracted. The olfactory nerve may be coagulated and divided with scissors.
3. A DeMartel, Yasargil, or Greenberg self-retaining retractor is placed to maintain exposure. Aneurysm clips and applicators should be available to control unexpected bleeding from major vessels. The microscope may be moved into place.
4. The surgeon uses the bipolar ESU for hemostasis around the tumor capsule and incises it with a #11 blade on a long knife handle; the tumor is removed with a pituitary rongeur or cup forceps.
5. Small stainless-steel, copper, or Ray curettes, as well as suction, may be used during tumor removal.
6. A wide clip may be applied to the stalk of the pituitary, which may then be cut distally. A long angulated scissors is especially helpful for this.
7. If the tumor capsule is to be removed, bayonet forceps, cup forceps, nerve hooks, and suction aid in the dissection.
8. Closure and dressing are as described for craniotomy.

Extreme caution must be used in removing fluid from the capsule of a craniopharyngioma because the fluid is extremely irritating and may cause chemical leptomeningitis. Calcified pieces of tumor are dissected and removed in the same manner as the capsule of a pituitary adenoma. This is an extremely difficult procedure because of deposits on the carotid arteries, optic nerves, and optic chiasma. The tumor capsule is often left behind on the hypothalamus to avoid stripping off blood vessels supplying this structure. Many moist cottonoid strips are used to protect the surrounding areas from the cystic contents.

Suprasellar meningiomas usually arise from the tuberculum sellae just anterior to the optic nerves and chiasma. Tumor removal is similar to that of a pituitary adenoma except that the electrosurgical cutting loop may be used to excavate the interior of the tumor. After the tumor has been removed, the site of its attachment to the dura is thoroughly electrocoagulated to prevent recurrence. Other meningiomas arising at the base of the skull are treated by similar techniques.

Suboccipital Craniectomy for Posterior Fossa Exploration

The posterior occipital bone is perforated and removed using a drill and rongeurs, and the foramen magnum and arch of the atlas are exposed to remove a lesion in the posterior fossa (Figure 20-53). Posterior fossa lesions include lesions in the cerebellum, the fourth ventricle, and the brainstem; posterior fossa meningiomas; and nerve sheath tumors.

Procedural Considerations. Depending on the type and size of the lesion, the exposure may be unilateral or bilateral. The operation may include the removal of the arch of the atlas. This approach gives the surgeon access to the fourth ventricle, the cerebellum, the brainstem, and the cranial nerves.

The prone position with the head of the OR bed elevated is the preferred position, but other positions may also be used. An extra-high instrument table or two Mayo stands and standing stool are necessary for the surgical technologist.

Operative Procedure

1. Before the initial surgical incision, the surgeon may make an occipital burr hole for placement of a ventricular catheter. This can be done as a separate procedure or concurrently with the procedure.
2. The incision may be made from mastoid tip to mastoid tip, in an arch curving upward 2 cm above the external occipital protuberance. Alternatively, a posterior midline incision can be used.
3. Scalp bleeding is controlled, and the skin flap is retracted with Weitlaner retractors.
4. The surgeon uses a periosteal elevator to free the muscles, and then divides them with an electrosurgical blade. The incision is deepened. A self-retaining retractor is used. The laminae of the first two or three cervical vertebrae may be exposed.
5. One or more holes are drilled in the occipital bone. The Midas Rex or Anspach drill is used to perform the craniectomy.
6. The dura mater is stripped from the bone. A double-action rongeur, Raney punch, Kerrison punch, or Leksell rongeur is used to enlarge the hole and smooth the edges.
7. Osseous and cerebellar venous bleeding is controlled at each step with bone wax, Gelfoam, and electrocoagulation to prevent air embolism.
8. The dura mater is opened. A small brain spoon or cottonoid strip is used to protect the brain as the initial nick is extended with scalpel or scissors. The dural incision is continued until the cerebellar hemispheres, the vermis, and the cerebellar tonsils can be visualized. Hemostatic clips are used on the dura mater as necessary. Dural traction sutures are placed.
9. The cisterna magna is opened, emptied of spinal fluid, and protected with a cottonoid strip.
10. The cerebellar hemispheres are inspected. Bleeding is controlled with the bipolar coagulator. A needle may be introduced through a small, coagulated incision into the cerebellar hemisphere in an attempt to palpate or tap a deep lesion.
11. Brain retractors over cottonoid strips are placed for exposure. The handle of the retractor must be kept dry to avoid slippage in the surgeon's hand. However, the inserted edge should be wet to prevent damage or tears in the brain surface. These retractors may be positioned in areas that control respiration or other vital functions, so every effort must be made to avoid jarring these instruments in the operative field. When the pathologic entity is identified, a self-retaining retractor may be placed.
12. Long bayonet forceps, bayonet cup forceps, pituitary forceps, suction, and the electrosurgical loop tips may be used to remove the lesion. Clips may be used to aid in hemostasis. A nerve stimulator may be used to identify cranial nerves; EPs for brainstem monitoring are becoming routine practice.
13. After the lesion has been removed and bleeding controlled, further checking for adequate hemostasis is required. Venous pressure in the patient's head is increased by the anesthesia provider by generating Valsalva's maneuver.
14. The dura mater may be partially or completely closed. The cranial defect may be repaired with titanium mesh. The muscle, fascia, and skin are closed. A dressing is applied.

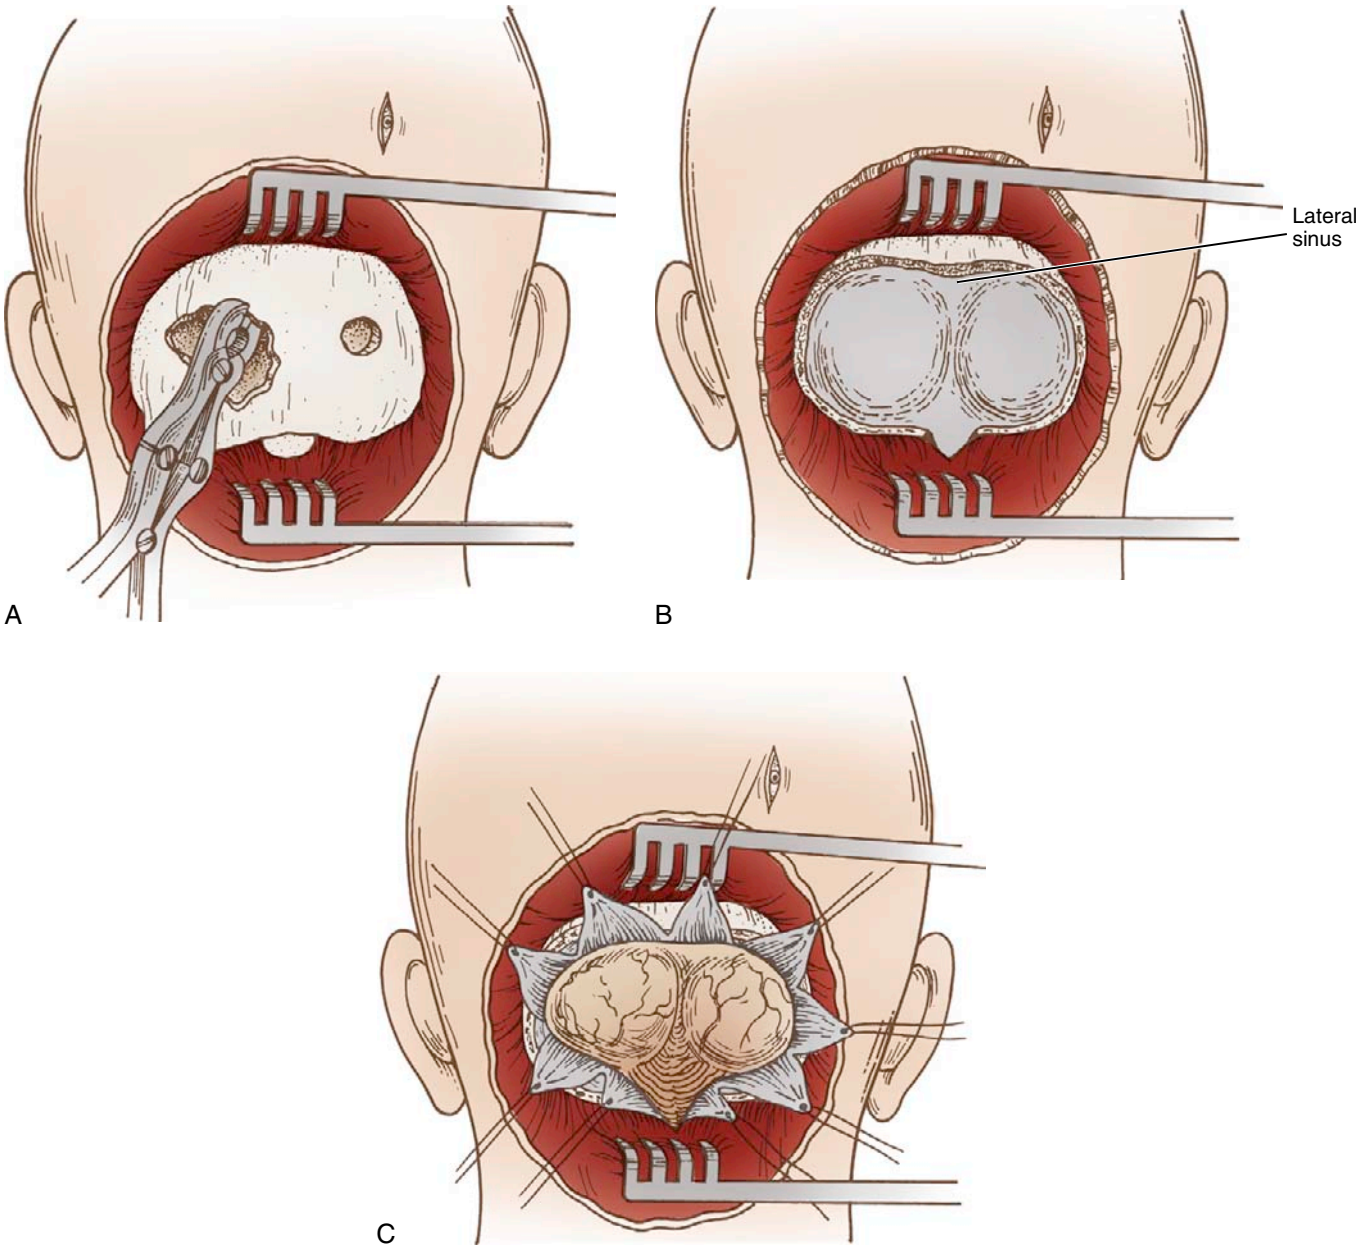

FIGURE 20-53 Suboccipital craniectomy. **A**, Craniectomy being performed. **B**, Dura exposed. **C**, Dura incised and cerebellum exposed.

15. The patient must remain anesthetized until the supine position is achieved and the prongs of the headrest are removed. Particular attention must be given to the patient's head when these prongs are removed to prevent tearing the scalp or damaging the eyes.

Retromastoid Craniectomy for Microvascular Decompression of the Trigeminal Nerve

Trigeminal neuralgia (tic douloureux, fifth cranial nerve pain) is a condition characterized by brief, repeated attacks of excruciating, lancinating pain in the face. The etiology of this facial pain is believed to be the compression of the trigeminal nerve at its exit from the pons by an adjacent artery that has elongated over time to become wedged against the nerve, resulting in demyelination. Pain distribution follows one or all of the trigeminal nerve branches. It is characteristically severe, with sudden onset, short duration, and paroxysmal nature. Triggers often precipitate the pain, such as touching the face, chewing, and talking. When pharmacologic measures fail, surgery to decompress the nerve is undertaken. Frequently more than one treatment is necessary during the course of the disease. Newer options include Gamma Knife radiosurgery.

Procedural Considerations. The patient is in the supine, lateral, or sitting position, depending on the surgeon's preference. An endoscope can be used along with the microscope to improve visualization.

Operative Procedure

1. The surgeon makes a vertical retromastoid incision.
2. The soft tissue is freed from the bone with a periosteal elevator. The bone exposure is maintained with a self-retaining retractor.
3. A burr hole is made, and the dura mater is freed.
4. The surgeon uses a drill and rongeurs to enlarge the burr hole to a diameter of about 2½ inches.
5. With a moist brain retractor, the dura mater overlying the pons and cerebellum is retracted.
6. A self-retaining brain retractor is placed deeper into the wound to retract the cerebellum. The microscope is used to provide light as well as magnification.
7. The surgeon identifies the pons, the superior cerebellar artery, and the trigeminal nerve.
8. Additional blunt dissection frees the vessel from the nerve. A synthetic microsponge is inserted between the vessel and nerve to maintain the separation.
9. The dura and cranial defect are repaired, the incision is closed, and dressings are applied.

Transsphenoidal Hypophysectomy

Endocrine pituitary disorders (such as Cushing's syndrome, acromegaly, malignant exophthalmos, and hypopituitarism resulting from intrasellar tumors) as well as nonpituitary disorders (such as advanced metastatic carcinoma of the breast and prostate, diabetic retinopathy, and uncontrollable severe diabetes) have been successfully treated by transsphenoidal hypophysectomy (TSH). A transnasal or a sublabial incision can be used for rapid access to the sella turcica.

More recently, an endoscope has been used to assist with access through the sphenoid sinus into the pituitary fossa. Otorhinolaryngologic surgeons can be consulted to assist the neurosurgeon with this approach. The endoscope and instrumentation access the sphenoid sinus by the transnasal route. Endoscopic transsphenoidal surgery eliminates the need for an incision and the need for a microscope. When the sphenoid sinus is reached, instruments and technique are similar to the microsurgical technique. Stereotactic image-guided navigation can also be used with the transsphenoidal technique.

All these approaches produce similar results. Complete extracapsular enucleation of the pituitary in cases of hypophysectomy and possible complete removal of small pituitary tumors, with the remaining normal portion of the gland left intact, can be achieved. Patients are relatively free from pain after surgery. No visible scar remains.

Procedural Considerations—Microsurgical Approach for Transsphenoidal Hypophysectomy. General endotracheal anesthetic, combined with a local anesthetic is used. The surgical team places the patient in a semisitting position, with the head against the headrest. The surgeon may use a subnasal midline rhinoseptal approach or a transnasal route, both exposing the sphenoid bone, the sphenoid sinus behind the bone, and the sella containing the tumor. Frequently, an otorhinolaryngologist assists the neurosurgeon in gaining access to the surgical site.

The face, mouth, and nasal cavity are prepped with an antiseptic solution. The surgeon infiltrates the patient's nasal mucosa and gingiva with a local anesthetic agent containing 1:2000 epinephrine to initiate submucosal elevation and diminish oozing from the mucosa. A sterile adhesive plastic drape is applied to the entire face, with additional sterile drapes to ensure a relatively sterile operative field. Sterile sponges (or cotton) are placed in the patient's mouth so that only the upper gum margin is exposed.

Although sterile technique is used, this approach through the nose or mouth is technically not a sterile procedure. Therefore a separate sterile field and instruments must be maintained for adjunct procedures. The thigh or abdomen is prepped if a muscle or fat graft is to be taken. A lumbar drain may be placed preoperatively or postoperatively.

Specialized transsphenoidal instruments are required. The operating microscope is used for the cranial portion of the procedure. A fluoroscopy unit with C-arm may be used to verify the anatomic location of the sella.

Operative Procedure—Microsurgical Approach for a Transsphenoidal Hypophysectomy

1. Using the biopsy setup on a separate small Mayo table, the surgeon may take a small piece of muscle from the previously prepared thigh or a fat graft from the abdomen to be used later in the procedure. This is kept in a moist sponge or soaked in antibiotic solution.
2. An incision is made in the middle of the upper gum margin. The soft tissues of the upper lip and nose are elevated from the bone with an elevator, and the nasal septum is exposed. The nasal mucosa is elevated from either side of the nasal septum, which is flanked by the blades of a Cushing bivalved speculum. The transnasal approach avoids the sublabial incision, instead operating through a bivalve speculum inserted directly through the nares. The inferior third of the anterior cartilaginous septum and osseous vomer are resected, as is the floor of the sphenoidal sinus, exposing the sinus cavity. The floor of the sella turcica can then be identified.
3. The surgeon opens the floor with a sphenoidal punch, and incises the dura mater. The hypophyseal cavity should be opened only in patients undergoing surgery for pituitary adenoma. In these patients, the gland is explored and the tumor is identified and removed.
4. The extracapsular cleavage plane is identified, and the superior surface of the pituitary is dissected until the stalk and the diaphragmatic orifice are found. Cotton pledgets are applied for exposure, hemostasis, and protection of structures.
5. Using a sickle knife, the surgeon sections the pituitary stalk and uses an enucleator to dissect the lateral posterior and inferior surfaces of the gland.
6. The gland is removed, and the sellar cavity may be packed to prevent CSF leakage. The packing is accomplished with muscle obtained previously from the thigh or with the fat graft previously obtained from the abdomen or thigh. The floor is reconstructed with cartilage from the nasal septum.
7. Antibiotic powder may be used and nasal packing introduced for 2 days. If a gingival incision is used, it is closed with suture of the surgeon's preference.
8. Some surgeons prefer to perform this operation by means of a lateral rhinotomy with a transantral-transsphenoidal approach.

SURGERY OF THE SPINE

Surgery of the spinal column is also discussed in Chapter 19, Orthopedic Surgery.

Anterior Cervical Decompression and Fusion

Anterior cervical decompression and fusion (ACDF) is performed to treat cervical disk herniation or cervical spondylosis (degeneration in the spine) with myelopathy (disorder of the spinal cord) or radiculopathy (disorder of the nerve roots). Symptoms include pain in the neck, shoulders, arms, and hands; and weakness of the upper extremity. An ACDF entails a corpectomy (removal of a vertebral body), diskectomy, and fusion of the vertebral bodies. Bone grafts for the fusion are obtained from the patient's iliac crest (autograft) or from a bone bank (allograft).

Procedural Considerations. Awake endoscopic intubation may be required if the patient's neck is unstable or unable to extend. Neurologic monitoring is commonly employed to prevent further injury during surgery. The patient is placed in the supine position, with a small shoulder roll placed horizontally for mild neck extension. The perioperative nurse ensures the patient's arms are tucked, and the hip is elevated for exposure if bone graft is to be taken from the iliac crest (Figure 20-54). Intraoperative x-ray may be employed to confirm the correct surgical site and verify placement of the graft and related hardware.

Operative Procedure

1. The surgeon may harvest the iliac crest bone graft before the neck procedure begins, or it may be completed after exposure of the anterior cervical spine. An incision is made over the iliac crest, at least 3 cm posterior to the anterior superior iliac spine. The skin and subcutaneous tissues are retracted with a Weitlaner retractor.
2. Soft tissue is dissected until the crest is reached and exposed.
3. The surgeon uses an osteotome or oscillating saw to remove the bone graft. The graft is soaked in antibiotic solution and set aside. The perioperative nurse initiates a sponge and sharp count for this portion of the procedure. Following verification of a correct count, the surgeon irrigates and closes the wound and covers it with a sterile towel.
4. A transverse or horizontal skin incision is made on one side of the neck, directly over the involved cervical level.
5. A Weitlaner retractor is placed, and the surgeon uses sharp dissection to divide the platysma.
6. The medial edge of the sternocleidomastoid muscle is defined with the scissors by blunt and sharp dissection.
7. Using blunt finger dissection, the surgeon creates a vertical plane of dissection between the carotid artery laterally and the trachea and esophagus medially. This plane is held open with retractors.
8. The anterior surface of the spine is identified, and the long muscles of the neck are peeled off the anterior surface of the spine with periosteal elevators or peanut dissectors. The bipolar ESU is used for hemostasis.
9. A 20-gauge spinal needle is inserted a short distance into the disk space, and the location is confirmed radiographically.
10. Self-retaining retractors are inserted into the neck incision. Care is used to protect the carotid artery and the esophagus. A combination of sharp and dull blades is used to acquire the best retraction. If a toothed blade is used, the teeth are carefully hooked beneath the long muscle of the neck.

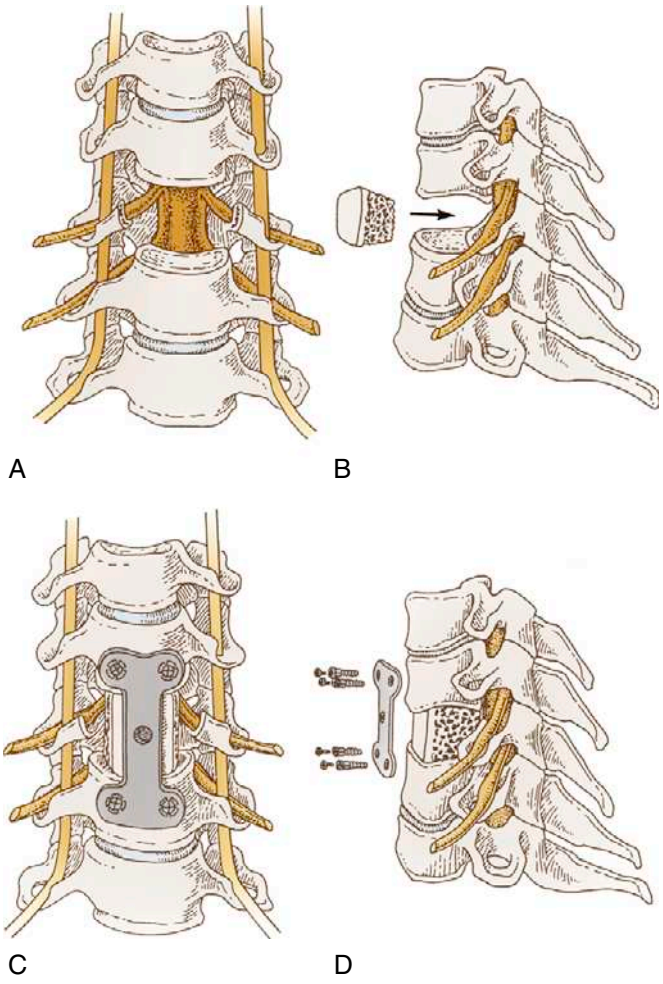

FIGURE 20-54 Anterior cervical decompression and fusion. **A** and **B**, A bone graft from the iliac crest or fashioned from bank bone is tailored to fit the site of corpectomy, resting on the vertebral endplates. **C** and **D**, An anterior spinal plate and screws are secured to the vertebral bodies above and below the spanned segment to stabilize and promote a stable fusion.

11. The surgeon uses a #15 or #11 blade on a #7 knife handle to incise the disk space; a pituitary rongeur is used to remove the disk material, which may be saved as a specimen. A vertebral spreader may be inserted into the vertebral space to widen the area. Residual disk material is removed with the rongeur or small curettes (angled or straight, #0 to #4-0) until the entire surface of both vertebrae is clean. A small burr may also be used until complete anterior decompression of the nerve root or dural sac is obtained. Nerve hooks may be used for demonstration of adequate decompression.
12. A depth gauge and caliper measure the size of the interbody defect. The bone graft is cut to the appropriate size and placed into the defect with a tamp and a mallet.
13. The anterior cervical plate and screws are secured to the vertebral bodies above and below the bone graft.
14. Lateral x-ray or fluoroscopy is done to confirm location, degree of distraction, and alignment.

15. Hemostasis is obtained, and the wound is irrigated. A drain may be placed. The platysma is closed with absorbable suture. A subcuticular closure of the skin is done, and wound closure strips are applied.
16. A cervical collar is placed before the patient awakens.

Posterior Cervical Approach

The posterior cervical approach is used for laminectomy for decompression, intradural tumor removal, cordotomy, diskectomy, and fusion (Connolly et al, 2009).

Procedural Considerations. A patient with severe spondylosis may require fiberoptic intubation. Intraoperative neurologic monitoring should be used to detect a change in neurologic status. The patient is positioned prone with a three-pin skull clamp (Mayfield). The OR bed is positioned in mild reverse Trendelenburg's position to encourage venous drainage. The patient's arms are tucked. If allograft bone graft is desired for fusion, the posterior iliac spine will be prepped. A cervical collar may be required postoperatively.

Operative Procedure

1. The cervical spinous processes are palpated to plan the incision, and a midline incision is made.
2. Soft tissue dissection is done, and a clamp is placed on the spinous process to verify the correct level with x-ray.
3. Self-retaining retractors help to gain exposure. A subperiosteal dissection is made to the lateral margins of the involved facets using the Bovie, suction, and a cervical Cobb elevator.
4. Hemostasis is maintained with the bipolar ESU, Gelfoam, and patties.
5. A laminectomy is performed using a drill, Leksell rongeurs, curettes, a nerve hook, and Kerrison punch rongeurs.
6. Disk is removed with pituitary rongeurs and curettes.
7. If a fusion is required, instrumentation and allograft or autograft may be needed.
8. The wound is irrigated. A drain may be placed.
9. Bupivacaine may be injected into the paraspinal muscles and subcutaneous tissue for postoperative pain.
10. Absorbable sutures are used to close the fascia and subcutaneous layers. Suture or staples are used for the skin.

Anterior Thoracic Approach

A transthoracic thalamotomy is done to access the spine for a thoracic diskectomy, burst fracture, osteomyelitis, and metastatic disease (Connolly et al, 2009). Usually a thoracic surgeon assists the neurosurgeon in obtaining adequate exposure.

Procedural Considerations. The anesthesia provider may need to place a double-lumen endotracheal tube to allow for deflation of the lung for exposure of the higher thoracic levels. Lateral position with a bean bag is preferred. If intraoperative fluoroscopy is necessary, a Jackson table is needed. A bean bag interferes with fluoroscopy. For T1 to T4, a right-sided approach is preferred to avoid the aortic arch and heart. For T5 to T12, a left-sided approach is preferred because the aorta is safer to manipulate than the vena cava (Connolly et al, 2009). If allograft is desired for fusion, prep the iliac spine.

At times, an anterior thoracic surgery is performed in combination with a posterior thoracic surgery. In this case, the patient is repositioned prone after the completion of the anterior portion of the surgery. The posterior surgical site is prepped and draped, and the posterior portion of the surgery is completed.

Operative Procedure

1. A thoracotomy incision is made, and the latissimus dorsi and other muscles are transected. A rib may be resected with a rib cutter to gain exposure.
2. The parietal pleura is opened, and a thoracotomy retractor is placed. If necessary, the lung is deflated manually.
3. A localization x-ray is done to verify the correct level. The parietal pleura is incised further onto the vertebral body and cleared with blunt dissection. Segmental vessels are ligated as necessary with hemoclips and transected to mobilize the aorta.
4. For diskectomy or decompression, a drill, rongeurs, and curettes may be needed. For spinal fusion, instrumentation and autograft or allograft may be used.
5. The wound is irrigated, and a chest tube is placed. The ribs are reapproximated with a rib approximator and sutured with heavy absorbable suture.
6. The fascia and subcuticular layers are closed.

Laminectomy

Laminectomy is removal of one or more of the vertebral laminae to expose the spinal canal. Laminectomy, hemilaminectomy, and the interlaminar approach are performed to reach the spinal canal and its adjacent structures to treat compression fracture, dislocation, herniated nucleus pulposus, and cord tumor, as well as for spinal cord stimulation. Section of the spinal nerves, including cordotomy and rhizotomy, requires similar surgical exposure.

Procedural Considerations. Laminectomy is done with the patient in the prone or lateral position. It is performed on the cervical, thoracic, or lumbar spine. Laminectomy instruments include the basic neurosurgical set, the retractor of the surgeon's choice, and an assortment of specialty rongeurs.

Operative Procedure—Laminectomy for Spinal Stenosis

1. The surgeon makes a midline vertical incision at the operative site.
2. Two self-retaining retractors (Cone, Weitlaner, or Beckman-Adson) are inserted for exposure.
3. The fascia is incised in the midline with Mayo scissors, electrosurgical cutting tip, or a scalpel.
4. The surgeon uses sharp dissection to expose both sides of the spinous processes.
5. Correct surgical level is verified by lateral spine x-ray film.
6. The paraspinous muscles and periosteum are stripped off the laminae with sharp periosteal elevators. Dissection with the ESU may be used.
7. As each area is stripped, the surgeon packs a radiopaque sponge around the bony structures with a periosteal elevator to aid in further blunt dissection of muscles from the laminae and to tamponade bleeding.
8. A laminectomy retractor is then placed. A Scoville (with a blade on the tissue side and a slightly shorter hook on the bone side), Tower, Crank, or Adson-Beckman retractor can be used.
9. Cottonoid strips or patties may be placed in the extremes of the field for hemostasis.

10. The surgeon removes the spinous processes over the involved area with a rongeur. The bone edges are waxed.
11. The ligamentum flavum is cut with a scalpel, Metzenbaum scissors, or a rongeur. Cottonoid strips or patties are passed through this incision to protect the underlying dura, and a window is cut into the flaval ligament with a #15 blade on a #7 knife handle.
12. Additional ligaments in the lateral gutter of the spinal canal may be removed with a large curette or a Cloward rongeur after first protecting the dural sac.
13. Bleeding from the epidural veins is controlled by packing with narrow cottonoid strips and if necessary by careful coagulation with a bipolar bayonet forceps.
14. Various rongeurs are used to remove the laminae after edges are defined with a curette. Bone drills are commonly used to reduce bone down to epidural fat, saving time and wear on the surgeon's hands.
15. Rongeurs—straight and angled, narrow and wide—are used to remove further bony areas until the cord with its dural covering is exposed and decompressed.
16. The surgeon uses a blunt nerve hook to explore the nerve roots and extradural space.
17. If no further stenosis is felt, hemostasis is secured.
18. The cottonoid strips are removed from the epidural space, and the area is further irrigated. All cottonoid strips and patties and retractors are removed, and the wound is closed.

Operative Procedure—Laminectomy for Intradural Spinal Cord Tumor

1. The fascial incision is made in the midline, both sides of the spinous processes are dissected out, and the paraspinous muscles are reflected bilaterally, one side at a time. The level is confirmed with x-ray.
2. One or more Gelpi or Adson-Beckman self-retaining retractors are placed to maintain the bony exposure.
3. The surgeon performs a midline laminectomy and excises the spinous processes. Various rongeurs (e.g., Leksell, double-action, Cloward) are used to remove the laminae after the edges are defined with a curette. The Midas Rex drill may also be used. The bone edges are waxed for bleeding.
4. The remaining flaval ligament is removed with scissors, scalpel, and Kerrison or Cloward rongeurs. Epidural fat is removed so that the dura mater is fully exposed.
5. A wide, moist cottonoid strip is placed over the superficial soft tissues and muscle down to the bone bordering the exposed dura mater. This provides additional hemostasis.
6. Intraoperative ultrasound may be employed to verify the exact location of the tumor beneath the dura.
7. The surgeon elevates the dura mater with a small hook and nicks it with a #15 blade. A grooved director is inserted beneath the dura mater, and the dural incision is extended over it using long forceps and fine scissors. Alternatively, the surgeon may lengthen the incision with Metzenbaum scissors. Traction sutures of 4-0 silk or braided nylon on dura needles are placed in the dural edges, and the cord is exposed (Figure 20-55). The operating microscope may be used.
8. The cord is explored for the pathologic area. Aspiration through a #22 needle on a plain-tipped syringe may be carried out. Whenever possible, the tumor mass is dissected free and removed using suction, the dissecting scissors, the bipolar forceps, small (pituitary) scoops, curettes, pituitary rongeurs, or an ultrasonic aspirator. Bleeding is controlled with moist cottonoids, hemostatic clips, gelatin gauze, and topical hemostatics. Bipolar electrocoagulation is used around the nerves and spinal cord.
9. The wound is irrigated and hemostasis is obtained, being careful to protect the spinal cord.
10. The dura mater is closed with a braided nylon or polytetrafluoroethylene (PTFE) suture.
11. The incision is checked for further bleeding, and the paraspinous muscles are approximated with absorbable suture. The remainder of the wound is closed.

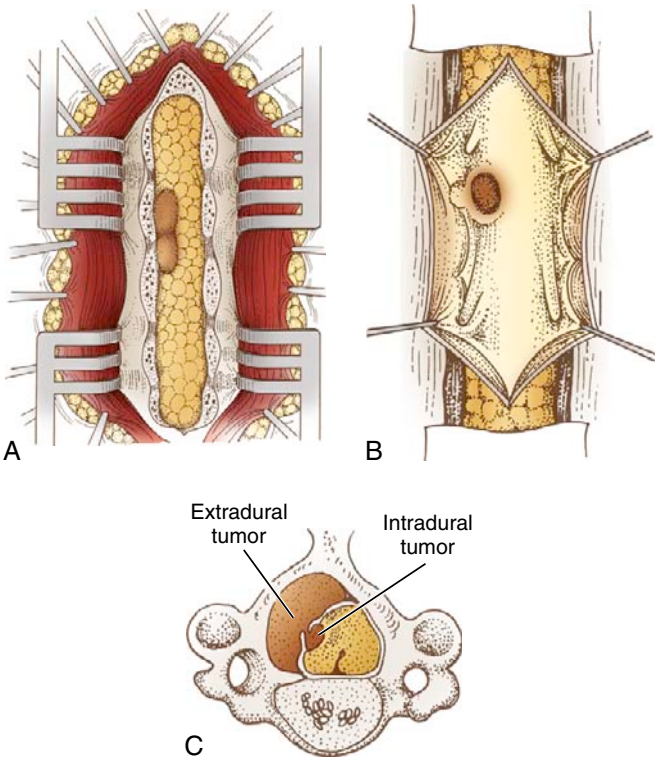

FIGURE 20-55 A, Laminectomy completed: dura mater and tumor exposed. B, Dura mater incised and retracted, revealing pia arachnoid over spinal cord and part of tumor. C, Diagram of cross section of tumor site and location of extradural and intradural pathologic areas.

In the case of extradural tumors, invasion of the dura is avoided. Once the dura is opened from a tear or an incision, the neurosurgeon may require that the patient remain flat for 24 hours or longer to allow healing of the dura.

Laminotomy

Laminotomy is the traditional approach to posterior microdiskectomy at the cervical, thoracic, and lumbar levels. Laminotomy is performed on the symptomatic side with resection of a small portion of the medial facet. The goal of this surgery is the resolution of leg pain with little to no residual back pain and a return to preinjury activity and lifestyle. In the twenty-first century, patients with herniated lumbar disks will continue to have a range of minimally invasive surgical options, many of which will be performed on an outpatient basis. Some of these newer procedures include nucleoplasty (decompression of a contained herniated disk by ablating and coagulating part

of the nucleus), intradiskal electrothermal therapy (IDET), and selective endoscopic diskectomy (Singh et al, 2005). Disk replacement is discussed in Chapter 19.

Procedural Considerations. The operating microscope has improved this surgical approach by offering magnification and illumination, which allows for smaller incisions and less tissue dissection. This surgical procedure is associated with less postoperative discomfort and shorter hospital stays. The majority of patients who undergo this procedure can be discharged home on the same day (Figure 20-56) (Ambulatory Surgery Considerations).

Operative Procedure—Lumbar Laminotomy and Microdiskectomy

1. With the patient in prone position or modified knee-chest position, a midline skin incision is made, extending from the spinous process above the involved level to the spinous process below. The correct surgical level is confirmed radiographically.
2. Dissection is carried down through the subcutaneous tissue to fascia, which is incised through a paramedian incision on the symptomatic side.
3. Paravertebral muscles are then dissected off the spinous processes and laminae.
4. A self-retaining retractor is placed to provide a visual field.
5. The hemilaminotomy, with a small portion of the medial facet removed, is performed.
6. The ligamentum flavum is incised longitudinally and removed with curettes or rongeurs, exposing the thecal sac.
7. A foraminotomy is then performed to expose and decompress the nerve root.
8. The epidural space is explored with a blunt dissector, nerve hook, dental tool, or Penfield #4 dissector.
9. The root is then gently retracted medially, exposing the disk bulge or herniation.
10. A window is made in the disk annulus with a #15 blade, and the disk space is entered.
11. Curettes and disk rongeurs are used to remove loose fragments of disk.
12. After diskectomy, the epidural space and the intervertebral foramen are explored with a blunt nerve hook to confirm patency and resolve nerve root pressure.
13. Hemostasis is achieved, and the wound is irrigated generously with saline/antibiotic solution.
14. The wound is then closed in layers.

For cervical or thoracic disks, only the protruding fragment is removed. Limited, if any, exploration of the interspace is performed because attempts at adequate interspace exploration require retraction of the dural sac, which contains the spinal cord at these levels. Such retraction would result in cord injury and paralysis. For a thoracic disk, a costotransversectomy or transthoracic approach is used.

Endoscopic diskectomy for far lateral disk herniations and annular tears has become an applied surgical approach in this subgroup of patients. Endoscopic spine systems have been developed, and further development and evolution of endoscopic equipment will continue to make minimally invasive procedures attractive to both the patient and the neurosurgeon.

AMBULATORY SURGERY CONSIDERATIONS

Microdiskectomies

Microdiskectomies are one of several spinal surgeries performed to relieve pain caused by disk herniations. Patients selected for this specific procedure typically complain of leg pain longer than 6 weeks in duration, and receive minimal relief from prescribed pain medications. An MRI confirming the level of nerve root compression as well as a detailed history and physical will determine if the patient is a candidate for surgery.

Ambulatory surgeries are designed for patients who have a nominal health history and pose minimal risk for operative complications. Microdiskectomies have the flexibility of being performed either in a same-day surgery center or in a hospital OR suite. The procedure is typically performed using a general or spinal anesthetic, depending on the needs of the patient. Once the anesthesia provider has control of the airway, the patient is positioned prone for maximum operative accessibility. Positioning may take time, and it is essential that every precaution is taken to prevent patient injury. If the patient is awake, talking should be kept to a minimum, and OR traffic should be closely monitored by the perioperative nurse. Before making the incision the surgeon may inject a local anesthetic containing epinephrine into the lumbar spine to minimize bleeding intraoperatively.

The procedure is approximately 2 hours in duration, and many patients are able to return home the same day. Postoperative pain relief is maximized by the use of intraoperative topical steroids on the nerve root, local anesthetics, and prescribed oral pain medications.

Possible complications include bleeding, infection, and, on rare occasions, nerve damage. Upon discharge the patient is instructed to keep the surgical site clean, restrict activity, and notify the surgeon immediately if he or she experiences excessive pain, swelling, or discharge from the incision site. Follow-up appointments are generally scheduled 2 weeks following the procedure, and most patients can return to work after 4 to 6 weeks.

Spinal Cord Stimulators

A spinal cord stimulator (SCS) is an implantable, non-destructive, medical device used to treat chronic intractable pain of the trunk and limbs. The device generates an electrical impulse to the epidural space which produces a tingling sensation that masks the perception of pain.

The goal of the stimulation is to lower the perception of pain, reduce medication use, increase function, and improve quality of life. Patients who are considered good candidates for a spinal cord stimulator placement undergo a trial to check for efficacy prior to permanent implantation. During the trial, a temporary percutaneous lead is placed and connected to an external pulse generator for approximately 3 to 7 days. The patient must experience at least 50% improvement in pain to be considered a candidate for permanent lead placement. The trial is generally performed in the OR using monitored anesthesia care (MAC) or general anesthesia.

The permanent spinal cord stimulator lead is implanted into the epidural space, and the impulse generator (IPG), which is the device battery, is implanted in the abdomen or buttocks. The lead is positioned at a specific level of the spinal cord. The targeted level is determined by the individual patient's symptoms, and by information obtained from the trial. A thoracic spinal cord stimulator is placed for lower back and leg pain.

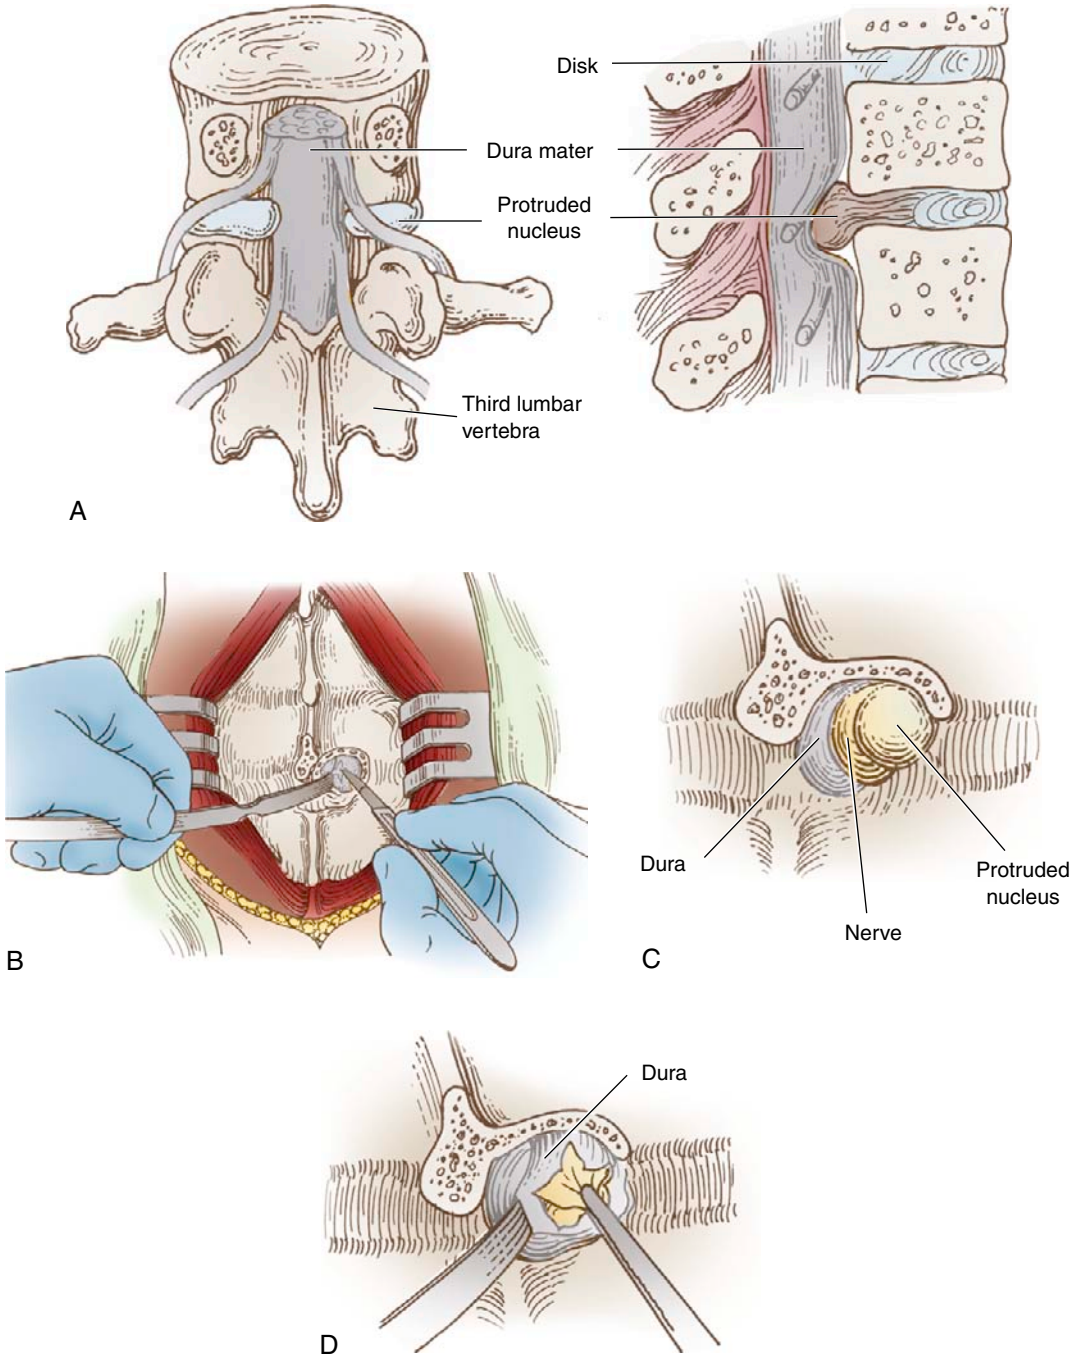

FIGURE 20-56 **A**, Normal and herniated nucleus pulposus (disk). **B**, Window has been made in lamina, and ligament has been incised to expose underlying dura mater and nerve root. **C**, Relationship of dura mater, nerve root, and protruded nucleus pulposus (disk). **D**, Retraction of nerve root over dura mater and removal of disk.

A cervical spinal cord stimulator is placed for upper extremity pain. Peripheral nerve stimulators are an alternative or conjunctive neuromodulation technique that targets peripheral nerves.

Procedural Considerations. Lead placement must be assessed during the surgery. This can be done by waking the patient during the surgery and asking them where they feel the stimulation. To secure the airway, lateral position is used with this method. Alternatively, electromyogram (EMG) monitoring may be used while the patient is under general anesthesia to verify motor responses in the targeted muscle groups. Fluoroscopy is also employed to verify lead placement.

The surgeon determines the battery site and directs the patient's position accordingly. The prone position is used if the battery will be inserted into the subcutaneous tissue of the buttocks. The lateral position is used if the battery is placed in the subcutaneous tissue of the abdomen, or if the patient will be awakened during surgery. The perioperative nurse ensures that the spinal cord stimulator system, the product representative, and the fluoroscopy unit are available, and that the OR bed is compatible with fluoroscopy. The surgeon marks the operative site before the patient is prepped. The surgical prep includes the entire area from the lead placement site to the IPG site.

Operative Procedure

1. The surgeon makes a midline incision at the proper level over the spine and uses sharp and dull dissection through the subcutaneous tissues to reach the fascia.
2. Paravertebral muscles are then dissected off the spinous process and lamina. A self-retaining retractor is placed to provide a visual field.
3. Instruments such as Kerrisons, pituitaries, and rongeurs are then used to perform a surgical laminectomy. The stimulator lead is placed in the epidural space. Proper placement is confirmed by testing with the stimulator programmer while waking and assessing the patient's perception of the stimulation, or while using EMG monitoring. Lead placement is also verified with fluoroscopy or x-ray. Once testing is complete, the surgeon anchors the lead with a 4-0 non-absorbable suture.
4. The surgeon creates a pocket in the subcutaneous tissue of the buttocks or the abdomen for IPG placement.
5. Using a tunneling device the lead is tunneled from the lead site to the battery location. The IPG is attached. Excess wire is protected by placing it beneath the IPG.
6. The IPG is anchored with 2-0 non-absorbable suture to prevent migration.
7. Both incisions are irrigated and closed
8. An abdominal binder is applied to compress the battery site.
9. A postoperative x-ray is obtained to confirm lead placement.

Intrathecal Pump Therapy

An intrathecal pump (ITP) is a specialized device that offers precise, targeted, and adjustable medication treatment for patients with spasticity and/or chronic pain. It delivers medication directly into the CSF via a small catheter attached to a pump.

The pump is controlled via a radio-telemetry link from an external programmer. This controls the rate and mode of infusion. The pump reservoirs are refilled with medication in the physician's office. Baclofen for spasticity or morphine sulfate for pain are most commonly used.

All patients are carefully screened for specific criteria, such as ineffective results or intolerable side effects with oral medication, limited functional abilities, no significant addiction history, and a diagnosed pathology. Contraindications for ITP therapy include active or frequent infections, medication allergy, failed screenings, and lack of patient reliability, resources, or support. ITP complications can include:

- Infection
- Mechanical failure
- CSF leak
- Overdose or adverse drug reactions

Each patient undergoes a trial injection that lasts 6 to 8 hours. Positive results must be noted before final implantation. Trials are performed in the physician's office, while final implantation is performed in the OR using MAC or general anesthesia.

Procedural Considerations. The nurse ensures the availability of the intrathecal pump system and the prescribed intrathecal medication before the procedure. A representative from the manufacturer should be present to assist with pump programming. Intraoperative fluoroscopy is used to verify proper placement of the catheter, so a compatible OR table is necessary. The surgeon will determine the patient's preference for pump placement (right or left abdomen) and mark the abdomen and back incisions. The back incision is typically marked at the area of L3-4. The abdominal incision is marked strategically to avoid the belt line, umbilicus, and the iliac crest. The perioperative nurse assists with placing the patient in the lateral position, using pillows and side braces as positioning aids. The surgical prep extends from the posterior incision site to the abdominal pump site.

Operative Procedure

1. The surgeon makes an incision in the patient's back and extends it through the subcutaneous tissue to the fascia. Hemostasis is obtained with the ESU.
2. A Tuohy needle is inserted paraspinally and at a 30-degree angle through the fascia into the intrathecal space, usually at L3-4. The surgeon confirms proper needle placement by removing the inner stylet of the Tuohy needle and visualizing a flow of CSF through the outer cannula.
3. The surgeon threads the catheter through the needle and feeds it to the proper level of the spine. This is determined by the patient's symptoms and the type of medication that will be administered. The catheter placement is verified under fluoroscopic visualization and is secured with anchors and a 4-0 non-absorbable suture.
4. The abdominal incision is made to create a pocket approximately 2.5 cm deep subcutaneously for pump placement.
5. Using a tunneling device the surgeon tunnels the catheter from the back to the abdominal pocket. The flow of CSF is once again verified through the catheter before it is connected to the pump. The pump is placed in the abdominal pocket and secured with 2-0 non-absorbable suture to prevent migration.
6. Both the back and abdominal incisions are irrigated and closed.

7. Dressings are applied to both incisions, and an abdominal binder is secured. In the recovery room, the pump is set with the external programmer.

Additional spine techniques are covered in Chapter 19.

PERIPHERAL NERVE SURGERY

Sympathectomy

Sympathectomy is excision of a portion of the sympathetic division of the autonomic nervous system. Most sympathectomies are performed on the paravertebral chain and are named for the region resected, such as cervical, thoracolumbar, and lumbar. The periarterial sympathectomy, vagotomy, and presacral neurectomy are other procedures that are occasionally performed on the autonomic system. The principal diseases treated by sympathectomy are vascular disorders of the extremities, intractable pain from certain nerve injuries, chronic abdominal conditions, and hyperhydrosis (overactivity of sweat glands).

The position of the patient depends on the region to be resected. Basic dissecting instruments and the microscope are used. For retropleural and transthoracic approaches, rib-resecting instruments are added. For the thoracic approach, Beckman or Scoville laminectomy retractors and an assortment of handheld retractors, including malleables, Deavers, and Richardsons, are added. For the abdominal approach, Balfour self-retaining retractors are added.

Cervicothoracic Sympathectomy—Dorsal. Dorsal sympathectomy entails removal of the cervicothoracic chain, often from the fourth cervical to the third thoracic ganglion. Sympathetic denervation of the upper extremities and heart may be accomplished by cervicothoracic sympathectomy. The vasospastic phenomenon of Raynaud's disease is relieved by this procedure. It also may be beneficial in relieving intractable angina pectoris.

PROCEDURAL CONSIDERATIONS. For the anterior approach, both the laminectomy set and rib instruments are used, plus deep retractors and a nerve stimulator. The setup for the posterior approach is the same as that for the anterior approach, plus rib-resecting instruments, periosteal elevators, small rib retractors, a firm rubber pad, and OR bed attachments for the posterolateral position.

OPERATIVE PROCEDURE—ANTERIOR APPROACH

1. The patient is placed in a supine position with the head rotated to the opposite side. General endotracheal anesthesia is necessary because puncturing the pleura is a possibility.
2. A transverse incision is made one fingerbreadth above the clavicle, the clavicular head of the sternocleidomastoid muscle is severed, and the deep cervical fascia is divided.
3. The phrenic nerve and the jugular vein are protected, and the anterior scalene muscle is divided to expose and isolate the underlying subclavian artery. One of its branches, the thyroid axis, is ligated and divided.
4. The stellate ganglion, deep against the vertebral body, is brought into view and lifted on a nerve hook. The sympathetic chain is traced upward to the middle cervical ganglion and divided. Deep dissection behind the pleura exposes the upper thoracic ganglia, which are removed to below the third thoracic ganglion. Clips may be placed on the sympathetic nerves before their division.
5. The wound is closed, and dressings are applied.

OPERATIVE PROCEDURE—POSTERIOR APPROACH

1. The patient is placed in the lateral position, and a paravertebral incision is centered over the third rib. The trapezius muscle is divided, and the rhomboid is split in line with its fibers. The third and fourth ribs are isolated extrapleurally, and the posterior 4 to 5 cm is resected. The transverse processes may be removed to provide better exposure.
2. The sympathetic trunk, which lies on the anterolateral aspect of the vertebral body, is reached by carefully reflecting the pleura. The trunk is picked up on a nerve hook, traced up and down, and removed, usually from the stellate ganglion to the fourth thoracic ganglion. Clips may be applied to the nerve before the fibers are severed.
3. A firm rubber tube may be left in the wound during closure. Suctioning apparatus is applied to this tube as the last deep fascial suture is drawn tight; all air is aspirated, and the tube is quickly withdrawn.
4. The subcutaneous tissue and skin edges are closed.

Nerve Repairs

Peripheral nerve injuries are the most common indication for nerve repair. Nerve tumors are rare in comparison. When the continuity of a nerve is destroyed, function distal to the site of injury is lost. Recovery will occur only if regeneration of nerve axons takes place from the healthy proximal segments. These axons must grow down the axis cylinders of the nerve beyond the injury if they are to reinnervate their end-organs and allow function to return.

When a nerve is divided, the cut ends retract, become scarred, and form neuromas. Regenerating axons from the proximal segment cannot bridge such a gap or penetrate the scar tissue. An unobstructed path down the axis cylinder must be made available if nerves are ever again to move muscles or transmit sensation. All procedures are directed toward obtaining the best possible conditions for regeneration.

Procedural Considerations. A basic dissecting instrument set, microinstruments, a microscope, and a nerve stimulator are used. For lesser procedures such as spinal accessory–facial anastomosis in the neck, division of the volar carpal ligament for median nerve compression at the wrist, or repair of a small digital nerve, suitable modification may be made. The positioning, skin prep, and draping of the patient depend on the site of the injury. A large area is prepped.

General anesthesia is usually preferred, with the patient positioned for maximum accessibility to the injured nerve. Exposure must be adequate because considerable mobilization of the nerve is often necessary. A dry field may be achieved using a tourniquet on the involved extremity.

Operative Procedure

1. The site of injury is explored, with careful attention to hemostasis. Nerve ends are dissected from surrounding scar tissue, and neuromas are excised. Moist umbilical tapes, vessel loops, or Penrose tubing may be passed around the nerve to handle it more easily and with less trauma.
2. The nerve repair anastomosis is made with multiple fine sutures placed only through the nerve sheath or epineurium (Figure 20-57). Tension at the suture line is eliminated by maneuvers such as freeing a long length of nerve on either

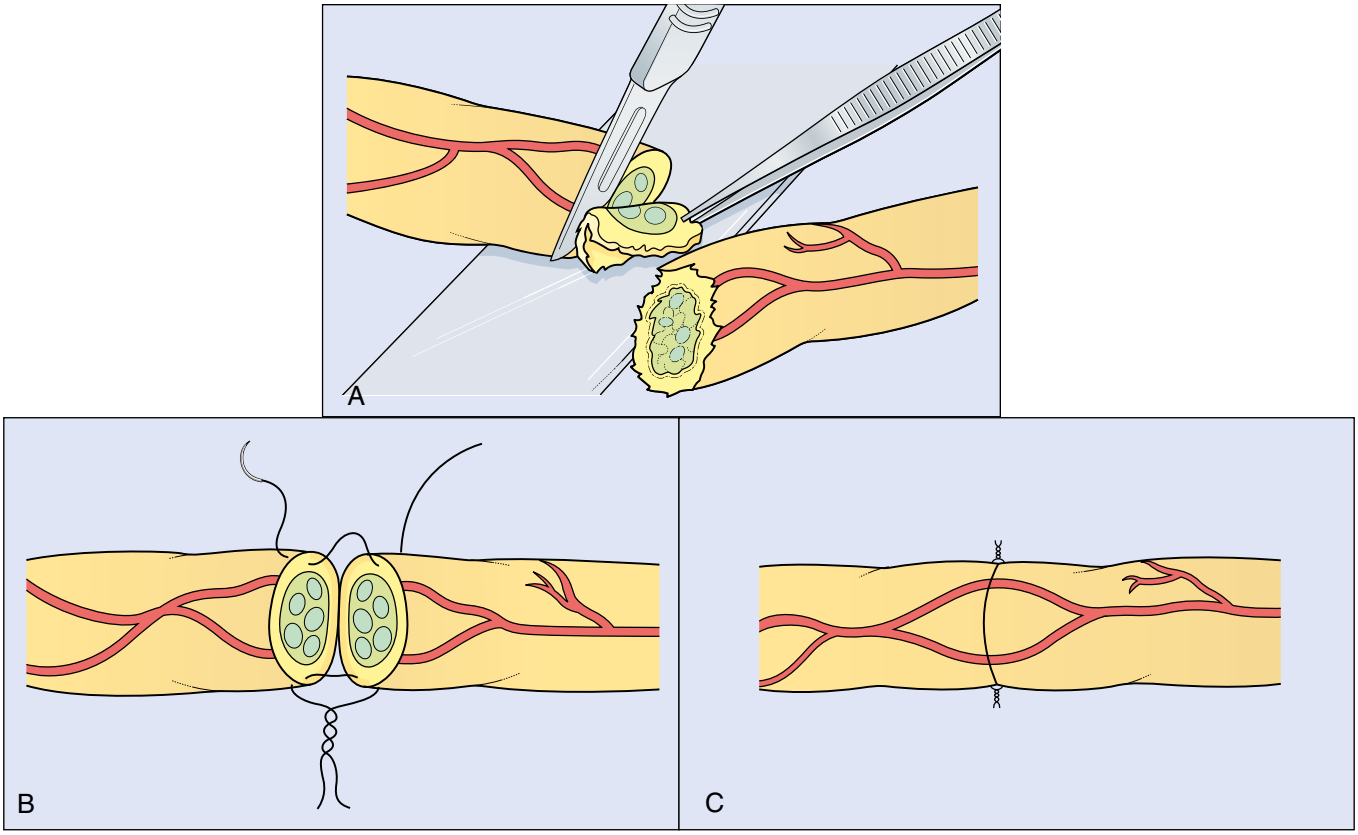

FIGURE 20-57 Nerve repair. **A**, Serial resection of neuroma to healthy nerve fibers. **B**, Placement of sutures in epineurium. **C**, Approximation and tying of sutures.

side of the point of injury, transposing the nerve to shorten its course, appropriately positioning the extremity with plaster splinting during the postoperative period, and, rarely, using a nerve graft. Some surgeons apply a cuff of inert material, such as silicone, around the anastomosis.

CHAPTER 21

Plastic and Reconstructive Surgery

VICTORIA DREGER

Derived from the Greek word *plastikos,* which means to mold or give form, plastic surgery is a medical specialty that restores or gives shape to the body. There are two different subspecialties of plastic surgery. *Cosmetic surgery* restores or reshapes normal structures of the body, to improve appearance and self-esteem. *Reconstructive surgery* treats abnormal structures of the body caused by birth defects, developmental problems, disease, tumors, infection, or injury to restore function and correct disfigurement or scarring (American Society of Plastic Surgeons [ASPS], 2009a.) As a surgical specialty, plastic surgery owes much of its heritage to knowledge gained from the wars of the twentieth century (History box).

Despite the economic downturn, 12.1 million cosmetic surgical procedures were performed [by surgeons certified by the American Society of Plastic Surgeons (ASPS)] in 2008, an increase of 3%; the majority were minimally invasive procedures. Females constituted 91% of all patients undergoing cosmetic procedures. Hispanic, Asian, and African American patients showed an increase in cosmetic procedures; the number of Caucasians undergoing cosmetic procedures decreased by 2%. Office-based cosmetic procedures increased by 13%, with a total of $10.3 billion dollars spent on the cosmetic procedures in the United States (Ambulatory Surgery Considerations). The 4.9 million reconstructive procedures also showed a 3% increase, although breast reductions decreased by 16% (ASPS Stats, 2009).

Surgical Anatomy

Plastic and reconstructive surgery is not limited to a single anatomic or biologic system. It is based on thorough understanding of the anatomy and biology of tissue. Operative techniques are complex and staged to achieve the expected results. The surgery also involves removing, reducing, enlarging, and recontouring, as well as camouflaging scars into existing skin lines (Figure 21-1). The tissues of the body can be transferred to use as various types of flaps. Free flaps are the transfer of

HISTORY

Origins and Growth of Plastic Surgery

Historically, battlefield combat has been an impetus for the development of new medical and surgical techniques based on the injuries sustained. As battlefield technology and the weapons of war became more sophisticated throughout history, the degree of injury and tissue devastation became more horrific. The trench warfare of World Wars I and II gave rise to a whole new category of facial injuries. Helmets protected combatant's skulls and the trenches offered some protection to the chest, but the face was exposed, and as a result, devastating burns and fractures of the face occurred. Special hospitals were created to address these problems, and even before the United States joined the first World War, the Harvard unit sent 35 physicians and surgeons, 3 dentists, and 75 nurses from various medical centers to assist in caring for the wounded. These visionaries were soon developing new techniques and procedures to correct the disfiguring injuries. They were credited as being the first generation of modern plastic surgeons, and helped give much needed respect to the specialty.

While World War I helped reinvent plastic surgery, the specialty has been identified as long ago as 600 BC, when a Hindu surgeon described using a cheek flap to reconstruct a nose. Another flap technique, this time using the forehead to reconstruct a severed nose, was performed around 1000 AD in India. The Italian surgeon Gaspare Tagliacozzi, also known as the "father of plastic surgery," developed still another flap surgery using the upper arm to reconstruct a nose. History tells us that the condition of the nose, whether from war, punishment, or social disease (syphilis), presented a story that often was undesirable. This resulted in impetus in the different societies to camouflage the injuries, thus propelling advances in plastic surgery.

Following the end of the first World War, plastic surgery turned its attention to the rest of society, and concentrated on deformities caused by birth or trauma. Soon, some surgeons began using their talents to improve less than desirable facial features. For example, Fanny Brice underwent a rhinoplasty in her apartment in 1923 to change the appearance of her nose from "prominent to decorative." In 1924 a New York newspaper had a contest to transform the city's homeliest woman into a beauty. Dr. John Howard Crum performed the first facelift on record in the Grand Ballroom of the Pennsylvania Hotel in New York City in 1931, during which "a pianist accompanied him with appropriate popular tunes, flashbulbs popped, and men and women fainted."

Modified from Feldman E: Before & after: cosmetic surgery was born 2,500 years ago and came of age in the inferno of the western front, *Am Herit* 55(1):60-70, 2004; *The history of plastic surgery: the early years,* available at www.plasticsurgery.org/About_ASPS/History_of_Plastic_Surgery.html. Accessed July 6, 2009.

AMBULATORY SURGERY CONSIDERATIONS

Patient Choices in Facility

There has been a dramatic shift toward encouraging patients to be more involved and informed in all of their healthcare decisions. Many organizations are focusing on active participation of patients in their own care. One aspect of this is choosing the outpatient facility for their plastic surgery. In keeping with this trend, the American Society of Plastic Surgeons (ASPS) has developed a brochure, with an excerpt available on-line, to help patients choose a facility. The brochure includes the following information:

- *Types of facilities*: For ambulatory (discharge same day as surgery) procedures, the facility may be part of the surgeon's office, a surgical suite adjacent to the office, a free-standing facility, or part of a hospital.
- *Choice and benefits:* Some patients prefer no overnight stay at a hospital. Cost savings and convenience along with added privacy and personalized care may all be factors.
- *Accreditation:* As a result of the strict guidelines for equipment, staff, anesthesia services, and hospital access, patients are encouraged to determine if a facility is accredited, as it could indicate the quality of the facility. (All ASPS member surgeons are required to operate in an accredited medical facility.)
- *Insurance:* The accreditation mentioned above also impacts financial aspects. Although facility fees are typically not covered by insurance providers for elective procedures, facility fees for reconstructive procedures may be covered. Reimbursement may be expedited for facilities that carry accreditation because the accreditation ensures that certain quality standards are met at that facility. Also, similar services at a hospital generally cost more than in an ambulatory facility.
- *Individual considerations:* Each patient must discuss the options with his/her surgeon. Depending on medical history and condition requiring surgery, ambulatory surgery may not be appropriate for everyone.

Modified from American Society of Plastic Surgeons: *Ambulatory facilities: same day facilities: choosing same day surgery facilities,* Arlington Heights, Ill, 2008, available at www.plasticsurgery.org/Patients_and_Consumers/Planning_Your_Surgery/Same_Day_Surgery_Facilities.html. Accessed June 17, 2009.

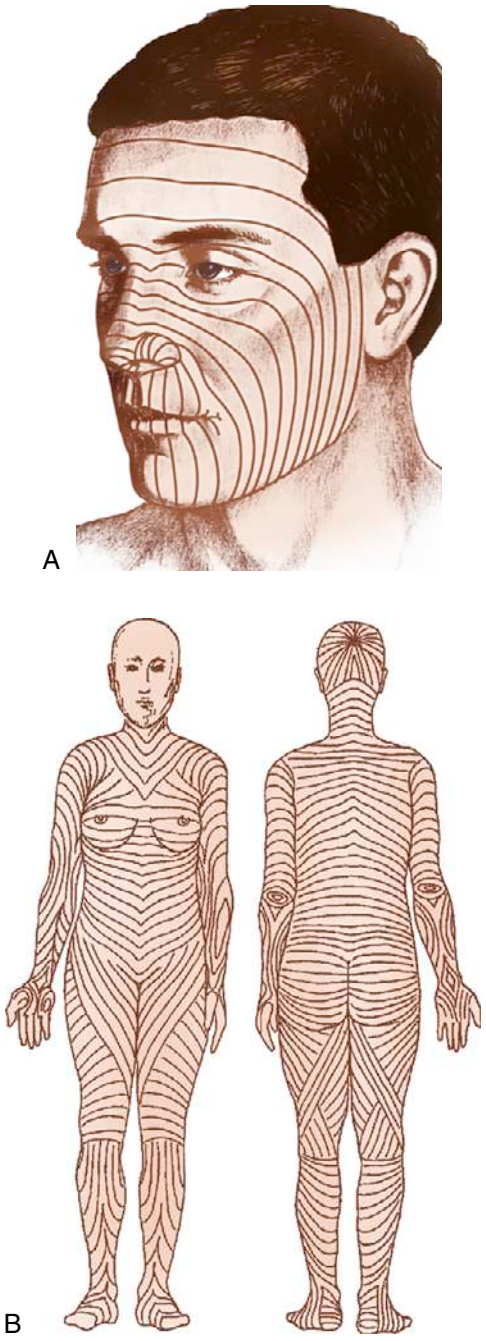

FIGURE 21-1 The surgeon adheres to several principles when planning skin incisions, one of which is to reduce the amount of tension across the wound, thus minimizing scarring. Elective incisions should preferably parallel relaxed skin tension lines (RSTLs) in the face (**A**) and the body (**B**).

tissue along with its vascular pedicle. When nerve is anastomosed with these flaps, they are called neurovascular free flaps. Flaps are used to cover defects or create new structures such as breasts, digits, or facial structures. Body parts can also be transplanted. By improving the patient's deformity, the patient's self-esteem will improve and the patient will feel more comfortable in public and social activities. The body changes as we age. The patient's concern with aesthetics, the variety of acquired defects, the diversity of operative techniques, and the psychologic responses of patients offer unique learning experiences and challenges for perioperative nursing care.

Perioperative Nursing Considerations

The prospect of surgery, even elective, can produce anxiety and fear. Because it is so often associated with body image and self-esteem, plastic and reconstructive surgery can trigger these emotions, especially when the proposed surgery is associated with potential disfigurement because of disease or trauma. Even a planned (desired) change in body image can be stressful. Many cosmetic patients lack the traditional support system one comes to expect during illness and recuperation because of a desire for confidentiality, making the sensitivity of the perioperative nurse all the more critical.

In general, the nurse creates a therapeutic environment in the following ways: introducing self and other members of the

surgical team; explaining all perioperative events and any sensations likely to be experienced; determining the patient's normal coping patterns; communicating with the patient in a calm, unhurried, and reassuring manner; encouraging the patient to verbalize feelings and concerns, and listening attentively; reducing distracting stimuli in the perioperative environment; providing reassurance and information about the progress of surgery (for awake patients); communicating progress reports to family; providing comfort measures (e.g., warm blankets, soft music of patient preference); and encouraging and assisting the patient to use personally effective coping strategies (e.g., meditation, guided imagery, relaxation).

Appropriate candidates for plastic surgery include those who have positive self-image but are bothered by a physical aspect that they would like to improve; after surgery, these patients maintain their positive self-image. Another category of appropriate surgical candidates includes patients who have a physical defect or cosmetic flaw that has lowered their self-esteem over time; these patients require time to adjust (rebuild confidence) postoperatively and generally their self-esteem is strengthened, even dramatically. Other patients are not as suitable for plastic surgery, including the following: patients in crisis or with unrealistic expectations; patients who are impossible to please (seeking multiple consultants for only answers they want to hear); patients obsessed with minor defects (again unrealistic about perfect life once defect is fixed); and patients who are mentally ill/psychotic, delusional, or paranoid (unless their seeking care is unrelated to psychosis). Some of the aforementioned patients could benefit from screening and referral with a psychiatrist as appropriate (ASPS, 2009b) (Research Highlight).

The nursing process is dynamic, fluid, and complex. The nature of plastic and reconstructive surgery is rarely simple, routine, or predictable, and the nursing care must mirror that fact. It must include thorough and ongoing assessment, establishment of nursing diagnoses and outcomes, fastidious planning, superior implementation, and thoughtful evaluation. The perioperative nurse's goal is to produce positive, high-quality outcomes in an environment that is safe and nurturing and will facilitate physical and emotional healing.

Throughout the nursing process, effective communication is necessary with the patient and the patient's family or significant others as well as with all members of the perioperative team. Communication is a two-way process that includes verbal and nonverbal messages. Respect for the individual, a nonjudgmental attitude, and effective communication skills are essential ingredients for the perioperative nurse caring for plastic surgery patients. Within this patient population, nurses must individualize the care based on assessment.

Assessment

As part of a holistic assessment, perioperative nurses consider physical and emotional factors of the planned procedure. A comprehensive review of the chart is the first step. The presence of a signed and witnessed informed consent, a systems review and health history, pertinent laboratory and diagnostic data, interdisciplinary planning, anesthesia evaluation, and the surgical plan will disclose vital information necessary to begin the assessment process. Visual inspection should include the patient's overall physical condition, the condition and integrity of the skin, nutritional status, and physical limitations. The next step is the patient interview, which includes checking patient identification, explaining the perioperative nursing role, and verifying the patient's understanding of the planned procedure. The perioperative nurse must be skilled in establishing communication quickly to create an instant relationship. Greeting the patient by name in a calm, comforting manner, perhaps with a gentle, caring touch (if welcomed by the patient), and maintaining good eye contact will help establish the rapport needed to assess emotional status, body image disturbances, and anxiety level. Asking the patient questions will help reveal any barriers to communication or learning; religious, cultural, or other preferences; mental status; and insight into compliance. Other vital pieces of knowledge the nurse must obtain include the presence of realistic expectations and motivation for surgery, as well as support systems available to the patient.

RESEARCH HIGHLIGHT

Nursing Survey of Psychologic Complications After Plastic Surgery

The author of this study notes that the two components of plastic surgery, aesthetic and reconstructive, both integrate the patient's sense of body image into the surgical process. Nurses must be aware of the scope and nature of negative psychologic complications resulting from plastic surgery to better understand and support the plastic surgery patient through the many intereactions that comprise the surgical experience.

An anonymous, confidential survey was mailed to 502 randomly selected certified plastic surgery nurses from a list of members of their professional organization (American Society of Plastic Surgical Nurses [ASPSN]). The response rate for the survey was 62%, with 312 nurses returning the survey.

The perceptions of the plastic surgery nurse indicated that psychologic complications occur at higher rates than do physical complications for this patient population. "Patients with pre-existing psychological conditions are more at risk for perioperative psychological complications. Nurses should be adequately prepared to screen, support, and coordinate psychological treatment for plastic surgery patients with the plastic surgeon."

The study concludes that patients experiencing physical complications are much more likely to experience psychologic complications at the same time. Lack of appropriate screening for mild or severe depression before plastic surgery leads to multiple, major problems in the postoperative period, specifically anger and hostility, sleep disorders, and disappointment. The most frequently seen psychologic complications include disappointment, anxiety, and depression. Patients exhibiting ongoing high anxiety, depression, or sleep disorders beyond a 2- or 3-week postoperative period need to be referred for appropriate psychiatric counseling or evaluation. The researcher discussed implications of these findings noting, "plastic surgeons and their staff need to…proactively manage their patients' emotional health in the perioperative period…Ongoing education regarding psychological and complementary treatment options must be a mandatory sequence of the plastic surgical team."

Modified from Rankin M: Psychological complications: national plastic surgical nursing survey, *Plast Surg Nurs* 29(1):25-30, 2009.

An important component of the assessment phase of nursing care involves communication with the surgeon and anesthesia provider to determine the need for special equipment, supplies, sutures, or implants. The perioperative nurse should verify the procedure and position and, in the case of multiple procedures on the same patient, identify the planned order of surgeries. The office staff of the plastic surgeon can be a useful source of information about the patient and the surgery and are often able to offer insight into the psychosocial dimensions of the patient.

Clear and effective hand-off communication is critical to patient safety. According to The Joint Commission, communication lapses among patient care providers cause more than two thirds of the serious medical errors reported. At least half those incidents occurred as responsibility for the patient was transferred from one team of care providers to another. In the perioperative suites, hand-offs occur as patients move to and from the ORs, involving many different care providers for one patient (Lenth, 2007).

The Department of Defense and the Agency for Healthcare Research and Quality of the U.S. Department of Health and Human Services initially developed the TeamSTEPPS™ approach, which emphasizes higher quality and safer patient care. "The goal of TeamSTEPPS is to produce highly effective medical teams that optimize the use of information, people, and resources to achieve the best clinical outcomes for their patients. TeamSTEPPS is scientifically-rooted in over 20 years of research and lessons learned from the application of teamwork principles in High-Reliability Organizations (HROs)" (DOD, 2009).

The Association of periOperative Registered Nurses (AORN) Presidential Commission on Patient Safety and the Department of Defense entered into an agreement that allowed AORN to expand and apply the more general information developed for TeamSTEPPS specifically to hand-off communications within perioperative units. Whatever form the hand-off communication takes at each facility, it must be standardized and provide thorough discussion of patient history, issues, special needs, and precautions for safety, with opportunity for the receiving provider to ask questions.

Nursing Diagnosis

Nursing diagnoses related to the care of the patient undergoing plastic and reconstructive surgery might include the following:

- Anxiety related to surgical interventions or outcomes
- Risk for Infection related to operative/invasive plastic/reconstructive procedure
- Deficient Knowledge related to perioperative process
- Disturbed Body Image related to congenital or acquired defect or developmental abnormality
- Risk for Ineffective Tissue Perfusion related to surgical intervention
- Impaired Comfort related to surgical/invasive procedure

Outcome Identification

Nursing diagnoses lead to the formulation of desired or expected patient outcomes. These are desirable and measurable patient states, including biologic or physiologic states; psychologic, cultural, and spiritual aspects; and the knowledge, behavior, or skills related to these states. As such, the patient outcome indicates progress toward or resolution of the nursing diagnosis. Outcomes should be mutually formulated with the patient, family, and other healthcare providers. Such formulations should be realistic, involve consideration of the patient's present and potential capabilities and resources, and provide direction for continuity of care, as well as determine satisfaction with that care. Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient will verbalize management of anxiety.
- The patient is free from signs and symptoms of infection.
- The patient participates in decision-making affecting the perioperative plan of care.
- The patient will acknowledge feelings about altered structure or function.
- The patient has wound/tissue perfusion consistent with or improved from baseline levels established preoperatively.
- The patient demonstrates knowledge of pain management.

Planning

The perioperative nurse designs a plan of care using critical thinking to integrate knowledge gained from prior steps with the plastic surgical patient. The nurse should seek to create and maintain a culture and environment of safety for the patient, the OR, and all members of the surgical team during the planning process. A Sample Plan of Care for a patient undergoing plastic and reconstructive surgery is on pp. 889–890.

Implementation

The implementation phase typically begins with preparation of the OR and requires a thorough understanding of the procedure and the special needs of the patient, surgeon, and anesthesia provider. The perioperative nurse must continuously monitor and reassess the patient as well as the needs of the perioperative team, implementing and documenting the delivery of care. Constant consideration is given to the safety of the patient and the perioperative environment during this phase.

Preparation of the OR Suite. Before transporting the patient to the OR, the perioperative nurse will assemble all necessary medical and surgical supplies, equipment, suture material, positioning aids, implantable devices, and medications. The nurse is responsible for ensuring that lights and video equipment are in working order, that emergency supplies are present, and that compressed gases are adequate. Depending on the procedure to be performed, the OR bed may need to be configured differently from the standard room setup. To minimize inefficiencies during the procedure the nurse should confirm with the surgeon and anesthesia provider the position of the bed and any proposed intraoperative changes to the bed or room configuration. Plastic and reconstructive surgeons frequently use preoperative photographs of the patient when attempting to restore or modify appearance. These photographs help the surgeon maintain perspective since features may change because of surgical positioning. The nurse should collaborate with the surgeon to determine the best placement of these photographs for intraoperative viewing. Preoperative and postoperative photos, in order to be accurate, should be taken with the same lighting, angle, and distance (Hagan, 2008).

Equipment and Special Mechanical Devices. Essential equipment for any OR includes a fully functional bed that may be positioned for any number of special needs and also has

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Anxiety related to surgical intervention or outcome

OUTCOME
The patient will verbalize management of anxiety.

INTERVENTIONS
- Broadly classify the patient's anxiety (mild, moderate, severe).
- Try to understand the patient's perception of the stressors or stressful situation or event.
- Identify contributing factors.
- Introduce self and other members of the surgical team.
- Explain all perioperative events and any sensations likely to be experienced.
- Determine the patient's normal coping patterns.
- Communicate with the patient in a calm, unhurried, reassuring manner.
- Encourage the patient to express feelings and concerns; listen attentively.
- Reduce distracting stimuli in the perioperative environment.
- Provide reassurance and information about the progress of the surgery (if the patient is awake); implement mechanism for family progress reports also.
- Provide comfort measures (e.g., warm blankets, soft music that the patient prefers).
- Use touch as appropriate (e.g., softly stroking the hand).
- Encourage and assist the patient to use personally effective coping strategies (e.g., meditation, guided imagery, relaxation).

NURSING DIAGNOSIS
Risk for Infection related to surgical/invasive plastic/reconstructive procedure

OUTCOME
The patient is free of signs and symptoms of infection.

INTERVENTIONS
- Assess susceptibility for infection and risk for inadvertent hypothermia.
- Assess nutritional habits and patterns.
- Implement thermoregulation measures and aseptic technique (create and maintain a sterile field, prevent contamination of open wounds, and isolate the operative site from the surrounding physical environment).
- Minimize the length of invasive procedure by planning care (coordinate team members' efforts to set priorities and efficiently accomplish the tasks necessary to achieve a common goal).
- Perform skin preparations.
- Administer prescribed antibiotic therapy and prophylactic treatments, verifying physician orders.
- Protect from cross-contamination; maintain continuous surveillance.
- Record devices implanted during the operative or invasive procedure (according to federal regulations for tracking).
- Administer care to wound sites and invasive device sites.
- Monitor for signs and symptoms of infection.
- Encourage deep-breathing and coughing exercises.
- Evaluate response to thermoregulation measures and progress of wound healing.

NURSING DIAGNOSIS
Deficient Knowledge related to the perioperative process

OUTCOME
The patient demonstrates knowledge of the expected responses to the operative or other invasive procedure.

INTERVENTIONS
- Determine knowledge level (assess knowledge and comprehension of new information and ability to apply in self-care activities); assess readiness to learn (evaluate factors that may affect abilities to learn or demonstrate knowledge).
- Provide instruction based on age and identified needs; identify barriers to communication and adapt instructions to these.
- Evaluate environment for home care; identify expectations of home care.
- Explain expected sequence of events related to perioperative care; include family members in preoperative teaching; identify family members' knowledge and provide education and support.
- Assess knowledge; provide and evaluate response to instructions (e.g., about wound care and phases of wound healing) (evaluate patient's/family members' understanding of instruction regarding perioperative experience and ongoing care, listening to explanations and observing return demonstrations, techniques of wound care, and signs and symptoms to report).
- Provide information and explain Patient Self-Determination Act.
- Include patient and family members in discharge planning, including resources available to facilitate the rehabilitation process.
- Initiate institution's checklist policy for correct site surgery.
- Verify surgical consent with OR schedule and patient's statement of planned surgery.
- Solicit the patient's questions; answer or refer questions as appropriate.
- Explain the sequence of perioperative events and their purpose, as appropriate (e.g., holding area, OR attire, insertion of lines and attachment of monitoring devices, type of anesthesia, postoperative recovery unit, protocols).
- Provide sensory (what the patient will hear and feel, using lay terms) as well as factual procedure-related information.
- Provide printed material to reinforce patient education (e.g., preoperative routines, explanations of surgical intervention, postoperative management of pain, discharge instructions).

NURSING DIAGNOSIS
Disturbed Body Image related to disease, congenital or acquired deformity, developmental abnormality

OUTCOME
The patient will acknowledge feelings about altered structure or function and identify effective, optimistic coping options.

INTERVENTIONS
- Identify psychosocial status; elicit perceptions of surgery.
- Identify individual values and wishes concerning care.
- Assess coping mechanisms.
- Implement measures to provide psychologic support.
- Maintain patient's dignity and privacy (e.g., keep OR doors closed, only expose body as needed for care).
- Assist patient to identify and discuss feelings, stressors, and perception of physical deformity.
- Provide environment (e.g., privacy, supportive listening) conducive to expression of feelings.
- Help patient identify significance of culture, religion, gender, and age on perceived changes in body structure or function or image.
- Determine patient's body image expectations and whether expectations are realistic; clarify unrealistic expectations or misconceptions.
- Convey sense of respect for abilities and strengths in coping with problems or concerns.

Continued

SAMPLE PLAN OF CARE—cont'd

- Assist patient to separate physical appearance from feelings of personal worth, self-concept, and self-esteem (as appropriate).
- Refer the patient to other health professionals (e.g., clergy, social worker, psychiatric liaison) or support groups as appropriate.

NURSING DIAGNOSIS

Risk for Ineffective Tissue Perfusion related to surgical intervention

OUTCOME

The patient has wound/tissue perfusion consistent with or improved from baseline levels established preoperatively.

INTERVENTIONS

- Assess factors related to risks for ineffective tissue perfusion (e.g., presence of diabetes, immunosuppression); assess history of previous radiation exposure.
- Evaluate postoperative tissue perfusion.
- Identify factors associated with an increased risk for hemorrhage or fluid and electrolyte loss (e.g., patients with recent traumatic injury, abnormal bleeding or clotting time, extensive surgical procedure, complicated renal/liver disease, and major organ transplant).
- Implement hemostasis techniques (provide supplies, instrumentation, and appropriate surgical techniques as needed to control hemorrhage).
- Evaluate for signs and symptoms of physical injury to skin and tissue.
- Note any sensory or perceptual alterations in the affected body part, and document them.
- Maintain body temperature with the use of warming device or reflective blankets, for example.
- Warm intravenous fluids, blood and blood products, and irrigating fluids.
- Increase the temperature in the OR as indicated.
- Collaborate with anesthesia provider in monitoring the patient's core temperature.
- Provide intraoperative medications as prescribed for local irrigation (e.g., heparinized saline); label all medications on and off the sterile field, and document their administration.
- Apply compression stockings and antiembolic devices as indicated.
- Monitor tissue perfusion (e.g., by assessing blanching and capillary refill; using Doppler ultrasound), as prescribed, and flap ischemic time; record results.
- Note any swelling, change in color or temperature, or drainage from graft sites before discharge from the OR.
- Provide warm blankets for the patient at the conclusion of the surgical procedure.
- Teach the patient or the family how to care for the incision, including signs and symptoms of infection and graft failure (as applicable).

NURSING DIAGNOSIS

Impaired Comfort related to surgical procedure

OUTCOME

The patient demonstrates knowledge of pain management.

INTERVENTIONS

- Assess pain control using validated pain scale.
- Identify cultural and value components related to pain (e.g., stoicism, alternative therapy, verbalization, meditation).
- Implement pain guidelines; provide pain management instruction (purpose, administration, and desired, side, and adverse effects of prescribed medications and nonpharmacologic techniques for managing pain).
- Evaluate response to pain management instruction and instruction about prescribed medications.
- Collaborate in initiating patient-controlled analgesia.
- Evaluate response to pain management interventions (physiologic parameters and subjective and objective findings) and response to medications.
- Implement alternative methods of pain control (diversified activities, therapeutic touch, meditation, breathing, and positioning to augment pain control methods).

accessory attachments, such as headrests and aids for extremity positioning. The room must also have well-positioned and numerous electrical outlets, good overhead lighting, suction equipment, mounted x-ray view boxes, and computer terminals for those facilities using electronic medical records. Step stools, tables, chairs, hand tables, tourniquets, microscopes, and intravenous (IV) poles should be in appropriate supply and accessible. Surgeons often provide their own digital cameras although facilities may have them available for use.

INSTRUMENTATION. Basic instrument trays are available for the plastic surgery OR. A "local" tray may include Bishop Harmon and Adson tissue forceps (with and without teeth); straight and curved iris, Stevens, and Metzenbaum scissors; fine mosquito forceps; and skin hooks. Minor and major trays for plastic surgery may contain a range of tissue forceps, scissors, hemostats, and retractors. With the addition of instruments for specific surgeries, these trays usually suffice for all plastic surgery operations. Adequate instrumentation should be available to avoid flash sterilization (Risk Reduction Strategies).

DERMATOMES. Dermatomes are used for removing split-thickness skin grafts (STSGs) from donor sites; they are of three basic types: knife, drum, and motor-driven (Figure 21-2). Sterile mineral oil and a tongue blade should be available when STSGs are being obtained.

SKIN MESHERS. Several types of skin meshers are available. Each is designed to produce multiple uniform slits in a skin graft, approximately 0.05 inch apart. These multiple apertures in the graft can then expand, permitting the skin graft to stretch and cover a larger area. Meshing also facilitates drainage through the graft, preventing fluid accumulation under a graft. The graft is placed on the carrier and passed through the mesher (Figure 21-3). The manufacturer supplies sterile carriers for meshers. They are usually available in several sizes, which determine the expansion ratio of the skin graft.

PNEUMATIC-POWERED INSTRUMENTS. Pneumatic-powered instruments use an inert, nonflammable, and explosion-free compressed gas as their power source. The motor may be activated by a foot pedal or hand control. The various attachments should be sterilized as recommended by the manufacturer to prolong instrument life and ensure effective sterilization. The following attachments may be used in plastic surgery:

- Wire driver and bone drill
- Oscillating saw
- Derma-Tattoo (used with reciprocating-saw handpiece)

RISK REDUCTION STRATEGIES

Flash Sterilization

With high volumes of plastic surgery cases, it may be tempting/convenient to flash autoclave instruments or even implants when insufficient instruments are available or sales representatives do not bring sets until the day of surgery. Centers for Disease Control and Prevention (CDC) guidelines have clear information about this practice: "Do not use flash sterilization for convenience, as an alternative to purchasing additional instrument sets, or to save time; do not flash sterilize implanted surgical devices unless doing so is unavoidable." Although challenging, two facilities showcased their effective efforts in reducing flash sterilization. To meet AORN's benchmark of ≤5% of sterilization cycles using flash autoclave, the team decided on various approaches, including the following:

- Provide administration with an estimated cost for purchasing needed instrumentation.
- Review safety issues with staff; staff should consult manager whenever flash sterilization is necessary.
- Ask vendors to bring trays the evening before the procedure.
- Coordinate/meet with sterile processing staff to discuss next day's instrument needs and priorities.
- Communicate with surgeons the day before surgery to discuss order of procedures to avoid flash sterilization.

These approaches allowed one facility to decrease their flash cycles from 42% in 2005 and 62.8% in 2006 to an average of <5% per month; with proactive planning and thoughtful, coordinated effort, benchmarks can be met. Similarly, safety can become an issue when using loaner instruments; the condition upon arrival may be questionable. Literature is also available on proper decontamination, sterilization, tracking, and overall processing of such loaner items.

Modified from Hunter-Kunish GG: Processing loaner instruments in an ambulatory surgery center, *AORN J* 89(5):861-866, 2009; Kaufman-Gonzales H, Swaffield J: Decrease flash cycles in the OR (Poster Presentation AORN Congress, 2009), *AORN J* 89(6):1061-1062, 2009; Marsch C, Allend-Smith J: A collaborative approach to reducing flash sterilization, *AORN J* 89(6):1061, 2009; Rutala WA, Weber DJ: Healthcare Infection Control Practices Advisory Committee (HICPAC): *Guideline for disinfection and sterilization in healthcare facilities, 2008,* Washington, DC, November 2008, Department of Health and Human Services, Centers for Disease Control and Prevention, available at www.cdc.gov/ncidod/dhqp/pdf/guidelines/Disinfection_Nov_2008.pdf. Accessed June 27, 2009.

- Reciprocating saw
- Dermabrader
- Sagittal saw

A pneumatic tourniquet with an inflatable cuff is used in most hand surgery procedures as well as in other upper and lower extremity surgical interventions. The tourniquet is described in Chapter 18.

ELECTROSURGICAL UNIT. The electrosurgical unit (ESU) and safety precautions taken by the perioperative nurse are described in Chapter 7.

BIPOLAR COAGULATION UNIT. Bipolar electrosurgery (also described in Chapter 7) is the use of electrical current in which the circuit is completed by means of two parallel poles located close to one another. One pole is positive; the other is negative. The flow of current is restricted between these two poles, which are usually the tines of the bipolar forceps. Because the poles are so close, low voltages are used to achieve the tissue effect. Because electrical current does not flow through the patient, a return electrode (dispersive pad) is

not necessary. This makes bipolar electrosurgery very safe and permits precise electrocoagulation.

LASERS. A variety of lasers are employed for plastic surgical procedures. The perioperative nurse must ensure that the laser safety accessories specific to the type of laser being used are available. Laser safety is discussed in Chapter 7.

FIBEROPTIC INSTRUMENTS. Examples of fiberoptic instrument attachments used in plastic surgery are a headlight for rhinoplasties, augmentation mammoplasties, and other procedures; a mammary retractor for augmentation mammoplasties; a rhytidectomy retractor; abdominoplasty retractors; and endoscopic face and forehead fiberoptic instrumentation.

LOUPES. Loupes (Figure 21-4) are magnifying lenses used by many plastic surgeons for microvascular surgery and nerve repairs and for numerous other instances in which cosmetic results are improved by the magnification effect. The nurse should inquire about the use of loupes before the surgeon dons a headlight because adjustments will need to be made to the headlight alignment if the loupes are required in midprocedure. Adjusting or removing the headlight in midprocedure has the potential to contaminate the sterile field.

MICROSCOPE. The microscope is frequently used in nerve repairs and microsurgical anastomoses; the nerves or vessels to be repaired, such as in hand surgery, and the suture used to do so (sometimes 9-0, 10-0, or even 11-0 size) can be finer than human hair and thus requires magnification. While each microscope has different features, an important matter to avoid confusion is whether the surgeon control overrides the assistant view, or if each can separately adjust the field of view.

WOOD'S LAMP. The Wood's lamp is an ultraviolet lamp used in a darkened room to determine the viability of skin flaps. After IV injection of fluorescein, the blood vessels appear bright purple (the skin appears yellow). Sodium fluorescein is excreted in the urine, and patients should be informed of this.

SPECIAL SUPPLIES. Surgeon-specific and procedure-specific special supplies are frequently added to instrument setups for plastic and reconstructive procedures. These commonly include the following: sterile marking pen or methylene blue; ruler; local anesthetic of choice for injection, with syringes and needles; and ESU, with active electrode (pencil) and tip of choice, with tip cleaner.

Sutures. Sutures range from permanent to absorbable and include monofilament and multifilament materials. The perioperative nurse should be a good steward of costly resources and should verify the type and number of sutures needed before opening suture packages, as well as needle preference, to prevent waste. Many plastic surgical procedures have multiple techniques, each of which necessitates very specific suture choices. See Chapter 6 for further discussion and explanations.

Dressings. Dressings are an essential part of the operative procedure in plastic surgery and may contribute to the ultimate outcome of the surgical intervention. Dressings are usually applied while the patient is still anesthetized. In general, the dressing should accomplish the following five goals:

1. Immobilize the surgical part.
2. Apply even pressure over the wound.
3. Collect drainage.
4. Provide comfort for the patient.
5. Protect the wound.

FIGURE 21-4 Loupes from Carl Zeiss, used for magnification.

Pressure dressings may be used to eliminate dead space, to prevent seroma and hematoma formation, and to prevent third spacing associated with liposuction and reconstructive procedures involving transfer of large muscle or tissue flaps. In some cases pressure can be achieved by the use of catheters or drains placed within the operative site and connected to closed-wound suction devices, such as a Hemovac or Jackson-Pratt. In smaller wounds a butterfly cannula may be inserted into the operative site, with the needle end placed into a red-top tube, such as a blood collection tube, that has a vacuum (evacuated tube).

The perioperative nurse should be familiar with the following common general dressings and supplies available in sterile form and various sizes:

- Nonadherent gauze (e.g., Betadine gauze, Adaptic, Nu Gauze, Xeroform, Biobrane, Scarlet Red)
- Petrolatum gauze, ½ inch (or other packing material, such as Merocel sponge for nasal packing)
- Telfa
- Fine mesh gauze
- Interface
- Gauze dressing sponges, 4 × 4 inches, 2 × 2 inches
- Kling, Kerlix fluff, and Kerlix gauze rolls (2, 4, and 6 inches wide)
- Abdominal pads (most commonly used are 5 × 8 inches)
- Cotton sheets and balls
- Webril
- Tape (paper; silk; and foam; skin tapes, flesh-colored and regular [⅛, ¼, ½, and 1 inch wide])
- Benzoin spray or swab or Mastoplast
- Ace bandages
- Coban
- Casting supplies and splints (as required for postoperative immobilization)
- Abdominal binders and other postoperative garments
- Slings

In some instances, such as a free flap, transparent dressings are used so that the flap can be monitored and observed for vascular flow. Compression garments and support devices are also frequently used by plastic surgeons. Proper fit is essential to minimize vascular compromise. Compression garments are typically applied over a light dressing. A proper garment is selected based on its characteristics (e.g., fabric, stretch, softness, antimicrobial properties) and proper sizing according to measurement instructions. Educating patients of the needs and benefits of compression garment use as well as providing hints for their proper application (avoid ripping with long nails,

instructions on how to don the garment) promotes comfort and compliance (Gladfelter, 2007).

Implant Materials. The range of materials available for implantation and augmentation in the specialty of plastic and reconstructive surgery has benefited from ongoing research. Perioperative nurses are responsible for complying with tracking regulations for implantable materials and devices (Patient Safety).

Biologic materials (autogenous grafts) are preferred when available. Autologous human tissue successfully utilized includes fat, solid dermis, and collagen. Human cadavers are used as a source for acellular collagen (AlloDerm) (Figure 21-5). This product is available in various sizes of sheeting and must be rehydrated in several steps. AlloDerm integrates with the body's tissue and helps to prevent rejection over the long term.

Implant failure may be directly linked to bacterial contamination; therefore meticulous aseptic technique with minimal handling is essential when using implants of any sort. Most alloplastic implants are presterilized from the manufacturer.

Anesthesia. A variety of anesthesia techniques are employed with plastic surgery procedures. Local, regional, tumescent, conscious sedation, deep sedation, and general anesthesia may be used, depending on the type of procedure, the patient's anesthetic history, the American Society of Anesthesiologists (ASA) physical status classification, and the surgeon's preference. Regardless of the type of anesthesia, patients should have baseline vital signs recorded and fully monitored, including blood pressure, heart rate, respirations, cardiac rate and rhythm, oxygen saturation, and $ETCO_2$ pressure if indicated. If a local or regional anesthetic is employed without an anesthesia provider, appropriate staffing should be determined based on patient assessment and nurse competency. The presence of a

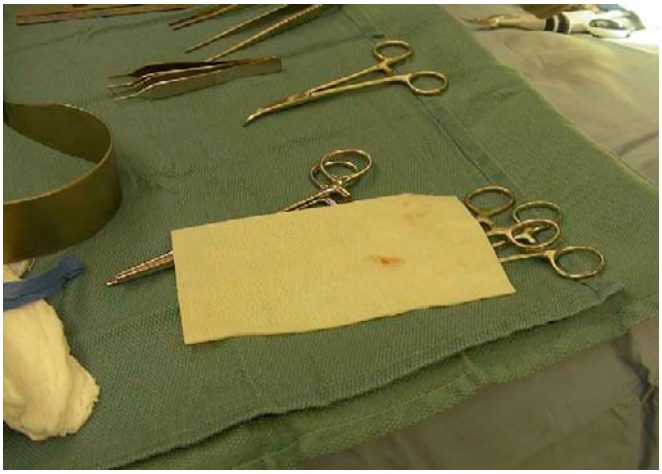

FIGURE 21-5 AlloDerm.

PATIENT SAFETY

Tracking Medical Devices

A variety of implantable devices are used in aesthetic and reconstructive plastic surgery procedures. Tracking of these devices is critical to patient safety. The manufacturer of the device must have a mechanism to locate implantables after they have been distributed. Devices may be recalled for sterility issues, malfunction, or any event that is found to pose a serious health risk.

The U.S. Food and Drug Administration (FDA) regulates the process of tracking medical devices and directs the tracking of devices whose failure would result in serious, adverse health consequences; devices that are intended to be implanted in the human body for more than 1 year; and devices that are life-sustaining and life-supporting and are used outside of a facility such as a hospital, nursing home, or ambulatory surgery center.

The perioperative nurse plays an important role in the accurate documentation of implantable devices for tracking purposes. Information that the nurse typically will gather for tracking purposes includes:

- Device identification (i.e., lot, batch, model number, serial number)
- Date of device manufacture and shipping
- Name, address, telephone number, and social security number of the patient who received the device
- Location the device was implanted
- Name, address, and telephone number of the physician who is caring for the patient, if different from the prescribing physician

If an implantable device is sterilized within the sterile processing department of the facility, monitoring requirements include the use of a process challenge device containing a biologic indicator. The load should be quarantined until the result of the biologic indicator is determined. Documentation should include a record of the sterilizer load identification number on the patient's medical record, or the patient's name on the load record. Lot identification provides a method for tracing problems in the event of a recall. Flash sterilization of implantable devices is not recommended.

Patients have the right to refuse tracking of their devices and may refuse to have their social security number used for tracking. The patient's consent for tracking should be obtained before the procedure. If the patient refuses to have the device tracked, the nurse will document the refusal along with the required product information and report these data to the manufacturer.

Under the Safe Medical Device Act, institutions must also report any incident of death or serious injury relating to the use of a medical device. The FDA has classified and identified more than 1700 different devices that must be reported if the device is suspected of causing serious injury or death to an individual. Nurses should work within their institutional policies to report these incidents.

Modified from Association for the Advancement of Medical Instrumentation: *Comprehensive guide to steam sterilization and sterility assurance in health care facilities,* Arlington, Va, 2006, AAMI; Chard R: Clinical issues, *AORN J* 90(1):117, 2009; Denholm B, Downing D: Clinical issues, *AORN J* 87(2):432-434, 2008; U.S. Food and Drug Administration: *Medical device tracking, guidance for industry and FDA staff,* available at www.fda.gov/cdrh/comp/guidance/169.html. Accessed July 6, 2009; U.S. Food and Drug Administration: *Medical device reporting,* available at www.fda.gov/cdrh/devadvice/351.html. Accessed July 6, 2009.

perioperative registered nurse whose sole responsibility is to monitor the patient may be warranted, depending on clinical assessment and patient behavior. This nurse must be sufficiently skilled in assessment and knowledgeable about the agents being used so that changes in the patient's status can be promptly reported and appropriate interventions to prevent complications can be initiated (AORN, 2009).

Injectable anesthetics are frequently used, not only for strictly local cases but also in conjunction with regional, sedation, and even general anesthesia. Local anesthetics (e.g., Xylocaine, Marcaine, Citanest) act by reversibly blocking nerve impulses—they stop nerve conduction by blocking sodium channels in the axon membrane. When combined with a vasoconstrictor such as epinephrine, local blood flow is decreased and systemic absorption of the anesthetic delayed. This prolongs anesthesia time and reduces the risk of toxicity. In addition, infiltration of a local anesthetic can help define tissue planes through hydrodissection. Use of epinephrine is contraindicated in areas with limited vascularity, such as digits, the penis, nasal tip, and ears. Systemic toxicity from the vasoconstrictor itself (palpitations, tachycardia, nervousness, and hypotension) may occur. For excessive symptoms, α- and β-adrenergic antagonists may control the symptoms (Lehne, 2007).

Although true allergic reactions to local anesthetics are rare, they are still possible; they are more likely with ester-type anesthetics (e.g., procaine). Amides (e.g., lidocaine) may be used when allergies contraindicate use of ester-type anesthetics. Thus amide-type anesthetics often replace ester-type agents for injection (Lehne, 2007).

Central nervous system toxicity from local anesthetics is a more frequent occurrence and is dose related. Maximum doses for several local anesthetics (volume for 70-kg adult) are 70 ml of 0.25% bupivacaine, 28 ml of 1% lidocaine solution, or 50 ml of a 1% solution of lidocaine with epinephrine (1:200,000) (Barberio, 2007). The nurse must be familiar with the signs and symptoms of toxicity, which are frequently heralded by restlessness. Early symptoms may include lightheadedness, dizziness, nystagmus, and numbness of the tongue and lips; these may progress to slurred speech, disorientation, psychosis, muscle twitching, tremors and convulsions, and cardiac arrest (Rapid Response Team box). Lehne (2007) notes, "toxicity is greater risk since absorption occurs more readily through mucous membranes than through skin. Extent of absorption is also proportional to the surface area covered so risk is greater with large areas covered. Applying topical anesthetics to the smallest surface area needed, and avoiding application to injured skin minimizes absorption and risk of toxicity."

Topical anesthetics used by the plastic surgeon include tetracaine (Pontocaine) 2% ophthalmic drops (for blepharoplasty or before application of eye shields), EMLA (eutectic mixture of local anesthetics) for penetration on intact skin (associated with laser surgery), and cocaine 4% for mucous membranes (for rhinoplasty).

Preoperative Skin Preparation. Most surgical interventions require that the operative site and adjacent areas be cleansed before surgery. The physician may prescribe that the patient carry out this treatment before surgery. Special attention is given to the fingernails for patients undergoing hand surgery; to hair for surgery of the head, face, or neck; and to oral hygiene for surgery in or near the mouth. The perioperative nurse should verify with the patient that the prescribed regimens have been performed. All body jewelry that pierces the skin should be removed before the skin prep. The operative site should be inspected for any rashes, bruises, open sores, cuts, or other skin conditions. Hair should only be removed if it interferes with the procedure. Shaving is avoided and clippers, not a razor, are used if needed, because shaving creates an access for the entry of bacteria into the operative site (Health Stream, 2007). The eyebrows and eyelashes, in particular, are left intact to preserve facial appearance and expression. The surgical site is marked before surgery by the surgeon to designate the correct site and to define landmark areas. Either a povidone-iodine solution, an iodine-alcohol mixture, chlorhexidine gluconate (CHG), or another broad-spectrum agent may be selected for the antimicrobial skin prep. The use of CHG should be avoided around the ears and eyes. It is important to place shields on the eyes if prepping the periorbital site or performing an extensive head and neck prep, place plugs in the ear canals, and prevent pooling of the prep agent. The perioperative nurse should query the patient regarding any allergies to antimicrobial agents. If indicated, the plan of care should be changed to avoid the use of these products. When prepping for a skin graft procedure, separate skin prep setups are needed for the graft and donor sites.

Positioning and Draping. The OR bed must be positioned so that the remaining space in the room can comfortably accommodate anesthetic equipment, members of the surgical team, instrument tables, and any adjunct equipment (hand table, drills, microscope, laser) to be used. The patient is carefully positioned on the OR bed so that all operative sites may be appropriately exposed and the airway easily observed and accessed.

Before implementing any positioning changes, the perioperative nurse should verify the appropriate placement of the OR bed and the desired patient position. Adequate numbers of personnel and supportive positioning devices must be present. No changes should begin until the anesthesia provider gives permission. Whereas a majority of plastic surgical procedures are performed in the supine position, many also take place with the patient prone or lateral. Liposuction and postbariatric body contouring procedures may also require repositioning one or more times during surgery. Abdominal procedures may start supine and usually require repositioning to facilitate closure. With each new position, reassessment and documentation of the position and devices used to stabilize the patient should occur. Chapter 5 reviews patient positioning and appropriate safety measures for the supine, lateral, and prone positions, all of which may be used during plastic surgical patient care. The perioperative nurse pays particular attention to the patient's arms during positioning to ensure that they are placed on padded armboards with the palms up and fingers extended (for the supine position). Armboards are maintained at less than a 90-degree angle to prevent brachial plexus stretch. If there are surgical reasons to tuck the arms at the side, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail.

RAPID RESPONSE TEAM

Local anesthetics are often utilized and administered via various routes for plastic surgery procedures (e.g., regional blocks, local/subcutaneous infiltration, indwelling catheters, and topical preparations). While widely used, they are not free from hazards. A recent FDA warning notes that the potential life-threatening complications, "such as irregular heartbeat, seizures, breathing difficulties, coma and even death," can occur when applied to a large area of skin or when the area of application is covered. The FDA encourages collaboration and clear instructions between healthcare professionals and patients who may use the products.

Teamwork within the plastic surgery department requires all to be vigilant in monitoring the patient during use of local anesthesia. This corresponds to the following *2009 National Patient Safety Goals and Requirements for Hospitals:* "Goal 2—improve the effectiveness of communication among caregivers; Goal 3—improve the safety of using medications; Goal 13—encourage the patient's active involvement in their care as a patient safety strategy; and Goal 16—improve recognition and response to a patient's condition" (Blanchard, 2008).

The principle of rapid response is to intervene early, to prevent life-threatening complications. Again, teamwork and sharing of information are pivotal to patient safety and optimal outcomes. Early signs and symptoms may be easier to detect with an awake, "strictly local" patient; they should serve as an alert for the anesthesia provider or surgeon to immediately stop administration of the local anesthetic, assess the situation, and intervene to prevent progression. Although rare, adverse events and toxic effects are dose related; symptoms may include metallic taste, tinnitus, light-headedness, syncope, visual disturbances, numbness of the tongue or lips, confusion, tremors, shivering, generalized seizures, initial tachycardia and hypertension, progressing with increased toxicity to ventricular dysrhythmias, cardiac arrest, and respiratory arrest (Ogg, 2008). Treatment may include administration of additional benzodiazepine, or small bolus doses of propofol in the event of tonic-clonic seizures. Airway support with oral or nasal airway insertion and oxygen via facemask is essential (Clark, 2008).

To effectively and rapidly intervene in a situation involving local anesthetic toxicity, the perioperative nurse must have a comprehensive knowledge of the mechanism of action driving toxicity and resuscitative protocols. The perioperative nurse needs to keep abreast of developments within fields of other disciplines to be able to respond to urgent situations and avoid potentially fatal patient outcomes. An example of a newer treatment for local anesthetic toxicity is lipid emulsion (LE) rescue therapy, which has been used in isolated situations for bupivacaine toxicity. Lipid rescue therapy is thought to be effective because the high lipid solubility of bupivacaine and rapid binding of excess local anesthetic with lipid infusion reduce the plasma drug level and allow for restoration of hemodynamic stability. An American Society of Anesthesiologists' newsletter discusses the evolution and science of using lipid emulsion therapy for patients not responding to conventional cardiopulmonary resuscitation after local anesthetic toxicity. An editorial in an anesthesia journal describes a difficulty, "There is little question that the absolute, scientific 'proof' of lipid emulsion's efficacy in reversing local anesthetic-induced cardiac arrest is yet lacking. Such a proof would require prospective, double-blind, placebo-controlled studies in humans, and such studies will thankfully never be performed, for obvious ethical reasons. However, when deciding on the patient safety implications of a novel, potentially life-saving, therapy, one must consider the tenuous and often unknown balance between the purported benefits and potential risks" (Brull, 2008). A summary of medical judgment shows a balance: "CNS symptoms such as loss of responsiveness, disorientation, tremors, or seizures must be treated conventionally by ensuring oxygenation and ventilation, securing the airway to protect aspiration of gastric contents in patients at risk, administering anticonvulsants, and instituting advanced cardiac life support protocols in the case of cardiac arrest. Once these conventional treatment modalities have begun, however, immediate IV administration of LE would seem very reasonable and desirable."

Correct draping procedures depend on the location of the operative site or sites. Disposable drapes (see Chapter 3) are often used because of their barrier qualities, ease of handling and storage, and versatility in adapting to a variety of plastic surgery procedures. Two of the most frequently used draping techniques in plastic surgery are the head drape and the hand drape. Both of these draping techniques have the goal of providing maximum mobility of the operative part. The head drape includes a fluid-resistant drape that encircles the head and the addition of a drape to cover the remainder of the body. The following techniques represent methods of obtaining maximum accessibility and sterile coverage for facial surgery:

1. A barrier sheet, folded in half, and two towels are placed beneath the patient's head with the towels uppermost. The folded barrier sheet covers the headrest or head portion of the OR bed. One towel is brought around the patient's head on each side to cover all hair, leaving the entire face (and ears, as necessary) exposed; the towel is then secured with nonpenetrating towel clamps. For craniofacial procedures a towel folded lengthwise in quarters may be placed under the head to assist with moving the head from side to side. Two additional towels are then placed diagonally across the neck, just under the chin; they are secured to each other (with nonpenetrating towel clamps) in the middle over the neck and are secured on each side to the towel around the head. A full sheet is then added to cover the patient from neck to feet.
2. After the head portion of the drape is placed, a split, or U, drape is added to cover the patient from neck to feet.

Additional Considerations. Preparation is a key ingredient in success. Having backup supplies or equipment, sometimes as elementary as an extra bulb for the light source, can mean the difference in a positive outcome for the patient. Occasionally, during the course of a procedure, a flap may become

congested and fail, the anatomy may dictate a change in the surgical plan, or perhaps a preselected implant just may not be right. Flexibility, meticulous preparation, and a willingness to improvise and innovate will always serve the perioperative nurse well when working with plastic surgeons.

Evaluation

During the surgical intervention, the perioperative nurse is constantly evaluating the patient's response to nursing interventions, anesthesia, and the surgery itself. Progress or lack of progress toward the identified patient outcomes is continuously assessed. The results of this ongoing evaluation enable the perioperative nurse to reassess the patient, reorder priorities of patient care, establish new patient outcomes, and revise the perioperative plan of care.

At the conclusion of the surgical intervention the perioperative nurse reviews whether identified patient outcomes have been achieved. The patient's skin integrity is assessed; dressings are applied and their integrity is established before discharge from the OR. Any drains or tubes incorporated in the dressing should be noted. Infusion sites are inspected, and the type of infusing solution, flow rate, and amount infused are noted in the patient record. Local anesthetics, sedatives, or other medications received by the patient are similarly documented. The patient's response during the perioperative period is noted; any unusual or untoward responses are reported to the nurse in the recovery unit. The transport vehicle is obtained; any special equipment needed for patient transport is also obtained and checked for proper functioning. Warm blankets may be provided, and the patient is gently moved to the transport vehicle. The patient who is recovering from general anesthesia is placed in a safe position on the vehicle; the awake patient should be assisted to a position of comfort.

The perioperative nurse, in collaboration with the anesthesia provider, should give the hand-off report to the nurse in the postanesthesia care unit (PACU). Areas requiring ongoing patient observation should be noted in this report; the patient's preoperative, intraoperative, and immediate postoperative statuses are also reported. Using the Sample Plan of Care introduced earlier in this chapter, the perioperative nurse may give part of the report based on patient outcomes. If they were achieved, they may be stated as listed under the Outcomes section.

Patient and Family Education and Discharge Planning

Education of the plastic surgery patient begins at the time of consultation. Anxiety inhibits the retention of information; therefore it is always helpful to have written information or other tools for the patient to use as a reference source, beginning with the preoperative instructions as well as postoperative information. The approach to teaching should lend itself to the patient's preferred learning style (e.g., auditory, visual). Specifics that should be addressed include pain management (Surgical Pharmacology), self-care, diet, exercise, care of incisions and drains, return to the clinic for follow-up appointments, signs and symptoms of infections or complications, and how to reach the physician in case of an emergency.

Benefits of an effective education intervention are numerous; it serves to decrease anxiety, improves compliance, reduces the incidence of complications, empowers the patient to become an active participant in his or her own care, and maximizes independence, allowing the patient to more quickly return

SURGICAL PHARMACOLOGY

Postoperative Pain Medications/Administration Options

A discussion about postoperative pain management is an important component of the patient education process. Patients undergoing plastic surgery procedures have several options available for pain control. The perioperative nurse must be familiar with analgesic medications used in the immediate and discharge phases of postanesthesia recovery to provide safe care and appropriate education to the patient.

PATIENT-CONTROLLED ANALGESIA

Depending on the extent and scope of the procedure, patient-controlled analgesia (PCA) may be an effective option in the inpatient setting. PCA is controlled by a special infusion pump that is programmed to administer a calculated intravenous dose of medication when the patient presses a button on the hand control. Opioid analgesics are typically used for PCA.

LOCAL ANESTHETIC INFUSION SYSTEMS

An alternative technique for managing postoperative pain is the continuous instillation of local anesthetic to the surgical site by way of multilumen catheters placed intramuscularly or in the subcutaneous tissue.

As the procedure is ending, the surgeon places the catheters in the surgical wound, exiting through the skin. The catheters are attached to a pump that can contain up to 300 ml of local anesthetic. The surgeon or registered nurse first assistant (RNFA) fills the pump reservoir during the intraoperative phase of care, calculating the volume needed based on the anticipated length of time the pump will be in use and the volume to be administered per dose. Alternatively, the pump may come prefilled from the pharmacy. A tissue adhesive agent may be used at the exit site to prevent leakage of the local anesthetic. The catheters are secured with wound closure strips at the exit site and covered with a transparent, occlusive dressing.

The pump enables a continuous infusion of the local anesthetic agent for the desired number of days (usually 2 to 4). A new option for this technique is a device that offers on-demand delivery of local anesthetic by the patient, which features a protective lockout that prevents overdosage. Plastic surgeons routinely use this technique after submuscular augmentation, abdominoplasty, and breast reconstruction.

NURSING IMPLICATIONS

Refer to Chapter 4 for information relating to local anesthetics. Commonly used agents include bupivacaine (Marcaine, Sensorcaine), levobupivacaine (Chirocaine), ropivacaine (Naropin), and lidocaine (Xylocaine).

SURGICAL PHARMACOLOGY

Postoperative Pain Medications/Administration Options—cont'd

Contraindications for use of the pump include known allergy to local anesthetic, significant kidney or liver disease, insulin-dependent diabetes, a current bacterial infection, or long-term use of local anesthetic. The patient may be sent home with the catheters in place; however, since there is no maintenance once the reservoirs are filled and secured, it is not necessary to use home health nurses. The perioperative nurse should make sure the patient or caregiver has the necessary information to monitor for signs of local anesthetic toxicity: tinnitus, blurred vision, confusion, a metallic taste or numbness of the tongue, or tingling of the fingers or toes. Signs of infection (temperature >38.5° C, warmth or drainage from the catheter insertion site) should also be reviewed. Patients will need the following information: possible need for opioid analgesia for breakthrough pain; driving restrictions; protecting the surgical limb and taking sponge baths instead of showers; and how and when to stop the infusion and how to remove the catheter.

Medication	Dosage	Side Effects	Nursing Implications
Morphine sulfate	Loading dose: 5-10 mg Intermittent bolus: 0.5-3 mg Lockout interval: 5-12 min	◆ Sedation ◆ Hypotension ◆ Nausea	◆ Monitor for respiratory depression. ◆ Initiate deep-breathing and coughing exercises. ◆ Provide instruction to patient on how to operate system.
Demerol (meperidine hydrochloride)	Loading dose: 50-100 mg Intermittent bolus: 5-30 mg Lockout interval: 10-20 min	◆ Vomiting ◆ Dizziness ◆ Diaphoresis ◆ Somnolence	◆ Breakthrough pain may be possible as administration ceases when the patient is asleep. ◆ Monitor patient's response to PCA and treat oversedation per institutional protocol.

Modified from Hodgson BB, Kizior RJ: *Saunders nursing drug handbook 2010,* St Louis, 2010, Saunders; Paul M: Breast augmentation and abdominoplasty: postoperative management with pain pumps, *Aesthet Surg J* 25:69-71, 2005; Banks A: Innovations in postoperative pain management: continuous infusion of local anesthetics, *AORN J* 85(5):904-914, 2007.

to an optimal state of health. The patient's readiness to learn, needs, and styles of learning must be assessed. A teaching plan should be individualized based on the desired outcomes of all parties. The teaching should be implemented with respect to the most effective methods of learning for the individual, taking into account cultural, psychologic, physical, and cognitive limitations.

Older adults need to learn the same material as other patients, such as usual expectations for before, during, and after surgery and during the recovery period. Depending on sensory deficits, the nurse may need to speak slower, more clearly and concisely, allowing time for the patient to respond, absorb the information, and ask questions. It is important to verify the patient's understanding by asking the patient to repeat back the information. The nurse should take cues from the patient and family about how much information they want to know, as some prefer less detail (Clayton, 2008).

Surgical Interventions

Reconstructive Plastic Surgery

Reconstructive plastic surgery seeks to restore or improve function after trauma, disease, infection, congenital anomalies, or acquired defects while trying to approximate an aesthetic appearance.

REMOVAL OF SKIN CANCERS

The estimated number of new skin cancer cases diagnosed in 2009 is 1 million (National Cancer Institute [NCI], 2009). The three most common skin cancers are basal cell, squamous cell, and melanoma (Gutierrez and Peterson, 2007). Basal cells account for approximately 70% of all skin cancers (Figure 21-6, *A*). If basal cell cancer is left untreated, it will grow locally, but rarely metastasizes (Box 21-1). Treated early, it may be cured by simple excision and closure (with pathologic diagnosis to ensure disease-free margins). Squamous cell skin cancers are considered more aggressive (Figure 21-6, *B*). Surgical treatment is the same as that for basal cell carcinomas. Melanoma accounts for the smallest percentage of skin cancers (5%), but it is treated much more aggressively because of its high mortality rate, comprising 75% of skin cancer deaths (Sladden et al, 2009) (Figure 21-6, *C*). Excision of melanoma may involve sentinel node mapping and excision. Early diagnosis of melanoma is imperative to successful treatment (Evidence for Practice). A Cochrane Database Systematic Review is underway (Sladden et al, 2009) since various international organizations varied in their recommendations regarding optimal excision margins. Excision margins that are too narrow may result in higher local recurrence rates and/or mortality; wider excisions may increase hospital length of stay and require costlier procedures such as skin grafting and anesthesia.

Procedural Considerations

Consideration must be given to the type of skin cancer to be excised and the anticipated closure technique. Simple excision and closure with adjacent tissue will be the simplest technique, requiring a local plastic tray accompanied by skin markers and the electrosurgical unit (ESU), and usually involving use of a local anesthetic with epinephrine. A simple excision may be performed with the patient administered a local or general anesthetic or after induction of sedation. If additional procedures will be performed (e.g., reconstruction with skin graft, flap, or sentinel node mapping), refer to those sections for additional procedural considerations.

Operative Procedure—Simple Excision

1. The site is prepped and draped.
2. The surgeon infiltrates the site with a local anesthetic.
3. The lesion is curetted or excised and may be sent for frozen section or pathologic diagnosis.

4. Hemostasis is obtained.
5. The surgeon closes the wound if necessary.

Mohs' Surgery

Mohs' surgery is a specialized excision used to treat basal and squamous cell skin cancers. The procedure involves excising the lesion layer by layer and examining each layer under the microscope until all the abnormal tissue is removed.

Procedural Considerations. Mohs' surgery is usually completed on an ambulatory basis with the patient administered a local anesthetic. The procedure can be very time-consuming to accomplish, but it typically results in the preservation of the surrounding healthy tissue. Because the procedure is lengthy, patient preparation and comfort are essential to facilitate cooperation during the procedure. A minor plastic surgery set is required, along with fine (5-0 or 6-0) suture material.

BOX 21-1

Important Trends for Skin Cancer

INCIDENCE
Approximately 1 million cases per year with the majority being the highly curable basal or squamous cell cancers, accounting for more than 50% of all cancers; not as common is the most serious malignant melanoma, with an estimated 68,720 cases per year.

MORTALITY
Total estimated deaths for 2009 were 8650 from malignant melanoma and 11,590 from other skin cancers.

RISK FACTORS
- Excessive exposure to ultraviolet radiation from the sun
- Fair complexion
- Occupational exposure to coal tar, pitch, creosote, arsenic compounds, and radium
- Exposure to human papillomavirus and human immunodeficiency virus
- Skin cancer negligible in African Americans because of heavy skin pigmentation

WARNING SIGNALS
Any unusual skin conditions, especially a change in the size or color of a mole or other darkly pigmented growth or spot.

PREVENTION AND EARLY DETECTION
Avoid sun when ultraviolet light is strongest (e.g., 10:00 AM to 3:00 PM); use sunscreen preparations, especially those containing ingredients such as *para*-aminobenzoic acid (PABA). Basal and squamous cell cancers often form a pale, waxlike, pearly nodule or a red, scaly, sharply outlined patch; melanomas are usually dark brown or black pigmentation; they start as small molelike growths that increase in size, change color, become ulcerated, and bleed easily from a slight injury.

TREATMENT
The four methods of treatment are surgery, electrodesiccation (tissue destruction by heat), radiation therapy, and cryosurgery (tissue destruction by freezing). For malignant melanomas, wide and often deep excisions and removal of nearby lymph nodes are required.

SURVIVAL
For basal cell and squamous cell cancers, cure is virtually ensured with early detection and treatment. Malignant melanoma, however, metastasizes quickly; this accounts for a lower 5-year survival rate for Caucasian patients with this disease.

Modified from American Cancer Society (ACS): *Cancer facts and figures 2009,* Atlanta, 2009, The Society; Huether SE: Structure, function, and disorders of the integument. In Huether SE, McCance KL: *Understanding pathology,* ed 4, St Louis, 2008, Mosby.

EVIDENCE FOR PRACTICE

Melanoma Awareness, Prevention, and Detection

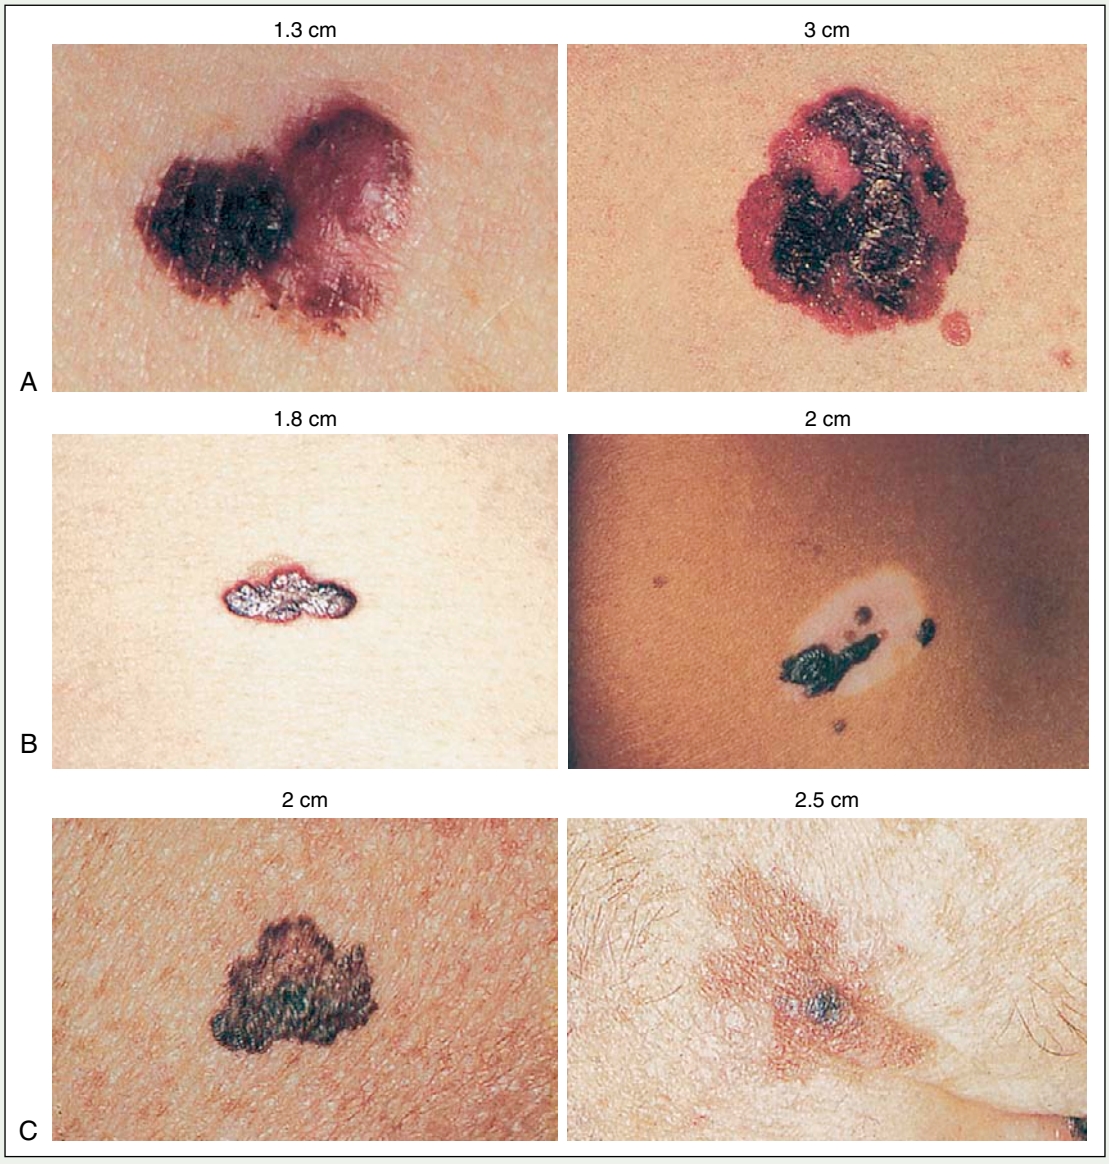
It is estimated that more than 68,720 men and women will be diagnosed with melanoma in 2009, according to the American Cancer Society. In the most recent time period, rapid increases have occurred among young white women (3.8% annual increase since 1995 in those aged 15 to 34 years) and older white men (8.8% annual increase since 2003 in those 65 and older). Although the exact cause of developing a melanoma is not known, certain risk factors have been identified:
- **Ultraviolet (UV) radiation:** sunlight, tanning beds
- **Moles:** more than 50 = greater risk
- **Fair skin:** fair skin, freckling, red or blond hair
- **Family history:** 10% have a relative with melanoma
- **Immune system compromise:** taking antirejection medications after organ transplantation surgery
- **Age:** increased risk in older adults
- **Gender:** men more than women
- **Previous melanoma:** increased risk for having another melanoma

PREVENTION
Limit UV radiation exposure:
1. Wear protective clothing (tight weave) and a hat with a broad brim.
2. Shade is good—avoid too much sunlight; remember that it reflects off water, sand, concrete, and snow.
3. Use sunscreen—SPF 15 or higher; apply 20 to 30 minutes before sun exposure; reapply every 2 hours; protect your lips.
4. Do not forget your eyes—look for sunglasses with 99% UV absorption.
5. Stay away from tanning beds and lamps—more UV exposure; try using self-tanning lotions.
6. Children need sunscreen—their skin is fragile; most damage to skin is acquired before the age of 18 years.
7. Take an inventory—know your moles and what they normally look like so you can detect changes if and when they occur.

KNOW YOUR A-B-C-Ds
A: Asymmetry—one half of the lesion looks different from the other side.
B: Border irregularity—instead of a smooth edge, the border is ragged or irregular.
C: Color—the color is usually irregular as well; may have a number of different hues and colors.
D: Diameter—lesions larger than 6 mm have a greater chance of being a melanoma.

EVIDENCE FOR PRACTICE

Melanoma Awareness, Prevention, and Detection—cont'd



Malignant melanomas. Note presence of "ABCDE" characteristics (*a*symmetry, irregular *b*order, variation in *c*olor, *d*iameter >6 mm, *e*nlargement and *e*levation). **A**, Superficial spreading melanoma. **B**, Nodular melanoma. **C**, Lentigo malignant melanoma.

Modified from American Cancer Society (ACS): *Cancer facts and figures 2009,* Atlanta, 2009, The Society.

Operative Procedure. Current procedures involve removal of all visible portions of the skin cancer lesion. A horizontal layer of tissue is removed and divided into sections that are color-coded with dyes. A map of the surgical site is then drawn. Frozen sections are immediately prepared and examined microscopically for any remaining tumor. If tumor is found, the location or locations are noted on the map and another layer of tissue is resected. The procedure is repeated as many times as necessary to completely remove the tumor.

BURN SURGERY

A majority of burns result from exposure to high temperatures, which injures the skin. Flame, scalding, or direct contact with a hot object may cause thermal skin injury. Similar destruction of skin can result from contact with chemicals such as acid or alkali or contact with an electrical current. The latter, however, often involves extensive destruction of the underlying tissue and physiologic systems in addition to the skin. A 2007 fact sheet on burn statistics includes the following information:

FIGURE 21-6 **A**, Basal cell carcinoma. **B**, Squamous cell carcinoma. **C**, Melanoma.

approximately 500,000 burn injuries receive medical treatment yearly; 40,000 patients are hospitalized in the United States for burn injuries, with 25,000 of those admitted to the 125 hospitals with specialized burn centers (American Burn Association [ABA], 2007).

Intact skin provides protection against the environment for all underlying tissues and organs. It aids in heat regulation, prevents water loss, and is the major barrier against bacterial invasion. The tissue injury resulting from a burn disrupts this normal protective function, resulting in local and systemic effects (Box 21-2). Burn patients are therefore some of the most acutely ill patients brought to the OR. The greater the degree of injury to the skin, expressed in percentage of total body surface area (BSA) and depth of burn, the more severe the injury. One method of measuring BSA in adults is by use of the rule of nines (Song et al, 2007) (Figure 21-7).

Partial-thickness (first- and second-degree) burns heal by regeneration of skin from dermal elements that remain intact. First-degree burns involve the epidermis, which appears pink or red; sunburn is usually a first-degree burn. Second-degree burns, also called partial-thickness burns, involve the epidermis and some of the dermis. Full-thickness (third-degree) burns (Figure 21-8) involve the epidermis, the entire dermis, and the subcutaneous tissues; they require skin grafting to heal because no dermal elements remain intact. Both partial- and full-thickness burns may require debridement of necrotic tissue (eschar) before healing can occur by skin regeneration or grafting. An allograft may be used to cover the burned area during the initial healing process. However, the allograft must be carefully tested for immunodeficiency diseases. A xenograft (e.g., pig skin) may also be used for covering the burned area.

SURGICAL PHARMACOLOGY

Topical Medications Used in Burn Therapy

Agent	Indication	Implications
Petroleum-based antimicrobials (bacitracin, Neosporin, polymyxin B)	Partial-thickness burns	Provides barrier protection to wound. Has mild antimicrobial activity. Cleaning wound before applying prevents caking. Maintain layer adequate to keep wound from drying.
Silver sulfadiazine (Silvadene)	Deep partial to full-thickness burns Wound infection	Has broad-spectrum antimicrobial action against gram-negative bacteria, gram-positive bacteria, and *Candida* organisms. Penetrates eschar to inhibit bacterial growth at dermis-eschar interface. Soothes pain with ¼-inch layer applied directly to wound or on impregnated gauze applied 2-3 times daily. May cause slimy, grayish appearance with repeated applications. Inhibits epithelial tissue development. Discontinued when eschar no longer present. Side or toxic effects include skin rash on unburned tissues, transient decrease in WBCs for 24-48 hr after application. Contraindicated in patients with sulfa hypersensitivities.
Mafenide acetate (Sulfamylon)	Deep partial to full-thickness burns Wound infection	Is bacteriostatic against gram-negative and gram-positive bacteria. Is applied in ¼-inch layer directly to wound or on impregnated gauze 2-3 times daily. 11.1% cream: penetrates thick eschar and cartilage; inhibits epithelial tissue development. 5% solution: antimicrobial solution used to prevent and treat wound infections. Discontinued when eschar no longer present. Side or toxic effects include pain on application (may necessitate pain management), metabolic acidosis (when applied to more than 40% total body surface area), hypersensitivity rash, pruritus, fungal growth.
Silver nitrate (5% solution)	Deep partial to full-thickness burns Wound infection	Is bacteriostatic against gram-negative and gram-positive bacteria. Has poor penetration of eschar. Side or toxic effects include staining of the wound black (making assessment difficult), pain on application (may necessitate pain management), staining of clothing and linens, decreases in electrolytes (sodium, potassium, calcium, chloride).

Modified from Green-Nigro CJ: Burns. In Monahan F et al, editors: *Phipps medical-surgical nursing,* ed 8, St Louis, 2007, Mosby.

Procedural Considerations

The essentials of skin grafting are discussed under Skin and Tissue Grafting. This section therefore deals only with the procedure for debridement of burn wounds.

A basic plastic instrument set is required, plus a knife dermatome, an ESU, topical thrombin solution, a pneumatic tourniquet for isolated extremity burns, and a topical antimicrobial agent of choice.

Because patients who have sustained burns are vulnerable to hypothermia from the loss of body surface area (BSA), the perioperative nurse should ensure the temperature and humidity in the OR are increased and exposure is limited only to the areas related to the planned surgical event. Anesthesia is often induced while the patient is on the burn unit bed; transfer to the OR bed is done carefully and gently, with attention to maintaining the airway. Most burn patients arrive in the OR with dressings covering their wounds. The dressings are removed after the patient has been anesthetized to minimize pain and loss of body heat through the open burn wounds. Throughout the procedure, the temperature in the OR is constantly monitored to prevent hypothermia. The OR team caring for burn patients coordinates activities to prevent any delays in obtaining required equipment or supplies. The perioperative nurse will need to collaborate with the anesthesia provider in determining fluid replacement requirements. A variety of topical agents are used to dress wounds. Perioperative nurses must be familiar with these agents and their uses (Surgical Pharmacology).

Operative Procedure

1. The surgeon excises all nonviable tissue down to underlying muscle fascia.
2. An alternative method is tangential excision of the burn wound, which is performed with a knife dermatome. This type of excision is usually carried down only to the bleeding subcutaneous fat, rather than to fascia.
3. Hemostasis is obtained with the ESU or use of topical thrombin solution.
4. Dressings saturated with the topical antimicrobial agent of choice are applied.

Although skin grafting may be done at the time of wound debridement, it is usually performed several days later, particularly in burns that are extensive.

BOX 21-2

Pathophysiology of Burn Injuries

Thermal and chemical injuries disrupt the normal protective function of the skin, causing local and systemic effects. The extent of these effects depends on the type, duration, and intensity of exposure to the causative agent. With electrical burns, heat is generated as the electrical current passes through body tissues, causing thermal burns along the path taken by the current. Local damage is marked by histamine release and severe vasoconstriction, followed in a few hours by vasodilation and increased capillary permeability, which allows plasma to escape into the wound. Damaged cells swell and platelets and leukocytes aggregate, causing thrombotic ischemia and escalating tissue damage. Systemic effects, which are caused by vascular changes and tissue loss, include hypovolemia, hyperventilation, increased blood viscosity, and suppression of the immune system. The severity of the burn determines the extent of local and systemic effects. Severity is judged by the depth of the burn and the quantity of tissue involved. The depth of the burn is classified by degree. First-degree (superficial) burns affect the epidermis only; second-degree burns (split thickness) affect the epidermis and dermis; third-degree burns (full thickness) affect all skin layers and extend to subcutaneous tissue, muscle, and nerves; fourth-degree burns involve all skin layers, plus bone. The percentage of body surface area (BSA) system of the American Burn Association classifies quantity as follows:

- Minor burn: full-thickness burns over less than 2% of BSA; partial-thickness burns over less than 15% of BSA
- Moderate burns: full-thickness burns over 2% to 10% of BSA; partial-thickness burns over less than 15% to 25% of BSA
- Major burns: full-thickness burns over 10% or more of BSA; partial-thickness burns over 25% or more of BSA; any burn to face, head, hands, feet, or perineum; inhalation and electrical burns; burns complicated by trauma or other disease processes

From Langford RW, Thompson JD: *Mosby's handbook of diseases,* ed 3, St Louis, 2005, Mosby.

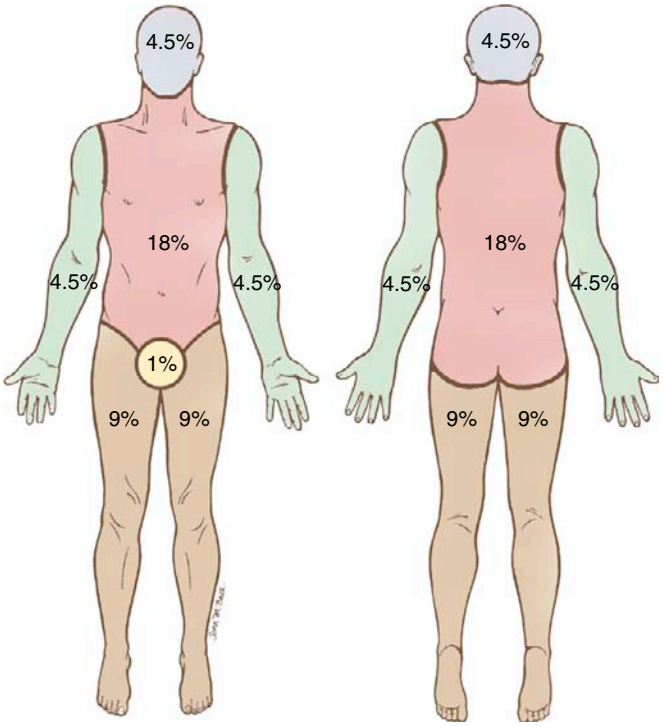


FIGURE 21-7 The "rule of nines." The amount of skin surface burned in an adult can be estimated by dividing the body into 11 areas of 9% each.

FIGURE 21-8 Full-thickness thermal injury.

EXCISIONAL DEBRIDEMENT

Excisional debridement is the act of removing dead or devitalized tissue to promote healing. Plastic surgeons use debridement in conjunction with treatment of injuries, trauma, and infection. Additional information on wound debridement may be found in Chapter 8.

TREATMENT OF PRESSURE ULCERS

Pressure ulcers result from prolonged compression of soft tissues overlying bony prominences (Figure 21-9). However, whether excessive pressure is sufficient to create an ulcer depends on the intensity and duration of the pressure as well as on tissue tolerance. Factors that contribute to pressure ulcer development are immobility, sensory and motor deficits, reduced circulation, anemia, edema, infection, moisture, shearing force, friction, and nutritional debilitation (Cuzzell and Workman, 2010). The most common sites of pressure ulcers are the sacrum, the ischium, the trochanter, the malleolus, and the heel; these are called decubitus ulcers. These ulcers are different from chronic ulcers such as vascular, diabetic, and neurogenic ulcers. Surgical interventions for pressure ulcers are usually based on ulcer staging (also referred to as *grading*). In stage I the ulcer involves the epidermis and has soft tissue swelling that is irregular and ill-defined; heat and erythema at the ulcer site are characteristic. A stage II ulcer involves the epidermis and dermis but not the subcutaneous fat. Stage III ulcers show full-thickness skin loss with injury to underlying tissue layers and may contain necrotic material. Thorough excisional debridement is performed, and IV antibiotic therapy is instituted. Although debrided stage III ulcers often heal on their own, surgical excision and closure may be done to prevent a lengthy spontaneous closure, which may result in a weak, unstable scar with resultant recurrence. Stage IV ulcers are the deepest, requiring more radical excisional debridement. Adequate soft tissue cover may be obtained by either split-thickness or full-thickness skin grafting or tissue flaps (Figure 21-10). Tissue expansion may be used when

there is not enough tissue adjacent to the ulcer site to provide flap coverage.

The use of a CO_2 laser minimizes blood loss and possibly reduces infection rates in the presence of gross contamination. Although many techniques and flaps are surgical options, basic principles apply to all pressure ulcer closure procedures. The following procedure is for an adjacent flap.

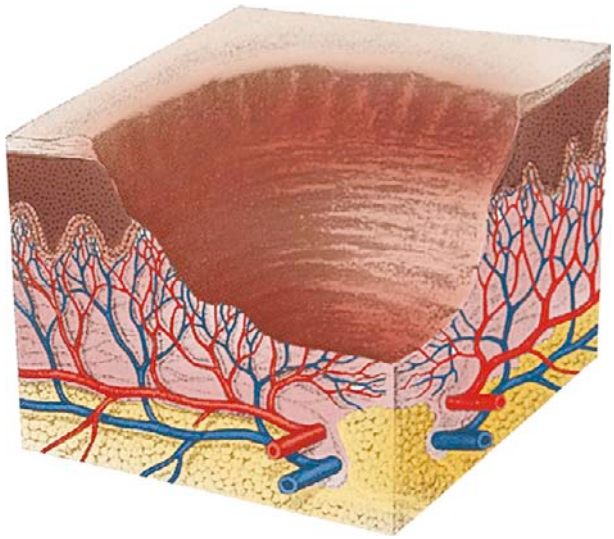

FIGURE 21-9 Pressure ulcers often appear after blood flow to an area slows or is obstructed because of pressure on bony prominences. Infections often follow, since lack of blood flow causes tissue damage or death.

Procedural Considerations

A basic plastic instrument set is required, as well as assorted sizes of osteotomes (straight and curved), a mallet, the Gigli saw and handle, assorted curettes, a Key periosteal elevator, a duckbill rongeur, bone wax, the dermatome of choice, the ESU, a sterile marking pen, and a closed-wound drainage system. The patient is positioned and draped so that the pressure ulcer, adjacent flap donor site, and skin graft donor site are well exposed.

Operative Procedure

1. The area to be excised and the local flap are outlined.
2. The surgeon excises the ulcer along with the underlying bony prominence.
3. Large suction catheters are placed into the defect left by excision of the ulcer and beneath the flap.
4. The flap is sutured in place.
5. A split-thickness skin graft generally is used to resurface the flap donor site.
6. A stent dressing is placed over the skin graft, and gauze dressings or a plastic spray dressing is applied over the suture lines of the flap.

DIABETIC FOOT CONDITIONS

In the past decade, the incidence of diabetes and concomitant severe foot infections has risen significantly. The severity of these infections is conveyed by diagnoses and sequelae (e.g., necrotizing fasciitis, gas gangrene, ascending cellulitis,

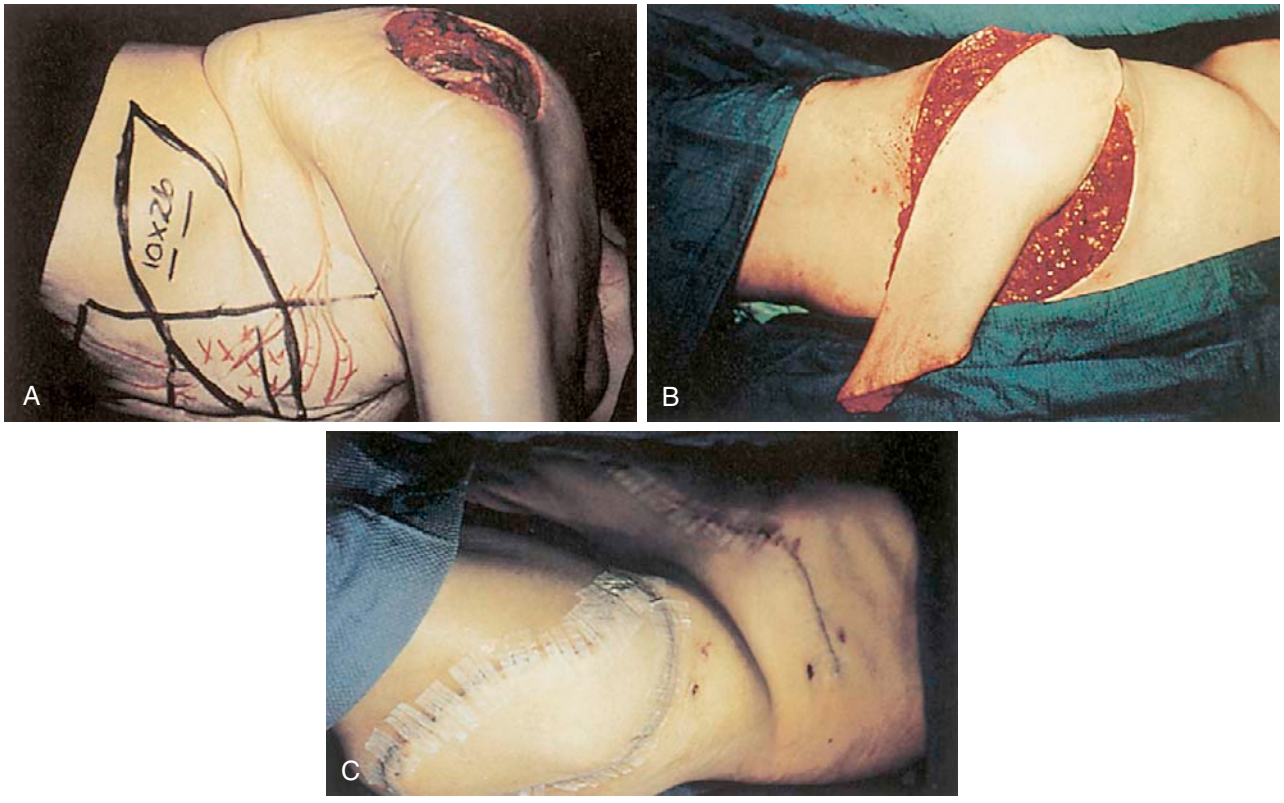

FIGURE 21-10 **A**, Rotational flap from abdomen for pressure sore coverage. **B**, Placement of flap. **C**, Completed coverage with flap placement.

and infection with systemic toxicity or metabolic instability). Because patients with diabetes mellitus may have peripheral neuropathies, they may not feel and therefore not notice any tenderness or early signs of infection. These foot infections can lead to hospitalization and eventual lower extremity amputation for patients with preexisting ulcerations; surgical management is often required for the severe infections. The experienced surgeon determines when and how to intervene. Main principles for management include stabilization of the patient; adequate debridement along with antibiotic therapy; vascular evaluation and revascularization as necessary; delayed soft tissue reconstruction; and postoperative information and intervention for medical and surgical issues. In addressing all these aspects, the surgeon optimizes the possibility for limb salvage. This overview serves as a reminder to emphasize the importance of overall adherence in managing diabetes mellitus to prevent further complications (Zgonis et al, 2008a).

These complex patients are best handled with multidisciplinary consultations to coordinate care and determine optimal timing for soft tissue reconstruction. Primary closure may not be an option and secondary healing is not necessarily reliable. The proactive surgical approach aims to salvage the diabetic limb by improving overall health and to provide a stable, mechanically sound limb that will resist further breakdown once the patient is able to walk again. To prevent complications, patients need ongoing support and validation. Hospital care focuses on dressing changes, wound care, physical therapy, limb position, shower privileges, and laboratory testing. Postoperative nursing care should provide instruction for follow-up and frequency of monitoring of the surgical results, ambulatory status, work and social restrictions, and bathing. Especially important for the perioperative nurse to review with the patient are identification of infection and ways of contacting the surgical team if problems arise (Zgonis et al, 2008b).

SKIN AND TISSUE GRAFTING

Skin grafting provides an effective way to cover a wound if vascularity is adequate, infection is absent, and hemostasis is achieved. Skin from the donor site is detached from its blood supply and placed in the recipient site, where it develops a new blood supply from the base of the wound. Color match, contour, and durability of the graft are all considerations in selection of an appropriate donor area. Other types of grafts that are available for surgical reconstruction include bone, cartilage, nerve, tendon, and autologous fat grafts.

Split-Thickness and Full-Thickness Skin Grafts

Skin grafts can be either split-thickness (STSGs) or full-thickness grafts (FTSGs) (Figure 21-11). A split-thickness (or partial-thickness) skin graft contains epidermis and only a portion of the dermis of the donor site; it varies from a thin graft to a thick graft. Although this type of graft becomes vascularized more rapidly and the donor site heals more rapidly than a full-thickness graft, it may exhibit postgraft contraction, be minimally resistant to surface trauma, and be least like normal skin in texture, suppleness, pore pattern, hair growth, and other characteristics. A split-thickness skin graft may be meshed (Figure 21-12); meshed grafts can expand to many times their original size. Meshing allows the graft to be placed on an irregular recipient area; however, its appearance may be aesthetically undesirable. A full-thickness skin graft contains both epidermis and dermis; any remaining subcutaneous tissue is trimmed before the FTSG is applied to the graft site. The advantages of this type of graft are that it causes minimal contracture, can be used in areas of flexion, has a greater ability to

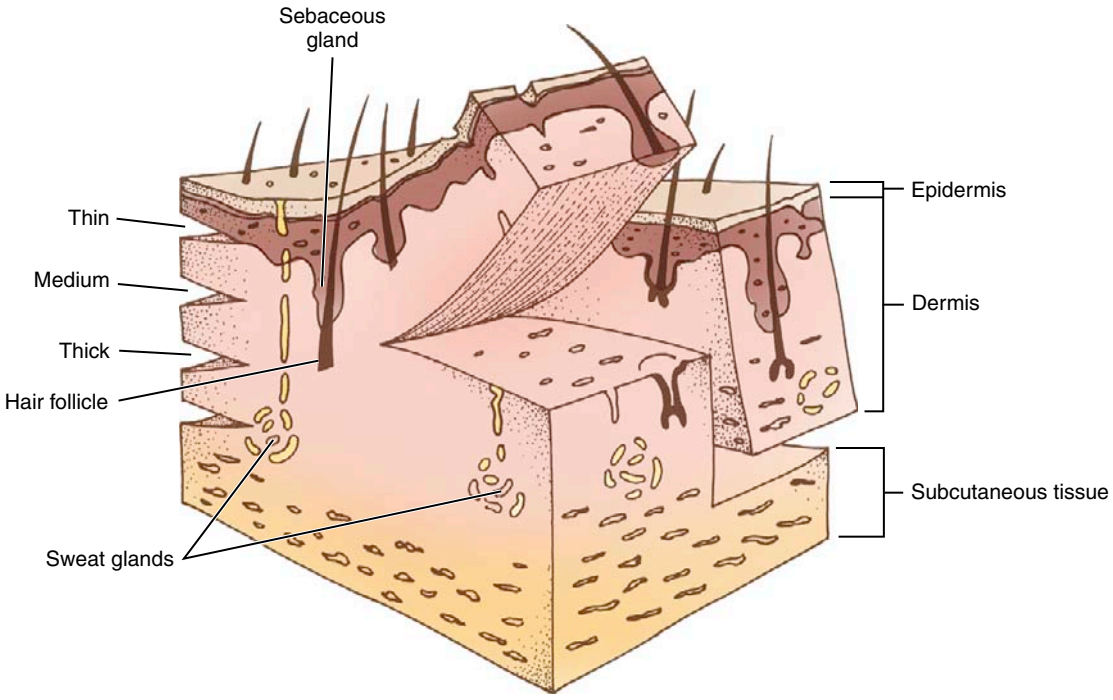

FIGURE 21-11 Split-thickness and full-thickness skin grafts.

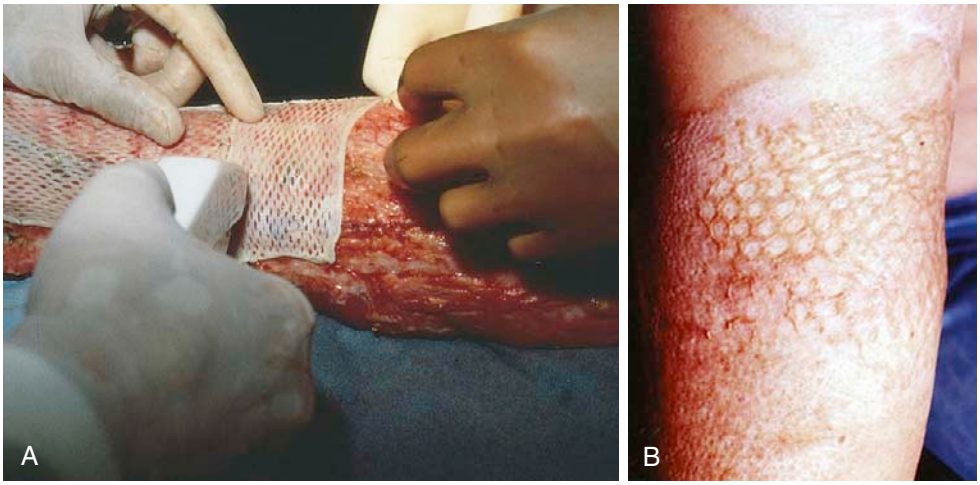

FIGURE 21-12 **A**, Split-thickness skin is meshed and used to cover a marginal wound. Minimal expansion is used, and the holes provide drainage. **B**, Appearance of the graft after healing.

withstand trauma, can add tissue where a loss has occurred or where padding is required, and is aesthetically more acceptable than an STSG. The donor site can be closed primarily, leaving a minimal defect.

The donor site for an STSG heals by regeneration of epithelium from dermal elements that remain intact. Thus only a dressing is placed over this donor site. Because no dermal elements remain when an FTSG is taken, this donor site does not heal spontaneously. It heals either when the wound edges of the donor site are sutured together (primary closure) or when an STSG is applied over it. A scar remains at the donor site of a skin graft; therefore donor sites that are covered by clothing are generally chosen.

For a graft to survive, the vascularity of the recipient area must be adequate, contact between the graft and recipient bed must be maintained, and the graft-bed unit must be adequately immobilized.

Color, temperature, signs of infection, blanching of the skin, excessive pain and discomfort, edema, vasoconstriction, and venous congestion should be noted and any change reported to the surgeon.

Any changes should be documented. If the patient is discharged to home after surgery, patient and family education should include reportable signs and symptoms of potential complications.

A stent or tie-over dressing is often placed over a skin graft (Figure 21-13). This exerts even pressure, ensuring good contact between graft and recipient site. It also eliminates potential shearing forces at the graft and recipient site interface that might disrupt new blood vessels growing into the graft.

Procedural Considerations. A plastic local instrument set is required, with the addition of a dermatome of choice, a skin mesher, and sterile marking pen. The patient is positioned so that both donor and recipient sites are well exposed. Both areas are prepped and draped to maintain adequate exposure and mobility, as required.

Operative Procedure

1. The recipient site is prepared as necessary. This step may involve excision of a benign or malignant skin tumor, debridement of an open wound, or release of a scar contracture.

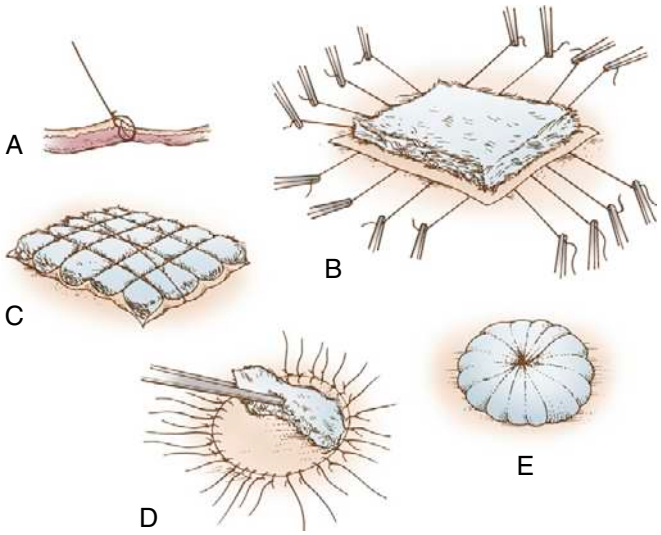

FIGURE 21-13 **A**, Method of fixation of skin graft to edges of wound. **B**, Nonadherent dressing is applied over skin graft, on top of which is placed a generous pad of acrylic fiber. **C**, Long ends of suture are tied over fiber to produce area of pressure between graft and base. **D**, Similar dressing is applied to circular graft. **E**, Long suture ends are tied over circular graft (often called *stent dressing*).

2. Careful planning and marking before harvesting the graft from the recipient site are essential. Patterns matching intended recipient site and the donor site are outlined with a sterile marking pen.
3. STSGs are harvested with a knife dermatome or powered dermatome of the surgeon's choice (Figure 21-14).
4. Moist sponges soaked in normal saline, an antibiotic solution, or a solution of 20 mg of phenylephrine HCl (Neo-Synephrine) per 1000 ml of normal saline may be applied to the donor sites to aid hemostasis. Medication labels indicating strength are placed on all solutions, including Neo-Synephrine, to further identify all solutions on the sterile field. These sponges are removed, and the donor site is covered with Biobrane or OpSite.
5. If the graft is to be meshed, it is now applied to specifically supplied carriers for use with certain skin meshers.

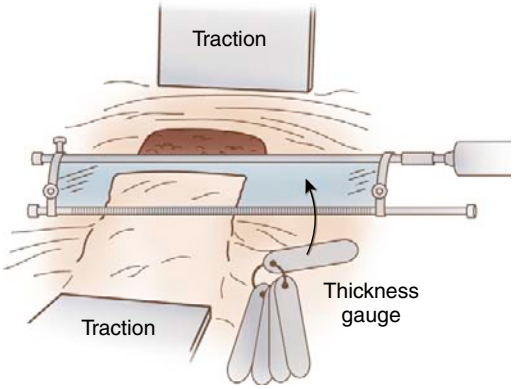

FIGURE 21-14 Harvesting a split-thickness skin graft (STSG) with the Humby knife.

6. A graft that is not immediately applied to the recipient site dries quickly, particularly a meshed graft. The surgical technologist should ensure that the graft is kept on the carrier and covered with moist gauze sponges to prevent inadvertent loss of the graft. Meshed skin should not be removed from its carrier until it is applied directly to the recipient site. Whether applied as a sheet or meshed, the STSG may be sutured or stapled with a skin stapler. Nonadherent gauze is usually applied as the first layer of dressing over a graft. Moist dressings should be applied to all meshed grafts to prevent desiccation and loss of the graft.
7. Fat adherent to the graft is trimmed. The graft is applied to the recipient site and usually sutured at the edges, and these sutures are left long to tie over a stent dressing. Blood clots beneath the graft are removed by saline irrigation before the dressing is applied.

Composite Graft

Composite grafts are composed of skin and underlying tissues that are completely separated from the blood supply of the donor site and transplanted to another area of the body. The survival of a composite graft depends on ingrowth of new blood vessels from the recipient site around the periphery of the graft. Therefore composite grafts are usually small so that no portion of the graft is more than 1 cm from its periphery. An example of compound tissues used as composite grafts is hair transplants, composed of skin, fat, and hair follicles, which are used to treat male pattern baldness. The term *composite* thus indicates a defect that requires a graft be transferred to the area to meet more than one type of tissue deficiency.

Procedural Considerations.

A plastic local instrument set is required, plus a sterile marking pen. The patient is positioned, prepped, and draped such that adequate exposure of both donor and recipient sites is achieved.

Operative Procedure

1. The recipient site is prepared by excising tissue, such as a scar or a benign or malignant skin lesion.
2. When feasible, the surgeon makes a pattern of the recipient site and transfers it to the donor site.
3. The surgeon excises the composite graft. The donor site is either closed by approximating its skin edges or left unsutured (as in hair transplant donor sites).
4. Meanwhile, the composite graft is kept in a moist sponge until it is sutured to the edges of the recipient site.
5. Dressings of choice are applied to the composite graft and donor site.

Replacement of Lost or Absent Tissue

When coverage for a defect cannot be achieved through skin grafting, plastic surgeons rely on other techniques to replace tissue. Just as the flap has evolved, other techniques for tissue restoration through biologic engineering have also evolved. Four principal avenues have been explored to make new tissues for biologic replacement: the injection of isolated cell populations, the placement of polymer scaffolds to guide tissue regeneration, the development of encapsulated systems, and the transplantation of cells in polymer matrices (Marler and Upton, 2006). A discussion of flap techniques follows.

Flaps

The term *flap* refers to tissue that is detached from one area of the body and transferred to the recipient area with either part or all of its original blood supply intact. In a free flap the flap is detached from one part of the body with its vascular pedicle and then reestablished by reanastomosis with the recipient vascular system; thus it has a self-contained vascular system. The base or pedicle of the flap is that portion through which the blood supply enters or exits. Because flaps carry their own blood supply, they generally are used to cover recipient sites that have poor vascularity and full-thickness tissue loss. Flaps are used for reconstruction or wound closure. They are useful for covering exposed bone, tendon, or nerve. They may be used if surgery through the wound may be necessary at a later date to repair underlying structures. Flaps containing skin and subcutaneous tissue retain more properties of normal skin and shrink less than skin grafts. Flaps, however, have some disadvantages, such as bulky appearance, failure to match tissue of the recipient site in texture or color, and the possibility of requiring multiple operations and prolonged hospitalization.

Flaps may be classified according to blood supply. *Random pattern flaps* consist of skin and subcutaneous tissue vascularized by random perforators with limited length/width ratio. *Axial pattern flaps* have a well-defined arteriovenous supply along the long axis; they can be comparatively long in relation to width. Flaps may also be classified according to position or how they are rotated after elevation. *Advancement flaps* are cut and advanced to reconstruct a nearby defect. *Transposition flaps* are advanced along an axis that forms an angle to the flap's original position. *Rotation flaps* are similar to transposition flaps but are semicircular and rotate along a greater axis. *Island flaps* of isolated sections of skin and subcutaneous tissue are tunneled beneath the skin to new sites. *Pedicle flaps* were the forerunners of muscle and musculocutaneous flaps. These consist of skin and underlying muscle; they are very mobile and can be rotated into distant defects. *Free flaps* are actually a form of tissue transplantation. Using microvascular techniques, a defined amount of skin, muscle, or bone can be isolated, totally detached, and reattached at the recipient site by microvascular anastomoses between recipient site blood vessels and the major vessels that supply the flap. The vascular pedicle may contain functional nerves, yielding sensory flaps to provide protective

sensation or motor flaps to restore function. Bone and joints may be transplanted as free flaps, as in the case of toe-to-thumb site transfers.

Procedural Considerations. The perioperative nurse should consult with the surgeon in advance of the procedure to determine the donor site, the patient's position(s), and the surgical sequence of the procedure. Generally the surgical site and flap area are marked preoperatively with the patient in a functional position because landmarks and aesthetics are influenced by surgical positioning. If marking is undertaken on the anesthetized and surgically positioned patient, inaccuracies in tissue placement could occur. Flap procedures may involve two teams of surgeons working simultaneously: one raising the flap and closing the resulting defect, and the other preparing the site, repositioning the flap in its new site, and, in the case of a free flap, microscopically reanastomosing the blood vessels. For any lengthy procedure, a Foley catheter, sequential compression devices, warming units, and positioning aids that are safe for the skin will be needed. Skin grafts are sometimes used to achieve closure of the flap donor site; if this is anticipated then the nurse and surgical technologist should add appropriate instrumentation for harvesting a skin graft.

A basic plastic instrument set is required, plus the following:

- ESU
- Sterile marking pen
- Extra hemostats
- Dermatome of choice
- Skin mesher
- Microvascular instruments (as appropriate)

Operative Procedure—Advancement, Transpositional, Rotational, Island, and Pedicle Flaps

1. The recipient site is prepared in the same manner as for a skin graft.
2. Patterns matching the recipient and donor sites are drawn/marked.
3. The surgeon incises, elevates, and transfers the flap to the recipient site.
4. The edges of the flap are sutured to the periphery of the recipient site.
5. The flap donor site is repaired by approximating the skin edges directly or by covering the defect with a skin graft or another flap.
6. Drains are usually placed under flaps.
7. Dressings are applied with particular attention given to immobilization of the flap, which may require a stockinette, padding, or plaster of paris.
8. NOTE: Before a pedicle flap is detached from the donor site, the surgeon may want to determine the adequacy of circulation within the flap. One method to check circulation involves placing rubber-shod clamps across the base of the pedicle and injecting sodium fluorescein intravenously. After 10 minutes have elapsed, all lights in the OR are turned off and a Wood's lamp is held over the flap to determine the presence or absence of fluorescence within the flap. Fluorescein may be injected locally for the same purpose.

Operative Procedure—Free Flaps. See Operative Procedure for free TRAM flap described under Reconstructive Breast Surgery.

RECONSTRUCTIVE BREAST SURGERY

The loss of a breast because of cancer may have a devastating effect on a woman. Fortunately, the option of breast reconstruction is available to virtually any woman who loses her breast to cancer (ASPS, 2009c). Reconstruction has the ability to offer hope and a return to wholeness and normalcy. Normal, of course, is subjective, and although breasts may be reconstructed, there is a wide range of outcomes, and it must be stressed that breast reconstruction is not a one-time surgery. Revisions are the rule and not the exception. Techniques and options continue to evolve and improve, and women have many options. Breast reconstruction may be offered at one of many times during this process—initially, at the time of mastectomy; before or after adjunct therapy; or even many years later. The important fact is that each woman and her oncologic status are individual, so the decision for reconstruction must be made according to the woman's wishes coupled with her most favorable circumstances. Reconstruction has no known effect on the recurrence of breast cancer (ACS, 2009). Breast reconstruction options include alloplastic (artificial materials), autogenous (flaps), or a combination of both. Flaps may be pedicle-based or free flaps, requiring microsurgical techniques for their reconstruction.

Breast Reconstruction Using Tissue Expanders

Mastectomy may leave a shortage of skin that prevents creation of a breast mound. For these patients, extra tissue can be created locally with the use of tissue expanders (Figure 21-15). Tissue expansion is a technique used to stretch normal tissue that is adjacent to a defect, mechanically creating redundancy of normal tissue to correct the defect. For breast reconstruction, the expander resembles the shape of a breast prosthesis. The expander has a metal-backed, self-sealing silicone valve at its dome. Another type of expander used less frequently has a small, dome-shaped reservoir with a fill tube that is positioned subcutaneously at a distance from the expander but connected to it. Following surgery, the tissue expander is gradually filled with percutaneous injections of normal saline during routine office visits. The expander may be filled as often as weekly, or it may remain unused until chemotherapy or radiation is completed. Once the tissue expander is filled to the appropriate volume, it may be removed and replaced with a permanent reconstructive mammary prosthesis, either saline or silicone, as an ambulatory surgical procedure. Silicone can be used for breast augmentation for patients older than 21 years. If silicone is chosen, both the surgeon and the patient must participate in an adjunct clinical study at this time; the patient may opt out. Another option is the use of combination tissue expander and breast prosthesis, which remains in place once the desired amount of saline has been sequentially added. The benefit of this prosthesis is the ability to add or remove saline in case an adjustment proves necessary. The recent introduction of allografts helps to achieve better shape and fast expansion and is less painful.

Procedural Considerations. A basic plastic set may be used with the addition of fiberoptic breast retractors. Positioning is usually supine with both arms extended on armboards. Both inframammary folds are marked preoperatively, and both sides of the chest should be prepped and draped. The breast shape

FIGURE 21-15 Tissue expanders are inflatable plastic reservoirs of various shapes and volumes that are implanted under the skin. The skin over the expander is stretched during a period of several weeks as the expander is gradually filled by percutaneous injection of saline into an incorporated part of the remote-fill port. Expanders are useful for breast reconstruction.

expander is supplied in a sterile package from the manufacturer and is available in a variety of sizes. Meticulous sterile technique is required, and the expander should be handled as little as possible. This procedure may be performed immediately following mastectomy or at a later date. Drains are usually placed to prevent hematoma and seroma formation, the latter of which could cause rotation or malposition of the tissue expander. If a surgical bra is used, care must be taken that it is not too tight and does not compromise circulation to the skin flaps.

Operative Procedure

1. Skin flaps are assessed for adequate blood supply, and then the pectoralis fascia is incised along its lateral border. The surgeon creates a submuscular pocket for the temporary expander by undermining the muscle over the sternal attachments and down over the lower ribs.
2. Recently, allograft material is being used to bridge the gap created from the elevated pectoral and serratus muscles to the inframammary fold.
3. The tissue expander is tested before insertion for watertight integrity.
4. After hemostasis is achieved, the surgeon checks the expander for integrity and then inserts it into the pocket. Muscle coverage is assessed, and if adequate the reservoir is positioned subcutaneously and connected, the wound is closed, and the expander is filled with sterile saline solution until slight blanching of the skin is achieved. The amount is recorded on the patient record.

Second-Stage Tissue Expander Breast Reconstruction

Once the tissue expander has been expanded to the desired size, the patient is taken back to surgery for the next stage of her breast reconstruction. This is a relatively minor procedure in which the tissue expander is deflated and replaced with a permanent mammary prosthesis (Figures 21-16 and 21-17, *A* and *B*). At this time, if there is asymmetry of the contralateral breast, surgery may be performed to create bilateral symmetry. The patient may require correction of breast ptosis through mastopexy, with or without the addition of a breast implant; alternatively, a reduction mammoplasty may be needed on the opposite breast. This procedure is usually performed on an outpatient basis in which the patient is administered a general anesthetic.

FIGURE 21-16 While discussing options in surgeon's office, samples of tissue expanders, textured and smooth saline and silicone implants, are shown to patients for their selection.

Breast Reconstruction Using Myocutaneous Flaps

Flaps are described by the types of tissue they contain, the blood supply of the tissues, and the method by which the flaps are moved from the donor site to the recipient site. The latissimus

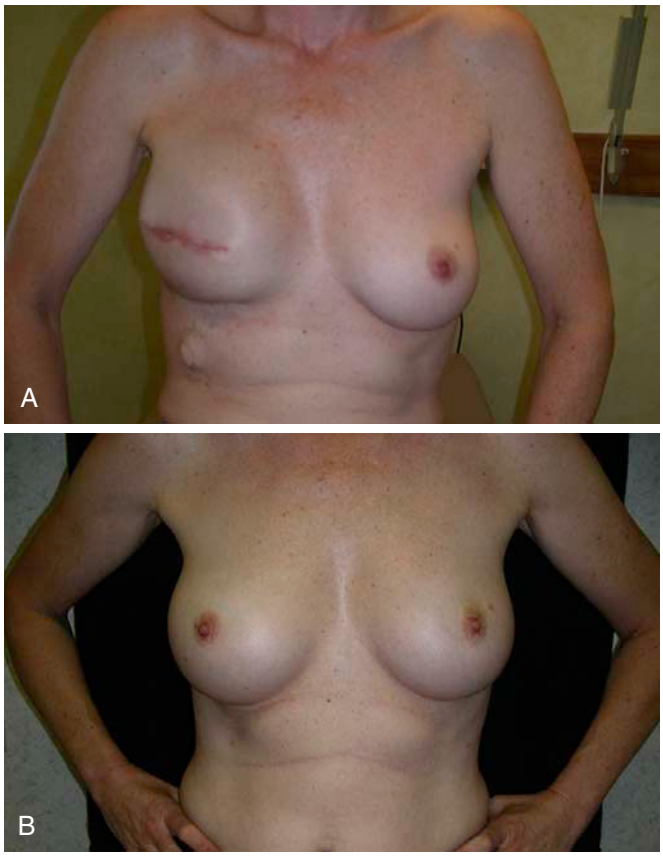

FIGURE 21-17 **A**, Tissue expander is used to create extra tissue after mastectomy so a breast mound can be created. **B**, Postoperative result after tissue expander replaced with breast prosthesis.

dorsi myocutaneous flap is used during reconstruction of the breast after mastectomy. This procedure may be staged. Because the flap consists of skin combined with muscle, it is described as *myocutaneous*. This flap is used when significant tissue deficiency occurs after a mastectomy or when abdominal flap (transverse rectus abdominis myocutaneous [TRAM]) reconstruction is not an option. The latissimus dorsi muscle is a wide, flat muscle extending over the midthoracic portion of the back and inserting into the humerus. Its blood supply comes from the thoracodorsal artery and from perforators of the upper lumbar arteries and intercostal vessels. This rich vascularity allows the surgeon flexibility in orienting and positioning the flap to the pattern of the deficit on the anterior chest wall. Latissimus dorsi flaps are usually used in conjunction with a reconstructive breast prosthesis, in order to create a more natural breast mound.

According to the U.S. Department of Labor, The Women's Health and Cancer Rights Act of 1998 (WHCRA) mandates financial coverage of all breast reconstruction related procedures. One other option is the superior gluteal artery perforator (SGAP) flap, which is becoming more refined recently. Some women choose to use their own tissue for reconstruction, as they prefer what they consider more realistic, supple breasts that would not need to be replaced or removed as is possible with implants. The SGAP flap does require microsurgical skills and is not offered at all institutions. Factors for choosing reconstructive options include the patient's size and availability of appropriate abdominal or gluteal tissue. Even very thin patients generally have enough skin and fat for the SGAP procedure, and the consistency of the buttock fat (thicker than abdominal) provides the more supple result. Positioning is especially challenging, and some operative efficiency may be achieved by using two OR beds (Edwards et al, 2009).

Procedural Considerations. The surgeon marks the donor site of the latissimus dorsi with its skin island, along with the intended recipient site, before surgery with the patient in a sitting position. In the OR, the patient is placed in a lateral position, donor side up, with the arm extended and safely supported. The perioperative nurse should assemble extra padding and positioning aids in preparation for the patient's arrival. Once the donor muscle has been mobilized and exteriorized through the area of defect, the back incision is closed and the patient repositioned supine with the arm extended on an armboard. Instrumentation should include a basic plastic instrument set, fiberoptic breast retractor, vascular instruments, sterile marking pens, suction, and long tissue forceps and scissors, and a Doppler probe should be available.

Operative Procedure

1. Initially the island of skin is incised transversely across the back, being careful to ensure that a bra or bathing suit will cover the resulting scar (Figure 21-18, *A*).
2. The surgeon frees the muscle, subcuticular fat, and fascia from the overlying skin by undermining so that part or all of the muscle may be mobilized (Figure 21-18, *B*).
3. The skin island and the muscle are then tunneled under the axilla to the chest wall (Figure 21-18, *C*). The insertion of the muscle on the humerus and accompanying blood vessels are left undisturbed. The latissimus dorsi muscle fills the space left by the missing pectoralis muscle.
4. The island of skin is oriented to the recipient site, and the surgeon sutures both into place (Figure 21-18, *D*).
5. A mammary prosthesis is placed under the muscle before suturing to reconstruct the breast mound.
6. The wound is drained by closed-wound drains.
7. The nipple-areola complex may also be reconstructed by sharing the nipple on the unaffected side or by using groin, adjacent tissue, thigh, or auricular tissue. This can be done at the time of reconstruction or at a later date as a minor procedure with the patient administered a local anesthetic (Figure 21-18, *E*).
8. If a surgical bra is used, care must be taken not to compromise blood supply to the flap.

Transverse Rectus Abdominis Myocutaneous Flap

TRAM flaps are the most common pedicle-based flaps used for breast reconstruction. The rectus muscle is the broad, wide abdominal muscle that reaches from under the ribs to the pubis, and either one or both sides of the muscle may be used for reconstruction. The blood supply (superior epigastric artery and vein) is carried within the muscle pedicle. The muscle along with its pedicle is severed at its most distal origins and pulled through a subcutaneous tunnel to the chest to form a breast. Although this procedure has the added benefit of an abdominoplasty, if there is inadequate abdominal tissue the patient may require a small mammary prosthesis.

The several types of TRAM techniques are based on blood supply, but the procedure still follows a basic format. As with

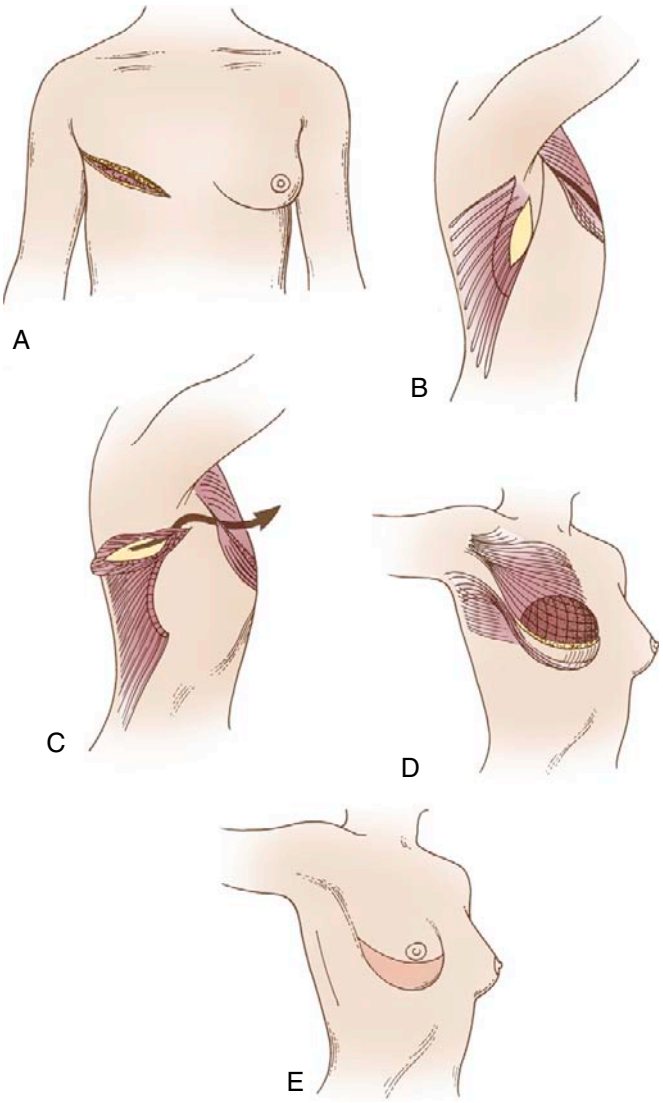

FIGURE 21-18 Latissimus dorsi flap for reconstruction after mastectomy (see text for procedure).

other types of breast reconstruction, TRAM flaps may be performed immediately following mastectomy or planned for a later stage in the patient's recuperative phase.

Procedural Considerations. The surgeon marks the surgical landmarks preoperatively with the patient in a standing position. A basic plastic instrument set is used as for the latissimus dorsi flap. The patient is positioned supine with arms extended on armboards. Positioning the patient for this procedure is particularly difficult because of the need to promote closure of the abdominal wound, support circulation to the flap, and protect the patient from injury. The OR bed is often flexed; additional padding of the lower extremities may be required. The skin prep should extend from the lower neck to midthigh.

Operative Procedure

1. The surgeon excises the skin from the mastectomy scar and makes the abdominal incision. The abdominal flap is dissected with care being taken not to shear the skin and subcutaneous tissue from its underlying muscle attachments (Figure 21-19, *A*).
2. The transverse rectus abdominis muscle is divided from its inferior-most attachment (Figure 21-19, *B*).
3. The flap is rotated and passed through to its new location on the chest wall (Figure 21-19, *C* and *D*) and sutured medially; the thinnest portion of the flap is superior and medial, and the thickest portion is inferior and lateral.
4. Because of the amount of tissue available, an implant is often unnecessary (Figure 21-19, *E*).

Free Transverse Rectus Abdominis Myocutaneous Flap

The free TRAM flap is indicated when there is concern about the absence of one or both of the rectus muscles following the procedure or when there are concerns about vascularity, either with the pedicle used in the standard TRAM flap with any other factors that may compromise vascularity of the flap. A newer technique of the free TRAM (deep inferior epigastric perforator procedure) has the advantage of not requiring the entire rectus muscle, because only a small portion of the rectus muscle that carries a segment of the deep inferior epigastric perforator vessels is needed to move with the fat and skin to its new location. It is also used when the buttock tissue (superior gluteal perforator flap) is planned to replace the absent breast or breasts.

Procedural Considerations. Care of the patient undergoing a free TRAM procedure is identical to that of patients undergoing pedicle TRAM flaps with the addition of the surgical microscope. Refer to the Procedural Considerations under Transverse Rectus Abdominis Myocutaneous Flaps (TRAM). Two surgical teams may be used, one for harvesting and one for site preparation. Meticulous attention must be paid to positioning and protection from pressure injuries because of the length of the procedure. During the preoperative verification process, the perioperative nurse should determine if the patient has made preoperative autologous blood donations and if the appropriate blood work has been performed.

Operative Procedure

1. The site is prepped, and the recipient site blood vessels are identified for anastomosis.
2. The surgeon dissects and isolates the recipient vessels.
3. Donor vessels are selected based on pedicle length, and the flap is prepared.
4. The anesthesia provider administers heparin to prevent clotting and vasospasm.
5. Once recipient vessels are ready, the surgeon severs the flap.
6. The microscope is positioned in place and draped with a sterile drape.
7. The free flap is transferred to the recipient site, and the surgeon anastomoses the blood vessels.
8. The breast mound is shaped and sutured in place.
9. The donor site is closed, covering with a skin graft if necessary.

Nipple Reconstruction

Although nipple reconstruction can be performed at the time of breast reconstruction or replacement of the tissue expander with a mammary prosthesis, some surgeons prefer to wait and let the new breast tissues "settle" and mature in order to

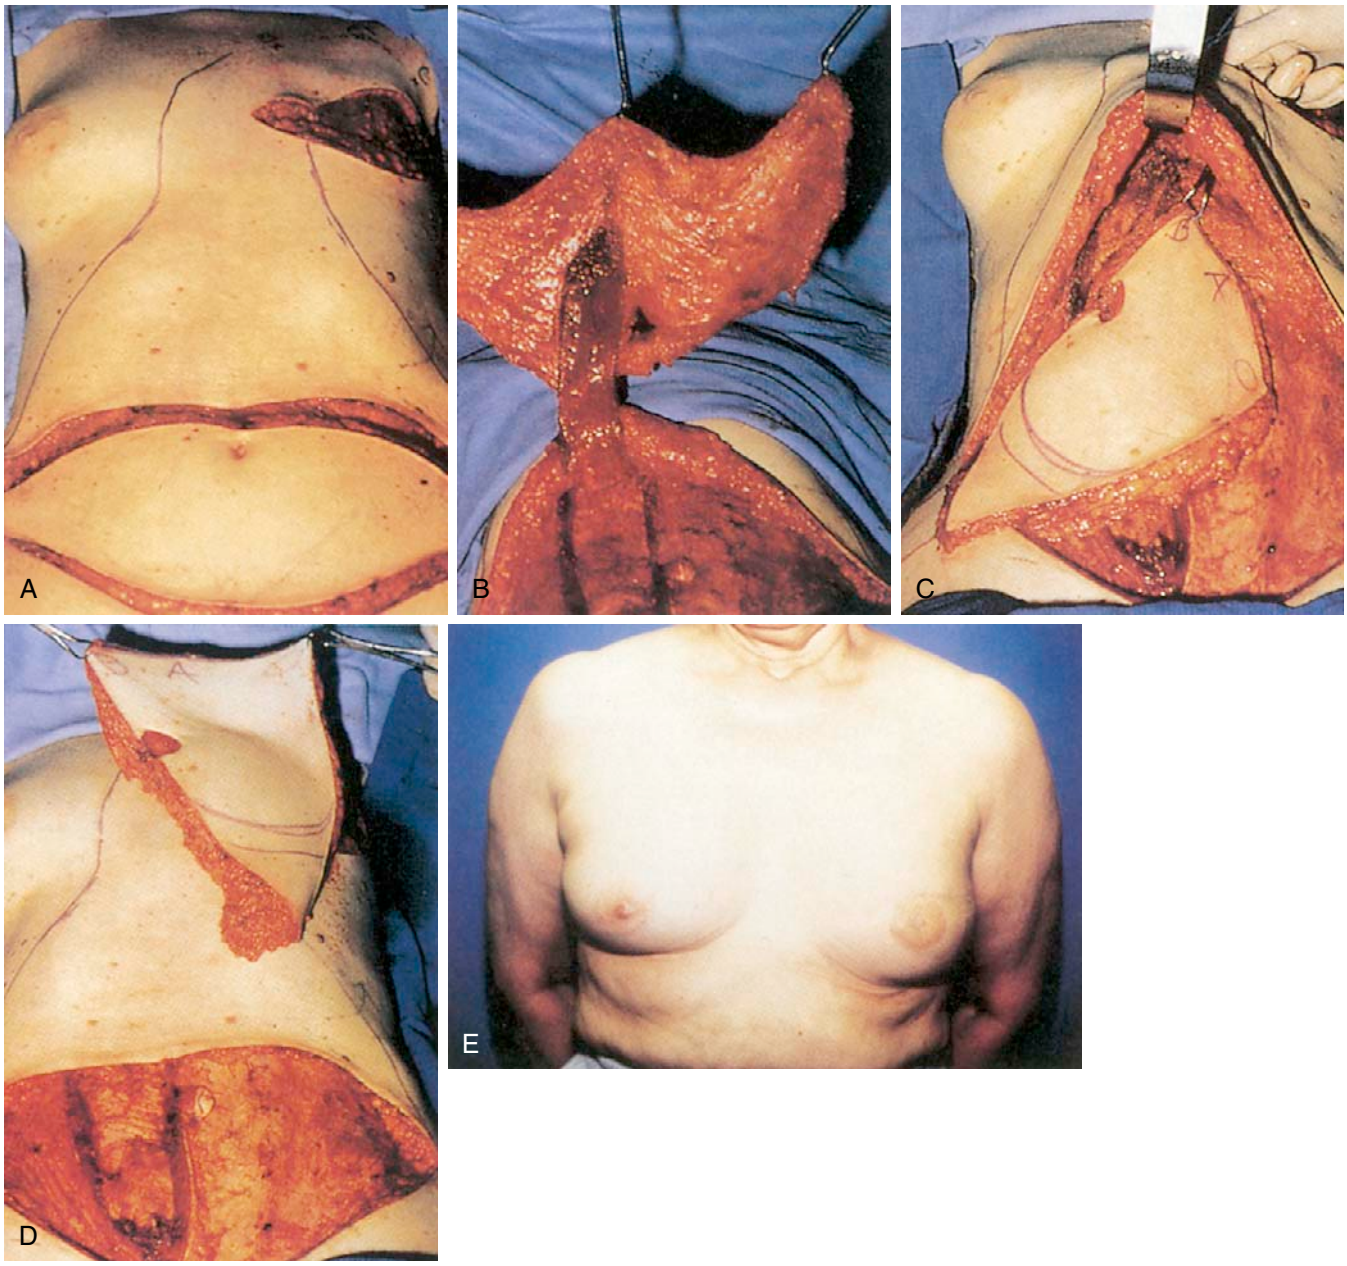

FIGURE 21-19 Transverse rectus abdominis myocutaneous (TRAM) flap for postmastectomy breast reconstruction (see text for procedure).

reconstruct the new nipple in the most accurate anatomic position. Generally this may take a minimum of 6 to 8 weeks. Tissue for the new nipple can be recruited locally by raising a flap or be grafted from the opposite nipple. The areola is reconstructed with skin grafting from the groin, buttock crease, or auricle (Figure 21-20). The areolar skin may be tattooed to create a very pleasing nipple-areolar complex (Figure 21-21, *A* and *B*).

MICROSURGERY

Microsurgery is a fundamental tool in reconstructive plastic surgery. It allows an almost unlimited choice of reconstructive methods, replacement of lost tissue with similar components, and optimal selection of donor sites with minimal morbidity (Wei and Suominen, 2006). Reconstructive microsurgical procedures include, but are not limited to, replantation of amputated body parts, repair of facial nerves, repair of lacerated nerves and blood vessels, treatment of extensive trauma to extremities and hands, reconstruction following removal of extensive cancers, and female to male transsexual reassignment. Today's physicians skilled in microsurgery can successfully anastomose the ends of a vessel measuring less than 1 mm in diameter. The surgeon's use of an operating microscope or loupes for microsurgical procedures depends on the procedure to be performed, condition of the tissue, and personal preference. Endoscopic harvesting of tissues for microsurgical grafting is possible in some circumstances. The success of microsurgery depends on several factors besides patient factors: (1) the individual

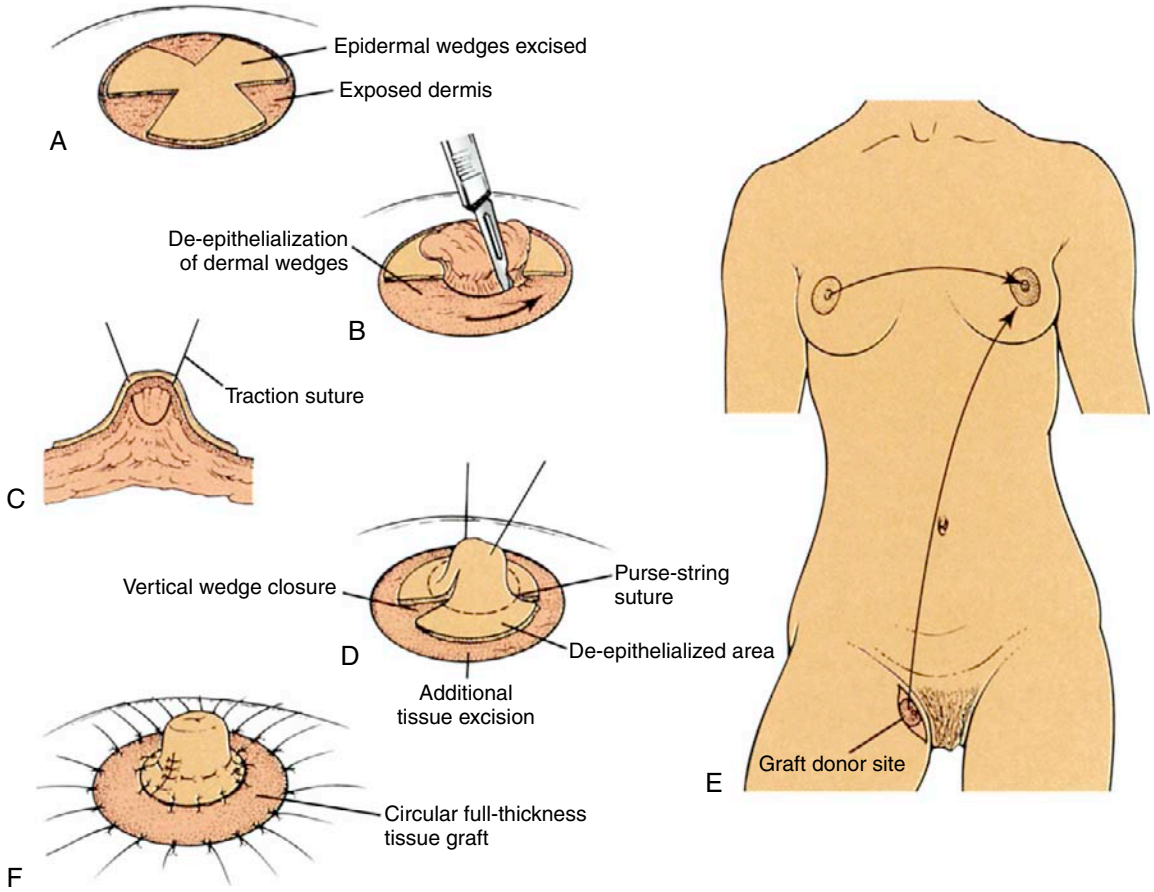

FIGURE 21-20 **A**, Circumferential demarcation of the nipple periphery with removal of dermal wedges. **B**, Dermal wedges are deepithelialized from the rim toward the center. **C**, A traction suture is used to elevate the central future nipple tip. **D**, Traction is applied to the future nipple tip as the wedges are approximated to create a permanent projected surface. A purse-string suture is placed, and excess tissue is excised. **E**, Possible full-thickness donor site areolar color match may be found in the labial folds. **F**, The donor graft is measured, cut, and secured to the dermal ring of the neonipple-areolar complex.

and collective experiences of the surgical team and the members' ability to work together, relieving each other as necessary during long operations; (2) the surgeon's knowledge of the physiology of the microcirculation; (3) many hours of practice in the laboratory by the surgical team; and (4) the availability of proper microscopes, microvascular instruments, and microvascular suture.

Replantation of Amputated Body Part

Replantation is an attempt to reattach a completely amputated digit or other body part. Revascularization is the procedure performed on incomplete amputations, when the part remains attached to the body by skin, artery, vein, or nerve. Good candidates for replantation are those with the following amputations: (1) thumb, (2) multiple digits, (3) distal portion of hand at palm level, (4) wrist or forearm, (5) elbow and above the elbow, and (6) almost any body part of a child.

The success of digital replantation depends primarily on the microsurgical repair of one digital artery and two digital veins. Replantation of an amputated part is ideally performed within 4 to 6 hours after injury, but success has been reported up to 24 hours after injury if the amputated part has been cooled. Proper care of the amputated body part or parts before surgery is vital to successful replantation. The ultimate aim of replantation is the restitution of function beyond that provided by a prosthesis.

Procedural Considerations. A regional anesthetic is usually given to replantation patients if the anticipated length of surgery permits. Because of the length of these surgeries (12 to 16 hours), positioning is important. The OR bed and armboards should be carefully padded with pressure-reducing materials to support the supine patient. The surgeon may request the room temperature increased before the patient arrives because the warm room will reduce vasoconstriction in the extremities. A warming device, such as a forced air warming blanket, is usually applied to maintain the patient's core body temperature. The surgeon usually brings the amputated part to the OR before the patient arrives to ensure ample time for preparation of the amputated part for replantation. The amputated body part should be maintained by wrapping it in saline-soaked gauze sponges, placing it in an occlusive bag, and immersing it in a container of iced saline. If radiographs of the amputated body part and amputation site have not been taken before the patient's arrival in the OR the

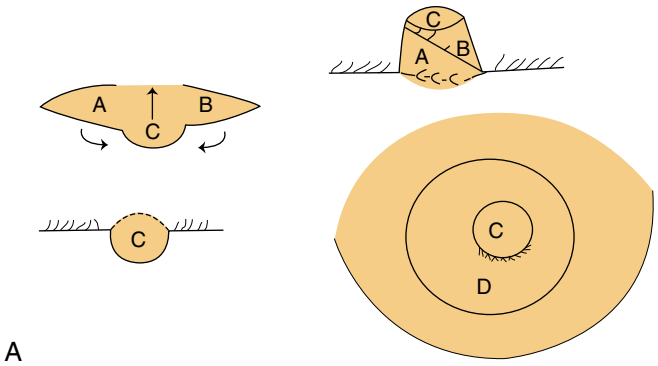

FIGURE 21-21 **A**, Breast nipple reconstruction. A and B represent wing flaps raised from side and wrapped around C; the central flap was raised superiorly. D represents areolar skin created with skin grafted either from pigmented groin skin or from opposite areolar skin by tattooing. **B**, Areolar tattoo.

perioperative nurse should arrange for these to be taken. Radiographic films are crucial to determine bone trauma and loss.

The hand drape (described later in this paragraph) can be applied to either upper or lower extremities, as required by the surgical procedure. Before a hand drape is placed, a pneumatic tourniquet cuff is often applied to the upper arm over padding. The patient is supine on the OR bed, with the affected arm extended and supported on a hand table. While an assistant holds the patient's arm with both hands around the tourniquet cuff, the skin prep solution is applied from fingertips to tourniquet cuff. Care is taken to keep the cuff dry and free of solution. Then two folded barrier sheets are used to cover the hand table. The first sheet is placed with the folded edge nearest the patient (thus forming a cuff). A double-thickness, 4-inch stockinette is used to cover the extremity, and the edge is rolled over the tourniquet. The upper arm and upper half of the body are covered by a folded sheet, with the folded edge placed across the part of the stockinette that covers the tourniquet cuff. A small, nonperforating towel clamp that grasps the edge of the folded top sheet, the stockinette, and the edge of the cuff of the bottom sheet is placed on each side of the arm. This excludes the tourniquet cuff from the sterile field. The remainder of the body is covered with one or two additional sheets. A commercially prepared extremity drape that has an aperture incorporated into the drape may also be used.

Instrumentation includes a plastic hand instrument set, microvascular instruments, a Kirschner wire driver, Kirschner wires, an operating microscope, and a bipolar ESU.

Operative Procedure

1. The surgeon shortens the bone ends to eliminate tension on vascular anastomoses to be done later; the bone is stabilized by means of internal fixation with Kirschner wires.
2. Flexor and extensor tendon repairs are usually performed next.
3. The digital nerves are repaired with the aid of loupes or the operating microscope.
4. With microsurgical instruments and techniques, two digital veins are repaired, followed by repair of one digital artery. If ischemic time has been prolonged, digital vessel repair may precede repair of tendons and nerves.
5. The skin is sutured.
6. A bulky supportive hand dressing is applied.

Toe-to-Hand Transfer

The reconstructive procedure of toe-to-hand transfer involves surgical removal of a single toe or multiple toes and anastomosis of the vessels of the toes to those on the hand to restore finger and thumb functions. It is lengthy surgery (12 to 16 hours) and entails a two-team approach; one team is at the foot for toe removal, and one team is at the recipient site—the hand.

Procedural Considerations. The patient is placed in the supine position on the OR bed. The patient is administered an anticoagulation regimen during the anastomosis procedure. Two tourniquets are needed—one on the thigh of the operative foot and one on the operative arm. Both extremities are separately prepped and draped. Instrumentation includes a plastic hand set, microvascular instruments, power Kirschner wire driver, and Kirschner wires. Additional equipment includes the operating microscope, two tourniquet power sources, two bipolar ESUs, a sterile marking pen, and an Esmarch bandage.

Operative Procedure

1. The surgeon preparing the hand determines adequate blood flow and vessel location on the thumb site (Figure 21-22, *A*). This may prevent a needless amputation of the toe.
2. Appropriate skin flaps are incised to expose the veins on the dorsum of the hand and clamped with vessel microclips.
3. The radial artery or its branches are dissected out and prepared for anastomosis.
4. The flexor and extensor pollicis longus tendons are located and transfixed.
5. The bone at the base of the thumb is prepared for the toe.
6. The nerves to the thumb are dissected out with adequate length for suturing without tension.
7. The toe is circumscribed with a racket-shaped incision (Figure 21-22, *B*), and the veins are isolated through the dorsal aspect and clamped with vessel microclips.
8. The extensor tendon is dissected proximally and transected over the base of the metatarsal.
9. The dorsalis pedis artery is dissected to the digital vessels with ligation of all branches of that vessel to prepare for the anastomosis.

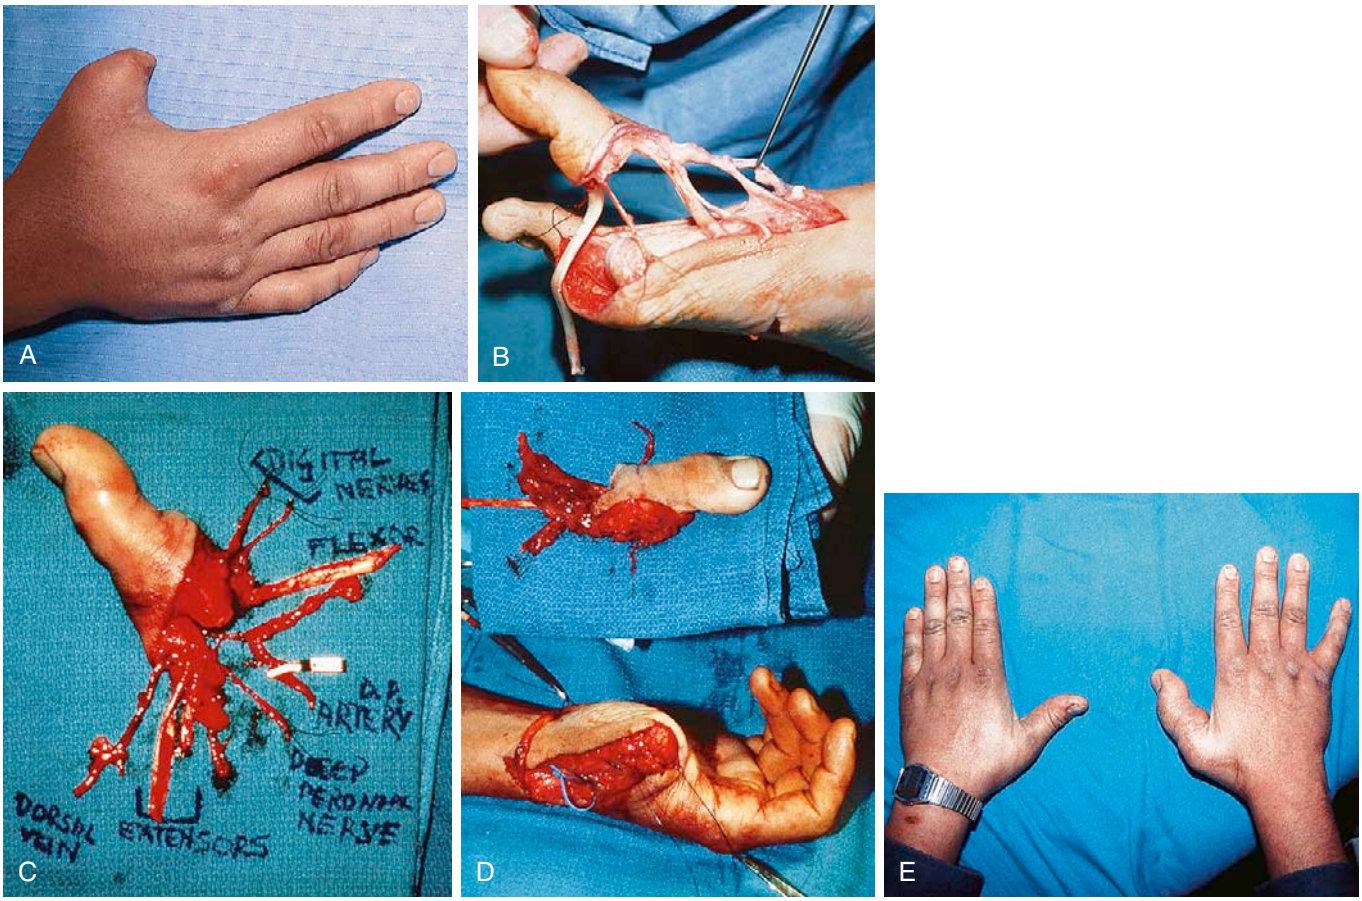

FIGURE 21-22 Toe-to-hand transfer. **A**, Preoperative appearance of hand. **B**, Harvest of toe. **C**, Identification of vessels and nerves. **D**, Transfer of toe to thumb site. **E**, Postoperative view of toe-to-thumb site transfer.

10. On the plantar surface, the digital nerves and flexor tendons are transected at levels of adequate length for anastomosis (Figure 21-22, *C*).
11. The toe is transected at the level previously determined for adequate length of the thumb.
12. The toe vessels are anastomosed microsurgically to the thumb vessels. The toe is attached to the thumb area by Kirschner wires (Figure 21-22, *D*).

An aesthetic and functionally effective hand can be achieved through this procedure (Figure 21-22, *E*).

RECONSTRUCTIVE MAXILLOFACIAL SURGERY

The need for maxillofacial surgery results from blunt or penetrating trauma, disease, or congenital anomaly. Regardless of the cause, the principles are the same: establishment of preinjury/predisease/normal anatomic dental occlusion, anatomic reduction, stabilization of the fracture, and healing for functional results (Pfiedler Enterprises, 2007). The technique and approach must be individualized to optimize the visual reduction (or reconstruction) of the procedure as well as minimize facial scarring and nerve injury, whether it be a mandibular free flap tissue and bone reconstruction or open reduction and internal fixation of any number and combination of facial fractures. In addition to midface fractures, other common facial fractures include nasal, orbital (blow-out) floor, zygomatic, and mandibular fractures.

Procedural Considerations for Maxillofacial Surgery

The perioperative nurse should ask the surgeon about the precise injuries and the expected surgical treatment plan: open or closed reduction; intraoral or extraoral approach; the order of multiple procedures; need for intraoperative x-rays; and type, number, and sizes of screws and compression plates to be placed if rigid fixation is to be employed. Orbital fractures may require alloplastic implant material. Wire is used less frequently for immobilization because of the greater degree of stability afforded by plating systems. The head should be immobilized and stabilized in a gel-type head ring; the position is almost always supine. Both eyes should be protected, and care must be taken not to displace endotracheal tubes. Instrumentation needs include a plastic surgery set, periosteal elevators, power drill for plating systems, bone hooks, Rowe disimpaction forceps (for maxillary fractures), the ESU, sterile marking pens, and suction. For application of arch bars, the nurse should assemble arch bars, wires, elastics, wire cutters, wire twisters, and dull retractors for good exposure of the teeth.

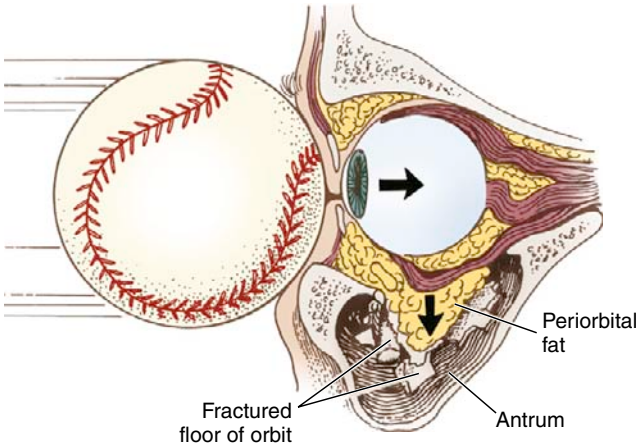

FIGURE 21-23 Ball has struck rim of orbit and has pressed orbital contents backward, displacing fragments of bone into maxillary sinus. Inferior rectus muscle is incarcerated in fracture. Inferior oblique muscle may also be involved.

Reduction of Nasal Fracture

Usually a closed reduction of the bony nasal fragments is performed by digital and instrumental manipulation. Occasionally an open reduction with interosseous wire fixation of nasal bone fragments is necessary. A nasal fracture may involve a fracture of the nasal bones or cartilage (including the septum). Closed reduction of a nasal fracture is most often performed with the patient administered topical and local anesthetics. Procedural considerations and the surgical intervention are described in Chapter 18.

Reduction of Orbital Floor Fractures

The orbital floor is the eggshell-thin bone on which the eye and periorbital tissues rest. It separates the orbit from the maxillary antrum. Orbital floor fractures usually occur in combination with fractures of the infraorbital rim (maxillary and zygomatic fractures). An isolated depressed orbital floor fracture with an intact infraorbital rim is called a *blow-out* fracture.

Fractures of the walls of the orbit may be caused by direct blows or by extension of a fracture line from adjacent bones. Isolated orbital floor, or blow-out, fractures usually occur after injury to the region of the eye by an object the size of an apple or an adult's fist (Figure 21-23). Orbital contents herniated into the maxillary sinus, and the inferior rectus or inferior oblique muscle, may become incarcerated at the fracture site. A Caldwell-Luc antrostomy may be done with reduction of the fracture from below, or the fracture site may be approached directly through the lower lid along the orbital floor; the prolapsed tissue is reduced, the orbital floor is reduced, and the orbital floor defect is bridged with bone grafts, molded metal implants, or plastic material.

Procedural Considerations. A graft set may be used for implantation of autogenous graft or synthetic graft materials of various sizes and thicknesses, along with a flexible narrow-width retractor. Interosseous wiring may be required for fractures of the frontozygomatic junction. Microplates and screws to stabilize fractures involving the fragile facial and orbital bones may also be used. A general anesthetic is usually administered.

Operative Procedure

1. The surgeon tests the maximum ocular rotation by exerting traction with a forceps on the tendon of the inferior rectus muscle to determine if the inferior muscle sling is trapped in the fracture.
2. To distribute tension over the lower lid and stretch the orbicularis muscle, the surgeon inserts a traction suture through the lower lid margin.
3. With a #3 knife handle and a #15 blade, the surgeon incises the lower lid in the lid fold above the orbital rim.
4. The skin is separated from the orbicularis muscle, and the orbital septum is identified by blunt dissection. Dissection is continued down to the periosteum of the orbital rim by means of scissors, loop retractors, elevators, and forceps.
5. The periosteum of the orbital rim is incised with a #15 blade. With periosteal elevators, the floor of the orbit is exposed and explored. When the fracture site is identified, bone spicules (needle-shaped bone fragments) are removed and the herniated contents are freed from the maxillary antrum. The contents of the orbit are elevated by means of narrow-width, flexible retractors. A 4-0 traction suture is placed around the tendon of the inferior rectus muscle.
6. An autogenous graft is taken from the iliac crest, or an alloplastic material of proper size is used to repair the bony defect. The material may or may not be anchored to the orbital rim by wire sutures.
7. The periosteum is carefully closed with 4-0 absorbable sutures.
8. The skin is closed with 6-0 nonabsorbable sutures, and a pressure dressing is applied.

Reduction of Zygomatic Fractures

Fractures of the zygoma (the cheek or malar bone) are corrected by either closed or open reduction. The two most common types of zygomatic fractures are depressed fractures of the arch and separation at or near the zygomaticofrontal, zygomaticomaxillary, and zygomaticotemporal suture lines, which constitutes a trimalar fracture. Although fractures of the zygoma can interfere with the ability to open and close the mouth properly, their chief consequence is a flattening of the cheek on the involved side, which results from a depressed trimalar or zygomatic arch fracture. Treatment is directed toward elevating the depressed fracture and maintaining the reduction. Closed reduction is the procedure used for treatment of zygomatic arch fractures, whereas most trimalar fractures are reduced by means of open reduction with internal fixation.

Procedural Considerations. A plastic instrument set, a Suraci zygoma hook-elevator, and a jaw hook are required for a closed reduction. A basic plastic instrument set, along with the following instruments and supplies, is required for an open reduction: a Hall II air drill; stainless-steel wires (#26, #28, and #30); the Suraci zygoma hook-elevator; a jaw hook; a Kerrison rongeur; two Blair retractors; the bipolar ESU; a sterile marking pen; epinephrine 1:200,000 for injection; and a miniplating rigid fixation set. The patient is placed in the supine position on the OR bed. The head drape is used.

Operative Procedure. Closed reduction is performed by elevating the depressed fracture with a percutaneous bone hook. Stabilization of a trimalar fracture may then be achieved by

inserting a transantral Kirschner wire from the fractured side to the normal side.

The technique of open reduction of a trimalar fracture is as follows:

1. Incisions are marked along the lateral area of the eyebrow and lower eyelid over the zygomaticofrontal suture line and zygomaticomaxillary suture line (infraorbital rim) fractures, respectively.
2. After injection with epinephrine 1:200,000 for hemostasis, the surgeon incises along the premarked lines down to bone, and suture lines are identified and exposed.
3. The depressed zygoma is elevated with a Kelly hemostat or periosteal elevator placed behind the body of the zygoma through the lateral eyebrow incision. Bone hooks placed percutaneously or at the fracture sites may be used instead.
4. The surgeon drills holes into bone on each side of the fracture lines. Stainless-steel wires are passed through the hole and twisted down tightly to maintain the reduction. (Reduction and stabilization of two of the three fractures are sufficient.) Alternative methods of stabilization of the fractures are interosseous wiring of the zygomaticofrontal fracture and placement of a transmural Kirschner wire or stabilization with micro/mini plates and screws.
5. Using a subcuticular technique, the surgeon closes the incisions.
6. An eye-patch dressing may be applied.

Reduction of Maxillary Fractures

Midface fractures are usually classified according to a system developed in the early 1900s by Dr. Rene Le Fort: (1) Le Fort I, or transverse maxillary, fracture—this horizontal fracture includes the nasal floor, septum, and teeth; (2) Le Fort II, or pyramidal maxillary, fracture (unilateral or bilateral)—this type often involves the nasal cavity, hard palate, and the orbital rim; and (3) Le Fort III, or craniofacial dysjunction, fracture—this type includes fractures of both zygomas and the nose (Pfiedler Enterprises, 2007) (Figure 21-24). Like a mandibular fracture, a maxillary fracture also produces malocclusion. In addition, depending on the severity of the fracture, it may produce considerable deformity of the middle of the face, usually perceived as a flattening or smashed-in appearance.

Closed reduction with intermaxillary fixation suffices for treatment of Le Fort I and some Le Fort II fractures. The more severe Le Fort II and all Le Fort III fractures require open reduction in addition to intermaxillary fixation.

Procedural Considerations. The basic plastic instrument set is required as well as an air drill; stainless-steel wires (#25, #26, and #28); Rowe maxillary forceps, right and left; a Brown fascia needle; polyethylene buttons (for suspension wire pull-through for Le Fort III repair); a small, foam-rubber pad; a sterile marking pen or methylene blue; the ESU; epinephrine 1:200,000 for injection; periosteal elevators; and a rigid fixation system. A separate Mayo setup for the application of arch bars is required, as described for reduction of mandibular fractures. The patient is placed in the supine position on the OR bed. The head drape is used.

Operative Procedure. Arch bars are applied before or after the open reduction, or they may be the only mode of treatment in closed reduction. In addition to ligating the maxillary arch bar to the teeth, it must also be suspended from stable bones superior to the fractured maxilla (which is unstable). In Le Fort I fractures, suspension may be around both zygomatic arches by passage of percutaneous wires. In Le Fort II and Le Fort III fractures, suspension wires are placed through holes drilled bilaterally into the zygomatic process of the frontal bone. This requires incisions into both lateral eyebrow areas. The following description pertains to open reduction of Le Fort II and Le Fort III fractures:

1. After injection of epinephrine 1:200,000 for hemostasis, the surgeon makes bilateral incisions to expose the infraorbital rims and zygomaticofrontal suture lines.
2. The surgeon applies Rowe maxillary forceps intranasally and intraorally to disimpact and reduce the maxilla. Holes are drilled into bone on each side of fracture lines along the infraorbital rim (and zygomaticofrontal area for Le Fort III fractures, after reducing the zygomatic fractures).
3. Stainless-steel wires are passed through these holes and twisted down tightly to maintain the reduction.
4. Suspension wires are passed from the eyebrow incisions, behind the zygomatic arches, and into the mouth with the Brown fascia needle. A pullout wire is looped through each suspension wire within the eyebrow incision, brought out through the skin near the hairline, and tied down over a polyethylene button and foam-rubber padding. Self-tapping screws, mini compression plates, and bone grafts may also be used, based on the surgeon's preference. Incisions are closed.
5. When indicated, reduction of a nasal fracture is then performed.

FIGURE 21-24 Practice skulls are provided in seminars to practice fixation techniques. See text for Le Fort classification of fractures.

FIGURE 21-25 Teeth in occlusion with arch bars in place. Tongs on arch bars will accept latex bands, which maintain occlusion for several weeks (wires around tongs are shown).

Reduction of Mandibular Fractures

The purpose of treatment for a mandibular fracture is to restore the patient's preinjury dental occlusion. With some types of fractures, a closed reduction with immobilization by means of intermaxillary fixation is sufficient for treatment. With a majority of mandibular fractures, however, an open reduction with wire fixation is necessary, plus supplemental intermaxillary fixation to achieve adequate immobilization for healing.

Intermaxillary fixation is most often accomplished when arch bars are applied to the maxillary and mandibular teeth. Stainless-steel wires (#24 or #25) are placed around the necks of the teeth and are ligated around the arch bars to hold the latter in place. Latex bands are attached to the tongs on the maxillary and mandibular arch bars to fix the teeth in occlusion (Figure 21-25). If the patient is edentulous, arch bars are attached to dentures or specially fabricated dental splints. The dentures or splints are held in place by means of wires placed around the mandible (for the mandibular arch bar) and through the nasal spine and around the zygomatic arches (for the maxillary arch bar). Scissors or wire cutters must be sent with the patient to the PACU and the postoperative patient care unit to prevent aspiration if the patient vomits or chokes.

Procedural Considerations—Open Reduction. In addition to a basic plastic instrument set, the following instruments and supplies are needed for an open reduction of a fractured mandible: a Hall II air drill, two Dingman bone-holding forceps, a nerve stimulator, a sterile marking pen, stainless-steel wires (#24, #26, and #28), the ESU, epinephrine 1:200,000 for injection, and a rigid fixation system.

For the application of arch bars or other types of interdental wiring techniques, a separate Mayo setup with the following instruments and supplies is required: a set of coil arch bars and latex bands; stainless-steel wire (#25 or #26); two Mayo-Hegar needle holders, 8 inch; a wire suture scissors, 4¾ inch; a wire twister; a Yankauer suction tube; two Wieder tongue depressors, large and small; six mosquito hemostats, curved, 5¼ inch; a Brown fascia needle (if dentures or splints are used); a Freer septal elevator; and a small drain.

If arch bars are applied before the open reduction is performed, this former setup must be kept completely separate from the instruments used for the open reduction. Because the mouth is a contaminated area, a complete change of gowns, gloves, and drapes is necessary after the intraoral procedure.

Operative Procedure

1. Arch bars may be applied before or after the open reduction.
2. A line inferior and parallel to the lower border of the mandible at the fracture site is marked, and the area is infiltrated with epinephrine 1:200,000 for hemostasis.
3. The surgeon places the incision to expose the inferior border of the mandible. The nerve stimulator may be used to aid in identification of the marginal mandibular branch of the facial nerve in fractures of the posterior body and angle of the mandible.
4. The fracture is reduced by manipulation. Holes are drilled into the mandible on each side of the fracture line with the Hall II air drill while an assistant holds the reduced fracture with the aid of Dingman bone-holding forceps.
5. Stainless-steel wire is inserted through the holes and twisted tightly to secure the fracture fragments in anatomic alignment.
6. In the event that rigid fixation is desired with the use of plates and screws, the appropriate drill bit, tap, and depth gauge are chosen. With these items, the proper-size prosthesis is placed and the fracture is approximated, aligned, and placed in anatomic position.
7. A small drain is sometimes placed into the wound, and the wound is closed in layers (periosteum, platysma muscle, and skin).
8. The latex bands may be applied to the arch bars at this time but more frequently are applied later, after the patient is fully awake and reactive.
9. A moderate compression dressing is applied to cover the submandibular wound and drain.

Elective Orthognathic Surgery

A large number of patients have either acquired or congenital facial defects that affect the maxilla, the mandible, or both. The condition of many of these patients can be improved dramatically with orthodontic care; however, many also require surgical rearrangement of the maxilla or mandible.

Procedural Considerations. Psychosocial and functional deficits are related to abnormalities of the maxilla and mandible. Surgical correction of these defects can improve patients' quality of life. Surgery is usually delayed until an adequate number of permanent teeth are in place for postoperative immobilization. Coordinated preoperative planning is of great importance to the success of these procedures.

Operative Procedure

1. Arch bars are applied for postoperative immobilization.
2. Intraoral incisions provide exposure.
3. The maxilla or mandible is cut as indicated by the preoperative workup.
4. Bone is advanced or set back to a predetermined position.
5. Bones are wired in place, with grafts placed in defects as needed.

GENDER REASSIGNMENT

Transsexualism is defined as the condition in which an individual with chromosomes and internal and external organs normal to one gender identifies psychologically and socially with attributes of the opposite gender. Reassignment of gender by means of surgery is the last step to be taken in treatment of transsexuals. It is performed only after the patient has been treated with hormones of the opposite gender, has experienced a period of cross-gender living, and has had intensive psychiatric evaluation. Most institutions performing this type of surgery have gender-identity teams who evaluate and treat transsexuals. These teams usually include a variety of professionals: psychiatrist, psychologist, endocrinologist, plastic surgeon, urologist, gynecologist, and social worker.

The surgical techniques for assignment of male to female are technically easier. A breast augmentation may be performed if hormone therapy has not sufficiently changed breast size. Construction of the neovagina includes radical penectomy, bilateral orchiectomy, urethroplasty, perineal dissection, creation of a neovaginal vault, vaginoplasty, and vulvoplasty.

The surgical technique for female to male is technically more difficult and requires multiple surgical procedures. Considerations that must be addressed are twofold: the neophallus must be constructed to (1) allow the patient to stand to void and (2) permit stimulation of a sexual partner during intercourse. This may require a radial artery forearm free flap with a later-stage surgical insertion of a penile prosthesis for attaining an erection.

AESTHETIC SURGERY

Aesthetic surgery may be performed after induction of general anesthesia, monitored anesthesia care, or local anesthesia with moderate sedation. The perioperative nurse must be qualified and prepared to monitor the patient during the procedure according to AORN recommended practices (AORN, 2009). Baseline vital signs should be recorded in the OR record. A blood pressure cuff, pulse oximeter, and cardiac monitor electrodes should be placed (with staff capable of interpreting cardiac data). IV fluids should be administered. The OR should be kept quiet and patient privacy protected. Care should be taken to avoid conversation that could be misinterpreted by the patient.

Scar Revision

Scar revision involves the rearranging or reshaping of an existing scar so that the scar is less noticeable. The simplest form of scar revision is excision of an existing scar and simple resuturing of the wound. This may improve scars that are wide.

The Z-plasty is the most widely used method of scar revision (Figure 21-26). It breaks up linear scars, rearranging them so that the central limb of the Z lies in the same direction as a natural skin line. Scars that are parallel to skin lines are less noticeable than scars that are perpendicular to skin lines. A contracted scar line can also be lengthened with a Z-plasty.

Procedural Considerations. A plastic local instrument set and a sterile marking pen are required. The procedure may be performed with the patient administered a local or general anesthetic. The patient is positioned, prepped, and draped so that the scar that is to be revised is well exposed.

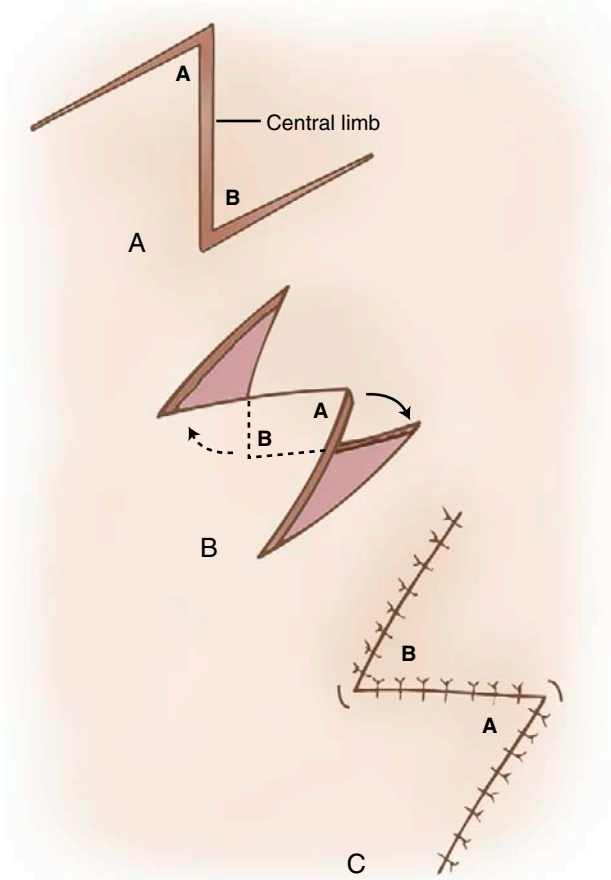

FIGURE 21-26 Z-plasty for scar revision. **A**, The central limb of the Z-plasty is over the scar that needs to be revised. **B**, Two other limbs are incised—each equal in length to the central limb and diverging from it at an equal angle. The flaps are then transposed. **C**, Flaps transposed, and original Z rotated 90 degrees and reversed.

Operative Procedure

1. The surgeon marks the pattern for the planned revision.
2. The scar is excised.
3. The surrounding tissue is undermined, and the wound edges are approximated according to the surgeon's markings.
4. Dressings may or may not be applied.

Endoscopic Brow Lift

The aging process affects the area above the eyes and brows in several ways. Loss of skin elasticity can cause the appearance of a heavy brow and emphasize hooding of the upper eyelids. Repetitive muscle action results in horizontal forehead lines and furrows as well as creases between the brows. The goal of endoscopic brow/forehead surgery is to minimize the heaviness of the brow and improve the frown lines of aging, reduce upper eyelid hooding, reposition the eyebrows if necessary, and create a more youthful, refreshed appearance of the forehead and brow area, all through multiple, short incisions in the scalp.

Procedural Considerations. Positioning the patient at the very top of the OR bed is necessary for good utilization and mobility of the endoscopic instruments. For patients with medium to long hair, the hair may be sectioned and tied with

FIGURE 21-27 **A**, Preoperative and **B**, postoperative rhytidectomy.

sterilized rubber bands to minimize interference with the planned incision. The surgeon marks the patient's incision lines and anatomic landmarks before the surgery. The entire head (scalp, face, ears, and neck) should be prepped and draped with impervious drape material. The patient's eyes may be protected with ointment and shields for the duration of the procedure; ear canals may also be protected from pooling of prep solution by using sterile cotton balls. During preparation of the room, the perioperative nurse and surgical technologist perform a check of all endoscopic equipment to ensure it is functioning properly. Endoscopic instrumentation includes elevators, scissors, clamps, needle holders, camera, and light sources. Depending on the method of fixation, screws and accompanying instrumentation may be necessary.

Operative Procedure

1. The surgeon injects a local anesthetic and places three to five small scalp incisions (one midline and one or two paramedian).
2. Using blunt dissection, the surgeon elevates the forehead skin.
3. The endoscope is placed to allow visualization of muscles, vessels, nerves, and tissues.
4. Using endoscopic instruments the surgeon dissects the corrugator and procerus muscles and soft tissues. The area is redraped to produce a smoother appearance and desired repositioning of brows.
5. Screws are placed in the outer table of the cranium at designated points, and sutures are placed through the galea and tied around screws to facilitate elevation of the brow and forehead.
6. The surgeon staples or sutures the scalp incisions for closure.

Rhytidectomy (Facelift)

As the aging process progresses, the skin of the face and neck becomes loose and redundant. This is particularly noticeable in the "jowl" areas and just beneath the chin. A facelift is performed to correct the sagging skin. A common misconception is that a facelift involves only the face. Actually, one of the most common complaints of aging is the appearance of the neck and submental skin. The typical facelift treats the face and neck and involves removal and redraping of excess skin of the face and neck once repositioning of the underlying muscle and platysma has been performed. The result is a smooth, rested appearance, without unnatural tightness or distortion of facial features (Figure 21-27). Rather than excising the redundant skin directly, incisions adjacent to or within hairlines are used so that the scars are virtually indiscernible.

Procedural Considerations. The perioperative nurse assists with positioning the patient supine with the head and shoulders slightly elevated. Attention should be given to safety by using proper positioning to prevent pressure injuries, using sequential compression devices (SCDs), maintaining normothermia, and preventing eye injuries by using shields. Depending on the complexity of the procedure and planned surgical time, the nurse may insert an indwelling urinary catheter.

Specialized scissors of varying lengths should be available, along with smooth and toothed tissue forceps and various sizes of needle holders. A fiberoptic lighted retractor is standard for facelifts. To avoid flash sterilization, contact with the surgeon or office staff should be initiated before the day of surgery to discuss special requests.

There are numerous techniques for rhytidectomy, and a well-prepared perioperative nurse will ask the surgeon about the specific technique in order to have the appropriate suture material and special needles available. The underlying superficial muscular aponeurotic system (SMAS) may be repositioned, the cheek may be elevated independently, the midface may be lifted, and there may or may not be accompanying liposuction. Facelift procedures are customized specific to the anatomic needs of the individual patient. The entire head, neck, ears, and scalp are prepped and draped.

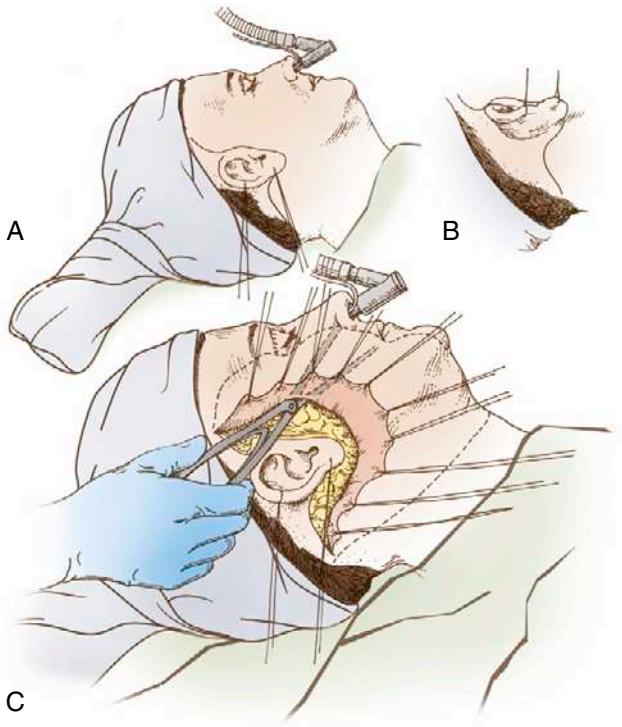

FIGURE 21-28 Rhytidectomy: line of incision and undermining. **A**, Traction sutures of 4-0 silk placed into auricle; temporal incision curved posteriorly for better support of upward pull. **B**, Incision carried under earlobe and then curved posteriorly upward and then caudad toward midline. **C**, Skin undermined almost to nasolabial fold, to area of mental foramen, and to midline of neck as far down as thyroid cartilage. Care is taken to avoid injury to submandibular branches of facial nerve and facial artery.

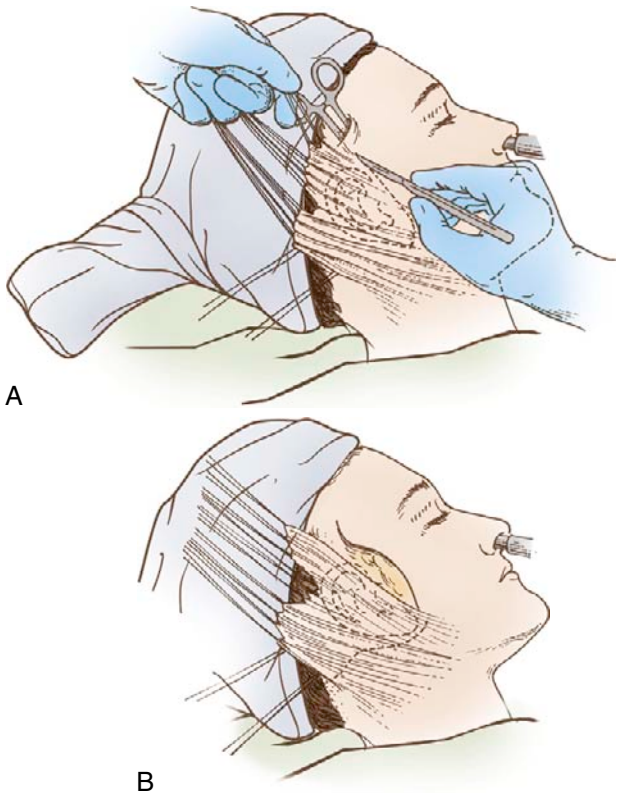

FIGURE 21-29 Rhytidectomy: removal of superfluous skin. **A**, Skin drawn upward to proper degree of tension, and incision made along posterior margin of clamp. **B**, Incision continued upward around posterior margin of auricle and then backward to excise skin specimen.

Operative Procedure

1. The surgeon marks bilateral incision lines from the temporal scalp, around the earlobe, around the posterior margin of the auricula, and into the occipital scalp (Figures 21-28 and 21-29).
2. The incision lines, both temples, cheeks, upper neck, and the submental area are injected with the local anesthetic agent.
3. The surgeon may use liposuction on the neck, jowls, or cheeks before placing the incisions.
4. After the incisions are made, the surgeon elevates the temporal and cheek skin. The SMAS is plicated cephalad and caudally, elevating and tightening the SMAS and platysma.
5. The surgeon elevates and repositions the malar pad; it is then anchored with suture.
6. The facial skin flap is then elevated in a superior and slightly posterior direction and tacked, and excess skin is trimmed at the flap edges.
7. Through a submental incision, the surgeon undermines the neck, and identifies and plicates the plastysmal bands. Excess tissue is trimmed and tacked postauricularly. Small drains are placed beneath the skin flaps and secured.
8. Incisions are closed in one or two layers.
9. A moderate pressure dressing is applied.

Blepharoplasty

The aging process causes a sagging or relaxation of eyelid skin and the orbital septum. As the latter becomes weaker, it allows periorbital fat to bulge. These changes are perceived as baggy eyelids, which give the patient a chronically tired appearance. The goal of blepharoplasty is to improve the patient's appearance by removing excess eyelid skin, removing or repositioning bulging periorbital fat, and tightening and smoothing the muscles under the eye (Figure 21-30). The upper eyelid skin can be so redundant that it encroaches on the patient's field of vision, and removal of excessive hooding of the upper eyelid skin may even improve peripheral vision. The upper eyelid crease may also be enhanced. Not all patients need removal of skin; for selected individuals, CO_2 skin resurfacing may be the procedure of choice to achieve a smoother appearance of the lower eyelid skin. Incisions in the subconjunctival mucosa of the lower lids are sometimes used for this group of patients if resection or repositioning of the periorbital fat is also indicated. Blepharoplasty is often performed with rhytidectomy. Blepharoplasty may be performed on both the upper and lower lids, upper lids only, or lower lids only.

Procedural Considerations. A plastic local instrument set is required. Delicate, short instruments are used, with special attention to scissors (curved Kaye blepharoplasty); fine

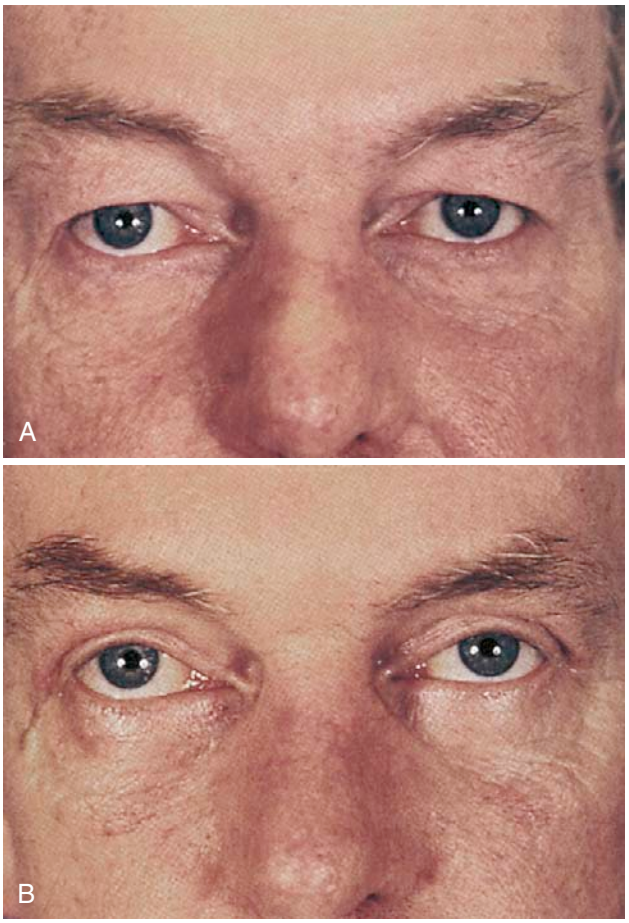

FIGURE 21-30 **A**, Preoperative and **B**, postoperative blepharoplasty.

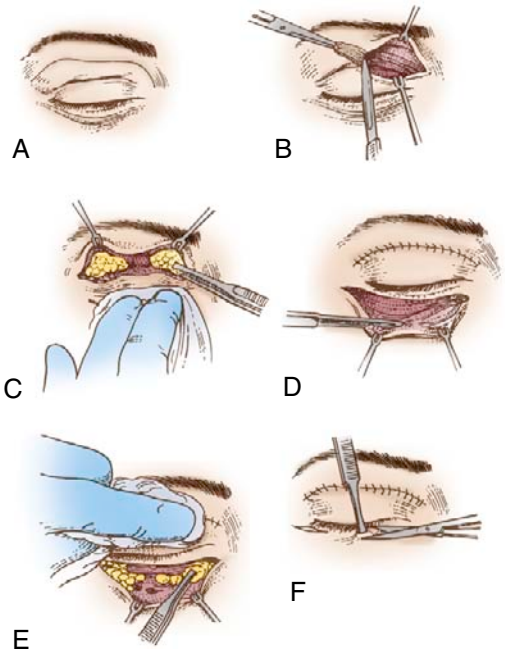

FIGURE 21-31 Blepharoplasty for baggy eyelids. **A**, Areas of proposed skin excision marked with methylene blue or a sterile marking pen. **B**, Strip of skin excised from upper lid; fat pad shining through orbital fascia and orbicular muscle of eye. **C**, Orbital fascia opened in two places (medially and laterally). Pressure on eyeball causes fat pads to bulge. They are eased out meticulously. **D**, Upper lid incision sutured with continuous 6-0 suture material of choice. Orbital muscle fibers of lower lid are separated from skin. **E**, Orbital fascia opened; fat pads bulge because of digital pressure and are teased out meticulously. **F**, Skin tailored to fit and sutured.

Adson forceps with teeth; calipers; and fixation forceps. Webster needle holders are frequently desired. A bipolar ESU unit may be used. A needle tip for the active electrode may be requested if the monopolar ESU is used. (With the monopolar ESU, a lower setting is used. The perioperative nurse should verbally repeat back the settings requested by the surgeon.) Blepharoplasty is usually performed using a local anesthetic with monitored anesthesia care. The patient is in the supine position on the OR bed. The face is prepped, and the head drape is used. Corneal shields may be used to protect the cornea.

Operative Procedure—Upper Lids

1. The surgeon marks the lines of incision and injects local anesthetic.
2. The incision is placed, and excess skin is removed. Hemostasis is obtained (Figure 21-31, *A* to *C*).
3. The surgeon trims the orbicularis oculi muscle and identifies and excises the septum orbitale. Excess periorbital fat is trimmed and coagulated.
4. Upper lid incisions are closed; and the procedure is repeated for the opposite upper lid.
5. Finely crushed ice on moist gauze 4 × 4 pads may be applied to the periorbital region; other means of reducing swelling, such as cold compresses or a mechanical cold mask, may be similarly applied. Compresses are changed as often as they become warm.

Operative Procedure—Lower Lids

1. The surgeon marks the lines of incision and injects local anesthetic.
2. A subciliary incision (1 mm below eyelashes) is made and brought out in a natural line in the outer canthal skin.
3. The skin-muscle flap is raised, leaving a 3-mm strip of muscle attached to the tarsus (Figure 21-31, *D*).
4. The skin-muscle flap is dissected down below the level of the orbital rim.
5. The surgeon incises the arcus marginalis, and redundant fat with the overlying septum orbitale is draped over the orbital rim (Figure 21-31, *E*) and sutured.
6. Hemostasis is obtained. Skin is redraped in an upward and outward fashion with attention to prevention of ectropion.
7. Excess skin is trimmed (Figure 21-31, *F*).
8. Lateral muscle is sutured to periosteum.
9. The surgeon closes the lower lid incision, and repeats the procedure for the opposite lower lid.
10. Compresses are applied as described in the upper lid procedure.

Rhinoplasty

Deformities of the external nose and nasal septum may be congenital or secondary to previous trauma. The goal of rhinoplasty is to improve the appearance of the external nose. This is accomplished by reshaping the underlying framework of the nose, which allows the overlying skin and subcutaneous

tissue to redrape over the new framework. Reshaping the nasal skeleton usually includes use of a rasp for dorsal hump reduction, partial excision of lateral and alar cartilages, shortening of the septum, and osteotomy of nasal bones. A procedure to alter the nasal septum—septoplasty, or submucous resection (SMR)—often accompanies rhinoplasty. The goal of SMR is to improve the nasal airway by resecting a segment of septal cartilage. Septoplasty reshapes the existing septal cartilage; it may aid in altering the appearance of the nose or in improving the airway. Rhinoplasty may be performed as an open procedure by making an external incision across the base of the columella, or it may be performed entirely through the nostrils by using internal incisions. Small external incisions at the alar bases are used to narrow the nostrils, and internal incisions placed alongside the base of the nasal bones are used to narrow the entire nose once the hump is removed or dorsum is incised. A full description of rhinologic procedures may be found in Chapter 18.

Laser Surgery

Several different types of lasers are commonly used in plastic and reconstructive surgery (Box 21-3). One of the most popular types of laser is the skin resurfacing, or CO_2, laser. The laser is attracted to the water in the skin cells and ablates the cells at a predetermined depth. The collagen material is also heated, resulting in smoother and slightly tighter skin. This treatment has virtually replaced dermabrasion, because it is much more consistent in terms of depth of penetration and less dependent on user technique or skill.

Tattoo removal and destruction of vascular lesions, such as facial telangiectasias, spider veins, and hemangiomas, may be achieved with the use of other types of lasers. Whether using lasers for skin resurfacing or tattoo removal procedures, the areas must first be numbed with a local anesthetic. Use of sedation depends on the anxiety level of the patient as well as the total surface area to be treated. Vascular lesions may be treated without local anesthesia, although there is some temporary discomfort with each pulse of the laser.

Procedural Considerations. Laser safety and procedures are described in great detail in Chapter 7.

Liposuction

Liposuction is a surgical technique designed to remove excess deposits of fat and improve the contour of the body (Figure 21-32). It is not a treatment for obesity or simply a weight reduction procedure; rather, the ideal candidate is of normal weight and desires to remove localized fat that has proved resistant despite diet and exercise. By extension, liposuction patients must adhere to lifestyle changes (e.g., proper nutrition, adequate exercise) to maintain optimal results (Logan and Broughton, 2008). Although most often associated with contour correction, liposuction may also be used for treatment of gynecomastia or to remove lipomas. Areas that may be suctioned include face, neck, back, breasts (not a replacement for reduction mammoplasty, only contour correction), waist, abdomen, midriff, flanks, upper arms, hips, medial and lateral thighs, knees, and ankles (Figures 21-33 and 21-34).

Multiple techniques have been developed to enhance the final results as well as ease the removal of the fat. These techniques are not always used in isolation of each other; rather, some may be combined both to achieve the best possible outcome and to address the surgeon's preferences. Each procedure has specific equipment needed for that technique and often has highly specific cannulae and other instrumentation. Since multiple areas are usually treated, the perioperative nurse should determine the sequence of liposuction the surgeon prefers to be prepared for positioning.

Procedural Considerations. Immediate preoperative preparation includes asking the patient to stand while the area of deformity is outlined. The surgeon usually draws two lines on the skin surface—one delineating the major area of defect and the other placed a short distance outside the first area. These lines make it easier for the surgeon to make a smooth transition toward the normal tissue by adjusting the amount of fat removed from the center to the periphery of the

BOX 21-3

Lasers in Plastic Surgery

Common uses for lasers in plastic surgery include exfoliation, treatment of vascular malformations, removal of hair and tattoos, and tightening of collagen fibers in aging skin. A variety of lasers are available; selection of the appropriate laser is dependent on the patient's diagnosis because the effect of the laser on the skin tissue is dependent on its wavelength. The types of lasers and their common uses are described below.

Laser	Use
CO_2	Desiccation of benign lesions of skin, skin resurfacing, cutting tissue
Excimer	Eye surgery, psoriasis
Argon	Hemangiomas, telangiectasias
Nd:YAG	Benign pigmented lesions and red tattoos
Candela dye	Tattoos, pigmented benign lesions, hemangiomas
Helium-neon	Biostimulation, wound healing alleviation, acupuncture
Diode	Hair removal, tattoo removal
Ruby	Nevi removal, dark tattoos
Erbium:YAG	Rhytides
Q-Switch	Benign pigmented lesions and dark tattoos

deformity. The patient may remain standing and be prepped circumferentially with a spray bottle of antimicrobial skin solution. The perioperative nurse provides for the patient's privacy and uses appropriate measures to protect the patient from hypothermia.

Preoperative patient education should include a discussion of the compression garment, which is typically worn for 2 to 4 weeks postoperatively. Patients should also be informed about the likelihood of the puncture sites leaking tumescent solution during the first 24 hours of the postoperative period. Absorbent dressings are required to minimize soiling of clothing and bedding during this period as well as to maintain the cleanliness of the compression garment.

Depending on the areas targeted for liposuction, draping may require a good deal of innovation. Minimal instrumentation is necessary—knife handle, towel clips, tissue forceps, scissors, clamps, and needle holder are used along with the suction cannulae specific to the proposed liposuction technique. A general anesthetic, moderate sedation, or epidural anesthetic may or may not be used. However, the surgeon

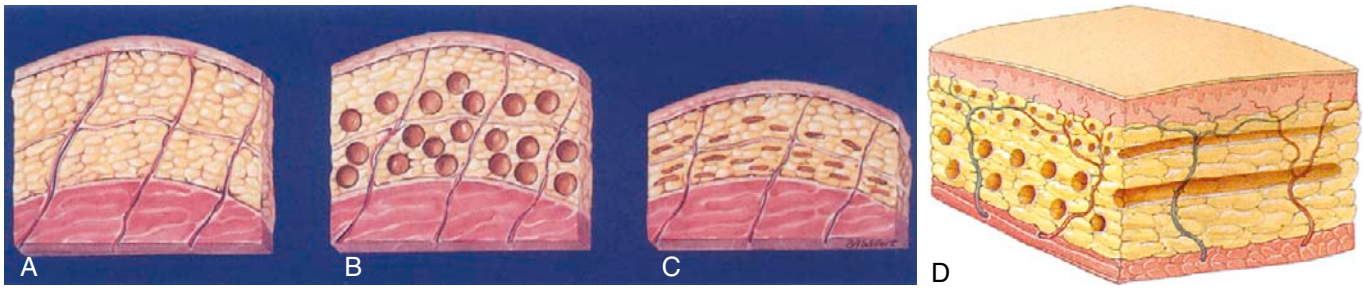

FIGURE 21-32 **A**, Normal appearance of excess fat. **B**, Removal of deep fat by larger-diameter cannulae. **C**, Corrected contour following removal of excess fat by liposuction. **D**, Removal of superficial fat involves using narrower-gauge cannulae.

typically injects a medicated solution into the fatty areas before removal because of concerns about large fluid volume shift and blood loss after lipectomy. The solution contains IV solution (e.g., lactated Ringer's), lidocaine, and epinephrine. Using more than 70 ml/kg of wetting solution for infiltration can lead to fluid overload; this may present as increased blood pressure, jugular vein distention, bounding pulses, cough, dyspnea, lung crackles, and pulmonary edema. For safety issues, the nurse needs to communicate and verify with the surgeon the total lipoaspirate and volume of wetting solution used. Additionally, it is imperative that warmed wetting solution be used for suction-assisted lipectomy (Logan and Broughton, 2008).

In the tumescent technique, large volumes of this solution are administered. The "super-wet" technique uses less solution; usually the amount of fluid injected approximates the amount of fat to be removed—thus the name, which refers to the swollen and firm ("tumesced") state of the tissues when they are filled with solution. The perioperative nurse should inquire if the surgeon will be infiltrating tumescent solution and, if so, what ingredients are used for his or her technique. Also, the nurse should ask whether the surgeon uses internal or external ultrasound (sound waves that liquefy fat) or power-assisted liposuction. One of the newer techniques is the use of Vaser-Assisted LipoSelection, which incorporates thermal energy to liquefy the fat, thus aiding greatly in its removal.

FIGURE 21-34 Submental liposuction. **A**, Preoperative. **B**, Postoperative.

Operative Procedure

1. The surgeon places stablike incisions in concealed areas to access sites to be liposuctioned.
2. Tumescent solution is infused.
3. Depending on technique, at this point either internal or external ultrasound or the Vaser technique is performed at predetermined settings and length of time.
4. Liposuction is performed with the use of various sizes and lengths of cannulae. The cannula is attached to large-bore, firm suction tubing and connected to an aspirating unit. The high vacuum pressure caused by the unit causes the fat cells to emulsify so that they can be suctioned through the vacuum opening near the rounded tip of the cannula. Areas are usually cross-suctioned to achieve the best outcomes. Stab wounds may be closed with absorbable suture or left open to drain.
5. The patient's skin is cleaned, and bulky dressings and compression garments are applied.

Abdominoplasty

Abdominoplasty is particularly useful in improving the appearance (and to a certain extent, function) of persons who have lost a great deal of weight or who suffer from laxity of abdominal skin following pregnancy. Obesity produces distention and stretching of the skin of the abdomen. Weight loss reduces the volume of the underlying fat; however, it does not produce concomitant reduction in the excess surface area of the overlying skin, which results from destruction or insufficiency of elastic fibers in the skin. The rectus abdominis fascia is also stretched in obese patients, and weight loss does not restore its integrity.

There are several versions of the abdominoplasty procedure and the choice of which technique to use depends upon the degree of deformity of the abdominal skin and muscle. All techniques are designed to improve the appearance of the abdomen by tightening the abdominal area (abdominal wall/rectus muscles) and removing excess skin or fullness.

If there is minimal to no laxity of the skin and mostly fullness of the lower abdomen, then a "mini-abdominoplasty" may be indicated. With this technique it is not necessary to relocate or incise the umbilicus and a short incision, resembling a Pfannenstiel, may be effectively utilized. However, if there is laxity of the periumbilical and upper and lower abdominal skin accompanied by protrusion of the abdominal wall with diastasis (separation) of the rectus muscle, then full abdominoplasty is the procedure of choice. This version requires relocation of the umbilicus and an incision that stretches from hip to hip. Endoscopic abdominoplasty is another option if only muscle repair (correction of the diastasis deformity or shortening of the rectus muscles) is needed.

Procedural Considerations. A basic plastic instrument set is required, as well as extra retractors and clamping instruments, an ESU, and a sterile marking pen. Frequently tumescent anesthetic solution will be added to minimize bleeding, reduce postoperative discomfort, and aid in dissection. The perioperative nurse should ask the surgeon about the use of tumescent as well as preference for ingredients. A lighted fiberoptic retractor should be available. Sequential compression devices or antiembolism hose are usually in place or applied in the OR. The patient is in the supine position with slight flexion at the hips. Draping is such that the entire abdomen, lower costal margins, upper thighs, and both anterior iliac spines are exposed.

Operative Procedure

1. The surgeon makes a low transverse abdominal incision across both inguinal areas laterally and the superior border of the mons pubis in the midline down to fascia.
2. A large flap of skin and subcutaneous tissue is elevated away from the fascia of the anterior abdominal wall.
3. The umbilicus is circumscribed and left in its normal position.
4. The surgeon elevates the abdominal flap until the xiphoid process of the sternum and the lower costal margins are reached.

FIGURE 21-35 Belt lipectomy and thigh liposuction. The patient was a 40-year-old woman 40 months after gastric bypass surgery with a weight loss of 269 pounds.

5. If diastasis of the rectus abdominis fascia is present, the surgeon plicates it with suture from the xiphoid process to the mons pubis.
6. The flap of abdominal skin and subcutaneous tissue is pulled inferiorly, and excess tissue is excised.
7. A small incision is made in the midline of the flap to accommodate the umbilicus, which is then sutured peripherally to the flap.
8. Drains are inserted, followed by closure of the lower abdominal incision in layers.
9. Postoperatively the patient is placed in the hospital bed in high-Fowler position.

Post–Bariatric Surgery Body Contouring

Successful bariatric surgery produces significant weight loss. The weight loss may result in a trunk that lacks waist and hip definition; ptosis of the mons pubis; and various degrees of skin, fat, and abdominal wall laxity. Upper and lower back rolls accompany the anterior truncal deformities; the buttocks are lower and lack fullness. Upper arms and thighs exhibit similar deformities.

Treatment is aimed at removing the excessive skin and creating a desirable body contour. Most patients are candidates for some form of circumferential recontouring (belt lipectomy) (Figure 21-35) in combination with any number of other recontouring procedures: brachioplasty (Figure 21-36), thigh lifts (Figure 21-37), and mastopexy. For the perioperative nurse, these surgeries offer a logistical challenge because of the combination of procedures and positioning required. The malabsorptive effects of the original bariatric surgery may compromise postoperative wound healing after body contouring procedures. The perioperative nurse must be familiar with the complications relating to post–bariatric surgery body contouring to provide comprehensive care for this unique group of patients.

Procedural Considerations. Any form of body contouring will begin in the preoperative area, where extensive measuring and marking are performed by the plastic surgeon. The perioperative nurse should inquire about the ordering of the procedures and positioning if more than one is planned. Sequential compression devices and a Foley catheter should be used once the patient arrives in the OR. During prepping and draping, attempts should be made to preserve the patient's body temperature. Repositioning is a standard part of these procedures. Pressure points should be well padded with appropriate positioning aids to maintain functional alignment and stable positioning. With each repositioning activity, the patient must be reassessed for safety in terms of skin and nerve compression and competence of the grounding pad, Foley catheter, and all monitoring devices (Ide et al, 2008). A basic plastic surgery instrument set with additional towel clamps is used. Other supplies include a stapler for skin approximation, multiple drains, and the ESU. The surgeon may choose to use tissue adhesive products in

FIGURE 21-36 Brachioplasty.

FIGURE 21-37 Thigh lift.

combination with suture material to reduce the incidence of seroma. Compression garments may be applied, but care must be taken not to compromise the vascularity of the skin flaps.

Operative Procedure—Belt Lipectomy

Sites addressed are the abdomen, including mons pubis, upper and lower back, lateral trunk skin, buttocks, and lateral upper thighs.

1. The surgeon infuses dilute tumescent solution to aid in hemostasis and facilitate undermining of flaps.
2. Incisions are made and taken down to the level of the fascia, and flaps are elevated to previously marked margins. Liposuction cannulae without vacuum attachments may be used for undermining.
3. Liposuction is used if indicated for contouring only.
4. Muscle plication is performed when indicated.
5. The surgeon approximates and sutures the superficial fascia with permanent sutures.
6. Skin flaps are approximated, and excess skin is excised.
7. Closed-wound suction drains are inserted and secured with suture.
8. The patient is repositioned; depending on position at the start of the procedure, this could be lateral decubitus or supine.
9. Similar techniques are used for defects in areas presented by the new position and repeated until all areas are addressed, including relocation of the umbilicus.
10. The patient is cleaned, incisions are dressed, and a garment is applied at the surgeon's preference.
11. The patient is transferred to a stretcher or bed and placed in the flexed position.

Breast Surgeries

A variety of surgical procedures are available to enhance the aesthetic appearance of the breasts. Patients may choose to enlarge, reduce, and change the position of their breasts.

Augmentation Mammoplasty. Breast augmentation is performed for correction of hypomastia, to correct breast asymmetry, and to recreate the breast after mastectomy. A prosthesis is inserted to enlarge or form the breast mound.

Breast Implants. The two basic types of breast implants are saline filled and silicone gel filled. Both are now approved by the FDA for elective breast augmentation; in November 2006 the FDA approved the use of silicone gel filled breast implants for breast augmentation and breast reconstruction and revision surgeries (Gladfelter and Murphy, 2008). Of the total breast implants performed in 2008, 53% used saline and 47% used silicone (ASPS Stats, 2009).

Implants are configured into round or teardrop (also known as anatomic) shapes and may have a smooth or textured

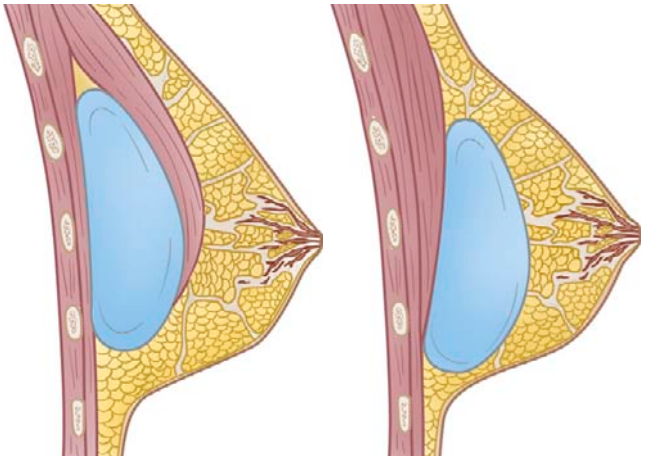

FIGURE 21-38 A, Augmentation mammoplasty implant under muscle. B, Implant under breast tissue.

surface. The surfaces are designed to minimize capsular contracture and migration. The choice to use a round or an anatomic implant is based on the shape and form of the existing breast.

PROCEDURAL CONSIDERATIONS. The perioperative nurse verifies style and size of implant and handles the implant according to the manufacturer's recommendations. Handling implants as little as possible assists in efforts to reduce the potential for implant contamination. A basic plastic instrument set is used, plus lighted fiberoptic retractors. The breast implants are packaged in sterile containers from the manufacturer and given to the scrub person when breast size is determined. Breast implants should only be filled with sterile injectable saline using a closed system designed for that purpose. The patient is supine. The arms may be extended on armboards to approximately 60 degrees. Prepping and draping are carried out in the routine manner to expose the operative site.

OPERATIVE PROCEDURE. The surgeon may perform augmentation mammoplasty through circumareolar, inframammary, axillary, or transumbilical incisions using an open or endoscopic approach. Depending on the anatomy of the patient and the surgeon's preference, breast implants may be placed subglandularly, subpectorally (Figure 21-38), or biplanar (partial muscle coverage).

OPERATIVE PROCEDURE—UNFILLED SALINE IMPLANTS

1. The surgeon may inject local anesthetic to decrease bleeding and provide analgesia.
2. An incision is made, the pocket is dissected, and hemostasis is achieved.
3. The surgeon may utilize breast implant sizers (gel or saline) to evaluate the size of the pocket and determine the size of the final implant.
4. With the sizers in place, the anesthesia provider elevates the patient to the 90-degree position so the surgeon can evaluate the appearance from various angles and plan for any adjustments or revisions to the pocket.
5. The sizers are removed, and the surgeon finalizes the pocket.
6. The perioperative nurse verifies the implant type and size again with the surgeon and dispenses it to the sterile field.
7. The surgeon rolls the implant into a cylindric shape in preparation for insertion.
8. The pocket is irrigated with saline or antibiotic solution.
9. The surgeon inserts the implant and unrolls it, and once it is properly positioned, the surgeon inflates the implant with an appropriate amount of saline.
10. The procedure is repeated for the opposite breast.
11. The incision is closed in two layers.
12. The patient is cleaned, and bandages and a surgical bra are applied.

Capsulotomy. Capsule contracture results from an exaggerated scar response to a foreign prosthetic material. All surgical implants undergo some degree of encapsulation, but clinical problems arise when this scar formation becomes excessive (Maxwell and Hartley, 2006). Depending on the extent of the contracture, an open capsulotomy may be used to release the constrictive tissue, or a capsulectomy may be indicated to actually remove the tissue (A Board Certified Plastic Surgeon Resource [ABCPSR], 2009).

PROCEDURAL CONSIDERATIONS. The patient is prepared and positioned in the same manner as for breast augmentation. Although patients receive education about capsule contracture as part of the informed consent process for breast augmentation, the actuality of the event may cause emotional distress for the patient. The patient may verbalize disappointment over the results and express fear related to additional postoperative changes in the appearance and functioning of the breast. In addition, the patient now faces the surgical and anesthetic risks associated with a second surgical procedure and may also be struggling with a possible financial burden because these procedures may not be covered by the patient's health plan. An empathetic and understanding approach is paramount to easing the patient's anxiety.

OPERATIVE PROCEDURE

1. The surgeon incises the skin and exposes the capsule.
2. The capsule is scored in multiple areas to achieve the desired release. Depending on the degree of contracture, circumferential incisions may be necessary to release the contracture.
3. If capsulotomy is not effective in releasing the capsule, a partial or full capsulectomy may be required to physically remove all or a portion of the capsule.
   a. The capsule is excised, and the breast implant is removed.
   b. The breast implant may be replaced in the same area, exchanged and replaced, or placed in a new pocket.
4. The site is irrigated with antibiotic solution. Drains are placed if a capsulectomy was performed.
5. The surgeon closes the incision in two layers.
6. The patient's skin is cleaned, and dressings are applied.

Reduction Mammoplasty. Reduction mammoplasty is indicated for the patient with macromastia with resulting back pain, intertrigo (chronic skin infection), or deep grooving in the shoulders from the bra straps because of the weight of the breasts (Patient and Family Education) (Research Highlight) (Figure 21-39, *A*). The procedure may also be performed to achieve symmetry after a mastectomy on the contralateral side. Excessive breast tissue and its overlying skin are excised, with reconstruction of the breast contour, size, shape, and symmetry (Figure 21-39, *B*).

PATIENT AND FAMILY EDUCATION

Patient Education for Breast Reduction

GENERAL INFORMATION

Women with very large, pendulous breasts (a condition known as macromastia) can experience a number of physical and emotional problems. Macromastia is generally defined as excessive breast size, usually a bra cup size of D or larger. This condition is seen in young girls to middle-aged women. The condition probably is caused by hormonal factors but is also associated with obesity. Often there is a family pattern of large breasts.

COMMON SIGNS AND SYMPTOMS

- Breast size that is out of proportion to the torso and larger than the accepted norm
- Upper back and neck pain
- Shoulder pain
- Arm pain
- Breast pain
- Rashes and sometimes infections of the skin under the breasts
- Shoulder grooving from bra straps
- Hyperpigmentation (dark marks) in the bra strap lines
- Difficulty in finding bras or clothing that fits
- Possibly shyness or other personality changes because of appearance and the effects of excessively large breasts

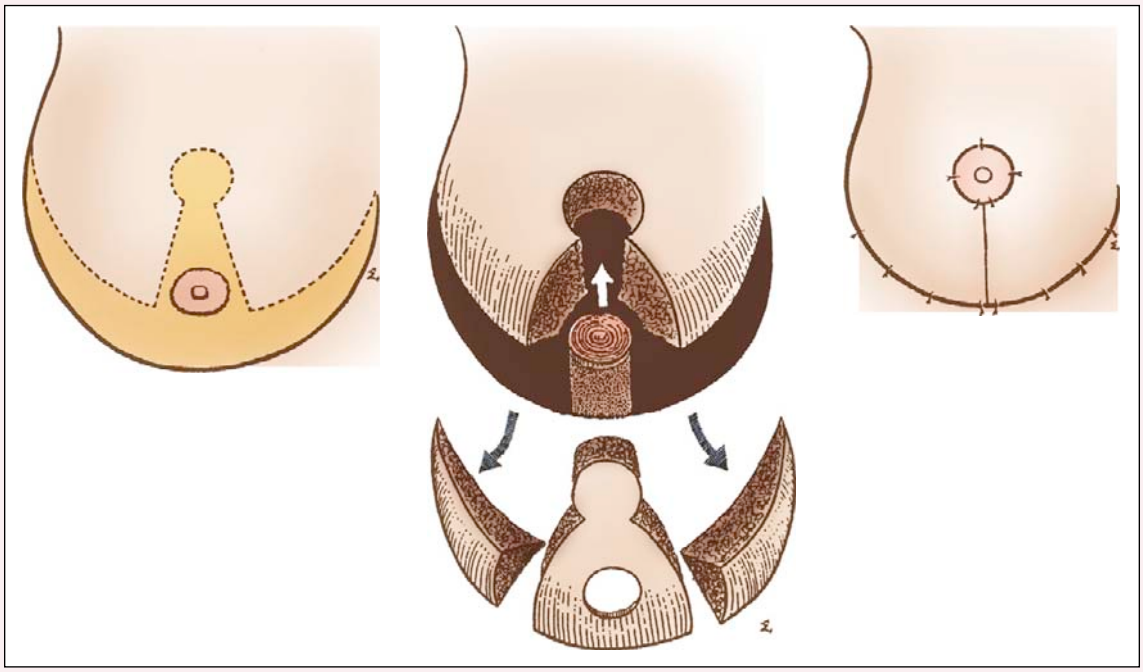
DIAGNOSIS

The surgeon will confirm the diagnosis of macromastia by examining the breasts carefully and relating the findings of the patient's history.

TREATMENT

- Women with large breasts have often tried custom bras and weight loss as a way of reducing breast size or adding support. Physical therapy and pain medications may also be used in an effort to relieve symptoms. After trying these methods without success, many women seek surgical help in the form of breast reduction surgery. Technically, breast reduction surgery is known as reduction mammoplasty.
- The best candidates for breast reduction usually have at least two of the symptoms listed in the aforementioned Common Signs and Symptoms category.
- Breast reduction surgery should be delayed if the breasts are still growing; also, if the patient is gaining or losing weight, they should consider delaying breast reduction until their weight has stabilized.
- The aims of the operation are the following:
  - To remove enough breast tissue to be able to construct a normal-appearing breast mound
  - To reposition the nipple-areola complex in a suitable position in the "new" breast

There are many operations to reduce large breasts. A common technique is shown in the figures.



PATIENT AND FAMILY EDUCATION

Patient Education for Breast Reduction—cont'd

PREPARING FOR THE OPERATION

- The surgeon will examine and measure the breasts and will probably photograph the patient for reference during the surgery and afterward.
- A mammogram may be ordered if patient is 35 years or older.
- If patient smokes, they should avoid smoking completely for at least 1 month before surgery. Smoking affects the blood vessels in the skin and can slow healing.
- The surgeon may instruct patient to avoid taking aspirin, nonsteroidal antiinflammatory drugs (ibuprofen [Motrin]), vitamin E, fenfluramine, or phentermine at least 2 weeks before surgery. These substances may interfere with normal blood clotting or with the ability to heal after surgery.
- Before surgery patient may want to do the following:
  - Wash hair (will not be able to shower or bathe immediately after surgery).
  - Arrange for temporary care for any house pets that may jump on him.
  - Move "daily use" items within arm's reach.
  - Fill any prescriptions from the surgeon.
- Following are common after this operation:
  - The sensation in the nipples probably will be decreased.
  - Patient may not be able to breastfeed.
  - Reading the mammogram may become more difficult for the physician because of the scarring inside the breast.
  - The scars from the operation may be prominent.
- On the day of the operation, the places where the incisions will be made on the breasts and the new position of the nipple-areola complex will be marked with dissolving ink while patient is in a sitting position.
- Patient may be given medicine that will make them feel drowsy before they are brought to the OR.

THE OPERATION

- Most women have general anesthesia (going to sleep) for breast reduction. Some surgeons may perform the procedure with a local anesthetic and sedation.
- The operation generally takes 3 to 4 hours.

AFTER YOUR OPERATION

- Patient will be taken to a recovery room and observed. When blood pressure, pulse, and breathing are stable, they will be taken to a regular hospital room.
- Patient will be wrapped in elastic bandages or a surgical bra over gauze. Small plastic tubes will be coming from the breast incisions and will be connected to small plastic bulbs. They drain any extra fluid that needs to come out.
- Many breast reduction surgeries are done as outpatient procedures, in which case the patient will go home after they wake up from the anesthesia and the pain is under good control. In some cases they may stay in the hospital after surgery for a short period (1 or 2 days).
- Recovery is different for every patient, but bed rest may only be needed for 1 or 2 days after the procedure. Even in the first 24 to 48 hours after surgery it is important for them to get out of bed and walk around every 2 hours during the day and early evening. Continuous bed rest after surgery may increase your risks for pneumonia or blood clots.
- As with any operation, complications are always possible. With this type of operation, they can include bleeding, infection, delayed wound healing, abnormal scarring, and shape irregularities.

HOME CARE

Patient will want to take it easy at first, but may walk about as they wish, even climb stairs, but should not overdo things. Avoid heavy exercise, heavy lifting, or stress on the upper body for 1 month. Items that can be helpful as you recover include the following:

- A body or sitting support pillow
- Cordless phone
- Variety of easy-to-cook or precooked meals
- Two or three loose-fitting robes or housedresses with snaps in the front and large pockets
- Slip-on shoes
- Soft sponge for bathing before showering is allowed
- Small containers for drinks (gallon containers are very heavy)
- A listing of physicians, pharmacy, and caregivers/helpers with telephone contact information. The patient should call the surgeon if any of the following occurs:
  - The incisions become red or swollen, or there is drainage from them.
  - The patient develops a temperature higher than 37.8° C (100° F).
  - The patient has any questions.

Modified from *Consumer's guide to breast reduction,* available at www.plasticsurgery.org/Patients_and_Consumers/Procedures/Reconstructive_Procedures/Breast_Reduction/Consumers_Guide_to_Breast_Reduction.html. RESEARCH HIGHLIGHT

A Phenomenologic Study in Breast Reduction Patients

Researchers explored women's perception of life after breast reduction surgery in an effort to understand subjective issues for these patients. A limitation of this study was the use of a small convenience sample of nine patients interviewed at follow-up visits; in addition, one of the researchers was a novice in this field. However, the data collected gave a qualitative aspect to an event that had been studied for surgical technique or physical symptoms. The study intended to gather detailed, descriptive information to reflect women's experiences after this surgery.

After obtaining informed consent data were collected in a private exam room in the office. Open-ended questions were asked, such as "What is life like following your breast reduction?" Prompts (e.g., "tell me more") were also used in an unstructured interview. Field notes were taken and interviews audiotaped for later analysis.

Findings revealed the following themes; explanations through patient quotes were listed in the article:

- Enhanced physical health
- Improved body image
- Increased self-esteem
- Increased self-confidence
- Dissatisfaction with the postoperative recovery period/though pleased overall with above aspects (this may be due to method, in that patients requiring follow-up care 5 months to 3 years after surgery may have more issues than a typical patient)

Implications for nursing and future research emphasize the need for adequate patient education for realistic expectations. As patient advocates, nurses should encourage communication with the plastic surgery team to facilitate referral for possible breast reduction surgery when patients verbalize issues commonly seen with breast hypertrophy. Nurses working in plastic surgery should ensure preoperative education includes important surgical and postoperative findings based on the evidence. Future research includes determining whether patients are receiving adequate information prospectively to have realistic expectations following surgery. Understanding the rationale for postoperative difficulties or for the extended time in making the decision to have breast reduction surgery could lead to new nursing interventions. Finally, this research should be replicated in patients who did not need to return to the plastic surgeon's office following the routine 90-day postoperative period.

Modified from Woodman R, Radzyminski S: Women's perception of life following breast reduction: a phenomenological study, *Plast Surg Nurs* 27(2): 85-95, 2007.

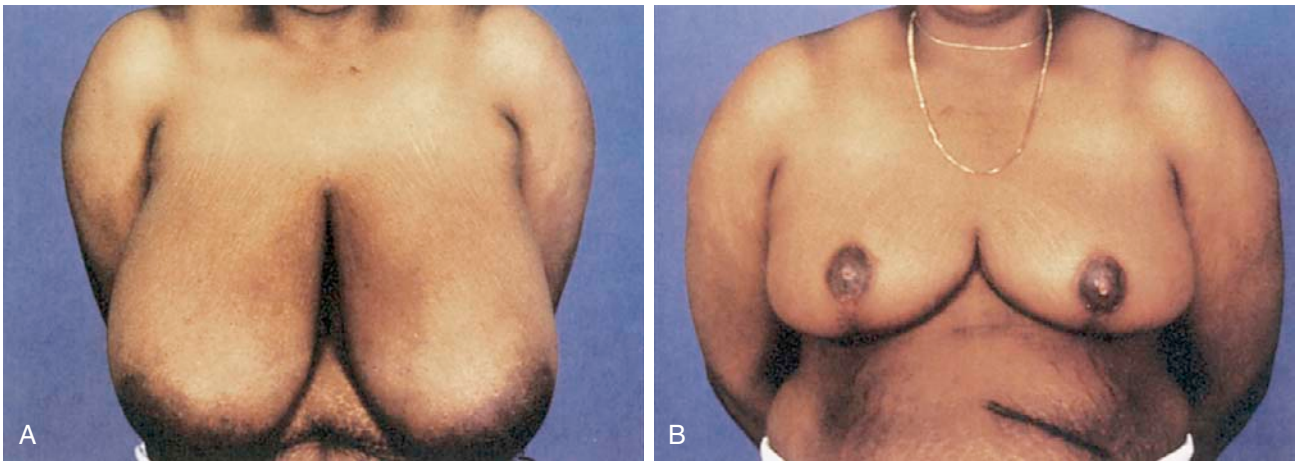

FIGURE 21-39 A, Preoperative view of reduction mammoplasty. B, Postoperative view.

PROCEDURAL CONSIDERATIONS. A basic plastic instrument set is used with the addition of a "cookie cutter" areola marker or a "keyhole" pattern marker, a sterile marking pen, skin stapler, tape measure, baby Deaver retractors, and two closed-wound suction systems. The ESU and a scale for weighing specimens should also be available, and tissue from each side should be carefully weighed and marked appropriately. The perioperative nurse should ensure the scale is calibrated correctly before weighing any tissue. Numerous blades will be used if deepithelializing breast skin. If the nipple is removed and placed as a free nipple graft, extra suture will be necessary for tie-over bolsters. There are numerous choices in the reduction mammoplasty technique; therefore before opening suture or other supplies, the perioperative nurse should ask the surgeon which technique will be employed. The surgeon will mark the skin to be excised and the new site for the nipple preoperatively with the patient in a sitting position.

The patient is supine with arms slightly extended on padded armboards. The hips should be positioned at the break in the OR bed so that the patient may be raised to a sitting position if necessary. Standard prepping and draping are done. Care should be taken not to remove the preoperative markings.

OPERATIVE PROCEDURE. The standard reduction mammoplasty procedure is described below. If the surgeon is using the "short scar" technique, the breast tissue is incised and removed according to the technique chosen. The nipple pedicle technique, wherein the nipple is mobilized and secured in a new position, may be chosen, or a free nipple graft may be utilized.

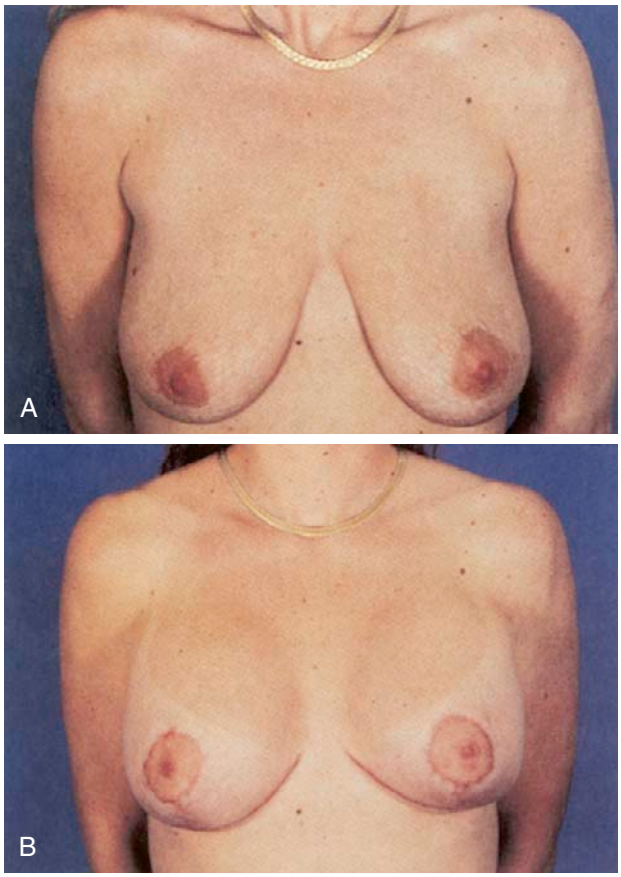

FIGURE 21-40 Mastopexy. **A**, Preoperative view. **B**, Postoperative view; ptosis corrected.

1. The surgeon incises and removes the skin between the new and the old nipple sites, with the nipple remaining attached to the underlying breast tissue. On patients with very large breasts, the nipples are removed and then reapplied as free grafts when the reduction is complete.
2. The redundant segment of breast tissue inferior to the nipple is excised through an inverted-T incision. Tissue from each breast is weighed and kept separate.
3. The surgeon mobilizes the nipple and adjacent tissue and sutures them in place.
4. The medial and lateral skin edges are approximated in a vertical suture line inferior to the nipple.
5. The inframammary elliptic incision is trimmed and closed transversely. Closed-wound suction catheters may be placed. The wound is dressed.

Mastopexy. Breast ptosis is corrected by moving the nipple to a more normal position and removing excess breast skin (Figure 21-40). With mastopexy surgery there is usually minimal to no removal of breast tissue, although it may be necessary to add a breast implant to achieve the desired result.

PROCEDURAL CONSIDERATIONS. The surgeon will mark the patient before surgery. Positioning is similar to that used for breast augmentation. Skin incision choices are periareolar only; periareolar combined with a vertical (known as a short scar or vertical mastopexy); the classic inverted T, which adds an inframammary incision to the previous incision; or the horizontal inframammary, which combines the periareolar and inframammary, leaving out the vertical component. Mastopexy may involve reduction of the skin envelope only or combine skin removal with glandular reshaping and placement in a more desirable position.

OPERATIVE PROCEDURE

1. Incisions are placed; one or more of the following techniques are used:
   a. Excess skin is removed.
   b. The breast cone is reshaped by invagination of lower midbreast tissue.
   c. The lower submammary breast tissue pedicle is advanced below the breast tissue and tacked superiorly to the pectoral muscle.
   d. Lower midbreast tissue is incised and overlapped.
   e. A superiorly based (on the nipple-areolar complex pedicle) wedge tissue flap is created, turned under, and superiorly attached.
   f. The upper pole of breast tissue is mobilized and advanced superiorly and tacked to the pectoral muscle fascia.
2. The breast may be sutured entirely at this time or approximated, and the same procedure is applied to the opposite breast, closing both at the end of the procedure.
3. The operative area is cleaned, dressings of choice are applied, and a surgical bra is applied.

Excision of Gynecomastia. Gynecomastia is a relatively common pathologic condition that consists of bilateral or unilateral enlargement of the male breast. It occurs primarily during puberty or after the age of 40 years. Although it may be produced by a variety of diseases or be the result of side effects related to certain medications, it is usually related to excessive hormone production or alterations in hormonal balance. It may also be seen in elderly men and in men after excessive use of marijuana. All subareolar fibroglandular tissue is removed, and the resultant defect is surgically closed (Figure 21-41). The patient may be positioned in a supine position or semi-Fowler position, according to the surgeon's preference. Supplies and equipment needed are the same as those for a simple mastectomy, plus a basic plastic instrument set. Because suction-assisted lipectomy (SAL) may be used for contouring, suction cannulae, associated supplies, and an aspirator should also be available. All breast tissue removed should be weighed and then sent for pathologic examination. Although infrequent, men are not immune from breast cancer.

OPERATIVE PROCEDURE

1. The surgeon instills local anesthetic and makes a stab wound incision for introduction of the liposuction cannula.
2. Liposuction is performed. If satisfactory removal of breast tissue is accomplished, the incision is closed and a compression garment applied.
3. If additional surgery is required, the surgeon makes a periareolar incision. Through this incision, the fibrous and ductal attachments of the underlying glandular tissue to the nipple are divided.
4. A cuff of fatty tissue is left attached to the underlying nipple surface to protect the blood supply.
5. The breast tissue mass is dissected. Carrying the dissection to the pectoralis fascia is usually necessary to remove the entire mass.
6. Hemostasis is achieved.
7. Closure is performed, the area cleaned, and a compression garment applied.

CHAPTER 22

Thoracic Surgery

BRIAN BLANCHARD

Thoracic surgery, like other specialties, has evolved with the development of surgical techniques and treatments, such as blood transfusion, anesthetic delivery, and screening procedures. During the past 50 years the understanding of pathophysiology and improved techniques have expanded the field of thoracic surgery. The thoracic specialty extends beyond the surgical arena into infectious disease, trauma, and oncology. Improved technology and the determination to treat diseases previously considered untreatable with operative and other invasive procedures continue to improve the recovery rate for patients experiencing thoracic diseases. As the ability to treat thoracic disease has improved, the responsibilities of the perioperative nurse have expanded, resulting in accomplishments throughout the years that have provided an extensive knowledge base and specialized perioperative practitioners.

Surgical Anatomy

The skeletal framework of the thorax is formed anteriorly by the sternum and costal cartilages, laterally by the 12 pairs of ribs, and posteriorly by the 12 thoracic vertebrae (Figure 22-1). This airtight compartment is enclosed in the root of the neck by Sibson's fascia and is separated from the abdomen by the diaphragm.

The sternum forms the anterior thoracic wall in the midline. It consists of three parts: (1) the upper part, or manubrium; (2) the body, or gladiolus; and (3) the lower cartilage, or xiphoid process. The manubrium articulates with the clavicles and the first two ribs on each side; the gladiolus articulates with the remaining true ribs by separate costal cartilages; and the xiphoid fuses with the gladiolus in early development and is attached to the diaphragm by the substernal ligament.

Normally the lateral walls of the thorax are formed by the 12 pairs of ribs. Posteriorly, each pair of ribs articulates with its corresponding thoracic vertebrae. Anteriorly, the first seven ribs articulate with the sternum. The eighth, ninth, and tenth ribs articulate with the costal cartilages of the rib above; however, the eleventh and twelfth ribs are not fixed to the costal arch (see Figure 22-1).

The muscles of each hemithorax (Figures 22-2 and 22-3) include the 11 external and 11 internal intercostal muscles, which fill the spaces between the ribs. An intercostal artery, vein, and nerve accompany each intercostal muscle. The arteries communicate with the internal thoracic artery anteriorly and arise from the aorta posteriorly. The intercostal veins follow the course of the arteries and communicate with the mammary veins anteriorly and with the azygos and hemiazygos veins posteriorly.

During surgery, great care is taken to prevent injury to the intercostal nerve, which passes forward and alongside the posterior intercostal artery and shares with the superior branch of the artery the intercostal groove on the inferior edge of the corresponding rib. When the nerve must be disturbed, an anesthetic agent may be injected to prevent postoperative pain.

The thoracic outlet is a junction bound anteriorly by the manubrium, anterolaterally by the first ribs, and posteriorly by the first thoracic vertebrae and posterior angles of the first ribs of the space. The great vessels of the head, neck, and arm pass through this space. Compression of these structures causes thoracic outlet syndrome.

The mediastinum is divided into anterior, middle, and posterior compartments. The anterior mediastinum is bound anteriorly by the sternum and posteriorly by the pericardium and great vessels. It contains the thymus gland, lymph nodes, and pericardial fat. The middle mediastinum is bound anteriorly by the pericardium and great vessels and posteriorly by the anterior border of the vertebral bodies. The posterior mediastinum is bound anteriorly by the vertebral bodies and extends posteriorly to the chest wall.

The chest cavity is subdivided into the right and the left pleural cavities, which contain the lungs separated by the mediastinum, which lies medially between the two pleural membranes. The parietal pleura, the membrane that lines the inner surface of each hemithorax, is adjacent to the inner surfaces of the ribs posteriorly and the mediastinum medially and covers the surface of the diaphragm except at the central portion. Part of the parietal membrane is reflected back at the root of each lung to form a sac around it. This reflection is called the *visceral pleura.* The pleural space holds about 50 ml of pleural fluid, a serous secretion that provides lubrication between these two membranes to minimize friction during inspiration and expiration (Coughlin and Parchinsky, 2006).

The lungs are the essential organs of respiration. The base of each lung rests on the diaphragm, whereas its apex (upper end) projects into the base of the neck at a level above the first rib. The bronchus, the nerves, the lymphatics, and the pulmonary and bronchial vessels enter and leave the lung on the mediastinal surface in a structure known as the *hilum,* or *root,* of the lung. Deep fissures divide the spongy, porous lung into lobes. The primary bronchi divide and then subdivide into each lobe and eventually become bronchioles. The right lung has an upper, a middle, and a lower lobe; the left lung has only an upper and a lower lobe (Figure 22-4). However, the lungs are similar in that each is composed of 10 major segments

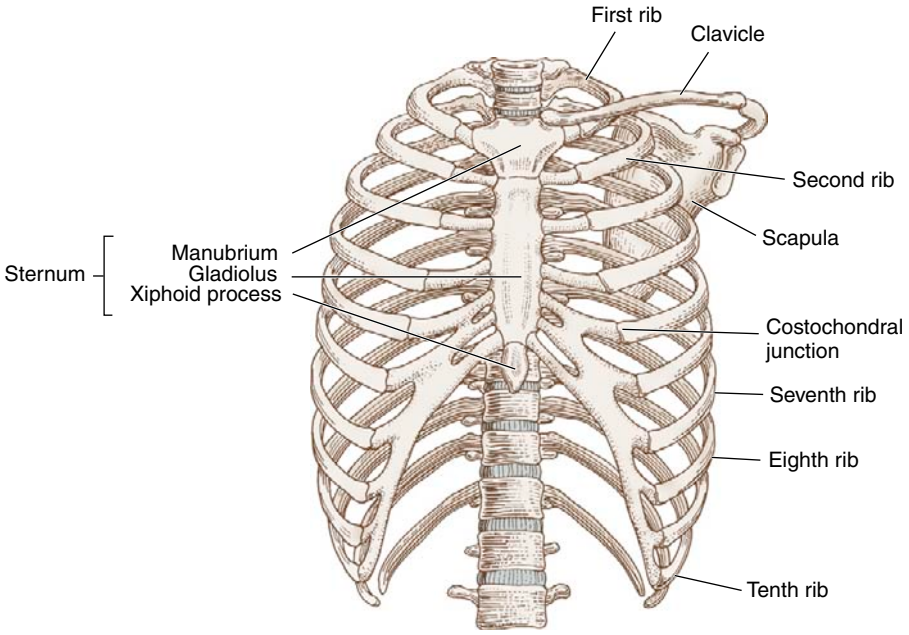

FIGURE 22-1 Bony thorax.

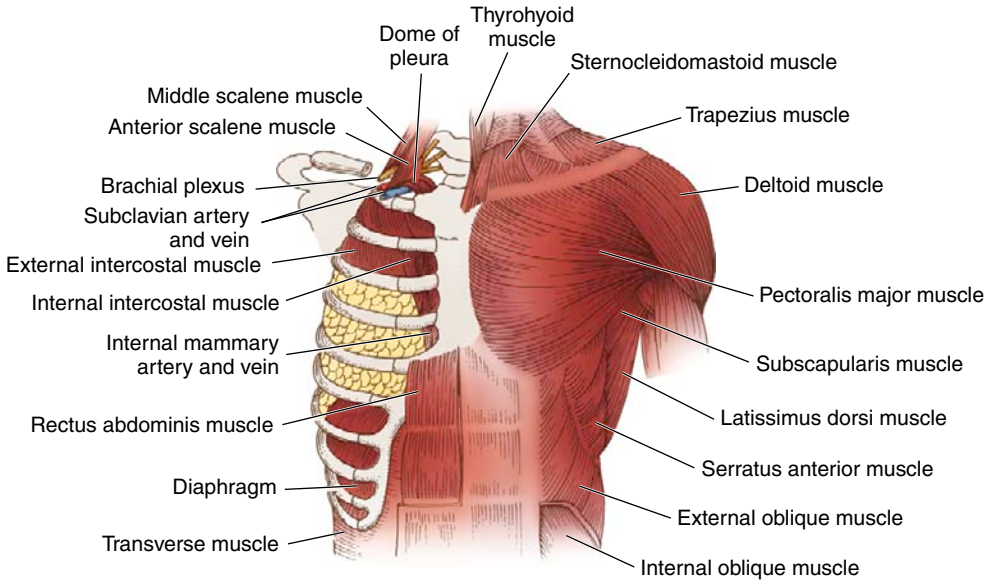

FIGURE 22-2 Anterior view of thorax and contiguous portions of base of neck and anterior abdominal wall. *Right half,* Superficial layer of muscles and fascia; *left half,* relations of deep muscles of neck and abdomen to rib cage, intercostal muscles, diaphragm, and internal mammary vessels; relations of muscles, nerves, and vessels with first rib; and anterior relations of lung.

(Figure 22-5). Each segment extends to the pleural surface, expanding in volume from its center to its peripheral edges. Each segment also has its own bronchus and branches of the pulmonary artery and vein.

The bronchial arteries, arising from the aorta, supply nourishment to the lungs. They vary in their number and course. The arrangement may include two branches to the left lung and one branch to the right lung, which later branches into two, or there may be one or two branches for each lung. The pulmonary arteries carry the blood to the pulmonary parenchyma, and the pulmonary veins transport the oxygenated blood to the left atrium.

The nerves of the lungs are a part of the autonomic nervous system (see Chapter 20). They regulate constriction and relaxation of the bronchi and of the blood vessels within the lungs.

Although the thoracic cavity is an airtight space, the lungs receive outside air through the nasal passages, trachea, and bronchi. The main function of the lungs is to exchange carbon dioxide for oxygen. Normally, as the thorax expands, the lungs also expand as air is drawn in; during expiration, the

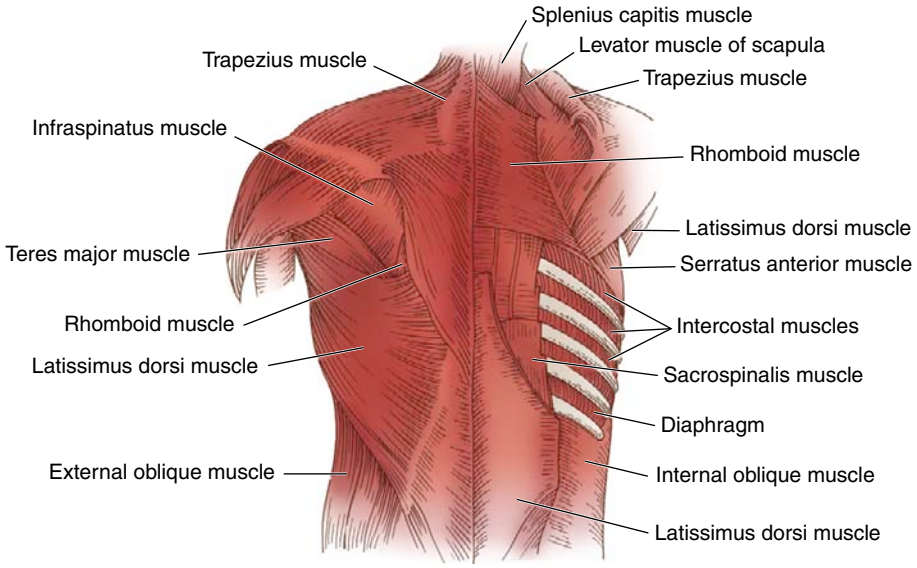

FIGURE 22-3 Posterior view of thorax and contiguous portions of neck and abdominal wall. *Left half,* Superficial muscles; *right half,* deeper muscles.

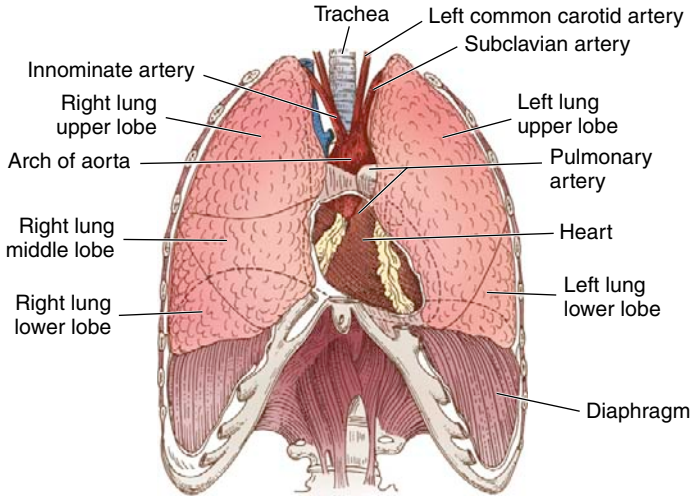

FIGURE 22-4 Organs of thoracic cavity. Part of pericardium has been removed to expose heart.

thorax relaxes and the lungs passively contract as air is forced out. Inspiration normally takes place when the intrathoracic pressure is slightly below atmospheric pressure (76 cm Hg, or 760 mm Hg) and when a partial vacuum exists between the parietal and visceral pleural (intrathoracic) surfaces. As the muscles of inspiration contract to enlarge the chest cage, the lungs passively follow the diaphragm and chest wall because of decreased intrathoracic pressure. The acts of inspiration and expiration are the result of air moving in and out of the lung, causing pressure to equalize with that of the atmosphere at the end of expiration.

The normal intrapleural pressure varies from –9 to –12 cm H_2O during inspiration and from about –3 to –6 cm H_2O during expiration. The greatest amount of air that can be expired after a maximum inspiration is termed the *vital capacity,* and the volume of gas remaining in the lungs after maximal expiration is *residual volume.* Size, age, gender, and pulmonary disease of the patient influence vital capacity. Any condition that interferes with the normally negative intrapleural pressure affects respiratory function.

Perioperative Nursing Considerations

Assessment

During assessment, the perioperative nurse gathers information that is important to planning patient care. Signs and symptoms demonstrated by the patient are confirmed by the perioperative nurse during the admission assessment. The nurse may begin data collection by identifying the patient (Patient Safety) and confirming the correct surgical site. A thorough review of the patient's medical record, including

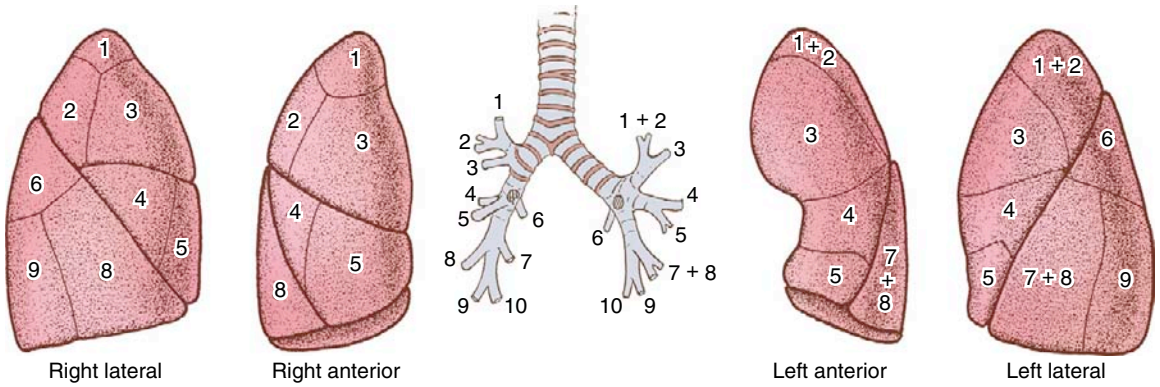

FIGURE 22-5 Segments of the pulmonary lobes. *RLL*, Right lower lobe.

PATIENT SAFETY

Patient Identification

Like the hospital gown, the wrist identification band is a traditional part of the "patient" persona and is linked to the routine of verification before administering medications, treatments, or procedures. When the wristband is present and has correct information, it can be a reliable identifier.

Patients undergoing thoracic procedures are at risk for identification errors because their wristbands are often removed to provide access for starting intravenous (IV) and other invasive monitoring lines or may be inaccessible because of positioning or draping. Correctly identifying the patient is an important Joint Commission National Patient Safety Goal. Research from The Joint Commission found that incorrect patient identification was involved in 13% of surgical errors and 67% of transfusion errors. The nurse must be familiar with the institutional policy regarding patient identification and the methods and procedures used to accomplish it. If a band is removed it should never be retaped in a new location or taped or pinned to the patient's gown. The band that is retaped or repaired may not maintain its integrity. A band pinned to a gown is easily lost if the gown is removed or replaced. The nurse should anticipate that identification bands may need to be removed for access purposes and ensure replacement bands are available. If the patient's arms are not accessible, the nurse should consider placing the new band on the patient's ankle.

Some organizations use color-coded identification bands to indicate allergies, blood type, or do-not-resuscitate (DNR) orders. Nurses must be familiar with the color coding used by the institution to avoid misidentification.

Technology is available to support the patient identification process. Many identification bands include bar codes that can be read with handheld bar code readers. Bar codes allow nurses to verify identity and capture other important data. A bar code identification band meets the American Hospital Association's guidelines for a tamperproof, nontransferable identification band.

Newer technology uses radiofrequency identification (RFID) systems for accurate patient verification. RFID remotely collects information and stores it on a system consisting of tags (transponders) and readers (interrogators). Microchips inside the tags contain more than 100 times the information of bar codes. The chip can contain patient information such as name, blood type, allergies, and medications.

The Joint Commission has updated their Patient Safety Goals for 2009. In these new goals a two-patient identifier, a pre-procedural identification, and a time-out procedure are added. First, the two-patient identifier simply means that the nurse must use more than one method of identification to identify the patient. Using the wristband alone is not enough. Second, the pre-procedural identification is performed, usually, in the postanesthesia care unit, by the surgeon and a nurse. This is used to correctly identify each patient just before going into the operating suite. Lastly, the time-out procedure is performed in the operating suite by the surgeon and the perioperative team—time is taken to properly identify the patient, procedure, and site of surgery. This is the final identifier before the actual operation is performed.

Regardless of the system used, the perioperative nurse plays a key role in identifying the patient and reinforcing subsequent verification procedures as necessary throughout the surgical experience to provide a safe environment of care.

Modified from The Joint Commission International Center for Patient Safety: *Using identification bands to reduce patient identification errors,* available at www. jcipatientsafety.org/show.asp?durki=12346. Accessed April 11, 2009; The Joint Commission: *2009 National Patient Safety Goals (NPSGs),* available at www. jointcommission/NR/rdonlyres/31666E86-E7F4-423E-9BE8-F05BD1CB0AA8/0/HAP_NPSG.pdf. Accessed May 7, 2009; Inglesby JM, Inglesby T: Automatic identification barcoding and RFID, *Patient Safety Quality HealthCare,* available at www.psqh.com/sepoct05/barcodingrfid2.html. results of the history, physical examination, laboratory tests, other diagnostic workups, and the nursing history and assessment, is critical for subsequent care planning. It is valuable to assess the patient's understanding of the disease process and of the anticipated procedure. In addition to assessing the patient's knowledge and understanding of the proposed surgical procedure and outcomes, the perioperative nurse ensures that the patient has adequate support to assist the patient through the surgical experience and recovery. The nurse should also assess emotional status, since patients with a possible diagnosis of carcinoma may be very anxious. A focused assessment of the respiratory system should be included during the physical assessment. The nurse questions the patient or otherwise confirms the presence of an increased frequency of cough, increase in sputum production, recurrent hemoptysis, malaise, shortness of breath, substernal chest discomfort, weight loss, poor appetite, status of nutrition, and hypoxia. The results of the physical examination of the chest should be reviewed; the perioperative nurse may auscultate the chest and confirm the presence of crackles or wheezes on inspiration or expiration, which should be documented on the medical record.

The review of diagnostic and laboratory tests may include the chest x-ray films, sputum analysis obtained during bronchoscopy, cytology reports, arterial blood gas (ABG) results, and pulmonary function studies (Table 22-1). Laboratory tests including the complete blood count (CBC) should be within normal limits but can indicate anemia. The chest x-ray film remains an indispensable diagnostic tool and will be needed in the OR. This film outlines the lesion, if any is present, and defines its shape and space-occupying nature (e.g., tracheal shift). The presence of air in the hilar region, pleural effusion, or atelectasis may also be confirmed by radiologic evidence. Sputum analysis for culture and sensitivity may alert the perioperative nurse to an infectious process; cytologic examination may confirm a malignancy. The patient may have already undergone diagnostic bronchoscopy or mediastinoscopy; if so, the findings for acid-fast bacillus smear, culture, bronchial washing, and biopsy should be reviewed. A three-dimensional image reconstruction and display technique—virtual bronchoscopy—may have been undertaken for noninvasive airway evaluation (Amdo, 2009). Pulmonary function tests with a forced expiratory volume in 1 second (FEV_1) less than 1.0 L indicate the patient is at extremely high risk for pulmonary complications in the postoperative period. Computed tomography (CT) scans of the chest, as well as of the brain, liver, and abdomen, may reveal the presence or absence of metastasis, pleural calcification, thickening, or plaque. Radioisotope scans may have been done for similar reasons as the CT. Magnetic resonance imaging (MRI) detects vascular relationships to masses or vascular lesions. Positron emission tomography (PET) is a noninvasive study demonstrated to be highly accurate in diagnosing malignant pulmonary nodules and lymphadenopathy. MRI and PET are sometimes performed to rule out metastasis of the lesion. Transbronchial needle aspiration is useful in diagnosing mediastinal lymphadenopathy and staging lung cancer. Ventilation and perfusion studies show the distribution of each function in the lung. These results assist the perioperative nurse in collaborating with the surgical team to maintain effective gas exchange during the surgical intervention. The results are also valuable in predicting postoperative respiratory function and metabolic responses. Patients hospitalized for surgery related to carcinoma may have received chemotherapy or radiation therapy before surgery. Assessment of the skin and the patient's general condition is important in preventing perioperative complications. The nurse should also assess the patient's pain tolerance to determine necessary teaching or tools that will assist in achieving positive postoperative outcomes.

The nurse should assess the patient's smoking history (including the use of cigars, pipes, tobacco, or controlled substances) and any exposure to secondhand smoke within the home and/or workplace and reinforce the need to abstain following surgery (Rees, 2010). Patients might be sensitive about smoking history because of the assumed relationship between smoking and lung disease. The nurse should phrase questions in a way that will not result in guilt about smoking habits or assumptions that the diagnosed condition is associated with smoking.

After a general and focused review of the patient's medical record and patient interview, the perioperative nurse formulates nursing diagnoses. These statements reflect problems that will require perioperative nursing intervention, either independently or collaboratively with other members of the surgical team. Nursing diagnoses should be individualized and prioritized for each patient.

Nursing Diagnosis

Nursing diagnoses related to the care of patients undergoing thoracic surgery might include the following:

- Impaired Gas Exchange related to surgical intervention
- Risk for Impaired Skin Integrity related to surgical positioning, length of surgical intervention, or use of chemical antimicrobial agents on the skin
- Risk for Imbalanced Fluid Volume related to decreased surface area of the lung for perfusion and to administration of intravenous (IV) fluids during surgery
- Risk for Infection at surgical site related to inadequate secondary defenses (presence of existing disease process) and surgical disruption of tissues
- Impaired Comfort related to pain following surgical intervention

Outcome Identification

Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient will experience adequate gas exchange during the surgical procedure.
- The patient's skin integrity will be maintained.
- The patient will maintain appropriate fluid balance.
- The patient will be free from postoperative surgical site infection.
- The patient's pain will be monitored and managed.

Planning

A Sample Plan of Care for a patient undergoing thoracic surgery is included on pp. 942-943.

Implementation

During implementation of the plan of care, the perioperative nurse is concerned with both preparatory patient considerations (e.g., procedure explanation and teaching for the patient; verification of the patient, surgical procedure, and site; positioning; presurgical diagnostic interventions; draping) and the requirements of the surgical intervention (e.g., medication

TABLE 22-1

Laboratory Studies and Tests for Assessment of Patients Undergoing Thoracic Procedures

Laboratory Study	Normal Results	Significance of Abnormal Findings
PERFUSION STUDIES—ARTERIAL BLOOD GASES (ABGS)		
pH	7.35-7.45	Changes indicate metabolic or respiratory acidosis.
$Paco_2$	35-45 mm Hg	Elevations indicate possible COPD, asthma, pneumonia, anesthetic effects, or use of opioids (respiratory acidosis). Decreased levels indicate hyperventilation/respiratory alkalosis.
HCO_3^-	21-28 mEq/L	Elevations indicate possible respiratory acidosis as compensation for primary metabolic alkalosis. Decreased levels indicate possible respiratory alkalosis as compensation for primary metabolic acidosis.
Pao_2	80-100 mm Hg	Elevations may indicate possible excessive oxygen administration. Decreased levels indicate possible COPD, asthma, chronic bronchitis, cancer of bronchi and lungs, respiratory distress syndrome, or any other cause of hypoxia.
O_2 saturation	95%-100%	Decreased levels indicate possible impaired ability of hemoglobin to release oxygen to tissues.
COMPLETE BLOOD COUNT		
RBCs	*Male:* 4.7-6.1 million/mm^3 *Female:* 4.2-5.4 million/mm^3	Elevated levels may be due to excessive production of erythropoietin, which occurs in response to a hypoxic stimulus, such as COPD. Decreased levels may indicate anemia, hemorrhage, or hemolysis.
Hemoglobin	*Male:* 14.8 g/dl *Female:* 12-16 g/dl	Same as for RBCs.
Hematocrit	*Male:* 42%-52% *Female:* 37%-47%	Same as for RBCs.
WBCs	5000-10,000/mm^3	Elevations indicate possible acute bacterial infections or inflammatory conditions (smoking). Decreased levels may indicate overwhelming infection or immunosuppression.

Pulmonary Function Tests

Test	Purpose
FVC (forced vital capacity): Records maximum amount of air that can be exhaled as quickly as possible after maximum inspiration	Provides an indication of respiratory muscle strength and ventilatory reserve. Often reduced in obstructive disease (because of air trapping) and in restrictive disease.
FEV_1 (forced expiratory volume in 1 sec): Records maximum amount of air that can be exhaled in first second of respiration	Effort dependent and declines with age. Reduced in certain obstructive and restrictive disorders.
FEV_1/FVC: Ratio of expiratory volume in 1 sec to FVC	Provides a more sensitive indicator of obstruction to airflow. Ratio is normal or increased in restrictive disease.
$FEF_{25-75\%}$: Records forced expiratory flow over 25%-75% volume (middle half) of FVC	This measure provides a more sensitive index of obstruction in smaller airways.
FRC (functional residual capacity): Amount of air remaining in lungs after normal expiration	Increased FRC indicates hyperinflation or air trapping, which may result from obstructive disease.
TLC (total lung capacity): Amount of air remaining in lungs at end of maximum inhalation	Increased TLC indicates air trapping associated with obstructive pulmonary disease. Decreased TLC indicates restrictive disease.
RV (residual volume): Amount of air remaining in lungs at end of a full, forced exhalation	RV is increased in obstructive pulmonary disease, such as emphysema.
DL_{co} (diffusion capacity of carbon monoxide): Reflects surface area of alveolocapillary membrane	DL_{co} is reduced when alveolocapillary membrane is diminished, such as in emphysema, pulmonary hypertension, and pulmonary fibrosis.

COPD, Chronic obstructive pulmonary disease; *HCO_3^-*, bicarbonate ion; *$PaCO_2$*, partial pressure of arterial carbon dioxide; *PaO_2*, partial pressure of arterial oxygen; *RBC,* red blood cell; *WBC,* white blood cell.

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Impaired Gas Exchange related to surgical intervention

OUTCOME
The patient will experience adequate gas exchange during the surgical procedure.

INTERVENTIONS
- Determine the preoperative status of gas exchange by reviewing laboratory results and assessing the patient; report deviations from preoperative laboratory values and patient assessment findings.
- Obtain chest x-ray films for the intraoperative period.
- Verify that a double-lumen endotracheal tube with a soft, inflatable cuff is available for the anesthesia provider.
- Collaborate in obtaining equipment for and monitoring arterial blood gases (ABGs); document results.
- Obtain equipment for and assist with patient preparation for hemodynamic monitoring: electrocardiogram (ECG), CO_2 analyzer, pulse oximeter, arterial pressure line, and central venous pressure line; collaborate with the anesthesia provider in evaluating results provided by these monitoring devices during the procedure.
- Apply thermal unit (forced-air warming device or other device as available in institution); check equipment before procedure; monitor and note patient temperature during procedure.
- Collaborate in positioning the patient to provide access to the endotracheal tube, enable efficient ventilatory function, and prevent injury.
- Obtain and label specimens (e.g., ABG, blood count) to be sent to laboratory; document specimens sent, and evaluate results. Report abnormal values to the anesthesia provider and surgical team.

NURSING DIAGNOSIS
Risk for Impaired Skin Integrity related to surgical positioning, length of surgical intervention, or use of chemical antimicrobial agents on the skin

OUTCOME
The patient's skin integrity will be maintained.

INTERVENTIONS
- Assess skin integrity and condition of the skin preoperatively. Document findings; report the presence of any lesions, rashes, cuts, nicks, or reddened areas.
- Determine presence of preexisting conditions that could compromise skin integrity (e.g., age, obesity, diabetes, allergies, radiation therapy).
- Apply principles of positioning for efficient circulatory function for lateral or supine position during the procedure; pad and protect vulnerable neurovascular bundles and dependent pressure areas:
  - *Lateral position:* ear, acromion process, iliac crest, greater trochanter, medial and lateral condyles, malleolus
  - *Supine position:* occiput, scapula, olecranon, sacrum, ischial tuberosity, calcaneus
- Position the patient in the best possible body alignment to allow visualization of the operative field.
- Assess for preexisting conditions (e.g., joint implants, arthritis, restricted movement) to prevent patient injury during positional maneuvers.
- Stabilize the patient in lateral position (e.g., beanbag, sandbag, soft shoulder roll, pillows between knees); check for tape sensitivity if adhesive tape is used. Flex the upper arm slightly (not exceeding 90-degree extension) above the head on a raised, padded armboard or supported on padding.
- Use adequate number of individuals to position the patient for the lateral position.
- Assess the area where the electrosurgical dispersive pad will be placed; clip the area if necessary. Document assessment and pad placement on the intraoperative record.
- If hair must be removed from the operative site, use clippers or a depilatory (check patient sensitivity); shave the patient with wet shave if a razor must be used.
- Prevent pooling of skin prep solutions at the bedline, site of ECG electrodes, and electrosurgical dispersive pad.
- Decrease surgical time by anticipating needs of the patient and surgical team.
- Observe and document skin integrity and condition postoperatively; compare with preoperative status.

NURSING DIAGNOSIS
Risk for Imbalanced Fluid Volume related to decreased surface area of the lung for perfusion and to administration of intravenous (IV) fluids during surgery

OUTCOME
The patient will maintain appropriate fluid balance.

INTERVENTIONS
- Insert indwelling urinary catheter; use aseptic technique.
- Position drainage bag off floor, where it is readily observable.
- Monitor urinary output hourly during the procedure; report output less than 30 ml/hr.
- Provide access for administration of IV fluids; assist with fluid administration and insertion of lines. Keep lines protected and patent during positional changes.
- Monitor results of hemodynamic parameters; document and report appropriately.
- Monitor blood loss during the procedure; document and report appropriately.
- Provide blood (including autologous) or blood products for fluid replacement; assist in replacement therapy and patient monitoring.
- Observe for signs of shock (e.g., hypotension, abnormal ECG); report signs, and initiate corrective nursing actions.
- Observe for signs of excess blood loss (e.g., rapid, weak pulse; rapid respirations; cool, moist skin; early, slight rise in blood pressure); report signs, and initiate corrective nursing actions.
- Observe for signs of fluid excess (e.g., tachycardia, increased blood pressure); report signs, and initiate corrective nursing actions.
- Have available and administer furosemide (Lasix) and other diuretic agents as prescribed; monitor for therapeutic results.

NURSING DIAGNOSIS
Risk for Infection at surgical site related to inadequate secondary defenses (presence of existing disease process) and surgical disruption of tissues

OUTCOME
The patient will be free from surgical site infection.

INTERVENTIONS
- Create and maintain a sterile field immediately before use; monitor the sterile field, and take corrective action if breaks in technique occur.
- Administer preoperative antibiotics at least 1 hour before the procedure.
- Do not remove hair preoperatively unless the hair at or around the incision site will interfere with the surgical procedure. If hair must be removed, it should be done immediately before the surgical procedure, preferably using a means other than a razor.

SAMPLE PLAN OF CARE—cont'd

INTERVENTIONS—cont'd

- Practice aseptic technique when opening supplies, moving around the sterile field, catheterizing the patient, inserting IV lines, completing skin preparation, and draping the surgical site.
- Complete skin preparation at the incision site and point of insertion of monitoring lines to decrease microbial contamination. Use an appropriate antiseptic agent, applied in concentric circles moving toward the periphery. The prepped area should be extensive enough to extend the incision or create new incisions or drain sites.
- Monitor traffic patterns; limit the number of persons entering and leaving the OR.
- Administer prescribed antibiotics for irrigation and IV administration; check for patient allergies; record all medications administered by the perioperative nurse or scrub person at the sterile field.
- Decrease surgical time by anticipating patient and surgical team needs.
- When visible soiling with blood or other body fluids of surfaces or equipment occurs during the procedure, use an Environmental Protection Agency (EPA)–approved hospital disinfectant to wipe the affected area (confine and contain).
- Correctly classify the surgical wound according to the institution's wound classification system on completion of the surgical procedure.
- Using sterile gloves, apply sterile dressings to the surgical site before the drape is removed.

NURSING DIAGNOSIS

Impaired Comfort related to pain following surgical intervention

OUTCOME

The patient's comfort will be assessed, monitored, and managed.

INTERVENTIONS

- Teach the pain assessment scale preoperatively.
- Provide education to the patient regarding the physiology of pain and the importance of treating pain before it becomes unmanageable.
- Discuss pain management techniques and options (i.e., oral, intramuscular [IM], IV medications, patient-controlled analgesia [PCA], epidural use, intercostal blocks).
- Assist anesthesia provider in initiating pain control methods (i.e., epidural placement, nerve blocks).
- Assess pain before and following administration of pain medication or use of comfort measures (e.g., repositioning, applying support devices).
- Monitor the effects of pain management strategies and document.
- Assess verbal and nonverbal cues during procedures requiring monitored anesthesia care and administration of local anesthesia.
- Teach pain control methods and medication uses and side effects before discharge.

delivery; instrument, equipment, and supply availability). These patient care needs are coordinated with the other nursing interventions identified in the specific patient's plan of care.

Positioning. The type of position used in thoracic surgery is determined by the operative procedure planned. Bronchoscopy is performed in the supine position with a shoulder roll. Thoracotomy can be performed with the patient in one of three common positions: (1) lateral for the posterolateral approach, (2) semilateral for the anterolateral approach (Figure 22-6), and (3) supine for the median sternotomy approach. Arms are placed on padded armboards with the palms up and fingers extended. Armboards are maintained at less than a 90-degree angle to prevent brachial plexus stretch. If there are surgical reasons to tuck the arms at the side, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail.

The prone position can also provide access in some procedures (see Chapter 5 for safe positioning interventions). Adequate padding and safe transfer should be implemented to prevent pressure injury.

Draping. Draping may be minimal for bronchoscopic procedures. The principles of draping for other procedures (see Chapter 3) are followed in all other thoracic procedures. Drapes may consist of a fenestrated sheet or single sheets surrounding the incision site. To prevent instruments from falling from the field, the surgical technologist may place a magnetic pad on the drapes below the incision site when the patient is placed in lateral position. The perioperative nurse ensures a forced-air warming blanket is placed on the patient before draping to maintain normothermia. Sequential compression devices are often applied also to prevent the development of deep vein thrombosis (DVT).

Instrumentation. Bronchoscopy instruments are designed to directly inspect and observe the larynx, trachea, bronchi, or mediastinum; to remove secretions; to obtain washings or tissue for bacterial and cytologic studies; or to remove tissue. They are also designed to remove foreign bodies. Instrumentation for thoracic surgery includes the laparotomy instrument set (see Chapter 10) and specialty items. Instruments used for a thoracotomy or chest procedure include a combination of delicate and heavy instruments. Stapling equipment commonly is used as suturing devices and requires staplers and reload staples of appropriate sizes. The delicate instruments are used to cut tissue and vessels or to clamp tissue in an atraumatic manner. The heavier instruments are used for bone cutting, dissecting, or retracting. Instrumentation must also be available for hemostasis and suturing of all types of tissue.

The surgical technologist should determine the arrangement of items on the instrument table and Mayo stand; this arrangement should be an effective standard method that applies principles of work simplification and thorough knowledge of procedures. Lengthy incisions are often required for thoracic procedures; therefore it is critical that an instrument count be performed before closure.

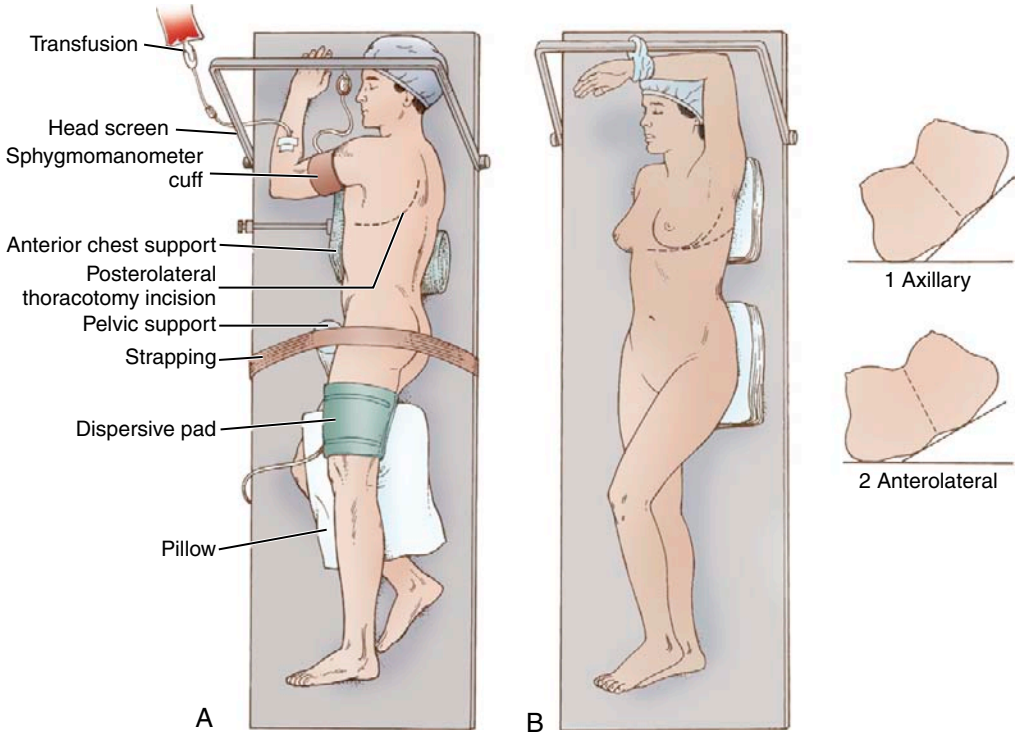

FIGURE 22-6 Positions for thoracotomy incisions. **A**, Lateral position for posterolateral incision. **B**, Semilateral position for axillary or anterolateral position.

Equipment. In thoracic surgery, a variety of equipment is used, including a forced-air warming unit, fiberoptic headlights, fiberoptic light sources, video equipment, sequential compression devices, and anesthesia supplies. Double-lumen endotracheal tubes are commonly used for thoracotomies.

The neodymium:yttrium-aluminum-garnet (Nd:YAG) or CO_2 laser can be used for treating tracheobronchial lesions with use of a bronchoscope. Obstruction of the mainstem bronchus and trachea caused by benign and malignant lesions can also be effectively treated with laser therapy. Use of laser equipment requires a thorough understanding of the equipment, the safety issues, the responsibilities (see Chapter 7), and the planned surgical procedure.

Monitoring. Monitored anesthesia care, local anesthesia, or topical anesthesia may be used during some bronchoscopic procedures. General anesthesia may also be used for bronchoscopic procedures and is used for other thoracic procedures. Team members work in cooperation to constantly monitor laboratory results (e.g., ABGs), oxygenation, temperature, blood loss, and urine output. Monitoring sequential compression device settings and patient position is also important in providing safe patient care. Results are communicated with other team members and documented for continuity of care.

Blood Replacement. Blood replacement therapy during or after the procedure may be required because of extensive tissue dissection in a highly vascular area. The patient may have autologous blood ordered; however, the diagnosis may prohibit patient donation of his or her own blood. The patient's blood type and amount of blood ordered should be noted before the procedure and its availability confirmed. During the procedure, every effort should be made to control and monitor bleeding. If blood collection or reinfusion systems are used, the manufacturer's instructions and institutional protocols should be followed. Bloodless surgery programs are available at some institutions and can prevent the need for allogeneic or autologous blood use (Fox et al, 2008).

Chest Drainage Systems. Chest tube and chest drainage system management represents an important intervention for perioperative nurses (Risk Reduction Strategies). In the presence of restrictive and obstructive pulmonary disease, the lung may not fully expand or contract, causing a reduction in alveolar ventilation with resultant hypoxia. Other conditions that interfere with respiratory function are excessive accumulation of mucus, pleural effusions, a foreign body in a bronchus, closed pneumothorax (simple and tension types), open pneumothorax, hemothorax, and multiple rib injuries that produce paradoxic motion of the thoracic cage, or flail chest (Figure 22-7).

The normal function of the lungs is supported by elasticity and negative intrapleural pressure. Collapse of the normal lung follows any condition that reduces or eliminates the negative intrapleural pressure if the lung is not adhering to the chest wall. When the pleural space is filled with air, reducing the negative pressure, the lung collapses. This action may cause complete collapse if the pressure within the intrathoracic (pleural) space becomes positive.

A diminished negative pressure or the occurrence of actual positive pressure in one pleural space may cause the mediastinum or trachea to shift toward the opposite side.

RISK REDUCTION STRATEGIES

Chest Tube Safety

The use of chest tubes is almost synonymous with thoracic surgery. Effective strategies for the management of chest tubes and chest tube drainage systems promote reduction of risk to patients for this aspect of thoracic surgery.

According to the U.S. Agency for Healthcare Research and Quality (AHRQ), major sources of adverse outcomes include breaks in sterile technique, inadequate anesthesia, incorrect insertion techniques, and inadequate self-protection by clinicians. The agency issued the following findings:

- Trying to perform multiple procedures concurrently is a major source of error.
- Equipment trays should be positioned near the surgeon's dominant hand.
- A patient's discomfort can make it difficult to perform a sterile procedure. While adequate anesthesia is important, the patient may also need verbal and physical comforting. If a patient's movements cannot be controlled, the anesthesiology team should be called.
- Correct techniques can prevent damage to the lung and surrounding tissue, contamination of the wound, and leakage of fluid.
- Universal Precautions against bloodborne infections are crucial to protect clinicians and their patients. In U.S. urban trauma centers, HIV rates among trauma patients are as high as 10%, and hepatitis C rates are as high as 15%; therefore Universal Precautions should be practiced for all chest tube insertions.

Additional management strategies include the following:

- Ensure that the dressing on the chest around the tube is tight and intact. Palpate the area for puffiness or crackling that may indicate subcutaneous emphysema.
- Assess for difficulty breathing.
- Assess breathing effectiveness by pulse oximetry.
- Check alignment of the patient's trachea.
- Keep the drainage system lower than the patient's chest.
- Keep the chest tube as straight as possible, avoiding kinks and dependent loops; do not "strip" the chest tube.
- Ensure the chest tube is securely taped to the connector and the connector is taped to the tubing that enters the collection chamber.
- Assess bubbling in the water-seal chamber; should be gentle bubbling on patient's exhalation, forceful cough, position changes.

The physician or rapid response team should be notified when the following are observed:

- Tracheal deviation
- Sudden onset or increased intensity of dyspnea
- Oxygen saturation less than 90%
- Drainage greater than 70 ml/hr
- Visible eyelets on the chest tube
- Chest tube falls out of the patient's chest or disconnects from the drainage system

Modified from Problems and Prevention: *Chest tube insertion. Patient safety: findings in action,* AHRQ Publ No. 06-P024, Sept 2006, Agency for Healthcare Research and Quality, Rockville, Md, available at www.ahrq.gov/qual/chesttubes.htm. Accessed May 12, 2009; Workman ML: Care of patients with noninfectious lower respiratory problems. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, Philadelphia, 2010, Saunders.

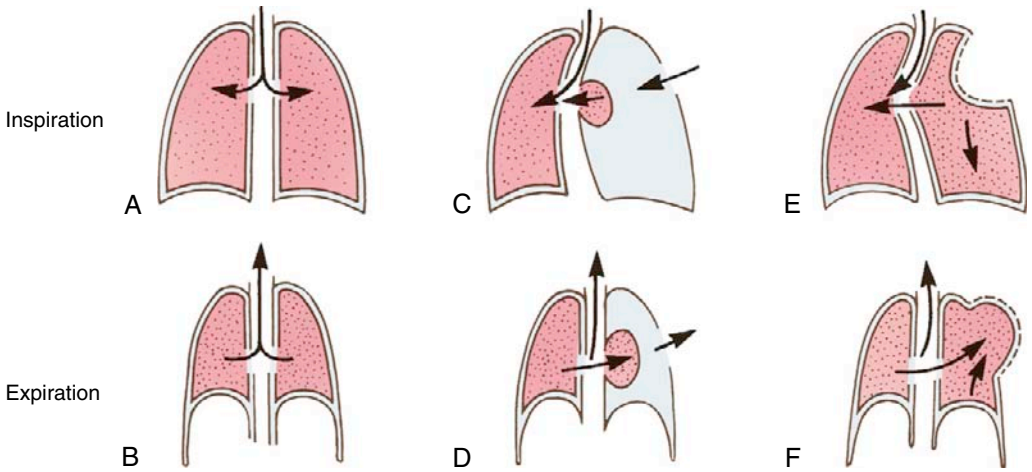

FIGURE 22-7 Pathophysiology of severe chest injuries. **A** and **B**, Normal physiology of inspiration and expiration. **C** and **D**, Open (sucking) wound of thorax. On inspiration, air at atmospheric pressure rushes in through defect (**C**), collapsing lung. Next, positive pressure causes mediastinum to shift, compressing opposite lung. On expiration (**D**), air from lung on uninjured side reenters collapsed lung and is rebreathed in next inspiration. Impaired cardiopulmonary function in presence of sucking wound of chest is caused by (1) collapse of lung on injured side, (2) partial collapse of opposite lung, (3) increased functional dead space caused by rebreathing of unoxygenated air from collapsed lung, and (4) diminished venous return to right side of heart. **E** and **F**, Primary effect of paradoxic motion resulting from flail or stove-in chest is diminution of pulmonary ventilation and extensive rebreathing from one lung to the other. Venous return to right side of heart is impaired. Appropriate treatment requires intubation of trachea and use of volume-limited ventilator.

When this occurs, not only the affected lung collapses because of a positive pressure in the pleural space but also the function of the lung on the opposite side may be impaired as a result of compression by the mediastinal shift. Tension pneumothorax can produce serious effects as air continues to escape from the lung into the intrapleural space. The air cannot return to the bronchi to be exhaled, thereby increasing the intrapleural pressure. When a large opening in the chest wall allows direct communication of the pleural space with atmospheric pressure, it may cause death if the mediastinum becomes mobile.

Paradoxic motion of the chest results from severe instability of the chest wall because of multiple and often bilateral rib fractures; with inspiration, partial collapse of the thoracic space occurs. The blunt injury that caused the multiple rib fractures also causes severe contusion of the lung itself. This contusion contributes to impairment of lung function by affecting gas exchange, which may result in severe, life-threatening hypoxia.

One or more chest catheters (tubes) may be inserted for postoperative closed-chest drainage. The chest tubes provide a conduit for drainage of air, blood, and other fluid from the intrapleural or mediastinal space and reestablishment of negative pressure in the intrapleural space. Drainage systems use three mechanisms to drain fluid and air from the pleural cavity: positive expiratory pressure, gravity, and suction. The chest tubes are connected to a sterile water-seal or gravity drainage system. Water-seal suction may be necessary when a persistent air leak cannot be controlled by drainage alone. Several compact, disposable units are available. The disposable units have three or four compartments for drainage, water seal, and suction. The first chamber collects the drainage from the intrapleural space, the second chamber provides the water seal, and the third provides the suction control determined by the level of water (Figure 22-8). If two chest tubes are inserted, they may be attached by a Y connector to a single drainage unit or may be attached individually to two separate units. Chest tubes are generally removed within 5 to 7 days.

FIGURE 22-8 Commercial chest drainage system.

Documentation. The nurse's documentation of perioperative care includes a summary of preoperative assessment information that supports formulated nursing diagnoses, nursing interventions, and postoperative evaluation. Documentation for a patient undergoing a thoracotomy specifically addresses patient assessment information related to position of the patient, positioning aids used, medications administered, results of laboratory tests completed, special equipment used, urine output, blood replacement, insertion of chest tubes and drainage systems, and postoperative evaluation of patient care outcomes.

Transfer Report. The patient is transferred from the OR to the postanesthesia care unit (PACU) after thoracotomy. The report to the PACU nurse is often a collaborative effort of the nurse and anesthesia provider. The perioperative nurse reports the procedure performed, particularly if it varies from the anticipated or scheduled procedure, and describes the patient's preoperative status, including anxiety level and understanding of the procedure, to assist the PACU nurse in meeting the emotional and educational needs of the patient. The nurse's description of the patient's position during the procedure provides criteria for assessment and evaluation of mobility. Results of immediate postoperative assessment, including skin integrity, location and type of dressing applied, location and type of drains, blood loss, fluid replacement, medications administered, and laboratory results obtained during the procedure, are reported by the nurse and anesthesia provider as a baseline control for assessment in the PACU. The perioperative care plan should be reviewed and patient outcomes reported.

Postprocedural Concerns. The patient's endotracheal tube may remain in place to maintain an adequate air exchange. Air exchange and effective ventilation are two immediate clinical needs after thoracotomy. Chest tubes are connected to suction except for postpneumonectomy procedures. The thoracotomy is considered a painful procedure and, when coupled with muscle injury, affects functional capacity. Anesthesia providers frequently use postprocedure epidural catheters for pain management to improve the comfort level of the patient as postoperative activities are encouraged.

Fluid volume overload can lead to acute life-threatening respiratory disease syndrome that should be avoided (Rapid Response Team box). Monitoring urine output is important, but postthoracotomy patients should be maintained in a state of hydration that does not require a fluid bolus for low urine output.

Patients are often anxious about their limitations, the environment, and the results of the procedure. Patients and families will benefit from preoperative teaching about pain management techniques and use of the institution's pain assessment tool. Patients and families should also be encouraged to discuss their feelings and needs both before and after the surgical procedure. The perioperative nurse should facilitate notification of the patient's status to the family members during and as soon as possible after the procedure.

RAPID RESPONSE TEAM

Surgical adverse events (SAEs) account for 50% to 75% of all adverse events in studies of healthcare complications. As the number and complexity of surgical procedures performed increase, the incidence and severity of SAEs are also likely to increase. Trigger Tool methodology employs a retrospective review of a random sample of inpatient hospital records, using "triggers" (or clues) to identify possible adverse events. This methodology is easy-to-use for identifying adverse events (harm) and measuring their rate of occurrence over time. Within the Institute for Healthcare Improvement's (IHI) Trigger Tool are 14 care process triggers, 1 of which is rapid response team (RRT) activation. The RRT may be activated for a code, cardiac or pulmonary arrest, or other condition/event requiring a rapid response. The IHI notes that cardiac or pulmonary arrest that occurs intraoperatively, in the postanesthesia care unit (PACU), or within the first 24 hours postoperatively should always be considered an adverse event. In 1 study undertaken within the IHI perioperative collaborative, 11 hospitals submitted data from surgical inpatient records. From record review, it was determined that the prevalence of SAEs was 14.6% and that 8.7% of the events required life-saving intervention. As more institutions use Trigger Tool methodology, it may be possible to investigate the effectiveness of RRT activation intraoperatively and improve the impact of interventions initiated in response to the RRT call.

Modified from Griffin FA, Classes DC: Detection of adverse events in surgical patients using the trigger tool approach, *Qual Saf Health Care* 17:253-258, 2008; Griffin FA, Resar RK: *IHI Global Trigger Tool for Measuring Adverse Events (Second Edition), IHI Innovation Series white paper,* Cambridge, Mass, Institute for Healthcare Improvement, 2009, available at www.IHI.org. Accessed May 19, 2009.

Evaluation

At the completion of the surgical procedure, perioperative nursing goals are evaluated. They may be restated as brief outcomes. For the goals identified for the patient undergoing thoracic surgery, outcomes could be stated as follows:

- The patient's gas exchange was unimpaired; ventilation/perfusion ratios were adequate as evidenced by laboratory results, and vital signs were within normal limits; skin, nailbeds, and mucosa were pink; lung fields were clear bilaterally; and chest excursion was normal.
- The patient's skin integrity was maintained; reddened or discolored skin and other signs of altered tissue perfusion were not present.
- Fluid balance was maintained; there were no fluid excesses or deficits; mental orientation was consistent with preoperative level; serum electrolytes and ABGs were within normal limits; urinary output was adequate.
- A postoperative surgical site infection will not be experienced; the incision site will remain approximated and dry, without redness, drainage, or undue tenderness. (This is a long-term goal, and its evaluation will require the collaboration of the nurse in the patient care unit.)
- Comfort will be managed and pain levels assessed.

Patient and Family Education and Discharge Planning

Discharge status will be determined by the type of procedure being performed. General patient concerns might include mobility and activity levels/restrictions, pain management, wound care, dietary recommendations, medication regimens, follow-up appointments, and any prescribed outpatient care or referrals. Both the patient and the family need specific instructions for discharge that relate to the specific procedure. The nurse should review this information verbally and provide it in written form, with verification of understanding and time for questions and concerns.

After a bronchoscopy, patients will be discharged within hours of the procedure. Their main concerns might be the results of biopsy and diagnosis. The patient and family should be aware of the length of time until results will be available and the method used to obtain those results. Patients should also be reminded of the need to rest for 2 to 3 days after the procedure. Side effects might result from medications used for moderate sedation or untoward intraoperative outcomes (e.g., the patient may experience bloody sputum, difficulty breathing). In addition, patients should be reminded that their throats might feel numb 2 to 3 hours after the procedure and difficulty with swallowing will subside (Ambulatory Surgery Considerations).

After a surgical procedure such as thoracoscopy or thoracotomy, vigorous pulmonary toileting is encouraged, including use of a spirometer, deep breathing, and turning and coughing every 1 to 2 hours while awake. Patients will transfer to the chair or ambulate on the day of surgery; length of time until discharge might be a few days to 1 week or more. Patients who progress without difficulty after a thoracoscopy or thoracotomy will be monitored for drainage from the chest tubes and for pain management or complications. Postoperative air leaks or pulmonary infections will delay discharge from the healthcare setting.

In-home nursing care may be initiated to monitor oxygen levels, wound care needs, and pain management. The patient may be discharged with supplemental oxygen (Patient and Family Education). This will require that the patient be weaned and demonstrate satisfactory ambulatory Sao_2 (i.e., percent saturation of arterial oxygen) rates of 88% to 90%, which will most likely be supervised by homecare nurses.

Surgical Interventions

ENDOSCOPY (DIAGNOSTIC OR THERAPEUTIC)

Endoscopy refers to examination of hollow body organs or cavities with instruments that permit visual inspection of their contents and walls. The endoscopic procedures pertinent to thoracic surgery are bronchoscopy, mediastinoscopy, and thoracoscopy. Each endoscopist has preferences regarding the type of endoscope, positioning of the patient, type of anesthetic, and equipment. Invasive diagnostic or therapeutic measures enhance the decision to pursue surgical intervention by providing information related to the disease process, including histologic characteristics, location of the lesion, and lesion extent. Therapeutic endoscopy provides treatment by removal of the lesion or foreign body.

AMBULATORY SURGERY CONSIDERATIONS

Ambulatory Thoracic Surgery

The concept of ambulatory surgical procedures is not new to the thoracic specialty; patients undergoing bronchoscopy or endoscopic sympathectomy have often completed their procedures on an outpatient basis. With the increased trend towards more minimally invasive procedures and improved technology to accomplish those procedures, the indications for ambulatory thoracic surgery are growing. Proper patient selection is key to the success of an ambulatory thoracic program. The surgeon must weigh the risks and benefits of performing surgery on a patient and allowing a discharge to home within several hours of the procedure. Anesthesia risk can be assessed according to the individual patient's American Society of Anesthesiologists (ASA) physical status classification. The surgeon considers the complexity of the surgery, the patient's medical and surgical history, and other factors on a case-by-case basis before surgery to ensure the most appropriate patients are selected for outpatient procedures. Because the majority of thoracic procedures entail entry into the chest, the patient's level of pain, amount of chest tube output, presence or absence of an air leak, and pneumothorax status must be closely monitored before the final determination for discharge that same day.

There are many ambulatory surgical centers in the United States that offer an array of thoracic services. Mediastinoscopies, endoscopic and minimally invasive procedures on the lungs and nerves of the mediastinum, are the most frequently performed thoracic surgeries on an outpatient basis. Through proper patient selection, excellent surgical technique, and exceptional postoperative care the majority of patients treated at these centers can safely be discharged to home the day of surgery. Essential teaching points to cover with the patient and caregiver include pain control, respiratory treatments (to include deep breathing and coughing as ordered by the surgeon), and activity. Because the chest wall has been entered, the nurse must emphasize the importance of seeking emergency care if the patient experiences difficulty breathing, sudden chest pain, palpitations, uncontrollable cough, or bloody sputum.

Though they do not meet the standard definition of outpatient surgery, there is a movement towards programs to fast-track thoracic patients to earlier discharge to reduce inpatient stays. These fast-track programs usually operate, recover, and discharge a patient within a few days of being admitted. The postoperative recovery periods at these centers focus on pain relief and advances in chest tube management. Patients are often able to be discharged home safely with chest tubes in place using either a Heimlich valve or a portable drainage collection system. As more fast-track programs evolve and are able to demonstrate successful outcomes, new indications for outpatient care are likely to evolve.

Modified from Cerolio R, Brant, AS: Does minimally invasive thoracic surgery warrant fast tracking of thoracic surgical patients? *Thorac Surg Clin* 18:301-304, 2008; Molins L et al: Outpatient thoracic surgery, *Thorac Surg Clin* 18:321-327, 2008.

PATIENT AND FAMILY EDUCATION

Patient Education and Home Care Teaching for Oxygen Therapy

GENERAL INFORMATION

- Review the physician's order for the type of delivery system and liter flow or percentage of oxygen to be delivered.
- Give the patient and the caregiver both *oral* and *written* instructions. Provide them with the name and telephone number of the physician to call if questions arise. Use visual aids to assist in instruction.

HOME CARE

- Explain the purpose for oxygen therapy and how it will be delivered to the patient.
- Warning signs (Review the signs and symptoms that should be reported to the physician):
  - Irregular, shallow, or slow breathing; difficulty in breathing
  - Restlessness or anxiety
  - Tiredness, drowsiness, trouble waking up
  - Persistent headache
  - Slurred speech
  - Confusion, difficulty in concentrating
  - Bluish fingernails or lips
- Inform the patient about the symptoms of oxygen toxicity:
  - Sore throat
  - Cough
  - Nausea
  - Anxiety
  - Numbness
  - Muscular twitching
  - Chest pain with deep inspiration

PATIENT AND FAMILY EDUCATION

Patient Education and Home Care Teaching for Oxygen Therapy—cont'd

- Special instructions:
  - Assist the patient to obtain a home healthcare referral for follow-up at home.
  - Explain the importance of maintaining the appropriate flow rate, since high flow rates in patients with chronic obstructive pulmonary disease can suppress the respiratory drive.
  - Teach the patient how to remove and reposition the oxygen equipment to permit wiping and drying the face, blowing the nose, and eating.
  - Instruct the patient on skin care procedures, since prolonged oxygen therapy can cause skin irritation and breakdown, which can provide an additional route for microorganisms. Advise patient to use non–petroleum-based cream on the face, lips, and nostrils to relieve the drying effects of oxygen.
  - Stress the importance of not smoking and not allowing others to smoke near the patient because of the possibility of combustion, fire, or explosion.
  - Ensure that no candles or matches are lit in the immediate area where oxygen is being administered.
  - Explain the necessity of checking all electrical equipment used in the same room as oxygen administration for frayed cords or the potential for sparking to avoid combustion and fire or explosion.
  - Advise the patient to obtain a fire extinguisher and keep it near the oxygen equipment.
- Activity:
  - Encourage walking and other activities as tolerated. Advise the patient to use a portable oxygen source because continuous oxygen therapy can limit mobility.
  - Suggest that the patient use oxygen, as ordered, during meals, showers, or sexual activities.
- Alternative therapy:
  - Discuss the use of relaxation techniques to minimize anxiety associated with shortness of breath.

FOLLOW-UP CARE AND REFERRALS

- Stress the importance of regular follow-up visits. Make sure the patient has the necessary names and telephone numbers.
- Discuss with the patient and caregiver the need to notify the local fire department and electric and gas utility companies of the presence of oxygen in the home.
- Instruct the patient to keep emergency numbers by the telephone.
- Assist the patient to obtain referral services, supplies, and information about support groups.

From Canobbio MM: *Handbook of patient teaching,* ed 3, St Louis, 2006, Mosby.

Standard Bronchoscopy Using Rigid Bronchoscope

Standard bronchoscopy is the direct visualization of the mucosa of the trachea, the main bronchi and their openings, and most of the segmental bronchi. It also includes removal of material for microscopic study if necessary.

Bronchoscopy is an integral part of the examination of patients with pulmonary symptoms such as persistent cough or wheezing, hemoptysis, obstruction, and abnormal roentgenographic changes. Common causes of bleeding (hemoptysis) are bronchiectasis, carcinoma, and tuberculosis. Congenital anomalies and suspected presence of a foreign body, especially in infants and children, are responsible for emergency examination of the respiratory tract.

The surgeon performs bronchoscopy to determine the presence of a lesion in the tracheobronchial passages, to identify and localize that lesion accurately, and to observe periodically the effects of therapy. It can be completed for dilating structures, debriding tumors, or evacuating clots. In suspected carcinoma, the aspirated secretions obtained by bronchoscopy may contain malignant cells.

Procedural Considerations. Flexible bronchoscopy on an adult patient may be completed after induction of local (topical) anesthesia or monitored anesthesia care; a child usually receives a general anesthetic. Patients undergoing rigid bronchoscopy should be paralyzed and ventilation continued to minimize trauma. The adult patient administered a local anesthetic may experience discomfort and anxiety. To reduce anxiety, the perioperative nurse should introduce members of the surgical team, explain intraoperative activities, and provide reassurance to the patient (Patient and Family Education, p. 950). The oral structures, including the teeth and lips, should be assessed for integrity. Loose teeth may require removal before or during the procedure.

The anesthesia provider or nurse providing moderate sedation may administer IV sedatives or analgesics during the procedure. See Chapter 4 for perioperative nursing considerations when the patient is receiving local or monitored anesthesia care. The topical (or local) anesthetic setup should include a headlight for visualization, laryngeal mirrors of various sizes, a lingual spatula, sprays with straight and curved cannulae, and anesthetic drugs, as ordered. Other items include the laryngeal syringe with straight and curved cannulae, Jackson cross-action forceps, and the Schindler pharyngeal anesthetizer, if desired. Luer-Lok 10-ml syringes and 20- and 22-gauge needles are needed for transtracheal injection. The surgical technologist ensures that all requested instrumentation is available to avoid delays and ensure the procedure is performed efficiently for the patient.

Anesthetic drugs frequently used for local or topical anesthesia are lidocaine (Xylocaine), procaine (Novocain), and tetracaine (Pontocaine, Cetacaine) with or without epinephrine. Pauses of 3 to 4 minutes are taken between applications of the anesthetic agent to the tongue, palate, and pharynx and then to the larynx and to the trachea. The surgeon or anesthesia

PATIENT AND FAMILY EDUCATION

Patient Education and Teaching for Bronchoscopy with Patient Administered Local Anesthetic

PREPROCEDURAL TEACHING

- Review the physician's explanation of the procedure and the reason for it; encourage the patient to ask questions and to discuss any fears or anxieties.
- Discuss who will perform the procedure and where it will take place.
- Instruct the patient to have someone available after the procedure to drive the patient home.
- Review the medications that will be used preoperatively (medications to decrease secretions, sedatives) and immediately before the procedure (topical anesthetics). Explain that the topical anesthetic may cause a cold, unpleasant sensation in the throat.
- Explain that the patient will be able to breathe around the bronchoscope.
- Reassure the patient that the nurse will provide emotional support during the procedure.

POSTPROCEDURAL TEACHING

- Explain that after the procedure the patient's vital signs will be monitored frequently; discuss the need to maintain nothing-by-mouth (NPO) status until the gag reflex returns.
- Provide explanations about any temporary hoarseness and sore throat. Lozenges and throat gargles can be provided after the gag reflex returns.
- Review the signs and symptoms that should be reported immediately to a physician or nurse:
  - Difficulty breathing
  - Chest pain
  - Inability to swallow
  - Excessive bloody mucus
- Establish a regular routine of deep breathing and ambulation at least every 2 hours; avoid coughing within the first 24 hours following a biopsy.
- Inform the patient that a soft diet may be needed for the first day or until throat pain disappears.
- Explain that extremely hot foods or liquids should be avoided.
- Encourage fluid intake to thin secretions unless contraindicated.
- Discuss the importance of not smoking.

From Canobbio MM: *Handbook of patient teaching,* ed 3, St Louis, 2006, Mosby.

provider applies the anesthetic agent by means of a spray or laryngeal syringe with a straight or curved cannula.

Some physicians prefer to have the patient sit upright and gargle with the topical anesthetic mixture, rinse it around in the mouth, and then expectorate it, thereby producing a partial anesthesia of the buccal mucosa and pharynx.

For direct bronchoscopy, the surgeon or anesthesia provider uses a long metal cannula attached to a syringe to apply the anesthetic agent to the surface of the vocal cords; then the agent is injected through the anesthetized glottis into the trachea. This act causes the patient to produce a sharp, sudden cough. For intrabronchial anesthesia, a portion of the anesthetic agent is introduced through the bronchoscope.

The patient may be positioned either in the supine position—with the shoulders elevated on a small roll, gel pad, or a sandbag to gently extend the head and neck—or in the sitting position.

The setup includes the bronchoscope, telescopes of desired types, fiberoptic light cords, and the fiberoptic light source. Each standard scope requires a fiberoptic light carrier, cord, and light source. The surgical technologist ensures that duplicates of each, along with the appropriate replacement lightbulbs for the light source, are available for immediate use. The light source should be tested periodically and immediately before use. To test the fiberoptic light carrier and telescope, the instrument should be held vertically by the ocular end. The endoscope should always be tested immediately before passage into the patient. The light-intensity dial should be set at the proper level, as specified by the manufacturer. The light source should be switched on and off to test its function. During a procedure, the perioperative nurse switches the light source to standby mode whenever it is not in active use to conserve the life of the bulb and promote cooling.

Other supplies that will be needed are suction tubing, aspirating tubes, specimen collectors, sponge carriers, and the desired type of forceps. The metal sponge carrier consists of two parts: an inner rod, which has two jaws protruding from its distal end; and an outer band, which is screwed down on the inner rod so that a sponge can be held securely within the jaws. Small gauze sponges are used to keep the field dry, remove secretions, and apply a topical anesthetic agent. Cytologic specimen collectors, such as the Clerf or Lukens, are used to hold secretions as they are obtained. Aspirating tubes of different lengths and designs are used to remove secretions and collect material for microscopic examination and culture(s). The straight aspirating tube with one or two openings at the distal end is used to remove material from the pharynx, larynx, and esophagus. The curved aspirating tube with a flexible tip is used to remove secretions from the upper and dorsal orifices of the bronchi.

The surgeon uses various types of forceps to remove foreign bodies or tissues for histologic study. Biting-tip forceps may be used to secure tissue for pathologic study. Forceps with jaws that veer laterally at about a 45-degree angle from the instrument's axis permit visualization during the biopsy maneuver. Bronchoesophageal forceps consist of a stylet, a cannula with a handle, a screw, a locknut, and a setscrew. Forceps for laryngeal and bronchial regions are designed to remove tissue specimens. The nurse should prepare several specimen containers with the identifying patient information label, along with laboratory

slips for specific requests. If brush specimens are collected, slides and alcohol are required.

The standard bronchoscope is a rigid speculum used for visualizing the tracheobronchial tree. The rigid bronchoscope might be selected for biopsy of a large central mass, for removal of a foreign object, or to control hemorrhage during biopsy of a vascular mass. The rigid bronchoscope remains the instrument of choice for removal of foreign bodies in infants and children. A fiberoptic light carrier is inserted into the bronchoscope to illuminate the distal opening. A side channel is incorporated into the bronchoscope to permit aeration of the lungs with oxygen or anesthetic gases. An additional device, the Sanders Venturi system, which is available to the anesthesia provider, provides adequate patient ventilation during bronchoscopies and laryngoscopies.

The endoscopist risks contamination in the presence of communicable diseases. For this reason, the endoscopist and assistants should wear facemasks and eye protection or wear a transparent shield attached to a headband (see Chapter 3 for specific Transmission-Based Precautions). With increasing numbers of patients with tuberculosis, particulate respirators are recommended as protective devices. Aseptic technique is used to prevent cross-contamination.

Operative Procedure

1. The patient's head is placed in position for visualization of the bronchus—to the left when the right main bronchi are inspected and to the right when the left bronchi are inspected. The head is lowered for inspection of the middle lobe.
2. The endoscopist places a tooth guard to protect the patient's teeth. The bronchoscope is inserted over the surface of the tongue, usually through the right corner of the mouth. The patient's lip is retracted from the upper teeth with a finger of the endoscopist's left hand. The epiglottis is identified and elevated with the tip of the bronchoscope.
3. The endoscopist passes the distal end of the scope through the true vocal cords of the larynx, and views the upper tracheal rings. A small amount of anesthetic solution may be sprayed through the tube on the carina of the trachea and into the bronchus with the bronchial atomizer or spray. The patient's head is moved to the left to obtain a view of the right bronchi. The right-angle telescope is inserted with the light adjusted into the bronchoscope.
4. The segmental bronchial orifices of the upper right lobe bronchi are viewed, and the telescope is removed. The endoscopist uses suction and aspirating tubes to clear the field of vision and remove accumulated secretions.
5. The endoscopist inserts an oblique 45-degree–angle telescope or right-angle telescope and advances it to inspect the middle lobe branches. The patient's head is lowered to view the right middle lobe or turned to the right to view the left main bronchus.
6. Secretions are aspirated by the endoscopist for study. Biopsy forceps are used if indicated; foreign bodies are removed with forceps.
7. The bronchoscope is removed, and the patient's face is cleansed.

The nurse encourages patients who have undergone bronchoscopy after administration of a local anesthetic to sit on the edge of the OR bed before transfer to the stretcher. An emesis basin and sponges should be provided for the patient's use. Assistance and support are provided to the patient to prevent a fall.

Postprocedural Concerns. Patient safety during and after endoscopy using topical anesthetics, local anesthetics, or monitored anesthesia care is a concern attributable to the medications administered. The gag reflex may not return for 2 to 3 hours. The patient may be positioned on his or her side or with the head of the bed elevated to promote drainage of secretions. The patient should be restricted from any oral intake until the gag reflex has returned. During bronchoscopy, particularly with a rigid bronchoscope, teeth could be loosened or oral structures damaged. The lips, teeth, and oral mucosa should be examined to ensure undisturbed integrity. Patients are often anxious to know the results of the procedure, and they benefit from the perioperative nurse's openness and willingness to discuss when results might be available, as well as the patient's feelings and concerns.

Bronchoscopy Using the Flexible Bronchoscope

Flexible bronchoscopy is performed to view structures that cannot be observed with a rigid scope. Flexible bronchoscopy may be performed in addition to a standard rigid bronchoscopy or as an independent procedure. If performed independently, the patient may remain on the transporting stretcher during the procedure. Flexible bronchoscopy is completed for the same reasons as rigid bronchoscopy. Flexible fiberoptic telescopes permit visualization of the upper, middle, and lower lobe bronchi. They can be passed in patients with a jaw deformity or cervical bone rigidity with less difficulty than the rigid scope. Flexible fiberoptic bronchoscopes are more frequently used, as is video endoscopy.

Procedural Considerations. Patient considerations are as described for rigid bronchoscopy. Instruments and equipment used include the flexible bronchoscope, fiberoptic light source, flexible biopsy forceps, flexible brush (optional; if used, slides and alcohol are necessary to collect specimen), labeled specimen collectors, pathology requests, syringe for wash, and suction tubing with collection tube attached to collect the wash specimen.

Operative Procedure

1. The lubricated bronchoscope is passed through the adapter on the endotracheal tube, which is held secure by the anesthesia provider. If local or monitored anesthesia care is used for the procedure, the lubricated bronchoscope may be passed nasally.
2. The suction tube is positioned with the specimen collector attached for collection of bronchial washings. When indicated, the suction tubing is connected to the bronchoscope; the container for collection is held securely in an upright position to prevent loss of the specimen through the suction.
3. The endoscopist or surgical technologist injects approximately 5 ml of saline solution into the channel. Suction is quickly reapplied. This procedure may be repeated as necessary.

After completion of the procedure, the perioperative nurse sends the specimens to the laboratory for analysis.

Mediastinoscopy

Mediastinoscopy is the direct visualization and possible biopsy of lymph nodes or tumors at the tracheobronchial junction, under the carina of the trachea, or on the upper lobe bronchi or subdivisions. Mediastinoscopy may precede an exploratory thoracotomy in known cases of lung carcinoma or may be completed to assist in accurately staging the patient's lymph node status. Patients with positive findings may be treated with radiation or chemotherapy, as indicated. The mediastinoscope is a hollow tube with a fiberoptic light carrier. A fiberoptic light source with a light-intensity dial provides power and control of illumination.

Procedural Considerations. The setup for mediastinoscopy includes a set of instruments for incising, cutting, retracting, and suturing similar to those needed for a minor procedure. In addition, the desired type of mediastinoscope, fiberoptic light cords, fiberoptic light source, suction tubing, aspirating tubes, biopsy forceps, electrosurgical unit (ESU), and an 8-inch, 20-gauge endocardiac needle are required. Depending on institutional policy, a thoracotomy tray may be in the OR on standby in the event of uncontrolled bleeding after biopsy.

The anesthesia provider administers a general anesthetic agent and assists with positioning the patient as described for a tracheostomy (see Chapter 18).

Operative Procedure

1. The surgeon makes a short (approximately 2-cm) transverse incision above the suprasternal notch, and exposes and incises the pretracheal fascia.
2. Using blunt (digital) dissection, the surgeon tunnels alongside the trachea into the mediastinum.
3. The surgeon introduces the mediastinoscope under direct vision deep to the fascial plane and advances it along the side of the trachea toward the mediastinum.
4. The scope is manipulated to visualize the tracheal bifurcation, bronchi, aortic arch, and associated lymph nodes.
5. Lymph node tissue is located for biopsy and aspirated with a small-gauge needle and syringe to verify that it is a nonvascular structure.
6. The surgeon inserts a biopsy forceps through the scope, and obtains a tissue specimen. Pressure can be applied to the excision site with a bronchus sponge on a holder. The mediastinum is reinspected for bleeding.
7. The mediastinoscope is withdrawn.
8. Subcutaneous tissue is sutured with absorbable sutures. The surgeon closes the skin with nonabsorbable material on a small cutting needle.
9. A small dressing is applied.

Video-Assisted Thoracic Surgery

Video-assisted thoracic surgery (VATS) is a minimally invasive operative technique that has evolved over the past decade. It uses an endoscopic approach to visualization of the thoracic cavity for diagnosis of pleural disease or treatment of pleural conditions, such as cysts, blebs, and effusions; for biopsy of mediastinal masses; to perform wedge resections, lobectomy, pericardectomy, lung volume reduction surgery, and cervical sympathectomy; to obtain hemostasis; and to evacuate blood clots or divide adhesions (Khraim, 2007). Pleurodesis with instillation of talc, tetracycline, or other sclerosing treatment can be accomplished through the thoracoscope (Surgical Pharmacology). VATS has many benefits, including the elimination of a thoracotomy incision, decreased pain, shortened hospital stay, and reduced morbidity. VATS may also be used in conjunction with robotically assisted thoracic procedures such as robotic lobectomy.

SURGICAL PHARMACOLOGY

Agents for Chemical Pleurodesis

Pleurodesis is undertaken as a treatment for malignant pleural effusion and for unresolved spontaneous pneumothorax. A variety of chemical agents are used to cause adherence of the pleural layers. Adherence of the pleural layers is thought to prevent the accumulation of pleural fluid in the case of pleural effusion and to prevent subsequent pneumothoraces. Commonly used agents for chemical pleurodesis are listed. Other agents may be used according to the surgeon's preference, surgical region, and agent availability. Perioperative nurses should consult with the surgeon before the procedure to determine the agent used.

Agent	Mechanism of Action	Dosage	Side Effects	Nursing Considerations
Talc	Stimulates mesothelial cells to coordinate an inflammatory response	5-10 g in 250 ml of sodium chloride	Pain, infection, ARDS, pulmonary edema	May be administered as a poudrage, aerosol, or slurry. Facial talc is unsterile, contains asbestos, and requires stringent sterilization technique. Commercially available sterile talc is preferable.
Antineoplastics	Chemical pleural irritation and fibrosis of pleural surfaces	Bleomycin: 60 units mixed with 100-200 mg of lidocaine	Pain, fever, neutropenia	Antineoplastics require special handling to reduce personal exposure. Nurses should follow hospital policies and procedures for safe medication handling procedures.

SURGICAL PHARMACOLOGY

Agents for Chemical Pleurodesis—cont'd

Agent	Mechanism of Action	Dosage	Side Effects	Nursing Considerations
Cyclines	Indirectly stimulate pleural macrophages, activating pleural mesothelial cells; low pH initiates an inflammatory reaction, causing fibrosis	Minocycline: 7 mg/kg Doxycycline: 500 mg in 30-50 ml of sodium chloride	Pain, fever, hemothorax, neutropenia	Determine if patient is allergic to cycline medications before procedure.
Silver nitrate	Coagulates cellular protein to form pleural eschar	20 ml of 0.5% silver nitrate	Pain, fever	Handle with care. Solution stains skin and clothing.
Quinacrine	Causes systemic inflammatory response	500 mg in 200 ml of saline	Pain, fever	Not available in United States or Canada.
Iodopovidone	Mechanism of action unknown	20 ml of 10% iodopovidone in 80 ml of saline	Severe pain, hypotension	Assess patient for allergies to iodine.

ARDS, Acute respiratory distress syndrome.

Modified from Colt HG, Davoudi M: The ideal pleurodesis agent: still searching after all these years, *Lancet Oncol* 9(10):912-913, 2008; Demmy TL, Nwogu C: Malignant pleural and pericardial effusion. In Selke FW et al, editors: *Sabiston & Spencer surgery of the chest,* ed 7, Philadelphia, 2005, Saunders; Dikensoy O, Light RW: Alternative widely available, inexpensive agents for pleurodesis, *Curr Opin Pulmonary Med* 11:340-344, 2005; Khaleeq G, Musani AI: Emerging paradigms in the management of malignant pleural effusions, *Respir Med* 102:939-948, 2008; Kilic D et al: Management of recurrent malignant pleural effusion with chemical pleurodesis, *Surg Today* 35:634-638, 2005.

Procedural Considerations. Endoscopic instrumentation and equipment used for a thoracoscopy include 5- and 10-mm telescopes, light cord, camera, graspers, dissectors, scissors, ligators, and endoscopic soft tissue instruments (scissors, hemostats, suction tips, retractors) and stapling devices. Accessory equipment for video (television monitors, videocassette recorder, printer, light source for camera and scope, slave television monitor) and insufflation is also used. The perioperative nurse will assist in positioning the patient supine, semilaterally or laterally, depending on the anatomic structures involved.

Operative Procedure

1. The surgeon creates a 2- to 3-cm incision between the fifth and seventh intercostal spaces for insertion of the 10- or 12-mm trocar. The zero-degree telescope is inserted to view the site so that the approach can be determined.
2. If the procedure can be completed by thoracoscopy, the surgeon creates additional puncture sites for insertion of additional trocars to allow instrument manipulation. The size of trocars and types of instruments vary for the diagnosis.
3. After the selected procedure, the surgeon inserts a chest tube through one of the surgical puncture sites and secures it to the skin. Trocar sites are closed, and small dressings or adhesive skin tapes are applied.

Endoscopic Thoracic Sympathectomy

Hyperhidrosis is defined as excessive sweating, usually affecting the palms, axillae, and soles of the feet. It may also affect the face, groin, or legs. Patients with severe hyperhidrosis may produce 40 times the normal amount of sweat (Solish et al, 2008). Hyperhidrosis affects approximately 2.8% of the general population, with 1.4% of these individuals projected to have axillary hyperhidrosis and 0.5% to have sweating that is intolerable or interferes with daily activities (Weksler et al, 2008). Familial history of hyperhidrosis is implicated in 30% to 65% of cases (Solish et al, 2008). Endoscopic thoracic sympathectomy (ETS) is a thoracoscopic intervention used to surgically treat hyperhidrosis (Research Highlight). To treat palmar hyperhidrosis, the surgeon interrupts the sympathetic chain at the T2 level. Compensatory sweating, defined as increased sweating in other areas following the procedure, is the most common side effect of this procedure. The incidence of mild compensatory sweating varies from 14% to 90% and the incidence of severe compensatory sweating ranges from 1.2% to 30.9% (Dumont, 2008). Many patients who undergo ETS do so on an ambulatory basis or require only an overnight stay. The procedure produces dramatic and immediate results and is associated with a positive outcome for the patient. ETS may also be used to surgically treat pain syndromes (e.g., complex regional pain syndrome), facial blushing, and Raynaud's syndrome.

Procedural Considerations. The patient is positioned supine, and the anesthesia provider inserts a double-lumen endotracheal tube. Video monitors are placed on each side of the patient to allow the surgeon an unobstructed view from either side, because the procedure is performed bilaterally.

Operative Procedure

1. The anesthesia care provider deflates the patient's lung as directed by the surgeon.
2. The surgeon uses the scalpel to make a small (2 mm or less) incision between the patient's second and third ribs in the axillary plane.
3. A disposable thoracic port is inserted through the incision, and the surgeon inserts a small (2- or 5-mm) telescope through the port.
4. The surgeon identifies the sympathetic chain at the T2 level (Figure 22-9, *A* and *B*), and uses endoscopic scissors to open the pleura.
5. The nerve is grasped with a bipolar forceps and divided with bipolar electrocoagulation (Figure 22-9, *C*). Alternatively, clips may be applied to the nerve.

RESEARCH HIGHLIGHT

Thoracoscopic Sympathectomy versus Medical Management for Severe Hyperhidrosis

Hyperhidrosis can be an extremely disabling condition for which medical management is the first-line treatment. While many patients are able to control their hyperhidrosis through medical management (e.g., topical aluminum chloride, anticoagulants, botulinum toxin A injections, use of iontophoresis [a treatment that uses water to conduct an electrical current through the skin's surface that results in microscopic thickening of the outer layer of the skin, which blocks the flow of sweat to the skin surface]), these treatments are temporary, require a high degree of patient commitment, and are associated with side effects. The researchers in this study sought to compare the outcomes of medical versus surgical management for palmoplantar hyperhidrosis (e.g., excessive sweating of the hands and feet) and evaluate the efficacy and side effects of both treatments.

Researchers conducted a prospective and retrospective study of 192 patients who met the criteria of (1) massive palmar sweating to the point of dripping or near-dripping, (2) plantar sweating approximating the palmar sweating, (3) simultaneous onset either in early childhood or at puberty, and (4) exacerbation with the use of ordinary hand lotion. The vast majority of patients met all four criteria, and no patient had fewer than three of the criteria. A total of 46 patients in the prospective group used the medical treatments for at least 2 weeks, and their responses and side effects were noted. If the medical treatment was unsatisfactory because of intolerable side effects or lack of response, the group was offered endoscopic thoracic sympathectomy (ETS). Only 1 patient from the prospective group and 1 patient from the retrospective group were satisfied enough with the results of medical management to forgo ETS surgery; 89 patients in the retrospective group underwent ETS.

Data analysis revealed that six (3.2%) patients who underwent ETS experienced severe compensatory sweating that resulted in significant discomfort. One patient experienced a pneumothorax, but no other significant complications were reported from ETS. Complications reported from medical management included palmar reactions (from topical solutions), with cracking and continued sweating through the cracks, and mouth dryness/discomfort, blurred vision, mental changes, and headaches. All of the patients who used botulinum toxin A experienced palmar pain, and one third of patients in the iontophoresis group developed pain and irritation from the treatments. Researchers concluded that ETS can "safely and confidently" be recommended as a first-line treatment of severe palmoplantar hyperhidrosis.

Modified from Baumgartner FJ et al: Superiority of thoracoscopic sympathectomy over medical management for the palmoplantar subset of severe hyperhidrosis, *Ann Vasc Surg* 23:1-7, 2009.

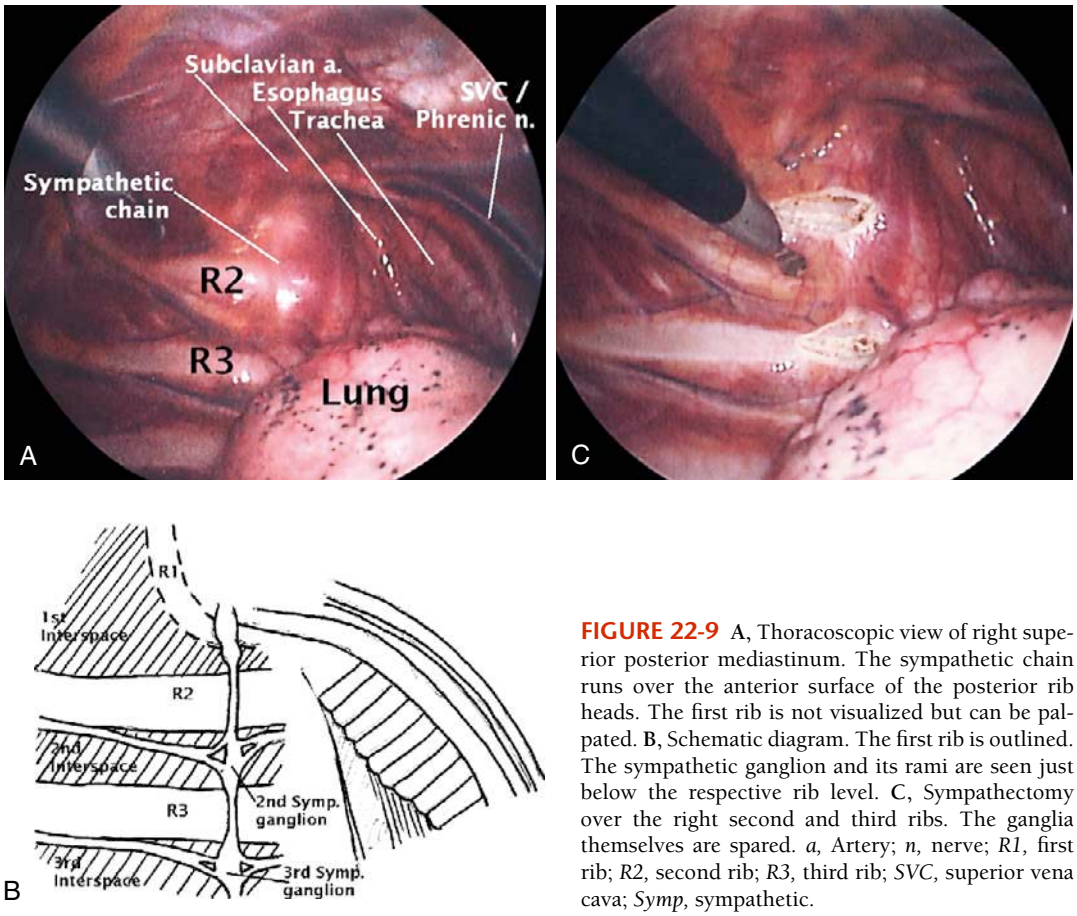

FIGURE 22-9 **A**, Thoracoscopic view of right superior posterior mediastinum. The sympathetic chain runs over the anterior surface of the posterior rib heads. The first rib is not visualized but can be palpated. **B**, Schematic diagram. The first rib is outlined. The sympathetic ganglion and its rami are seen just below the respective rib level. **C**, Sympathectomy over the right second and third ribs. The ganglia themselves are spared. *a*, Artery; *n*, nerve; *R1*, first rib; *R2*, second rib; *R3*, third rib; *SVC*, superior vena cava; *Symp*, sympathetic.

6. The port is removed, and a small thoracic catheter is inserted through the incision.
7. The surgeon closes the incision, and the lung is reexpanded. As the air is forced out of the pleural cavity, the catheter is removed and wound closure is completed.
8. The procedure is repeated for the opposite side.
9. Adhesive skin tapes are placed over the incision sites.
10. A postoperative chest x-ray film is obtained in the PACU to rule out any residual pneumothorax.

Robotic-Assisted Surgery

Robotic-assisted thoracic procedures have evolved since the introduction of robotic technology in the 1990s; they enhance the speed, accuracy, and safety of VATs (Kernstine et al, 2008). During traditional thoracotomy the surgeon's view is hampered by the size of the incision and rigidity of the chest wall. An advantage to the robotic-assisted approach is the superior three-dimensional view of the operative field and thoracic cavity, allowing the surgeon superior visualization, increased magnification, and better maneuverability. Smaller incisions are used for robotic surgery, so patients experience less postoperative pain and morbidity (Figure 22-10). A variety of robotic-assisted procedures are performed by specially trained surgeons, including mediastinal tumor resection, lobectomy, and sympathectomy. Continued advances in technology will allow for the development of additional applications and procedures within the thoracic specialty. The procedure for robotic-assisted lobectomy is described below.

Procedural Considerations. Refer to Chapter 7 for a general discussion of the equipment and instrumentation (e.g., robotic console, chassis) used for the procedure. In addition to preparing for the robotic procedure, the perioperative nurse and surgical technologist ensure that they have also gathered instrumentation and supplies to convert to an open procedure in the event an emergency arises or the surgeon is unable to complete the procedure through the minimally invasive approach. The nurse assists the anesthesia provider with inserting a double-lumen endotracheal tube and helps to position the patient in the lateral position with the operative side up. After the patient is prepped and draped, the anesthesia provider places the patient in reverse Trendelenburg's position. The nurse assists with positioning the robot, video monitors, and three-dimensional vision console equipment.

Operative Procedure

1. The surgeon consults the patient's preoperative CT scans to determine the placement of the thoracoports based on the location of the lesion.
2. The surgeon incises the skin at the seventh to eighth intercostal space along the midposterior axillary line and inserts the 12-mm thoracoport.
3. The robotic system is positioned, and the surgeon inserts a 30-degree scope through the thoracoport and connects the scope to the camera arm.
4. The surgeon incises the skin at the sixth to seventh, fourth to fifth, and fifth to sixth intercostal spaces, inserts the remaining thoracoports, and passes the dissecting instruments through the ports and connects them to the instrument arms.
5. A combination of blunt and sharp dissection is used by the surgeon around the hilar structures to gain exposure to the pulmonary vessels.
6. The surgeon ligates the pulmonary vein and artery using suture and/or robotic clips.
7. The surgeon dissects the lobar bronchus and nodes.
8. A 3.5-mm endostapler is passed through the appropriate thoracoport, clamped, and fired to complete the bronchial transaction.
9. The specimen is placed in a sterile removal bag and removed via the port site.
10. The surgeon tests the bronchial stump for leaks under water.
11. The pleural space is vented and the surgeon places a closed suction drain before closing the incisions.
12. Dressings are applied.

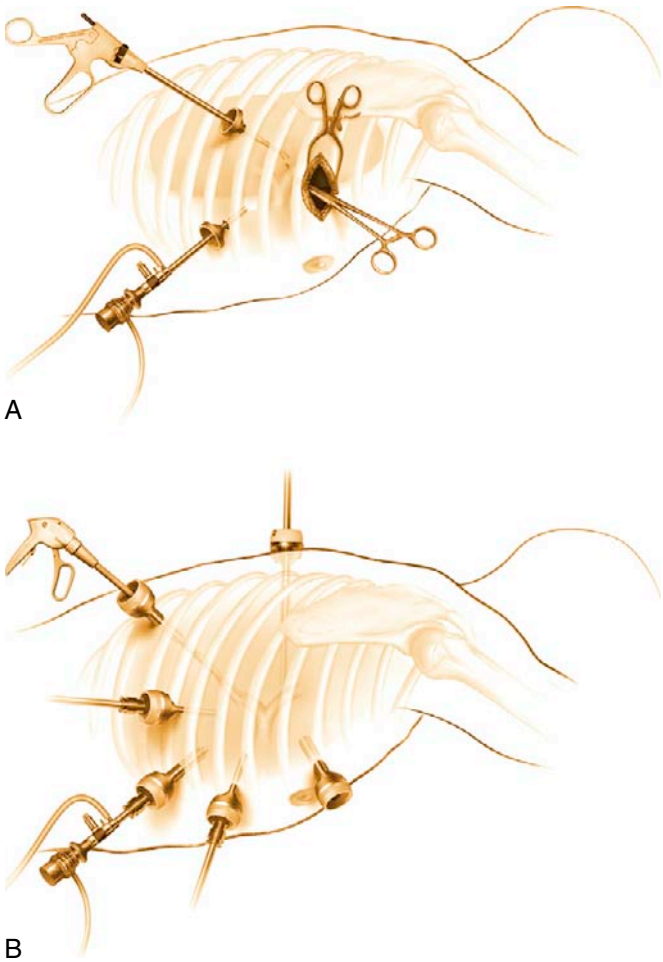

FIGURE 22-10 Comparison of VATS lobectomy to robotic lobectomy: The two patients shown are undergoing hilar dissection. **A**, VATS resection. There are three incisions shown, one for the videoscope and the other two for the right-angle clamp and stapler. The manipulation of the instrumentation and the arcs of rotation occur outside of the chest. The fulcrum of the instrumentation occurs at the chest wall, compressing and distending the intercostal nerves. **B**, Robotic resection. The arcs of rotation and management of the instrumentation for dissection are within the chest, allowing surgical dissection to occur in small spaces.

LUNG SURGERY

Thoracotomy

Thoracotomy involves an incision in the chest wall through a median sternotomy or a lateral or posterolateral incision for the purpose of operating on the lungs (History box). Thoracotomy may be performed for a variety of benign and malignant conditions. Lung cancer (Figure 22-11) is a common diagnosis associated with thoracotomy. Patients with lung cancer may have specific treatment based on their tumor, node, and metastasis (TNM) characteristics. The TNM system defines tumor (T) as the size, location, and spread (pulmonary or extrapulmonary). The designation of nodes (N) refers to spread to a lymph node or group of lymph nodes. Metastasis (M) relates to metastatic tumor activity in distant organs (e.g., brain, liver) (Box 22-1). Staging is based on TNM findings (Figure 22-12). Intraoperative patient care is similar for various thoracotomy procedures, with consideration of the patient's history and disease process, planned procedure, and individualized patient needs. Basic thoracic instrumentation is used and may include a sternal saw and stapling devices. Preparation by the anesthesia care provider with careful monitoring of the patient is a priority. Insertion of a double-lumen endotracheal tube, an arterial line for monitoring ABG samples, and a central venous line to ensure patent access for fluids are procedures performed by the anesthesia provider. An epidural catheter may be inserted for intraoperative and postoperative pain management. Patient preparation by the surgical team includes positioning, placement of devices for prevention of complications (e.g., sequential compression devices, thermal-regulating blanket, electrosurgical dispersive pad), insertion of a urinary catheter, and ongoing evaluation and communication of the patient's status to the family throughout the procedure.

Pneumonectomy

Pneumonectomy is the removal of an entire lung, usually to treat malignant neoplasms. Other reasons for this procedure include removal of an extensive unilateral bronchiectasis (e.g., irreversible dilation of the bronchi) involving the greater part of one lung, drainage of an extensive chronic pulmonary abscess involving portions of one or more lobes, removal of selected benign tumors, and treatment of any extensive unilateral lesion. Other resections are often combined with pneumonectomy, such as resection of mediastinal lymph nodes, resections of portions of the chest wall or diaphragm, and removal of parietal pleura.

HISTORY

Important Events in Thoracic Surgery

As early as 3000 BC, treatments related to the lungs and chest were undertaken as a result of injuries and wounds. It was not until the eighteenth century, however, that physiologic studies and animal experiments included the respiratory system. Several early reports discussed trauma, noting that wound closure helped the patient breathe easier. Thus the relationship between respiration and lung function was first established. During World War I there was increased awareness of the value of immediate closure of chest wounds.

The first thoracic procedure, recorded in 1499, was an unsuccessful excision of a herniation of the lung. From that time, the physiologic effect on the lungs and perceived difficulty entering the chest resulted in hesitancy to perform thoracic procedures. Until the 1880s the only thoracic procedures performed were to drain empyema and lung abscess or to treat traumatic chest injury. In 1823 the first purposeful resection of a part of the lung for accidental injury was reported by Milton Antony, and in 1861 the French surgeon Péan removed part of a lung for tumor.

Treatment of tuberculosis (TB) also provided an impetus for new developments in thoracic procedures. Thoracoplasty became widely used as a means of collapsing the lungs for treatment of TB, followed by other forms of treatment. In 1907 an article was published describing surgical techniques for access to the thoracic cavity. In 1913 Jacobeus is credited with dividing adhesions with an electrosurgical unit (ESU) passed through one cannula while through another he passed a cystoscope-like instrument he called a *thoracoscope.* Student textbooks in the 1920s contained only a short paragraph on cancer of the lung. From that time until the first successful pneumonectomy in 1933, many attempts were made to remove carcinomas, with limited success.

In 1899 the first important article on tumors of the chest wall was written. It summarized case reports of 46 other cases and classified the various tumor types. The first accounts of pulmonary resection were published in 1896, and one of the first cases of cancer of the lung to be reported in the United States was in 1851. Equipment and instrument development also improved the ability to study lung function. Although the bronchoscope was introduced in 1937, it was not used to study chest diseases until later. Using the bronchoscope became more important to remove secretions when Papanicolaou identified the advantages of applying cytologic technique to diagnosis of cancer.

The nursing care of patients with thoracic conditions evolved over time as medical and surgical treatments advanced and technology made new treatments available. Modern-day thoracentesis is generally accomplished using a presterilized disposable kit from a manufacturer. In the 1920s nurses who assisted with thoracentesis were responsible for acquiring a rubber sheet to protect the bed, sterile sheets to create a sterile field, sterile cotton, a hypodermic syringe and needle, sterile gloves and powder for the physician, and the aspirating set. The aspirating set consisted of a graduated 5- to 8-pint glass bottle with a rubber stopper fitted with a bifurcated metal tube and stopcocks. Rubber tubing with metal connectors was attached to the metal tube, and the sterile aspirating needle was connected to one branch of the tubing. The other branch of the tubing was connected to an exhaust pump. The nurse was responsible for testing the apparatus before the physician arrived, because the apparatus was used instead of a syringe for aspiration. Postprocedure treatment for the patient was described as "the patient must remain quietly in bed, in the recumbent position and no exertion or sudden movements should be allowed. The greatest precautions should be taken to prevent the entrance of infection."

BOX 22-1

TNM Definitions and Staging for Lung Cancer

T—PRIMARY TUMOR

T_x	Tumor that cannot be assessed, or malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy.
T_{is}	Carcinoma in situ.
T_0	No evidence of primary tumor.
T_1	A tumor that is 3 cm or less in greatest dimension, surrounded by lung or visceral pleura, and with no evidence of tumor invasion proximal to a lobar bronchus as determined at bronchoscopy.
T_2	A tumor that is either (1) more than 3 cm in greatest dimension or (2) invasive of the visceral pleura or associated with atelectasis or obstructive pneumonitis that extends to the hilar region. At the time of bronchoscopy the proximal extent of the tumor must be within a lobar bronchus or at least 2 cm or more distal to the carina. Any atelectasis or obstructive pneumonitis must not involve the entire lung.
T_3	A tumor of any size that invades the chest wall (including superior sulcus tumors), diaphragm, the mediastinal pleura, or the pericardium, but not involving the heart, great vessels, trachea, esophagus, or vertebral body. A tumor in the main bronchus within 2 cm of the carina without involving it or associated atelectasis or obstructive pneumonitis of entire lung is also a T_3 tumor.
T_4	A tumor of any size that invades the mediastinum, heart, great vessels, trachea, esophagus, vertebral body, or carina; or presence of malignant pleural or pericardial effusion; or with satellite tumor nodules within the ipsilateral, primary tumor lobe of the lung.

N—NODAL INVOLVEMENT

N_x	Regional lymph nodes cannot be assessed.
N_0	No metastasis to regional lymph nodes.
N_1	Metastasis to lymph nodes in the peribronchial or the ipsilateral hilar region or both, including direct extension.
N_2	Metastasis to ipsilateral mediastinal lymph nodes and subcarinal lymph nodes.
N_3	Metastasis to contralateral mediastinal lymph nodes, contralateral hilar lymph nodes, or ipsilateral or contralateral scalene or supraclavicular lymph nodes.

M—DISTANT METASTASIS

M_x	Distant metastasis cannot be assessed.
M_0	No (known) distant metastasis.
M_1	Distant metastasis present.

Stage	TNM Subsets
0	T_{is}, N_0, M_0
IA	T_1, N_0, M_0
IB	T_2, N_0, M_0
IIB	T_2, N_1, M_0
	T_3, N_0, M_0
IIIA	T_3, N_1, M_0
	T_{1-3}, N_2, M_0
IIIB	T_4, N_{0-2}, M_0
	Any T, N_3, M_0
IV	Any T, any N, M_1

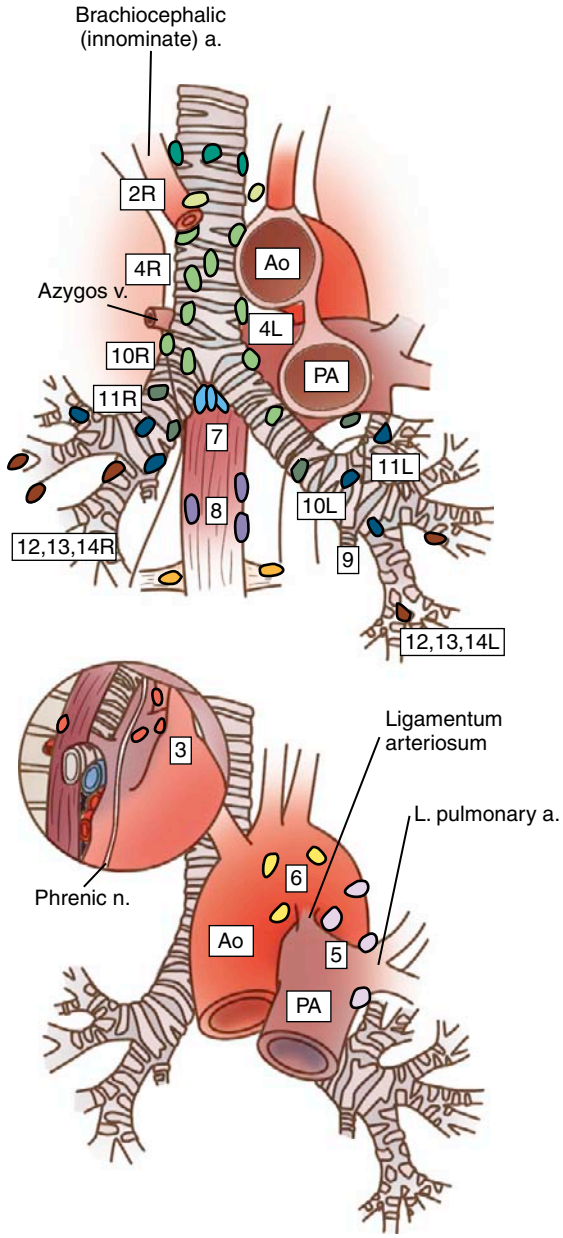
BOX 22-1

TNM Definitions and Staging for Lung Cancer—cont'd



Superior Mediastinal Nodes

- 1. Highest mediastinal
- 2. Upper paratracheal
- 3. Prevascular and retrotracheal
- 4. Lower paratracheal (including azygos nodes)

N_2 = single digit, ipsilateral

N_3 = single digit, contralateral supraclavicular

Aortic Nodes

- 5. Subaortic (A-P window)
- 6. Para-aortic (ascending aorta or phrenic)

Inferior Mediastinal Nodes

- 7. Subcarinal
- 8. Paraesophageal (below carina)
- 9. Pulmonary ligament

N_1 Nodes

- 10. Hilar
- 11. Interlobar
- 12. Lobar
- 13. Segmental
- 14. Subsegmental

Regional lymph node stations for the staging of non–small cell lung cancer. Mediastinal nodes (i.e., N_2 nodes) are depicted by single digits, and intrapulmonary nodes (i.e., N_1 nodes) are depicted by two digits.

Procedural Considerations. The basic thoracic instrumentation is used. The perioperative nurse facilitates positioning the patient in the lateral position for a posterolateral incision.

Operative Procedure

1. The surgeon incises the skin, subcutaneous tissue, and muscle with a scalpel and the ESU. Hemostasis is attained. If a rib is to be excised, bone instruments are required.
2. The ribs and tissue are protected with moist sponges; the rib retractor is placed (Figure 22-13) and opened slowly and gently.
3. The surgeon frees any peripheral adhesions to mobilize the lung and divides the pulmonary ligament. Dissection to the hilum of the involved lobe is carried out.
4. The superior pulmonary vein is gently retracted, and the pulmonary artery is dissected.

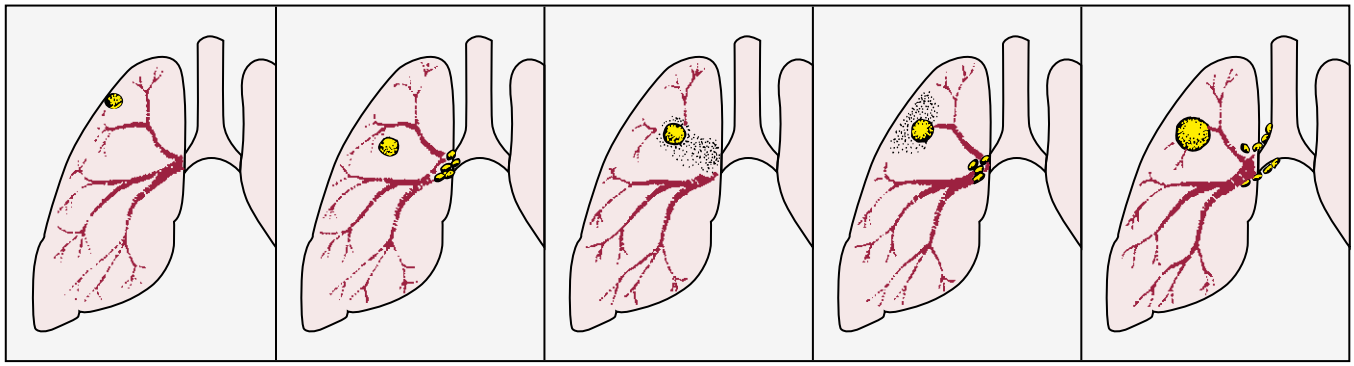


FIGURE 22-12 Staging of lung cancer by TMN system. **A** and **B**, Stage I disease includes tumors classified as T_1 with or without metastasis to the lymph node in the ipsilateral hilar region. **C**, Also included in stage I are tumors classified as T_2 but having no nodal or distant metastases. **D**, Stage II disease includes those tumors classified as T_2, with metastasis only to the ipsilateral hilar lymph nodes. **E**, Stage III includes all tumors more extensive than T_2 or any tumor with metastasis to the lymph nodes in the mediastinum with distant metastasis.

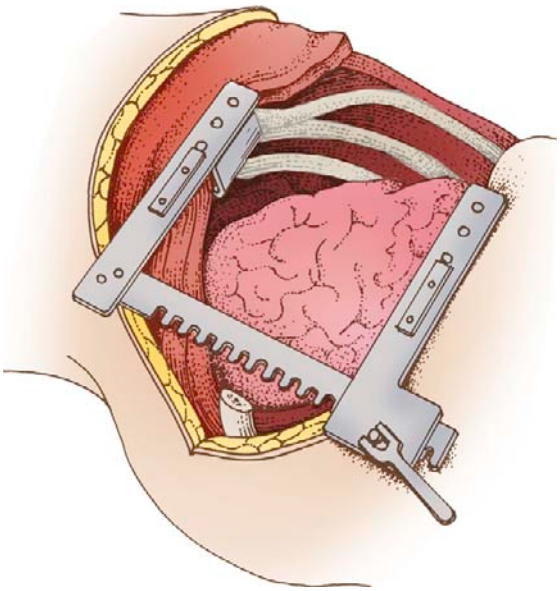

FIGURE 22-13 Rib retractor placed for thoracotomy.

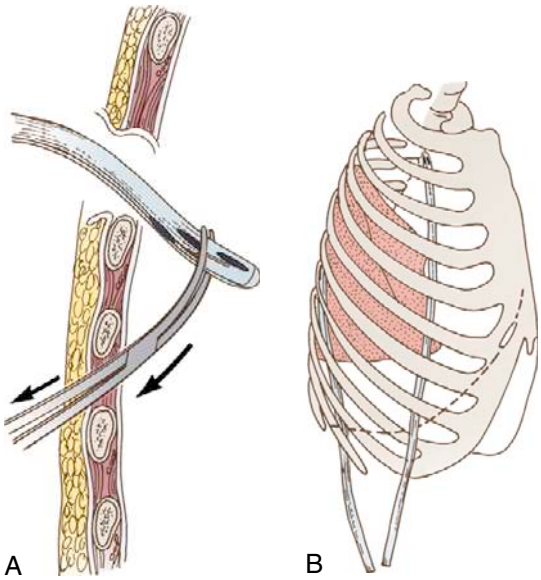

FIGURE 22-14 **A**, Introduction of chest drainage tube through a stab wound. **B**, Placement of apical and basal drainage tubes after upper and middle lobectomy.

5. The surgeon clamps the branches of the pulmonary artery and vein of the involved lobe, places double ligatures, and divides them with fine right-angled vascular clamps, scissors, and nonabsorbable suture.
6. The inferior pulmonary vein is exposed by incising the hilar pleura and retracting the lung anteriorly. The inferior pulmonary vein is clamped, doubly ligated, and divided.
7. The surgeon applies a bronchus clamp and divides the bronchus near the tracheal bifurcation. The stump is closed with atraumatic nonabsorbable mattress sutures or bronchus staples. If staples are applied, the scalpel is used to complete division of the bronchus. The lung is removed from the chest.
8. The surgical technologist supplies normal saline to irrigate the pleural space and check for hemostasis and air leaks during positive-pressure inspiration.
9. A pleural flap is created and sutured over the bronchial stump (other methods of securing the bronchus might be used).
10. Hemostasis is ensured in the pleural space.
11. Chest tubes (28-French to 30-French) are inserted into the pleural space and exteriorized through a stab wound at the eighth or ninth interspace near the anterior axillary line (Figure 22-14). An upper tube is inserted through a second stab wound if indicated to evaluate leaking air. The tubes are secured with heavy sutures and connected to water-seal drainage after closure of the pleural space.
12. The surgeon places the rib approximator (Figure 22-15) and begins closure with interrupted sutures.
13. The muscle, subcutaneous tissue, and skin are closed. Drains are anchored to the chest wall with suture.

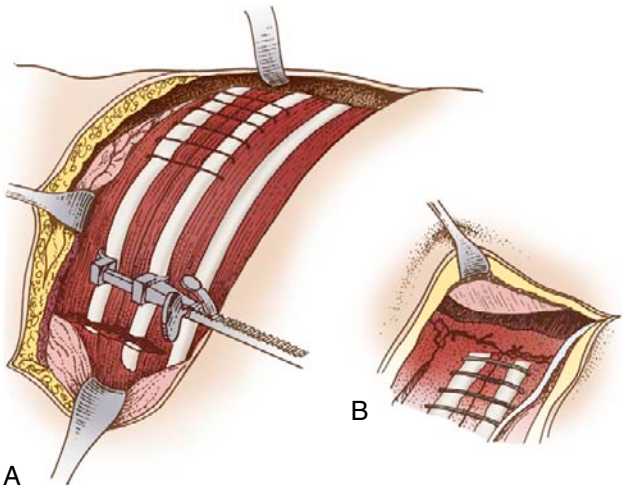

FIGURE 22-15 **A**, Rib approximator placed for closure of incision. **B**, Heavy-gauge suture used for closure of ribs.

14. The dressing is applied.
15. Chest tube connections are secured with Parnham bands or tape and labeled (anterior or posterior).

Lobectomy

Lobectomy is excision of one or more lobes of the lung. It is performed when the primary tumor is located in a particular lobe or to remove metastatic lesions when the tumor is peripherally located and hilar nodes are not involved. Other conditions affecting the lung and treated by lobectomy might be bronchiectasis; giant emphysematous blebs or bullae; large, centrally located benign tumors; fungal infections; and congenital anomalies.

Procedural Considerations. Basic thoracic instrumentation is used. The perioperative nurse assists with placing the patient in a lateral position for a posterolateral approach; the supine position may be used for upper- and middle-lobe resections. The procedure varies with the specific lobe to be removed depending on the anatomic structure.

Operative Procedure

1. The surgeon incises the skin, subcutaneous tissue, and muscle using a blade and the ESU. Hemostasis is attained. If a rib is to be excised, bone instruments are required.
2. The ribs and tissue are protected with sponges. The rib retractor is placed and opened slowly and gently.
3. The surgeon enters the pleura and frees the peripheral adhesions with scissors, blunt dissection, or a sponge on a sponge-holding forceps.
4. The hilar pleura is incised and separated.
5. The branches of the pulmonary arteries and veins are isolated, clamped, doubly ligated, and divided with fine, right-angled vascular clamps, scissors, and nonabsorbable suture.
6. The surgeon identifies the main trunk of the pulmonary artery and the fissure between the lobes.
7. The bronchus clamp is applied. The remaining lung is inflated to identify the line of demarcation. The bronchus is divided with a scalpel or heavy scissors.
8. Bronchial secretions are suctioned.
9. The surgeon closes the bronchus with atraumatic nonabsorbable mattress sutures or bronchus staples. If staples are applied, a blade is used to complete division of the bronchus.
10. Incomplete fissures are divided between hemostats with fine Metzenbaum scissors. Edges may be sutured closed.
11. A pleural flap is created and sutured over the bronchial stump (other methods of securing the bronchus might be used).
12. The pleural cavity is thoroughly irrigated with normal saline, and hemostasis is ensured. The remaining lobes are inflated to check for air leaks, and the degree of expansion of the remaining lobes is assessed.
13. The pleural space is irrigated, and the procedure is completed as described for a pneumonectomy.

Segmental Resection

Segmental resection is removal of one or more anatomic subdivisions of the pulmonary lobe. It conserves healthy, functioning pulmonary tissue by sparing remaining segments. Segmental resection is indicated for any benign lesion with segmental distribution or diseased tissue affecting only one segment of the lung with compromised cardiorespiratory reserve. The most common cause for removal is bronchiectasis. Other conditions requiring removal include chronic, localized inflammation and congenital cysts or blebs.

Procedural Considerations. Basic thoracotomy instrumentation is used. The perioperative nurse assists the surgical team in placing the patient in the lateral position.

Operative Procedure

1. The surgeon incises the skin, subcutaneous tissue, and muscle using a blade and the ESU.
2. The parietal pleura is incised with a scalpel and scissors. Adhesions are divided with sharp or blunt dissection.
3. The segmental artery is identified to provide accurate identification of the bronchus of the diseased segment.
4. The surgeon ligates the segmental pulmonary vein and branches.
5. The surgeon clamps the bronchus with the bronchus clamp, and the remaining lung is inflated. The intersegmental boundary is confirmed, and proper placement of the clamp is ensured.
6. The visceral pleura is incised around the diseased segment, beginning anterior to the hilum and progressing toward the periphery. Exposure is facilitated with a malleable or other type of retractor. The intersegmental vessels are clamped with thoracic hemostats and ligated.
7. The surgeon transects the segmental bronchus and closes the stump with atraumatic nonabsorbable mattress sutures or bronchus staples (Figure 22-16).
8. Dissection is continued to separate segmental surfaces, and vessels are ligated as needed. The segment of the lung is removed.
9. The surgeon creates a pleural flap and sutures it over the bronchial stump (other methods of securing the bronchus may be used).
10. The anesthesia provider reinflates the lung and the surgeon irrigates with normal saline. Bleeding is controlled with ligatures or hemoclips.
11. The procedure is completed as described for pneumonectomy.

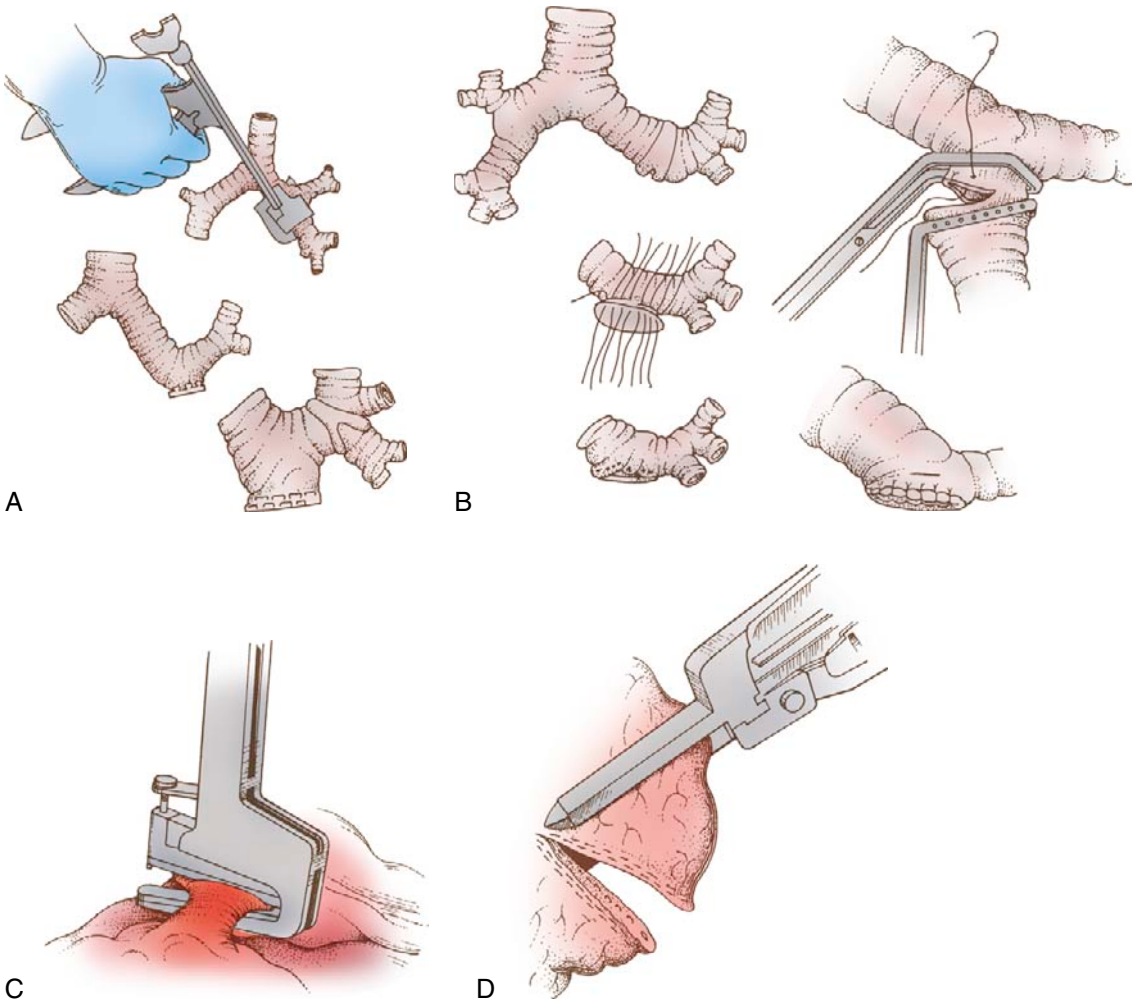

FIGURE 22-16 **A**, Staple suturing of bronchus. **B**, Conventional suturing of bronchus; application of bronchus clamp and incision; closure of stump. **C**, Staple suturing of pulmonary vessels. **D**, Staple suturing of lung tissue (wedge resection or lung biopsy).

Wedge Resection

Wedge resection is removal of a wedge-shaped section of parenchyma that includes the identified lesion, without regard for intersegmental planes. The resection is also used for removal of small, peripherally located benign primary tumors and peripherally located inflammatory disease, as well as for biopsy in patients with chronic, diffuse lung disease.

Procedural Considerations. Thoracic instrumentation is used. The team positions the patient to allow access to the operative site with consideration of the area of lung to be resected.

Operative Procedure

1. The surgeon incises the skin, subcutaneous tissue, and muscle using a blade and the ESU.
2. The rib retractor is placed.
3. The surgeon controls bleeding and secures the small bronchi with clamps and ligature. Large bronchi are ligated or sutured to prevent persistent air leak.
4. The wedge is outlined for excision, with a margin of normal tissue left, using one of the following techniques:
   a. Long hemostatic clamps are applied in three rows to outline the wedge. Excision is accomplished with a scalpel. The tissue is sutured with a running absorbable suture behind the clamps before removal. The edges of the tissue are oversewn with a continuous or interrupted suture (Figure 22-17).
   b. The lobe is grasped with a lung clamp, and the thoracic stapling instrument is applied to the parenchymal portion of the lung. Staples are applied, and the wedge is excised with the scalpel. Staples are reapplied to the opposite side of the lesion adjoining the staple lines.
5. The specimen is removed. The surgeon checks for air leaks by irrigation and inspection. Bleeding is controlled with ligation or hemoclips. The procedure is completed as described for pneumonectomy.

Lung Volume Reduction Surgery

Lung volume reduction surgery (LVRS) is an alternative surgical treatment for patients with chronic pulmonary emphysema (Figure 22-18). The surgery is intended to increase

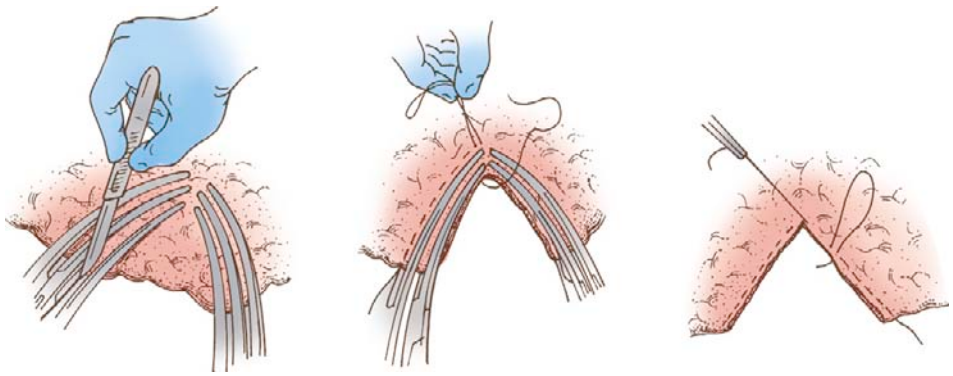

FIGURE 22-17 Wedge resection. Clamps applied to edge of lung tissue to be excised with blade and sutured with a running suture and oversewn.

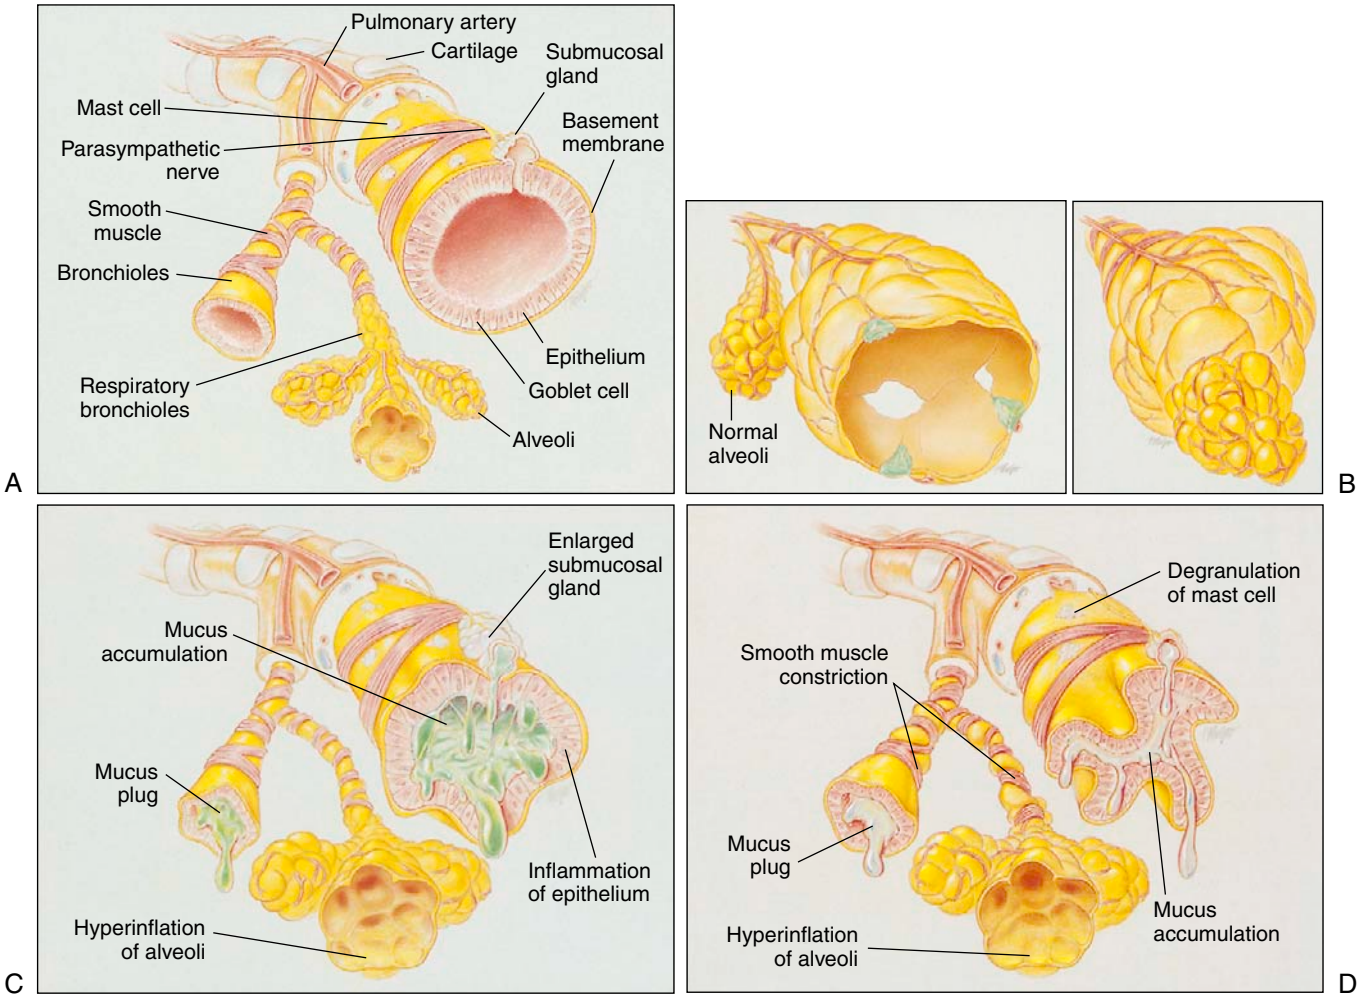

FIGURE 22-18 Airway obstruction caused by emphysema, chronic bronchitis, and asthma. **A**, The normal lung. **B**, Emphysema enlargement and destruction of alveolar walls with loss of elasticity and trapping of air; *(left)* panlobular emphysema showing abnormal weakening and enlargement of all air spaces distal to the terminal bronchioles (normal alveoli shown for comparison only); *(right)* centrilobular emphysema showing abnormal weakening and enlargement of the respiratory bronchioles in the proximal portion of the acinus. **C**, Chronic bronchitis: inflammation and thickening of mucous membrane with accumulation of mucus and pus leading to obstruction; characterized by cough. **D**, Bronchial asthma: thick mucus, mucosal edema, and smooth muscle spasm causing obstruction of small airways; breathing becomes labored, and expiration is difficult.

expiratory airflow, maximal exercise capacity, and respiratory muscle strength, thereby relieving dyspnea. The procedure may also be referred to as *lung volume reduction*, or *pneumoplasty*. Candidates for the procedure are those who have progressive, severe dyspnea secondary to pulmonary dysfunction; those whose medical management is ineffective; and those in whom disease distribution is limited to target areas of severity (Evidence for Practice). The two operative approaches for LVRS are median sternotomy and video-assisted thoracic surgery (VATS). Median sternotomy provides excellent bilateral exposure and flexibility, whereas the VATS approach has the advantage of a shorter hospitalization, fewer days of postoperative air leaks, and fewer days on the ventilator (McKenna, 2007). Patients undergoing LVRS participate in vigorous pulmonary rehabilitation as a standard practice in preparation for surgery. Pulmonary rehabilitation programs not only improve airway clearance and diaphragmatic function but also ensure that optimal conditioning is achieved, which improves surgical outcomes, improves tolerance for surgery, and decreases postoperative complications. An alternative procedure, bronchoscopic lung volume reduction (BLVR), using either an implanted valve system or a distributed sclerosant, is currently being evaluated in clinical trials in the United States (Mamary and Criner, 2008) (Research Highlight).

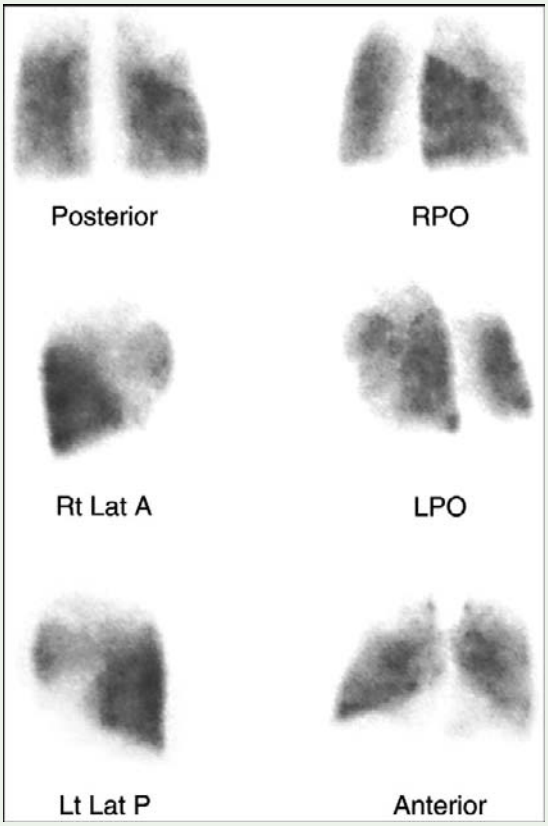
Procedural Considerations. The basic thoracotomy setup and instrumentation are used, along with stapling devices, chest tubes, and a water-seal drainage system. A laser may be required, as may other materials for sealing the resected edges (e.g., bovine pericardium, collagen). Positioning is a particular

EVIDENCE FOR PRACTICE

Determining Candidates for Lung Volume Reduction Surgery

Although lung volume reduction surgery (LVRS) is considered an effective procedure to treat patients with emphysema, successful outcomes depend on factors such as appropriate patient selection, surgical technique, and surgeon experience. After the reintroduction of LVRS to the medical community in 1995, there was a resurgence of interest in the technique. However, surgical interventions were accompanied by significant morbidity and mortality. As a result, the Health Care Financing Administration (HCFA) organized a clinical trial (the National Emphysema Treatment Trial [NETT]) to identify factors that contribute to successful outcomes. The NETT suggests the following criteria as patient eligibility for LVRS:

- High-resolution computed tomography evidence of moderate to severe bilateral heterogeneous emphysema or moderate to severe bilateral homogeneous emphysema; if emphysema is homogeneous, additional physiologic criteria may be required
- Target zones of poorly perfused lung
- Nonsmoker (tobacco products) for a minimum of 4 months before interview for screening, with willingness to sustain nonsmoking status
- Body mass index below 31.1 kg/m^2 (men) or below 32.3 kg/m^2 (women)
- No previous laser surgery or LVRS
- No giant bulla (one third or more of the volume of the lung in which the bulla is located)
- No previous coronary artery bypass surgery
- Oxygen requirement of 6 L/min or less to keep saturation at 90% or higher during an oxygen titration assessment
- No cardiac dysrhythmia that, in the judgment of the supervising physician, might pose a risk to the patient during exercise testing or training
- Postbronchodilator total lung capacity (TLC) at 110% or more of predicted
- Postbronchodilator residual volume (RV) at 220% or more of predicted
- Postbronchodilator forced expiratory volume in 1 second (FEV_1) at 45% or less of predicted and, if age 70 years or older, postbronchodilator FEV_1 at 15% or more of predicted
- FEV_1 postbronchodilator increase of 30% or less, or 300 ml or less
- DL_{co} (lung diffusing capacity for carbon monoxide) at 70% or less of predicted
- Consent for screening and patient registry
- Consent for pulmonary rehabilitation



Pulmonary perfusion scintigraphy demonstrating typical upper lobe predominant emphysema that is viewed as the most suitable morphology for lung reduction surgery. (From Selke FW et al, editors: *Sabiston & Spencer surgery of the chest*, ed 7, Philadelphia, 2005, Saunders.)

Modified from Benditt JO: Surgical options for patients with COPD: sorting out the choices, *Respir Care* 51(2):173-182, 2006; Meyers BF, Cooper JD: Surgery for emphysema. In Selke FW et al, editors: *Sabiston & Spencer surgery of the chest,* ed 7, Philadelphia, 2005, Saunders.

RESEARCH HIGHLIGHT

Bronchoscopic Lung Volume Reduction Surgery

Although LVRS is a viable treatment for emphysema, the surgical trauma associated even with the VATS approach is considerable and many patients who could benefit from LVRS do not meet eligibility requirements because of their existing morbidity and overall condition. Bronchoscopic lung volume reduction (BLVR) procedures may provide a new option for some patients.

There are currently three BLVR systems undergoing clinical trials in the United States. Two of the systems use one-way endobronchial valves that the surgeon deploys into the patient's bronchi through a flexible or rigid bronchoscope using a catheter or guidewire system. Although structured differently (e.g., one employs a duckbill valve, the other an umbrella frame), the two valve systems are both designed to prevent inspiratory airflow and facilitate expiratory air and secretion drainage. The intent is to produce volume reduction through progressive deflation and absorption atelectasis. The other system involves the use of a bronchoscope with a dual-lumen catheter to apply a liquid hydrogel to targeted areas of lung; the hydrogel contains biocompatible and biodegradable substances composed of fibroblast growth factor, chondroitin sulfate, thrombin, and tetracycline. The solution collapses the areas where it is applied and instigates an inflammatory reaction that leads to the formation of scar tissue. The scar tissue shrinks the lung and reduces its volume over a period of weeks.

Wan reported the results of a study involving 98 patients at nine centers in seven countries who were treated with an endobronchial valve configured with the duckbill valve system. Patients ranged in age from 50 to 80 years with a distribution of 20 females and 78 males. All patients had symptomatic emphysema with shortness of breath during activities of daily living that was unresponsive to maximal medical management. Valves were placed either unilaterally or bilaterally using a guidewire system via a flexible bronchoscope. The most frequent serious complication was prolonged air leak beyond the seventh postoperative day. Other complications included exacerbation of COPD, pneumothorax, and pneumonia. The researchers were able to demonstrate improvements in the study participants' spirometry results, diffusing capacity for CO_2, and exercise tolerance. Ongoing studies are underway to confirm the efficacy of the devices and refine the criteria for patient selection.

Reilly's study evaluated six men with COPD who underwent a chemically induced lung volume reduction via the unilateral instillation of a sclerosant composed of a fibrinogen suspension combined with thrombin. The mean age of the men in the study was 66 years, and all tolerated the procedure with minimal side effects (which were attributed to bronchoscopy) and were discharged within 24 hours of the procedure. The researchers noted that while the primary purpose of the study was to examine safety, all patients reported improvements in pulmonary function and exercise tolerance at their 3-month follow-up appointment.

Additional studies for both methods are ongoing and needed before FDA approval is granted.

Modified from Mamary AJ, Criner GJ: Lung volume reduction surgery and bronchoscopic lung volume reduction in severe emphysema, *Respir Med* 4:44-59, 2008; Reilly J et al: Biological lung volume reduction: a new bronchoscopic therapy for advanced emphysema, *Chest* 131:1108-1113, 2007; Wan IYP et al: Bronchoscopic lung volume reduction for end-stage emphysema: report on the first 98 patients, *Chest* 129:518-526, 2006.

concern for this patient population, who are often malnourished and are at increased risk for positioning injury. The perioperative nurse must collaborate with the surgeon and anesthesia provider to ensure that the best possible positioning practices are implemented.

Operative Procedure

1. The surgeon exposes the patient's lungs through a transverse anterior thoracotomy incision using the sternal saw to separate the sternum. Adhesiotomies are performed, and the inferior pulmonary ligaments are incised.
2. The anesthesia provider deflates the patient's lungs to allow for visualization of the portions of the lung where air is trapped in emphysematous lung tissue.
3. A lung-grasping forceps is used to hold the portion of the lung to be excised. A surgical stapling device is lined with bovine pericardium and positioned on either side of the lung. The stapling of emphysematous lung tissue continues, and staple lines are overlapped to prevent air leaks. Alternative means of sealing the resection line include the use of a pleural flap or the application of collagen.
4. The anesthesia provider reinflates the lung to identify air leaks. If air leaks are found, the lung is deflated and the stapling procedure continues.
5. One or two chest tubes are placed into each pleural space. The chest tubes are connected to water-seal drainage systems without suction.
6. The surgeon reapproximates the ribs and sternum using stainless-steel surgical wire. The muscle layer, subcutaneous tissue, and skin are closed, and dressings are applied.

Lung Biopsy

Lung biopsy is the resection of a small portion of the lung for diagnosis. The biopsy allows removal of relatively large specimens for microscopic examination of the lung tissue. Indications include (1) failure of closed methods (needle biopsy) for diagnosis and (2) the presence of small, localized lesions that can be removed by biopsy.

Procedural Considerations. In addition to the basic instrument setup, a rib retractor, a lung-grasping forceps, dissecting scissors, a chest tube and water-seal system, and an endostapling device are required. More than one specimen container may be needed. The patient is positioned in a semilateral position for an anterolateral incision.

Operative Procedure

1. A short incision (approximately 5 cm) is made at the fifth intercostal space. The surgeon incises the pleura and retracts the ribs.
2. The lung is secured and exteriorized using a Duval lung clamp.
3. Using a Satinsky clamp or a stapling device, the surgeon segments the tissue to be biopsied. The tissue to be removed is

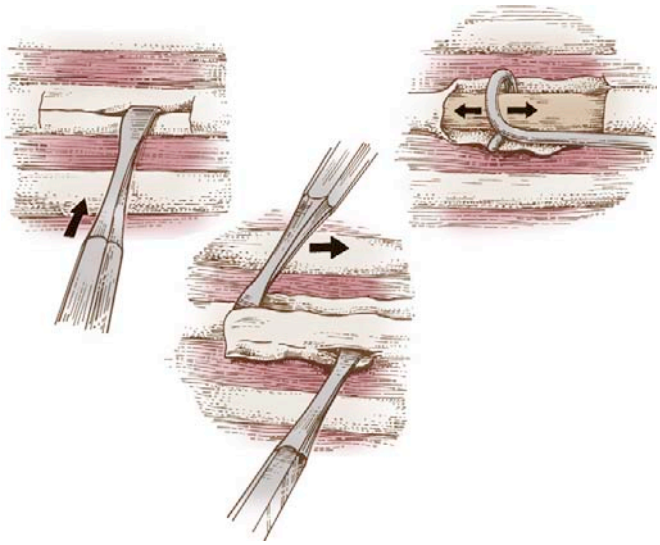


FIGURE 22-19 Separation of muscles of rib with a periosteal elevator and rib stripper.

excised with a scalpel. After application of the clamp, tissue edges are approximated with absorbable suture.

4. Bleeding is controlled by the application of a moist sponge at the incision site. The area is irrigated and inspected for air leaks.
5. The chest tube (28F to 30F) is inserted and connected to suction.
6. The incision is closed, the chest tube is anchored to the chest wall, and a dressing is applied.

Decortication

Decortication of the lung is removal of any fibrinous deposit, cancer, or restrictive membrane on the visceral and parietal pleura that interferes with pulmonary ventilatory function. It may also be done in conjunction with a pleurectomy for patients with pleural-based tumors, such as mesothelioma. The procedure results in blood loss and trauma and should be used only if the underlying lung is healthy. The objective is to return the lung to near-normal function.

Procedural Considerations. The basic thoracic instrumentation is used. The perioperative nurse assists with positioning the patient in a lateral position for a posterolateral incision.

Operative Procedure

1. The surgeon incises the skin, subcutaneous tissue, and muscle using a blade and the ESU.
2. A rib, usually the fifth or sixth, is stripped (Figure 22-19) and resected.
3. The surgical technologist provides moist sponges to protect the ribs and tissue. The rib retractor is placed and slowly and gently opened.
4. Parietal adhesions are divided to the margins of the lung, mediastinal surface, and pericardium with thoracic scissors, forceps, and a moist sponge on sponge-holding forceps.
5. The fibrous membrane is incised and separated from the visceral pleura using blunt and sharp dissection, handling the tissues gently (Figure 22-20). The procedure is completed as described for pneumonectomy.

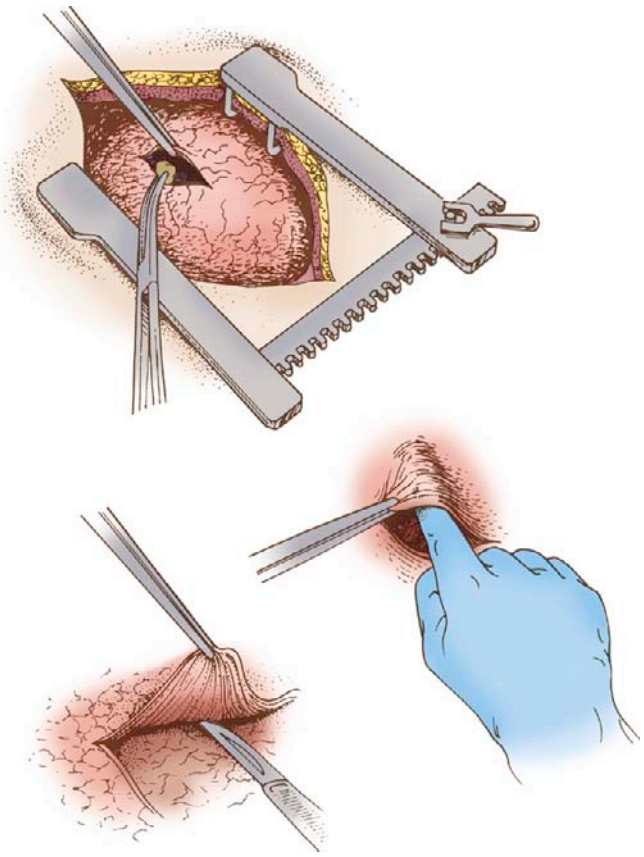

FIGURE 22-20 Decortication. Methods of separating fibrous membrane from visceral pleura.

Drainage of Empyema

The accumulation of pus in the pleural space might be associated with acute or chronic infection. Acute empyema may result from a lung abscess, pneumonia, or infection after thoracotomy. Parapneumonic effusions occur in 20% to 60% of patients hospitalized for bacterial pneumonia; 5% to 10% of these parapneumonic effusions progress to empyema. The mortality of empyema in the elderly and debilitated is 25% to 75% (Lee, 2005). Empyema (other than a pure tuberculous type) must be drained to prevent fibrothorax, and patients with empyema may require further treatment with decortication. When the infection is not extensive the procedure can be performed with the patient administered a local anesthetic. Prolonged intrapleural infection results in chronic empyema, which can create additional complications such as mediastinal shift, swallowing difficulties, respiratory limitations, bronchus erosion, and chest deformity. Talc poudrage may be the treatment of choice for patients able to tolerate additional procedures and who experience relief of pleural effusion by thoracentesis. Postoperative empyema or empyema occurring in immunosuppressed patients is effectively treated with a rib resection and drainage.

Procedural Considerations. If the patient is administered a general anesthetic, the basic thoracic instrumentation is

used. The team positions the patient in a lateral position for an anterolateral incision. A catheter for instillation of the sclerosing agent is required. The chest cavity is irrigated profusely during and on completion of the procedure.

Operative Procedure

1. The surgeon incises the skin and tissues with a scalpel to expose the affected area of the lung. Suction is used to prevent spillage of drainage from the chest.
2. The adjacent rib is resected, and the intercostal neurovascular bundle is divided.
3. The underlying thickened pleura is incised, and gross pus is evacuated. An inflammatory response might be created by stripping the parietal pleura from the visceral pleura by sharp or blunt dissection.
4. A large-bore catheter (46F) is inserted, and the sclerosing agent is instilled when indicated.
5. The surgeon closes the incision site as described for other thoracotomy procedures.
6. A dressing is applied.

Open Thoracostomy—Partial Rib Resection

Partial rib resection is removal of a portion of selected rib or ribs through an open thoracostomy incision to allow healing and reinflation of an infected lung. The procedure is performed for treatment of chronic empyemic lesions to establish a mechanism for continuous drainage.

Procedural Considerations. The basic thoracic instrument set and bone-cutting instruments are used. An ESU, chest tube, and water-seal drainage system are required, as are culture tubes for aerobic and anaerobic laboratory analysis. The patient is placed in a lateral position for a posterolateral incision. The surgical procedure can be completed with the patient administered a local anesthetic.

Operative Procedure

1. The surgeon incises the skin, subcutaneous tissue, and muscle using a blade and the ESU.
2. The rib is resected, and the pleura is incised. Suction is used to control anticipated drainage.
3. Aerobic and anaerobic swabs for culture and sensitivity are obtained. The chest cavity is irrigated.
4. A large chest tube is inserted through the pleural opening. The incision is closed or packed open (depending on the extent of the disease process).
5. The chest tube is secured with a suture of heavy-gauge material on a cutting needle.
6. The chest tube is connected to a water-seal drainage system, and connections are secured.
7. A dressing is applied. A number of layers of dressing may be necessary to absorb drainage.

Closed Thoracostomy—Intercostal Drainage

Closed thoracostomy is insertion of a chest catheter through an intercostal space for establishment of closed drainage. The procedure provides continuous aspiration of air, blood, or infectious fluid from the pleural cavity. It is indicated for treatment of spontaneous pneumothorax, traumatic hemothorax, pleural effusion, and acute empyema. Malignant pleural effusions (Figure 22-21) may be managed by drainage and chemical pleurodesis by way of the thoracostomy tube.

Procedural Considerations. The thoracostomy may not take place in an OR setting. The procedure is usually done with monitored anesthesia care and local anesthesia. A local anesthesia set, including syringes, needles, and an anesthetic agent of choice for local injection, will be needed. The minor instrument set is used, in addition to disposable chest catheters, water-seal drainage system, two aspirating needles, and culture tubes. The patient is placed in a lateral or sitting position. Despite the administration of local anesthetic, thoracostomy can be uncomfortable for the patient. The perioperative nurse should provide explanations and emotional support to the patient during the procedure.

Operative Procedure

1. The surgeon estimates the correct depth of insertion and marks the catheter. The operative site is anesthetized.
2. An aspirating needle attached to a syringe is introduced into the chest cavity to verify the presence of purulent drainage, air, or blood.
3. The surgeon incises the skin and introduces a clamp through the incision into the intercostal space and pleural cavity.
4. Next, the surgeon inserts a catheter through the incision site and clamps it to prevent egress of air as it is inserted into the cavity.
5. The incision site is sutured, and the catheter is secured.
6. The catheter is attached to water-seal drainage, and the tubing is secured. The clamp is removed, and a dressing is applied.

Decompression for Thoracic Outlet Syndrome

Thoracic outlet syndrome is a compression of the subclavian vessels and brachial plexus at the superior aperture of the thorax (Figure 22-22). The first rib is the usual cause of the compression, because of either a congenital deformity or a traumatic injury that results in anatomic changes. Fibromuscular bands

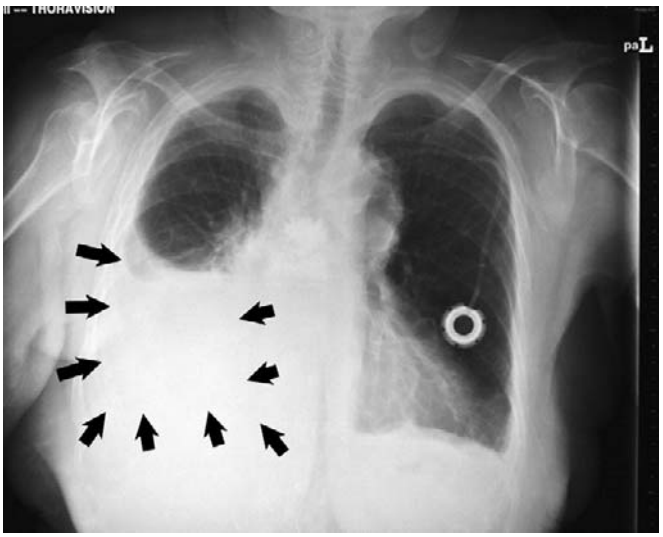

FIGURE 22-21 Chest x-ray showing large right pleural effusion outlined by arrows.

may also form between the cervical rib and other structures (i.e., scalenus tubercle) and cause compression. Symptoms depend on whether nerves, blood vessels, or both are compressed at the thoracic outlet. Decompression is accomplished through partial or entire removal of the rib using an open technique or video-assisted endoscopic techniques.

Procedural Considerations. Soft tissue and bone instrumentation is used. An ESU is required. The patient is positioned in a lateral decubitus position.

Operative Procedure—Open Technique

1. The surgeon incises the skin, subcutaneous tissue, and muscle using a blade and the ESU. Soft tissue dissection continues to identify the neurovascular bundle.
2. The first rib is meticulously dissected subperiosteally using the periosteal elevator. The rib elevator, stripper, and rib raspatories may be required. Undue traction on the brachial plexus and damage to the subclavian artery or vein are avoided during the dissection.
3. A wedge is taken from the midportion, or the rib is removed in its entirety using rib shears.
4. A drain is placed, and the incision is closed. A dressing is applied.

Excision of Mediastinal Lesion

Excision of a mediastinal lesion involves removal of a lesion from the anterior, middle, and posterior sections of the mediastinum. Identifying the compartment is important for planning a surgical approach to the resection, for optimal exposure and access. A mediastinoscopy should be performed to determine the diagnosis of an anterior mediastinal lesion. Indications for excision of a mediastinal lesion include miscellaneous cysts and tumors, thymoma, lymphoma, and neurogenic tumor.

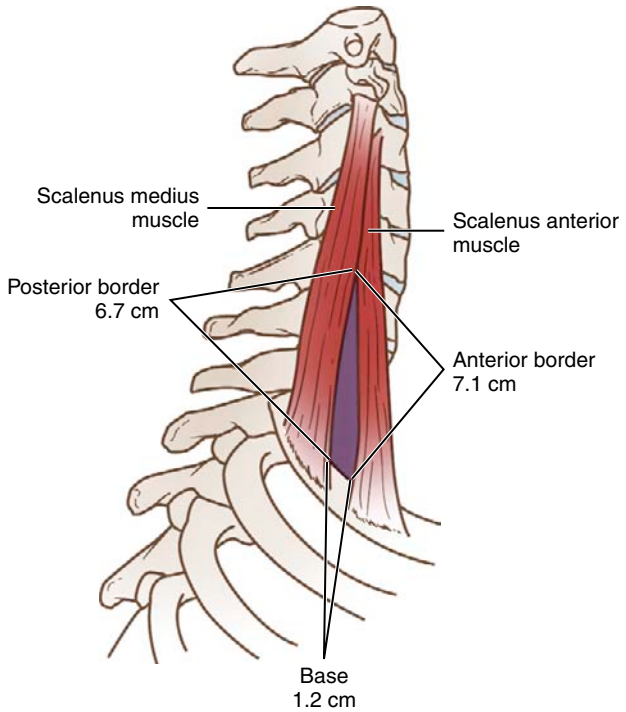

FIGURE 22-22 The scalene (anterior) triangle showing its measurements and the narrow space through which the neurovascular bundle passes.

Procedural Considerations. The thoracic instrumentation set is used. A procedure on the superior mediastinum might require use of thyroid instruments (see Chapter 15). The ESU and bone wax are needed. The perioperative nurse assists with placing the patient in a supine position for a median sternotomy incision (alternatively, lateral position may be used).

Operative Procedure—Thymectomy

1. The surgeon incises the skin, subcutaneous tissue, and muscle using a blade and the ESU.
2. The sternum is transected with a power saw or sternal knife. Bleeding is controlled at the bone edges with bone wax.
3. The thymus gland is dissected; vessels are clamped, ligated, and divided. The gland is removed.
4. The incision is closed. The sternum is reapproximated and closed with heavy wire. The skin is sutured closed. A dressing is applied.

Lung Transplantation

Since 1988 more than 17,000 lung transplants have been performed (Organ Procurement & Transplantation Network, 2009). Indications for single-lung transplantation (SLT) include restrictive lung disease, emphysema, pulmonary hypertension, and other nonseptic end-stage pulmonary diseases. Double-lung transplantation (DLT) is indicated for patients with cystic fibrosis or patients with a chronic infection in end-stage pulmonary failure. The procedure involves the allografting of one or both lungs from a cadaver or donor who has met clinical criteria for brain death. Developments in SLT include donor contribution from living relatives for patients who have chronic disease and a high risk for death while waiting on the donor transplantation list. Contraindications for transplantation include multisystem disease other than the lung, history of carcinoma or sarcoma, current infection, significant renal or hepatic dysfunction, cigarette smoking within 3 or 4 months, drug or alcohol abuse, psychologic instability, or poor medication compliance. Although the surgical technique is increasingly successful, it is anticipated that future application of lung transplantation techniques may be limited by donor supply. As the field of lung transplantation continues to evolve, questions will need to be answered regarding quality of life after transplantation and whether the single or double procedure is ultimately best for patients with chronic obstructive lung disease and primary pulmonary hypertension. Issues include the shortage of suitable donors, improved methods for early detection of chronic rejection, and improved immunosuppressive agents and regimens.

Procedural Considerations. Selection of the donor and recipients, preservation of the lung, and administration of anesthetic agents are considerations in this procedure. The nursing plan of care is modified considerably for each patient, since nursing personnel are caring for two patients with different needs. Recipient patients will have been started preoperatively on immunosuppressive therapy and infection prophylaxis. The patient's positioning will vary for the techniques being employed. The instrumentation is similar to that used for

a thoracotomy. Cardiopulmonary bypass (CPB) may be required, as described in Chapter 24, along with the ESU, cold perfusion solution, and surgical stapling devices. The perioperative nurse will need to collaborate with the anesthesia provider, since continuous hemodynamic monitoring, oximetry, and ventricular function assessment by transesophageal echocardiography (TEE) are all performed intraoperatively.

Operative Procedure—Single-Lung Transplantation

DONOR HARVESTING

1. The patient's skin is prepped from chin to knees and laterally to the midaxillary line. A median sternotomy incision or thoracotomy incision may be used.
2. The surgeon opens the pleura longitudinally posterior to the sternum, and divides the pericardium back to the hilum on both sides. The inferior pulmonary ligament is dissected, pleural adhesions are incised, and the proximal pulmonary arteries are dissected at their origin.
3. After heparinization and hypotensive anesthesia, the superior vena cava is ligated and divided and heavy silk ties are placed around each vessel.
4. The surgeon dissects the aortic arch free, and divides the ligamentum arteriosum. The anterior and inferior margins of the pulmonary artery are separated from the main artery and ascending aorta. Umbilical tapes are placed around the pulmonary artery and aorta. A purse-string suture is placed for infusion of the cardioplegia solution in the heart.
5. Once cardioplegia and pulmoplegia are accomplished, the heart is prepared for removal; veins and arteries are separated, and the heart is removed and placed in cold Collins solution.
6. Using blunt and sharp dissection the surgeon dissects the pulmonary arteries free from the mediastinum to the hilum anteriorly and then posteriorly to the anterior aorta and hilum. The trachea is dissected free. The lungs are inflated before stapling and dissection. The lungs are removed and immersed in cold Collins solution.

RECIPIENT PREPARATION AND TRANSPLANTATION

1. The perioperative nurse assists with positioning the patient laterally, and performs a wide skin prep for exposure of the chest and abdomen (nipple line to knees).
2. An incision is made for a thoracotomy. The procedure depends on which lung is to be removed. If the right lung is being removed, the pulmonary vein is isolated extrapericardially; the pulmonary artery is isolated as close to the lung as possible. The surgeon ligates and divides the azygos vein; the pulmonary artery is dissected.
3. If the left lung is being removed, the ligamentum arteriosum is divided.
4. The anesthesia provider collapses the lung to be removed, and the proximal pulmonary artery is occluded. If instability occurs after occlusion, partial femoral arteriovenous bypass is initiated. If the patient remains stable, the pneumonectomy is performed.
5. Pulmonary veins are divided extrapericardially. The first branch of the pulmonary artery and descending branch are separated. The blood supply to the bronchus is preserved by not dissecting tissue around the bronchus.
6. The surgeon divides the bronchus and removes the lung. The pericardium is opened around the pulmonary veins to allow room for the atrial clamp.
7. Inferior and superior pulmonary veins are incised and joined.
8. Three anastomoses are completed for a single-lung transplant: bronchus to bronchus, pulmonary artery to pulmonary artery, and recipient pulmonary veins to donor atrial cuff. Techniques used to minimize bronchial anastomotic complications include shortening the donor bronchial stump, reinforcing the anastomosis with a vascularized tissue pedicle such as omentum or intercostal muscle pedicle flap, or using an intussuscepting bronchial anastomosis technique.
9. After anastomoses and restoration of circulation, the lung is fully inflated and observed.
10. After closure of the chest, the surgeon performs a bronchoscopy to remove secretions and to ensure that the anastomosis is intact.

CHAPTER 23

Vascular Surgery

PATRICIA WIECZOREK

Atherosclerosis continues to be one of the leading causes of death and disability in the Western world. It is estimated that peripheral atherosclerosis, including carotid, mesenteric, renal, and peripheral arterial disease (PAD) (also referred to as peripheral arterial occlusive disease [PAOD]), affects about 5% of Americans older than 60 years and up to 15% who are older than 70 years (Linsky et al, 2008). This is particularly striking, given that by the year 2030 the percentage of the U.S. population older than 65 years will increase to 20% (Federal Interagency Forum on Aging-Related Statistics, 2008). Many of these people will require interventions for the syndromes of peripheral ischemia, aneurysm, and venous disease.

Interventional therapy for peripheral atherosclerosis has become common. Aortic procedures are now routinely performed with minimal mortality. Carotid endarterectomy has also proven to be safe and effective. Peripheral angioplasty and bypass have a high initial success rate, but restenosis, graft failure, and progression of distal disease still lead to limb loss in certain patients after several years. Thus emphasis has been placed on decreasing morbidity and hospital stay associated with revascularization. Minimally invasive methods and strategies, including endovascular aortic aneurysm repair (Pearce, 2005), carotid artery stenting (Liu et al, 2009) (Research Highlight), stenting for lower-limb ischemia (Rosen and Karmy-Jones, 2009), and percutaneous transluminal angioplasty (Zeller et al, 2009), have been developed, and their application and popularity continue to increase. New technologies, such as miniature shavers and laser arthrectomy devices for arterial plaque, continue to be developed (Nguyen and Garcia, 2008). Perioperative nurses must be prepared for the demands of patient care in vascular surgery. This chapter reviews surgical anatomy, perioperative nursing considerations, and surgical interventions for a variety of vascular procedures.

RESEARCH HIGHLIGHT

Long-Term Results of Carotid Stenting versus Endarterectomy in High-Risk Patients

With the continued evolution of endovascular techniques, carotid stenting has become an option in high-risk patients. The authors previously reported that carotid stenting did not produce inferior results to carotid endarterectomy for the treatment of carotid artery disease at 30-days and at 1-year postprocedure. This study now reports the results of those same patients at 3 years. The prespecified major endpoint at 3 years was a composite of death, stroke, or myocardial infarction within 30 days after the procedure or death or ipsilateral stoke between 31 days and 1080 days. Data were available for 260 patients (77.8% of the initial group). The prespecified endpoint occurred in 41 patients in the stenting group (cumulative incidence, 24.6%) and 45 patients in the endarterectomy group (cumulative incidence, 26.9%); 15 patients in each group had a stroke. The authors concluded that in their trial of patients with severe carotid artery stenosis and increased surgical risk, no significant difference was seen in the long-term outcomes between the two groups. Further studies focusing on preprocedural variables are recommended as well as longer-term outcome results.

Modified from Gurm H et al: Long-term results of carotid stenting versus endarterectomy in high risk patients, *N Engl J Med* 358(15):1572-1581, 2008.

Surgical Anatomy

Basic knowledge of anatomy is essential when caring for perioperative patients with a vascular disorder. Figure 23-1 depicts the principal arteries and veins of the body. Arteries and veins have three layers:

- Tunica intima (innermost layer)
- Tunica media (muscular middle layer)
- Tunica adventitia (fibrous outer layer)

Arteries differ from veins in function and slightly in structure (Figure 23-2). Structurally, arteries have a thicker muscle layer and more elastic fibers than veins. The properties of elasticity and distensibility enable arteries to compensate for changes in blood pressure and volume. Because of the thicker muscle layer, severed arteries are capable of contracting and constricting enough to stop hemorrhage. In contrast, veins are more fragile than arteries, and whether its cause is traumatic or iatrogenic, venous bleeding may be difficult to control. Another difference is the presence of semilunar intimal folds, or valves, in veins that prevent backflow. Veins and arteries are nourished by a tiny network of vessels (the vasa vasorum), as well as from the intraluminal blood flow. Both are regulated by the autonomic nervous system, with veins having fewer nerve fibers than arteries. The two systems are connected (except for the pulmonary artery and pulmonary venous system): major arteries carry oxygenated blood, they branch into smaller arteries and arterioles, and then blood moves into capillaries to venules and to veins. The work of exchanging nutrients and metabolic waste is done at the capillary level.

Blood flow is a complex process that depends on many factors. Blood flows through arteries such that the blood in the center of the vessel moves faster than the blood at the

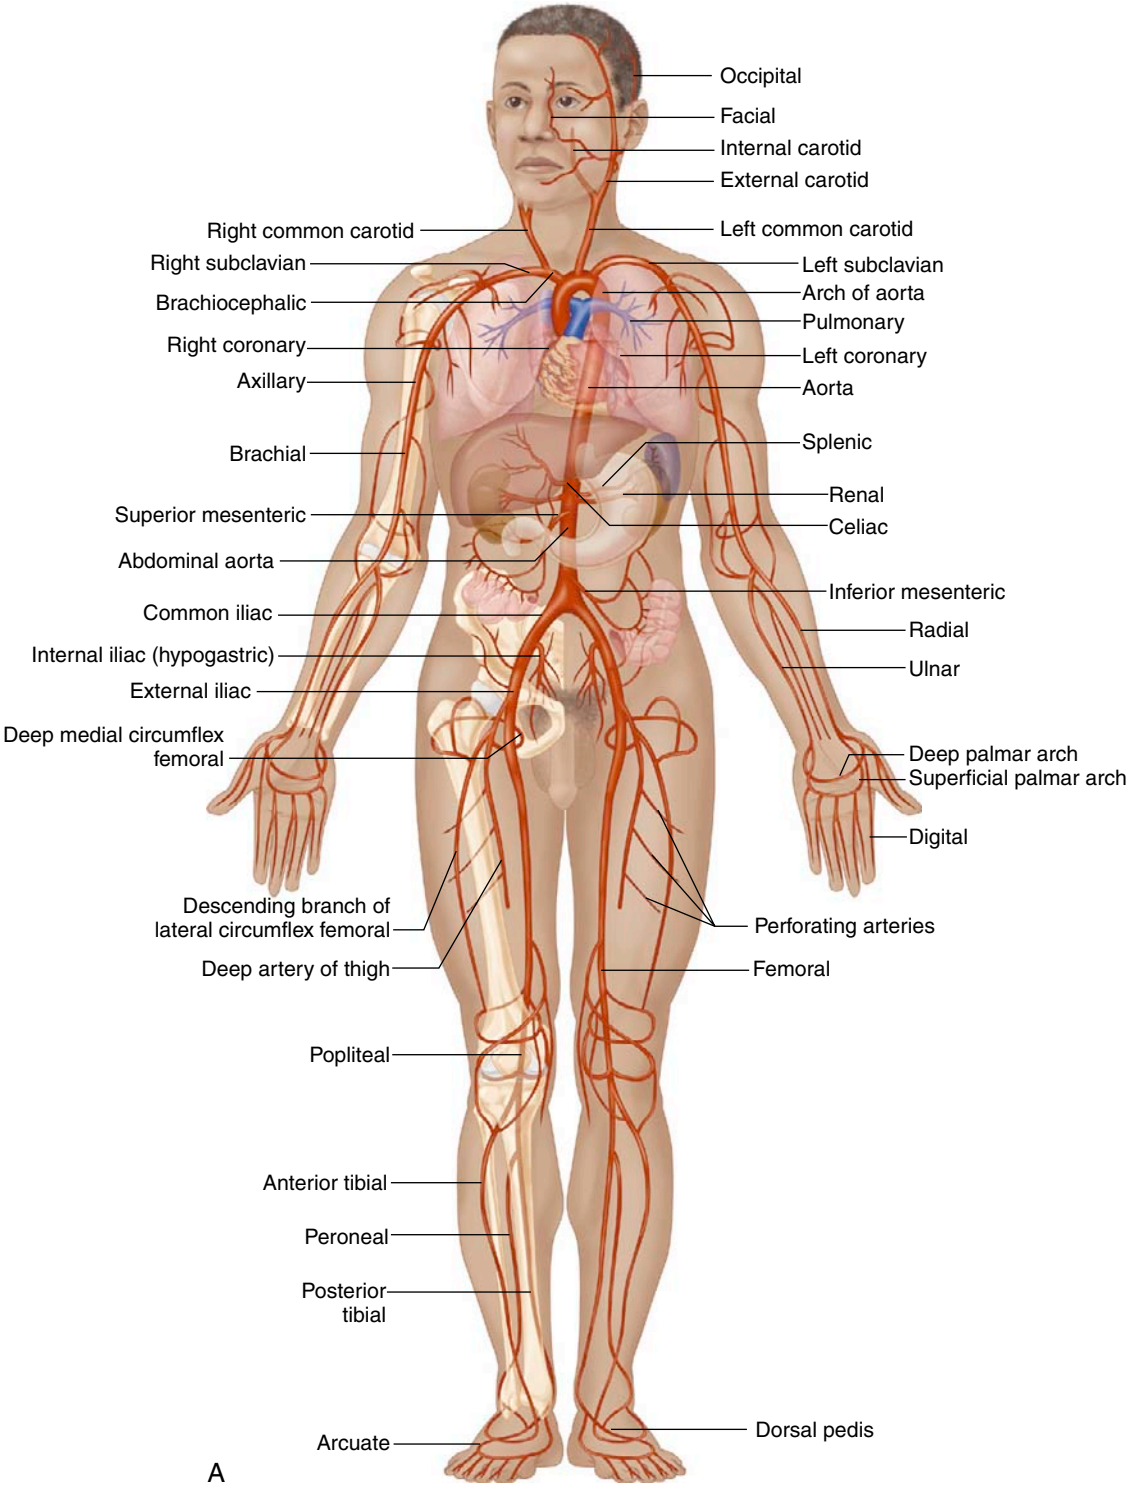

FIGURE 23-1 A, Principal arteries of the body.

periphery. Because the movement of the blood is in parallel lines, it is referred to as *laminar*. When flow is disrupted by an obstruction, stenosis, curve, or bifurcation, the particle motion is referred to as *turbulent*. Turbulence may be evidenced by the presence of a bruit (e.g., turbulent noise), detected by auscultation, or detected by a characteristic Doppler signal. Flow depends on blood viscosity, vessel wall resistance, and the peripheral resistance of the arterioles. There must be a difference in pressures, or a pressure gradient, to allow blood to flow. The gradient is provided by the contraction of the left ventricle. The negative pressure created by the relaxed right ventricle assists in venous return by creating a suctioning effect and the skeletal and visceral muscles help propel venous return toward the heart.

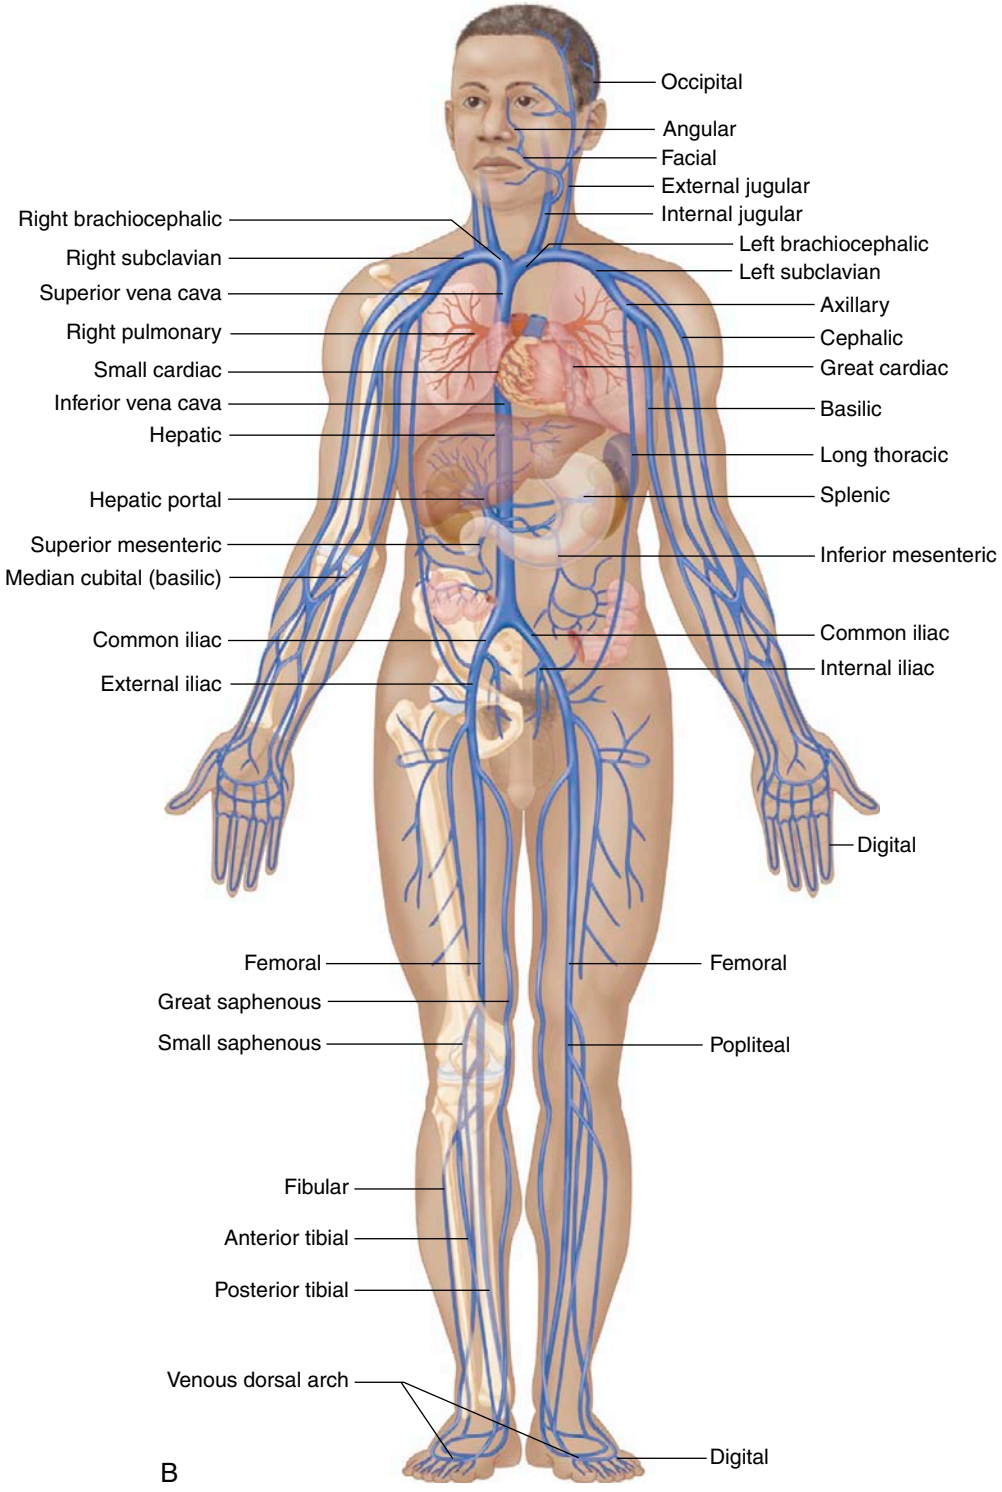

FIGURE 23-1 cont'd B, Principal veins of the body.

ARTERIAL DISEASE

Aneurysmal Disease

The most common cause of an arterial aneurysm is atherosclerotic degeneration of the arterial wall (Gloviczki and Ricotta, 2008). The pathogenesis is a multifactorial process, involving atherosclerosis along with genetic predisposition, aging, inflammation, and localized activation of proteolytic enzymes (Gloviczki and Ricotta, 2008). A true aneurysm is a dilation of all layers of the artery wall. A dissecting aneurysm results from a tear in the artery wall, allowing blood to dissect between the layers of the vessel wall. A false aneurysm, or pseudoaneurysm, is not an aneurysm but a disruption through all the layers of a vessel wall with the escaping blood being contained by the

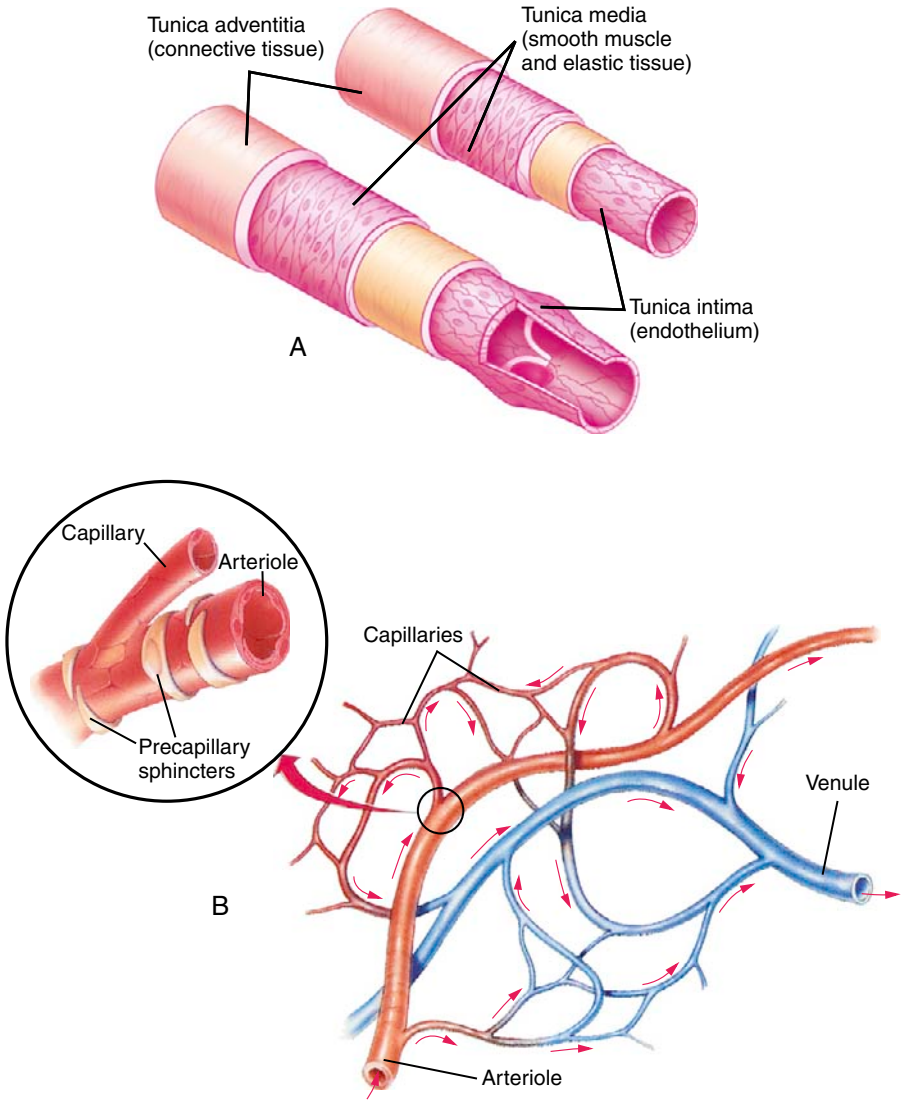

FIGURE 23-2 **A**, Layers of artery and vein. Drawings of a sectioned artery and vein show the three layers of large vessel walls. **B**, Microcirculation. The smaller blood vessels—arterioles, capillaries, and venules—cannot be observed without magnification. Note that the control of blood flow through any particular region of a capillary network can be regulated by the relative contraction of precapillary sphincters in the walls of the arterioles (*inset*). Note also that capillaries have a wall composed of only a single layer of flattened cells, whereas the walls of the larger vessels also have a smooth layer.

perivascular tissues. False aneurysms may result from trauma, infection, or disruption of an arterial suture line after surgery. True aneurysms are most frequently found in the abdominal aorta but are also found in the thoracic aorta and iliac, femoral, and popliteal arteries. More men than women are affected, and aneurysmal disease tends to be a disease of older persons. As early as 1977, a familial tendency was observed that subsequent research verified; as many as 18% of patients with abdominal aortic aneurysms have a first-degree relative with a similar diagnosis (Gloviczki and Ricotta, 2008).

Abdominal aortic aneurysms (AAAs), which account for most aneurysms, occur primarily between the renal arteries and the aortic bifurcation (Ignatavicius and Walicek, 2010). An aneurysm involves intimal damage of the aorta and weakening of the tunica media (Alberto et al, 2008) or elastic portion (collagen and elastin defects) of the arterial wall. Gradually the vessel wall in the damaged area expands and atheroma develops within the aneurysm sac (Figure 23-3). An AAA has minimal symptoms and is generally discovered on routine history and physical examination. In men, the diameter of the infrarenal aorta normally measures between 14 and 24 mm and in women it measures between 12 and 21 mm. An AAA is diagnosed if the diameter is 3 cm or larger for men or 2.6 cm or larger for females (Gloviczki and Ricotta, 2008). Mortality is low with elective resection of the aneurysm. Dissection and rupture of the aneurysm (aortic dissection) dramatically increase operative mortality because of the abrupt and massive hemorrhagic shock that accompanies the rupture. Aortic dissection is believed to arise from a sudden tear in the aortic intima, opening the way for blood to enter the aortic wall.

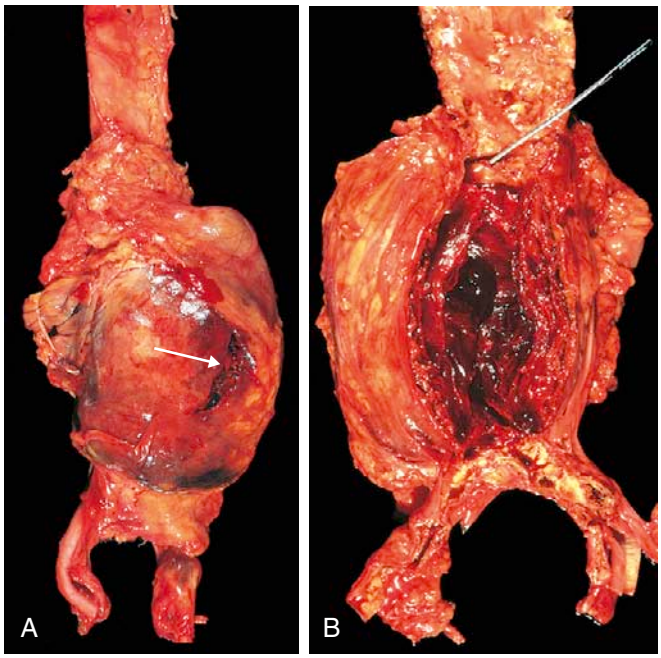

FIGURE 23-3 Abdominal aortic aneurysm. **A**, External view, gross photograph of a large aortic aneurysm that ruptured (*arrow*). **B**, Opened view. The wall of the aneurysm is thin and the lumen is filled with a large quantity of thrombus. The probe indicates the track of the rupture.

BOX 23-1

Risk Factors for Atherosclerosis

FIRMLY ESTABLISHED FACTORS
- Hypercholesterolemia
- Cigarette smoking
- Hypertension
- Diabetes mellitus

RELATIVE FACTORS
- Advanced age
- Male gender
- Hypertriglyceridemia
- Hyperhomocystinemia
- Sedentary lifestyle
- Family history

From Hirsch A et al: ACC/AHA 2005 practice guidelines for the management of patients with peripheral arterial disease: a collaborative report, *Circulation* 113(11):e463-e654, 2006.

Acute Arterial Insufficiency

Arterial insufficiency may result from an acute occlusion, as in embolic disease, or from the rupture of an unstable atherosclerotic plaque, causing acute thrombosis of the vessel. Emboli usually arise from the heart as a result of atrial fibrillation but may occasionally result from a myocardial infarction (MI), where a clot forms on the endocardium (the lining of the heart) in an area of muscle damage. Atherosclerotic plaque can also break loose from other areas and result in an acute arterial blockage. Patients with acute arterial occlusion usually present with the onset of the six *P*'s: sudden severe *p*ain, *p*ulselessness, *p*aresthesia, *p*aralysis, *p*allor, and *p*oikilothermia (coolness) of an extremity (Ignatavicius and Walicek, 2010). Heparin is the mainstay to prevent the enlargement of emboli while allowing time for collateral blood flow to develop. However, in the threatened limb there are basically two options: surgical removal of the clot (embolectomy) or chemical removal of the clot with the use of a thrombolytic medication. If the limb reaches the point where the muscle is rigid, the limb is not salvageable and amputation is a lifesaving procedure.

Chronic Arterial Insufficiency

Chronic arterial insufficiency occurs because of the deposition of calcium and cholesterol within the wall of the artery. Arteriosclerosis is a natural part of the aging process and occurs when the walls of the arterial vasculature undergo changes such as increased thickness and hardening, reducing the elasticity of the arteries. The decrease in elasticity should not be confused with atherosclerosis obliterans, which is a pathologic process that affects the intimal layer of the artery with the buildup of a fibrous plaque of lipids that can calcify and necrose. Atherosclerosis is the most common cause of PAOD, the probable mechanism being initial damage to the intima and subsequent activation and aggregation of the body's platelets. Inflammation follows, with the deposition of lipoproteins forming an atheroma. Calcification of this lesion leads to the development of an atherosclerotic plaque, resulting in inadequate muscle perfusion and ischemia (Rosen and Karmy-Jones, 2009). The process is a gradual one, and a localized lesion usually indicates systemic disease. The body develops a network of collateral vessels as an adaptive mechanism to supply the tissues with oxygenated blood. Many theories have been postulated to explain the process of atherogenesis. The inflammatory process of intimal injury, as just described, seems to be the current and most widely accepted hypothesis. Box 23-1 presents risk factors for atherosclerosis. A large number of vascular surgical procedures revolve around the results of chronic arterial insufficiency.

Arterial Insufficiency: Cerebrovascular Disease and Stroke

Cerebrovascular accident (CVA or stroke) is a leading cause of death in the United States and most industrialized countries. In the United States, approximately 795,000 persons experience a stroke each year (Lloyd-Jones et al, 2009). Cerebrovascular disease may manifest itself as a transient ischemic attack (TIA) or as a major or minor stroke. A TIA is an episode of neurologic dysfunction that resolves in 24 hours. It may be caused by atheromatous debris or a thromboembolism from a carotid artery or the vertebral basilar system. Vascular lesions in the carotid artery occur primarily at the bifurcation of the common carotid artery into the internal and the external carotid arteries. The internal carotid artery supplies the brain with needed oxygenated blood. Obstruction in this arterial vessel leads to cerebrovascular insufficiency.

The right and the left carotid and vertebral arteries supply the brain (Figure 23-4). The first major branch of the internal carotid artery is the ophthalmic artery. Thromboembolic events that affect this artery may result in visual disturbances, ocular

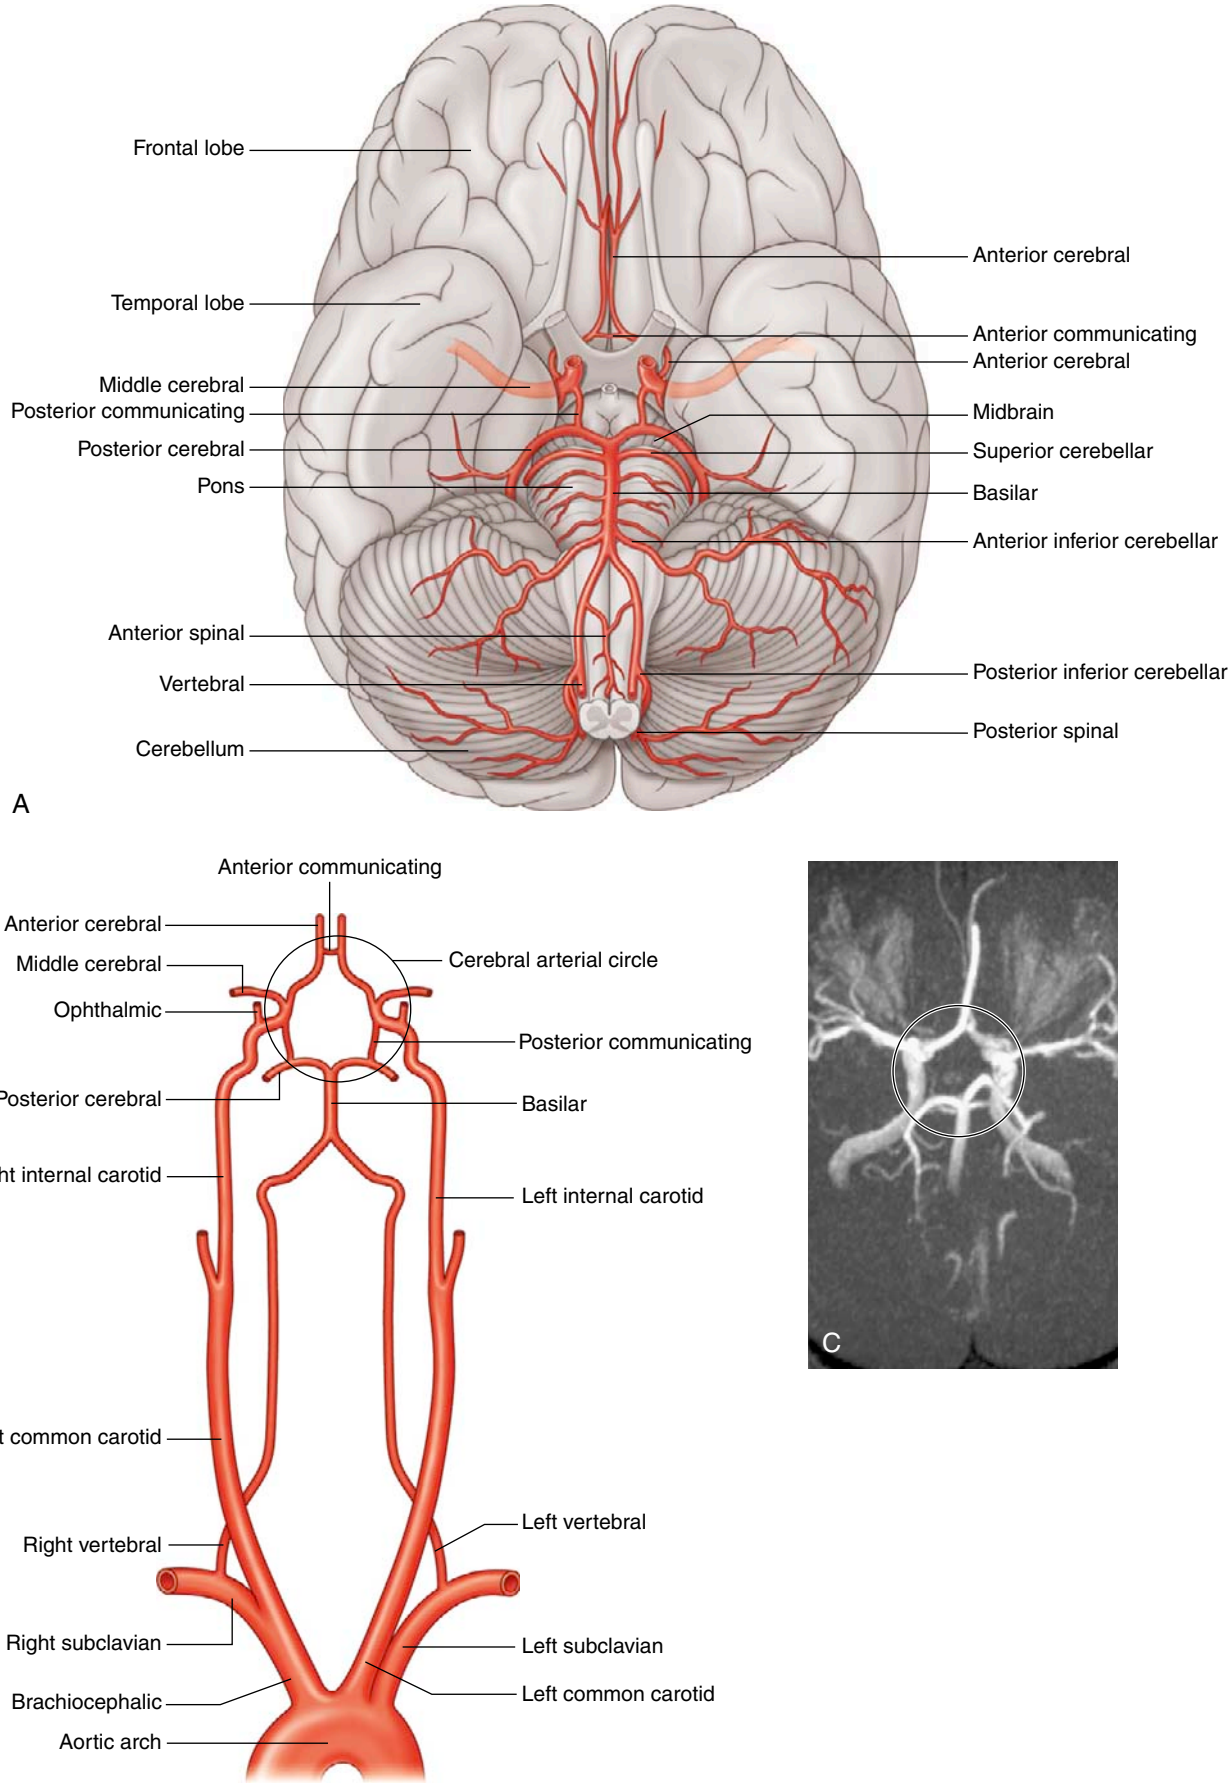

FIGURE 23-4 Arteries at the base of the brain. **A**, Diagram shows the cerebral arterial circle (of Willis) and related structures on the base of the brain. Note the arterial anastomoses. **B**, Origins of blood vessels that form the cerebral arterial circle. **C**, Magnetic resonance image of the cerebral arterial circle.

TIAs, or "amaurosis fugax" (complete or partial loss of vision). Patients will often describe amaurosis fugax as a curtain over a partial field of vision, usually the top. Clinical conditions that generally indicate the need for a carotid endarterectomy (CEA) are transient cerebral ischemia, asymptomatic severe stenosis, and stable strokes. Carotid disease may recur after a CEA. Redo surgery for restenosis poses the same complication risks as the original procedure.

Arterial Insufficiency: Peripheral Vascular Disease

The initial and most important symptom of vascular disease in the aortoiliac vessels and distal arteries is intermittent claudication. The term *claudication* is derived from the Latin word "claudicare," which means "to limp" (History box). This is the most common symptom of lower-extremity PAD and occurs distal to the arterial obstruction while the patient is exercising. Many patients are asymptomatic and do not experience pain. When this symptom does occur, it is typically located in the working muscle, occurs with the same amount of exercise each time, and is relieved with rest. This is referred to as functional ischemia; blood flow is adequate at rest but inadequate to sustain exercise. The increased muscle demand for oxygen with exercise cannot be met distal to the arterial obstruction. Anaerobic metabolism occurs, and muscle cramping develops. Surgery is not usually performed for claudication unless it is unusually disabling.

The second symptom—rest pain, which is located in the foot—develops as the vascular disease progresses (Faisal and Cooper, 2008). At this stage the ischemia is termed *critical*. Rest pain occurs without exercise and is a constant discomfort, often aggravated at night. The body is now unable to meet the oxygen needs of distal tissues even at rest. Rest pain may be somewhat relieved by analgesics or by lowering the legs off the bed. Gravity assists in increasing the tissue perfusion and oxygen supply to decrease the pain. Unless the vascular disease is corrected, nonhealing ulcers and gangrene can develop. Gangrene occurs when the arterial vessels are unable to meet the oxygen needs of distal tissues even at complete rest.

HISTORY

Osler's Recognition of Intermittent Claudication

Surgery on the vascular system has been performed since antiquity. In 1902 Osler described a theory of intermittent claudication. He noted that this phenomenon had been earlier described by a French veterinarian's studies of a horse. Later, the analogy was made between a male patient and a condition that corresponded to the intermittent claudication described in the horse. The patient was unable to walk more than one quarter of a mile without experiencing cramps in the legs. After a period of rest, he would improve and be able to resume walking. This patient died, and on autopsy a ball was found encysted in the vicinity of the iliac artery; a traumatic aneurysm was found as well that had obliterated the artery in its lower part. Osler further noted that the circulation was carried by the collateral channels, which were ample to maintain nutrition while the patient was at rest and for short periods of exertion.

Since the early writings of Osler, significant advancements have occurred in vascular surgery. Contributing to this rapid forward progress have been the development of effective anticoagulants, availability of arterial allografts, expansion of surgical techniques, improvements in suture materials, refinements in angiography, and the advent of noninvasive diagnostic methods. Current endovascular surgical devices continue to be modified, expanding the possibilities for their use and broadening the vascular surgery frontier.

Modified from Fye WB, editor: *William Osler's collected papers on the cardiovascular system,* Birmingham, AL, 1985, The Classics of Cardiology Library.

VENOUS DISEASE

Acute Venous Insufficiency

Acute venous insufficiency is caused by a clot in the deep venous system, or deep vein thrombosis (DVT). Such venous insufficiency can be a diagnosis of DVT, phlebitis, thrombophlebitis, or phlebothrombosis, which merely indicates that there is a clot, usually in the lower extremity. Virchow, a pathologist, identified the three elements that trigger venous thrombosis. Referred to as Virchow's triad, these elements, or risk factors, are endothelial injury, venostasis, and hypercoagulability (Ignatavicius and Walicek, 2010). The cause of hypercoagulability is sometimes unknown but is seen in patients with tissue trauma (e.g., surgery, burns, or stroke), malignancy, sepsis, pregnancy or estrogen use, and diabetes mellitus. The patient may be asymptomatic or present with limb swelling, pain, and a skin color change. The danger lies in the potential emboli migrating to the right ventricle and proceeding to the lungs. Pulmonary emboli (PEs) can be fatal. The majority of pulmonary emboli cases are caused by DVT. The majority of these originate in the lower extremities. The use of heparin and bed rest is the usual medical treatment. In cases that preclude the use of systemic heparin or in which heparin is ineffective, surgical insertion of a vena cava filter may be indicated.

Chronic Venous Insufficiency

Patients with chronic venous insufficiency (CVI) have not been treated surgically as often as patients with arterial disease for several reasons. CVI is generally not life-threatening or limb-threatening. Improved imaging techniques (e.g., duplex ultrasonography) allow better diagnoses of the precise problem. The treatment of the majority of venous disorders is nonsurgical and aimed at increasing venous return and decreasing edema. CVI, which presents with stasis ulcers from postphlebitic syndrome, usually occurs in one leg. The leg is usually very swollen with a cyclic edema, which does not change visibly after overnight leg elevation. Stasis ulcers and hyperpigmentation usually are found in the "gaiter" area and above the medial malleolus on the leg. The condition is caused by incompetent perforator valves. The perforating veins connect the superficial and deep venous systems. The usual management is to apply 20 to 30 mm Hg of external pressure by means of special pressure stockings. Surgical interventions such as valvuloplasty (direct repair of the valve), valve transposition or transplantation (moving a valve from the arm to the leg), or perforator interruptions are occasionally performed but have had limited success. Patient selection is critical, and long-term results are mixed.

Perioperative Nursing Considerations

Assessment

Nursing Responsibilities. A preoperative assessment is necessary for an adequate understanding of the patient's disease, the patient's response, and the proposed surgical procedure. Knowledge of vascular disease and its progression assists the perioperative nurse in performing a critical review of the comprehensive assessment and developing a plan of care for patients undergoing vascular surgical procedures.

The perioperative nurse should assess the patient, reviewing an already completed, current nursing assessment for the development and extent of vascular symptoms. The nurse must assess medical conditions—including cardiac, renal, and pulmonary disease; coagulation status; and allergies (Box 23-2)—to ensure that the patient can tolerate a possible angiogram, because the contrast medium is toxic and increased fluid volumes are needed if angioscopy is planned. This is a shared responsibility of the nursing, surgical, and anesthesia providers. The patient's nutritional status, the patient's use of alcohol and tobacco, and the existence of any skin lesions should also be noted. Preoperative location, grading, and marking of distal peripheral pulses assist the perioperative nurse with intraoperative and postoperative assessment of tissue perfusion. The nurse shares pertinent information gathered during the assessment phase with the rest of the surgical team, including the surgical technologist, as appropriate.

The nurse greets the patient by name and verifies identification using two unique identifiers. When possible, the patient should confirm such identification. Identification must also be confirmed by the name band, medical record, surgical consent, OR schedule, and marked surgical site. Safety is always the first priority. The surgical procedure must be confirmed and the patient's understanding of the procedure and associated risks assessed; inaccuracies or misconceptions must be clarified before proceeding with surgery. Written consent is designed to protect the patient by providing written clarification of the proposed procedure. The National Quality Forum (NQF) has identified Safe Practice 10 for informed consent, recommending that each patient (or legal surrogate) be asked to "teach back" what he or she has been told during the informed consent discussion (Wu et al, 2005). Consents that are valid and obtained freely from a competent person remain in effect for as long as the person still agrees to the surgery or procedure. This may vary by institutional modification.

The nurse assesses patient comfort before continuing the interview and assessment. This reflects caring and will promote nurse-patient rapport and facilitate obtaining accurate and complete information. The acuity of the patient's condition will also affect the order of priority of the assessments and interactions. After reviewing the results of the patient's physical examination, the perioperative nurse should verify signs and symptoms of vascular disease that need to be considered during intraoperative care. Muscle and skin atrophy, the presence of tissue ulceration or necrosis, pain, neurovascular status, skin color and temperature, and other integumentary changes should be noted. Elderly, cachectic, or obese patients are at increased risk for pressure injuries.

The perioperative nurse should assess the patient's mental status and determine the level of understanding and emotional response to the surgery. Patients with vascular disorders usually have systemic disease, and the fear of a stroke (if the patient is having a carotid procedure), amputation (if the patient has an ischemic limb), or other complications may be a realistic concern. A skin assessment should include notation of color, integrity, pain, and pulses. Any musculoskeletal problems that preclude patients moving themselves to the OR bed and any weaknesses that may have resulted from a stroke or that would modify the positioning for surgery should be noted. Correction of misunderstandings is possible only if the perioperative nurse identifies the patient's current level of knowledge. Identification of the patient's fears and concerns helps with planning supportive nursing interventions.

Vascular surgery can be lengthy. The nurse must consider the effects of hypothermia during long procedures. The patient's extremities should be assessed for color, temperature, and strength of pedal pulses before the surgical procedure so that baseline data will be available for comparison with perioperative assessment data. This assessment evaluates tissue perfusion distal to the arterial obstruction.

Preoperative Tests. A variety of tests may be required to plan for surgical interventions. Segmental pressure measurements give partial anatomic information in that they assist in locating lesions. Hemodynamic tests provide information on the flow of blood, such as that to the brain or an extremity, and the effects on flow caused by a vascular lesion.

ANGIOGRAPHY. Invasive diagnostic tests may be performed preoperatively to identify the extent and location of the patient's peripheral vascular disease (Faisal and Cooper, 2008). The introduction of a contrast medium through a catheter into the arterial or venous system of the patient facilitates this visualization. Angiography also involves injecting a contrast medium into the patient's arterial system and taking serial radiographs of the movement of the dye through the arteries.

BOX 23-2

Review of Patient's Medical Record

The perioperative nurse should review the patient's medical record, confirming or obtaining information for the following items:

- Correct and current medical record/chart
- Surgical consent
- History and physical examination
- Baseline vital signs (including height and weight)
- Mental status
- Medications
- Allergies or adverse reactions to drugs, topical agents, or other substances (e.g., latex)
- Skin tone and integrity
- Physical limitations
- Laboratory data (e.g., prescribed blood work, electrocardiogram [ECG] report, urinalysis, ultrasound or x-ray studies, other pertinent tests)
- Religious, cultural, ethnic preferences
- Nursing plan of care or other notations from transferring nurse
- Presence or disposition of prosthetic devices (e.g., hearing aids, dentures, glasses)

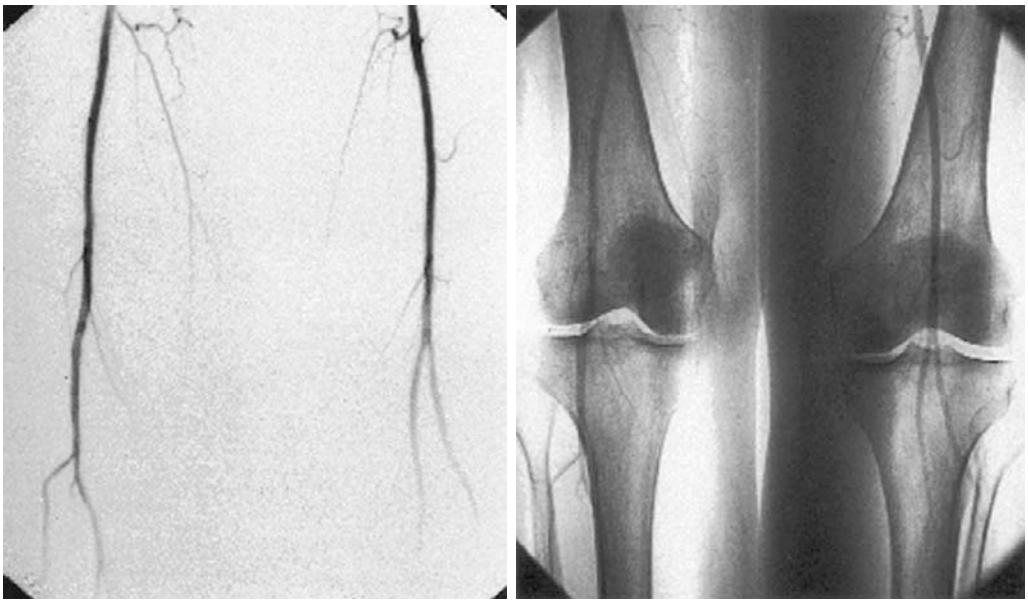

FIGURE 23-5 Digital subtraction angiography.

Digital subtraction angiography (DSA) is one such technique that uses a computer along with contrast medium injection to make the image (Figure 23-5). Usually one side of the film shows the bone for orientation, and the other side subtracts the density of the bone and soft tissue to allow a clearer view of the vessels. Arteriography provides information on arterial anatomy and the location of stenotic or occluded vessels and assists the surgeon in planning bypass procedures. A venogram (contrast venography) is performed to show venous abnormalities in extremities, the vena cava, and the hepatic and renal systems. Ascending venography can differentiate between acute and chronic thrombosis and can define anatomy. Descending venography assesses valve competence of the lower extremities.

DOPPLER SCANNING. The Doppler effect is the change in the frequency of echo signals that occurs whenever there is a change in the distance between the sources of a sound and the receiving object. The probe, or transducer, is aimed toward the blood vessel at an angle of 45 to 60 degrees. This directs an ultrasound beam that is reflected back to the probe by moving red blood cells (RBCs). The velocity of the flow of cells is converted into an audible signal heard through a speaker. The signal is described as a swishing sound. The sound is called a signal, not a pulse. The tip of the probe is made of an element called a ceramic piezoelectric crystal, which can send, receive, and convert signals when an electric current is applied. The element becomes thicker and thinner, thus resulting in a pressure wave converted to an audible signal. The simplest form is the continuous wave (CW) Doppler probe. It has two elements: one sends a high-frequency wave, and the other receives it. In a pulsed Doppler probe, the same element sends and receives signals. The pulsed Doppler probe has the advantage of being able to differentiate among vessels of different depths. A normal arterial Doppler signal is either biphasic or triphasic. The first sound corresponds to systolic flow and is forward-moving and of high velocity. The second sound is related to early diastole and has a lesser reversal of flow. The third sound is later diastole and is smaller, forward-flowing, and of a lower velocity. The pitch is described as rising quickly in systole and dropping quickly in early diastole. An abnormal signal, indicating stenosis or occlusion, is heard as low-pitched and monophasic. These abnormal arterial signals may sound like venous signals.

The Doppler probe can provide information in three forms: the audible signal, a visible graph printout similar to an electrocardiogram (ECG) tracing, and a spectral analysis that appears on a screen and may be recorded on paper as well. The Doppler transducer is the most widely used instrument for vascular study. It has the advantages of being readily available, inexpensive, and easy to use. A small, portable battery unit is durable and can be transported and stored easily. When the probe is used on intact skin, a water-soluble gel is needed to conduct a signal. Probes can be used directly on a vessel intraoperatively. The probes are heat-sensitive and must either be sterilized according to manufacturer's instructions or be inserted into a sterile sleeve or probe cover. If they are handled gently, the probes have a reasonable life span. Care must be taken to protect the sensitive tip from being dropped or crushed. The biggest drawback of the Doppler probe is a negative finding in the presence of a stenotic lesion pronounced enough to produce a flow disturbance that results in an altered signal.

A bruit is a sound disturbance that is sometimes described as a low-pitched, blowing sound. It can be heard through a stethoscope over an area of blood flow turbulence that occurs at points of vessel stenoses. Bruits do not provide information on the extent of a lesion—only that an abnormal flow may exist. They occur at points of significant stenosis and are not heard when severe flow restriction or total flow occlusion occurs. The Doppler probe is noninvasive and painless for patients.

ULTRASONOGRAPHY. Ultrasonography is done to obtain information about structures through the emission of high-frequency sound waves. These sound waves are reflected, or

bounced back, to the probe or transducer that emits them and are electronically transformed into an image.

B-Mode Ultrasonography. B-mode is brightness modulation, a technique in ultrasound imaging that projects a two-dimensional image on an oscilloscope screen. The image appears as dots from the echoes of the signal. The strength of the echo is shown by the intensity and brightness of the dots on the screen.

Duplex Ultrasonography. A duplex ultrasound machine is a combination of the pulsed Doppler image and the so-called real-time B-mode image ultrasonogram. "Real time" simply refers to the image projecting current, undelayed information. B-mode image is best when the probe is perpendicular to the vessel, but the Doppler probe does not pick up signals at a perpendicular angle. Some manipulation of the probe angle is required to obtain the best results. Color duplex imaging converts the detected signals caused by blood flow into a color, depending on the direction of flow. Flow toward the probe may be displayed as red, away from the probe as blue, and turbulence as multiple colors. This imaging provides both hemodynamic and anatomic information. The technology is also used in transesophageal echocardiography (TEE) and is the diagnostic method of choice for venous insufficiency.

Pulse Volume Recording (PVR), or Sequential Volume Plethysmography. A plethysmograph measures and records the changes in the sizes and volumes in extremities by measuring the blood volumes at blood pressure cuffs placed at intervals along the extremity. The methods include electrical impedance, mercury in Silastic strain gauges, and air or fluid displacement. This test, which is used to determine the location of an arterial lesion and estimate the severity of the disease, requires careful limb positioning and a cooperative patient. A negative study is a good predictor of low risk for pulmonary embolus (PE).

This test is inexpensive, has good predictive value, and is accurate in detecting thrombosis. It has the disadvantage of a high rate of false-positive results in the presence of old DVT, congestive heart failure (CHF), and external compression.

Magnetic Resonance Imaging. Magnetic resonance imaging (MRI) measures the behavior of atoms in a strong magnetic field. This test provides detailed and three-dimensional images of anatomy for evaluation of carotid, aortic, and lower-extremity disease (Faisal and Cooper, 2008). An MRI provides more detail than ultrasonography or computed tomography (CT) scan and avoids the complications of contrast medium injection and exposure to x-rays. MRI is contraindicated for patients with pre-existing implantable devices.

Nursing Diagnosis

Nursing diagnoses related to the care of patients undergoing vascular surgery might include the following:

- Anxiety related to the surgical intervention and its outcomes
- Hypothermia related to surgical exposure and anesthesia
- Risk for Deficient Fluid Volume related to loss of body fluids
- Risk for Impaired Skin Integrity and Ineffective Tissue Perfusion related to surgical positioning, presence of vascular disease, and vascular clamping

Based on the perioperative nurse's assessment, identification and prioritization of nursing diagnoses aid in the development of an individualized plan of care.

Outcome Identification

Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient will have all questions answered, will verbalize decreased anxiety and understanding of surgical procedure and perioperative routines, and will exhibit increased relaxation as shown by facial expression or other body language.
- The patient's body temperature will remain within normal limits as evidenced by postoperative temperature equivalent to preoperative level and absence of postoperative shivering.
- Fluid balance will be maintained as evidenced by postoperative pulses equivalent to preoperative level, hourly urine output of at least 30 ml, and good skin turgor.
- Skin integrity will be maintained. Skin temperature and color will be within normal limits. No skin injury lesions will be evident, and the electrosurgical unit (ESU) dispersive pad site will be intact.

Planning

Before the patient is transported to the OR, the perioperative nurse should procure the necessary supplies and equipment for the intended surgical intervention. Because the need for intraoperative arteriography or fluoroscopy for endovascular procedures is a possibility, the patient with a vascular disorder should be positioned on an appropriate OR bed with x-ray capabilities. The perioperative nurse needs to coordinate the availability of x-ray department personnel. Appropriate contrast media, catheters, and impermeable sterile x-ray covers must be available. Radiation-protection devices, such as lead aprons and shields, should be used for the patient, when possible, and for surgical team members. A typical plan of care for a patient undergoing vascular surgery, using the suggested nursing diagnoses, is seen in the Sample Plan of Care on p. 979.

Arterial procedures, especially those that involve the aorta, may place the patient at risk for significant blood loss. The perioperative nurse should confirm the availability of ordered blood-replacement products. The use of rapid infusion systems or blood salvage equipment should be determined and planned.

Implementation

Site Verification: "Time Out." Patient safety is of utmost importance. It is the entire surgical team's responsibility to verify that the correct patient is receiving the correct procedure on the correct site immediately before the start of any surgical procedure. The surgical site needs to be marked and visible after draping if laterality is involved. The "time out" is a requirement of The Joint Commission. During the time-out, the patient's name, procedure, site verification, and laterality are reviewed. Other items that may be discussed include the consent, anesthesia plan/concerns, the patient's allergies, antibiotics ordered, the patient's position, required instruments and special equipment, availability of blood, and anticipated length of the procedure. Such briefings improve team communication and intraoperative patient care (Makary et al, 2007).

Intraoperative Monitoring. Intraoperative monitoring for patients with vascular disorders includes the use of the basic ECG, pulse oximeter, and blood pressure cuff. For patients undergoing saphenous vein stripping or amputation, these

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Anxiety related to the surgical intervention and its outcomes

OUTCOME
The patient will have all questions answered. The patient will verbalize decreased anxiety and understanding of surgical procedure and perioperative routines. The patient will exhibit increased relaxation as shown by facial expression or other body language.

INTERVENTIONS
- Include the family, significant others, or both in explanations of perioperative routines.
- Allow time for patient's questions; provide explanations, or make appropriate referral.
- Observe verbal and nonverbal indications of anxiety; assist the patient with anxiety-reducing/coping techniques that have proven personally effective in the past, such as meditation, prayer, rhythmic breathing, music, self-guided imagery, massage, and relaxation.
- Encourage expression of concerns and fears; clarify any misperceptions, and reinforce information provided by other members of the healthcare team.
- Provide emotional support and comforting nursing measures (e.g., touch, a warm blanket).
- Demonstrate warmth, calmness, and acceptance of the patient's anxiety.
- Maintain a quiet environment; minimize distractions.
- Document patient's reactions.

NURSING DIAGNOSIS
Hypothermia related to surgical exposure and anesthesia

OUTCOME
The patient's body temperature will remain within normal limits as evidenced by postoperative temperature equivalent to preoperative level and absence of postoperative shivering.

INTERVENTIONS
- Limit the patient's physical exposure; expose only those body surfaces required for skin preparation.
- Cover the patient's head with a blanket or cap.
- Use a warming device (e.g., a forced-air warming unit).
- Provide the anesthesia provider with a fluid warmer.
- Consult with the anesthesia provider regarding the patient's temperature.
- Use warm saline for irrigation.
- Provide warm blankets at the end of the surgical procedure.

NURSING DIAGNOSIS
Risk for Deficient Fluid Volume related to loss of body fluids

OUTCOME
The patient's fluid balance will be maintained as evidenced by postoperative pulses equivalent to preoperative level, hourly urine output of at least 30 ml, and good skin turgor.

INTERVENTIONS
- Determine the availability of replacement blood or blood products.
- Assist with the insertion of intravenous (IV) lines and fluid replacement therapy. Keep IV lines patent.
- Estimate blood loss on sponges and drapes; communicate to the anesthesia care provider and surgeon.
- Initiate autotransfusion or use of an autologous blood salvage unit as required.
- Record the amount of irrigation used.
- Document the contents of the suction canisters.
- Monitor and document hourly urine output (as applicable); communicate results of measurements.
- Collaborate with the collection and interpretation of intraoperative blood analyses.

NURSING DIAGNOSIS
Risk for Impaired Skin Integrity and **Ineffective Tissue Perfusion** related to surgical positioning, presence of vascular disease, and vascular clamping

OUTCOME
The patient's skin integrity will be maintained. Skin temperature and color will be within normal limits. No skin injury lesions will be evident, and the electrosurgical unit (ESU) dispersive pad site will be intact.

INTERVENTIONS
- Assess and document the patient's preoperative skin condition and tissue perfusion.
- Position the patient on a pressure-reducing mattress on the OR bed.
- Collaborate with the anesthesia care provider in modifications of surgical position required for access to airway and monitoring devices.
- Keep OR bed sheets dry and wrinkle-free.
- Pad all bony prominences.
- Maintain body alignment.
- Place restraining straps snugly but not tightly.
- Protect vulnerable neurovascular bundles from compression.
- Monitor and record tissue perfusion (e.g., color, temperature, pulses) as required.
- Elevate drapes off the patient's toes; use appropriate positioning accessories.
- Implement safety precautions for proper use of ESU.
- Reassess and document the patient's postoperative skin condition and tissue perfusion.

are usually adequate. For lengthy procedures, such as arterial bypass or reconstruction, an arterial line is usually placed percutaneously into the radial artery. This is kept open by a pressurized heparin drip line attached to a transducer, and a waveform monitor reads the systolic and diastolic pressures. The monitor calculates the mean arterial pressure (MAP), which aids in the evaluation of the perfusion of systemic and cardiac circulation. This arterial line also allows easy access for collecting specimens for arterial blood gas (ABG) analysis. Continuous assessment of the patient's arterial pressure is a critical part of the surgical procedure. Pulmonary capillary wedge pressure, as an index of left atrial pressure (LAP), may be monitored depending on the patient's physiologic status. A general anesthetic may be administered and the patient intubated; local or regional anesthesia may also be used, depending on the surgical intervention. Epidural catheters may be placed to provide intraoperative anesthesia that can be augmented to accommodate increased surgical time, as opposed to a spinal anesthetic, which provides a finite period of anesthesia. Epidural catheters may be left in place postoperatively for pain

management as well. Because many patients undergoing vascular surgery have generalized atherosclerotic disease, the perioperative nurse should be constantly alert for cardiac dysrhythmias and blood pressure changes. Acid-base balance and pulmonary gas exchange are assessed from the ABG analysis.

A central venous pressure (CVP) catheter or pulmonary artery (PA) catheter may be inserted, usually by way of the right internal jugular vein. The CVP line allows assessment of blood volume and vascular tone. The PA catheter monitors cardiac output, fluid balance, and the cardiac response to medications. PA catheters are commonly used for patients undergoing aortic surgery or for patients with cardiac disease.

TEE may be used to monitor the heart noninvasively during aortic surgery. The device looks similar to a bronchoscope and can be passed down the esophagus to provide an ultrasonic image. The cardiac structures, blood flow, wall motion, and great vessels can be observed. Use of TEE requires highly skilled personnel and may not be available in all surgical settings.

Electroencephalographic (EEG) monitoring is used for patients undergoing a carotid endarterectomy and allows for immediate observation of the slowing of brain waves caused by cerebral ischemia or reduced perfusion. The surgeon may elect to place a temporary shunt in the artery if this occurs during clamping, potentially reducing the chances of perioperative stroke.

The perioperative nurse inserts a urinary catheter for many procedures, including the following: if the proposed procedure involves the renal arteries or clamping of the aorta above the renal arteries; if considerable blood loss is anticipated; if the planned procedure time is lengthy; or whenever spinal or epidural anesthesia is used, because they delay the patient's ability to void voluntarily. Urinary catheterization facilitates accurate hourly measurements of urine during and after the surgical procedure and assists in the assessment of renal perfusion and fluid status.

Positioning. Positioning of the patient undergoing vascular surgery is of particular importance because of restricted circulation distal to the area of arterial obstruction and a generalized state of poor circulation. Particular care must be exercised in positioning elderly patients (see Chapter 26). Awareness of joint range-of-motion limitations attributable to immobility or joint surgery is critical even for a procedure as routine as urinary catheter insertion. Again, preoperative assessment can prevent injury and decrease OR time. Whenever possible, the perioperative nurse should have the awake patient demonstrate the ability to assume the position for the proposed procedure and provide feedback. A footboard may be applied to the OR bed to prevent the weight of drapes resting on the patient's lower extremities. A head support may be used to position the head. A roll may be placed between the scapulae. For surgical procedures involving a lower extremity, the patient's thigh may be externally rotated and abducted with the knee flexed. A small bolster may be used under the knee to support the patient's leg. Proper skeletal alignment during surgery prevents injury to the neuromuscular system. The nurse pays close attention to the skin overlying bony prominences, especially the heels, sacrum, and elbows, and uses the proper supports and pads to prevent pressure and potential positioning injury to the patient. If the procedure will be lengthy, a pressure-reducing mattress or pad can be placed on the OR bed to help prevent patient injury. Arms are placed on padded armboards with the palms up and fingers extended. Armboards are maintained at less than a 90-degree angle to prevent brachial plexus stretch. If there are surgical reasons to tuck the arms at the side, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail. During the procedure the perioperative nurse and surgical technologist continually monitor the sterile field to ensure heavy instruments and drapes do not rest on the patient's body and cause pressure injuries.

Skin Preparation and Draping. Skin preparation for vascular surgery may be extensive. Hair should be removed preoperatively only if it interferes with the procedure; if hair removal is necessary, it should be done immediately before the surgical procedure using clippers (Evidence for Practice), not a razor (Association of periOperative Registered Nurses [AORN], 2009). For abdominal aortic surgery, the patient's skin is prepped from the nipple line to the midthigh area. For peripheral vascular surgery on the lower extremities, the patient is prepped from the umbilicus to the feet. The patient's legs are prepped circumferentially. For carotid surgery, the patient is prepped from the ear and chin on the affected side to below the clavicle. It is important that alcohol-based prep solutions are allowed to dry completely before applying the surgical drapes and starting the surgical procedure.

Draping should permit the surgeon free access to involved areas. For example, abdominal surgery may also require exposure of the groin region for possible exploration of the femoral arteries. A femoral-popliteal bypass on one leg may require access to the other leg for saphenous vein harvesting. Impervious drapes should be used to prevent contamination of the surgical field from blood and irrigation fluids.

EVIDENCE FOR PRACTICE

Reducing the Risks of Surgical Site Infections: Preoperative Hair Removal

Surgical site infections (SSIs) can be devastating to patients. An infection may mean a prolonged hospital stay, additional surgical procedures, or even death in an extreme case. A systematic literature review by Tanner (2007) showed that clinical studies done 20 years ago indicated that shaving with a razor increased the frequency of SSIs and that using clippers is the preferred method for hair removal when hair removal is deemed necessary. The increased SSI risk associated with shaving versus clipping is attributed to microscopic cuts in the skin that later serve as foci for bacterial multiplication. The Centers for Disease Control and Prevention (CDC) developed guidelines to reduce the risks of surgical site infections using this evidence of best practice from the literature. Following the CDC's recommended guidelines for hair removal to reduce the risks of SSIs equates to providing optimal patient care.

Modified from Tanner J: Preoperative hair removal: a systemic review, *J Periop Pract* 17(3):118-121, 2007; Mangram A et al: Guidelines for prevention of surgical site infection, *Infect Control Hosp Epidemiol* 20(4): 247-278, 1999, available at www.cdc.gov/ncidod/dhqp/pdf/guidelines/SSI.pdf. Accessed April 28, 2009.

Medications and Solutions. In vascular surgery, several medications may be present on the sterile field at any given time. These may include heparin, heparinized saline, and papaverine, as well as local anesthetic medications and contrast dye. All medications and solutions on and off the sterile field must be labeled (Crum, 2006) (Risk Reduction Strategies). Heparin is the most common medication used in vascular surgery (Surgical Pharmacology) and may be given as an intravenous (IV) bolus by the anesthesia provider for systemic anticoagulation. When administered parenterally, heparin has a rapid onset of action, peaks in minutes, and has a 2- to 6-hour duration. Because it is metabolized in the liver and excreted by the kidneys, the effects of heparin may be prolonged in patients with liver and renal disease. The anticoagulant effects may be monitored by measurement of the activated partial thromboplastin time (APTT) or partial thromboplastin time (PTT). Patients are given anticoagulants just before the placement of a vascular clamp to prevent a thromboembolic event. The effects of systemic heparin may or may not need to be reversed at the end of the surgical procedure. Monitoring the activated clotting time (ACT) intraoperatively provides useful data for judging the need for reversal or additional medication. The effects of heparin can be reversed by the administration of protamine sulfate.

Since protamine sulfate is derived from fish sperm and testes, caution is advised when administering it to patients who are allergic to fish or who have received protamine-containing insulin. One milligram of protamine neutralizes 100 mg of heparin. The dose should be calculated to offset half of the last dose of heparin. Protamine must be given slowly, at a maximum rate of 50 mg in 10 minutes, or dyspnea, flushing, bradycardia, and severe hypotension may occur. Another reason for monitoring heparin dose is that protamine, given in the absence of circulating heparin, acts as an anticoagulant and could delay hemostasis intraoperatively.

Heparinized saline solution is often used during vascular surgery for irrigation. It may be used to irrigate a blood vessel lumen during surgery, usually after the patient has been systemically heparinized. It is also commonly used to flush the lumen of tubes used to shunt blood. The strength of the heparin solution

RISK REDUCTION STRATEGIES

Medication Safety During Surgical Procedures

In vascular surgery, at any given time several medications may be present on the sterile field in basins or syringes. These may include heparin, heparinized saline, and papaverine as well as local anesthetics and contrast dye. Confusion that occurs during procedures as a result of unlabeled medications and solutions may result in serious medication errors. All medications and solutions on and off the sterile field must be labeled to help prevent an untoward event. The Association of periOperative Registered Nurses has helpful guidance statements and a medication safety toolkit to assist in the development of policies and protocols. The following risk reduction strategies are included: ensure concurrent verification, both verbally and visually, between the perioperative nurse and scrub person of all medications introduced to the sterile field, including medication name, strength, dose, and expiration date; use preprinted medication labels or have blank labels and a sterile marking pen available to label all solutions and medications as they are introduced to the sterile field; remove any unlabeled medication or solution from the field; for reference, keep all containers from medications used during any procedure in the OR until the conclusion of the procedure; verify all medications concurrently with the entering and exiting personnel at shift change or break relief.

Modified from Sheridan DJ et al: Labeling solutions and medications in sterile procedural settings, *Jt Comm J Qual Patient Saf* 32(5):276-282, 2006; AORN guidance statement: safe medication practices in perioperative practice settings. In *Perioperative standards and recommended practices,* Denver, 2009, The Association.

SURGICAL PHARMACOLOGY

Heparin—A High-Alert Medication

Heparin sodium is an anticoagulant that interferes with blood coagulation by blocking conversion of prothrombin to thrombin and fibrinogen to fibrin. It has no effect on a blood clot that has already formed or on ischemic tissue injured as a result of inadequate blood supply caused by a clot.

It is considered a high-alert drug, so designated by The Joint Commission and the Institute for Safe Medication Practices (ISMP) because it may cause life-threatening or permanent harm to the patient if administered incorrectly.

It is used for prophylaxis and/or treatment of vascular thromboembolic disorders, such as venous thrombosis and peripheral arterial embolism, and for prevention of thromboembolus during vascular surgical procedures. The number of units per milliliter varies in available dosage forms (supplied in vials). The most often used form is 5000 units/ml. One milligram of heparin is the equivalent of 100 units. Heparin may be administered by the anesthesia provider as an intravenous medication, administered by the surgeon as a full-strength injection during certain vascular procedures, or prepared as an irrigating solution for the scrub person. Standardized practices in the OR should be used to reduce the risk of an adverse drug event from the administration of anticoagulants such as heparin.

Sound-alike caution: Hespan. Institutions should identify and at a minimum annually review look-alike/sound-alike drugs to prevent errors involving the interchange of such drugs.

Labeling requirements: Any medication container, such as a syringe, medicine cup, or basin, containing heparin or a heparin solution must be labeled whether it is on or off the sterile field in perioperative or other procedural settings. Labels should be verified by two qualified individuals if the person preparing the medication is not the person administering it; this may be the case during relief of OR personnel (Crum, 2006).

Modified from *Drug information handbook for perioperative nursing,* Hudson, Ohio, 2006, Lexi-Comp; The Joint Commission: Preventing errors relating to commonly used anticoagulants, *Sentinel Event Alert,* September 24, 2008, available at www.jointcommission.org/SentinelEvents/SentinelEventAlert/sea_41.htm. Accessed April 15, 2009; ISMP Medication Safety Alert! ISMP Quarterly Action Agenda—January-March 2008, *The Institute for Safe Medication Practices,* available at www.ismp.org/Newsletters/acutecare/articles/A2Q08Action.asp. Accessed April 15, 2009; Crum BG: Revised national patient safety goal on medication handling, *AORN J* 83(4):955-957, 2006.

will vary according to the manufacturer's recommendations for certain implant devices or by the surgeon's preference. A reasonable range is 250 to 1000 units in 250 ml of normal saline.

Surgeon preferences differ regarding solutions with which to distend, irrigate, or store vein grafts. Some surgeons prefer a cold solution to decrease the metabolic demands of the vessel, whereas others believe this may lead to spasm. Spasm may be of particular concern when working with the small vessels of the distal leg or foot. Papaverine hydrochloride (HCl) may be added to a heparinized saline solution for its direct antispasmodic effect on the smooth muscle of the vessel wall and for its vasodilating properties. A reasonable dose is 120 mg in 250 ml of saline. The pressure of a handheld syringe to distend vein grafts has been viewed as a potential cause of graft failure or graft stenosis because this causes endothelial damage. Papaverine HCl, as a smooth muscle relaxant, allows distention at a lower pressure and may decrease the risk of injury. Concentrations for infiltration range from 0.05 to 0.6 mg/ml, or 12.5 to 150 mg per 250 ml of solution.

Topical hemostatic agents may be needed. Absorbable hemostatics are effective by creating an environment that promotes the adhesion of platelets. For example, an absorbable gelatin sponge may be applied to a bleeding surface to provide a matrix into which clots form. It may be applied dry, moistened with saline, or soaked in a topical thrombin-saline solution; 100 to 2000 NIH units of thrombin per 1 ml of saline or blood may be applied to control bleeding.

Infections of prosthetic vascular grafts are rare but are extremely serious. Infection may be life-threatening for patients with aortic grafts or may be limb-threatening in lower-extremity procedures. Protecting the prosthetic graft from contact with the skin is essential to prevent bacterial contamination. Prophylactic IV antibiotics that provide coverage for any likely organisms to be encountered in the procedure should be administered within 1 hour before the surgical incision (Hawn et al, 2006). In some institutions, medical staff–approved protocols are available for selection of the appropriate antibiotic.

Vascular Prostheses. Vascular grafting materials and techniques are of major importance to the field of vascular surgery for bypass procedures and reconstruction. The understanding, study, and comparison of new prosthetic grafts; utilization and preparation of autogenous grafts; and knowledge of long-term patency rates are critical to improving patient outcomes. Grafts are made in various sizes and configurations; they may be straight, tapered, or Y-shaped (i.e., bifurcated); or they may be pieces of material cut for use as a patch. The arteriotomy from a carotid endarterectomy may be closed primarily or with a patch of either vein or synthetic fabric. In aortic surgery, a straight tube or a bifurcated synthetic graft is used. Dacron (polyester) grafts are the usual choice and have been used successfully for many years. Large vessels, such as the aorta, have high flow rates and thus have a low incidence of thrombus formation and excellent graft-patency rate. Desirable characteristics for vascular grafts are that they are reasonably priced, readily available in a variety of sizes, suitable for use anywhere in the body, biocompatible and hypoallergenic, and able to survive repeated sterilizations. Grafts should be easy to handle and last a lifetime while permitting blood passage without clotting or infection.

Prosthetic grafts are nonantigenic; tissue incorporates well, which helps prevent infection, and such grafts generally resist thrombosis. For years, knitted polyester grafts were preferred over woven polyester because they were easier to handle, although they had to be preclotted because of their high porosity. Woven grafts are somewhat stronger and bleed less through the fabric interstices but can be less flexible. Newer grafts have been developed to incorporate the best of both by using velour polyester. They are often impregnated with albumin, collagen, or gelatin to provide ease in handling without the need to preclot. The surgical technologist ensures the graft is preclotted by submerging it into a basin containing a small quantity of the patient's own blood collected before systemic heparinization. This makes the graft impervious by allowing fibrin to fill in the fabric spaces.

The other popular prosthetic material is polytetrafluoroethylene (PTFE), which is available in straight, tapered, and bifurcated styles of varying lengths and may have external support rings to prevent compression. These grafts do not stretch, and needle-hole bleeding may be troublesome.

Cryo-preserved saphenous vein grafts are commercially available for patients who have no veins available because of previous bypass procedures, saphenous vein stripping, or poor quality or size of available veins. The nurse and surgical technologist must follow the manufacturers' instructions for rinsing these grafts to remove all traces of preservative.

Volumes have been written about vascular grafts, and the reader should consider this chapter an introduction only. The American National Standards Institute (ANSI), the U.S. Food and Drug Administration (FDA), and the Association for the Advancement of Medical Instrumentation (AAMI) are a few of the organizations active in setting standards and regulating usage and development of grafts.

Autogenous vein grafting for infrainguinal bypass is considered the criterion standard. Undamaged endothelial cells inhibit the clotting mechanism by the natural release of fibrinolytic substances and plasminogen factors. Two methods of grafting veins have been extensively studied, and the results are not totally conclusive that one method is better than the other. These are the in situ graft and the reversed vein graft. The in situ method leaves the vein in its place, side branches are ligated to prevent arteriovenous fistulas, and the valves that would impede arterial flow are disrupted with instruments specifically designed to cut valves, called *valvulotomes* (Figure 23-6). Reoperation is more frequent with the in situ method because of missed valves and residual arteriovenous fistulas. Reversal of a vein graft is performed per the surgeon's preference or when it must be harvested from the contralateral limb. Vein grafts are used in below-knee (BK) bypass procedures. Above-knee (AK) bypasses may use PTFE or other synthetic grafts for vein sparing, or they may be used in high-risk patients who may not tolerate the longer vein harvesting or have a life expectancy of less than 3 years. *Atraumatic* clamps with rubber, plastic, or hydrostatic jaw clamps are used to protect vein grafts from injury. Distal bypasses, particularly those in persons with diabetes, are more successful today as a result of improved tissue handling. The surgeon may also use the pneumatic tourniquet as an alternative to clamping the vessels.

Sutures. Most vascular sutures are made of synthetic nonabsorbable materials, such as Dacron, polyester, PTFE, and polypropylene. Vascular sutures have swaged-on needles of various sizes and are available in sizes 0 to 10-0. The suture may be

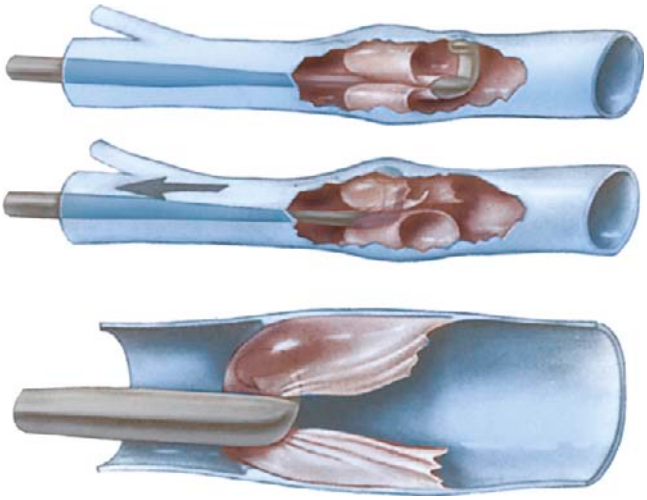

FIGURE 23-6 Valve incision with valvulotome.

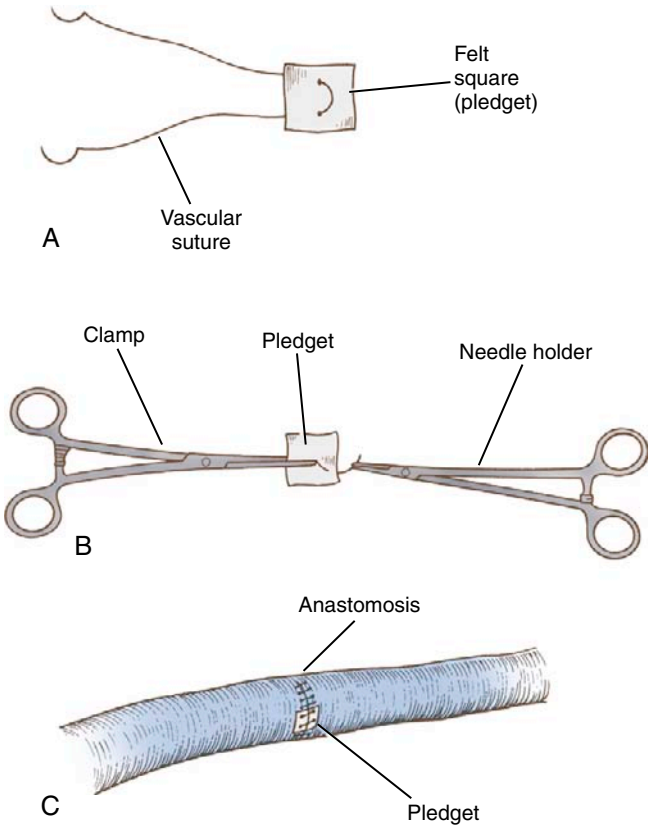

FIGURE 23-7 Pledgetted suture. **A**, Double-armed vascular suture prepared with pledget. **B**, Technique for surgeon to add pledget to suture already in use. **C**, Appearance of suture line with pledget in place.

single-armed or double-armed (i.e., a needle on one or both ends). The size and curve of the needle depend on the vessel and its location. Teflon felt or leftover pieces of graft material (synthetic or vein) may be used as pledgets or buttresses under a suture. They are used when tissue is friable to keep the suture from tearing through or when an anastomosis leaks and needs a better seal. The pledget may be loaded onto the vascular suture or added by the surgeon to a suture already in use. The pledget remains on the suture line (Figure 23-7).

Vascular Monitoring Equipment. Assessing blood flow through diseased vessels by palpation is often difficult. Physical assessment of the patient's hemodynamic status during surgery can be further complicated by spasm of the vessel walls, the cool environment of the OR, and alterations in blood pressure caused by hemorrhage. Therefore the surgeon often uses vascular monitoring equipment to evaluate tissue perfusion and flow. The Doppler device is critical when pulses cannot be palpated. With a coupling gel, the unsterile Doppler probe can be placed on the patient's skin distal to the surgical site. Some probes can be sterilized and used within the sterile field to assess the flow in an arterial graft or determine whether the blood supply to the intestines or other structures is intact after aortic surgery. Besides providing an audible signal, the Doppler probe can provide a permanent record of the sound if a recorder is attached.

An EEG accurately determines reduced cerebral perfusion during a CEA. This enables the surgeon to decide whether to use a temporary shunt in the carotid artery or if the patient can tolerate clamping. Sterile IV tubing connected to an arterial transducer can also be used to check pressure gradients intraoperatively. The stump pressure of unclamped carotid arteries before thromboendarterectomy can also determine the need for intraoperative shunting. Trained personnel are necessary to operate this equipment.

Instrumentation. Most vascular procedures begin with a basic laparotomy set (for scissors, clamps, and retractors) and a vascular set. Items specific to each surgical procedure are then added. For abdominal surgery, a large self-retaining retractor should be added. Additional individually wrapped, sterile aortic clamps; some long clamps (cystic duct and right angle); and long forceps for larger patients should be available in the OR. Smaller vascular clamps and vascular bulldog clamps should also be kept sterile in the OR. For peripheral procedures, a variety of Weitlaner self-retaining retractors should be available. Carotid surgery requires carotid shunt clamps, shunts, microforceps, and dissectors for peeling plaque from the artery. The surgeon may use the saphenous vein as a graft conduit by removing and reversing it or by using it in situ. A variety of instruments are available for disrupting the valves to permit arterial flow in the in situ procedure. Amputations do not require vascular instrumentation. A minor basic set and appropriately sized bone instruments are needed.

Documentation. During the implementation of perioperative nursing care, documentation of patient problems and nursing actions addressing these identified problems is important. Every patient is identified and assessed for allergies; the surgical procedure is verified; and any other interventions performed by the nurse for patient safety and mandated by institution policy are documented. A brief mental status and neurologic assessment is especially important for vascular patients who are at risk for stroke. For a patient undergoing vascular surgery, documentation may include the preoperative and postoperative assessment of the integrity of the patient's

skin, the presence or absence of peripheral pulses, the surgical position and positioning devices used, fluid intake and output measurements, and the achievement of patient goals. During surgery, various local anesthetic medications and irrigating solutions, such as thrombin, antibiotic, and heparin solutions, may be used. The surgical technologist ensures that each medication or solution container on the sterile field is labeled with the medication name, strength, and amount. Labels should be verified by two qualified individuals if the person preparing the medication is not the person administering it (Crum, 2006). The perioperative nurse maintains an accurate record of the solutions used and the amounts administered. The recording of ischemic times is captured when vascular clamps are applied and removed from arteries. The type, size, and serial and lot numbers of vascular implants should be documented according to institutional policy and procedure.

Evaluation

Evaluation is an ongoing process during which the perioperative nurse determines the extent to which the patient goals are met. Patient evaluation is continuous as the perioperative nurse assesses, observes, and appraises the results of nursing interventions. The conclusion of the intraoperative phase is the transfer of the care of the vascular surgical patient to colleagues in the postanesthesia care unit (PACU) or the intensive care unit (ICU). A nursing hand-off report should be given, which includes identification of the patient, the surgical procedure performed, any allergies or special needs, and the achievement of patient outcomes.

Some of the desired patient outcomes are achieved at the end of the intraoperative phase of surgical patient care. Others require ongoing evaluation during the postoperative phase. Because perioperative nursing practice is collaborative, the perioperative nurse develops a plan of care that extends from the admission to the surgical suite through safe recovery from surgery. Some goals can be measured immediately upon discharge from the OR; others require the collaboration of the PACU or unit nurse for final evaluation. The perioperative nurse thus develops and contributes to a comprehensive, holistic plan of patient care. Such planning and measurement of outcomes provide evidence of quality patient care and provide a mechanism of communication and continuity of care with other healthcare professionals.

Outcomes identified for the stated nursing diagnoses could be stated as follows:

- The patient verbalized an understanding of the surgical procedure and routines. All questions were answered to the patient's satisfaction. The patient appeared calmer as evidenced by facial expression and other body language.
- The patient's temperature remained within normal limits.
- The patient's fluid balance was maintained. Intake and output measurements were documented.
- The patient's skin remained intact, with no lesions or reddened areas; skin color, temperature, and turgor were adequate.

Patient and Family Education and Discharge Planning

All surgical patients need basic instruction on care of their wounds, identification of the signs and symptoms of infection, review of medications (Patient Safety), schedule of follow-up appointments, and procedure for contacting healthcare providers. Proper handwashing should be reviewed and emphasized to prevent wound infection. Patients who have undergone a lower-extremity arterial bypass are most interested in information that will assist them in recognizing, preventing, and managing complications. They need instruction on incision care and bathing to optimize incision healing. Many have had experience with slow healing of wounds because of their arterial disease. Pain, sleep disturbances, and fatigue have been identified as important areas for instruction. Patients are often capable of identifying their discharge learning needs in the preoperative period. Patients should be taught to manage the discomfort of incisions and leg swelling to prevent sleep disturbances. The need to balance activity and rest should be emphasized. Patients in the immediate postoperative period are often

PATIENT SAFETY

Teaching the Patient Discharged Home and Prescribed Anticoagulant Therapy

Anticoagulant therapy is prescribed to prevent the formation of blood clots. The length of time a patient is prescribed anticoagulant therapy depends on the underlying condition for which it is prescribed. It can be of short duration or lifelong. The patient and family or other caregiver should be provided with both verbal and written instructions. These should include the condition requiring anticoagulation therapy; reasons and benefits of therapy; name of the anticoagulant prescribed along with dosage, time of administration, and side effects; importance of follow-up monitoring; compliance issues; potential for any drug interactions; and safety precautions. After the patient and family member or other caregiver are instructed, they should "teach back" information in their own words. In this way, the nurse can verify their understanding. Additional helpful information to provide includes the following:

- Use only an electric razor or hair removal cream; do not use a straight razor.
- Take precautions to avoid injury. For example, do not use tools such as saws or hammers, which could lead to an accident. Avoid contact sports and other hazardous activities that can increase the risk of tissue injury.
- Report any signs and symptoms of bleeding, such as excessive bleeding from cuts; blood in urine, stool, or vomit; nosebleeds; bleeding from the gums; excessive menstrual bleeding; unusual bruising for unknown reasons; a change in mental status; dizziness; severe headache; or blurred vision.
- Take the prescribed dose of medication at the precise time it is prescribed to be taken.
- Do not stop taking the medication abruptly; the surgeon usually tapers this medication gradually.
- Carry or wear a Medic-Alert bracelet or tag, and carry information in your wallet naming the specific medication.
- Avoid eating foods high in vitamin K, such as tomatoes, dark leafy vegetables, bananas, and fish.
- In the event of a missed dose, do not make up for any missed dose or double-up on doses. Call your physician if you are unsure about what to do in the event of a missed dose.

Modified from Ignatavicius DD, Walicek SH: Interventions for clients with vascular problems. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, St Louis, 2010, Saunders; Canobbio MM: *Mosby's handbook of patient teaching,* ed 3, St Louis, 2006, Mosby.

receptive to counseling on risk-factor modification, such as cessation of smoking and control of hypertension, diabetes, and stress (Faisal and Cooper, 2008). Assisting the patient in setting realistic goals without overwhelming demands is usually most productive. Patients must believe that their efforts will make a difference in improving their quality of life for lifestyle changes to be sustained.

Patient and family education related to postoperative activities and discharge planning for vascular procedures varies. Following an integrated care pathway improves efficiency and length of stay. Major vascular procedures, such as the resection of an AAA, have different educational concerns than peripheral vascular surgery. Patient and family education and discharge teaching for various procedures are presented in the Patient and Family Education box.

Surgical Interventions

ABDOMINAL AORTIC ANEURYSM RESECTION

Abdominal aortic aneurysmectomy is surgical obliteration of the aneurysm, which may or may not include the iliac arteries, with insertion of a synthetic prosthesis to reestablish functional continuity. The majority of AAAs begin below the renal arteries (infrarenal), and many extend to involve the bifurcation and common iliac arteries. Severe back pain, along with symptoms of hypotension, shock, and distal vascular insufficiency, usually indicates rupture and represents a true emergency condition. The prime surgical consideration when a rupture occurs is the control of hemorrhage by occlusion of the aorta proximal to the point of rupture. AAAs are usually asymptomatic and are

PATIENT AND FAMILY EDUCATION

Education for Various Vascular Procedures

ABDOMINAL AORTIC ANEURYSM RESECTION

Postoperative care procedures include the following:

- Maintain intubation and ventilation for 12 hours (varies with setting and surgeon preference).
- Monitor cardiac, respiratory, and renal function.
- Maintain nothing-by-mouth (NPO) status and nasogastric tube placement until bowel signs and flatus return; diet is advanced as tolerated.
- Perform hourly assessment of lower-extremity perfusion.
- Assessment of pain: Provide pain relief via epidural and/or patient-controlled analgesia (PCA); provide periods of rest.
- Prescribe bed rest, with the patient out of bed on postoperative day 1 and ambulating on postoperative day 2.

Discharge planning education includes the following instructions to the patient:

- Feelings of fatigue are normal and take weeks to resolve.
- Incision care: Showering is permitted; use soap and water only, and pat dry. Protect incision from oils, lotions, and powder. If wound closure strips are in place, showering is permitted. The strips will peel away in about 5 to 7 days.
- Activity is allowed with specific restrictions per surgeon:
  - Avoid lifting more than 5 to 10 pounds for 6 weeks to allow abdominal healing.
  - Walk to increase strength and improve circulation; progress gradually.
  - Climb stairs and walk outside as desired.
  - Avoid sitting for more than 1 or 2 hours.
  - Avoid crossing legs.
  - Driving requires permission from surgeon, usually after first office visit and when pain medication is discontinued.
- Smoking should be stopped because it has a profound effect on vascular disease and wound healing.
- Follow surgeon's instructions regarding dietary recommendations and medication use.
- Antibiotics may be prescribed before any endoscopy procedures, surgery, or dental procedures.
- Notify surgeon of the following: changes in wound (e.g., redness, swelling, increased tenderness, bleeding, drainage), fever, change in bowel habits.

ENDOVASCULAR ABDOMINAL AORTIC ANEURYSM REPAIR

Postoperative care procedures include the following:

- Transfer patient from OR to PACU.
- Monitor cardiac, respiratory, and renal function.
- Assess peripheral pulses every 15 minutes for 1 hour, every hour ×4, every 2 hours ×4, and then every 4 hours (in general).
- Assess presence of abdominal or back pain, sensation, and movement in lower extremities.
- Provide pain management as ordered (encourage patient to request pain medication).
- Transfer to a general nursing unit within 2 hours.
- Advance patient from clear liquid to regular diet the first evening after surgery. Patient is NPO after midnight for ultrasound examination on day 2, with regular diet resumed after the examination.
- Perform gradual ambulation three times on day 1 (within 4 to 6 hours after surgery) and ambulation at will on day 2.
- Discharge to home generally on day 2.

Discharge planning education includes the following instructions to the patient:

- Showers are permitted; tub soaks are not.
- Intercourse is permitted as comfortable, with no restrictions.
- No driving is permitted until cleared by surgeon.
- No lifting more than 5 pounds is allowed for 6 weeks.
- Soap and water on sterile wound closure strips is permitted; strips will gradually fall off.
- Stair climbing is permitted.

Continued

PATIENT AND FAMILY EDUCATION

Education for Various Vascular Procedures—cont'd

ARTERIAL RECONSTRUCTIVE PROCEDURES OF THE LOWER EXTREMITY

Patient and family education and discharge planning include the following instructions to the patient:

- Diabetes and hypertension control is very important.
- Smoking should be stopped because it has a profound effect on vascular disease and wound healing.
- Observe for signs and symptoms of graft failure; assess pulses.
- Implement a foot care program as noted below:
  - Inspect daily (use mirror-assistive methods, or have family member help).
  - Observe for cracks, ulcers, blisters, rashes, or discoloration.
  - Trim nails properly for prevention of ingrown toenails.
  - Shoes must fit properly (avoid walking barefoot).
  - Avoid tight socks or hose.
- Incision care is essential for avoiding infection and promoting wound healing.
- Ace wraps for leg swelling (normal after surgery) should be applied per surgeon's instructions.
- Sleep disruption and fatigue are normal after surgery. Ongoing pain management is important; pain levels should decrease gradually.
- Driving with surgeon's approval is allowed after follow-up office visit (approximately 2 weeks postoperatively).
- No heavy lifting, vigorous exercise, or prolonged upright sitting is allowed; walking, stair climbing, and going outside are permissible as able.
- Gentle range-of-motion exercise of leg prevents flexion contractures.
- Showering is permitted.
- Diet: Resume previous diet; follow special diets (e.g., diabetic, low salt, low fat) per surgeon's instructions.
- Notify surgeon of the following: return of preoperative symptoms; wound changes (e.g., redness, swelling, drainage, pain); fever; change in color, temperature, sensation, or use of leg, foot, or toes.
- Antibiotics may be recommended before any dental or endoscopic procedures if a synthetic graft was implanted.

CAROTID ENDARTERECTOMY

- Teach patient about possibility of reperfusion headaches (patients may fear that they are having recurrent symptoms unless they know about this possibility).
- Explain that if there are no postoperative complications, discharge to home will occur within 24 to 48 hours after surgery.
- Explain that activity may return to normal as tolerated and driving may be resumed when neck discomfort no longer restricts range of motion and the surgeon has examined patient 2 weeks postoperatively.
- Explain that fatigue for 4 to 6 weeks after surgery is normal.
- Explain incision care: Keep incision clean and dry; may shower with transparent dressing in place. Remove transparent dressing in 3 or 4 days. Wash incision with soap and water; pat gently to dry. Avoid the use of powder and lotion. Do not shave over incision until it is well healed.
- Explain that numbness around the incision and extending to the ear is normal, as well as mild swelling.
- Teach the patient about any cranial nerve deficits that may be the result of manipulation of nerves during surgery. Assist the patient in understanding the difference between an intraoperative stroke and cranial nerve deficits; that is, nerve injury or trauma from surgical manipulation occurs on the same side as surgery except for eye symptoms. Use diagrams and pictures to review pertinent anatomy.
- Encourage relevant lifestyle changes as indicated (e.g., low-cholesterol diet, review of diabetic diet, smoking cessation).
- Teach the patient and family to observe for and report any new symptoms, transient ischemic attacks (TIAs), mental status changes, personality changes, or speech difficulties.
- If a synthetic patch is in place, explain that the patient will need antibiotics before dental procedures or scope procedures. Instruct the patient to notify dentists and other healthcare providers of this need.
- Explain that if a vein was used for a patch, occasional swelling in the leg may occur. If this occurs, elevate leg above the level of the heart. Swelling may take 4 to 6 weeks to completely resolve.

VENA CAVA FILTER INSERTION (INFERIOR VENA CAVAL INTERRUPTION)

Postoperative patient teaching for vena cava filter insertion includes the following:

- For a femoral vein insertion site, do not bend leg for about 8 hours.
- Avoid strenuous activity or lifting more than 5 pounds.
- Expect that bruising of the insertion site may occur because this is common in patients who are or have been receiving anticoagulant therapy.
- Inspect the incision site for bleeding; apply pressure using appropriate method if bleeding at insertion site occurs.
- Report signs of local infection or significant bleeding.
- Elevate affected leg and wear elastic stockings to relieve lower-extremity swelling, which may be temporary side effect of the underlying deep vein thrombosis (DVT).
- Understand the purpose of and proper way to wear support stockings.
- Report sudden or severe leg swelling.
- Follow instructions for DVT prophylaxis.

VARICOSE VEIN SURGERY

- Provide instruction on the proper way to wrap an Ace bandage, the timing of rest and leg elevation, and how to apply manual pressure if bleeding occurs.
- Remind patient that walking is permitted, but sitting should be limited as should standing in one place. Legs should be elevated when sitting.

found on routine physical examination. They occur more frequently in men than in women. Aneurysmal disease is caused by a disruption of the tunica media, which structurally weakens the aortic wall. Aneurysmal aortas are found to have a significantly decreased amount of collagen and elastin in the vessel wall. Rupture carries less than a 50% death rate for patients in stable condition with a contained rupture. Risks from AAA surgery include massive hemorrhage and hypotension, injury to the ureters, renal failure, spinal cord ischemia, and death. Because peripheral vascular disease is a manifestation of a systemic disorder, it is not surprising that patients with aneurysms often have concomitant coronary artery disease. Patients are at risk of myocardial ischemia, myocardial infarction, hypotension, and hypertension. Myocardial infarction is the leading cause of death after AAA repair; therefore it is imperative that a patient with cardiac symptoms or ECG abnormalities have a thorough preoperative cardiac assessment.

The perioperative nurse must be alert to the fact that at the time the aortic clamp is released to permit distal flow, "declamping shock" or severe hypotension may occur. This may be attributable to the presence of inadequate volume replacement, the sudden reestablishment of flow to dilated distal vessels, or the release of acidic metabolites. Declamping shock and hemorrhage have been proposed as causes of renal failure from acute tubular necrosis.

Procedural Considerations

The patient is placed in the supine position. General endotracheal anesthesia is used. The anesthesia provider inserts a central venous catheter and arterial line. After inserting the urinary catheter, the perioperative nurse preps the fields for a midline abdominal incision, and the surgical technologist assists with draping to permit access to the groin region for possible exploration of femoral arteries. The nurse ensures the patient's pedal pulses are marked before the beginning of the procedure so that they may be located easily when the surgeon requests a check of the pulses. This assessment of pulses can be done manually or with a Doppler probe.

Operative Procedure—Transperitoneal Approach

1. The surgeon opens the patient's abdomen through a long midline incision (Figure 23-8, *A*) from the xiphoid process to the symphysis pubis and achieves hemostasis.
2. An abdominal self-retaining retractor is inserted into the wound. The surgeon and assistant retract the patient's small bowel, including the duodenum, to the right; they may place it outside the abdomen and cover it with moist laparotomy packs for better exposure.
3. The retroperitoneum overlying the aneurysm is incised and extended superiorly to expose the aneurysm and also inferiorly over the bifurcation and beyond the iliac arteries. Metzenbaum scissors, smooth forceps, and hemostats are used.
4. Careful blunt and sharp dissection is used to expose the aorta above the aneurysm to permit placement of an aortic clamp while avoiding the renal artery and ureters. The surgeon inspects the iliac vessels and bifurcation for evidence of small aneurysms, thrombosis, and calcification.
5. The anesthesia provider administers a dose of heparin intravenously, and the surgeon applies and closes an aortic clamp such as a DeBakey, Fogarty, or Satinsky around the aorta. Distal runoff vessels are also clamped. Opening of the aneurysm is undertaken with a scalpel or electrosurgical blade and heavy scissors (Figure 23-8, *B*).
6. The aneurysm is completely opened, and all atheromatous and thrombotic material is removed. The aneurysm walls may be excised but usually are left in place for eventual coverage of the prosthesis. In either case, the posterior aspect of the aorta is left intact (Figure 23-8, *C*). The surgeon controls bleeding, especially from the lumbar vessels, which enter posteriorly, by oversewing their orifices with vascular suture.
7. At the direction of the surgeon, the surgical technologist prepares the prosthetic graft of appropriate size for insertion. If the aneurysm does not involve the aortic bifurcation, a straight tubular graft is used; otherwise, a bifurcated or Y-shaped graft is necessary. Preclotting of a knitted graft may be accomplished by immersing the graft into a small quantity of the patient's own blood before systemic heparinization, or a manufactured graft impregnated with collagen, albumin, or gelatin may be used.
8. The aortic cuff is prepared for anastomosis by irrigating it with heparinized saline solution and by removing all fibrotic plaques. One or two vascular sutures (double-armed) are used to accomplish the anastomosis by a through-and-through continuous suture (Figure 23-8, *D*). Additional interrupted sutures may be needed if the anastomosis leaks on completion. A strip of Teflon felt may be used along the suture line for reinforcement.
9. The surgeon opens and inspects the distal vessels for backbleeding, and may inject heparinized saline solution to prevent clotting.
10. Each limb of the graft is anastomosed to the iliac artery, using a smaller vascular suture and similar technique (Figure 23-8, *E*). After the first side of the anastomosis has been completed, blood is permitted to circulate and the remaining limb of the graft is clamped to prevent leaking during the last part of the anastomosis.
11. The aneurysm may be closed over the graft.
12. The peritoneum is closed to exclude contact of the intestine with the graft, and the abdominal wound is closed.

ENDOVASCULAR ABDOMINAL AORTIC ANEURYSM REPAIR

Endovascular aneurysm repair (EVAR) differs from open surgical repair in that the surgeon introduces the prosthetic endograft or stent-graft into the aneurysm through a surgically exposed femoral artery and fixes it in place to the nonaneurysmal infrarenal neck and iliac arteries with self-expanding or balloon-expandable stents rather than sutures (Figure 23-9). A major abdominal incision is thus avoided, and patient morbidity related to the procedure is much reduced. The benefits of this procedure are a hospital stay of 1 to 2 days, a rapid return to normal physical activity, and a reduction in the mortality and complication rates compared with those of the conventional surgical procedure (Egorova et al, 2008). The procedure may also be applicable to high-risk patients.

A number of commercially manufactured stent-grafts have been developed since the first endovascular aneurysm repair was carried out in 1991, using a Dacron graft sutured onto

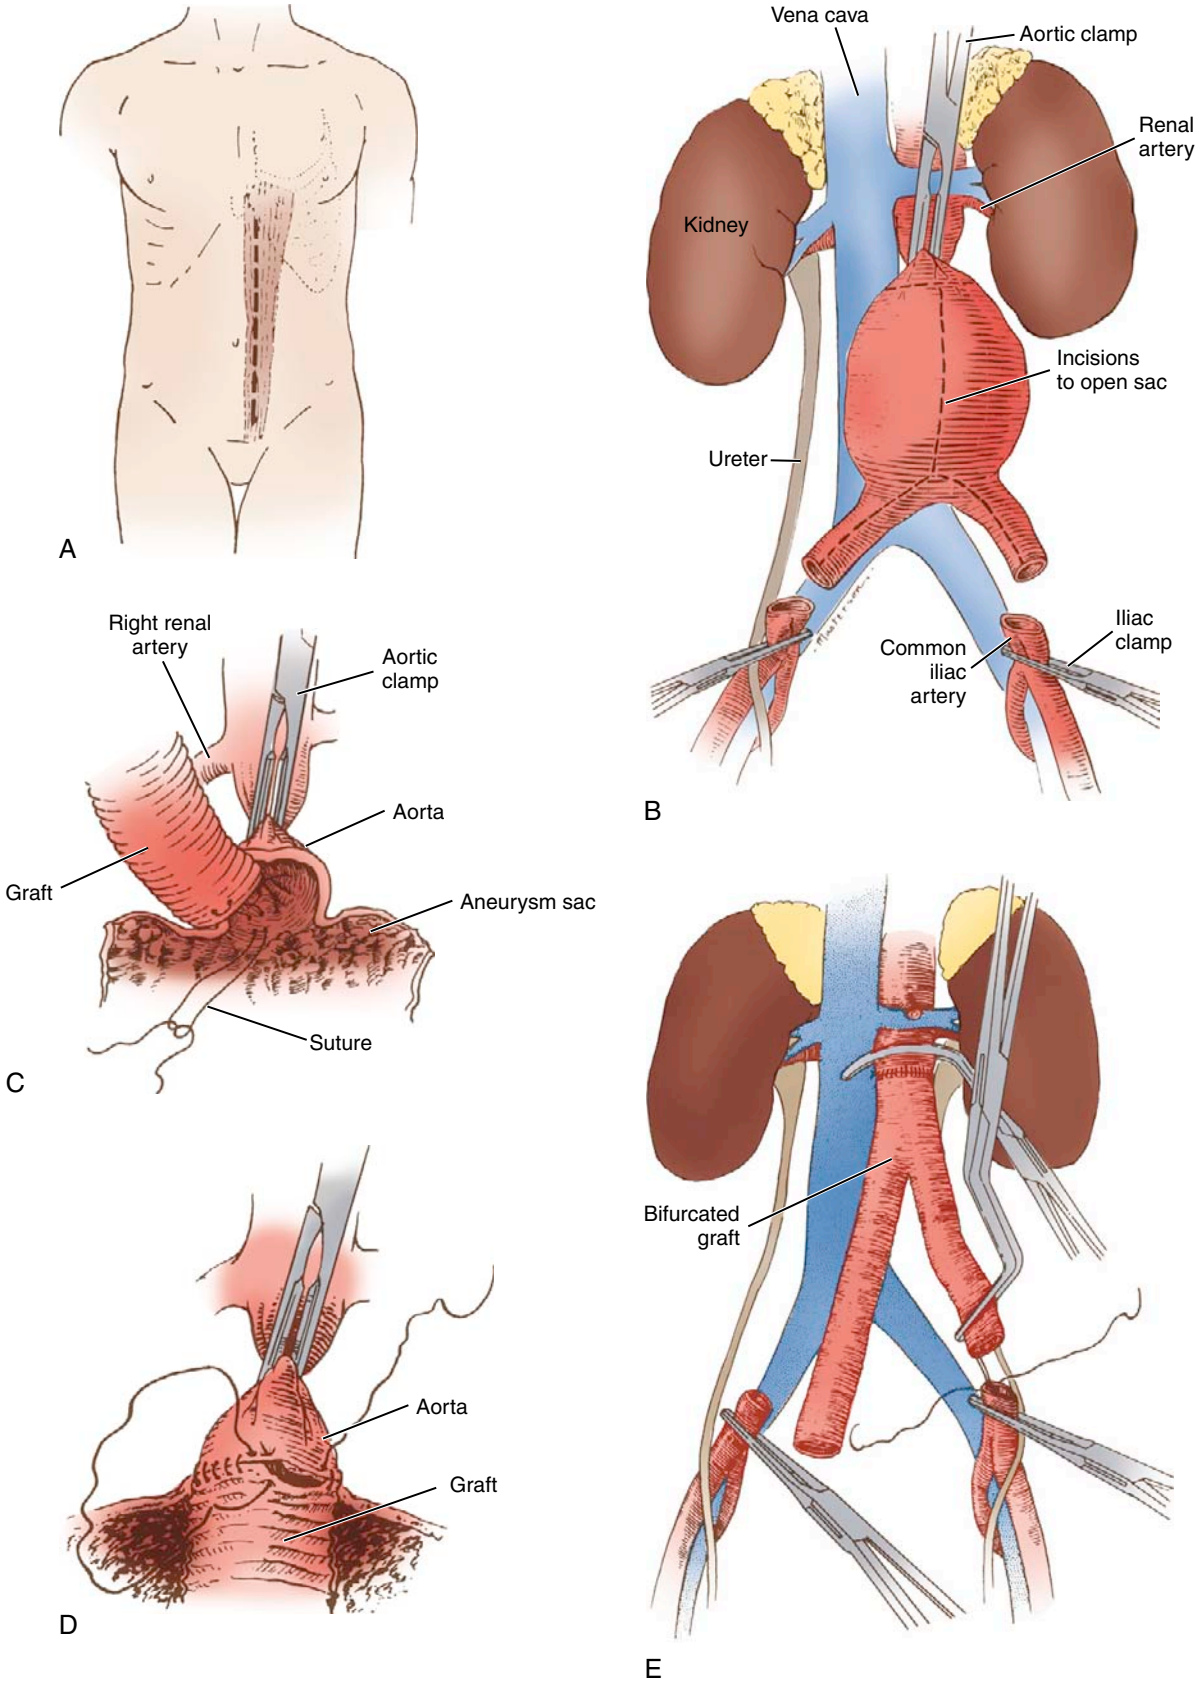

FIGURE 23-8 Resection of abdominal aortic aneurysm. **A**, Midline abdominal incision. **B**, Aneurysm sac is opened. **C**, Prosthetic graft is sewn to back wall of aorta, creating a cuff. **D**, Completion of aortic graft anastomosis. **E**, Iliac artery anastomosis.

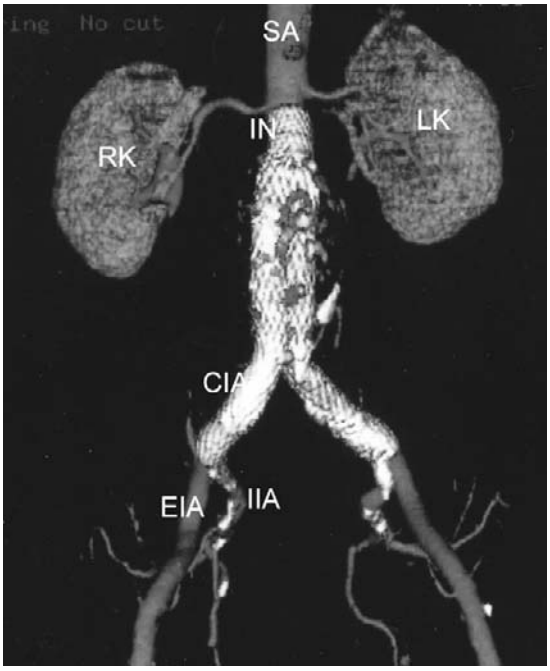

FIGURE 23-9 Endovascular abdominal aortic aneurysm repair involves aneurysm exclusion with an endoluminal aortic stent-graft introduced remotely, usually through the femoral artery. An endovascular graft extends from the infrarenal aorta to both common iliac arteries, preserving the flow to the internal iliac arteries. *SA,* Suprarenal aorta; *IN,* infrarenal aortic neck; *CIA,* common iliac artery; *EIA,* external iliac artery; *IIA,* internal iliac artery; *RK,* right kidney; *LK,* left kidney.

balloon-expandable Palmaz stents. Early tubular grafts have largely been replaced by modular bifurcated grafts that have expanded the applicability of this therapy. Different graft configurations, depending on the anatomic problem, are available. For patients with an AAA that is limited to the aorta and in whom there is both a neck between the renal arteries and the aneurysm and a neck between the lower portion of the aneurysm and the iliac bifurcation, a graft of tubular configuration is available. For those patients in whom the abdominal aneurysm extends to the iliac bifurcation, a bifurcated or Y-shaped graft is available. For those patients who have both an AAA and an aneurysm of one or both iliac arteries, a tapered tube graft that excludes both the aortic aneurysm and one iliac aneurysm is usually selected. The technical details of endovascular repair vary with each specific device, but the general principles are similar. Candidates for this procedure include patients with a proximal infrarenal neck at least 1 to 2 cm in length and common iliac arteries for proximal and distal fixation of an endograft, without excessive tortuosity and with appropriate iliofemoral access. Long-term follow-up data are ongoing, and patients undergoing this procedure should understand that prolonged follow-up with periodic imaging will be required and that reintervention may become necessary. Nonetheless, the future of endoluminal grafting continues to evolve and has the potential of significant rewards (Schermerhorn et al, 2008).

Procedural Considerations

The team positions the patient supine on a radiolucent OR bed with a special marker board. The board has remotely controlled radiopaque cursors that are used to fluoroscopically detect proximal and distal positions for graft deployment. An ample supply of lead gowns needs to be available. The anesthesia provider may administer a general anesthetic or an epidural anesthetic. If an epidural anesthetic is used, mechanical ventilation is available in case conversion to the traditional surgical procedure is required. The anesthesia provider inserts a central venous catheter and an arterial catheter for hemodynamic monitoring. The perioperative nurse inserts a urinary catheter, and ensures that the patient's abdomen and groin areas are prepped and draped to allow conversion to the traditional surgical technique if necessary.

Operative Procedure

1. The surgeon performs bilateral groin cutdowns and dissects both common femoral arteries.
2. After the anesthesia provider administers IV heparin, the surgeon clamps the right common femoral artery, performs an arteriotomy, and introduces an 8-French (8F) sheath into the right external iliac artery.
3. The left femoral artery is punctured, and the surgeon places a 12F sheath into the left external iliac artery. An angiocath is inserted, and an arteriogram is obtained to clearly mark the renal arteries and aortic bifurcation. The final length of the device to cover the aorta from the renal arteries to a suitable section of the common iliac arteries is chosen.
4. A snare is introduced into the aorta through the left femoral artery, and a pull wire is introduced into the aorta by way of the right femoral artery. The pull wire is snared above the aortic bifurcation and retracted into the left iliac artery. This step is done to help position the limbs of the graft into the iliac arteries.
5. The surgeon inserts the grafting device into the right femoral artery, advances it into the proximal part of the aorta, and positions it above the aortic bifurcation. Fluoroscopy is used to determine proper position of the stent.
6. The device is exposed by retracting a covering jacket, and the graft limbs are positioned in the iliac arteries. The hooks of the graft become attached to the walls of the aorta and the iliac arteries as the attachment systems are deployed.
7. The balloon on the device is inflated to secure the proximal attachment system to the aorta and the contralateral and ipsilateral systems to the iliac arteries.
8. An arteriogram is obtained to confirm proper positioning and complete exclusion of the AAA. Ideally, the graft is positioned to occlude the inferior mesenteric artery to prevent persistent blood flow within the aneurysmal sac.
9. After all the sheaths are removed, the surgeon closes the wounds with subcuticular sutures.

PERCUTANEOUS TRANSLUMINAL ANGIOPLASTY

Percutaneous transluminal angioplasty (PTA) is performed with a local anesthetic and minimal sedation, as a same-day surgery admission. Although initially performed only in the common iliac artery for stenosis, PTA is routinely used to treat short-segment occlusions as well as external iliac lesions. Iliac artery PTA may be particularly useful to help improve inflow before a more distal surgical reconstruction.

The use of iliac artery stents has also begun to play an increasing role in the management of patients with aortoiliac

occlusive disease. Iliac artery stents are most useful after initial suboptimal results from PTA. However, they are used primarily in the treatment of complex lesions. When PTA is not an option, a number of surgical alternatives are available. Depending on the condition of the patient and the patient's pathologic anatomy, the options include aortobifemoral bypass, aortoiliac thromboendarterectomy, axillofemoral bypass, iliofemoral bypass, and femorofemoral bypass.

FEMORAL-POPLITEAL AND FEMORAL-TIBIAL BYPASS

Femoral-popliteal bypass is the restoration of blood flow to the leg with a graft bypassing the occluded section of the femoral artery (Research Highlight). The bypass may be a saphenous vein or straight synthetic graft. The patient must have a patent outflow artery for a successful bypass procedure. If popliteal patency is doubtful, artery exploration is necessary as the first procedure. Involvement of the popliteal artery may necessitate the exposure and use of the tibial vessels for the lower anastomosis. If this occurs, the procedure could require the use of microvascular instruments and technique.

Procedural Considerations

The patient is placed in a supine position. The hip is externally rotated and abducted with the knee flexed. Prepping and draping include the entire groin and leg. The instrument setup includes the basic minor and vascular sets, plus the following: Gelpi retractors, Garrett or Weitlaner retractors, a device to tunnel, and supplies and equipment for operative arteriograms.

RESEARCH HIGHLIGHT

Below-Knee Revascularization in Patients with Critical Limb Ischemia: Long-Term Comparison of Redo versus Primary Interventions

The purpose of this study was to evaluate the authors' experience in below-knee revascularization for patients with critical limb ischemia by comparing the long-term outcomes of primary and secondary interventions. The study examined 140 consecutive below-knee revascularizations in patients with critical limb ischemia at the Department of Vascular Surgery, University of Florence (Florence, Italy). Early and long-term results in terms of survival, graft patency, and limb salvage were studied. Group 1 contained 105 patients (75%) who underwent a primary intervention and group 2 contained the remaining 35 patients (25%), who received a secondary intervention for a late (<30 days) bypass graft thrombosis. One patient died in the early postoperative period and the 30-day thrombosis and amputation rates were poorer in group 2 than group 1 (17.1% and 4.8%; 37.1% and 16.2%, respectively). After 60 months there were no significant differences (NS) between the two groups in terms of survival (90.1% and 90.9%, respectively; P = NS) and primary patency (43.5% and 31.9%, respectively; P = NS). The estimated limb salvage rate was significantly poorer in group 2 than in group 1 (64.1% and 77.7%, respectively; P = 0.05). The researchers concluded that redo below-knee revascularization in patients with critical limb ischemia provides acceptable results in terms of primary and secondary patency, but limb salvage was worse in patients who underwent redo procedures.

Modified from Troisi N et al: Below-knee revascularization in patients with critical limb ischemia: long-term comparison of redo vs. primary interventions, *J Cardiovasc Surg* 49:489-496, 2008.

Operative Procedures

Exploration of Common Femoral Artery

1. A vertical incision, extending downward about 3 to 5 inches along the medial aspect of the thigh, is made by the surgeon over the femoral artery below the inguinal area, and the field is exposed with a self-retaining retractor.
2. The surgeon locates the common femoral artery and dissects it in both directions for complete exposure.
3. The surgical technologist supplies moist umbilical tapes or vessel loops, which the surgeon passes around the common femoral, the superficial femoral, and the deep femoral arteries.

Exploration of Above-Knee Popliteal Artery

1. The surgeon makes a vertical incision along the medial aspect of the lower area of the thigh. If the popliteal artery is diseased, an additional incision below the knee is made to expose the distal popliteal artery.
2. A Weitlaner retractor is used to retract the muscles and expose the artery.
3. The surgeon flexes the patient's knee, dissects the popliteal artery, and passes a moist umbilical tape around the popliteal artery. Arteriograms may be performed at this time if doubt exists about the patency of the popliteal artery or distal arterial tree.
4. The saphenous vein is exposed via joined femoral and popliteal incisions the length of the thigh or through multiple short incisions along the medial area of the thigh. If the vein is suitable, the surgeon resects the necessary length or prepares it for in situ grafting. If a prosthesis will be used, the surgeon determines the length and size and the surgical technologist preclots the graft as previously described.
5. The surgeon ligates the side branches of the saphenous vein with fine silk. Finally, because of venous valves, the vein is reversed so that the end originally in the groin is anastomosed to the popliteal artery.
6. If a synthetic graft is used, the surgeon passes a tunneling device beneath the sartorius muscle from the popliteal fossa to the groin.
7. The graft is carefully pulled through the tunnel and positioned to prevent kinks or twists.
8. The anesthesia provider administers IV heparin to the patient before the surgeon applies a vascular clamp to the femoral artery. An incision is made into the femoral artery with a #11 knife blade and extended with a Potts angulated scissors.
9. The graft is anastomosed to the artery with fine vascular sutures.
10. The patient's knee is flexed, and the surgeon places vascular clamps on the popliteal artery at the site of the distal anastomosis.
11. An incision is made into the popliteal artery as explained for femoral arteriotomy.
12. The graft is sutured to the popliteal (or tibial) artery, and before completion the femoral occluding clamp is momentarily opened to eliminate air and debris.
13. All occluding clamps are removed, and the graft is assessed for anastomotic leaks.
14. The incision is closed as described previously.

FEMORAL-POPLITEAL BYPASS IN SITU

In situ femoral-popliteal bypass is the restoration of blood flow to the leg, bypassing an occluded portion of the femoral artery with the patient's saphenous vein, which remains in place. The procedure includes incising the venous valves and interrupting the venous tributaries. The adequacy of the patient's saphenous vein may be validated before the surgical procedure by an ultrasound duplex scan. Varicose veins or a previous saphenous vein ligation and stripping are contraindications to the procedure. The advantages of a vein-bypass procedure include increased graft availability and improved patency. A disadvantage is the time-consuming aspect of this technique.

Procedural Considerations

The surgeon uses microvascular scissors, a valvulotome, or a leather in situ valve cutter kit to incise the valves within the vein. An angioscope may be used to monitor the lysis of valve leaflets.

Operative Procedure

1. The procedure is similar to that for a femoral-popliteal bypass. The surgeon extends the groin incision downward over the course of the saphenous vein. A skin bridge may be left between the groin and the popliteal incisions.
2. The saphenous vein is exposed and divided at its proximal and distal ends. Venous tributaries are occluded with vessel clips, such as hemoclips, or fine nonabsorbable sutures.
3. The surgeon passes a valvulotome from below to the top, usually through side branches. The valvulotome is used to incise the internal valve (see Figure 23-6). In angioscopically assisted bypass, valve lysis is done under direct vision.
4. The saphenous vein is distended with heparinized saline, papaverine, or heparinized blood to identify any valvular obstruction or open venous tributary. Another pass of the valve cutter alleviates the obstruction. Open branches of the saphenous vein can also be ligated with vessel clips or fine nonabsorbable sutures.
5. The incompetent saphenous vein is used to bypass the occluded segment of the femoral artery (see steps 8 through 14 of the femoral-popliteal bypass procedure described under Exploration of Above-Knee Popliteal Artery).

FEMOROFEMORAL BYPASS

Femorofemoral bypass is an extraanatomic (a route that is outside the normal path) bypass that is performed to restore blood flow to one leg when an inflow procedure is necessary but a major aortic procedure is not desired. This type of bypass procedure is also used when the surgical risks for the patient are high because of a complicated medical condition or there are technical problems with the procedure (Figure 23-10). Studies continue to examine the long-term patency rate and outcomes for this patient population. Severe cardiac or pulmonary disease may prevent the patient from undergoing a more extensive procedure. Subcutaneous vascular grafting is an option in these conditions because the procedure bypasses normal vascular anatomy and can be performed using a local anesthetic with adjunct moderate sedation and analgesia. The patient must have one good iliac artery for inflow for a femorofemoral bypass to be considered. Another extraanatomic procedure that can be done in these instances is an axillofemoral bypass involving the subcutaneous placement of a prosthesis from the axillary artery to the femoral artery on the same side (Figure 23-11).

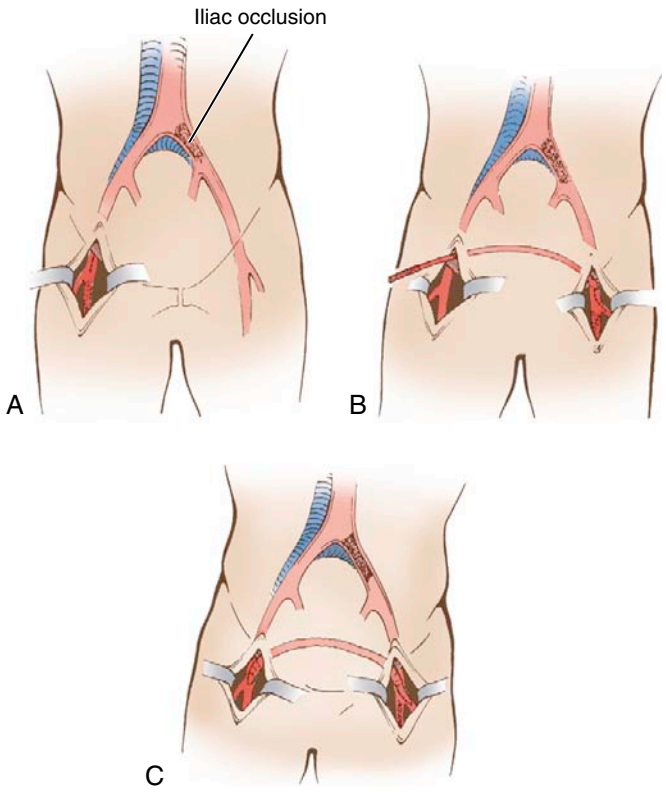

FIGURE 23-10 Femorofemoral bypass to restore blood flow to left leg. **A**, Left iliac artery occlusion and right femoral artery exposure. **B**, Exposure of the right and left femoral arteries: tunneling device creating a path for the graft in the subcutaneous tissue. **C**, Femorofemoral bypass graft in place.

Procedural Considerations

The perioperative nurse assists with positioning the patient supine on the OR bed with a small pad placed under each knee. The area prepped for surgery extends from the umbilicus to midthigh area. The genitalia are covered with a sterile towel.

Operative Procedure

1. A longitudinal incision is made by the surgeon over each femoral artery from the inguinal ligament to just below the femoral bifurcation.
2. Each common femoral artery, superficial femoral artery, and deep femoral artery are dissected free, mobilized, and secured with umbilical tapes or vessel loops.
3. The surgeon creates a graft tunnel between the two femoral arteries across the symphysis pubis in the subcutaneous tissue with digital dissection, scissors dissection, or the passage of a clamp or tunneling device across the preperitoneal space.
4. A Dacron or PTFE vascular graft is passed through the subcutaneous tunnel with care to prevent kinking of the graft.
5. The anesthesia provider administers IV heparin, and the surgeon places vascular clamps on the common femoral, superficial femoral, and deep femoral arteries. A longitudinal arteriotomy is made in the common femoral artery.

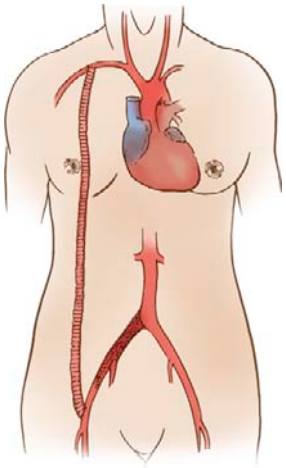

FIGURE 23-11 Axillofemoral bypass graft for right iliac artery occlusion.

6. The surgeon performs an end-to-side anastomosis using nonabsorbable vascular sutures to join the graft with the common femoral artery. A similar anastomosis is done on the other side.
7. After the clamps are released and flow is restored, the patient's pulses are checked with a sterile Doppler; the perioperative nurse may be asked to assess the patient's feet for warmth and color.
8. The femoral incisions are closed.

ARTERIAL EMBOLECTOMY

Arterial embolectomy entails an incision made in the affected artery to remove thromboembolic material and restore blood flow. Emboli may be clot particles, a foreign body, air, fat, or a tumor that circulates through the bloodstream and becomes lodged as the vessel decreases in size. More often the direct source is a cardiac mural thrombus, associated with cardiac or vascular disease. Pain or numbness distal to the obstruction is the initial symptom, accompanied by other signs of vascular occlusion, such as pallor and absence of pulses.

Procedural Considerations

The patient is placed in the supine position, the skin area is prepped, and draping is completed to permit access to the affected area. The instrument setup includes the basic instrument and vascular sets, including embolectomy catheters and irrigation catheters. Heparinized saline is required.

Operative Procedure—Femoral Embolectomy

1. After making a groin incision the surgeon exposes the femoral artery to permit the application of vascular clamps (Figure 23-12, *A* and *B*).
2. An incision is made into the artery with a #11 blade and a Potts scissors. An embolectomy catheter is carefully inserted beyond the point of clot proximally and distally. The balloon is inflated, and the catheter is withdrawn along with the detached clot (Figure 23-12, *C* and *D*).
3. As backflow is obtained, the surgeon applies a vascular clamp below the arteriotomy (Figure 23-12, *E*).
4. The artery may be flushed by injection of heparinized saline solution through a small irrigating catheter. Angioscopy or an arteriogram may or may not be requested at this time.
5. The arterial closure is completed with vascular sutures (Figure 23-12, *F*). The wound is closed, and dressings are applied.

AMPUTATION

Amputations involving the lower extremity are performed to eliminate ischemic, gangrenous, necrotic, or infected tissue; relieve pain; and promote maximum independence. Amputations may be necessary because of trauma or malignancy or when the lower limb cannot be salvaged by arterial reconstruction. In the immediate postoperative period, patients may experience phantom limb pain, described as shooting, burning, throbbing, stabbing, or squeezing. Phantom limb pain may recur, but less frequently, in the months following surgery (Hanley et al, 2006).

Procedural Considerations

It is critical to verify the correct limb for this procedure. Because amputations are often performed with the patient administered a regional anesthetic, the perioperative nurse must be sure that the patient does not witness the wrapping or transport of the amputated limb. Toes or partial foot amputations may be done in certain instances, but often a below-knee (BK) or above-knee (AK) amputation is indicated. Syme's amputation, through the ankle, is seldom performed because of improved prosthetics and rehabilitation that favor mid-calf amputation. The level is based on the health of the patient, level of vascularity, and potential for healing and rehabilitation. Severe infection or toxemia may require amputation as a lifesaving procedure. Operative risks for amputation are higher than those for reconstruction, possibly because of more extensive vascular disease. BK amputations are best done at the junction of the upper and middle thirds of the lower leg. This allows for an immediate postoperative prosthesis, aids in better healing, and may reduce phantom limb pain. AK amputations may be at the middle or lower third of the thigh. Flaps are tailored to provide fascial and skin coverage to cushion the smoothed end of the bone. Meticulous hemostasis and drainage are needed to decrease hematoma formation, since healing is both problematic and critical in these patients. Persons with diabetes are at highest risk for amputation because of their neuropathy, altered response to infection, and vascular insufficiency.

Operative Procedure

1. The surgeon determines the level of amputation, and marks the incision line to create a long posterior flap for a BK amputation. For an AK amputation, the anterior and posterior flaps are fairly equal in size (Figure 23-13).
2. Blood loss may be reduced by using a sterile tourniquet after the leg is raised to drain venous blood. The tourniquet is inflated and the surgeon makes the incision and divides the muscle and soft tissue. The periosteum is raised with an elevator.
3. The surgeon cuts the bones—the tibia with a Gigli or oscillating saw and the fibula with a bone cutter—and bevels their anterior aspect and smoothes them with a rongeur and rasp. The specimen is handed off the field.

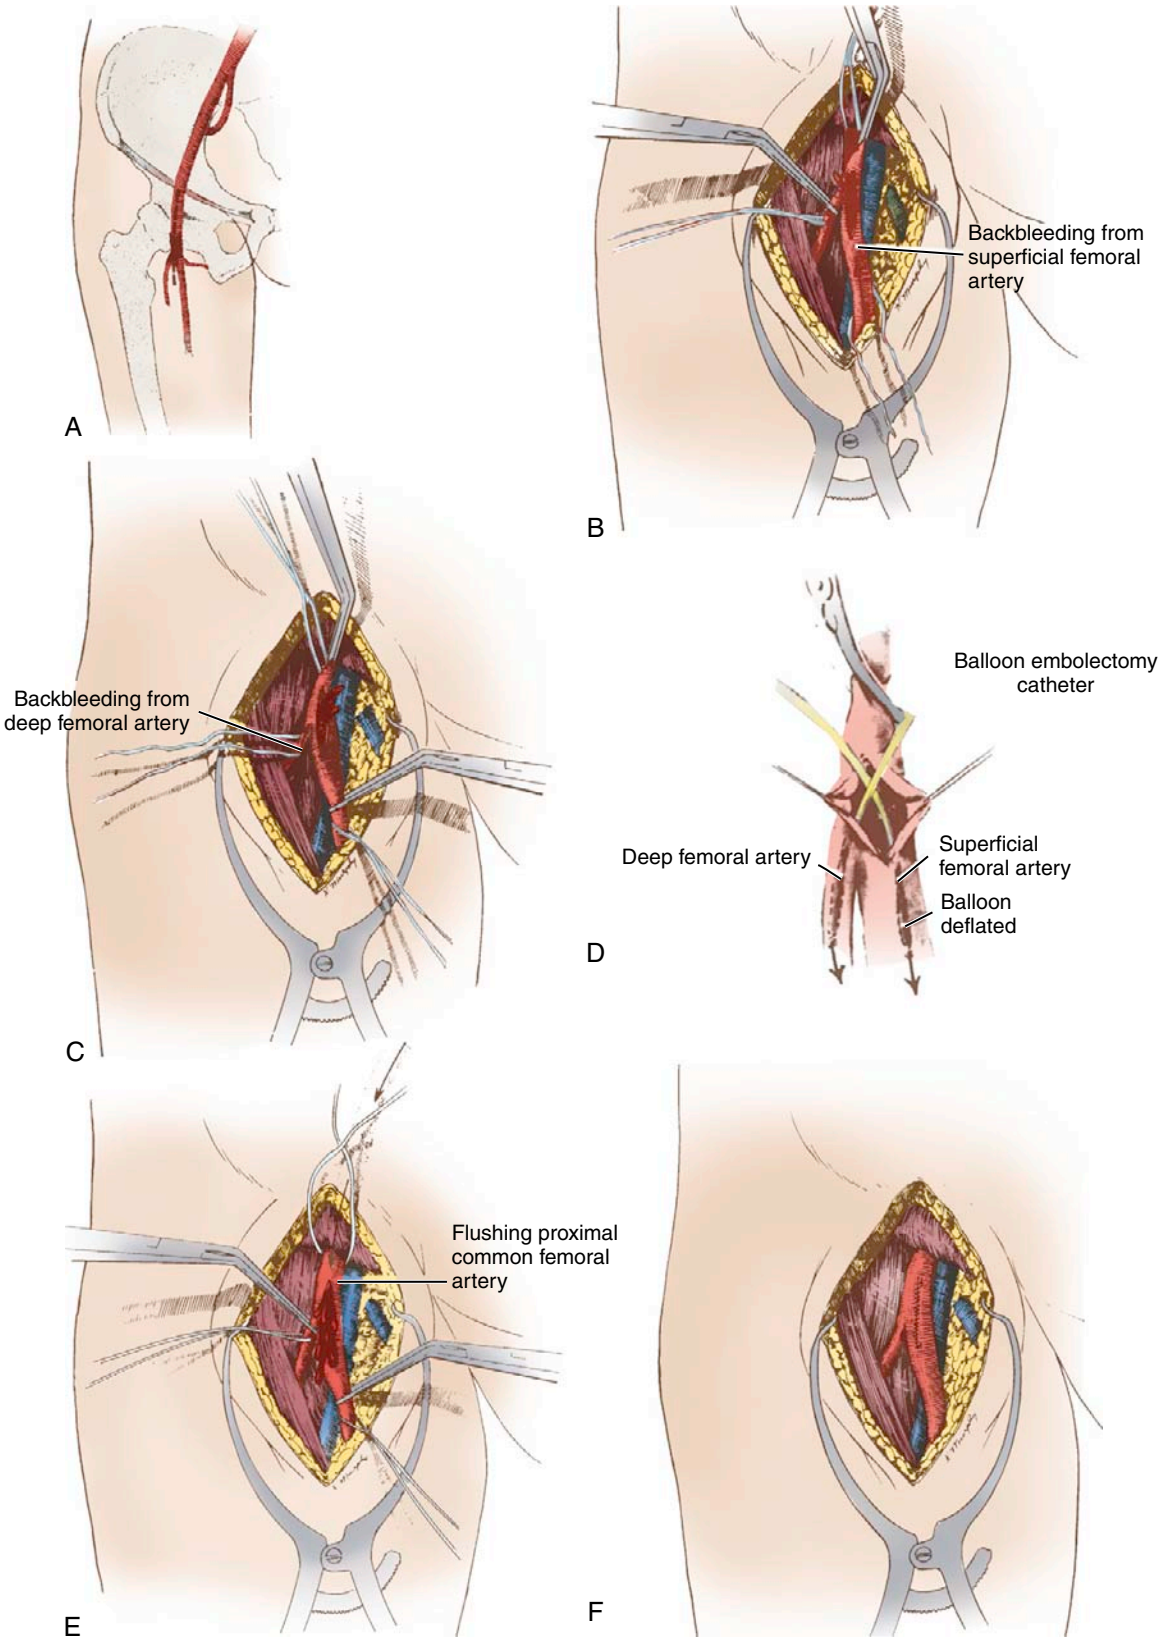

FIGURE 23-12 Femoral embolectomy. **A**, Femoral arteriotomy. **B**, Clamp on common femoral and deep femoral (profunda femoris) arteries. Backflow of blood from superficial femoral artery (SFA) is checked. **C**, Clamp on common femoral artery and SFA. Backflow of blood from deep femoral artery is checked. **D**, Balloon embolectomy catheters are passed into SFA and profunda. **E**, Proximal (common femoral) artery is unclamped and flushed. **F**, Arteriotomy is closed.

4. The stump is gently irrigated, and hemostasis is achieved.
5. A closed-wound drainage system may be inserted.
6. Fascia is closed with interrupted sutures.
7. Skin is approximated and closed with interrupted suture or staples.
8. An immediate postoperative stump dressing may be applied to prevent flexion contracture.

CAROTID ENDARTERECTOMY (CEA)

CEA is the removal of an atheroma (plaque) at the carotid artery bifurcation to increase cerebral perfusion and decrease the risk of embolization and consequent stroke (Liu et al, 2009) (Rapid Response Team box). In most settings, the patient is discharged on the first postoperative day. Lessening the likelihood of any transient or permanent neurologic deficit is a major concern during a CEA. The use of a temporary carotid artery shunt (Figure 23-14), such as an Argyle or Javid shunt, allows for continuous blood flow through the carotid artery and to the brain. Some disadvantages in using this temporary device are that additional dissection is necessary for its placement and that there is a possibility of dislodging debris when the shunt is inserted. Also, it is difficult to view the endarterectomy endpoint and suturing a patch is more difficult.

Two techniques that facilitate continual assessment of cerebral perfusion are the use of a cervical plexus block for anesthesia and the use of electroencephalography. A conscious patient with a cervical plexus block can be observed for neurologic deficits encountered during the procedure. The patient who is administered a general anesthetic can be monitored with an EEG. If either method demonstrates reduced cerebral perfusion, the surgeon may decide to use a temporary carotid artery shunt. The shunting device should always be available and sterile at the beginning of the procedure.

Procedural Considerations

The perioperative nurse assists with positioning the patient supine on the OR bed with the head supported on a head support. The head is turned away from the operative side, and the neck may be slightly hyperextended. A roll may be placed between the scapulae.

RAPID RESPONSE TEAM

Stroke continues to be a significant cause of morbidity and mortality in the United States. Approximately 750,000 Americans have a new or recurrent stroke each year. Stroke remains the third leading cause of death and is the leading cause of disability in the United States (Schwamm, 2006) when considered independently from other cardiovascular diseases. Major advances have been made during the past several decades in stroke prevention, treatment, and rehabilitation. Despite successes in delivering effective new therapies, significant obstacles remain in ensuring that scientific advances are consistently translated into clinical practice. A best practice (often referred to as evidence-based practice [EBP]) is using "best evidence" to make clinical decisions and eliminate inappropriate or ineffective care. Patients with asymptomatic carotid stenosis have a low risk of stroke. However, carotid disease includes stenosis as well as stable and unstable plaque formation. Patients with cerebral ocular events, an irregular plaque surface, recent ischemic events, and carotid stenosis are likely candidates for surgery.

In 2005 the American Stroke Association formed a task force on the development of stroke systems of care. One critical element of the multidisciplinary stroke system is the hospital-based acute stroke team. The team should consist of neuroscience nurses and neurologists who work in conjunction with the primary care nurse and physician through prompt recognition and intervention of stroke symptoms in hospitalized patients. Acute stroke teams facilitate the rapid evaluation and treatment of acute stroke patients that result in improved patient outcomes.

Part of the recommendations related to acute treatment includes the following:

- Acute stroke teams
- Written care protocols
- Continuing medical education
- Interface with Emergency Medical Service (EMS)
- A stroke unit for stroke admissions
- Neuroimaging and laboratory services
- Access to neurosurgical services

Modified from Mathiesen C et al: Best practices in stroke rapid response, *Medsurg Nurs* 15(6):364-369, 2006; Schwamm L et al: *Recommendations from the American Stroke Association's task force on the development of stroke systems*, available at www.stroke.ahajournals.org. Accessed April 17, 2009.

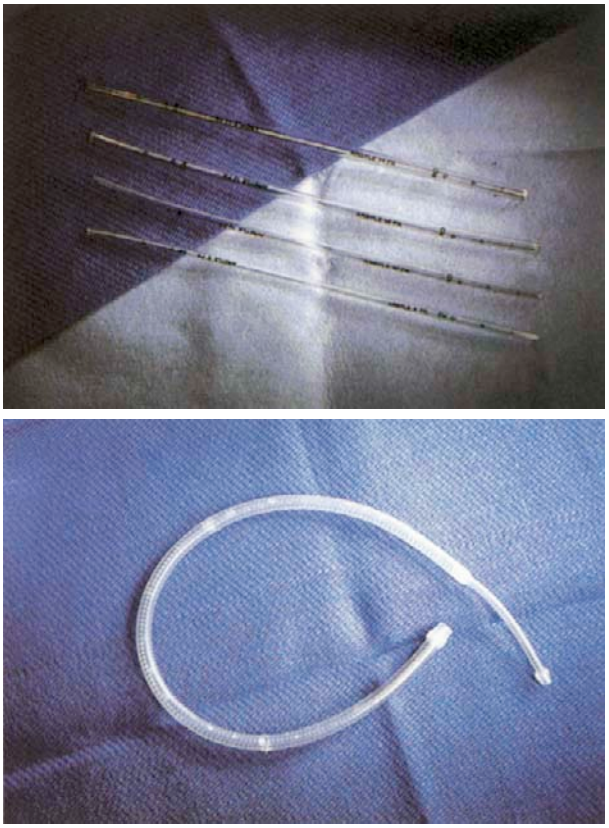

FIGURE 23-14 Example of temporary carotid artery shunts that are used to permit blood flow during carotid endarterectomy procedures.

Operative Procedure

1. The surgeon makes a longitudinal incision over the area of the carotid bifurcation (Figure 23-15, *A*) and places a Weitlaner self-retaining retractor for exposure.
2. With Metzenbaum scissors, the surgeon dissects the soft tissue to expose the carotid artery and its bifurcation (Figure 23-15, *B*).
3. A moistened umbilical tape or vessel loop is passed around the vessel for ease of handling. Systemic heparin is given to the patient by the anesthesia provider.
4. The surgeon clamps the external, common, and internal carotid arteries.
5. The surgeon uses a #11 knife blade to create an arteriotomy over the stenotic area and lengthens the incision with a Potts angulated scissors to expose the full extent of the occluding plaque.
6. Using a blunt dissector, the surgeon dissects the plaque or plaques free from the arterial wall. Heparin solution is used as an irrigant to clean the intima.
7. The surgeon closes the arteriotomy with fine vascular sutures. A synthetic (polyester or PTFE) or autogenous (vein) patch graft may be used to restore the arterial lumen if it is small (Figure 23-16). Before complete closure, blood flow is temporarily restored through the arteries to wash away any free plaques, air, or thrombi. For this to be done, the occluding clamps are opened and closed individually, with flushing of any debris away from the internal carotid artery. The closure of the arteriotomy is completed (Figure 23-17).

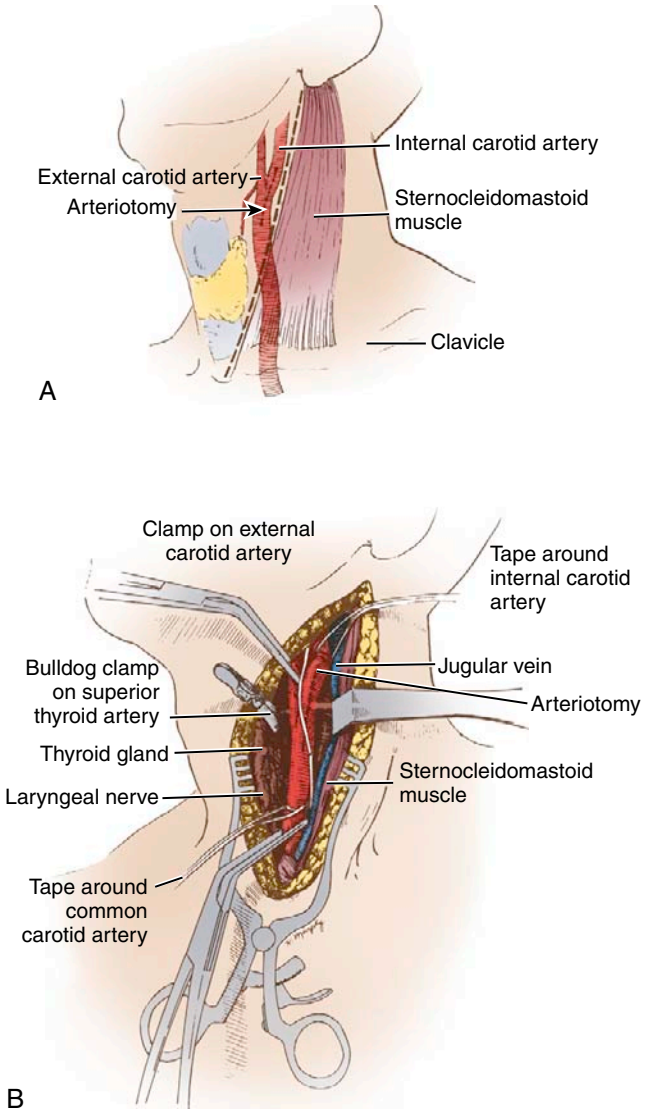

FIGURE 23-15 Left carotid endarterectomy. **A**, Incision and anatomy. **B**, Exposure of carotid bifurcation.

8. The occluding clamps are removed from the external and common carotid arteries; the internal carotid artery clamp is removed last. This sequence ensures that any minor debris missed will be flushed harmlessly into the external rather than the internal carotid artery.
9. Additional interrupted sutures may be needed to control leakage.
10. A closed drainage system is inserted by way of a separate stab incision.
11. The wound is closed, and dressings are applied.

CAROTID ENDARTERECTOMY WITH SHUNT

Operative Procedure

1-5. The first five steps as described for carotid endarterectomy are followed.

6. To maintain cerebral blood flow the surgeon inserts either a piece of tubing (polyethylene or Silastic) with a suture tied around its center or a commercially prepared shunt device

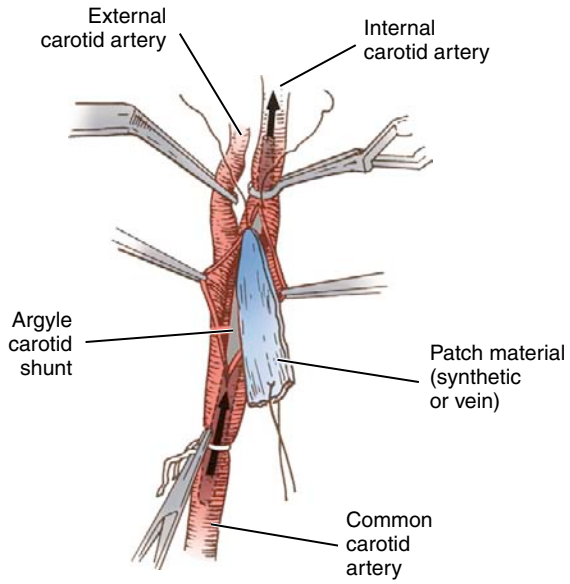

FIGURE 23-16 Left carotid endarterectomy illustrating initial placement and suturing of a patch (a shunt is in place).

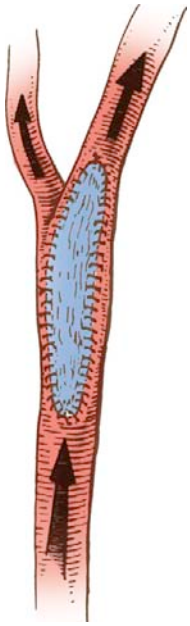

FIGURE 23-17 Left carotid endarterectomy (patch angioplasty) with patch sewn in place.

into the common carotid artery and the internal carotid artery. The surgeon then stabilizes the tube or shunt with vessel loops or shunt clamps (Figure 23-18).

7. The surgeon removes the plaque as described for carotid endarterectomy and the arteriotomy is closed with or without a patch.
8. Before the arteriotomy closure is completed, the surgeon releases the shunt clamp or vessel loop on the internal carotid artery and removes the shunt. The external carotid occluding clamp is removed, followed by the common carotid artery clamp, and, last, the internal carotid artery occluding clamp.
9. The wound is closed, and dressings are applied.

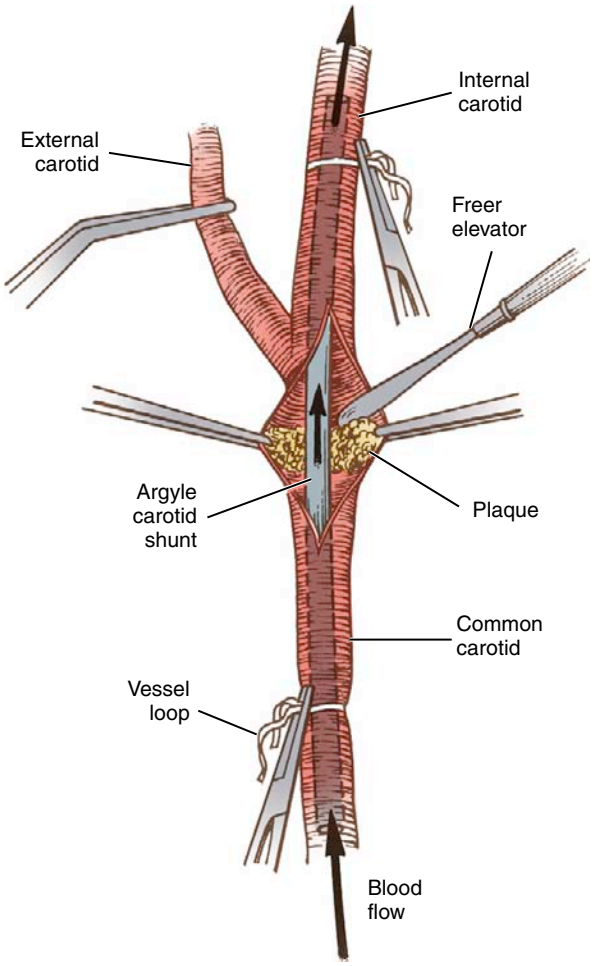

FIGURE 23-18 Left carotid endarterectomy. Argyle carotid shunt in place to allow blood flow to the brain. Stenotic plaque being removed with Freer elevator.

ARTERIOVENOUS FISTULA

Arteriovenous fistulas—direct connections between an artery and a vein—are the standard means of vascular access for long-term renal dialysis. The dilated vein can then be used for direct cannulation with large-bore needles for hemodialysis. This method is preferable to an external shunt, which carries a high risk of thrombosis and infection. The best access is achieved using the patient's own vessels and creating a subcutaneous connection between the artery and vein, referred to as an arteriovenous shunt, or bridge fistula. Other choices include using a bovine carotid artery, a human umbilical vein graft, or a synthetic vascular graft, usually PTFE. Four anastomoses that can be created between the artery and vein are side of artery to side of vein, end of artery to side of vein, end of vein to side of artery, and end of vein to end of artery (Parker et al, 2008) (Figure 23-19). The Brescia-Cimino fistula is a connection between the radial artery and cephalic vein at the wrist (Figure 23-20). A basic principle of creating a fistula is to start in the distal arm and move proximally with subsequent fistulas. These include ulnar artery to basilic vein and brachial artery to brachial or cephalic vein (Figure 23-21).

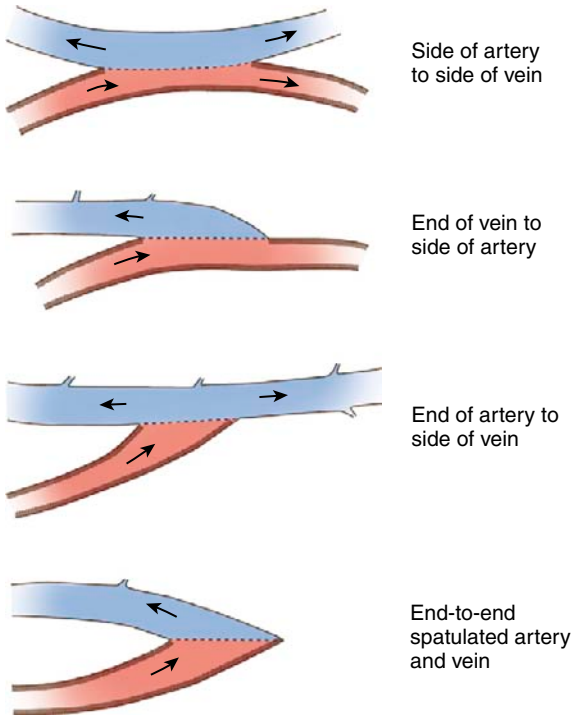

FIGURE 23-19 Four types of anastomoses between radial artery and cephalic vein.

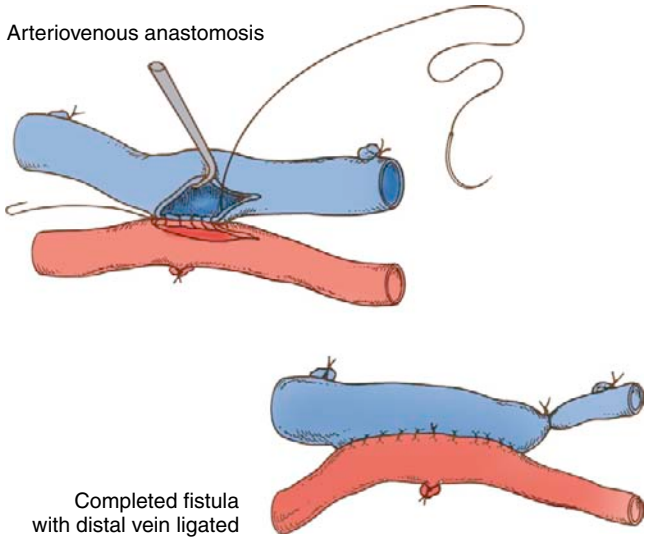

FIGURE 23-20 Arteriovenous anastomosis. The artery is anastomosed to the vein.

Arteriovenous shunts are indicated for long-term renal dialysis access. Patients with end-stage renal disease have their creatinine clearance levels observed. When the creatinine clearance level falls to 10 ml/min, a Cimino fistula may be created in anticipation of the need for dialysis. A Cimino (or Brescia-Cimino) type of fistula has proved to have the longest patency and lowest infection rate. It is created to connect the patient's artery to a vein that will dilate and become thick-walled (its muscle layer hypertrophies). This occurs from the high rate of blood flow delivered by the connection to the artery. The arterialization, or maturation process, necessary to allow the

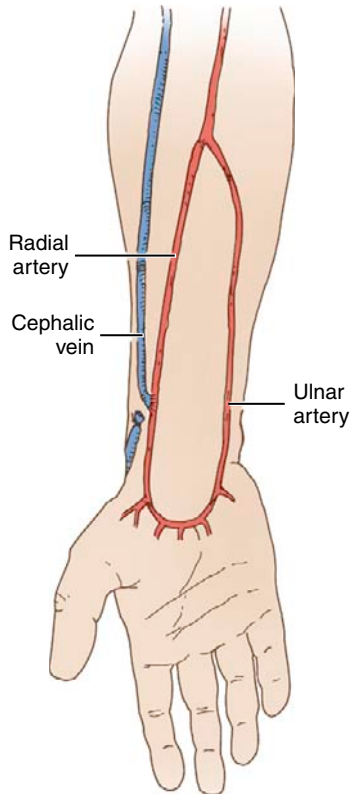

FIGURE 23-21 End of the cephalic vein anastomosed to the side of the radial artery at a site superior to the usual location of the radiocephalic fistula. This technique can be useful if the distal radial artery is small or the cephalic vein at the wrist is thrombosed.

fistula to withstand the repeated needle punctures of dialysis takes about 3 weeks.

Bridge fistulas do not need to mature and therefore are available for immediate dialysis use. For connections between an artery and a vein that are in proximity, a U-shaped graft is placed. Grafts that are far apart require a straight or slightly curved graft. Although the saphenous vein, an umbilical vein graft, and the bovine carotid artery are used, the PTFE grafts work the best and are most commonly used for bridge fistulas. Some surgeons prefer to use a specially designed PTFE step-graft, or tapered graft. These have a short segment of 4 mm in diameter at one end and the majority of the graft with a 7-mm diameter. This graft may avoid an output or flow rate that is so high it causes cardiac overload. Primary sites for bridge fistulas include the upper arm between the brachial artery and axillary vein and the forearm between the brachial artery and antecubital vein or between the brachial artery and basilic vein (Figure 23-22). The axillofemoral graft for dialysis is reserved for those patients who have exhausted other fistula sites. A regular-walled (versus a thin-walled) graft is placed from the axillary artery to the common femoral vein. PTFE grafts can be used immediately, but it may be better to wait 2 weeks for anastomotic healing to occur.

The side-to-side fistula was the original subcutaneous method introduced by Brescia in 1966. The side-to-side fistula is technically the easiest to perform and creates the highest flow rate. The arterial end-to-vein side fistula has a lower flow rate. The arterial side-to-vein end fistula is technically more

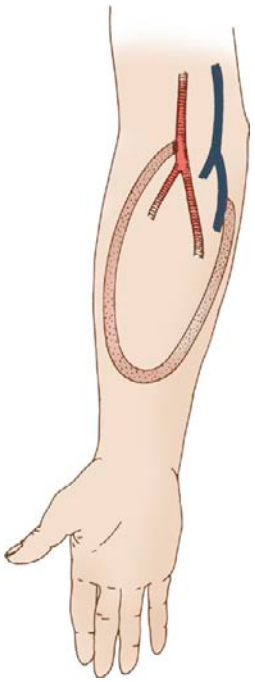

FIGURE 23-22 An example of a loop fistula. A synthetic graft has been used to create a loop brachiocephalic fistula.

difficult to create but has a lower incidence of venous hypertension. The end-to-end construction has the lowest rate of venous hypertension but also has the lowest flow rate. There is a trend toward performing fewer side-to-side fistulas and more artery side-to-vein end fistulas.

Since the patency of fistulas is limited, dialysis patients return for revision or embolectomy in attempts to salvage their function. Unfortunately, the success rate for salvage is low and access may be better managed by the creation of another site or a bridge fistula. Risk factors for complications include female gender, African American race, older than 65 years, and presence of diabetes. Treatment for the most common complication, stenosis, is surgery. Stenosis usually results in thrombosis. Stenosis most often involves the venous anastomosis, and a patch angioplasty is usually performed to revise a thrombosed fistula. Other complications include aneurysm and pseudoaneurysm formation, infection, subclavian steal syndrome, and high-output CHF.

VENA CAVA FILTER INSERTION

Vena cava filter (VCF) insertion entails the partial occlusion of the inferior vena cava with an intravascular filter, such as a Greenfield filter, inserted under fluoroscopy using a local anesthetic or moderate sedation and analgesia (monitored anesthesia care). VCFs are generally placed in the OR or angiography suite with fluoroscopic guidance. The Greenfield device offers the option of jugular or femoral vein insertion, and the correct kit must be selected. Box 23-3 gives indications for a caval filter. Several types of filters have been used during the past 20 years, as illustrated in Figure 23-23. The Greenfield filter is the most successful and widely used device, and the mortality and morbidity have been extremely low. The device has progressed from an early design that required an incision and venotomy

BOX 23-3

Indications for a Vena Cava Filter

- Recurrent thromboembolism despite "adequate" anticoagulation
- Deep venous thrombosis in a patient with contraindications to anticoagulation
- Chronic pulmonary embolism and resultant pulmonary hypertension
- Complications of anticoagulation
- Propagating iliofemoral venous thrombus in anticoagulation

From Chung J, Owen R: Using inferior vena cava filters to prevent pulmonary embolism, *Can Fam Physician* 54:49-55, 2008.

to the current percutaneous titanium vena cava filter. The filter maintains a patent vena cava but prevents PE by trapping the emboli at the apex of the device.

Procedural Considerations

The perioperative nurse assists the patient to the supine position on a radiopaque OR bed to permit fluoroscopic visualization at the level of the renal veins. This procedure may be performed in the OR, radiology suite, or ICU for critical patients. The head is turned to the left for jugular vein insertion, or the groin is exposed for femoral vein insertion. The right femoral vein is preferred over the left because the anatomy of the left vein often makes threading the filter more difficult. The nurse ensures that local anesthetic, heparinized saline to flush the device, and contrast media are available.

Operative Procedure

1. The right groin area is prepped and draped and infiltrated with local anesthetic.
2. An 18-gauge entry needle is used for right femoral venotomy.
3. The surgeon inserts the guidewire and advances it to a level above the renal veins under fluoroscopic guidance.
4. The sheath or dilator is inserted over the guidewire after all device lumens have been flushed with heparin solution.
5. The surgeon removes the sheath, and inserts and advances the introducer catheter to the implantation site.
6. The introducer catheter carries the preloaded, radiopaque carrier capsule. The sheath is retracted, the filter is discharged, and the sheath is removed.
7. Pressure is applied to the puncture site for approximately 5 minutes or until hemostasis is achieved.

VARICOSE VEIN EXCISION AND STRIPPING

Varicose veins are enlarged and distended veins that are visible and palpable beneath the skin. Varicose veins are described as primary or secondary. Primary varicose veins are more prevalent and are not associated with a pathologic condition of the deeper venous system, that is, post-thrombotic syndrome or a history of DVT. Secondary varicose veins are believed to be a result of insufficiency of the deep venous system. Disease may prevent the normal functioning of these valves, resulting in distention; as the vein wall weakens and dilates, venous pressure increases and the valves become incompetent. The veins

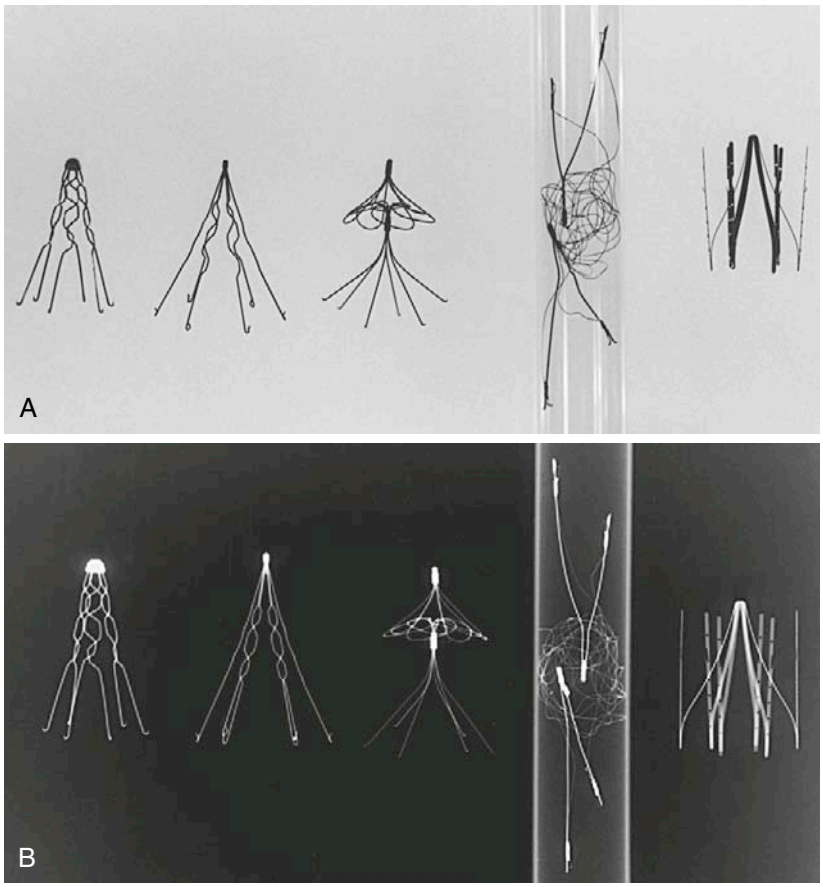

FIGURE 23-23 Vena cava filters. **A**, Actual filters. **B**, Radiographic images. *Left to right,* Kimray-Greenfield, titanium Greenfield, Simon nitinol, Gianturco bird's nest, and Vena Tech.

gradually become dilated. Veins in the lower extremities are most frequently affected, particularly the long saphenous vein. Risk factors include female gender, increased age, pregnancy, geographic location, and race (more prevalent in Caucasians).

Dilation of the saphenous vein produces venous stasis, which may be followed by secondary complications, such as stasis ulcers. Venous obstruction causes an increase in venous pressure, which leads to an increase in capillary pressure. This causes fluid to leak from the capillaries and produce edema. The objective of surgical intervention is to remove the diseased veins, thus preventing ulceration, secondary edema, pain, and fatigue in the extremity.

Procedural Considerations

Before sedation or entrance into the OR, the patient should stand and the varicose veins should be marked with an indelible marker. This ensures adequate visualization for complete removal of the varicosities, since the patient is often placed in the Trendelenburg position intraoperatively to decrease venous congestion, which could interfere with visualization of the varicosities. The perioperative nurse assists with positioning the patient on the OR bed in a supine position with the legs slightly abducted. Ligation or stripping of the lesser saphenous veins and branches may require placing the patient in the prone position. In the stab avulsion technique, multiple small (2 to 3 mm) incisions are made over the identified varicosities, and the affected vein segments are removed (Figure 23-24). Stripping indicates removal of a long segment of vein by means of a special device (Figure 23-25). Drapes are placed to enable flexing and lifting at the knee. Instruments include a basic minor instrument setup, plus the following: Weitlaner self-retaining retractors, #11 blades, skin hooks, mosquito hemostats, vein strippers with various tips available, and elastic bandages. Endovenous laser ablation (EVLA) is an innovative nonsurgical procedure for varicose veins and offers patients an alternative treatment to surgical vein stripping (Ambulatory Surgical Considerations).

Operative Procedure

1. The surgeon makes an incision in the upper area of the thigh, parallel to the crease in the groin, and clamps and ligates any bleeding vessels.
2. The saphenous vein is identified and isolated. Margins of the wound are separated with a Weitlaner self-retaining retractor.
3. The surgeon double ligates the saphenous vein branches with black silk ties, or they are transfixed, clamped, and divided. The proximal stump is dissected upward to the point at which it enters the femoral vein, where it is carefully ligated.
4. If the saphenous vein is to be excised, the surgeon makes an incision at its distal portion at the ankle, and the vein is identified, ligated, and divided.

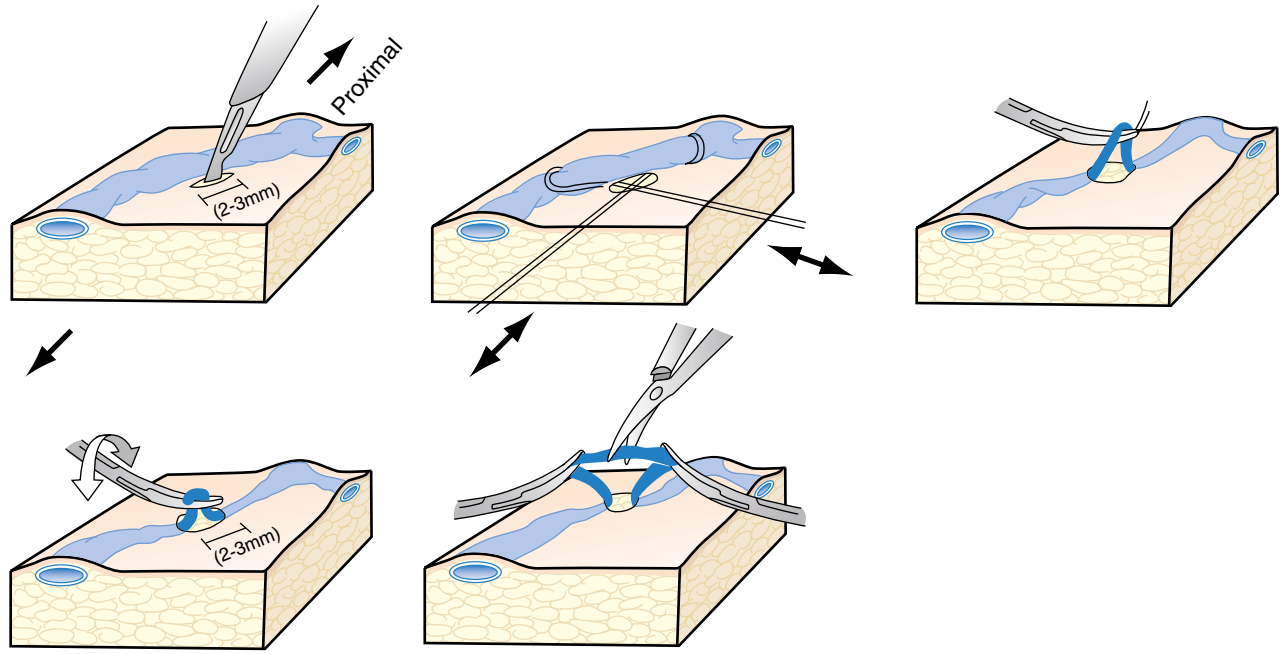

FIGURE 23-24 Technique of stab avulsions of varicosities.

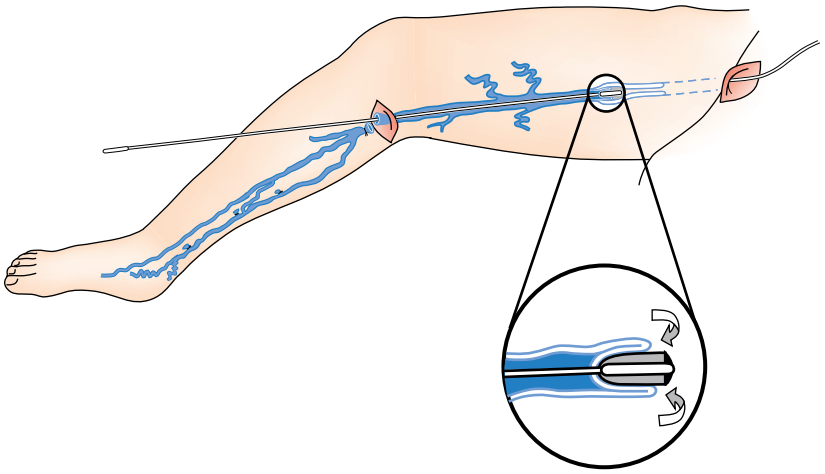

FIGURE 23-25 Inversion stripping of the saphenous vein for superficial venous reflux caused by an incompetent saphenofemoral junction.

AMBULATORY SURGERY CONSIDERATIONS

Post-Discharge Follow-Up: Endovenous Laser Ablation for Varicose Veins

Endovenous laser ablation (EVLA) is an innovative nonsurgical procedure for varicose veins that offers an alternative treatment to the often painful surgical ligation (or stripping) of veins, which is performed with the patient administered a general anesthetic and often has a long recovery time. During EVLA, by delivering laser energy through a fiberoptic catheter a particular vein is sealed to prevent blood flow. The catheter is inserted into the vein with ultrasound guidance. The entire procedure can be done in 1 hour as an ambulatory surgery procedure with the patient administered a local anesthetic. Once the procedure is completed, the skin puncture site is approximated with an adhesive strip. A graduated compression stocking or wrap is applied to the affected extremity from the base of the toes to the groin; it is constantly kept in place for 2 weeks and thereafter for 6 weeks when ambulatory to help maintain occlusion of the vein. Immediate and frequent ambulation is encouraged to decrease the incidence of DVT formation.

An important consideration for vascular procedure patients in the ambulatory setting is postoperative and discharge education. Patients need detailed instructions regarding recovery and convalescence since this phase is not complete upon discharge. Those instructions should include possible complications, activity level, wound care, pain management, and the plan for follow-up. Postoperative phone calls, 24 to 48 hours after discharge, have proven beneficial to identify any adverse events and answer patient questions. In a study by Forster and colleagues (2008), an automated system was developed for follow-up. Several patients requested to speak to a nurse directly for worsening postoperative symptoms and for additional clarification of the discharge instructions. Although all patients received detailed education, new questions arose. The post-discharge phone call can stress the importance of wearing the compression stocking or wrap to prevent complications.

Modified from Orenstein BW: Replacing vein stripping, *Radiol Today* 6(12):22-27, 2005; Forster AJ et al: Automated patient assessments after outpatient surgery using an interactive voice response system, *Am J Manag Care* 14(7):429-436, 2008.

5. A vein stripper is inserted and advanced to the proximal end of the vein in the groin, where it is secured with a heavy suture, and the tip is attached.
6. As the surgeon pulls the stripper up the leg, external compression is applied by the assistant or surgical technologist.
7. Tributaries may be excised through numerous small incisions along the course of the vein.
8. The surgeon closes the groin wound in layers, and other small incisions are closed with skin sutures or staples. Dressings and circular compression bandages are applied.

CHAPTER 24

Cardiac Surgery

PATRICIA C. SEIFERT

Cardiac surgery (History box) reflects individual and collaborative innovation, risk-taking, and problem-solving. Anastomotic techniques to join blood vessels, advances in the development of atraumatic vascular instruments, endovascular approaches in the repair of great vessels, and improvements in myocardial protection strategies represent a few of the many advances that have led to remarkable achievements in the surgical repair of congenital and acquired cardiovascular diseases (Stoney, 2008). Cardiac surgeries continue to evolve and reflect societal mandates for personal safety, enhanced functional outcomes, institutional efficiency, staff competence, and operational cost-effectiveness (Lytle, 2008). Evidence of these achievements can be seen in the rapid growth of endoscopic and robotic technology, minimally invasive procedures, off-pump techniques, combined (hybrid) surgical and percutaneous interventions, and molecular-level treatments for cardiovascular disease. Many newer procedures require smaller incisions, promote faster healing, and enable patients to achieve their desired functional outcomes more quickly.

These trends have not replaced the need for traditional techniques; rather, they have expanded treatment options for coronary artery disease (CAD), valvular dysfunction, thoracic aneurysms, conduction disturbances, congenital abnormalities (Sommer et al, 2008a, b, c), heart failure, intracardiac masses (Kuchukarian et al, 2007), and end-stage cardiac disease. Therapeutic options may employ laser, radiofrequency, and cryo energies. Stem cell therapy, used to induce cardiac neorevascularization at the cellular level (Menasche, 2009), and mechanical assist devices are effective alternatives to allograft transplant organs, which are in scarce supply. Great strides have been made to reduce mortality from coronary artery disease (Gardner, 2009; American Heart Association, 2009a), but significant challenges associated with the aging population, obesity, diabetes, and other risk factors continue to affect the cardiovascular system and the need for surgical treatment.

Surgical Anatomy

The heart (Figure 24-1) is a four-chamber muscular pump that propels blood into the systemic and pulmonary circulatory systems. It is enclosed in a pericardial sac within the mediastinum, which lies between the lungs, posterior to the sternum, and anterior to the vertebrae, esophagus, and descending portion of the aorta. The diaphragm is positioned below the heart (Figure 24-2). The cardiac wall is composed of three layers: the epicardium, the outer lining; the myocardium, or muscular layer, which is the important functional layer; and the endocardium, the inner lining (Figure 24-3).

Two thirds of the heart is located to the left of the midline, and the remaining one third is to the right. Although functionally divided into right and left halves, the heart is rotated to the left, with the right side located anteriorly and the left side situated relatively posteriorly. Each half of the heart contains an upper and a lower communicating chamber: the atrium and the ventricle, respectively. The right atrium (RA) receives desaturated blood from the inferior and superior venae cavae and from the coronary circulation by way of the coronary sinus. The left atrium (LA) receives oxygenated blood from the lungs by way of the pulmonary veins. From the atria, blood flows through the atrioventricular (AV) valves into the ventricles.

The left ventricle (LV) pumps blood into the major vessels of the *systemic circulatory system* by way of the aorta and its main branches to the head, upper extremities, abdominal organs, and lower extremities. The right and left internal (thoracic) mammary arteries, used as grafts during coronary bypass surgery, branch off the subclavian arteries and course behind and parallel to the edges of the sternum. The arteries of the circulatory system subdivide into arterioles and eventually into capillaries, where internal respiration and metabolic exchange occur. From the capillary beds, desaturated blood flows into the venules and veins and finally returns to the RA.

In the *pulmonary circulatory system,* blood is pumped from the right ventricle (RV) through the pulmonary valve into the main pulmonary artery (PA). The PA divides into the right and left pulmonary arteries, which further subdivide into the arterioles and capillaries of the lungs. External respiration occurs in the capillary beds and the alveoli, where carbon dioxide is exchanged for oxygen. Freshly oxygenated blood from the lungs flows through the pulmonary veins into the left atrium.

Coronary circulation (Figure 24-4) supplies oxygen and nutrients to, and removes metabolic waste from, the myocardium; internal respiration occurs in the *myocytes*. The heart receives its blood supply from the left and right coronary arteries, which originate in the sinuses of Valsalva behind the cusps of the aortic valve in the ascending aorta. The left main coronary artery divides into the left anterior descending (LAD) coronary artery and the circumflex coronary artery; along with the right coronary artery (RCA), these arteries represent the three main vessels of the coronary arterial system. In coronary arteries affected by coronary artery disease (CAD), focal or diffuse atherosclerotic plaques develop and progressively enlarge, jeopardizing myocardial blood flow and oxygenation, producing ischemic pain (in many, but not all, cases). Occlusion of an artery by expanding atherosclerotic lesions causes myocardial

infarction (MI) and irreversible damage to the region of the myocardium perfused by the obstructed artery. Coronary artery bypass procedures increase blood flow to the affected ischemic areas by attaching a bypass graft conduit to the artery distal to the narrowed portion of the artery. A totally occluded (infarcted) artery does not benefit from bypass surgery because the myocardial injury is irreversible.

The main coronary arteries are situated in the epicardium, which facilitates accessibility during coronary bypass procedures. From these arteries arise the septal perforators and other branches that penetrate the entire myocardium. The cardiac veins empty into the right atrium by way of the coronary sinus; the thebesian veins, prominent in the walls of the right atrium and the right ventricle, open directly into these chambers.

HISTORY

History of Cardiac Surgery

Although the notion of the heart as the seat of the soul is an ancient concept, cardiac surgery is one of the youngest clinical specialties, partly because of religious restrictions and partly because of physiologic constraints. Rehn's suture repair of a right ventricular stab wound in 1896 opened the door to the specialty of cardiac surgery. The introduction of positive-pressure endotracheal anesthesia allowed surgeons to access the heart and enter the pleural cavities without causing the lungs to collapse; the introduction of electrical defibrillation and chemical arresting solutions made it possible to stop, and then restart, the heart with predictability. Diagnostic techniques to visualize anatomy and physiology of the heart, record electrical activity, measure blood pressure and flow, and assess ventricular function expanded opportunities to precisely identify the cardiac pathologic condition and to tailor the surgical intervention to the needs of the patient. The ability to isolate the heart and lungs from the circulation without producing irreversible cerebral anoxia was first demonstrated in 1953 when Gibbon repaired an atrial septal defect using extracorporeal circulation with a pump oxygenator that he and his wife had designed. Anastomotic techniques devised by Carrel in the early twentieth century made it possible for numerous advances, including innovations in the repair of aortic aneurysms developed by DeBakey and Cooley in the 1950s, direct myocardial revascularization with the internal mammary artery and saphenous vein introduced by Favaloro and others in the mid-1960s, and cardiac transplantations presented by Barnard and Shumway in the late 1960s. The development of plastics, polyesters, and new metal compounds fostered the creation of prosthetic implants for cardiac valve replacement, first performed in 1960 by Harkin and Starr for the aortic and the mitral valves, respectively. Implantation of a long-term total artificial heart by DeVries in 1988 was possible in no small part because of developments in the chemical industry and laid the foundation for subsequent devices now widely employed to provide mechanical support—or replacement—for one or both failing ventricles. Perioperative nurses along with their surgeon colleagues contributed to these advances by actively participating in the design of equipment, supplies, and instruments (e.g., vascular clamps that would be both atraumatic and secure in clamping vascular structures). Nurses also made significant contributions by coordinating the complex operational and staffing requirements of a cardiac service, characteristic of collaborative team efforts in delivering quality care to perioperative patients.

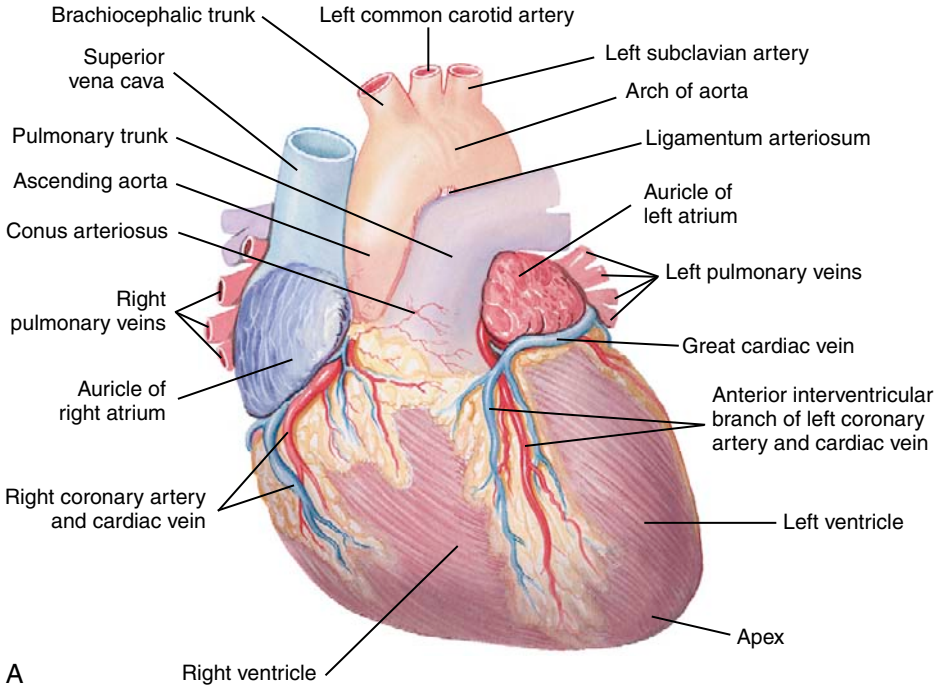

FIGURE 24-1 A, Anterior view of heart illustrates major vessels and chambers.

Continued

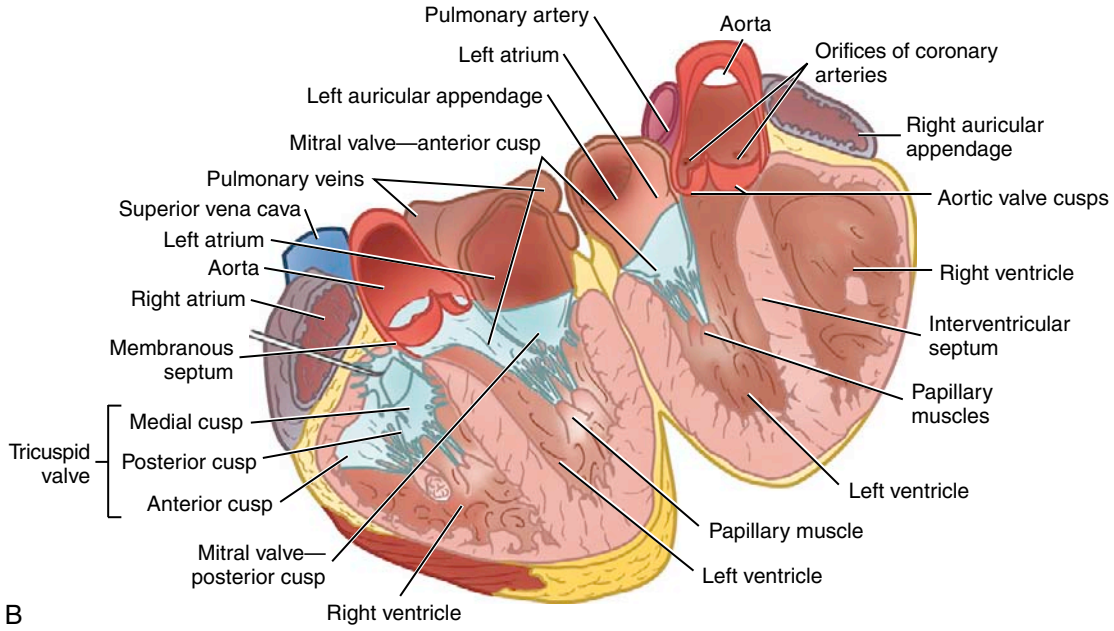

FIGURE 24-1, cont'd **B**, Drawing of a heart split perpendicular to the interventricular septum illustrates the anatomic relationships of the leaflets of the atrioventricular and aortic valve, and the receiving chambers (atria) and the pumping chambers (ventricles). Systemic venous blood returns to the heart by way of the inferior and superior venae cavae. It enters the right atrium, flows through the tricuspid valve into the right ventricle, and is ejected through the pulmonic valve (not shown) into the pulmonary circulation. The blood is oxygenated in the lungs and returns to the left atrium through the pulmonary veins. From the left atrium, it flows through the mitral valve into the left ventricle, where it is ejected through the aortic valve into the aorta and the systemic circulation.

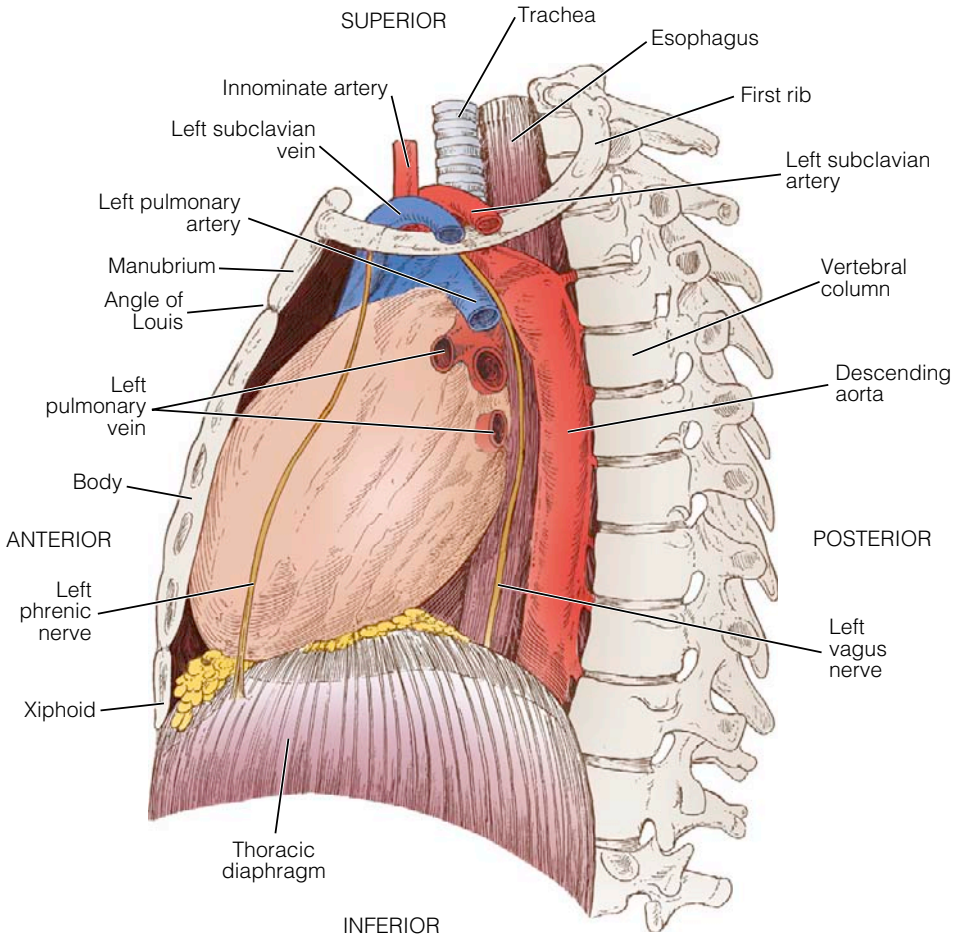

FIGURE 24-2 Regions of the mediastinum.

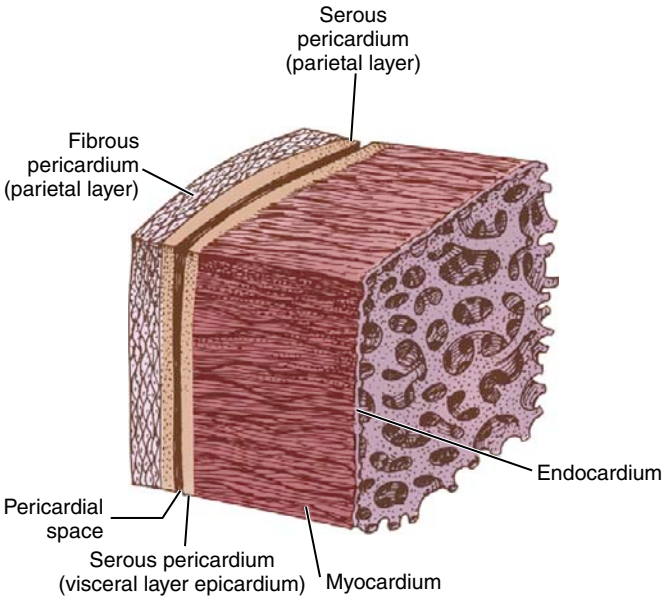

FIGURE 24-3 Cross section of cardiac muscle showing its three layers (endocardium, myocardium, epicardium) and pericardium.

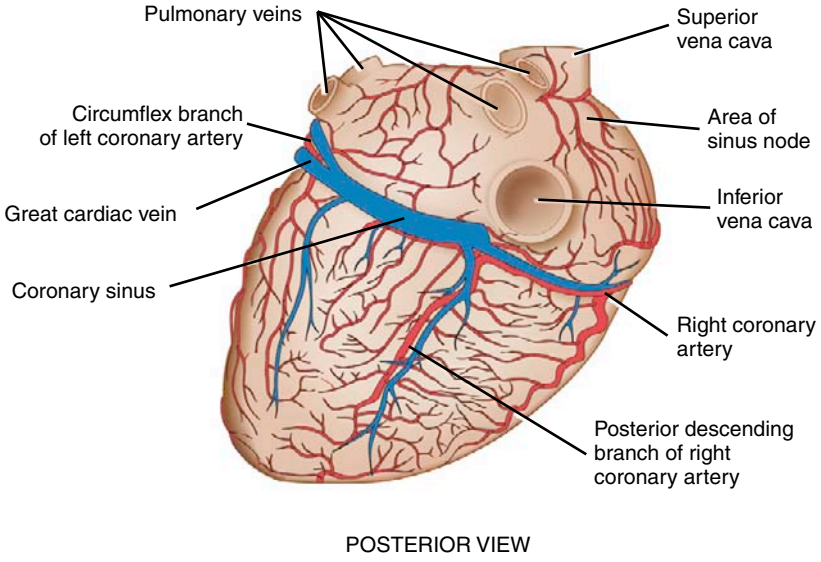

FIGURE 24-4 Anterior and posterior surfaces of the heart, illustrating the location and distribution of the principal coronary arteries and veins.

Nerve impulses to the heart travel from the medulla oblongata along the middle cervical nerve, composed of sympathetic fibers, and the vagus nerve, composed of parasympathetic fibers. Sympathetic fibers increase the force and rate of contraction, while parasympathetic fibers control heart rate. Running vertically along the right and left sides of the pericardium are major branches of the phrenic nerve, which innervate the diaphragm and stimulate it to contract. Identifying this nerve is important to protect the diaphragm in procedures in which the lateral pericardium is incised or excised. Within the myocardium itself, certain areas of tissue are modified to form a *conduction system* (Figure 24-5). The process of excitation and contraction originates in the sinoatrial (SA) node, located in the area where the superior vena cava (SVC) meets the right atrium. The impulse spreads to the atria through internodal pathways and travels to the AV junction (which contains the AV node) located medial to the entrance of the coronary sinus in the right atrium, close to the tricuspid valve. From the AV junction, the impulse spreads to the bundle of His, which extends down the right side of the interventricular septum. The bundle of His divides into the right and left bundle branches, which terminate in a network of fibers called the *Purkinje system*. Purkinje fibers are spread throughout the inner surface of both ventricles and the papillary muscles, which when stimulated produce contraction of the heart muscle. The location of conduction tissue is clinically significant during surgical repair of atrial or ventricular septal defects.

During myocardial contraction and relaxation, spiral fibers of the heart contract and relax (Figure 24-6, *A*). To prevent regurgitation of blood, the four cardiac valves (Figure 24-6, *B* and *C,* and Figure 24-7) open and close to maintain unidirectional blood flow. The AV valves are located between the atria and the ventricles. The right AV valve is called the *tricuspid valve* and contains three leaflets. The left AV valve, called the *mitral valve,* consists of two leaflets (see Figure 24-6). Each AV valve is a complex system consisting of a fibrous annulus surrounding the valve orifice, the valve leaflets (or cusps), the chordae tendineae, the atrium, and the papillary muscles, which anchor the valve to the inner ventricular wall (see Figure 24-1). The mitral valve annulus is a dynamic structure with a three-dimensional "saddle" shape, which has stimulated the design of newer prosthetic annuloplasty rings (Fedak et al, 2008). When the ventricle contracts, these muscles and the chordae tendineae, connected to the valve leaflets, prevent the leaflets from everting into the atrium. All parts of the system must function for the valve to work properly. If the shape of the ventricle has been changed by dilatation or hypertrophy, for example, the altered geometry of the ventricle impairs ventricular function. Conditions such as hypertension, myocardial injury, and aortic stenosis promote a pathologic *remodeling* of the heart that can lead not only to valvular dysfunction but also to heart failure and malignant dysrhythmias (Hill and Olson, 2008).

The semilunar valves are at the outlets of the left and right ventricles. These valves are known as the *aortic* and *pulmonic* valves, respectively. They are less complex than the AV valves, and they open and close passively with cyclic fluctuations in the blood pressure and volume that occur during systole and diastole.

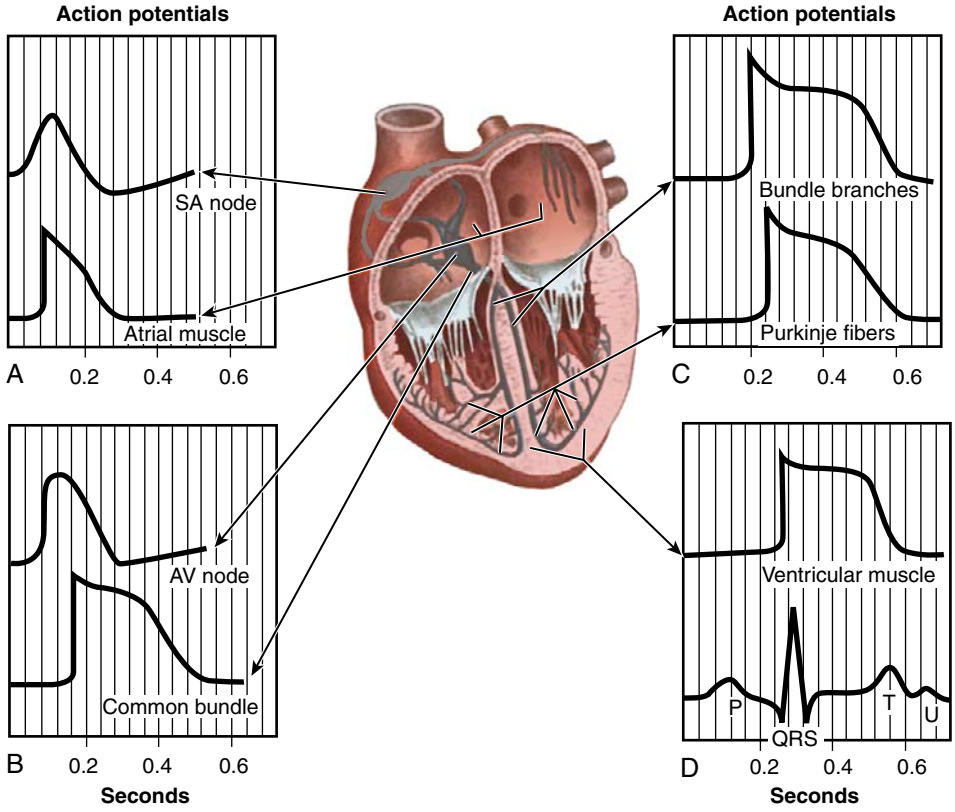

FIGURE 24-5 Heart with normal conduction pathways and transmembrane action potential of sinoatrial *(SA)* node, **A**; atrioventricular *(AV)* node (AV junction), **B**; bundle branches, **C**; and ventricular muscle, **D**.

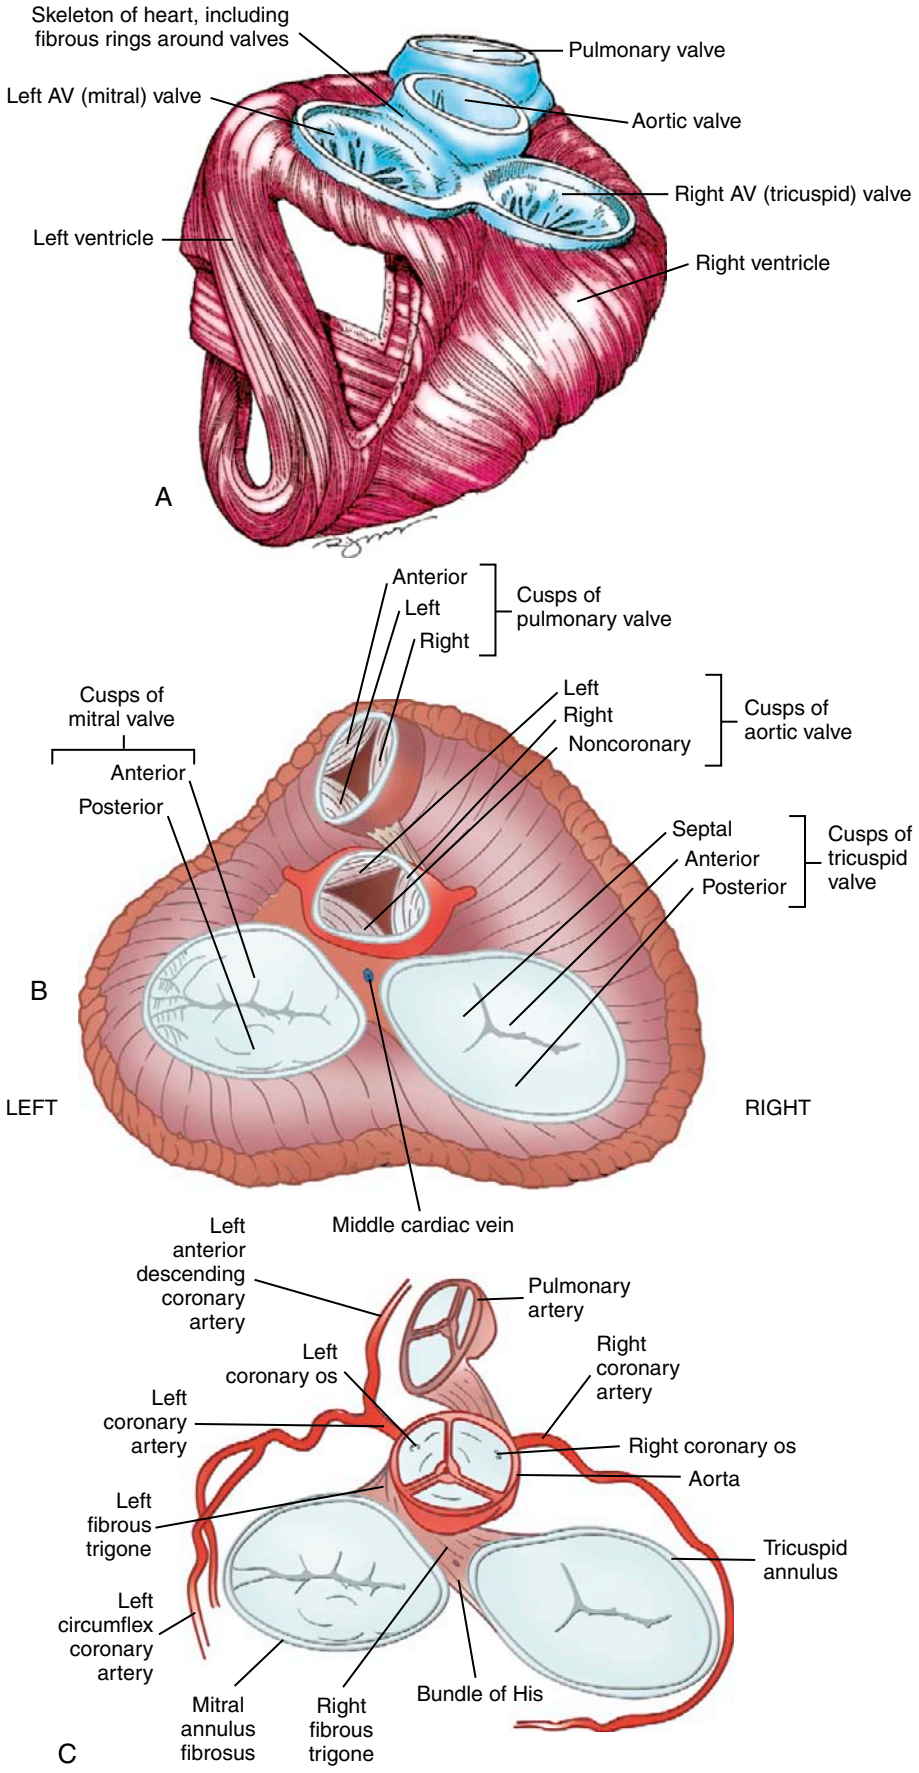

FIGURE 24-6 **A**, Location of the heart valves in relation to the spiral fibers of the myocardium. *AV,* Atrioventricular. **B**, Superior view of cardiac valves: pulmonary *(top)*; aortic *(middle)*; mitral *(bottom left)*; and tricuspid *(bottom right)*. **C**, Superior view of valves in relation to coronary arteries and conduction tissue.

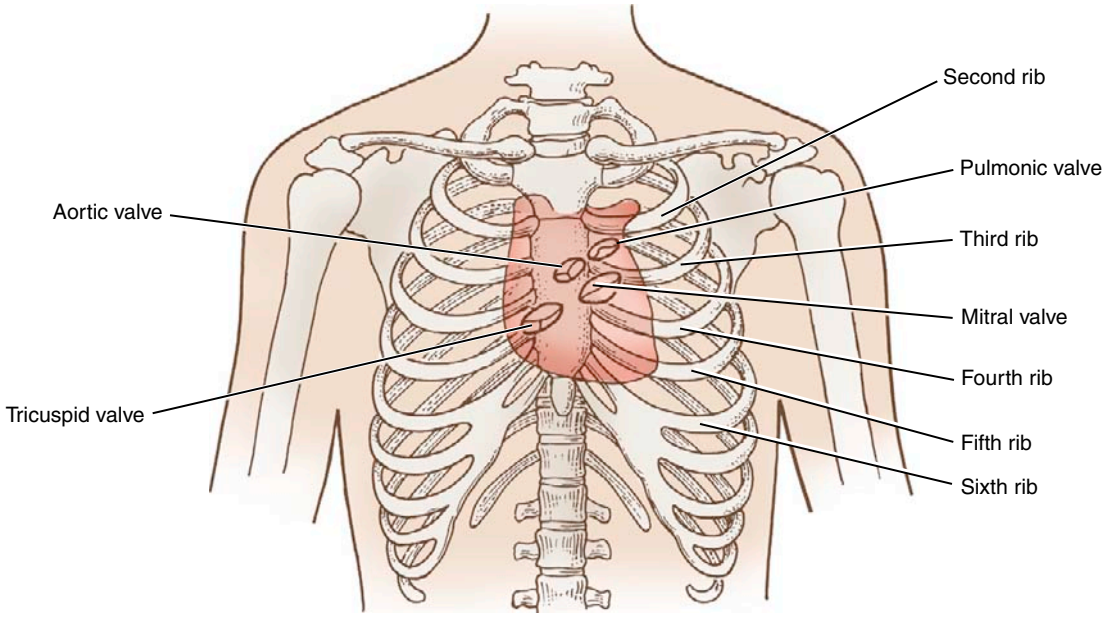

FIGURE 24-7 Anatomic position of cardiac valves. Note relationship of left ventricular apex to fourth and fifth ribs—a frequent site for minimally invasive incisions.

Abnormalities such as stenosis, insufficiency, or a combination of both impair the mechanical function of the valves. Stenosed valves have leaflets that are fibrous and stiff, with uneven and adherent margins. Regurgitant, insufficient, or incompetent valves, such as those with leaflet degeneration or perforations, dilated annuli, or ruptured chordae tendineae, produce regurgitation of blood into the originating chamber. These conditions, or a combination of stenosis and insufficiency, strain the myocardium by increasing intracardiac pressure, volume, and workload. The sound of blood flowing through a narrowed or incompetent valve produces an abnormal sound called a *murmur*.

Any of the four valves may be congenitally deformed. Acquired valvular heart disease most commonly affects the mitral and aortic valves and is believed to be exacerbated by increased stress associated with the higher pressures within the left chambers of the heart.

Perioperative Nursing Considerations

Specialized nursing considerations that are indicated for thoracic surgery (see Chapter 22) and vascular surgery (see Chapter 23) also often apply to cardiac surgical patients. Pediatric cardiac procedures are discussed in Chapter 25.

Assessment

Because the severity of pathologic changes varies among patients throughout the life span, knowledge of physical status, psychosocial concerns, and functional health patterns enables the perioperative nurse to plan and manage patient care. The perioperative nursing database should include the patient's biopsychosocial history, the physical examination, and results from laboratory and diagnostic imaging tests.

BOX 24-1

New York Heart Association's Functional Classification System (NYHA Classes) and Associated Objective Evidence*

Class I	Patients with cardiac disease do not display symptoms of syncope, undue fatigue, dyspnea, or anginal pain with ordinary physical activity; no objective evidence of cardiovascular disease (e.g., normal electrocardiogram).
Class II	Patients with cardiac disease are comfortable at rest but display the above symptoms during ordinary physical activity; objective evidence of minimal cardiovascular disease (e.g., minimal mitral valve regurgitation on echocardiography).
Class III	Patients with cardiac disease, although comfortable at rest, are considerably limited functionally and display symptoms with less-than-ordinary exercise; objective evidence of moderately severe cardiovascular disease (e.g., ischemic electrocardiographic changes).
Class IV	Patients with cardiac disease are unable to engage in any physical activity without discomfort and may have symptoms of cardiac insufficiency even at rest; objective evidence of severe cardiovascular disease (e.g., enlarged heart shadow on x-ray).

* *Objective evidence* refers to measurements such as electrocardiograms, stress tests, x-rays, echocardiograms, and radiologic images.
Modified from The Criteria Committee of the New York Heart Association: *Nomenclature and criteria for diagnosis of diseases of the heart and great vessels,* ed 9, pp 253-256, Boston, 1994, Little, Brown; *American Heart Association review of 1994 revisions to classification of functional capacity and objective assessment of patients with diseases of the heart,* available at www.americanheart.org/presenter.jhtml?identifier=1712. Accessed July 5, 2009.

History. The history includes information about the patient's health status as well as the response to the disease and the recommended intervention or interventions. Patients with cardiac disease may display symptoms including ischemic chest pain (angina pectoris), fatigue, dyspnea, and syncope. Depending on their severity, these *subjective* symptoms affect the patient's functional status and ability to engage in activities of daily living; the New York Heart Association's Functional Classification System (Box 24-1) is often used to assess functional ability. Updates to the classification system also include *objective* measurements such as x-rays and echocardiograms (The Criteria Committee of the New York Heart Association, 1994; AHA, 2009b,c). The Canadian Cardiovascular Society Classification System (Box 24-2) specifically grades the amount of activity producing angina pectoris (Campeau, 1975; Fang and O'Gara, 2008).

Atypical ischemic chest pain is more likely in women than in men, and angina may be attributed to vasospastic angina, mitral valve prolapse, or psychologic factors. CAD is unusual in premenopausal women, but after cessation of menses the risk is similar to that of men (McSweeney and Lefler, 2008; Mosca et al, 2007). Estrogen hormone replacement therapy is not recommended in postmenopausal women, according to the *Evidence-Based Guidelines for Cardiovascular Disease Prevention in Women: 2007 Update* (Mosca et al, 2007) (Evidence for Practice).

A cardiovascular disease risk factor profile (Box 24-3) is helpful in planning care for hospitalization and discharge by focusing on areas that might require further patient education. For example, the presence of diabetes is notable because diabetes affects the vascular system and may retard healing and predispose the patient to infection. Of special concern are the epidemic growth of type 2 diabetes in particular and

BOX 24-2

Canadian Cardiovascular Society Classification System for Angina Pectoris

Class 0	Patient has no angina.
Class I	Walking, climbing stairs, and other ordinary physical activity do not produce angina. Angina may occur with strenuous, prolonged, or rapid exertion.
Class II	Ordinary activity may be slightly limited. Angina may occur with moderate activity, such as walking rapidly, walking uphill, or walking after meals or in cold weather.
Class III	Ordinary activity is markedly limited. Angina may occur after walking one or two blocks on level ground or climbing one flight of stairs at a normal pace.
Class IV	Angina may be present at rest. Any physical activity produces discomfort.

Modified from Libby P et al, editors: *Braunwald's heart disease,* ed 8, Philadelphia, 2008, Saunders; Campeau L: Grading of angina pectoris, *Circulation* 54:522, 1975.

EVIDENCE FOR PRACTICE

Practice Guidelines for Females Undergoing Coronary Artery Bypass Surgery

Numerous inconsistencies surround the issue of gender-based differences between the outcomes of women and men undergoing coronary artery bypass grafts (CABGs). The Society of Thoracic Surgeons (STS) Workforce on Evidence-Based Surgery reviewed published information and proposed the following guidelines that focus specifically on *perioperative* management and are based on available evidence. Additional recommendations, not reviewed here, are incorporated in the guidelines.

1. Use of the internal mammary artery (IMA)
   - a. IMA underused in women
   - b. Use of IMA associated with significant reduction in mortality (compared with CABG using venous conduits alone)
   - c. At least one IMA used to bypass stenotic coronary artery
2. Management of hyperglycemia
   - a. Diabetes more common in women than in men undergoing CABG
   - b. Adverse effects of diabetes more pronounced in women
   - c. Hyperglycemia produced incremental risk in CABG
   - d. Maintain blood glucose levels below 180 mg/dl
3. Intraoperative management of anemia
   - a. Hematocrits below 22% associated with operative mortality
   - b. Strategies to increase red blood cell concentration: hemoconcentration, ultrafiltration, minimizing pump prime volume, rapid autologous priming
   - c. Maintain adequate hematocrit level at or greater than 22%
4. Use of off-pump CABG
   - a. Improved outcomes after off-pump CABG versus on-pump CABG may be related to increased use of IMA with off-pump CAB
   - b. No major differences in outcomes associated with *valve* surgeries
   - c. Absent of firm evidence that off-pump CABG is superior, the guidelines suggest that the indications for off-pump CABG are the same for women as for men
5. Optimization of thyroxine treatment for women with hypothyroidism
   - a. Hypothyroidism associated with impaired contractility and increased risk of myocardial infarction
   - b. Greater incidence of women with hypothyroidism (compared with men) undergoing CABG
   - c. Maintain in a euthyroid state during surgery
6. Consideration of preoperative hormone replacement therapy (HRT)
   - a. HRT not a significant predictor of mortality in multivariate analyses
   - b. HRT associated with complications such as thromboembolism
   - c. HRT not used for postmenopausal women undergoing CABG

Modified from Edwards FH et al: Gender-specific practice guidelines for coronary artery bypass surgery: perioperative management, *Ann Thorac Surg* 79:2189-2194, 2005; Puskas JD et al: Off-pump techniques benefit men and women and narrow the disparity in mortality after coronary bypass grafting, *Ann Thorac Surg* 84:1447-1456, 2007; Toumpoulis IK et al: Assessment of independent predictors for long-term mortality between women and men after coronary artery bypass grafting: are women different from men? *J Thorac Cardiovasc Surg* 131:343-351, 2006, available at http://jtcs.ctsnetjournals.org/cgi/content/full/jtcs;131/2/343. Accessed July 4, 2009.

BOX 24-3

Risk Factors for Coronary Artery Disease

NONMODIFIABLE
- Age
- Male gender (but postmenopausal women have risk similar to that of men)
- Heredity, genetic makeup, family history
- Race
- Menstrual status (estrogen levels may be modifiable; postmenopausal women have risk similar to that of men)

MODIFIABLE
- Elevated levels of serum cholesterol and other lipids
- Hypertension
- Cigarette smoking
- Obesity, metabolic syndrome
- Diabetes mellitus
- Psychologic stress
- Personality type
- Physical inactivity

NEWER, NOVEL CONTRIBUTING FACTORS
- Elevated homocysteine levels (increase platelet aggregation)
- Inflammation (the atherosclerotic process is inflammatory)
- High C-reactive protein level (CRP is a marker for inflammation associated with atherogenesis)
- Periodontal disease (a marker for inflammation and possible infection)
- Atrial and ventricular natriuretic peptides (hormones secreted by the atria and ventricles in response to volume expansion and fluid retention; predictive of a variety of cardiac problems)

Modified from Libby P et al, editors: *Braunwald's heart disease,* ed 8, Philadelphia, 2008, Saunders; Moser DK, Riegel B, editors: *Cardiac nursing: a companion to Braunwald's heart disease,* St Louis, 2008, Saunders; Hlatky MA et al: Criteria for evaluation of novel markers of cardiovascular risk: a scientific statement from the American Heart Association, *Circulation* 119:2408-2416, 2009; Seymour GJ et al: Infection or inflammation: the link between periodontal and cardiovascular diseases, *Future Cardiol* 5(1):5-9, 2009, available at www.medscape.com/viewarticle/587591. Accessed April 3, 2009; American Heart Association, 2009; Daniels LB, Maisel AS: Natriuretic peptides, *J Am Coll Cardiol* 50 (25), 2007, available at www.medscape.com/viewarticle/567064. Accessed January 17, 2008.

the role of hyperglycemia in general. Although type 2 diabetes was formerly considered an adult-onset disease, children are increasingly vulnerable because of a greater incidence of increased body weight, sedentary lifestyle, and accelerated insulin resistance in this population (Warziski et al, 2008). Altered glucose metabolism (in the absence of diagnosed diabetes mellitus) has shown a significant correlation to atherosclerosis (Lamendola, 2008), and control of hyperglycemia during coronary bypass surgery is an important strategy to reduce the risk of adverse clinical outcomes (Lorenz et al, 2005). This information should become an integral component of patient assessment, especially in patients at risk.

Inflammation has been increasingly implicated in the development of coronary artery disease; in particular, elevated homocysteine levels (which increase platelet aggregation) and high C-reactive protein (CRP) levels (CRP is a biologic marker for inflammation and is associated with increased risk for CAD) have been implicated (Ruz and Lennie, 2008; Seymour et al, 2009). Targeting low-density lipoprotein ("bad" cholesterol) levels of less than 100 mg/dl is often recommended (Grundy, 2008); some authors also stress the importance of increasing the levels of high-density lipoproteins ("good" cholesterol) (Superko and King, 2008).

Additional recognized risk factors include metabolic syndrome (central obesity, hypertension, insulin resistance, and dyslipidemia) and obesity (Lamendola, 2008). Hypertension and obesity increase the workload of the heart; obesity may also increase the risk for postoperative infection because adipose tissue is poorly vascularized. Patients who are obese and those who are underweight (compared with patients in the high-normal and overweight categories) have a higher risk of death after coronary artery bypass surgery (Jin et al, 2005).

Among the newer biomarkers denoting cardiovascular diseases are the *natriuretic peptides*—cardiac hormones synthesized and secreted by the atrium (atrial natriuretic peptide [ANP]) and the ventricle (B-type natriuretic peptide [BNP]). Discovered in 1981, the natriuretic peptides have a regulatory effect that causes myocardial relaxation in response to acute increases in ventricular volume. Measurement of circulating peptides is increasingly used to identify heart failure and sudden cardiac death (Korngold et al, 2009; Hlatky et al, 2009). Another biomarker under intensive study as a risk factor is lipoprotein(a) (Lp[a]), which has been identified from genetic studies as a causal link to myocardial infarction. According to the researchers (Kamstrupp et al, 2009), Lp(a) levels need to be tested only once in a lifetime as the levels do not change over time. Optimal therapy has not been established, but niacin has been shown to reduce the level of Lp(a) in some individuals.

The risk for complications and major adverse cardiac events (MACE) after cardiac surgery has also shown some gender differences (Puskas et al, 2007; Edwards et al, 2005). Investigations of risk factors in men and women for sternal wound infection showed that three significant risk factors were identified and occurred at significantly different rates in men and women: smoking, use of a single internal mammary artery (IMA), and age more than 70 years. Smoking and the use of a single IMA for bypass grafting were more common risk factors in men compared with women; women tended to be older than men at the time of surgery (Hussey et al, 2001). Fewer MACE were seen in women undergoing coronary bypass surgery without the use of cardiopulmonary bypass (CPB) compared to surgery with CPB (Puskas et al, 2007); however, malignant ventricular dysrhythmias (e.g., ventricular tachycardia), a calcified aorta, or preoperative renal failure were poor prognostic signs in women (Gray and Sethna, 2008). These findings can be incorporated into patient/family teaching plans with recommendations for lifestyle changes as indicated.

Other risk factors associated with postoperative infection include previous cardiac surgery, extensive length of surgery, use of cardiopulmonary bypass (CPB) and/or blood transfusion, amount of postoperative blood loss, and length of preoperative hospitalization. Female gender, obesity, and arterial occlusive disease of the legs are related to impaired wound healing at the saphenous venectomy site after coronary bypass surgery; bilateral IMA grafts in patients with diabetes, obesity, and postoperative inotropic support have also been implicated (Newby and Douglas, 2008; Pradhan et al, 2008).

A history of rheumatic fever or frequent tonsillitis as a child is significant because the sequelae of rheumatic fever and streptococcal infections can lead to damage of the cardiac

valves. Although the incidence of rheumatic fever has declined significantly in wealthy countries, rheumatic heart disease is a significant problem in less industrialized countries (Carapetis, 2007). Given the increasing number of immigrants to the United States, it is expected that treatment for rheumatic heart disease will continue to grow.

In addition to risk factors and health status, the perioperative nurse reviews the patient's medication history with particular attention to vasoactive drugs, anticoagulants, and other medications that can affect the surgery. Nurses should note that patients taking aspirin and other antiplatelet drugs (such as 2b/IIIa inhibitors) may require intraoperative replacement of platelets (Miller and Beauman, 2008). Lipid-lowering drugs (statins) may affect postoperative coronary bypass graft patency; angiotensin-converting enzyme inhibitors (ACEIs), used for patients with a history of MI or heart failure, may induce labile postoperative blood pressures (Miller and Beauman, 2008). Patients taking herbal medicines may be at risk for increased bleeding, hypoglycemia, or other complications, depending on the specific side effects of some herbal drugs (Surgical Pharmacology).

Patients' knowledge and understanding of cardiovascular disease and related risk factors and their effect on functional, physiologic, and psychologic status should also be part of the perioperative nursing assessment. The patient's personal strengths, external resources, and coping strategies should be determined. The perioperative nurse should note any cultural, ethnic, spiritual, or religious beliefs that are relevant to perioperative patient care.

Physical Examination. The physical assessment provides the perioperative nurse with baseline data and information about potential problems that might require intervention. Table 24-1 lists some normal, age-specific changes in the very young and the elderly populations that should be differentiated from pathologic conditions (Hayman, 2008; Rich, 2008; Association of periOperative Registered Nurses [AORN], 1997a,b,c,d).

In addition to age-specific changes, there are a growing number of adults with acquired heart disease who underwent surgery in childhood for repair of congenital cardiac lesions (Moons et al, 2008). For example, patients with a previous Blalock-Taussig shunt for tetralogy of Fallot (see Chapter 25) may have altered pulmonary and subclavian artery anatomy; patients with a mechanical closure device inserted for an atrial septal defect may be at risk for endocardial injury if the heart is retracted or otherwise manipulated too forcefully. The nurse should be aware that anatomic anomalies associated with the original congenital defect, or its subsequent repair, may alter the current surgical plan. Consultation with the surgeon can alert the staff to anticipate different anatomy (and surgical landmarks), special supplies and prosthetic materials, and potential complications.

Before a review of systems is initiated, it is helpful to assess the patient's functional capacity. How are activities of daily living accomplished? What are the barriers that make independent living difficult? How are activities performed when there are disabilities? What support systems are available? What educational resources are available? These and other questions will alert the clinician to the need for referrals and other resources to help the patient achieve optimal outcomes.

The review of systems often starts with the skin. The appearance of the skin offers clues to cardiovascular status. Dryness, coolness, diaphoresis, paleness, edema, poor capillary refill, bruising, and petechiae can reflect impaired cardiovascular function. Visual problems and headaches may be related to inadequate cardiac output, atherosclerotic disease, peripheral vascular disease, aortic valve stenosis, or medications such as digitalis. The presence of chronic or local infection should be identified; if untreated, these may become potential sources of postoperative infection. Nutritional status (including metabolic syndrome) is assessed to determine increased risk for infection, skin breakdown, impaired wound healing, or other complications.

The patient's level of consciousness, memory, comprehension, and emotional status should be assessed. Confusion, restlessness, slurred speech, numbness, and paralysis can signal impaired perfusion. Their presence preoperatively should be

SURGICAL PHARMACOLOGY

Perioperative Effects of Herbal Medicines

Agent	Pharmacologic Action	Concerns and Considerations
Echinacea (purple coneflower root)	Activates cell-mediated immunity.	Decreases effectiveness of immunosuppressants; should not be taken by organ transplant patients.
Ephedra	Increases heart rate and blood pressure through sympathomimetic effects.	Increases risk of stroke and myocardial ischemia; may cause intraoperative hemodynamic instability.
Garlic	Inhibits platelet aggregation; increases fibrinolysis.	Increases risk of bleeding, especially in combination with other platelet inhibitors.
Ginger	Inhibits platelet aggregation; antiemetic.	Increases risk of postoperative bleeding.
Gingko	Inhibits platelet activation.	Increases risk of bleeding, especially in combination with other platelet inhibitors.
Ginseng	Inhibits platelet activation; lowers blood glucose level; has many diverse effects.	Increases risk of bleeding; has potential to decrease anticoagulant effect of warfarin; may cause hypoglycemia.
St. John's wort	Inhibits neurotransmitter reuptake.	Induces enzymes that affect warfarin and many other drugs; may affect calcium channel blockers and decrease serum digoxin levels.

Modified from Drain CB: Basic principles of pharmacology. In Drain CB, Odom-Forren J, editors: *Perianesthesia nursing,* ed 5, St Louis, 2009, Saunders; Association of periOperative Registered Nurses (AORN): *Safe medication administration tool kit,* Denver, 2005, The Association, available at www.aorn.org.

TABLE 24-1

Physiologic Features of the Very Young and the Very Old (Compared with Others)

Very Young	Very Old
CARDIOVASCULAR SYSTEM	
Myocardium	
Less contractile tissue	Increased subendocardial fat
Less compliant	Increased heart weight
Cardiac output increased by faster heart rate	Reduced resting cardiac output
Valves	
Less tension created by papillary muscle	Fibrous thickening; calcification of leaflets and annulus
Coronary Arteries	
Rarely, anomalies of coronary arteries	Coronary arteriosclerosis, atherosclerosis; tortuous epicardial arteries
CONDUCTION SYSTEM	
Impulse conduction faster	Impulse conduction slower
BLOOD VOLUME	
Total circulating small amount; volume per kilogram of body weight relatively greater	Reduced plasma volume; reduced blood water content
RESPIRATORY SYSTEM	
Inadequate cough reflex	Decreased ability to eliminate secretions
Increased chest wall compliance; decreased pulmonary compliance	Increased chest wall rigidity; decreased lung compliance
Higher oxygen consumption	Reduced vital capacity and maximum ventilation volume
Short, narrow airway obstructed easily	
RENAL SYSTEM	
Glomeruli small and immature	Fewer functional glomeruli
Tubular concentration of fluids and electrolytes diminished	Reduced renal blood flow and glomerular filtration rate
Inability to excrete increased electrolytes and hydrogen ions (acids)	Impaired ability to excrete increased amount of water and electrolytes; reduced ability to secrete hydrogen ions
OTHER	
Temperature Control	
Immature regulating system: rapid heat loss	Decreased control
Metabolic Rate	
Higher	Lower
Stress Response	
Decreased phagocytic capability of leukocytes	Limited capability to retain homeostasis
Immature immunoglobulin synthesis	Decreased adrenal activity
Physical Appearance	
Good grooming suggests attentive care	Good grooming suggests positive mental status, ability to perform activities of daily living

noted by the perioperative nurse and communicated to the nurses receiving the patient postoperatively.

During respiratory assessment the perioperative nurse should note the use of accessory muscles or nostril flaring and should auscultate breath sounds. Adventitious sounds, such as crackles and wheezes, may point to pulmonary edema. Orthopnea, shortness of breath, or dyspnea may require elevation of the head of the stretcher and assistance during transfer onto the OR bed. If the patient is receiving oxygen, the flow rate and method of administration should be observed. Alleviating pain is a prime consideration in the care of the cardiovascular patient because pain is a myocardial stressor. A patient with angina may arrive in the OR after nitroglycerin tablets have been administered or transdermal patches have been applied. Cold also increases the workload of the heart because the shivering that accompanies chilling elevates the metabolic rate; the patient should be kept warm.

Heart sounds, murmurs, and friction rubs provide clues to congenital, ischemic, valvular heart disease, or pericarditis. The patient may experience palpitations. Apical, radial, and femoral pulses also reflect cardiac function; their rate, rhythm, and quality should be determined. The presence of cyanosis or peripheral edema should be noted.

The blood pressure may be high, normal, or low. The hypertensive patient may have left ventricular hypertrophy, and the hypotensive patient may display changes in neurologic, gastrointestinal, and renal function. Blood pressures should be checked bilaterally. Unequal pressures in the arms may be a

BOX 24-4

Diagnostic Tests Commonly Performed for Cardiovascular Disorders

NONINVASIVE*
- Resting ECG
- Exercise ECG (stress test)
- Chest radiography
- Echocardiogram (TTE, TEE)
- Carotid Doppler echocardiogram
- Resting MUGA
- Exercise thallium
- Exercise MUGA
- CT scan
- PET scan with stress
- CMRI, MRA

INVASIVE
- Aortography
- Arteriography
- Digital subtraction angiography
- Electrophysiology
- Cardiac catheterization
- Ventriculography
- Endomyocardial biopsy

*When dye is injected into the vascular system, the test is considered semiinvasive.
CT, Computerized tomography; *CMRI,* cardiovascular magnetic resonance imaging; *ECG,* electrocardiogram; *MRA,* magnetic resonance angiogram; *MUGA,* multiple uptake gated acquisition; *PET,* positron emission tomography; *TEE,* transesophageal echocardiogram; *TTE,* transthoracic echocardiogram.
Modified from Libby P et al, editors: *Braunwald's heart disease,* ed 8, Philadelphia, 2008, Saunders; Pagana KD, Pagana TJ: *Mosby's diagnostic and laboratory test reference,* ed 9, St Louis, 2009, Mosby.

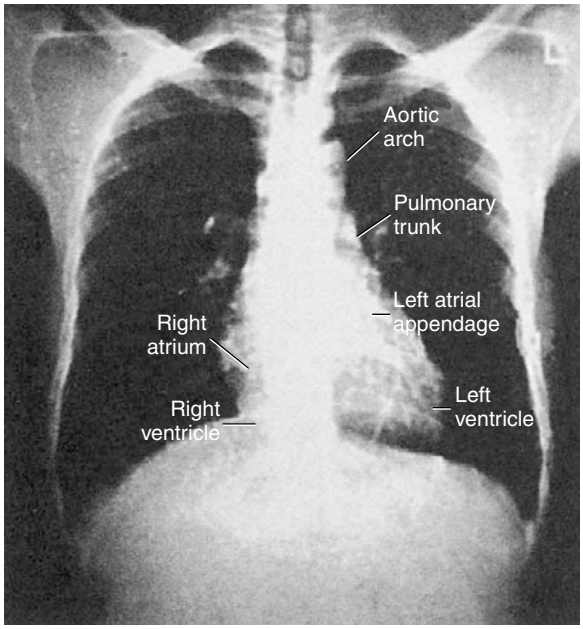

FIGURE 24-8 Anteroposterior chest radiograph (normal).

contraindication for the use of the IMA as a bypass graft on the side of the lower blood pressure, where perfusion may not be optimal. Radial and ulnar artery pulses should be checked bilaterally when the radial artery is to be used as a bypass graft. Patients with dissections or aneurysms may have unequal carotid, femoral, brachial, or radial artery blood pressures when the lesion occludes one or more of these vascular branches.

Because cardiac function affects all the body's organ systems, assessment of the patient should be comprehensive whenever possible. A thorough assessment also alerts the physician and perioperative nurse to the need for special diagnostic tests and laboratory procedures.

Diagnostic Studies. Most patients referred for surgery have had clinical evaluations including both invasive and noninvasive studies (Box 24-4). After the history and physical assessment, a resting electrocardiogram (ECG) is ordered. An exercise ECG (stress test) is often performed because ST-segment changes indicating myocardial ischemia may be apparent only during or after exercise. In patients with intractable dysrhythmias, electrophysiology (EP) studies may be performed to locate the site of irritable atrial or ventricular foci that can be surgically ablated, excised, or controlled with pharmacologic therapy. EP studies are also performed to determine the need for internal defibrillators or antitachycardia devices. Bradycardia may be an indication for pacemaker insertion.

Chest radiography provides information about the size of the cardiac chambers, thoracic aorta, and pulmonary vasculature as well as the presence of calcium in valves, pericardium, coronary arteries, and aorta (Figure 24-8). Lateral chest radiographs of patients with prior sternal operations show the chest wires and extent of pericardial adhesions. Magnetic resonance imaging (MRI) is used to assess myocardial viability and can also be employed to image vascular structures with MRI angiograms that provide great clarity (Figure 24-9, *A*). In patients with suspected aortic or other vascular abnormalities, a computerized tomography (CT) scan of the chest with intravenous injection of a contrast medium is used to create x-ray serial "slices" of the body area under study (Figure 24-9, *B*), and CT angiography is especially useful for imaging the aorta and great vessels. CT scans may be contraindicated in very unstable patients because the patient's position in the tubelike scanner makes patient access difficult. Less frequently performed is arteriography with radiographic contrast material (dye) to determine the size and location of the lesion and the site of the intimal tear in aortic dissections (Figure 24-10); digital subtraction angiography (DSA) provides clear images and requires less contrast material (Libby et al, 2008).

Echocardiography is a noninvasive test that evaluates both the structure and the function of the heart by transmitting sound waves to the heart and measuring those sound waves reflected back to the transducer (Figure 24-11). The sound waves are processed by the transducer, which creates visual images of the structure's movements. This test is commonly used to assess ventricular and valvular function before, during, and after surgery and to determine the degree of valvular stenosis or regurgitation. It can also demonstrate a tumor, thrombus, or air in the ventricular or atrial cavities. Two-dimensional and color-flow Doppler techniques have greatly enhanced the functional assessment of valvular performance and carotid artery stenoses. Echocardiography is the gold standard for diagnosing mitral stenosis, and it is widely used to assess other valvular

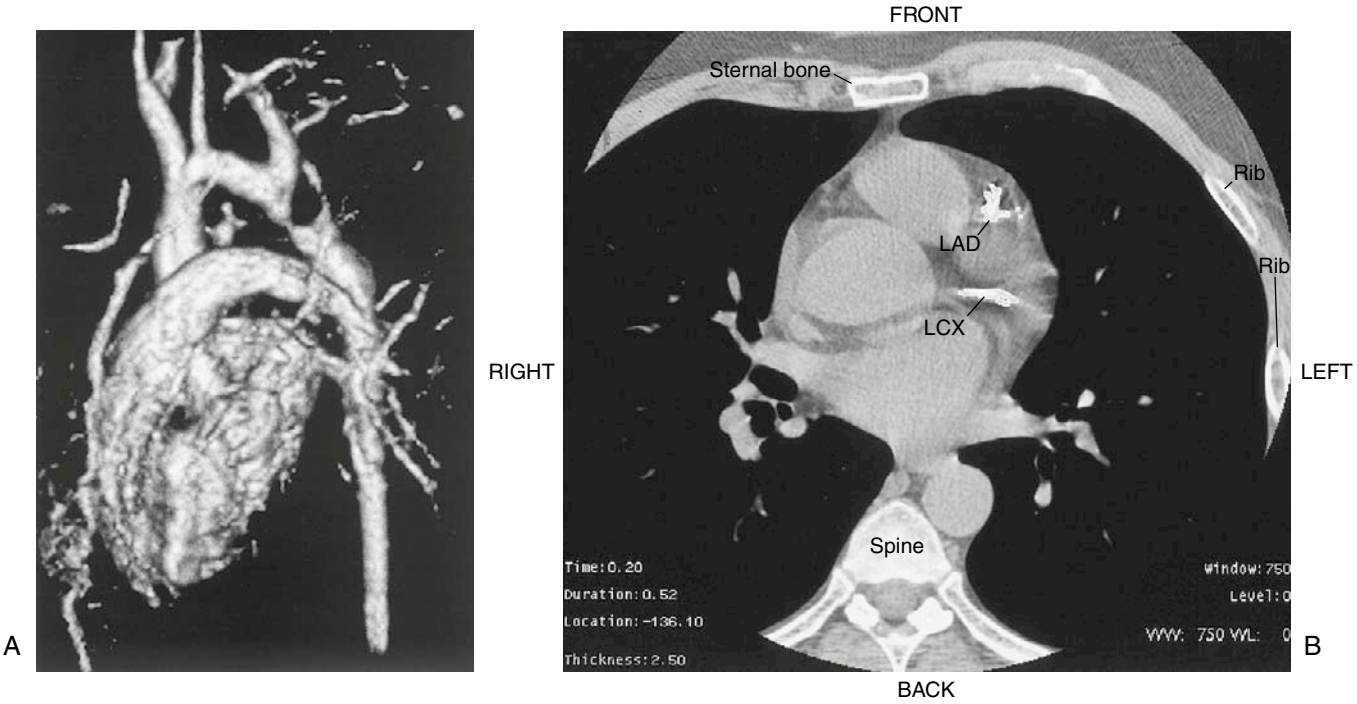

FIGURE 24-9 **A**, Three-dimensional reconstruction of a contrast medium–enhanced magnetic resonance angiogram of the thoracic aorta, illustrating a severe coarctation (narrowing) of the aorta. **B**, High-resolution cross-sectional computed tomography (CT) scan of the heart, illustrating calcification within the left anterior descending *(LAD)* coronary artery and left circumflex *(LCX)* coronary artery.

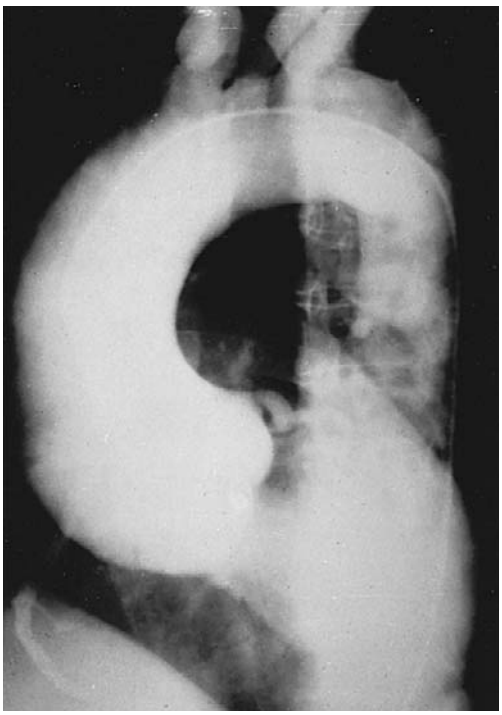

FIGURE 24-10 Aortogram of ascending aortic dissection, with aortic valve insufficiency. Note regurgitation of dye into left ventricle.

disorders and congenital heart disease. Transesophageal echocardiography (TEE) is also employed to evaluate the effectiveness of valve repairs and other surgical procedures.

Radionuclide imaging is employed to illustrate wall motion and blood flow through the heart and to quantify cardiac function. These noninvasive techniques are generally well tolerated by patients, especially when patients may be too unstable to withstand a cardiac catheterization. These techniques may also be used as a complement to catheterization.

Cardiac catheterization provides definitive information about the extent and location of ischemic heart disease and is an adjunct to echocardiography for diagnosing valvular heart disease (Todd and Phippen, 2009). A radiopaque plastic catheter is inserted retrograde through the aortic valve into the left side of the heart by a percutaneous puncture or a cutdown to the vessels of the brachial artery (Sones technique) or the femoral artery (Judkins technique). The right side of the heart is approached percutaneously by the superior or inferior vena caval route. To perform coronary angiography that demonstrates intracoronary anatomy, a contrast medium is injected into the coronary ostia. Obstructions (Figure 24-12), flow, and distal perfusion can be assessed. Ventriculography illustrates contractile weaknesses of the ventricles as well as shunting and regurgitation of blood. These studies are used to assess the degree of myocardial dysfunction and to plan interventions such as coronary artery bypass grafting, valve repair or replacement, repair of congenital anomalies, and cardiac transplantation. The cardiologist can compute the orifice of a stenosed valve or determine the degree of regurgitation of an incompetent valve.

Ventricular, atrial, and pulmonary pressures are recorded, and cardiac output and ejection fraction are estimated (Box 24-5

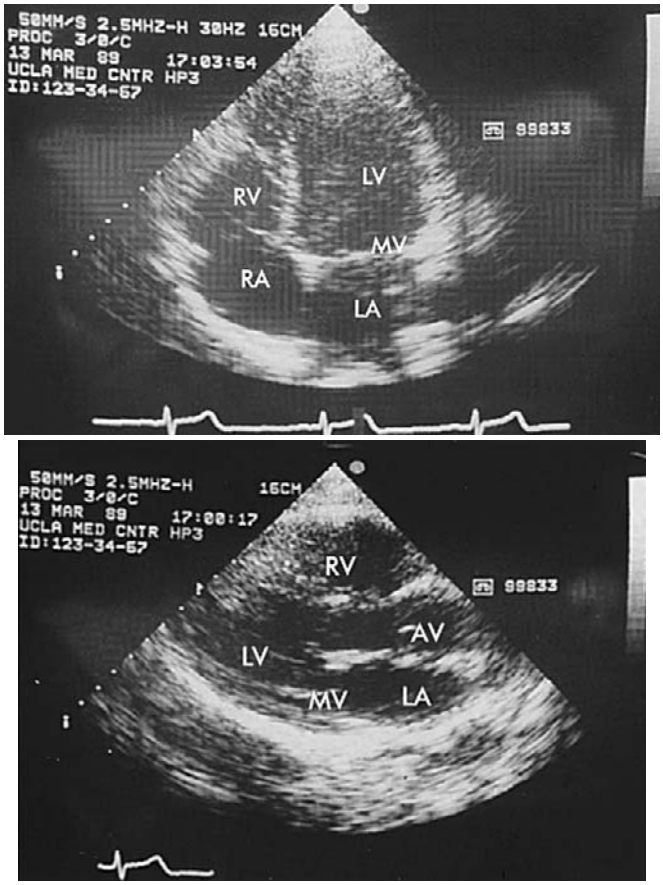

FIGURE 24-11 Two-dimensional echocardiography showing two views of the cardiac chambers. *LA,* Left atrium; *LV,* left ventricle; *MV,* mitral valve; *RA,* right atrium; *RV,* right ventricle.

and Table 24-2). Oxygen saturation of cardiac chambers and the ratio of pulmonary to systemic blood flow (Q_p/Q_s) are calculated for patients with shunts and congenital or acquired defects. Cinearteriograms record the movement of the heart, and cut films or digitized versions of the cines may be displayed during surgery.

The cardiac catheterization laboratory also performs percutaneous coronary interventional (PCI) therapies for evolving and acute myocardial infarctions (Leeson et al, 2008). Coronary thrombolysis with fibrinolytic drugs can dissolve fresh blood clots and reopen, or recanalize, the artery; antiplatelet agents such as aspirin, dipyridamole, and clopidogrel are often prescribed to block platelet aggregation that can lead to restenosis. Percutaneous transluminal coronary angioplasty (PTCA) followed by insertion of intracoronary (bare metal or drug-eluting) stents is often performed to dilate and maintain the patency of the recanalized artery. Laser angioplasty and atherectomy to excise intraluminal plaque may also be employed (Todd and Phippen, 2009). In many instances these interventions may obviate the need for surgical bypass grafting, although the progressive nature of CAD may eventually lead to patients requiring surgical revascularization. OR availability may be recommended for unstable patients undergoing stent insertion and atherectomy, but the need for on-site cardiac surgical availability has been questioned. One study demonstrated that patients undergoing PCI at facilities without surgical backup had rates of morbidity, emergency cardiac surgery, and mortality related to emergency surgery that were similar to those in facilities with surgical backup (Kutcher et al, 2009).

BOX 24-5

Hemodynamic Concepts

Cardiac output	Amount of blood (in liters) ejected by left ventricle per minute; product of heart rate times stroke volume.
Cardiac index	Cardiac output corrected for differences in body size.
Preload	Volume and pressure of blood in the ventricle at the end of diastole. Central venous pressure (CVP) measures right-sided heart preload; pulmonary artery wedge pressure (PAWP) indirectly measures left-sided heart preload.
Afterload	Impedance, or resistance, the heart must overcome to pump blood into the systemic circulation; left ventricular wall tension during systole; systemic vascular resistance.
Contractility	Inotropic state of the heart; ability of the ventricle to pump.
Ejection fraction	Percentage of end-diastolic volume ejected into systemic circulation; indicator of ventricular function.

EP studies are performed to diagnose conduction disturbances and to provide therapeutic interventions, such as radiofrequency or cryologic ablation of foci producing atrial fibrillation or accessory pathways seen in Wolff-Parkinson-White syndrome. Insertion of a pacemaker for bradydysrhythmias or an internal cardioverter defibrillator for ventricular tachydysrhythmias is commonly performed in EP laboratories. However, insertion of these devices may require an OR when percutaneous access is unfeasible or when concomitant cardiac surgery is being performed.

Laboratory Tests. Preoperative laboratory tests are used to assess physiologic function (Table 24-3). Hematologic tests include a detailed coagulation profile to uncover hemorrhagic

TABLE 24-2

Cardiac Catheterization Data

Hemodynamic Data	Normal Values		
FLOW			
Cardiac output (CO)	3.0-6.0 L/min		
Cardiac index (CI)	2.8-4.2 L/min/m^2		
Ejection fraction (EF)	60%-70%		
Left ventricular end-diastolic volume (LVEDV)	90-180 ml		
Stroke volume (SV)	60-130 ml/beat		
Stroke volume index (SVI)	35-70 ml/beat/m^2		
	Systolic	**Diastolic**	**Mean**
RESISTANCES (WOOD UNITS)			
Systemic vascular resistance (SVR)	<20		
Total pulmonary resistance	<3.5		
Pulmonary vascular resistance (PVR)	<2.0		
SHUNTS (Q_P/Q_S)			
Pulmonary flow/systemic flow		1:1	
% OXYGEN SATURATION

TABLE 24-3

Laboratory Data

Test	Conventional Values
ARTERIAL BLOOD GASES	
pH	7.35-7.45
Po_2	95-100 mm Hg
Pco_2	35-45 mm Hg
BLOOD CHEMISTRY	
Glucose (fasting)	70-110 mg/dl
Protein (total)	6.8-8.5 g/dl
Blood urea nitrogen (BUN)	8.0-25 mg/dl
Uric acid	3.0-7.0 mg/dl
CARDIAC ENZYMES	
Creatine phosphokinase (total CPK)	Male: 55-170 units/L; female: 30-135 units/L
CPK-BB (isoenzyme, CPK_1)	0%
CPK-MB (isoenzyme, CPK_2)	0%
CPK-MM (isoenzyme, CPK_3)	100%
Troponin T	<0.2 mcg/L
Troponin I	<0.03 mcg/L
COAGULATION PROFILE	
Platelet count	150,000-400,000/mm^3
Prothrombin time (PT)	Depends on thromboplastin reagent used; typically 9.5-12.0 sec
Thrombin time	Depends on concentration of thrombin reagent used; typically 20-29 sec
Partial thromboplastin time (PTT)	Depends on phospholipid reagent used; typically 60-70 sec
Activated PTT (aPTT)	Depends on activator and phospholipid reagents used; typically 30-40 sec
Fibrinogen	200-400 mg/dl
Fibrinogen split products	10 mg/dl
COMPLETE BLOOD CELL COUNT	
Hemoglobin (Hgb)	
1-3 days old	14-24 g/dl
2 mo old	10-17 g/dl
6-18 yr old	10-15.5 g/dl
Adult	
Male	14-18 g/dl
Female	12-16 g/dl
Hematocrit (Hct)	
2 days old	44%-64%
2 mo old	35%-50%
Adult	
Male	42%-52%
Female	37%-47%
Red Blood Cells (RBCs)	
1 wk old	4.8-7.1 × $10^6/\mu l$
3-6 mo old	3.5-5.5 × $10^6/\mu l$
2-6 yr old	4.0-5.5 × $10^6/\mu l$
Adult	
Male	4.7-6.1 × $10^6/\mu l$
Female	4.2-5.4 × $10^6/\mu l$
White Blood Cells (WBCs)	
1 day old	9000-30,000/mm^3
1 mo old	6200-17,000/mm^3
Adult	5000-10,000/mm^3
CREATININE (URINE, 24-HOUR)	
Male	107-139 ml/min
Female	87-107 ml/min
ELECTROLYTES	
Potassium (K^+)	3.5-5.0 mEq/L
Sodium (Na^+)	136-145 mEq/L
Chloride (Cl^-)	98-106 mEq/L
Magnesium (Mg^{++})	1.3-2.1 mEq/L
LIPIDS	
Cholesterol	<100 mg/dl*
Triglycerides	10-190 mg/dl
Phospholipids	150-380 mg/dl
Free fatty acids	9.0-15.0 mM/L
C-reactive protein	<1.0 mg/dl
Homocysteine	4-14 μmol/L
LIVER FUNCTION	
Albumin (serum)	3.5-5 g/dl
Alkaline phosphatase	30-120 units/L
Globulin (serum)	2.3-3.4 g/dl
Serum bilirubin (total)	0.3-1.0 mg/dl
PULMONARY FUNCTION	
	Normal values vary depending on patient's age, gender, weight, and race. The following are generally calculated: Residual volume (RV) Tidal volume (TV) Expiratory reserve volume (ERV) Inspiratory reserve volume (IRV) Total lung capacity (TLC) Vital capacity (VC)
URINALYSIS	
Color	Amber, yellow
Clarity	Clear
pH	4.6-8
Specific gravity (SG)	1.005-1.030
Protein	0.0-8 mg/dl
Sugar, ketones, RBCs, WBCs, casts	Negative

*Current recommendations are to target cholesterol levels below 100 mg/dl. See LaRosa JC et al: Intensive lipid lowering with atorvastatin in patients with stable coronary artery disease, *New Engl J Med* 352:1425-1435, 2005.

Modified from Pagana KD, Pagana TJ: *Mosby's diagnostic and laboratory test reference,* ed 9, St Louis, 2009, Mosby.

disorders. In patients who have been taking aspirin or dipyridamole, platelet activity is decreased; this alerts the perioperative nurse to anticipate prolonged bleeding necessitating replacement of this blood product. The patient's blood type is also determined, and the appropriate order is placed with the blood bank. Precautions are taken to test the blood for viral contamination and for cold antibodies that could produce agglutination of the patient's blood during surgery when the patient is cooled to hypothermic temperatures. Blood is brought to the OR suite before the start of surgery and stored in a monitored blood refrigerator. Although the use of bank blood products has been reduced with autotransfusion techniques, the occasional, emergent need for blood necessitates the immediate availability of bank blood packed red blood cells.

Liver and kidney function test results may be abnormal in patients with chronic heart failure, possibly because of congestion related to right heart failure in the former and reduced blood flow in the latter. Progressive improvement in hepatic and renal function is anticipated with successful operative intervention. The use of statins and other cholesterol-reducing drugs that can adversely impair hepatic function also alerts the nurse to review liver function laboratory results (Pagana and Pagana, 2009). Blood glucose levels are tested, monitored, and controlled, especially in patients with impaired glucose metabolism and both type 1 and type 2 diabetes mellitus.

Additional perioperative laboratory examinations may include arterial blood gases and enzyme biomarkers of myocardial damage (e.g., troponin I and troponin T; creatine kinase MB isoenzyme, known as *MB bands*), especially in the presence of persistent angina (Moser and Riegel, 2008). Pulmonary function tests may be performed to determine baseline data and to plan postoperative care. Postoperative respiratory function may be impaired as a result of the use of extracorporeal circulation and the associated inflammatory response, and stasis of lung secretions that accompany prolonged surgery.

Ongoing genetic studies have created a burgeoning body of knowledge about genetic mutations associated with risk factors such as C-reactive protein and possible pathways linking inflammatory processes with CAD (Elliott et al, 2009). It is likely that genetic information will become a common component of the history and review of systems performed during patient assessment.

Nursing Diagnosis

After a comprehensive review of individual patient data, the perioperative nurse identifies relevant nursing diagnoses, from which the perioperative plan for patient care is derived (see the Sample Plan of Care on pp. 1019-1020).

Nursing diagnoses related to the care of patients undergoing cardiac surgery might include the following (AORN, 2008; Petersen, 2007; Seifert, 2008, 2009; Seifert and Collins, 2009):

- Decreased Cardiac Output related to emotional (fear), sensory (pain), or physiologic (electrical, mechanical, or structural) factors
- Risk for Infection related to surgical incision(s), catheters and intravascular lines, and altered cardiac function
- Risk for Perioperative Positioning Injury
- Risk for Bleeding related to surgical incision(s), tissue dissection, altered coagulation function, and inadvertent hypothermia
- Deficient Knowledge related to the physiologic effects of the cardiac disorder, proposed surgical procedures, and immediate perioperative events
- Risk for Impaired Tissue Integrity (myocardial, peripheral, renal, and cerebral) related to surgery, hypothermia, CPB, or surgical particulate or air emboli

Outcome Identification

Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient's cardiac function will be consistent with or improved from baseline levels established preoperatively as evidenced by hemodynamic indicators (blood pressure, oxygenation, ECG) within expected range; warm, dry skin; and urine output more than 30 ml/hr.
- The patient will be free from signs and symptoms of infection at the surgical or other incisional sites as evidenced by absence of redness, edema, purulent incisional drainage, or untoward postoperative temperature elevation.
- The patient will be free from signs and symptoms of injury related to surgical position as evidenced by the absence of acquired neuromuscular impairment and tissue necrosis.
- The patient will be free from excessive bleeding as evidenced by chest tube drainage less than 100 ml/hr, dressings dry and intact, normal coagulation function studies (or undergoing replacement treatment for deficient clotting factors), and normal body temperature.
- The patient will demonstrate knowledge of the physiologic responses to the cardiac disorder (at his or her level of understanding), the proposed surgical treatment, and the immediate perioperative events as evidenced by verbalization of disease state, purpose of surgery, sequence of events, anticipated outcomes, and recovery process.
- The patient's myocardial, peripheral, renal, and cerebral tissue integrity will be adequate or improved as evidenced by absence of new electrocardiograph manifestations of infarction, the presence of palpable peripheral pulses, adequate urine output, and a clear or improving sensorium postoperatively.

Additional nursing diagnoses, based on individual patient assessment, should have a corresponding outcome statement. The outcome should be measurable, with criteria by which to evaluate its achievement. For example, for the outcome "The patient's cardiac function will be consistent with or improved from baseline levels established preoperatively as evidenced by blood pressure within expected range; warm, dry skin; and urine output more than 30 to 50 ml per hour," the perioperative nurse might identify criteria such as vital signs and hemodynamic status consistent with or better than preoperative parameters; fluid and electrolyte balance consistent with preoperative levels; adequate urine output; normal temperature and pink mucosa; absence of rate, rhythm, or conduction disturbances; absence of iatrogenic injury to the heart; and normal levels of clotting parameters. Each of these criteria becomes evidence that the outcome was achieved. When outcomes are evaluated, they should be documented in the perioperative record. Some outcomes will have been achieved at the conclusion of the surgical procedure; others require ongoing evaluation in the postoperative period to be adequately measured. The Evaluation section indicates the requirement for ongoing goal measurement by the use of the word "will" rather than stating the outcome as "having been" achieved.

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS

Decreased Cardiac Output related to emotional (fear), sensory (pain), or physiologic (electrical, mechanical, or structural) factors

OUTCOME

The patient's cardiac function will be consistent with or improved from baseline levels established preoperatively as evidenced by hemodynamic indicators (blood pressure, oxygenation, ECG) within expected range; warm, dry skin; and urine output more than 30 ml/hr.

INTERVENTIONS

- Identify baseline cardiac status.
- Use monitoring equipment to assess cardiac status.
- Identify and report the presence of implantable cardiac devices.
- Institute anxiety-reduction measures; address fear-producing concerns; clarify misconceptions, and answer questions.
- Measure pain level with pain scale; provide comfort measures and pharmacologic interventions as ordered; confirm and document degree of pain relief, measures used, and any medications administered.
- Check results of clotting function, coagulation profile, and electrolyte values; report abnormalities.
- Monitor blood pressures (arterial, central venous pressure [CVP], pulmonary artery wedge pressure [PAWP]) and ECG.
- Maintain adequate supply of and assist with administration of replacement blood or blood products.
- Follow institutional protocol for allergic blood reaction; document same according to institutional protocol.
- Have inotropic and antidysrhythmic medications available; assist with administration; document same according to institutional protocol.
- Monitor, report, and record urine output and chest tube drainage; keep tubes and catheters patent.
- Have available defibrillator (with appropriate internal and external paddles and settings), fibrillator, external pacemaker, temporary epicardial pacemaker leads, and appropriate ECG cables for cardioversion and intra-aortic balloon pump.
- Evaluate postoperative cardiac status.

NURSING DIAGNOSIS

Risk for Infection related to surgical incision(s), catheters and intravascular lines, and altered cardiac function

OUTCOME

The patient will be free from signs and symptoms of infection at the surgical or other incisional sites as evidenced by absence of redness, edema, purulent incisional drainage, or untoward postoperative temperature elevation.

INTERVENTIONS

- Administer prescribed prophylactic treatments.
- Verify that prescribed preoperative prophylactic antibiotic has been administered within 1 hour of the surgical incision; document same according to institutional protocol.
- Assess individual patient risk factors for infection.
- Encourage/reinforce previous teaching regarding deep-breathing and coughing exercises.
- Classify surgical wound; document same according to institutional protocol.
- Implement and maintain aseptic technique.
- Initiate and maintain traffic control.
- Minimize length of invasive procedure by prioritizing, organizing, and planning care.
- Completely drape central line insertion sites.
- Dress all invasive arterial and venous lines.
- Perform skin preparation, using care to prevent pooling of solution; implement fire safety precautions during prepping. Prepare anatomic area to knees (or lower if leg vein needed) with antimicrobial antiseptic agent; document same according to institutional protocol.
- Use depilatories or electric clippers to remove hair at the surgical site; avoid shaving with razors.
- Monitor aseptic technique; correct breaks; accurately reclassify surgical wound on perioperative nursing record if a break in technique occurs.
- Have available prescribed topical antibiotics; document their administration according to institutional protocol.
- Manage culture specimen collection as indicated; use safe specimen management practices. Document specimens collected according to institutional protocol.
- Protect from cross-contamination.
- If the OR bed is raised, lowered, or turned from side to side, take measures to maintain sterility of field.
- Confine and contain instruments used in groin or leg; change gown and gloves when moving from lower extremities to chest.
- Protect sterility of closed urinary drainage system.
- Maintain continuous surveillance.
- Provide/apply surgical dressings to wound and invasive device sites.
- Maintain sterility of instrument setup until patient is discharged from the OR.
- Document implants according to institutional protocol.
- During patient rewarming, avoid excessive heat loss: cover exposed areas, irrigate with warm solutions, and increase room temperature.
- Use forced warm air systems before and after period of induced hypothermia.
- Monitor for signs and symptoms of infection.

NURSING DIAGNOSIS

Risk for Perioperative Positioning Injury

OUTCOME

The patient will be free from signs and symptoms of injury related to surgical position as evidenced by the absence of acquired neuromuscular impairment and tissue necrosis.

INTERVENTIONS

- Obtain and prepare appropriate positioning accessories; verify that these are clean and in working order.
- Identify any physical alterations that require additional precautions for procedure-specific positioning.
- Verify presence of prosthetics or corrective devices; document same according to institutional protocol.
- Position the patient, maintaining proper body alignment.
- Pad and protect vulnerable neurovascular bundles and dependent pressure areas.
- Prevent pooling of skin preparation agents at bedlines.
- Pad thermia blanket.
- Keep all OR bed surfaces dry and wrinkle-free.
- Ensure patency and security of peripheral and central lines, catheters, and ESU dispersive pad on positional changes.
- Have adequate personnel to assist with patient transfer to and from the OR bed and positional changes; lift (do not pull) patient during all positioning maneuvers.
- Safely secure patient to OR bed; ensure that safety straps are not too tightly placed yet maintain patient stability.

Continued

SAMPLE PLAN OF CARE—cont'd

INTERVENTIONS—cont'd

- Confirm correct position during time-out.
- Evaluate for signs and symptoms of injury as a result of positioning.

NURSING DIAGNOSIS

Risk for Bleeding related to surgical incision(s), tissue dissection, altered coagulation function, and inadvertent hypothermia

OUTCOME

The patient will be free from excessive bleeding as evidenced by chest tube drainage less than 100 ml/hr, dressings dry and intact, normal coagulation function studies (or undergoing replacement treatment for deficient clotting factors), and normal body temperature.

INTERVENTIONS

- Review results of clotting function and coagulation profile; report abnormalities.
- Check patient history for use of anticoagulant medication and other drugs affecting bleeding time and clotting function.
- Measure and report blood loss (e.g., suction, sponges).
- Use autotransfusion system per protocol.
- Have topical hemostatic agents available.
- Monitor, report, and record chest tube drainage; keep tubes patent.
- Before postoperative transfer, alert surgeon to chest tube drainage in excess of 100 ml/hr.
- Maintain adequate supply and assist with administration of replacement blood, blood products, clotting factors.
- Follow institutional protocol for allergic blood reaction.
- Adjust room temperature as needed; room temperature should be warm (20° to 24° C) or (68° to 75° F) before and after completion of cardiopulmonary bypass.
- Apply dressings to all incision sites (chest incision, conduit excision sites, and central line insertion sites).
- Monitor for development of inadvertent hypothermia.
- Evaluate for signs and symptoms of excessive bleeding.

NURSING DIAGNOSIS

Deficient Knowledge related to the physiologic effects of the cardiac disorder, proposed surgical procedures, and immediate perioperative events

OUTCOME

The patient will demonstrate knowledge of the physiologic responses to the cardiac disorder (at his or her level of understanding), the proposed surgical treatment, and the immediate postoperative events as evidenced by verbalization of disease state, purpose of surgery, sequence of events, anticipated outcomes, and recovery process.

INTERVENTIONS

- Explain or describe the following events; solicit feedback from patient:
  - Purpose and expectations of surgery
  - Disease state producing need for surgery
  - Sequence of events during perioperative period
  - Recovery and rehabilitation process
  - Nothing-by-mouth (NPO) status
  - Administration and effects of preoperative medication
  - Transport to OR
  - Preoperative unit
  - Insertion of peripheral, arterial, and venous lines
  - OR environment (temperature, room furniture and equipment, sounds of monitors and other machines, staff functions, induction of anesthesia)
  - Skin preparation
  - Anticipated length of surgery
  - Minimally invasive versus standard cardiac procedures
  - Surgical ICU and patient status (e.g., unable to talk while intubated and plans for alternative methods of communication)
- Assess knowledge regarding wound care and phases of wound healing.
- Provide information about wound care and anticipated phases of wound healing.
- Determine patient's desire for additional knowledge (respect denial).
- Answer questions; clarify misperceptions.
- Know where family or significant others will be waiting during surgery; provide communication per institutional protocol.
- Evaluate response to information about wound care and phases of wound healing.

NURSING DIAGNOSIS

Risk for Impaired Tissue Integrity (myocardial, peripheral, renal, and cerebral) related to surgery, hypothermia, CPB, or surgical particulate or air emboli

OUTCOME

The patient's myocardial, peripheral, renal, and cerebral tissue integrity will be adequate or improved as evidenced by absence of new electrocardiograph manifestations of infarction, the presence of palpable peripheral pulses, adequate urine output, and a clear or improving sensorium postoperatively.

INTERVENTIONS

- Identify baseline tissue perfusion.
- Assess factors related to risks for ineffective tissue perfusion.
- Place padded thermia blanket on OR bed.
- Preoperatively, provide warm blankets as required.
- Expose only those body areas required for surgical intervention.
- Use forced warm air systems during period requiring normothermia (keep patient warm before and after arrest; warm throughout for "warm heart" surgery).
- Monitor patient's temperature (esophageal, pulmonary, rectal, bladder, or ventricular septal).
- Adjust room temperature as needed.
- Inspect cardiopulmonary bypass lines for patency and presence of particulate matter; alert surgeon as indicated.
- Use solutions of appropriate temperature when irrigating the heart (cold during hypothermia arrest; warm before and after arrest); warm throughout for "warm heart" surgery.
- Avoid large ice particles on heart.
- Evaluate postoperative tissue perfusion.
- Evaluate progress of wound healing as applicable.

The nursing interventions in the Sample Plan of Care incorporate data elements from the Association of periOperative Registered Nurses' (AORN's) Perioperative Nursing Data Set (PNDS) (Petersen, 2007). With increasing emphasis on correlating patient outcomes with clinical interventions, the PNDS is a valuable resource for demonstrating the nurse's ability to influence positive patient outcomes.

Planning

Once the diagnoses and outcomes have been established, a plan of care (see Sample Plan of Care) is devised that will enable the perioperative nurse to achieve the goals that have been set. Patient and family needs, elicited from interviews when possible, should be integrated into the planning. The

perioperative nurse should identify criteria specific to the patient for each of the stated outcomes in the Sample Plan of Care.

Implementation

Some considerations, in addition to those previously mentioned, can be useful in implementing the perioperative plan of care for patients undergoing cardiac surgery.

Safety Considerations. The safety of the perioperative patient is a primary responsibility of the nurse. Equipment should be functioning properly and undergo routine testing by the biomedical engineering department. Supplies should be used according to manufacturers' instructions, and instruments should be regularly scrutinized to ensure that there are no burrs that could injure tissue, that the jaws of vascular and other clamps align properly, and that small items are accounted for at the end of surgery. Toxic material, such as the glutaraldehyde storage solution of bioprosthetic valves, should be thoroughly rinsed before implantation. Monitoring the aseptic practices of team members as well as visitors is an important safety consideration.

Staff safety is also important. Protective personal equipment should be consistently and properly worn. Gloves should be used by personnel whenever contact can occur with blood or other body fluids. The effects of electrical, chemical, and other potentially hazardous materials within the OR can be minimized by reinforcing safe practices to decrease the risks of injury.

Special Facilities. The OR must be large enough to accommodate bulky, highly specialized equipment while maintaining aseptic technique. Multiple electrical outlets, auxiliary lighting, and additional suction outlets should be available. Ceiling-mounted, mobile booms for housing electrosurgical units (ESUs), headlight sources, suction, medical gases, electrical outlets, and other items can reduce floor clutter and enhance the safety of the environment for patients and staff.

A growing number of hybrid suites have been designed that combine the traditional surgical controlled environment and the fluoroscopic imaging capabilities of interventional cardiologic laboratories. A typical hybrid procedure may consist of a surgical coronary anastomosis under direct vision or with a robot that is combined with percutaneously inserted coronary artery stents under fluoroscopy (Jansens et al, 2009).

Instrumentation and Equipment. The basic setup described for thoracic procedures (see Chapter 22) is used, along with some specialized cardiovascular instruments and equipment.

Vascular clamps, which are designed to occlude blood flow partially or completely, must be maintained in good condition if they are to prevent fracture of the delicate tunica intima of the blood vessels and still retain their specific holding qualities. There are many variations in construction of vascular instruments. The jaws may consist of single or double rows of fine, sharp, or blunt teeth or special crosshatching or longitudinal serrations. The working angles of the clamps also vary. All clamps are designed to hold the vessels securely and without trauma (Figure 24-13).

Minimally invasive procedures require special instrumentation to access the heart by way of smaller incisions in the anterior and/or lateral aspects of the chest wall (Figure 24-14). Retractors, dissecting instruments, suturing devices, coronary artery stabilizers, and vascular clamps are available.

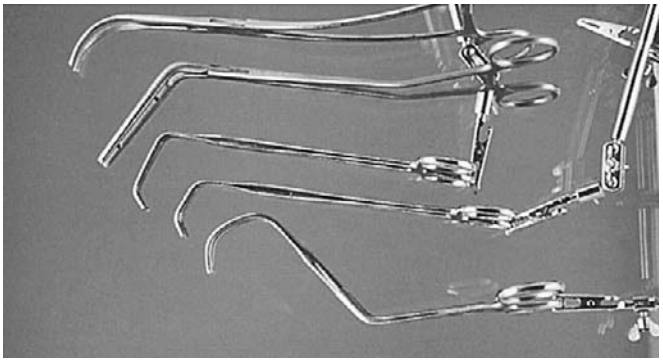

FIGURE 24-13 Cardiovascular clamps *(top to bottom):* Semb suture passer, Fogarty cross-clamp (angled), Beck partial occlusion clamps (medium and small), Lambert-Kay partial occlusion clamp.

Sternal and rib retractors are available to meet specific needs. IMA retractors expose the retrosternal artery bed by elevating the sternal border (Figure 24-15). Some sternal retractors have attachments that provide improved exposure of the left atrium during mitral valve replacement (MVR) (Figure 24-16). Exposure of the left or right atrium or the aortic root may also be accomplished with handheld retractors. Special rib spreaders provide exposure for mini-thoracotomy procedures. Coronary artery stabilizer systems with left ventricular apical suction retractors (Figure 24-17) are widely employed for beating heart coronary bypass surgery.

Other equipment commonly used (or available) for cardiac surgery may include the following:

- Sternal saw and motor
- Irrigation fluid cooling/warming machine
- Autotransfusion/cell saver system
- Electrical fibrillator
- Direct current (DC) defibrillator with internal paddles (Figure 24-18) and adhesive external pads
- Thermia unit (mattress or forced-air warming)
- External and internal pulse pacemaker generator (single and dual chamber)
- Pump oxygenator/CPB machine
- Epicardial pacemaker leads (temporary and permanent)
- Fiberoptic headlight and light source
- Intra-aortic balloon pump (IABP)
- Mechanical ventricular assist devices (VADs)
- Cryoablation energy ablation source (for atrial fibrillation surgery)
- Radiofrequency energy ablation source (for atrial fibrillation surgery)
- Ultrasonic cutting/coagulation device (Harmonic scalpel)
- TEE probe and monitor
- Minimally invasive, video-assisted vein-harvesting system
- Thoracoscopic equipment
- Video equipment

Lasers (for transmyocardial laser revascularization) and robots (for valve repair; retraction during port-access, video-assisted procedures) increasingly are also part of the equipment found in a cardiac OR.

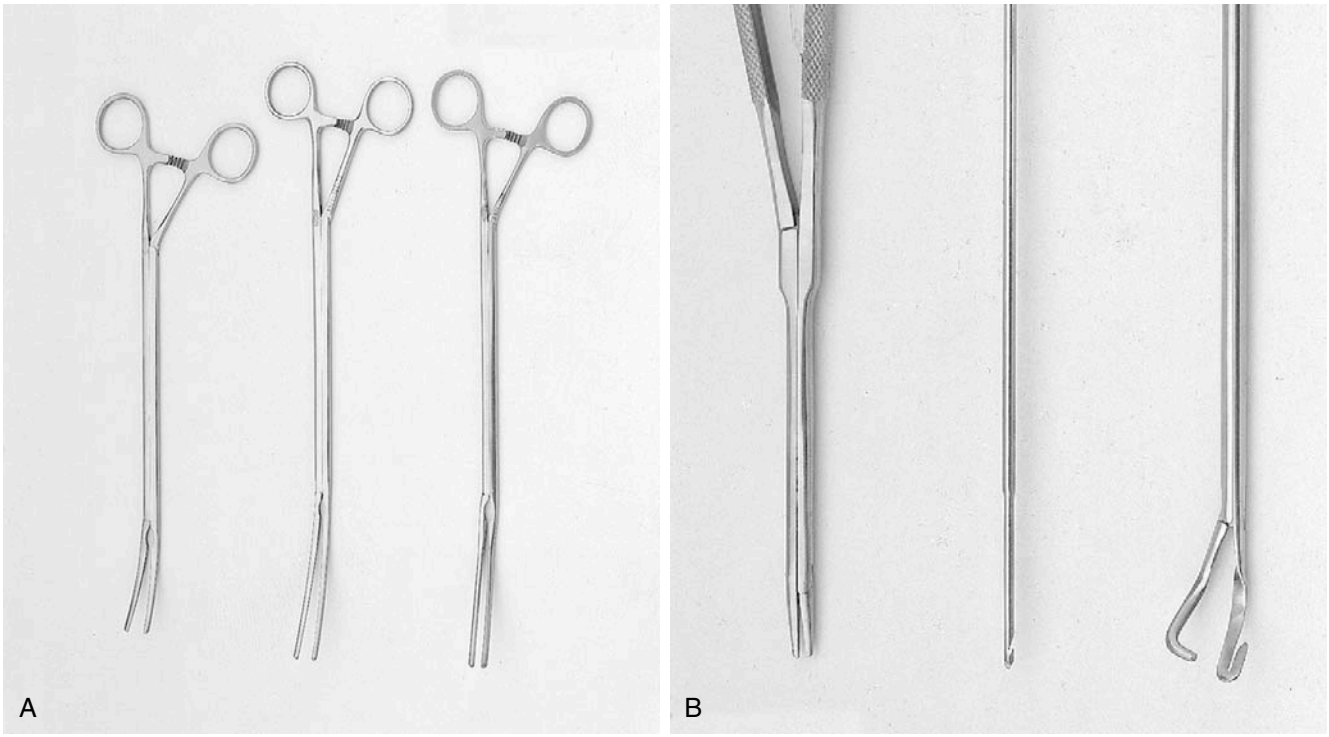

FIGURE 24-14 **A**, Transthoracic DeBakey vascular clamps are designed to pass through the chest wall by way of smaller incisions for minimally invasive procedures. **B**, Close-up views of minimally invasive needle holder, trocar/suture puller, and knot slider.

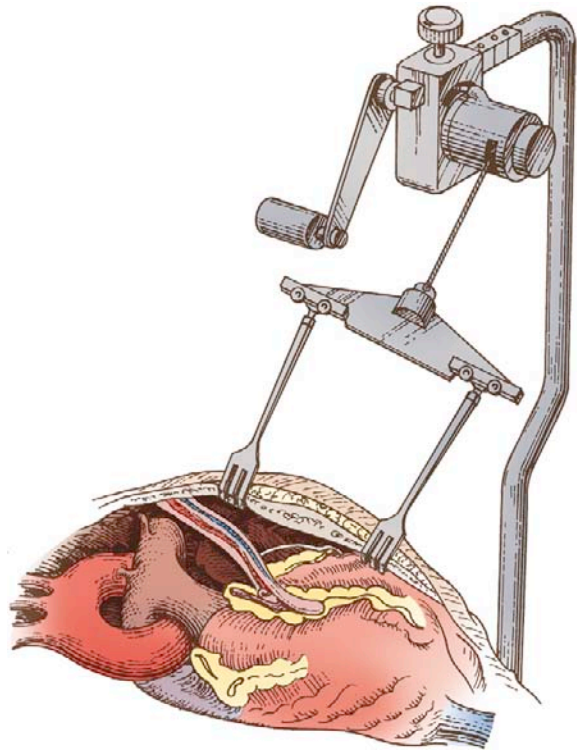

FIGURE 24-15 Retractor used to elevate sternal border for exposure of the internal mammary artery.

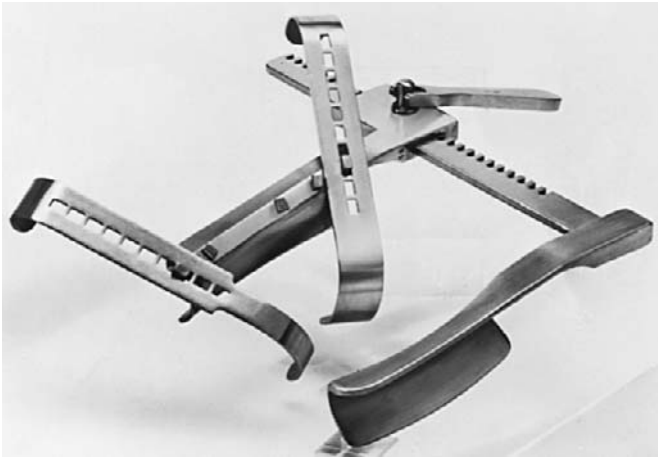

FIGURE 24-16 Sternal self-retaining retractor with attachments for left atrial retraction during mitral valve replacement.

Suture Materials. A variety of nonabsorbable cardiovascular sutures with atraumatic needles are available from most suture manufacturers. Synthetic sutures of Teflon, Dacron, polyester, or polypropylene are usually selected for insertion of prostheses and for vascular anastomoses. Most sutures are double armed with a needle on each end. Because of the number of stitches required for prosthetic valve repair and replacement, alternately colored suture and slotted, numbered suture holders may be helpful to avoid confusion. Polytetrafluoroethylene (PTFE) sutures can be used for replacement of mitral valve chordae. Vessel loops and umbilical tapes are commonly used

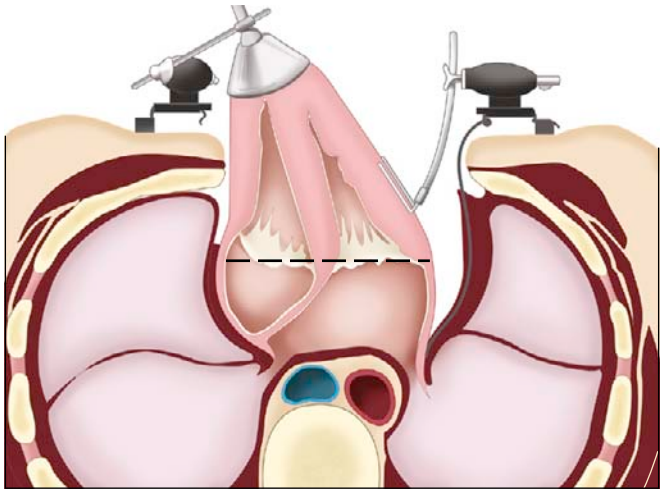

FIGURE 24-17 Cross-section of chest showing *(top left)* left ventricular apical suction cup to expose lateral and posterior coronary arteries for bypass grafting during off-pump surgery. The platform stabilizer *(top right)* isolates and immobilizes the section of the coronary artery to be anastomosed.

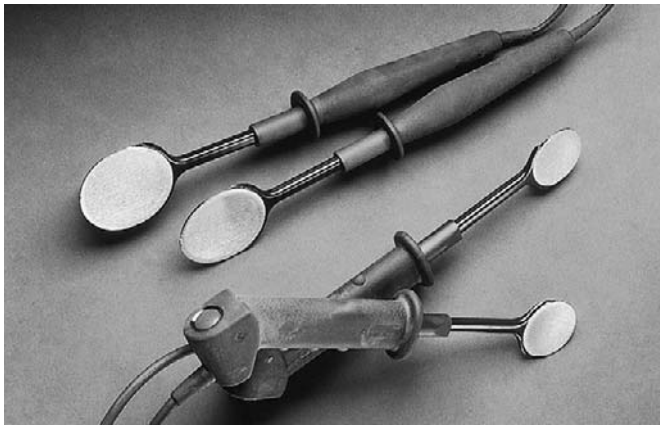

FIGURE 24-18 Internal defibrillator paddles are available in an array of sizes and designs: the paddles may be activated through the handles or by pressing the button on the defibrillator. Smaller internal paddles are used for infants and children.

to identify and to retract blood vessels and other structures. Wire (monofilament or twisted cable) commonly is used to approximate the sternum (Figure 24-19), with plastic, metal, or nylon bands occasionally added to reinforce fragile bone. Skin staplers may be used to close skin incisions; a staple remover must accompany the patient to the postanesthesia area if staples have been used to close the chest.

Supplies

The following supplies are generally used in most cardiac procedures. Depending on the surgeon's preference, other items may be added or substituted.

- Rubber shods (placed on the tips of hemostats to protect suture clamped by the hemostat)
- Pill sponges (gauze dissectors)
- Various-sized Silastic or polyvinyl chloride tubing
- Tourniquet catheters

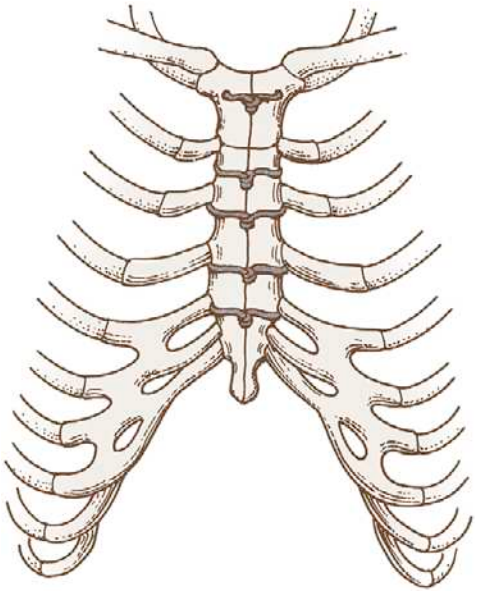

FIGURE 24-19 Technique for wire closure of the sternum. A variety of closing mechanisms have become available. These may consist of monofilament wire (shown), twisted wire cables, or (in some instances) plates and screws. In selected patients in whom disruption may be anticipated, such as elderly, obese, or malnourished patients, two or more heavy bands of nylon may be passed around the sternum and secured by a twisted stainless-steel wire in addition to the wire sutures. A figure-of-eight technique may also be employed.

- Disposable drapes
- Foot-control and hand-control ESU pencils, ultrasonic scalpel
- Adapters, connectors, stopcocks
- Extra syringes and needles for injections, infusions, and blood samples
- Sterile marking pen to identify anastomotic sites and mark grafts
- Irrigation cannulae
- Disposable vascular (bulldog) clamps
- Coronary occluders and stabilizers
- Autotransfusion supplies
- Chest tubes, chest drainage system
- Topical hemostatic agents
- Femoral arterial blood pressure supplies (hypodermic needle, guidewire, stopcocks, pressure tubing)
- Intra-aortic balloon pump (IABP) insertion supplies (hypodermic needle, guidewire, vascular dilators, stopcocks, pressure tubing, IABP catheter)
- CPB and myocardial protection cannulae, tubing, connectors, stopcocks

Prosthetic Material. In addition to these general supplies, special supplies are needed for repair or replacement of cardiovascular structures. Intracardiac patches, heart valves, and synthetic grafts should be handled with care to prevent damage or the introduction of foreign materials. Teflon, a fluorocarbon fiber, and Dacron, a polyester fiber, are available in a variety of meshes, fabrics, felts, tapes, and sutures and are also combined with other materials in prosthetic heart valves (Figure 24-20).

FIGURE 24-20 Assorted prosthetic materials to repair intracardiac and extracardiac defects: tapes, Teflon and Dacron patches, and pledgets.

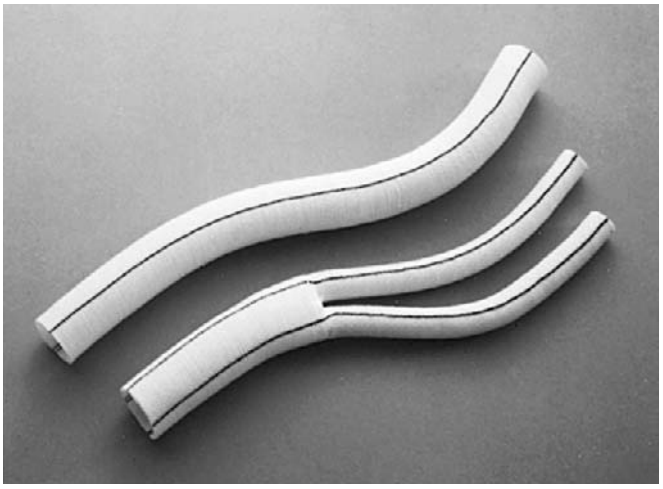

FIGURE 24-21 Straight and bifurcated arterial tube grafts.

FIGURE 24-22 Thoracic aortic endovascular stented prosthesis made from expanded polytetrafluoroethylene (PTFE). The compressed device is inserted percutaneously through the femoral artery by way of a delivery catheter and guided to the desired position in the thoracic aorta under fluoroscopy. When the correct position has been confirmed, the device expands automatically after it is deployed from the delivery catheter. The delivery catheter is then withdrawn, and hemostasis of the femoral incision site achieved.

Teflon patches are made in a variety of forms for intracardiac and outflow tract use. Varying degrees of firmness, thickness, and porosity are available for specific uses. Low reactivity, strength retention, and tissue acceptance are important properties to be considered in the selection of such patches.

Dacron arterial tube grafts are commonly used in cardiac surgery, although reinforced expanded PTFE grafts are also available. There are two types of Dacron grafts: knitted and woven. Woven prosthetic grafts are usually employed when the patient has been fully heparinized because the interstices of woven grafts are tighter than those in knitted grafts and bleeding is usually reduced. Compared to woven grafts, the advantages of knitted grafts are that they do not fray as readily, they are easier to handle, and they reendothelialize more quickly. Grafts are available in a variety of sizes and may be straight or bifurcated (Figure 24-21). Knitted and woven grafts impregnated with collagen to reduce interstitial bleeding are useful in the thoracic aorta and do not have to be preclotted, even when the patient is fully heparinized for cardiopulmonary bypass. Graft sizers are available for determining the correct size.

Specially designed tube grafts for the aortic arch incorporate prosthetic branches for the head vessels (bracheocephalic, left common carotid, and subclavian arteries); and tube grafts for replacement of the aortic root and ascending aorta are available with preformed sinuses of Valsalva incorporated into the prosthesis (Cameron et al, 2009).

Endovascular, expandable stented tube grafts are available for both the abdominal aorta and the descending portion of the thoracic aorta (Figure 24-22). The endovascular graft is inserted percutaneously into the femoral artery and advanced to the desired position in the abdominal or descending thoracic aorta, where the prosthesis is opened, implanted, and secured (Tinkham, 2009; Thompson and Bertling, 2009).

Valve Prostheses. Valve prostheses are selected according to their hemodynamics, thromboresistance, durability, ease of insertion, anatomic suitability, and patient acceptability; cost, patient outcome, and value are also important considerations (Rahimtoola, 2003, 2004). Most mechanical prostheses employ a tilting disk design. The ball-and-cage prosthesis was the first implanted mechanical valve (Starr and Edwards, 1961) but currently is implanted infrequently. Prosthetic valves allow complete closure with slight regurgitation to prevent stasis of blood (Figures 24-23 to 24-26).

Bioprostheses are derived from porcine, bovine, or equine tissue (Figures 24-27 to 24-29). Porcine valves consist of an aortic valve from a pig that can be sutured to a Dacron-covered

FIGURE 24-23 St. Jude Medical bileaflet tilting disk valve prosthesis.

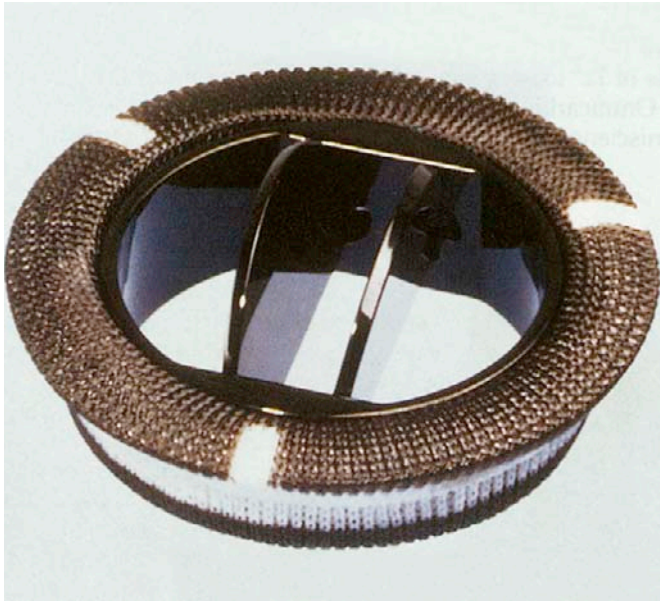

FIGURE 24-24 CarboMedics supraannular aortic prosthesis designed for the small aortic root.

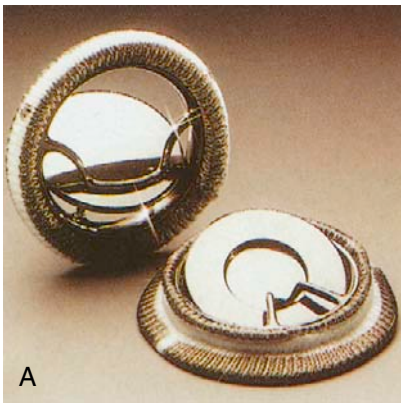
FIGURE 24-25 Starr-Edwards ball-and-cage aortic valve prosthesis.



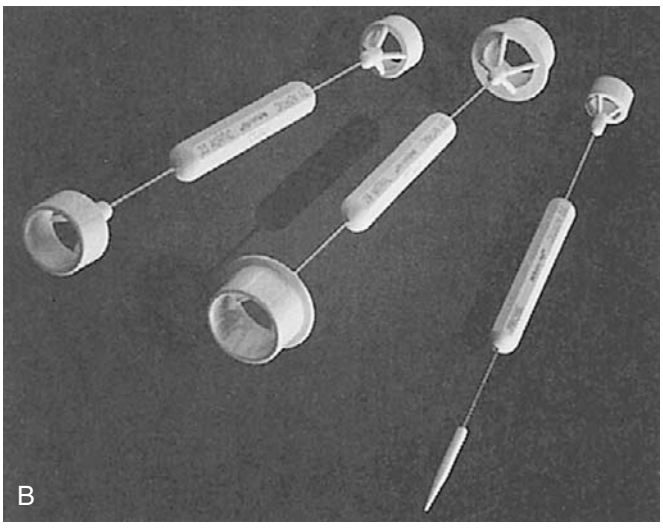


FIGURE 24-26 **A**, Medtronic-Hall tilting disk valve prosthesis. **B**, Double-ended sizing obturators for the Medtronic-Hall prosthesis *(left and center)* and probe *(right)* to test leaflet movement. All valve prostheses have sizing obturators specific to the prosthesis itself.

stent (Figure 24-27, *A*), or the porcine aortic valve may be "stentless" (without a sewing ring) to enhance the hemodynamics, especially in patients with a small aortic root (i.e., orifice less than 21 mm) (see Figure 24-27, *B*) (Pepper et al, 2009). The bovine (calf) (see Figure 24-28) pericardial bioprosthesis is created by cutting leaflet-shaped pieces from the pericardium and sewing them onto a Dacron ring; the equine (horse) (see Figure 24-29, *A*) pericardial prosthesis is created by cutting pieces of the pericardium, shaping the pieces into a tube, and attaching the prosthesis to a ring of Dacron material. The advantage of these biologic valves is that administration of long-term anticoagulants is not necessary in most patients. Obturators for sizing prosthetic valves as well as valve holders are specific to the prostheses (see Figures 24-26, *B*, and 24-29, *B*). Tables 24-4 and 24-5 compare mechanical and biologic prosthetic heart valves. Tissue-engineered heart valves may offer a future potential cure for valvular heart disease (Hjortnaes et al, 2009).

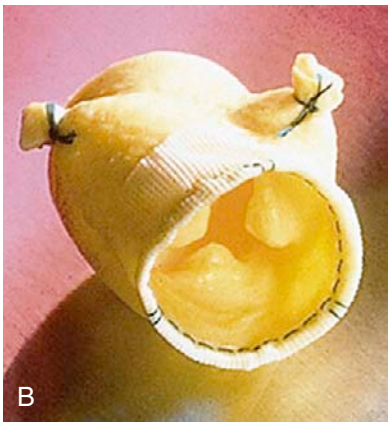

FIGURE 24-27 **A**, Medtronic Mosaic porcine aortic *(top)* and mitral *(bottom)* bioprostheses. **B**, Stentless porcine aortic valve. The absence of a stent and sewing ring provides a greater orifice area through which blood can flow.

Aortic valve allografts (homografts) have little or no risk of thromboembolism, optimal hemodynamic function, no need for anticoagulation drugs, and no risk of sudden catastrophic failure. Moreover, they demonstrate a lower incidence of infective endocarditis than that found in mechanical or biologic valves and their long-term durability is comparable with that of bioprostheses. Allograft root replacement is also a valuable technique in the setting of prosthetic valve endocarditis. The entire ascending aorta and valve (Figure 24-30) or the valve alone (Figure 24-31) may be inserted. Allografts are cryopreserved and must be thawed in saline according to the vendor's protocol before implantation. Because stentless aortic valves (see Figure 24-27, *B*) are more easily available than allografts, they are increasingly preferred for aortic root replacement.

Conduits consisting of mechanical or biologic aortic valves attached to a tube graft (Figure 24-32) are used in procedures such as repair of aortic dissections requiring replacement of the aortic valve and ascending aorta. If vein grafts must be inserted into the conduit or if a direct coronary ostial anastomosis is required, an eye electrocoagulator is used to make the opening

FIGURE 24-28 Carpentier-Edwards bovine pericardial aortic bioprosthesis.

FIGURE 24-29 **A**, ATS Medical equine pericardial aortic prosthesis. **B**, Obturators for ATS Medical 3f prosthesis.

into the graft and at the same time heat-seal the cut edges of the prosthesis. Conduits with *biologic* valves interposed between tube graft materials may be used when patients are at increased risk for bleeding complications associated with the need for chronic anticoagulation therapy. Allograft conduits may be used for these procedures as well.

Although allografts and stentless bioprostheses avoid the complications associated with prosthetic mechanical valve replacement, valve repair rather than replacement is preferred,

TABLE 24-4

Mechanical Valve Prostheses*

	Ball-and-Cage (Rarely Used)	Tilting Disk	
	Starr-Edwards	**Medtronic-Hall, Omniscience**	**St. Jude Medical, CarboMedics**
Model/description	6120 Mitral 1260 Aortic	Spherical (single) tilting disk	Bileaflet tilting disk
Advantages	Long-term durability Good hemodynamics Inaudible Least risk of sudden thrombosis	Long-term durability Good hemodynamics in all sizes Low profile	Long-term durability Good hemodynamics in all sizes Low profile Low TE rate for mechanical valve
Disadvantages	Anticoagulation required Higher incidence of TE than disk valves Large profile Suboptimal hemodynamics in small aortic sizes (less than 23 mm) High profile not optimal in small LV or aortic root Higher risk of TE in mitral position	Anticoagulation required Potential for sudden thrombosis Noisy Higher risk of TE in mitral position If Coumadin must be discontinued, there is increased risk of catastrophic thrombosis	Anticoagulation strongly recommended Potential for sudden thrombosis Some noise Higher risk of TE in mitral position If Coumadin must be discontinued, there is increased risk of catastrophic thrombosis
Special considerations	Sizers and handles specific to prosthesis; must be sterilized Poppet of aortic valve removable to facilitate tying sutures; replaced before aorta closed; mitral poppet not removable Aortic model has three struts; mitral has four	Sizers and handles specific to prosthesis; must be sterilized	Sizers and handles specific to prosthesis; must be sterilized Frequently used in children needing prosthetic valve
Resterilization	Not recommended	Not recommended	Not recommended

*All prostheses should be stored in a cool, dry, contamination-free area.
LV, Left ventricle; *TE,* thromboembolism.

TABLE 24-5

Biologic Valve Prostheses

	Heterograft (Xenograft)		
	Stentless Porcine Bioprostheses	**Stented Porcine Heterograft; Bovine and Equine Pericardial Valve Prostheses**	**Allograft (Homograft)**
Model/description	For use in aortic position Stentless (aortic): no sewing ring; includes porcine aortic root with coronary ostial branches	Pericardial valve used in aortic position Porcine heterograft used in aortic, mitral, and tricuspid positions Porcine heterograft (from excised pig aortic valves; leaflets attached to sewing ring) Aortic bovine and equine pericardium (cut and shaped into trileaflet valve)	Aortic valve allograft (cadaver, organ donor, excised cardiomyopathic heart from transplant recipient; mitral valve allograft also available)
Advantages	Incidence of TE very low; anticoagulation rare after AVR Stentless has excellent flow, especially in small aortic annulus (≤21 mm) No hemolysis Good hemodynamics Use may avoid need for aortic root enlargement Central flow Gradual failure allows elective reoperation Little residual gradient Durability good after age 60 yr Stentless graft has many advantages of allograft valves	Incidence of TE very low; anticoagulation rare after AVR No hemolysis Good hemodynamics in all sizes Central flow Gradual failure allows elective reoperation Residual gradient minimal	Incidence of TE very low; anticoagulation rare; used for AVR and MVR No hemolysis Excellent hemodynamics (especially with stentless technique) Central flow Gradual failure allows elective reoperation No residual gradient
Disadvantages	Durability may be less than 15 yr Accelerated fibrocalcific degeneration in children, patients with hypertension, or patients needing chronic renal dialysis Cross-clamp time and CPB longer than those for insertion of stented valve because of greater complexity of subcoronary insertion	Durability not yet established In small aortic root of large body, may produce prosthesis-patient mismatch Accelerated calcification may be a problem in children, renal patients, or those with hypertension	Limited availability Insertion technique more complex than stented valve Possible immunologic reaction (newer decellularization process strips cells from graft and reduces immune response)
Special considerations	Sizers and handles specific to prosthesis; must be sterilized before insertion; must be rinsed in saline to remove storage solution before insertion; follow manufacturer's instructions for rinsing; frequent irrigation recommended to prevent drying Diets low in calcium recommended for children, renal patients	Sizers and handles specific to prosthesis; must be sterilized before insertion; must be rinsed in saline to remove storage solution before insertion; follow manufacturer's instructions for rinsing; frequent irrigation recommended to prevent drying Diets low in calcium recommended for children, renal patients	No specific sizers; may use sizers for heterografts; cryopreserved allograft must be thawed per protocol; used for aortic or mitral valve replacement; stent can be attached if indicated for use in other positions
Resterilization	Not recommended	Not recommended	Not recommended

AVR, Aortic valve replacement; *CPB,* cardiopulmonary bypass; *MVR,* mitral valve replacement; *TE,* thromboembolism.

RISK REDUCTION STRATEGIES

Varying Rinsing Procedures for Biologic Heart Valves

Glutaraldehyde storage solution is used for many bioprostheses, and rinsing procedures for its removal vary among bioprosthetic heart valve manufacturers. Both the amount of rinsing solution in each rinsing basin and the time for each rinse (total of three rinsing baths) should be followed according to each manufacturer's instructions. Some manufacturers (see ATS Medical) recommend a *fourth* basin for storing the bioprosthesis until implantation. The following sampling of rinsing processes reflects the differences among manufacturers' recommended rinsing procedures. The person rinsing the valve should collaborate with the circulating nurse when following the instructions for that particular valve.

PERICARDIAL (EQUINE) AORTIC VALVE (ATS MEDICAL 3F)

Prepare *four* rinse basins with a minimum of *500 ml of saline* solution in each basin. Gently agitate the valve for *30 seconds in each of the first three basins* for a total of *1.5 minutes (90 seconds)*. Allow the bioprosthesis to remain in the *fourth basin* until required by the surgeon.

ATS Medical 3f rinse procedure, ATS 3f Aortic Bioprosthesis (Model 1000), Implant Procedure, ATS Medical, Minneapolis, Minn, available at www.atsmedical.com/uploadedFiles/Public_Site/Physicians_International/Biological_Valves/st_broc_3f.pdf. Accessed July 9, 2009.

PERICARDIAL (BOVINE) VALVE (CARBOMEDICS)

Prepare three rinse basins with a minimum of *300 ml of saline solution in each basin*. Gently agitate the valve for *2 minutes in each basin for a total of 6 minutes*. Allow the bioprosthesis to remain in the third basin until required by the surgeon.

CarboMedics rinse procedure, available at www.carbomedics.com/professional_faq.asp?faq=HPBio#27. Accessed July 3, 2009.

PERICARDIAL (BOVINE) VALVE (EDWARDS LIFE SCIENCES PERIMOUNT MAGNA 3000TFX)

Prepare two rinse basins with a minimum of *500 ml of saline solution in each basin*. Gently agitate the valve (keeping it submerged) *for a minimum of 1 minute in each basin for a total of at least 2 minutes*. Allow the bioprosthesis to remain in the third basin until required by the surgeon.

From Edwards Life Sciences: *Instructions for use,* available at http://www.edwards.com/products/heartvalves/mmimplantprep.htm?MagnaMitral=1. Accessed November 25, 2009.

PORCINE VALVE (MEDTRONIC MOSAIC 305)

Prepare three rinse basins with a minimum of *500 ml of saline solution in each basin*. Gently agitate the valve (keeping it submerged) *for 2 minutes in each basin for a total of 6 minutes*. Allow the bioprosthesis to remain in the third basin until required by the surgeon.

Medtronic rinse procedure, available at www.medtronic.ch/cardsurgery/products/pdf/200102908b%20EN.pdf. Accessed July 3, 2009.

PORCINE STENTLESS VALVE (MEDTRONIC STENTLESS FREESTYLE 995)

Prepare three rinse basins with a minimum of *500 ml of saline solution in each basin*. Gently agitate the valve (keeping it submerged) *for 2 minutes in each basin for a total of 6 minutes*. Allow the bioprosthesis to remain in the third basin until required by the surgeon.

From Medtronic: *Instructions for use*. Package insert. Medtronic, Inc., Minneapolis, MN, 2007.

PERICARDIAL VALVE (SORIN *FREEDOM SOLO*)

This is a newer valve detoxified by, but not stored in, glutaraldehyde (other bioprostheses are stored in glutaraldehyde); *eliminates the need for rinsing* (although the prosthesis should be kept moist with saline to prevent drying of the tissue).

Mirzaie M et al: A new storage solution for porcine aortic valves, *Ann Thorac Cardiovasc Surg* 13:102-109, 2007, available at www.atcs.jp/pdf/2007_13_2/102.pdf. Accessed July 3, 2009; see also the review at www.ces.clemson.edu/bio/documents/Publications/Simionescu%20-%20Expert%20Opinion%202004.pdf.

FIGURE 24-32 Valved conduit with Medtronic-Hall tilting disk valve prosthesis.

particularly with mitral and tricuspid valves. Fedak and colleagues (2008) listed more than 30 mitral valve rings and bands commercially available in 2007; the authors also described additional newer prostheses in development for both surgical and interventional percutaneous reparative procedures. When repairing the native valve with an annuloplasty ring, obturators specific to various kinds of annuloplasty rings are used to size the annulus (Figure 24-33, *A* and *B*).

Safety considerations include storing prosthetic materials in a clean, protected environment and using them according to manufacturers' instructions. Before implantation, biologic valves must be rinsed in three saline baths to remove the glutaraldehyde (or other) storage solution (Mirzaie et al, 2007). The prescribed amount of physiologic fluid in each rinsing bath and the recommended rinsing time for each bath vary among bioprosthetic manufacturers. Nurses should adhere to the specific instructions for each prosthesis (Risk Reduction Strategies). It should be noted that some bioprostheses do not require rinsing because they are stored in a physiologically neutral solution (i.e., not glutaraldehyde). However, before and during insertion, all bioprostheses should be kept moist with saline. Mechanical valves should be protected from scratching and other injury.

Preinduction Care. The patient is transferred to the OR suite, where a focused preoperative assessment is performed and the

perioperative nurse reviews the chart for completion and documentation of informed consent, advance directives, laboratory results, diagnostic data, and other pertinent information. The nurse confirms the identity of the patient and the intended operation, including identification and confirmation of the site and side, and the required position as applicable. Verification of which leg (i.e., right or left) will be used for vein harvest in bypass patients may not be necessary if this decision depends on the operator's preference rather than a specific clinical indication. However, some institutions may require site marking of bypass harvesting sites, and the nurse should follow institutional policy for guidance.

Preoperatively, cardiac surgical patients may exhibit more stress and anxiety than other types of patients. Perioperative nurses should anticipate and prepare for this reaction because anxiety increases myocardial oxygen consumption. Efforts to reduce the family's anxiety level are also important and result in less emotional stress being transmitted to the patient.

A peripheral arterial pressure line and venous infusion lines are inserted. A local anesthetic may be used at the insertion sites, and a sedative may be injected intravenously. Occasionally, a patient's response to sedation results in impaired respiration as evidenced by shallow respirations, decreased oxygen saturation, and a respiratory rate of 8 breaths (or less) per minute (Mancini and Bubien, 2008). The nurse noticing these respiratory changes can call a rapid response team (RRT) to assess the patient and initiate treatment before the patient develops more serious reactions, such as cardiopulmonary arrest. In this situation the RRT may consist of the anesthesia providers and staff in the immediate preoperative area rather than a specific hospital-wide RRT. For patients awaiting transfer from the preoperative area to the OR for cardiac surgery, the concept of a clinician acting promptly on changes in a patient's status and initiating a "rapid response" is an important aspect of enhancing a culture of patient safety (Rapid Response Team box).

Admission to the OR. Depending on the patient's response to sedative medications received preoperatively, the patient may require assistance onto the OR bed. Warm blankets should be provided for comfort and to reduce shivering; the nurse should ensure that the blanket temperature does not produce thermal injury (Bujdoso, 2009).

After application of the ECG leads and the pulse oximeter finger cot, the hands, elbows, and feet can be padded. The perioperative nurse confirms that the peripheral arterial pressure line is functioning properly and may reposition the arm as necessary in collaboration with the anesthesia provider. Pulse oximetry function is confirmed. The nurse should be aware that skin pigment, especially in darker-skinned individuals, may overestimate arterial oxygen saturation measured by pulse oximetry (Bickler et al, 2005). Additional monitoring devices are listed in Table 24-6. A "time out" is performed to comply with The Joint Commission's *Universal ProtocolTM* (see Chapter 2).

Anesthesia Induction. The choice of anesthetic agent or agents depends on the cardiovascular effects of the anesthetic, the patient's hemodynamic status and general health, and the anticipated length of stay in the surgical intensive care unit (SICU). Newer, fast-acting anesthetic agents are used to "fast-track" patients postoperatively, whereby the patient is extubated in the OR, or very shortly after admission to the SICU, to speed the recuperation process (Camp et al, 2009).

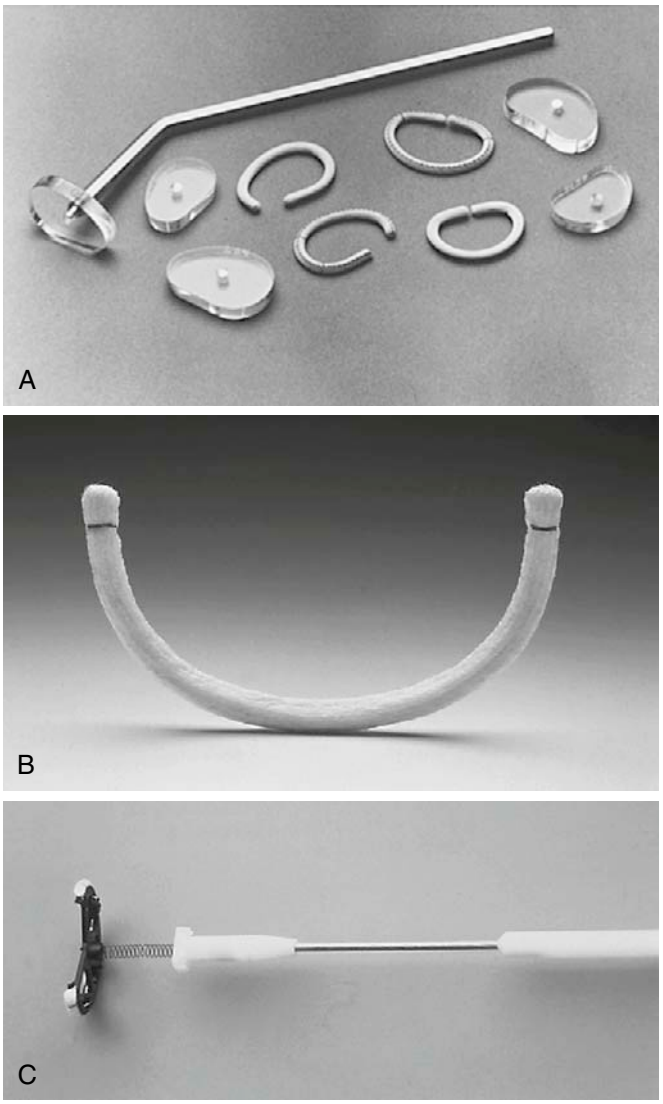

FIGURE 24-33 **A**, Carpentier-Edwards "classic" tricuspid and mitral annuloplasty rings, sizers, and sizer handle. The tricuspid rings are notched in the area corresponding to conduction tissue in the tricuspid annulus to avoid suture injury. **B**, Cosgrove annuloplasty ring. **C**, Ring attached to ring holder and handle.

Because the period of induction is one of the most critical during the procedure, close monitoring of the patient is required, especially for patients with ventricular ischemia from congenital or acquired disease (Moss and Moss, 2009). Anesthetic management focuses on maintaining an adequate cardiac output by keeping myocardial oxygen demand low and the oxygen supply high (DiNardo and Zvara, 2008). (See Chapter 4 for additional considerations related to anesthesia care monitoring.)

Medication Safety. In addition to anesthetic medications, multiple other drugs are employed to cause vasodilation or vasoconstriction, enhance heart rate and contractility, promote anticoagulation, result in diuresis, and provide antibiotic prophylaxis (Surgical Pharmacology). Antibiotic prophylaxis for

RAPID RESPONSE TEAM

Patients' responses to preoperative sedative medication administration can vary, even when the same dose and drug are administered. Some patients may display a reduced respiratory rate, shallow breathing, and decreased oxygen saturation; in more severe cases there may be hemodynamic instability.

In anticipation of changes in respiratory function, circulating nurses (and/or the preoperative nursing caregivers) should routinely ensure that patients in the preoperative area are connected to an ECG monitor, have a pulse oximeter finger cot attached to measure oxygen saturation, and have supplemental oxygen available. Additionally, the patient transport vehicle should be able to be placed into Trendelenburg's position.

When impaired breathing is noticed, the nurse can initiate a *rapid response* by contacting the anesthesia provider(s) caring for the patient. In the cardiac surgery suite, anesthesia personnel are usually immediately available to intercede. An official, institutional *rapid response team* may not be required even if anesthesia personnel have momentarily stepped away from the patient. Anesthesia staff will assess the patient and intervene to improve respiratory function by increasing oxygen flow and possibly treating the patient with small doses of ephedrine or phenylephrine to stimulate the respiratory center. The patient should not be left alone and will be transported to the OR and intubated promptly.

TABLE 24-6

Perioperative Patient Monitoring

Monitoring Device	Location	Measures
Electrocardiogram (ECG)	Lateral, posterior electrode placement	Electrical activity of heart
Arterial line	Peripheral radial artery	Arterial blood pressure (direct)
	Central femoral artery	
	Aorta (with needle attached to pressure tubing, or with sensor in bypass circuit)	
Blood pressure (BP) cuff	Upper arm	Arterial BP (indirect)
Central venous pressure (CVP)	Right atrium (RA)	RA pressure (e.g., CVP)
Pulmonary artery (PA) catheter (Swan-Ganz)	RA (proximal port)	RA pressure (e.g., CVP)
	Right ventricle (RV) (midline port)	RV pressure
	Distal PA (distal port)	PA and pulmonary artery wedge pressure (PAWP)
		Indirect measure of left atrial and left ventricular (LV) pressure
		Cardiac output
Left atrial (LA) line	Left atrium	LA, LV pressure
Pulse oximeter	Finger, earlobe	Oxygen saturation of arterial hemoglobin
Urinary drainage catheter	Urinary bladder	Urine output, renal perfusion/function, temperature
Temperature probes	Esophagus	Temperature (core and peripheral)
	Nasopharyngeal	
	Urinary bladder	
	Rectum	
	Ventricular septum	
	Bypass circuit	
	Tympanic	
	Face/forehead (adhesive patch)	
Neurologic monitoring		
Electroencephalogram (EEG)	Head	Electrical activity of brain; awareness
Transcranial Doppler		Detects cerebral arterial emboli
Bispectral index (BIS)		Detects anesthesia awareness
Cerebral oximetry		Measures cerebral tissue oxygen saturation with sensors placed bilaterally on patient's forehead
Transesophageal echocardiogram (TEE)	Esophagus	Cardiac function, presence of air, integrity of valve repair

Adapted from DiNardo JA, Zvara DA: *Anesthesia for cardiac surgery,* ed 3, Malden, Mass, 2008, Blackwell Publishing; Savino JS, Cheung AT: Cardiac anesthesia. In Cohn LH, editor: *Cardiac surgery in the adult,* ed 3, New York, 2007, McGraw Hill; Moss CJ, Moss R: Assist the anesthesia provider. infection prevention in the cardiac patient is an important consideration and the nurse should confirm that the antibiotic has been infused before the surgical incision is made (Simmonds et al, 2008). According to Engelman and colleagues (2007), *Staphylococcus aureus* is the most frequently cultured organism in cardiac surgical site infection (SSI). The recommended primary prophylactic antibiotic for adult cardiac surgery is a first-generation cephalosporin (usually cefazolin); vancomycin (one preoperative dose and an additional dose) may be a reasonable adjunct to cephalosporin. In patients allergic to penicillin, vancomycin may be considered the primary prophylactic antibiotic with additional gram-negative coverage.

SURGICAL PHARMACOLOGY

Medications Used in Adults During Cardiac Surgery

Medication	Purpose/Description/Delivery
ANALGESICS AND ANESTHETICS	
Thiopental	Induction, ultra–short-acting barbiturate, intravenous bolus
Fentanyl (Sublimaze)	Synthetic narcotic, intravenous bolus and/or infusion
Sufentanil (Sufenta)	Synthetic narcotic, intravenous bolus and/or infusion
Alfentanil (Alfenta)	Synthetic narcotic, intravenous bolus and/or infusion
Remifentanil (Ultiva)	Synthetic narcotic, intravenous bolus and/or infusion
Morphine sulfate	Narcotic, intravenous bolus
Halothane (Fluothane)	Inhalation anesthetic, maintenance
Enflurane (Ethrane)	Inhalation anesthetic, maintenance
Isoflurane (Forane)	Inhalation anesthetic, maintenance
Methohexital (Brevital)	Three times more potent and faster clearance than thiopental
Remifentanil (Ultiva)	Synthetic narcotic, intravenous bolus and/or infusion
Propofol (Diprivan)	Intravenous anesthetic; bolus and/or infusion; very fast acting
Sevoflurane (Ultane)	Inhalation anesthetic, maintenance
Desflurane (Suprane)	Inhalation anesthetic, maintenance
MUSCLE RELAXANTS	
Vecuronium (Norcuron)	Intubation, maintenance of muscle relaxation
Atracurium	Maintenance of muscle relaxation; relatively free of circulatory effects
Doxacurium	Maintenance of muscle relaxation; relatively free of circulatory effects
Pancuronium (Pavulon)	Maintenance of muscle relaxation
Pipecuronium	Maintenance of muscle relaxation; relatively free of circulatory effects
Rocuronium (Zemuron)	Fast-acting muscle relaxant; allows hemodynamic stability
Succinylcholine	Fast-acting muscle relaxant, 0% renal elimination
AMNESIACS	
Midazolam (Versed)	Hypnotic; anxiety-reducing sedative
Scopolamine	Sedative; amnesic
Lorazepam (Ativan)	Hypnotic sedative; premedication
CARDIOVASCULAR AGENTS	
Anticholinergics	
Atropine	Decreases vagal tone; treats sinus bradycardia
Glycopyrrolate (Robinul)	Similar to atropine but has less incidence of dysrhythmias than atropine with slower onset
Vasopressors	
Norepinephrine (Levophed)	Increases force and velocity of contraction; increases systemic and pulmonary vascular resistance
Phenylephrine (Neo-Synephrine)	Arteriolar and venous vasoconstriction; increases blood pressure and systemic vascular resistance
Vasodilators	
Nitroglycerin (Tridil)	Dilates coronary arteries; reduces preload
Phentolamine (Regitine)	Decreases systemic and pulmonary resistance
Prostaglandin E_1 (Prostin VR)	Vascular smooth muscle dilator, potent pulmonary vascular dilator; used to maintain patency of ductus arteriosus in cyanotic neonates, patients with severe pulmonary hypertension
Nitroprusside (Nipride)	Arteriolar and venous vasodilation; reduces preload and afterload
Inotropic Agents	
Amrinone (Inocor)	Increases cardiac output, force and velocity of contraction
Calcium chloride	In iodized form, increases cardiac output, blood pressure (BP), and contractility
Dopamine (Intropin)	In low doses, increases renal and mesenteric perfusion; with moderate doses, increases heart rate, contractility, and cardiac output; in higher doses, increases systemic and pulmonary vascular resistance
Dobutamine (Dobutrex)	Increases contractility with less increase in heart rate than occurs with dopamine; has vasodilation effect on vascular bed
Ephedrine	Increases contractility, cardiac output, BP
Epinephrine (Adrenalin)	Increases rate and strength of contraction, BP (effective bronchodilator)
Isoproterenol (Isuprel)	Increases heart rate, contractility, cardiac output; decreases systemic vascular resistance
Milrinone (Primacor)	Increases cardiac output, force and velocity of contraction

SURGICAL PHARMACOLOGY

Medications Used in Adults During Cardiac Surgery—cont'd

Medication	Purpose/Description/Delivery
Antidysrhythmics	
Lidocaine (Xylocaine)	Acts on ventricles; decreases automaticity of ischemic ventricular tissue
Bretylium (Bretylol)	Prolongs duration of action potential and refractory period; useful for ventricular dysrhythmias refractory to therapy
Digoxin (Lanoxin)	Decreases ventricular rate in atrial fibrillation or flutter and other supraventricular dysrhythmias; avoid in patients with Wolff-Parkinson-White syndrome and other accessory atrioventricular pathways
Nifedipine (Procardia)	Calcium channel blocker; reduces coronary artery spasm; produces coronary vasodilation; extremely light-sensitive; must be given orally or by way of nasal or oral mucosa; antihypertensive
Procainamide (Pronestyl)	Decreases automaticity and conduction in all cardiac tissue (normal and ischemic); stabilizes cellular membranes
Quinidine	Similar to procainamide; atrial and ventricular dysrhythmias
Verapamil (Calan, Isoptin)	Calcium channel blocker; used to treat atrial dysrhythmias; slows ventricular rate in atrial fibrillation or flutter; can be given intravenously
Adenosine	Supraventricular dysrhythmias
DIURETICS	
Furosemide (Lasix)	Decreases renal absorption of sodium and chloride; increases excretion of water and electrolytes, especially potassium, sodium, chloride, magnesium, and calcium
Mannitol	Osmotic diuretic; pulls free water out of organs (reducing cerebral edema); protects kidneys
ANTICOAGULANTS/COAGULANTS	
Heparin	Systemic anticoagulation during CPB; blocks activation of thrombin (and intrinsic clotting cascade)
Protamine sulfate	Heparin antagonist
Bivalirudin	Short-acting direct thrombin inhibitor
ANTIBIOTICS	
Cephalosporins (Mandol, Ancef, Keflex, Keflin, Cefadyl)	Broad-spectrum prophylaxis
Tobramycin (Nebcin)	Aerobic gram-negative and gram-positive bacteria
Vancomycin	Severe endocarditis
Bacitracin	Topical irrigation
MISCELLANEOUS	
Diazepam (Valium)	Sedative, induction of anesthesia
Nitric oxide (NO)	Vascular (especially pulmonary) relaxation; inhaled; reduces pulmonary hypertension
Lidocaine 1% (plain)	Local anesthetic for insertion of invasive monitoring
Naloxone	Opioid antagonist; reverses narcotic-induced respiratory depression
Papaverine	Reduces arterial spasm (e.g., mammary artery)
Potassium	Replaces electrolyte loss
Sodium bicarbonate	Corrects acidosis
Insulin (e.g., NPH)	Corrects hyperglycemia in diabetic patients
Topical hemostatic agents	Intraoperative control of bleeding
Desmopressin (DDAVP)	Pharmacologic hemostatic agent

Adapted from Savino JS, Cheung AT: Cardiac anesthesia. In Cohn LH, editor: *Cardiac surgery in the adult,* ed 3, New York, 2007, McGraw Hill Medical; Simmonds PK et al: Cardiovascular pharmacologic agents. In Conte JV et al, editors: *The Johns Hopkins manual of cardiac surgical care,* ed 2, St Louis, 2008, Mosby; Seifert PC, Collins J: Cardiac surgery. In Phippen ML et al, editors: *Competency for safe patient care during operative and invasive procedures,* Denver, 2009, Competency & Credentialing Institute.

Additional safety precautions include labeling all medications on the field (including irrigating fluids and H_2O). Of particular importance are heparinized solutions, papaverine (to reduce spasm in IMA and radial artery conduits), and saphenous vein infusions. Containers and syringes are labeled and the circulating nurse and the scrub person visually and verbally confirm drug name, dose, route, strength, and outdate of every medication passed onto the field.

Monitoring. Extensive monitoring of hemodynamic and other variables is indicated during cardiac surgery (see Table 24-6). After intubation (or before, depending on the anesthesia provider's preference), additional pressure lines may be inserted to measure central venous pressure (CVP) and pulmonary artery pressures (PAPs). Maximal sterile barriers should be used for insertion of central lines (Clancy, 2009; Hu et al, 2004) (Evidence for Practice). Peripheral and central arterial

EVIDENCE FOR PRACTICE

Optimal Draping for Central Venous Catheters

Central venous catheters are associated with bacterial colonization of the catheter, local infection at the site of insertion, and bloodstream infection. According to Clancy (2009), 250,000 central line–associated bloodstream infections (CLABSIs) occur in U.S. hospitals each year, and add $36,000 in additional cost per patient. In addition to the use of maximal barriers, infection prevention measures include handwashing, skin cleansing with chlorhexidine gluconate, avoiding the femoral site, and removing catheters as soon as possible.

The use of maximal barriers—although time-consuming, more expensive, and more cumbersome than other techniques employing minimal draping—has been shown to reduce the number of CLABSIs. Hu and colleagues (2004) calculated the total direct medical costs and the incidence of CLABSIs, bacterial colonization of the catheter, and death. When compared to minimal barriers, the researchers determined that the use of maximal barriers resulted in the following: lower costs (from $621 to $369 per patient), decreased bloodstream infections (from 5.3% to 2.8%), decreased catheter colonization with local infection (from 5.5% to 2.9%), and decreased death rates (from 0.8% to 0.4%). The authors calculated that $68,000 would be saved with maximal barrier application for every 270 catheter placements, 7 episodes of catheter-related infections would be avoided, and 1 death would be prevented. The results of this study support routine maximal draping for the insertion of central lines.

Modified from Clancy CM: Reducing central line-related bloodstream infections, *AORN J* 89(6):1123-1125, 2009; Hu KK et al: Use of maximal sterile barriers during central venous catheter insertion: clinical and economic outcomes, *Clin Infect Dis* 39, November 15, 2004.

and venous pressures are usually monitored directly by means of a transducer and oscilloscope. Perioperative nurses may be required to collaborate in the preparation and placement of central lines; they should observe the ECG monitors for signs of ventricular irritability, such as ectopy or tachycardia, and be prepared to assist with defibrillation of the patient if necessary. If the patient cannot be resuscitated, the chest is opened rapidly and internal cardiac massage is performed to perfuse the circulatory system.

An indwelling urinary catheter is inserted for measuring urine output and monitoring renal function, especially during and after CPB. The urinary catheter may contain a thermistor temperature probe. Other temperature probes may be placed, usually in the esophagus, nasopharynx, or rectum, or on the forehead. Temperatures can also be recorded from the pulmonary artery catheters and the arterial infusion line of the bypass circuit. Ventricular septal temperatures can be recorded by insertion of a needle probe while the patient's heart is arrested. Monitoring of cerebral oxygenation and the level of anesthesia awareness is frequently employed.

The skin is carefully inspected before ECG and ESU dispersive pads are placed. Bony prominences, such as the coccyx and the back of the head, are padded to prevent pressure necrosis resulting from hypoperfusion and hypothermia during bypass. Because elderly patients are especially vulnerable to skin breakdown, additional precautions to avoid pressure injuries are recommended (Walton-Geer, 2009). Monitoring aseptic practice is an important infection control strategy.

Positioning. The supine position provides optimal exposure for the institution of CPB and the surgical repair of the heart and great vessels. In addition, respiratory impairment and discomfort are reduced with this approach (Bishop, 2009). When the supine position is used, the hands and arms are tucked along either side of the body. The legs may be slightly "frog-legged" to provide access to the femoral arteries for insertion of pressure lines and IABP lines or to excise the saphenous vein. Measures to avoid pressure injury (especially in the elderly, debilitated, or obese patient) include padding the coccyx and applying heel protectors. Measures to protect the occipital area from pressure ulcers include placing pillows under the head and repositioning the head during surgery. Significant factors associated with the development of pressure ulcers include preexisting diabetes mellitus; lower preoperative hemoglobin, hematocrit, and serum albumin levels (Walton-Geer, 2009); and the presence of intra-aortic balloon pumps.

A semilateral position may be employed for thoracoabdominal aneurysms in order to expose both the descending thoracic aorta and the abdominal aorta. A thoracotomy position may be used for some minimally invasive procedures including surgery on the descending thoracic aorta. For minimally invasive surgery, the right or left side of the chest may be elevated with a roll or other positioning device to provide adequate exposure for one or more small thoracotomy incisions. The presence of severe mediastinal adhesions may also necessitate this approach in some repeat valve operations. Thoracotomy positioning aids should be available to position arms and legs per the surgeon's protocol (see Chapter 5 for a discussion of positioning).

Prepping and Draping. For procedures requiring excision of the saphenous vein, the prep extends from the jaw to the toes and includes the anterior (or lateral) area of the chest, abdomen, groin, and legs. The legs and feet are prepped circumferentially and the chest and abdomen from bedline to bedline.

In procedures not requiring saphenous vein excision, the prep extends to a level below the knees to give the surgeon access to the femoral artery or saphenous vein in the thigh area. (Some surgeons prefer to have both legs prepped circumferentially for all cardiac procedures.) Femoral artery access may be required for arterial pressure monitoring or insertion of an intra-aortic balloon. Saphenous vein exposure facilitates access if a bypass conduit is required. In the lateral position, the patient is prepped bedline to bedline anteriorly and posteriorly at least to the knees.

After the prep, the patient is draped so that the anterior areas of the chest, abdomen, and inguinal area are accessible. The perineum is covered, and a towel folded lengthwise (to create a "belt") may be placed across the umbilicus to connect the side drapes. When the saphenous vein is to be excised, both legs remain exposed, with only the feet covered. When draping, the perioperative nurse should consider the placement of bypass lines so that they remain securely attached and do not become contaminated. A small drape or towel may be placed over the groin area when access to it is not immediately necessary. If the femoral artery needs to be accessed, the drape can be discarded. Similarly, towels may be placed over the legs after saphenous vein excision to reduce inadvertent cooling.

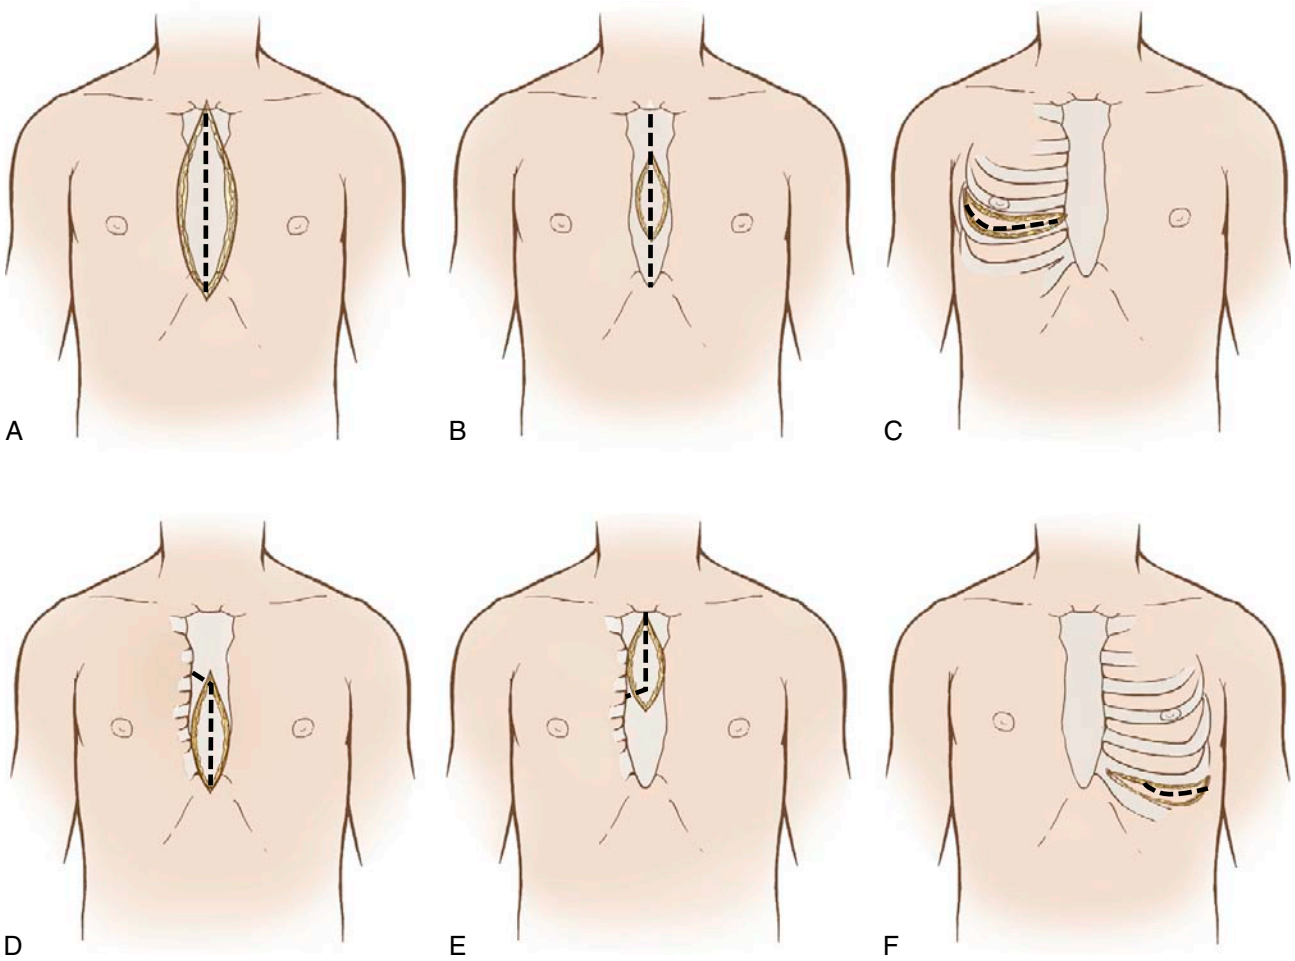

FIGURE 24-34 Schematic representation of traditional incision and sternotomy, **A**, compared with a variety of less-invasive incisions (*dotted lines* represent chest wall incisions). Limited skin incision/full sternotomy, **B**, is gaining popularity because of improved cosmesis and reduced trauma from the limited chest wall retraction. The parasternal approach, **C**, is used less frequently because of the residual chest wall defect. Partial lower or upper sternotomy, **D** and **E**, respectively, has been used predominantly in valve procedures. Right anterior thoracotomy, **F**, is a useful approach, particularly in mitral valve reoperations.

Incisions. A variety of incisions can be used. The standard median sternotomy is most common but mini-sternotomy, mini-thoracotomy, or full thoracotomy incisions are used according to the surgeon's preference and type of procedure (Figure 24-34).

MEDIAN STERNOTOMY. The skin incision for full sternotomy extends from the sternal notch to the linea alba below the xiphoid process (Figure 24-35). Nurses should realize that some women may be unprepared for a sternal scar (Research Highlight). For mini-sternotomy, the sternum is partially divided starting from either the sternal notch or the xiphoid process (depending on the cardiac structures to be exposed). The sternum is divided with a saw, and a sternal retractor is inserted. If the IMA or the saphenous vein will be used, it is made available at this time. The pericardium is incised and the pericardial edges are retracted with (six to eight) sutures sewn to the subcutaneous tissue; this technique enhances exposure by elevating the heart and creates a well to contain irrigation solutions.

In repeat sternotomy, adhesions from a previous cardiac operation must be dissected. The sternum may be divided with an oscillating saw and the retrosternal tissue dissected free. Increased risk of fibrillation from manipulation of the heart and bleeding and laceration of the right ventricle should alert the perioperative nurse to the possibility of instituting femoral vein–femoral artery bypass (discussed later). In addition, disposable defibrillation patches are applied preoperatively to the left lateral chest and the right upper posterior chest; these patches can be activated for defibrillation if the heart has not been exposed. Sterile external paddles may also be available.

Anteroposterior and lateral chest radiographs are useful to determine the extent of retrosternal adhesions and to count the number of chest wires for removal. On occasion, a patient presents for repeat mitral valve surgery. If the initial operation was performed through a thoracotomy incision, sternal adhesions may be minimal or nonexistent and the special precautions associated with repeat sternotomy may not be necessary. Conversely, if the primary chest incision was a sternotomy, a

RESEARCH HIGHLIGHT

Perceptions of Sternal Scars in Women after Cardiac Surgery

The subjective perception of a sternal scar is important to women. The Women's Recovery from Sternotomy Trial (WREST) was undertaken to interview women who had undergone cardiac surgery via median sternotomy. The study aims were to examine the qualitative impact of the cosmetic result of sternotomy and the quantitative association between subjective satisfaction and objective ratings of the sternal scar. Researchers from the nursing faculty at the University of Calgary (Alberta, Canada) undertook a small descriptive exploratory study of women (n = 13) who participated in semistructured audio-taped interviews.

Although participants realized that the scar represented the "cost" of benefits of cardiac surgery, they were not prepared to live with the scar. Significantly more women than men (35% versus 14%, respectively) verbalized that they "did not like" or "hated" their scar. According to the researchers, the scar represented a personal reminder to the participants that they had a health problem and that they had undergone serious surgery, and they felt less attractive because of the scar. Moreover, the visual reminder produced by the scar was perceived by the participants as causing a judgment from members of the public.

Little association was found between the participants' subjective satisfaction (rated on a Likert-type scale) and the objective scar rating using the Beausang clinical scar assessment (r = 0.348, p = 0.294). Many of the participants were "angry," "shocked," and/or "amazed" by their scar, and evidently did not know what would happen during the cardiac procedure. The researchers recommend appropriate preprocedure preparation and postoperative counseling and support regarding the sternal scar in three areas:

1. Initiate a discussion about the potential impact of the sternal scar during consultation about cardiac surgery (i.e., preoperatively).
2. Enable patients to talk with health caregivers about their life in the early recuperative period.
3. Clinicians should clearly differentiate between the patient's objective rating of the surgery and subjective perceptions related to the scar.

Perioperative nurses should be aware of potential alterations to body image and be sensitive to (or initiate) discussions related to body image or what the patient thinks will be the physical and psychologic result of the surgery. Nurses also should be prepared for clinical questions from women about the scarring process itself. It is important to remember also that men may be sensitive to cosmetic results and issues of self-image and self-esteem.

Adapted from King KM et al: A descriptive examination of the impact of sternal scar formation in women, *Eur J Cardiovasc Nurs* 8(2):112-118, 2009.

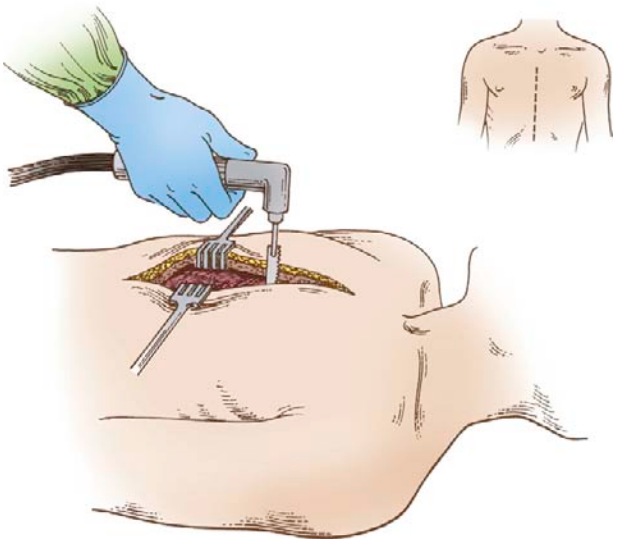

FIGURE 24-35 Median sternotomy with sternal saw.

right or left lateral thoracic incision may provide better exposure because of the presence of fewer adhesions.

MINI-THORACOTOMY. For minimally invasive cardiac procedures, a variety of smaller (up to approximately 4 to 8 cm) incisions and/or ports can be used. These include anterolateral chest incisions small enough for the insertion of specially designed instruments (see Figure 24-14), including video cameras and robotic arms. Minimally invasive cardiac procedures using smaller incisions may be performed under direct visualization or, increasingly, by means of video assistance.

CARDIOPULMONARY BYPASS. The temporary substitution of a pump oxygenator for the heart and lungs allows the surgeon to stop the heart to perform cardiac procedures under direct vision in a relatively dry, motionless field. It also allows the surgeon to manipulate the heart without the attendant risk of producing ventricular fibrillation and reduced cardiac output that jeopardize perfusion to the myocardial, peripheral, and cerebral tissues.

Under some circumstances, access to the anteroapical portion of the heart can be achieved without excess manipulation of the heart. Special retraction/stabilization devices (see Figure 24-17) allow the surgeon to create coronary artery bypass grafts (CABGs) to the anterolateral coronary arteries without the use of CPB and induced cardiac arrest. This enables surgery to be performed on a beating heart (discussed later).

In traditional CPB circuits, systemic venous return to the heart flows by gravity drainage through cannulae (Figure 24-36) placed in the superior and inferior venae cavae (Figure 24-37) or through a single two-stage cannula in the right atrium (Figure 24-38) into tubing connected to the bypass machine. Blood is oxygenated, filtered, warmed or cooled, and pumped back into the systemic circulation through a cannula placed in the ascending aorta or occasionally in the femoral artery (Figure 24-39) or the axillary artery (Khonsari et al, 2008). Because the CPB machine (Figure 24-40) oxygenates blood, the lungs do not need to function and can be deflated to provide better exposure of the mediastinal structures.

A percutaneous method of instituting femoral vein–femoral artery CPB can be used for minimally invasive (or conventional open) procedures (Figure 24-41) and in emergency situations where the environment is not conducive to traditional CPB methods (e.g., in the cardiac catheterization laboratory,

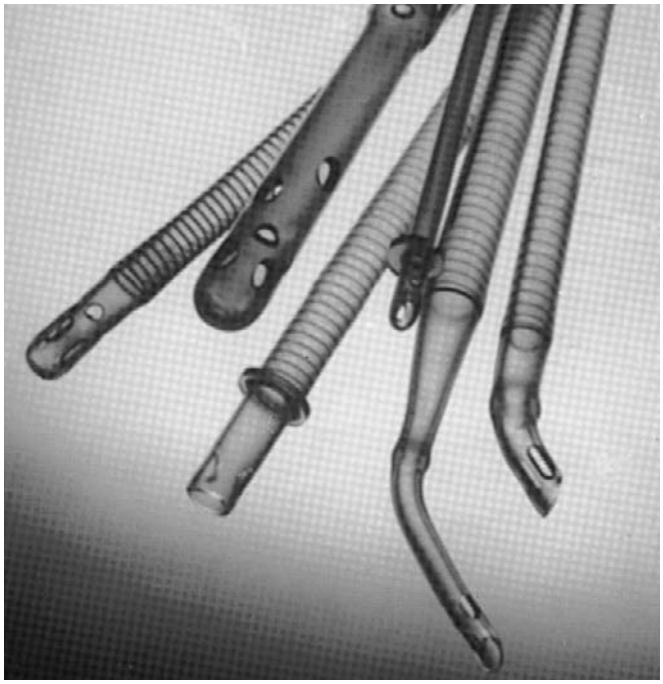

FIGURE 24-36 Arterial and venous perfusion cannulae.

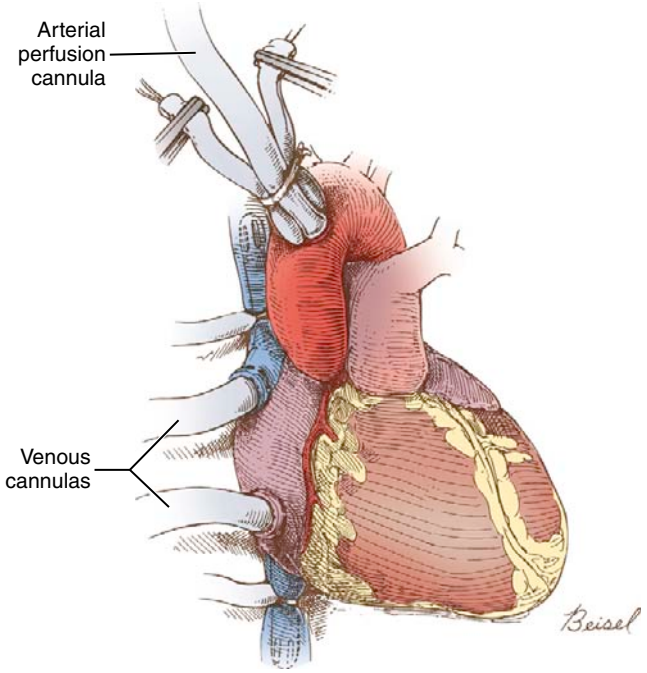

FIGURE 24-37 Bicaval cannulation of the superior and inferior venae cavae; aortic cannulation.

the intensive care unit, and the emergency department). The system employs thin-walled, wire-reinforced catheters inserted into the femoral vein or artery, or both. The resistance of the small-bore cannula used in the femoral vein can impede gravity drainage; to overcome this, a centrifugal pump may be used to actively siphon blood to the pump oxygenator. Other advances include the use of heparin-bonded bypass circuits and tubing; this reduces (but does not obviate altogether) the amount of heparin required to achieve systemic anticoagulation and can reduce bleeding and the associated need for blood products. Efforts to reduce platelet destruction and the inflammatory response by coating components of the CPB circuits with phosphorylcholine and other newer materials have shown some encouraging results (Schulze et al, 2009).

By diverting blood away from the heart, CPB also decompresses the ventricles, thereby reducing myocardial wall tension, which is a significant determinant of myocardial oxygen demand. This principle is evident when CPB or other means of ventricular support are employed to "rest" the heart. Further decompression is achieved by venting the left ventricle to remove air and accumulated thebesian and bronchial venous return as well as systemic return flowing around the venous cannulae (Figure 24-42). The venting catheter is inserted into the left ventricle by way of the right superior pulmonary vein or, less commonly, through the left ventricular apex. The venting line is connected to the suction lines of the bypass machine. A small venting catheter may also be inserted into the ascending aorta to remove air. Occasionally a vent is inserted into the pulmonary artery. Venting can reduce the incidence of gaseous microemboli. Ambient air removal can also be accomplished in cases when the heart is opened (e.g., valve surgery) with the insertion of a CO_2 gas diffuser; the gas is insufflated into the pericardial well. The CO_2 gas dissolves in blood approximately 25 times faster than room air; CO_2 retained within the cardiac chambers is better tolerated than ambient air and less harmful to tissue (Svenarud et al, 2004).

Improved bypass technology has also reduced the incidence of bypass-related microemboli and cellular injury with the use of finer filters for air and particulate emboli and moderation of the strength of siphoning pressures (Groom et al, 2009). Membrane oxygenators incorporated into the bypass circuit (see Figure 24-39) perform gas exchange (removing CO_2 and adding oxygen to the blood) more efficiently and less traumatically. Gases diffuse through a semipermeable membrane that separates the oxygenating gas and the venous blood. Although membrane oxygenators preserve platelet and red blood cell function better than the older "bubble" oxygenators, there does remain considerable morbidity associated with the use of CPB. Extracorporeal circulation causes fluid retention and intercompartmental fluid shifts, multiple organ dysfunction, showers of microemboli, inflammatory responses, and unique bleeding complications (Gourlay and Qureshi, 2008; Groom et al, 2009; Seifert, 2009). The mechanism of injury is believed to be related to the exposure of the blood to the abnormal surfaces of the bypass circuit, hypothermia, shear forces, and altered blood flow. These can initiate a systemic inflammatory response (complement activation), which releases vasoactive substances. Attempts to minimize the inflammatory reaction have focused on modifying the activation of platelets and blood factors that play a major role in initiating the response (Sniecinski and Levy, 2008). To avoid the complications associated with CPB, clinicians have stimulated greater use of "beating heart" ("off-pump") techniques for myocardial revascularization. It should be noted that "off-pump" techniques are not indicated for procedures requiring the heart to be opened (e.g., mitral valve surgery, left ventricular aneurysm repair) because air within the opened chamber would embolize to the brain. CPB enables the heart to be isolated from the systemic

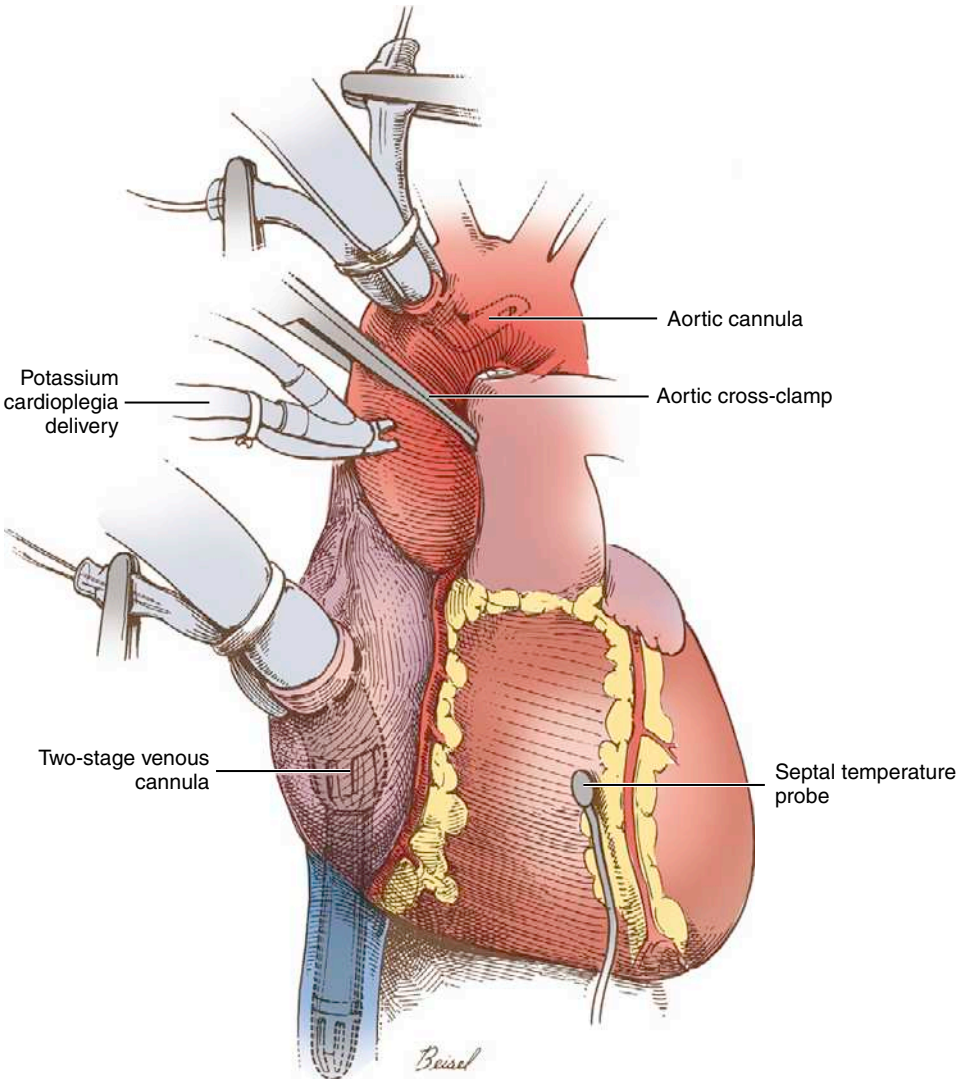

FIGURE 24-38 Diagram showing aortic and venous cannulae during aortic cross-clamping. Also shown is antegrade cardioplegic solution delivery catheter in the aorta proximal to the cross-clamp and a temperature probe. The single (two-stage) venous cannula has openings in the distal end of the cannula to drain the inferior vena cava; the openings in the midportion (right atrial area) of the cannula drain the superior vena cava and the coronary sinus venous return.

circulation so that after the repair is completed (and before the cross-clamp is removed) residual air can be removed through various venting techniques.

Two types of pumps are available: roller pumps and centrifugal pumps. Roller pumps have roller heads that propel blood forward by compressing blood-filled tubing against a smooth, metal housing. Centrifugal pumps use cones or blades that rotate at high speed to produce forward flow. All pumps produce some hemolysis from turbulence and shear forces, but careful calibration and minimal use of connectors can provide relatively atraumatic flow for short periods (e.g., less than 6 hours). Arterial blood flow on bypass is largely nonpulsatile, although modifications to the pump can simulate phasic (systolic/nonsystolic) flow (Gourlay and Qureshi, 2008); the arterial blood pressure is usually manifested by a mean arterial waveform on the oscilloscope during CPB.

Suction lines are ordinarily used during CPB to return shed blood to the venous reservoir and the oxygenator. These lines may combine conventional handheld suction tubes and ventricular decompression lines or sumps (see Figure 24-42). Before the initiation of CPB, the entire extracorporeal circuit must be primed and rendered free of air to prevent air emboli.

The priming solution is usually a combination of colloid and crystalloid fluids with a balanced electrolyte component. Priming volumes (i.e., within the CPB circuit) are generally between 1400 and 2000 ml (Frumento and Bennett-Guerrero, 2008). When the patient's blood volume mixes with the prime, there is some hemodilution and a subsequent reduction of the hematocrit (Hct) level. Advantages of hemodilution include reducing the number of homologous serum reactions and the incidence of hepatitis and human immunodeficiency virus (HIV) as well as providing better perfusion of the capillary beds because of reduced blood viscosity. Hct levels as low as 25% may be adequate during CPB, but once CPB is terminated, transfusion of red blood cells may be required to enhance the blood's oxygen-carrying capacity. In low-weight, low-hematocrit

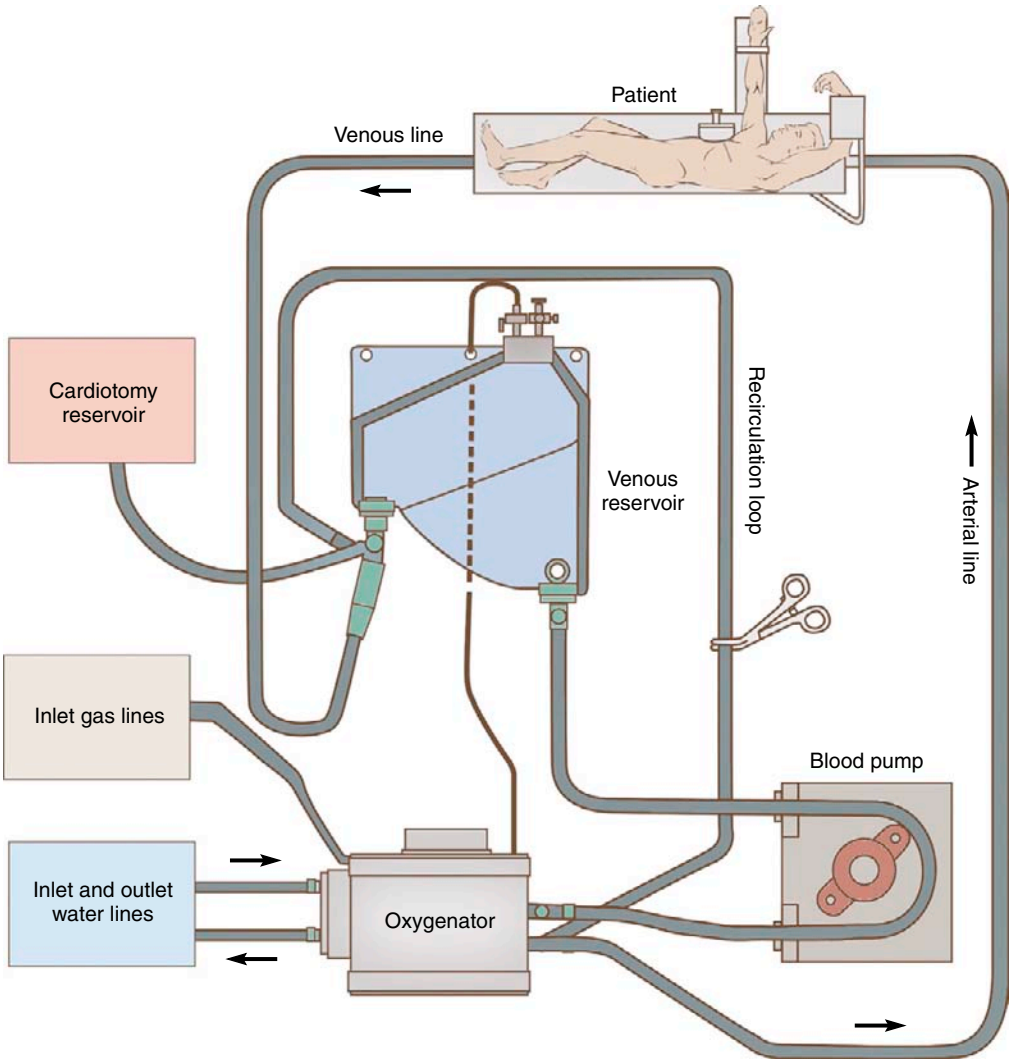

FIGURE 24-39 Cardiopulmonary bypass circuit. Venous blood is drained by gravity from the right atrium or venae cavae into an oxygenator that incorporates a blood reservoir and a heat exchanger, which warms or cools the blood as needed. The ventilating gas flowing into the oxygenator removes carbon dioxide and adds oxygen to the blood. Saturated blood leaves the oxygenator and is pumped from the reservoir into the arterial system by the use of a roller pump. Filters and monitors are incorporated into the circuit. Additional roller pumps are used to suction shed blood from the pericardial well and the intracardiac chambers (cardiotomy suckers); the blood is returned to the cardiotomy reservoir. Another roller pump is used to vent air and blood through a right superior pulmonary venous catheter that is inserted into the left ventricle.

patients, hemodilution may not be tolerated. One method to decrease hemodilution is to employ the technique of *rapid-autologous-prime* (RAP). First, the perfusionist shortens the length of bypass tubing (thereby reducing the volume of prime solution in the CPB circuit). After the surgeon inserts the arterial cannula into the aorta and connects it to the arterial tubing leading to the bypass machine (but before initiation of bypass), the perfusionist allows a predetermined amount of the patient's arterial blood to drain from the line and fill part of the bypass circuit; the perfusionist then clamps the circuit. The clamps are removed at the initiation of bypass (Frumento and Bennett-Guerrero, 2008).

The amount and kind of drugs used in the priming solution vary among institutions, but heparin is routinely added to block clot formation in the bypass circuit. Anticoagulation is routinely monitored during bypass, and more heparin is given as needed to maintain an activated clotting time (ACT) exceeding 600 seconds. Other ingredients are added to maintain normal pH and electrolyte status (Frumento and Bennett-Guerrero, 2008).

Arterial blood flow rates are estimated according to the patient's height, weight, and body surface area. Depending on the arterial and venous pressure values and the results of blood gas determinations, the flow is adjusted.

Myocardial Protection. Improvement in the results of cardiac surgery is attributable in great part to progress made in the protection of the myocardium. Coronary circulatory interruptions, ischemia, and hypoperfusion accompanying induced cardiac arrest are often necessary to permit the surgeon

sufficient time to repair cardiac lesions under direct vision. Unless measures are taken to protect the myocardium during these periods, irreversible damage can result. The main protective strategies are cooling the heart (and the rest of the body) to reduce metabolic demand, rapidly arresting the heart so that myocardial energy resources are preserved, and restoring intracellular homeostasis (e.g., by correcting pH, oxygen, and electrolyte imbalances) to avoid postischemic reperfusion injury (Mentzer et al, 2007).

FIGURE 24-40 Cardiopulmonary bypass pump. Modular system with integrated centrifugal pump driver.

HYPOTHERMIA. Hypothermia in cardiac surgery is the deliberate reduction of body temperature for therapeutic purposes. A moderate degree of hypothermia, to 28° C (82.4° F), permits reduction of oxygen consumption by 50%. At 20° C (68° F) there is a further reduction of about 25%. Systemic circulatory cooling is achieved with the heat exchanger of the heart-lung machine. When very cold temperatures (less than 20° C [68° F]) are desired for myocardial protection in prolonged, complex cases, additional surface cooling of the heart with topical application of cold saline/slush or continuous irrigation of the pericardial wall can be used. Large ice chips in pericardial irrigating fluids should be avoided to prevent injury to the phrenic nerve within the right and left lateral pericardium and other cardiac tissue. Insulation pads placed behind the heart can reduce heat conduction from relatively warmer organs. Transmural cooling of the heart is achieved with cardioplegia (discussed later).

Ventricular fibrillation can occur during the cooling process although it is less likely at temperatures greater than 32° C (89.6° F). Other complications are related to the adverse effects that hypothermia has on coagulation and wound healing; this may delay hemostasis after heparin reversal and have an impact on recuperation (Edmunds, 2004; Mentzer et al, 2007).

CARDIOPLEGIC ARREST. Rapidly arresting the heart during diastole is beneficial because an arrested heart uses less energy than a fibrillating or beating heart. Cardioplegia with hypothermia can reduce energy requirements even further

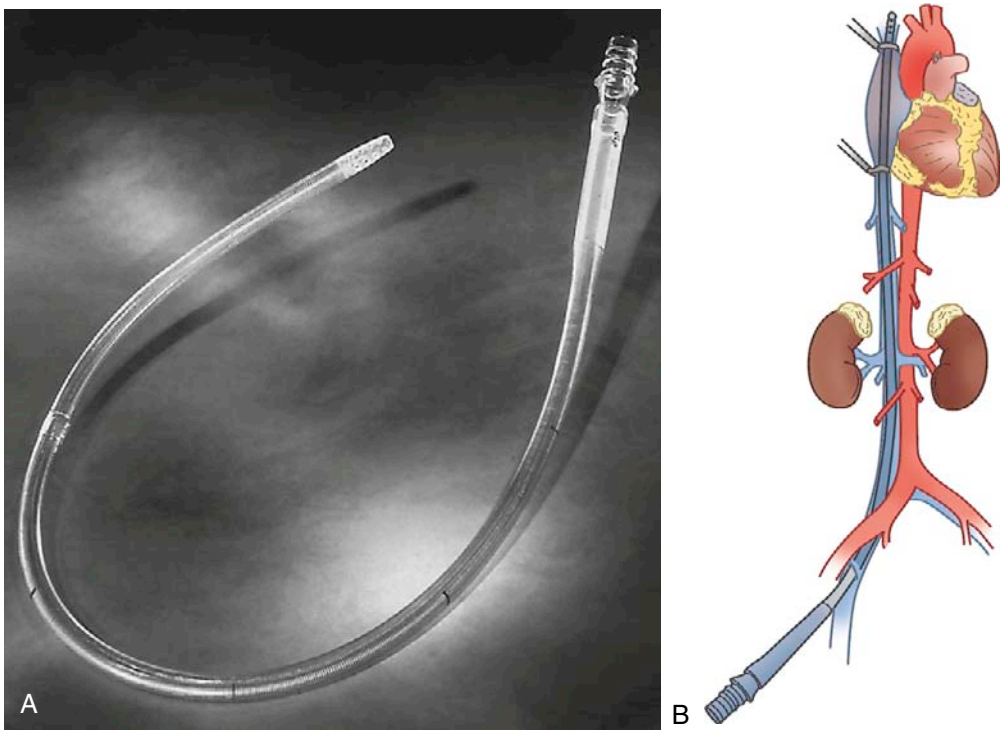

FIGURE 24-41 **A**, Venous endovascular cannula. **B**, The catheter tip is inserted into the femoral vein and threaded to the right atrium; the distal tip is positioned in the superior vena cava (SVC) to drain the upper body.

(Mentzer et al, 2007). Both "warm" and "cold" heart surgery proponents concur that infusing a warm initial bolus of cardioplegia acts as a form of active resuscitation in energy-depleted hearts. There is also concurrence that providing a warm terminal bolus of cardioplegia helps to avoid reperfusion injury (caused by oxygen free radicals and lactic acid buildup) by providing oxygen and other nutrients to the heart. The controversy lies in the use of normothermic ("warm") cardioplegia during the period of arrest when the actual surgical repair or bypass construction occurs. Proponents of warm arrest techniques seek to avoid the complications associated with hypothermia; warm cardioplegia is delivered continuously while the surgical repair is performed (Salerno, 2007). Opponents of continuous warm cardioplegia cite the technical difficulty associated with a constant flow of cardioplegia obscuring the surgical site. Some authors favor intermittent cold cardioplegia infusions because if cardioplegia infusions are even momentarily interrupted to enhance visualization, myocardial protection is jeopardized (Mentzer et al, 2007; Khonsari et al, 2008).

CARDIOPLEGIA DELIVERY. Cardioplegic arrest is accomplished by infusing the coronary arteries with a 4° to 10° C (39.2° to 50° F) solution containing potassium (2 to 50 mEq/L) and buffering agents to counteract ischemic acidosis. Potassium acts by depolarizing the myocardial cell membrane and arresting the heart in diastole.

Delivery of the solution may be by the antegrade or the retrograde route (Figure 24-43). With antegrade delivery, a needle is inserted into the aortic root proximal to the aortic cross-clamp; the cardioplegic solution is infused under pressure that closes the aortic valve leaflets. The only remaining route for the solution is into the right and left coronary arteries and the coronary circulation (see Figure 24-38). If the aortic valve does not close properly, the cardioplegic solution will flow preferentially into the left ventricular chamber, causing distention; in these cases direct cannulation of the coronary ostia is performed. Direct infusion into vein grafts protects the myocardium distal to coronary lesions and enhances transmural cooling. Retrograde infusion is achieved with a catheter placed transatrially into the coronary sinus; the perfusate enters the coronary venous system and flows through the myocardial circulation, leaving through the coronary ostia. The retrograde route is especially useful in the presence of coronary artery obstructions and left ventricular hypertrophy.

When the heart is sufficiently arrested, the ECG reflects a straight line; when electrical activity is noted on the monitor (fine fibrillation), the cardioplegic solution is reinfused when continued cooling is desired (approximately every 15 to 20 minutes).

Minimally invasive techniques for myocardial protection have also been developed (described under Cardioplegic Delivery). Percutaneously inserted catheters can infuse antegrade cardioplegic solution through a catheter threaded into the aortic root; retrograde cardioplegic solution is infused through a catheter inserted into the internal jugular vein and then passed into the SVC, the right atrium, and the coronary sinus.

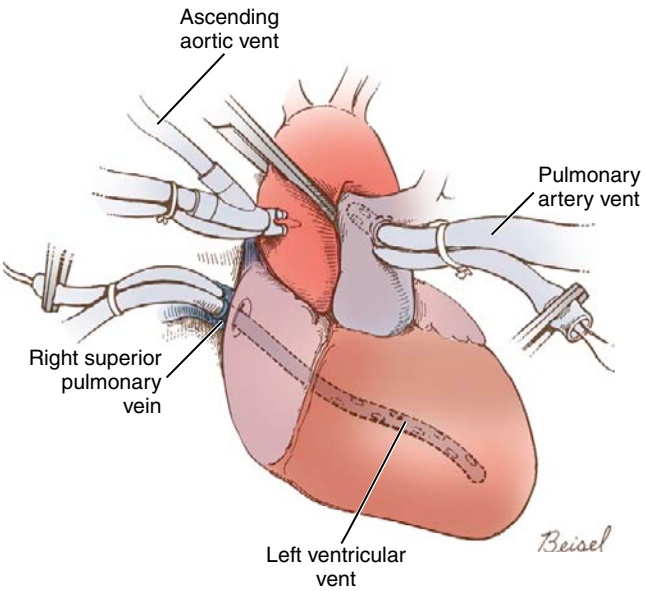

FIGURE 24-42 Types of venting catheters.

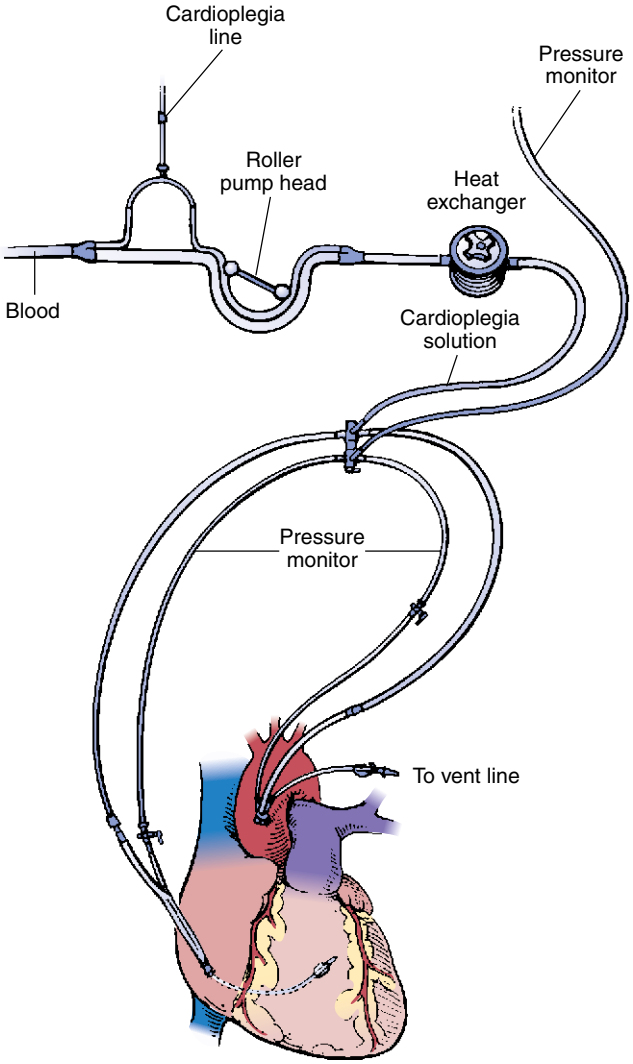

FIGURE 24-43 Antegrade-retrograde cardioplegia system. The antegrade cardioplegia catheter is inserted into the aorta proximally to the cross-clamp; the catheter is Y-ed into a vent line and into the retrograde cardioplegia catheter, which is inserted transatrially into the coronary sinus. The coronary sinus pressure is monitored; its pressure should remain less than 50 mm Hg.

CIRCULATORY ARREST. In some highly complex procedures, such as those involving the aortic arch, it may be impossible to place an occluding clamp across the aorta. In these cases, circulatory arrest may be used to maintain a dry operative site. Because all blood flow will be interrupted, additional protection is required to protect myocardial, cerebral, and other tissue from ischemia.

The patient is cooled with the heat exchanger to approximately 18° C (65° F), at which point the bypass pump is turned off (Pretre and Turina, 2007). The incision is made, and the repair is performed. The small amount of collateral drainage entering the field can be removed with a suction catheter. When the repair is completed, air is removed and CPB is slowly reinstituted. Rewarming is performed at a rate of approximately 1° C every 3 minutes.

CEREBROPLEGIA. Circulatory arrest poses additional risk to the brain. Cerebral protection, cerebroplegia, is provided by the infusion of oxygenated blood to the brain. *Antegrade* cerebral perfusion is achieved with the insertion of cannulae directly into the innominate artery, the right common carotid artery, or another branch of the aortic arch. *Retrograde* cerebral perfusion is accomplished using a cannula that has been Y-ed to the superior vena cava drainage cannula that connects to the arterial infusion line. When blood flow is stopped (during circulatory arrest), the venous line is clamped, the connection to the arterial line is opened, and the retrograde cerebral perfusion line is used to infuse cerebroplegia into the head vessels (Pretre and Turina, 2007). Blood returning from the head (through the carotid or vertebral arteries) is suctioned from the field.

Termination of Cardiopulmonary Bypass. Near the end of the repair, the heart is allowed to rewarm while the perfusionist rewarms the patient systemically with the oxygenator's heat exchanger. Air is evacuated from the left ventricle and the proximal portion of the aorta. The cross-clamp is removed. The heart often converts spontaneously to sinus rhythm, but internal (or external) defibrillation may be necessary. Temporary epicardial pacing wires may be sutured to the right atrial appendage or the right ventricle; these are used postoperatively if the patient has transient bradycardia, supraventricular tachycardia, or other dysrhythmias. Atrial fibrillation (AF) is a common postoperative complication that is associated with a greater risk of embolic events and increases the patient's length of stay (Sethares et al, 2008).

When the heart is contracting, the patient is gradually weaned from CPB. Ventilation of the lungs is restarted. Venous flow is gradually reduced by clamping the venous line or lines, and a commensurate reduction in arterial flow is made by the perfusionist. When heart action is sufficient and systemic and pulmonary blood pressures are stabilized, the bypass is terminated and the cannulae are removed.

Measures to actively promote body heat retention are implemented to enhance clotting mechanisms, immune function, and oxygenation. Maintenance of normothermia after the termination of CPB has also been recommended to reduce the risk of postoperative infection (Savino and Cheung, 2007).

Closing. After hemostasis is achieved, catheters are inserted into the pericardium for mediastinal drainage of shed blood. If either or both pleurae have been entered, chest tubes are inserted to drain shed blood entering from the pericardium and to create negative intrapleural pressure to facilitate lung expansion. The tubes are connected to a water-seal drainage system or an autotransfusion drainage system by using straight or Y connectors. Chest tube drainage of greater than 100 ml/hr requires investigation of possible causes (Sethares et al, 2008). The clinician anticipates possible blood studies to determine whether clotting factors require replacement, hemostasis of anastomoses is present, or bypass conduits require exploration. Reopening the chest may be necessary to control bleeding.

Chest closure in median sternotomy is achieved with wire sutures (see Figure 24-19). The wire sutures are twisted, excess wire is cut, and the wire ends are buried into the sternal periosteum. Some surgeons use small metal crimpers to approximate and hold the wires (rather than twisting and burying the wire ends). In a frail sternum, a long sternal closing wire may be threaded longitudinally along the right and left lateral margins of the sternum; the crossed sternal wires are inserted through the longitudinal wires and then approximated to close the sternum. This reinforces the sternal closure and reduces the possibility of sternal dehiscence. In some thin patients with little subcutaneous tissue over the sternum, one (or more) of the sternal wires may continue to cause discomfort after the sternum has fully healed. In these patients the surgeon may elect to remove the wire as an ambulatory (outpatient) procedure (Ambulatory Surgery Considerations).

The linea alba is closed with suture. A layer of sutures is placed to approximate the fascia over the sternum; the subcutaneous tissue and skin are closed. If metal staples are used on the skin, a staple remover should accompany the patient to the recovery area. Thoracotomy incisions are closed in standard fashion.

Before transferring the patient, the perioperative nurse telephones a report to the recovery area, usually the cardiovascular SICU. Figure 24-44 lists information commonly supplied. The patient's special concerns and fears as well as significant physiologic alterations should be communicated.

Perioperative documentation follows the standard protocol and includes a description of the procedure performed and identification of medications and all implanted material (with lot and serial numbers). Hospital policy should be followed to ensure compliance with the Safe Medical Devices Act.

AMBULATORY SURGERY CONSIDERATIONS

Removal of Sternal Wire

Ambulatory surgery patients undergoing removal of one or more sternal wires are placed in the supine position. Monitoring generally consists of an electrocardiogram and pulse oximetry. Anesthesia may be "straight local" or monitored anesthesia care. The anterior chest is prepped and draped, and the surgeon may inject a local anesthetic over the skin covering the sternal wire. A small incision is made over the wire and the tissue and adjacent adhesions are divided. The wire is cut with a wire cutter and the wire is removed with a heavy needle holder. Hemostasis is achieved, the incision is closed, and dressings are applied. After a short period in the PACU or other recovery area, the patient is discharged.

Postoperatively, complications associated with cardiac surgery are outlined in Table 24-7. Excessive or sudden hemorrhage producing cardiac tamponade may initiate the need for a rapid response team to control the hemorrhage and achieve hemostasis.

Evaluation

Evaluation of perioperative care includes the determination of whether the patient met the outcomes identified in the plan of care. Such evaluation assists perioperative nurses to determine whether the nursing interventions designed for a specific patient were successful. This type of data collection becomes the basis of the development of future plans of care for similar patients. Evaluation should be documented in the perioperative record. For the nursing diagnoses and the subsequent plan of care presented in this chapter for the cardiac surgery patient, outcome statements might be as follows:

- The patient's cardiac function was consistent with or improved from baseline levels established preoperatively as evidenced by blood pressure within expected range; warm, dry skin; and urine output more than 30 ml/hr.
- The patient will be free from signs and symptoms of infection at the surgical site or sites as evidenced by absence of redness, edema, purulent incisional drainage, or untoward elevation of temperature postoperatively.
- The patient was free from signs and symptoms of injury related to surgical position as evidenced by the absence of acquired neuromuscular impairment and tissue necrosis.

TABLE 24-7

Complications of Cardiac Surgery

Body System	Complication	Treatment Measures
Cardiovascular	Bleeding	Transfusion Replacement of clotting factors Control of hypertension Maintenance of normothermia Possible return to OR for exploration and hemostasis
	Cardiac tamponade	Release of constricting blood via chest tube insertion or operative exploration
	Myocardial ischemia/infarction	Monitor ECG for ischemic changes Measure serum enzymes Minimize oxygen demand Administer medications to reduce cardiac workload and dysrhythmias Insertion of an IABP
	Dysrhythmias	Administer antidysrhythmic drugs Correct electrolyte imbalances Correct acid-base, hypovolemia Employ pacemaker therapy Cardiovert or defibrillate as necessary Maintain adequate CO
Pulmonary	Hemothorax/pneumothorax	Maintain chest tube patency Check chest tubes for air leaks Insert additional chest tube (pleural or mediastinal)
	Atelectasis/pneumonia	Check ventilator settings and endotracheal tube Suction endotracheal tube Monitor breath sounds Monitor pulse oximetry Obtain chest x-ray film Elevate head of bed Ensure proper function of NG tube After extubation, encourage mobilization and use of incentive spirometry Frequent staff handwashing
	Pulmonary embolus	Frequent patient mouth care Employ compression stockings Assess for acute chest pain and SOB Perform radiologic examination Possible surgical embolectomy
	Failure to wean from ventilator	Maintain aggressive pulmonary toilet Monitor pulse oximetry Frequent mobilization (even while on ventilator) Pain and anxiety management Incentive spirometry once extubated Possible tracheostomy
Kidneys	Renal insufficiency/failure	Promote adequate CO, renal perfusion Monitor urine output Diuretics for oliguria Administer volume (vs. drugs) to increase renal perfusion Possible dialysis
Gastrointestinal (GI)	Ileus	Assess bowel sounds and distention Maintain NG tube function Progress diet slowly
	GI bleeding	Maintain NG tube function to differentiate upper and lower GI bleeding Stress ulcer prophylaxis Monitor complaints of nausea Use extra caution with anticoagulants
Neurologic	Stroke	Avoid hypotension Assess neurologic function Restart preoperative antidepressant drugs
	Neurocognitive dysfunction/ postcardiotomy delirium	Avoid hypoperfusion Correct metabolic derangements Avoid hypoxemia Orient frequently to time and place Discontinue medications that may promote delirium Ensure a safe environment

TABLE 24-7

Complications of Cardiac Surgery—cont'd

Body System	Complication	Treatment Measures
Immune	Nosocomial infection	Frequent staff hand cleansing Strict aseptic technique Dressing care, urinary catheter care Early removal of central lines, urinary catheters, chest tubes Administer antibiotics
	Mediastinitis	Strict aseptic technique Administration of antibiotics
Metabolic	Hyper/hypoglycemia	Limited blood transfusion Glucose (hyperglycemic) control Possible return to OR for debridement and muscle flap repair Avoid hyperglycemia (maintain glucose at less than 200 mg/dl) Avoid hypoglycemia Monitor for potential rebound from insulin administered during surgery

CO, Cardiac output; *ECG,* electrocardiogram; *IABP,* intra-aortic balloon pump; *NG,* nasogastric; *OR,* operating room; *SOB,* shortness of breath.
Modified from Sethares K et al: Care of patients undergoing cardiac surgery. In Moser DK, Riegel B, editors: *Cardiac nursing: a companion to Braunwald's heart disease,* St Louis, 2008, Saunders; Gray RJ, Sethna DH: Medical management of the patient undergoing cardiac surgery. In Libby P et al, editors: *Braunwald's heart disease,* ed 8, Philadelphia, 2008, Saunders; Babb M: Clinical risk assessment: identifying patients at high risk for heart failure, *AORN J* 89(2):273-288, 2009.

- The patient was free from excessive bleeding as evidenced by chest tube drainage less than 100 ml/hr, dressings dry and intact, normal coagulation function studies (or undergoing replacement treatment for deficient clotting factors), and normal body temperature.
- The patient demonstrated knowledge of the physiologic responses to the cardiac disorder (at his or her level of understanding), the proposed surgical treatment, and the immediate perioperative events as evidenced by verbalization of disease state, purpose of surgery, sequence of events, anticipated outcomes, and recovery process.
- The patient's myocardial, peripheral, and cerebral tissue integrity was adequate: there were no new electrocardiographic manifestations of infarction, peripheral pulses were palpable, and his/her sensorium was improving after extubation in the OR.

Patient and Family Education and Discharge Planning

Many patients are admitted to the cardiac service on the day of surgery; teaching sessions can be scheduled before admission along with preoperative laboratory testing. Perioperative nurses should include details about the surgical procedure, sights and sounds that the patient may sense, and anesthesia care. With hospital length of stay shortened from 1 week or more to 3 to 5 days, patient education and preparation for home care maintenance has become even more critical for enhancing positive patient outcomes. The perioperative nurse acts to reinforce, review, clarify, and add to important information and instructions the patient and family or significant others need in planning for surgery, recovery, and discharge. Although patients undergoing repeat operations have had experience with cardiac surgery, they still have significant learning needs because changes in their own disease, alterations in surgical techniques, and the introduction of newer devices alter the expectations of patients (Setheres et al, 2008). Published articles about innovative endovascular thoracic repairs (Thompson and Bertling, 2009) as well as procedures becoming increasingly common, such as endoscopic vein harvesting (Pear and Williamson, 2009), are valuable resources. The *AORN Journal* initiated a "Patient Education" page to accompany many clinical articles in order to assist perioperative nurses in their cardiovascular patient teaching activities (see Thompson and Bertling, 2009; Tinkham, 2009; Cherry et al, 2009). The *Journal of the American Medical Association* (JAMA, 2009) offers a patient education page. Another area of intense patient interest is minimally invasive surgery and comparisons of "on-pump" and "off-pump" techniques (Patient and Family Education).

Additional resources (electronic, peer support) can supplement traditional education strategies. An expanding array of internet sites developed by professional organizations can be accessed for examples of patient information. The American College of Surgeons (ACS, 2009a,b), the American Heart Association (AHA, 2009b,c), the American Society of Anesthesiologists (ASA, 2009), and the Society of Thoracic Surgeons (STS, 2009) all have cardiac-related information for consumers as well as staff. Support groups such as The Mended Hearts (www.mendedhearts.org/) provide education, support, and social networking among cardiac surgical patients. Electronic mail (e-mail) is an increasingly popular form of communication between patients and caregivers and some cardiac surgical practice groups as well as healthcare institutions have interactive web sites.

In addition to specific information about the perioperative period, the cardiac patient's preoperative state of mind may be a significant factor. Depression and anxiety are associated with major adverse cardiac events (MACE) such as myocardial infarction, cardiac arrest, or cardiac death (Frasure-Smith and Lesperance, 2008). Halpin and Barnett (2005) showed that a negative (i.e., pessimistic) state of mind (compared with an optimistic state) may be predictive of an increased length of stay, increased possibility of stroke, and prolonged ventilation time. Having the patient complete a preoperative mental health status questionnaire, or being aware of the results of a previously completed questionnaire, can provide insight into the patient's frame of mind and serve as an opportunity to alter

PATIENT AND FAMILY EDUCATION

Patient Teaching Considerations for Minimally Invasive Surgery (On/Off Pump)

	Beating Heart/Off-Pump	Arrested Heart/On-Pump
Definition	CABG without CPB or induced cardiac arrest; HR and contractile force may be pharmacologically reduced; stabilizer used at anastomotic site; apical retractor used to expose lateral and posterior coronary arteries	CABG with CPB and endovascular technique for CPB and induced cardiac arrest
Indications	Multiple-vessel disease, angioplasty contraindicated, medical problems, poor anatomy, accessible target arteries, previous CABG with blocked grafts	Multiple-vessel disease, angioplasty contraindicated, need to stop heart to enhance technical precision, accessible target arteries, valve or other cardiac disease requiring entry into a heart chamber
Contraindications	Intramyocardial lesions, hemodynamic instability	Highly complex lesions, posterior targets
Incisions	Sternotomy or mini-sternotomy (cephalad or caudad); 1-3 small right or left rib or submammary incisions	1-4 small rib incisions, 1 or 2 groin incisions, 1 or 2 neck incisions
CPB	No, available on standby	Yes
Cardioplegia	No	Yes
Procedure time	2 hr or more	2 hr or more
Hospital LOS	2-5 days (vs 4-6 for sternotomy)	3-5 days (vs 4-6 for sternotomy)
Advantages	Avoids CPB, ischemic arrest, and hypothermia; may enable more complete revascularization with postoperative insertion of intracoronary stents into posterolateral coronary arteries in cardiac catheterization laboratory ("hybrid" procedure); may reduce MACE in patients with LMD	Allows repair of more complex lesions without technical challenge of a moving heart; better able to produce more complete revascularization; significantly reduces air embolism as a result of opening cardiac chambers
Potential complications and disadvantages	Learning curve technically more challenging; may cause VF; may have to revert to standard sternotomy with CPB and induced arrest	Learning curve technically more challenging; may have to revert to standard sternotomy; potential for endovascular injury to cannulated blood vessels
Discharge planning	Anticipated faster recovery of 1-2 wk (vs 4-12 wk for sternotomy), earlier ambulation, need to identify reportable signs and symptoms (angina, difficulty breathing, infection)	Anticipated faster recovery of 1-2 wk (vs 4-12 wk for sternotomy), earlier ambulation, need to identify reportable signs and symptoms (angina, difficulty breathing, infection)

CABG, Coronary artery bypass grafting; *CPB,* cardiopulmonary bypass; *HR,* heart rate; *LMD,* left main coronary artery disease; *LOS,* length of stay; *MACE,* major adverse cardiac events; *VF,* ventricular fibrillation.

Modified from Sarin EL et al: Off-pump coronary bypass grafting is associated with reduced operative mortality and in-hospital adverse events in patients with left main coronary artery disease, *Innovations* 4(2):80-85, 2009; Verma S et al: Off-pump coronary artery bypass surgery, *Circulation* 109:1206-1211, 2004.

pessimistic attitudes amenable to conversion to a more positive state of mind. Patient attitudes also may be affected by the anticipation of pain and the hesitation to complain of pain or request pain medication. Perioperative nurses can anticipate those fears and encourage patients to ask for pain medications in order to facilitate early postoperative ambulation, deep breathing and coughing, and other activities that promote recovery.

Specific information may be required. Patients undergoing prosthetic (i.e., mechanical) valve replacement can expect to require long-term anticoagulation therapy. Important information includes drug dosage, reportable signs and symptoms of complications and side effects (e.g., bleeding, poor healing), and a follow-up protocol for monitoring bleeding times.

The patient's ability to cough and breathe deeply should be determined; the patient should be instructed to use a cough pillow or splinting techniques. Required lifestyle changes should be reviewed and the patient's feelings about these modifications elicited. The perioperative nurse should verify that the patient knows reportable signs and symptoms associated with the specific procedure and understands prescribed medications, including medication dosages, potential side effects, and signs and symptoms of complications (see Table 24-7). Any misconceptions should be clarified or referred to an appropriate source. The family or significant others' ability and willingness to assist the patient in home care maintenance should be queried; referrals to an agency for assistance at home may be required.

Quality of life is an important goal for patients. Although objective measures are often used by clinicians to determine the patient's level of satisfaction with the quality of care received, measuring the patient's quality of life experienced after surgery has been largely limited to evaluating angina relief and return to work. However, other important variables may reflect quality of life, and nurses can assist patients with recovery and recuperation by incorporating these variables into the discharge plan. Quality of life for family caregivers also needs to be considered because with shortened lengths of stay, patients increasingly depend on others to assist them in the recuperative process. Support for caregivers is an important adjunct

RESEARCH HIGHLIGHT

Perioperative Nurse Postoperative Visits

Since 2001 perioperative cardiac nurses at a hospital in Orebro, Sweden, have made postoperative visits to cardiac surgical patients. A prospective exploratory study (N = 74 patients) was designed to evaluate the quality of the postoperative follow-up and to determine if the quality of the visit was related to gender or type of admission. The measurement instrument contained 16 items designed to elicit patients' perception of quality. There were statistically significant higher scores measuring quality in patients who had undergone emergency surgery compared with patients having elective surgery (e.g., coronary artery bypass grafting, valve surgery, aortic dissection repair). The postoperative follow-up visit by the perioperative nurse was perceived to be valuable by patients, especially by those who had undergone emergency surgery.

Compared to men, women rated a significantly higher quality score in two items:

1. "I had [the] possibility to see and feel material used during a heart operation, as an example, sternum suture, mechanical valve, and graft suture" (p. 108).
2. "I had satisfactory information about the technical equipment used at the operation, as an example, the heart-lung machine" (p. 108).

Both men and women assigned high scores to experiencing respect and seriousness and having a meaningful postoperative follow-up visit by the theatre (i.e., perioperative) nurse.

The study authors suggest that a caring relationship is established during the follow-up visit as a result of meeting the patient as an individual with his/her own experience, and meeting patients' desire for information about the pre-, intra- and postoperative periods of the surgery. Perioperative nurses should employ drawings and "props" (such as mechanical heart valves, suture, and short sections of bypass tubing) to supplement their teaching. This study reinforces the value of postoperative visits to cardiac surgical patients by perioperative nurses.

Adapted from Falk-Brynhildsen K, Nilsson U: Cardiac surgery patients' evaluation of the quality of theatre nurse postoperative follow-up visit, *Eur J Cardiovasc Nurs* 8(2):105-111, 2009.

in the patient's recovery. Nurses can help patients set realistic postoperative goals and develop strategies for appropriate lifestyle changes. The subjective perceptions of patients usually accurately reflect the patient's quality of life. At times when the quality of life is perceived as suboptimal (e.g., during a difficult recuperative period), the nurse can reassure patients that physical, emotional, and psychologic improvement is a progressive process (Dickson and McMahon, 2008; Seifert, 2008).

A patient's perception and the clinical indications for treatment may not be congruent but clinicians should recognize that the patient's definition of "quality of life" should be investigated and addressed whenever feasible. Postoperative visits can elicit patient needs (Falk-Brynhildsen and Nilsson, 2009) (Research Highlight). In some individuals who have little tissue covering the sternum, one or more chest wires may become a significant irritation following complete sternal healing. Patients may constantly rub the tissue over the wire, increasing risk for injury to the skin and subcutaneous tissue. As previously noted, removal of the irritating chest wire can be performed on an ambulatory basis (see Ambulatory Surgery Considerations). Although there are relatively few ambulatory procedures related to cardiac surgery, nurses should be as sensitive to relatively "minor" patient concerns as they are to the more serious problems jeopardizing hemodynamic stability.

Surgical Interventions

The following section describes operations for acquired forms of heart disease. Both traditional "open" procedures and minimally invasive techniques are described. Traditional procedures are performed through a median sternotomy incision using aortocaval CPB (see Figures 24-37 and 24-38) and antegrade-retrograde cardioplegia (see Figure 24-43) with routine chest drainage and closure. Minimally invasive procedures are described for CPB, saphenous vein harvesting, coronary artery bypass grafting, atrial fibrillation, and MVR. These procedures may be performed through a median sternotomy or an anterior left or right thoracotomy; some lesions may be approached through a cephalad or caudal mini-sternotomy.

EXTRACORPOREAL CIRCULATION PROCEDURES

Operative Procedures

Aortic-Caval Cannulation by Way of Sternotomy

1. A longitudinal pericardial incision is made, and the pericardial edges are retracted by suture to the chest wall.
2. If the aorta is to be cannulated for arterial blood return to the patient, it is partially dissected from the pulmonary artery.
3. Purse-string sutures are placed in the aorta (twice) and right atrium (or both venae cavae) for the eventual placement of the perfusion cannulae. Tourniquets are placed over the suture ends and held with a hemostat.
4. For ascending aortic cannulation, the aorta is incised inside the purse-string sutures with a knife (the surgeon places a finger over the aortotomy); the cannula is inserted, and the purse-string sutures are firmly secured with the tourniquet. It is important to have the distal end of the cannula clamped before it is inserted into the aorta to prevent backbleeding from the aorta. To prevent air emboli, the arterial connection is made under a saline drip, or by having the perfusionist slowly pump priming solution out of the arterial line. Arterial cannulation is generally performed before caval cannulation so that direct access for blood replacement is available if needed.
5. Venous cannulation is performed in one of the following ways:
   a. Single, two-stage cannulation for venous return to the pump-oxygenator: An incision is made into the right atrial appendage and the two-stage cannula (see Figure 24-38) is inserted into the atrium. The distal end of the

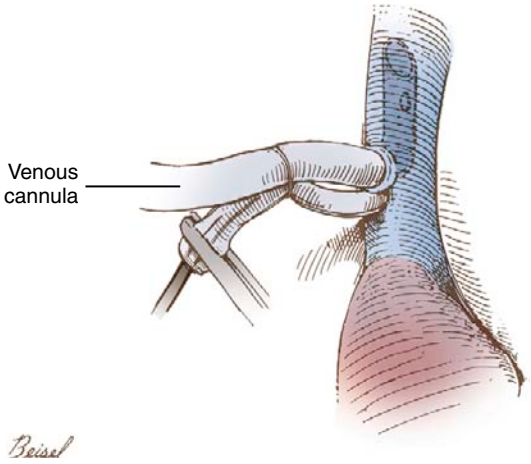

FIGURE 24-45 Right-angle cannula in superior vena cava.

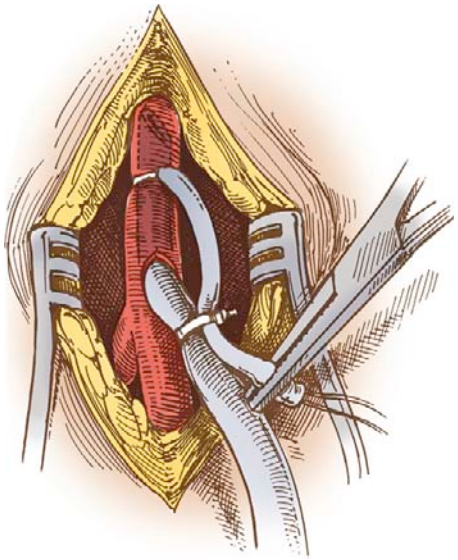

FIGURE 24-46 Cannulation of femoral artery.

cannula is placed into the inferior vena cava (IVC). The purse-string suture is secured with a tourniquet, and the catheter is permitted to fill partially with blood before being connected to the venous line.

b. Double cannulation: For double cannulation, a second incision is made into the atrial wall within the purse-string suture and the cannulae are placed in the inferior and superior venae cavae (see Figure 24-37). To force all venous return into the cannulae, umbilical tapes with tourniquets may be placed around each cava and then tightened. This forces systemic venous return to enter the cannulae, producing total CPB (see Figure 24-42).

6. In procedures where greater exposure of the right atrium is required (e.g., tricuspid valve surgery, closure of atrial septal defects in adults), a right-angle cannula may be inserted into the SVC (Figure 24-45).

Femoral Vein–Femoral Artery Cannulation

1. A vertical or oblique incision is made into the femoral triangle, and the femoral vein and artery are exposed. Umbilical compression tapes are passed around the vessels above and below the proposed venotomy and arteriotomy. Vascular clamps may be applied above and below the incision into each vessel.
2. A purse-string suture is placed in the femoral artery. A needle is inserted into the artery, followed by a guidewire. The needle is removed, and dilators are threaded over the guidewire to enlarge the artery. The dilators are removed, and the perfusion catheter (occluded distally with a tubing clamp) is inserted retrograde into the arteriotomy as the proximal clamp or tourniquet is released. The proximal tourniquet is tightened (Figure 24-46). The cannula is connected to the arterial line.
3. An incision is made into the femoral vein, and the venous catheter is inserted into the vein as the proximal clamp or tourniquet is released. After the cannula is in place, the proximal tourniquet is tightened to prevent bleeding from the venotomy. The cannula is occluded at the distal end with a tubing clamp to prevent bleeding from the cannula. The cannula is connected to the venous line, and the tubing clamp is removed.

MINIMALLY INVASIVE CANNULATION. Femoral cannulation techniques are employed. Femoral arterial cannulation is as just described. Venous drainage is achieved with an extended catheter inserted into the exposed femoral vein, and the distal tip is advanced to the SVC to the inferior portion of the RA (see Figure 24-41). Side ports along the distal portion of the cannula allow drainage of blood from the SVC, the right atrium, and the IVC. Because of the higher resistance to drainage flow compared with right atrial cannulation, a centrifugal pump or vacuum-assisted drainage incorporated in the CPB circuit is used to augment venous drainage.

PUMP-OXYGENATOR PREPARATION. After the arterial and venous connections are completed and the lines secured, bypass is slowly begun and the desired flow rate is gradually achieved. Arterial infusion is calibrated to match venous outflow in order to maintain a consistent cardiac output and blood volume. Perfusion flow is adjusted as necessary during the operation (Mongero and Beck, 2008).

Axillary Artery Cannulation. Although infrequently used for arterial perfusion, the right axillary artery (AA) is a useful cannulation site when circulatory arrest is necessary for surgery on the aorta. Another indication for its use occurs in the presence of acute or chronic aortic dissection when retrograde flow through the femoral artery may produce femoral artery dissection and malperfusion of the central organs (e.g., the kidneys). The AA is usually free of atherosclerosis and has excellent collateral flow from the thyrocervical trunk to the suprascapular and transverse cervical arteries, which helps to avoid upper extremity ischemia during cross-clamping (Kokotsakis et al, 2005). Use of the AA also facilitates antegrade cerebral perfusion during hypothermic arrest. The artery can be cannulated directly, but the risk of dissection favors indirect cannulation via an 8-mm to 10-mm Dacron tube graft anastomosed to the artery (Khonsari et al, 2008; Kokotsakis et al, 2005).

The patient is positioned supine with a roll under the shoulders to enhance access to the artery; the OR bed may be tilted

PATIENT SAFETY

Patient Safety Considerations for Axillary Artery Cannulation

During high-risk, low-volume procedures, such as axillary artery (AA) cannulation, less frequently encountered patient safety factors should be scrutinized with care. These factors include understanding the purpose and plan for the procedure, having the necessary supplies, anticipating possible complications, and preparing for alternate techniques. The considerations listed are pertinent to the use of the axillary artery.

BLOOD PRESSURE (BP) MONITORING

- Use bilateral radial artery BP lines to compare right- and left-sided pressures and to confirm the absence of a pressure gradient.
- Use a right radial artery line to monitor antegrade cerebral perfusion during hypothermic arrest.
- Cerebral perfusion pressure should be kept at 50 mm Hg (or less).

PREVENTION OF INJURY TO BRACHIAL PLEXUS

- Traction and manipulation should be avoided.
- Do not use electrosurgical energy in area of brachial plexus.

CANNULATION

- Ensure absence of preexisting dissection in *axillary* artery when *aortic* dissection is present.
- There is increased risk of dissection with *direct* cannulation of axillary artery; attachment of tube graft for *indirect* cannulation is often performed.
- During cardiopulmonary bypass (CPB) the BP tends to be higher on the side of the arterial (axillary) cannulation; contralateral BP line should be used for monitoring.
- Known, severe atherosclerosis of the axillary artery is a contraindication to its use.

AVOIDANCE OF VASCULAR INJURY

- Closing the artery after completion of CPB should avoid narrowing the arterial lumen; the graft can be cut in a way that does not impinge on the vessel lumen and also does not leave residual graft material, which can allow stasis of blood and increase the risk for thromboembolus.

HEMOSTASIS

- If metal ligating clips are used to close the graft, ensure proper function of the clip applier.

Adapted from Khonsari S et al: *Cardiac surgery: safeguards and pitfalls in operative technique,* ed 4, Philadelphia, 2008, Lippincott Williams & Wilkins; Kokotsakis J et al: Right axillary artery cannulation: surgical management of the hostile ascending aorta, *Texas Heart Inst J* 32(2):189-193, 2005.

to the left for better exposure of the artery during cannulation. The right arm may be positioned next to the body with the elbow flexed slightly; the arm may be extended in some procedures, depending on surgeon preference. Additional patient safety considerations are listed in the Patient Safety box.

CANNULATION PROCEDURE

1. The right axillary (or subclavian) artery is exposed via a small incision below and parallel to the midportion of the right clavicle. The tissue is dissected toward the insertion of the pectoralis minor muscle and the deltopectoral groove; the pectoralis major muscle is dissected and divided, and the axillary vein and underlying artery are exposed and gently mobilized for about 2 cm.
2. The brachial plexus is located (cephalad to the vessels); manipulation is avoided to protect the plexus during cannulation and the operative procedure.
3. A partial occlusion clamp is applied to the artery and an 8-mm to 10-mm Dacron tube graft is anastomosed end-to-side to the artery with 4-0 or 5-0 polypropylene suture.
4. A straight arterial cannula is inserted through the graft and a heavy silk tie or umbilical tape is tied around the graft over the cannula to prevent bleeding.
5. Arterial flow is slowly initiated. Blood pressures via both the right and left radial arteries are compared to confirm the absence of a pressure gradient; after confirmation, arterial flow is increased to the initial desired rate of 2.2 to 2.8 L/min/m^2.
6. Completion of bypass and removal of the AA cannula: After CPB has been discontinued, the arterial cannula is gradually withdrawn and the AA graft is clamped (or ligated with two large metal clips); the graft is cut a few millimeters above the artery and oversewn with polypropylene suture. The surgeon is careful to avoid narrowing the AA or leaving a graft "stump" (which could become a source of emboli) during closure (Khonsari et al, 2008; Kokotsakis et al, 2005).

Cardioplegic Delivery

ANTEGRADE CARDIOPLEGIA. A purse-string suture and tourniquet are placed into the anterior ascending aorta proximal to the aortic cross-clamp, and a needle-tipped catheter is inserted. Both the catheter and the cardioplegic tubing are flushed to remove residual air. The catheter tubing is Y-ed into a vent line so that alternatively the needle can be used to infuse the cardioplegic solution into the aortic root or vent air and blood from the aorta and left ventricle. Individual lines incorporated into the antegrade infusion system can be used to selectively infuse the coronary bypass graft or grafts. Handheld cardioplegic cannulae may be used to infuse cardioplegic solution directly into the coronary ostia, but the risk of injuring ostial tissue usually favors this technique when retrograde delivery cannot be achieved.

RETROGRADE CARDIOPLEGIA. A purse-string suture is placed into the lateral wall of the right atrium, and a tourniquet is applied to the suture. A stab wound is made into the atrium, and the retrograde catheter is inserted and palpated into the coronary sinus. Blood is aspirated from the catheter, and the catheter is connected to the flushed retrograde infusion line and to a pressure line. Infusion pressure should be between 20 and 45 mm Hg (Khonsari et al, 2008). Because a full right atrium facilitates insertion of the catheter, insertion is performed before the initiation of CPB when possible. If the patient is already on CPB, the surgeon can fill the atrium by clamping the venous drainage line momentarily, thereby diverting blood into the heart.

MINIMALLY INVASIVE ENDOVASCULAR ANTEGRADE-RETROGRADE CARDIOPLEGIA. A system of endovascular multilumen catheters designed to infuse solutions, vent air and blood, measure intravascular pressures, and occlude the aorta may be used (Figure 24-47). Fluoroscopy or TEE can be employed to confirm proper catheter placement.

The intravascular aortic catheter has three lumens. The first lumen has an inflatable balloon at the tip that, when inflated inside the vessel, occludes the aorta and serves as an internal "cross-clamp." The second lumen can be used either to infuse antegrade cardioplegic solution or to vent the ventricle. The third lumen is used to measure aortic root pressure. The catheter is introduced into the femoral artery and advanced into the ascending aorta. Either the femoral artery used for arterial inflow or the contralateral femoral artery is used.

A triple-lumen coronary sinus retrograde cardioplegic catheter is inserted percutaneously through the jugular vein into the SVC. The catheter is guided into the coronary sinus under fluoroscopy. One lumen allows manual catheter balloon inflation; another lumen is used to infuse retroplegic solution; and the third lumen measures coronary sinus pressure.

A third catheter is used as a venting-and-decompression device. It is inserted into the jugular vein (through a separate sheath from the retrograde catheter) and advanced into the main pulmonary artery.

These catheter systems allow surgeons to use minimally invasive techniques to treat lesions, such as mitral valve stenosis, that cannot be performed safely with a beating heart.

Termination of Cardiopulmonary Bypass

1. After the intracardiac procedure has been completed, all air is evacuated from the left ventricle. A warm dose of cardioplegic solution may be given, after which the cross-clamp is removed. The warm solution dilates the coronary vascular bed and enhances coronary perfusion once the cross-clamp is removed.
2. Defibrillation is often spontaneous with removal of the aortic cross-clamp and the entry of warm blood into the coronary circulation. If not, internal defibrillation is necessary. Endovascular, minimally invasive procedures will require external defibrillation with sterile external paddles or patches. Temporary epicardial pacing wires attached to the atrium and to the ventricle are used to adjust the heart rate and optimize cardiac output.
3. Venous flow to the pump is reduced. Arterial flow is also reduced to equal the reduced venous return. When heart action is sufficient and systemic arterial blood pressure is stabilized, venous return is further reduced and the patient is taken off bypass by clamping all lines and stopping the pump.
4. As the cannulation catheters are removed, the purse-string sutures are tightened and tied. Additional sutures may be required for hemostasis.
5. Chest tubes are inserted into the pericardium (and the pleural cavity if the pleura has been opened).
6. Protamine sulfate, a heparin antagonist, is administered.
7. The pericardium is usually left open so that accumulating drainage does not produce cardiac tamponade.

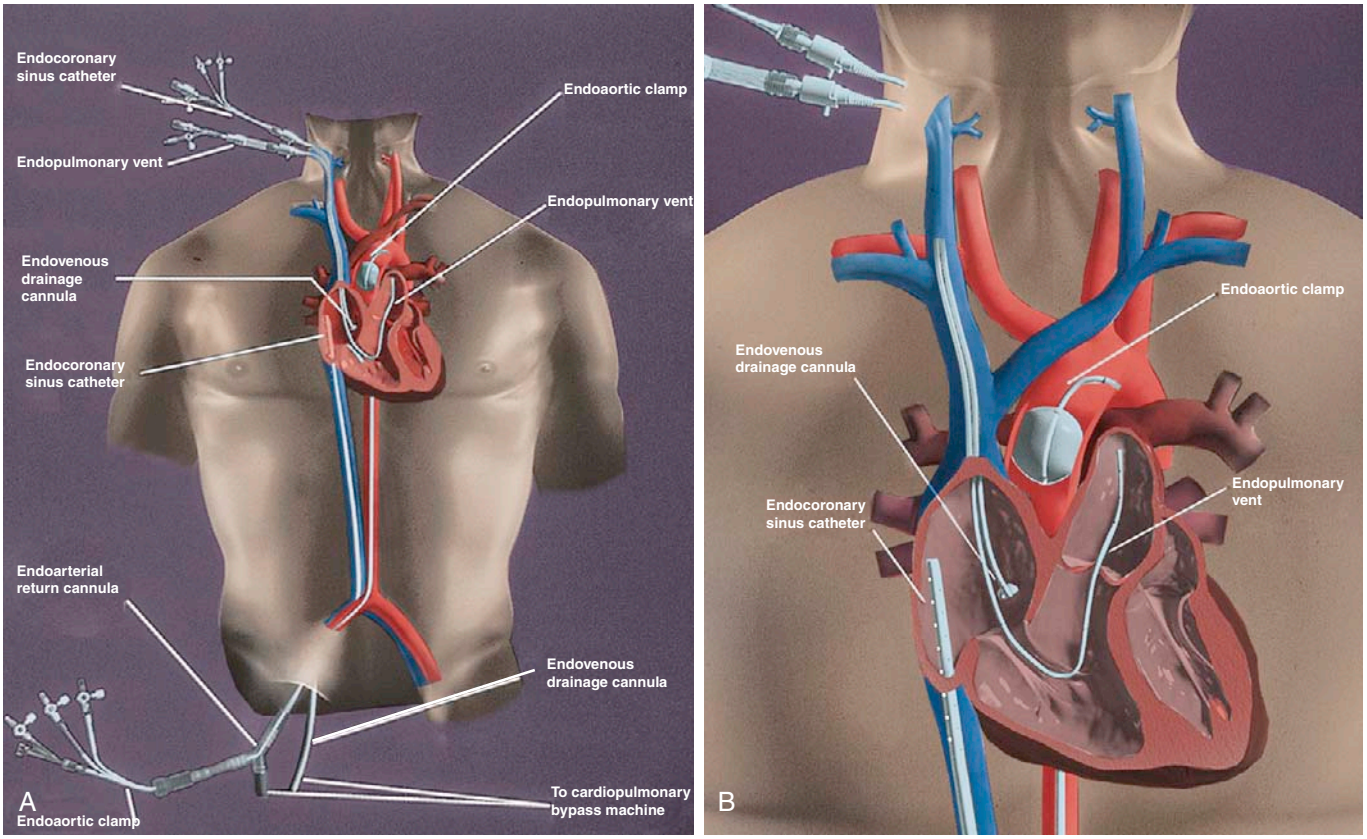

FIGURE 24-47 **A**, Endovascular cardiopulmonary bypass and myocardial protection system (see text). **B**, Intracardiac placement of catheters.

Closure of Femoral Incisions

1. The femoral catheters are removed, and the arteriotomies are closed with nonabsorbable cardiovascular suture. Compression tapes and bulldog clamps, if used, are removed.
2. The incision is closed with absorbable sutures, and the skin is closed with interrupted or continuous sutures.
3. Dressings are applied to all incisions.

PERICARDIECTOMY

Pericardiectomy is the partial excision of the adhered, thickened fibrotic pericardium to relieve constriction of compressed heart and large blood vessels. The adhered portions of the scarred, thickened pericardium restrict diastolic filling and myocardial contractility. As the pericardial space is obliterated and calcification of the pericardium occurs, the heart is further compressed. Ascites, elevated venous pressure, decreased arterial pressure, edema, and hepatic enlargement result. In most patients the etiology is unknown although there are documented cases caused by chronic pericarditis, which may be of tubercular, rheumatic, viral, or neoplastic origin. Either the supine position or the left lateral position may be used for a left anterolateral thoracotomy (Lachman et al, 2009; Kouchoukos et al, 2003).

Procedural Considerations

The use of CPB is rare, but it may be requested on a standby basis. The supplies and instruments for bypass should be available.

Operative Procedure

1. The lungs are hypoinflated to enhance exposure of the heart. The right and left phrenic nerves are identified and carefully protected. The pericardium is incised.
2. The outer, thickened pericardium is removed as indicated. Cartilage scissors may be required. The fibrous portions adhering to the atria and ventricles are carefully dissected with dry dissectors and scissors. Caution is exercised to prevent perforation of the atria and right ventricle; thus small islands of adherent pericardium may be retained.
3. Dissection is continued, and the large blood vessels are exposed and freed as indicated.
4. Drainage catheters are placed near the heart or through the pleural spaces, and connections to the water-seal drainage system are established.

SURGERY FOR CORONARY ARTERY DISEASE

The growth of minimally invasive surgical techniques (including off-pump CABGs) and percutaneous coronary interventions (PCIs) is most evident in the treatment of CAD. PCIs with bare metal or drug-eluting stents are performed in more than 2 million patients annually. Although there is some evidence that drug-eluting stents have a higher rate of thrombotic occlusion than bare metal stents, Kirtane and colleagues (2009) found comparable results with either type of stent.

When compared to PCI with stent insertion, CABG remains the standard of care for patients with left main or three-vessel CAD (Serruys et al, 2009; Patel et al, 2009; Li et al, 2009) although there is ongoing controversy about the preference for PCI or CABG among subsets of patients with CAD (Smith, 2009). Hybrid rooms facilitate a combination of both traditional surgical techniques and fluoroscopically-guided PCI.

In addition to PCI, revascularization procedures for the ischemic myocardium include an expanding array of options such as port-access, robotic, endoscopic, and video-assisted procedures using smaller thoracic or sternal incisions (Table 24-8). Other forms of revascularization include left ventricular aneurysmectomy and transmyocardial laser revascularization. Endoscopic saphenous vein and radial artery excision is performed frequently.

Off-pump coronary artery bypass (OPCAB) is popular, and procedures employing CPB can be performed with minimally invasive systems (Sarin et al, 2009; Sellke et al, 2005). Table 24-9 lists revascularization procedures that can be performed using a variety of on- or off-pump techniques. Advantages of the minimally invasive techniques, with or without CPB, include more cosmetic incisions, less perioperative bleeding, fewer surgical wound infections, and earlier postoperative ambulation. Previous disadvantages attributed to OPCAB (e.g., more technically challenging, prolonged operative time, and less complete revascularization) have been overcome, as depicted in a review of two randomized, controlled trials that showed similar outcomes, including health-related quality of life (Angelini et al, 2009). Procoagulant activity in the first 24 hours after OPCAB increases the risk of graft thrombosis. Therefore perioperative anticoagulation therapy should be "more aggressive" than that for conventional CABG, according to Shimokawa and colleagues (2009, p. 1419). In patients with myocardial infarction (MI), off-pump CABG surgery performed within 6 hours of the onset of symptoms showed better results than CABG with CPB (Fattouch et al, 2009).

Distal and proximal anastomotic devices have the potential to make it easier to perform bypass procedures in confined spaces on a beating heart, but many of these devices require further refinement. These new vascular connectors employ a variety of designs: grasping hooks that attach the vein to the aorta, magnets, U clips, and other coupling systems (Nasso et al, 2009). Another innovative proximal anastomotic technique consists of a clampless device that reduces the risk of disrupting aortic atherosclerotic plaque, which may be dislodged and embolize after the application of a partial occlusion clamp (Shimokawa et al, 2009).

Standard surgical treatment of CAD includes myocardial revascularization with CABG by use of the internal (thoracic) mammary artery (IMA), greater saphenous vein, radial artery, and other autogenous arterial and venous conduits. CABG often alleviates angina pectoris and prolongs life in patients with CAD of the left main and left anterior descending coronary arteries (Serruys et al, 2009; Patel et al, 2009; Li et al, 2009). The IMA demonstrates excellent long-term patency (Morrow and Gersh, 2008), and this has promoted the use of arterial conduits such as the radial artery (Collins et al, 2008), especially in diabetic patients (Singh et al, 2008); the gastroepiploic artery (Sasaki, 2008); and the inferior epigastric artery (Tavilla et al, 2004). The saphenous vein remains an effective conduit when multiple grafts are needed (Ozcan et al, 2008). Although the majority of saphenous vein grafts currently are harvested via the endoscopic technique (see #3 in the outline on p. 1054), a large study of approximately 2900 patients (Lopes et al, 2009) has shown less optimal outcomes with the endovascular technique. The increasing number of reoperations for CAD has also stimulated the use of alternative conduits (Box 24-6).

TABLE 24-8

Thoracic Incisions

Incision	Position	Possible Indications	Special Patient Needs
Median sternotomy: Incision along center of sternum	Supine	Most adult cardiac procedures except those on branch pulmonary arteries, distal transverse aortic arch, and descending thoracic aorta; OPCAB	Padding for hands, elbows, feet/heels, back of head, dependent bony prominences
Mini-sternotomy: Partial upper or lower sternal incision starting either from sternal notch or from xiphoid process and extending to midportion of sternum; lower-end sternal splitting (LESS)	Supine	MAS, or OPCAB procedures	Same as median sternotomy
Parasternotomy: Resection of right or left costal cartilages (from second to fifth cartilage, depending on surgical target)	Supine; small roll may be placed under affected side	Left: MAS CABG Right: MAS CABG, valve procedures	Same as median sternotomy; risk of postoperative chest wall instability
Anterolateral thoracotomy: Curvilinear incision along subpectoral groove to axillary line	Supine with pad or pillow under operative site; arm supported in sling or overarm board; arm on unaffected side may be tucked along side	MAS, MIDCAB, trauma to anterior pericardium and left ventricle; repeat sternotomy	Padding for extremities; pillow or other device to elevate affected side; armboard or sling for arm on affected side
Left anterior mini-thoracotomy; right anterior mini-thoracotomy: One or more small incisions (or ports) on left or right side	Supine with small roll under affected side	Left: MAS, MIDCAB, port-access for robotic surgery Right: MAS valve procedures, surgery for atrial fibrillation ("mini-MAZE"); port-access for robotic surgery	Same as anterolateral thoracotomy
Lateral thoracotomy: Curvilinear incision along costochondral junction anteriorly to posterior border of scapula	Placed on side with arms extended and axilla and head supported; knees and legs protected	Lung biopsies; first-rib resection; lobectomy	Armboard, overarm board, axillary roll, padding for extremities, pillow between legs; sandbags, straps, wide tape, or other devices to support torso
Posterolateral thoracotomy: Curvilinear incision from subpectoral crease below nipple, extended laterally and posteriorly along ribs almost to posterior midline below scapula (location of intercostal incision depends on surgical site); used less frequently with availability of VATS techniques	Lateral with arms extended and axilla and head supported; knees and legs protected	First-rib resection; lobectomy	Similar to needs for lateral thoracotomy
Transsternal bilateral anterior thoracotomy ("clamshell"): Submammary incision extending from one anterior axillary line to other across sternum at fourth interspace	Supine	Bilateral lung transplant; emergency access to heart when sternal saw not available	Same as median sternotomy; requires transection of left and right IMA
Subxiphoid incision: Vertical midline incision from over xiphoid process to about 10 cm inferiorly (may divide lower portion of sternum to enhance exposure)	Supine	Pericardial drainage, pericardial biopsy, attachment of pacemaker electrodes, MAS	Same as median sternotomy

TABLE 24-8

Thoracic Incisions—cont'd

Incision	Position	Possible Indications	Special Patient Needs
Thoracoabdominal incision: Low curvilinear incision on left side extended to anterior midline, continued vertically down abdomen	Anterior thoracotomy with chest at 45-degree angle to table; abdomen supine	Thoracoabdominal aneurysm	Same as anterolateral thoracotomy

CABG, Coronary artery bypass graft; *IMA,* internal mammary artery; *MAS,* minimal access surgery; *MIDCAB,* minimal access direct coronary artery bypass; *OPCAB,* off-pump coronary artery bypass; *VATS,* video-assisted thoracoscopic surgery.

TABLE 24-9

Types of Myocardial Revascularization

Acronym	Procedure Name	Incision	Indication
MIDCAB	Minimally invasive direct coronary artery bypass (infrequent)	Left anterolateral thoracotomy	Single left anterior descending (LAD) and/or diagonal coronary artery anastomosis with left internal mammary artery (LIMA)
LATCAB	Lateral anterior thoracotomy coronary artery bypass	Anterolateral thoracotomy	Saphenous vein or radial artery from descending aorta to circumflex coronary artery system
OPCAB	Off-pump coronary artery bypass	Median sternotomy with full or limited skin incision	Multiple anastomoses
TECAB (also called ECABG)	Totally endoscopic coronary artery bypass; endoscopic coronary artery bypass graft (CABG)	Thoracic ports	Multiple anastomoses; on or off bypass
PACAB (also called port-access CAB)	Port-access coronary artery bypass	Thoracic ports	Multiple anastomoses; robot may or may not be used
Robotic CAB	Minimally invasive surgery (MIS) employing robotic assistance	Thoracic ports, small incisions	Multiple anastomoses
Robotic or nonrobotic LTMR	Laser transmyocardial revascularization	Thoracic ports, small incisions	Multiple anastomoses
Hybrid	Combined surgery and percutaneous coronary intervention (PCI)	Sternotomy (usually)	CABG: LAD and/or diagonal coronary artery; PCI: lateral and/or posterior coronary arteries

Modified from McCarthy P: Surgical management of heart failure. In Libby P et al, editors: *Braunwald's heart disease,* ed 8, Philadelphia, 2008, Saunders; Bridges CR et al: The Society of Thoracic Surgeons practice guideline series: transmyocardial laser revascularization, *Ann Thorac Surg* 77:1494-1502, 2004; Yuh DD et al: Totally endoscopic robot-assisted transmyocardial revascularization, *J Thorac Cardiovasc Surg* 130(1):120-124, 2005.

Dysrhythmias, and AF in particular, are common after CABG and can lead to hemodynamic compromise, systemic embolism, the need for extended anticoagulation therapy (with its attendant risk of bleeding complications), cardiac pacing, patient discomfort and anxiety, and increased cost and length of stay. Preoperative, intraoperative, or early postoperative administration of amiodarone is effective in reducing the incidence of postoperative AF (Gray and Sethna, 2008).

Increasing controversy over gender differences and their effect on outcomes after CABG has stimulated perioperative practice guidelines for CABG in women (Babb, 2009; Edwards et al, 2005; Puskas et al, 2007; Toumpoulis et al, 2006) (Evidence for Practice, p. 1009). In particular, the guidelines focus on use of the IMA, glycemic control, avoidance of anemia and hypothyroid states, the questionable value of hormone replacement therapy, and off-pump CABG.

Other ischemia-related disorders (including heart failure) that can benefit from surgery include postinfarction ventricular septal defect (VSD), mitral regurgitation (MR), and certain ventricular (e.g., tachycardia) and supraventricular (e.g., AF) dysrhythmias.

BOX 24-6

Alternative Conduits for Use as Coronary Bypass Grafts

- Splenic artery
- Lesser saphenous vein
- Cephalic vein
- Basilic vein
- Greater saphenous vein allografts (homografts)
- Synthetic grafts (e.g., Dacron, PTFE)

PTFE, Polytetrafluoroethylene
Modified from Hsia TY et al: Coronary artery disease. In Conte JV et al, editors: *The Johns Hopkins manual of cardiac surgical care,* ed 2, St Louis, 2008, Mosby.

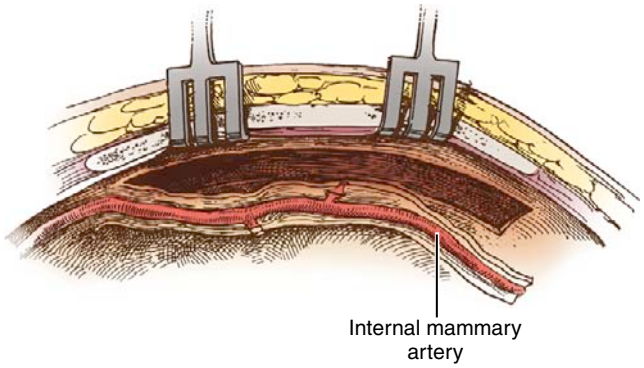

FIGURE 24-48 Dissection of internal mammary artery (IMA). Bleeding from side branches is controlled by vascular clips on the IMA side and electrocoagulation on the sternal side. Dilute solution of papaverine is sprayed onto or into the lumen of the IMA to dilate the artery and reduce muscular spasm. The IMA pedicle is placed in the pleural cavity until needed for anastomosis.

Coronary Artery Bypass Grafts with Arterial and Venous Conduits

Operative Procedure

Coronary artery instruments are added to the basic setup for cardiac surgery.

1. A median sternotomy is performed as described.
2. Conduit preparation:
   a. *IMA.* A special retractor, such as the one shown in Figure 24-15, elevates the sternum to expose the IMA. The surgeon dissects the IMA from its retrosternal bed until the necessary length is obtained (Figure 24-48). The surgeon clamps the exposed artery, cuts the IMA caudal to the clamp, and confirms that blood flow through the IMA is adequate. The surgeon may inject papaverine (or another antispasmodic drug) into the IMA lumen with a blunt-tip needle and then occlude the tip of the IMA with a small bulldog clamp. The surgeon may wrap the pedicle with a papaverine-soaked sponge and store the vessel in the left (or right) pleural space until needed. The remaining clamped portion of the distal IMA is ligated with a tie to prevent backbleeding. Occasionally, both right and left IMAs are used. Heparin is given before arterial grafts are clamped and cut to prevent intraluminal thrombosis.
   b. Endoscopic IMA dissection can be performed through thoracic ports (see Table 24-9) inserted into the left anterior thorax at the level of the fourth intercostal space. Ligation of arterial branches and venous tributaries is performed with hemostatic clips and electrocoagulation.
   c. *Radial artery.* Generally the artery is taken from the patient's nondominant arm; adequate blood flow through the ulnar artery must be confirmed (commonly by Doppler). The artery may be removed endoscopically or through a longitudinal incision beginning 3 cm distal to the elbow crease lateral to the biceps tendon and ending 1 cm before the wrist crease (Figure 24-49). The artery is exposed and mobilized with a vessel loop and harvested as a free graft with adjacent veins and fatty tissue. The artery is ligated proximally and distally after systemic heparinization. Papaverine may be injected into the lumen to reduce spasm. The arm incision is closed and may be dressed and repositioned along the patient's side; additional drapes may be applied to maintain sterility of the field.
   d. *Gastroepiploic artery.* When an additional arterial conduit is needed, the gastroepiploic artery may be used, although the required entry into the peritoneum to dissect the artery increases the risk of postoperative complications (Figure 24-50).
   e. *Saphenous vein.* The necessary length of saphenous vein is harvested from one or both legs either with video-assisted endoscopic techniques or (less commonly) by a traditional open incision (Figure 24-51). Tributaries on the leg side are ligated, electrocoagulated, or clipped. After the saphenous vein is dissected free, it is removed and tributaries on the vein side are ligated. The distal end of the vein is identified to place the vein in a reversed position so that the semilunar valves do not interfere with the flow of blood. The vein is flushed with heparinized blood or saline and kept moist until needed.
3. With the endoscopic technique, saphenous vein harvesting is performed through one to three incisions over the vein at the knee and at the ankle and the groin if necessary. The vein is located under direct vision; the remaining length of vein is excised using a 5-mm angled endoscope and endoscopic scissors. An endoscopic clip applier and bipolar electrocoagulation can be used to seal tributaries on the leg side. Once the vein is removed, the vein tributaries are ligated with silk ties. To reduce postoperative tunnel dead space and minimize fluid accumulation, the leg is wrapped with a pressure bandage.
4. CPB with mild hypothermia is instituted. (If CABG is performed without CPB, the patient is not cooled. CPB standby is usually available.) Antegrade-retrograde cardioplegic solution is infused after the aorta is cross-clamped.
5. Coronary anastomoses using the saphenous vein, free arterial grafts, and in situ arterial grafts (e.g., IMA and gastroepiploic artery) are performed.
   a. The affected coronary artery is identified, and a small incision is made into the artery. The graft conduit is beveled to approximate the incision (side-to-side jump grafts may be performed as well).

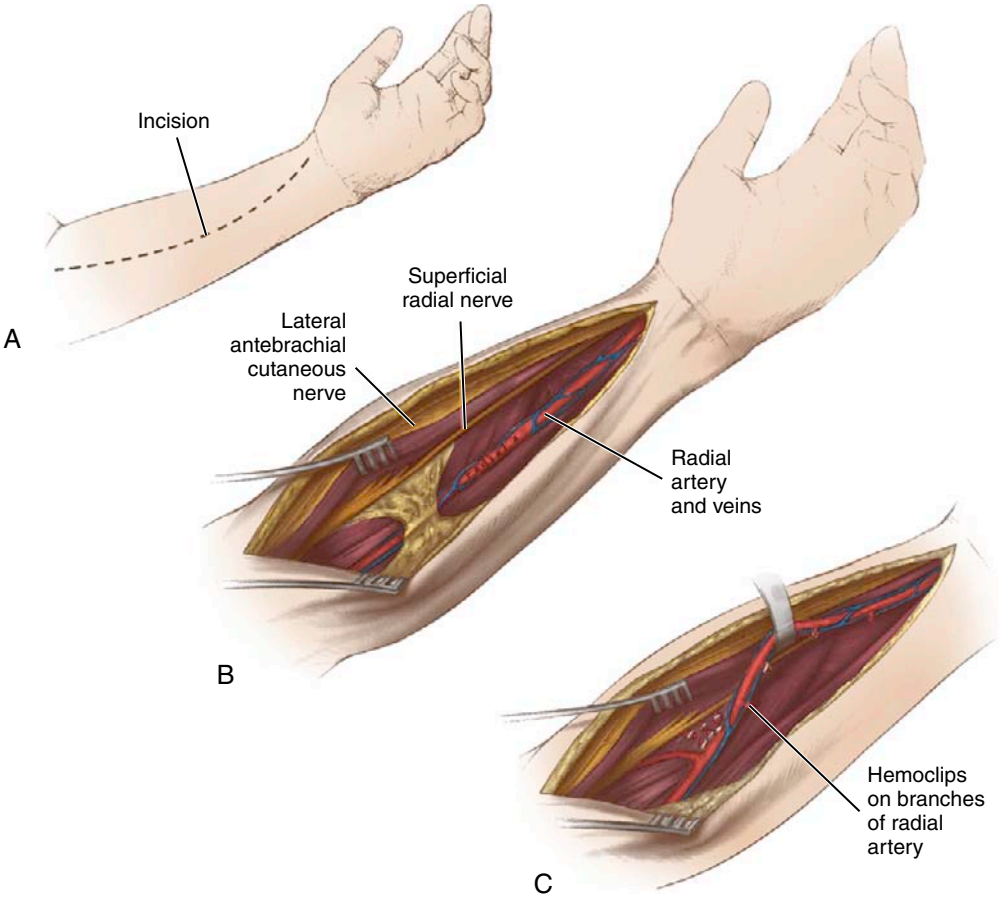

FIGURE 24-49 Dissection of radial artery. Before removal of the radial artery, Allen's test is performed to ensure that the ulnar artery will provide sufficient blood flow to the hand if the radial artery is excised: the radial and ulnar arteries are compressed to produce blanching of the hand. The ulnar artery is released while compression is maintained on the radial artery. The skin on the palm of the hand should immediately become red as blood flow is restored through the ulnar artery to the hand. **A**, Incision line. **B**, Deep forearm dissection exposes the radial artery and vein pedicle. **C**, Radial artery pedicle is mobilized, and the multiple side branches are clipped. The artery is removed and may be irrigated with a vasodilator. A continuous intravenous infusion of diltiazem helps to prevent vasoconstriction of the artery.

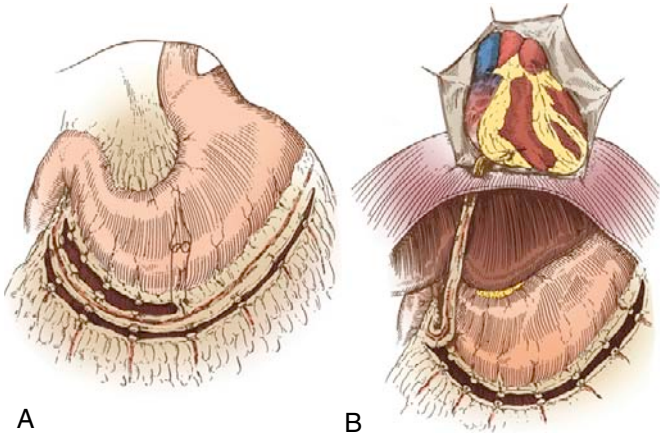

FIGURE 24-50 Right gastroepiploic artery mobilization. **A**, Branches to the stomach are divided with clamps and ties; omental branches may be divided with a staple gun. The gastroepiploic pedicle is isolated proximally to its origin from the gastroduodenal artery. **B**, The pedicle is brought up into the pericardium and anastomosed to the right coronary artery (shown here). The artery can also be grafted to the distal right and left anterior descending coronary arteries.

b. The anastomoses are made with fine cardiovascular sutures (Figure 24-52). Before each anastomosis is completed, the distal coronary artery may be probed to ensure patency.

6. Steps 5a and 5b are repeated for each subsequent anastomosis.
7. The distal anastomosis of the IMA to the coronary artery is done as described for the anastomosis of the saphenous vein graft to the coronary artery. No aortic (proximal) anastomosis is required because the IMA remains attached proximally to the subclavian artery. Because the IMA has demonstrated superior long-term patency—and the left anterior descending (LAD) coronary artery is a critical source of blood to the left ventricle—the IMA is commonly attached to the LAD coronary artery.
8. Aortic anastomoses:
   a. Proximal aortic anastomoses may be performed with a partial occlusion clamp but more often the anastomoses are performed during a single aortic cross-clamping to avoid excessive manipulation of the aorta that could lead to intimal injury or dislodgment of atherosclerotic

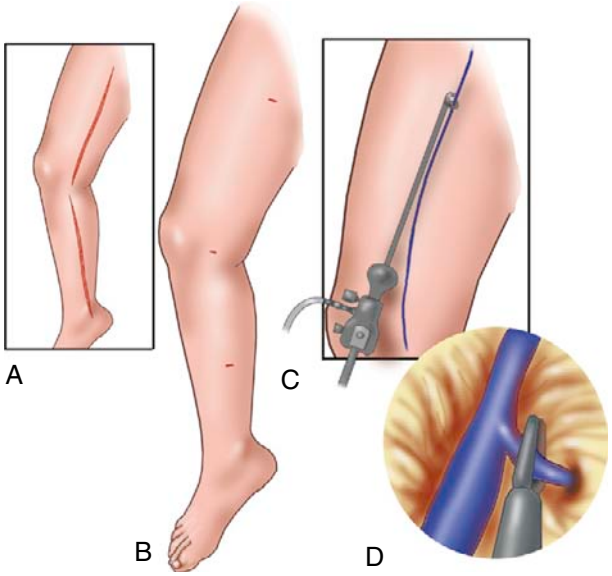

FIGURE 24-51 Excision of greater saphenous vein. **A**, Traditional open incision. **B**, Incision sites (ankle, knee, groin) for video-assisted, endoscopic vein harvesting. **C**, Endoscope inserted into medial knee incision and used to dissect the vein. **D**, Venous tributaries may be divided and electrocoagulated or clipped on the leg side; silk ties are commonly used on the vein side.

material. Increasingly, the aorta is assessed with TEE before the anastomoses are performed to identify proximal anastomotic sites that are relatively free of atherosclerotic plaque. After the proximal anastomoses are completed, the aortic cross-clamp is removed and the heart is defibrillated. Assessment of the aorta is especially helpful during *beating heart surgery* (usually through a median sternotomy) that requires proximal aortic anastomoses (with a saphenous vein or other free graft) to be completed while the heart is contracting. After identification of a suitable site (i.e., relatively free of plaque), the proximal anastomoses may be performed with a partial occlusion clamp. The aorta is partially occluded with an angled vascular clamp, and a small segment is resected (approximately the diameter of the vein graft). The aortotomy is made with a knife blade and the opening is enlarged with a punch (Figure 24-53).

   b. The conduit is anastomosed, end to side, to the aorta with fine vascular sutures (Figure 24-54). The partial occlusion clamp (if used) is removed, so that the proximal portion of the vein graft can fill with blood. Needle aspiration of the vein graft is performed to prevent air from entering the coronary circulation.

   c. When proximal anastomoses are performed during a single period of cross-clamping, air is aspirated from the grafts before the cross-clamp is removed.

9. The aortic anastomoses of the vein grafts may be marked with radiopaque clips or rings for future identification.
10. Cardiopulmonary bypass is discontinued, and the sternum is closed.
11. Minimally invasive procedures:
   a. Minimally invasive direct coronary artery bypass (MIDCAB) may be performed, albeit less frequently, in patients with lesions (e.g., narrowings in the LAD and

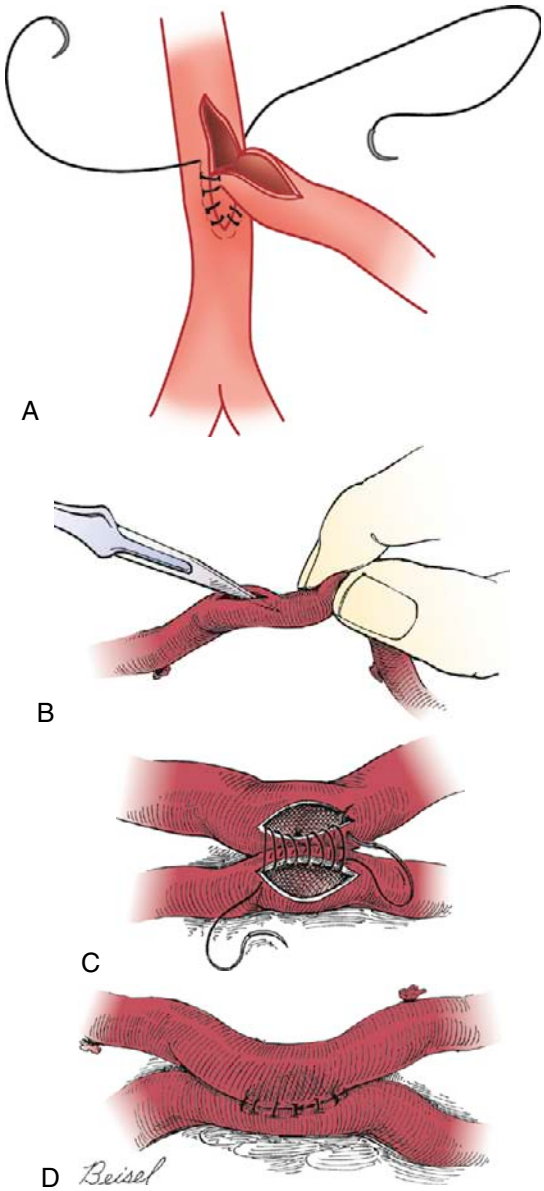

FIGURE 24-52 **A**, End-to-side coronary anastomosis with bypass graft conduit. Side-to-side coronary anastomosis with bypass graft conduit. **B**, Arteriotomy made with #11 blade is shown. **C**, Double-ended suture used to create anastomosis. **D**, Completed anastomosis. Side-to-side anastomoses are used to make more than one attachment of a conduit to an artery, especially when there may be insufficient available conduit material.

diagonal coronary arteries) that are easily accessible through an anterior thoracotomy. Beating heart procedures performed through a median sternotomy allow surgeons to access lateral and posterior arteries. When endovascular CPB and cardioplegic solution are used, more lateral and posterior arteries (e.g., obtuse marginal and right coronary arteries) may be grafted because ventricular fibrillation secondary to stimulation of the heart is obviated with induced cardioplegic arrest. A double-lumen endotracheal tube may be inserted so that the left lung can be hypoventilated to enhance visualization of

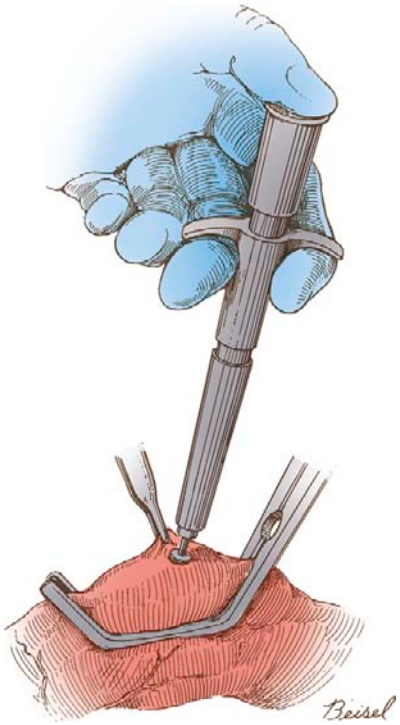

FIGURE 24-53 Proximal anastomosis of bypass graft. A partial occlusion clamp isolates the portion of the ascending aorta where the aortotomy is to be made with the punch.

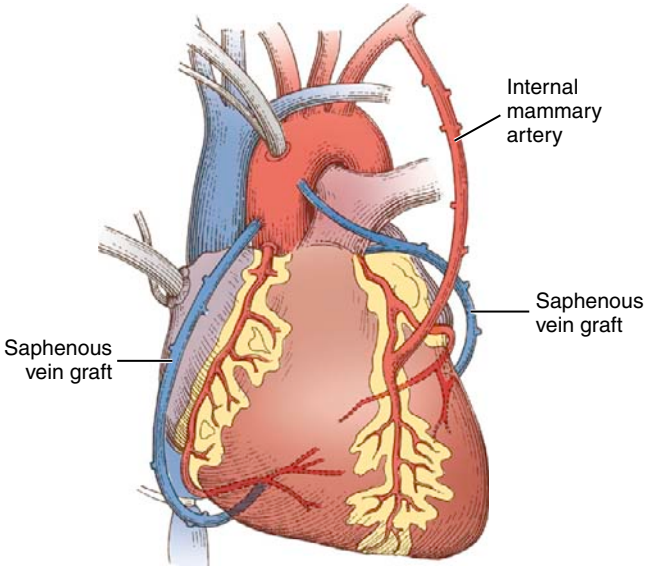

FIGURE 24-54 Coronary artery bypass grafts with reversed saphenous vein and the left internal mammary artery.

the LAD (and the IMA) while the right lung is ventilated sufficiently to oxygenate pulmonary blood flow.

b. With OPCAB, cardiac contraction may pose a technical difficulty for the surgeon in creating a precise anastomosis. Coronary stabilizers are used to reduce the motion of the heart in the vicinity of the anastomosis (Figure 24-55). These attachments fit onto the retractor, thereby freeing the surgeon's hands to suture the anastomosis.

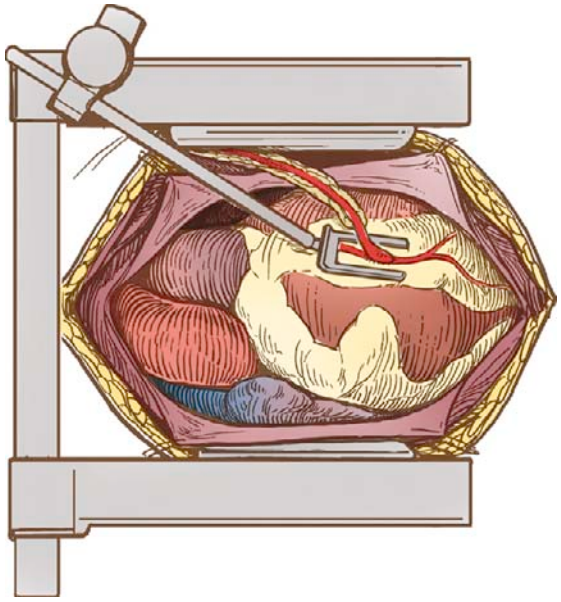

FIGURE 24-55 Coronary anastomotic site stabilizer used during beating heart bypass surgery. The horseshoe-shaped foot has a nonsmooth surface to provide an atraumatic grip on the epicardium, reduce the movement of the beating heart, and isolate the target coronary artery site for anastomosis.

Left ventricular apical suction cups allow the apex to be retracted, thereby exposing lateral and posterior coronary arteries (see Figure 24-17). Pharmacologic cardiac motion reduction has been achieved with beta-blocker drugs and adenosine, but the newer stabilizers have reduced the need for these drugs. Bleeding from the arteriotomy (because of the continued beating of the heart) obscures the field; a fine mist of humidified CO_2 gas sprayed over the anastomotic site and the use of elastic coronary artery tourniquets may be used to control bleeding.

c. Port-access procedures (Figure 24-56) may be performed with a robot and the use of endovascular catheters (see Figure 24-47). Anastomoses are achieved with video-assisted thoracoscopic techniques. If better visualization is desired or required, the surgeon can convert to a median sternotomy.

Laser Transmyocardial Revascularization

Patients with chronic, severe angina who cannot be revascularized with either coronary bypass surgery or PCI may be appropriate candidates for laser transmyocardial revascularization (TMR) (Horvath and Zhou, 2007). Channels are created in the left ventricular wall with laser energy (e.g., CO_2, holmium:yttrium-aluminum-garnet [Ho:YAG]). Endoscopic, laser, robot-assisted TMR can further enhance the role of TMR as a surgical treatment or as an adjunct to PCI. Laser safety precautions should be followed.

Ventricular Aneurysmectomy

Left ventricular aneurysmectomy (LVA) is the excision of an aneurysmal portion of the left ventricle and reinforcement with synthetic patch material. LVA is a form of left ventricular reconstruction undertaken to optimize cardiac function.

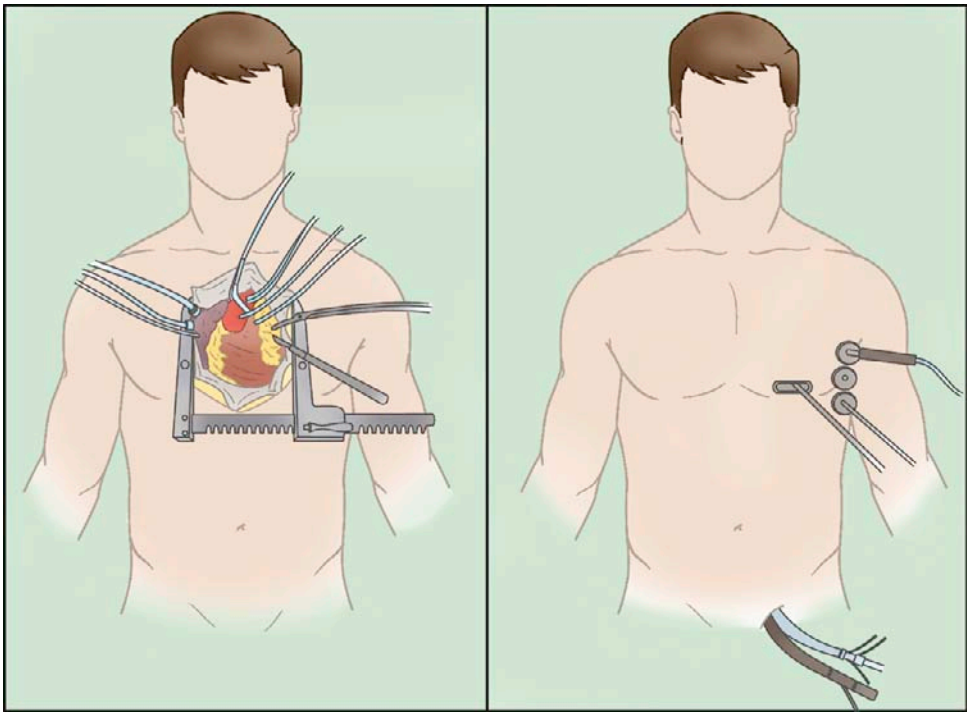

FIGURE 24-56 Traditional sternotomy *(left)* compared with minimally invasive incisions *(right)* that provide access to the heart and to the femoral artery and vein.

An aneurysm of the left ventricle occasionally develops after a severe myocardial infarction in which part of the myocardium is replaced by thin scar tissue that can rupture. The LV undergoes *remodeling* when the scar stretches as a result of the left ventricular pressure and forms an aneurysm (McCarthy, 2008). The aneurysm is usually adherent to the pericardium; it may not be possible to dissect it free until CPB has been established.

Procedural Considerations. The patient is placed in the supine position. The setup is the same as that described for open-heart surgery, with the addition of synthetic patch material, Teflon felt pledgets, and 0, 3-0, and 4-0 cardiovascular sutures. Occasionally, Teflon felt strips are required to bolster the suture lines. Patch closure of the ventriculotomy (endoaneurysmorrhaphy) is performed more often than the traditional excision, plication, and oversewing of the ventricular tissue. Patch closure better preserves the geometry of the left ventricle (McCarthy, 2008; Lundblad et al, 2009).

Operative Procedure

1. A median sternotomy is performed, and CPB is begun as previously described.
2. The scar tissue of the ventricle is excised, and any clot is carefully removed (Figure 24-57, *A* and *B*).
3. A circular cuff of scar tissue is left, through which a purse-string suture with felt pledgets is placed through the rim of the scar (Figure 24-57, *C*).
4. A patch of woven Dacron is sewn to the rim with interrupted sutures (Figure 24-57, *D*). A second (internal) patch of pericardium may be placed for hemostasis.
5. The edge of the patch is reinforced with a running suture (Figure 24-57, *E*).
6. The left ventricle may be vented with a catheter inserted into the right superior pulmonary vein; after the ventricle is deaired, the catheter is removed and closure of the incision completed.

Postinfarction Ventricular Septal Defect. Ventricular septal or free-wall rupture is a catastrophic complication of myocardial infarction, creating an acute left-to-right shunt and cardiac failure requiring early surgical repair. The defect is closed with a prosthetic patch and other materials commonly used for postinfarction ventricular aneurysm. Felt strips and plicating sutures may be used to reinforce the suture line (McCarthy, 2008).

SURGERY FOR HEART FAILURE

Early procedures to reconstruct the left ventricle, introduced by Batista and modified by Dor, were developed for patients with heart failure mainly caused by ischemic coronary disease and hypertension (McCarthy, 2008). The dilated, hypokinetic portions of the ventricle are excised and repaired to produce a more efficient pumping chamber. Techniques for ventricular reconstruction have expanded options for surgical treatment of heart failure. Additional interventions include mitral valve repair (see following section) for ischemic mitral regurgitation (de Varennes et al, 2009), mechanical and biologic support, and cardiac transplantation (described later).

SURGERY FOR THE MITRAL VALVE

Mitral *stenosis* (MS) is a narrowing of the valve orifice such that it causes impedance to forward blood flow. It is often caused by rheumatic fever. The normal orifice area of the valve is about

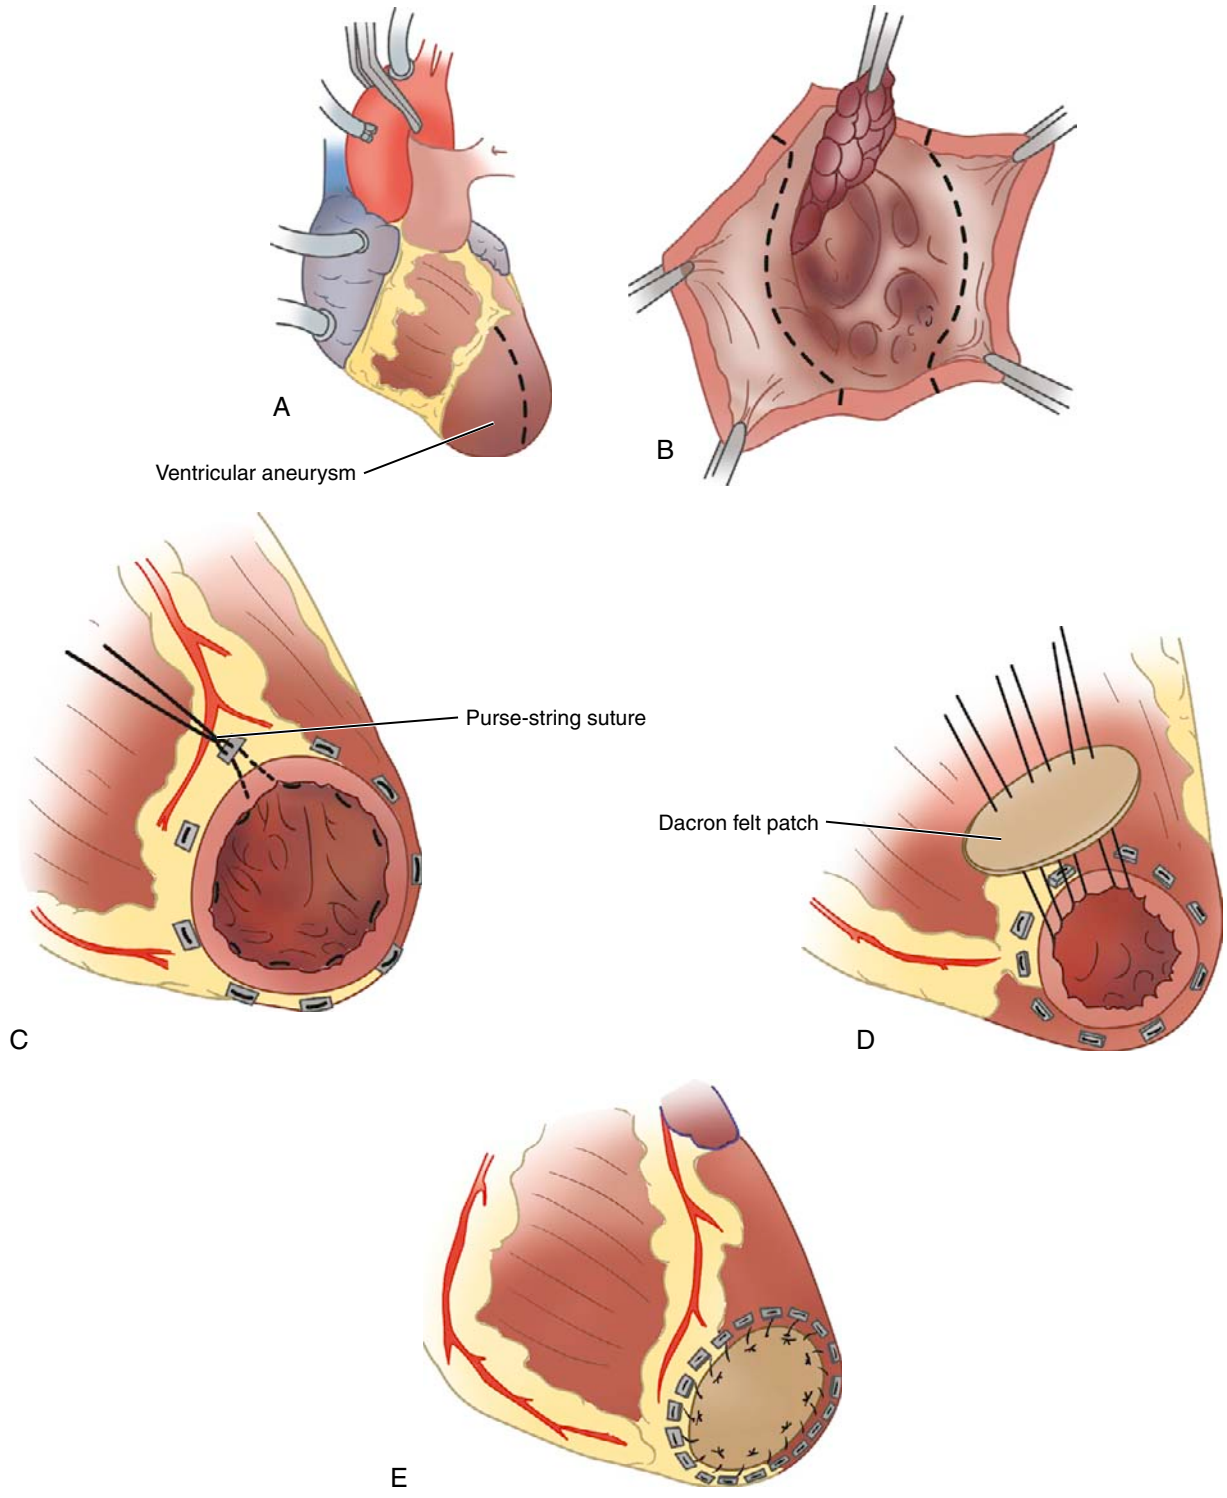

FIGURE 24-57 Repair of left ventricular aneurysm. **A**, Left ventricular apical aneurysm. **B**, Intracavitary clot is removed. **C**, Pledgetted sutures placed around the edge of the excised ventricular tissue. **D**, A patch is inserted. **E**, Completed repair.

5 cm^2. As the disease progresses, the mitral valve becomes a narrow slit in a fibrotic plaque, severely limiting blood flow into the left ventricle. MS causes a rise in pressure and dilation of the left atrium. This pressure is transmitted throughout the pulmonary vascular bed, with subsequent pulmonary hypertension, right ventricular hypertrophy, and possibly tricuspid valve regurgitation (Otto and Bonow, 2008). The major symptoms of MS are dyspnea, fatigue, and orthopnea. Late findings are severe pulmonary congestion and right ventricular failure. A characteristic diastolic murmur is heard, and AF is not unusual. Thromboembolism may result from stasis of blood in the left atrial appendage.

Mitral *regurgitation* (MR) occurs when the valve leaflets do not close properly or when the leaflets are perforated and blood escapes back into the left atrium during ventricular systole (Stout and Verrier, 2009). Common causes of MR are myxomatous degeneration and a secondary result of aortic valve stenosis. Other causes of MR are degenerative, ischemic, and dilated cardiomyopathy. During ventricular diastole, the blood regurgitated into the left atrium augments blood volume entering the left ventricle. MR may accompany MS or be attributable to leaflet tears, annular dilation, or elongated or ruptured chordae. Ischemic heart disease may produce papillary muscle dysfunction, which prevents sufficient anchoring of the leaflets in the closed position. Symptoms are primarily dyspnea on exertion and easy fatigability related to pulmonary congestion.

The surgeon's selection of the procedure (repair or replacement) is determined by the mitral valve anatomy, stage of disease, presence or absence of calcification, history of thromboembolism and dysrhythmia, the patient's ability to tolerate long-term anticoagulation therapy (required after insertion of a mechanical valve prosthesis), the patient's willingness to undergo reoperation if a bioprosthesis deteriorates, and additional associated pathologic defects (Kumar, 2008). Improvements in imaging capabilities with two-dimensional, three-dimensional, and color-flow Doppler echocardiography have enabled surgeons to diagnose more precisely and subsequently to identify the most appropriate reparative procedure (Lee and Bonow, 2008). Improved imaging has also fostered the development of a consistent nomenclature to describe specific segments of the mitral valve leaflet anatomy. Quill and colleagues (2009), building on the studies of Kumar and associates (1995) and the classic work of Carpentier (1983), have suggested dividing each mitral leaflet into an alpha-numeric system: (1) the *anterior* leaflet is divided into three sections that are designated from the lateral to the medial position (left to right): *A1* (lateral), *A2* (middle), and *A3* (medial); (2) the *posterior* leaflet is divided into three sections that are designated (left to right): *P1* (lateral), *P2* (middle), and *P3* (medial) (see mitral valve in Figure 24-6, *B*). The goal of this system is to provide consistent descriptions for planning, performing, and documenting the care for this highly variable, complex, and dynamic structure.

Consistency in description also promotes reproducibility of the reparative procedures performed to preserve the native valve. Mitral valve repair is widely employed because the complications associated with prosthetic replacement and anticoagulation therapy can be avoided. The technique selected must be tailored to the unique pathophysiologic findings; therefore the surgeon carefully evaluates the leaflets and related structures at the time of surgery before deciding which procedure to perform. Because there is a possibility that the valve may have to be replaced, instruments (and prostheses) for replacement as well as repairs should be available. Also included are atrial handheld or self-retaining retractors, obturators for sizing prosthetic rings and valves, sizer or prosthesis handles, and special sutures if requested. Bicaval cannulation often is used to enhance exposure of the operative field and to decompress the heart (see Figure 24-37). TEE is used to establish a cardiac functional baseline and to confirm efficacy of the repair both after the cross-clamp is removed and the heart resumes beating and after bypass is discontinued. TEE is also used intraoperatively to assess left ventricular function and to detect the presence of air (seen as white specks) within the cardiac chambers.

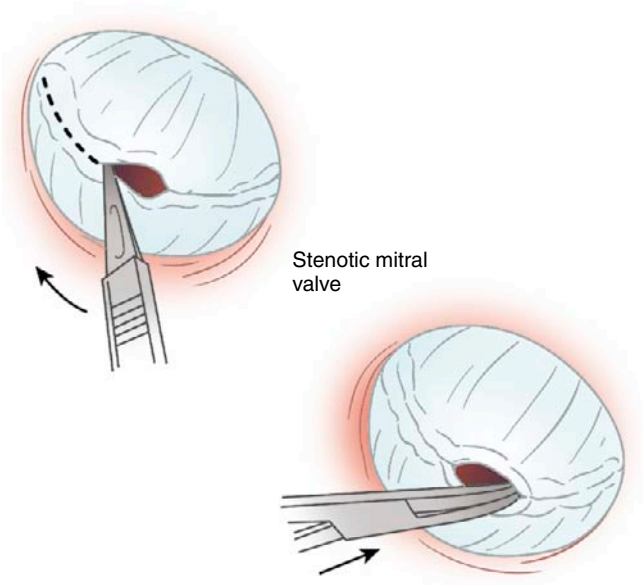

FIGURE 24-58 Mitral commissurotomy (see text).

Mitral Valve Repairs

Open Commissurotomy of the Mitral Valve for Mitral Stenosis. Open commissurotomy is the separation of fused, adherent leaflets of the mitral valve.

PROCEDURAL CONSIDERATIONS. The patient is placed in the supine position for a median sternotomy. The setup is the same as that described for open-heart procedures, with mitral valve instruments.

OPERATIVE PROCEDURE

1. A median sternotomy is performed, and bicaval cannulation is performed for CPB.
2. The left atrium is incised, and the valve is inspected; in some cases, a transseptal approach (right atrium to left atrium) may be used.
3. Fused leaflets are separated with vascular forceps and scissors or a knife (Figure 24-58). A dilator may be used to enlarge the mitral valve orifice.
4. The valve is again inspected for any resultant insufficiency.
5. An annuloplasty ring may be inserted to reinforce the repair.
6. The left atrium is closed with a continuous cardiovascular suture.

Mitral Annuloplasty for Mitral Regurgitation. Mitral annuloplasty is the reduction of a dilated annulus by inserting a prosthetic ring. Although it has been assumed that only the posterior leaflet is subject to annular dilation, it has been demonstrated that the anterior portion can also be affected. Prostheses are available to repair the entire circumference of the annulus (see Figure 24-33, *A*) or only the posterior leaflet (see Figure 24-33, *B*). The techniques (and associated prostheses) introduced by Carpentier (1983) and others continue to expand.

OPERATIVE PROCEDURE

1. The left atrium is incised, and sump suctions are inserted into the atrial cavity to remove blood.
2. The annulus, leaflets, chordae, and the rest of the mitral complex are inspected.

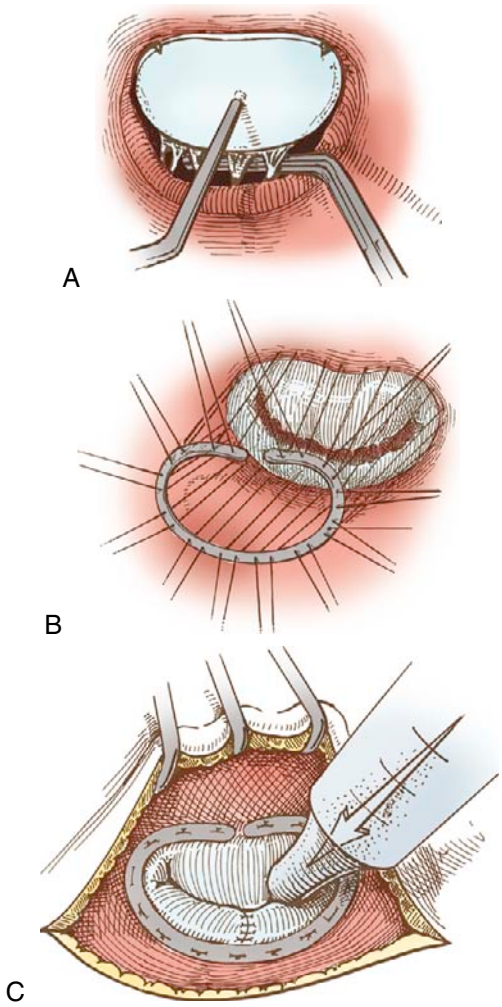

FIGURE 24-59 Mitral valve annuloplasty (see text).

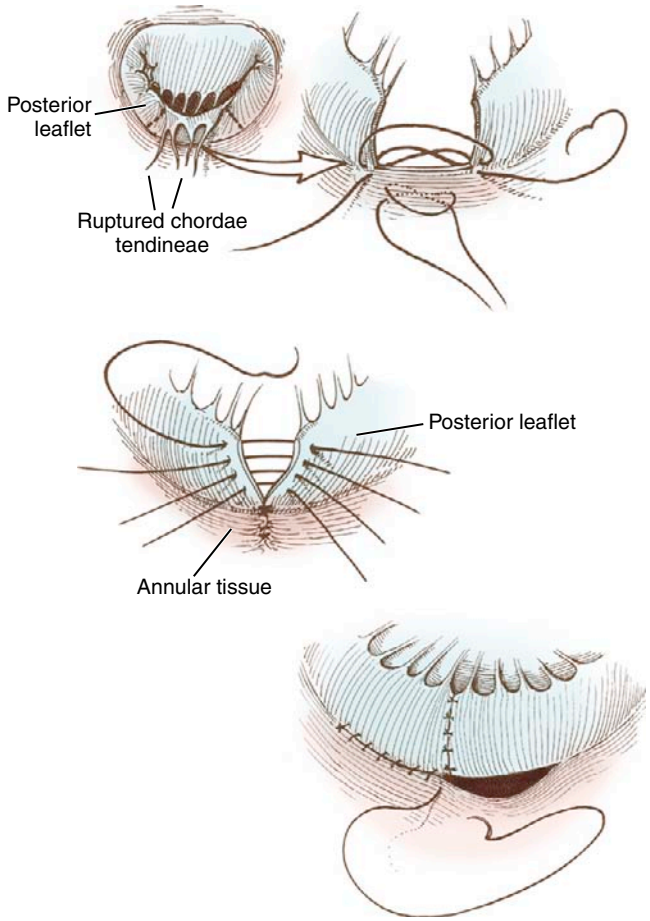

FIGURE 24-60 Quadrangular resection of nonsupported posterior leaflet tissue caused by ruptured chordae tendineae (see text). A similar technique can be used to resect *redundant* tissue causing mitral regurgitation.

3. If generalized annular dilation is present, an annuloplasty ring is inserted; a C-shaped ring may be used for dilation affecting the posterior leaflet (see Figure 24-33). An obturator is used to determine the appropriate-size ring (Figure 24-59, *A*). Interrupted sutures are placed around the circumference of the annulus and then into the ring (Figure 24-59, *B*). When the stitches are tied, the excess annular tissue of the posterior leaflet is evenly drawn up against the prosthesis (Figure 24-59, *C*).
4. The valve is inspected for competency; a bulb syringe filled with saline may be used to distend the ventricle and confirm the competence of the valve leaflets. The left atrium is closed.

Mitral Valvuloplasty Repairs for Mitral Regurgitation. Mitral valvuloplasty is the repair of the valve leaflets or related structures. Selection of the appropriate repair for perforated or redundant valve leaflets or for shortened or elongated chordae tendineae requires careful assessment and evaluation of the abnormalities present. Historically most mitral valve repairs have been performed on the posterior leaflet, but a number of anterior leaflet repairs have been developed (see steps 5 to 8 in the following Operative Procedure).

OPERATIVE PROCEDURE

1. Perforated leaflets can be patched with pericardium.
2. Redundant, prolapsed *posterior* leaflet tissue can be resected (Figure 24-60). The cut edges of the posterior leaflet are sewn together, and the corresponding annular segment is plicated. An annuloplasty ring is inserted to reinforce the leaflet repair and reduce annular dilation.
3. Shortened, fused chordae tendineae can be lengthened and mobilized by their division into secondary chordae or by incising the tip of the papillary muscles.
4. Redundant tissue of elongated chordae may be implanted into the papillary muscle head or folded over itself and secured with a suture (rarely performed).
5. *Anterior* leaflet prolapse is a greater challenge and traditionally has been an indication for valve replacement. A small triangular resection of the anterior leaflet (reinforced with annuloplasty ring insertion) can be performed.
6. Elongated or ruptured chordae may be replaced with polytetrafluoroethylene (PTFE) suture (Figure 24-61).
7. A chordal flip procedure (Figure 24-62) can be used to reestablish chordal attachment to the *anterior* leaflet. A section of the posterior leaflet with attached chordae is cut, swung over to the anterior leaflet, and sewn onto the anterior

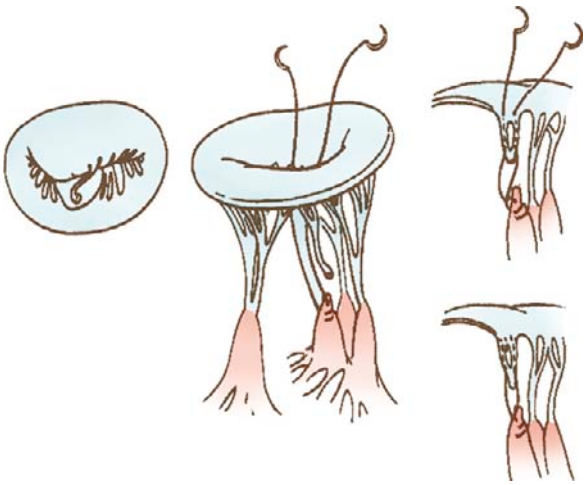

FIGURE 24-61 Chordal replacement with polytetrafluoroethylene (PTFE) (see text).

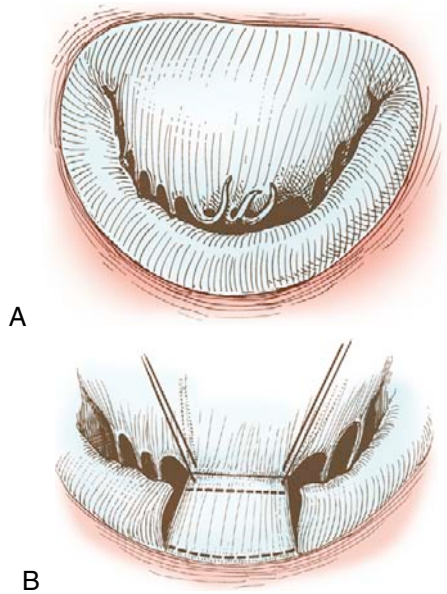

FIGURE 24-62 Chordal flip procedure. Although portions of the posterior leaflet can be resected with success, the same is not true of the anterior leaflet because the shape of the valve and the coaptation margin are altered. **A**, When there are ruptured chordae of the *anterior* leaflet of the mitral valve, the flip procedure can be used to reestablish chordal support for the anterior leaflet. **B**, A portion of normal posterior leaflet tissue with attached chordae is cut, swung over, and sewn onto the flail segment of the anterior leaflet.

leaflet. The remaining posterior leaflet defect is closed with suture (see step 2).

8. The edge-to-edge technique introduced by Alfieri and colleagues (2001) can be used to repair mitral valves with bileaflet prolapse (i.e., both the *anterior* and *posterior* leaflets are incompetent, producing severe MR). The free edges of the mitral leaflets are approximated, and a figure-of-eight suture (or percutaneously-delivered clip) is placed in the central portion of the apposed leaflets. This creates a double-orifice mitral valve that can significantly reduce MR and preserve the native valve (Mascagni et al, 2005). Frequently an annuloplasty ring supplements the Alfieri technique (Fedak et al, 2008).

Percutaneous mitral valve repair employing various devices and delivery methods is under investigation. The complex nature of the mitral valve apparatus poses particular challenges to avoid injury to the valve components or other cardiac structures (Fedak et al, 2008).

Mitral Valve Replacement

Mitral valve replacement (MVR) is the excision of the mitral valve leaflets and replacement with a mechanical or biologic prosthesis. Generally, the mural (posterior) leaflet and associated chordae and papillary muscles are retained to maintain left ventricular configuration (*geometry*), thereby enhancing postoperative ventricular function. If possible, the anterior leaflet is also retained if it does not interfere with prosthetic function and it is not too heavily calcified.

Median sternotomy is performed in most cases, but right thoracotomy incisions are useful in selected cases (e.g., reoperation, especially in patients with CABG IMA and vein grafts to the LV coronary circulation). Minimally invasive (and robotic) procedures on the mitral valve can also use right and left thoracotomy incisions or ports.

Procedural Considerations. Although the surgeon may intend to implant a specific type of prosthesis, patient-related factors (Box 24-7) or prosthetic valve complications (Box 24-8) may modify the plan (Oakley et al, 2008). A complete range of the surgeon's preferred valves should be available, as well as saline to rinse the glutaraldehyde storage solution (see Risk Reduction Strategies box on p. 1029) from biologic prostheses if they are used. Pledgetted sutures of alternating colors are used, and suture holders may be available additionally to keep the stitches in the correct order. Venting catheters and aspirating needles are used to remove air from the heart and ascending aorta. A small dental mirror may be used after a bioprosthesis has been implanted to ensure that sutures are not caught in the struts of the valve.

Operative Procedure. Double venous cannulation is used.

1. The aorta is cross-clamped, and cardioplegic solution is infused through the aortic root and/or retrograde through the coronary sinus.
2. The left atrium is incised along the interatrial groove to expose the mitral valve (Figure 24-63, *A*).
3. The valve is assessed, and the anterior leaflet is excised. The posterior leaflet and occasionally the anterior leaflet are retained to enhance the ventricular configuration and postoperative function. Rongeurs may be used to debride heavy calcification; loose debris is removed. A margin of the valve annulus is retained to insert fixation sutures to the prosthesis (Figure 24-63, *B*).
4. A valve sizer is used to determine the correct size of the prosthesis, which is delivered to the field.
5. Nonabsorbable cardiovascular sutures (15 to 20 or more) are placed in the annulus of the valve and then placed into the sewing ring of the prosthesis.

BOX 24-7

Patient-Related Factors and Risks for Valve Surgery

- Age
- Gender
- Residence
- History of atrial fibrillation
- Endocarditis (preoperative)
- Connective tissue disorders (e.g., myxomatous changes)
- Congenital anomalies (e.g., bicuspid aortic valve)
- Enlarged left atrium
- Left atrial thrombus
- Coronary artery disease
- Left ventricular function (e.g., functional class, myocardial infarction, heart failure)
- Syncope
- Mismatch between native valve orifice and patient body size
- Anticoagulation therapy compliance
- Preexisting medical problems (e.g., diabetes mellitus, hypertension, hepatic or renal disease)
- Valve lesion, anatomic anomalies
- Previous cardiac surgery

BOX 24-8

Valve-Related Risks and Complications

- Thromboembolism
- Anticoagulation-related hemorrhage
- Prosthetic valve endocarditis
- Mismatch between prosthetic valve orifice and patient body size
- Periprosthetic leak
- Prosthetic failure

Modified from Oakley RE et al: Choice of prosthetic heart valve in today's practice, *Circulation* 117:253-256, 2008; Stout KK, Verrier ED: Acute valvular regurgitation, *Circulation* 119:3232-3241, 2009; Rahimtoola SH: Choice of prosthetic heart valve for adult patients, *J Am Coll Cardiol* 41(6):893-904, 2003; Pepper J et al: Stentless versus stented bioprosthetic aortic valves. A Consensus Statement of the International Society of Minimally Invasive Cardiothoracic Surgery (ISMICS) 2008, *Innovations* 4(2):49-60, 2009; Ascione R et al: Mechanical heart valves in septuagenarians, *J Cardiac Surg* 23:8-16, 2007.

6. The sutures are held taut (and moistened with saline) as the prosthesis is guided into position and secured, and the sutures are tied and cut (Figure 24-63, *C*).
7. Continuous nonabsorbable sutures are used to partially close the atriotomy. The patient is placed in the Trendelenburg position, and the lungs are inflated to remove air from the pulmonary veins and atrium. Air is aspirated from the left ventricle through a hypodermic needle inserted into the LV apex or through the vent catheter, and the atrial closure is completed.

Endoscopic, video-assisted, robotic mitral valve surgery has progressed from a technical curiosity to an acceptable method (albeit with a significant learning curve) of intracardiac, telemanipulated valve repair. Both mitral valve repair and replacement have been performed with these techniques (Figure 24-64), as well as procedures to correct other intracardiac structural lesions (Chitwood, 2005; Chitwood et al, 2008).

SURGERY FOR THE TRICUSPID VALVE

Right-sided valve disease "deserves a little more respect" according to the title of a review by Bruce and Connolly (2009, p. 2726). The authors recommend more aggressive therapy in patients with both tricuspid and pulmonary valve disease before clinical deterioration occurs. Among the treatment options for tricuspid valve disease are suture annuloplasty, ring annuloplasty, and valve replacement with either a biologic or a mechanical prosthesis. Percutaneous approaches have been investigated in the experimental setting (Rogers and Bolling, 2009).

Like the mitral valve, the tricuspid annulus is saddle-shaped and techniques to repair the valve should consider this anatomic configuration for optimal repair (Rogers and Bolling, 2009). Annuloplasty ring insertion may be preferable to suture annuloplasty (Tang et al, 2006; Bruce and Connolly, 2009).

Tricuspid Valve Annuloplasty

Tricuspid valve annuloplasty reduces a dilated annulus with a suture technique (Rabago et al, 1980) or a prosthetic ring. Tricuspid valve regurgitation may be caused by bacterial or viral endocarditis, the presence of a pacemaker or defibrillator lead through the valve annulus, or the functional result of mitral valve disease. After mitral valve correction, tricuspid valve function may return to normal, although this theory has been questioned (Rogers and Bolling, 2009; Bruce and Connolly, 2009). Preoperatively, if the tricuspid annular dilation is diagnosed to be severe, ring repair (similar to mitral annuloplasty) or valve replacement may be performed. Caution is taken to avoid injury to the conduction tissue in the area of the AV node. A pulmonary artery catheter is usually not inserted preoperatively because it can interfere with the surgical field. A catheter may be inserted after the repair is completed.

Patients with significant tricuspid stenosis or regurgitation or failed tricuspid (suture or ring) annuloplasty may require insertion of a prosthetic biologic or mechanical valve (Bruce and Connolly, 2009). There are no specific tricuspid prosthetic valves; rather, a mitral prosthesis would be implanted.

Operative Procedure

1. Double venous cannulae are inserted so that they do not cross one another in the right atrium, and occluding tapes are tightened around the cavae and cannulae to prevent venous return from entering the right atrium and obscuring the surgical site. A right-angled venous cannula may be placed into the superior vena cava to enhance exposure.
2. The right atrium is opened longitudinally to expose the tricuspid valve. Sump suctions are inserted to remove coronary sinus drainage.
3. In the DeVega (Rabago et al, 1980) suture annuloplasty technique (Figure 24-65), a double-armed, felt-pledgetted suture is placed in the valve annulus, beginning at the anteroseptal commissure and continued around to the level

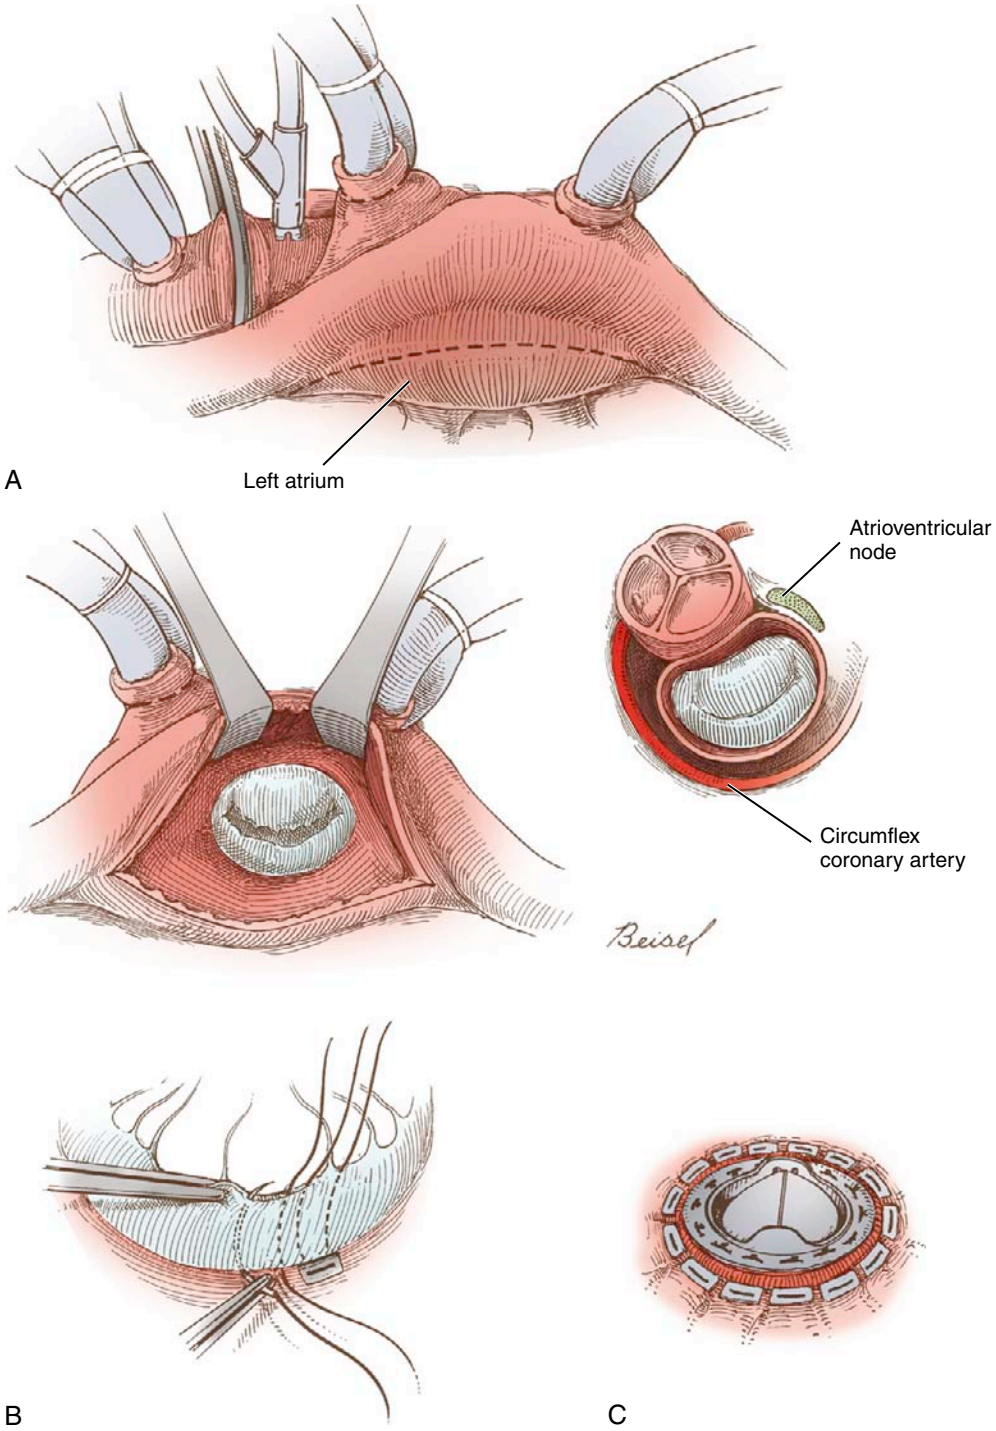

FIGURE 24-63 Mitral valve replacement. **A**, Line of incision and cannulation for bypass, anatomic relationship between mitral and aortic valves with location of conduction node, and exposure of valve. **B**, Placement of pledgetted double-armed sutures in native valve annulus. **C**, Completed valve replacement.

of the coronary sinus orifice. The remaining arm of suture is similarly placed. The suture is tied over a pledget with sufficient tension to reduce the annular area to the size desired.

4. In the ring annuloplasty technique, a prosthetic ring is inserted in a manner similar to that used for mitral valve annuloplasty (see Figure 24-59).
5. For valve replacement, the surgeon selects the desired prosthesis and inserts it in a manner similar to that for mitral valve replacement (see Figure 24-63).
6. Saline may be injected into the ventricle to test the competence of the repair, and TEE is also employed.
7. The right atrium is closed with nonabsorbable suture.

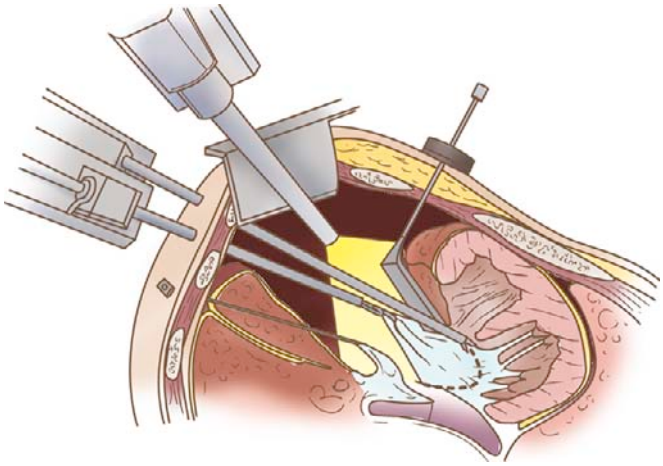

FIGURE 24-64 The 1-cm robotic instrument arms are placed through the chest wall. A transthoracic retractor arm elevates the interatrial septum toward the sternum. The three-dimensional camera is placed through a 4-cm incision, which also serves as a working port for the assistant.

SURGERY FOR THE PULMONARY VALVE

Pulmonary valve surgery in the adult is unusual, although patients with genetic deformities or those who have undergone repair of congenital pulmonary valve or right ventricular outflow tract obstruction (see Chapter 25) may present with significant pulmonary valve disease (Bruce and Connolly, 2009). Generally mild or moderate pulmonary stenosis (PS) produces few symptoms. For patients with severe PS, treatment options include valvulotomy or valve replacement via percutaneous or standard surgical techniques. Generally an aortic bioprosthesis or an allograft is inserted for valve replacement.

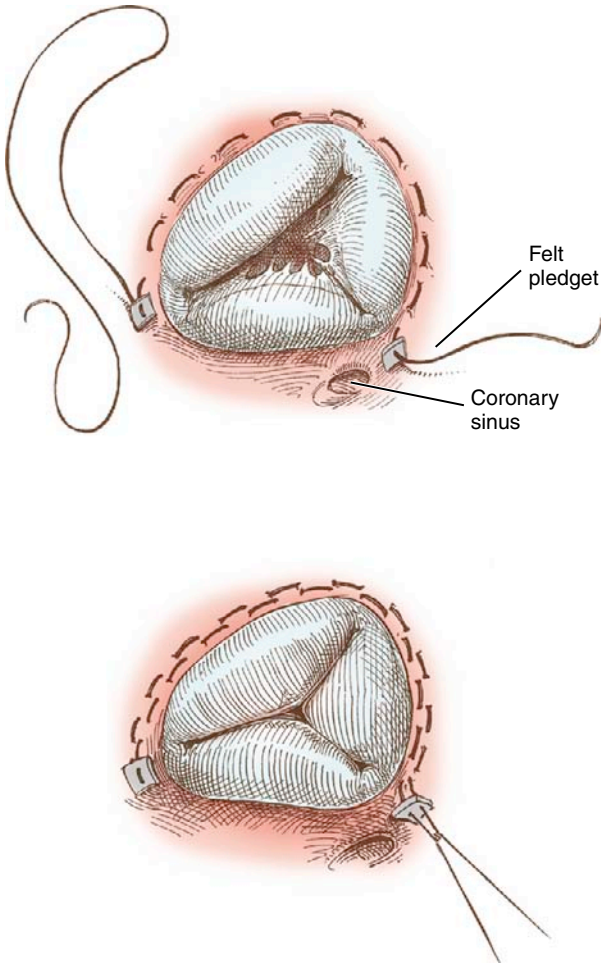

FIGURE 24-65 DeVega tricuspid valve suture annuloplasty.

SURGERY FOR THE AORTIC VALVE

Aortic *stenosis* (AS) produces obstruction to left ventricular outflow. Whether caused by rheumatic fever, a congenital bicuspid valve, or calcification, the fused valve leaflets present an increasing resistance to left ventricular outflow, thus increasing the pressure inside the left ventricle. Recent histopathologic and clinical data suggest that calcified AS is not a "degenerative" passive process but, rather, an active and possibly inflammatory disease process (Otto and Bonow, 2008).

To compensate for the increased pressure load, the ventricle hypertrophies so that it can generate sufficient pressure to eject blood through the narrowed opening. When disease is severe, large pressure gradients are often measured during cardiac catheterization, with differences in systolic pressures between the ventricle and the aorta reaching 50 mm Hg or more. In the early stages of the disease, a systolic ejection murmur may be heard, but patients are rarely symptomatic. Eventually, fatigue, exertional dyspnea, angina pectoris, syncope, and congestive heart failure may develop, presenting a grave prognosis. Although infrequent, sudden death may be the first sign of AS in asymptomatic patients who are not well monitored (Cohanes and Davidoff, 2009; Dal-Bianco et al, 2008).

In developing countries aortic *insufficiency (regurgitation)* is most often caused by rheumatic fever, and in developed countries it is usually caused by congenital anomalies (commonly a bicuspid aortic valve) (Otto and Bonow, 2008). Although *repair* of the aortic valve is challenging because of the precise closing mechanism of the valve leaflets, aortic valve reparative techniques have been employed successfully in selected patients (Otto and Bonow, 2008). Total valve excision and replacement with a prosthesis or an allograft are commonly performed.

Interventional percutaneous and minimally invasive techniques have been developed. Transcatheter aortic valve implantation performed in the cardiac catheterization laboratory is increasingly employed as a treatment option; long-term data are not widely available, but the trend is toward more percutaneous interventions in high-risk patients (Webb et al, 2009). Mini-sternotomy incisions can be employed although objective advantages over conventional sternotomy have not been seen with this technique (Brown et al, 2009).

In addition to selection of access, other challenges include the choice and size of a prosthetic valve. Selection is based on achieving appropriate hemodynamic function in relation to body size. The small aortic root (e.g., less than 21 mm) presents challenges to provide an adequate cardiac output. In patients with a small aortic annulus and large body mass (referred to as *patient/prosthesis mismatch*), the surgeon selects a prosthesis that will provide flow adequate to meet the body's needs. The stentless aortic valve (see Figure 24-27, *B*) is frequently used

because of the excellent hemodynamics (Cheng et al, 2009). Patch enlargement of the small aortic root is another option (Feindel, 2006; Sellke and Ruel, 2009) (described in the following Operative Procedure), and the patient's own pulmonary valve can be used as an autograft to replace the aortic valve; the pulmonary valve is then replaced with an allograft. Allografts may be used to replace the aortic valve as well.

Aortic Valve Replacement

The aortic valve is excised and replaced with a mechanical or biologic prosthesis or an aortic valve allograft or autograft.

Procedural Considerations

To the basic setup the following may be added:

- Aortic valve instruments
- Aortic valves, sizers, and holders
- Coronary sinus retrograde-infusion cannula and venting catheters
- Saline and three basins to rinse the glutaraldehyde storage solution from bioprostheses
- Saline bath to thaw frozen allografts

Operative Procedure

1. After the institution of CPB, a left ventricular vent is inserted through a stab wound into the right superior pulmonary vein and the tip is advanced into the left ventricle. A retrograde cardioplegia catheter is inserted into the coronary sinus (Figure 24-66, *A*).
2. The aorta is cross-clamped. If aortic insufficiency is present, the initial bolus of cardioplegic solution is infused retrogradely; subsequent cardioplegic infusions are also given retrogradely. Occasionally, direct coronary perfusion (Figure 24-66, *B*) is given if a retrograde catheter cannot be inserted; however, direct perfusion is avoided when possible (because of the risk of injuring the coronary endothelium). If aortic stenosis is present, the initial bolus of cardioplegic solution may be infused by needle through the aorta into the aortic root. Once the heart is arrested, the aorta is opened.
3. The native valve is inspected. The valve is carefully excised to avoid injury to the annulus and underlying structures (Figure 24-66, *C*). Calcium is debrided from the annulus with scissors or rongeurs, or both. Narrow packing may be used in the left ventricle to confine small, loose, calcified fragments that could subsequently embolize. Instruments should frequently be wiped clean with a moist sponge.
4. The annulus is sized, the proper prosthesis is selected, and a prosthesis holder is attached.
5. a. If a biologic valve is selected, it is delivered to the field and rinsed in three saline baths according to the manufacturer's instructions (see Risk Reduction Strategies box on p. 1029). Biologic valves should be kept moist with frequent saline rinsing; they should *not* be immersed in antibiotic solution.
   b. If an allograft is used, it is delivered to the field and thawed in saline baths according to protocol.
   c. If a mechanical valve is chosen, it should be protected from scratches or other injury.
6. a. The new valve is implanted (Figure 24-66, *D* and *E*) by use of a technique similar to that previously described for MVR.
   b. If the aortic annulus is too small to accept a prosthesis of adequate size, the annulus and proximal portion of the ascending aorta can be enlarged. A patch of bovine pericardium or Dacron graft can be placed longitudinally in the proximal anterior ascending aorta where the aortic annulus has been incised (Figure 24-67, *A* and *B*). The valve prosthesis is sutured to the natural annulus and then to the patch (Figure 24-67, *C*). The patch is sutured to the remaining edges of the aortotomy (Figure 24-67, *D*).
7. The aorta is closed with nonabsorbable sutures, and the cross-clamp is removed.
8. The left side of the heart is deaired (by vent, by moving the OR bed side to side, or by other maneuvers chosen by the surgeon). The patient is placed in the Trendelenburg's position, and the lungs are inflated. The heart is not allowed to eject blood until the surgeon is satisfied that no air remains within the left ventricle. TEE is used to identify residual air. The heart is defibrillated if it does not resume beating spontaneously.
9. Rewarming of the heart continues, the venting catheter or catheters are removed, and the chest is closed in the routine manner.

Combined Surgery

When CABG is to be performed with aortic valve replacement, the procedure usually is done in the following order:

1. The diseased valve is excised, the annulus is sized, and the prosthesis is selected.
2. Distal coronary anastomoses are performed.
3. The prosthetic valve is inserted.
4. The aorta (or left atrium in MVR) is closed.
5. The proximal coronary anastomoses are inserted into the aorta, after which the aortic cross-clamp is removed.

Double Valve Replacement

When the *aortic and mitral valves are both replaced,* the valves are first excised and the annuli sized. Then the mitral valve prosthesis is first implanted, followed by the aortic valve. (If the aortic prosthesis is inserted first, the firm prosthetic aortic annular ring could cause cardiac injury and make insertion of a mitral prosthesis difficult.) The aorta is closed, and after sufficient deairing of the left ventricle, the left atrium is closed.

SURGERY FOR THE THORACIC AORTA

Thoracic aortic aneurysmectomy is excision of an aneurysmal portion of the ascending aorta, aortic arch, or descending thoracic aorta and replacement with a prosthetic graft, valve-graft conduit, or intra-aortic prosthesis. Collagen-impregnated grafts have significantly reduced interstitial bleeding and obviated the need for preclotting techniques.

Aneurysms may be caused by atherosclerosis, trauma, infection, or cystic medial degeneration (Isselbacher, 2008). *Atherosclerosis* affects large and medium arteries with tunica intima deposits of plaques containing cholesterol, lipoid material, and lipophages. Atherosclerosis generally affects the smaller arteries rather than the aorta. *Arteriosclerosis* is a condition characterized by loss of elasticity and by thickening and hardening of the arteries. Both conditions may lead to aneurysm formation within an artery.

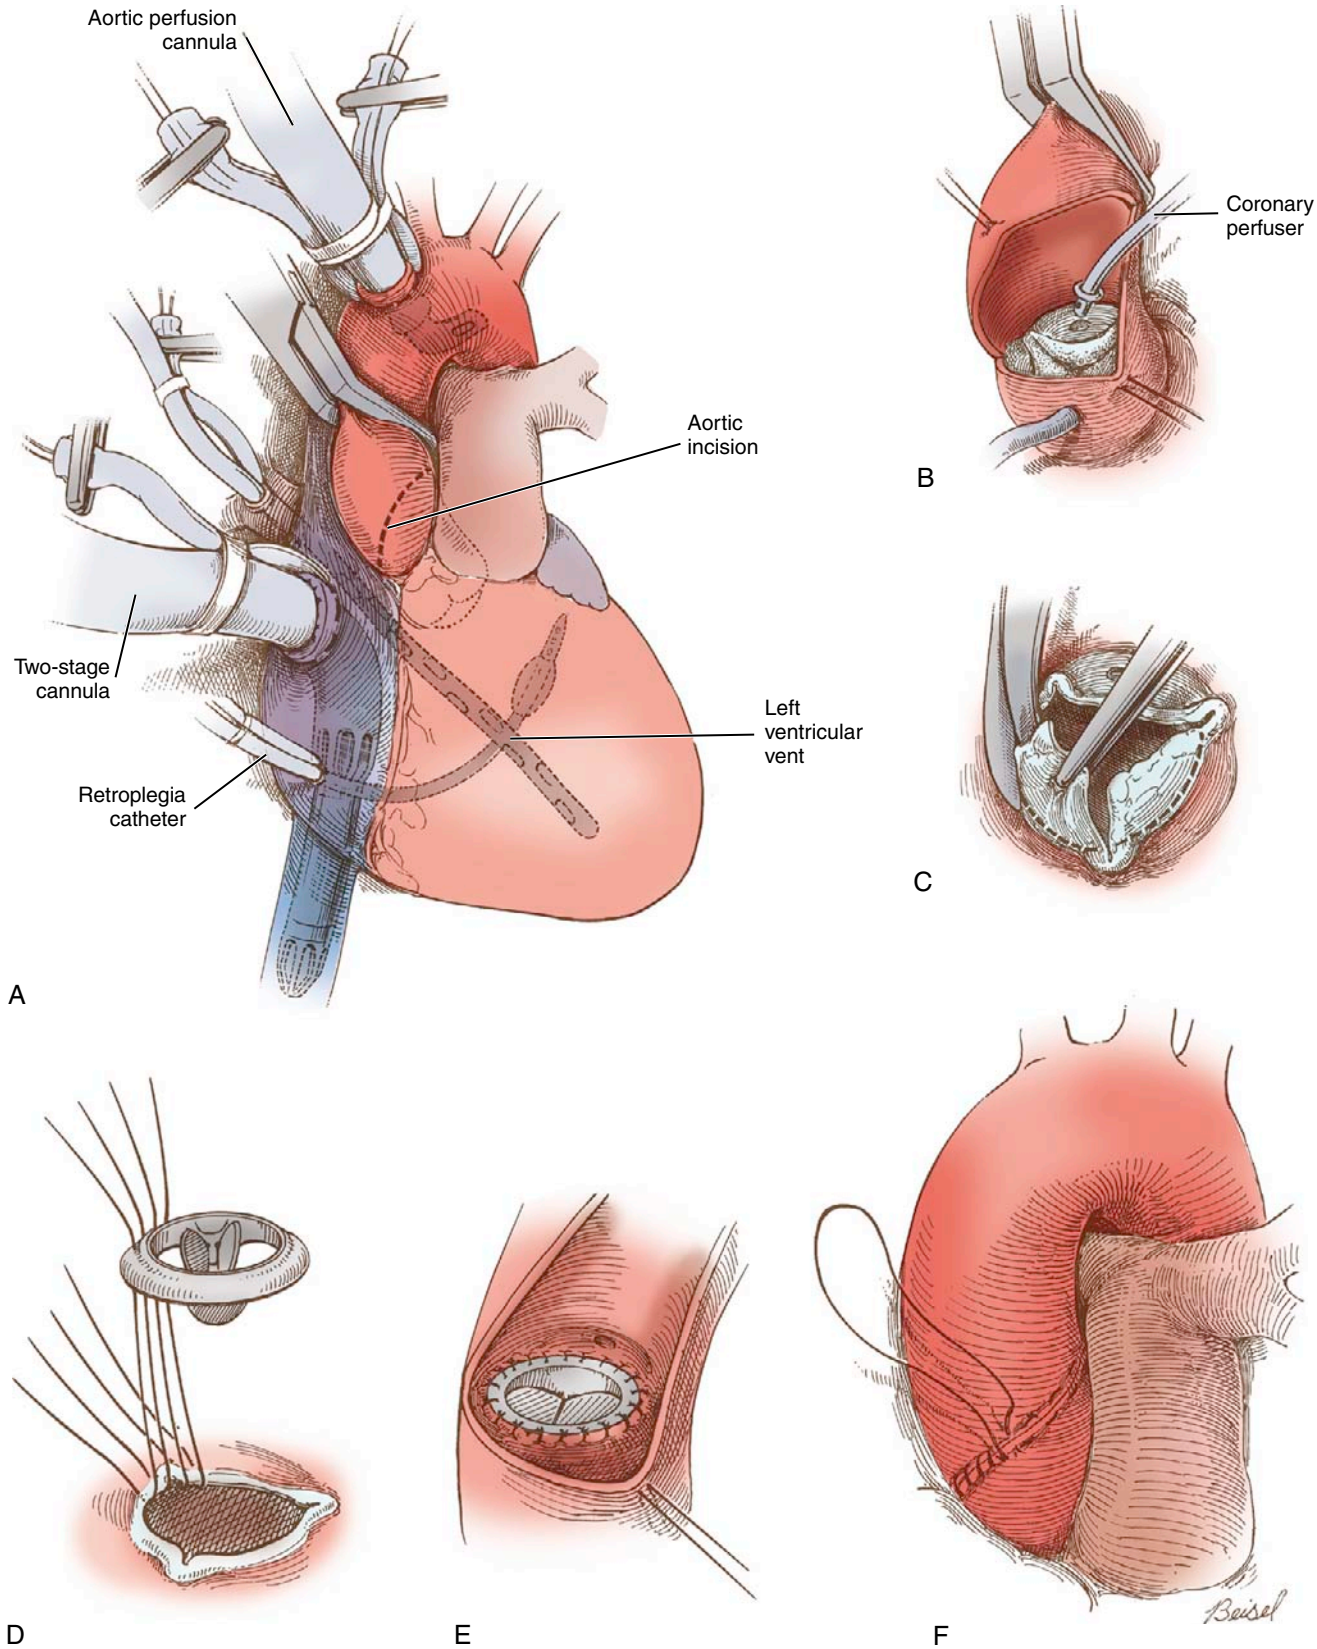

FIGURE 24-66 **A**, Cannulation, retrograde cardioplegia, and vent sites for aortic valve procedures. Note incision line. **B**, If retrograde cardioplegia is not used, handheld coronary ostial catheters can deliver antegrade cardioplegic solution. **C**, Diseased valve is completely excised. **D**, Sutures are placed in the valve annulus and the prosthetic sewing ring. **E**, Stitches are tied and cut. **F**, Closure of the aortic suture line.

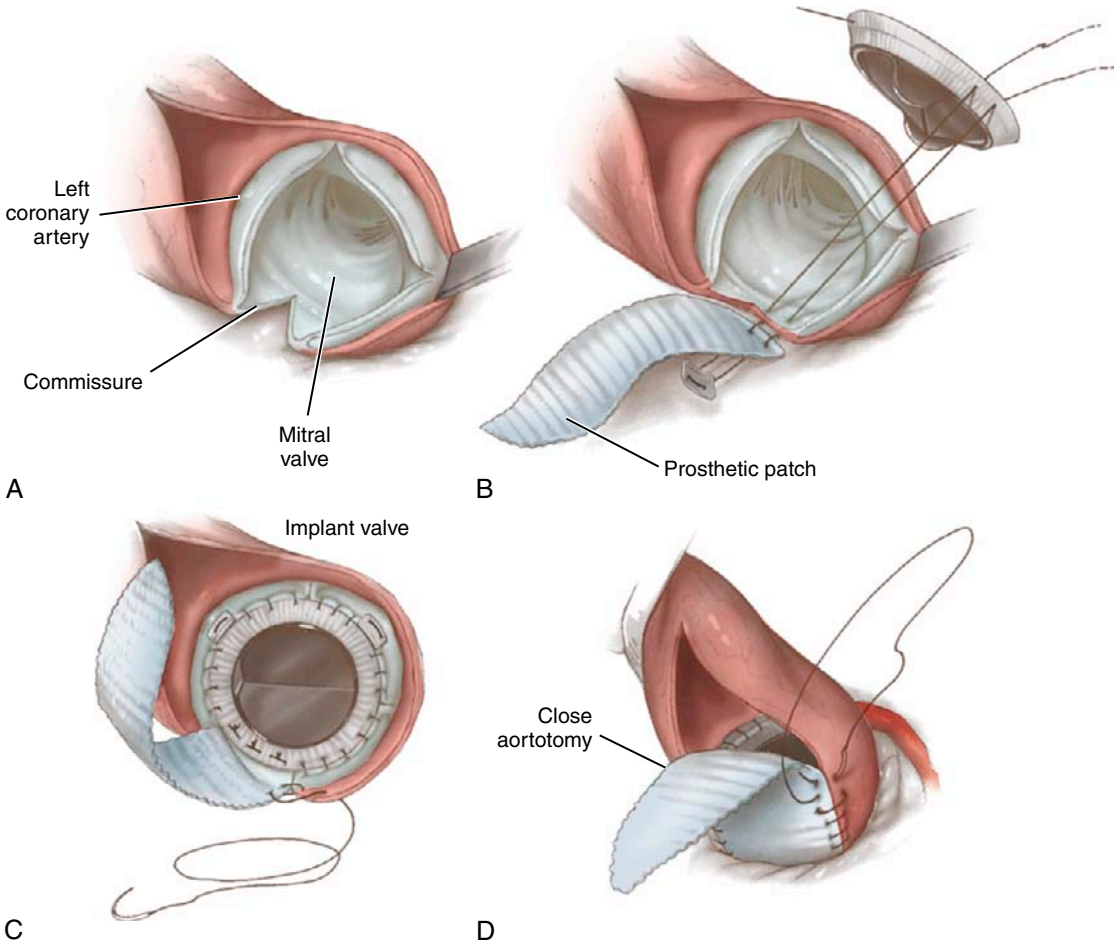

FIGURE 24-67 Technique for aortic enlargement (Nicks-Nuñez operation). **A**, The aortotomy is extended through the commissure separating the left and noncoronary cusps. **B**, A prosthetic patch is sewn into the cut portion of the aorta and into the prosthetic valve. **C**, The prosthetic valve is seated, and the stitches are tied and cut. **D**, The patch is incorporated into the aortotomy closure.

Aortic *dissection* is a unique entity and is related to a tear in the tunica intima of the aorta that exposes underlying degenerative changes in the tunica media layer of the artery. Intraluminal blood flow penetrates and flows through the tear, resulting in subsequent dissection of the tunica media (Isselbacher, 2008). As blood passes between the layers of the wall, it forms a false channel; as the channel extends and enlarges, the blood flow can be obstructed through the aorta and its branches, or the aorta can rupture, causing severe hemorrhage (Figure 24-68, *A*).

Surgical intervention becomes necessary when presenting symptoms indicate a compromised circulation or danger of rupture; generally, medical management with hypotensive agents to reduce stress on the vessel is the preferred initial treatment until surgical repair can be performed.

Aneurysms can be characterized morphologically as follows: (1) saccular—a sac type of formation with a narrowed neck projecting from the side of the artery; (2) fusiform—a spindle-shaped formation with complete circumferential involvement of the artery. Dissections can be characterized in at least two systems according to type, origin, and extent of the lesion (Table 24-10).

Procedural Considerations

Several methods of surgical treatment are described in the classic study by Crawford (1990). In situations where ascending aortic aneurysm or aortic dissection produces annular dilation with subsequent aortic valve insufficiency, a modified Bentall-DeBono procedure with a composite graft-valve conduit and reimplantation of the coronary ostia may be performed to replace the aortic valve and the aneurysmal aorta (Quigley et al, 2008; Isselbacher, 2008) (Figure 24-69). Retrograde cardioplegia is usually employed to arrest the heart; if necessary, selective coronary infusion may be used. The Bentall-DeBono procedure necessitates reimplanting the right and left coronary ostia into the prosthetic graft; in patients with CAD, vein grafts may be inserted and anastomosed proximally to the prosthesis.

The type of CPB depends on the location of the aneurysm or dissection. Generally, the atrium can be cannulated for venous return and the femoral or axillary artery is used for arterial inflow (because the weakened ascending aorta cannot be safely cannulated). Deep hypothermia with circulatory arrest and cerebroplegia may be needed to protect the heart and brain in particularly complex lesions of the aortic arch where placement

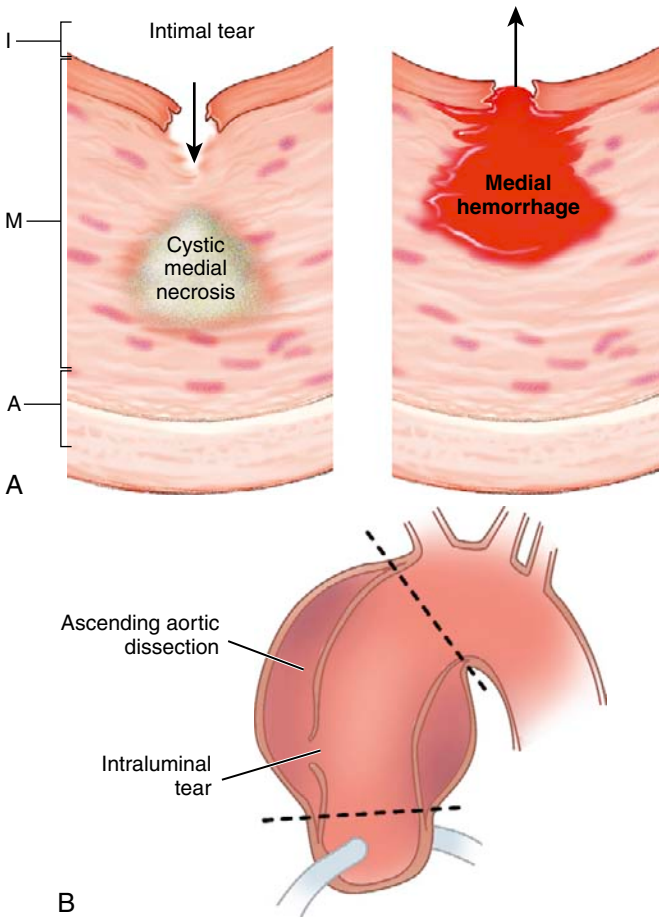

FIGURE 24-68 Aortic dissection. **A**, Proposed mechanism of the initiation of an aortic dissection (*A* = adventitia; *M* = media; *I* = intima). **B**, Intimal tear in the ascending aorta causing a dissection.

of a cross-clamp is difficult. Cerebral oximetry may be used to monitor oxygenation of the brain.

Traditionally, during the open repair of descending thoracic aortic aneurysms, the heart is not arrested; it continues beating to perfuse the upper body. Femoral bypass may be instituted to perfuse the kidneys and lower extremities; however, normothermia usually is maintained. Hypothermic CPB can be used to repair complex descending and thoracoabdominal aneurysms to provide protection against paralysis and renal, cardiac, and visceral organ system failure. Increasingly, an endovascular stent (see Figure 24-22) is used for aneurysms and dissections (Svensson, 2009); the prosthesis is inserted through the femoral artery and guided under fluoroscopy to the area of the descending aortic aneurysm.

In complex lesions involving the ascending aorta, arch, and descending aorta, the ascending aorta and arch repair may be performed with an open technique. Subsequently, repair of the descending aorta may be performed with an endovascular graft (see Repair of Descending Thoracic Aortic Aneurysm p. 1070) (Isselbacher, 2008).

Repair of Ascending Thoracic Aortic Aneurysm or Dissection

Procedural Considerations. To the basic setup are added aneurysm instruments. Valve instruments, coronary instruments, and an array of tube grafts, valves, or valved conduits should be available. Bicaval cannulation for venous drainage is preferred, but if the cavae cannot be safely accessed, the femoral vein is used initially for venous drainage. Once the aneurysm is controlled, the femoral venous line can be Y-ed to a vena caval cannula.

TABLE 24-10

Commonly Used Classification Systems to Describe Aortic Dissection

Type	Site of Origin and Extent of Aortic Involvement
DEBAKEY	
Type I	Originates in ascending aorta, propagates at least to aortic arch and often beyond it distally
Type II	Originates in and is confined to ascending aorta
Type III	Originates in descending aorta and extends distally down aorta or, rarely, retrograde into aortic arch and ascending aorta
STANFORD	
Type A	All dissections involving ascending aorta, regardless of site of origin
Type B	All dissections not involving ascending aorta
DESCRIPTIVE	
Proximal	Includes DeBakey types I and II or Stanford type A
Distal	Includes DeBakey type III or Stanford type B

Modified from Libby P et al: *Braunwald's heart disease,* ed 8, Philadelphia, 2008, Saunders.

Operative Procedure

1. The patient is positioned for a median sternotomy.
2. Cannulation for CPB is performed.
3. The sternum is opened, and the aneurysm is inspected.
4. The involvement of the aortic annulus is then considered.
   a. If the aortic annulus is not involved, the aneurysm is incised longitudinally and a woven graft is anastomosed proximally and distally to the healthy aorta (Figure 24-70). Felt strips incorporated into the anastomosis may be used to bolster friable tissue.
   b. If the aortic annulus is involved, the ascending aorta is incised to the annulus and the aneurysm may be excised. The leaflets are excised, and the annulus is measured. The proximal end of a valved conduit is inserted. An eye electrocoagulator is used to create openings in the graft at the location of the right and left coronary ostia, which are mobilized and anastomosed to the graft. (If the patient has concomitant CAD, saphenous vein grafts are inserted.) The distal end of the conduit is sutured to healthy aorta.
5. Bypass is discontinued, and all incisions are closed.

Repair of Aortic Arch Aneurysm

Procedural Considerations. Aneurysm instruments and woven grafts are available. If deep hypothermia is to be used, the patient's head may be covered with bags of ice at the beginning of the procedure to reduce cerebral oxygen demand. Precautionary measures (e.g., padding) to prevent

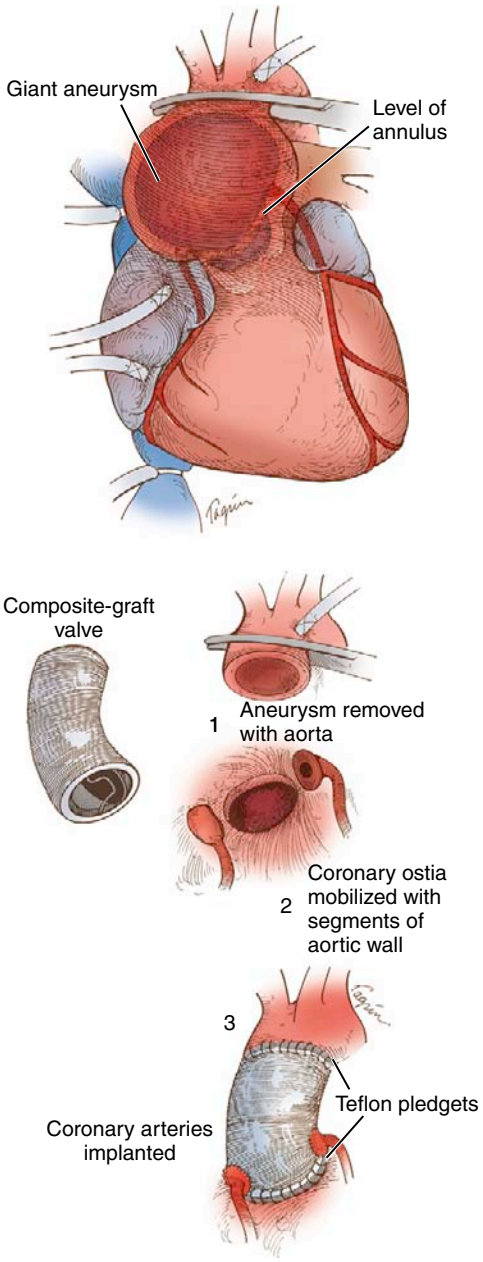

FIGURE 24-69 Bentall-DeBono procedure (see text).

frostbite are instituted. The location of the aneurysm will determine the positioning. Aneurysms of the proximal arch can be accessed through a median sternotomy; distal arch aneurysms may require a modified thoracotomy position to optimize exposure. Selective cerebral perfusion may be used during circulatory arrest to perfuse the brain. *Retrograde* cerebral perfusion is performed via the superior vena caval venous line that is Y-ed off the arterial line; arterial blood is slowly infused through the SVC line into the cerebral circulation while the distal aortic anastomosis is performed. *Antegrade* cerebral perfusion is achieved by infusing arterialized blood through one or more catheters into aortic arch vessels (i.e., brachiocephalic artery and left common carotid artery).

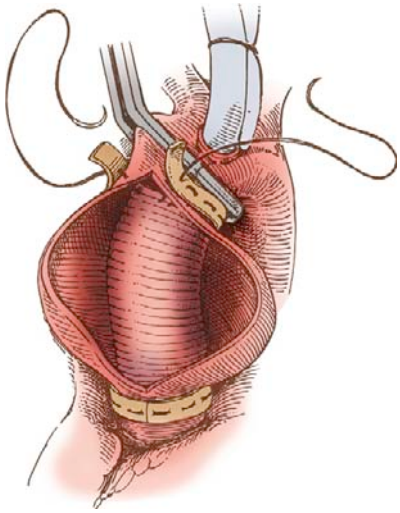

FIGURE 24-70 Resection and graft repair of ascending aortic aneurysm.

Operative Procedure

1. Cannulation of the right atrium and femoral or axillary artery is performed.
2. Once the patient is cooled to the desired temperature, the arch vessels are individually cross-clamped (Figure 24-71, *A* and *B*). (If circulatory arrest is indicated, cross-clamps are not used.) The aneurysm is incised, a tube graft (with or without side branches) is selected, and the anastomosis to the descending aorta is performed.
3. An opening is made into the side of the graft, and the graft is anastomosed to the common origin of the brachiocephalic, left carotid, and left subclavian vessels. Alternatively, when a graft with side branches is used, individual anastomoses to the head vessels are created. The graft is cross-clamped proximally to the arch and deaired (Figure 24-71, *C*).
4. The proximal aorta is anastomosed to the graft while the patient is rewarming. The graft is deaired, and the patient is weaned from bypass (Figure 24-71, *D*).
5. All incisions are closed.

Repair of Descending Thoracic Aortic Aneurysm

Procedural Considerations. *Endovascular* repair (see Figure 24-22) of descending aortic aneurysms and dissections has largely replaced the traditional open technique, although anatomic considerations may increase the difficulty of placing the straight endovascular tube graft into the angled portion of the proximal descending aorta (just distal to the left subclavian artery). Additionally, endovascular insertion requires nondiseased tissue for implantation of the device in the areas proximal and distal to the lesion (the "landing zones"); in patients with diffuse atherosclerotic disease or extensive dissection, viable tissue may not be present (Thompson and Bertling, 2009). It is not unusual to deploy more than one graft in order to cover the lesion. Endovascular instruments, guidewires, introducer sheaths, pigtail catheters, intravascular dye, dilators, catheters, an array of stent graft sizes, and deployment devices are required. The procedure is performed with fluoroscopy and is usually performed on an OR bed that

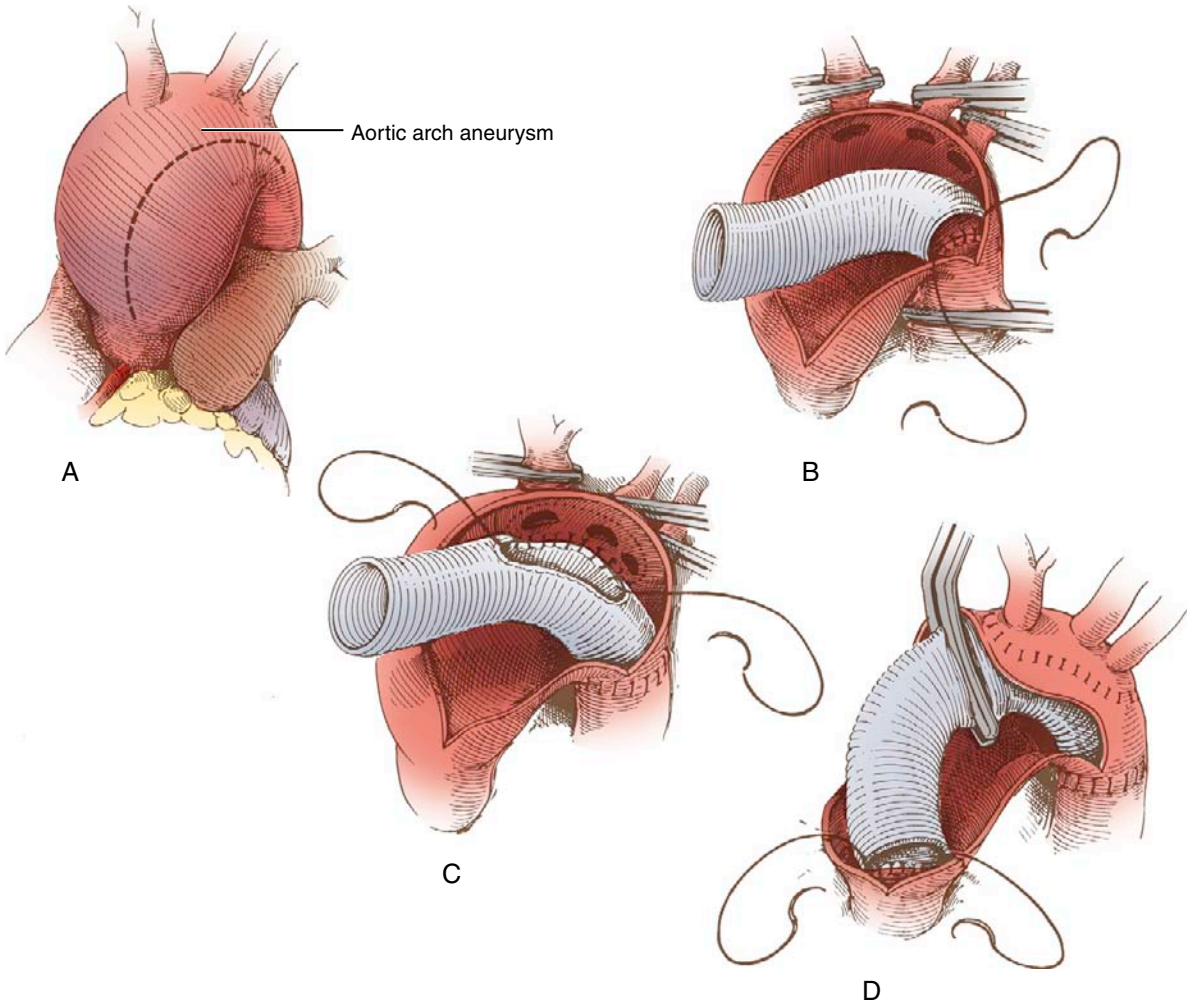

FIGURE 24-71 Repair of aortic arch aneurysm. **A**, Incision. **B**, Distal anastomosis. **C**, Anastomosis of graft to common origin of arch vessels. **D**, Proximal anastomosis.

allows imaging without extensive manipulation of the bed. Radiation precautions must be taken. The guidewires may be more than 6 feet in length so the scrub person should protect the sterility of the distal portion of the guidewire by anchoring the wire with towels or other sterile objects when not being used. The postoperative period is considerably shorter than that for a thoracotomy approach. Potential complications include bleeding and migration of the device (requiring adjustment and/or insertion of another device) (Thompson and Bertling, 2009).

For *open* repair, thoracotomy instruments and supplies are added to the basic setup; additional long aortic cross-clamps may be needed. Prosthetic grafts are available. The patient is positioned for a left posterolateral thoracotomy. Femoral vein–femoral artery bypass may be performed to perfuse the lower body. In this situation, the heart perfuses the upper body proximal to the aneurysm and normothermia is maintained.

If hypothermic CBP with circulatory arrest is employed, instruments and supplies per the surgeon's request should be available. Protective covering for the patient's head, face, and extremities may be required to avoid frostbite.

Operative Procedure—Endovascular Repair

1. One or both femoral arteries are accessed via a percutaneous (Seldinger) or cutdown technique. A hypodermic needle is inserted into the femoral artery. A guidewire is passed through the needle and threaded into the aorta. Fluoroscopy may be used to image the aortic lumen and measure targeted segments of the aorta. The hypodermic needle is removed and a sheath inserted (through which the device will be inserted).
2. A delivery catheter housing the graft is inserted into the descending aorta.
3. A monitoring device may be inserted through the contralateral femoral artery to measure intraluminal pressures.
4. Under fluoroscopy, the graft is guided into position and deployed into the aorta (see Figure 24-22). The device self-expands; a balloon may be inflated against the inside of the graft to secure the prosthesis against the aortic lumen.
5. Fluoroscopy is used to image the aorta and to confirm exclusion of the aneurysm/dissection.
6. The deployment devices and other intraluminal catheters and wires are removed and the incision(s) is (are) closed.

Operative Procedure: Open Repair

1. Cannulation for femoral vein–femoral artery bypass is performed.
2. A thoracotomy incision is made, the aneurysm is exposed, and the surrounding structures are inspected. (Occasionally the surgeon makes two thoracotomy incisions for better access to and control of the aorta.) Renal involvement is assessed; if indicated, measures to protect the kidneys are instituted (e.g., local cooling).
3. Normothermic femoral bypass is initiated.
4. The aneurysm is incised longitudinally, and the aorta is sized.
5. A woven graft (Figure 24-72) is inserted, and the aneurysmal remnants are wrapped around the graft.

ASSISTED CIRCULATION

Mechanical circulatory support has been available for more than 35 years (Gemmato et al, 2005), expanding the treatment for heart failure into a rapidly growing specialty that also includes coronary artery revascularization, left and right ventricular reconstruction, circulatory assist device implantation, and cardiac transplantation (McCarthy, 2008). Formerly, ventricular assist devices were reserved for those patients who could not be weaned from CPB after open-heart operations, or who had end-stage cardiomyopathy. Current indications and choices have expanded and a variety of active and passive devices are available to support the circulation for short-, intermediate-, and long-term support (Wilson et al, 2009). Selected ventricular assist devices have been approved for "destination" therapy, while other devices are indicated for patients awaiting a donor heart ("bridge-to-transplant" devices) (McCarthy, 2008; Naka and Rose, 2008; Miller et al, 2007).

Biologic assistance in the form of an autogenous muscle wrap (*cardiomyoplasty*) may be useful in some patients who may not be candidates for transplantation, but the procedure is used infrequently. The left latissimus dorsi muscle is dissected from the back and repositioned around the heart, where it is sewn around the ventricle. This (skeletal) muscle is then transformed into a continuously beating muscle by a cardiomyostimulator that paces the muscle with increasing frequency, allowing the muscle to become fatigue-resistant. The muscle wrap squeezes the heart in synchronization with natural electrical impulses moving through the heart muscle.

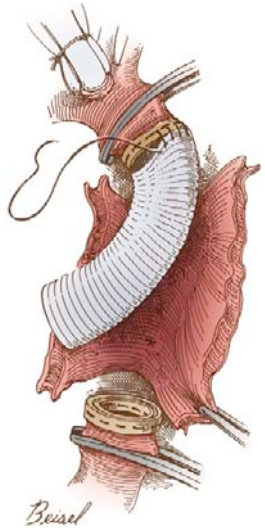

FIGURE 24-72 Resection and graft replacement for descending thoracic aortic aneurysm.

Intra-Aortic Balloon Pump

The most widely used short-term device is the intra-aortic balloon pump (IABP). The IABP (Figure 24-73) employs the principle of counterpulsation to increase coronary blood flow and decrease afterload (i.e., the resistance the ventricle must overcome to open the aortic valve).

Operative Procedure

1. A flexible guidewire is passed through a percutaneous needle into the femoral artery. The needle is removed, and graduated dilators are inserted over the guidewire to dilate the overlying tissue and the artery wall.
2. The IABP catheter (with the furled balloon) is inserted into the artery and advanced to a position just distal to the left subclavian artery. The catheter can be marked at the proximal end with a silk tie to measure the distance the catheter should be inserted.
3. The balloon is unfurled and activated.

Ventricular Assist Device

VADs are designed to augment cardiac output from the left (LVAD), right (RVAD), or both (biventricular—BiVAD) ventricles and to decrease the workload of the heart by diverting blood from the ventricle or ventricles to an artificial pump that maintains systemic perfusion. Patients with an LVAD can become better transplant candidates because the LVAD enhances anabolism, ambulation, and improved organ function. LVADs are employed as a bridge to cardiac transplantation by supporting the circulation while a suitable donor heart can be found. Based on the results of the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial (Lietz et al, 2009; Long et al, 2005; Park et al, 2005; Rose et al, 2001), the use of the HeartMate (vented electric) LVAD (see Thoratec HeartMate LVAD section) was approved by the U.S. Food and Drug Administration in November 2002 for *destination therapy*/permanent replacement for the left ventricle. Although complications (e.g., bleeding, thromboembolism, infection, device failure) persist, they have been reduced with the newer VADs (Naka and Rose, 2008).

Among the increasing number of designs are the axial flow pump based on Archimedes' third-century screw pump that was used to raise well water for irrigation; the pump is inserted into the left ventricle to propel blood flow and the distal end is anastomosed to the descending aorta. Miniaturized centrifugal pumps, totally implantable pulsatile devices incorporating a transcutaneous energy transmission (and power regeneration) system, and artificial hearts (Naka and Rose, 2008) are some of the innovative responses for the treatment of heart failure.

Procedural Considerations. Insertion of an assist device may be indicated for patients who cannot be weaned from CPB with the use of IABP; device insertion also may be scheduled. Depending on the system, components of the system should be collected and prepared according to the manufacturer's instructions. Device components may include external centrifugal

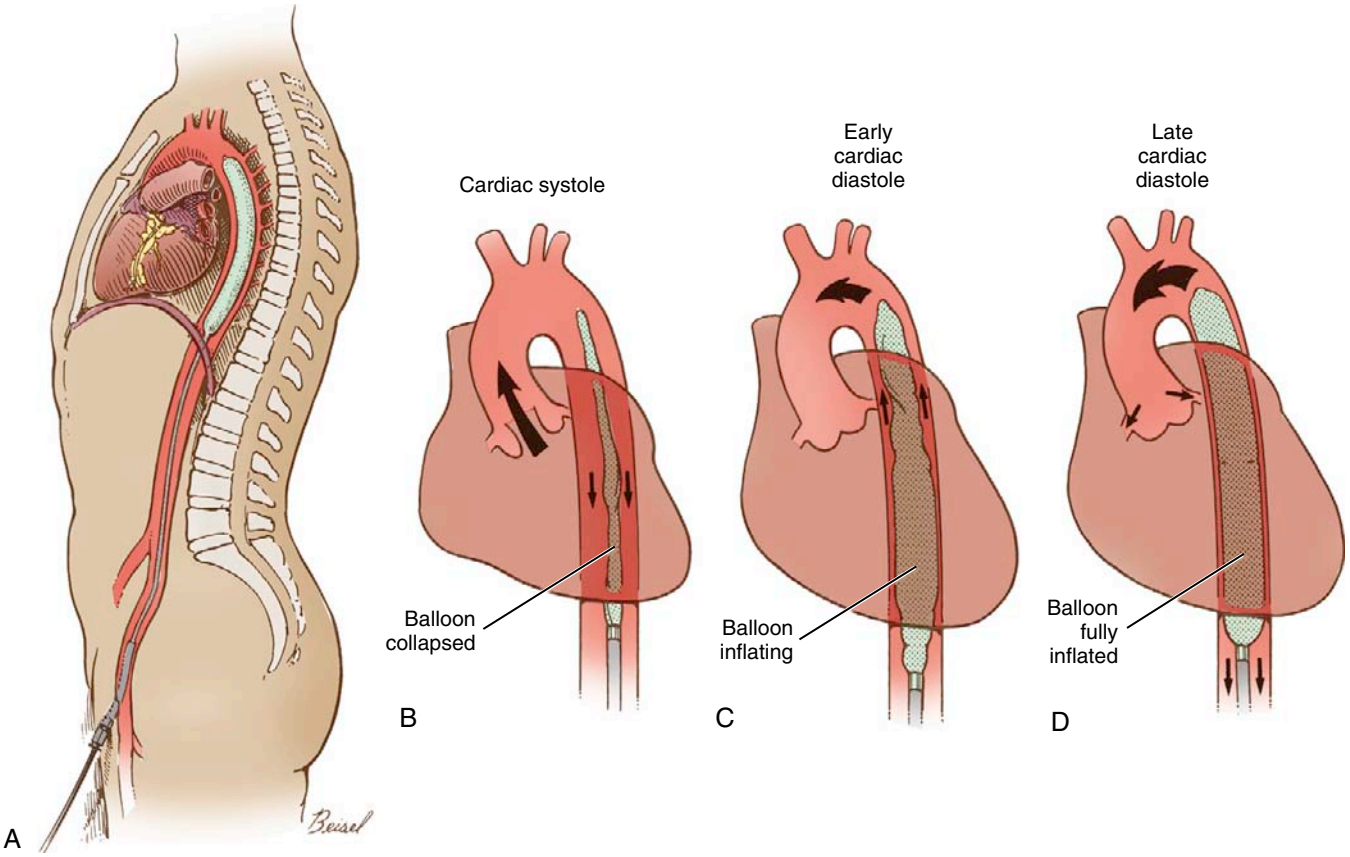

FIGURE 24-73 Phases of balloon pumping. **A**, Balloon inflation occurs from closure of aortic valve to end of diastole. Inflation causes retrograde flow of blood in aorta, increasing coronary perfusion pressure without increasing myocardial work or oxygen demand. Inflation also causes antegrade flow, increasing mean arterial pressure, renal flow, and cerebral flow. **B**, Balloon deflation occurs from just before opening of aortic valve to closure of aortic valve. Deflation encourages antegrade flow, decreasing afterload or resistance to left ventricular ejection. Deflation also decreases oxygen required by left ventricle, shortens systolic ejection, and increases stroke volume. **C** and **D**, When the balloon reinflates, the cycle is repeated.

pumps, internal pneumatically (Figure 24-74) or electrically powered assist devices, or wholly implantable systems with transcutaneous, rechargeable power sources.

The LVAD device described in the following section is approved for support of the left ventricle when right ventricular function is normal. Prosthetic valves are incorporated into the circuit to maintain unidirectional blood flow. All VADs will differ and preparation should be specific to the device. In preparation for VAD insertion, perioperative nurses are encouraged to discuss the type of VAD, insertion considerations, possible complications, and trouble-shooting scenarios with the surgeon.

Operative Procedure

THORATEC HEARTMATE LVAD

1. A median sternotomy incision is made and extended to the umbilicus (Figure 24-74, *A*).
2. A preperitoneal pouch is made for placement of the assist device.
3. CPB is established, and the aorta is cross-clamped. The atrial septum is inspected for defects, which are closed if found.
4. A Dacron graft is anastomosed to the aorta (Figure 24-74, *B*).
5. The left ventricular apex is mobilized, and an opening is created in the apex (Figure 24-74, *C*).
6. A connector is inserted into the apex, and the flange is sewn to the surrounding left ventricular myocardium with pledgetted sutures. The inflow conduit is attached to the apical connector (Figure 24-74, *D* to *G*).
7. An opening is made into the diaphragm near the location of the apical connector and inflow conduit. The conduit is passed through the diaphragm and attached to the assist device.
8. The aortic graft is attached to the outflow conduit, which is connected to the assist device (Figure 24-74, *H* and *I*).
9. The driveline is tunneled to the left lower quadrant, where it exits through the skin. The driveline can be connected to the drive console or to a battery pack. Blood flows from the left ventricular apex, to the device, and back into the body through the aortic conduit (Figure 24-74, *J*).
10. CPB is discontinued, and incisions are closed.

To remove or replace the pump, the patient is returned to the OR, the sternotomy is reopened, the cannulae are removed, and the device is removed (or replaced).

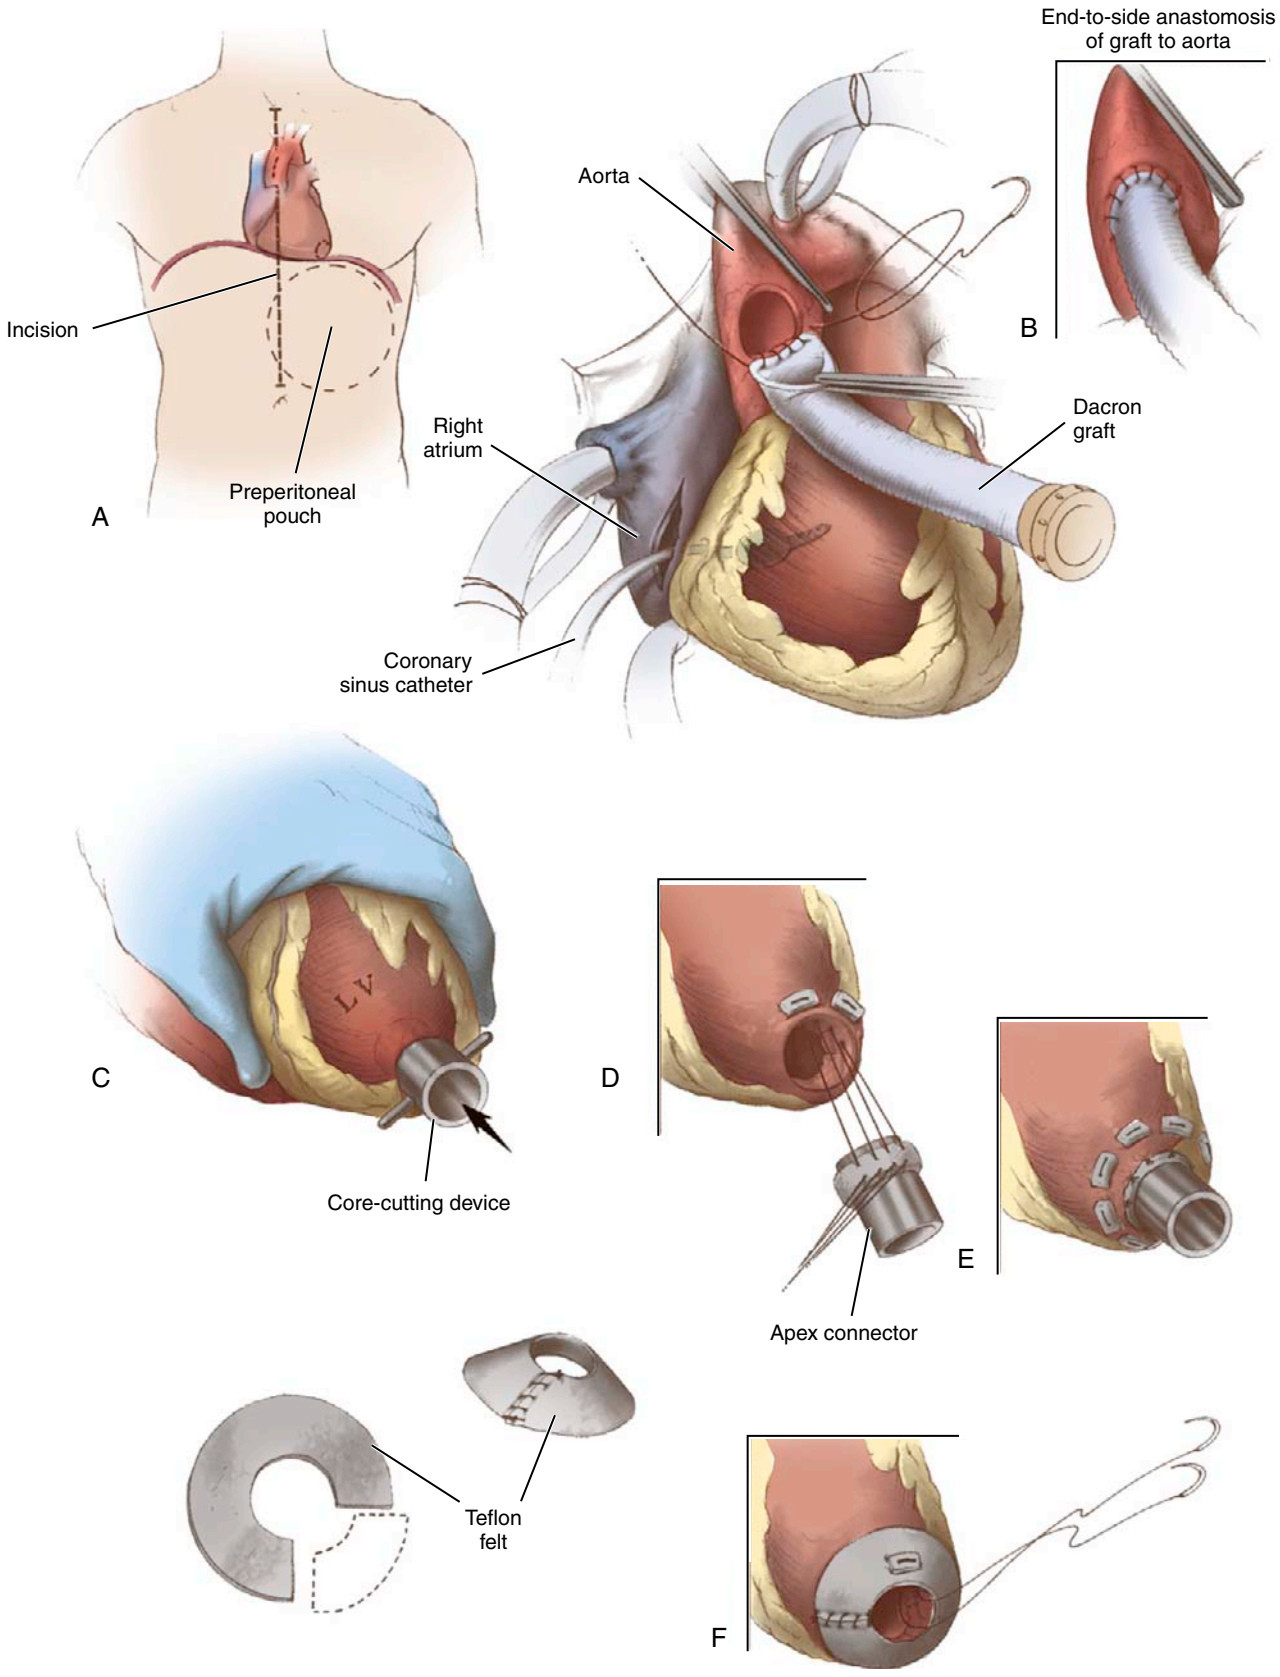

FIGURE 24-74 Left ventricular assist device (see text).

Total Artificial Heart

The total artificial heart (TAH) continues to be refined and implanted in patients with end-stage biventricular failure. Complications associated with thromboembolism and infection have been reduced, but not eliminated, with technical and material refinements of VAD systems. Long-term right or left VADs have been increasingly employed as a bridge to cardiac transplantation by supporting the circulation until a suitable donor heart can be found (Naka and Rose, 2008).

Implantation of the first totally artificial heart by AbioCor—approved for implantation by the Food and Drug Administration (FDA) in 2006—was performed in June 2009 in a 76-year-old male who did not qualify for heart transplantation because of his age. The device employs two pumping chambers made of titanium and plastic. An internal rechargeable battery powers the device (Rothman, 2009). With greater emphasis on interventions for heart failure, nurses can anticipate an increased demand for univentricular and biventricular mechanical support.

HEART AND HEART-LUNG TRANSPLANTATION

Heart Transplantation (Figure 24-75)

Orthotopic transplantation (replacing one heart with another) is most commonly performed; less commonly, heterotopic (piggyback) and combined heart-lung procedures are performed. Important considerations continue to be recipient and donor selection, the immune response, and infection control. Older recipients and donors (older than 65 years) have demonstrated acceptable morbidity and survival (McCarthy, 2008; Hunt, 2006).

Modification of the traditional transplantation technique (e.g., atrial-atrial anastomoses) has reduced some of the dysrhythmias and valvular dysfunction associated with the traditional method of transplantation. End-to-end anastomoses between the donor and recipient SVC and the donor and recipient IVC are created, producing a more physiologic atrial contribution to ventricular filling and less distortion of the mitral and tricuspid annuli (McCarthy, 2008; Blanche et al, 1997). Tricuspid suture or ring annuloplasty may be performed on the donor heart to minimize tricuspid insufficiency (Jeevanandam et al, 2004). Revised pulmonary venous connections produce fewer dysrhythmias. These changes also lead to less AV valve regurgitation. Pulmonary artery and aortic anastomoses are performed in the traditional manner.

Procedural Considerations. Individual instrument setups are necessary for the donor and the recipient.

Operative Procedure

DONOR HEART. The donor heart is exposed through a median sternotomy. The aorta, pulmonary artery, and venae cavae are dissected. The venae cavae are occluded, the left atrium is opened to decompress the ventricle, and the heart is rapidly cooled and arrested.

The heart is excised by incision of the SVC and the IVC, the left atrium, the aorta, and the pulmonary artery (Hunt, 2006). The donor heart is immediately placed into cold saline and transported to the site where it will be inserted into the recipient.

RECIPIENT HEART. The recipient is placed on bypass with cannulation of the IVC and the SVC; caval tapes are placed around the cavae. The patient is cooled to approximately 32° to

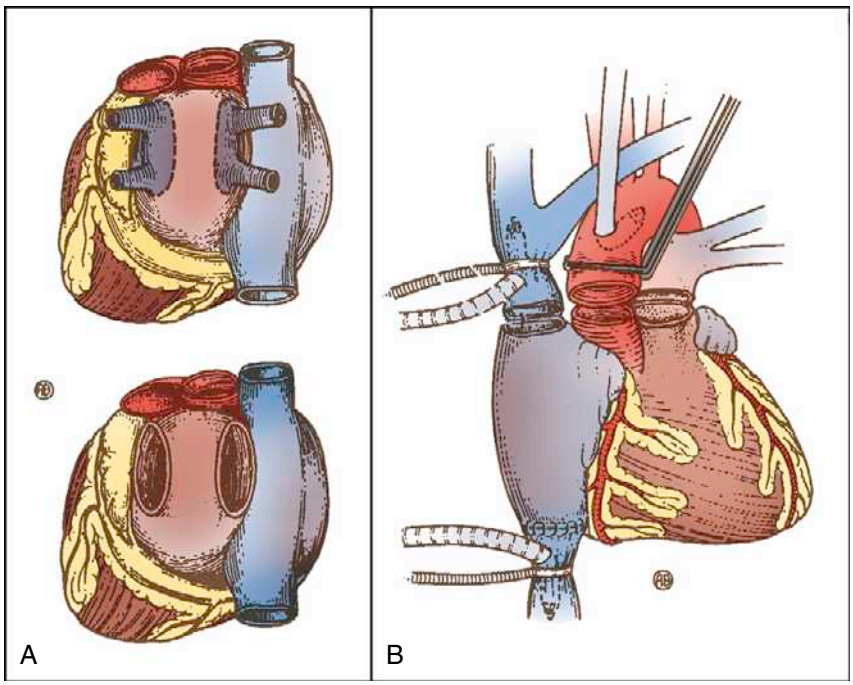

FIGURE 24-75 **A**, Heart transplantation with pulmonary venous anastomoses on right or left side, and caval anastomoses at the superior and inferior vena cavae. **B**, Aorta and pulmonary artery are joined last.

34° C (89.6° to 93.2° F), and the caval tapes are tightened. The pulmonary trunk and aorta are dissected immediately above their respective semilunar valves; the left atrium is incised to leave intact portions of the left atrial wall and the atrial septum of the recipient; and the right atrium is incised, retaining the SVC and IVC for anastomosis to the donor heart. The recipient heart is then removed.

The donor heart is placed in the pericardial well. The pulmonary anastomoses are performed (see Figure 24-75, *A*). The SVC and IVC are anastomosed with running cardiovascular sutures (see Figure 24-75, *B*). The donor and recipient aortas and pulmonary arteries are similarly joined. Air is removed from the left side of the heart. Before the pulmonary artery is sutured, all caval and atrial suture lines are carefully inspected for significant bleeding areas, and the cross-clamp is removed. Figure 24-76 illustrates the traditional (but less frequently anastomosed) right atrial suture line; aortic and pulmonary anastomoses are similar to the technique just described.

Defibrillation of the ventricles is usually effected with a single direct-current shock. A needle vent in the ascending aorta allows residual air to escape. The patient is then gradually weaned from the bypass. Cannulae are removed from the venae cavae and the aorta. The incisions are closed as described previously.

Heart-Lung Transplantation

Newer techniques for lung and heart-lung transplantation incorporate the bicaval anastomoses used for orthotopic heart transplantation and also employ a bibronchial anastomosis that reduces bleeding and enhances the integrity of the airway. To maximize the allocation of scarce donor organs, transplantation procedures for the lungs may use a single lung or bilateral lungs; heart-lung transplantation is infrequent (Cooper, 2004). Preservation of the *donor's* sinus node and the *recipient's* recurrent laryngeal, vagus, and phrenic nerves are important surgical considerations.

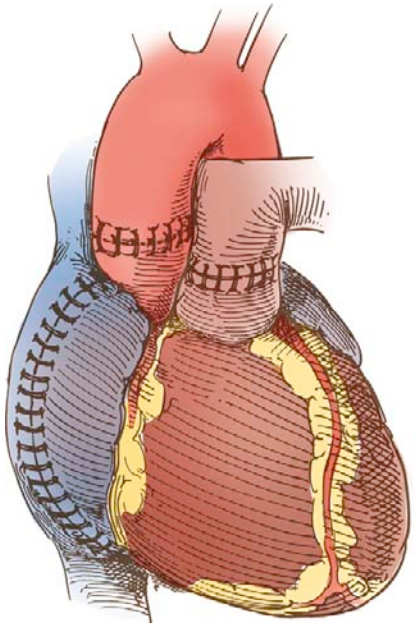

FIGURE 24-76 Traditional atrial anastomosis for heart transplantation.

Operative Procedure. The recipient's diseased heart and lung(s) are excised separately or en bloc, with care taken not to injure the major nerves listed previously. The recipient's right atrium, SVC, and IVC are saved to create bicaval attachments to the donor heart. The bronchi are transected. The donor heart and lungs are brought onto the field. The right lung is placed in the right pleural space, and the left lung is positioned in the left pleural space. The bronchial and the bicaval anastomoses are performed, and rewarming is begun. The aortic anastomosis is performed, the aorta is deaired, and the cross-clamp is removed.

SURGERY FOR CONDUCTION DISTURBANCES

Disturbances of the conduction system affect the rate, rhythm, and effectiveness of the contracting heart. Surgical techniques have been developed to treat a variety of supraventricular dysrhythmias (e.g., atrial fibrillation [AF] and Wolff-Parkinson-White reentry tachycardia) and both ischemic and nonischemic ventricular tachydysrhythmias (e.g., ventricular tachycardia or fibrillation). Preprocedural electrophysiologic mapping of the patient's conduction pathways identifies and locates aberrant pathways, tachydysrhythmias, and the existence of additional pathways, as well as the effects of medications on a particular dysrhythmia. Indications for pacemaker implantation (including resynchronization therapy) and antitachycardia-antifibrillation devices have been expanded. Many (but not all) pacemaker and internal cardioverter defibrillator (ICD) insertions are currently performed in the electrophysiology (EP) laboratory or the cardiac catheterization suite. Ablation procedures for AF may be performed in the EP laboratory. Depending on the anticipated origin of the problem, the electrophysiologist inserts a catheter percutaneously into the femoral vein or artery and threads the catheter retrograde to the right or left atrium and ventricle. The electrophysiologist tests various areas of the heart in an attempt to reproduce the dysrhythmia and then ablates the area of the heart where the rhythm disturbance originates. Postoperative considerations are similar to those for atrial fibrillation surgery. Surgical correction is performed in the OR.

AF is the most common cardiac dysrhythmia, affecting more than 2 million adults in the United States (AHA, 2009b). Atrial fibrillation is an abnormal heart rhythm that causes discomfort and stasis of blood in the atria. AF was considered a "benign" condition in the past, but the serious consequences associated with the dysrhythmia have made it the subject of intense study. AF interferes with the atrial kick (which contributes a significant amount of "preload") and the dysrhythmia can lead to insufficient cardiac output. Moreover, the stasis of blood within the atria promotes the formation of thrombus (clotting), which leads to cerebrovascular accident or pulmonary embolism.

Although *intermittent* AF commonly occurs after CABG, it is potentially preventable by treatment with amiodarone, beta-blockers, angiotensin-converting enzyme (ACE) inhibitors, and/or nonsteroidal antiinflammatory drugs. Treatment includes restoration of sinus rhythm (when possible), control of ventricular rate, and administration of anticoagulants. New techniques to treat *continuous* AF are based on research demonstrating that the pulmonary veins are an important source of the ectopic beats that can initiate paroxysms of AF (Haissaguerre et al, 1998). Surgical interventions for AF have

expanded beyond Cox's original Maze procedures (Cox et al, 1991), in which extensive atrial incisions were sutured to create a maze through which electrical impulses were directed from the SA node to the AV node. The early research of Cox (Cox et al, 1991) demonstrated that electrical impulses are unable to cross incised and sutured tissue and consequently cannot regenerate the reentry circuits producing the dysrhythmia. Cox revised the cut-and-sew technique of the initial Maze procedures with a cryosurgical technique that ensures the creation of transmural lesions in the vicinity of the pulmonary veins and in other areas of the heart, generating impulses producing AF. This "mini-Maze" can be performed through a sternotomy or through a minimally invasive thoracic route and requires placement of fewer lesions in the left and right atria. Currently, the focus is on the selective ablation (with cryotherapy [Figure 24-77] or ultrasonic or radiofrequency [RF] energy sources) of tissues surrounding, for example, the pulmonary veins to reestablish normal conduction pathways.

Surgery for Atrial Fibrillation (The "Maze" Procedure)

Surgery for AF may also be performed through an open sternotomy or right mini-thoracotomy incisions. The appropriate supplies (including energy sources) should be available (Seifert et al, 2007). By creating small areas of scar tissue in the cardiac muscle, electrical impulses are forced to follow an alternative conduction path or "maze."

Operative Procedure—Sternotomy

1. The surgeon performs a midline sternotomy.
2. Cannulation of the superior and inferior venae cavae is performed for total cardiopulmonary bypass.
3. The ascending aorta is occluded, and cardioplegic solution is infused through the aortic root and into the coronary arteries.
4. A right atriotomy is performed, and the first set of lesions is ablated in the right atrium (Figure 24-78, *A*).
5. A left atriotomy is performed, and the left atrial lesions are ablated (Figure 24-78, *B*).
6. The atriotomies are closed, and the aorta is unclamped.
7. Cardiopulmonary bypass is discontinued, and the cannulae are removed.
8. Chest tubes and pacing wires are inserted, and the wound is closed.

Postoperative Considerations. Postoperatively, patients are monitored for heart rhythm problems. In patients treated for AF, it may take up to 3 months for the heart to resume beating in a normal manner. Additional postoperative considerations include monitoring for bleeding, infection, and other potential complications related to heart surgery.

Insertion of Permanent Pacemaker

A permanent pacemaker (pulse generator and electrodes) initiates atrial or ventricular contraction, or both. Complete heart block and bradydysrhythmias (i.e., slow heart rates) are the most common indications for pacemaker implantation. The development of multiprogrammable and physiologic pacemakers has made possible the treatment of many forms of dysrhythmias and neuroconductive disturbances as well as tachydysrhythmias.

FIGURE 24-77 Articulated cryo probe for Maze procedure.

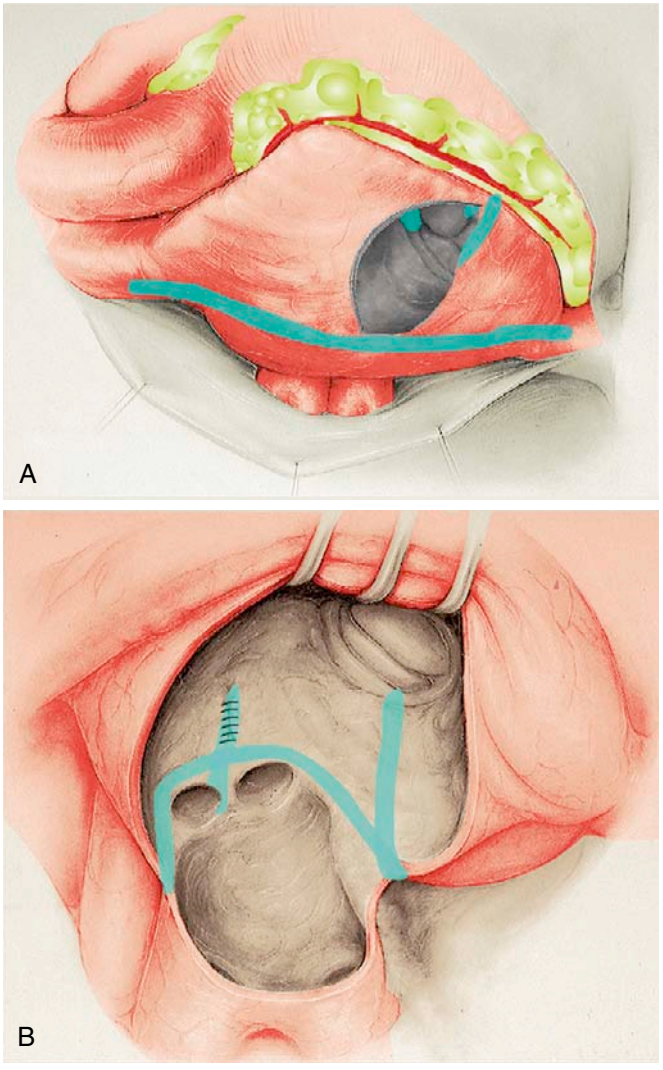

FIGURE 24-78 **A**, First lesion set for Maze procedure. **B**, Second lesion set for Maze procedure.

A temporary pacemaker may also be used for acute forms of heart block and dysrhythmias that occasionally occur during and after cardiac surgery (Hayes and Zipes, 2008).

Dual-site pacing of both the right and the left ventricle is another treatment for patients with dilated cardiomyopathy and heart failure. *Cardiac resynchronization therapy* (CRT) employs leads placed on the right atrium and the right ventricle. Left ventricular pacing is achieved with an electrode introduced transvenously into the coronary sinus and extended into the great cardiac vein (or a tributary) to a position in the left side of the heart; this electrode functions as the second ventricular lead. The three electrodes are connected to the pacemaker generator. Resynchronization improves the mechanical pumping action between the right and left ventricles and optimizes AV synchrony; as a result, hemodynamic function is improved in heart failure patients.

The *transvenous* or the *epicardial* approach may be used to place the electrodes. The transvenous route is most commonly used because it does not require a major thoracotomy or a general anesthetic and is therefore safer for high-risk patients. Permanent epicardial electrodes may be placed during cardiac operations when the chest is opened and the heart is exposed; however, if a permanent pacemaker is required, it is likely to be inserted transvenously during the postoperative period (pacing is achieved with the temporary electrodes placed during surgery). To avoid opening the sternum a subxiphoid approach may be used to place epicardial leads.

Insertion of Transvenous (Endocardial) Pacing Electrodes

Procedural Considerations. The patient is placed in the supine position. Continuous ECG monitoring is essential. A defibrillator and emergency drugs should be available because lethal dysrhythmias can occur during catheter insertion. The patient should be made as comfortable as possible because this procedure can sometimes be lengthy and is frequently performed using local or local standby anesthesia (monitored anesthesia care).

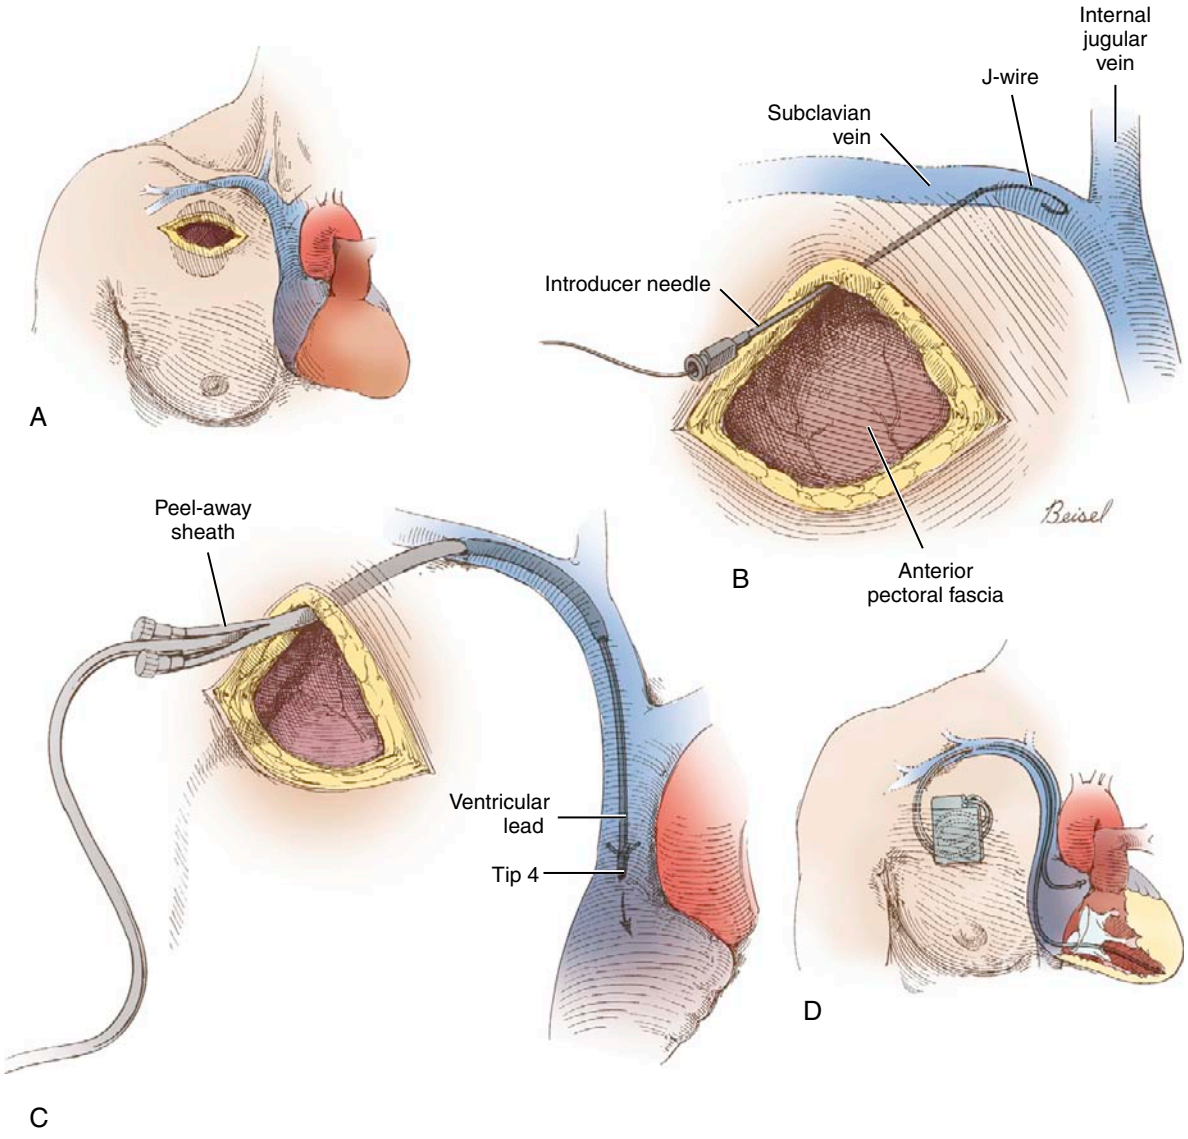

FIGURE 24-79 Insertion of transvenous pacemaker (see text).

Fluoroscopy is required; thus either a portable image intensifier is needed or the procedure is done in the special studies section of the radiology or cardiac catheterization department. A minor set of instruments is used, plus the following:

- Vascular dissecting instruments
- Tunneling instrument
- Sterile pacemaker and electrodes
- Introducer set
- External pacemaker (for testing) or a pacing system analyzer (PSA)
- Alligator test cables
- Screwdriver and other accessory items as needed

Operative Procedure

1. The skin and subcutaneous tissue are infiltrated with a local anesthetic, and the patient is placed in the Trendelenburg position (to engorge the vein for easier access and to avoid air emboli).
2. A skin pocket is made close to the subclavian vein (Figure 24-79, *A*). The vessel may be encircled with a heavy suture.
3. A venotomy is performed with an introducer needle (Figure 24-79, *B*). A guidewire is threaded to the desired cardiac chamber, and the needle is removed. The pacing electrode is inserted through a peel-away dilator sheath, which is withdrawn after the lead insertion (Figure 24-79, *C*). The guidewire is withdrawn. A stylet is then inserted to help position the electrode.
4. The electrode is advanced under direct fluoroscopic vision into the right atrium, through the tricuspid valve, and into the right ventricle (Figure 24-79, *D*).
5. The surgeon attempts to entrap the tip of the electrode in the trabeculae carneae cordis of the right ventricular apex to stabilize it. Once the electrode is positioned and tested with alligator test cables and the pacing analyzer to confirm proper placement and function, the stylet is removed. If a dual-chamber pacemaker is inserted, the second lead is entrapped in the right atrial appendage (Figure 24-79, *D*).
6. The electrode or electrodes are brought down and attached to the pulse generator.
7. The pulse generator is placed into the pocket, and the incision may be irrigated with an antibiotic solution. If the pocket must be made farther away from the vein, a tunneling device may be used to thread the electrode to the pocket.
8. The incision is closed in layers with absorbable sutures.

Insertion of Myocardial (Epicardial) Pacing Electrodes

A subxiphoid left anterior thoracotomy approach or sternotomy approach can be used; the setup is the same as that described for placement of endocardial electrodes. The subxiphoid process

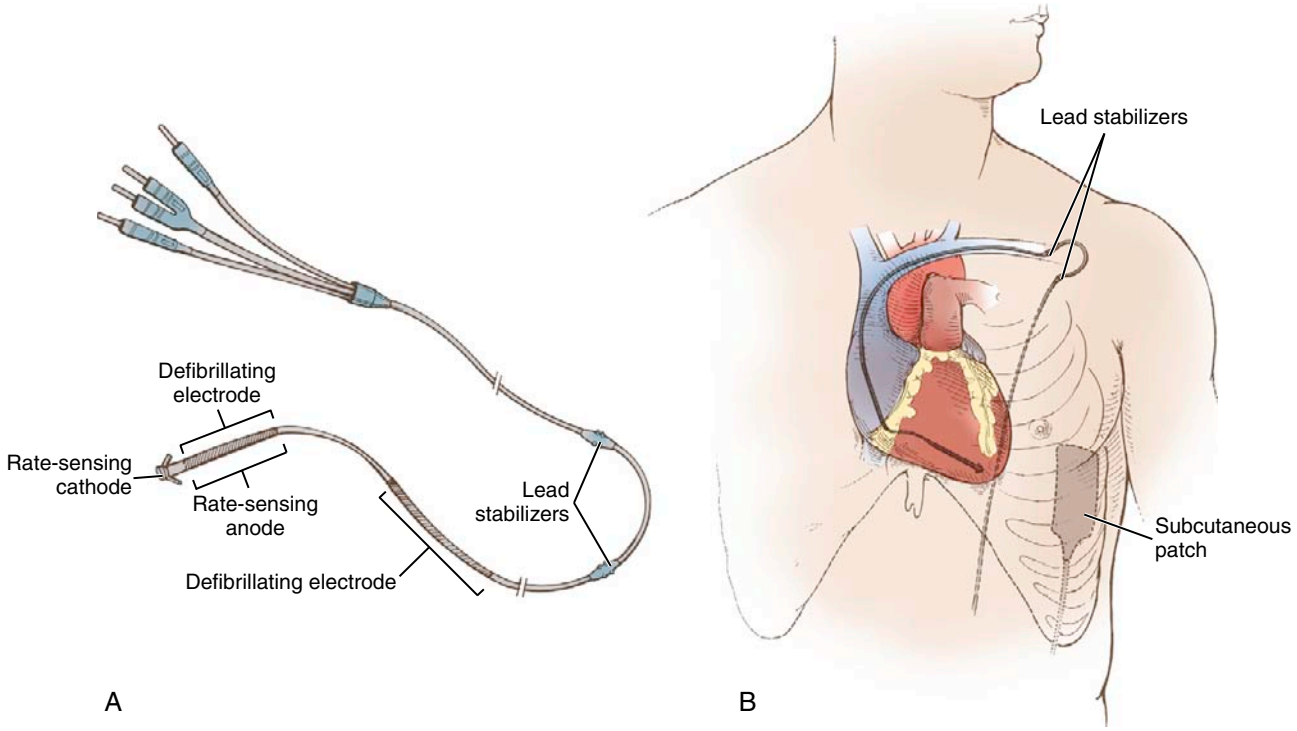

FIGURE 24-80 Nonthoracotomy internal cardioverter defibrillator (ICD) insertion. **A**, The lead system is composed of sensing and defibrillating electrodes in one unit and is inserted transvenously. **B**, The proximal end of the electrodes is tunneled to the abdomen (or the chest) and attached to the generator (not shown). The rate-sensing cathode at the tip relays information to the generator, which initiates an electrical shock by means of the defibrillating electrodes. A second (patch) electrode, placed subcutaneously on the left chest wall, may be necessary if the transvenous electrode alone cannot successfully defibrillate the patient during testing of the unit. If the nonthoracotomy system does not result in suitable defibrillation thresholds, a left thoracotomy or subxiphoid approach may be used to place sensing leads and defibrillation patches directly on the heart.

and left upper quadrant area are infiltrated with the anesthetic agent. A small transverse incision is made below the xiphoid process and is extended down to the linea alba. A tunnel is created under the xiphoid process to the pericardium, which is incised to expose the heart. The pacing electrode, mounted on its carrier, is screwed into the ventricular myocardium, and the carrier is removed. The remainder of the procedure is the same as that described for insertion of the endocardial electrode.

For the sternotomy approach, the mediastinum is opened for a concomitant cardiac procedure and an area of myocardium is chosen for placement of the pacing electrodes. The electrode tips are either screwed into or sutured to the myocardium and are attached by an appropriate cable to an external pulse generator or pacing analyzer for testing. The pocket and subcutaneous tunnel are created as described for insertion of the endocardial electrode.

Insertion of Implantable Cardioverter Defibrillator

Surgery or pharmacologic intervention may not prevent malignant ventricular dysrhythmias (ventricular fibrillation and ventricular tachycardia) in persons who survive sudden cardiac death. The ICD is an electronic device designed to monitor cardiac electrical activity and deliver prompt defibrillator shocks. The ICD differs from a pacemaker in that the former senses ventricular tachycardia or fibrillation and the latter senses asystole. Current models are capable of tiered therapy, whereby increasingly stronger impulses are delivered depending on the underlying dysrhythmias; some devices can also be used to terminate AF. These devices are capable of pacing as well as defibrillating (pacing cardioverter defibrillators [PCDs]). The ICD device consists of a generator and sensing and defibrillator electrodes (Figure 24-80). Many ICD electrodes currently employed consist of transvenous electrodes inserted into the generator much like a transvenous pacemaker system. Myocardial or thoracic subcutaneous patches may be added if the transvenous catheters alone do not adequately defibrillate the heart. Patients with previously applied defibrillator patches may present for removal of a patch or patches; perioperative nurses should be prepared for emergency intervention if there is excessive bleeding or lethal dysrhythmia. EP studies are performed before and after insertion to diagnose the dysrhythmia and to evaluate device function, respectively.

The transvenous route with fluoroscopy is commonly employed, and insertion is similar to that described for transvenous pacemaker insertion (Figure 24-80, *B*). The free ends of the lead system are tunneled to the generator, which is implanted in a subcutaneous pocket in the chest wall. The device is tested, and the incisions are closed.

CHAPTER 25

Pediatric Surgery

LEIGH ANN DiFUSCO

Pediatrics is a specialty focused on the health and well-being of neonates, infants, children, and adolescents. The pediatric patient often needs surgery for congenital anomalies that threaten life or the child's ability to function. Trauma also impacts a child's health far more often than an adult's; injury is a common reason for surgical intervention. Pediatric surgery is an area of practice unto its own because the pediatric patient is so very different from an adult. The field is even further subdivided into all the surgical specialties. It is important to recognize that the difference between pediatric care and adult care is not just a size issue; from birth onward, the body and organs exist in a continual state of development, and multiple physiologic changes occur with age. Major areas of distinction are the airway and pulmonary status, cardiovascular status, temperature regulation, metabolism, fluid management, and psychologic development. A thorough knowledge of these differences is integral to the provision of nursing care for the pediatric patient in the OR.

Advances in surgical interventions for children have been phenomenal in the last two decades for many reasons. The advancement of improved diagnostic and interventional technology, the development of new anesthetics and pharmacologic agents for pain management, and the creation of even smaller and more delicate instrumentation have revolutionized perioperative care of the pediatric population. Numerous pediatric surgeries that were once performed as open cavity procedures are now being done endoscopically with minimally invasive techniques, resulting in shorter hospital stays and faster recovery times. Improvements in the transport of critically ill children and the intensive care management of neonatal and pediatric patients as well as the development of new surgical procedures are also saving more lives yet presenting medical professionals with a new and unique set of problems as complex, medically fragile children are now surviving into adulthood.

PEDIATRIC SURGICAL ANATOMY

Airway/Pulmonary Status

Respiratory mechanics alter dramatically from infancy to adulthood, resulting from increases in airway size, transformations in the rigidity of airway and chest structures, and major changes in neuromuscular status. A proportionally large head, a short neck, and a large tongue in relation to jaw size create more of a challenge for airway management. The glottis is very anterior, moving from the level of the second cervical vertebra to the level of the third to fourth vertebrae in the adult. The epiglottis is floppy and more curved, and the vocal cords are slanted anteriorly. The airway forms an inverse cone with the narrowest portion at the cricoid cartilage until 8 years of age; endotracheal tube size is therefore very important, since a tube that passes easily through the glottis may be too tight at the subglottic area, compromising the child's airway in the immediate postoperative period because of swelling. The infant is an obligate nasal breather, and the chest wall of an infant is very compliant, leading to increased work of breathing with any type of airway compromise. Infants also have type 2 respiratory muscle fibers until age 2 years, which fatigue more easily than type 1 muscle fibers. Premature infants are at risk for postanesthetic apnea until 60 weeks after conception age. There is a depression in the CO_2 response curve in infants; compared to an adult, the respiratory rate does not increase as readily in response to a rising CO_2 level, although all ages undergo a CO_2 response depression related to inhalational agents and narcotics. One of the most important considerations is that children have a much smaller pulmonary functional residual capacity; a child becomes hypoxic more quickly if the airway is lost. Alveolar maturation is not complete until 8 years of age. Smaller airways have higher resistance; airway resistance decreases approximately 15 times from infancy to adulthood, again with a major change occurring around 8 years of age. It is important to note that smaller airways can become compromised with even a minor amount of swelling. Be aware that loose teeth are common in children aged 5 to 14 years; a dislodged tooth is a potential airway foreign-body risk.

Cardiovascular Status

The most dramatic changes in the cardiovascular system occur at birth with the transition from fetal circulation. Even in full-term infants, persistent transitional circulation may occur. Heart rate is the predominant determinant of cardiac output in infants and children; bradycardia drastically decreases cardiac output and requires swift intervention. There is a decreased cardiac compliance because of a lower proportion of muscle to connective tissue until age 1 to 2 years, making infants preload insensitive. Young children are predisposed to parasympathetic hypertonia (increased vagal tone), which can be induced by painful stimuli such as laryngoscopy, intubation, eye surgery, or abdominal retraction. Attention to blood loss in young patients is very important because the patient's total blood volume is very small. Blood volume in neonates is 80 to 90 ml/kg; at 1 to 6 years it is 70 to 75 ml/kg; and at age 6 years to adult it is 65 to 70 ml/kg. At birth, 70% to 90% of the hemoglobin is fetal hemoglobin with a high affinity for oxygen. It is normal for hemoglobin levels to fall at about 2 to 3 months of age (physiologic anemia) to a hematocrit level of 29% and a hemoglobin level of 10 mg/dl as the infant's body begins to produce its own

blood cells. A cardiology evaluation is essential if a murmur is auscultated. A murmur can be from a patent foramen ovale, which normally closes at 3 to 12 months; a patent ductus arteriosus, which can be present for up to 2 months; a previously undetected cardiac anomaly; or an innocent flow murmur. The evaluation is critical because anesthetic agents cause vasodilation and potentiate cardiac dysrhythmias.

Temperature Regulation

Infants and young children are most at risk of hypothermia because of their increased body surface area/weight ratio and thin fat layer. Cold stress leads to increased oxygen consumption, resulting in hypoxia, respiratory depression, acidosis, hypoglycemia, and pulmonary vasoconstriction. Hypothermia alters drug metabolism, prolongs the action of neuromuscular blockers, and delays emergence from anesthesia. The child's temperature must be monitored continuously throughout the intraoperative experience. An axillary temperature probe is acceptable for short procedures in healthy children; an esophageal or rectal temperature probe provides more accurate monitoring of the child's temperature for longer cases. Hyperthermia should also be avoided, because it leads to increased oxygen consumption and increased fluid losses.

It is vital to maintain normothermia in children, and the easiest way to do this is by exposing only the area on which surgery is being performed. Additional thermoregulatory interventions include altering the room temperature before the child enters the room, using a water-filled temperature-regulating blanket under the patient, or using a forced air–warming blanket over nonsurgical areas of the child. An overhead heater can be used during the anesthetic induction and patient preparation period immediately before prepping and draping. The anesthesia ventilation circuit can be heated and humidified, as can insufflated carbon dioxide during minimally invasive surgical procedures. For surgical procedures with large areas of exposure, warmed solutions should be available for use instead of room temperature solutions. Intravenous (IV) solutions can also be warmed before administration.

Metabolism

Infants have a higher basal metabolic rate than adults, and it is greatest at 18 months. Most importantly, children younger than age 2 years have immature liver function; pharmacologic response is altered, and there is slower hepatic clearance, decreased hepatic enzyme function, and decreased protein binding. Drug distribution is different in neonates and infants compared with older children and adults because of an increased percentage of total body weight and extracellular body fluid. Infants have an immature blood-brain barrier and decreased protein binding, which results in an increased sensitivity to sedatives, opioids, and hypnotics.

Fluid Management

Renal function at birth is immature, and the ability of the kidneys to concentrate urine is limited, so the infant is much more prone to dehydration. Complete maturation of renal function occurs at about 2 years. Compared to an adult, a child has a higher body water weight, a higher body surface area, and an increased metabolic rate, resulting in increased fluid requirements per kilogram of body weight. Despite these significant points, it is also important to remember that the body weight of the child, the length of time without fluids, and surgical losses are the primary factors in the calculations of the child's hydration needs.

PSYCHOLOGIC DEVELOPMENT

A child's comprehension of and responses to the environment are based on his or her developmental age. A key factor is that a child's developmental age does not necessarily match the chronologic age. Nursing care should be tailored to the developmental age of the child to optimize the child's ability to understand the situation, to minimize the child's and family's stress and anxiety, and to facilitate the development of a trusting and supportive medical relationship. The types of fears are also related to the child's level of psychologic development. Predictable stages mean predictable behaviors. The stages of growth have been described from a variety of different aspects; Dr. Jean Piaget described the stages by changes in cognition and the ability to think, and Dr. Erik Erikson based the stages on psychosocial and emotional needs. Their work provides an excellent guideline for assessing the pediatric patient's developmental level in order to use appropriate interventions (Table 25-1).

Perioperative Nursing Considerations

Assessment

The initial patient assessment provides information necessary to develop a plan of care specific to the needs of each particular pediatric patient related to age, developmental level, and diagnosis. The unique aspects of care of the pediatric surgical patient revolve around the fact that the child is constantly growing and changing. The perioperative nurse must have a good understanding of the normal physical and psychologic parameters for pediatric patients and be able to recognize and act upon deviations from these parameters (Rapid Response Team box). In addition, the perioperative nurse must be familiar with normal growth and developmental factors for each age-group. During any given day, the perioperative nurse may care for a variety of pediatric patients ranging from neonates through adolescents. In some instances, children undergoing an ambulatory surgical procedure may visit the OR complex and ambulatory surgery area with their families 1 to 2 weeks before surgery, depending on the developmental level of the child and the availability of a preoperative pediatric education program. If the child has a complex medical history or an extensive surgical procedure is planned, the child and family members will meet with a member of the anesthesia team during this advance visit. A tour may be provided by a child life specialist (Patient and Family Education), along with pictures and age-appropriate explanations of what the child will see and experience. Visiting before the day of surgery can help decrease the anxiety related to the novelty of the experience.

Occasionally the child's history and physical, surgical consent, and any necessary tests or lab work are done in advance in the surgeon's office setting, and the child and family have no introduction to the surgical experience until the day of surgery. Information related to the child's scheduled procedure is either

TABLE 25-1

Developmental Stages

Approximate Ages	Piaget's Stage	Erikson's Stage	Developmentally Based Fears	Appropriate Nursing Interventions
Infancy to 1 yr (Erikson) Infancy to 2 yr (Piaget)	Sensorimotor Uses senses and motor skills to understand world Develops memory; begins to imitate others	Trust vs. mistrust—develops belief that world can be counted on to meet basic needs Who to trust? Identifies strangers at 7-8 mo	Separation	Use soothing voice; sing, hold child, give child objects to hold to provide distractions. Meet child, family without touching child at first. Allow personal item into OR for comfort/security.
Toddlerhood	Preoperational Use of symbols, creative play (can pretend) Is very egocentric	Autonomy vs. shame, doubt Develops free will; increasing control of their bodies Feels regret, sorrow for inappropriate behavior	Separation Forced dependence	Give only simple choices; involve child in actions when possible, use distractions, sing songs child may recognize. Allow personal item into OR for comfort/security.
Early childhood, preschool	Preoperational continues	Initiative vs. guilt Begins to explore, imagine Feels remorse for actions Thinking dominated by perceptions—distorted reasoning	Separation Body mutilation	Magical thinkers—use stories during induction. Likes colorful Band-Aids. Allow child to handle unfamiliar objects to decrease stress (e.g., mask, pulse oximeter probe). Allow personal item into OR for comfort/security.
Middle childhood, elementary school age (Erikson) Ages 7-11 yr (Piaget)	Concrete operations Uses symbols, logic, principles to solve problems Classifies, sorts everything	Industry vs. inferiority Beginning to understand time and unseen body functions Is cooperative; desires recognition for achievements	The unknown Body mutilation Inadequate performance	Provide simple information to decrease stress. Be honest at all times. Do not expect child to act like an adult yet. Allow personal item into OR for comfort/security.
Adolescence, puberty	Formal operations Uses logical and abstract thinking Understands hypothetical concepts	Identity vs. role diffusion Peer group has increased importance Body image, clothing, activities help define identity	Altered body image Death	Query patient about concerns; offer information to decrease fears. Provide as much privacy as possible if disrobing is necessary. Use mental imagery to decrease stress. Offer to hold hand to provide comfort; personal item still permitted.

Modified from Taylor E: Providing developmentally based care for toddlers, *AORN J* 87(5):992-999, 2008; Taylor E: Providing developmentally based care for school-aged and adolescent patients, *AORN J* 90(2):261-269, 2009; *Stages of social-emotional development in children,* available at www.childdevelopmentinfo.com/development. Accessed August 23, 2009.

sent home with the family from the surgeon's office or mailed to the family the week before the surgery is scheduled. The surgical facility contacts the family the day before surgery to inform them when the child should arrive at the facility and to review preoperative eating and drinking instructions. In these instances, the initial interview performed by the perioperative nurse is especially crucial to provide a thorough, documented assessment of the child's growth (height and weight), current physical status (vital signs, heart and breath sounds, skin integrity), current medication history, allergies, nothing-by-mouth (NPO) status, recent illnesses, current medical concerns, and behavioral responses to the interview process. The perioperative nurse confirms the intended surgical procedure with the child and family as it is written on the surgical consent as well as their understanding of the operation. This information is critical to the intraoperative nursing team's plan of care during the surgical procedure.

Children may undergo surgery at ambulatory surgery facilities or in a hospital setting. Certain criteria must be met for children to qualify for surgery at an ambulatory facility (Ambulatory Surgery Considerations). Children who are inpatients may be visited by a perioperative nurse in the hospital on the day before surgery. The nurse reviews the patient's chart, giving particular attention to the patient's age, developmental level, diagnosis, and intended surgical procedure. Current nursing diagnoses and the ongoing plan of care are examined. A discussion with the primary nurse can facilitate data collection, assist in providing continuity of care, and provide the perioperative nurse with information regarding preoperative education previously provided. The perioperative nurse can meet the child and any family members present at the time of the visit. The interview can be used to gather information helpful to developing the intraoperative plan of care and to decreasing the anxiety related to the child's impending surgery

RAPID RESPONSE TEAM

Cardiopulmonary arrest in hospitalized children is a rare event, but one that occurs in 0.19 to 2.45 of 1000 admissions. Comparable figures for adult cardiopulmonary arrest range from 2.6 to 6.5 per 1000 admissions. Rapid response teams (RRTs), common in facilities providing care to adults, have demonstrated effectiveness in preventing complications by initiating interventions when a patient begins to decline. The goal of RRTs is to interrupt the cascade of events that often results in cardiac arrest. Clinicians are generally familiar with the signs of impending cardiopulmonary arrest in adults. The origin of cardiopulmonary arrest in adults is generally cardiac related and is often preceded by hypotension. Despite the fact that some hospitalized children may suffer arrest attributable to dysrhythmia, airway obstruction, or other events, the majority of cardiopulmoary arrests in children are often related to respiratory failure. Children have greater reserves than adults and may not appear to be unstable as quickly as an adult. By the time a child exhibits signs of secondary cardiopulmonary arrest the period of hypoxemia has been longer, vital organs have been deprived of oxygen, and outcomes are generally worse. Clinicians must recognize the differences between adults and children to intervene appropriately when caring for pediatric patients.

The trend towards dedicated pediatric RRTs is increasing. In facilities where pediatric RRTs exist, staff that are credentialed with Basic Life Support (BLS) or Advanced Life Support (ALS) initiate resuscitation and emergency services within the scope of their certification and activate the RRT. Staff who are not certified in BLS or ALS must contact the RRT and remain with the victim until assistance arrives. Often, patient care areas with high acuity (such as the OR, pediatric intensive care unit [PICU], cancer intensive care unit [CICU], newborn infant center, emergency department, or cardiac catheterization lab) do not routinely use the RRT, except in those instances where a parent or visitor exhibits signs consistent with intervention. The OR also benefits from the close proximity of anesthesia and critical care attending physicians within the patient care areas. When critical incidents occur in the OR during times of limited resources (weekends, off-shifts, holidays), the staff have the option of activating the Code Team, rapid response team or communicating with the charge nurse in the PICU to mobilize additional clinical support in addition to in-house attending physicians, residents, and fellows already assigned to the OR.

PATIENT AND FAMILY EDUCATION

The Role of the Nurse Educator and Child Life Specialist in Supporting Education

In the pediatric setting, patient and family education is accomplished through many avenues. Patient and family education manuals contain teaching and information inserts that include but are not limited to explanations of conditions, procedures, diagnostic studies, and home management techniques. These manuals also contain lesson plans that a provider can access before providing teaching to a patient or family at the bedside or in a family learning center.

Many institutions have family learning centers on-site that adapt teaching and learning techniques to suit both inpatient and outpatient clients and their families. A patient may be referred to the family learning center in preparation for discharge, so that medical care can be effectively managed at home. Family learning centers promote learning in a safe, quiet environment with one-to-one instruction by a nurse educator. Care is simulated using mannequins, models, and other realistic tools and validated by return demonstration from the patient or caregiver. In addition, patients and caregivers are provided with feedback and additional materials to support the management of medical care in the home environment.

Institutions may also assign child life specialists to pediatric units and floors. Child life specialists are experts in child development who promote effective coping through play, preparation, education, and self-expression activities. They provide emotional support for families, and encourage optimum development of children facing a broad range of challenging experiences, particularly those related to healthcare and hospitalization. Understanding that a child's well-being depends on the support of the family, child life specialists provide information, support, and guidance to parents, siblings, and other family members. They also play a vital role in educating caregivers, administrators, and the general public about the needs of children under stress.

by providing a familiar face on the day of the procedure. The focus of this visit is to discuss the perioperative process, not always to provide preoperative education regarding the surgery. In pediatric centers in the inpatient setting, preoperative education may be provided by the primary nurse, child life therapist, or clinical nurse specialist. During the preoperative visit the perioperative nurse can explain, at a developmentally appropriate level, what the child will experience in the preoperative, intraoperative, and postoperative phases of care. The perioperative nurse may briefly describe the roles of various staff members who will be a part of the team responsible for the child's care in the OR. Common concerns that families express are the length of time that they will be separated from their child and their child's pain management. Explanations to children should be provided within a developmental framework, taking into account each child's cognitive and psychosocial abilities. Medical play items, audiovisual aids, puppets, and photographs are all helpful in the education process.

The perioperative nurse who will be participating in the intraoperative care of the child will review the patient's

AMBULATORY SURGERY CONSIDERATIONS

Guidelines for Pediatric Ambulatory Surgery

Candidates for ambulatory surgery in a pediatric institution should:

- Be categorized as either class I or class II in accordance with the American Society of Anesthesiologists (ASA) guidelines; in some cases, patients who are categorized as class III may be eligible for ambulatory surgery with the approval of the medical director or attending surgeon
- Be older than 6 months of age

Procedures that are eligible for scheduling in ambulatory surgical settings should:

- Be no more than 4 hours in duration and have a total 4 hours of direct supervised recovery unless exceeded by patient condition demands that cannot be anticipated before surgery
- Be able to be performed using local or regional anesthetics, monitored anesthesia care (MAC), or general anesthetic with a duration of less than 4 hours
- Be able to be performed without the risk of extensive blood loss, major prolonged invasion of body cavities, or direct involvement of major blood vessels

Modified from Children's Hospital of Philadelphia: *Ambulatory Surgery Policy and Procedure Manual, 5.2.1 approved surgical procedures for ambulatory surgical centers; Ambulatory Surgery Policy and Procedure Manual, 2.1.1 patient selection criteria for the ambulatory surgery center.*

information and meet with the patient and the family before the child is transferred to the OR. In addition to reviewing the documentation, the nurse validates the patient's identification using two patient identifiers, confirms that the surgeon has marked the child's surgical site per institutional protocol, and seeks verbal verification from the patient, parent, or legal guardian about the scheduled procedure, making sure that it matches what is written on the surgical consent (Figure 25-1). If implants are to be used, availability must be confirmed before the patient's transport to the surgical suite. Frequently children will be given a premedication in the 20- to 45-minute period before their transportation to the OR. A premedication such as midazolam can greatly decrease a child's anxiety, minimizing the stress of separation for both child and family. The surgeon and anesthesia provider will each meet with the child and family, usually while the OR is being prepared for the patient. The perioperative nurse will assess the child's psychologic state, review the intended surgical procedure with the child and family, and ensure that they have no additional questions or concerns. A final communication among the anesthesia provider, surgeon, and nursing staff for the room confirms the team's state of readiness for the delivery of care before the nurse transports the child to the OR.

Informed Consent. Informed consent from the parent or legal guardian of the pediatric patient is required unless the patient is an emancipated minor. An emancipated minor is one who is legally under the age of consent but is recognized as having the legal capacity to consent. Minors may become emancipated by pregnancy, marriage, high school graduation, independent living, and military service. It is important for children to develop a trusting relationship with medical professionals and that these older children are in agreement (within their developmental capabilities) with their family's decision regarding surgery.

FIGURE 25-1 Perioperative nurse and parent verify the surgical site marking on pediatric patient matches consent.

Child Abuse and Neglect. Perioperative nurses are obligated to screen all pediatric patients for abuse or neglect. Child abuse and neglect are defined as "physical or mental injury, sexual abuse or exploitation, negligent treatment or maltreatment" (Betz and Sowden, 2008). Child abuse is found in all segments of society, crossing cultural, ethnic, religious, socioeconomic, and professional groups. The perioperative nurse is in a unique situation to assess for the presence of abuse because the patient will be disrobed in the OR. Box 25-1 lists the clinical manifestations of child abuse. Every state has a child abuse law that dictates legal responsibility for reporting abuse and suspicion of abuse, and nurses are mandated reporters. Failure to report suspected child abuse could result in a fine or other punishment, according to individual statutes (Betz and Sowden, 2008).

Nursing Diagnosis

Nursing diagnoses related to the care of pediatric patients undergoing surgery might include the following:

- Anxiety related to separation from family and friends
- Fear related to developmental level (fear of the unknown, fear of painful procedures and surgery)
- Risk for Infection related to surgical intervention and other invasive procedures
- Risk for Imbalanced Fluid Volume related to invasive surgery and accompanying blood loss
- Risk for Hypothermia related to loss of body surface heat to environment and immature temperature-control mechanism

Outcome Identification

Perioperative nursing care is predicated on relevant nursing diagnoses and their corresponding desired outcome. Outcomes should be measurable with criteria by which to judge their attainment. Thus for the desired outcome, "The patient will demonstrate some ability to manage anxiety," measurable criteria (e.g., the child will have posture, facial expressions,

BOX 25-1

Clinical Manifestations of Child Abuse and Neglect

SKIN INJURIES
Skin injuries are the most common and easily recognized signs of maltreatment of children. Human bite marks appear as an ovoid area with tooth imprints, suck marks, or tongue thrust marks. Multiple bruises in inaccessible places are indications that the child has been abused. Bruises in different stages of healing may indicate repeated trauma. Bruises that take the shape of a recognized object are generally not accidental.

TRAUMATIC HAIR LOSS
Traumatic hair loss occurs when the child's hair is pulled or used to drag or jerk the child. The result of the pulling on the scalp can cause the blood vessels under the skin to break. An accumulation of blood can help differentiate between abusive and nonabusive loss of hair.

FALLS
If a child is reported to have experienced a routine fall but appears to have severe injuries, the inconsistency of the history with the trauma sustained indicates suspected child abuse.

EXTERNAL HEAD, FACIAL, AND ORAL INJURIES
Cuts, bleeding, redness, or swelling of the external ear canal; facial fractures; tears or scarring of the lip; oral, perioral, and/or pharyngeal lesions; loosened, discolored, or fractured teeth; dental caries; tongue lacerations; unexplained erythema or petechiae of the palate; and bilateral black eyes without trauma to the nose may all indicate abuse.

DELIBERATE OR UNEXPLAINED THERMAL INJURIES
Immersion burns, with a clear line of demarcation; multiple small circular burns, in varying stages of healing; iron burns (show iron pattern); diaper area burns; and rope burns suggest intentional harm.

SHAKEN BABY SYNDROME
A shaken baby may suffer only mild ocular or cerebral trauma. The infant may have a history of poor feeding, vomiting, lethargy, and/or irritability that occurs periodically for days or weeks before the initial healthcare consult. In 75% to 90% of the cases, unilateral or bilateral retinal hemorrhages are present but may be missed unless the child is examined by a pediatric ophthalmologist. Shaking produces an acceleration-deceleration (shearing) injury to the brain, causing stretching and breaking of blood vessels that results in subdural hemorrhage. Subdural hemorrhage may be most prominent in the interhemispheric fissure. However, cerebral edema may be the only finding. Serious insult to the central nervous system may result, without evidence of external injury.

UNEXPLAINED FRACTURES AND DISLOCATION
Posterior rib fractures in different stages of healing, spiral fractures, or dislocation from twisting of an extremity may provide evidence of nonaccidental injury in children.

SEXUAL ABUSE
Abrasions or bruising of the inner thighs and genitalia; scars, tearing, or distortion of the labia/hymen; anal lacerations or dilation; lacerations or irritation of external genitalia; repeated urinary tract infections; sexually transmitted disease; nonspecific vaginitis; pregnancy in young adolescent; penile discharge; and sexual promiscuity may provide evidence of sexual abuse.

NEGLECT
The symptoms of neglect reflect a lack of both physical and medical care. Manifestations include failure to thrive without a medical explanation, multiple cat or dog bites and scratches, feces and dirt in the skinfolds, severe diaper rash with the presence of ammonia burns, feeding disorders, and developmental delays.

Modified from Betz CL, Sowden LA: *Mosby's pediatric nursing reference,* ed 6, St Louis, 2008, Mosby.

gestures, and activity levels that reflect decreased anxiety and will demonstrate increased focus) might be identified.

Outcomes identified for the selected nursing diagnoses for the pediatric patient could be stated as follows:

- The child will demonstrate some ability to manage anxiety.
- The child will verbalize less fear.
- The child will remain free from signs and symptoms of surgical site and invasive procedure site infection.
- The child will be maintained in a state of fluid and electrolyte balance.
- The child will be maintained in a state of normothermia.

Planning

Assessment data, combined with information about the planned surgical procedure, enable perioperative nurses to anticipate requirements for surgical positioning, instrumentation, equipment and supplies, medications, and activities necessary for the provision of safe, competent care for the pediatric patient. Knowledge of the child's developmental level allows the nurse to plan her or his approach and interactions with the child and family (Figure 25-2). The perioperative nurse identifies criteria appropriate to the child and surgical setting for each of the desired outcomes. A Sample Plan for Care for the pediatric patient is shown on p. 1091.

FIGURE 25-2 Perioperative nurse engages in play with a young toddler during preoperative assessment.

Implementation

Age-appropriate communication is important in implementing the pediatric nursing plan of care. Implementation begins during the perioperative nursing assessment and continues

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Anxiety related to separation from family and friends

OUTCOME
The child will demonstrate some ability to manage anxiety; a toy or other comfort/security object will remain with the child, and he or she will cooperate with requests.

INTERVENTIONS
- Provide an atmosphere of warmth and acceptance for both child and family members.
- Maintain a calm and relaxed manner; try to smile at the child. Talking with the child, being calm, and smiling can provide comfort.
- Explain to the child when he or she will be reunited with parents.
- Speak softly and slowly. When speaking, try to get down to the child's eye level so he or she can see your face. Do not assume you were understood. Repetition may be necessary.
- Allow the child to keep familiar security objects (e.g., toy, blanket).
- Administer preoperative sedation as prescribed; note effects.
- Encourage parents to stay with the child as long as permitted and according to their wishes.
- Encourage parents to hold child until child falls asleep, if desired (may vary according to institution policy).
- Touch the child, and hold his or her hand.

NURSING DIAGNOSIS
Fear related to developmental level (fear of the unknown, fear of painful procedures and surgery)

OUTCOME
The child will verbalize less fear; he or she will respond in an age-appropriate manner to comfort measures and recognize that the perioperative nurse is present to help.

INTERVENTIONS
- Assess the child's growth and development, noting any variations from expected normal age-appropriate maturational levels.
- Provide preoperative education for the child and family, using audiovisual aids such as photographs, drawings, items for medical play, or a tour of the surgical suite.
- Provide explanations according to the child's level and the parent's level of understanding; use age-appropriate terminology that is familiar to the child, such as for body function.
- Place unfamiliar equipment out of the child's view to decrease fear.
- Encourage the child to handle items that may seem strange or threatening.
- Reassure the child that certain body parts can be removed without producing harm (e.g., blood, tonsils, appendix).
- Provide ongoing age-appropriate explanations for procedures/events during the perioperative period. Do not try to explain everything at once; explain procedure-by-procedure.
- Allow choices whenever possible, such as wearing pajamas or clothing to the OR.
- Respect need for modesty; expose only those body parts necessary.
- Provide diversional activities to decrease fear.
- Use pain assessment questions if the child is fearful of procedures.
- Be honest about the possibility of pain or discomfort; do not lie to the child.
- Reassure the child that you are there to help.

NURSING DIAGNOSIS
Risk for Infection related to surgical intervention and other invasive procedures

OUTCOME
The child will remain free from signs and symptoms of infection at the surgical site and invasive procedure sites; the surgical site will heal by first intention, and white blood cell count and differential will remain within normal limits.

INTERVENTIONS
- Administer antibiotic prophylaxis as prescribed.
- Follow Standard Precautions.
- Maintain aseptic technique, and monitor members of the surgical team for breaks in technique.
- Teach family members signs and symptoms of surgical site infection:
  - Redness
  - Swelling
  - Warmth
  - Tenderness
  - Pain
- Teach family members importance of and proper handwashing techniques.
- Apply dressing to surgical site before sterile drapes are removed to prevent contamination of incision.

NURSING DIAGNOSIS
Risk for Imbalanced Fluid Volume related to invasive surgery and accompanying blood loss

OUTCOME
The child will maintain fluid balance as evidenced by blood pressure within expected/acceptable range, palpable peripheral pulses, moist mucous membranes, and absence of peripheral edema.

INTERVENTIONS
- Maintain and protect patency of intravenous lines.
- Review laboratory analyses for results of total blood volume.
- Calculate estimated total blood volume using formula of 85 to 90 ml/kg of body weight if total blood volume has not been determined by laboratory tests.
- Provide gram scales for weighing sponges discarded from operative field; weigh sponges, and report estimated loss.
- Provide suction units with reservoirs that measure in 5-ml to 10-ml increments.
- Measure and record quantity of irrigating fluid used.
- Provide appropriate amounts of intravenous fluid replacement (e.g., 250-ml containers).
- Measure and record urinary output and output from other drainage tubes.
- Send laboratory specimens for analysis as indicated; review results indicating fluid status.

NURSING DIAGNOSIS
Risk for Hypothermia related to loss of body surface heat to environment and immature temperature-control mechanism

OUTCOME
The child will maintain normothermia as evidenced by body temperature within normal limits/expected range.

INTERVENTIONS
- Adjust room temperature approximately 1 hour before arrival of the child: 26° to 27° C (78.8° to 80.6° F) for infants and newborns; 23° to 24° C (73.4° to 75.2° F) for older children.
- Keep child covered as much as possible.
- Consider wrapping lower extremities in soft gauze or stockinette and encasing in plastic bag for newborns and infants.
- Provide radiant heat lamp for use during placement of monitoring lines, induction of anesthesia, positioning, skin prep, and draping.
- Warm blankets, skin prep solutions (according to manufacturer's instructions), and irrigation and other solutions to body temperature before use.
- Use warmers during administration of intravenous fluids and blood products; temperature settings should not exceed 38° C (100.4° F).
- Monitor body temperature by rectal, esophageal, tympanic membrane, or other automatic temperature-monitoring device.
- Document temperature at prescribed intervals; take appropriate action for temperature extremes.

through discharge to the postanesthesia care unit (PACU) or other area. The presence of a parent during much of the preoperative period, including during anesthesia induction in the OR and after anesthesia emergence in the PACU, can help decrease anxiety for both young children and their families and facilitates family-centered care (Evidence for Practice).

Infants, reliant on family to meet their basic needs, are difficult to pacify when NPO for surgery. The facility should provide rocking chairs, pacifiers, warm blankets, and simple distractions such as music or toys. Preoperative teaching should include telling the family to provide fluids for the infant until the deadline for NPO status. Unnecessary delays should be avoided at all costs. Parents may need reassurance and support during the period immediately before surgery.

The toddler or preschooler fears parental separation and abandonment. Toddlers fear, among other things, strangers, the dark, and machines. They attribute lifelike qualities to inanimate objects, believing that the objects, like them, have feelings. Thus a blood pressure cuff that squeezes the child's arm may be perceived to be doing so because it is angry with the toddler. Toddlers may also believe that their body is held together by their skin; anything that violates the skin integrity is feared. For this reason, bandages are very important. Toddlers and preschoolers interact with the environment using their senses. To integrate this into the patient's care, the perioperative nurse should give the toddler the opportunity to touch and play with objects that he or she will encounter. An example is to give the child a small anesthesia mask to put on his or her teddy bear. Sensory information should be provided in a soft, gentle voice (i.e., what the toddler will see, feel, touch, and hear). A security object is extremely comforting. The OR should be quiet; background noise should be controlled. Instruments that are frightening should be kept from view. To allow quick induction of anesthesia the toddler should be transferred into the surgical suite when the room and staff are completely prepared.

The school-age child may still perceive hospitalization or surgery as a punishment but can evaluate painful intrusive actions in terms of logical function (e.g., getting an IV line hurts, but then I can get medicine in it to make me feel better). Feelings of inadequacy may be associated with something the child thinks he or she should be expected to do or know. Fear of body injury or mutilation, loss of control, and fear of the unknown characterize this developmental stage. These children benefit from simple, concrete explanations in familiar terms; a book or other teaching aid can be helpful. The concepts of time and unseen body functions can now be incorporated in the explanations. The child should be allowed to make choices when possible (e.g., letting the child decide in which hand to place the IV line or which flavor to add to the anesthetic mask).

Adolescents may fear altered body image, peer rejection, disability, and loss of control or status. The fear of death is more prevalent in this age-group than any other, and adolescents may find explanations of monitoring and safety measures reassuring. They need as much privacy as possible, and their attempts to be independent should be respected (e.g., walking into the OR instead of being wheeled in on a stretcher if the

EVIDENCE FOR PRACTICE

Timely Postoperative Visitation

Parental visitation in the postanesthesia care unit (PACU) has been identified as a standard of care in some hospitals, but not all. In this study, researchers at a facility in Pennsylvania reviewed the literature to summarize the benefits of early parental visitation in the PACU, and then established a baseline within the unit. Through objective data collection and anecdotal reporting, they found that in 2004 only 44% of parents were reunited with children during the immediate postoperative phase. The team established a target goal of 75% parental visitation in the PACU within 6 months of initiating a quality improvement program.

Their quality improvement program consisted of a survey distributed to ambulatory surgery patients and families in April 2005 to ask families questions such as the following: Did they believe that their children were adequately prepared for the surgery? What aspects of care were most important to the family? What was the family's overall satisfaction with the ambulatory surgical experience? The results of the survey indicated that speaking with their child's surgeon after the procedure and being present with their child in the PACU as soon as possible after surgery were the top two priorities for family satisfaction.

The team decided to address barriers that prevented parental visitation in the PACU. Among the top concerns were the high acuity of patients upon arrival to the PACU; a change in efficiency related to phase I procedures and care; risks to patient safety because of negative reactions from parents related to laryngospasm, airway obstruction, and respiratory compromise; and increased risks to the safety of parents who were unable to effectively cope with seeing their child during the immediate postoperative period.

The first step in garnering support for change was recognition from nursing leadership that the concerns shared by the nursing staff regarding the delivery of patient care balanced with parental visitation were real and valid. The team worked to help the nursing staff understand that they all owned the process, and accepted that resistance was more a result of a caring and committed staff. In order for timely postoperative visitation to occur, resources, adequate systems, and support from management were readily available. In addition, the practice was championed and clear expectations were shared with the staff.

Ultimately, change could only occur with multidisciplinary acceptance of the new practices. A team represented by various stakeholders in the surgical process, including members from a family advisory committee, was created to establish a foundation for work, review the current philosophy of care and key elements of family-centered care, and develop a theoretical framework for the group's work. Any staff member who provided direct patient care was educated about the quality improvement program, and before surgery all patients were provided with education and information regarding parental visitation in the PACU.

Their target goal was reached in January 2005 and has continued to increase. In January 2007, 90% of parents were reunited with their child within 30 minutes of the patient's arrival to the PACU.

Modified from Kamerling SN et al: Family centered care in the pediatric postanesthesia care unit: changing practice to promote parental visitation, *J Perianesth Nurs* 23(1):5-16, 2008.

patient has not been sedated). The adolescent may not wish to show any fear; questions might not be asked while the parents are present. Information and explanations should be provided as reasonably and truthfully as possible. If appropriate, some choices should be allowed, such as wearing underwear to the OR. Patient care procedures that violate privacy, such as hair removal, skin preparation, or insertion of an indwelling urinary catheter, should be conducted after the patient is anesthetized.

Key points in providing perioperative care to pediatric patients include remaining alongside the child until the child is anesthetized, keeping the room quiet during induction, accepting a child's need to express fear and fearful behaviors (e.g., crying), and using simple words without double meanings to explain care. Security objects should remain with the child until induction has been completed. A child's behavior during induction is likely to be the same during emergence; thus all attempts should be made to provide calm, reassuring care. Parents should be alerted to delays in the surgery schedule; in some instances, the child may be allowed to have fluids if the surgery is delayed by several hours.

Implementing the nursing plan of care includes continual reassessment of the patient's needs as well as the efficient execution of activities that facilitate the surgical intervention. Remaining with the child during induction, positioning, and prepping the surgical site; creating and maintaining a sterile field; collecting, documenting, and disposing specimens; and administering medications are all part of helping to provide a safe environment for the pediatric surgical patient. Making sure that the pediatric patient's family receives regular updates of the child's status is also a part of the perioperative nurse's responsibilities and will decrease their anxiety and help foster a sense of trust in the healthcare professionals caring for their child.

Instrumentation. The same types of instruments used in adult surgery are used in pediatric surgery. However, pediatric instruments are usually shorter, have more delicate or less pronounced curves, and are smaller. A complete range of instrument sizes is necessary to make the appropriate size available to each child, since pediatric patients can range in size from less than 1 kg to more than 100 kg. Fewer instruments are normally required because incisions in children are shorter and shallower than those in adults. Use of basic instrument sets, grouped according to types of surgery performed (e.g., minor, major), facilitates instrument counts. These sets are easily adapted to the patient's needs as well as the surgeon's preferences and eliminate unnecessary instruments from the sterile field.

The following sets are examples of instrumentation used in pediatric surgery. The minor set is used for procedures such as inguinal hernia repair, head and neck procedures, and pyloromyotomy. The major set is used for major chest and abdominal cases, such as tracheoesophageal fistula (TEF) and diaphragmatic hernia repair, omphalocele repair, bowel resection, and pull-through for Hirschsprung's disease. Smaller and larger instruments should be in separate, additional sets to be dispensed to the surgical field as determined by the patient's size.

In addition to basic instruments, the minor pediatric instrument set should include curved Knapp iris scissors, both sharp and blunt; a Jacobsen curved clamp for delicate dissection; straight and curved Halstead mosquito clamps; sharp and blunt Senn retractors (two of each); 0.5-mm Castroviejo forceps; single-toothed Adson forceps; 6-inch fine DeBakey forceps; a small Weitlaner retractor; an Andrews-Pynchon 9½-inch suction; sizes 7- and 9-French (9F) Frazier suctions; a Castroviejo locking needle holder; and two Webster needle holders. The major pediatric instrument set should include the components of the minor set, slightly longer (7- to 8-inch) basic instruments (scissors, forceps, needle holders), and the following: curved Schnidt forceps; fine Kelly clamps; Gemini right-angled clamps; Army-Navy, small Deaver, and Richardson retractors (two of each size); Gerald forceps; Singley ring forceps; a set of malleable retractors; a grooved director; and a Poole suction.

Sutures. A variety of sutures are used with the pediatric population because of the wide range of patient size; needles from size 0 to 7-0 are routinely stocked. Both absorbable and nonabsorbable sutures on cutting and tapered needles are employed. The most frequently used sizes are 3-0 to 5-0 with ½- and ⅜-circle needles. Staples, both pediatric and regular sizes, are occasionally used. Many skin incisions are closed with subcuticular techniques, over which adhesive strips or cyanoacrylate glue is then applied. The use of tape to apply dressings is done conservatively because of the delicate nature of children's skin; frequently, either a small transparent or an elastic net dressing is used to hold gauze dressings in place.

Anesthetic Considerations. Anesthesia is approached differently in pediatric patients than it is in adults. The equipment and supplies are scaled down to match the size of the patient, and different anesthesia circuits and delivery systems may be used. The most common technique used in the pediatric population is a general inhalational anesthetic administered by facemask, laryngeal airway, or endotracheal tube. Selection of the endotracheal tube involves several considerations; the tube must be large enough to permit ventilation but small enough to minimize damage to the trachea while maintaining a seal to prevent aspiration. Pressure from the cuff can cause tracheal damage (Cote, 2005). Uncuffed endotracheal tubes are used in children up to 8 years of age. Table 25-2 provides a guide to choosing endotracheal tubes and laryngoscope blades for pediatric patients.

Microdrip IV tubing and burettes are commonly used to avoid the administration of excess fluids in pediatric patients under the age of 8 years, and only 500-ml bags of IV solution are used. The patient's IV line is usually started in the OR after induction with mask anesthesia, depending on the patient's diagnosis and medical history. Patients who require emergency surgery who have not been NPO; have increased intracranial pressure, an unusually difficult airway, or neuromuscular disease; or have been diagnosed with malignant hyperthermia require an IV placement before anesthesia induction. If the IV line is started before induction, measures should be taken to lessen the discomfort, such as an intradermal injection of 1% buffered lidocaine or saline at the site or the application of topical anesthetic creams. If possible, the surgical team should allow the child the option of sitting up or lying down during IV placement; if developmentally appropriate, hold the child's hand and tell the child about each step in the placement of an IV line.

Preoperative sedation is generally accomplished by the oral administration of midazolam. Midazolam is the most commonly used pediatric premedication in the United States and

TABLE 25-2

Recommended Sizes and Distance of Insertion of Endotracheal Tubes and Laryngoscope Blades for Use in Pediatric Patients

Age	Internal Diameter of Endotracheal Tube (mm)	Recommended Size of Laryngoscope Straight Blade	Distance of Insertion (cm)
Premature (<1250 g)	2.5	0	6-7
Full term	3.0	0-1	8-10
1 yr	4.0	1	11
2 yr	5.0	1-1.5	12
6 yr	5.5	1.5-2	15
10 yr	6.5	2-3	17
18 yr	7-8	3	19

Modified from Cote CJ: Pediatric anesthesia. In Miller RD, editor: *Miller's anesthesia*, vol 2, ed 6, Philadelphia, 2005, Churchill Livingstone.

can be given orally, nasally, rectally, intramuscularly, or intravenously (Cote, 2005). Oral midazolam should be administered in a flavored base to mask the bitter taste. Relaxation is noted 15 to 45 minutes after administration; the child should be kept in a safe, observable environment after being medicated. Other agents used for premedication include fentanyl and, infrequently, ketamine.

Depending on institutional policy, a parent may be present during induction to comfort the child and decrease the child's anxiety. The perioperative nurse should provide the parent an explanation of how the OR will appear and who will be present in the OR, how the child's anesthesia induction will be performed, and how the child will appear as the anesthetic takes effect. An additional staff person, such as a parent services' provider or child life therapist, should be present to escort the parent to and from the OR so that the perioperative nurse can focus on providing care for the patient once the child has been anesthetized.

Distraction methods during the induction of anesthesia can help minimize a child's stress and anxiety. Singing softly, telling a story, and, for the older child, providing a relaxing mental image are effective diversion techniques.

Malignant hyperthermia (MH), although very rare, may be more prevalent in the pediatric population as a result of the administration of inhalational anesthetics and succinylcholine (see Chapter 4). In addition, physiologic conditions present in some pediatric patients are associated with a higher risk of MH. These conditions are myotonia congenita, Duchenne's muscular dystrophy, Becker's muscular dystrophy, osteogenesis imperfecta, arthrogryposis, kyphoscoliosis, and King-Denborough syndrome (Gronert, 2005). Careful assessment of family history is essential to identify patients at risk for developing MH. The management of an MH crisis is described in Chapter 4.

Pain Management. In the past, many common fallacies existed about pain in the pediatric population. Some of these mistruths were that infants do not feel pain; children have better pain tolerance than adults; children cannot tell the healthcare provider where they hurt; children always tell the truth about pain; children become accustomed to pain or painful procedures; and narcotics are more dangerous for children than they are for adults. Research into this important area has revealed that infants do demonstrate behavioral and physiologic indicators of pain. Compared to adults, children have less pain tolerance; their pain tolerance increases as they mature. Children are able to indicate pain, and children as young as 3 years can use pain-rating scales. Often children may not admit to having pain; they may believe that others know how much they hurt, or they fear receiving an injection. Children may also feel that pain and suffering are punishment for some misdeed, or they may not know what the word *pain* means. Children do not become accustomed to pain or painful procedures. They actually may demonstrate increased behavioral signs of pain with repeated procedures. Many factors, such as developmental level, culture, coping ability, temperament, and activity levels, influence the behavioral manifestations of pain exhibited by the patient. Narcotics are no more dangerous for children than they are for adults and are not excluded as a treatment modality. The evaluation of a pediatric patient's level of pain is performed using a variety of assessment tools (pain scales) that are based on the age and developmental level of the child. Often, these scales are tested for reliability and validity (Research Highlight). In infants and nonverbal children, evaluation is based on physiologic changes and observation of behaviors. Children with verbal skills are able to articulate pain. One assessment strategy to use with pediatric patients is the *QUESTT* method:

Question the child.
Use pain-rating scales.
Evaluate behavior and physiologic changes.
Secure the parents' involvement.
Take cause of pain into account.
Take action, and evaluate results.

Questioning the child provides the most reliable indicator of pain. Children may not be familiar with the word *pain* and may be more comfortable with words like "ouch," "hurt," or "owie." It may also be helpful to ask the child to point to where it hurts. The FACES pain scale uses cartoon faces with a variety of expressions ranging from happy to crying. The child selects the face that best describes his or her pain (see Chapter 9). The Oucher scale has a numeric component and a component similar to the FACES scale but uses actual photographs of children. The adolescent pediatric pain tool (APPT) is a line drawing of a body; the child marks the drawing where he or she has pain. Other tools include Likert-type scales rating pain on a score of 0 (no pain) to 10 (worst pain) or incorporate several components of pain assessment (subjective and objective data).

RESEARCH HIGHLIGHT

Behavioral Observational Pain Scale (BOPS)

The Behavioral Observational Pain Scale (BOPS) is a postoperative pain measurement scale geared towards children ages 1 to 7. The scale assesses facial expression, verbalization, and body position in an attempt to score the degree of pain felt by a child. A prospective study was conducted on a day surgery unit and a neurosurgical postoperative unit to determine the validity and reliability of the BOPS. The sample size consisted of 76 children ages 1 to 7 who were scheduled for elective surgical procedures. The study was divided into interrater reliability (based on different nurses scoring patients on the BOPS), concurrent validity (comparing the BOPS to the Children's Hospital of Eastern Ontario Pain Scale to determine whether each described similar behaviors), and construct validity (assessing baseline pain scores and the effect of analgesic on pain scores at 15, 30, and 60 minutes after administration). The findings of this study indicated that there was extensive agreement between different nurses who scored patients on the BOPS. Positive correlation between the BOPS and the Children's Hospital of Eastern Ontario Pain Scales indicated that both tools described similar behaviors ($p < .001$). There was significance ($p < .01$) before the administration of analgesia and at 15, 30, and 60 minutes after medication administration; in addition, there was no significant difference ($p < .01$) between results recorded at 15 and 60 minutes. The BOPS allows for evaluation and documentation of pain scales in a manner that is reliable and consistent. The scoring system is simple, and can be easily incorporated into a postoperative unit. These findings indicate the potential for improved postoperative pain treatment when using the BOPS in children ages 1 to 7.

Modified from Hesselgard K et al: Validity and reliability of the Behavioural Observational Pain Scale for postoperative pain measurement in children 1-7 years of age, *Pediatr Crit Care Med* 8(2):102-108, 2007.

Physiologic indicators of pain, such as increased blood pressure, respirations, and heart rate and restlessness, are the same for children as for adults but may not be as reliable, except in neonates and nonverbal children. These indicators may also reflect anxiety or fear and should not be the sole indicator used to determine pain. Children may also tug or hold painful areas or show preference to a painful extremity.

Parental involvement in pain management is important. Parents know their child's normal behavior and can provide input into the behaviors being exhibited in the perioperative setting. Parents should be queried about the child's previous experiences with pain and be taught the nonverbal behaviors that may indicate pain.

Nurses should investigate all complaints of pain or discomfort and be sensitive to behavioral and nonverbal cues to determine treatment. Postoperative pain should be assessed after all surgical procedures, regardless of their nature. It is also critical to assess and document the child's response to the interventions provided for relief of pain.

Effective pain management requires a willingness to use a variety of methods and modalities to achieve optimal results. Pharmacologic methods include the administration of analgesics, both narcotic and non-narcotic. Patient-controlled analgesia (PCA) is an option for children. Children as young as 4 years have the cognitive and physical capabilities to successfully use this modality with appropriate instruction and support (Wu, 2005). Nonpharmacologic methods include distraction, relaxation, guided imagery, behavioral contracting, and cutaneous stimulation. Nonpharmacologic methods should never be used as substitutes for appropriate medication administration but instead should be used to enhance the management of pain.

Evaluation

The perioperative nurse evaluates care provided throughout the perioperative period. At the conclusion of the surgical intervention, the skin is inspected, especially at dependent pressure points and at the site of the electrosurgical dispersive pad. Inspection is carried out to detect any reddened, irritated areas or evidence of compression injury. If povidone-iodine or chlorhexidine gluconate preparations were used for skin prep, the area needs to be checked for any signs of chemical irritation. The patient's temperature is reassessed. The cardiopulmonary status is closely monitored as the child emerges from anesthesia. The perioperative nurse should assist the anesthesia team during emergence, remaining at the patient's bedside. Warm blankets are provided; hydration status is evaluated as replacement fluids continue to be administered, and fluid output is noted. The child is transferred to and positioned on the stretcher, crib, neonatal intensive care unit (NICU) warmer, or ICU bed; the airway and respiratory effort are reassessed before departing the OR. Tubes, IV lines, drains, and drainage devices must be carefully protected during the move from the operating table. Supplemental oxygen is always given during transport from the OR to the PACU for pediatric patients.

The perioperative nurse provides a hand-off report to the PACU nurse, focusing on the condition of the child, the response to surgery and anesthesia, the presence of catheters and drains, the quality and amount of wound drainage, a description of the dressings applied, and any special needs. Part of this report should focus on the outcomes established in the perioperative plan of care. For the plan of care presented in this chapter, they might be as follows:

- The patient demonstrated decreased anxiety.
- The patient was protected from infection related to operative intervention; principles of asepsis and infection control were maintained.
- The patient remained free from injuries related to positioning for the surgery.
- The patient's temperature was maintained in the desired range during the perioperative period.

The perioperative nurse may receive further feedback on the child's progress after the child is discharged from the PACU; information may be relayed by the surgeon, unit nurse, or anesthesia team. This type of informal feedback helps the perioperative nurse collect additional data regarding effectiveness of the plan of care, providing information about the achievement of identified outcomes.

Patient and Family Education and Discharge Planning

Patient and family teaching varies significantly based on the type of surgery performed. Some hospitals provide special preoperative teaching and hospital tours for pediatric patients and their parents to help them prepare for the surgical experience. Sometimes information is discussed with the child and family at the time of the office visit, when the surgery is scheduled. For same-day procedures, the day-surgery nursing staff

BOX 25-2

Sample Discharge Instructions

- Leave the wound open to the air.
- Do not apply any creams or ointments to the wound.
- For the first 24 hours, keep the incision clean and dry.
- Do not allow the incision to be under water for the first week after surgery.
- On the second day after surgery gently wash the incision twice a day with mild soap or shampoo. Make a small lather in your hand and wash with warm water. Do not rinse under water. Use a warm, wet paper towel and blot the lather away. Do not use terry cloth washcloths. The fabric loops may snag and pull on the stitches.
- If the stitches are clear, they will dissolve and do not need to be removed. If they are blue or black, they need to be removed about 10 days to 2 weeks after the surgery. Your physician will tell you how long the stitches should remain in position. Call the surgeon's office soon after going home if you need an appointment for stitch removal.
- Check the wound daily. It is normal to have some redness around the stitch holes or on the incision line. Call the surgeon's office if you notice that the area around the outside of the incision is red, hot, tender or has pus draining from it. Also call if your child has a fever.

From Children's Hospital of Philadelphia, 2008.

might teach postoperative care immediately before patient discharge. Basics of postoperative care are reviewed with the parents at this time. In some cases, written material may be provided (Box 25-2). Parents should be advised to be alert for certain signs and symptoms during the postoperative recovery period that could indicate an infectious process, such as fever, pain, nausea, redness around the incision area, drainage from the wound, or difficulty breathing. These signs and symptoms may develop days or even weeks after surgery. It is important that parents understand the necessity of not ignoring any of these signs and symptoms and of reporting them to the surgeon promptly so that an early diagnosis can be made and treatment prescribed. Although discharge information depends on the type of surgery performed, it typically includes recommendations about activity restrictions, return to school or day care, wound care, bathing or showering, diet, and follow-up appointments. The printed discharge instructions are reviewed with the parents, and their understanding is verified. This time should provide the family with an opportunity to ask questions or seek clarification of the instructions. Phone numbers for the surgeon and the main hospital are provided in case the family has concerns or questions during the child's recovery period at home. An appointment for the child's follow-up visit may be made before discharge, or the parents are instructed to call the physician's office to schedule an appointment.

Surgical Interventions

As mentioned, children require surgery for congenital malformations, an acquired disease, or trauma. The field of pediatric surgery is further subdivided into all the specialties. Several surgical procedures that may be designated pediatric are presented in previous chapters of this text under particular specialty headings. The surgical interventions presented here represent procedures that are most commonly performed on children.

VASCULAR ACCESS

Vascular access in pediatric patients may be established intraoperatively for short-term (weeks) or long-term (months, years) use. Examples of short-term use include peripherally inserted central venous catheters (PICC lines) for antibiotic therapy. Central venous lines or implanted ports are placed for long-term access to provide parenteral nutrition, chemotherapy, bone marrow transplantation, or multiple IV access lines for the critically ill patient. Common complications of vascular access include infection; thrombosis; catheter occlusion; extravasation/migration; malposition/displacement; vascular stenosis; catheter fracture/embolization; surgical damage to nerves, lymphatics, vessels, or pleura; and poor cosmesis (Turner, 2005). The potential for central line–associated bloodstream infections (CLABSIs) has been recognized in many institutions throughout the country. The Risk Reduction Strategies box addresses ways in which the integrity of these lines can be preserved.

Central Venous Catheter Placement

The preferred site of placement is the external jugular vein. The internal jugular vein may be chosen if the external jugular vein has been used or is too small. From the cannulation site the catheter is tunneled under the skin about 5 to 10 cm. This is done to inhibit contamination of the bloodstream from frequent dressing changes. Subcutaneous ports are placed in a similar fashion. In cases where the internal or external vein sites are unavailable, the catheter may be placed into the external iliac vein by way of a cutdown in the greater saphenous vein. In these cases the catheter is tunneled into the abdominal wall.

Procedural Considerations. The manufacturer's instructions for handling and preparing the catheter must be followed. The catheter must not contact lint, glove powder, or other foreign matter. Before insertion, the catheter is flushed and filled with heparinized saline (1 unit of heparin to 1 ml of saline) to prevent air bubbles from entering the circulatory system and to eliminate blood clots in the catheter lumen. Fluoroscopy is used to confirm proper placement of the catheter; lead shielding must be provided for patient and staff, with appropriate warning signs placed on room doors. The use of a lead shield for the patient should be documented in the perioperative record.

The child is appropriately positioned as dictated by the site chosen for cannulation, and organs are protected with a lead shield. The area is prepped and draped.

Operative Procedure—External Jugular Vein Site

1. The surgeon uses a needle and syringe to puncture the external jugular and aspirates to confirm blood flow.
2. The syringe is removed from the needle, and a guidewire is fed through the needle into the vein. An intraoperative x-ray is taken to confirm correct position.

RISK REDUCTION STRATEGIES

Preventing Central Line–Associated Bloodstream Infections (CLABSIs)

When patients with a central venous catheter are admitted into the OR for surgical procedures, staff may take the following precautions to prevent central line–associated bloodstream infections (CLABSIs):

- Make every effort not to access the central line for general purposes in the OR; use peripheral lines as much as possible.
- Practice hand hygiene before and after handling a central line.
- If a central line needs to be used in the OR, healthcare providers must perform a 10-second hub scrub that encompasses the threads of the catheter hub.
- If a central line dressing needs to be changed* in the OR, keep the following in mind:
  - Don nonsterile exam gloves to remove the old dressing.
  - Dried blood, crusty accumulations should be cleaned with an alcohol pad.
  - ChloraPrep is the solution of choice in some hospitals for central line dressing changes.
  - Establish a sterile field with prep solution and new dressing material.
  - If using ChloraPrep, apply the solution using a "back and forth" motion as opposed to concentric circles. The "back and forth" motion creates more friction on the skin and helps to decrease the bacterial load.
  - Scrub the area for 30 seconds (recommended time for some hospitals).†
  - Allow the prep solution to dry.
  - Don sterile gloves to apply transparent, semi-permeable dressing.‡
  - Write the date on the dressing label and apply to the central line dressing site.

*Central line dressings are routinely changed every 7 days, unless there is a need to do so (e.g., soiled, bloody). Smartsites (Clave) are changed every 72 hours unless damaged.
†If the central line is in the femoral/groin area, scrub the site for 2 minutes.
‡SorbaView dressing is only recommended for those patients who have a contraindication (e.g., sensitivity, reaction) to Tegaderm dressings.
Modified from Children's' Hospital of Philadelphia Blood Stream Infection (BSI) Task Force, 2008-2009.

3. Once the position is confirmed, the surgeon makes an incision over the insertion site. A silver probe or tendon passer is used to create a tunnel beneath the skin to the desired exit site of the catheter. A second incision is made over the tip of the probe or passer.
4. The implantable end of the catheter is attached to the end of the passer or probe and pulled through the subcutaneous tunnel. The catheter is cut to a desired length.
5. The needle is removed from the vein, leaving the guidewire in place. An obturator is placed over the guidewire, and the wire is removed. The catheter is placed through the obturator into the vein and an intraoperative x-ray is taken to confirm position.
6. The catheter is secured at the exit site on the chest wall with nonabsorbable sutures, flushed with a "super flush" of heparinized saline (10 units of heparin to 1 ml of saline in children younger than 12 months or 100 units of heparin to 1 ml of saline in children older than 12 months), and clamped.
7. An occlusive transparent dressing is placed over the catheter site. The catheter is coiled under this dressing to avoid tension on the line and accidental displacement.

MINIMALLY INVASIVE SURGERY

Improvements in instrumentation and the development of equipment in smaller sizes have resulted in the evolution of minimally invasive surgery (MIS) from that of a rapidly growing field to one of routine practice in the pediatric surgical arena. Much like the adult population, many traditional "open" pediatric surgical procedures are being replaced by MIS procedures. Because the field of pediatric MIS is relatively new, surgeons are at an advantage because they are able to combine virtual reality techniques and robotics with the most current technology and instrumentation (Harrington et al, 2008). Advantages of minimally invasive surgery include diminished postoperative pain, improved cosmetic results, decreased prevalence of adhesion formation, and accelerated recovery periods and shorter hospital stays.

Despite the technical congruence with adult MIS procedures, the pediatric populations undergoing these procedures have specific needs that must be satisfied in order to promote positive outcomes. Anesthesia providers must take the size and age of the patient into consideration because of the risk of physiologic compromise related to insufflation. Likewise, steps are taken intraoperatively to decrease the likelihood of intraabdominal injury, such as insertion of an appropriate size Foley catheter to decompress the bladder or application of thromboembolic hose or sleeves to prevent deep vein thrombosis.

Common pediatric MIS procedures for general surgery include diagnostic laparoscopy, pyloromyotomy, splenectomy, gastric fundoplication, and cholecystectomy. Thoracoscopic approaches may be used for correction of pectus excavatum, lung biopsy, sympathectomy, and closure of a patent ductus arteriosus (PDA). Procedures that are currently less common but increasing in prevalence include pancreatectomy for focal lesion, choledochal cyst excision, lobectomy for congenital cystic adenomatoid malformation (CCAM), and repair of congenital diaphragmatic hernia (CDH) and transcutaneous esophageal fistula (TEF). Minimally invasive procedures in other disciplines include (but are not limited to) ventriculoscopy, which can be used to view the ventricles of the brain; functional endoscopic sinus surgery (FESS); and nephrectomy and pyeloplasty, both of which may involve the use of a surgical robotic system.

Laparoscopic Pyloromyotomy for Pyloric Stenosis

Pyloric stenosis (Figure 25-3) is the most common cause of gastric outlet obstructions in children and is the most common condition requiring surgery in the newborn. Signs and symptoms of high gastrointestinal (GI) obstruction appear at 2 to 6 weeks of age. The first sign is bile-free projectile vomiting after feeding. The infant usually fails to gain weight adequately, and there may be a severe loss of body fluids and electrolyte imbalance, evidenced as hypochloremic, hypokalemic metabolic alkalosis. Once the diagnosis of hypertrophic pyloric stenosis is made, either through physical examination or by imaging techniques, surgical intervention is planned.

Electrolyte imbalances must be corrected before surgery. The Fredet-Ramstedt pyloromyotomy for pyloric stenosis is an open procedure that involves the incision of the muscles of the pylorus to treat congenital hypertrophy of the pyloric sphincter that is obstructing the stomach. However, laparoscopic pyloromyotomy has replaced the open procedure as the standard for repair. The laparoscopic procedure is described in the following Operative Procedure.

Procedural Considerations. The stomach is emptied just before induction of anesthesia, and the nasogastric tube is removed to guard against reflux of gastric contents around the tube during induction. The patient is positioned transverse on the OR bed so that the operating surgeon stands at the patient's feet. A video monitor is positioned above the patient's head. The abdomen is prepped in the usual manner, and trocar sites are injected with a local anesthetic. The perioperative nurse must consider the location of the incision and position the patient in a fashion that facilitates maximum exposure of the surgical site. Appropriate-sized instrumentation and sterile supplies must be available, along with the appropriate imaging equipment. Insufflation flow rate should be set to the lowest acceptable level for achieving pneumoperitoneum and increased slowly.

Operative Procedure

1. The surgeon makes a small incision in the umbilicus and places a 3-mm or 5-mm trocar through it to accommodate the telescope. Insufflation tubing is attached to this trocar and the abdomen is insufflated (maximum pressure of 10 mm Hg).
2. Using a #11 blade, the surgeon makes a small stab incision laterally, slightly above the umbilicus on each side.
3. The 3-mm laparoscopic instruments are passed directly through the stab incisions.
4. The surgeon makes an incision in the serosa on the anterior wall of the pyloric mass from the duodenal junction proximally to a point proximal to the area of hypertrophied muscle using an arthroscopic knife and laparoscopic grasper. The circular muscle is spread with the 3-mm laparoscopic pyloric spreader on the submucosal base, so that all muscle fibers are completely divided (Figure 25-4).
5. The anesthesia provider injects 60 to 120 ml of air into the stomach through an orogastric (OG) tube to ensure that there are no air bubbles at the pyloric incision.
6. The umbilical incision is closed using absorbable suture and cyanoacrylate glue applied to each incision.

Laparoscopic Nissen Fundoplication

Nissen fundoplication is indicated for infants and children who experience severe gastroesophageal (GE) reflux. The cause of GE reflux in these patients is believed to be an inadequate anti–reflux barrier. The anti–reflux barrier normally consists of a combination of anatomic and physiologic factors, including sufficient amount and strength of muscle fibers located in the lower esophageal sphincter, adequate length of the abdominal esophagus, and a high-pressure zone in the lower esophagus. An incompetent anti–reflux barrier can result in life-threatening complications, including obstructive apnea, aspiration pneumonia, esophagitis, and failure to thrive. The goal of the Nissen fundoplication is to create a competent anti-reflux barrier. Nissen fundoplications can be performed using open or laparoscopic technique. There are several types of laparoscopic fundoplications. The traditional laparoscopic wrap is described in Chapter 10. The partial laparoscopic wrap (Toupet) is described below.

Procedural Considerations. The patient is positioned supine for induction of general anesthesia. The anesthesia provider inserts an OG tube, which serves as a stent for the wrap during the procedure. Once the endotracheal tube location is confirmed and secured, the patient is moved to the foot of the OR

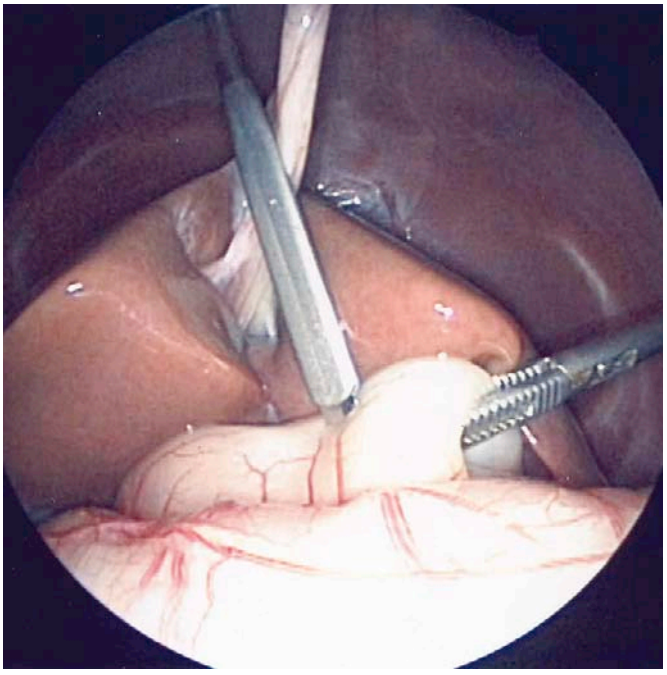

FIGURE 25-3 Pyloric stenosis.

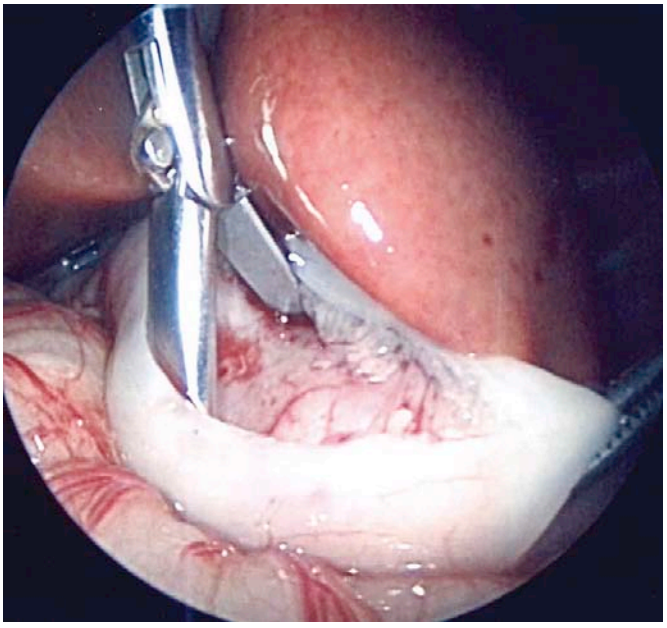

FIGURE 25-4 Laparoscopic pyloromyotomy.

bed and positioned in low lithotomy position using stirrups and protective padding. The operating surgeon stands in the area between the patient's legs. A video monitor is positioned above the patient's head. The abdomen is prepped in the usual manner, and trocar sites are injected with local anesthetic. The perioperative nurse must consider the location of the incision and position the patient in a fashion that facilitates maximum exposure of the surgical site. Appropriate-sized instrumentation and sterile supplies must be available, along with the appropriate imaging equipment. Insufflation flow rate should be set to the lowest acceptable level for achieving pneumoperitoneum and increased slowly.

Operative Procedure

1. Using a #15 blade the surgeon creates a tiny fasciotomy, places a trocar, and insufflates the abdomen with CO_2 gas. After insufflation, the abdomen is inspected for gross abnormality. Additional fasciotomies and trocars are placed to accommodate camera, telescope, and instrumentation.
2. A Colorado clamp is used to elevate the liver away from the stomach, and gastrohepatic connections are cut from the right crus. The crus is carefully dissected away from the esophagus, taking care to preserve the integrity of the peritoneum.
3. Any adhesions on the left side of the stomach are taken down in order to mobilize the fundus and provide access to the left crus.
4. The surgeon uses a blunt dissector to create a retroesophageal tunnel for the esophageal length. The hiatus is reapproximated and tightened using endoscopic suturing devices.
5. A 270-degree (Toupet) wrap is completed. Two sutures incorporate the esophagus, stomach, and crus at the 10 o'clock and 2 o'clock positions on the diaphragmatic hiatus. Four sutures create intraabdominal esophageal length with stitches anchored at the gastroesophageal junction, giving the fundoplasty the appearance of a "hot dog in a bun" (Figure 25-5).
6. The OG tube is removed and a final barrel suture is placed at the posterior portion of the wrap to anchor it to the right crus and keep it from unwrapping.
7. The stomach is inspected again to rule out gross abnormality or injury and desufflated. Incisions are closed in layers using absorbable suture and sealed with cyanoacrylate glue.

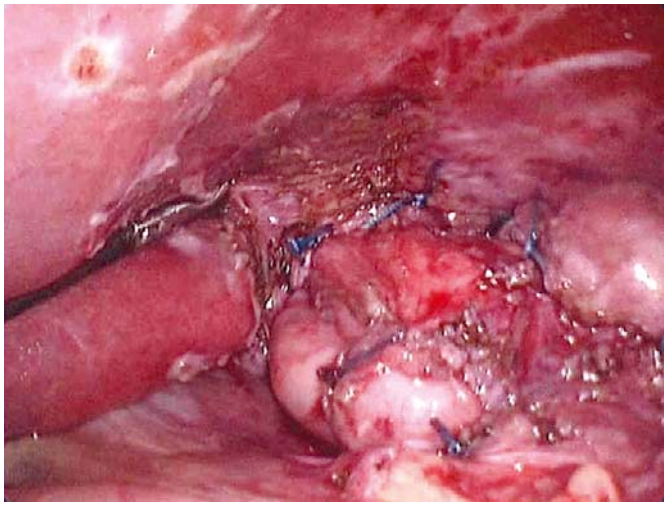

FIGURE 25-5 Laparoscopic Nissen fundoplication, 270-degree (Toupet) wrap.

Endoscopic Correction of Pectus Excavatum—Nuss Procedure

Pectus excavatum (funnel chest) is a visually obvious defect of the sternum, seen as a deep depression on the chest as a result of posterior displacement of the sternum (Figure 25-6). It is usually associated with kyphosis. The defect may be asymmetric, most often deeper on the right side, with sternal angulation. In a majority of cases, surgical treatment is cosmetic; impaired cardiorespiratory function is the underlying reason for surgical intervention in fewer cases. The procedure is most commonly performed in patients between 10 and 16 years of age, when children become embarrassed to undress in front of peers (Research Highlight). Rigid fixation has become a choice for correction of the defect, wherein a metal retaining strut is added to gain chest wall stability and prevent recurrence. This strut must be removed 2 to 4 years later (Nuss et al, 2005). Other treatments may cosmetically correct the situation over the short term but usually result in progressive retraction of the sternum.

Procedural Considerations. Adolescent endoscopic instrumentation is used along with a camera, telescopes, corresponding thoracic instrumentation, and a fixation rod. The patient is positioned supine with the arms positioned along the sides and the elbows flexed 90 degrees and propped so that they are anterior to the chest. The hands are propped so that they are anterior to the elbows. The upper chest is elevated on a soft roll or sheets. A Foley catheter may be placed, and the patient is prepped and draped in sterile fashion.

RESEARCH HIGHLIGHT

Pectus Excavatum Repair

Surgical repair of pectus excavatum is often dismissed as a strictly cosmetic intervention. However, correction of the defect may dramatically improve body image and physiologic and psychosocial functioning. In this study, 264 patients (ages 8 to 21) and 291 parents completed a pectus excavatum evaluation questionnaire during the immediate postoperative period. Responders rated questions on a scale of 1 to 4, with higher scores indicating less desirable outcomes.

A follow-up questionnaire was repeated at the 1-year mark (n = 247 patients and 274 parents). Although there was no correlation between the severity of the defect and preoperative psychosocial functioning, 97% of the patients felt that surgical repair of pectus excavatum improved the appearance of their chest, which resulted in improved perceptions of body image (score improved from 2.30 to 1.40). Parental survey results described an overall reduction of emotional (score improved from 1.81 to 1.24) and physical difficulties (score improved from 2.86 to 1.33) in the child and an increase in self-confidence (score improved from 2.14 to 1.32). These results indicate that both the physical as well as the psychosocial implications of pectus excavatum should be considered when evaluating candidates for surgery.

Modified from Kelly RE et al: Surgical repair of pectus excavatum markedly improves body image and perceived ability for physical activity: multicenter study, *Pediatrics* 22(6):1218-1222, 2008.

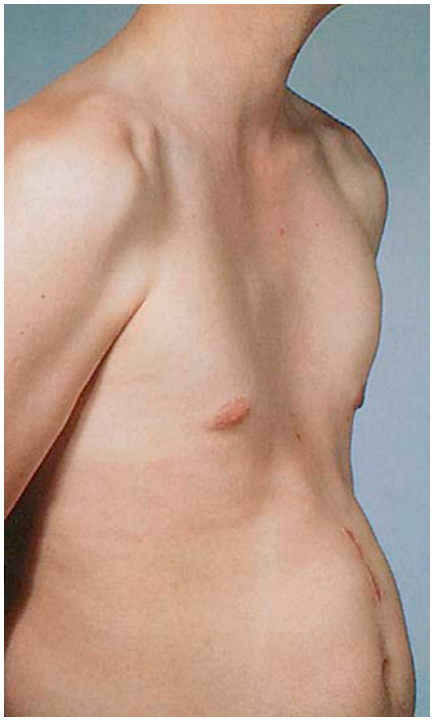

FIGURE 25-6 Pectus excavatum.

Operative Procedure

1. The surgeon measures the patient's chest to determine the size of the stabilization bar to be used, and bends an aluminum template to the desired shape of the chest. A stainless-steel bar is bent to match the aluminum template using plate benders.
2. Two lateral chest incisions are made in-line with the deepest part of the pectus using a #15 blade and subcutaneous pockets are created.
3. A port is placed into the left chest through which gentle insufflation takes place.
4. An incision is made via the subcutaneous pocket in order to pass the Lorenz introducer. The introducer is positioned through one side of the chest, across the mediastinum, and out the other side guided by thoracoscopic visualization techniques.
5. A doubled tracheostomy tape is placed at the end hole of the Lorenz introducer and brought through the anterior mediastinal tunnel. The tracheostomy tape is then tied to the stainless-steel bar, which is brought through the chest using the same tunnel and flipped using a flipping device. Chest configuration is checked for correction, contour, and symmetry.
6. A side bar (strut) is placed on each side of the bar and a stainless-steel wire is wrapped around the main bar both medially and laterally. Two sutures are placed between the chest wall and the end holes of the side and main bars. The suture knots are buried within the holes and the thoracic cavity may be irrigated with antibiotic irrigation.
7. The wounds are closed in layers using absorbable suture and a chest x-ray is obtained postoperatively to rule out pneumothorax.

Video-Assisted Thoracoscopic Surgery for Patent Ductus Arteriosus (PDA)

Although thoracoscopy was first described in 1910 (Rao, 2009), the application of video-assisted thoracoscopic surgery (VATS) to the pediatric population for cardiovascular repairs did not occur until recently. The procedure requires thoracoscopic equipment and supplies, including 0-degree and 30-degree, 4.0-mm and 2.7-mm thoracoscopes, depending on the surgeon's preference and the patient's age and size. The endoscopic instruments, made smaller for the pediatric patient, include an electrocoagulation hook; Castroviejo type of scissors; graspers and right-angle clamps; fan lung retractors of varying sizes, either medium or medium-large; large endoscopic clip appliers; trocars with ports; and suction tip, preferably one that has a porthole to occlude when suction is required. Instrumentation for closure of PDA by thoracotomy is also set up in case the thoracoscopy fails or a complication arises and the chest needs to be opened emergently.

Procedural Considerations. Before the procedure, the television cameras are set up on either side of the OR bed. The patient is placed in a right lateral position.

Operative Procedure

1. Usually four small incisions are made along the line of the posterolateral thoracotomy incision and ports are introduced.
2. The surgeon inserts the thoracoscope. The first assistant holds the lung retractor while the second assistant holds the camera. Some institutions use a mechanical articulating arm.
3. A grasper is used to elevate the pleura overlying the aorta near the insertion of the PDA and pulmonary artery, and careful dissection is begun with electrocoagulation. Suction is required to keep the area of dissection clear to enhance the surgeon's vision.
4. When the ductus has been clearly identified, a right-angle clamp may first be introduced and a tie applied to the duct. The clip applier is then inserted, and clips are applied.
5. Transesophageal or transthoracic echocardiography is usually performed by a cardiologist before closure of the porthole incisions to ensure closure of the ductus. Also, a chest tube will be inserted into the pleural space, the lungs are inflated, and the chest tube is removed; alternately, a chest tube may be left in place before porthole incision closures.

BARIATRIC SURGERY

More than 15% of children and adolescents are obese, a prevalence that has more than tripled in the past 2 decades. Obesity in adolescents is defined as having a body mass index (BMI; kg/m^2) greater than the 95th percentile for age and weight. Overweight or "at risk" for overweight has been defined as a BMI greater than the 85th percentile for age and weight (Inge et al, 2005). Risk factors that have been identified for pediatric obesity are low birth weight, bottle feeding, having a diabetic mother, and parental obesity (Inge et al, 2005).

Bariatric surgery is gaining popularity as a treatment option for obesity in some adolescents. The timing of the surgical procedure is critical. The patient must be physically mature. Skeletal maturation is generally complete by age 13 to 14 years in

BOX 25-3

Characteristics of "Good" Adolescent Patients for Bariatric Surgery

- Patient is motivated and has good insight.
- Patient has realistic expectations.
- Family support and commitment are present.
- Family is compliant with healthcare commitments.
- Family and patient understand long-term lifestyle changes are needed.
- Patient and family agree to long-term follow-up.
- Decisional capacity is present.
- Well-documented and at least temporarily successful weight loss attempts have been made.
- No major psychiatric disorders that may complicate postoperative regimen adherence are present.
- No major conduct/behavioral problems are present.
- Patient has had no substance abuse in preceding years.
- Patient has no plans for pregnancy in upcoming 2 years.

From Inge TH et al: Bariatric surgical procedures in adolescence. In Ashcraft KW et al, editors: *Pediatric surgery,* ed 4, Philadelphia, 2005, Saunders.

girls and age 15 to 16 years in boys. Bariatric surgery can be safely performed once the child has attained more than 95% of adult stature. Candidates undergo psychologic evaluation before surgery to ensure they are cognitively mature enough to participate in decision-making and to comply with postoperative regimens. Box 25-3 details desirable attributes of the adolescent bariatric surgery candidate.

Procedural Considerations

The bariatric procedure most commonly performed in adolescents is the laparoscopic Roux-en-Y gastric bypass. The adjustable gastric band (i.e., lap band) has not been approved by the U.S. Food and Drug Administration for use in adolescents. The perioperative nurse must plan carefully for this surgical intervention with an emphasis on obtaining the appropriate-sized transport vehicle and monitoring devices (e.g., larger blood pressure cuff, possibly longer electrocardiogram [ECG] leads to accommodate placement on a larger patient), an OR bed rated for the patient's weight, and appropriate-length instruments in case conversion to an open procedure is necessary. Obesity places this patient group at risk for deep vein thrombosis (DVT); the nurse should ensure that elastic stockings and sequential compression devices are available.

Operative Procedure

The operative procedure is described in Chapter 10.

GENERAL SURGERY—GASTROINTESTINAL PROCEDURES

Repair of Atresia of the Esophagus

Esophageal atresia is a congenital anomaly that may develop between the third and sixth weeks of fetal life. Several types are recognized, the most common being an upper segment of esophagus ending in a blind pouch and a lower segment of esophagus communicating by a fistula with the trachea (esophageal atresia with TEF). Ideally this defect is recognized in the first hours of life, but more often the diagnosis is made in the first 36 to 48 hours of life. Drooling, the need for frequent suctioning, and coughing or cyanosis during oral feeding are the most common presentations (Spitz, 2005). Prompt surgical intervention allows the child to breathe and eat without the danger of aspirating mucus, saliva, feedings, or stomach contents. Atresia of the esophagus is repaired through a right retropleural thoracotomy, with closure of the TEF and anastomosis of the segments of the esophagus.

Procedural Considerations. A bronchoscopy is done to promote accurate placement of the endotracheal tube before surgical repair. Additionally, a gastrostomy may be done first to decompress the air-distended stomach, thus facilitating chest movement and ventilation and preventing reflux of stomach contents into the trachea. The patient is then positioned for a right thoracotomy (sometimes rather posteriorly), prepped, and draped. The major instrument set and a thoracotomy set are required with the appropriate size of chest tube and infant chest drainage system.

Operative Procedure

1. The surgeon enters the chest through the fourth intercostal space. Removal of the rib is not necessary (Figure 25-7, *A*).
2. The pleura is gently dissected off the chest wall (Figure 25-7, *B*).
3. As the dissection proceeds posteriorly, the azygos vein is identified, which is reflected inferiorly after its highest intercostal branches are divided to expose the fistula beneath (Figure 25-7, *C*).
4. The surgeon passes an umbilical tape or vessel loop under the fistula to apply traction gently (Figure 25-7, *D*). Dissection of the mediastinum begins with the TEF and distal end of the esophagus. The vagus nerve is an important landmark for the distal end of the esophagus.
5. The fistula is clamped and transected, leaving a thin cuff of esophageal tissue on the tracheal side to allow closure of the trachea without narrowing it and compromising the lumen of the airway (Figure 25-7, *E*).
6. To close the fistula, three or four interrupted atraumatic sutures of 5-0 nonabsorbable suture are used.
7. The upper esophageal pouch is dissected; passage of a nasogastric tube by the anesthesia provider aids in its identification. The proximal pouch is identified and dissected as needed to allow it to reach the distal esophageal segment with minimal tension for anastomosis. At this point the surgeon decides whether to attempt primary anastomosis. If primary anastomosis is impossible, the distal esophagus is closed and tacked high on the prevertebral fascia. Infrequently the gap between the proximal and distal portions of esophagus is so long that esophageal replacement is required. In these cases the upper pouch is brought out to the neck in the form of a cervical esophagostomy.
8. Primary anastomosis is performed with 5-0 or 6-0 nonabsorbable suture, taking full-thickness bites along anterior and posterior borders (Figure 25-8). Some surgeons prefer the Haight, or two-layer, anastomosis (Figure 25-9). The inner layer is composed of the upper pouch mucosa sutured to the full thickness of the distal esophagus. The muscular sleeve of the upper esophagus is then pulled down over the inner anastomosis and sutured to the muscular layer of the inferior esophagus. The incision is irrigated with saline.

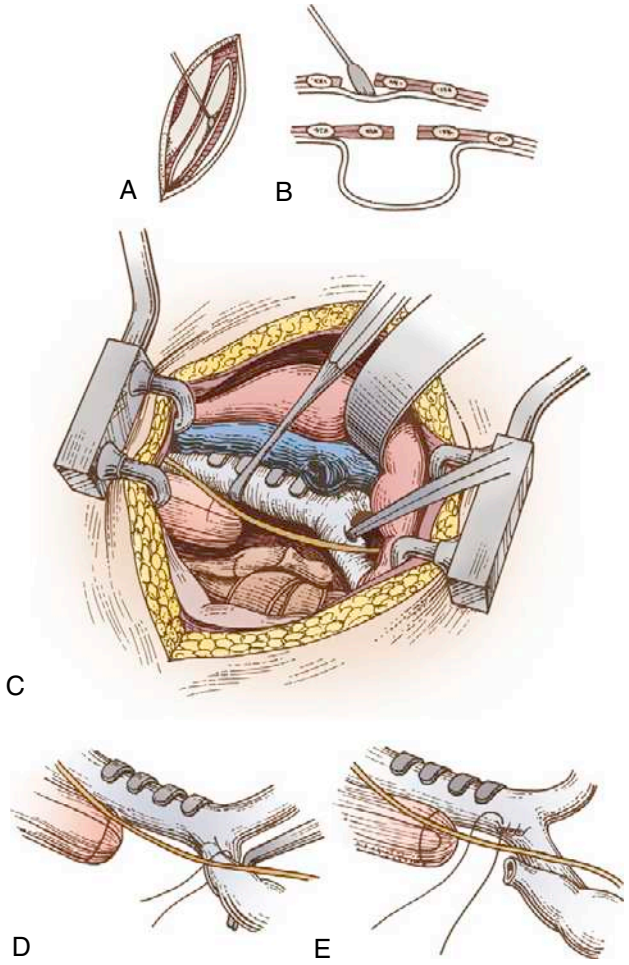

FIGURE 25-7 Repair of atresia of the esophagus. **A**, Incision at fourth intercostal space. **B**, Dissection of pleura off chest wall. **C**, Identification and division of azygos vein to expose fistula beneath. **D**, Traction applied to fistula. **E**, Transection of fistula leaving 3-mm cuff on trachea.

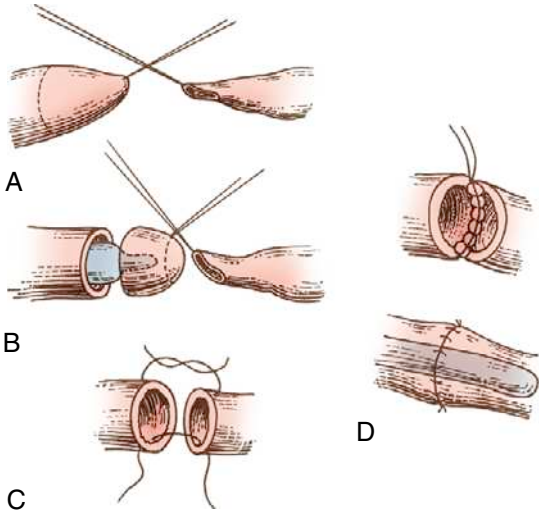

FIGURE 25-8 Primary repair of atresia of the esophagus: single-layer repair. **A**, Traction applied to proximal and distal portions of esophagus. **B**, Blind proximal pouch transected. **C**, Full-thickness bites of anterior and posterior borders. **D**, Repair completed with Replogle tube in place to allow adequate lumen of esophagus.

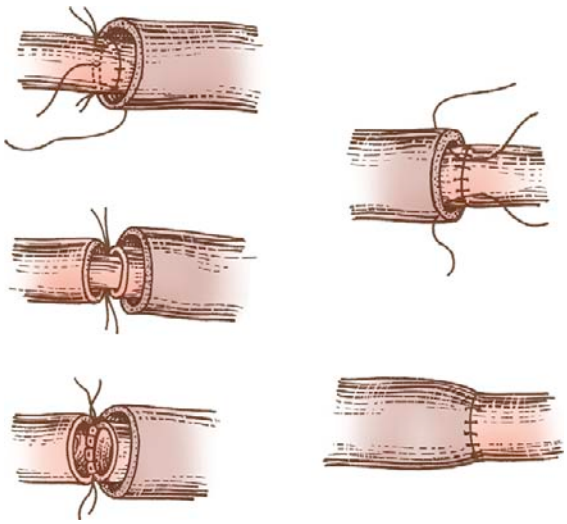

FIGURE 25-9 Haight anastomosis. Mucosal layer of proximal pouch sutured to full thickness of distal esophagus. Muscular sleeve of upper pouch pulled down over inner anastomosis and sutured to muscle of distal esophagus.

9. Some surgeons place a 14F or 16F extrapleural chest tube near the anastomosis through a posterior stab wound. It is secured with sutures to prevent it from putting direct pressure on the anastomosis.
10. Muscle layers and fascia are closed with nonabsorbable sutures.
11. Skin is closed with a continuous absorbable suture. The incision is approximated with cyanoacrylate glue or Mastisol and wound closure strips.
12. The extrapleural chest tube is water-sealed after ensuring that the number of centimeters of water and the suction-control chamber are appropriate for the size of the infant. A chest x-ray examination is performed.

When the child reaches 1 year of age, esophageal replacement is attempted through colon interposition or construction of a reverse gastric tube (Figure 25-10).

Gastrostomy

Gastrostomy is establishment of a temporary or permanent channel from the gastric lumen to the skin to permit gastric emptying, liquid feeding, or retrograde dilation of an esophageal stricture. The procedure may be completed as a separate procedure or be performed with other surgical procedures to facilitate care of the infant or child after surgery. A growing number of surgeons are inserting low-profile (e.g., button, Gastroport) devices upon initial creation of the gastrostomy, as these are preferred for children receiving long-term feedings through the device. Low-profile devices, which protrude slightly from the abdomen, are more cosmetically acceptable and allow more mobility for the child. A gastrostomy tube can be placed in the OR as an open or laparoscopic procedure, or it can be performed as a percutaneous procedure under fluoroscopy; both require the patient to receive a general anesthetic. The open surgical procedure is described in the following section.

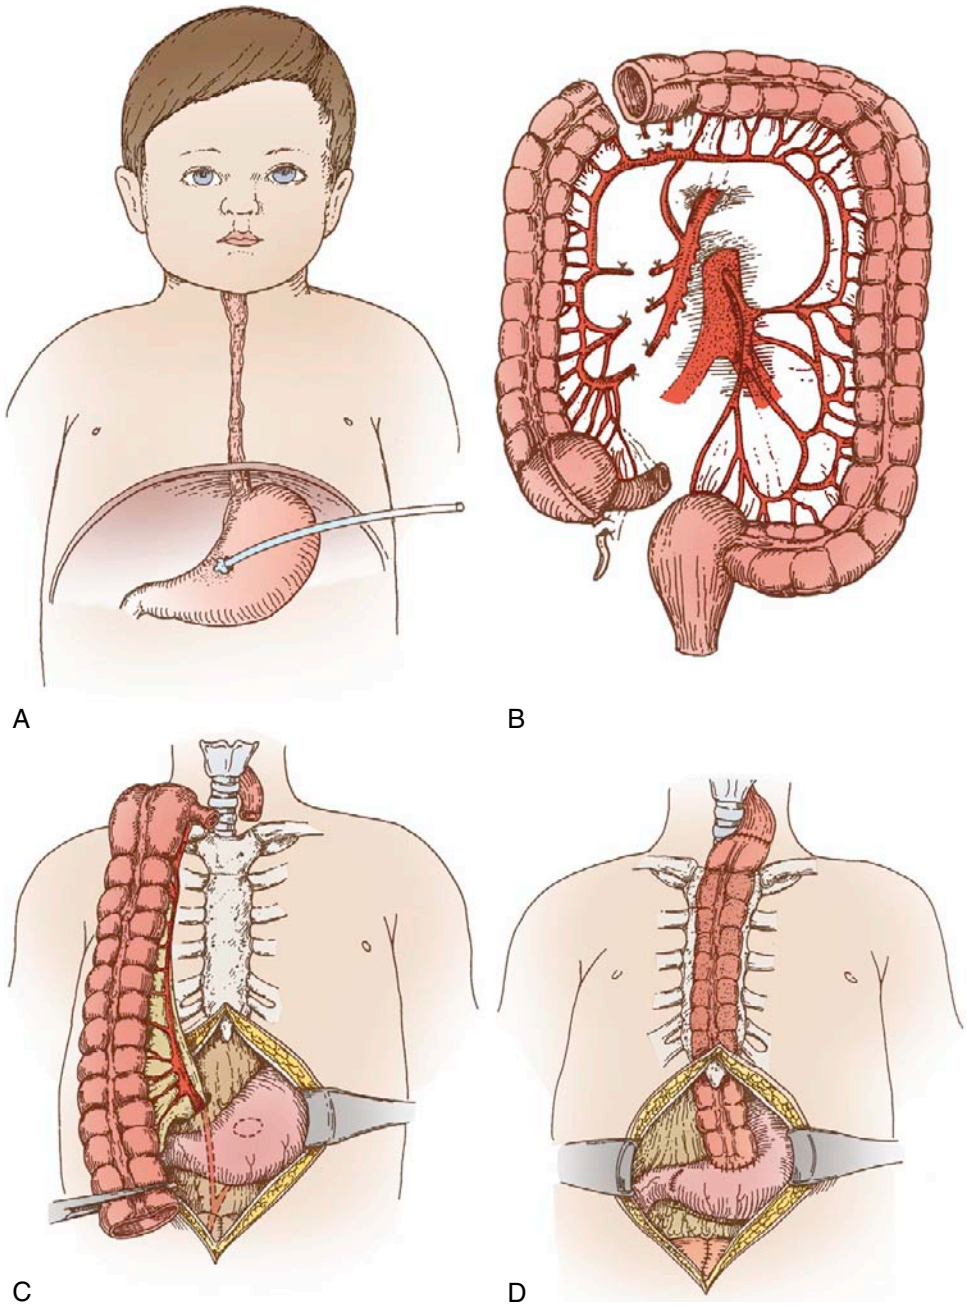

FIGURE 25-10 Esophageal replacement. **A**, Gastrostomy. **B**, Isolation of right colon and ileum. **C**, Colon pedicle prepared for anastomosis. **D**, Anastomosis.

Procedural Considerations. A minor instrument set is required, plus a gastrostomy feeding catheter (generally a 14F or 16F for infants, or an 18F, 20F, or 22F for older children) and a #11 knife blade on a knife handle. A variety of latex-free gastrostomy catheters are available.

Operative Procedure

1. The surgeon makes a short incision over the outer border of the left rectus muscle (Figure 25-11, *A*).
2. The subcutaneous tissues and rectus fascia are exposed with two small retractors (Figure 25-11, *B*).
3. The anterior rectus fascia is opened, and the rectus muscle is split for exposure of the posterior rectus sheath (Figure 25-11, *C*).
4. The peritoneum is opened for exposure of the liver edge and the greater curvature of the stomach (Figure 25-11, *D*).
5. The stomach is pulled out through the wound with Babcock forceps. A circular, nonabsorbable purse-string suture is placed: in the center of this a very small incision is made with the #11 blade through the gastric wall (Figure 25-11, *E*).

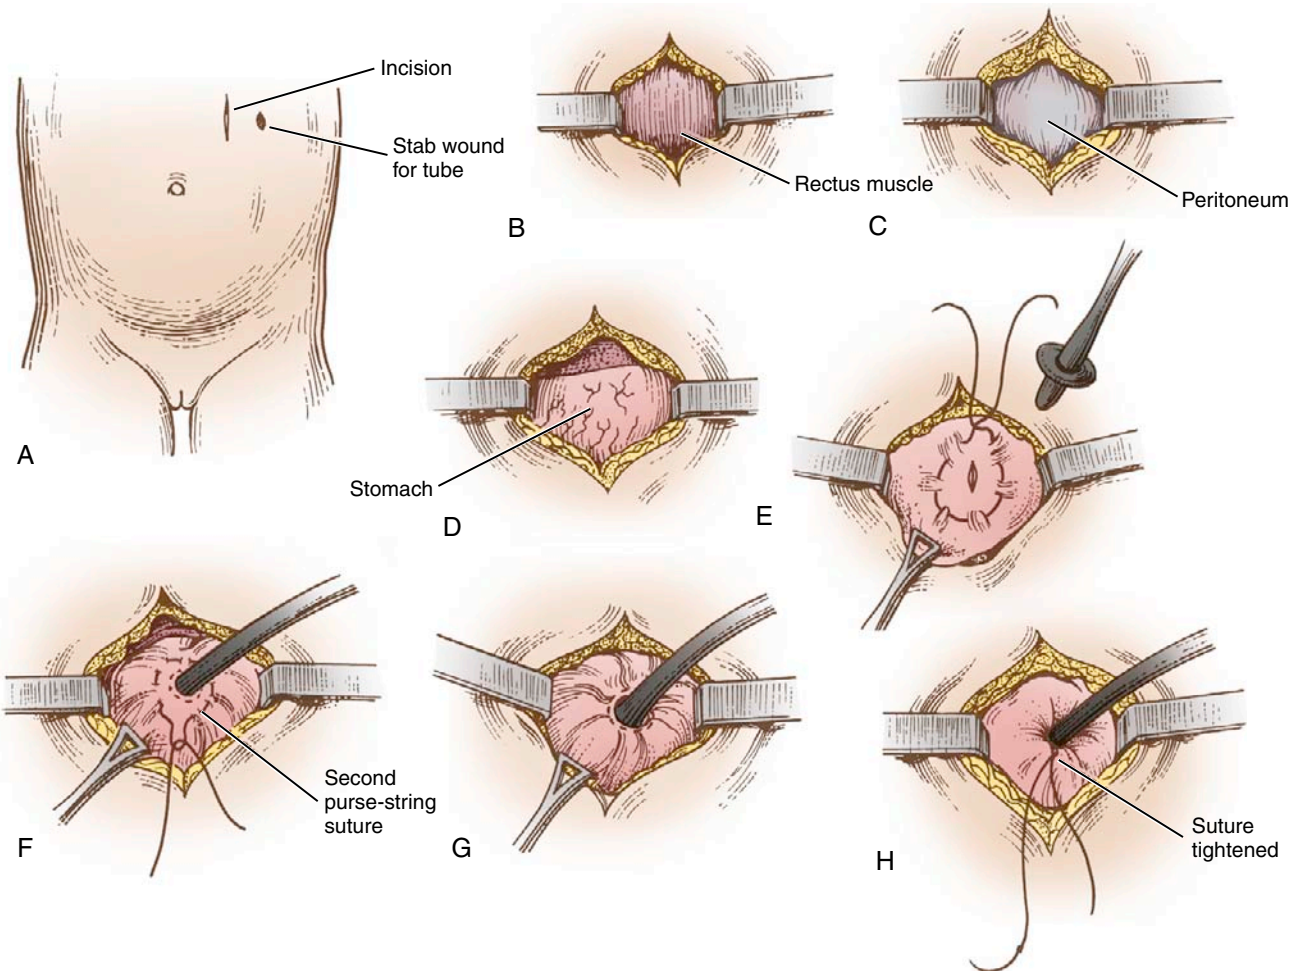

FIGURE 25-11 Gastrostomy. **A**, Incision. **B**, Rectus muscle exposed. **C**, Posterior rectus sheath exposed. **D**, Peritoneum opened. **E**, Purse-string suture placed. **F**, Second purse-string suture placed. **G**, Mushroom catheter inserted. **H**, Suture tightened.

6. A second purse-string suture is placed outside the first one, and the same needle is then taken through the peritoneum and the posterior surface of the rectus fascia to place the stomach against the peritoneum and thus prevent leaks (Figure 25-11, *F* and *G*).
7. The feeding catheter is inserted into the stomach through the small incision, and the purse-string suture is tied (Figure 25-11, *H*). Some surgeons may choose to use a dilator kit to assist with proper insertion of the tube. When inserting a gastrostomy tube with a balloon, sterile water and water-based lubricant should be used to avoid breakdown of the tube itself.
8. The catheter is then exteriorized through the skin by way of a small stab wound left, lateral to the skin incision (see Figure 25-11, *A*).
9. The stomach wall adjacent to the gastrostomy site is tacked to the undersurface of the peritoneum with interrupted nonabsorbable sutures.
10. Routine abdominal closure is performed. The gastrostomy tube is left open to straight drainage at the end of the surgical procedure.

Reduction of Intussusception

Intussusception is the telescopic invagination of a portion of intestine into an adjacent part, with mechanical and vascular impairment (Figure 25-12). It is relieved by reduction of invaginated bowel by the hydrostatic pressure of a barium enema or by laparotomy and manual manipulation. The highest incidence of intussusception occurs in infants between the ages of 5 and 9 months. More than half the cases occur within the first year of life, and only 10% to 25% of cases occur after the age of 2 years (Fallat, 2005). The most common site for intussusception is the ileocecal junction. Intussusception in most children is idiopathic; in others, causes may include Meckel's diverticulum, polyps, or hematoma of the bowel. Early diagnosis and reduction are essential to bowel viability.

Procedural Considerations. The child is prepped for surgery as described previously. Reduction by barium enema is attempted only with the collaboration of the radiologist, surgeon, and pediatrician, with the OR team on standby. If reduction is unsuccessful, a surgical reduction by laparotomy

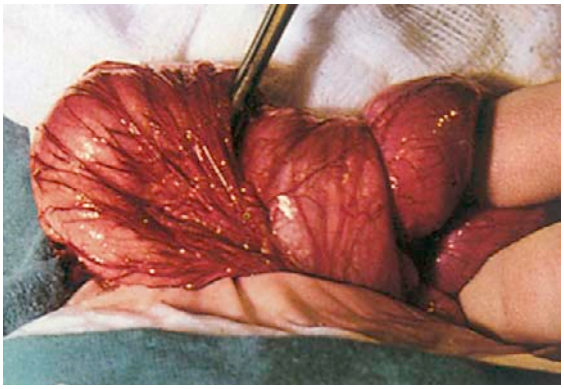

FIGURE 25-12 Operative view of intussusception.

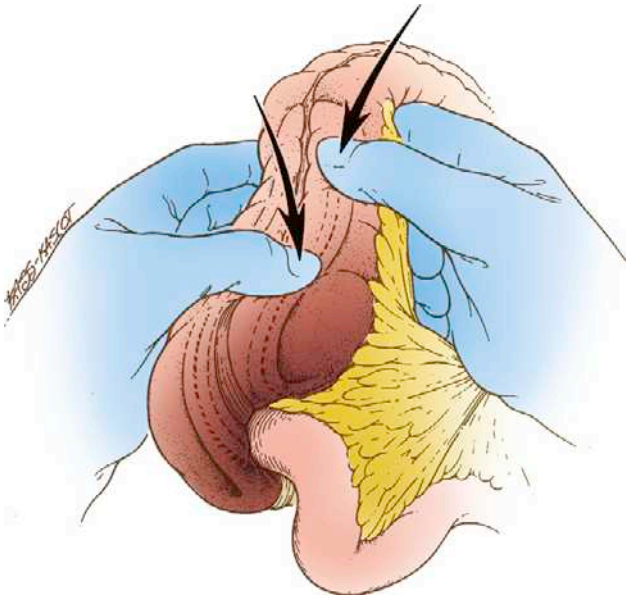

FIGURE 25-13 Manual reduction of intussusception.

or laparoscopy must be performed. The open procedure is described in the following Operative Procedure, and requires a major instrument set and pediatric bowel clamps.

Operative Procedure

1. The surgeon makes a right lower quadrant transverse or right paramedian incision and enters the peritoneum.
2. The cecum and ileum are identified; the intussusception is located and elevated with fingers.
3. If there is no evidence of bowel compromise, the bowel immediately distal to the intussusception is occluded with one hand and stripped proximally with the other in an attempt to achieve manual reduction (Figure 25-13). If the serosa splits during attempted reduction or if the mass cannot be reduced, bowel resection is done.
4. The abdomen is closed in layers, and the wound is dressed.

Bowel Resection and Colostomy for Necrotizing Enterocolitis (NEC)

Necrotizing enterocolitis (NEC) is a condition that manifests with death of intestinal lining and sloughing of corresponding tissues. Its exact cause is unknown, but it is suspected that NEC may result from two mechanisms: decreased blood flow to the bowel, which prevents the bowel from secreting the protective mucus that protects the GI tract; or bacteria within the intestine (Medline Plus Medical Encyclopedia, 2007). NEC primarily affects premature newborns. When surgical intervention is needed, the patient undergoes a bowel resection and ostomy procedure. The type of ostomy created depends on the location of the necrotic bowel. The procedures for bowel resection and colostomy are described in the following sections.

Procedural Considerations. The major instrument set and pediatric bowel clamps are required. The infant is positioned supine, and routine prepping and draping of the abdomen are done.

Bowel Resection

Operative Procedure

1. An abdominal incision is made.
2. The intestines are explored to determine the location of the obstruction. The entire bowel must be examined to rule out multiple areas of involvement in infants with atresia or stenosis. If aganglionosis of the colon is suspected, sequential biopsy specimens are sent fresh immediately to the pathology laboratory to determine the segment of large bowel to be resected.
3. Resection is performed as indicated.

Colostomy

Operative Procedure

1. A transverse incision usually is preferred, and the abdomen is entered in the right upper quadrant for a transverse colostomy or the left lower quadrant for a sigmoid colostomy.
2. The loop of colon is freed of peritoneal attachments until it can be brought easily through the abdominal wall without tension.
3. The edges of the mesentery are then sutured to the parietal peritoneum, and the serosa of the colonic loop is sutured with fine absorbable suture materials to the peritoneum and fascia as well as to the skin.
4. The colostomy may be sutured immediately. Some surgeons prefer to close the skin under a colostomy loop; others prefer to suture mucosa directly to skin edges. This decision may depend on the location of the colostomy. An important point is that each layer must be securely attached to the serosa of the colon to prevent evisceration and prolapse. The posterior wall of a loop colostomy may be divided by electrosurgery several days after surgery.

Resection and Pull-Through for Hirschsprung's Disease (Reconstruction)

Hirschsprung's disease is characterized by the absence of ganglion cells in a distal portion of the bowel. The distal colon is more frequently involved, but the disease may encompass the entire colon, with a less favorable prognosis. The absence of ganglion cells results in a lack of peristalsis. The normal proximal colon becomes dilated with stool, since intestinal contents do not pass through the involved segment normally. The child presents with an abnormally distended abdomen. Barium enema reveals proximal distention of the colon and then a transition zone where the bowel appears funnel-shaped, followed by the distal

aganglionic segment, which is narrowed. The child is taken to the OR for a leveling colostomy. Multiple frozen-section biopsy specimens from the muscularis of the proximal portion of the colon are taken to determine the presence of ganglion cells. The colostomy is performed at the most distal portion of the colon that contains ganglion cells. Some surgeons prefer a routine right transverse colostomy at this time and delay frozen-section biopsy specimens until the time of the definitive procedure. Resection and pull-through for Hirschsprung's disease, the definitive surgical procedure, consists of the removal of the aganglionic portion of the bowel and anastomosis of the normal colon to the anus. The child is returned to the OR for the definitive repair at 1 year of age if clinical and nutritional status permit.

Several surgical techniques have been devised. The procedure may be done laparoscopically or by an open approach. The Soave procedure of endorectal pull-through employs internal bypass of the involved segment. The internal sphincter muscle of the anus is kept intact for continence.

Procedural Considerations. The child is prepped and draped from the nipples down to and including the buttocks, genitalia, perineal area, and upper thighs to permit positioning for the perineal stage without redraping. (Before prepping, the rectum may be irrigated with warm saline solution.) An indwelling catheter is inserted to keep the bladder empty during the operation. The major instrument set, a minor instrument set, and pediatric intestinal clamps are needed.

Operative Procedure

1. A left paramedian incision that includes the sigmoid colonic stoma, if present, is made.
2. The surgeon frees the stoma from the abdominal wall, and mobilizes the left portion of the colon. (If there is no sigmoid colonic stoma, the extent of aganglionic intestine is established by biopsy and frozen section, and all involved colon is excised. If a stoma is present and the area has already been established as normal, the colon above it constitutes the proximal end of the resection.)
3. The mesocolon and the vessels of the intestine to be resected are divided close to the intestine, with care taken to preserve the blood supply to the rectum (Figure 25-14, *A*).
4. The mucosal tube is freed from the outer muscular layers by sharp dissection with Metzenbaum scissors and blunt dissection (Figure 25-14, *B*).
5. A muscular sleeve is transected, and 4-0 nonabsorbable traction sutures are placed on the distal edge (Figure 25-14, *C*).

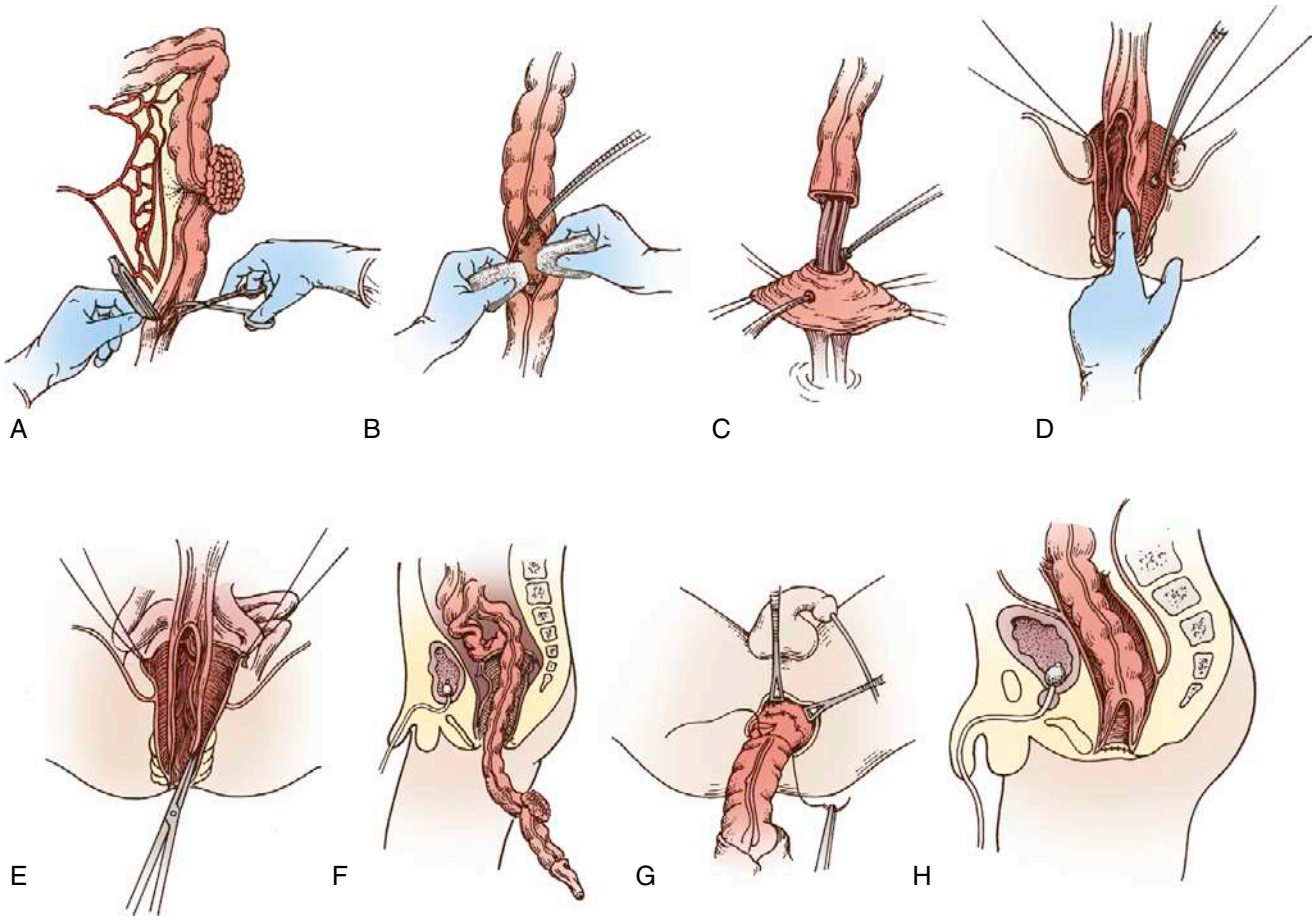

FIGURE 25-14 Pull-through for Hirschsprung's disease. **A**, Dissection of mucosal tube begun through longitudinal incision. **B**, Blunt dissection with sponges used to dissect entire circumference of tube. **C**, Muscular sleeve transected. **D**, Depth of dissection determined by insertion of finger into anus. **E**, Circumferential incision made. **F**, Mucosal tube and proximal portion of colon and stoma pulled through rectal muscular cuff. **G**, Anastomosis performed among all layers of colon and anal mucosa. **H**, Anastomosis completed.

The mucosa is stripped down to the anus. The depth of the dissection may be checked by inserting a finger into the anus (Figure 25-14, *D*).

6. When the mucosa is adequately freed, the perineal phase is started and the perineal instrument table is used.
7. The anus is dilated and retracted with Allis forceps. A circumferential incision is made, and the mucosal stripping is completed (Figure 25-14, *E*).
8. The proximal portion of the intestine is pulled through the rectal muscular sleeve and out the anus (Figure 25-14, *F*). If the portion of colon to be resected is large, it is excised abdominally before the proximal portion of the intestine is pulled through the anus.
9. Absorbable sutures are used to secure the seromuscular layers of the intussuscepted colon to the rectal muscular cuff. The colon is divided into axial or longitudinal quadrants, and an anastomosis is performed with 3-0 absorbable sutures (Figure 25-14, *G*).
10. Gowns and gloves are changed, and abdominal instruments are used. The abdominal phase of the operation is completed by approximating the proximal edge of the muscular cuff to the seromuscular layer of the colon with 4-0 nonabsorbable sutures (Figure 25-14, *H*). The abdomen is closed in the routine manner, without the use of drains.

Repair of Imperforate Anus

Congenital imperforate anus (Figure 25-15) presents in a variety of forms, classified as low, intermediate, and high lesions. Baby girls commonly have low lesions, and baby boys primarily exhibit high lesions. A covered anus and anovulvar fistula is an example of a low lesion. A high lesion consists of a blind rectal pouch, a "flat bottom," and a posterior urethral fistula or a fistula to the bladder. This type is the most prevalent and the most difficult to repair. An imperforate anus is repaired by establishing colorectoanal continuity through the external anal sphincter and closure of fistulas, if present.

Repair of Low Imperforate Anus in a Girl—Anal Transposition

Procedural Considerations. The infant is placed in the lithotomy position. A Foley catheter is inserted, and the perineum is prepped and draped. The major instrument set is required, with the addition of both a nerve and a muscle stimulator. The anesthesia team must avoid the use of neuromuscular blocking agents for the nerve/muscle stimulator to work during the surgical procedure.

FIGURE 25-15 Imperforate anus.

Operative Procecure

1. An electrical stimulator is applied to elicit muscle contractions and serve as a guide to the midline of the anus. The goal is to leave equal innervated tissue on both sides of the anus, so that the child can be continent of stool.
2. Stay sutures are placed in the fistula, and it is excised using an oval incision (Figure 25-16, *A*).
3. The surgeon dissects the bowel free from surrounding structures, taking care not to damage the vagina (Figure 25-16, *B*).
4. When the dissection is complete, a vertical midline incision is performed at the opening of the true anus and the fibers of the external sphincter are identified (Figure 25-16, *C*).
5. The mobilized rectum is pulled down through the subcutaneous tissue to its new location.

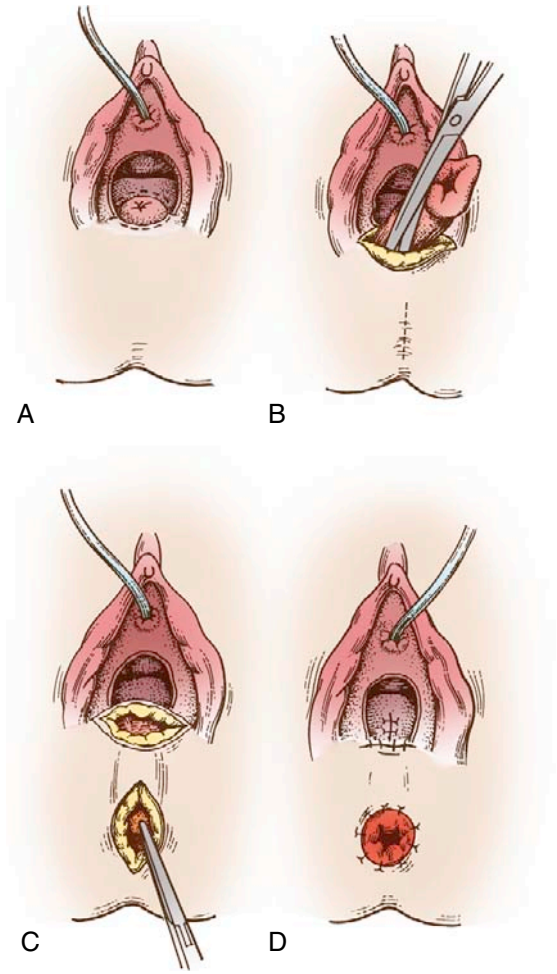

FIGURE 25-16 Anal transposition. **A**, Fistula excised by means of oval incision. **B**, Dissection of bowel from surrounding structures. **C**, Vertical midline incision at site of true anus; identification of external sphincter fibers; mobilized rectum pulled down through subcutaneous tissue to new location. **D**, External sphincter sutured to rectal mucosa; new anus constructed with interrupted sutures through all layers.

6. The end of the fistula is amputated. Using 4-0 nonabsorbable interrupted sutures, the surgeon sutures the external sphincter to the rectal serosa.
7. Using 4-0 absorbable suture, the surgeon constructs a new anus with interrupted sutures through all layers (Figure 25-16, *D*).
8. A drain may or may not be placed in the anterior incision before it is closed in layers with interrupted 4-0 absorbable sutures.
9. A Hegar dilator is used to calibrate the size of the new anus after closure.

Repair of High Imperforate Anus—Posterior Sagittal Anorectoplasty

When a high imperforate anal anomaly presents, surgical intervention is indicated within 24 to 48 hours of birth. A transverse or sigmoid colostomy is performed to irrigate the hiatal lumen and to remove meconium plugs while allowing proximal colon function. After the colostomy, further diagnostic studies, such as cystograms and vaginograms, are done. The posterior sagittal anorectoplasty (PSARP) is the definitive surgical procedure and is performed when the condition and size of the child permit—usually around 1 year of age.

The PSARP is a highly technical procedure that uses electrostimulation throughout and may require position changes.

Procedural Considerations. The child is placed in jackknife position with the hips flexed. Adequate padding must be placed under the hips to avoid compression injury to the femoral nerves. The major instrument set, nerve stimulator, and intestinal instruments are required.

Operative Procedure (Figure 25-17)

1. The surgeon uses the electrostimulator to locate the true anus, and makes a midsagittal incision through the skin from the midsacrum to the anterior border of the anal site.
2. Dissection continues through subcutaneous tissue until the external sphincter muscle layers are identified.
3. With electrostimulation, the surgeon dissects the fibers midsagittally, exactly in the midline.
4. A midsagittal split of the coccyx is performed, and the striated muscle complex found beneath the coccyx is incised sagittally, along with the visceral endopelvic fascia. Electrostimulation is used to aid in identifying muscle complexes.
5. Next, the surgeon identifies the rectal pouch and urethra, and incises the bowel vertically to expose the fistulas.
6. The fistula is closed in layers—first the mucosa with interrupted absorbable sutures and then the muscle layer with 5-0 nonabsorbable sutures.
7. The rectum is then mobilized and tapered to allow its placement within the muscle complexes. Tapering consists of excising a wedge of bowel from either the ventral or the dorsal surface. The edges are approximated, and the mucosal layer is closed with 5-0 absorbable interrupted sutures. The muscularis layer is closed with interrupted 5-0 nonabsorbable sutures.
8. Again using electrostimulation, the tapered rectum is placed deep within the muscle complex. Then 5-0 nonabsorbable sutures are used to reconstruct the muscles. The seromuscular layer of the bowel is incorporated into these sutures to keep it securely positioned within the muscle complex.
9. The external sphincter muscles and coccyx are reapproximated.
10. Excess bowel is trimmed before it is secured to the skin edges of the anus.
11. The surgeon closes the skin with running absorbable subcuticular sutures.

In cases of very high rectal pouches and fistulas, an abdominal approach may be required. After the midsagittal incisions and dissections are completed, a rubber drain is placed through the pelvis with one end in the peritoneal cavity and the other through the center of the anus to the skin, where it is temporarily sutured. The child is then turned supine, and an abdominal incision is made. The rectal pouch is mobilized, and the fistula is closed. The bowel is tapered as described previously, and the terminal portion is attached to the rubber tube, which then is used to pull the rectum through the anal orifice. The bowel is sutured to the muscle complex, and reapproximation of the coccyx and external sphincter muscle is done as described earlier.

GENERAL SURGERY—HERNIAS

Umbilical Hernia Repair

Umbilical hernias are frequently seen in pediatric populations and are 10 times more common in African American children than in Caucasians (Garcia, 2005). These hernias are also common in premature infants and are corrected by repair of the defect where the intestine protrudes at the umbilicus. An umbilical hernia is always covered by skin. Small umbilical hernias may be left untreated. They usually close within a few months to 1 year. If surgical repair is required in a large fascial defect, it may be delayed until the child is at least 2 years of age; some surgeons delay repair until 5 years of age.

Procedural Considerations. Surgical correction of umbilical hernia may be an ambulatory surgical procedure. A general anesthetic is used. A minor instrument set is required. Several variations in technique have been used; an infraumbilical approach is most common, and its description follows.

Operative Procedure

1. An incision is made below the umbilicus through the skin and subcutaneous tissue.
2. Flaps of skin and subcutaneous tissue are mobilized and held back with small retractors to expose the rectus fascia and hernial protrusion.
3. The hernia sac, which is between the rectus muscle sheaths in the midline, is completely freed from all surrounding structures.
4. The hernia sac may be invaginated, dissected free and ligated, or excised.
5. The peritoneum is closed with interrupted suture, and each suture is tagged, and then closed all at once.
6. The two edges of the rectus fascia are approximated using interrupted 3-0 nonabsorbable sutures.
7. Subcuticular closure of the skin with a continuous fine absorbable suture is performed, and a pressure dressing is applied.

Inguinal Hernia Repair with Laparoscopic Exploration of Contralateral Side

An inguinal hernia is a protrusion into the inguinal canal of a sac that contains the intestine. The testis develops high on the posterior wall of the abdomen. It gradually descends into the scrotum. Before the testis enters the inguinal canal, the processus vaginalis projects downward but retains a communication

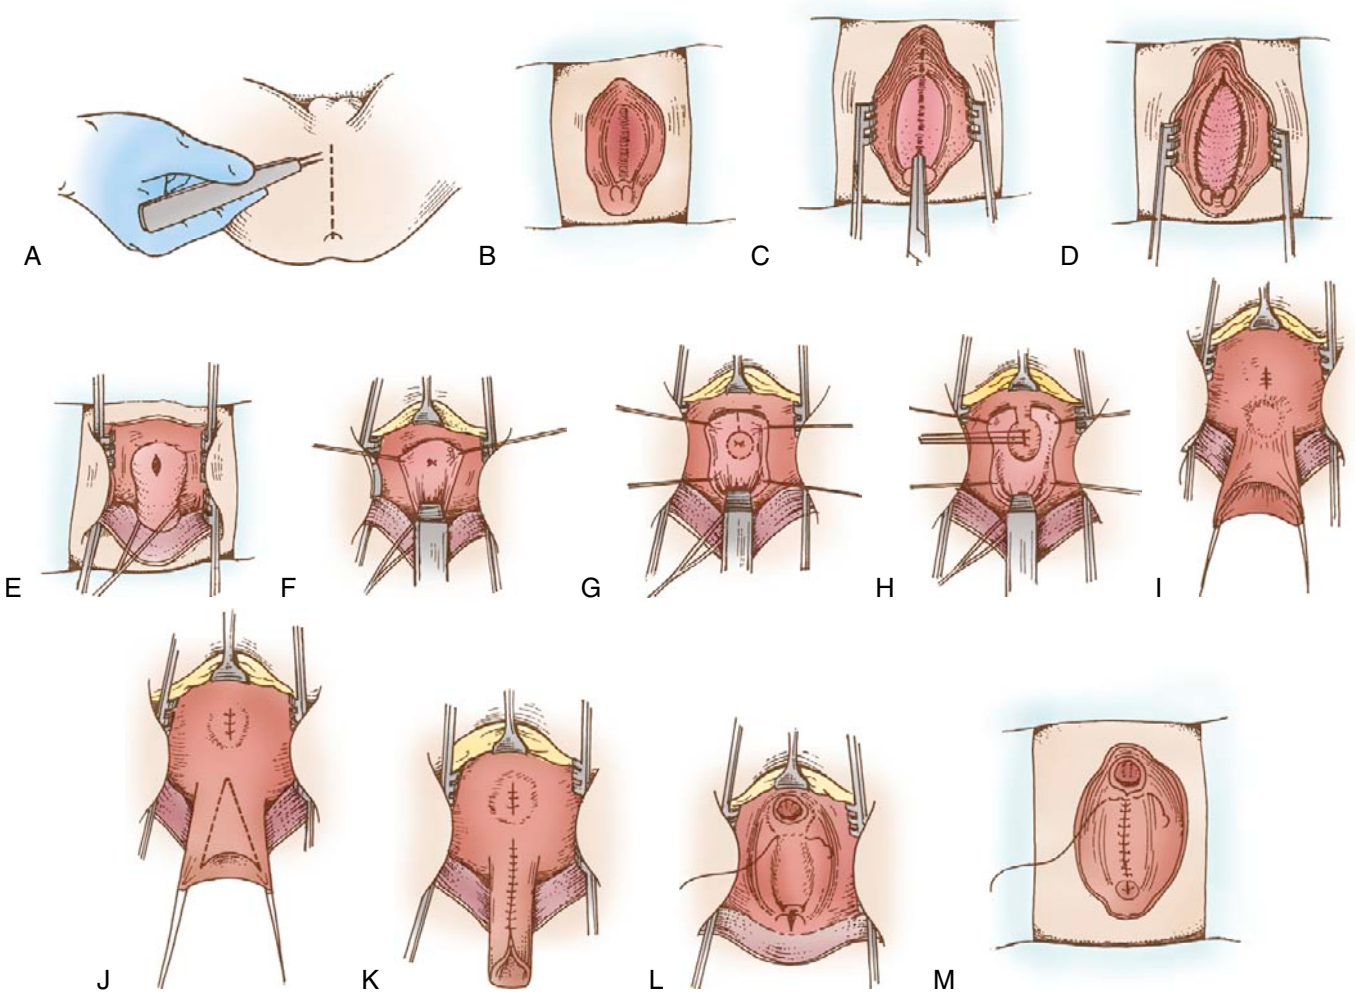

FIGURE 25-17 Posterior sagittal anorectoplasty. **A**, Line of incision and electrical stimulation to determine appropriate anal site. **B**, Midsagittal incision through coccyx and external sphincter fibers of anus, showing striated muscle complex deep to anal site; subcutaneous external sphincter extending about halfway to coccyx; superficial external sphincter inserting on coccyx; levator deeper in midline. **C**, Right-angled forceps beneath levator ani. **D**, All layers of striated muscle partially retracted laterally to expose visceral endopelvic fascia. **E**, Sagittal incision in terminal bowel after proximal dissection around rectum and placement of tape around rectum proximally. **F**, Retracted rectotomy showing fistula site. **G**, Semicircumferential incision through mucosa-submucosa for placement of first sutures to close fistula. **H**, Completed closure of fistula orifice. **I**, Stippled area where muscular bowel wall is left in place and clear area above where peritoneum may be encountered. **J**, Extent of anterior wedge resection for tapered repair of rectum *(dotted line)*. **K**, Approximation of tapered edges of rectum. **L**, First and deepest suture for approximation of levators to establish beginning of canal. **M**, After reapproximation of levator ani to coccyx, interrupted sutures are placed in edges of superficial external sphincter muscle.

with the peritoneal cavity. The upper part of the processus does not project downward; the remaining sac constitutes an indirect inguinal hernia. In a female child, a similar hernial sac is contiguous with the round ligament.

Procedural Considerations. A minor instrument set is used. A laparoscope may be used to visualize the contralateral side, as it is not uncommon for inguinal hernias to occur bilaterally. In these instances, a camera, insufflation tubing, 20-gauge intravenous catheter, 2.7-mm telescope, and light cord must be presented to the sterile field. The child is positioned supine, and routine prepping is done.

Operative Procedure

1. The surgeon makes an incision over the inguinal area in the direction of the skin crease.
2. The subcutaneous tissue is opened, and hemostats are placed on bleeding vessels, which are then ligated or electrocoagulated.
3. Right-angle retractors are placed inferiorly and medially.
4. The surgeon identifies the external ring, and uses small Metzenbaum scissors to free and clean the external oblique fascia.
5. Using a #15 blade, the surgeon opens the external oblique fascia and frees the upper flap. The lower flap is freed to expose the inguinal ligament.

6. Cord structures are opened at the upper end of the cord. Two forceps are used to grasp tissues at the same level and to separate them.
7. The hernia sac is grasped with a hemostat, and structures of the cord are peeled downward and away from the sac with forceps until the sac is freed. Care is taken to protect the spermatic cord and major vessels as the sac is freed.
8. After the sac is opened, the surgeon's index finger is inserted and the sac is pulled upward. The upward traction is maintained with two or three hemostats.
9. If laparoscopic exploration of the contralateral side is taking place, the 20-gauge intravenous catheter is inserted over the opposite inguinal area. The insufflation tube is connected, and CO_2 instilled. The contralateral side is explored using a 2.7-mm telescope.
10. The sac is ligated with 3-0 nonabsorbable suture, and excess sac is removed. Repair of the inguinal canal may be done with nonabsorbable sutures.
11. The subcutaneous tissue is closed with interrupted fine sutures; closure of the skin is with fine nonabsorbable subcuticular sutures. Cyanoacrylate glue or wound closure strips are applied.
12. If a bilateral hernia is diagnosed, steps 1-10 are repeated on the contralateral side.

Omphalocele and Gastroschisis Repair

An omphalocele is the protrusion of abdominal viscera outside the abdomen through a defect in the umbilical ring into a sac of amniotic membrane and peritoneum at the base of the umbilical cord. There is no skin covering (Figure 25-18). Gastroschisis is the protrusion of the viscera through a defect in the abdominal wall to the right of the umbilical cord. No amniotic membrane or peritoneum covers the defect.

Omphalocele occurs during the eleventh week of fetal life when the viscera fail to withdraw normally from the exocoelomic position to occupy the peritoneal cavity. The resulting abdominal wall defect can vary in size from 2 to 15 cm. The sac may contain only a few loops of bowel, or nearly all the intestines and the liver and spleen. Associated anomalies can include disorders of the cardiac, musculoskeletal, genitourinary, and nervous systems, along with malrotation and abnormal fixation of the bowel. Gastroschisis, on the other hand, is generally not associated with major congenital defects other than intestinal atresia (Davis, 2007) (Figure 25-19).

Because the infant is at risk for hypothermia, hypoglycemia, shock, sepsis, and vascular injury to the bowel, immediate management after birth is necessary (Klein, 2005). Treatment consists of inserting a nasogastric tube to prevent distention and aspiration, and beginning IV access with fluid resuscitation and antibiotic therapy. Surgical intervention is necessary to prevent rupture of the sac, infection, or both. If intrauterine rupture of the sac has occurred, the newborn is kept warm, and the bowel is inspected for perforation and torsion. In certain cases, a petroleum gauze dressing may be applied to the defect, but care must be taken to keep it moist.

Omphaloceles and gastroschisis are repaired by placement of the viscera in the abdominal cavity, with reconstruction of the abdominal wall. Surgical procedures for omphaloceles may be primary (Shuster procedure) or staged (giant omphaloceles). Mesh may be used as a barrier to create tension that helps to push the internal organs into the abdominal cavity. In some cases of gastroschisis, a silo is applied to the defect. The silo is made of a flexible ring that sits inside the abdomen and its size is gradually decreased to facilitate movement of the organs back to the abdominal cavity. Silo material may be prepackaged and kept at the patient's bedside if the patient is unable to tolerate an immediate trip to the OR.

Procedural Considerations. Particular attention to maintaining body temperature is essential because of the massive exposed surface area from which body heat can be lost. The use of nitrous oxide as an anesthetic agent is avoided during this procedure because it causes increased gas in the intestine, which in turn makes the reduction of abdominal contents into the peritoneal cavity very difficult. Repeated rectal irrigation with warm saline to evacuate meconium from the bowel may be carried out before the abdominal prep to aid in bowel decompression.

The major instrument set is required. The infant is positioned supine; the abdomen, umbilical cord, and sac are gently prepped with a povidone-iodine solution.

FIGURE 25-18 Newborn with giant omphalocele containing liver and intestine.

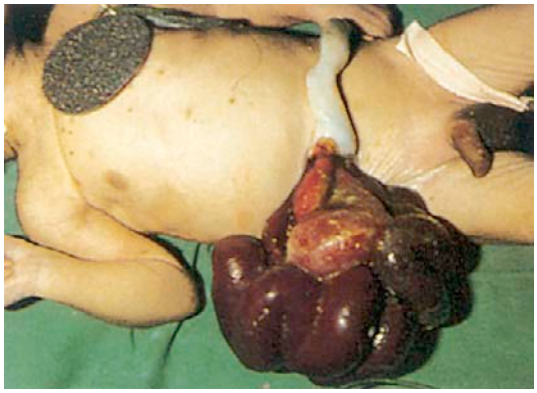

FIGURE 25-19 Gastroschisis. A large amount of small intestine has eviscerated through a defect to the right of a normal-appearing umbilical cord. No sac is visible, and the intestine is thickened, edematous, and ischemic in areas.

Gastroschisis with Silo Placement

Procedural Considerations. A major instrument set is required. The patient is positioned supine for the procedure. The abdomen, umbilical cord, and sac are gently prepped with povidone-iodine.

Operative Procedure

1. The surgeon examines the bowel and measures the size of the defect to determine silo size. The silo is applied so that the flexible ring is positioned inside the abdomen (Figure 25-20).
2. The patient returns to the OR every 48 hours for a reduction of the silo, which is accomplished by decreasing the size of the ring to help guide the contents back into the abdominal cavity.
3. The height of bowel in the silo and length of reduction are measured with each procedure. When the amount of bowel remaining in the silo is 1 cm or less, the patient is transferred to the OR for closure of the defect.
4. The silo is trimmed and the spring-loaded ring is removed. The wound site and bowel are inspected and cleaned with surgical prep material.
5. The surgeon closes the defect using synthetic purse-string sutures or, if the defect is too large, using running sutures that begin at each end of the wound and meet in the middle to preserve the umbilical cord stump.
6. The inferior aspect of skin is wrapped around the stump and secured with absorbable suture. Any redundant skin is trimmed and the stump is ligated using nonabsorbable suture.
7. A subcutaneous drain may be left in place and a dry, sterile dressing is applied.

Omphalocele Repair

Procedural Considerations. The patient is positioned supine for the procedure and the abdomen is prepped as described for silo placement.

FIGURE 25-20 Operative view of silo for the intestines.

Operative Procedure

1. The surgeon dissects the amnion of the omphalocele circumferentially from the dermis.
2. The umbilical vein is identified and ligated with absorbable suture. Umbilical cord structures and arteries are dissected and ligated with absorbable suture, and then oversewn with nonabsorbable suture.
3. Organs connected to the omphalocele are dissected, reduced (if necessary), and mobilized, and the internal mucosal layer is closed with running nonabsorbable suture.
4. The outer muscular layer is closed with interrupted nonabsorbable suture, organs are returned to the peritoneal cavity, and fascia is closed with interrupted nonabsorbable suture.
5. If necessary, an umbilicoplasty may be performed using interrupted absorbable suture. Dry, sterile dressings are placed over the incision.

In certain cases in which the defect is of medium to large size, a primary closure may not be accomplished. In these situations a staged procedure is done using prosthetic reduction. In the first stage the infant is brought to the OR and positioned and prepped as previously described. Then the following steps are performed:

1. The sac is excised, and the umbilical vein and arteries are ligated.
2. A gastrostomy may be performed at this time.
3. A barrier is then created with Silastic mesh. The mesh is secured through all layers of the edge of the defect using a continuous locking nonabsorbable suture. The open end of the barrier is closed in the same manner.
4. The open end of the cylinder is closed with umbilical tape or, alternatively, attached to a specifically designed roller clamp.
5. The mesh barrier suture line and edge of the defect are wrapped with roller gauze dipped in an iodophor solution to prevent infection. The infant is transferred to an open Isolette, and the silo is suspended from the top of the Isolette. Plastic wrap is applied to the barrier to prevent heat loss. The infant is then transported to the NICU, where daily reduction of abdominal contents is performed by adding a lower tie of umbilical tape or by adjusting the roller clamp. The abdominal viscera are gradually reduced over several days, taking care to avoid respiratory compromise from abdominal distention. When reduction has successfully approached skin level, the infant is returned to the OR for the final stage of repair.
6. The mesh barrier is removed, and the remaining abdominal contents are brought into the peritoneal cavity. The peritoneal fascia is closed with interrupted nonabsorbable sutures. The skin is closed with interrupted nonabsorbable suture. In an attempt to create the appearance of an umbilicus, a purse-string suture is used to close the inferior 2 cm of incision.

GENERAL SURGERY—ABDOMINAL PROCEDURES

Correction of Biliary Atresia—Hepatic Portoenterostomy (Kasai Procedure)

Biliary atresia is a congenital defect that results from nonpatent extrahepatic bile ducts. Bile is unable to drain from the liver to the small intestine, leading to eventual cirrhosis and death. The Kasai

procedure is the construction of a bile drainage system by use of an intestinal conduit. This procedure is indicated in patients with extrahepatic biliary atresia who are younger than 3 months. All atretic segments of the existing bile ducts are removed. An intraoperative cholangiogram and frozen-section biopsy of the hepatic duct remnant are included in the surgical procedure.

Procedural Considerations. The infant is positioned supine over a radiographic plate, or fluoroscopy is used. Both a major instrument set and bowel clamps are required, as well as radiopaque dye and a 6F or 8F catheter for the cholangiography.

Operative Procedure

1. The surgeon makes a right upper quadrant incision and exposes the gallbladder.
2. A small catheter is placed into the gallbladder and secured with a purse-string suture. Radiopaque dye is instilled into the gallbladder, and an x-ray examination is done. The surgeon observes for free flow of the dye through the ducts and into the duodenum, which occasionally is seen. These patients are then categorized as having correctable biliary atresia. In such situations, a liver biopsy is performed and the incision is closed. The majority of patients with correctable biliary atresia demonstrate progressive improvement. More commonly, however, there is a very small amount of flow or none at all, for which the Kasai procedure is performed.
3. A thorough inspection of the intraabdominal organs is then done because of the high prevalence of associated anomalies.
4. The hepatoduodenal ligament is explored, and all drainage structures are ligated (Figure 25-21, *A*).
5. The hepatic duct remnant is identified and traced to the liver hilum. The remnant is transected as high as possible using frozen-section biopsy specimens as a guide. Frozen-section biopsy specimens are also obtained at the porta hepatis to denote the presence of ductules. Precise identification of this location is essential (Figure 25-21, *B*).
6. The proximal portion of the jejunum is generally used as the intestinal conduit. A meticulous anastomosis is performed at the porta hepatis as previously identified, using a single running layer of absorbable sutures (Figure 25-21, *C*).
7. The conduit is exteriorized with a double-barreled Roux-en-Y approach (Figure 25-21, *D*).
8. A liver biopsy is then performed.
9. A drain is placed, and the incision is closed in layers.

The procedure just described is one approach of many. Others include exteriorization of the jejunal conduit as a cutaneous jejunostomy and use of double Roux-en-Y loops, avoiding any need for an enterostomy. If none of these procedures is successful, the child may be a candidate for liver transplantation.

Repair of Congenital Diaphragmatic Hernia

A congenital diaphragmatic hernia (CDH) is repaired by replacement of the displaced viscera into the abdominal cavity with surgical correction of the diaphragm defect (Figure 25-22). The conventional surgical repair is through the abdomen, though some cases of CDH can be repaired using a thoracic approach. The concurrence of intraabdominal abnormalities is somewhat high in infants with diaphragmatic hernia; therefore treatment is facilitated with an abdominal approach. It is technically easier to extract the viscera from below than to push them out of the thorax. The abnormal intrathoracic intrusion of the abdominal viscera usually causes severe compromise of intrathoracic pulmonary and vascular activities. Therefore urgent restoration of more normal intrathoracic and intraabdominal relationships is the rule in these newborns. The lung may be hypoplastic because of prolonged compression in utero by the displaced abdominal viscera. A residual intrapleural space usually remains for a few days after surgery.

Procedural Considerations. Direct suturing of the margins of the defect is usually possible. Insertion of prosthetic Silastic sheeting is occasionally required and should be available. The major instrument set is required. The infant is positioned supine.

Operative Procedure

1. The surgeon makes a subcostal incision on the side of the defect, going through all muscle layers.
2. The abdominal viscera are withdrawn from the chest and held downward through the abdominal wound. Because abnormalities of abdominal viscera, such as malrotation, are

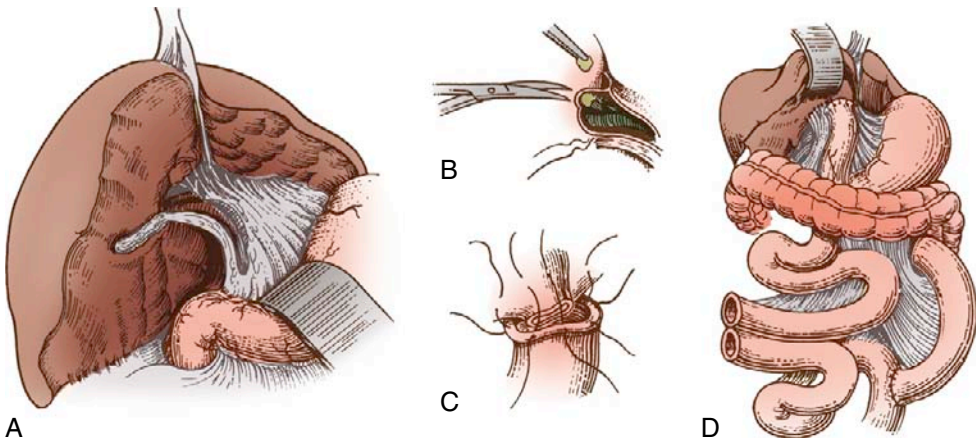

FIGURE 25-21 Kasai procedure. **A**, Exploration of hepatoduodenal ligament and ligation of drainage structures. **B**, Transection of hepatic duct remnant using frozen-section biopsy specimens as a guide. **C**, Anastomosis of jejunal conduit at porta hepatis. **D**, Exteriorization of conduit using double-barreled Roux-en-Y approach.

associated with diaphragmatic hernia, the organs are carefully inspected at this time. If a malrotation is found, the surgeon may repair it if the clinical condition of the infant is amenable to the procedure.

3. The defect is then carefully inspected, including a search for a hernia sac, which is present in fewer than 5% of cases. If a sac is identified, it is excised.
4. The posterior and anterior rims of the diaphragm are identified, and primary closure is performed with mattress sutures of nonabsorbable material. If the rim of tissue is too small for mattress sutures, ample nonabsorbable sutures are used. Occasionally, reinforced Silastic sheeting may be needed if sufficient diaphragm is not available for primary closure.
5. The abdominal wall is then closed, followed by subcutaneous tissue and skin closure. If the musculature cannot accommodate the abdominal viscera, it is left open and the skin is closed to leave a ventral hernia. In severe cases, the patient may be given extracorporeal membrane oxygenation (ECMO) for several days before repair of the defect. The infant is returned to the OR within 7 days for repair of the ventral hernia.

Pancreatectomy

Pancreatectomy is the treatment for several disorders, including congenital hyperinsulinism (HI) and pancreatitis. A pancreatectomy may be total, meaning that the entire pancreas is removed. In some cases, the common bile duct, spleen, gallbladder, and portions of the small intestine and stomach may be removed along with it. Pancreatectomies may also be partial—only the body and tail of the pancreas are removed. Pancreatectomy for congenital hyperinsulinism is described in the following Operative Procedure. Congenital hyperinsulinism is a condition in which the release of insulin is not properly regulated and insulin (beta) cells of the pancreas secrete too much insulin at the wrong time (Children's Hospital of Philadelphia [CHOP], 2009). Treatment of HI is focused on regulating blood glucose level to reduce the risk of brain damage. Surgical intervention is recommended when medical management of HI proves unsuccessful. The procedure for a total pancreatectomy for congenital hyperinsulinism is described in the following section.

Procedural Considerations. Multiple specimens are sent to the pathology laboratory for frozen-section analysis throughout the procedure in order to confirm the extent of the disease. The child is positioned supine with the hips elevated.

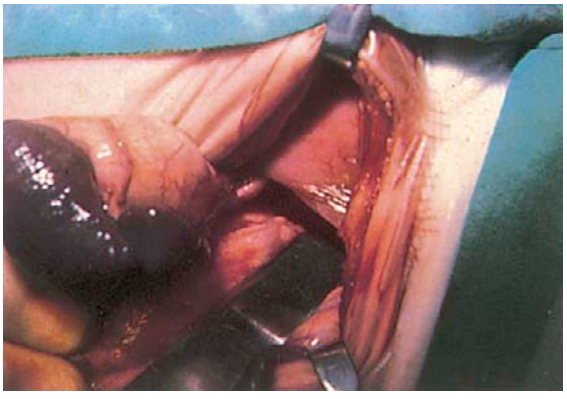

FIGURE 25-22 Defect in the posterolateral aspect of the left diaphragm (diaphragmatic hernia).

Operative Procedure

1. The surgeon makes a transverse supraumbilical incision using a #15 blade. The Denis Brown retractor is placed.
2. The body and tail of the pancreas are exposed for biopsy for analysis by frozen section.
3. The hepatic flexure of the colon and the duodenum are exposed for additional biopsy and frozen section.
4. If results indicate the need for total pancreatectomy (large nuclei in islet cells), the dissection is begun at the pancreatic tail, and then extended to the body and head.
5. A vessel loop is used to isolate the common bile duct and care is taken to preserve duodenal blood supply to the pancreatic head during dissection. Once the uncinate process is mobilized from behind the superior mesenteric vessels and the common bile duct is dissected away from its entry point into the duodenum, the pancreatic head is freed.
6. A pancreatectomy is performed and blood supply to the duodenum is evaluated. In the event that a pancreatic remnant remains, it is ligated using nonabsorbable interrupted horizontal mattress sutures. Omentum is tacked down to the dissected area, and the gallbladder is milked to evaluate patency and test for bile leak.
7. In certain cases, a gastrostomy tube may be placed.
8. The abdominal incision is closed in layers using nonabsorbable suture for fascia and absorbable sutures for subcutaneous and subcuticular tissue. The incision is dressed with Mastisol adhesive and wound closure strips.

GENERAL SURGERY—RESECTION OF TUMORS

Nearly two thirds of childhood cancers occur as solid tumor malignancies. As is always the case, the therapy administered depends on the type of tumor. Examination and judicious investigation of all unusual masses are imperative. Thorough diagnostic workup and prompt definitive treatment may result in cure, even if the tumor is malignant. Chemotherapy and radiation therapy are adjuncts to surgical excision of tumors.

Wilms' Tumor

Wilms' tumor, also known as *nephroblastoma,* is the most common intraabdominal childhood tumor. It presents as a painless mass whose enlargement may laterally distend the abdomen (Figure 25-23). The child may be asymptomatic or may have weight loss, malaise, or abdominal pain. Nephroblastomas may cause obstruction of the vena cava, hepatic veins, or renal veins.

Procedural Considerations. The child is positioned supine with a roll under the affected side. Both chest and abdomen are prepped. Infrequently the tumor extends into the inferior vena cava as well as the right atrium of the heart, and in such cases cardiopulmonary bypass (CPB) should be readily available. Lines are placed into the arms and neck to facilitate clamping of the inferior vena cava if needed. Separate sterile gloves and instruments should be available for inspection of the contralateral kidney. Careful attention should be given when handling tumor and lymph nodes to avoid tumor spillage.

Operative Procedure

If the tumor is operable, the following aspects are important:

1. The transabdominal approach, which may be extended to a combined transabdominal-transthoracic approach, is used to inspect abdominal contents and clamp the vessels of the renal pedicle before tumor dissection.
2. All suspicious lymph nodes are removed, placed into separate containers, and labeled. If no suspicious nodes are present, biopsy specimens are obtained of those in adjacent areas.
3. The opposite kidney is explored before dissection of the tumor.
4. The extent of the tumor can be marked with hemostatic clips to facilitate radiation therapy.
5. The entire primary tumor is removed if doing so does not place the patient in jeopardy.
6. Any residual tumor is marked with clips.
7. Because of its proximity to the kidney, the adrenal gland is usually removed.
8. The abdominal cavity and viscera are thoroughly inspected for evidence of tumor extension or metastases. Extensive surgery may include partial colectomy or partial resection of the diaphragm.

Neuroblastoma

Neuroblastoma is responsible for 6.9% of all childhood cancers and is the third most common childhood cancer after leukemia and brain and nervous system cancers (American Cancer Society [ACS], 2009). It arises from neural crest tissue and can develop anywhere sympathetic nerve tissue is found; the most common sites are the retroperitoneum and adrenal medulla. The mass is usually firm, irregular, and nontender. It is a silent tumor in its early stages and metastasizes rapidly, often to the lymphatics, liver, skin, bone marrow, lung, brain, or orbits. Treatment includes an operation to ligate the tumor's blood supply and remove as much of the tumor as possible, as well as chemotherapy and radiation.

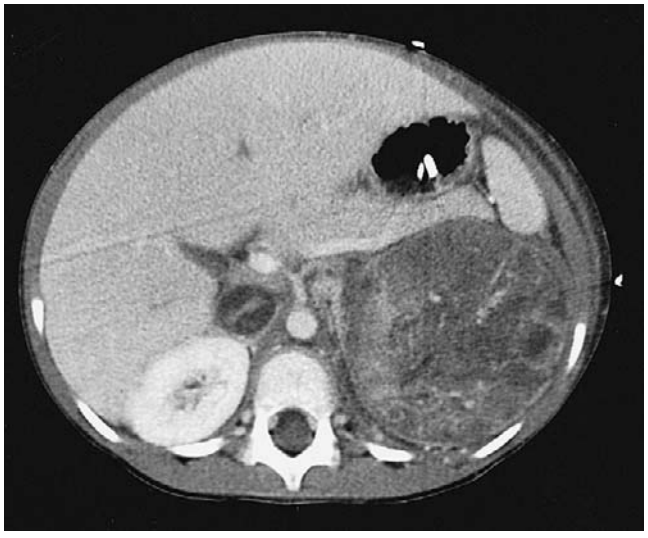

FIGURE 25-23 Computerized tomographic scan showing left-sided Wilms' tumor with compression of the inferior vena cava.

Sacrococcygeal Teratoma

A sacrococcygeal teratoma is a tumor that originates early in embryonic cell division. The tumor consists of cell types from more than one embryonic germ layer. Teratomas range from benign, well-differentiated cystic lesions to solid, malignant lesions. They are the most common tumor in newborns, occurring in 1:35,000 to 1:40,000 births (Laberge et al, 2005). The sacrococcygeal area is the most common extragonadal site of teratoma, usually presenting as a large protuberance rising from that site (Figure 25-24). It may be irregular or symmetric, may vary in size, and may be pedunculated.

A sacrococcygeal teratoma is usually resectable but may undergo malignant changes if not removed early in life. Sacrococcygeal teratomas can be resected prenatally using fetal surgery techniques (see Chapter 13) or postnatally. Tumors resected in the newborn period show microscopic evidence of malignant cells, but surgical cures have been achieved. Early surgical resection is important because these tumors are not sensitive to irradiation and are only temporarily responsive to chemotherapy.

The tumor is in the area of the sacrum and coccyx but may extend into the pelvis or abdomen. Resection is usually feasible by placing the patient in the jackknife position and excising

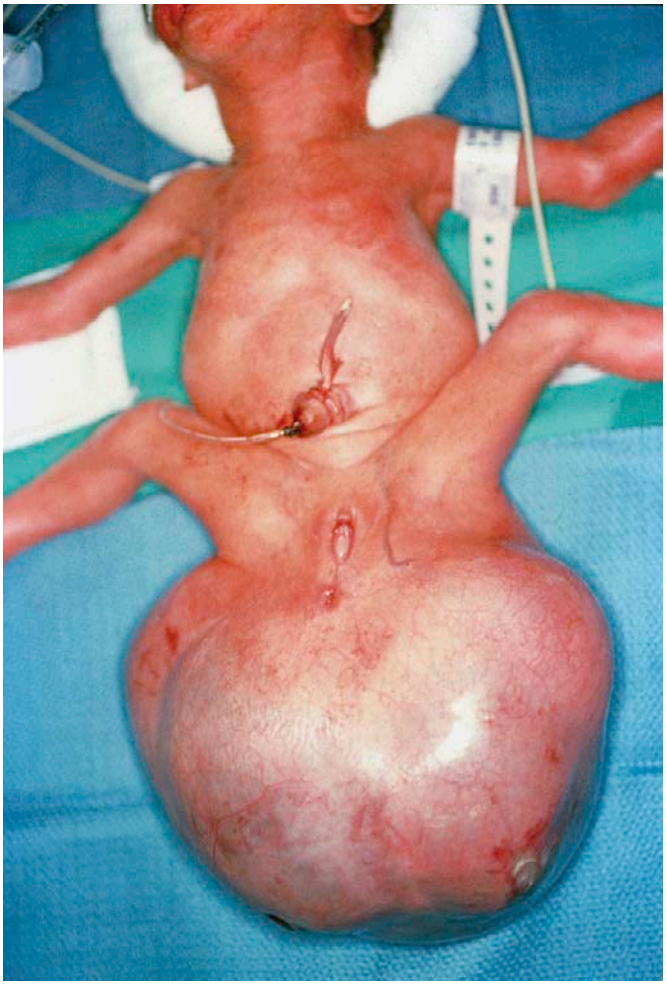

FIGURE 25-24 Infant with large sacrococcygeal teratoma.

the tumor mass and coccyx en bloc. In cases where the tumor extends high into the pelvis, an abdominal incision may also be required.

GENITOURINARY SURGERY

Pediatric Cystoscopy

Pediatric cystoscopy is endoscopic examination of the lower urinary tract of pediatric patients. The major difference between adult and pediatric cystoscopy is the size of the instruments used and consideration of the small, delicate orifices of the pediatric patient. Indications for pediatric cystoscopy include urinary tract infections, enuresis, urethral valves, vesicoureteral reflux, diverticula, bladder neck contractures, bladder tumors, and urinary tract obstructions. Pediatric cystoscopy may also be used in conjunction with Deflux injection for minimally invasive treatment of vesicoureteral reflux.

Procedural Considerations. The cystoscopy setup will have the same type of components as those for the adult cystoscopy patient, except that the size of the cystourethroscope system will be specific to the pediatric patient's needs.

Each pediatric cystourethroscope is designed to fit specific component parts and is very delicate. Therefore the perioperative nurse must be familiar with the proper use of the system and handle the components carefully. The resectoscope loop is commonly used to resect urethral valves and occasionally bladder tumors. The cold knife may be used with the resectoscope to cut urethral strictures and occasionally to resect a urethral valve.

The most common type of anesthesia used for the pediatric patient is general anesthesia. After induction of anesthesia, the child is placed in a lithotomy or frog-leg position and prepped and draped according to established procedure.

Operative Procedure. The pediatric cystourethroscope is lubricated and inserted through the urethra into the bladder. The light cord and irrigation tubing are attached to the telescope and cystoscope, and the examination is performed. Most commonly the interior of the bladder is viewed on a video monitor by means of a camera attached to the cystoscope.

Circumcision

Circumcision is the excision of the foreskin (prepuce) of the glans penis. Circumcision may be done for therapeutic reasons or for perceived prophylactic benefits; it may also be done for religious reasons, as is required in specific faiths. Provision should be made to observe the religious needs and preferences of the parents.

Therapeutic indications include correction of phimosis or paraphimosis or treatment of balanoposthitis. Phimosis is a condition in which the orifice of the prepuce is stenosed or too narrow to permit easy retraction behind the glans. Balanoposthitis is characterized by an inflamed glans and mucous membrane with purulent discharge and may require circumcision. Paraphimosis is a recurrent condition in which the prepuce cannot be reduced easily from a retracted position.

Procedural Considerations. Newborns are generally positioned on a specially constructed board that facilitates restraint by immobilizing the limbs and exposing the genitalia. Although it was once thought that circumcision caused infants little pain, the neonatal foreskin contains mature nerve endings that allow for the transmission of pain. Measures to ameliorate the pain of the procedure include local dorsal penile nerve block, a ring block with buffered lidocaine and bupivacaine, or the topical application of a eutectic mixture of local anesthesia (EMLA) cream. Older children require general anesthesia.

For infants, the setup includes fine plastic surgery instruments. A Gomco clamp of the appropriate size, a Plastibell, or the Hollister disposable circumcision device may be employed. The Hollister device includes sutures that are sealed in a sterile packet ready for use. The Plastibell technique uses a plastic ring and suture tied around the foreskin like a tourniquet. The excess tissue is trimmed, and in about 5 to 8 days the ring falls off. For older patients, the circumcision clamp is not needed, and only a plastic surgery instrument set is used. Petrolatum gauze for dressing should be available.

Operative Procedure *(Figure 25-25)*

1. If the prepuce is adherent, the surgeon may use a probe or hemostat to break up adhesions. The prepuce is clamped in the dorsal midline and incised toward the coronal mucosa margin, leaving about 5 cm of coronal mucosa intact. A similar procedure is performed ventrally. The two incisions are then joined circumferentially. Alternatively, a superficial circumferential incision is made in the skin with a scalpel at the level of the coronal sulcus and mucosa at the base of the glans. The redundant skin is undermined between the circumferential incisions and removed as a complete cuff.
2. Bleeding vessels are coagulated or clamped with mosquito hemostats and tied with fine absorbable ligatures. Before closure, the area may be cleansed with an appropriate antiseptic solution.
3. The raw edges of the skin incision are approximated to a coronal cuff of mucosal prepuce, generally with interrupted 4-0 or 5-0 absorbable sutures on fine plastic cutting or GI needles. The wound is usually dressed with petrolatum gauze or an antibiotic ointment. A penile block with bupivacaine is often done for immediate postoperative pain, thus providing a more comfortable emergence from anesthesia.

Hypospadias Repair

Hypospadias is a developmental anomaly characterized by a urethral meatus that opens onto the ventral surface of the penis proximal to the end of the glans (Figure 25-26). There are varying degrees of hypospadias. The meatus may be on the ventral surface of the glans, on the corona, anywhere along the shaft, in the scrotum, or even in the perineum. The more proximal the opening, the greater the degree of chordee (downward curvature of the penis). Chordee is caused by fibrous bands that extend from the hypospadiac urethral meatus to the tip of the glans and represent the abnormally developed urethra and its investing layer of Buck's fascia, dartos, and skin. In some cases of clinical curvature, however, these fibrous bands may not be present. Although these curvatures are still termed *chordee,* they are not true fibrous chordee.

The principal methods of hypospadias repair are meatoplasty and glanuloplasty, orthoplasty (release of chordee, thereby straightening the penis), urethroplasty (reconstruction of the urethra), skin cover, and scrotoplasty. These may be done in one- or two-stage repairs depending on the extent of the condition.

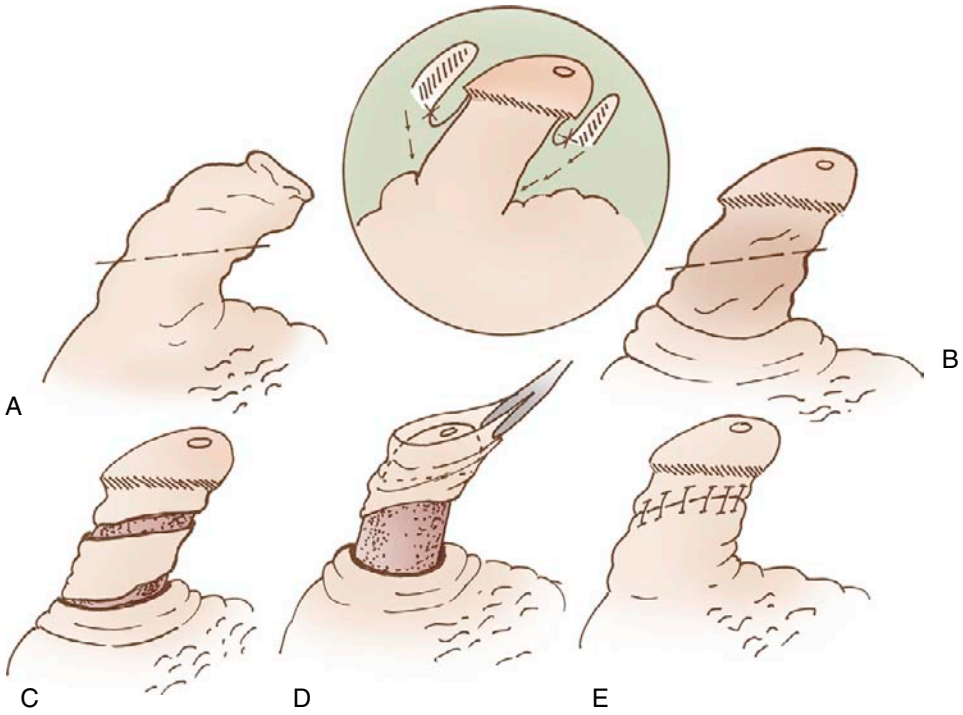

FIGURE 25-25 Circumcision. **A**, Initial incision made in the shaft. **B**, Second incision made in subcoronal sulcus. **C**, Amount of tissue to be removed. **D**, Removal of tissue. **E**, Shaft skin sutured to subcoronal skin.

FIGURE 25-26 Hypospadias.

Recently efforts have increased to relocate the meatus to the apex of the glans, especially in the more extensive one-stage repair.

One complication of hypospadias repair is urethral fistula formation, which can be repaired without much difficulty. Correction of strictures is more troublesome.

Procedural Considerations. The patient (the majority are infants and young children) is placed in the supine position with legs apart. The urine may be diverted with a urethral catheter intraoperatively. The instrument setup varies according to the surgeon's preference. However, a minor set with fine plastic surgery instruments is generally required. Owens gauze, Elastomull, Coban, and Elastoplast, as well as adhesive tape, are generally required for the dressing, which is an important part of the hypospadias repair.

Meatoplasty and Glanuloplasty Incorporated (MAGPI) Procedure

OPERATIVE PROCEDURE

1. The surgeon makes a subcoronal circumferential incision about 8 mm proximal to the meatus and corona. The skin is stripped back from the phallus by subcutaneous dissection (Figure 25-27).
2. A bridge of tissue between the meatus and glanular groove is made, with a transverse closure of the dorsal (upper) meatal edge to the distal glanular groove.
3. Three traction sutures are placed where the foreskin stops, at the apex of the ventral meatus (on the lower side) and lateral areas of the glans.
4. The edges of the glans are sutured together ventrally in a V configuration, and the redundant edges are excised. Vertical mattress sutures are used to approximate the glans beneath the meatus.
5. If foreskin is excessive, it may be trimmed, followed by a sleeve style of reapproximation of the penile skin. If a ventral skin defect is present, a rotational skin flap closure is used.
6. An indwelling catheter is placed, and the wound is dressed.

Orthoplasty. *Orthoplasty* is the proper designation for the plastic procedure performed to straighten the penis. *Chordee repair* is the more common term employed. In true fibrous chordee the penis is curved downward, with the meatus and glans in proximity to one another.

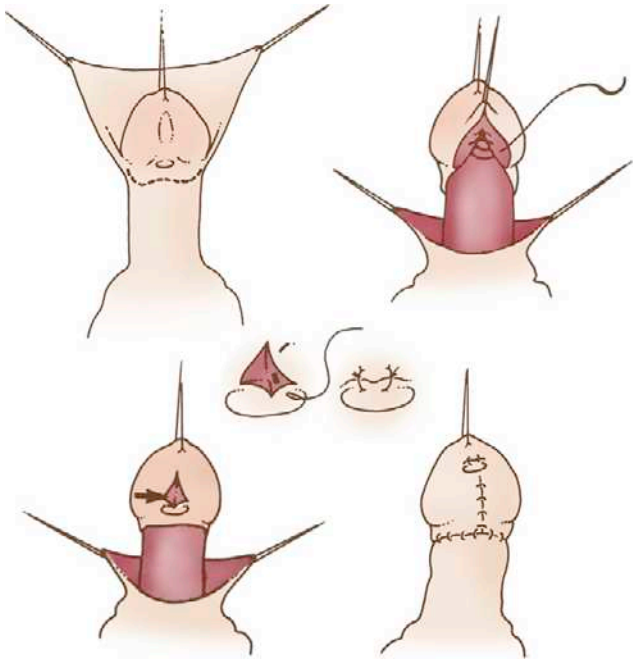

FIGURE 25-27 Meatal advancement and granuloplasty.

Artificial erection is achieved by injecting 0.9% preservative-free, injectable saline solution into the corpus cavernosum. Both corporal bodies fill, making it possible to determine the degree of curvature before and after the resection of the fibrous bands.

OPERATIVE PROCEDURE

1. The surgeon makes a circumferential incision around the corona and carries it distally to the urethral meatus and well below the glans cap (Figure 25-28, *A*). Dissection continues to the level of the tunica albuginea of the corpora cavernosa.
2. With proximal dissection the adherent fibrous plaque is freed, working in a side-to-side fashion. The urethra is elevated from the corpora during this process (Figure 25-28, *B*).
3. The chordee generally surrounds the urethral meatus and often extends for some distance. It is important to free it completely along the entire penile shaft to the penoscrotal junction or, in severe cases, into the scrotum or perineum.
4. After release of the chordee, the glans penis is closed with 4-0 absorbable sutures in a circular manner (Figure 25-28, *C*).
5. If urethroplasty is either delayed or unnecessary, excess dorsal skin is excised (Figure 25-28, *D*) and the incision is closed along the dorsal midline with interrupted absorbable mattress sutures (Figure 25-28, *E*). The wound is dressed according to established protocol.

Urethroplasty. Many procedures are described for reconstruction of a urethra. They may be divided into three general groups: adjacent skin flaps, free skin grafts, and mobilized vascular flaps. There are also many combinations of these procedures. In all the procedures, some type of temporary urinary diversion, such as a perineal urethrostomy, may be used.

The procedural considerations are the same as those for chordee repair.

Adjacent Skin Flap. It is possible to tubularize skin adjacent to the meatus to create a neourethra in a one-stage repair. Transfer of dorsal skin to the ventrum will also provide graft material close to the meatus. However, this is generally done in two stages, and the vascularity of this thin rotational flap is less than optimum, with results that are prone to complication.

OPERATIVE PROCEDURE

1. The surgeon places traction sutures in the tip of the penis and in the glans wings for stabilization and exposure.
2. The distance between the glans tip and the lower edge of the meatus is measured. An outline of the proposed incision is drawn on the penile shaft (Figure 25-29, *A*). In a one-stage approach the distal length must be increased to compensate for the added penile length after chordee release.
3. An incision is made around the outlined flap and carried proximally to a point on the shaft that corresponds to the distance required to reach the glans tip. A flap width of 14 to 16 mm is usually sufficient to ensure good circumference of the neourethra.
4. Once incised, the tube is rolled over an 8F or 10F catheter (Figure 25-29, *B*) with an inverted running stitch of 4-0 or 5-0 absorbable suture.
5. The glans penis is incised, and the glans wings are undermined and freed. The neourethra is carried to the distal portion of the glans and sutured in place (Figure 25-29, *C*).
6. The glans wings are sutured around the neourethra with absorbable interrupted mattress sutures. The redundant foreskin is split down the midline, and the flaps are transposed in a Z-plasty manner (Figure 25-29, *D*).
7. A dry, sterile pressure dressing is applied. The patient can often be discharged on the same day, without the need for an indwelling catheter.

Free Skin Graft. Free skin grafts should be of full thickness. Because the free graft must be revascularized, it is important that it have a perfect skin cover of dorsal preputial penile skin that is well vascularized. This type of graft is generally used with a one-stage hypospadias repair.

OPERATIVE PROCEDURE

1. A V-shaped incision is made on the glans, and the penile skin is mobilized after the chordee is released (Figure 25-30, *A*).
2. Glans wings are developed in a triangular fashion, and ventral preputial skin is used for the full-thickness free graft (Figure 25-30, *B*).
3. The graft is formed into a neourethra over a stenting catheter (Figure 25-30, *C*).
4. The graft is anastomosed proximal to the urethra with the suture line of the graft next to the corpora. The middle glans dart is fixed to the corpora (Figure 25-30, *D*).
5. A meatoplasty with the dorsal glans dart is accomplished.
6. Fine absorbable interrupted sutures are placed around the meatus and glans and along the dorsal penile shaft (Figure 25-30, *E*).
7. The wound is dressed according to established protocol.

Mobilized Vascularized Flaps. Vascularized flaps of preputial penile skin may be mobilized to the ventrum by leaving them attached to the outer surface of the prepuce or as an island flap. One modification is the transverse preputial island-flap neourethra with glans-channel positioning for the meatus. Preputial skin seems to be preferred because of its rich, reliable blood supply.

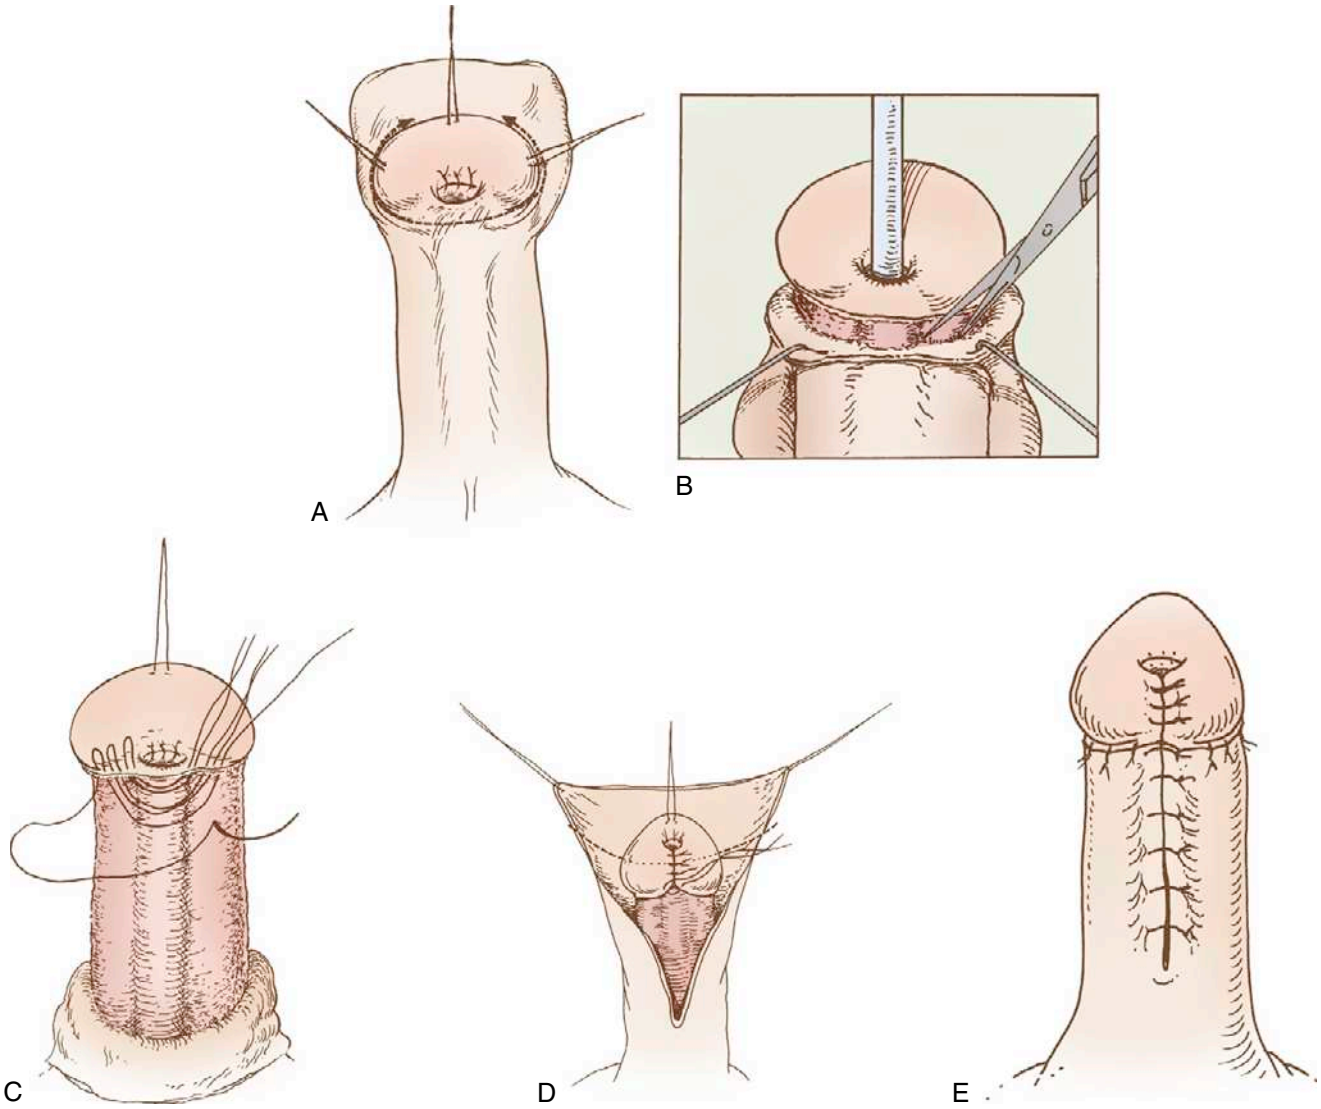

FIGURE 25-28 Orthoplasty.

OPERATIVE PROCEDURE

1. The chordee is released (Figure 25-31, *A*).
2. Ventral preputial skin is dissected free and fanned out (Figure 25-31, *B*).
3. The rectangle of skin is rolled into the neourethra and measured (Figure 25-31, *C*).
4. The island flap is developed by dissection of the subcutaneous tissue from the dorsal penile skin (Figure 25-31, *D* and *E*).
5. A glans channel is created with fine scissors in a plane just above the corpora. The glans tissue is removed with the 14F channel, and the island-flap urethra is spiraled to the ventrum (Figure 25-31, *F*).
6. The neourethra is anastomosed proximal to the urethra (Figure 25-31, *G*).
7. The neourethra is carried to the tip of the glans (Figure 25-31, *H*).
8. The dorsal penile flaps are transposed laterally to the midline, and excess skin is excised. Closure is with fine absorbable interrupted mattress sutures around the glans and down the penile shaft (Figure 25-31, *I*).
9. Dressings are applied according to established protocol.

Skin Cover. After orthoplasty and urethroplasty, the penis must be resurfaced with skin. Abundant excess dorsal foreskin is usually adequate to achieve the desired results.

OPERATIVE PROCEDURE

1. Preputial tissue is transposed through a small buttonhole opening in the midline (Figure 25-32, *A*).
2. The vasculature is spread laterally, and the glans penis is delivered through the hole (Figure 25-32, *B*).
3. The skin flap is then sutured with fine absorbable interrupted mattress sutures (Figure 25-32, *C*).

Epispadias Repair

An epispadias is a congenital anomaly characterized by a urethral opening on the dorsum of the penis. The surgical procedures employed in the correction of epispadias depend on the extent of the deformity. In mild, incomplete defects the repair is the same as a simple hypospadias repair. Complete deformity is always associated with urinary incontinence because of little or no development of the bladder neck; thus the operation is much more involved. The least severe forms of the exstrophy-epispadias complex are (1) balanic epispadias, in which the urethra

opens on the dorsum of the glans, and (2) penile epispadias, in which the urethra opens on the shaft of the penis. The more severe variety, which occurs when the urethra opens on the proximal end of the shaft or in the penopubic position, is generally associated with severe dorsal chordee and urinary incontinence.

Procedural Considerations. The setup for an epispadias repair is the same as that described for hypospadias repair.

Operative Procedures

FIRST-STAGE EPISPADIAS REPAIR

1. The surgeon makes a vertical incision distal to the epispadial meatus and extends it circumferentially to the dorsal coronal margin.

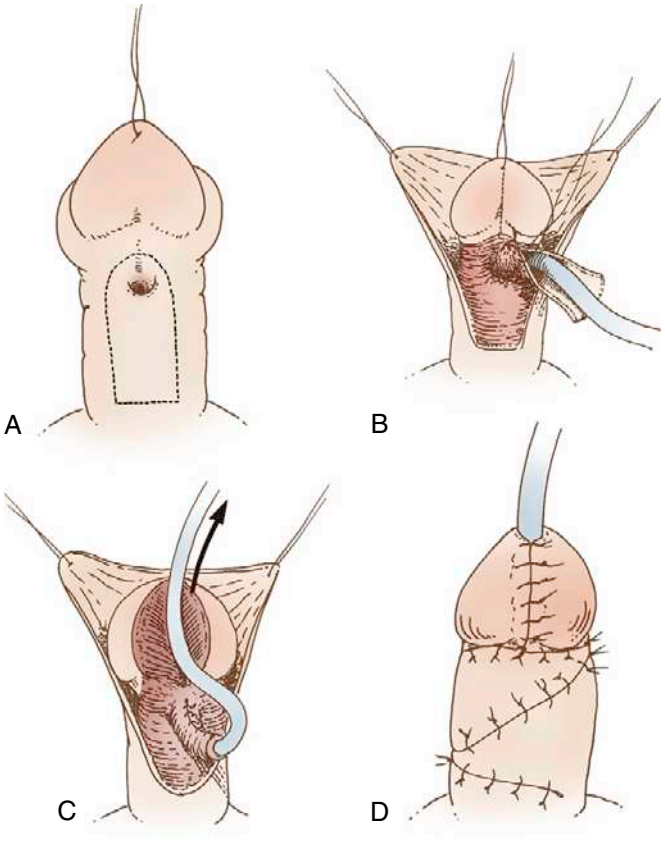

FIGURE 25-29 Urethroplasty with adjacent skin flap.

2. The foreshortened dorsal urethral strip is lifted off the corpora cavernosa, and the ventral prepuce (foreskin) is rotated dorsally to cover the dorsal skin defect created by penile straightening.

SECOND-STAGE EPISPADIAS REPAIR

1. A vertical suprapubic incision is made to expose the anterior bladder wall and widened vesical neck. A wedge section of the anterolateral prostatic urethra is removed on either side so that when it is reconstructed, a more normal-caliber prostatic urethra is formed.
2. The roof of the membranous urethra is removed.
3. The prostatic urethra is closed, including muscle that is sutured together in the midline, with absorbable sutures. The bladder is closed so that an indwelling suprapubic catheter is left. The abdomen is closed in layers.
4. The anterior urethra is closed after an appropriate size of octagonal strip of dorsal penile skin is outlined.
5. The remainder of the repair—the creation of the urethra and its coverage with lateral penile skin—is the reverse procedure of a second-stage hypospadias repair.

Bladder Exstrophy Repair

Bladder exstrophy repair corrects a more severe form of epispadias, in which the anterior bladder wall as well as the roof of the urethra is absent. Bladder exstrophy is always accompanied by wide separation of the rectus muscles of the lower abdominal wall and by diastasis of the pubic bone with anterior displacement of the anus. Repair of bladder exstrophy requires an adequate size of bladder for ultimate continence to be achieved. It is preferable to perform this procedure in the neonatal period.

Procedural Considerations. The infant is placed in a supine position, and the abdomen and thighs are prepped and draped. Instruments are the same as those required for hypospadias repair.

Operative Procedure

1. The surgeon makes an incision around the exposed bladder medial to the paravesical neck mucosa. The incision is carried distally across the epispadial urethra distal to the verumontanum. The paravesical mucosa is preserved for urethral lengthening. The bladder is then freed from the rectus fascia and the peritoneum. The dorsal chordee is released, and the mobilized paravesical mucosa is apposed in the midline and sutured to the proximal end of the urethra just distal to the verumontanum.

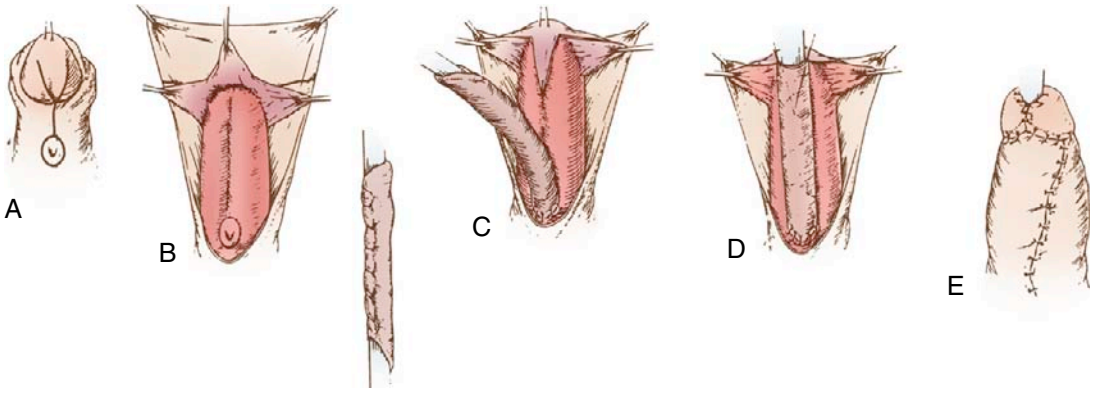

FIGURE 25-30 Urethroplasty with free graft.

2. The bladder wall is closed vertically in two layers with 3-0 absorbable sutures; a suprapubic tube is inserted for drainage.
3. The bladder neck is loosely reconstructed by approximating the interpubic ligament, which extends between the proximal end of the phallus and the pubic bone.
4. The symphysis pubis is approximated with a heavy nonabsorbable suture. During this step the assistant rotates the iliac bones anteriorly.

Hydrocelectomy

A hydrocele is an abnormal accumulation of fluid within the scrotum. The fluid is contained within the tunica vaginalis. Excessive secretion or accumulation of hydrocele fluid may be the result of infection or trauma. A hydrocelectomy is the excision of the tunica vaginalis of the testis to remove the enlarged, fluid-filled sac. In older patients, the procedure is performed through a scrotal incision.

Procedural Considerations. The patient is placed in the supine position. Preparation and draping of the patient include routine cleansing of the external genitalia and draping of the patient with a fenestrated sheet. A minor instrument set is required, plus a small drain; a 30-ml syringe with a 20-gauge, 2-inch aspirating needle; and a suspensory dressing.

Operative Procedure

1. The surgeon makes an anterolateral incision in the skin of the scrotum over the hydrocele mass with a #10 or #15 blade (Figure 25-33, *A*). Bleeding is controlled with the electrosurgical unit (ESU).
2. Small retractors may be placed, after which the fascial layers are incised to expose the tunica vaginalis (Figure 25-33, *B*). With fine scissors, forceps, and blunt dissection, the hydrocele is dissected free and delivered (Figure 25-33, *C*). The sac is opened, and the fluid contents are aspirated.
3. The sac is inverted so that it surrounds the testis, epididymis, and distal cord. Excess tunica vaginalis is excised, and the edges of the tunica are sutured with a continuous 4-0 absorbable suture behind the testicle (Figure 25-33, *D*). The testicle is "bottled" by the inverted tunica vaginalis, and this may then be returned to the sac.

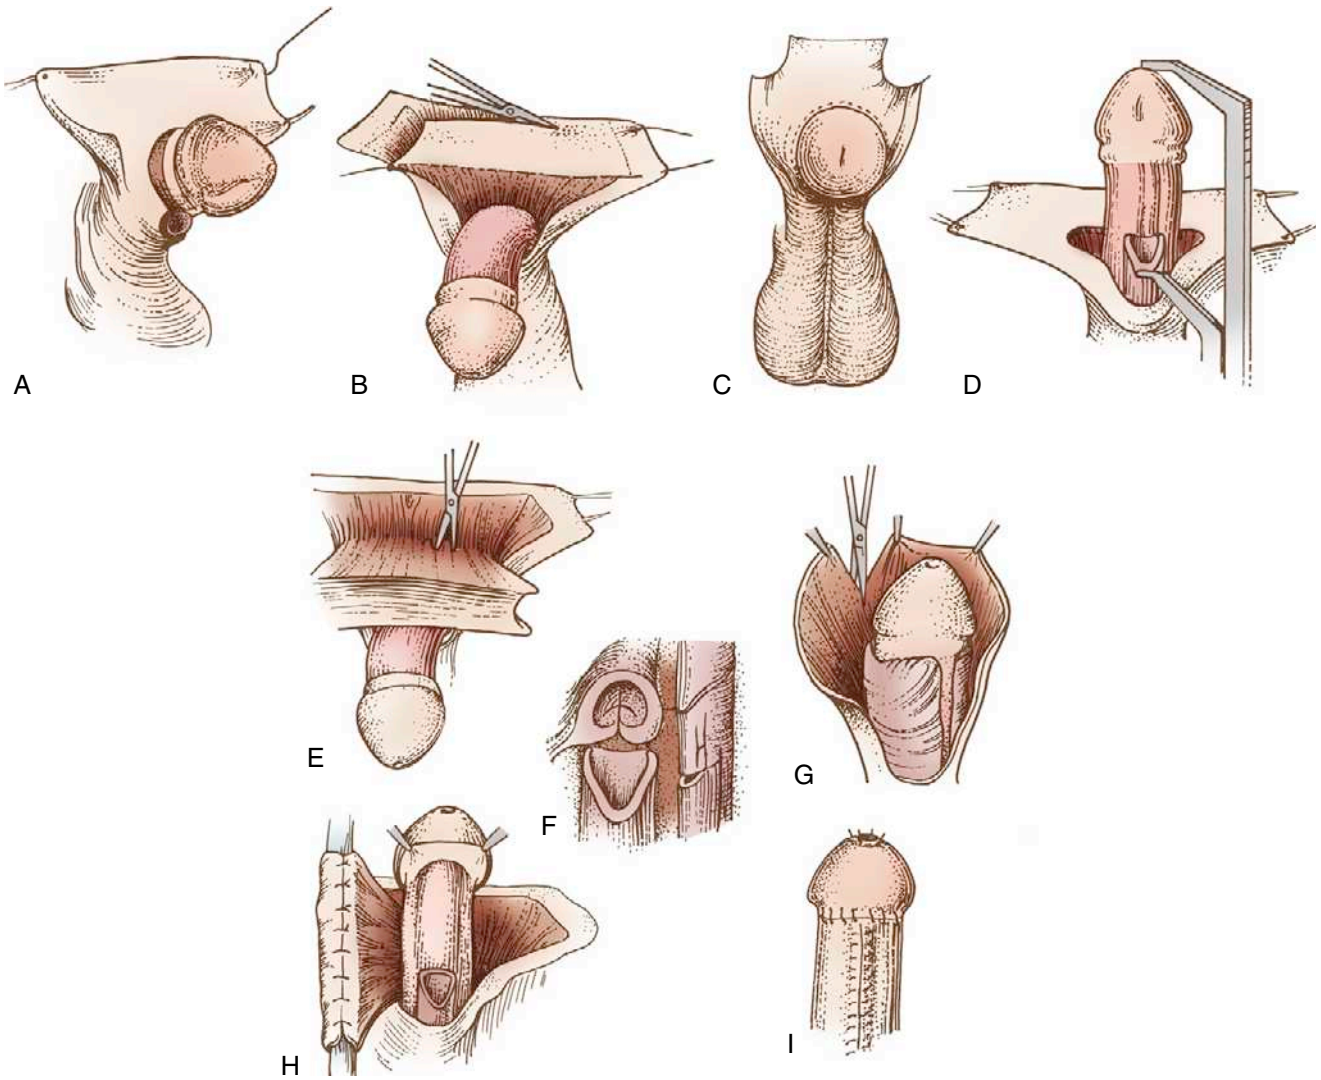

FIGURE 25-31 Urethroplasty, island flap.

4. A drain is placed within the scrotum and exteriorized through a stab wound in the most dependent portion of the scrotum. The scrotal incision is closed in layers with 3-0 and 4-0 absorbable sutures. A fluff compression dressing contained in a scrotal support (suspensory) helps reduce postoperative scrotal edema.

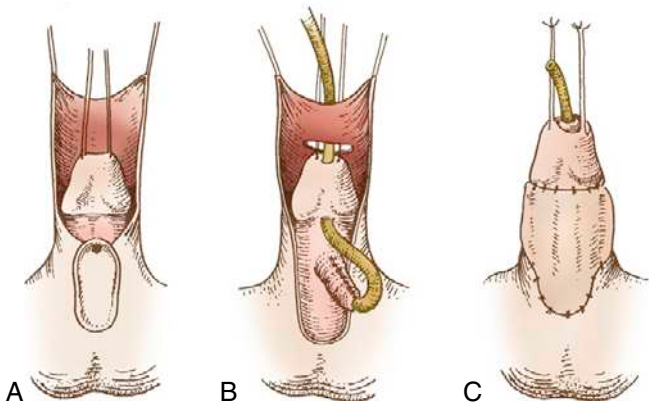

FIGURE 25-32 Skin cover procedure.

Orchiopexy

An orchiopexy is the surgical placement and fixation of the testicle in a normal anatomic position in the scrotal sac. If the testis fails to descend into the scrotum during gestation, it is considered undescended. An undescended testis becomes arrested somewhere along its normal path of descent. If it is palpable in a position other than its normal path of descent, its position is considered to be ectopic.

A retractile testis has fully descended into the scrotum but retracts out of the scrotum as a result of contraction of the cremaster muscle. Gentle manipulation allows replacement of the testis in the most dependent portion of the scrotum. Retractile testes require no surgical or hormonal treatment.

All testes that are undescended after 1 year, including those that are unresponsive to hormone injections, require surgical placement in the scrotum for optimum maturation. Laparoscopic exploration may also be used to determine position, existence, or size of a "hidden" testis.

Procedural Considerations. The setup is the same as that described for hydrocelectomy. Prepping and draping include the lower abdomen, genitalia, and thighs. Because this operation is

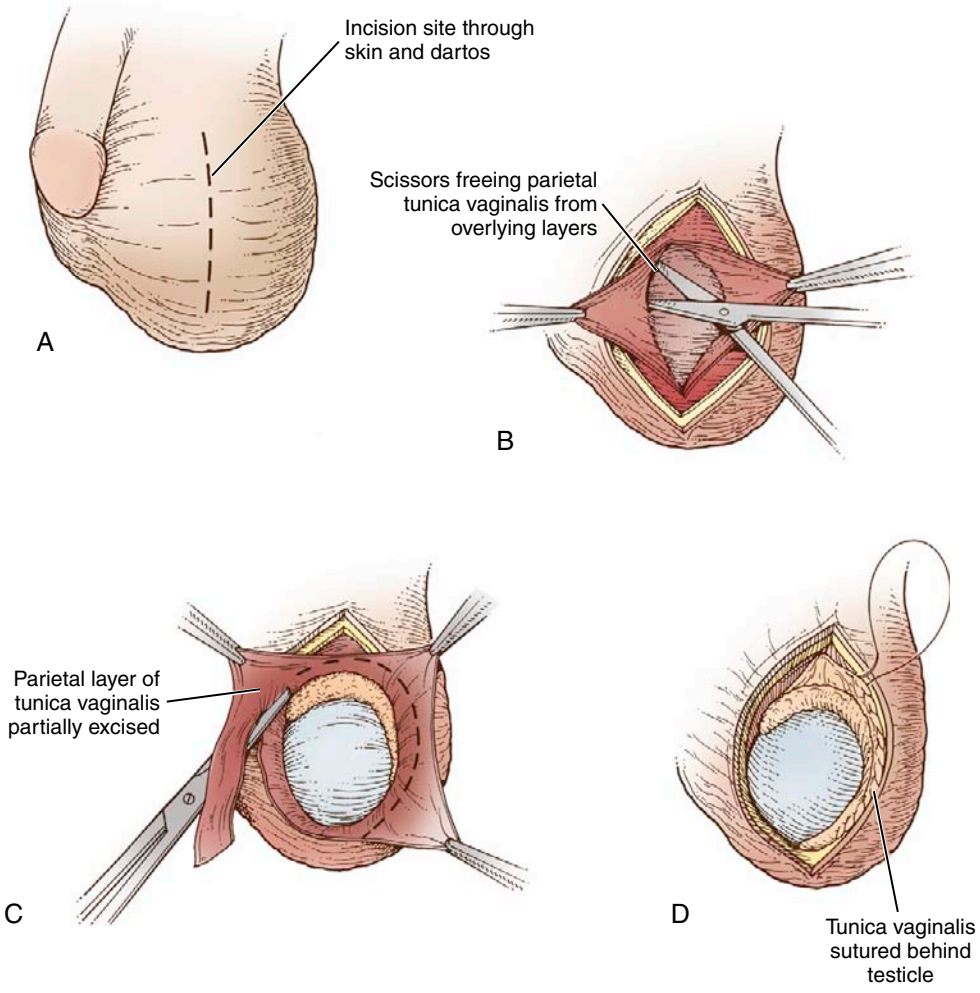

FIGURE 25-33 Hydrocelectomy.

usually performed on children, a setup containing small, delicate instruments and sutures is required.

Operative Procedure

1. An inguinal incision is generally employed for exploration of undescended testes (Figure 25-34, *A*). Most undescended testes are located in the superficial inguinal pouch or inguinal canal.
2. The external oblique aponeurosis is opened through the external inguinal ring to expose the inguinal canal; the gubernacular attachments of the undescended testis are dissected free as high as the internal inguinal ring or into the abdominal cavity (Figure 25-34, *B*).
3. All adhesions and the associated inguinal hernia sac are freed to lengthen the cord so that the testis is allowed to reach the scrotal cavity (Figure 25-34, *C*). The hernia sac is transected, twisted, and ligated with sutures.
4. To draw vessels into the inguinal canal, more proximal to the scrotum, the floor of the inguinal canal may have to be divided at the internal ring (Figure 25-34, *D*).
5. The lateral portion of the internal ring is closed to prevent herniation. A scrotal pocket is created, and the testis is anchored in a normal anatomic position within the scrotum with absorbable sutures (Figure 25-34, *E* to *K*).

Orchiopexy may be accomplished by several surgical methods. The dependent portion of the undescended testis may be sutured to the base of the scrotum with absorbable or nonabsorbable sutures exteriorized through the scrotal wall and tied over a peanut dissector or pledget. The most popular method is to anchor the testis into a dissected subdartos pouch. In this procedure, a small midtransverse scrotal incision is made and the skin and dartos muscle are dissected to create a pouch. The testis is then moved through a small hole in the dartos into the subdartos pouch and anchored in position by the traction suture. The overlying skin of the subdartos pouch is closed with fine absorbable suture material. The inguinal incision is repaired in layers with 3-0 absorbable sutures. The skin is closed with a subcuticular suture, and cyanoacrylate glue is used for dressing.

Vesicoureteral Reflux

Vesicoureteral reflux (VUR) is defined as the retrograde flow of urine from the bladder to the ureter and even to the kidney pelvis. Children are usually initially diagnosed with the occurrence of a febrile urinary tract infection (UTI). The workup for reflux will include a renal bladder ultrasound with prevoid and postvoid views as well as a voiding cystourethrogram (VCUG). The VCUG is used to grade the reflux, with grade I being the least and grade V being the most extensive reflux. Children with VUR are given prophylactic antibiotics and checked yearly. Children with unresolved reflux or breakthrough infections will probably require repair of the reflux. Currently there are two types of repair. For lower-grade reflux the most common approach is the minimally invasive approach of cystoscopy with injection of Deflux at the ureteral orifice into the bladder wall (Research Highlight). If the reflux is more severe, the child may require reimplantation of the ureter into the bladder wall.

Procedural Considerations—Deflux. The setup for Deflux injection includes the same basic instrument setup as described for cystoscopy including a 10F offset cystoscope, light cord with a light source, cystoscopy fluid delivery tubing, Deflux needle, syringe of Deflux, and camera and monitor for the surgeon to view the procedure. The offset scope is the key to a good injection because the lens is offset at approximately a 45-degree angle and the port to insert the needle through the scope comes straight off the end of the scope. The patient is placed in dorsal lithotomy position for the procedure.

Operative Procedure

1. The pediatric offset cystourethroscope is lubricated and inserted through the urethra into the bladder. The light cord, camera, and irrigation tubing are attached to the cystoscope, a urine specimen for culture is obtained, and then an examination is performed.
2. The bladder is partially filled, to allow for visualization.
3. The irrigation fluid is jetted into the ureteral orifice, opening it wide (hydrodistention), and then the needle is introduced under the mucosa of the midureteral tunnel at the 6-o'clock position. The needle tip is positioned just under the urothelium and is advanced 4 to 5 mm in the submucosal plane of the ureter. Deflux is then injected until a prominent bulge appears, and the orifice has assumed a volcano-like shape.
4. The needle is kept in position for 15 to 30 seconds after the injection to prevent extravasation of Deflux.

RESEARCH HIGHLIGHT

The Deflux Procedure Reduces the Incidence of Urinary Tract Infections in Patients with Vesicoureteral Reflux

A prospective review of 100 charts between June 2003 and June 2005 was conducted to evaluate the effectiveness of a single application of dextranomer/hyaluronic acid co-polymer (Deflux) in reducing the incidence of urinary tract infections (UTIs) in children with vesicoureteral reflux (VUR). The mean age of the study population was 3.8 years, and 76% were female. Study demographics included the number of UTIs preoperatively and postoperatively, a radiographic grade of VUR on a voiding cystourethrogram (VCUG), and the presence of VUR on a radionuclide VCUG 3 three months following the procedure. The t-test was used to analyze data.

A total of 155 ureters were graded and treated with a single injection of Deflux; 10 ureters had grade I reflux, 42 had grade II, 76 had grade III, 25 had grade IV, and 2 had grade V. After the initial injection, 77.4% of the study population reported grade 0 reflux at 3 months. A second injection was needed in 22 ureters. After the second injection, the success rate of the procedure was 83.9% overall. The success rates for each grade of reflux were as follows: grade I reflux experienced a 100% success rate; grade II reflux experienced an 88.1% success rate; grade III reflux experienced an 86.8% success rate; grade IV reflux experienced a 64% success rate; grade V reflux experienced a 50% success rate. Of the 100 patients, 75 had a UTI before the Deflux procedure and 13 had a UTI after the Deflux procedure. These results contributed to a decrease in the incidence of annual UTIs from a mean of 0.68 to 0.12 ($p = 0.001$). These results indicate that Deflux is effective in eliminating VUR and reducing the incidence of UTIs and antibiotic use in children with VUR.

Modified from Wadie GM et al: The Deflux procedure reduces the incidence of urinary tract infections in patients with vesicoureteral reflux, *J Laparoendosc Adv Surg Tech A*, 17(3):353-359, 2007.

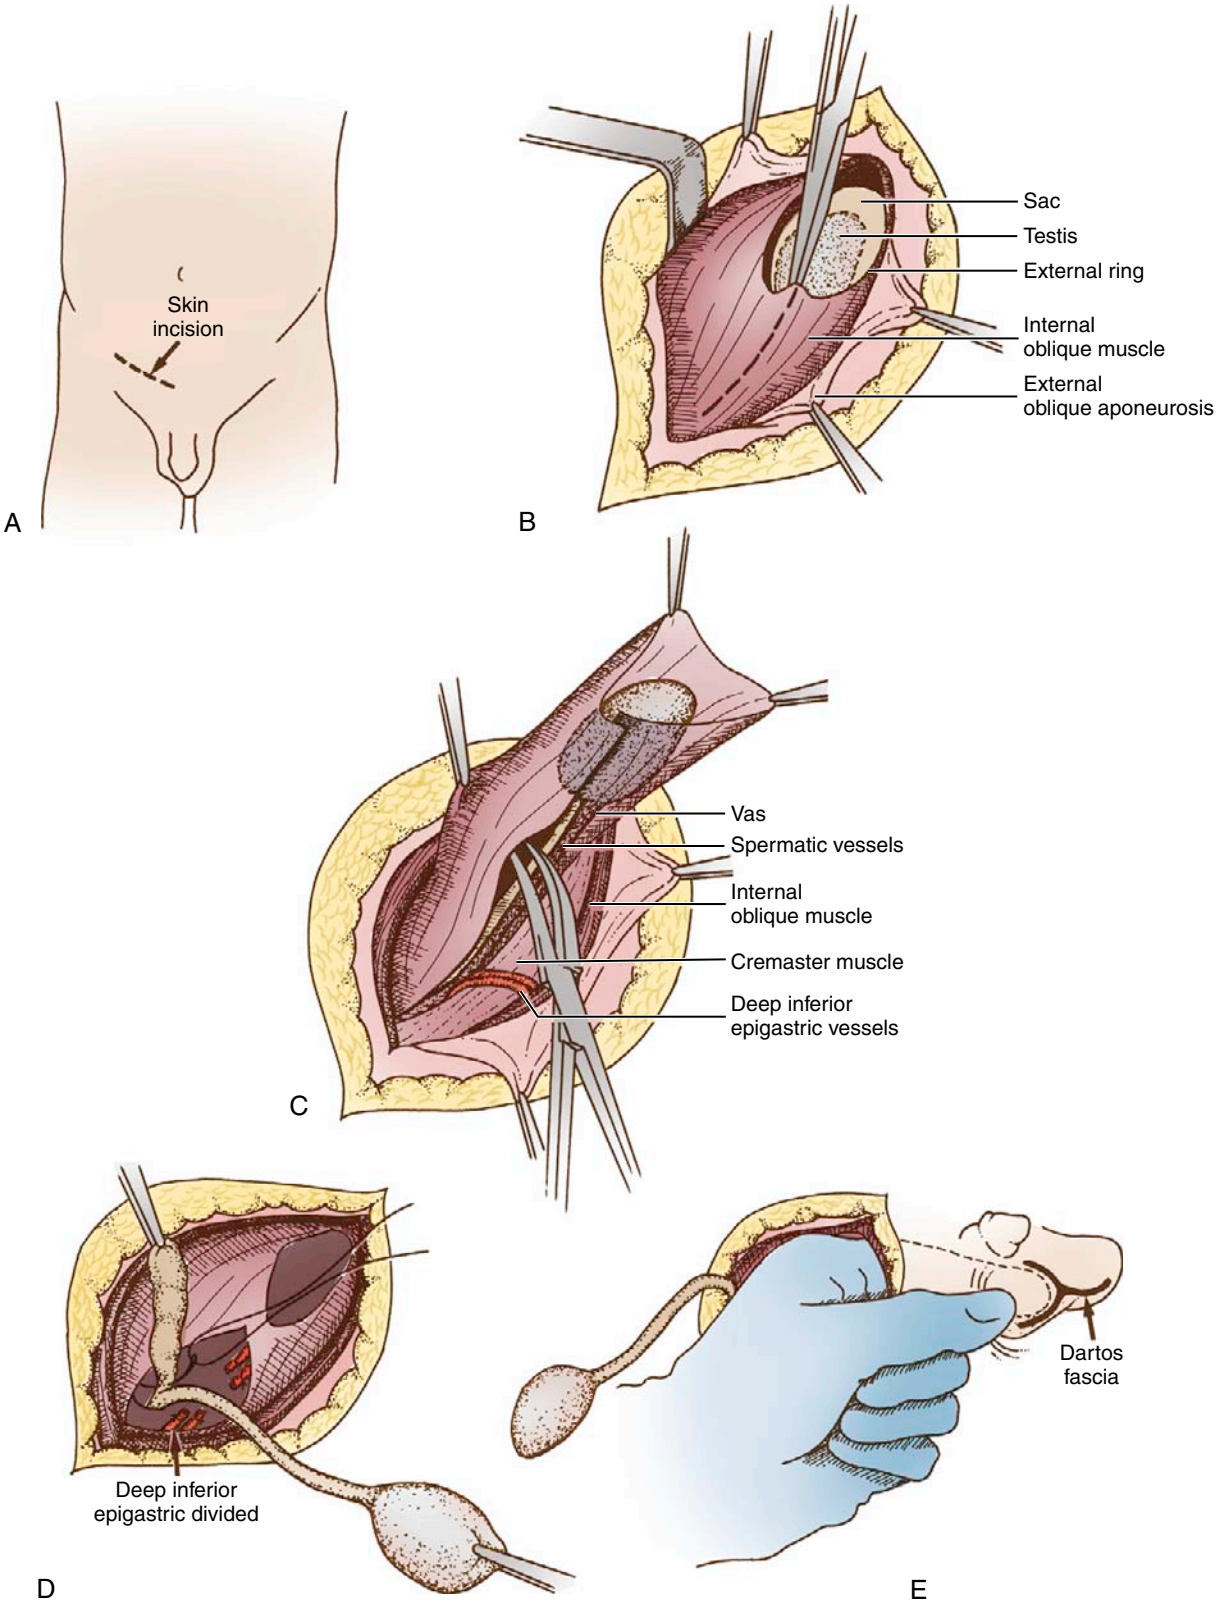

FIGURE 25-34 Orchiopexy.

Continued

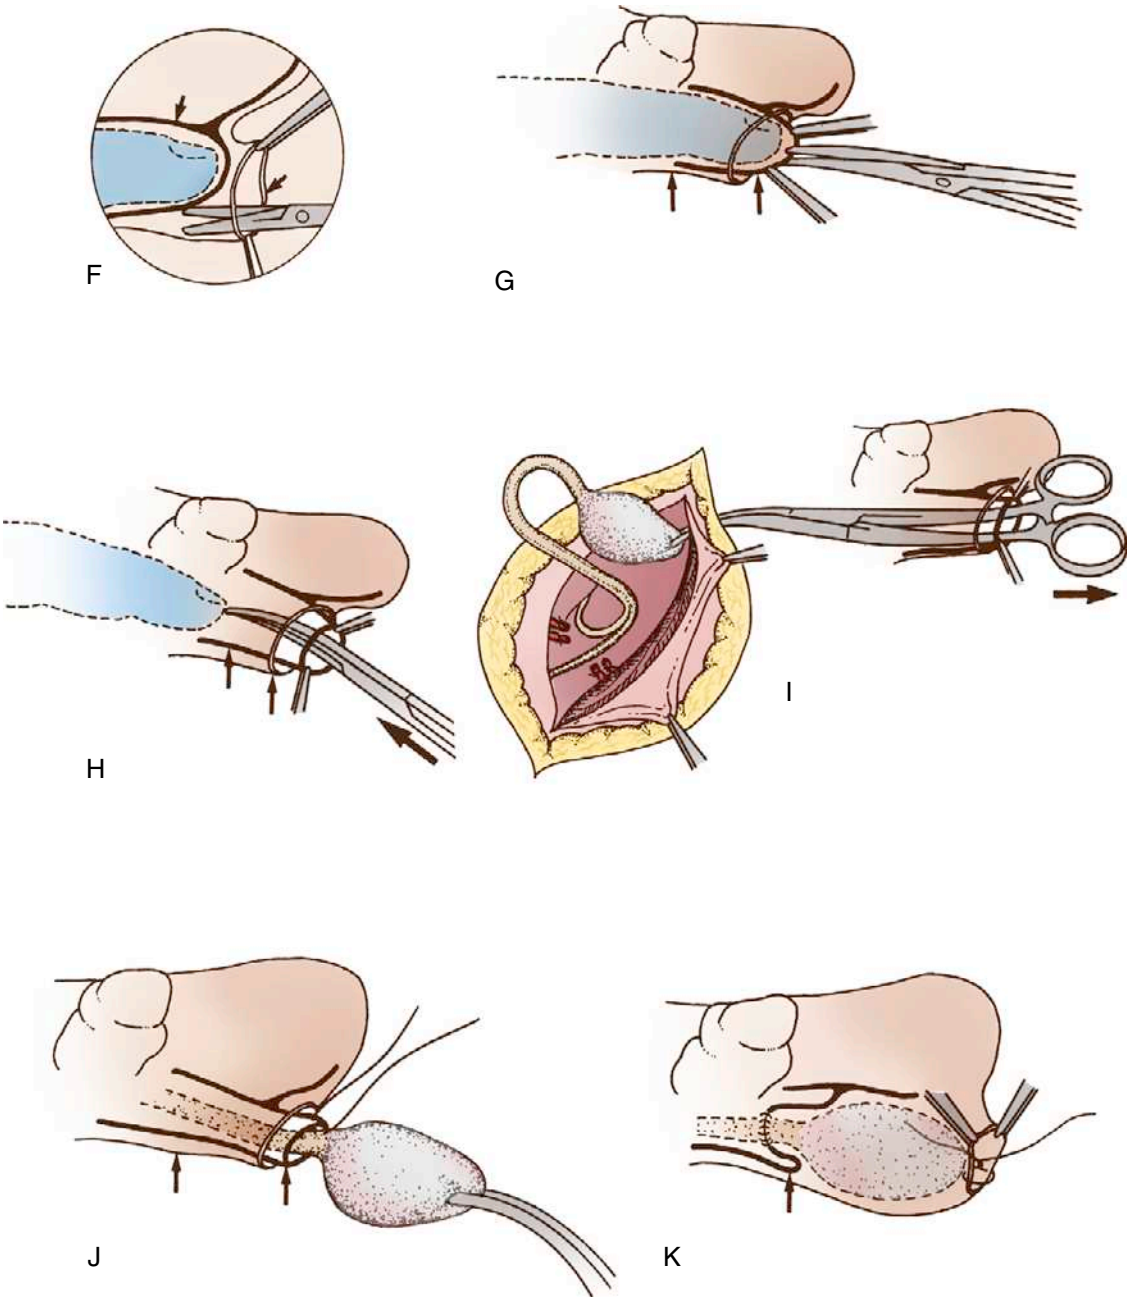

FIGURE 25-34, cont'd Orchiopexy.

5. The needle is removed, the bladder is decompressed, the scope is removed, and the patient is returned to the supine position.

Procedural Considerations—Reimplantation of the Ureter. Reimplantation of the ureter is indicated in children with high-grade VUR. The patient rarely requires a cystoscopy before the operative procedure. A Foley catheter will be placed intraoperatively. The patient is placed in the supine position.

Operative Procedure

1. The surgeon makes a Pfannenstiel incision.
2. The anterior rectus fascia is opened transversely, and then flaps are developed superiorly and inferiorly above the muscle using blunt dissection.
3. The rectus muscle is separated at the midline along the linea alba.
4. The bladder is exposed and then opened in the midline approximately 2 cm above the bladder neck. The bladder is decompressed and then packed with radiopaque sponges.
5. A Denis-Brown retractor is placed, and the trigone is exposed.
6. The ureter is identified, and a 6F or 8F feeding tube is placed; then the ureter is dissected with minimal tissue handling and an absorbable stitch is used to tag the orifice. The ureter is then further dissected sharply with tenotomy scissors, completely freeing it from the bladder wall and allowing it to move freely.

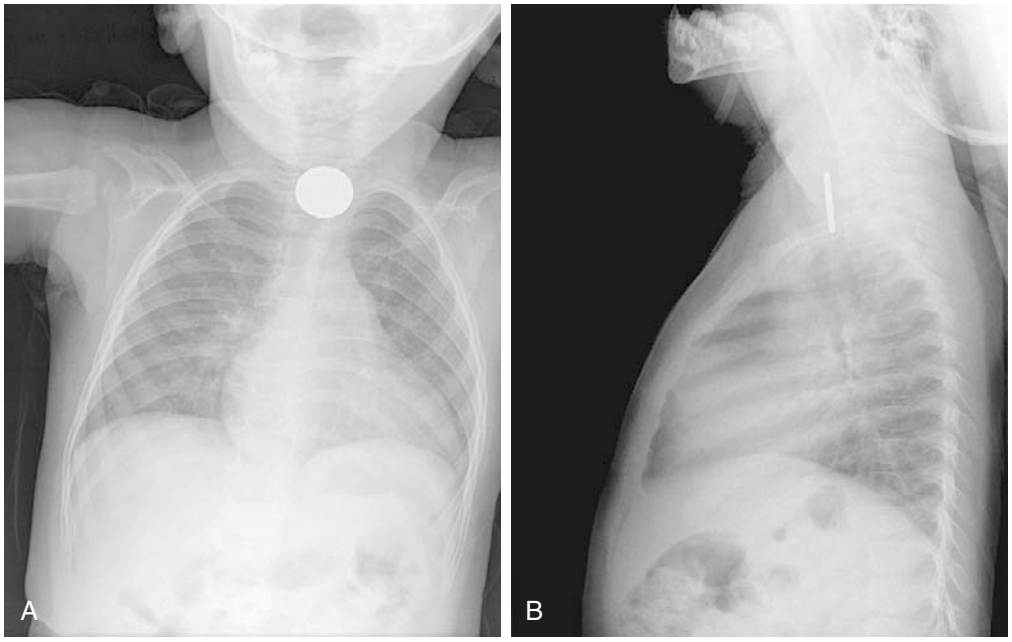

FIGURE 25-35 **A**, Anteroposterior view of coin trapped in esophagus. **B**, Lateral view.

7. The original ureteral orifice is then used to begin the dissection for a tunnel leading to the new outlet between the bladder mucosa and the detrusor muscle.
8. The suture tag is then passed through the tunnel, bringing the ureter to its new outlet.
9. The ureter is sutured in place with interrupted absorbable stitches circumferentially, and the feeding tube is removed from the ureter. If ureteral catheters are left in place, they are exteriorized through the bladder and skin and sutured in place.
10. The sponges are removed from the bladder.
11. The Denis-Brown retractor is removed from the field.
12. The bladder is closed with a running absorbable suture (a suprapubic tube may be placed during the closure). A Penrose drain may be inserted and stitched in place with a nylon suture.
13. The fascia is closed with a running absorbable suture, and the skin is approximated with a running subcuticular closure. Cyanoacrylate glue is applied. If a drain is used, an absorbent wound dressing is applied and Montgomery straps are used in order to make dressing changes easier for the child, using twill tape to string in shoelace-like fashion to close the dressing.

OTORHINOLARYNGOLOGIC PROCEDURES

Foreign-Body Removal

In the normal course of exploration and play, children often ingest foreign objects or place objects in their noses or ears. Most foreign bodies that are ingested pass safely through the digestive tract without incident and do not need to be removed. If the foreign body is sharp, is caustic (i.e., batteries), or becomes lodged (Figure 25-35), it may need to be removed by esophagoscopy (see Chapter 18) or through an open procedure.

The external ear canal and nose are other areas of interest to curious children. Common objects placed in the nares and external ear canal are dried beans, buttons, plastic objects, metals, food, erasers, nuts, seeds, and button batteries. Items placed in the ear can cause bleeding and difficulty with hearing. A high index of suspicion should be raised in the child with unilateral rhinorrhea, nasal crusting, and air outflow obstruction because these symptoms are often caused by a nasal foreign body. Foreign bodies in the nose and ear may require removal in the OR setting with conscious sedation or a general anesthetic.

The most significant risk of foreign-body ingestion is aspiration. Children are more prone to aspiration than adults because their laryngeal sphincters are immature, they do not have molars to chew all foods adequately, and they often run, shout, and play with objects in their mouths. A study conducted at the Johns Hopkins Hospital tracked common aspirated items between 1939 and 1991 (History box). Today, children continue to present with the similar trends in terms of commonly aspirated food items—candy/gum, peanuts and other nuts, seeds, popcorn, hot dogs, vegetable matter, meat matter, and fish bones. The most commonly aspirated nonfood items are coins, toy parts, crayons, pen tops, tacks, nails, needles, pins, beads, and screws. Aspiration may produce a complete or partial airway obstruction (Figure 25-36). Foreign objects in the respiratory tree are removed by means of rigid or flexible bronchoscopy (see Chapter 22).

Tonsillectomy and Adenoidectomy

A tonsillectomy and adenoidectomy is indicated primarily either for relief of pharyngeal obstruction or for recurrent pharyngitis or tonsillitis.

Pharyngeal obstruction is revealed by a history of sleep-disordered breathing. Mouth breathing, snoring, pauses in breathing, restless sleep, waking at night, and enuresis may be related to obstruction. Daytime somnolence and an inability to concentrate may also be indicators of poor sleep quality. Tonsil size is graded on a scale of 1 to 4, with 1 being contained within the tonsillar fossa and 4 with the tonsils touching each

HISTORY

Pediatric Tracheobronchial Foreign Bodies

Direct laryngoscopy and bronchoscopy date as far back as 1895, and the first successful bronchoscopy in the United States took place in 1898. At that time, the death rate for patients with tracheobronchial foreign bodies was 50%. Chevalier Jackson is renowned for developing the diagnostic and therapeutic principles that are the cornerstone of foreign-body evaluation as well as for advancing pediatric foreign-body aspiration treatment. These techniques, in conjunction with improvements in instrumentation and anesthetic management, have resulted in a death rate that is less than 1% today.

A historical review of 167 pediatric tracheobronchial foreign bodies between 1939 and 1991 indicated that 60% were of the vegetable origin, with peanuts accounting for 39.9% overall. Other popular foreign bodies included plastic toys, safety pins/tacks, edible seeds, small hardware (nails, screws), and miscellaneous food items. Foreign-body aspiration occurs most commonly in children ages 6 months to 4 years and is a serious and potentially fatal occurrence. Although foreign-body aspiration is classically diagnosed by a triad of sudden onset of paroxysmal coughing, wheezing, and decreased breath sounds on the affected side, these symptoms may not present in all cases. Furthermore, chest radiographs may show no obstruction, which supports the practice of bronchoscopy as a method to rule out foreign-body aspiration when it is clinically suspected.

Modified from Hughes CA et al: Pediatric tracheobronchial foreign bodies: historical review from the Johns Hopkins Hospital, *Ann Otol Rhinol Laryngol* 105(7):555-561, 1996.

other in the middle of the pharynx. Adenoids are not able to be visualized through the mouth, but symptoms of adenoid enlargement can include mouth breathing, nasal congestion, rhinorrhea, and hyponasal speech. Flexible nasolaryngoscopy and lateral neck radiography can aid in diagnosis of nasopharyngeal obstruction.

Recurrent episodes of pharyngitis sufficient enough to warrant surgical removal should take into consideration the amount of time a child is absent from school, the amount of work time the parent misses, the number of days a child requires antibiotics, and the child's risk for poststreptococccal complications such as glomerulonephritis or mitral valve damage. Three episodes of β-hemolytic streptococcus pharyngitis or more than five episodes of streptococcal/non-streptococcal pharyngitis in the course of a 1-year period would generally merit surgical removal.

An additional reason for tonsillectomy would be a marked difference in tonsil size. Lymphoma on rare occasion may present in this fashion. Unusually enlarged tonsils in an immunosuppressed transplant recipient may also be indicative of post-transplant lymphoproliferative disorder.

Other indications include dysphagia from obstructing tonsils, halitosis from tonsilloliths, and recurrent adenoiditis contributing to sinusitis or otitis media.

A variety of surgical techniques are currently used for tonsillectomy and adenoidectomy. The technique most commonly used is electrosurgery for both (hot) dissection and hemostasis. Other techniques include cold dissection (adenoid curettage and #12 blade for tonsillectomy), radiofrequency, coblation, and laser.

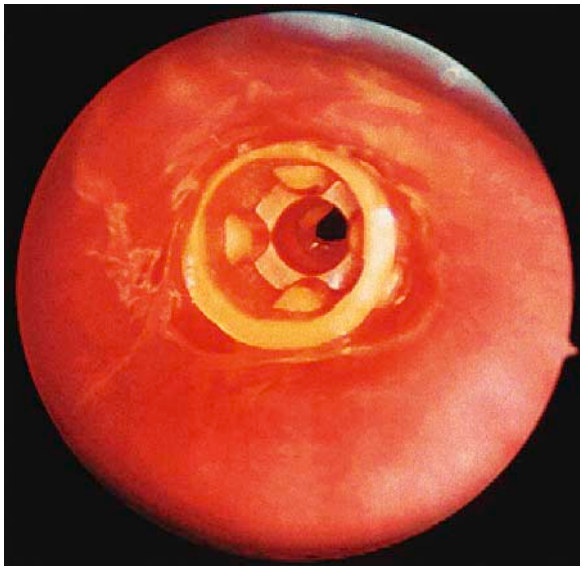

FIGURE 25-36 Foreign body causing partial airway obstruction.

Procedural Considerations. The patient is positioned supine. An oral endotracheal tube with a preformed bend, such as the Ring, Adair, or Elwin (RAE), is used to facilitate visualization of the surgical field. The neck is extended by placing a small roll under the shoulders. Typical draping includes a head drape and an impervious sheet over the patient; no prep is used. The following description is of a hot (electrocoagulation) dissection tonsillectomy with microdebrider dissection adenoidectomy.

Operative Procedure

1. The surgeon inserts a mouth gag retractor with a size-appropriate tongue blade, taking care to keep the tongue in midline position with the endotracheal tube protected by the blade.
2. The posterior and lateral walls of the pharynx are carefully inspected and palpated to detect abnormally positioned vessels.
3. The soft palate is palpated to detect a submucous cleft palate. A bifid uvula is often associated with this anomaly. If this is the case, complete removal of the adenoids can cause velopharyngeal insufficiency.
4. The tip of a 12F red rubber catheter is advanced through one of the nares, into the nasopharynx and out through the mouth. The catheter is gently stretched and the two ends are clamped snugly with a Kelly clamp near the upper lip to retract the soft palate forward.
5. The adenoids are visualized with a laryngeal mirror and removed under direct visualization using either a microdebrider or a suction electrocoagulator. Care is taken to preserve the torus tubarius surrounding the eustachian tube opening. If a microdebrider is used, the nasopharynx is then packed firmly with thoroughly moistened radiopaque tonsil sponges.
6. The superior pole of the first tonsil is grasped with an Allis clamp. A monopolar electrosurgery pencil with a guarded spatula tip is used to make mucosal cuts along the anterior tonsil pillar and superior edge of the fossa.
7. The tonsil is carefully dissected out, following the plane of the tonsillar capsule, while retracting the tonsil medially with the Allis clamp.

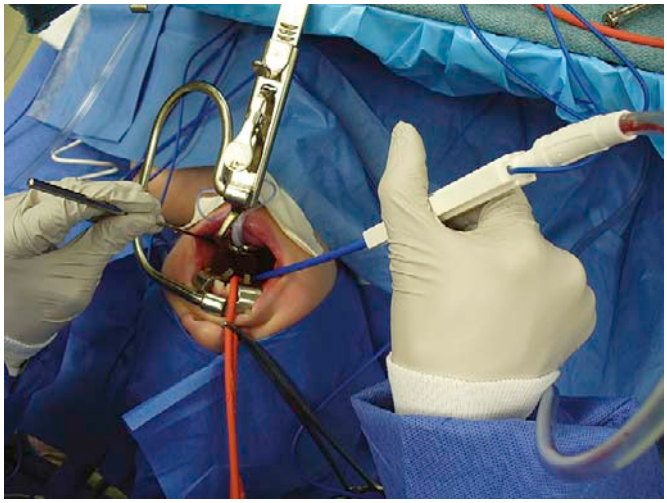

FIGURE 25-37 Electrocoagulation of bleeding in the adenoid bed.

8. The final attachment of the inferior portion of the pharyngeal tonsil to the lingual tonsil is transected with the electrocoagulator. Any vessels encountered during the dissection are electrocoagulated.
9. Monopolar suction electrocoagulation is used to attend to any residual bleeding or prominent bleeding vessels. A Hurd dissector is used to retract the anterior tonsillar pillar and improve exposure of the tonsillar fossa during hemostasis. The laryngeal mirror is used to help visualize the recessed superior pole of the tonsillar fossa.
10. This procedure is repeated for removal of the left tonsil.
11. The sponges packing the nasopharynx are then removed. Any areas of bleeding in the adenoid bed are electrocoagulated using the suction electrocoagulator and laryngeal mirror (Figure 25-37).
12. At this point, the mouth gag is released for a brief period, and then reopened. The nasopharynx and oropharynx are reinspected to ensure that there is no further bleeding from vessels that may have been compressed by the opened mouth gag.
13. The oropharynx may be irrigated with 50 to 60 ml of normal saline solution to evaluate for any additional signs of bleeding. The endotracheal tube cuff should be inflated or the anesthesia provider should maintain positive-pressure inflation during the irrigation to prevent inadvertent passage of the irrigation into the trachea.
14. The red rubber catheter is removed. The mouth gag retractor is carefully removed from the oral cavity to prevent inadvertent extubation of the patient.
15. Dentition, temporomandibular joint mobility, and perioral skin are reinspected for inadvertent surgical complications

Excision of Branchial Cleft Cyst/Remnant/Sinus Tract

Congenital branchial cleft anomalies are remnants of the branchial arch apparatus that failed to disappear during early embryologic development. At approximately 5 weeks' gestation, the branchial arches are associated with an external cleft of ectodermal origin and an internal pouch of endodermal origin. Anomalies that remain from incomplete resolution can be in the form of a branchial cleft cyst, a sinus, or a fistula. The location of branchial cleft anomalies ranges from the preauricular area (type 1) to the lateral neck along the sternocleidomastoid muscle (types 2, 3, and 4). A cyst may not become apparent until later in childhood, typically during times of acute infection or possible abscess formation, and can occur anywhere along the course of a branchial sinus tract or fistulous tract. A sinus tract usually has an external opening to the neck, generally along the anterior border of the sternocleidomastoid muscle. A fistula has both an external opening and an internal opening; the internal opening is usually in the area of the pyriform sinus near the tonsil on that side. Excision of the branchial cleft anomaly is indicated if it is cystic in nature or if it has become infected. The infection must be treated before surgical excision; if an abscess is present an incision and drainage may be needed.

Procedural Considerations. Imaging studies (computed tomography [CT], magnetic resonance imaging [MRI]) are helpful to determine the presence of an associated tract. The patient will be positioned supine with a roll under the shoulders to slightly extend the neck. A surgical drain, such as a rubber band, is frequently placed. Antibiotics are usually given intraoperatively before surgical incision. Description of a branchial cyst (type 2) excision follows.

Operative Procedure

1. A transverse skin crease overlying the lesion and 1.5 cm below the margin of the mandible is selected. The surgeon injects the proposed incision line with 1% lidocaine with 1:100,000 epinephrine.
2. The surgeon makes the skin incision with a #15 blade through the skin and subcutaneous tissues.
3. The platysma muscle is divided with the ESU.
4. The tissues overlying the cyst are gently dissected with fine forceps and small scissors or a small gauze peanut.
5. The cyst is gently grasped with a Babcock clamp. Surrounding tissue is dissected free from the cyst using small scissors to spread between the cyst capsule and surrounding tissue and then to cut through fibrous attachments.
6. If a pedicle or fibrous tract is identified, it is followed as far cephalic as possible before it is clamped, cut, and tied with 3-0 absorbable suture.
7. A small rubber band drain is usually placed to prevent accumulation of fluid or blood in the dissected cavity. A safety pin or suture is attached to the distal end of the drain; the drain is removed within 24 hours.
8. The wound is closed in layers. The skin is closed with subcuticular sutures, and adhesive strips are applied to keep the wound edges approximated.

NEUROSURGICAL PROCEDURES

Neuropathologic conditions requiring surgical intervention can be found in any age group. The most common problems requiring neurosurgical procedures in infants and children include meningocele, myelomeningocele, encephalocele, craniosynostosis, hydrocephalus, brain tumors, and trauma. The surgical approach, instruments, and equipment required for brain tumors and trauma are relatively similar to those required for adults; consequently, the majority of these procedures are as described in Chapter 20.

Myelomeningocele/Meningocele

Myelomeningocele (Figure 25-38) is a form of spina bifida and is always associated with Chiari type II malformations. It occurs because of a congenital flaw in neural tube closure at approximately 8 to 12 days after conception. The failure of the neural tube to close correctly causes a defect in the posterior elements of the lumbar vertebrae, fascia, and dura, allowing the meninges, spinal cord, and nerve roots to protrude out in a sac or cyst through the skin. The exposed spinal cord is called the neural placode and is not properly developed; there is always some degree of paralysis and loss of sensation below the defect. The amount of disability depends on the vertebral level of the spina bifida and frequently includes loss of bladder and bowel function and hydrocephalus. Meningoceles are similar to myelomeningoceles but not as neurologically devastating: meninges and cerebrospinal fluid (CSF) protrude into the defect but not the spinal cord.

Procedural Considerations. Infants born with either of these defects need to be given broad-spectrum antibiotics immediately after birth and taken to the OR within 24 hours for closure of the defect. Nursing care includes ensuring the area of the defect is covered with sterile gauze kept moistened with normal saline solution; positioning the infant so that the defect is not compressed; and maintaining the infant's body temperature, a more difficult task because of the need to keep the exposed defect moist. A very high percentage of children with this defect develop an allergy to latex; surgical closure and all subsequent surgical procedures should be performed in a latex-free environment.

Operative Procedure

1. The surgeon makes an elliptical incision around the defect with a #15 blade.
2. Metzenbaum scissors are used to remove the pearly epithelial tissue around the neural placode. Retention of the epithelial tissue can lead to formation of a postoperative epidermoid.
3. Using the Metzenbaum scissors, the surgeon performs blunt dissection following the nerve tissue on the ventral side of the placode down to the spinal canal.
4. The dura is then separated from the fascia with the Metzenbaum scissors.
5. Using 4-0 braided nylon suture, the surgeon closes the dura over the neural placode.

FIGURE 25-38 Examples of meningocele and myelomeningoceles. **A**, Meningocele. Lesion is covered by skin and meninges. **B**, Myelomeningocele. Neural component evident at central strip of lesion. **C**, Thoracolumbar myelomeningocele. **D**, Severe myelomeningocele. Neural tissue in center represents the open spinal canal.

6. A #11 blade and Metzenbaum scissors are used to free the fascia from the muscle layer.
7. Braided nylon suture is used to close the fascial layer over the dura.
8. The muscle layer is then closed, followed by skin closure.

Craniectomy for Craniosynostosis

Craniosynostosis is the premature fusion of one or more cranial sutures. The condition can occur as part of a syndrome or as an isolated process. Craniosynostosis is characterized as "simple" when only one suture line is involved and "compound" when two or more suture lines are involved. The defect occurs in utero, and the exact etiology remains unknown. The purpose of the cranial sutures is to allow the calvaria to bend during the birth process and to allow the skull to expand to accommodate normal brain growth during infancy. The normal brain is finished growing by 2 years of age; at this time fusion of the cranial sutures normally begins. The fusion process is complete by 8 years of age.

Sagittal synostosis accounts for approximately 50% to 58% of all the synostoses with equal distribution between males and females (Sheth et al, 2008). The sagittal suture runs in the midline of the skull, connecting the anterior fontanelle to the posterior fontanelle. Premature closure of this fontanelle produces an elongation of the skull in the anteroposterior plane. Surgical intervention involves a linear strip craniectomy to excise the sagittal suture line from the anterior fontanelle to the lambdoidal suture line. Surgery is generally performed on the infant between 6 weeks and 6 months of age, with the best cosmetic results coming from the earlier repair. A craniectomy for sagittal synostosis is described.

Procedural Considerations. The infant is positioned supine using a cerebellar headrest. Additional measures need to be taken to maintain the infant's normal body temperature; room temperature should be elevated, and a forced air–warming blanket should be used. An overbed warmer should be used during anesthesia induction and IV placement.

Operative Procedure

1. A sinusoidal incision is made midway between the anterior and posterior fontanelles from ear to ear, just posterior to the pinna.
2. The scalp is elevated off the skull anteriorly and posteriorly to expose the anterior fontanelle, posterior fontanelle, and asterion. Care is used to leave the pericranium attached to the skull to minimize bleeding.
3. A burr hole is made on each side of the sagittal suture on the lambdoidal suture.
4. A craniotome is used to cut anteriorly to the anterior fontanelle on each side of the sagittal suture. A Leksell or Lempert rongeur is used to cut across the sagittal suture and connect the burr holes.
5. A Cobb periosteal elevator is used to carefully dissect the sagittal suture off the underlying dura.
6. A burr hole is placed at the asterion on each side. The craniotome is used to make a curvilinear cut just posterior to the coronal suture.
7. The parietal bone is then "greensticked" (fractured but leaving the periosteum intact) laterally.
8. The skin is then closed with 3-0 and 4-0 absorbable sutures.

Ventriculoatrial and Ventriculoperitoneal Shunts

Hydrocephalus is characterized by excess production of CSF or is associated with a blockage in the ventricular drainage system. Early intervention is indicated in infants to prevent cranial distortion caused by the increasing size of the ventricles (Figure 25-39).

The two most widely used pediatric surgical procedures to divert excessive CSF from the ventricles to other body cavities from which it can be absorbed are ventriculoatrial (ventriculocardiac) (Figure 25-40) and ventriculoperitoneal shunts. See Chapter 20 for complete information related to these two procedures.

ORTHOPEDIC PROCEDURES

Pediatric orthopedic surgery may encompass the following areas: spine disorders, sports medicine, cerebral palsy, musculoskeletal tumors and injuries, foot and ankle disorders,

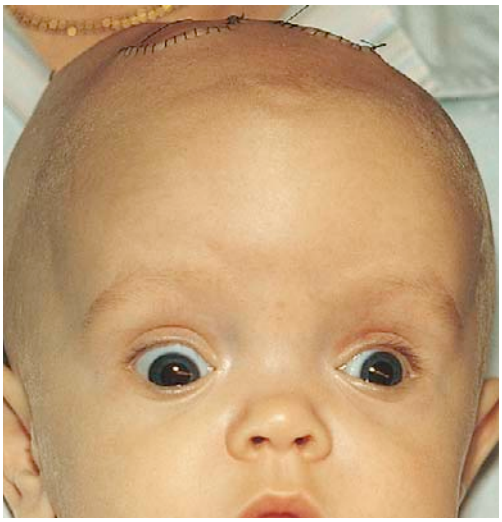

FIGURE 25-39 Infant with hydrocephalus.

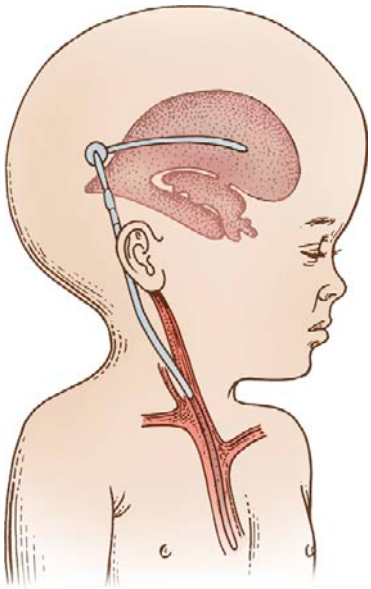

FIGURE 25-40 Placement of ventriculoatrial shunt.

limb length discrepancy, hip disorders, hand surgery, limb deficiency (amputations), thoracic insufficiency, and trauma. The majority of instrumentation, equipment, and procedural considerations are similar to those described in Chapter 19, Orthopedic Surgery. Nonetheless, there are treatment modalities and procedures that are more commonly performed in the pediatric population than in the adult population. Procedures for developmental dysplasia of the hip, abductor and adductor tenotomy, and variations of clubfoot will be described in this section.

Developmental Hip Dysplasia

Until recently, dislocation of the hip seen in newborns was referred to as "congenital dislocation of the hip" (CDH). The term *developmental dysplasia of the hip (DDH)* has replaced the former name to reflect the evolutionary nature of hip problems in the first few months of life. DDH is a progressive condition in which the hip structures fail to develop adequately. Because the pathologic process leading to hip dysplasia may not be present or identifiable at birth, periodic exams of every infant's hips are essential at each routine baby exam until the child is 1 year old. About 1% of infants have dislocated, dislocatable, or subluxatable hips. Sixty percent of DDH cases occur in females, and 60% of all cases involve only the left hip (Wilson et al, 2008). DDH encompasses the entire spectrum of abnormalities involving the growing hip, ranging from simple dysplasia to dysplasia with subluxation or dislocation of the hip joint. The goal of DDH management is to achieve and maintain a concentric reduction of the femoral head within the acetabulum, in order to provide the optimal environment for the normal development of both structures. When proper alignment is disrupted, soft tissue and bony changes cause contractures of the hip muscles, a shallow acetabulum, and possibly a deformed femoral head. Treatment of congenital dislocation of the hip varies depending on the age of the patient and the stability of the hip. A Pavlik harness is the most commonly used nonoperative device in infants. If the Pavlik harness fails, the infant is brought to the OR and anesthetized for a closed reduction of the hip (proper positioning of the femur head within the acetabulum) confirmed by intraoperative arthrogram and fluoroscopy, with application of a spica cast. Failure of closed reduction and immobilization necessitates an open reduction with an adductor tenotomy to allow adequate abduction to reduce the femoral head; after surgery, children younger than 2 years are then placed in a postreduction spica cast. For children older than 3 years the surgeon may need to perform a shortening varus femoral osteotomy (derotational osteotomy) to facilitate reduction of the femoral head into the acetabulum. In addition, if the acetabulum coverage is inadequate, a pelvic realignment (pelvic osteotomy) procedure may be necessary. Many of the pediatric orthopedic plating systems offer congenital dysplastic hip implants, which can be used in the reconstruction.

Procedural Considerations. The patient most often is in the lateral position for these procedures. An anterior incision is usually made for open reduction, whereas a lateral incision is made for the subtrochanteric femoral osteotomy. A soft tissue set and bone set (appropriate for age) are required as well as an oscillating saw, a wire driver, Steinmann pins, blade plate implants, and instrumentation.

Operative Procedure

DDH OPEN REDUCTION (Figure 25-41)

1. The hip joint is opened, and the soft tissue in the acetabulum is excised.
2. The femoral head is then reduced into the acetabulum and held by suturing of the capsule.

DEROTATIONAL OSTEOTOMY. A derotational osteotomy is performed when the femoral head is improperly seated in the acetabulum.

1. The femur is placed in internal rotation and divided.
2. The distal fragment is rotated externally to place the knee and foot straight ahead.
3. If the patient is a young child, the osteotomy is frequently performed in the supracondylar region, and the patient is immobilized in a plaster spica cast.

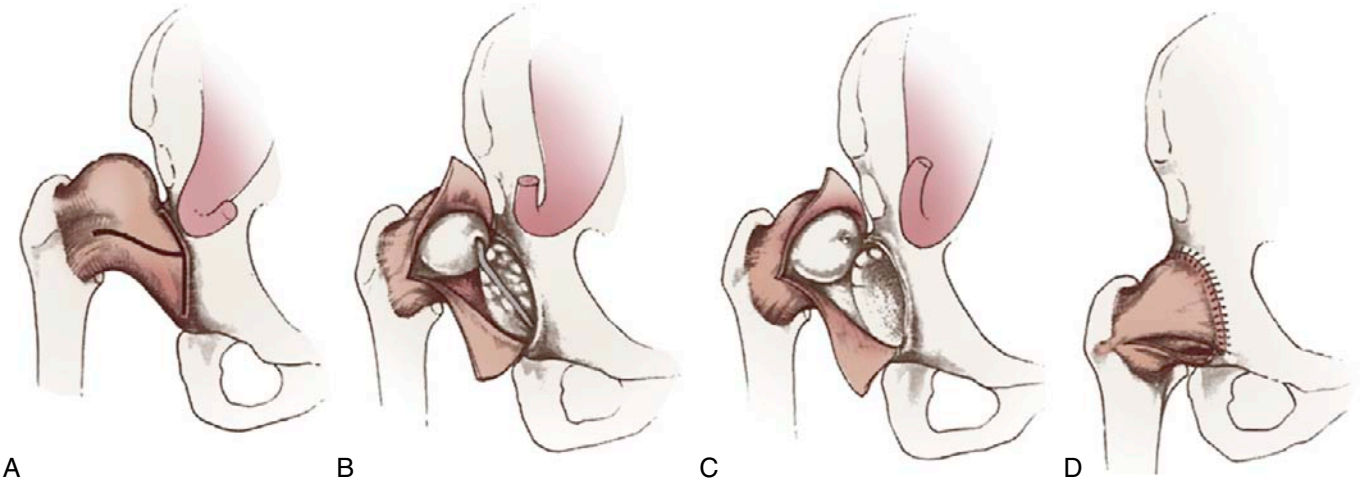

FIGURE 25-41 Repair of congenital hip disorder using open reduction. **A**, T-shaped incision of capsule. **B**, Capsulotomy of the hip and locating the true acetabulum. **C**, Removal of tissue from the depth of the acetabulum. **D**, Capsulorrhaphy.

4. For an older child, the osteotomy is frequently done in the subtrochanteric region and the osteotomized fragments are held with an osteotomy blade plate or an intermediate compression screw. Immobilization may not be necessary.

PELVIC OSTEOTOMY

1. A complete division of the wing of the ilium is made by an osteotomy from the sciatic notch to the anterior margin of the ilium, superior to the acetabulum.
2. The ilium is then wedged down to increase the depth of the acetabulum when the osteotomy site is opened and a bone graft is inserted.
3. Heavy suture is used to close the capsule, and a spica cast is applied for postoperative immobilization.

Tenotomy/Lengthening Procedures

Tenotomies and lengthening procedures are commonly recommended for children with cerebral palsy to treat contractures or because the spasticity of these muscles makes mobility and abduction and adduction of the extremities difficult (Wilson, 2008). These procedures may also be recommended as treatment for groin injuries where traditional medical treatment has failed. Once the tendons are cut, the affected extremity may be immobilized in a cast, brace, or splint to allow for healing and promote normal growth patterns. In other cases, a dressing may be applied without immobilization. The procedure may be performed open (as described here) or using percutaneous techniques.

Procedural Considerations. The patient is positioned supine for the procedure with the affected extremity or extremities draped free for prepping and draping.

Operative Procedure

1. The adductor longus, gracilis, and adductor brevis are lengthened through a medial groin incision to improve hip abduction.
2. The pectineus adductor brevis interval is exposed to locate the iliopsoas tendon. The iliopsoas tendon is divided to correct hip flexion contractures.
3. Wounds are irrigated and closed using absorbable suture. Cyanoacrylate glue dressing is applied to each incision line.

Clubfoot

Clubfoot is a complex deformity that is diagnosed prenatally through ultrasound or at birth. According to the American Academy of Orthopedic Surgeons (AAOS), clubfoot may occur unilaterally or bilaterally and may be idiopathic or one in a combination of other syndromes with associated anomalies (AAOS, 2007). The general characteristic for all cases includes inversion of the foot such that the anterior foot is located in the typical position of the posterior foot. Often, there is a deep crease in the midfoot. Each case of clubfoot differs in severity, but all require treatment. Treatment options include nonsurgical methods such as taping, bracing, physical therapy, or continuous passive motion exercise using a machine. When clubfoot is treated surgically, the following procedures are required: release of soft tissue and joint contractures, tendon lengthening, and temporary pin fixation of the joints in the foot. Many variations of surgical intervention exist, and one method is described in the following Operative Procedure.

Procedural Considerations. The patient is positioned supine for induction of anesthesia and surgical repair. A tourniquet is applied to the affected leg. The leg is prepped and draped free.

Operative Procedure

1. The surgeon makes an incision through the skin, subcutaneous tissue, and scar tissue posteriorly and medially on the affected foot with a #15 blade and dissects the tissue to locate the Achilles' tendon.
2. The Achilles' tendon is lengthened by tenotomy and scar tissue is removed.
3. The peroneal tendons are identified and lengthened by tenotomy, and dissection is carried around to the medial aspect of the foot.
4. The posterior subtalar capsule is identified and divided, and scar tissue is removed.
5. The posterior aspect of the ankle is identified, divided, and debrided of scar tissue. Dissection is carried around medially to the posterior tibialis tendon, taking care to isolate and protect the neurovascular bundle. The posterior tibialis tendon is released.
6. The medial aspect of the talonavicular joint is released. Foot flexion and rotation are verified and the surgical incision is irrigated and closed using absorbable dressings.
7. A bulky dressing and cast are applied to the affected foot and the tourniquet is deflated.

PLASTIC AND RECONSTRUCTIVE SURGERY

Cleft Lip Repair

The normal upper lip is composed of skin, underlying orbicularis oris muscle, and mucosa. Two skin ridges are situated near the midline of the central philtrum of the lip. The vermilion (red portion of the lip) peaks at the philtral ridge on each side and gently curves downward as it reaches the midline to form the Cupid's bow. A deficiency in tissue (skin, muscle, and mucosa) along one or both sides of the upper lip or, rarely, in the midline results in a cleft at the site of this deficiency. The deficiency of tissue present with a cleft lip results in distortion of the Cupid's bow, absence of one or both philtral ridges, and distortion of the lower portion of the nose. Cleft lip is usually associated with a notch or cleft of the underlying alveolus and a cleft of the palate.

Cleft lip repair is most often performed when the infant is about 3 months of age. Timing of the repair follows the "rule of 10": the infant is 10 weeks of age, weighs 10 pounds, and has a hemoglobin level of 10 g/dl. Early surgical correction aids in feeding and infant-parent bonding. Lip repair is directed toward rearrangement of existing tissues to approximate the normal lip as closely as possible. Some considerations may also be given to correcting the nasal deformity at the time of the cleft lip repair.

Procedural Considerations. A plastic surgery local instrument set is required, plus the following special instruments: Brown lip clamps; calipers; a Foment retractor; Beaver blades, #64 and #65; and a Logan bow. The OR bed is usually reversed

to create more knee room if the surgeon prefers to sit during the surgery. The patient is placed in the supine position, with the head at the edge of the OR bed. The face is prepped, and the head drape is used. The surgeon may stand or sit at the patient's side or just above the patient's head during the operation.

Operative Procedure

Many types of cleft lip repair are in common use, one of which is illustrated in Figure 25-42. The following steps are applicable to all lip repairs:

1. Normal landmarks are identified and marked or tattooed. Precise measurements, taken with calipers and a ruler, are made so that corresponding points can be marked along the cleft.
2. The lip may be infiltrated with epinephrine 1:200,000, or lip clamps may be used to aid hemostasis.
3. Incisions are made along the markings for the repair.
4. The abnormal musculature is dissected.
5. Additional dissection along the maxilla and nose may be performed.
6. Closure is done in three layers: muscle, skin, and mucosa. Adhesive strips may be used. A Logan bow is applied to the cheeks with tape strips, and elbow restraints are placed.

Cleft Palate Repair

The palate is composed of the bony or hard palate anteriorly and the soft palate posteriorly. The alveolus borders the hard palate. A separation or cleft of the palate occurs in the midline and may involve only the soft palate or both hard and soft palates. The alveolus may be cleft on one or both sides.

The major function of the soft palate is to aid in the production of normal speech sounds. An intact hard palate is necessary to prevent escape of air through the nose during speech and to prevent the egress of liquid and food from the nose.

Cleft palate repair is usually performed when the child is 6 months of age and should be achieved before the beginning of speech. Variable factors, including the child's weight and the possibility of other disease processes, can affect the timing of the surgery. The various operations used to achieve surgical closure of the palate all employ tissue adjacent to the cleft (in the form of flaps), which is shifted centrally to close the defect.

Procedural Considerations. A basic plastic surgery instrument set is required, plus the following special instruments: Dingman mouth gag with assorted blades; Blair palate hook; palate knives; Blair palate elevators; and Fomon lower lateral scissors, short and long. The patient is placed in the supine position, with the head at the edge of the OR bed. The head drape is used. Many surgeons sit just above the patient's head and cradle the head on their lap (with the patient's neck hyperextended).

Operative Procedure

One of the most frequently used cleft palate repairs is illustrated in Figure 25-43. The following steps are common to all palate repairs:

1. The Dingman mouth gag is inserted. Maintenance of the position of the endotracheal tube is crucial at this point. The surgeon may also insert a throat pack to absorb blood that may drain into the throat.

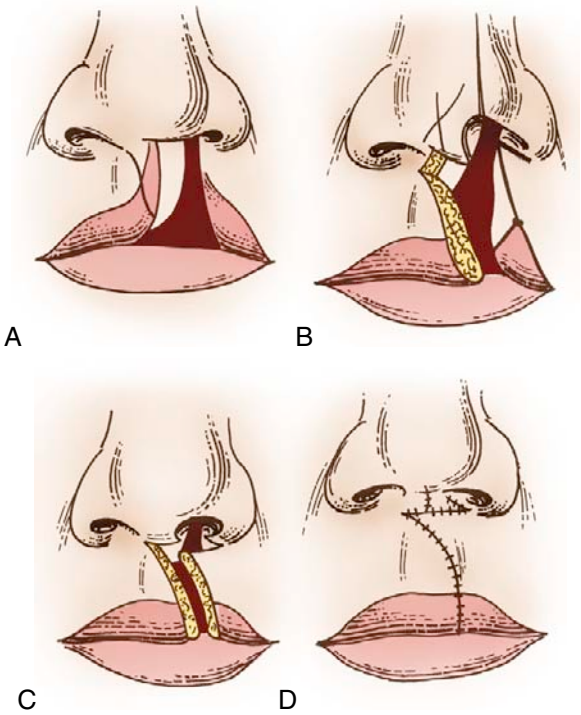

FIGURE 25-42 Rotation-advancement method to correct complete unilateral cleft of lip. **A**, Rotation incision marked so that Cupid's bow–philtral dimple component will rotate down into normal position; flap advances into columella to form nostril sill. **B**, Dimple component has dropped down; second flap has advanced into columella. **C**, Flap is being advanced into rotation gap, while skin-roll flap is interdigitated at mucocutaneous junction line. **D**, Scar is maneuvered into strategic position where it is hidden at nasal base and floor and at philtrum column; then it is interdigitated at mucocutaneous junction.

2. The outlines of the palatal flaps are marked.
3. The palate is injected with 1% lidocaine with epinephrine 1:100,000 for hemostasis.
4. The flaps are incised and elevated.
5. Closure is in three layers: nasal mucosa, muscle, and palatal mucosa.
6. A large horizontal mattress traction suture is placed through the body of the tongue. If the patient experiences upper airway obstruction after extubation, traction is placed on this suture to pull the tongue forward, rather than insert an airway that might harm the palate repair. The throat pack is removed.

Pharyngeal Flap

When abnormal speech (velopharyngeal insufficiency) results despite a cleft palate repair, a secondary surgical procedure may be necessary to improve speech. Primarily an excess of air escaping through the nose during speech characterizes typical "cleft palate speech." This hypernasality often results from insufficient bulk or movement of the muscles of the soft palate. To decrease or eliminate this problem, tissue from the pharynx, in the form of a pharyngeal flap, is added to the soft palate. This flap also reduces the size of the opening between the oropharynx and nasopharynx, thus decreasing or eliminating the nasal escape of air during speech.

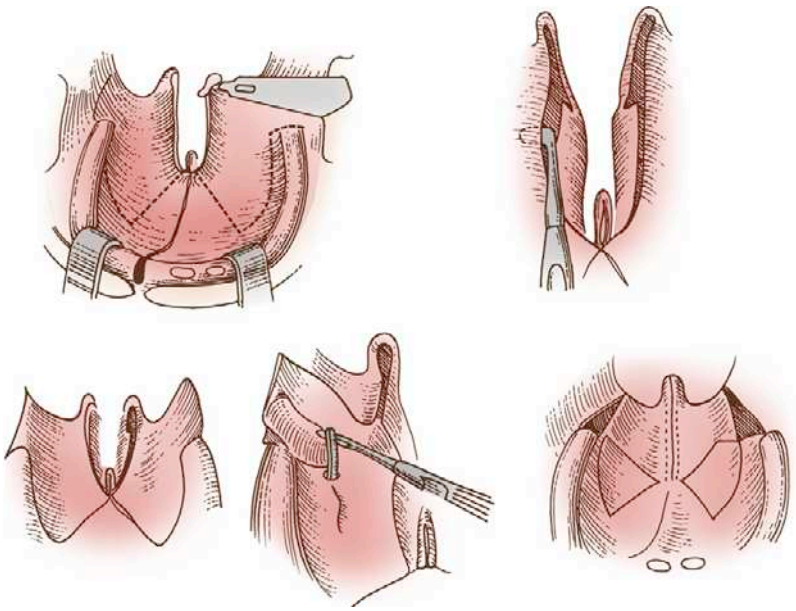

FIGURE 25-43 Closure of cleft of soft palate by V-Y (Wardill-Kilner) palatoplasty. A V-shaped incision is made on oral side of palate; mucoperiosteal flaps are elevated on oral and nasal sides, with preservation of blood vessels; Y-shaped closure (in three layers) closes cleft and lengthens palate.

A pharyngeal flap repair may be done at any age, but most are done before the patient is 14 years old. A pharyngeal flap also may be part of primary cleft palate repair.

Procedural Considerations. Positioning, draping, and instruments are the same as those described for cleft palate repair, with the addition of two 12F red rubber catheters.

Operative Procedure

1. The Dingman mouth gag is inserted. A throat pack may be inserted.
2. The surgeon injects the palate and posterior wall of the pharynx with 1% lidocaine with epinephrine 1:100,000 for hemostasis.
3. The palate is incised, and the pharyngeal flap is incised and elevated.
4. The pharyngeal wall donor site may be sutured or left open.
5. The pharyngeal flap is sutured to the palate, and the palate is closed.
6. A traction suture is placed through the body of the tongue. The throat pack is removed.

Total Ear Reconstruction

An absent external ear presents the surgical team with the objective of developing or restoring a part of the appearance that will help with self-esteem and confidence in daily interactions as well as enhance hearing, since the external ear funnels sound waves from the environment into the inner ear. Emotional support is a key aspect of the plan of care for these patients.

The external ear consists of skin, subcutaneous tissue, and cartilage. The surgical procedure to create an external ear involves the retrieval of rib cartilage, carving the cartilage, placing the newly fashioned ear on the side of the patient's head, and skin grafting and dressing of the operative sites, with continual assessment and reassessment of the preoperative sketches made of the patient's ear with relation to facial structure. This can be accomplished as a one-stage procedure or as a sequence of surgeries. For congenital defects, the ideal time for initiating the procedure is between 6 and 10 years of age. In the case of traumatic loss of the external ear (as from burns), the time is individually determined. The use of tissue expanders may be considered in some cases to stretch the skin surface required to cover the ear.

Procedural Considerations. A basic plastic surgery instrument set is required, with the addition of rib graft instrumentation for autologous rib cartilage retrieval in total ear reconstruction. A sterile Doppler probe with sterile conduction gel should be available for intraoperative use. Preoperative sketches of the ear are done with the use of unexposed x-ray film. Symmetric and anatomic landmarks are vital considerations in the patterns developed for the reconstruction. When the sketches are complete, the films are sterilized with care not to remove the markings made by the surgeon. The patient is supine with the arms tucked securely at the sides. Appropriate padding and protection of vulnerable neurovascular bundles and pressure sites are critical. Use of a sequential compression device and a forced air–warming unit over the lower half of the patient's body should be considered because of the anticipated length of the procedure. Before the skin prep, the surgeon will assess the vascular integrity of the temporoparietal flap with an unsterile Doppler probe and conduction gel and will mark the incision sites. Infiltration of the operative sites with local anesthetic with epinephrine 1:200,000 can be used for hemostasis. Epinephrine in higher concentrations (e.g., 1:100,000) is not recommended for use in the area of the flap because of the possible obliteration of the vascular complexes present. The perioperative nurse preps the patient's face, torso, and an

additional site if a skin graft is anticipated. A standard head drape and a split drape (or U drape) for the patient's torso allow the team access to the auricular area and chest, respectively. Usually two instrument tables are used, with one designated for carving the rib cartilage. Because the procedure is lengthy (6 to 8 hours on average), rolling sitting stools should be provided for the team. Periodic progress of the procedure should be relayed to the patient's family members in the surgical waiting room.

Operative Procedure

1. The temporoparietal fascia flap is lifted, and a sterile Doppler probe and sterile conduction gel are used to assess the vascular integrity of the flap.
2. The chest wall is incised, and the rib cartilage segments are removed with care to preserve the perichondrium. This will encourage bone growth and help to prevent a chest wall defect. The assessment of intact pleura is critical before closure of the chest. Instillation of saline into the wound is done; if bubbles appear, the pleura is not intact; a chest tube is then inserted and attached to a chest drainage system. If the integrity of the pleura is in question, an intraoperative chest x-ray film may be taken to assess for a pneumothorax. If the pleura is intact, closure of the wound is performed and injection of 0.25% bupivacaine to the intercostal incision area is performed.
3. While one team closes the chest, another team begins the process of carving the rib cartilage for the ear reconstruction. The previously marked radiographs are crucial aids for the artistic abilities of the surgeon, providing a blueprint for the sculpting phase of the procedure. Surgical wire is used to connect the carved pieces of rib cartilage as it is shaped to resemble the external ear.
4. A skin graft is taken, and the donor site is covered with a dressing of choice.
5. Hemostasis is maintained with the ESU, topical thrombin, and infiltration of local anesthetic with epinephrine.
6. The flap covers the sculpted ear, and the skin graft is used to cover any exposed areas (this is a technique used especially with burn patients who have less available skin for coverage).
7. Drains are placed and attached to closed-wound suction, or gauze stents wrapped with nonadherent gauze are sutured in place behind the ear. Soft, bulky dressings are applied to the ear and secured with a head wrap of rolled gauze. Standard dressings are applied to the chest wall.

Otoplasty

A congenital deformity in which the ear protrudes abnormally from the side of the head is generally the result of an absent or insufficiently pronounced antihelical fold of the external ear. The various methods of otoplasty are an attempt at correction by creating an antihelical fold that positions the ear more normally (Figure 25-44). Protruding ears may be unilateral or bilateral. An otoplasty is generally performed for children who are uncomfortable or self-conscious about the deformity, usually in the elementary school–age years.

Procedural Considerations. A plastic surgery instrument set is needed. The patient is placed supine on the OR bed, and a head drape is used, leaving both ears well exposed. The patient's head is turned with the affected ear up and with the lower ear well padded to avoid pressure injury.

Operative Procedure

1. The antihelical fold is created when the external ear is bent backward. The position of the antihelical fold is marked by placing 25-gauge or straight needles through the ear from anterior to posterior, applying methylene blue to the tips of the needles, and withdrawing them to mark the cartilage within.
2. An ellipse of skin is excised from the posterior surface of the ear after it has been infiltrated with 1% lidocaine with epinephrine 1:100,000.
3. The ear cartilage is usually incised near the antihelical fold, and the anterior surface of the cartilage is scored to allow it to bend backward.
4. Sutures are usually placed to hold the cartilage in its new position.
5. The skin incision is closed.
6. A drain may be placed to aid in the skin's adherence to the cartilage framework beneath.
7. A nonadherent dressing, such as petroleum gauze or cotton coated with Polysporin antibiotic ointment, is usually placed in front of and behind the ear, followed by fluffed gauze and a bulky dressing made of rolled gauze to exert moderate compression on the ear.

Repair of Syndactyly

Syndactyly refers to a congenital webbing of the digits of the hands or feet. It is occasionally seen in association with other abnormalities, such as extra fingers or toes (polydactyly), or with bony abnormalities. In syndactyly with normal digits, most

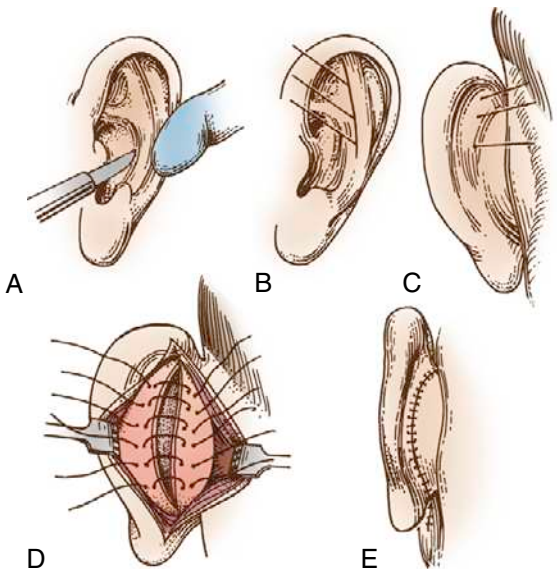

FIGURE 25-44 Otoplasty for correction of protruding ears. **A**, Antihelix defined by application of pressure to ear. **B**, Position of antihelical fold marked by the passage of straight needles through ear. **C**, Needle points visible along posterior surface of ear with ellipse of skin to be excised marked. **D**, Section of ear cartilage incised and scored or excised with sutures placed to hold cartilage back. **E**, Posterior ear incision sutured.

commonly seen, a web of skin joins adjacent fingers (Figure 25-45) but each finger has its own tendons, vessels, nerves, and bony phalanges. Although the skin web may appear loose, a deficiency in skin is always present when surgical separation is performed. Plans for taking a skin graft (usually full thickness) should always be made. Surgical separation of syndactyly is performed at any time, usually after approximately 12 months of age.

Toe syndactyly is less often treated surgically than finger syndactyly because proper function of the foot does not require fine movements of individual toes. Although the setup and description that follow are for the repair of finger syndactyly, they can also be applied to the repair of toe syndactyly.

Procedural Considerations. A plastic surgery local instrument set is required, plus a sterile marking pen, sterilized unexposed x-ray film, a pediatric pneumatic tourniquet, and an Esmarch bandage. The patient is placed supine on the OR bed with the affected arm extended on a hand table. A hand drape is used, and the affected hand and wrist are prepped and draped as well as both inguinal areas (donor sites for full-thickness skin grafts). Some surgeons prefer to use the wrist or forearm as donor sites.

Operative Procedure

1. The skin is incised and small flaps at the sides of fingers and in the web are elevated.
2. After the flaps have been sutured into position, patterns of areas of absent skin on the sides of fingers are made and transferred to the skin-graft donor site.
3. The skin graft is taken; if a full-thickness skin graft is used, it must be defatted before the graft is sutured in place.
4. Skin grafts are sutured to fingers.
5. Stent dressings are placed over the skin grafts. The entire hand is immobilized in a bulky dressing or in a long arm cast.

FIGURE 25-45 Syndactyly involving third and fourth fingers.

Orbital-Craniofacial Surgery

Some congenital anomalies involve the orbital-craniofacial skeleton. These include hypertelorism, in which the distance between the orbits is increased as seen in Crouzon's disease and Apert's syndrome. Crouzon's disease (Figure 25-46) is characterized by premature closure of the cranial sutures, resulting in an abnormally shaped skull, exophthalmos and hypertelorism, parrot's beak nose, and maxillary hypoplasia. Apert's syndrome (Figure 25-47) includes the same craniofacial deformities as Crouzon's disease and also syndactyly or other hand anomalies. Recent advances in plastic surgery make surgical correction of some of these deformities possible.

Binocular vision is normal in humans. It involves the coordinated use of both eyes to obtain a single mental impression of objects. Binocular vision is usually absent in craniofacial anomalies because of the increased distance between the orbits. The purposes of orbital-craniofacial surgery are to provide the patient with binocular vision by moving the orbits closer together and to provide the patient with a more acceptable appearance by moving the bones of the orbital-craniofacial skeleton into a more normal position. Correction of the

FIGURE 25-46 Crouzon's disease.

FIGURE 25-47 Apert's syndrome.

deformity seen in Crouzon's disease and Apert's syndrome involves a surgically created Le Fort III maxillary fracture.

Although an extracranial approach may be used, an intracranial approach is used in most cases; therefore a neurosurgeon and a plastic surgeon perform these operations through a bifrontal (coronal) craniotomy. A tracheostomy may be done before the start of the procedure. Bone grafts from hips or ribs are necessary to augment areas of bone deficit, which result from movement of the craniofacial skeleton.

Procedural Considerations. These operations are usually performed on children. They are very extensive procedures, often lasting 12 to 14 hours. Blood loss is considerable. Postoperative complications, such as cerebral edema or meningitis, can be formidable. The perioperative nurse must pay particular attention to the following important details: (1) insertion of a Foley catheter into the patient's bladder before the operation is started, (2) positioning of the patient on the OR bed so that all bony prominences are well padded, and (3) availability of accurate means for measuring blood loss. Use of a sequential compression device and forced air–warming units should also be anticipated.

A basic plastic surgery instrument set, craniectomy instruments and supplies (see Chapter 20), plastic hand instrumentation, and tracheostomy instruments and supplies are required. A high-speed drill, saws, and general orthopedic instrumentation are also needed. A separate setup is necessary for obtaining the bone graft.

The patient is positioned, prepped, and draped as described for bifrontal craniotomy (see Chapter 20). The entire face is left exposed, however, and may temporarily be covered with a plastic drape until the portion of the operation requiring access to the face is reached. The bone-graft donor site is also prepped and draped so that both iliac crests and the lower ribs are exposed.

Operative Procedure

1. Tracheostomy, if required, is performed first, followed by application of arch bars (when indicated as in Crouzon's disease and Apert's syndrome).
2. The bifrontal craniotomy with craniectomy is performed.
3. Bilateral orbital osteotomies (Figure 25-48, *A*) into the anterior cranial fossa are performed. Bilateral conjunctival (lower eyelid) and labiogingival sulcus incisions (for Crouzon's disease and Apert's syndrome) are made for orbital and maxillary osteotomies.

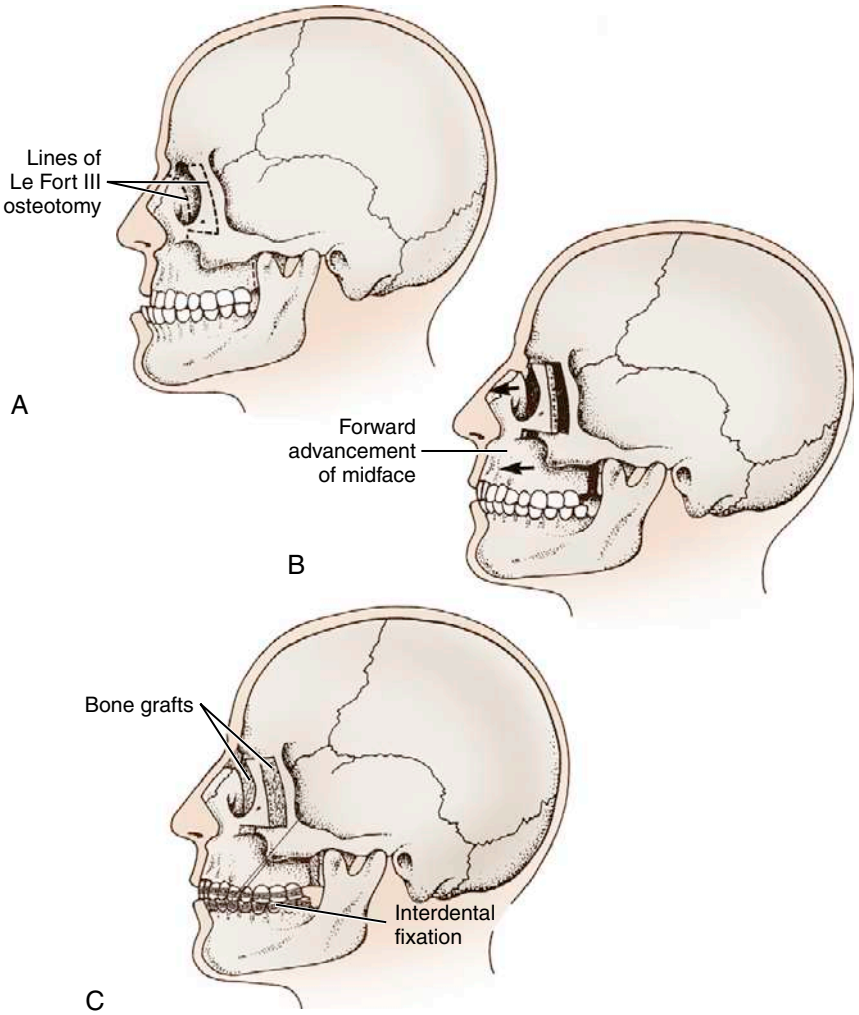

FIGURE 25-48 Steps in surgical correction of Crouzon's disease deformities.

4. The bones of the orbital-craniofacial region are now moved (Figure 25-48, *B*), based on measurement of the intercanthal distance (in hypertelorism) or occlusion of the teeth (in Crouzon's disease and Apert's syndrome).
5. Bone grafts may be taken from the calvaria, ribs, or hips to augment areas of bone deficit, which result from movement of the craniofacial skeleton.
6. Bone grafts are fixed in place with interosseous wires and by means of intermaxillary fixation applied to arch bars (for Crouzon's disease and Apert's syndrome) (Figure 25-48, *C*). Rigid plate-and-screw fixation is another option.
7. The craniotomy, conjunctival, intraoral, and bone-graft donor site incisions are closed and dressings applied.

Pediatric Ophthalmic Surgery

Although the anatomy of the eye remains the same (refer to Chapter 17), children experience different eye conditions from adults that are specifically related to vision development in the brain. Vision develops in the brain until approximately 9 years of age. It is affected by eyes that are not straight or do not focus correctly. Therefore it is imperative that any vision problems are detected and corrected early.

Pediatric ophthalmologists participate in specific programs of study that focus on examination and care of childhood vision problems and structural disorders of the eye. Their scope of practice includes not only examination and treatment, such as vision testing and treatment of eye infections, but also surgical management of disorders such as congenital nasolacrimal duct obstruction, pediatric cataracts, ptosis, strabismus, pediatric glaucoma, and eye injuries (American Association for Pediatric Ophthalmology and Strabismus [AAPOS], 2005). It is not uncommon for pediatric ophthalmology to be subdivided into specialty categories. The field of oculoplastics was first identified in 1966. Oculoplastics encompasses the merging of plastic surgery and ophthalmology in attempt to treat or repair the oculo-orbital region of the face, be it structural (drainage problems) or cosmetic in nature (Whitaker, 2002). Surgeons may also focus their practice on corneal disorders, retinal disorders, or neuro-ophthalmology.

***Eye Muscle Surgery for Strabismus** (Figure 25-49).* Any misalignment of the eyes is called strabismus. Strabismus is further subdivided into the categories listed in Box 25-4. Strabismus occurs as a result of poorly controlled neuromuscular eye movements. Any child can suffer from strabismus, but disorders that affect the brain (cerebral palsy, hydrocephalus, Down syndrome, brain tumors) are associated with an increased prevalence of the disorder. Additionally, strabismus may occur in conjunction with traumatic brain, nerve, or ocular injury.

The goal for treatment of strabismus is to straighten the eyes so that binocular vision functions appropriately. Nonsurgical treatments may include eyeglasses and eye exercises. Surgery may be recommended to change the alignment of the eyes relative to each other by strengthening, weakening, or repositioning the eye muscles. If a child presents with strabismus in addition to another eye disorder (e.g., ambylopia, cataract, or ptosis), the other condition will be treated before corrective surgery.

Skin incisions are not necessary to repair strabismus. Instead, the surgeon will use a lid speculum to retract the eyelid and incise the conjunctiva to expose the muscles. Box 25-5 differentiates between the methods of muscle repair. The repaired muscles are sutured using a standard knot or adjustable suture. Adjustable sutures consist of temporary knots (bow or slip) placed in an accessible position so that eye alignment can be altered approximately 24 hours after surgery. The lateral rectus recession and lateral rectus resection procedures are described below.

PROCEDURAL CONSIDERATIONS. The patient receives a general anesthetic, and the full face above the nose is prepped with half-strength Betadine. Both eyes are prepped so that the repair can be measured against the contralateral eye for symmetry.

OPERATIVE PROCEDURE—LATERAL RECTUS RECESSION

1. A lid speculum is placed in the affected eye and the unaffected eye is taped closed.
2. The infratemporal limbus is grasped using Moody locking forceps and the eye is rotated superonasally.
3. A conjunctival fornix incision is made posterior to the limbus in the infratemporal quadrant.

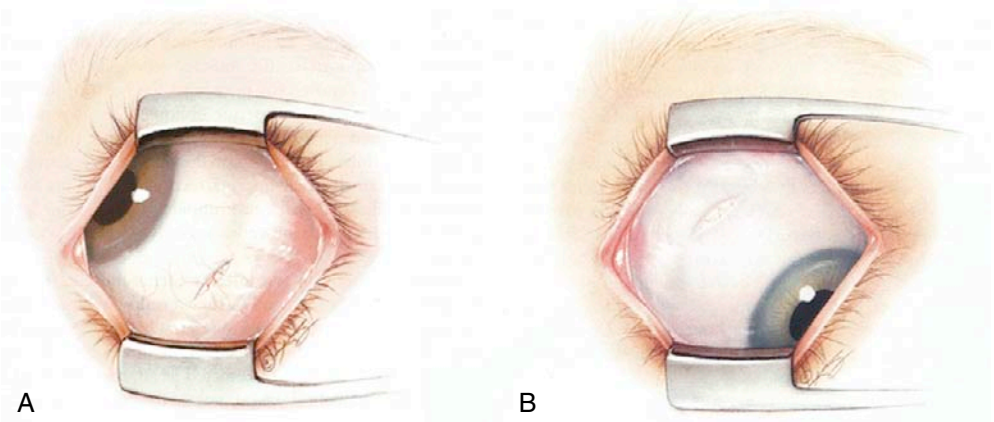

FIGURE 25-49 Forniceal incisions for strabismus surgery. All six muscles can be isolated from these two incisions. **A,** Inferotemporal incision: isolates the lateral rectus, inferior rectus, and inferior oblique muscles. **B,** Superonasal incision: isolates the medial rectus, superior rectus, and superior oblique muscles.

4. Tendons and episclera are dissected until bare sclera is reached, and the lateral rectus is isolated with a Green muscle hook.
5. A suture is passed through the original insertion of the lateral rectus muscle and locked on superior and inferior aspects. The muscle is then cut from its insertion on the globe using Aebli scissors.
6. Calipers are used to mark a location posterior to the insertion point, and suture is passed through the sclera using "crossed swords" technique.
7. The muscle is pulled up firmly to the globe and tied into position. The location is measured again using calipers.
8. Conjunctiva is closed using plain gut suture.
9. The surface of the eye may be covered in neomycin/polymyxin/dexamethasone and tetracaine ointment.

BOX 25-4

Types of Strabismus

- Esotropia: Inward turning of one or both eyes
- Exotropia: Outward turning of one or both eyes
- Hypertropia: One eye higher than the other
- Hypotropia: One eye lower than the other

BOX 25-5

Methods of Muscle Repair

RECESSION
- Is a weakening procedure.
- Alters the attachment site of the eye muscle on the eyeball.
- Muscle is cut from the surface of the eye and reattached at a point further back from the front of the eye.

RESECTION
- Is a strengthening procedure.
- Extraocular muscle is reattached to the eyeball at its original site.
- A section of the muscle is removed and a stitch is placed in the muscle at the intended new attachment site.
- The segment of muscle between the stitch and the eyeball is removed.
- The shortened muscle is reattached to the eye.

OPERATIVE PROCEDURE—LATERAL RECTUS RESECTION

1. A lid speculum is placed in the affected eye and the unaffected eye is taped closed.
2. The infratemporal limbus is grasped using Moody locking forceps and the eye is rotated superonasally.
3. A conjunctival fornix incision is made posterior to the limbus in the infratemporal quadrant.
4. Tendons and episclera are dissected until bare sclera is reached, and the lateral rectus is isolated with a Green muscle hook.
5. A suture is passed through the original insertion of the lateral rectus muscle and locked on superior and inferior aspects. The central sutures are tied together and a resection clamp is placed anteriorly.
6. The muscle is cut anterior to the resection clamp, and the remaining muscle stump is cut from its original insertion point.
7. The suture needles are passed through the original insertion in a perpendicular fashion and tied together.
8. The muscle is pulled up firmly to the globe and tied into position.
9. Conjunctiva is closed using plain gut suture.
10. The surface of the eye may be covered in neomycin/polymyxin/dexamethasone and tetracaine ointment.

Ptosis (Blepharoptosis) Surgery. Defined as a droopy eyelid, ptosis is either congenital or acquired. Congenital ptosis (Figure 25-50) is usually a result of a deficit in the levator palpebri muscle in the upper eyelid. Acquired ptosis occurs as a result of neurologic conditions that affect the nerves of the eye (myasthenia gravis, Horner's syndrome, third nerve paralysis). It can also manifest in conjunction with movement disorders, resulting in double vision. Ptosis may also result from orbital tumors.

Ptosis is treated with corrective lenses if amblyopia with astigmatism is present. Surgery is indicated for cases in which the droopy eyelid is blocking normal vision or causes the child to position their head with the chin up in attempt to compensate for the block in vision. The goal of surgery is to create as perfect of an anatomic result as possible by elevating the position of the lid, creating a lid fold, and preserving the contour and symmetry of both lids (Figure 25-51). The Fasenella-Servat procedure is indicated for mild congenital ptosis (less than 2 mm of lid droop) with good levator function. Variations of this procedure are favored over

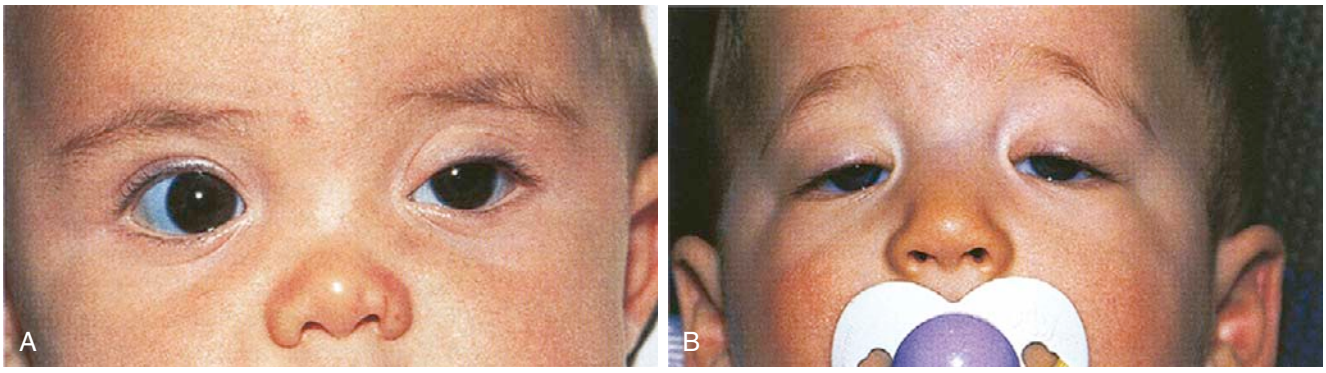

FIGURE 25-50 Simple congenital ptosis. **A**, Unilateral. **B**, Bilateral.

other types of repair, including Werb's procedure (Heher & Katowitz, 2002).

PROCEDURAL CONSIDERATIONS. The patient is positioned supine with the head on a gel ring. The eyes are prepped with half-strength povidone-iodine (1:1 povidone-iodine and normal saline solution). The patient is draped to expose both eyes for comparison during the procedure. Ointment is applied to the contralateral eye, and the eye is taped shut for protective purposes during surgery.

OPERATIVE PROCEDURE

1. A scleral shell is placed into the affected eye to protect the globe.
2. The upper lid is everted and two curved hemostats are placed at the upper tarsal border and adjusted so that the tips are centrally located (Figure 25-52, *A*).
3. Traction sutures are passed through the tissue at the nasal and temporal end, approximately 3 mm below the clamps (Figure 25-52, *B*).

FIGURE 25-51 Modified Fasenella-Servat procedure. **A**, Preoperative. **B**, Six months postoperative.

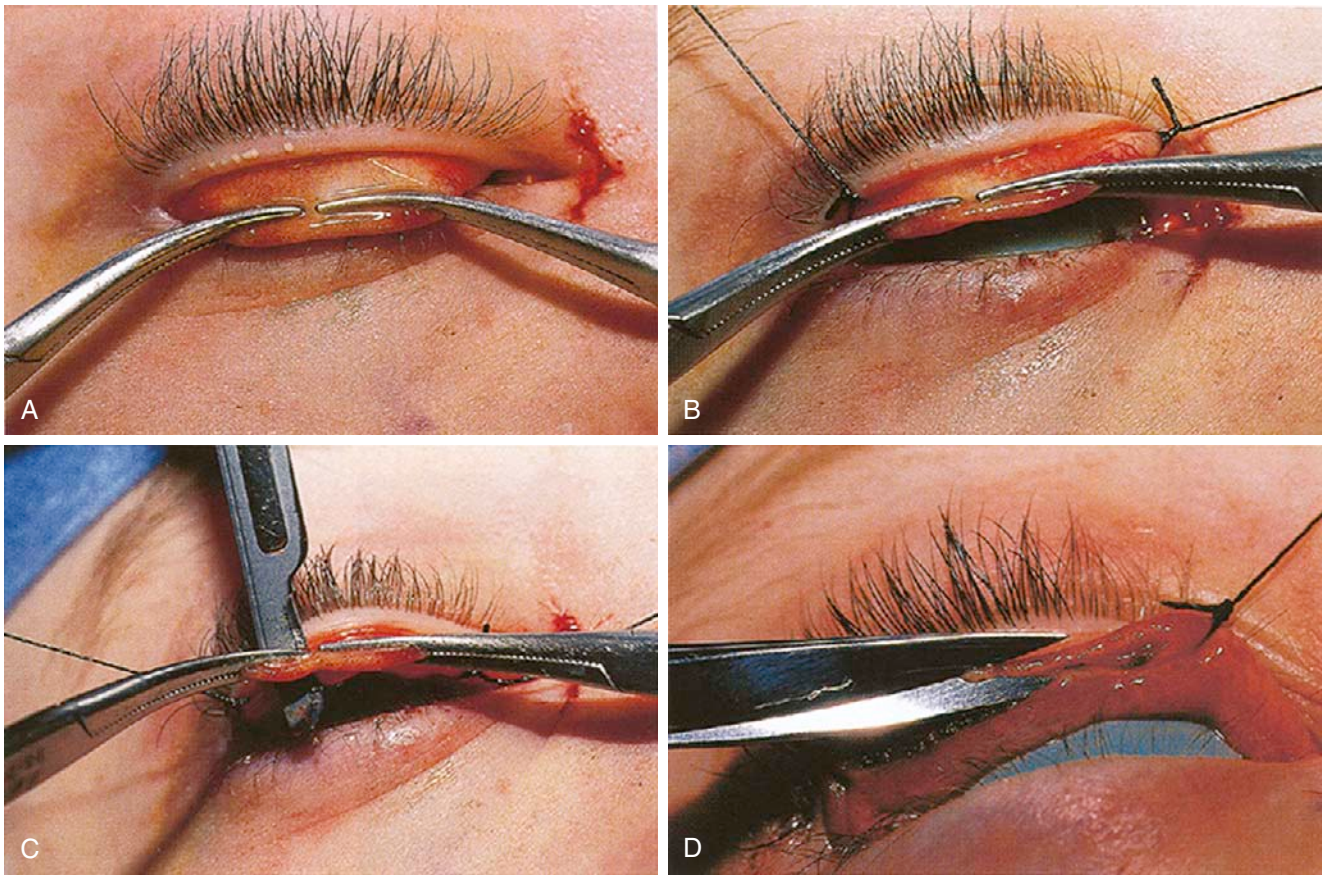

FIGURE 25-52 Modified Fasenella-Servat procedure. **A**, Hemostats at upper tarsal border. **B**, Passage of traction sutures. **C**, Excision of tissue using blade. **D**, Excision of tissue using sharp scissors.

Continued

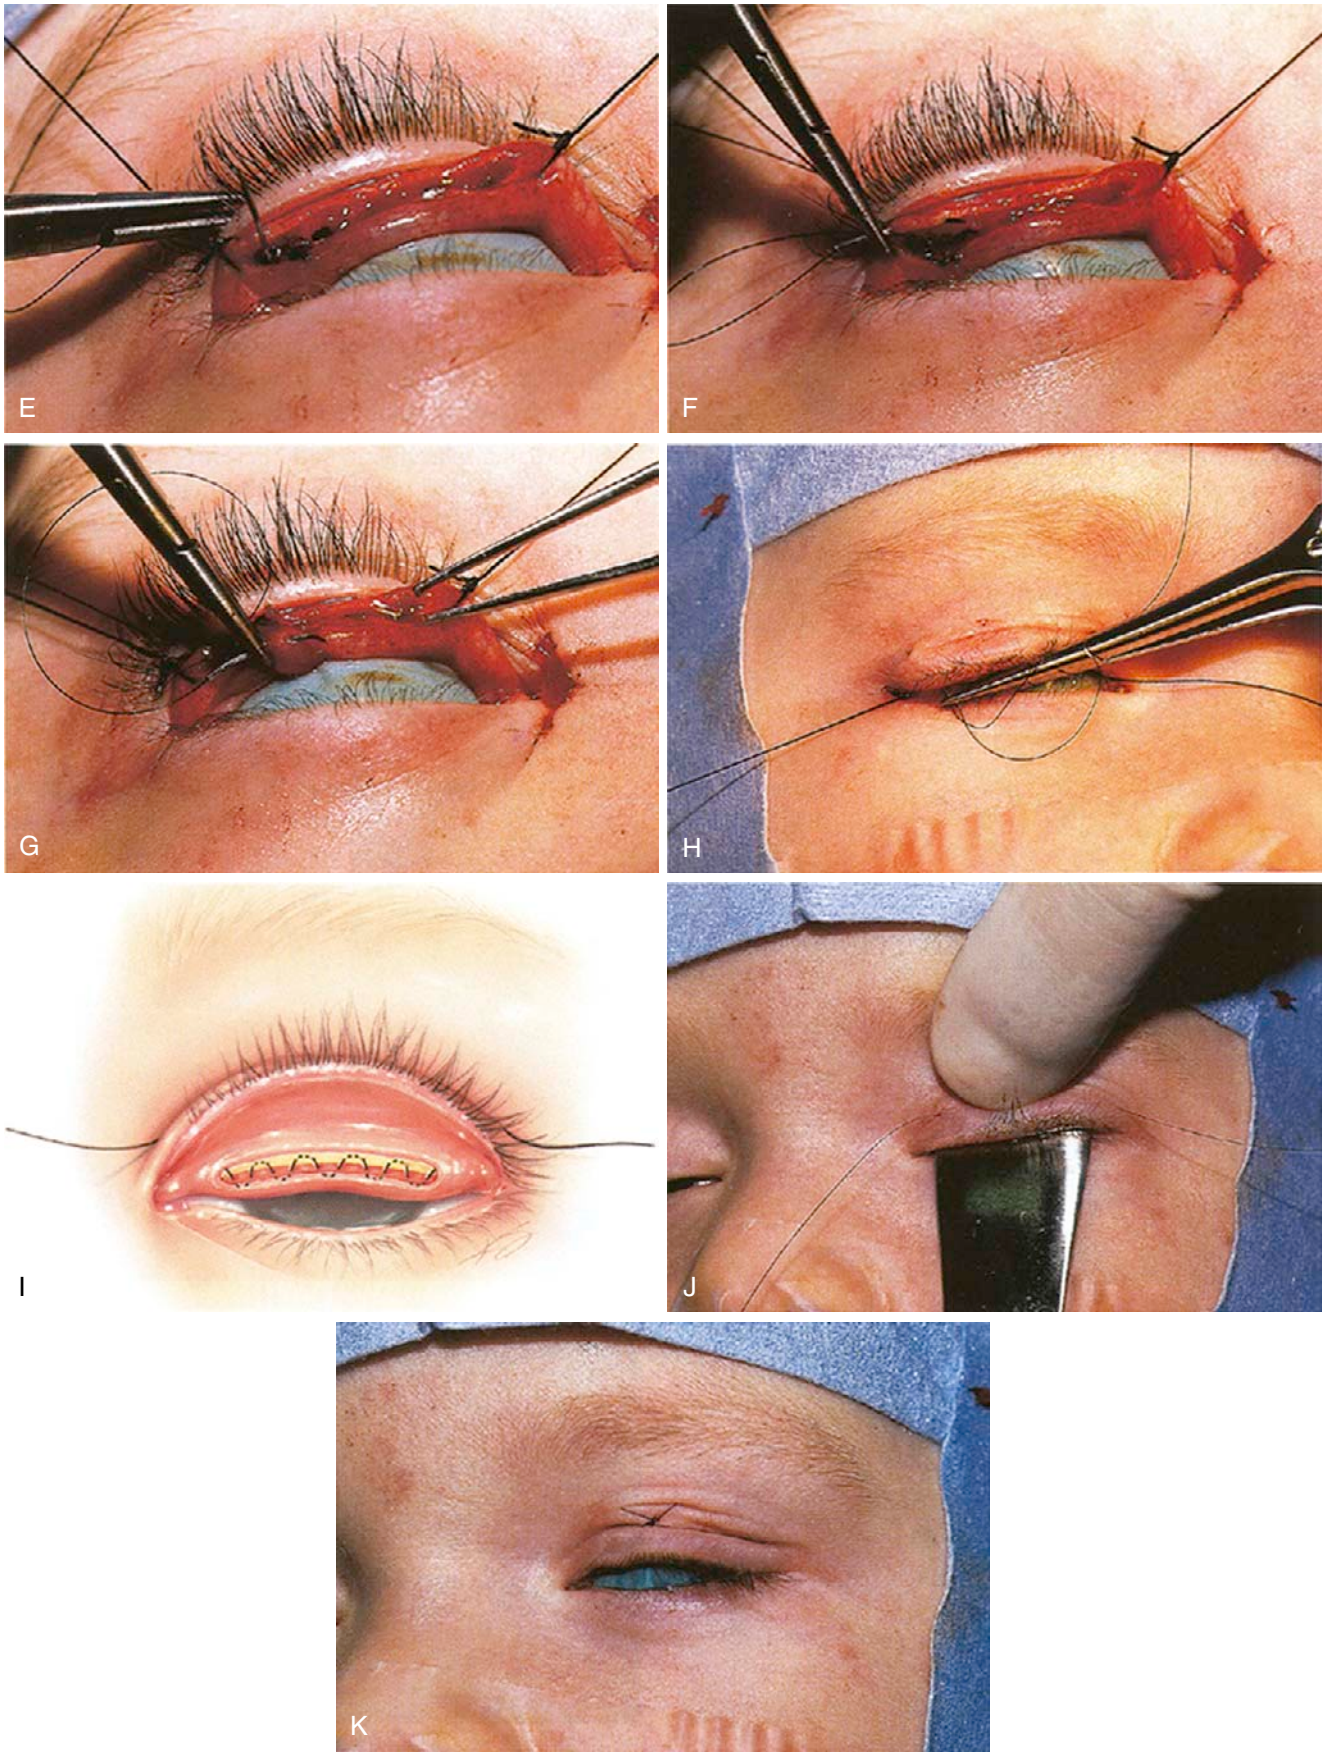

FIGURE 25-52, cont'd **E-G**, Reconnection of conjunctiva and Müller's muscle to edge of tarsus. **H** and **I**, Suture passed through apex of incision and out through crease. **J**, Smoothing incision line with lid plate. **K**, Nylon suture allows for lid adjustment.

4. The tissue between the two clamps and traction sutures is excised using a #15 blade (Figure 25-52, *C*) or sharp scissors (Figure 25-52, *D*).
5. A nylon suture is passed through the end of the lid crease out through the apex of the incision and run in a "serpentine" fashion. The suture reconnects the conjunctiva and Müller's muscle to the cut edge of the tarsus (Figure 25-52, *E* to *G*).
6. At the opposite end of the incision, the suture is passed through the apex of the incision and out through the crease, and then buried beneath the conjunctival surface (Figure 25-52, *H* and *I*).
7. The traction sutures are removed and the lid is returned to its normal position. A lid plate is used to smooth the incision line by pressing directly on the skin surface to flatten the tissues against the plate (Figure 25-52, *J*).
8. The nylon suture is tied snugly over the skin and remains in place approximately 1 week following surgery to allow for lid adjustment (Figure 25-52, *K*).
9. The scleral shell is removed and antibiotic ointment is applied to the eye and suture line. A dressing may be applied to the surgical site.

Cataract Surgery. Cataracts occur in approximately 3 out of 10,000 children and are primarily classified as nuclear, lamellar, or traumatic in nature (AAPOS, 2005) (Box 25-6). If a cataract causes significant vision loss, it must be removed as soon as possible. An intraocular lens may be used in order to replace the focusing power once the natural lens is surgically removed. Criteria for placement of an intraocular lens specify that the child must be 1 year of age or older, as these devices have not been approved by the U.S. Food and Drug Administration for younger populations. In these instances, other options include wearing glasses or contact lenses to correct the deficit.

Corneal Surgery. The cornea is only about 0.5 mm thick, and consists of many layers. The stroma is the thickest part of the cornea. Diseases of the cornea include, but are not limited to, allergies, conjunctivitis (pink eye), corneal infections, dry eye, herpes zoster (shingles), ocular herpes, pterygium, and Stevens-Johnson syndrome. In some cases, corneal surgery or a corneal transplant is necessary, particularly when high pressure from glaucoma allows fluid to accumulate in the stroma. Once this occurs, it may lead to a cloudy cornea.

Trabeculotomy for Glaucoma. The pathophysiology of glaucoma is markedly different for infants and children than in adults, and its occurrence is rare, occurring in approximately 1 in 10,000 births (AAPOS, 2005). Pediatric glaucoma is categorized according to age of onset (Table 25-3). Cases of glaucoma are classified as primary (without specific identifiable cause) or secondary (occurring in conjunction with another disorder, medication use, or eye trauma). Children with glaucoma could have other eye abnormalities in addition to the glaucoma, including opacities of the cornea (Peters' anomaly, for example).

Pediatric glaucoma is treated by a combination of medical and surgical intervention, as the goal of treatment is more than simply lowering intraocular pressure. Children diagnosed with congenital or infantile glaucoma often develop myopia and require glasses. There is also an increased occurrence of strabismus and amblyopia in children with glaucoma. Extreme cases may result in vision loss, supporting the need for early diagnosis and management of the disorder.

Pediatric glaucoma is commonly evaluated by examining the child under anesthesia (EUA). At this time, the ophthalmologist will measure intraocular pressure, corneal length, axial diameter, and refractive error and assess corneal clarity and the optic nerve. If the intraocular pressure is elevated, it can be treated medically or surgically. The majority of primary pediatric glaucoma cases are treated surgically.

The most common surgical approaches are trabeculotomy with goniometry. These procedures open the drainage canal and facilitate aqueous drainage. Other options, such as trabeculotomy with tube placement, create a bypass route to shunt aqueous drainage. Laser procedures are also effective in some cases of glaucoma. Successful management of the disease typically requires multiple examinations and procedures.

BOX 25-6

Types of Cataracts

- Nuclear: Cloudiness in the center part of the lens
- Lamellar: Cloudiness between the nuclear and cortical layers of the lens
- Traumatic: Results from blunt or penetrating force that damages the lens

TABLE 25-3

Categories of Glaucoma

Category	Age at Presentation	Symptoms at Presentation
Congenital	Glaucoma present at birth	Excessive tearing Light sensitivity Large, cloudy cornea Dull-appearing iris
Infantile	Glaucoma presents between 1 and 24 months of age	Excessive tearing Light sensitivity Large, cloudy cornea Dull-appearing iris
Juvenile	Glaucoma presents after 36 months of age	No obvious symptoms; presents similar to adult-onset glaucoma

Retinal Disorders. Retinal diseases include retinopathy of prematurity (ROP). ROP is one of the most common causes of visual loss in childhood and can lead to lifelong vision impairment and blindness. The most effective proven treatments for ROP are laser therapy or cryotherapy. Both laser treatments and cryotherapy are performed only on infants with advanced ROP. Severe cases (stage V) of this disorder are treated with scleral buckle and posterior vitrectomy (see Chapter 17).

TRAUMA

Principles governing surgical care of trauma patients are discussed in Chapter 27. However, when caring for the pediatric trauma patient in surgery, the perioperative nurse must possess additional knowledge in order to develop a detailed plan of

BOX 25-7

Trauma Transfer Criteria for Pediatric Patients Less Than or Equal to Age 14

CONSIDER TRANSFER TO PEDIATRIC TRAUMA CENTER

- Nonoperative management of solid organ injury
- Assessment of any of the following "negative points" on the pediatric trauma scale:
  - Weight less than 10 kg
  - Unstable airway
  - Blood pressure less than 50 mm Hg (systolic)
  - Coma
  - Major open, penetrating wound
  - Open, multiple fractures
- Injury severity score greater than 9
- Victim or nonaccidental injury that requires intervention from child protective team or other resources
- Anticipated complexity of care exceeds the capabilities of local resources at adult trauma center

TRANSFER TO PEDIATRIC TRAUMA CENTER

- Persistent physiologic demise
- Traumatic brain injury
- Intubation and mechanical ventilation with no expectation to wean within 24 hours
- Children with special needs or other co-morbid conditions

Modified from Pennsylvania Trauma Systems Foundation: *Adult trauma center accreditation, Appendix C: Transfer guidelines: adult trauma centers (level I, II, and III) to pediatric trauma centers*, 2009.

action that effectively drives the delivery of safe patient care. During all episodes of patient care, it is necessary for the perioperative nurse to communicate with members of the surgical and interdisciplinary team in a fashion that best supports positive patient outcomes. The urgency of injury will dictate the timeliness of surgical intervention—in some instances, pediatric trauma patients may require transfer to a level I trauma center. The criteria for transfer are outlined in Box 25-7. The perioperative nurse should be prepared to administer care to any type of injury in a safe and effective manner that is appropriate across all age levels.

Trauma is the leading cause of death in children from 1 to 14 years of age. Each year, another 100,000 children experience disability from trauma. Several factors, such as age, gender, behavior, and environment, influence the risk of traumatic injury. For instance, infants and toddlers are more prone to falls resulting in severe injury, which may be related to the pliable nature of their skeletal system. If broken bones are present, a severe force of injury must be assumed. Older children and adolescents are at higher risk for bicycle-related and motor vehicle–related injuries. In this age-group, blunt injuries resulting from motor vehicle accidents or direct blows (as with contact sports or child abuse) along with falls are the most common mechanisms of injury (Cooper, 2005). It is not uncommon for pediatric traumatic injuries to occur in the home environment, stressing the importance of community awareness and education as it relates to trauma prevention. Some of the most significant prevention strategies focus on car seat safety as a means of preventing injury from motor vehicle accidents (Patient Safety).

Throughout the pediatric population, neurologic injuries are the most common cause of traumatic death in children;

PATIENT SAFETY

Child Passenger Safety

The number one killer of children ages 3 to 14 is motor vehicle crashes. Parents and caregivers should be encouraged to follow these steps to reduce the risk of injury or death for children who ride in motor vehicles:

INFANTS

- Ride in rear-facing car seats until 1 year old and 20 pounds.
- Check the weight requirements of the car seat against the infant's height and weight—keep track of these measurements with each visit to the pediatrician.
- Harnesses should be even with or below the infant's shoulders and worn tightly. You should not be able to pinch extra webbing at the shoulder.
- Adjust the chest clip to armpit level.
- Recline the seat no more than 45 degrees.

TODDLERS

- Use a forward-facing seat until the harness no longer fits the child. Most children will outgrow the seat between ages 4 and 5.
- Check the weight requirements of the car seat against the child's height and weight—keep track of these measurements with each visit to the pediatrician.
- Harnesses should be even with or below the child's shoulders and worn tightly. You should not be able to pinch extra webbing at the shoulder.
- Adjust the chest clip to armpit level.
- If possible, use a top tether. Tethers limit the forward motion of the head in a crash.

BOOSTERS

- Booster seats are used in conjunction with the vehicle lap and shoulder belts for children who do not meet the size requirements for standard seat belts. Normal seat belts begin to fit children between the ages of 8 and 12.
- Boosters should be used in the back seat only.
- The weight range for booster seats is between 40 and 100 pounds.
- Use the lap and shoulder belts every time a child is in a booster seat. Never use only the lap belt, and make sure that the seat belt is properly buckled.

SAFETY BELTS

- Safety belts fit properly when the knees bend over the edge of the seat, the lap belt rests on the upper legs or hips, and the shoulder belt rests on the shoulder or collarbone.
- Never put the shoulder belt under a child's arm or behind a child's back.
- Ensure that children sit upright when wearing seat belts. Avoid leaning against windows, slouching, or lying down.

Modified from Safe Kids USA: *Child passenger safety,* 2006, available at www.usa.safekids.org/skbu/cps/index.html. Accessed February 21, 2009.

their head is proportionately larger in relation to their body mass and especially vulnerable to injury. Table 25-4 gives a guideline for using the Glasgow Coma Scale for infants and children. Because children have a much smaller reserve than adults, once a decline in vital functions is noted, demise is rapid. Information about commonly used medications in pediatric resuscitation is noted in the Surgical Pharmacology box.

IV access is often difficult in the pediatric patient, and an intraosseous line may be inserted by emergency rescue personnel before arrival at the hospital or in the emergency department

SURGICAL PHARMACOLOGY

Medications Used in Pediatric Resuscitation

Perioperative nurses must always be prepared in the event of a cardiac event in the pediatric patient. The information contained in this section provides several commonly used medications, their mode of action, and nursing implications for pediatric resuscitation.

Drug	Dosage	Action	Nursing Implications
Epinephrine HCl	Intravenous/intraosseous (IV/IO): 0.01 mg/kg (1:10,000) Endotracheal (ET): 0.1 mg/kg (1:1000) Repeat doses = 0.1 ml/kg (1:1000)	Adrenergic; acts on both alpha- and beta-receptor sites, especially heart and vascular and other smooth muscle	Most useful drug in cardiac arrest Disappears rapidly from bloodstream after injection; instill 2-3 ml of saline following ET administration May produce renal vessel constriction and decreased urine output
Sodium bicarbonate	IV/IO: 1-2 mEq/kg	Alkalinizer, buffers pH	Infuse slowly and only when ventilation is adequate; flush with saline before and after administration Do not mix with catecholamines or calcium Incompatible with epinephrine
Atropine sulfate	20 mcg/kg dose Minimum dose: 100 mcg Maximum single dose: infants and children, 0.5 mg; adolescents, 1.0 mg	Anticholinergic-parasympatholytic; increases cardiac output, heart rate by blocking vagal stimulation in heart	Used to treat bradycardia after ventilatory assessment; always provide adequate ventilation and monitor O_2 saturation Produces pupil dilation, which constricts with light
Calcium chloride	20 mg/kg IV 10.2 mg/kg May repeat dose every 10 min	Electrolyte replacement; needed for maintenance of normal cardiac activity	Used only for hypocalcemia, calcium blocker overdose, hyperkalemia, or hypermagnesemia Administer slowly, very sclerosing; administer in central vein Incompatible with sodium phosphate
Lidocaine HCl	0.5-1 mg/kg dose	Antidysrhythmic, inhibits nerve impulses from sensory nerves	Used for ventricular dysrhythmias only
Amiodarone	IV: 5 mg/kg over 30 min followed by continuous infusion starting at 5 mcg/kg/min; may increase to maximum 10 mcg/kg/min	Antidysrhythmic agent, inhibits adrenergic stimulation; prolongs action potential and refractory period in myocardial tissues; decreases atrioventricular (AV) conduction and sinus node function	Recommended as first choice for shock-refractory ventricular tachycardia Contraindicated in severe sinus node dysfunction, marked sinus bradycardia, second- and third-degree AV block Monitor for hypotension
Adenosine	First dose: 100 mcg/kg (maximum dose 6 mg) Second dose: 200 mcg/kg (maximum dose 12 mg) Follow with 2- to 3-ml normal saline flush	Antidysrhythmic, for supraventricular tachycardia (SVT) Causes temporary block through AV node and interrupts reentry circuits	Administer rapid IV push, followed by saline flush May cause transient bradycardia
Naloxone (Narcan)	0.01-0.1 mg/kg/dose (<5 years/20 kg) (>5 years/20 kg = 2 mg)	Reverses respiratory arrest caused by excessive opiate administration	Evaluate level of pain after administration because analgesic effects of opioids are reversed with large dose of naloxone
Magnesium sulfate	IV/IO: 25-50 mg/kg	Inhibits calcium channels and causes smooth muscle relaxation	Given as rapid IV infusion for suspected hypomagnesemia Have calcium gluconate (IV) available as antidote
IV INFUSIONS			
Epinephrine HCl infusion	0.1-1 mcg/kg/min	Adrenergic—see above	Titrate to desired hemodynamic effect
Dopamine HCl infusion	1-20 mcg/kg/min (maximum dose 50 mcg/min)	Agonist; acts on alpha receptors, causing vasoconstriction Increases cardiac output	Titrate to desired hemodynamic effect
Dobutamine HCl infusion	2.5-15 mcg/kg/min	Adrenergic direct-acting beta$_1$-agonist Increases contractility and heart rate	Titrate to desired hemodynamic effect Little vasoconstriction, even at high rates
Lidocaine HCl infusion	20-50 mcg/kg/min	Antidysrhythmic Increases electrical stimulation threshold of heart	See above Lower infusion dose used in shock Used for ventricular tachycardia

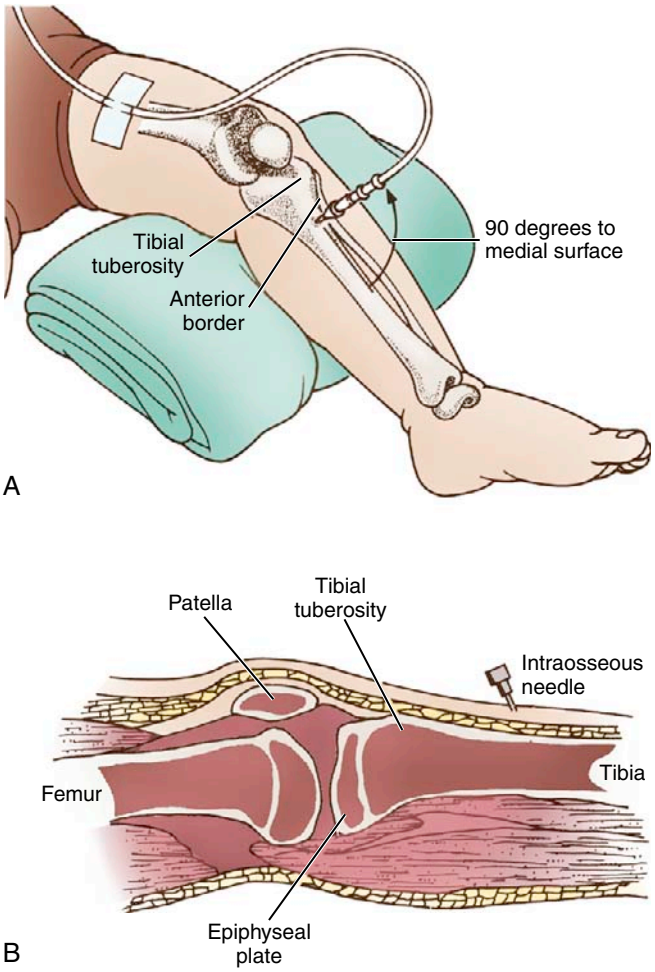

FIGURE 25-53 A, Intraosseous infusion technique. B, Insertion.

(ED). These lines are inserted by use of an intraosseous needle or bone marrow aspiration needle and are placed slightly below the knee on the anterior aspect of the tibia at a 90-degree angle (Figure 25-53). Stabilization of the line may be difficult, but the line can remain for up to 24 hours and provides rapid access when other routes are too time-consuming or difficult to access. Fluid resuscitation levels for children experiencing hemorrhage, as well as types and dosages of medications, are based on body weight, since weight provides a better mechanism of accuracy when calculating dosage.

Because of the nature of the trauma, exact body weight may be unable to be obtained. In these instances, body weight can be estimated using Broselow tapes or palmar methods. The body size of the patient determines the type of instrumentation required. Pediatric trauma instrument sets, including vascular clamps and retractors, and suture supplies should be available and organized in a fashion that promotes easy and timely access when urgent situations arise. Creative problem solving may be required of the perioperative nurse in adaptation of feeding tubes, drains, and other equipment.

Maintenance of body temperature is of utmost concern in the pediatric population, and undue skin exposure should be avoided. Fluids for irrigation and IV infusion may be warmed, depending on the preferences of the surgeon and the status of the child. Whenever possible, room temperature is elevated. Warming blankets and head coverings (stockinettes) may be used to prevent heat loss; this is especially critical with children who have sustained burns.

Traumas are graded based on the severity of injury (Table 25-5). The perioperative nurse should attempt to obtain a trauma history from ED personnel or the family if the patient comes directly to the OR. Initial vitals signs should be obtained and compared with those obtained during prehospital care or in the ED; Table 25-6 presents normal vital sign ranges for infants and children. Box 25-8 gives a formula for blood pressure estimation. As the perioperative nurse obtains the initial assessment, it is important to use a developmental approach to pediatric trauma patients, who respond differently from adults. During traumatic events, it is also imperative to consider the well-being of patients, families, and caregivers. The perioperative nurse plays an integral role in preparing those associated with the child for outcomes associated with trauma surgery and may help facilitate consults from the departments of child life, social work, and clergy.

Airway and breathing are part of the primary survey for pediatric trauma victims. Anatomic variations of the upper airway related to age must be considered. Airway patency must be assessed and secured. Initial assessment for all pediatric

TABLE 25-5

Trauma Grading

	Physiologic Considerations	Anatomic Considerations
Level I: Life-threatening injuries, unstable vital signs	Respiratory distress Intubated before transport Unstable airway Cardiac arrest Glasgow Coma Score (GCS) ≤8 Unstable vital signs Lateralizing neurologic signs or worsening neurologic exam Any signs of shock Severe uncontrolled hemorrhage Systolic blood pressure <80 mm Hg that does not respond to fluid resuscitation	Airway compromise Major vascular injury Crush injury Above-elbow or above-knee amputation with high probability of surgical intervention Penetrating injury to abdomen, chest, head, neck, or groin Burns >25% total body surface area Spinal cord injury with neurologic signs or symptoms and unstable vertebral fractures
Level II: Potentially life-threatening injuries, vital signs stable at present	GCS ≥9 and ≤13 Hypotension before transport, resolved during transport	Blunt abdominal trauma with abnormal exam Blunt chest trauma with ≥2 rib fractures Significant penetrating trauma to upper extremities or distal to groin Significant crush or amputation distal to elbow or knee with high probability of operative intervention

BOX 25-8

Estimating Blood Pressure for the Pediatric Patient

Systolic BP (mm Hg) = (2 × age in years) + 80
Diastolic BP (mm Hg) = ⅔ Systolic BP

trauma patients may best be obtained by application of the head tilt–chin lift or jaw-thrust method, depending on the age of the child and the nature of the injury. When the integrity of the spinal cord is questionable, in-line cervical traction should be applied. Collars and stabilizing devices must remain in place until cervical fracture has been ruled out and the spine "cleared," or declared free of injury by a radiologist. Airway equipment sizes may be selected based on age as well as whether the child is breathing spontaneously and whether the child is unconscious. An assessment of relevant systems will be performed on stabilization of the pediatric airway, and surgery will progress as planned.

SURGERY FOR CONGENITAL HEART DISEASE

Congenital heart disease (CHD) occurs in approximately 5 to 8 of every 1000 live births. Structural abnormalities of the heart and great vessels result in an embryologic failure in septation, malalignment, failure to develop, and/or failure to progress.

The etiology of CHD varies, although certain factors are associated with increased prevalence. For example, risk of CHD is increased secondary to environmental factors: rubella during the first 8 weeks of gestation may result in patent ductus arteriosus and pulmonary artery stenosis (along with other syndromes). Other risk factors include maternal chronic illnesses such as diabetes or poorly controlled phenylketonuria (PKU), alcohol consumption, and exposure to environmental toxins. The incidence of CHD is increased also in certain chromosomal defects; for example, atrial septal defects are seen in children with trisomy 21 (Down syndrome). In addition, an increased prevalence is seen in small-for-gestational-age (SGA) babies and in children who have a positive family history of CHD (that is, those families with a sibling or parent who has CHD).

Congenital cardiac abnormalities are classified as cyanotic or acyanotic as well as by their effect on pulmonary blood flow (Box 25-9). Of the acyanotic lesions, there are those that increase pulmonary blood flow, such as patent ductus arteriosus (PDA), atrial septal defect (ASD), ventricular septal defect (VSD), and atrioventricular canal defects (AVCs). With these abnormalities, blood flows from the high-pressure left side of the heart to the low-pressure right side of the heart because of an abnormal connection either between the septum or in the great arteries. The resultant increase in pulmonary blood flow causes the right side of the heart and lungs to become overloaded. Congestive heart failure (CHF) may develop, pulmonary vascular resistance may increase, and the pulmonary vessel walls may thicken; and if left untreated, the condition may become irreversible.

BOX 25-9

Classification of Congenital Cardiac Defects

ACYANOTIC WITH INCREASED PULMONARY BLOOD FLOW
- Patent ductus arteriosus
- Atrial septal defect
- Ventricular septal defect
- Atrioventricular septal defect

ACYANOTIC OBSTRUCTIVE LESIONS
- Coarctation of the aorta
- Aortic stenosis
- Pulmonary stenosis

CYANOTIC WITH DECREASED PULMONARY BLOOD FLOW
- Tricuspid atresia
- Tetralogy of Fallot
- Pulmonary atresia with intact ventricular septum

CYANOTIC WITH INCREASED PULMONARY BLOOD FLOW
- Total anomalous pulmonary venous connection (return)
- Truncus arteriosus
- Hypoplastic left heart syndrome

CYANOTIC WITH VARIABLE PULMONARY BLOOD FLOW
- Transposition of the great arteries
- Double-outlet right ventricle
- Double-outlet left ventricle
- Single ventricle

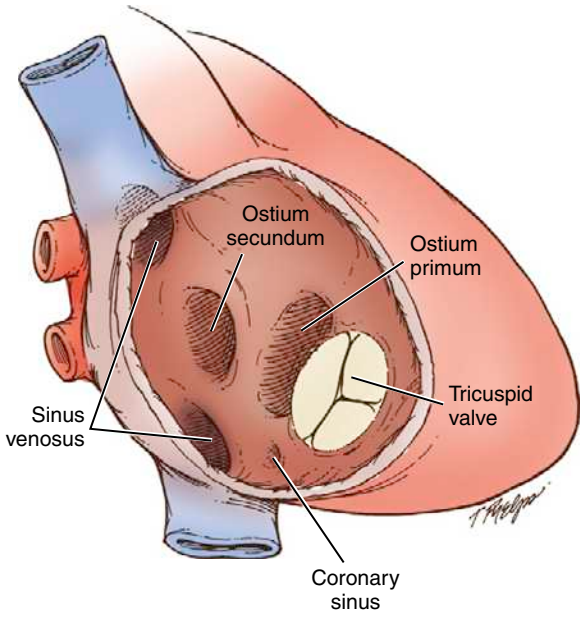

FIGURE 25-54 Various types of atrial septal defects (ASDs) viewed through the right atrium (ostium secundum, ostium primum, sinus venosus). An unroofed coronary sinus may also act as an ASD.

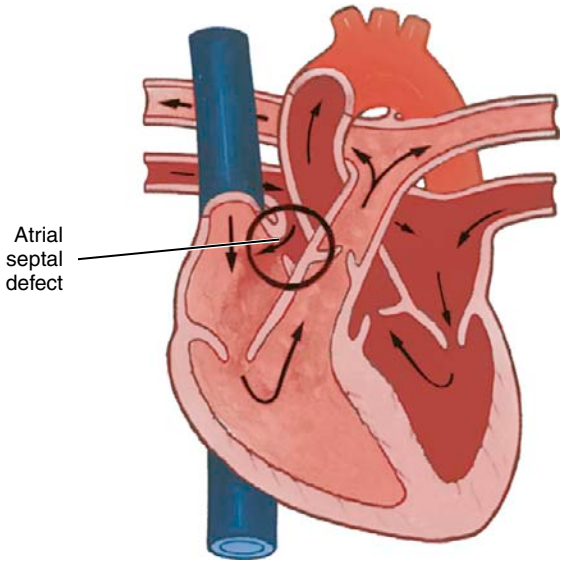

FIGURE 25-55 Atrial septal defect.

Acyanotic obstructive lesions, such as aortic stenosis, pulmonary stenosis, or coarctation of the aorta, increase the workload of the chamber that pumps against the obstruction (increases afterload). Cardiomegaly and ventricular hypertrophy may be seen in response to the increased workload, and if the obstruction is severe, heart failure may ensue.

The presence of cyanosis implies that one of the following conditions is present: right-sided heart obstruction with blood traveling right to left without passing through the lungs; mixing of venous and arterial blood within the heart or great vessels; or incorrect positioning of the great vessels. The degree of cyanosis depends on pulmonary blood flow and intracardiac mixing of blood through a shunt. This classification of lesions includes, but is not limited to, tetralogy of Fallot (TOF), pulmonary atresia with intact ventricular septum (PA/IVS), tricuspid atresia (TA), transposition of the great arteries (TGA), total anomalous pulmonary venous return (TAPVR), and hypoplastic left heart syndrome (HLHS). Treatment goals for these lesions include managing pulmonary blood flow and/or arterial oxygen saturation.

Repair of Atrial Septal Defect

Congenital defects in the atrial septum occur in approximately 10% of CHD cases (Melek, 2006). The classification within this group of defects is based on anatomic location and associated abnormalities (Figure 25-54). The ostium secundum defect is located in the superior and central portions of the septum. The ostium primum defect is located in the lower portion of the atrial septum and is associated with other defects in the atrioventricular canal, usually with a cleft of the mitral valve or occasionally of the tricuspid valve. An accompanying VSD may also be present. The sinus venosus defect is located at the right atrium–superior vena cava junction and is associated with partial anomalous pulmonary venous return.

An ASD results in a left-to-right atrial shunt whose direction and magnitude are determined by the size of the defect and relative resistance to flow into the ventricles and great vessels (Figure 25-55). ASDs are often tolerated well with no symptoms during childhood, especially if the defect is small. However, if the defect is large or of the ostium primum type, with a pronounced shunting of blood, the workload of the right side of the heart is increased. On assessment, there is a characteristic systolic pulmonary murmur at the second intercostal space at the left sternal border, and a fixed splitting of the second heart sound may also be heard. The right side of

the heart and the pulmonary artery and its branches become enlarged. The vascularity of the lung field is increased, with resulting pulmonary hypertension and subsequent failure of the right side of the heart. At this point the shunt may reverse. The initial symptoms may include fatigue, retardation of normal weight gain, and increased susceptibility to respiratory tract infections. Later signs and symptoms include those of failure of the right side of the heart and cyanosis with a reverse shunt. Asymptomatic children whose ASD is left unrepaired until adulthood may develop right atrial and right ventricular hypertrophy, atrial dysrhythmias, CHF, embolic events, and pulmonary vascular disease. The defect is common in children with Down syndrome.

Procedural Considerations. ASDs are closed, under direct vision, by a simple suture technique (primary closure) or by insertion of a synthetic prosthetic patch or pericardial patch.

The child is placed in the supine position for a median sternotomy or in a right anterior oblique position for an anterolateral thoracotomy. The instrument setup is the same as that described for basic open-heart surgery (see Chapter 24), with consideration given to the age and size of the child; intracardiac patch material, 2 × 2 inches or larger, may also be required.

Operative Procedure (Figure 25-56)

1. A median sternotomy incision is performed, and cardiopulmonary bypass (CPB) is instituted. (Infrequently, a right anterolateral incision is performed.) Many bypass strategies can be employed. With bicaval cannulation, the child remains on bypass during the repair and blood is directed away from the right atrium through cannulae in the superior and inferior venae cavae. Occasionally, with this method the cannulae may obstruct the view of the ASD. With single venous cannulation, a cannula is placed into the right atrium and the child remains on bypass during the repair. With this technique, the venous line is clamped immediately before the right atrium is incised and pump suctions are placed into the inferior and superior venae cavae during ASD closure. Deep hypothermic circulatory arrest is sometimes used in more complicated repairs, such as ostium primum ASD or sinus venosus defects associated with anomalous pulmonary venous return.
2. The right atrium is incised, and the pathologic defect is determined.
3. The defect is closed with a continuous suture, or a patch of pericardium or prosthetic material may be used. By filling the atrium with blood before the atriotomy is completely closed, the surgeon can express air from the atrium. For the ostium primum defect with a cleft mitral valve, repair of the cleft is accomplished by approximation, with use of interrupted (possibly pledgetted) sutures.

Repair of Ventricular Septal Defect

One of the most common congenital cardiac anomalies, VSDs (Figure 25-57) occur in approximately 2% to 7% of live births, with as many as 60% closing spontaneously (Ramaswamy et al, 2009). Most VSDs are small with little physiologic importance. As with ASDs, the classification of VSDs depends on location and associated lesions (Figure 25-58). Perimembranous VSDs (also called *conoventricular, subaortic, infracristal,* or *membranous*) are most commonly found. These defects occur directly

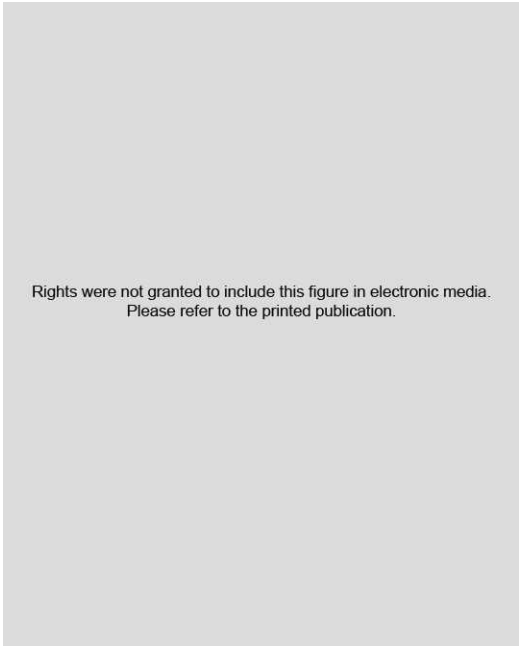

FIGURE 25-57 Ventricular septal defects: anatomic classification.

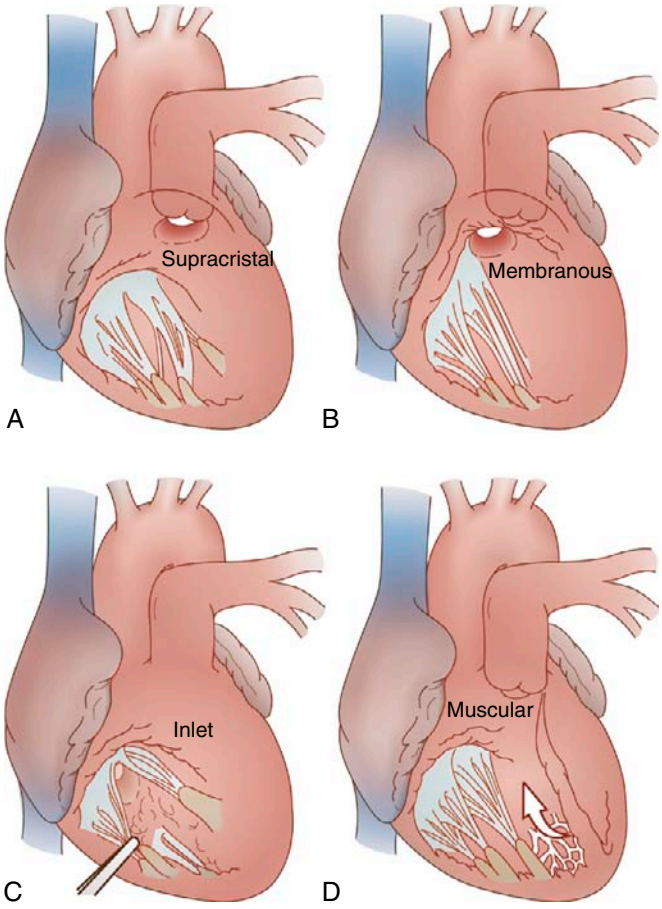

FIGURE 25-58 Various types of ventricular septal defects viewed within the right ventricle. **A**, Infundibular (supracristal). **B**, Membranous. **C**, Inlet (AV canal). **D**, Muscular (trabecular).

adjacent to the membranous septum and the fibrous trigone of the heart where the aortic, mitral, and tricuspid valves are in fibrous continuity. The tricuspid valve tissue sometimes forms an aneurysm of the membranous septum, which may be a mechanism of defect closure for this type of defect. Subpulmonary VSDs (also referred to as *supracristal, infundibular, intracristal, outlet, conoseptal,* or *conal*) are located above the crista supraventricularis within the outlet septum and border the semilunar valves. Muscular-type VSDs can be located anywhere in the muscular septum, including apical, anterior, or posterior, or in the midseptum inlet and outlet. Malalignment-type VSDs are created by a malalignment between the infundibular septum and the trabecular muscular septum. Canal-type or inlet defects are located posteriorly within the area confined by the tricuspid valve septal leaflet papillary muscles. The defect borders the tricuspid valve annulus.

The hemodynamics depend on the size and location of the defect as well as the pulmonary vascular resistance (PVR) and systemic vascular resistance (SVR). Newborns are often asymptomatic until the PVR decreases—then a left-to-right shunt occurs, and the corresponding murmur is auscultated. Small defects with moderate shunt and increased pulmonary blood flow but not increased pulmonary pressure may not produce any symptoms. A large VSD, however, may produce high pulmonary flow under high pressure and contribute to CHF. In

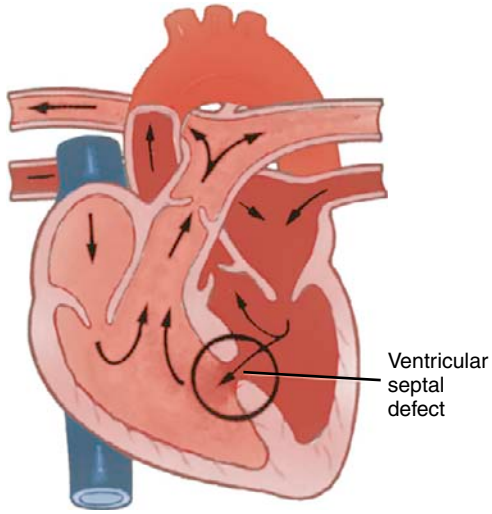

FIGURE 25-59 Ventricular septal defect.

this case the patient is at risk of developing pulmonary hypertension (Figure 25-59). Surgical closure of the defect should be performed to prevent increased pulmonary hypertension. If PVR further increases and rises above SVR, shunt reversal (Eisenmenger's syndrome, or shunting from right to left) and cyanosis may occur.

Operative Procedure. Under direct vision, a congenital defect in the ventricular septum (Figure 25-60) is closed by a simple suture technique or, in most instances, by insertion of a synthetic prosthetic or pericardial patch.

1. A median sternotomy is performed, and CPB is instituted.
2. The location of the defect determines the location of the incision. For membranous and canal defects, an incision is usually made in the right atrium, the atrium is retracted, and the VSD is identified by use of a pump suction through the tricuspid valve into the right ventricle. For supracristal VSDs, an incision is usually made in the pulmonary artery and may be extended into the right ventricle. A muscular VSD may require a ventriculotomy.
3. A patch is most frequently used to close the defect. To place the patch, a continuous 6-0 or 5-0 nonabsorbable suture on a small needle or an interrupted suture with or without pledgets may be used. Rarely is the defect closed primarily.
4. CPB is discontinued, and the sternum is closed.

Correction of Tetralogy of Fallot

TOF, described initially in the early nineteenth century, includes the association of four anatomic findings: VSD, subpulmonic stenosis, aortic override of the ventricular septum, and right ventricular hypertrophy (RVH) (Figure 25-61). Occurring in approximately 10% of congenital heart defects, TOF is actually the result of a single anatomic abnormality: anterior malalignment of the infundibular septum with the muscular septum (Davis, 2007).

The preoperative hemodynamics or physiology depends mainly on the degree of pulmonary stenosis. In patients with minimal obstruction to pulmonary blood flow, the physiology is similar to that of a VSD with left-to-right shunting. These patients will have pulmonary overcirculation and symptoms of

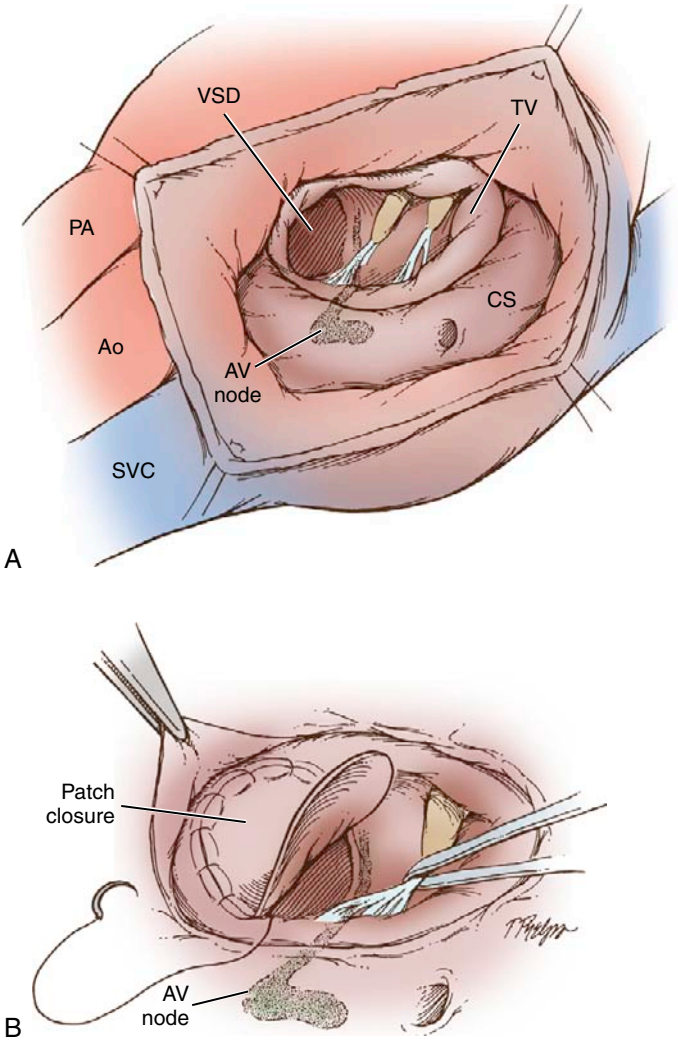

FIGURE 25-60 Ventricular septal defect *(VSD)* closure through the tricuspid valve *(TV)*. **A**, Open site. **B**, Partial closure. *Ao,* Aorta; *AV,* atrioventricular; *CS,* conduction system; *PA,* pulmonary artery; *SVC*, superior vena cava.

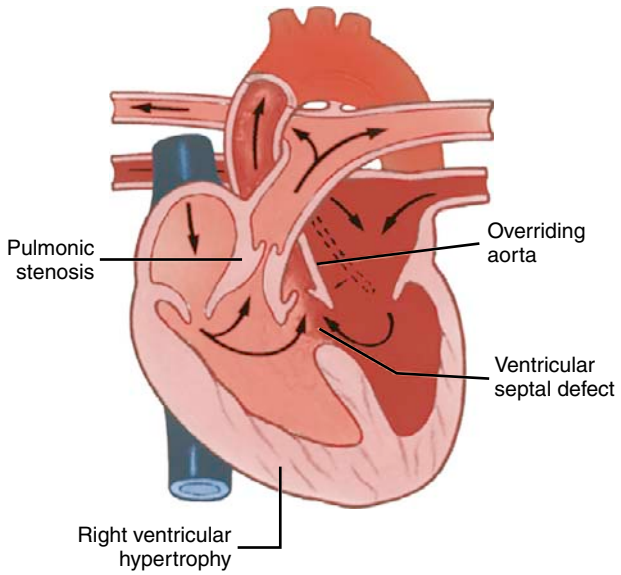

FIGURE 25-61 Tetralogy of Fallot.

CHF. Occasionally labeled as "pink tets," these patients have little to no right-to-left shunting and do not exhibit cyanosis.

At the other end of the spectrum of this particular type of heart defect are children with severe pulmonary stenosis, who may have significant right-to-left shunting at the VSD level and exhibit hypoxemia with oxygen saturations in the 60% to 80% range. Cyanosis, as seen in the superficial vessels of the skin, is the result of shunting unoxygenated blood into the systemic circulation. Other clinical manifestations may include episodes of acute dyspnea with cyanosis, retarded growth, clubbing of extremities, reduced exercise tolerance, and increased prevalence of "tet," or hypercyanotic spells. A systolic murmur and secondary polycythemia are usually present in the cyanotic child. Echocardiography is performed to confirm the diagnosis of TOF; occasionally a cardiac catheterization and angiography may be necessary in delineating other anatomic abnormalities, such as with the coronary arteries, before surgical repair.

The selection of a palliative or corrective procedure is based on the age and general condition of the child and the severity of the pulmonary stenosis. The treatment of choice is primary repair; contraindications for primary repair include anomalous origin of the anterior descending coronary artery and presence of pulmonary atresia. Complete or primary repair consists of closure of the VSD and repair of the pulmonic stenosis under direct vision.

Procedural Considerations. The child is placed on the OR bed in a supine position. The setup is the same as that described for open-heart surgery, with consideration given to the child's age and size. Additional items to be added to the basic open-heart setup include the following: intracardiac patch, 2 × 2 inch; outflow cardiac patch, 2 × 2 inch; and a felt or Gortex patch, 4 × 4 inch.

Operative Procedure

1. A median sternotomy is performed, and CPB with hypothermia is instituted.
2. A vertical ventriculotomy over the infundibular area may be performed (Figure 25-62, *A*).
3. The VSD is identified. Closure requires an intracardiac patch in almost all instances. This can be of a synthetic material or a piece of pericardium.
4. Interrupted or continuous cardiovascular sutures are placed in the septum with caution because of the danger of suturing a branch of the neuroconductive system.
5. The hypertrophied infundibular muscle is excised, as completely as possible, from the right ventricular outflow tract. If the pulmonic valve is stenosed, the fused commissures are incised.
6. An estimate is made about whether the right ventricle can be closed primarily or if a patch is necessary. If the pulmonic stenosis cannot be relieved adequately by valvulotomy and infundibulectomy, an outflow patch of synthetic material or pulmonary homograft tissue may be needed to enlarge the outflow tract (Figure 25-62, *B*). If the pulmonary artery or valve annulus is quite small, it may be necessary to extend the patch across the valve ring to the proximal portion of the pulmonary artery (Figure 25-62, *C*).
7. CPB is discontinued, and the sternum is closed.

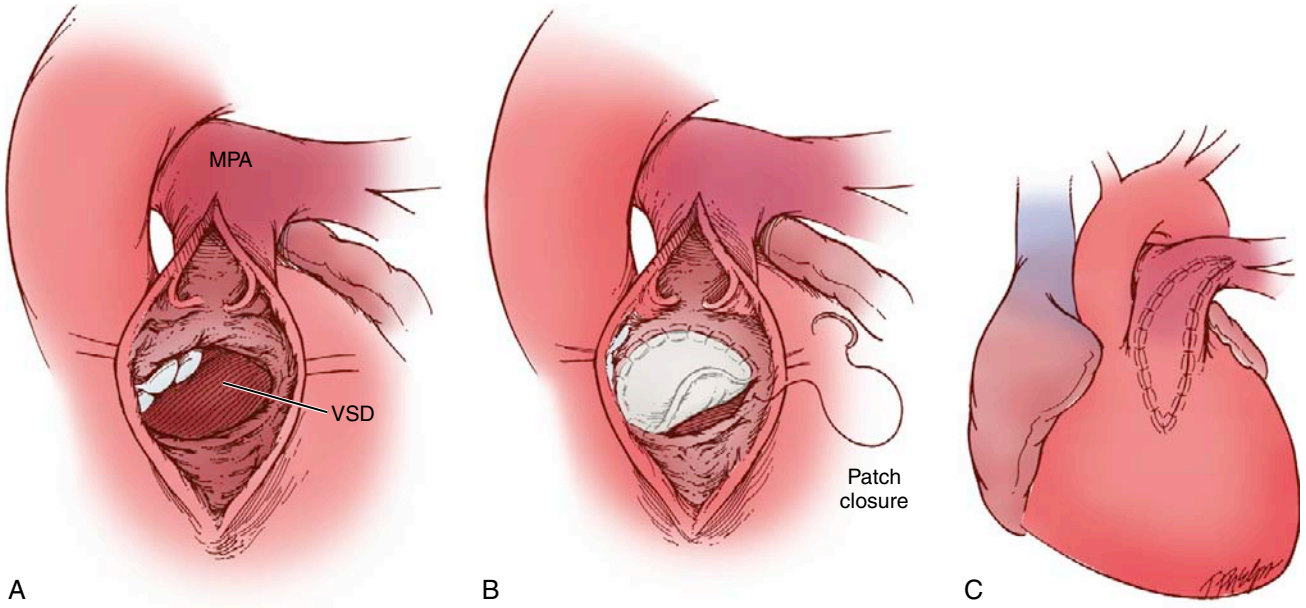

FIGURE 25-62 **A**, The most common ventricular incision used for repair of tetralogy of Fallot is vertical so that it can be extended as shown from the right ventricle across the pulmonary valve annulus and onto the main pulmonary artery *(MPA)*. It is possible to gain adequate exposure to the ventricular septal defect *(VSD)* by extending the incision a short distance beyond the infundibular septum. This "limited ventriculotomy" may help preserve late right ventricular function yet enable adequate enlargement of the hypoplastic area in the right ventricular outflow tract. **B**, The VSD is closed with a prosthetic patch. Right ventricular outflow obstruction is relieved when the outflow tract is enlarged with a patch as shown. **C**, In some cases it may be necessary to extend the incision onto the left pulmonary artery and to taper the patch at its most distal extent.

Closure of Patent Ductus Arteriosus

PDA occurs because of persistence of the fetal ductus arteriosus, which connects the pulmonary artery to the aorta. The condition is common in premature infants. In fetal life, blood bypasses the lungs, traveling directly to the systemic circulation through the PDA. This vessel normally closes shortly after birth as a result of the onset of respiration causing an increase in Pao_2 level and the release of circulating humoral substances. However, if this does not occur, the ductus arteriosus remains open (Figure 25-63), creating a shunt from the aorta through the ductus into the pulmonary circulation. This increases the workload of the heart and causes subsequent enlargement and hypertrophy of the left atrium and ventricle. However, when persistent patency of the ductus is associated with other malformations such as TOF and extreme stenosis of the pulmonary orifice, it is a means of maintaining life. Surgery is not performed if the PDA is serving in a compensatory capacity.

Many children have few symptoms because of the small size of the shunt. A frequent clinical sign associated with this condition is a harsh, continuous murmur. Because the blood passing through the shunt is oxygenated, there is no cyanosis, clubbing, or reduction in peripheral arterial oxygen saturation. However, growth is retarded in children who have a large ductus. Other signs and symptoms may include dyspnea, frequent upper respiratory tract infections, palpitations, limited exercise tolerance, and cardiac failure.

Procedural Considerations. Closure of the PDA is achieved by suture ligation or by division of the ductus. For newborns, the surgeon and anesthesia provider may elect to perform this procedure in the intensive care nursery bed because the operation is a short one. However, after the newborn period, the surgery is done in the OR. The child is placed in a right lateral position. The setup is the same as that described for open-heart surgery, but with special patent ductus clamps and without items for CPB. Generally a left posterolateral approach is used; in some cases, however, a left anterolateral approach is used.

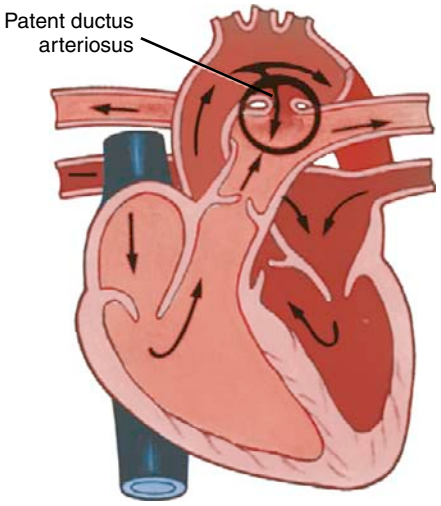

FIGURE 25-63 Patent ductus arteriosus.

Operative Procedure

1. The incision is carried through the muscles over the fourth interspace. The chest wall is entered through the third or fourth intercostal space, with use of items as described for thoracotomy (see Chapter 22). The wound edges are protected and retracted with a Finochietto rib spreader.
2. The pleura is incised with Metzenbaum scissors, and the left lung is protected and retracted with a moist pack and a malleable retractor.
3. The mediastinal pleura is opened between the phrenic and vagus nerves over the region of the ductus. The pleura is retracted by insertion of stay sutures. The recurrent laryngeal nerve is identified and protected. The aortic arch and pulmonary artery are dissected with fine scissors and dry dissectors. Fine arterial branches are divided and ligated with curved Crile or mosquito hemostats and nonabsorbable ligatures and cardiac suture ligatures.
4. The parietal pleura overlying the ductus is dissected with fine vascular forceps and scissors. Stay sutures may be inserted to facilitate retraction.
5. The adventitial layer of the ductus is dissected free. A small portion of the obscure posterior ductus is carefully freed to admit a right-angle clamp.
6. The final step is performed in one of the following ways:
   a. For the suture-ligation method (Figure 25-64, *A*), two ligatures are placed around the ductus—one near the aorta and the other near the pulmonary artery side, both of which are tied in place. Between these two ligatures, two transfixion sutures may be inserted.
   b. For the division of the ductus method, the patent ductus clamps are applied as close to the aorta and pulmonary artery as possible. The ductus is divided halfway through and partially sutured with mattress cardiovascular sutures and continued back over the free edge with an over-and-over whip suture (Figure 25-64, *B*). After both openings are sutured, a sponge is held on the area for compression while the patent ductus clamps are removed.
   c. In premature infants, only a hemoclip may be applied to the ductus because of the friable nature of the ductal tissue. The mediastinal pleura is closed with interrupted sutures. The lung is reexpanded, and a chest catheter may be inserted to establish closed drainage. In newborns, reexpansion of the lung may be accomplished by gradual withdrawal of a catheter during closure; no chest drainage tube is required unless there is oozing. The chest wall is closed in layers, and dressings are applied.

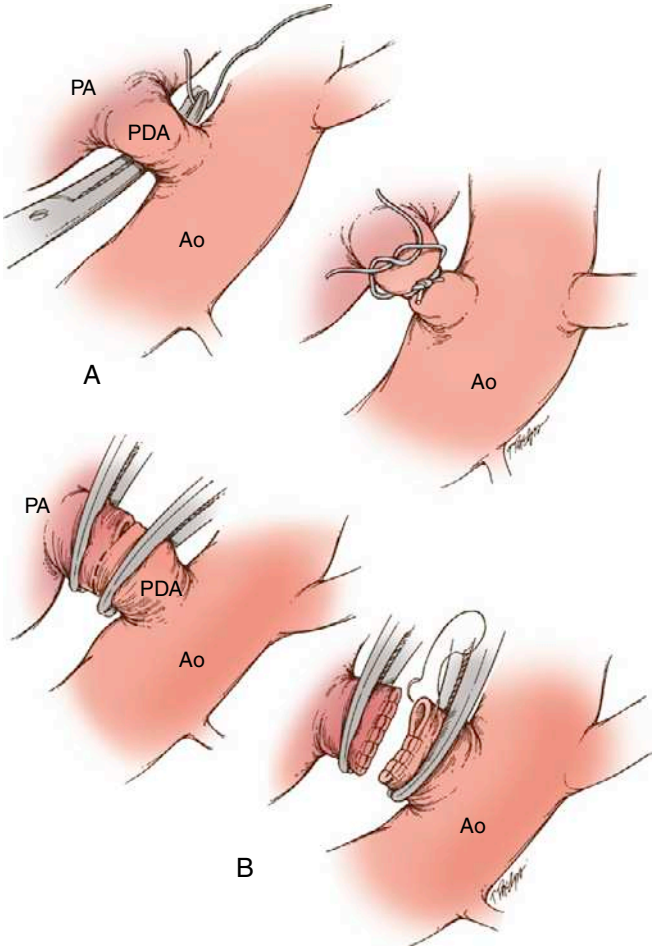

FIGURE 25-64 Surgical correction of patent ductus arteriosus *(PDA)*. **A**, Ligation of ductus arteriosus. **B**, Division of ductus arteriosus. *Ao,* Aorta; *PA,* pulmonary artery.

Repair of Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome (HLHS) (Figure 25-65) is one of the most common forms of single ventricle malformation. HLHS describes a range of congenital cardiac malformations that have in common underdevelopment of the left-sided heart structures, which include aortic valve atresia and stenosis with associated hypoplasia or absence of the left ventricle. The ascending aorta and arch are usually only a few millimeters in diameter and are functionally a branch of the ductus arteriosus–thoracic aorta continuum, with blood flowing retrograde through the aortic arch and into the small ascending aorta to the coronary arteries. Mitral valve atresia or stenosis also is present.

Survival in the newborn period depends on a PDA to maintain systemic circulation; therefore these infants are maintained on an infusion of prostaglandin E_1 (PGE_1) to maintain ductal patency before surgical intervention.

Newborns with HLHS typically present with cyanosis, respiratory distress, and variable degrees of circulatory collapse during the first few days of life. If left untreated, a majority of these neonates will die within the first month of life; without surgical intervention, HLHS is fatal.

It was not until the development of the Fontan procedure—a surgical correction for another form of single ventricle malformation (tricuspid atresia)—that long-term survival in patients with HLHS was considered possible. However, because of the neonate's high PVR, the Fontan procedure is not a surgical option in the newborn period. A palliative repair (stage I) was developed in the late 1970s by Norwood to prepare the heart for the Fontan procedure.

Two surgical options for patients with HLHS exist: a series of reconstructive procedures or heart transplantation. The series of reconstructive procedures usually involves three stages. Stage I is performed during the newborn period. The goals of stage I are to (1) maintain systemic perfusion, (2) preserve the function of the only ventricle, and (3) allow normal

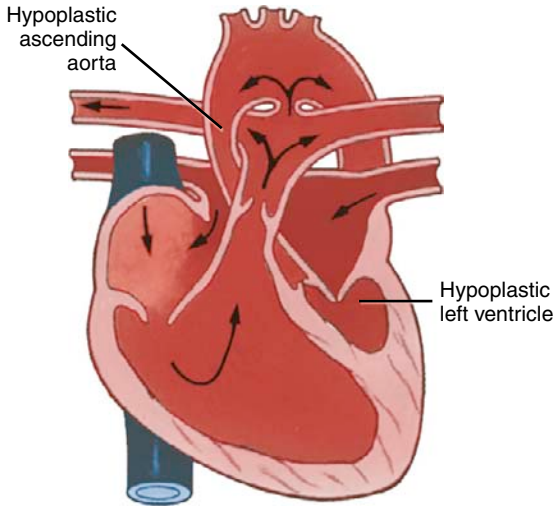

FIGURE 25-65 Hypoplastic left-sided heart syndrome.

maturation of the pulmonary ventricle. The first goal is met by creating an unobstructed communication between the right ventricle and the systemic circulation. This is accomplished by transecting the main pulmonary artery and creating a neoaorta from the main pulmonary artery, native aorta, and pulmonary homograft tissue. The other two goals are met by creating a right modified Blalock-Taussig (BT) shunt and a nonrestrictive interatrial communication. These measures allow for adequate pulmonary blood flow and for the PVR to decrease as the child grows while the volume interposed on the single ventricle is limited.

The modified Fontan procedure was initially performed on a child at approximately 18 months of age. However, since 1989 a staged approach to the Fontan procedure has been undertaken to minimize the effect of rapid changes in ventricular configuration and diastolic function that can be associated with a primary Fontan procedure and its accompanying postoperative complications. In the stage II procedure (hemi-Fontan or the bidirectional Glenn shunt), superior vena cava (SVC) blood flow is directed to the lungs and inferior vena cava (IVC) blood flow continues to flow to the right ventricle. The third and final stage, the modified Fontan procedure, separates the systemic and pulmonary circulations.

Procedural Considerations. Additional items for the open-heart setup include the following:

- Stage I: polytetrafluoroethylene (PTFE) tube graft, 3.5 or 4 mm, and pulmonary homograft tissue
- Stage II: oscillating saw and pulmonary homograft tissue
- Stage III: oscillating saw and PTFE tube graft, 10 mm; a higher-than-usual supply of blood should be available

Operative Procedure

STAGE I (NORWOOD PROCEDURE) (Figure 25-66)

1. A median sternotomy is performed. The aortic cannula is placed into the main pulmonary artery rather than the diminutive aorta, and the venous cannula is placed into the right atrium. CPB is instituted, and the right and left pulmonary arteries are immediately occluded with tourniquets to force the blood through the ductus arteriosus to the systemic circulation.
2. When deep hypothermic circulatory arrest is about to be instituted, the innominate and left carotid arteries are occluded with tourniquets. The venous and aortic cannulae are removed.
3. The septum primum is excised through the venous cannulation site; occasionally a right atriotomy is necessary to facilitate the atrial septectomy.
4. The main pulmonary artery is transected immediately before the bifurcation of the right and left pulmonary arteries.
5. The distal pulmonary artery is closed with a small patch of homograft tissue.
6. The ductus arteriosus is then exposed and closed using a 2-0 nonabsorbable tie. The tie is left long to better expose the thoracic aorta. The ductus is transected.
7. At the point where the ductus was attached to the aorta, the thoracic aorta is opened 1 to 2 cm, and the aortic arch and ascending aorta are opened to a point adjacent to the main pulmonary artery.
8. A gusset of homograft tissue is joined to the aorta starting at the thoracic end, and the pulmonary artery is incorporated at the proximal end of the ascending aorta. A continuous monofilament stitch is used. Occasionally interrupted sutures are used to attach the main pulmonary artery to the aorta.
9. To perform a right BT shunt, the innominate artery is cross-clamped and incised and a 3.5- or 4-mm PTFE tube graft is interposed.
10. CPB is instituted, and the pulmonary end of the shunt is performed by incising the pulmonary artery and interposing the distal end of the tube graft.
11. Immediately after the shunt is completed, the shunt is occluded with a bulldog clamp until termination of bypass.

STAGE II (HEMI-FONTAN PROCEDURE) (Figure 25-67)

1. Because these patients have had previous surgery, an oscillating saw is used for the median sternotomy.
2. The aorta, right atrium, and right BT shunt are exposed.
3. CPB is instituted, and the shunt is immediately occluded with a clip.
4. The branch pulmonary arteries are exposed.
5. Depending on the surgeon's preference, deep hypothermic circulatory arrest may be instituted.
6. An incision is made in the confluence of the pulmonary arteries, extending to the pericardial reflections.
7. An incision is made in the dome of the right atrium, extending to the SVC.
8. The pulmonary artery is then anastomosed to the SVC–right atrial junction.
9. The pulmonary arteries are augmented with a gusset of homograft tissue. In the hemi-Fontan procedure, part of the homograft tissue is incorporated intraatrially as a dam between the common atrium and the vena cava–pulmonary artery anastomosis. In the Glenn shunt, there is no intraatrial incorporation.
10. CPB is reinstituted until the patient is normothermic. CPB is then discontinued, and chest closure is completed.

STAGE III (MODIFIED FONTAN PROCEDURE) (Figure 25-68)

1. A median sternotomy is performed with an oscillating saw.
2. The aorta and right atrium are exposed.
3. CPB is instituted.
4. Deep hypothermic circulatory arrest may be used.

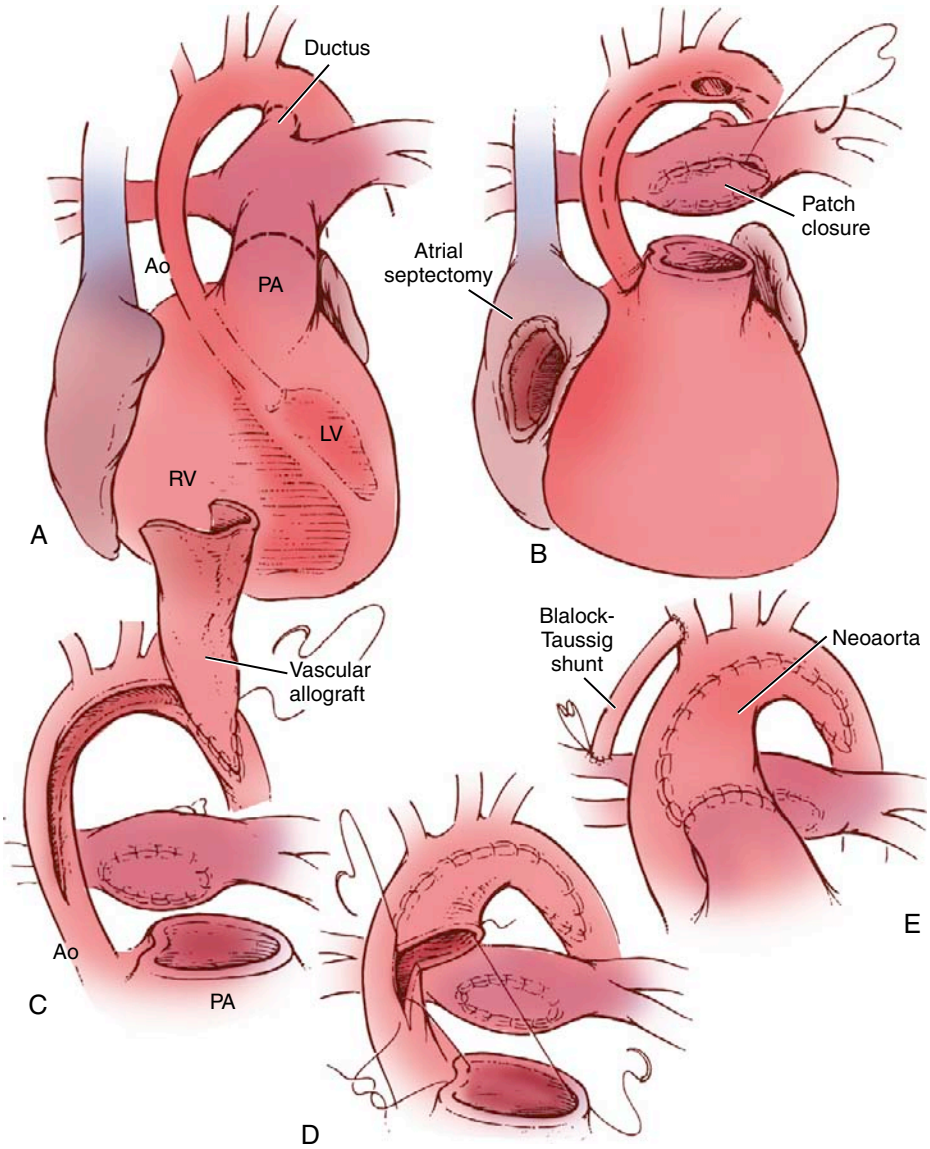

FIGURE 25-66 Stage I Norwood procedure. **A**, Transection points of the main pulmonary artery *(PA)* and ductus arteriosus. **B**, Atrial septectomy to avoid pulmonary venous hypertension. Patch closure of the distal main PA. Division and ligation of the ductus arteriosus. **C** and **D**, Construction of a "neoaorta" with use of the proximal main PA, diminutive ascending aorta, and vascular allograft. **E**, Pulmonary blood flow supplied by a right modified Blalock-Taussig shunt connecting the right subclavian artery to the right PA. *Ao,* Aorta; *LV,* left ventricle; *RV,* right ventricle.

5. A lateral incision is made in the right atrium.
6. A 10-mm PTFE tube graft is cut in half lengthwise and is placed intraatrially by suturing the inferior end of the graft around the orifice of the IVC and up the right lateral free wall of the right atrium to the superior dome of the right atrium. This creates a tunnel in which the inferior blood flow is directed to the pulmonary arteries. The superior vena cava blood flow was directed to the pulmonary arteries during the stage II repair. (The surgeon may perform variations on this procedure, such as excluding a hepatic vein or performing a fenestrated Fontan by making a series of small openings in the PTFE tube graft or a single 4-mm opening with an aortic punch in the graft material.)
7. The atria are closed, and CPB is reinstituted until the patient is normothermic. CPB is then discontinued, and chest closure is completed.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is a therapy used on pediatric patients who have reversible pulmonary or cardiac disease. Many patients are neonates with respiratory disease syndrome (RDS), persistent pulmonary hypertension (PPH), meconium aspiration (MA), or congenital diaphragmatic hernia (CDH) requiring adequate tissue oxygenation and waste removal from the body. In the cardiac patient, it may also be used as a bridge to heart or lung transplantation until donor

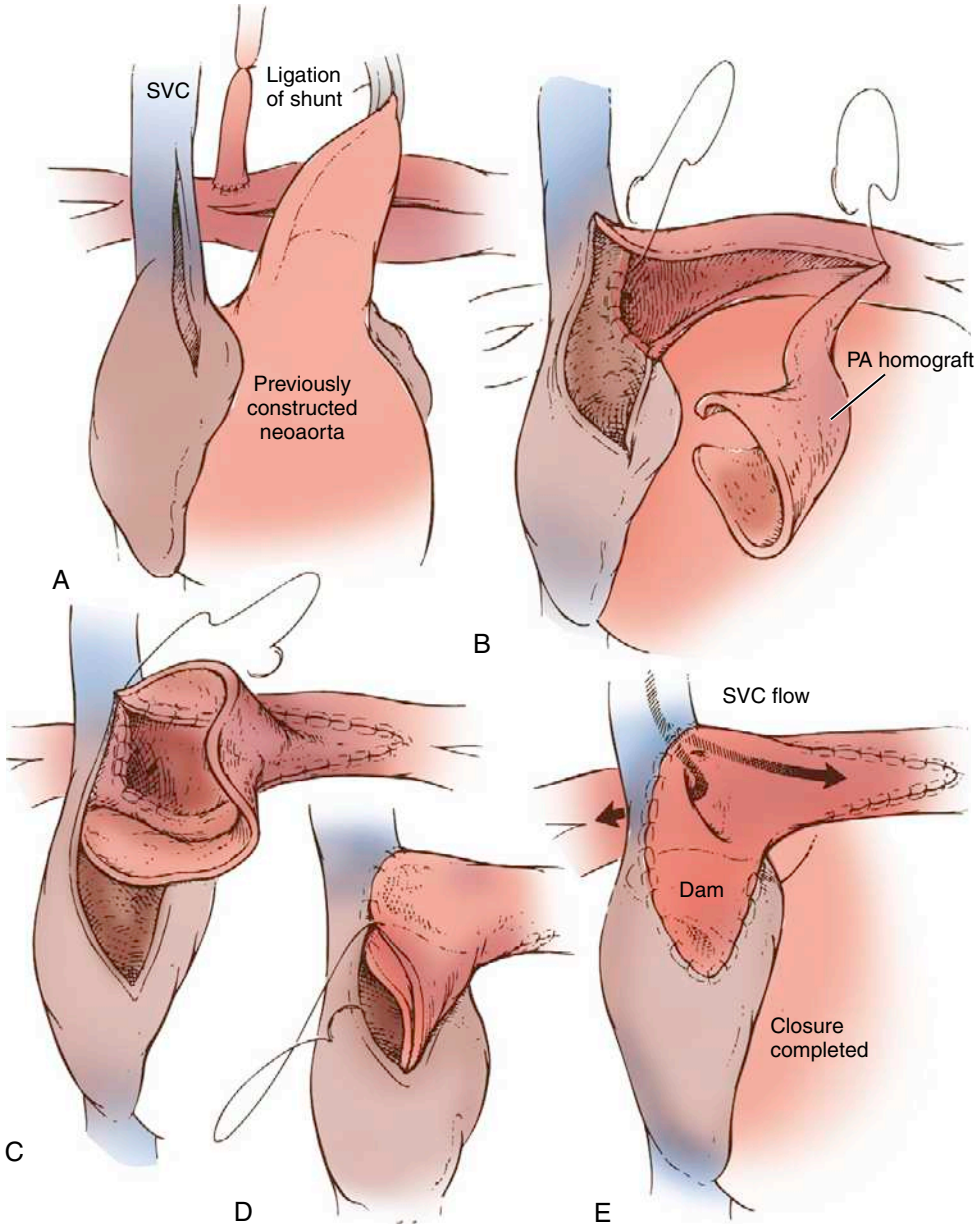

FIGURE 25-67 Hemi-Fontan procedure in a patient with hypoplastic left-sided heart syndrome. **A** and **B**, Ligation of the systemic-to-pulmonary artery shunt and side-to-side anastomosis of the superior vena cava *(SVC)* to the confluence of the pulmonary artery *(PA)* with allograft augmentation. **C** to **E**, Placement of a dam to close the junction of the atrium with the SVC so that saturated pulmonary venous blood mixes in the common atrium with desaturated blood draining from the inferior vena cava. Pulmonary blood flow is supplied exclusively through the SVC.

organs are available. To perform ECMO, a facility must have an established ECMO service.

Most of the time children are placed on ECMO in the ICU. For venoarterial ECMO the surgical approach is usually through the right carotid artery and internal jugular vein. For the cardiac patient after surgical repair, cannulation of the carotid artery and jugular vein provides good venous drainage of the right atrium, and the incision site is remote from the sternotomy wound. However, the surgeon may choose to reopen the sternum on postoperative patients and cannulate the aorta and right atrium. In the OR, for a patient who cannot be successfully weaned from bypass after surgery, the patient's bypass circuit may be switched to an ECMO circuit and the patient may be transferred on ECMO to the ICU.

Procedural Considerations. An area by the patient's bedside should be provided for the ECMO pump, surgical table and instrumentation, electrosurgical unit (ESU), surgeon's headlight, and defibrillator with external and sterile internal paddles. A wall suction outlet should be available. Appropriate surgical attire should be provided for everyone involved with the procedure, and traffic should be limited.

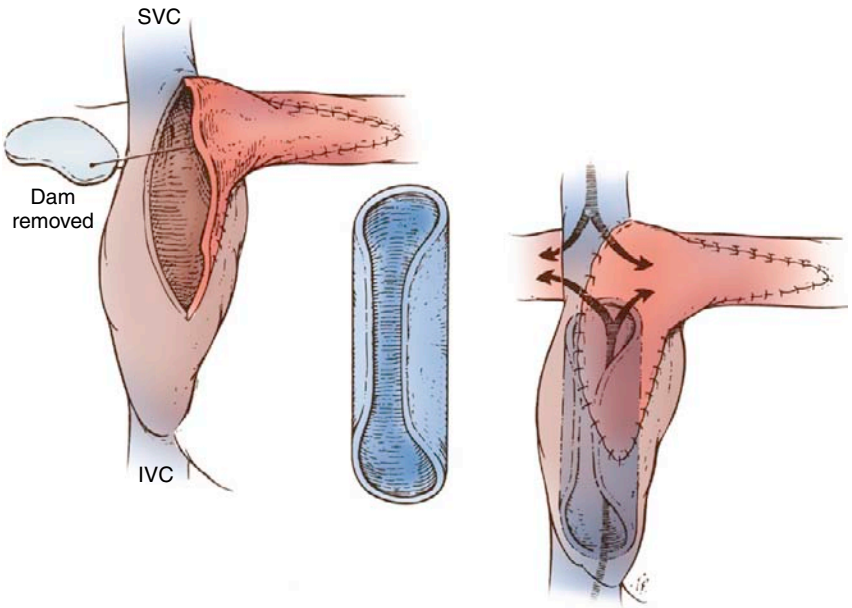

FIGURE 25-68 Conversion of hemi-Fontan to completion of Fontan. Excision of the dam between the right atrium and the superior vena cava–pulmonary artery anastomosis. Inferior vena cava flow is directed to the inlet of the superior vena cava–pulmonary artery anastomosis by a baffle. *IVC*, Inferior vena cava; *SVC*, superior vena cava.

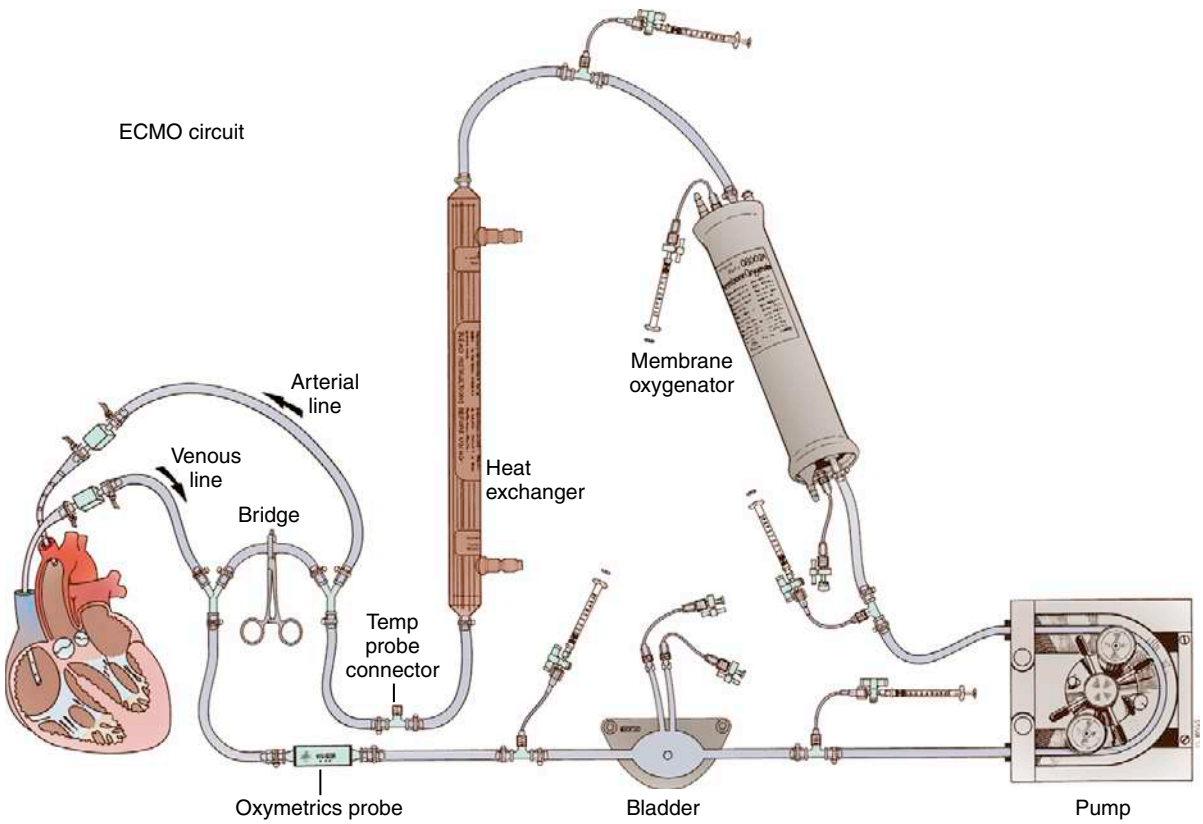

FIGURE 25-69 Extracorporeal membrane oxygenation (ECMO) circuit.

Operative Procedure

FOR NECK CANNULATION. A shoulder roll is placed under the patient, and the neck and chest to the nipple line are prepped and draped. The ears should also be exposed and prepped for use as reference points.

1. An incision is made in the neck, and the right common carotid artery and right internal jugular vein are exposed for venoarterial ECMO.
2. The surgeon may cannulate the vessels through a purse-string suture and then reconstruct these vessels at the time of decannulation.
3. After insertion of the arterial and venous cannulae, the clamped cannulae are connected to the ECMO circuit. All the air is eliminated (Figure 25-69).
4. The cannulae are secured to the skin. The neck incision is closed and dressed. The surgical instruments are kept sterile until proper positioning of the venous and arterial cannulae is confirmed by x-ray examination.

FOR MEDIAN STERNOTOMY CANNULATION. The patient is prepped from neck to umbilicus and draped.

1. The patient has usually had a prior sternotomy incision, and so the sternum is opened with wire cutters.
2. A chest retractor is inserted, and purse-string sutures for cannulation are placed in the aorta and right atrium.
3. The aorta and venous cannulae are inserted and clamped.
4. The clamped cannulae are connected to the ECMO circuit. All the air is eliminated.
5. The sternum is left open to prevent kinking of the cannulae and ECMO pump tubing. The wound is closed with a synthetic patch sutured to the skin. An antibiotic ointment may be applied and an "Open Chest" sign placed on top of the outer dressing to serve as a warning related to potential chest compressions.

CHAPTER 26

Geriatric Surgery

SHEILA L. ALLEN

Aging is a process that can be described in chronologic, physiologic, and functional terms. Human aging from a physiologic perspective has changed little in the past 300 years. In general, we age neither faster nor slower than we did in Colonial America. Chronologic age, the number of years a person has lived, is an easily identifiable measurement. Average/median life span, or life expectancy, is the age at which 50% of a given population survives. Maximum life span potential (MLSP) is the age of the longest-lived member or members of the population or species. The average life span of humans has increased dramatically, yet our MLSP has not changed substantially. Although the number of people living beyond their 90s has increased more recently, the MLSP, estimated at 125 years for women and somewhat less for men, has not changed significantly in recorded history. Chronologic age or MLSP may not be the most meaningful measurement of age, however. The youth-oriented culture of the United States tends to judge based on age and appearance. Nevertheless, many people who have lived a long time remain physiologically and functionally young, whereas others are chronologically young but physiologically and functionally old (Wold, 2008).

Many aspects of our society will be affected by the growth of the population that is 65 years old or older. Policymakers, families, businesses, and healthcare providers will be challenged to meet the needs of this growing age-group. With the aging of the baby boomers (born between 1943 and 1964), the gerontology boom will occur somewhere between 2010 and 2030, producing the most rapid increase in the older population. Economics will play a factor as individuals born before 1937 will still qualify for full Social Security benefits at age 65 with incremental increases regarding benefit age for all persons born after that time. Those born in 1960 or after will have to wait until age 67 to qualify for full benefits, with reduced benefits calculated for individuals who apply for benefits after age 62 but before the specified retirement age (Wold, 2008). Nearly 36 million people age 65 years and older lived in the United States in 2003, accounting for more than 12% of the total population, and they can be divided into four subgroups (Box 26-1). The population considered oldest-old (age 85 years and older) increased from just more than 100,000 in 1900 to 4.2 million in 2000. In 2011 baby boomers will start turning 65 years old; and this segment of the population will increase at such a rate that the 2030 population is projected to be twice as large as it was in 2000. The 65-year-old and older population will increase from 35 million to 71.5 million, representing nearly 20% of the total U.S. population. Updated figures from 2006 set the number of older Americans 65 and older at 37 million, just over 12% of the total population (Federal Interagency Forum on Aging-Related Statistics, 2008). The growth rate for this age-group is expected to slow after 2030 when the last of the boomers join the older population ranks. After 2030 the baby boomers will move into the oldest-old population (age 85 years and older), which will grow accordingly (Federal Interagency Forum on Aging-Related Statistics, 2008). Figure 26-1 provides population data. The U.S. Census Bureau estimates that the population age 85 years and older could grow from 5.3 million in 2006 to nearly 21 million by 2050 (Wold, 2008). The proportion of the older population (age 65 years and older) varies by state. This proportion is partly affected by the state fertility and mortality levels and partly by the number of older and younger people who migrate to and from the state. In 2006 Florida had the highest proportion of people age 65 years and older: 17%. Pennsylvania and West Virginia also had high proportions: more than 15%. The proportion of the population age 65 years and older varies even more by county. In 2006, 35% of McIntosh County, North Dakota, was age 65 years and older, the highest proportion in the United States. In several Florida counties, the proportion was more than 30%. At the other end of the spectrum was Chattahoochee County, Georgia, with only 2% of its population age 65 years and older (Federal Interagency Forum on Aging-Related Statistics, 2008).

As in most countries of the world, older women outnumber older men in the United States, and the proportion that is female increases with age. In 2006 women accounted for 58% of the older population and for 68% of the population age 85 years and older. The United States is fairly young by comparison with other countries, with just more than 12% of its population age 65 years and older. In most European countries, the older population comprised more than 15% of the population, and it included nearly 20% of the population in both Italy and Japan in 2006 (Ebersole et al, 2008). Mirroring the total U.S. population, the elder population is more racially diverse than ever before. By 2050 programs and services for older people will require greater flexibility to meet the needs of a more diverse population. In 2006 non-Hispanic whites accounted for nearly 81% of the U.S. older population; African Americans, just over 9%; Asians, nearly 3%; and Hispanics (of any race), nearly 6%. Projections are that by 2050 the composition of the older population will change to 61% non-Hispanic white, 18% Hispanic, 12% African American, and 8% Asian. The older Hispanic population is projected to grow the fastest, from just more than 2 million in 2005 to 15 million in 2050, and to be larger than the older African American population by 2028. In 2006 nearly 1 million older Asians lived in the United States; by 2050 this population is projected to be almost 7 million (Federal Interagency Forum on Aging-Related Statistics,

2008). Figure 26-2 illustrates resident population by racial and ethnic composition.

Those older than 100 years are the fastest-growing age-group among the U.S. population older than 65 years. The U.S. Census Bureau, generally conservative in its estimates of the aged population thus far, now estimates there will be more than 200,000 American centenarians in 2020 and 500,000 to 4 million by the year 2050. Translating these demographics into healthcare trends produces even more startling implications for perioperative patient care. As a result of the "graying" of America, healthcare will never be the same. Most older persons have at least one chronic condition, and many have multiple conditions. Chronic diseases that are rarely cured, such as heart disease, stroke, cancer, and diabetes, are among the most common and costly health conditions. These long-term health conditions negatively affect quality of life, contributing to declines in functioning and the inability to remain in the community. Although chronic conditions can be prevented or modified with behavioral interventions, five of the six leading causes of death among older Americans are chronic diseases (Federal Interagency Forum on Aging-Related Statistics, 2008). Figure 26-3 lists the percentages of chronic diseases by gender. Between 1992 and 1999, the hospitalization rate in the older population increased from 306 hospital stays per 1000 Medicare enrollees to 365 per 1000. In 2005 the rate decreased to 350 per 1000 enrollees; however, the average length of stay decreased from 8 days in 1992 to 5.7 days in 2005. The number of Medicare enrollees staying in skilled nursing facilities increased from 28 per 1000 in 1992 to 79 per 1000 in 2005. The utilization rates for many services change based on changes in medical technology and physician practice patterns (Federal Interagency Forum on Aging-Related Statistics, 2008). The dramatic growth in elderly surgical patients punctuates the necessity for perioperative nurses to recognize the special needs of these patients. Understanding how normal aging changes and chronic disease affect the successful outcome of any surgical procedure is critical and is therefore the emphasis of this chapter.

BOX 26-1

Categorizing the Aging Population

- 65 to 74 years of age: the young-old
- 75 to 84 years of age: the middle-old
- 85 to 99 years of age: the old-old
- 100 years of age or more: the elite-old

Perioperative Nursing Considerations

Preliminary Evaluation

Before an elderly patient actually arrives in surgery, the physician considers many factors to determine whether the benefits outweigh potential risks. In the past, elders were not considered good candidates for surgery merely because of age

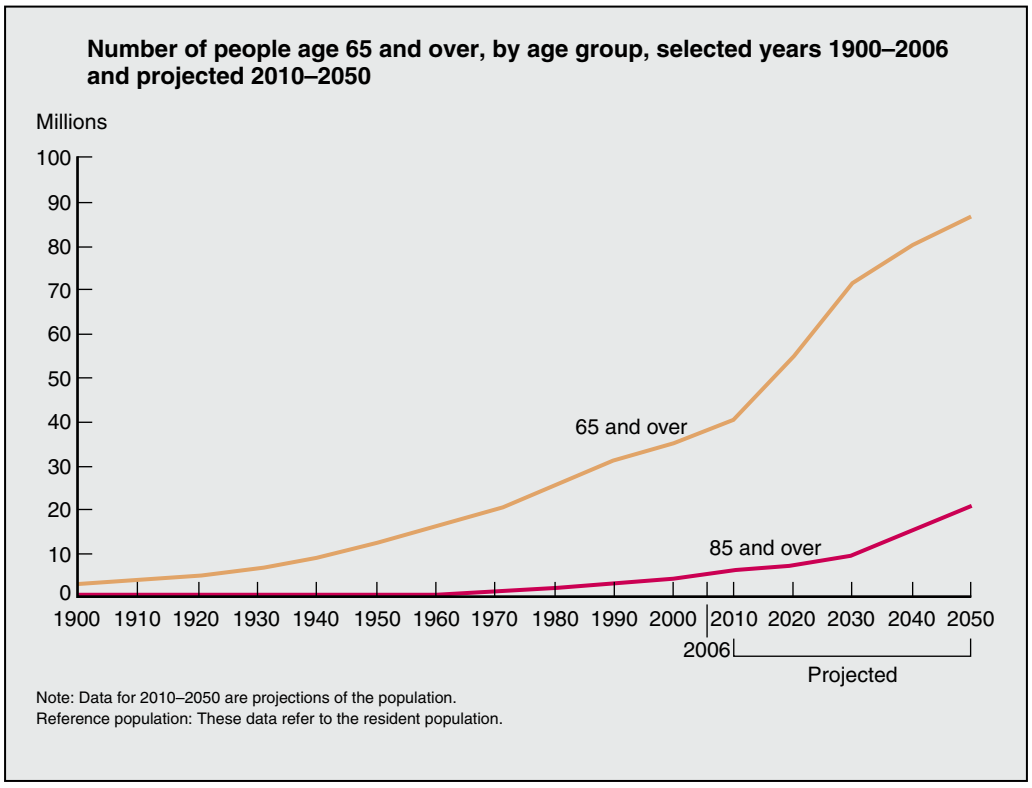

FIGURE 26-1 Actual and projected population data for people age 65 years and older.

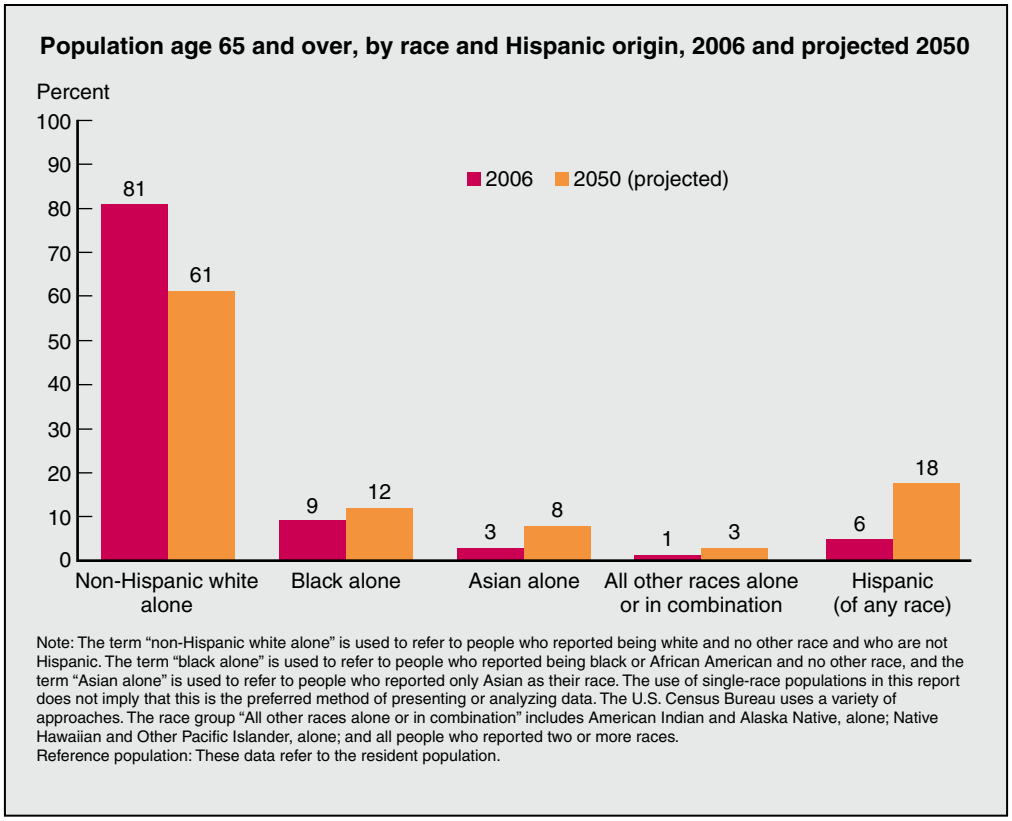

FIGURE 26-2 Ethnic population data for people age 65 years and older.

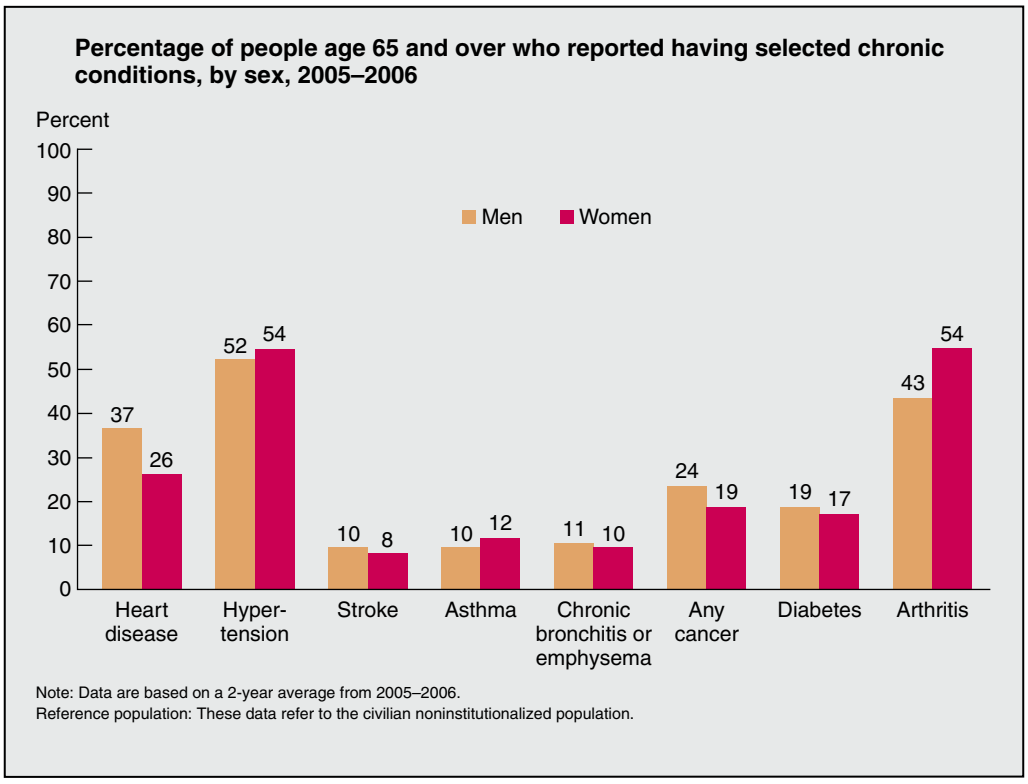

FIGURE 26-3 Chronic disease by gender in people age 65 years and older.

(History box). Uncertainty about the value of surgery in elders and about the operative risks prevailed. Because surgical morbidity and mortality increase with age and complexity of disease conditions, a thorough understanding of the physiology of aging is necessary when considering surgery on older patients (Evidence for Practice). Although improvements in technology, monitoring techniques, and anesthesia have made surgery safer for older patients, age remains a significant risk factor. Nevertheless, adequate assessments of the functional age and the physiologic reserve of the elderly surgical patient are of paramount importance (Wold, 2008).

According to Kim and Zenilman (2007), the occurrence of perioperative mortality in geriatric surgical patients is influenced by three factors—presence of co-existing disease, emergency surgery, and site of surgery:

1. *Presence of co-existing disease as quantified by the American Society of Anesthesiologists (ASA) Physical Status Classification.* Patients with an ASA status of IV or V are consistently

HISTORY

Evolution of Nursing Care for the Elderly

Societal attitudes toward the elderly population throughout the world have had a significant impact on elder status and access to resources. Historically, respect and reverence for elders were not always the societal norm. In ancient times, the Romans had little respect for elders. Egyptians dreaded the thought of getting old, and leaders such as Aristotle prevented elderly individuals from having any involvement in matters of government. Throughout the Dark and Middle Ages, and even into the Industrial Age, those who were youthful and productive had higher status. Elderly people were seen as nonproductive and a drain on resources.

Cultures that had no written language highly regarded their elders and looked to them as the teachers of succeeding generations. The ancient Chinese saw old age as a great accomplishment, deserving of honor. In general, the status of older persons has been influenced by the rate of societal change; slow rates of change were associated with higher status for elders, whereas rapid change found elders "out of touch," only knowing how things were, not how they are. Today we are in the midst of a rapidly changing society. Unlike anything that has happened before, elders' influence and status are rising along with their numbers.

Nursing care of the elderly population has transitioned through similar changes. Caring for older persons was a very unpopular segment of nursing practice. Nurses who aspired to care for elders were regarded as being less capable. It was not until 1966 that the first Division of Geriatric Nursing was established in the American Nurses Association (ANA). Ten years later, in 1976, the Division of Geriatric Nursing was changed to the Gerontological Nursing Division of ANA to more aptly reflect a broader scope of care. This change helped focus nursing attention toward a more accurate view of the elderly population, who were living life in all dimensions—not just as ill older adults. The Gerontological Society of America (GSA) devotes its efforts through interdisciplinary collaboration in research and practice.

In terms of surgical care of the aged, the definition of elderly has changed. The age that was considered too old for surgery has also changed—from patients only 50 years old in the early half of the twentieth century to patients well into their 80s, 90s, and even 100s in the early twenty-first century, now being successfully treated by surgical means. Perioperative nurses can expect to see the numbers of older and very old patients continue to rise in surgical settings. With the segmentation of age-specific competencies, perioperative nurses have more resources from which to base their care. Assisting elders to achieve the maximum benefit from their surgery with more meaning and quality of life is an integral component of perioperative patient advocacy and patient safety.

Modified from Ebersole P et al: *Toward healthy aging: human needs and nursing response,* ed 7, St Louis, 2008, Mosby.

EVIDENCE FOR PRACTICE

Considerations for Geriatric Surgery

The following principles of geriatric surgery can be used as a guide for practitioners to improve care for elderly surgical patients:

- Clinical presentation of disease may differ from the general population and may lead to delay in diagnosis.
- Lack of organ system reserve affects the elder's ability to handle severe stress, such as extensive or emergency surgery, and may be apparent only after surgery.
- Perioperative risk increases when preoperative preparation is decreased or suboptimal. Examples of preoperative preparation include cessation of smoking; administration of perioperative antibiotics; treatment of hypertension, anemia, and bronchitis; and prophylaxis of thromboembolic complications.
- Elective surgery produces far better outcomes than surgery performed under emergent conditions. Because of the elder's lack of reserve and the inability to conduct adequate preoperative preparation, the risk of emergency surgery is associated with at least a threefold increase in mortality and morbidity as compared to planned or elective procedures.
- Meticulous attention to detail can help avoid minor complications that may escalate into major adverse events in elderly patients. Restoring and maintaining homeostasis, lowering the risk of septic complications, preventing anastomotic leaks, and monitoring hemodynamics greatly reduce the surgical risk.
- Physiologic age is a better indicator of risk in surgery on elderly people than is chronologic age. Most surgeons agree that age alone is not a contraindication to surgery. In fact, studies confirm that even the very old can have successful positive surgical outcomes when their physical health status is considered to be uncomplicated by chronic disease.

Modified from *American Society of Anesthesiologists syllabus on geriatric anesthesiology,* available at www.asahq.org/clinical/geriatrics/prean_eval.htm. Accessed April 6, 2009.

found to have greater mortality than those with a physical status of I or II.

2. *Emergency surgery.* Surgical risk in elders increases dramatically when the surgery is of an emergent nature.
3. *Site of surgery.* Major vascular, intrathoracic, and intraabdominal procedures are reported to have a higher surgical risk than other surgical procedures in elders.

Surgical decision-making regarding elders can be difficult. As the baby boomers become seniors, they will be very different from healthcare consumers of the past. They will tolerate less and expect more. They will expect to be partners in decision-making regarding their care and will be more demanding in terms of quality and service (Williams, 2005). A frequent mistake is to compare the risk in elderly patients with that of younger patients. Elderly patients have an increased tendency for slower metabolism, multiple chronic diseases, and a decreased reserve capacity of their organs to respond to stress, as compared to younger patients (Berger et al, 2008). What should be considered is the risk of not operating and the quality of life expected. Although the recommendation for surgery is within the purview of the physician, perioperative nurses should be aware of its implications. Surgical intervention and management should be tailored to the patient's symptoms, overall functional and health status, and the predicted advantage of palliative intervention. Important factors that need to be evaluated are: (1) disease course versus life expectancy, (2) state of independence, (3) personal motivation, and (4) surgical risk versus nonoperative management.

1. *Disease course versus life expectancy:* Surgical intervention may not be appropriate if the prognosis of the disease is poor. However, if the patient has several years of life expectancy left and is likely to outlive the condition with minimal morbidity, surgical treatment may be the treatment of choice.
2. *State of independence:* The patient's right to self-determination and making healthcare decisions should always be considered. The need for independence is of utmost importance to elderly persons, and most of them are far more interested in maintaining health and independence than longevity. Complications of surgery are not well tolerated by elders and can quickly develop into life-threatening situations. If surgical intervention will further incapacitate an already debilitated person, alternative treatment should be considered. However, if surgery will help alleviate debilitating conditions and improve or maintain independence, it should be considered an appropriate modality of care.
3. *Personal motivation:* Evaluation of the elderly patient's level of motivation must be considered when surgery is planned. Many elderly patients are reluctant to undergo surgery because of concerns that the surgery will not improve their quality of life or will make them more dependent or destine them to a life in a care facility. In addition, they do not want to withstand the pain, discomfort, and rigors of surgery and the recuperative period necessary to treat a condition that does not really bother them very much or that they have "learned to live with." This lack of motivation will have a negative influence on the results of the surgery. Conversely, some elders expect and in some cases demand the best of care. They believe that the money they spend on taxes and healthcare entitles them to the very best that healthcare has to offer, regardless of its practicality. Nonetheless, patients who show a strong sense of determination in doing all that is necessary to get well and stay well are better candidates for surgery than those who believe illness is a prelude to death. Obviously, the outcome of surgery is enhanced if the patient is motivated to have a positive result.
4. *Surgical risk versus medical management:* Deciding between the risks of medical or nonoperative management and surgical intervention can be difficult for elderly patients. Surgical and anesthetic risks increase in proportion to the emergent nature of the patient's condition. When an acute emergency condition taxes an already overburdened physiologic state, survival is less likely. Patients may die even if the surgery was considered successful because of complications resulting from the complexity of the patient's co-morbid condition. Nonetheless, healthcare providers need to be sensitive to this possibility when communicating with family members. To increase the chances of survival from a surgical procedure, the elderly person must be in optimum condition and adequate preoperative assessment and preparation must precede an elective procedure.

The following considerations should be included when deciding to proceed with surgery in elders (Berger et al, 2008):

- Is there a clear indication for surgery, including a likelihood of disease progression?
- What practical limitations will be imposed on the patient with the progression of the disease?
- How much improvement can be expected after the surgical procedure?
- What is the expectation for quality of life with or without the surgery?
- How aware is the patient and the patient's family about the problem and proposed solutions?
- What risks are there for negative outcomes related to the procedure and the presence of co-morbid conditions?
- Has an adequate preoperative assessment and preparation preceded an elective procedure?

There are many important considerations related to the extent of surgical treatment. Therefore the decision for surgery relies heavily on the patient's physical status at the time of surgery and on the extent of disease progression. When treating patients who are nearing the end of life, attention should shift from solely maximizing survival to maximizing the quality of life and dignity while minimizing suffering. Early identification of problems with aggressive, preventive surgical treatment is considered more appropriate than waiting for problems to develop.

Perioperative nurses have a unique opportunity to assess and screen for signs of emotional and physical abuse in elderly patients during their preoperative assessment and while assisting with surgical positioning. Box 26-2 lists signs that may indicate abuse. If such signs are present, the perioperative nurse should report the suspected abuse to the appropriate authority. Reporting laws and regulations vary by state and facility.

In elderly patients, the consent process may require additional time to ensure that the patient understands and adequately answers the questions posed. If the older adult patient is comatose, has some disease or level of brain injury that inhibits decision-making, or is nondecisional, information must be relayed to the appropriate decision-maker (designated family member or person with power of attorney for healthcare). In advocating for the older adult, the perioperative nurse should

BOX 26-2

Signs That May Indicate Elder Abuse

- The older person demonstrates *excessive* agreement or compliance with the caregiver.
- The older person shows signs of poor hygiene, such as body odor, uncleanliness, or soiled clothing or underpants.
- The older person has malnutrition or dehydration.
- The older person has burns or pressure sores.
- The older person has bruises in various stages of healing that may indicate repeated injury.
- The older person lacks adequate clothing or footwear.
- The older person has not received adequate medical attention.
- The older person verbalizes lack of food, medication, or care.
- The older person verbalizes being left alone or isolated in some way.
- The older person verbalizes fear of the caregiver.
- The older person verbalizes his or her lack of control in personal activities or finances.

From Wold GH: *Basic geriatric nursing,* ed 4, St Louis, 2008, Mosby.

ensure any questions, concerns, or issues of the patient or the patient's decision-maker are addressed before the surgery. The principles of bioethics are the underlying basis for the nurse's ethical actions. The six principles are as follows:

1. Autonomy—respecting others and allowing individuals to make uncoerced, voluntary decisions
2. Beneficence—acting in the best interests of the patient
3. Fidelity—keeping promises by maintaining privacy and confidentiality of patient issues
4. Justice—treating individuals according to what is owed to them or fair
5. Nonmaleficence—directing healthcare providers to do no harm
6. Veracity—telling the truth

Regardless of the age of the patient, the development of ethical competency is an important component of the practice of perioperative nursing (Schroeder, 2004).

Assessment

In elderly persons a preoperative medical assessment is conducted to determine present physiologic functioning. Because of changes in biologic function of individuals over time, clinical pathways, rigid guidelines, algorithmic approaches, and other strategies of diagnostic investigation and resource allocation are likely to be less efficient for elders if based solely on age criteria. Healthcare providers, clinical investigators, and health policymakers must recognize that increasing variability becomes more important with chronologic age (Williams, 2005). Chronologic age as a valid predictor of a patient's response to surgery is not a reliable measurement. It gives little indication of the physiologic or biologic age and condition of a person. For example, a 75-year-old person can be in better physical and mental condition for surgery than a 65-year-old person. Biologic age as a measurement criterion is much more reliable. Establishing biologic age, however, becomes the greatest challenge. One tool, the Comprehensive Geriatric Assessment (CGA), is a multidimensional evaluation that scrutinizes medications, functional ability, co-morbid conditions, cognitive ability, mental function, nutritional status, and socioenvironmental factors. The CGA may be used both to identify at-risk individuals and to guide interventions. When evaluated as a screening tool in the geriatric community, it has been shown to detect new and unsuspected problems in 76% of elderly persons living at home. In geriatric medical studies the CGA has been found to be potentially beneficial in reducing the incidence of hospitalization, falls, delirium, and readmission. It is predictive of both morbidity and mortality in older patients (Kim and Zenilman, 2007).

Evaluation of functional status typically includes assessment of the patient's ability to perform activities of daily living (ADLs) (personal care tasks) and instrumental activities of daily living (IADLs) (everyday tasks). The scoring system that is employed for assessing co-morbidity in surgical patients is the American Society of Anesthesiologists Physical Status Classification. Additional measures of co-morbidity include the Cumulative Illness Rating Scale for geriatrics and the Charlson Comorbidity Index (Kim and Zenilman, 2007).

Impaired nutritional status is highly prevalent among the elderly; as many as 12% of men and 8% of women in the healthy geriatric population are considered undernourished. Higher rates of surgical complications and increased postoperative mortality have been observed in patients with poor nutritional status, as determined by a low body mass index, weight loss, a low preoperative serum albumin level, or a low Mini Nutritional Assessment score. Preoperative cognitive dysfunction has been associated with increased postoperative complications and worse survival in elderly surgical patients. Cognitive ability can be assessed with the Mini-Mental State examination (Kim and Zenilman, 2007).

Depression and the lack of social support are also linked to adverse outcomes in older surgical patients. A tool that is commonly employed in screening for depression in the elderly is the Geriatric Depression Scale. Several tools are available for quantifying social support resources in elderly patients. One such tool is the Medical Outcome Study Social Support Survey, which yields a score on a scale of 0 to 100 and includes "emotional" and "tangible" subscales. Another commonly used measure of social support is the Seeman and Berkman Social Ties Score, which measures social ties in four different areas.

An interdisciplinary approach is necessary to consider the complex health needs of the elderly patient in an effort to provide quality care. Application of these findings identifies operative risk, minimizes postoperative complications, and establishes the presence and status of any concomitant disease process that could negatively affect the outcome of the surgery. The preoperative nursing assessment is conducted to plan patient care throughout the perioperative period. In particular, assessment data are used to establish presurgical baseline data so that health status changes, primarily during the intraoperative and postoperative periods, are more readily recognized. The nurse's data collection includes the standard assessment information with considerations of co-existing conditions and a review of the patient's medication list (Box 26-3). Polypharmacy is an issue for many elderly patients and is a concern because of the physiologic changes associated with aging that lead to susceptibility to alterations in pharmacokinetics and susceptibility to adverse drug reactions.

BOX 26-3

Preanesthesia Evaluation Data

Preanesthesia evaluation data include but are not limited to the following:

- Complete medical history with systems' review and anesthetic history, including self or family difficulty with anesthesia
- Complete surgical history
- Proposed surgical procedure
- Allergies—drug, food, environmental, latex
- Routine medications—prescription, over-the-counter (OTC), herbal, diet, recreational
- Current physical information—height, weight, baseline vital signs
- Social history—cultural and religious beliefs, alcohol and tobacco use
- Mental status—emotional clues; learning barriers; sensory, sight, or speech impairments
- Prosthetics—dentures, glasses or contacts, hearing aids, assistive devices (walker, wheelchair), implanted devices, prosthetics, body piercings
- Socioeconomic issues—transportation, home support
- Advance directives—living will, do-not-resuscitate (DNR) directive

Modified from Woogler JM: Preoperative testing and medication management, *Clin Geriatr Med* 24:573-583, 2008.

Chronic conditions may interfere with the elderly person's ability to distinguish between recent and long-standing ailments. Therefore the preoperative interview, especially in elderly persons, should be conducted in a quiet, relaxed environment with as few distractions as possible. The elderly person should be allowed to respond to each question independently without prompting from a spouse or other family members unless absolutely necessary. This helps to maintain the patient's dignity, independence, and control, which are extremely important to the older adult.

Normal Age-Related Changes. Aging is a biologic process characterized by the inevitable, progressive, predictable evolution and maturation until death. Aging is not the accumulation of disease, although the two are related in subtle, complex ways. A fundamental principle is that biologic age and chronologic age are not the same. Different individuals age at different rates. Physical aging occurs in different organ systems at different rates, influenced by lifestyle choices and socioeconomic status (Williams, 2005). In general, the aging process imposes a decline in organ functions, atypical responses to pain and temperature, alterations in pharmacokinetics (Surgical Pharmacology), and atypical signs and symptoms of disease, all of which may vary from one elderly person to the next. Having a clear understanding of normal age changes helps establish appropriate nursing diagnoses and develop a plan of care (Box 26-4). The following review of systems focuses on age-specific changes of particular importance to the perioperative plan of care.

PHYSIOLOGIC CHANGES

Integumentary System. The nails become thick and tough, and the circulation in the feet may decrease (Table 26-1). A nick or cut can lead to a serious infection. Color and texture of hair change, and the loss of pigmentation results in graying of hair. Decrease in oil content makes the hair dull and lifeless, and the amount of hair decreases. The skin loses elasticity and subcutaneous fat and becomes more prone to shear force and pressure injury. Because of the thinness of the skin and small-vessel fragility, bruising and hemorrhaging are quite common. Dry skin develops because of decreased oil and sweat production from sebaceous and sweat glands, respectively. As a result, skin breakdown and pressure ulcers, as well as wound infections, develop more easily. The vascular system of the skin has nutritional and protective roles. It is necessary for body heat regulation, provides defenses against microbial and physical damage, provides nutrient supply to the avascular epidermis, and promotes wound healing. Having an intact vascular system to maintain these skin role characteristics is extremely important for a patient undergoing surgical intervention. However, papillary capillaries, responsible for epidermal nourishment and heat dissipation, degenerate with aging. What is left is only the horizontal arteriovenous plexus lying beneath the skin surface. This progressive impairment of vascular circulation and tissue nutrition and the loss of subcutaneous tissue predispose to a feeling of cold, especially in cool environments such as the OR. Therefore the ability to maintain thermoregulation is compromised in elders and must be controlled through external measures.

Respiratory System. Pulmonary complications in the elderly account for nearly 50% of postoperative complications in the total population of surgical patients (Wold, 2008). Lungs lose elasticity, which contributes to a decrease in functional residual capacity, residual volume, and dead space. Lungs increase in size and are lighter in weight with aging. A rigid chest wall is the result of calcification of costal cartilages, osteoporosis, and dorsal kyphosis. Muscles responsible for inhalation and exhalation may be weakened, resulting in a diminished ability to increase and decrease the size of the thoracic cavity. All these changes contribute to a minimal tidal exchange, which makes the elderly patient more susceptible to pulmonary complications, such as adult respiratory distress syndrome (ARDS), pneumonia, and aspiration. Lung changes are not usually obvious at rest. However, when the person becomes active, breathing may be more difficult. The ability to cough and clear the upper airway is lessened, and such reduction may increase the chance of respiratory tract infections and diseases, some of which can be severe enough to threaten the elderly person's life.

Cardiovascular System. A decrease in coronary artery blood flow is more likely in elderly persons. Because of a shift in blood flow, there is a greater decrease in circulation to the kidneys and liver than to the brain and heart. Blood pressure rises as a result of increased arterial resistance. When the elderly person is at rest, the heart rate remains approximately the same as that of a younger person. However, the older heart requires a longer recovery time after each beat, which means that it reacts poorly to stress and anxiety-produced tachycardia. In general, the capacity of the cardiovascular system to tolerate and buffer insults is limited. Activity, exercise, excitement, and illness increase the body's need for oxygen and nutrients. The older heart may be unable to meet these needs. Arteries lose their elasticity and become narrow, causing a weakened heart to work harder. As a result, less blood flows through the arteries, causing poor circulation in many parts

SURGICAL PHARMACOLOGY

Medication and the Elderly

Perioperative nurses caring for older adults must consider factors that affect the choice of medications and the effects of those medications on this population. Older adults may not tolerate the standard dosages used for younger adults and are at higher risk for side effects and toxicity. Dosages of drugs may initially be smaller than those used for the general adult population and then titrated based on the patient's response and therapeutic effect. Older adults have less reserve, and chronic disease may contribute to drug reactions. Physiologic changes may affect the absorption, distribution, metabolism, and excretion of medications. Older adults also have a higher prevalence of nonprescription drug use (e.g., analgesics, antacids, laxatives, supplements). A thorough medication history is essential to provide safe care. The nurse should partner with the surgeon and anesthesia provider to ensure that drug therapy is individualized based on the patient's baseline condition, actual physiologic impairments, and severity of preexisting illness.

Common adverse drug reactions in older adults include the following:

- Edema
- Dizziness
- Nausea and vomiting
- Urinary retention
- Anorexia
- Diarrhea
- Dry mouth
- Constipation
- Fatigue
- Confusion
- Weakness

Age-related changes that may impact medication administration in the perioperative period are as follows:

CHANGES IN ABSORPTION

- Increased gastric pH
- Decreased gastric blood flow
- Decreased gastrointestinal motility

CHANGES IN DRUG DISTRIBUTION

- Decreased amounts of total body water
- Increased ratio of adipose tissue to lean body mass, causing storage of lipid-soluble drugs and decreased plasma drug levels
- Decreased albumin levels
- Decreased cardiac output

CHANGES IN METABOLISM AND EXCRETION

- Decreased liver size
- Decreased hepatic blood flow
- Decreased liver enzyme activity
- Decreased renal blood flow
- Reduced glomerular filtration rate, leading to slower excretion times for medications and allowing serum drug levels to rise

Modified from Hodgson BB, Kizior RJ: *Saunders nursing drug handbook 2009,* St Louis, 2009, Saunders; Ignatavicius DD: Health care of older adults. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, St Louis, 2010, Saunders.

of the body. Elders have an increased risk for aortic arch disruption, myocardial contusion, and aneurysm development. A complete, comprehensive cardiac workup should be performed before the elderly patient is scheduled for any surgical procedure (Workman, 2010).

Digestive System. As a person ages digestive glands decrease the amount of secretions; mucus becomes thicker, causing dysphagia; and saliva becomes more alkaline. Loss of teeth or poorly fitted dentures make chewing difficult, resulting in digestion problems. Foods that are difficult to eat are avoided, and such avoidance can affect overall nutrition. Decrease in peristalsis and a reduction of gastric motility—the results of muscle tone loss—cause a delay in stomach emptying. Potential traumatic injuries to the bowel and mesenteric infarction are more likely to occur (Wold, 2008). The absorption of drugs is affected because of a reduction of blood flow to abdominal viscera, a reduction in the amount of hydrochloric acid secreted, and delayed gastric emptying. Decreases in the levels of total body water and plasma volume result in a smaller volume of distribution for water-soluble drugs. Because the percentage of body fat increases and the lean body mass decreases, the storage of lipophilic drugs, such as diazepam and lidocaine, is enhanced. These factors are of particular importance for assessing the patient's response to preoperative, anesthetic, and postoperative medications.

Urinary System. Nephrons decrease in function with age, so by 75 years of age a person has probably lost one third to one half of original nephron function. Elasticity and tone are lost in the ureters, bladder, and urethra, which lead to incomplete emptying of the bladder. By age 50 years at least 50% of all men have some degree of benign prostatic hypertrophy (BPH) and the prevalence increases with each decade of life (Ebersole et al, 2008). Difficulty in voiding and retention of urine are common with this condition. Total bladder capacity also declines, so elderly persons experience a more frequent and urgent need to urinate. Because blood flow to the kidneys is decreased, patients are at greater risk for fluid overload, fluid and electrolyte imbalance, and alterations in the elimination of medications. During the perioperative phase of the patient's

BOX 26-4

Age-Related Physiologic Changes

HEMATOPOIETIC AND LYMPHATIC SYSTEM
- Increased plasma viscosity
- Decreased red blood cell production
- Increased immature T cells

RESPIRATORY SYSTEM
- Decreased tissue elasticity, resulting in pooling of secretions in lower lung bases
- Increased calcification of cartilage, leading to increased rigidity of the rib cage, decreased lung capacity, and reduced cough efficiency
- Less ciliary activity by bronchial lining
- Reduction in number of capillaries, resulting in decreased gas exchange and drying of mucous membranes

CARDIOVASCULAR SYSTEM
- Changes in cardiac muscle tone and blood vessel elasticity, leading to decreased tissue oxygenation and decreased venous return
- Dysrhythmias; rapid or slow heartbeat
- High blood pressure related to atherosclerosis
- Chest pain or shortness of breath on exertion
- Decreased cardiac output, causing decreased circulation to extremities

DIGESTIVE SYSTEM
- Dental issues (e.g., tooth loss, periodontal disease), leading to chewing issues
- Decreased saliva production
- Relaxation of esophageal muscle tone, increasing the prevalence of esophageal reflux
- Decreased gastric secretions
- Bowel dysfunction from decreased peristalsis

URINARY SYSTEM
- Loss of nephron units
- Decline in renal tissue growth
- Reduced kidney size
- Reduced bladder capacity
- Increased prostate size in men
- Weakened bladder muscles with consequent postvoid residual

MUSCULOSKELETAL SYSTEM
- Progressive loss of muscle strength from decreased muscle mass
- Decreased fluid in intervertebral disks
- Postural changes, such as curvature of the spine from decreased bone calcium
- Joint and back pain/stiffness
- Bone breakdown overcomes bone building, with resultant osteoporosis
- Decreased tissue elasticity, resulting in decreased mobility and flexibility

NERVOUS SYSTEM
- Loss of neurons, leading to decreased reflexes
- Slower reaction time from loss of nerve fibers
- Changes in sleep patterns; less rapid eye movement (REM) and deep sleep
- Decreased amounts of neuroreceptors, resulting in decreased perception of stimuli

SENSORY SYSTEM
- Decreased tear production
- Increased lens discoloration, which decreases color perception
- Decreased muscle tone in eye, leading to decreased pupil diameter, decreased night vision, increased refractive errors, increased sensitivity to glare
- Loss of hair cells in inner ear, leading to balance problems
- Decreased joint mobility in bones of inner ear
- Decreased number of papillae on tongue

ENDOCRINE SYSTEM
- Decreased pituitary secretions (growth hormone), leading to decreases in muscle mass
- Reduction in the production of thyroid-stimulating hormone
- Decreased production of parathyroid hormone
- Increased prevalence of diabetes mellitus

REPRODUCTIVE SYSTEM

Female
- Decreased estrogen levels
- Decreased tissue elasticity
- Increased vaginal alkalinity

Male
- Decreased testosterone levels
- Circulatory changes

Modified from Wold GH: *Basic geriatric nursing,* ed 4, St Louis, 2008, Mosby.

hospital stay, the greatest number and variety of drugs are given; the cumulative effect increases the chances for adverse and consequential results.

Musculoskeletal System. Changes to the elderly person's skeleton, such as the loss of bone mass, contribute to skeletal instability and make fractures of the hip, rib, distal radius, and vertebrae very common. Curvature of the spine and arthritis of the joints are also common. Pain as a fifth vital sign is routinely evaluated for all patients. In elders, long-standing conditions such as arthritis, neuralgia, and ischemic disorders produce chronic pain. Back pain is related to dehydration and decreased flexibility of the vertebral disks. These changes result in a gradual loss of height, loss of strength, and decreased mobility. Poor posture tends to be proportional to the degree of back pain experienced and may greatly compromise internal organ function. Joint range of motion is impaired to varying degrees and may affect surgical positioning. Extra care in positioning patients in the OR should be taken with the elderly patient, ensuring appropriate padding and joint protection (Wold, 2008).

Nervous System. Although not functionally significant, a steady loss in the number of neurons begins at about 25 years of age. An inappropriate or slow response to stimuli is primarily a result of a decrease in some organ systems' ability to send reliable messages to the brain and spinal cord. Nerve cells are particularly sensitive to lack of oxygen. Because elderly persons may have, in varying degrees, cerebral arteriosclerosis and atherosclerosis, decreased blood flow and nervous system

TABLE 26-1

Age-Related Skin Changes

Physiologic Change	Results
Decreased vascularity of dermis	Increased pallor in white skin
Decreased amount of melanin	Decreased hair color (graying)
Decreased sebaceous and sweat gland function	Increased dry skin; decreased sweating
Decreased subcutaneous fat	Increased wrinkling
Decreased thickness of epidermis	Increased susceptibility to trauma
Increased localized pigmentation	Increased prevalence of brown spots (senile lentigo)
Increased capillary fragility	Increased purple patches (senile purpura)
Decreased density of hair growth	Decreased amount and thickness of hair on head and body
Decreased rate of nail growth	Increased brittleness of nails
Decreased peripheral circulation	Increased longitudinal ridges on nails, increased thickening and yellowing of nails
Increased androgen/estrogen ratio	Increased facial hair in women

From Wold GH: *Basic geriatric nursing,* ed 4, St Louis, 2008, Mosby.

deficits, such as insomnia, irritability, visual motor deficits, and memory loss, may occur. These patients are more likely to experience subdural hematomas or closed head injuries from falls. Other neurologic changes significant to perioperative care include a loss of position sense in the toes, decreased tactile sense, and atypical response to pain. In addition, aging is associated with disruption of thermoregulation (Wold, 2008); inadvertent hypothermia (temperature below 36° C [96.8° F]) is a common problem in elders (see Chapter 9 for a full discussion of preventing unplanned hypothermia in adult surgical patients). In the OR, maintaining balance between heat gain (e.g., metabolic production, muscular contraction, hot ambient temperature) and heat loss (e.g., radiation, convection, evaporation, ventilation, cold fluid infusion, blood loss, antithermoregulatory drugs, impaired heat production) can be difficult in older surgical patients.

SENSORY CHANGES. Sensory changes in vision, hearing, taste, smell, and touch may influence the patient's response to care. If preadmission communication is done, the perioperative nurse may ask about vision and hearing and remind patients to bring their glasses and hearing aids to the facility (Clayton, 2008). Farsightedness, or presbyopia, in the aging person is a result of the lens becoming more rigid and less pliable with age. Consequently, visual acuity and accommodation are decreased. Color perception changes as a result of a yellowing of the lens, which makes distinguishing blue, green, and purple more difficult for the elderly person. Of particular importance in the OR is an awareness of the older person's difficulty in adapting to changes in light. Moving patients from a dimly lit holding area to the bright lights of the OR can cause momentary "blindness."

Presbycusis, or loss of hearing sensitivity, is irreversible, bilateral, and primarily sensorineural, although metabolic and mechanical causes are also possible. It is the most frequent cause of hearing loss in the geriatric patient. Hearing loss, which appears to be greater in men than in women, is mostly within the higher frequencies (above 1000 Hz). In addition, cerumen thickens and the eardrum becomes less pliable, and such changes also contribute to diminished hearing. Often geriatric patients are labeled "confused" or "senile" because they respond inappropriately to questions they did not hear or they describe what they see inaccurately because of poor vision.

Changes in taste and smell begin to occur at approximately 60 years of age and become more pronounced with advanced age. Older adults have two to three times more difficulty in detecting flavors than do young adults. Oral hygiene, dental disease, and decreased salivary function may also alter tasting ability. There is a close association between the sense of smell and human behavior. Smell can affect emotions when a person recalls a particular odor. Other functions include protection of the individual by warning of danger in the air, such as smoke or gas fumes; assistance in digestion; and helping a person to remember or recollect. In elders, the sense of smell can be reduced, as well as the ability to identify odors (Wold, 2008).

Changes in sensitivity to touch often accompany the aging process, but the degree of change varies among individuals. In some cases, losses can be related to neuropathy caused by disease, injury, or circulatory problems. Decreased sense of touch can affect the elderly person's ability to localize stimuli and can also reduce the speed of reaction to tactile stimulation. For example, an older person may have difficulty differentiating among coins, fastening buttons, or grasping small items.

PSYCHOLOGIC CHANGES. Physiologic and psychologic stress may result in an acute state of confusion or delirium in the geriatric patient that is analogous to convulsions as a stress reaction in the pediatric patient. In elders, mental change can be a warning of some underlying problem. It is of pivotal importance to determine the patient's interpretation of pain in the assessment phase. Confusion or delirium should therefore not be dismissed as an expected behavior of the geriatric patient. Delirium occurs in more than 80% of intensive care patients and patients at the end of life and in as many as 50% of hospitalized elders. It is associated with increased length of stay, increased morbidity, poorer functional outcomes, increased risk of nursing home placement, and increased patient care costs. Several studies suggest that delirium is lessened when pain is appropriately managed, as determined in the study by Robinson and colleagues (2008) of hip fracture patients. The most important assessment factor is determining whether the confusion is

BOX 26-5

Strategies for Communicating with Impaired Elderly Adults

When communicating with elderly adults who have cognitive impairments, perioperative nurses and surgical technologists should consider the following strategies:

- Try not to startle the person when starting a communication.
- Approach from the front, knock, or announce your presence by calling the person's name.
- Approach patients who have a left-sided hemiparesis from the right side.
- Identify yourself.
- Communicate when the person is most alert.
- Eliminate or reduce noise and distractions.
- Make sure you have the person's attention before speaking.
- Try to use a variety of words or descriptions until meanings are clear.
- Ask clear, specific questions.
- Ask only one question at a time.
- Pay attention to the emotional context of conversation.
- Use pictures and gestures in addition to words.
- Have the person sit up for conversation whenever possible.
- Keep messages simple and repeat as needed.
- Be patient and do not interrupt. Slow down the pace of communication.
- Treat the person as normally as possible.

RESEARCH HIGHLIGHT

Older Surgical Patients at Greater Risk for Developing Cognitive Problems

Patients older than age 60 who have elective surgeries such as hysterectomies, joint replacements, and other nonemergent, inpatient procedures are at an increased risk for long-term cognitive problems. A Duke University Medical Center study found that elderly patients who developed postoperative cognitive problems were more likely to die in the first year following surgery. Memory and the ability to process information were measured in 1000 adult patients. Problems with cognitive dysfunction were more common in those patients with lower educational level and a history of stroke that left no noticeable neurologic impairment.

One hypothesis that explains why some patients suffer this dysfunction is that surgery and the accompanying anesthesia might cause inflammation in the brain that can affect the patient's ability to learn, retain, or remember information. The types of interventions to prevent or mitigate the detrimental effects of surgery and anesthesia on the aging brain will be the subject of further research.

Modified from Clinical Rounds: Older surgical patients at greater risk for developing cognitive problems, *AANA News Bulletin* 62(3):9, March, 2008.

chronic or acute. Chronic conditions, such as depression and Alzheimer's disease, can make communication with the patient difficult. Depending on the stage of disease, patients may or may not be able to understand explanations. Family members are the best resource to determine the patient's ability to comprehend and respond to questions and instructions. Behavioral changes, such as aggressiveness, agitation, and paranoia, are not uncommon. Soft restraints may be necessary during local procedures in the OR to ensure patient safety. Taking the time to talk slowly, being deliberate in movements, getting to know the patient, and developing a trusting relationship before surgery can help to lessen the patient's anxiety and control the combative outbursts that occur in some Alzheimer's patients (Box 26-5). A mnemonic for pain assessment in demented and nonverbal elders is described in Box 26-6. The American Society of Pain Management Nursing (ASPMN) has created guidelines for assessing pain:

- Ask the patient about pain.
- Search for potential causes of pain.
- Observe behaviors.
- Seek surrogate reports of pain.
- Do an empiric analgesic trial (Ferris, 2008).

Acute confused states or delirium in elders can be precipitated by a number of conditions and may be the sole manifestation of a life-threatening complication. Delirium in elders may be evidenced by alteration in level of consciousness, inattention, disorganized thinking, or an acute onset of mental status change.

Some of the most common predisposing factors for confusion or delirium in hospitalized elders are increasing age (Research Highlight), baseline brain damage, drug or alcohol addictions, fatigue, social and psychologic stressors, and sleep deprivation. Apparent confusion could be caused from drugs; infection; withdrawal from alcohol; metabolic, cerebrovascular, or cardiac disorders; trauma; or cancer. Conditions such as fecal impaction, changes in routine, urinary bladder distention, dehydration, electrolyte imbalance, and stress can also affect cognition in elders (Touhy, 2008). Even the disruption of relocation into the hospital, which brings the patient into an unfamiliar environment, can cause acute confusion, particularly during the postoperative period. Validation of the patient's previous mental state with a relative or significant other can help to determine if the onset occurred since hospitalization.

Routine Laboratory and Diagnostic Tests. The physiologic changes of aging do not significantly alter the diagnostic values of complete blood count (CBC), differential cell count, platelets, urinalysis, and blood chemistry results; therefore abnormalities should be evaluated. A slight increase may be noted in the levels of potassium, fasting blood glucose, postprandial blood glucose, oral glucose tolerance, total cholesterol, and

thyroid-stimulating hormone. A decrease in the amounts of vitamin B_{12}, folic acid, magnesium, and albumin and decreased creatinine clearance may also be noted. The chest x-ray film may reveal increased anteroposterior diameter, osteopenia, and degenerative joint disease. The heart size should appear normal, even in elders. Cardiomegaly can contribute to postoperative complications and should be evaluated. The electrocardiogram (ECG) may show P-wave notching, ST-segment depression or left ventricular hypertrophy, and T-wave flattening or inversion that are associated with an increased risk of myocardial ischemia (Berger et al, 2008). An increase in bundle branch block, hemiblock, and first-degree block may also be noted, largely as a result of degenerative disease of the conduction system. Opinion about the number of preoperative laboratory tests to be ordered varies. Use of a focused history and physical examination yields important information regarding which preoperative tests are indicated. Preoperative testing should be based solely on the history, physical examination, and planned surgical procedure.

Because many elderly patients take several medications, assessing their drug history is important. The patient's physician will determine which medication should be withheld during the preoperative period and which should be administered with a sip of water the morning of surgery. Any patient who has been receiving steroids within the previous 12 months should receive parenteral steroids starting the evening before surgery and continuing through the initial postoperative course.

Control of diabetes is often difficult during the perioperative period. For patients taking oral hypoglycemic agents, the medication is generally withheld and serum glucose and urinary glucose levels are closely monitored. Diabetic patients treated with long-acting parenteral insulin typically discontinue it on the day of surgery and regular insulin is given during the preoperative period. Diabetic patients who are fasting the morning of surgery should take their insulin as directed by the anesthesia provider and have an intravenous (IV) line inserted for infusion of 5% dextrose and water on admission to the OR.

Additional Assessment Data. Additional data regarding the patient can be gained from observation of appearance, behavior, dress, and language. For instance, does the patient's apparent age (how old the patient looks) match the chronologic age? Facial expressions and contradictory behaviors can help the nurse assess the patient's mental status. Perioperative nurses in the preoperative area can gather additional data by noting the patient's clothing. For example, does the clothing size indicate signs of weight loss? Is clothing stained or burned? What is the condition of the patient's shoes? The patient's use of language and communication skills should also be assessed when formulating a teaching plan.

Another important but often overlooked area of assessment is dental/oral health evaluation. Disorders of the oral cavity can affect the nutritional condition of the patient. Many elderly persons simply do not attempt to eat because of ill-fitting dentures or poor oral health. In addition, the condition of the patient's temporomandibular joint and the presence of an oral disorder, including loose teeth and dentures, can make the difference between a smooth and safe anesthesia induction and a disastrous anesthesia experience.

The risk for impaired nutritional intake is exacerbated by other factors, such as reduced salivary gland activity, receding gums, and thinner tooth enamel, with concomitant brittleness in the teeth. Esophageal mobility is reduced, and a more relaxed cardiac sphincter slows emptying in the esophagus. Moreover, weakened intestinal musculature and slower peristalsis in the lower gastrointestinal (GI) tract may lead to constipation. The confluence of these factors often results in poor nutrition. For the elderly surgical patient, this can have deleterious effects, especially for wound healing.

Life changes can also affect nutritional status. Of particular importance are the losses endured with aging, such as the loss of one's spouse, family, or friends through death or relocation; loss of a prior standard of living through retirement; and loss of physical or mental well-being. These changes can affect older people to the point that they either cannot afford to buy nutritious foods or lose the ability or interest to prepare food. The ultimate effect, among other things, is a nutritionally debilitated patient. Any nutritional deficits should be corrected before surgery because the success of the operative procedure, the rate of wound healing, and the length of hospital stay are directly related to the nutritional state.

Determination of Operative Risk. After assessment of the patient is completed, conditions that can add to the patient's operative risk may be identified (Box 26-7). Medical disorders (including cardiac, abdominal, and thoracic) as well as multiple operations performed on an emergency basis significantly increase operative risk. Whenever possible, medical conditions are treated before surgery. Sometimes correction is not possible, and the risk of forestalling surgery outweighs any other medical problem. The determination of operative risk for the patient is generally based on the ASA Physical Status Classification (Sieber and Pauldine, 2005). Although the anesthesia provider performs the actual classification of the patient, familiarity with the parameters from which a decision is made is important:

- Class I: normal, healthy patient; no gross organic disease
- Class II: patient with mild to moderate systemic disease with functional impairment
- Class III: patient with severe systemic disease that limits activity but is not incapacitating
- Class IV: patient with incapacitating systemic disease that is a constant threat to life
- Class V: moribund patient not expected to survive 24 hours with or without the operation
- Class E: emergency procedure (applied to any of the previous classifications)

The most common surgical procedures in the elderly population that pose a greater risk of death are as follows:

- Acute intestinal vascular insufficiency
- Fracture of neck of femur
- Malignant neoplasm of colon
- Perforated diverticulum of colon
- Peripheral arterial occlusive disease
- Ruptured abdominal aortic or thoracic aneurysm

Other factors that are considered in determining operative risk are the patient's cognitive and functional states. Surgeons and anesthesia providers can assess the patient's cognitive state through the use of tools such as the Folstein Mini-Mental State Evaluation (MMSE). The MMSE evaluates four areas: orientation, registration, attention/calculation, and language. Points are assigned to each area; a perfect score is 30. A score below 24 indicates cognitive impairment, which may increase operative

BOX 26-7

Risk Factors for Surgery in Elders

SURGICAL RISKS
- Emergency surgery
- Site of surgery
  - Vascular
  - Aortic
  - Intrathoracic
  - Intraperitoneal
- Duration of procedure (more than 3.5 hours)

ANESTHETIC RISKS
- American Society of Anesthesiologists (ASA) classifications III to V
- Age older than 75 years
- Preexisting medical disease (hypertension; diabetes mellitus; cardiac, renal, liver, or respiratory disease)

DISEASE-RELATED RISKS
- Cardiovascular
  - Angina
  - Previous myocardial infarction
  - Congestive heart failure
- Pulmonary
  - Bronchitis
  - Pneumonia
- Cigarette smoking
- Digestive
  - Poor nutritional status or malnutrition
  - Protein deficiency
  - Cirrhosis
  - Active peptic ulcer
- Endocrine
  - Adrenal insufficiency
  - Hypothyroidism

COGNITIVE IMPAIRMENT
- Dementia
- Acute confusional state (delirium)
- Alzheimer's disease

OTHER FACTORS
- Dehydration
- Anemia
- Recent stroke
- Malignancy
- Low albumin level
- Impaired mobility
- Patient living in institutional care

Modified from Kim SS, Zenilman ME: The elderly surgical patient. In Souba W et al, editors: *ACS surgery principles and practices,* ed 6, Ontario, Canada, 2007, BC Decker.

risk and increase the likelihood for postoperative complications. Functional status can be assessed through scoring the patient's ability to perform physical tasks. Each task is assigned a metabolic equivalent (MET). Tasks range from the ability to feed and dress oneself (1 MET) to the ability to participate in strenuous activity, such as football or skiing (10 METs). The inability to function above 4 METs is associated with increased perioperative cardiac events and long-term risk (Berger et al, 2008).

Nursing Diagnosis

In evaluating, synthesizing, and prioritizing the data collected during the preoperative assessment, the perioperative nurse can formulate nursing diagnoses that will form the basis of the plan of care.

Nursing diagnoses related to the care of geriatric surgical patients might include the following:
- Risk for Deficient Fluid Volume
- Ineffective Thermoregulation
- Risk for Impaired Skin Integrity
- Disturbed Sensory Perception (visual or auditory)
- Risk for Perioperative Positioning Injury
- Ineffective Family Therapeutic Regimen Management
- Risk for Infection

Outcome Identification

Outcomes identified for the selected nursing diagnoses could be stated as follows:
- The patient will maintain age-appropriate fluid volume levels intraoperatively and postoperatively.
- The patient will maintain normothermia ±1° F throughout the perioperative period.
- The patient's skin integrity will remain intact intraoperatively.
- The patient's perception and interpretation of environmental and sensory stimuli will be accurate throughout the perioperative period.
- The patient will be free from perioperative positioning injury.
- The patient receives appropriate medication or medications, safely administered during the perioperative period.
- The patient is free from signs and symptoms of infection.

Planning

As a result of anatomic and physiologic effects of aging, geriatric patients have, in varying degrees, a general decline in organ function and an altered ability to recover from stressful events. In addition to normal age changes, many older adults experience one or more chronic conditions that influence the risk of surgery. Successful surgical outcomes in the geriatric patient depend on elective versus emergency surgical procedures, optimum physical condition of the patient, thorough preoperative assessment, close intraoperative and postoperative monitoring, and preventive measures to decrease the likelihood of complications. Collaboration with the entire surgical team can create an environment that is safe, efficient, and caring and provides for a positive patient outcome.

A Sample Plan of Care for a geriatric surgical patient is shown on pp. 1170-1171.

Implementation

Perioperative geriatric patient care is very similar to the care provided to younger adults. However, modifications that involve consideration of age-specific differences between the

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Risk for Deficient Fluid Volume related to nothing-by-mouth (NPO) status and intraoperative blood and body fluid losses secondary to age-associated decrease in total body water and plasma volume

OUTCOME
The patient will maintain age-appropriate fluid volume levels intraoperatively and postoperatively.

INTERVENTIONS
- Review medical history for presence and number of chronic diseases.
- Review, document, and communicate significant abnormal laboratory findings.
- Monitor and record intraoperative intake and output.
- Monitor and calculate estimated blood loss on sponges and in suction canisters.
- Distinguish between blood and irrigation fluid amounts in suction canister or canisters.
- Ensure visibility of the urine drainage bag.
- Ensure availability of blood and fluid replacement products as needed.
- Monitor and report intake and output to anesthesia provider, surgeon, and postanesthesia care unit (PACU) nurse.

NURSING DIAGNOSIS
Ineffective Thermoregulation related to poikilothermy secondary to age-associated physiologic decompensation

OUTCOME
The patient will maintain normothermia (±1° F) throughout the perioperative period.

INTERVENTIONS
- Identify risk factors for unplanned hypothermia.
- Use warm blankets during transport to the OR, and replenish as needed throughout the perioperative period (include the patient's feet within blanket covering).
- Adjust and maintain ambient room temperature at comfortable levels.
- Place warmed sheet on OR bed before patient transfer.
- Use active warming intraoperatively by applying forced air–warming system.
- Monitor patient's temperature.
- Provide additional head covering (cloth, plastic, or reflective) during surgical procedures.
- Minimize exposure of patient.
- Use warmed irrigation and preparation solutions (as recommended by manufacturer).
- Administer warmed blood and blood products and intravenous (IV) fluids at room temperature.
- Remove wet linens before transport to the PACU.

NURSING DIAGNOSIS
Risk for Impaired Skin Integrity related to preoperative and intraoperative procedures secondary to alterations in skin turgor, sensation, peripheral tissue perfusion, and skeletal prominence

OUTCOME
The patient's skin integrity will remain intact intraoperatively.

INTERVENTIONS
- Review risk factors for intraoperative pressure ulcer development.
- Assess potential pressure areas before anesthesia induction and positioning, noting bruises, sores, skin tears, rashes, lesions, and pressure ulcers.
- Avoid friction and shearing forces by using a four-person lift, a liftsheet, or lifting device when transferring patient to or from OR bed and turning patient to desired surgical position.
- Prevent wrinkling of linen under the patient or positioning devices.
- Place electrosurgical dispersive pad in the most appropriate area while avoiding bony prominences.
- Avoid pooling of solutions under the patient.
- Apply tape sparingly to prevent skin injury during removal. If tape must be used, consider paper tape or a nonadherent dressing on fragile skin. Gauze wrap, stockinette, or tape alternatives may also be considered.
- Position the patient.
- Evaluate for signs and symptoms of physical injury to skin and tissue.

NURSING DIAGNOSIS
Disturbed Sensory Perception (visual or auditory) related to removal of eyeglasses or hearing aid in the OR secondary to age-associated changes in sensory organs

OUTCOME
The patient's perception and interpretation of environmental and sensory stimuli will be accurate throughout the perioperative period.

INTERVENTIONS
- If the patient uses an assistive device (e.g., hearing aid), leave in place as long as possible. Provide necessary information before removing assistive device.
- Remove OR mask to introduce self and explain procedures before surgery.
- Ask the patient to state his or her name, and continue to call the patient by stated name.
- Attract the patient's attention before speaking.
- Face the patient directly and on the same level (when possible) while speaking.
- Speak slowly and distinctly in a low-pitched, clear voice, frequently rephrasing and verifying communication.
- Control noise in the surgical setting.
- Use gestures to supplement words.
- Write instructions as needed to clarify information; use matte-finish paper.
- Allow ample time for patient to ask questions.
- Prepare patient for changes in light intensity, and allow time to adapt to lighting changes.
- Assist patient with transfers and mobility.
- Inform patient before positioning or procedures done before anesthesia induction.

NURSING DIAGNOSIS
Risk for Perioperative Positioning Injury related to positioning procedures secondary to musculoskeletal changes and associated chronic pain

OUTCOME
The patient will be free from perioperative positioning injury.

INTERVENTIONS
- Assess pain and skeletal/range-of-motion limitations before anesthesia induction and positioning.
- Assess potential pressure areas before anesthesia induction and positioning.
- Place safety strap above the knees; prevent undue pressure on the popliteal space and heels.
- Ensure that armboards are maintained at less than a 90-degree angle.

SAMPLE PLAN OF CARE—cont'd

INTERVENTIONS—cont'd
- Provide adequate padding to protect potential pressure areas.
- Maintain body alignment within restrictions imposed by chronic pain and musculoskeletal age-related changes.
- Use gentleness during positioning and turning.
- Keep head and neck in a comfortable position that limits hyperextension.

NURSING DIAGNOSIS
Ineffective Family Therapeutic Regimen Management

OUTCOME
The patient receives appropriate medications, safely administered during the perioperative period.

INTERVENTIONS
- Administer prescribed antibiotic therapy and immunizing agents as ordered.
- Administer prescribed medications and solutions.
- Administer prescribed prophylactic treatments.
- Label all medications on the sterile field.
- Validate medication orders with perioperative team.

NURSING DIAGNOSIS
Risk for Infection

OUTCOME
The patient is free from signs and symptoms of infection.

INTERVENTIONS
- Implement aseptic technique.
- Monitor for signs and symptoms of infection.
- Initiate traffic control.
- Administer care to invasive device sites.
- Assess susceptibility for infection.
- Protect from cross-contamination.

two groups are made. The perioperative nurse who recognizes the special needs of the elderly patient during what may be the most critical period of hospitalization helps to enhance the course of surgical intervention and postoperative recovery (Patient Safety). All members of the surgical team must work together in all phases of the perioperative continuum to provide an environment that focuses on the needs of the patient.

Preoperative Preparation. The preoperative period is an opportune time to evaluate the patient's psychosocial status and educational needs. As mentioned, the motivation of the patient can affect operative risk and successful surgical outcomes. Awareness of psychologic and emotional status is as important as awareness of physiologic status. Often the patient's concerns are focused on the spouse or other family members rather than on the impending surgery. An unexpected hospitalization can be very disruptive to an elderly patient who perhaps was the sole caretaker of an ill spouse, parent, or even a pet. In addition, the concern for quality of life and the fear of institutionalization after surgery can be extremely upsetting. This population has the highest morbidity and mortality in the adult population. Using the assistance of a discharge planner or case manager to arrange for resources may help allay the patient's concerns.

Sensory deficits, occurring either as a result of age-related changes or merely because eyeglasses and hearing aids are removed, can make communication with geriatric patients more difficult. Unresponsive or uncooperative behavior may be inappropriately diagnosed as dementia, expected as part of aging, and ignored. As discussed, acute confusion or delirium in elders is the most important indicator of possible underlying conditions that could seriously and adversely affect surgical intervention and outcomes. Knowing whether the patient's cognitive impairment is recent or chronic will provide direction for planning postoperative care.

The perioperative nurse should take advantage of the time spent in the preadmission interview, presurgical care unit, preoperative holding area, or the surgical corridor to introduce herself or himself and explain events to follow. Because a surgical mask is generally not required in these areas, this is the most opportune time for talking with the older adult. Once the patient is taken into the OR, a reassuring touch and remaining close to the patient, particularly during anesthesia induction, can help to decrease anxiety.

Anesthesia Induction. The perioperative nurse shares with the anesthesia provider any pertinent assessment data that may affect anesthesia. A medical history of asthma, previous patient or family anesthesia problems, abnormal laboratory data, and physical limitations affecting induction or airway management are important findings. The following anesthetic issues contribute to the morbidity and mortality of the older population:
- Active or unstable concurrent diseases
- Decreased mobility
- Intubation difficulties
- Gravity of the surgical procedure
- Myocardial depression from anesthetic agents
- Potentially altered respiratory and cardiac reserves

Elderly patients frequently have changes in airway anatomy that make appropriate ventilation difficult. Changes in facial contour from sunken cheeks or lack of dentition can result in an inadequately fitting anesthesia mask. Keeping dentures in place often offsets this problem; however, if intubation is planned, dentures are usually removed. The joints of the head and neck may exhibit limited range of motion, making intubation and airway management more difficult in elders. Identification of these potential problems before anesthetic administration facilitates a smooth induction period.

The choice of anesthesia in the elderly patient depends on physiologic status, length of the operative procedure, and preference of the anesthesia provider. IV sedation with local anesthesia may be selected for herniorrhaphy or other procedures that do not entail complicated manipulation of organs. Regional anesthesia (e.g., spinal, femoral, brachial, axillary, or peribulbar blocks) may be chosen over general anesthesia for specific surgical procedures (e.g., cataract extraction, transurethral resection of prostate [TURP]) because blood loss, deep vein thrombosis, and pulmonary embolism are less likely to occur (Sieber and Pauldine, 2005). The use of spinal anesthesia may be effective for orthopedic surgical procedures, such as

PATIENT SAFETY

Prevention of Deep Vein Thrombosis in the Elderly

Providing safe care for older adults in the perioperative setting requires the nurse and surgical technologist to have a thorough knowledge of the changes associated with aging and the risk factors for surgical complications. One change associated with aging is the increased risk for the development of deep vein thrombosis (DVT). The chances for developing DVT increase with age and double each decade of life over the age of 40 years. For example, a person who is 80 years old is twice as likely to develop DVT as someone who is 70 years old and 16 times more likely as someone who is 40 years old. The incidence of DVT is more than 150-fold higher among hospitalized patients than those in the community.

DVT is triggered by the Virchow triad: venostasis, hypercoagulability, and vessel wall inflammation, which leads to intravascular coagulation and the formation of a structureless mass of red blood cells, fibrin, and other cellular components. Several risk factors may increase the likelihood of DVT in an older person and include the following:

- Immobility; physical limitations that influence ambulation and movement
- Congestive heart failure
- Hypertension
- Use of diuretics, which contribute to dehydration and hypercoagulability
- Obesity
- Smoking
- Varicose veins
- Atherosclerosis

Prevention of DVT in the older person begins in the preoperative phase of care. Whenever possible, the nurse should contact the patient well in advance of the planned procedure to begin education on DVT precautions. Before surgery, patients should avoid long airline travel or immobility. Walking and increasing the activity level before surgery can improve the patient's venous return as well as overall health state. Unless contraindicated by the patient's condition or physician's order, the nurse should advise patients to drink adequate fluids up until the time of their nothing-by-mouth (NPO) status to help maintain hydration. Whenever possible, the patient should be instructed about leg exercises (e.g., ankle rolls, leg lifts) to be performed before and after the surgery.

When the patient arrives in the preoperative area, the nurse should consult with the surgeon to ensure that antiembolic stockings or sequential compression sleeves are ordered for the patient. Antiembolic stockings improve venous return by squeezing and closing venous valves, preventing pooling and stagnation of blood in the lower extremities. Sequential compression devices, which alternately inflate and deflate, serve to push the blood in the extremities back toward the heart. The nurse should demonstrate the leg exercises to be performed in the postoperative period and assess the patient's understanding and mastery through return demonstration and also discuss the benefits of early ambulation.

Before anesthesia induction, the nurse ensures the patient's antiembolic stockings are placed correctly with no wrinkles or rolling that might impede venous return and verifies that the sequential compression device is functioning normally. If the patient's feet are accessible during long procedures, the nurse should perform periodic passive range-of-motion exercises to maximize venous blood return (if possible without compromising the sterile field).

The nurse encourages the patient to move his or her legs and perform the recommended exercises as soon as possible in the postanesthesia care unit (PACU). The PACU staff should reinforce the preoperative teaching about DVT prevention and ensure the patient's caregiver also understands the instructions.

Pharmaceutical prophylaxis for DVT may be a consideration in some patients. Medications used for DVT prophylaxis are described in Chapter 23.

Modified from Wadlund DL: Prevention, recognition, and management of nursing complications in the intraoperative and postoperative surgical patient, *Nurs Clin North Am* 41:151-171, 2006; Jaffer AK, Brotman DR: Prevention of venous thromboembolism after surgery, *Clin Geriatr Med* 24:623-625, 2008; *Understanding deep vein thrombosis*, available at www.clotcare.com/clotcare/dvt.aspx. Accessed April 6, 2009.

hip fractures or knee replacements. Flexibility of the elderly patient or the presence of arthritic problems must be considered before attempting administration of a spinal anesthetic. In patients undergoing vascular or abdominal procedures, an epidural catheter may be considered for postoperative pain management.

Accurate predictions of how the elderly patient will respond to drugs or anesthetics are difficult to make because of a decrease in systems' function. Older patients have both an altered pharmacodynamic (relation between plasma concentration and drug effect) and an altered pharmacokinetic (distribution and elimination of drugs) response to drugs. These physiologic changes can affect medication administration because of a longer or shorter duration of action and less predictable effects. The increasing age of the patient decreases the dose requirement of anesthetic. This includes agents that induce anesthesia (e.g., thiopental sodium, etomidate, propofol) and narcotics. The induction dose of a barbiturate required for a 70-year-old patient will be less than that for patients 20 to 30 years old. Minimal blood levels of a drug may produce undesired side effects before therapeutic levels are reached. Likewise, reduced liver and kidney function, altered body composition, decreased albumin level, and decreased cardiac output all modify the aged person's ability to eliminate drugs from the body. Age-related changes in homeostatic mechanisms affect the older adult's ability to deal with physiologic stresses of surgery, such as fluid depletion, volume overload, or hypoxemia. Mild hypothermia of only 1° to 3° F below normal can increase postoperative myocardial ischemia and ventricular tachycardia. The incidence of hypothermia is greatest with combined epidural-general anesthesia (Sieber and Pauldine, 2005). The perioperative nurse should be prepared to respond quickly in assisting the anesthesia provider to stabilize the patient when adverse reactions occur.

Positioning. Protection of skin integrity is of utmost importance. Loss of subcutaneous fat, poor skin turgor, and tissue fragility can worsen a postoperative skin problem. Elderly patients should be lifted into position, rather than slid or dragged, to prevent shearing injuries. Aging changes in the

RISK REDUCTION STRATEGIES

Body Temperature and the Elderly

Temperature fluctuations are common in elders as a result of impaired thermoregulation. Response to cold, including vasoconstriction and shivering, is diminished in elders, and the core temperature must be lower to trigger a response than that required in younger adults. Intraoperative hypothermia may be associated with altered coagulation and increased surgical site bleeding (Rutherford et al, 2008). Other complications associated with hypothermia include vasoconstriction, poor tissue perfusion, and reduced oxygen tension, predisposing the patient to wound infection (Kulaylat and Dayton, 2008). For elderly patients with coronary artery disease, hypothermia may cause increased oxygen consumption, which could lead to myocardial ischemia (Sherwood et al, 2008).

Perioperative nurses collaborate with the anesthesia provider and the surgeon to ensure measures are in place to minimize the effects of hypothermia. Prevention of hypothermia is critical as the elderly patient generally lacks reserves to withstand prolonged shifts in temperature. Increasing the ambient OR temperature will help stabilize the effects of heat loss. Devices such as warmed blankets or forced air–warming blankets are highly recommended, particularly when a lengthy surgical procedure is expected. Special care should be taken by the perioperative nurse to prevent injury, such as burns, to the elderly patient with the use of such devices. When the body is exposed to cold temperatures, blood is shunted away from peripheral body parts to the head. Because the head lacks fat storage capacity and vasoconstriction capabilities, heat loss from the head can be as much as 25% to 60% of total body heat loss. The nurse should provide elderly patients some form of head covering to prevent additional effects of inadvertent hypothermia.

Prepping solutions should be carefully chosen to prevent skin irritation and should be warmed (if recommended by the manufacturer) to help decrease hypothermic effects. The nurse ensures the patient is not lying in a prep solution or on wet linens to reduce skin injury and inadvertent lowering of body temperature. The surgical technologist must be aware of the consequences of using cold irrigation solutions and ensure that any irrigation provided to the surgeon is appropriately warmed.

Modified from Kulaylat MN, Dayton MT: Surgical complications. In Townsend CM et al, editors: *Sabiston textbook of surgery,* ed 18, Philadelphia, 2008, Saunders; Rutherford EJ et al: Hematologic principles in surgery. musculoskeletal system accentuate bony prominences and decrease the range of motion. These skeletal changes coupled with limitations imposed by chronic pain make positioning one of the most important considerations of care. The provision of appropriate positioning devices is pivotal to the protection from injury for this population of surgical patients. Arms are placed on padded armboards with the palms up and fingers extended. Armboards are maintained at less than a 90-degree angle to prevent brachial plexus stretch. If there are surgical reasons to tuck the arms at the side, the elbows are padded to protect the ulnar nerve, the palms face inward, and the wrist is maintained in a neutral position (Denholm, 2009). A drape secures the arms. It should be tucked snuggly under the patient, not under the mattress. This prevents the arm from shifting downward intraoperatively and resting against the OR bed rail.

Often, because of musculoskeletal deformity and chronic pain, elderly patients cannot fully extend the spine, neck, or upper and lower extremities. Using padding devices to compensate for these limitations not only makes the patient more comfortable during the procedure but also prevents residual pain or injury postoperatively. Depending on the situation, positioning the patient before anesthesia induction may be best so that the patient can direct positioning efforts in regard to comfort.

Skin Preparation and Thermoregulation. Aging skin is more susceptible to rashes, infection, and inflammation. A common complaint of the elderly is dry skin that may be part of the natural aging process or can be related to diseases such as anemia, malignancy, kidney disease, or diabetes. Medications, such as corticosteroids, may cause skin to become more fragile. Changes in the dermal receptor cells can alter the ability of the elderly to perceive sensations of pressure and touch, as well as changes in temperature.

Decreased muscle tissue and activity, reduced subcutaneous fat, and diminished peripheral circulation are some of the changes in aging that can have a negative impact on thermoregulation (Wold, 2008). The perioperative environment can expose the elderly patient to cool temperatures and hazardous chemicals, thus requiring the perioperative registered nurse to assume extra caution in this environment (Risk Reduction Strategies).

Aseptic Techniques and Safety Measures. Age-related changes in functioning of the immune system and some age-associated diseases have a detrimental effect on the aging body's ability to appropriately respond to infection. The risk of developing a healthcare-associated infection in an acute-care facility ranges between 3% and 15% (Goldrick, 2005). Diminished cough reflex and reduced ciliary action weaken specialized defense mechanisms. Pneumonia is the second most common healthcare-associated infection, preceded only by urinary tract infections (UTIs) (Goldrick, 2005). Incomplete emptying of the bladder can cause a UTI, which causes significant morbidity in older adults.

Immobility and drug therapy alter flora in the intestines. Infection and delayed wound healing are poorly tolerated and sometimes fatal in debilitated elderly patients. In addition to adherence to aseptic technique, there are other measures employed in the OR to protect aging patients from the risk of infection. Because length of surgical procedure is related to incidence of infection, the nurse should ensure that needed supplies and equipment are readily available. The surgical technologist should be familiar with the procedure being performed to maximize efficiency to prevent unnecessary delays, decrease exposure of the surgical site, and reduce the length of time the elderly patient is anesthetized.

Fluctuations in fluid volume are common in aging patients. Volume deficits occur as a natural course of aging, whereas

TABLE 26-2

Important Clues in the Initial Assessment of Dehydration in Older Adult Patients

Clinical Indicator	Water Deficiency	Water + Electrolyte Deficiency
MEDICAL HISTORY	Recent >3% weight loss Impaired water intake Increased perspiration (fever, tachypnea, heat)	Recent >3% weight loss Vomiting, diarrhea, diuretic, drug use, diabetes, bleeding
PHYSICAL EXAMINATION		
Tongue dryness	Present	Present

Modified from Faes MC et al: Dehydration in geriatrics, *Geriatr Aging* 10(9):590-596, 2007, available at http://cme.medscape.com/viewarticle/567678-1. Accessed January 8, 2008.

volume excess can occur from intraoperative fluid replacement. The age-related failure of homeostasis to adjust for stressful disturbances has been demonstrated by changes in fluid balance. Large variability in the way different organs are affected by dehydration results in atypical symptoms in older adults (Faes et al, 2007). Table 26-2 provides important clues for assessing dehydration. Careful measurement of intake and output is essential. Communication among team members regarding blood loss during the procedure can prevent complications. The nurse and surgical technologist must collaborate to ensure accuracy in irrigation distributed to the sterile field and used during the procedure. The team closely monitors discarded sponges, suction canister contents, and urinary output as part of volume assessment. During the hand-off report, the nurse reports intraoperative IV fluid volumes, estimated blood loss, and other parameters to the postanesthesia care unit (PACU) staff for their continued assessment and evaluation.

Evaluation

Because of the relatively fine line between stability and development of postoperative complications, the elderly patient's response to surgery must be closely evaluated. Before transporting the patient to the PACU, the perioperative nurse should assess the care provided intraoperatively by evaluating expected versus actual outcomes. Specific outcome criteria established for each nursing diagnosis provide the basis for evaluation of care. Many of the nurse's actions at the end of the intraoperative phase provide data for evaluation of care.

The nurse collaborates with the anesthesia provider to complete and record the patient's intake and output measurements. Because of the consequences of postoperative dehydration or fluid volume overload in the elderly patient, fluids are increased or decreased accordingly. Blood loss is carefully evaluated, recorded, and reported.

The wound is closely observed for bleeding before dressing application and postoperatively because the elderly person's ability to recover from hemorrhage and shock is extremely poor. Anticipated frequency of dressing change, as in a draining wound, should govern the method used to secure the dressing. A minimal amount of tape should be used because its removal can cause additional skin trauma. Depending on the wound site and character, rolled gauze, stockinette, or similar bandaging over the primary dressing may be the best choice so that tape is not applied directly to the skin. Another alternative is the use of Montgomery straps. For smaller wounds, the least possible amount of hypoallergenic tape should be used. Because infection is poorly tolerated, the choice of dressing should maximize wound protection while being the least irritating to the skin.

The nurse examines the patient for signs of injury, particularly over bony prominences and under the electrosurgical dispersive pad. To prevent skin injury postoperatively the patient should be carefully lifted from the OR bed to the stretcher. Pain is assessed and compared with preoperative levels. Evaluation of musculoskeletal pain will determine intraoperative positioning effectiveness.

Evaluation of body temperature is particularly important in elders because postoperative hypothermia is quite common and can precipitate agitation and confusion or delirium. To prevent any adverse response, the nurse covers the patient with warmed blankets and uses a forced air–warming unit until the patient is transported to the PACU.

Depending on the patient's level of consciousness, the nurse should explain the impending transfer to the PACU as a form

BOX 26-8

Preoperative Risk Factors for Postoperative Delirium in Elders

- Age 80 years or older
- Decreased education level
- Decreased functional status
- Alcohol or sedative-hypnotic withdrawal
- Depression
- Drug interaction or polypharmacy; duration of anesthesia
- Endocrine and metabolic problems
- History of dementia-like symptoms
- Low mobility
- Presence of multiple diseases
- Sensory impairments
- Surgical procedures considered major in nature
- Emergent or urgent surgical procedures
- Dehydration
- Low serum albumin level
- Abnormal preoperative serum sodium, glucose, or potassium level
- American Society of Anesthesiologists (ASA) class III or IV
- Uncontrolled pain
- Urinary elimination problems

Modified from Rudolph JL, Marcantonio ER: Delirium. In Duthie EH et al, editors: *Practice of geriatrics,* ed 4, Philadelphia, 2007, Saunders; Bargi AS, Rico A, Ruiz JG: Evaluation and management of elderly patients at risk for postoperative delirium, *Clin Geriatr Med* 24:667-686, 2008.

of reality orientation for the patient. As appropriate, the nurse should introduce the patient to the PACU nurse and explain what to expect in the unit. Explanations should always precede any procedure. Often the elderly person is reluctant to cooperate simply because no one has taken the time to explain what is going to happen.

Verbal communication between the perioperative and PACU nurses should include any pertinent preoperative and intraoperative information that could affect postoperative care outcomes. This information includes pain levels; physical and sensory limitations; intake and output measurements; allergies; type and location of catheters, drains, packing, and implantable devices; anesthetics and medications received; and any unusual occurrences that could affect the patient's recovery. Perioperative nurses should be aware of the risk for the phenomenon known as postoperative delirium, a condition that can occur in elderly patients. Box 26-8 lists the most frequently identified preoperative risk factors for postoperative delirium.

Documentation of outcome evaluation can be phrased as follows:

- Skin integrity was maintained free from redness, bruises, and abrasions; patient reported no pain or impairment of the skin; and there were no apparent signs or symptoms of infection.
- Fluid balance was maintained; urinary output was within normal limits; the patient's forehead skin was checked and had good turgor; and vital signs were stable.
- Temperature was ±1° F of normal range; skin was warm to touch; and patient verbalized comfort.
- The patient accurately perceived and interpreted environmental stimuli, expressed and demonstrated understanding of procedures, and responded appropriately to auditory and verbal stimuli.
- Perioperative positioning injury was effectively prevented; and the patient had no complaints of increased pain and no compromise in musculoskeletal ability and range of motion from preoperative levels.
- Medications used during the intraoperative procedure caused no apparent adverse reaction.

The type and extent of surgery may affect postoperative pain. Elderly persons may not complain of pain, but this does not indicate that pain does not exist. Those patients with cognitive impairment may experience pain but may be unable to verbalize it. Box 26-9 gives key elements of pain assessment and management in older adults.

Contemporary pain control delivery systems and techniques offer a variety of treatment routes and modalities. Various routes may be employed to deliver medication for pain control: oral, intramuscular, IV, regional (i.e., spinal or epidural), or patient-controlled analgesia (PCA). Cognitive modalities that may be employed are distraction, relaxation (i.e., biofeedback), or hypnosis. Physical modalities that may be used are cold, exercise, heat, immobilization/rest, massage, positioning, or transcutaneous electrical nerve stimulation (TENS).

Clinical management of pain should be multimodal and individualized for the patient, procedure, and circumstance. Evaluation of the balance between pain control and side effects should be documented, timely, routine, and specific.

Patient and Family Education and Discharge Planning

Education should be conducted at a time when the patient is at rest rather than during preoperative or postoperative procedures. Too many stimuli from outside sources can interfere with the patient's ability to concentrate and motivation to learn. The nurse ensures the patient's physical comfort and privacy. Education will be ineffective in the patient who is uncomfortable or in pain. Age-related changes can affect the elderly patient's ability to learn new material; therefore modification of traditional teaching approaches should be used to enhance effectiveness. Patient education should consider health literacy and be individualized based on how the patient will best understand the information (Research Highlight).

A comprehensive discharge plan should identify and address communication barriers, incorporate the patient's current mental and physical condition, address environmental issues that can be improved to support recovery, and diminish the social support challenges. Sensory changes in vision and hearing, cognitive impairment, and literacy level can be communication barriers that interfere with the patient's ability to understand and retain information. Giving the patient postoperative instructions in written form helps with retention, and modifications using large, easy-to-read typeface on matte-finish paper of warm tones (yellow, tan) make the instructions easier to read. It may be helpful to have a magnifying glass available and supplemental light on the object or surface involved in the teaching/learning activity. Family members or significant others who are present should be included in the educational session so that they can provide reinforcement at home.

The discharge plan should consider the patient's ability to perform ADLs, ambulate, and manage his or her preexisting medical condition after surgery. The older person's basic

BOX 26-9

Pain and Older Adults

PREVALENCE OF PAIN

Recognize that older adults are at great risk for undertreated pain.

BELIEFS ABOUT PAIN

In addition to receiving less analgesia than younger adults, older adults tend to report pain less often. These findings may be related to beliefs and concerns about pain and the reporting of pain. Many older people hold the following beliefs and concerns about pain:

- Pain is something that must be endured; it is part of life.
- Expressing pain is unacceptable or is a sign of weakness.
- Complaining of pain will result in being labeled as a "bad" patient.
- Nurses are too busy to listen to complaints of pain.
- Pain signifies a serious illness or impending death.

Nurses should be aware of the beliefs of older patients regarding pain management. Nurses and other caregivers often undermedicate these patients and are sometimes reluctant to administer the prescribed analgesics.

ASSESSMENT

- Ask about present pain only.
- Use a standard scale, such as the numeric faces or Iowa thermometer rating scale.
- Explain the scale each time it is used.
- Use verbal descriptions other than pain, such as "ache," "sore," and "hurt."
- Use visual representations of pain measures rather than mental images of pain rating scales. Be sure that the patient is wearing glasses and hearing aids if needed and available.
- Alter a written pain scale to include large lettering, adequate space between the lines, nonglossy paper, and appropriate color for increased visualization.
- Provide adequate lighting and privacy to avoid distracting background noise.

CONSIDERATION FOR COGNITIVELY IMPAIRED PATIENTS

- Assess for nonverbal indications of pain (facial expressions, grimacing, vocalizations, body movements, behavioral changes).
- Remember to "assume pain is present" in cognitively impaired patients in the perioperative setting.
- Consider an analgesic trial.

MANAGEMENT OF PAIN

- Be aware of adverse effects of acetaminophen (hepatotoxicity and nephrotoxicity) and nonsteroidal antiinflammatory drugs (NSAIDs) (gastrointestinal [GI] bleeding and nephrotoxicity).
- Start low and go slow with opioid dosing.
- Avoid the use of meperidine, codeine, and propoxyphene.
- Use methadone and tramadol with caution.
- Older adults and those with renal disease should not take meperidine because of the prolonged half-life of its drug metabolite, normeperidine.
- Use nondrug pain-relief measures.

Modified from McGuire L: Pain: the fifth vital sign. In Ignatavicius DD, Workman ML, editors: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, St Louis, 2010, Saunders.

RESEARCH HIGHLIGHT

The Impact of Health Literacy on Consumer Understanding

Health literacy is a factor for perioperative nurses to consider when providing patient education. Health literacy includes both the ability to understand instructions on prescription drug bottles, appointment slips, medical education brochures, physician's directions, and consent forms and the ability to negotiate complex healthcare systems. Health literacy is not simply the ability to read. It requires a complex group of reading, listening, analytic, and decision-making skills, and the ability to apply these skills to health situations. Nearly half of all adults possess limited health literacy that may challenge their ability to understand and use health information. Older adults are particularly vulnerable. Two thirds of U.S. adults age 60 and older have inadequate or marginal literacy skills, and 81% of patients age 60 and older at a public hospital could not read or understand basic materials such as prescription labels.

The objective of this study was to explore the impact of health literacy on consumers' use and understanding of quality information about postacute rehabilitation facilities. Study participants were patients and caregivers of patients age 50 years or older who had a diagnosis of stroke, hip fracture, or joint replacement. A sample size of 29 participants consisting of 17 patients and 12 caregivers was used in the study. Researchers identified key terms essential to item comprehension, including functional status, cognitive status, discharge to home or community, length of stay, patient satisfaction, delirium, moderate to severe pain, and pressure ulcers. To determine comprehension and health literacy, researchers then asked patients and caregivers to define these terms in their own words. Study results indicated that patients had the most difficulty in defining the terms cognitive functional status and discharge to home or community. Approximately one in five respondents could not correctly define the key terms that were presented to them. Data analysis revealed that barriers to understanding and processing of concepts included complexity of the information presented, use of medical terminology, and partial comprehension.

Based on the study results, researchers recommend the following actions regarding health literacy that are applicable to perioperative nurses interacting with elderly consumers:

- Texts and graphs, if used for patient education, should be simplified by reducing details and wordiness.
- Healthcare providers should limit their use of medical terminology and jargon.
- Brief definitions of key terms should be provided when complex health concerns are discussed.
- Words that consumers use to define key concepts should be used.

Modified from Magasi S: Rehabilitation consumers' use and understanding of quality information: a health literacy perspective, *Arch Phys Med Rehabil* 90:206-212, 2009; National Network of Libraries and Medicine: *Health literacy,* available at http://nnlm.gov/outreach/consumer/hlthlit.html. Accessed April 14, 2009.

medical condition does not change because of surgery. Content should focus only on relevant information about surgical procedures or postoperative recoveries; relating it to previous life experiences helps the patient grasp the concepts more readily. The nurse should provide the most important information first. If motor skills (i.e., crutch walking, dressing change) are involved, all steps should be taught one at a time and mastery should be demonstrated before moving to the next step. Increased time is often necessary when teaching motor skills.

Discharge planning begins during the preoperative assessment. Sufficient time is needed to make appropriate decisions about postdischarge care to prevent complications, reduce the risk of rehospitalization, and minimize stress to the patient and the caregivers. Consideration should be given to the environment to which the patient will be transferred following the surgery. Although the plan should consider that older adults prefer to keep their autonomy, the postoperative care may require special facilities, such as a rehabilitation center or long-term care facility, at least for a time.

The type of surgery and expected postoperative recovery period determine the extent of resources and social systems needed, such as durable medical equipment, home health and homemaker services, extended care, social and community services, and physical rehabilitation. The success of postdischarge outcomes in elders is influenced by the patient's self-assessment of health as good or excellent, the complexity of the patient's medical condition, the patient's history of being able to maintain responsibility for his or her own health, and the patient's family or social networks. Many elders undergo procedures on an ambulatory basis (Ambulatory Surgery Considerations). Discharge needs of the patient should be evaluated as early as possible so that appropriate education, referrals, and home preparation can be completed before the patient leaves the hospital or ambulatory facility.

AMBULATORY SURGERY CONSIDERATIONS

Procedures of the Eye

Cataract surgery is among the most common ophthalmic surgical procedures performed in older adults. Some degree of cataract formation is expected in all people older than 70 years of age. The majority of these procedures are performed in an ambulatory setting, with patients returning home the day of surgery. Cataracts are associated with factors including trauma, inflammation, genetic predisposition, metabolic disease, and cigarette smoking, but aging is by far the most common factor. Most eye surgery patients make the decision to have the procedure done after months of deliberation and slow, progressive loss of vision. The overall risk of death is low and does not significantly change whether local or general anesthetic is used. Intraocular lenses can be safely implanted in the majority of patients. Microsurgical wound closure ensures a secure incision that allows immediate ambulation. The surgical stress is considered so low and visual rehabilitation so rapid that severe visual impairment is considered a reasonable indication to perform surgery even if the elderly patient is debilitated (see Chapter 17 for an in-depth description of cataract surgery).

Surgical Interventions

The elderly account for the majority of cancer patients; patients 65 and older account for 70% of cancer deaths and 56% of all newly diagnosed cancers. Surgical intervention is generally accepted to be a part of the standard of care. Breast cancer is six times higher in older patients and the biologic behavior of breast tumors differs in the elderly. Physicians must consider these differences along with the understanding that undertreatment is associated with increased morbidity and higher recurrence rates. More than 50% of lung cancer patients are older than 65. Colorectal cancer is the second most common cancer in the United States. The mainstay of treatment modalities for these kinds of cancer is surgical intervention (Kim and Zenilman, 2007).

Surgical procedures that are common among the geriatric population are governed more by pathologic condition than by anatomy and are directly related to the common diseases affecting older adults. Healing is an important consideration in the decision to perform surgery on this population. The level of tissue oxygen is the main factor in determining wound healing and is influenced by factors such as cardiovascular status and anemia. Other factors are included in Box 26-10. In the text that follows, some surgical procedures that are commonly seen in elderly patients are briefly discussed. Reference is made to other sections of the text for a more in-depth description of the technical aspects of the procedures.

COMMON SURGICAL PROCEDURES IN GERIATRIC PATIENTS

It is becoming common for patients well past 85 years of age to have surgery with relatively good outcomes. Decisions are no longer based solely on surgical risk but rather on optimal disease management and the preservation of quality of life. This shift in thinking has taken us beyond just getting the patient through the surgery and has produced a genuine concern about what the surgery will do for patients in the remaining years of life.

Thyroid Surgery

In the elderly population, thyroid gland dysfunction is common and associated with significant morbidity because the symptoms are often subtle, absent, or confused with co-existing

BOX 26-10

Factors That Influence Wound Healing

- Anemia
- Congestive heart failure
- Diabetes
- Hepatic failure
- Hypothyroidism
- Hypovolemia
- Malignancy
- Nutrition (protein, glucose, minerals, vitamins A and C)
- Peripheral vascular disease
- Renal failure
- Rheumatoid arthritis

Modified from Bradley SF: Infections. In Duthie EH et al, editors: *Practice of geriatrics,* ed 4, Philadelphia, 2007, Saunders.

diseases. Hypothyroidism occurs in 10% to 15% of patients older than 60 years and is more frequent in females than males (Rehman et al, 2005).

Typical symptoms of thyroid disorders may be absent or erroneously attributed to co-morbid conditions or normal aging. The polypharmacy used in the treatment of elderly patients can interfere with normal thyroid function. Drugs such as lithium or amiodarone may cause primary hyperthyroidism. For example, an elderly man taking medication for hypertension, congestive heart failure, and atrial fibrillation with complaints of fatigue, weakness, constipation, and weight gain may be considered to have these symptoms because of medication or medical conditions, whereas the symptoms could also be caused by hypothyroidism.

A rare complication of hypothyroidism, myxedema coma, affects patients older than 75 years. Confusion, disorientation, lethargy, thinning eyebrows and hair, hoarse voice, bradycardia, cardiomegaly, pericardial effusion, hypothermia, hyponatremia, and pseudomyotonic reflexes characterize this condition.

The great masquerader in the elderly population is hyperthyroidism and can easily be missed in patients older than 60 years. It can be severe and even life-threatening. Elderly patients may not have a goiter, exophthalmos, or other ophthalmopathy. Hyperthyroidism may also cause osteoporosis. Almost any condition that can make a person ill can cause euthyroid sick syndrome; so elders are more susceptible because of their co-morbid conditions. Medication to suppress hormone secretion by the gland, surgery to remove the hyperfunctioning tissue, and radioactive iodine (RAI) to destroy the gland are the three treatment options. Although surgery is a less attractive option, it must be employed when RAI is ineffective in the presence of a single nodule or multinodular toxic goiter or when the patient has dysphagia, tracheal compression, or suspected malignancy. Following surgery, the perioperative nurse must be aware of the possibility of a hyperthyroid storm that can be precipitated by the stress of the procedure, systemic infections, and anesthesia induction. (See Chapter 15 for an in-depth description of operations of the thyroid.)

Abdominal Surgery

Accurate diagnosis of abdominal disease is important in elders to plan timely and appropriate surgical interventions. However, clinical signs of abdominal disease, such as tenderness, pain, muscle rigidity, and fever, are frequently less obvious in elderly patients. The common use of nonsteroidal antiinflammatory drugs (NSAIDs) may mask symptoms or even predispose elderly patients to acute abdominal disease.

The most common causes of acute abdominal complaints in older patients are biliary tract disease, intestinal obstruction, GI hemorrhage, hernia, diverticulitis, and appendicitis. Common abdominal procedures in people older than 65 years include cholecystectomy, lysis of adhesions, appendectomy, and partial excision of the small bowel (Wold, 2008).

Most often, surgery is performed for complications of calculus disease and less often for malignant obstruction of the bile ducts. The prevalence of gallstones increases with age. Because laparotomy is a stressor in older ill patients, laparoscopic cholecystectomy is considered the preferred surgical approach in elderly patients with both symptomatic and asymptomatic gallstone disease. (See Chapter 11 for an in-depth description of operations of the biliary tract.)

The age-group older than 65 years has seen an increase of ulcer disease. Many believe that the higher incidence of *Helicobacter pylori* infection, prevalent use of NSAIDs, and prevalence of cigarette smoking in elders account for the age-related differences. Up to 80% of peptic ulcer–related deaths occur in patients older than 65 years (Berger et al, 2008).

GI bleeding is a frequent indication for hospitalization affecting a substantial number of elderly people. A coordinated approach to diagnose and manage these patients can optimize favorable outcomes. Per Yachimski and Friedman (2008) key points to remember include the following:

- Immediate attention should be focused on hemodynamic stabilization followed by diagnostic assessment to identify the source of bleeding.
- Outcomes are influenced by the use of anticoagulant therapy, the presence of medical co-morbidities, and the nature of the lesion.
- Peptic ulcer disease is usually the most frequent source of upper GI bleeding. Rebleeding and morbidity can be reduced with gastric acid suppression and endoscopic hemostatic therapy.
- Diverticular disease is the most frequent source of lower GI bleeding. Urgent colonoscopy to identify the bleeding site and perform hemostasis is indicated. Persistent, recurrent diverticular bleeding may necessitate emergency colectomy that is associated with higher morbidity and mortality.
- Tolerance of procedural sedation must be critically considered in providing safe, effective endoscopy for elderly patients.

In selecting the procedure to correct the source of GI bleeding, the surgeon considers the patient's overall condition, history of chronic versus acute symptoms, and bleeding location. Elderly patients tolerate a surgical procedure better than they tolerate prolonged or recurrent bleeding. (See Chapter 10 for an in-depth description of ulcer surgery.)

Hernia

The estimated incidence of abdominal wall hernia in persons older than 65 years is 13 per 1000, with a fourfold to eightfold increase in the incidence in men. Fifty percent of all hernias are indirect inguinal, 20% are direct inguinal, 10% are ventral, 6% are femoral, 3% are umbilical, and 1% are esophageal-hiatal (Berger et al, 2008). The elective repair of inguinal and femoral hernias is strongly advised because of the risk of incarceration with subsequent emergency surgery. Many hernia repairs in elderly patients are emergency procedures because of incarcerations and small bowel obstruction. When elective, the operation may be performed as an ambulatory procedure; IV sedation and local anesthesia provide a very satisfactory alternative to general or spinal anesthesia.

Laparoscopic techniques for hernia repair have gained popularity because of associated shorter hospital stay, minimal pain postoperatively, and early recovery. However, the necessity for general anesthesia makes this approach one that may not be advisable in elders. Decisions for local versus spinal or general anesthesia are made based on the patient's overall physiologic status and surgical risk.

In elderly men the co-existence of inguinal hernia and prostatism is fairly common. Depending on the size of the prostate, the hernia repair should be postponed until after the prostate surgery.

Not unusual in elders are large, neglected scrotal hernias. The repair of these hernias is not routine in that the abdominal wall defect may be so large that primary repair cannot take place without tension. Synthetic abdominal wall replacements are helpful in the management of such large hernias. The repair of huge scrotal hernias can have a tremendous benefit on the personality of the geriatric patient, who is much relieved after removal of what can be considered an accessory appendage that is offensive, difficult to clean, and often an impedance to daily activities. (See Chapter 12 for an in-depth description of herniorrhaphy.)

Genitourinary Surgery

The predominant reason for urologic surgery in elderly men is benign prostatic hypertrophy (BPH). BPH may be silent or have minimal symptoms in the presence of severe bladder decompensation. As part of history taking, the nurse should determine if symptoms such as dysuria, straining at micturition, and hematuria exist. Prostate surgery, especially transurethral resection of the prostate (TURP), is relatively safe and generally well tolerated. The majority of BPH operations are performed to relieve symptoms, such as nocturia, slow stream, intermittency, and double voiding. TURP is indicated if the surgeon believes that total resection can be accomplished in 1 hour and that no bladder disease or impairment to urethral access is present.

A surgical alternative to TURP is transurethral incision of the prostate (TUIP). The complications associated with TUIP are significantly fewer than those occurring after TURP, especially bleeding, retrograde ejaculation, and impotence. It is a more desirable alternative to TURP for patients with prostates weighing less than 30 g. Other alternatives are laser prostatectomy, transurethral vaporization of the prostate, microwave hyperthermia, and transurethral needle ablation. These techniques are gaining acceptance because they can be done as outpatient procedures using local anesthetic. Genitourinary (GU) procedures may also be performed to correct incontinence. Incontinence in elderly men can result from nerve-damaging events such as radical prostatectomy and spinal cord injury. Surgical treatments can include artificial sphincter creation, formation of a bulbourethral sling, and a urinary diversion procedure (Men's Guide to Urinary Incontinence, 2008).

Older women experience urinary incontinence more frequently than younger women. Sneezing, coughing, and laughing may cause urine to leak from the bladder. The decision to have surgery should always be based on appropriate diagnosis, evaluation of all treatment modalities, and realistic expectations from surgical intervention. Surgical choices can include urethral sling, retropubic suspension, and tension-free vaginal tape surgery. Factors that can impair a positive outcome include, but may not be limited to, obesity, radiation therapy, aging, chronic cough, poor nutrition, low estrogen level, postmenopausal, and strenuous physical activity (Women's Guide to Urinary Incontinence in Females, 2008). (See Chapter 14 for an in-depth description of GU procedures.)

Ophthalmic Surgery

Because of elders' long life span, undergoing eye surgery (most commonly for cataracts) is more likely than other surgical procedures. Most ophthalmic procedures are minimally invasive and have a high success rate. Because elderly patients may have concurrent systemic disease, even a low-stress procedure should not be treated lightly. Age-related changes, such as hearing loss and musculoskeletal disease, may pose a challenge during ophthalmic surgery because the patient must lie still for long periods and be able to follow verbal instructions. Patients with chronic lung disease lying in the supine position may experience coughing, which can increase intraocular pressure and jeopardize the outcome of the surgery.

Orthopedic Surgery

Osteoporosis is the most obvious skeletal change that occurs with advancing age. It leads to susceptibility to fracture, which doubles every 5 years after 50 years of age. An approximate loss of 25% to 40% of the mineral content of the bone must be present before detectable change is evident on x-ray films (Murray, 2010). To some degree, osteoporosis is related to a lessening of physical activity, but other risk factors are female gender, Northern European ancestry, multiparity, lean body build, and excessive alcohol intake (Murray, 2010). Osteoporosis is also related to decreased hormonal secretion; thus postmenopausal women are more prone to develop the condition and therefore more likely to sustain a hip fracture.

Age-related changes in bone increase the prevalence of displaced femoral and intertrochanteric fractures of the upper femur. The prevalence of hip fracture increases with advancing age, is more common in women, and is higher in institutionalized patients. Because the usual cause of death in patients with upper femur fracture is pulmonary embolus, surgery is designed to relieve the severe pain, allow movement in and out of bed, and return the patient to his or her former environment as quickly as possible with minimal debilitation. Between 25% and 50% of individuals who sustain hip fractures are more dependent after the fracture, with deterioration occurring more often in women older than age 75, those with a poor clinical result, and those who were already dependent before the fracture. More than 60% of all joint replacements are in individuals older than 65, and females are almost twice as likely as males to have joint replacement surgery. Outcomes depend on the number of procedures the surgeon and facility have performed; the timing of the surgery; and the patient's medical status, perioperative management, and rehabilitation (Ebersole et al, 2008). A displaced femoral neck fracture must be surgically repaired or healing will not occur. In elderly patients, 70 years and older, prosthetic replacement is usually done because it allows for early ambulation and will last throughout the remaining years of the patient's life. Intertrochanteric and subtrochanteric fractures are best treated with internal fixation. These methods also allow for early mobility.

Degenerative joint disease (osteoarthritis) and inflammatory polyarticular disease (rheumatoid arthritis) are the primary indications for total joint replacement in the hip and knee. In these patients, pain that disrupts normal daily activities and interrupts sleep is the major reason for surgery regardless of the patient's age. Octogenarians and nonagenarians achieve successful pain relief and report satisfaction after the procedure. Methyl methacrylate bone cement is often used in orthopedic procedures in spite of its cardiotoxic effect. Cardiac arrest from cement insertion is a possible risk for frail patients. Supplemental inspired oxygen at the time of insertion, irrigation of the bone to remove excessive marrow elements, and

retrograde insertion of the cement are methods to prevent the risk of adverse effects (Burlingame and Blanchard, 2009). Usually knee replacement procedures are elective, and patients have better functional status and a higher bone mass than those with hip fracture. (See Chapter 19 for an in-depth description of hip and knee surgery.)

Vascular and Cardiovascular Surgery

The most frequent vascular conditions treated surgically in the older population are abdominal aortic aneurysms, carotid artery disease, and peripheral vascular disease. In patients 65 years and older the mortality from elective aneurysm repair is less than 5% in spite of existing co-morbidities. Emergency repair for ruptured aneurysm carries an operative mortality of more than 50% (Berger et al, 2008). Peripheral vascular surgery for limb salvage can be safely performed in patients older than 80 years and may be indicated for ischemic rest pain and nonhealing ulcers.

Cardiovascular disease is a significant cause of death in older patients. More than 55% of coronary artery bypass graft procedures are performed on patients older than 65 years. Several risk factors associated with increased mortality include emergency procedure, severe left ventricular dysfunction, mitral insufficiency requiring combined procedure, elevated preoperative creatinine level, chronic obstructive pulmonary disease (COPD), anemia, and prior vascular surgery. Factors associated with morbidity in the elderly population include obesity, diabetes mellitus, aortic stenosis, and cerebrovascular disease (Berger et al, 2008). (See Chapters 23 and 24 for a more in-depth description of vascular and cardiac surgery, respectively.)

ADDITIONAL CONSIDERATIONS

Regardless of the age of the patient every surgical procedure possesses a certain amount of risk. With increasing life expectancy, the number of surgical procedures performed on older adults will increase. Nonetheless, just as co-morbidity and emergent surgery increase surgical risk so do the physiologic deficits of aging. Procedures that are performed in the thorax or the peritoneal cavity are considered high risk. Procedures of moderate risk include vascular and hip procedures, and low-risk procedures include prostatectomy and mastectomy. However, any procedure, even those considered low risk, can have poor outcomes, depending on the patient's overall condition. Caution is advised even with the ever-increasing numbers of minimally invasive surgeries (e.g., laparoscopy). It seems logical that elders would benefit from smaller incisions that produce less postoperative pain, atelectasis, and ileus. However, the extent of hemodynamic and pulmonary consequences of CO_2 pneumoperitoneum is still unclear. In patients with severe cardiac or pulmonary disease, recommendations include invasive monitoring to maintain adequate volume loading and use of alternate gas sources or gasless techniques.

When surgical intervention is being considered in elders, it is important to remember the following:

- Age alone should not be a barrier to surgery in elders.
- Elderly persons with conditions treatable by surgery have as much right as younger patients to benefit from modern surgery, anesthesia, and medical and intensive care techniques.
- Medical and surgical techniques that can enhance the older person's life should be equally available to patients regardless of age.
- Elderly patients have special needs because of their atypical presentation of disease, multiple medical disorders or co-morbidity, impaired homeostasis, and altered drug response.
- Most elderly patients are mentally competent and should therefore always be involved in making decisions about their plan of care.

An ethical consideration with elderly surgical patients centers on the dilemma of do-not-resuscitate (DNR) orders. The organization's policy must give the patient a voice in the intraoperative area. Even though the patient may have made end-of-life decisions, the fact that the patient has signed the surgical informed consent implies that he or she seeks to improve quality of life, which is incompatible with withholding cardiopulmonary resuscitation (CPR). It is difficult to differentiate between a cardiac arrest precipitated by anesthesia and one that is spontaneous. The anesthetic agent itself promotes cardiovascular instability. Consideration should be given to the medical indications for the procedure with the goal of treatment to alleviate pain and morbidity and provide for the patient's comfort. The guiding principle in the decision to maintain or suspend DNR orders should be respect for the patient's autonomy. Elderly patients have the right to participate in the process for making end-of-life decisions.

As more procedures are performed, there are ways to assist perioperative nurses to prepare for the care of the elderly population:

- Educate staff members by reviewing the special needs of this age-group.
- Develop a separate process for preoperative assessment, and use multiple screens for evaluation of older patients.
- Improve communication and collaboration among healthcare providers.

Understanding the age-specific needs of the older surgical patient will be critical to successful outcomes for these patients. The 2004 Institute of Medicine (IOM) report *Keeping Patients Safe: Transforming the Work Environment of Nurses* highlighted the critical connection between patient safety and safe work environment (Spence-Laschinger and Leiter, 2006). The report determined that a safe and supportive nurses' work environment reduces threats to patient safety in healthcare organizations. Numerous studies summarized in the report have linked inadequate staffing to negative clinical outcomes, such as cardiac arrests, death, increased length of stay, pneumonia, postoperative infections, and pressure ulcers. The recommendations from the report were knowledge based and centered on the four basic components of all organizations:

1. Organizational management
2. Workforce deployment practices
3. Work design
4. Organizational culture (Beyea, 2004)

An organizational culture of safety must include a blame-free response to medical mistakes. Potential for errors must be recognized as opportunities to review process and policy to prevent future mistakes. Perioperative nurses have the responsibility to contribute to the creation of a culture of safety in the workplace to improve safety in the workplace for patients and nurses.

To ensure that older Americans receive high-quality, appropriate care, the Institute of Medicine recommends the following steps:

1. Enhance the competence of all healthcare personnel involved in the delivery of geriatric care instead of depending on specialists.
2. Provide stronger incentives to recruit and maintain geriatric practitioners.
3. Apply more flexible models of care to enable self-care for patients and informal caregivers (Institute of Medicine, 2008).

Future technical advances in surgery and anesthesia will continue to provide for beneficial surgery performed on older and older patients. The perioperative nurse who approaches the care of elders with this in mind not only will enhance the surgical outcome but also will significantly affect the patient's overall quality of life.

CHAPTER 27

Trauma Surgery

DIANE CATHERINE SAULLO

Trauma is ranked as one of the foremost public health issues in the United States today. Unintentional injury related to trauma is the fifth leading cause of death today and the leading cause of death for persons aged 1 to 44 years (Barclay, 2009). Trauma is the leading nonobstetric cause of maternal mortality and is associated with fetal mortality directly related to the severity of maternal injury (Cusick and Tibbles, 2007). Whether the injury is a result of a motor vehicle collision, violence, crime, or work-related injury, trauma occurs unplanned and without warning. The unpredictable nature of trauma poses a major challenge to the perioperative nurse and the patient care team.

The potential for injury has existed since the beginning of humanity. Most of the major advances in care of critically injured patients have been accomplished through experience in the military. Clearly, the shorter the response time, the greater the survival rate for casualties. This was demonstrated by the success of the mobile army surgical hospitals (MASH) during the Korean conflict and again during the Vietnam conflict; MASH brought the necessary supplies, equipment, and personnel closer to the battlefields and, consequently, improved patient outcomes.

Eventually this concept was applied to the civilian population and is now commonly referred to as the "golden hour" of trauma care. More specifically, the golden hour refers to the time immediately after the injury when rapid and definitive interventions can be most effective in the reduction of morbidity and mortality. The golden hour starts at the scene, where prehospital personnel determine the severity of injury, initiate medical treatment, and identify the most appropriate facility to which to transport the patient. Traumatic deaths may occur in three phases, or time frames. The first occurs immediately after the injury. This accounts for approximately 50% of the deaths from trauma and is usually a result of lacerations to the heart or aorta or brainstem injury. These patients rarely survive transport to the hospital and die at the scene. The second phase occurs within the first 1 to 2 hours after the injury, representing approximately 30% of total fatalities. These patients have injuries to the spleen, liver, lung, or other organs that result in significant blood loss. This is the group in which definitive trauma care (i.e., appropriate and aggressive resuscitation with adequate volume replacement) may have the most significant effect (the golden hour). The third phase occurs days to weeks after the injury, often during the intensive care phase, and is usually caused by complications or a failure of multiple organ systems.

The wars in Iraq and Afghanistan have resulted in some changes in the way traumatic injuries are managed; the military has not set up convalescence centers as in Vietnam and Desert Storm. Rather, the doctrine of "essential care in theater" is followed. Physicians and nurses have been trained to provide immediate care, keeping in mind the treatment resources that will be available at the next level of care. Soldiers with upper body injuries are surviving because of body armor. However, there is no protection for upper extremities; therefore there are many amputations being performed, including above-elbow and shoulder disarticulations. The new philosophy is to stress continuity of care with the goal of returning the soldier to the highest possible level of function.

Time is of the essence in providing definitive care to the critically injured person. A significant number of patient deaths can be prevented if rapid transport is provided from the scene to a facility equipped to provide resuscitation and treatment in an efficient and timely manner. This concept is reflected in the national development of the Emergency Medical Services (EMS) system. Facilities and resources are allocated and coordinated to provide specific interventions for a group of patients. For example, facilities that meet certain criteria to accommodate the specialized needs of the critically injured patient are designated as *trauma centers*. Communities establish transfer and triage protocols that allow for a trauma patient to reach the appropriate facility with the least out-of-hospital time possible. This may be accomplished by a helicopter with a specially trained flight crew or by the use of ground transport with an Advanced Life Support (ALS) ambulance team (Figure 27-1).

Trauma centers (TC) are classified based on the scope of services and resources that are available. A level I TC is capable of providing total care for every type of injury. Accepting this designation commits the TC to providing qualified personnel and equipment necessary for rapid diagnosis and treatment on a 24-hour basis. A level II TC provides comprehensive care for all injuries but lacks some of the specialized clinicians and resources required for the level I designation. A level II facility may provide surgical intervention if the critical nature of the injury dictates immediate intervention before transfer to a level I facility. A level III facility provides prompt evaluation, resuscitation, emergency surgery, and stabilization, as needed, before transfer to a higher-level facility. The American College of Surgeons (ACS) recommends that in level II and III centers, an OR team is readily available at all times. Depending on the population served and the volume of urgent cases, this requirement may be met with on-call staff. A level IV trauma center has the ability to provide advanced trauma life support before patient transfer. These facilities may be located in rural areas with limited access and may be a clinic or a hospital.

Although the risk for death is 25% lower for a severe injury treated in a level I TC (Barclay, 2009), not all patients

require the services of a level I TC and so may be transported to the closest emergency department for care. New guidelines and recommendations for triage, first developed as a position statement by the ACS in 1986, have been published (Barclay, 2009). Known as the "Decision Scheme," this algorithm guides EMS personnel through the following four decision points: physiologic parameters, anatomic parameters, mechanism of injury (MOI), and other special considerations. Personnel review physiologic parameters. Patients with a Glasgow Coma Scale score less than 14, systolic blood pressure less than 90 mm Hg, or respiratory rate less than 10 breaths per minute or greater than 29 breaths per minute should be transported to the highest level facility available. The anatomic parameters include specific types of injuries, such as penetrating injuries of the neck or torso, flail chest, or proximal long bone fracture; these patients are also transported to the highest level facility available. The MOI and other special considerations, such as age or prior medical history, are also reviewed to determine to what level facility the patient is transported (History box).

Trauma patients require immediate access to the OR 24 hours per day, 365 days per year. A sudden influx of a large

FIGURE 27-1 New Hanover Health Network EMS Air Link rescue at the beach.

HISTORY

Triage Development

The origin of the term "triage" is sketchy but the earliest use was seen in the late 1700s and is attributed to Baron Dominique Jean Larrey. He said, "Those who are dangerously wounded should receive the first attention, without regard to rank or distinction."

Triage was further developed during the Civil War. The injured were separated into immediate treatment versus delayed treatment versus no treatment. Amputation was the most common life-saving procedure performed; gunshot wounds to the abdomen were often ignored because of high mortality and lack of resources. A more formal triage system was developed in World War I and was advanced in World War II. Air-medical transport was first used in the Korean War.

Field triage criteria for civilian injuries refer to the decisions of prehospital personnel about where to transport the injured. Before the 1970s the injured were simply transported to the nearest facility with little prehospital intervention. In 1976 the American College of Surgeons (ACS) established the designation of "trauma centers" and set standards of personnel, facility, and processes to provide optimal care of the injured. Prehospital triage in the 1970s and early 1980s was based on anatomic, physiologic, and mechanistic domains. The establishment of specialized trauma centers led to one of the first triage protocols for trauma patients in 1987, developed by the ACS and know as the *Optimal Resources' Guide*.

With the establishment of both specialized trauma centers and triage guidelines, the problems of overtriage and undertriage became evident, which included diagnostic and treatment delays or errors, increased morbidity and mortality, and missed injuries. In 1990 the ACS revised the field triage decision scheme to include, among other things, use of the Revised and Pediatric Trauma Scores. The 1990 revisions included mechanism of injury criteria related to vehicular deformity and motorcycle criteria and established a four-step versus the previous three-step process. The dictum of the ACS guidelines became, "when in doubt take to a trauma center." The guidelines were revised in 1993 and included changes in the Glasgow Coma Scale and the addition of automobile-bicycle collision criteria; the 1999 revisions changed the triage process within the trauma system so patients who met specific physiologic or anatomic criteria were taken to the highest level of care available.

Opportunities for further development of triage criteria include:

- Standardization of the criteria used to define overtriage and undertriage
- Improved balance between transport distance and severity of injury
- Incorporation of automated vehicular telemetry information to determine severity of injury

Modified from Mackersie RC: History of trauma field triage development and the American College of Surgeons criteria, *Prehosp Emerg Care* 10(3):287-294, 2006.

number of trauma patients to a trauma center may necessitate triage or classification of those less seriously injured as less urgent, allowing immediate access for the critically injured patients. The elective surgery schedule may need to be interrupted to expedite care for the trauma patient or patients. Scheduling policies and procedures are established collaboratively by the departments of surgery, trauma, anesthesia, and perioperative nursing services. Consequently, the perioperative nurse and surgical technologist need to be familiar with supplies and equipment located in the OR designated for trauma or in the ORs that are used most frequently for these patients.

Perioperative Nursing Considerations

Preliminary Evaluation: Mechanism of Injury

Because of the unpredictable timing of trauma, it is often the on-call perioperative nursing team who cares for injured patients requiring surgical intervention. In contrast to an elective surgical procedure, little information may be known about trauma patients and preparation time is often abbreviated. A working knowledge of the MOI is essential to assist the perioperative nurse in rapid patient assessment.

MOI, or kinematics, involves the action of forces on the human body and their effects. Knowing the forces applied provides valuable information in evaluation of the patient and injuries that may be present. The first EMS team to respond to the scene of an injury must carefully evaluate the patient in relation to the MOI. For example, the position of the victim in a car, whether the person was the driver or a passenger seated in the back seat or front seat, estimated velocity of the vehicle, location of impact, and use of a seat belt or air bag are all pieces of information used to determine the index of suspicion about the probable causes of injuries to the patient. After immediate threats to life are addressed, the MOI can provide valuable clues as to probable cause of injuries. This systematic approach can reduce morbidity and mortality (Table 27-1).

The MOI is a product of the type of injuring force and the resulting tissue response. The velocity of the collision, the shape of the object, and the tissue's flexibility influence the magnitude of the injury sustained. For example, long bone tissue has little or no flexibility. A strong collision involving a long bone most often results in a fracture of some type. In contrast, soft tissue injury from a colliding force may result in a contusion, since this tissue has greater flexibility.

Blunt trauma is injury resulting from a combination of forces, such as acceleration, deceleration, shearing, and compression, that do not result in a break of the skin. Morbidity and mortality may be greater than with penetrating trauma because identification of injuries is more difficult when injuries are less obvious. Causes of blunt trauma include motor vehicle collisions (MVCs), contact sports injuries, aggravated assault, and falls. Even low-energy trauma, such as that associated with low-level falls, can produce significant injuries.

TABLE 27-1

Biomechanics in Trauma

Mechanisms of Injury	Phases of Injury
	Examples
Vehicle of transfer of energy from environment to human host	Falls Motor vehicle crashes Bullets Stabbing instruments Blasts/bombs
	External Forces
DECELERATION FORCES	
Decrease in speed of a moving object or person	Victim strikes steering column Victim impacts ground
ACCELERATION FORCES	
Increase in speed of a moving object or person	Pedestrian thrown when struck by moving vehicle
BLAST FORCES	
Heat, light, pressure Low- and high-velocity missiles	Bomb explosion Bullets Stabbing instruments
	Internal Forces
Human body's response to kinetic energy load	Stress Cells separate, stretch, compress, or shear Strain Tissue damage or deformation from stress
	Types of Injuries
Describing for clinical and diagnostic purpose	Blunt vs penetrating Closed vs. open Primary vs secondary Direct vs. indirect

Modified from Emergency Nurses Association (ENA): *Trauma nursing core course,* ed 6, Des Plaines, Ill, 2007, Author.

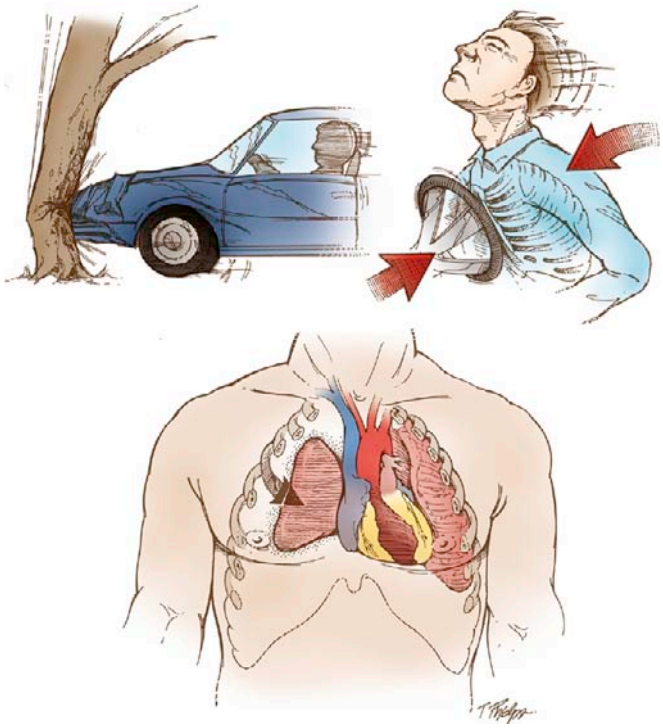

FIGURE 27-2 The three collisions of a head-on motor vehicle crash: the car hits an object; the occupant's body impacts on some surface within the motor vehicle; and the result is a collision between internal tissues and the rigid body surface structures.

Acceleration and deceleration injuries occur most frequently in blunt trauma. A ruptured thoracic aorta is an example of an injury that occurs as a result of these types of forces. In an MVC the large vessels are stopped or decelerated rapidly, resulting in vessel damage caused by stretching that exceeds the vessel's elastic ability. This affects the aorta at the ligamentum arteriosum, the anatomic point where it is affixed tightly to the chest wall, just below the origin of the subclavian artery. This shearing below the attachment site causes a rupture as the aorta continues to move in a forward motion after the chest wall motion has stopped.

MVCs account for a high degree of blunt trauma. During an MVC, actually three collisions occur (Figure 27-2). The first collision is that of a car into another object. The second collision is the impact of the occupant's body on the vehicle's interior. The third collision occurs when an internal body structure hits a rigid bony surface. A coup-contrecoup injury of the brain, for example, is the result of an acceleration force to one area of the brain and a deceleration force to an opposite area. Front and side air bag deployment along with the use of seat belts can decrease the severity of traumatic injury (Research Highlight).

Falls also cause a significant number of traumatic deaths in the United States. Injuries are most commonly associated with children experiencing falls more than twice their height. In adults, falls more than 10 to 15 feet are usually accompanied by significant injury. Deceleration forces in falls produce forces of stretching, shearing, and compression. Consequently, aortic injuries are also suspect in this group of patients. Skeletal injuries occur as well, because of the compressive forces present.

RESEARCH HIGHLIGHT

Impact of Airbags

Seat belts were introduced in motor vehicles more than 40 years ago and have been refined during that time. After mandatory use legislation, seat belt use increased and there was an associated decrease in crash fatalities by up to 50%. Today, it is clear that seat belts reduce injuries and save lives.

Airbag use has increased in the last 15 years, and while published data are limited, indications are that airbags are associated with less severe injury (based on a study of second-generation depowered airbags). One study showed an almost 50% decrease in injuries to the brain, face, and cervical spine. Another study demonstrated that airbags alone were associated with a decrease in fatalities; a combination of airbags and seat belts had a greater protective effect. Other studies concluded that airbags are associated with an increase in extremity injury and are more effective at higher speeds.

Using the trauma registry, the authors conducted a study looking at motor vehicle collision victims admitted over an 11-year period, for a total of 14,390 patients. The patients were divided into four groups: unrestrained (n = 7881), airbag only (n = 692), seat belt only (n = 4909), or airbag and seat belt (n = 908). Although separate use of airbags and seat belt was associated with reduced injury, a larger association was seen when both airbags and seat belts were used. The conclusion states that seat belts, with or without airbags, are associated with decreased in-hospital mortality and a change in injury pattern, as well as reduced injury severity and hospital resource use.

From Williams RF et al: Impact of airbags on a level 1 trauma center: injury patterns, infectious morbidity, and hospital costs, *J Am Coll Surg* 206(5):962-969, 2008.

Penetrating trauma is a result of the passage of a foreign object through tissue. The degree or extent of tissue injury is a function of the energy that is dissipated to the tissue and the surrounding areas. The anatomic structures most often injured include the liver, intestines, and vascular system. The extent of the injury relates to the nature of the foreign object (e.g., bullet caliber, knife size), distance from the weapon, structures penetrated, and amount of energy dissipated to the structures.

The velocity of a bullet is responsible for the degree of injury or cavitation to the tissue. A low-velocity bullet is one that travels at a lower speed (1000 feet per second or less) and disrupts only the bullet tract and its immediate surrounding area. A high-velocity weapon, such as used by the military, fires a bullet traveling at a greater speed (3000 feet or more per second) and causes significantly more damage and tissue destruction, since the bullet tract involves more extensive surrounding tissue (Figure 27-3). The distance from the weapon also influences the degree of injury because the velocity is greatest when the bullet leaves the weapon and decreases as it travels. In addition, the type of bullet (e.g., shotgun shells with multiple pellets and hollow-point bullets, which mushroom on impact) influences the degree of injury. Commonly the entrance wound is smaller than the exit wound because of the dissipation of energy, but an exit wound may not always be present. If the bullet completely fragments or is lodged in an internal structure, there will not be an exit wound. Depending on the position of the bullet and any injury that could be caused by attempting to remove it, bullets are not always removed.

Stab and impalement wounds are considered to be low-velocity wounds. The associated injuries usually correspond to the path of the penetrating object. Factors such as the object's width and length assist in identification of the possible occurrence of injuries. A single injury site may penetrate several different organs or cavities. Penetrating injuries located at or below the nipple line may cause both chest and abdominal injuries. This is attributable to the diaphragmatic excursion that occurs with inspiration and expiration. Impaled objects should not be removed at the scene or in the emergency department (ED). The impaled object provides a tamponade effect to injured blood vessels and is removed only when the ability to control potential bleeding from those vessels is present. Wound debridement may also be necessary. Therefore these objects are removed in the OR, where the needed supplies and instrumentation are located.

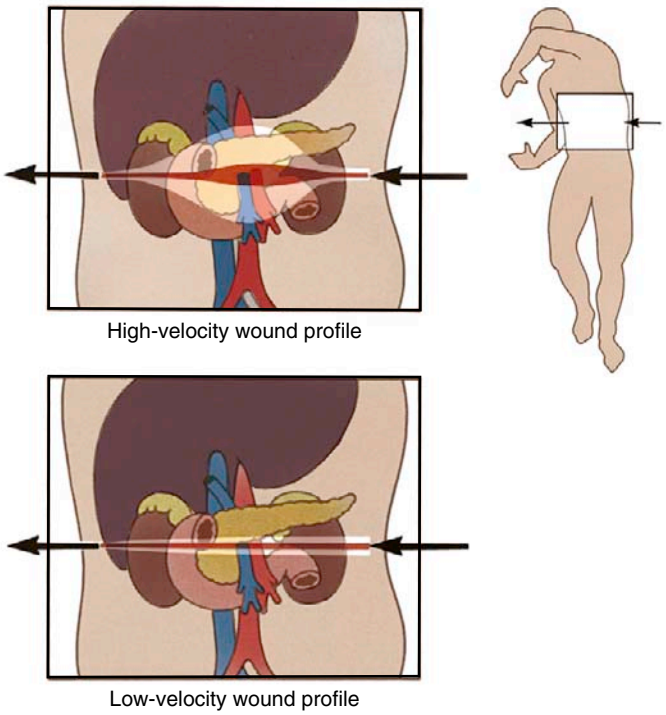

FIGURE 27-3 Potential injury path of high- and low-velocity bullets.

Injuries that result from explosions are related to the effects of the blast. With the threat of domestic terrorism on the rise, the treatment of blast victims may become more frequent in trauma settings. Blast trauma inflicts injuries in a number of ways. Primary blast injury is the result of a direct pressure wave on the body. Secondary injury is associated with the impact of debris and fragments energized by the blast, which act like high-velocity missiles. Tertiary injuries result from the blast wind, since air is accelerated and may cause traumatic amputations or limb or skull fractures (Born, 2005). The type of injury sustained and its intensity are directly related to factors such as the size of the blast and the proximity of the victim or victims. Patients from a blast explosion may present with penetrating injury, contusions, lacerations, amputations, abrasions, avulsions, evisceration, and various degrees of burns (Table 27-2).

Thermal and electrical tissue damage and inhalation injuries may occur from an explosion or as a sole mechanism of injury. These patients are usually resuscitated and require operative intervention for debridement on a nonemergent basis, unless the injury is limb- or life-threatening.

Injuries can be scored objectively according to their severity. This scoring system assists medical personnel in more effective triage and provides a universal method of communication among facilities, departments, and nursing personnel. According to Barclay (2009), the ACS guidelines, as published by the National Expert Panel on Field Triage, now recommend the use of the Decision Scheme (Table 27-3).

Assessment

The resuscitative process begins with arrival of emergency personnel on the scene and ends when the patient has been stabilized, received definitive care, and undergone a complete

TABLE 27-2

Mechanisms of Blast Injuries

Category	Areas Affected	Types of Injuries
Primary: Caused by blast itself	Gas-filled organs most susceptible:	
	◆ Eye	Rupture of globe
	◆ Middle ear/tympanic membrane	Rupture and permanent deafness possible
	◆ Lungs	Pneumothorax, alveolar rupture, air embolus
	◆ GI tract	Abdominal hemorrhage, contusions, rupture
	◆ Central nervous system	Diffuse cerebral hemorrhage, cerebral air embolism, concussion syndrome (injury without physical signs)
Secondary: Caused by debris and projectiles	Any body part	Varies depending on size of projectiles: penetrating or blunt injury
Tertiary: Caused by victim being thrown against stationary objects	Any body part	Similar to those seen in motor vehicle crashes: fractures, traumatic amputations, closed/open brain injury
Quaternary: Exacerbation or complications of existing conditions	Any body part	Burns, crush injuries, inhalation of dust or toxic gases causing exacerbation of asthma or COPD, angina

Modified from Emergency Nurses Association (ENA): *Trauma nursing core course,* ed 6, Des Plaines, Ill, 2007, Author.

and thorough physical examination to determine all injuries sustained. When the patient arrives in the ED, the trauma team initiates a primary assessment. This is a logical, orderly process of patient assessment for potential life threats. These assessment activities are based on established protocols for advanced trauma life support (ATLS). The mnemonic "ABCDE" is used, representing assessment of the following:

- ***A***irway (with cervical spine precautions)
- ***B***reathing
- ***C***irculation
- ***D***isability (brief neurologic examination)
- ***E***xposure (to reveal all life-threatening injuries) and ***e***nvironmental control (thermoregulation)

Airway interventions may include manual maneuvers (chin-lift, jaw-thrust), insertion of oral or nasopharyngeal airways, or intubation. The trauma team may also perform emergent procedures, such as tracheotomy or needle cricothyrotomy, to secure the patient's airway. Pulse oximetry and capnography monitoring are used. If cervical spine precautions were not implemented before arrival at the hospital, the team initiates them before performing any other procedures on the patient. A trauma team member can stabilize the head and neck, if necessary, until a cervical collar is placed. Once placed, the team does not remove it until a cervical radiograph clears the neck of injury.

During this time, the surgeon or ED physician and trauma team identify and correct life threats that are present before progressing to the next part of the examination. A patient requiring immediate surgery is transported to the OR, undergoes surgical intervention, and then is transferred to the postanesthesia care unit (PACU) or intensive care unit (ICU), depending on his or her condition. On the other hand, a patient may have a penetrating wound with evisceration of abdominal contents. However, correcting the obvious defect, which is currently not life-threatening, is postponed until the trauma team is assured that the patient has a patent airway and an effective breathing pattern and cervical spine precautions have been implemented. An evisceration needs to be corrected, but an inadequate airway is an immediate life threat and assumes priority.

Depending on the patient's injury, the surgeon may order an arterial blood gas (ABG) measurement. This test provides an accurate assessment of the ventilatory status of the patient and also evaluates resuscitative airway and breathing interventions (Table 27-4). Metabolic acidosis or a large base deficit (pH <7.35 or >7.45), with all other causes ruled out, may indicate internal bleeding.

After the trauma team completes the primary assessment and corrects any immediate life threats, they perform a secondary assessment. The purpose of the secondary assessment is to identify all injuries present. Sometimes the secondary assessment may be completed by the perioperative nurse, the PACU nurse, or the critical care nurse. This assessment is a more in-depth, head-to-toe evaluation of the patient. Inspection, palpation, percussion, and auscultation are used in the complete head-to-toe assessment to reveal any deformities, open injuries, tenderness, or swelling. The assessment begins at the head and face and then moves to the neck (including the spine), the chest, the abdomen, and the pelvis. The four extremities are next; distal pulses, motor function, and sensation are assessed. The final check is the back; the patient is carefully log-rolled to the side for a full visual and tactile assessment (Evidence for Practice).

The patient's vital signs, including a rectal or tympanic temperature, unless contraindicated, are obtained. Often during resuscitation, the nurse will insert a Foley catheter to monitor urine output and fluid resuscitation efforts. The nurse should inspect the urinary meatus for the presence of blood before inserting the catheter. If blood is noted, the nurse notifies the

TABLE 27-3

Decision Scheme Recommendations*

Steps	Transition	Recommendations
Step 1		Transport to TC for any of the following: GCS <14, systolic BP <90 mm Hg, respiratory rate <10 or >29 breaths/min
	1 to 2	These patients have potentially serious injuries and should be transported to highest level TC available
Step 2		Transport to TC for any of the following: penetrating injuries of head, neck, torso, and extremities proximal to elbow and knee; flail chest; 2 or more proximal long bone fractures; crushed, degloved, or mangled extremity; amputation proximal to wrist and ankle; pelvic fracture; open or depressed skull fracture; paralysis
	2 to 3	If yes to any criteria, transport to highest level TC available; if patient does not meet step 2 criteria, proceed to step 3
Step 3		Transport to TC for any of the following: falls >20 feet for adults, >10 feet or 2-3 times child's height; motor vehicle crash with partial or complete ejection of occupant; auto vs pedestrian/bicyclist thrown; motorcycle crash at speed >20 mph
	3 to 4	If yes to any criteria, transport to closest TC
Step 4		Consider transport to TC for the following: age >55 or <15, anticoagulation and bleeding disorders, burns, time-sensitive extremity injury, end-stage renal disease requiring dialysis, pregnancy, or provider judgment

*The Decision Scheme is an essential component of the trauma system, guiding EMS providers in transporting injured patients to the most appropriate facility, ensuring proper treatment, and thus reducing death and disability.

BP, Blood pressure; *GCS,* Glasgow Coma Scale; *TC,* trauma center.

TABLE 27-4

Laboratory Values: Arterial Blood Gases (ABGs)

NORMAL VALUES		
Pao_2	Pressure of oxygen in arterial blood	80-100 mm Hg
$Paco_2$	Pressure of carbon dioxide in arterial blood; measurement of how well lungs are discarding carbon dioxide (CO_2 level is controlled by lungs)	34-45 mm Hg
pH	Acidity or alkalinity of arterial blood; measurement of hydrogen ion concentration	7.35-7.45
HCO_3^-	Amount of bicarbonate in arterial blood; controlled by kidneys	21-28 mEq/L
O_2 saturation	Percentage of hemoglobin that is carrying oxygen	95-100%
ABNORMAL VALUES		**POSSIBLE CAUSE**
Pao_2	<50 mm Hg	Hypoxia
$Paco_2$	>45 mm Hg	Hypoventilation/CO_2 retention by lungs
pH	<7.35	Acidosis
	>7.45	Alkalosis
HCO_3^-	<22 mEq/L	Renal excretion of too much bicarbonate
	>26 mEq/L	Renal retention of too much bicarbonate

EVIDENCE FOR PRACTICE

Assessing Neurovascular Status in Patients with Musculoskeletal Trauma

Trauma patients frequently present to the OR with fractures or other musculoskeletal injuries. A thorough assessment of the patient's neurovascular status is imperative to establish a baseline for nursing and surgical interventions.

ASSESSMENT TECHNIQUE	NORMAL FINDINGS
SKIN COLOR	
Inspect the skin distal to the injury.	There is no change in pigmentation compared with other parts of the body.
SKIN TEMPERATURE	
Palpate the area distal to the injury (the dorsum of the hands is the most sensitive to temperature).	The skin is warm.
MOVEMENT	
Ask the patient to move the affected area or the area distal to the injury (active motion).	The patient can move without discomfort.
Move the area distal to the injury (passive motion).	There is no difference in comfort compared with active movement.
SENSATION	
Ask the patient if numbness or tingling is present (paresthesia).	There is no numbness or tingling.
Palpate with a paper clip (especially in the web space between the first and second toes or the web space between the thumb and forefinger).	There is no difference in sensation in the affected and unaffected extremities. (Loss of sensation in these areas indicates perineal nerve or median nerve damage.)
PULSES	
Palpate the pulses distal to the injury.	Pulses are strong and easily palpated; there is no difference between the affected and unaffected extremities.
CAPILLARY REFILL (LEAST RELIABLE)	
Press the nailbeds distal to the injury until blanching occurs (or the skin near the nail if nails are thick and brittle).	Blood return (to usual color) is within 3 sec (5 sec for older people).
PAIN	
Ask the patient about the location, nature, and frequency of the pain.	Pain is usually localized and is often described as stabbing or throbbing. (Pain out of proportion to the injury and unrelieved by analgesics may indicate compartment syndrome.)

BOX 27-1

Laboratory Values: Urinalysis (UA)*

NORMAL VALUES		ABNORMAL VALUES		In Trauma, May Indicate
Color	Amber yellow	Color	Dark or red	Presence of blood
Appearance	Clear	Appearance	Dark or red	Presence of blood
Specific gravity	1.005-1.030	Specific gravity	>1.030	Fluid volume deficit
pH	4.6-8.0	pH	Alkaline: >8.0	Alkalosis
Protein	Negative		Acidic: <4.6	Acidosis
Glucose	Negative	Glucose	Present	Diabetes
Ketones	Negative			Increased intracranial pressure
Microscopic findings		Protein	Present	Renal failure
◆ RBCs	0-2/high-power field (hpf)	Ketones	Present	Diabetes
◆ WBCs	0-4/hpf			Diarrhea and vomiting
◆ Epithelial cells	Few	Microscopic findings		
◆ Casts	0	◆ RBCs	>3/hpf	Kidney, ureteral, bladder trauma
◆ Crystals	0	◆ WBCs	>4/hpf	Urinary tract infection
◆ Bacteria	0	◆ Epithelial cells	↑	Renal tubular necrosis
◆ Yeast	0	◆ Casts	↑	Glomerular capsule trauma
		◆ Bacteria		Abnormalities not usually seen in early trauma

*A urinalysis is done to check for injury to the genitourinary system and for the presence of specific diseases.
Modified from Pagana KD, Pagana TJ: *Mosby's diagnostic and laboratory test references,* ed 9, St Louis, 2009, Mosby.

surgeon and does not insert the catheter. The patient may have a ruptured bladder or a urethral injury, either of which is commonly associated with a fracture of the pelvis. The surgeon may wish to perform a retrograde urethrogram to examine the bladder and urethra for the presence of tears or disruption. After catheter insertion, urine is obtained for a urinalysis and urine drug screen. The identification of specific drugs in the urine may assist in further diagnosis and treatment. The urine will also be tested to determine the presence of red blood cells (RBCs) (Box 27-1). Depending on the amount of hematuria present, a renal contusion or other renal injury may be present. In addition, a nasogastric tube may be inserted at this time.

The nurse obtains a brief history from the family or significant others when possible. This history is referred to as the "AMPLE" history and may be obtained even after the patient is transferred to the OR by the ED personnel. The history includes the following:

- ***A***llergies
- ***M***edications
- ***P***ast medical history
- ***L***ast meal, ***l***ast menstrual period (if appropriate)
- ***E***vents or ***e***nvironment leading to the accident or injury

If the history is obtained after the initiation of surgery, it is important to communicate it to the surgeon and the anesthesia providers.

Routine Laboratory Tests. Laboratory values aid the trauma team in evaluating the patient's status. Appropriate laboratory tests include a minimum of a complete blood count (CBC), hemoglobin and hematocrit (H&H) value, blood alcohol level (BAL), and a blood type and screen; other tests may be requested during evaluation. The results of the laboratory studies should be reviewed and communicated as appropriate (Box 27-2). An abnormal level of RBCs may signify dehydration, hypovolemia, or fluid overload (dilutional). An elevated white blood cell (WBC) count, indicating the presence of infection, may be related to inflammation, tissue necrosis, or immunocompromise. H&H values are also important to note. Caution is advised in evaluating an H&H drawn in the ED. The time delay between bleeding and a drop in the H&H value can be significant. It is only after hemodilution occurs (from shock compensation or crystalloid replacement) that hematocrit level drops. Frequently, abnormal values in the patient with blunt trauma alert the team to the possibility of internal bleeding.

BAL also assists the trauma team in their evaluation. If the patient's level is significantly high, the physical examination and response may be unreliable. In addition, the neurologic status of patients with high BALs is very difficult to assess. Abnormal clotting studies are of obvious significance in trauma patients. These results may be attributable to anticoagulant medication the patient is taking or the effects of profound hypothermia. Clotting times may also be prolonged in the presence of excessive alcohol ingestion or the use of anabolic steroids. Clotting times may decrease with the use of antihistamines and diuretics.

A blood type and screen shortens the time needed by the blood bank to obtain a crossmatch, if needed later. Most trauma centers have several units of type O–negative blood (universal donor) available in the event that a blood transfusion is required before a type and crossmatch (T&C) can be performed. Because of regional shortages of O-negative blood, O-positive blood can be used in male patients and adult female patients of non-childbearing age. Initially, trauma patients are fluid-resuscitated with warmed crystalloid solutions, such as lactated Ringer's solution or normal saline solution. If the patient's blood pressure responds, the diagnostic examination continues. However, if the hypotension returns, blood transfusions may be initiated and the patient may be transported immediately to the OR for exploratory surgery.

BOX 27-2

Laboratory Values: Blood and Serum Electrolytes

RED BLOOD CELLS (ERYTHROCYTES)

RBC values vary, depending on age, gender, and geographic location (in relation to sea level) of the patient.

Normal Values

Children	
Newborn	4.8-7.1 million/μl
2-8 wk	4-6 million/μl
2-6 mo	3.5-5.5 million/μl
6-12 mo	3.5-5.2 million/μl
1-6 yr	4-5.5 million/μl
6-18 yr	4-5.5 million/μl
Adults/Elderly	
Male	4.7-6.1 million/μl
Female	4.2-5.4 million/μl
Pregnant female	Decreased

Abnormal Value	Probable Cause
↑	Dehydration
↓	Hypovolemia
	Fluid overload (dilutional)

WHITE BLOOD CELLS (LEUKOCYTES)

A WBC count is obtained to identify the presence of an infection.

Normal Value

5000-10,000/μl (elevated in pregnancy)

Abnormal Value	Probable Cause
>10,900/μl	Infection/inflammation
	Tissue necrosis
	Immunocompromise

HEMATOCRIT (HCT)

A hematocrit value is obtained to determine the percentage of RBCs in whole blood.

Normal Values

Children	
Newborn	44%-64%
2-8 wk	39%-59%
2-6 mo	35%-50%
6-12 mo	29%-43%
1-6 yr	30%-40%
6-18 yr	3%-44%
Adult	
Male	42%-52%
Female	37%-47%
Pregnant female	>33%

Abnormal Values in Trauma	
↓	Hemodilution ◆ From compensated hypovolemia ◆ From excessive volume replacement
↑	Hemoconcentration

NOTE: When blood is lost acutely, the amount of hematocrit lost is in the same ratio as that of whole blood. Therefore the percentage of hematocrit in a whole blood sample would remain normal. It is only after hemodilution occurs (from shock compensation or crystalloid replacement) that the hematocrit value drops.

HEMOGLOBIN (HGB)

A hemoglobin value is obtained to measure the amount of hemoglobin in whole blood. The amount of hemoglobin determines the oxygen-carrying capacity of blood.

Normal Values

Children	
Newborn	14-24 g/dl
0-2 wk	12-20 g/dl
2-6 mo	10-17 g/dl
1-6 yr	9.5-14 g/dl
Adult	
Male	14-18 g/dl
Female	12-16 g/dl
Pregnant female	>11 g/dl
Elderly	Values slightly decreased

NOTE: When whole blood is lost acutely, the amount of hemoglobin that is lost is proportionate. It is only after hemodilution occurs (as a result of shock compensation or crystalloid volume replacement) that hemoglobin level drops.

PLATELETS (THROMBOCYTES)

A platelet count is obtained to test the amount of platelet function. Platelets play an essential role in coagulation. Particularly in vascular trauma, platelets are essential to hemostasis.

Normal Values

Newborn	150,000-300,000/μl
Infant	200,000-475,000/μl
Child	150,000-400,000/μl
Adult/elderly	150,000-400,000/μl

Abnormal Values	Probable Cause
↑	Splenectomy
	Living at high altitude
	Hemorrhage
↓	Disseminated intravascular coagulation

COAGULATION STUDIES: PROTHROMBIN TIME (PT, PRO TIME)

A prothrombin time is evaluated in trauma patients to measure clotting time (caused by factors I [fibrinogen], II [prothrombin], V, VII, and X). This is important in determining the blood's ability to clot.

Normal Value

11.0-12.5 sec

Abnormal Value	Probable Cause
↑	Deficiency of factors I (fibrinogen), II (prothrombin), V, VII, and X; 2.5× normal values means that there is a bleeding tendency.

NOTE: Clotting times may be prolonged in the presence of excessive alcohol ingestion or the use of anabolic steroids. Clotting times may decrease with the use of antihistamines and diuretics.

BOX 27-2

Laboratory Values: Blood and Serum Electrolytes—cont'd

COAGULATION STUDIES: ACTIVATED PARTIAL THROMBOPLASTIN TIME (APTT)

An APTT is obtained to screen for problems with intrinsic clotting factors (except factors VII and XIII). It can be used also to monitor the effectiveness of anticoagulation with heparin. This laboratory test measures the amount of time it takes for fibrin to form a clot. In the trauma patient it is used to determine the patient's tendency to bleed.

Normal Value

30-40 sec for the clot to form (after the clinical reagent is added)

Abnormal Value in Trauma	Possible Cause
>40 sec	Intrinsic factor deficiency

NOTE: Be sure to fill the laboratory tube completely because the tube contains anticoagulant and the ratio of blood to anticoagulant may be altered if the tube is not filled correctly, causing an inaccurate prolonged clotting time.

SERUM ELECTROLYTES: SODIUM (Na^+)

Sodium is one of the two major extracellular cations. It is the major cause of osmotic pressure in extracellular fluid. Sodium also plays a major part in both acid-base balance and neuromuscular function.

Normal Value

136-145 mEq/L

Abnormal Values	Possible Cause
>145 mEq/L (hypernatremia)	↓ Fluid intake/fluid loss ↑ Sodium intake
>136 mEq/L	↓ Sodium intake ↑ Sodium loss

SERUM ELECTROLYTES: POTASSIUM (K^+)

Because potassium is one of the two major cellular cations, it is essential for the maintenance of cellular osmosis. It plays a major role in the electrical conductivity of both cardiac and skeletal muscle. In addition, potassium plays a major role in both acid-base balance and kidney function.

Normal Value

3.5-5 mEq/L

Abnormal Values	Possible Cause
>5 mEq/L (hyperkalemia)	Major burns Renal failure Major crush injuries
<3.5 mEq/L (hypokalemia)	Hypovolemia

SERUM ELECTROLYTES: CHLORIDE (Cl^-)

Measurement of serum chloride concentration is important for the assessment of acid-base status. Chloride is a major extracellular anion that plays a role in the maintenance of oncotic pressure and thus blood volume and arterial pressure.

Normal Value

98-106 mEq/L

Abnormal Values	Possible Cause
>106 mEq/L (hyperchloremia)	Dehydration Renal failure Central nervous system (CNS) trauma with central neurogenic breathing
<98 mEq/L (hypochloremia)	Excess vomiting Excess gastric suctioning

Modified from Pagana KD, Pagana TJ: *Mosby's diagnostic and laboratory test references,* ed 9, St Louis, 2009, Mosby.

Many trauma centers are implementing massive transfusion policies (MTP) for the clinical management of patients experiencing massive hemorrhage and to coordinate interdisciplinary and interdepartmental resources. Nessen and colleagues (2008) define massive transfusion as the replacement of one or more blood volumes within a 24-hour period, or 50% of estimated blood volume in 3 hours or less. This volume is approximately equal to the transfusion of 10 units of red blood cells (RBCs). Current research (Malone et al, 2006) suggests that improved patient outcomes are associated with the use of packed RBC/plasma/platelet ratios of 1:1:1. This simple ratio not only is easy to use but also has the benefit of administration of higher plasma and platelet volumes.

Diagnostic Procedures

RADIOLOGY. Depending on the trauma center protocol, a blunt trauma radiographic series may be part of the resuscitative phase. This minimally includes a lateral view of the cervical spine and an anteroposterior (AP) view of the chest. In addition, the patient also undergoes lateral thoracic and lumbar spine films and an AP view of the pelvis. Any area with deformity, swelling, or pain may also be examined by x-ray. Trauma patients are always treated as if they have a cervical spine injury until proven otherwise. When reviewing the cervical spine films for cervical spine injury clearance, the clinician should consider any existing factors that place the patient at high risk for spine injury. These include age older than 65 years, a dangerous MOI, and paresthesias in the extremities. Patients with penetrating trauma injuries usually are transferred immediately to the OR for exploratory laparotomy.

If the resources are available, the trauma center protocol may also include a computerized tomography (CT) scan as a diagnostic or screening tool. Depending on the MOI, such as a fall, CT scans of the head and abdomen may be performed. Because injuries in blunt trauma are very difficult to diagnose, the CT scan is frequently done before patient transfer to the OR. A high index of suspicion is maintained for other injuries until proven otherwise. Bowel injuries may be missed during initial scanning. A CT scan of the brain revealing an injury incompatible with life may alter the course of definitive treatment for a patient.

A CT-angiogram may be indicated in diagnosis of vascular injuries. If the patient is hemodynamically stable, this test is of great value in determining the extent of the injury. It is particularly beneficial in the diagnosis of a ruptured thoracic aorta, in which extravasation of the dye at the area of aortic fixation to the chest wall is noted. Other uses include evaluation of penetrating wounds, especially in the extremity. Vessel injury can be noted and the need for surgical intervention determined.

TABLE 27-5

Comparison of DPL, FAST, and CT Scans

Diagnostic Peritoneal Lavage (DPL) Documents Bleeding	Focused Assessment with Sonography in Trauma (FAST) Documents Fluid	Computed Tomography (CT Scan) Documents Organ Injury
ADVANTAGES		
Early diagnosis	Early diagnosis	Most specific to injury
Performed rapidly	Noninvasive	92% sensitive
98% sensitive	Performed rapidly	98% accurate
Detects bowel injury	86-97% accurate	
	Repeatable	
DISADVANTAGES		
Invasive	Operator dependent	Increased cost and time
Low specificity	Bowel gas and subcutaneous air distortion	Misses diaphragm, bowel, and some pancreatic injuries
Misses diaphragmatic and retroperitoneal injuries	Misses diaphragm, bowel, and pancreatic injuries	

Modified from Emergency Nurses Association (ENA): *Trauma nursing core course,* ed 6, Des Plaines, Ill, 2007, Author.

OTHER DIAGNOSTIC TESTS. Cardiac monitoring is another component of the initial phase of trauma care and is particularly important in blunt trauma. Early detection of ventricular dysrhythmias may indicate a myocardial contusion, or bruising of the heart. An electrocardiogram (ECG) is obtained when indicated by the mechanism of injury or the patient's symptoms. Undiagnosed heart disease, as evidenced by an abnormal ECG, is noteworthy in a patient requiring operative intervention.

Focused assessment with sonography in trauma (FAST), used in the United States since the 1990s, may assist with diagnosis in difficult situations. FAST is a portable, noninvasive scan that can be used to determine the presence of free fluid in the chest or abdomen. The typical FAST scan consists of chest, pelvic, and four abdominal scans. The chest scan examines right and left chest views and can determine the presence of pericardial fluid. The upper right abdominal scan evaluates the hepatorenal area, the first area that shows the presence of air. The left upper scan examines the splenorenal area. The left and right paracolic gutters are also scanned. The pelvic scan assesses for free fluid near the bladder. FAST is also used in pregnant patients with blunt abdominal trauma; it is both faster and safer than a computerized tomography (CT) scan, which is contraindicated in the pregnant patient because of the use of iodinated contrast medium and ionizing radiation (Cunningham, 2008).

Although FAST is useful in diagnosing free fluid, it cannot determine damage to solid organs; therefore it complements rather than replaces other imaging scans. Diagnostic peritoneal lavage (DPL) may be performed to determine the presence of abdominal injury. This tool is of particular benefit when evaluation of the abdomen is difficult, such as when the patient is intoxicated, unconscious, or hemodynamically unstable. DPL can be performed in the ED, OR, PACU, or ICU. Nonetheless, retroperitoneal blood may be missed with a DPL, whereas the FAST approach may be quicker and visualize more structures, even pericardium; it is also less expensive and noninvasive. Thus FAST may be used with patients who are unstable and need a quick approach without the risk of a false-positive tap (Table 27-5).

Internal compartment pressures may be measured with an injury to the extremity as well as to the abdomen. Swelling of the muscles below the fascia covering may compromise circulation and result in the eventual loss of the extremity because of tissue necrosis. This is known as *compartment syndrome.* There are multiple compartments in the lower extremity that may be affected (Figure 27-4). Surgeons may measure compartment pressures with a manometer/stopcock/syringe or a commercial compartment pressure–measuring device. Normal compartmental pressures are less than 20 mm Hg. Pressures more than 30 mm Hg require a fasciotomy. Symptoms include severe pain, paresthesia, and a decrease in motor movement in the involved extremity, especially on passive movement (Table 27-6).

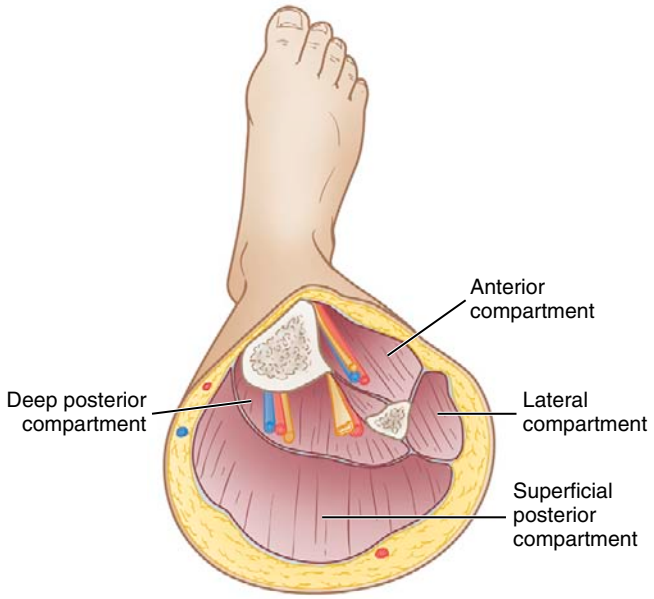

FIGURE 27-4 Compartments of the lower leg.

Massive intestinal edema may occur with trauma patients, causing compromise to internal organs and development of a different type of compartment syndrome. Abdominal compartment syndrome, also called abdominal hypertension, is characterized by increased intraabdominal pressure. Increased

TABLE 27-6

Signs and Symptoms Associated with Compartmental Syndromes

Compartment	Location of Sensory Changes	Movement Weakened	Painful Passive Movement	Location of Pain or Tenseness
LOWER LEG				
Anterior	First web space	Toe extension	Toe flexion	Along lateral side of anterior tibia
Lateral	Dorsum (top) of foot	Foot eversion	Foot inversion	Lateral lower leg
Superficial posterior	None	Foot plantar flexion	Foot dorsiflexion	Calf
Deep posterior	Sole of foot	Toe flexion	Toe extension	Deep calf—palpable between Achilles' tendon and medial malleoli
FOREARM				
Volar	Volar (palmar) aspect of fingers	Wrist and finger flexion	Wrist and finger extension	Volar forearm
Dorsal	None	Wrist and finger extension	Wrist and finger flexion	Dorsal forearm
HAND				
Intraosseous	None	Finger adduction and abduction	Finger adduction and abduction	Between metacarpals on dorsum of hand

Modified from Matsen FA: *Compartmental syndromes,* available at www.orthop.washington.edu/faculty/matsen/compartmental. Accessed May 14, 2009.

intraabdominal pressure (IAP) can have a negative impact on the respiratory, splanchnic, and cerebral functions. It contributes to sepsis or multiple organ failure seen in many trauma patients. Normal IAP is approximately 5 to 7 mm Hg; elevation to 25 mm Hg is often seen in patients with septic shock and correlates with high mortality (Vegar-Brozovic et al, 2008). IAP is graded from I to IV based on a 12 to >25 mm Hg scale. Adverse effects on organ function may be manifested as decreased cardiac output, oliguria, and hypoxia. Elevated intrathoracic pressure reduces left ventricular compliance, causing limitations in effective ventilation, often requiring ventilator support. Elevated IAP may cause an increase in intracranial pressure related to obstruction of cerebral venous blood outflow and increased intrathoracic and central venous pressure. Delay in treatment of IAP may lead to brain deterioration and damage.

Management involves a decompressive laparotomy. After a decompression, the greatest nursing priority is wound management. The swelling may render the abdomen difficult or impossible to close. If the abdomen is closed, intraabdominal pressure may rise to a level greater than 25 cm of H_2O, at which point it may lead to significant organ dysfunction (Kulaylat and Dayton, 2008). Intraabdominal pressure monitoring is accomplished with the use of a nasogastric tube in the stomach or a Foley catheter in the bladder. Simple water-column manometry is done at 2- to 4-hour intervals, although it is possible to connect a pressure transducer to a Foley catheter by way of the sampling port (Figure 27-5). By establishing a water column of urine in the Foley catheter with a clamp distal to the port, a pressure gradient is established. After zero-balancing the transducer, an 18-gauge needle is placed on the end of the pressure tubing and inserted into the sampling port. Using the pressure tubing and a 60-ml syringe, 50 to 60 ml of normal saline is then instilled into the Foley. On instillation of the saline, the waveform on the monitor is correlated to the existing bladder pressure. Normal intraabdominal pressure is zero or subatmospheric. A pressure of more than 25 cm of H_2O is considered diagnostic of abdominal compartment syndrome (Kulaylat and Dayton, 2008). Postoperatively, these patients are susceptible to fluid and heat loss. Continuous hemodynamic monitoring is essential in the critical care phase of treatment.

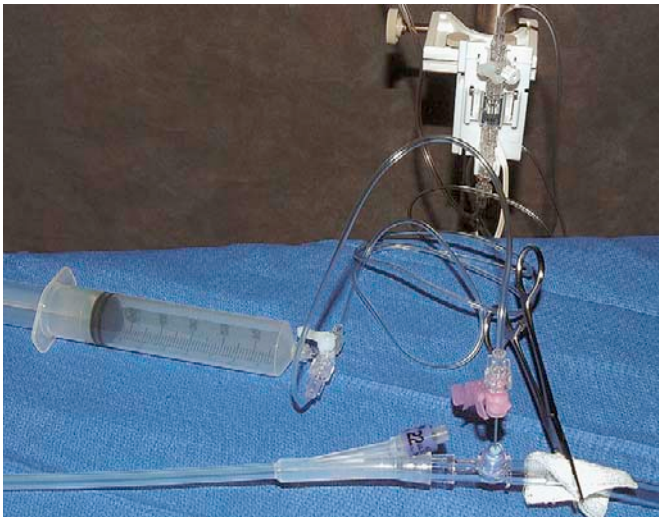

FIGURE 27-5 Setup for measuring abdominal compartment syndrome using a two-way Foley catheter and a pressure monitoring system.

Admission Assessment. The perioperative nurse may not obtain information concerning the trauma patient until the patient arrives in the OR for surgical intervention. If the patient's condition permits, the perioperative nurse should obtain a brief, precise report from the ED nurse that contains the following information: MOI, an AMPLE history (if available), condition on arrival (e.g., level of consciousness), availability of and prior administration of blood or blood products, spine clearance, injuries present, and any other pertinent information (e.g., family present, completion of secondary assessment). If the injury is life- or limb-threatening, implied

surgical consent is assumed (i.e., if the patient were able, consent would be given).

Additional data are collected as the perioperative nurse accompanies the patient to the OR. The status of the airway, as well as breathing patterns and circulatory condition, can be observed. The ED record also provides information concerning amount and type of intravenous (IV) fluid received, vital signs, core temperature, and laboratory and other diagnostic examinations performed. A quick visual and physical survey of the patient when the perioperative nurse is preparing the patient for the procedure enables identification of other sites of injury that might require attention (Patient Safety).

The patient's psychologic status can also be assessed. If the patient is conscious, the perioperative nurse is challenged to allay fear and anxiety. The trauma patient has endured a very frightening experience and is in need of support. The perioperative nurse is often the best member of the surgical team to communicate with the patient and explain the interventions occurring before anesthesia induction. A touch or handhold is an important aspect of this communication process, demonstrating the nurse's caring behaviors and offering comfort.

Nursing Diagnosis

Nursing diagnoses related to the care of trauma patients undergoing operative intervention might include the following:

- Anxiety and Fear (patient and family) related to unpredictable nature of condition
- Deficient Fluid Volume related to hemorrhage, fluid shifts, alteration in capillary permeability, alteration in vascular tone, or myocardial compromise
- Hypothermia related to rapid infusion of IV fluids, decreased tissue perfusion, and exposure
- Acute Pain related to effects of trauma/injury agents, experience during invasive procedures or diagnostic tests
- Risk for Aspiration related to reduced level of consciousness secondary to injury or concomitant substance abuse; impaired cough and gag reflex; trauma to head, face, or neck; and secretions and debris in airway

Outcome Identification

Outcomes identified for the selected nursing diagnoses could be stated as follows:

- The patient and family will experience decreasing anxiety and fear, as evidenced by orientation to surroundings, ability to verbalize concerns and ask questions to healthcare team, decreased fear-related behaviors (e.g., crying, agitation), and use of effective coping skills.
- The patient will have an effective circulating volume as evidenced by strong, palpable peripheral pulses; warm, dry skin of normal color; stable vital signs appropriate for age; maintenance of hematocrit level of 30 ml/dl or hemoglobin level of 12 to 14 g/dl or greater; and control of external hemorrhage.
- The patient will maintain a normal core body temperature, as evidenced by a core temperature measurement of 36.6° to 37.5° C (98° to 99.5° F) and warm, dry skin of normal color.
- The patient will experience relief of pain, as evidenced by diminishing or absent level of pain through patient's self-report, absence of physiologic indicators of pain (e.g., tachypnea, pallor, diaphoretic skin, increasing blood pressure), and ability to cooperate with care as appropriate.
- The patient will not experience aspiration, as evidenced by a patent airway; clear and equal bilateral breath sounds; regular rate, depth, and pattern of breathing; clear chest radiograph without evidence of infiltrates; and ability to handle secretions independently.

PATIENT SAFETY

Missed Injuries

The definition of a missed injury in trauma varies but is generally described as an injury not identified during the primary or secondary surveys or more than 24 hours after admission. Pfeifer and Pape (2008) identified patients with head injuries or a Glasgow Coma Scale score of 8 or less to be more likely to have a missed injury or delayed diagnosis. The literature review showed that the majority of errors occurred in the emergency department, intensive care unit, or OR. The injuries in the review were classified as minor, major, or life-threatening, with approximately 27% to 66% of missed injuries considered major and clinically significant (Pfeifer and Pape, 2008). The study also concluded that missed injuries result in significantly longer hospital stays and longer intensive care unit stays. Ekeh and colleagues (2008) studied diagnostic difficulties with blunt bowel and mesenteric injuries (BBMI) that cause delayed diagnoses even with computerized tomography (CT) scan, diagnostic peritoneal lavage, or FAST. They conclude that missed injuries are common in BBMI even with multislice CT capability.

Pfeifer and Pape (2008) reported that factors contributing to missed injuries include omission of radiographs of the specific area of injury, misinterpreted x-rays, clinical inexperience, assessment errors, interrupted diagnoses, and neighboring injuries. Howard and colleagues (2006) included patient-specific factors such as altered level of consciousness, intoxication, or sedation to the possible cause of missed injuries. Howard and colleagues stated that the most commonly missed injuries were extremity factures; they recommended increased focus on unconscious and/or intubated patients during the primary and secondary surveys. Howard and colleagues (2006) proposed the use of the tertiary survey to decrease the incidence of missed injuries. The tertiary survey, which includes a head-to-toe examination and review of all laboratory and radiologic studies, should be performed within 24 hours of admission. The conclusions of both studies call for adoption of the tertiary survey as the standard of care for all patients admitted to a level II trauma center. An unexpected outcome of the study by Howard and colleagues was the development of a culture of shared responsibility; nurses and therapists discovered injuries during their interactions with patients.

Modified from Ekeh AP et al: Diagnosis of blunt intestinal and mesenteric injury in the era of multidetector CT technology—are results better? *J Trauma* 65(2): 354-359, 2008; Howard J et al: Reducing missed injuries at a level II trauma center, *J Trauma Nurs* 13(3):89-95, 2006; Pfeifer R, Pape HC: Missed injuries in trauma patients: a literature review, *Patient Saf Surg,* 2008, available at www.pssjournal.com/content/2/1/20. Accessed May 16, 2009.

Planning

Because of the unexpected nature of trauma, planning perioperative care is of the utmost importance. Equipment, instruments, and supplies that have a high probability of use must be immediately available. Autologous blood salvage units should also be considered during patient care preparation, because blood salvage will be done if not contraindicated by the nature of the injury. A Sample Plan of Care for a trauma patient is shown below.

Implementation

Multiple Operative Procedures. Depending on the severity of the injuries, the multiple trauma patient may require many surgical interventions. Some of these procedures may be performed simultaneously. This is determined through a

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS

Anxiety and **Fear** (patient and family) related to unpredictable nature of condition

OUTCOME

The patient and family will experience decreasing anxiety and fear, as evidenced by orientation to surroundings; ability to verbalize concerns and ask questions to healthcare team; decreased fear-related behaviors (e.g., crying, agitation); and use of effective coping skills.

INTERVENTIONS

- Monitor the patient's level of anxiety by assessing the patient's state of alertness, ability to comprehend, and ability to comply with requests.
- Facilitate family's presence.
- Assist the family in identifying coping mechanisms; facilitate and support their use.
- Reassure patient and family during interactions by touch (when welcomed) and empathetic verbal and nonverbal communication.
- Explain perioperative environment to patient and what to expect to assist in reduction of anxiety.
- Discuss patient's postoperative appearance (i.e., drains, tubes, equipment) with the patient and family.

NURSING DIAGNOSIS

Deficient Fluid Volume related to hemorrhage, fluid shifts, alteration in capillary permeability, alteration in vascular tone, or myocardial compromise

OUTCOME

The patient will have an effective circulating volume as evidenced by strong, palpable peripheral pulses; warm, dry skin of normal color; stable vital signs appropriate for age; maintenance of hematocrit level of 30 ml/dl or hemoglobin level of 12 to 14 g/dl or higher; and control of external hemorrhage.

INTERVENTIONS

- Manage any uncontrolled bleeding by doing the following:
  - Applying direct pressure over bleeding site
  - Elevating extremities
  - Applying pressure over arterial pressure sites
- Ensure trauma profile laboratory work is complete.
- Verify that requested blood and blood replacement components are available in the OR.
- Prepare laboratory request slips as required; document time and type of analysis requested.
- Collaborate with anesthesia provider in monitoring cardiovascular changes suggestive of hypovolemia.
- Assist in accurate monitoring of intake and output during the surgical procedure.
- Administer blood and blood components as indicated.

NURSING DIAGNOSIS

Hypothermia related to rapid infusion of intravenous (IV) fluids, decreased tissue perfusion, exposure

OUTCOME

The patient will maintain a normal core body temperature, as evidenced by a core temperature measurement of 36° to 37.5° C (96.8° to 99.5° F) and warm, dry skin of normal color.

INTERVENTIONS

- Warm IV solutions and blood products using approved warming devices.
- Minimize body exposure during all phases of perioperative care.
- Use forced air–warming units and warm blankets to facilitate normothermia.
- Ensure irrigant solutions are warm.
- Monitor body temperature for signs of hypothermia, and report to anesthesia care provider.

NURSING DIAGNOSIS

Acute Pain related to effects of trauma/injury agents, experience during invasive procedures or diagnostic tests

OUTCOME

The patient will experience relief of pain, as evidenced by diminishing or absent level of pain through patient's self-report, absence of physiologic indicators of pain (e.g., tachypnea, pallor, diaphoretic skin, increasing blood pressure), and ability to cooperate with care as appropriate.

INTERVENTIONS

- Collaborate with anesthesia provider and surgeon regarding pain management therapy to increase the patient's level of comfort if condition permits.
- Assess nonverbal cues regarding level of pain and discomfort.
- If the patient is unable to provide verbal or nonverbal cues, assume that pain is present or that procedures will cause pain.
- Use a visual or numeric pain scale to assess pain levels and change in comfort if patient is conscious and able to respond.

NURSING DIAGNOSIS

Risk for Aspiration related to reduced level of consciousness secondary to injury or concomitant substance abuse; impaired cough and gag reflex; trauma to head, face, or neck; and secretions and debris in airway

OUTCOME

The patient will not experience aspiration, as evidenced by a patent airway; clear and equal bilateral breath sounds; regular rate, depth, and pattern of breathing; clear chest radiograph without evidence of infiltrates; and ability to handle secretions independently.

INTERVENTIONS

- Ensure operation of suction apparatus preoperatively, and maintain one open suction line solely for use by the anesthesia provider.
- Provide assistance with cricoid pressure under the direction of the anesthesia provider.
- Assist with placement of nasogastric or orogastric tube to evacuate stomach contents.

collaborative effort among the surgeons, anesthesia provider, and perioperative nurse. If a patient has sustained severe head and abdominal trauma, a surgeon will need to place an intracranial pressure (ICP) monitoring device. However, the abdominal exploration is also emergently indicated. Consequently, the severe condition of the patient may require performance of both of these procedures at the same time

Multiple procedures, either simultaneously or in succession, require a great deal of preparation by the perioperative nurse, surgical technologist, and the trauma team. The order of procedures is determined by the presence or absence of life threats. The usual order of priority is chest, abdomen, head, and extremities. However, this priority is determined for each individual patient's situation and adjusted accordingly. Performance of simultaneous procedures is preferable when physically possible. Anesthesia time is decreased for the critically ill patient, and definitive surgical interventions are accomplished more rapidly.

Increased Risk for Infection. Many trauma patients have wounds that are contaminated with roadside debris, dirt, grass, or automobile parts. Others have a perforated full stomach, and food particles are released into the peritoneum, increasing the risk of peritonitis. Consequently, many patients are at high risk for infection. Sterile technique may be compromised secondary only to immediate life threat. Pouring an antimicrobial solution across the surgical site may be the only surgical skin prep undertaken when an immediate life threat exists. The use of antimicrobial prophylaxis shortly before skin incision has become the standard of care for surgical procedures. Perioperative nurses are in a position to ensure the timely administration of antibiotics.

Wounds may need to be grossly decontaminated before the surgical skin prep. Sterile scrub brushes or a mechanical irrigation-under-pressure device may be used preoperatively and intraoperatively. Care must be exercised to remove as much contamination as possible, without creating further damage to the wound or body part. Perioperative personnel must wear personal protective equipment (PPE) during irrigation under pressure to prevent splashes and contamination from the lavage system. Traffic in the OR should be limited to essential personnel. Increased traffic in the room increases chances for contamination in an already compromised patient, as well as potentially interferes with the delivery of expedient care.

Procedure Preparation. Most level I trauma centers have a designated trauma OR that contains all equipment and supplies potentially needed for trauma patients. Many hospitals maintain an emergency abdominal procedure set, craniotomy procedure set, and chest procedure set either obtainable in the OR's sterile supply area or immediately available in the central supply department. This streamlines preparation for the surgical procedure and allows for the possibility of rapid preparation in those instances where the patient bypasses the emergency department on arrival and is transported directly to the OR.

Once the perioperative nurse is notified of the surgical procedure, OR determination is made in consultation with the anesthesia provider and surgeon. Considerations include the following:

- Equipment required by the surgeon or surgeons to perform the surgical procedure
- Room availability
- Room size (to accommodate equipment, staff, and multiple procedures)
- Need for additional staff
- Capability for autologous blood salvage
- Availability of emergency procedure supplies (including power equipment)
- Selection of OR bed

Additional diagnostic procedures are often required during multiple trauma procedures. A fluoroscopic electric OR bed provides increased flexibility in patient management. The bed can be rotated on its base to facilitate two teams operating at once. The fluoroscopic capabilities allow for additional radiographs and arteriograms as needed. The bed should easily transform into different positions, such as lithotomy or lateral rotation. If a fluoroscopic bed is not available, arrangements must be made in advance to perform diagnostic radiologic procedures intraoperatively.

Before transfer of the patient to the OR bed, the perioperative nurse must ascertain if the spinal column has been cleared by the surgeon or attending physician as free from injury. If the spine has not been cleared, the surgeon must be consulted before removal of the patient from the backboard. Safe transfer of the patient from the transport vehicle to the OR bed can be accomplished using the log-rolling technique.

Positioning of the patient is based on the surgical approach. Ascertaining the type and location of the wound (anterior or posterior) and type of operative procedure dictates the patient's position. For example, an aortic injury may be approached through a thoracotomy or a median sternotomy incision. The thoracotomy requires lateral positioning devices, and the sternotomy necessitates a supine position.

If several procedures are being performed, positioning may change intraoperatively. Changing the anesthetized patient's position is accomplished under the supervision of the anesthesia provider, with particular attention to maintenance of the airway. The patient is moved slowly, allowing for assessment of vital sign changes in response to the position movement. All precautions regarding positioning are reexecuted, with special attention given to the electrosurgical grounding pad. This pad may loosen during patient repositioning and require replacement to ensure adequate pad contact.

When the trauma patient is transferred to the OR, the extent of injury is not always known. The perioperative nurse should prep the patient from the suprasternal notch to the midthigh. This allows for rapid access to the chest to clamp the aorta should massive hemorrhage control be indicated; it also allows for exposure of the femoral arteries for potential cannulation and access to the thigh for harvesting a saphenous vein.

Established policies for counting sponges, instruments, and sharps should address surgical procedures of an emergent nature within the institution. Every attempt is made to verify appropriate numbers of counted items without compromising the timeliness of intervention in a life-threatening situation. If a preprocedural count is not performed, the perioperative nurse must document the occurrence and rationale used in accordance with established hospital policies and procedures. Some institutions require an x-ray examination postoperatively to examine the patient for the presence of a retained object. If counted sponges are intentionally left in the patient (e.g., in a damage control procedure at a level II, III, or IV center before transfer to a level I facility), the number and type of sponges

left in the wound should be documented on the perioperative nursing record (AORN, 2009). The operative dictation by the surgeon should also verify the presence of retained sponges, their type, and their number. This allows for accurate counts in subsequent procedures and prevents the potential for an inadvertent retained sponge.

In the presence of clotting difficulties or specific types of organ injuries with continuous oozing of blood, the surgeon may elect to pack the surgical site with laparotomy sponges and close the patient as a temporary measure. After a period of 24 to 48 hours, the patient returns to the OR for removal of the laparotomy sponges and primary closure if possible. In such instances the perioperative nurse must document and record accurately the number of sponges used for packing, as just noted. When the sponges are removed, the exact number is verified and the sponges are isolated and contained in accordance with established hospital policy and procedure.

Autotransfusion. Considering the high blood loss associated with traumatic injuries, autotransfusion has become a vital asset in trauma care. Preoperative blood loss that is associated with an isolated hemothorax is collected in a designated chest-drainage device for reinfusion within 4 hours to avoid bacterial contamination. Intraoperative blood loss is collected, filtered, and reinfused to the patient. This provides immediate volume replacement, decreases the amount of bank blood used, and reduces the possibility of transfusion reactions or risk of transfusion with bloodborne pathogens.

The autologous blood salvage unit requires specialized training for operation. Institutional policies vary regarding appropriate personnel designated for operation of the equipment. Capabilities for autotransfusion should be considered during procedure preparation, since additional qualified personnel may be required.

During autologous blood salvage the surgical technologist squeezes out additional blood and fluid from saturated sponges before discarding them from the surgical field. The blood salvage suction is used whenever possible to maximize the amount of blood salvaged. However, care must be taken to ensure that the blood collected in the salvage unit is free from contamination. For instance, if the abdomen is contaminated with free food particles or colonic perforation is present, the blood cannot be used. Similarly, once antibiotic irrigation is initiated, the blood salvage unit is not used.

Evidence Preservation. If the injury to the patient is a result of a violent crime, the team must give special attention to preservation of evidence during the course of patient care. Physical evidence (e.g., bullets, bags of powder, weapons, pills, and other foreign objects), trace evidence (e.g., hair and fibers), biologic evidence (e.g., body fluids and blood), and clothing are considered types of evidence to be preserved. Specific procedures on handling of evidence may differ by institution and law enforcement agencies.

Clothing must be handled properly. When clothing is removed from the patient, the person removing it should cut along the seams or around the bullet or stab wound holes. The shape of the hole may help identify the weapon used. Clothing is placed in paper bags, labeled appropriately, and given to law enforcement personnel. Plastic bags trap moisture and may facilitate growth of mold, which could destroy evidence. The transport vehicle sheet should also be handled in a similar manner, since evidence may be present. The nurse must ensure that descriptions of wound appearances, body markings consistent with gang or cult activity, and statements from the patient are accurately recorded.

The chain of custody for all evidence, including clothing, is followed. This process allows for identification of all people handling the evidence. Documentation must verify that the evidence has been in secure possession at all times. Records should be kept of all evidence discovered, including its site of origin and when and to whom the evidence was given. A system of documentation using receipts or a specific form should be established to ensure appropriate compliance.

Gunpowder residues, tissue, hair, or other valuable information may be present on the hands of a trauma patient. This evidence can be preserved by placing the patient's hands in a paper bag and securing it with tape. Washing the hands should be avoided until evidence is collected, or until directed to do so by the police.

Bullets and retained implements offer valuable evidence and may assist in identifying the assailant. The weapon firing the bullet and the bullet itself can be matched by the specific grooves and markings placed on the bullet when the gun was fired. Most bullets are composed of soft lead, and handling with metal instruments can interfere with the markings. Therefore the surgeon should avoid using metal instruments to handle bullets. Some of the newer exploding types of bullets can present a risk to perioperative team members during wound exploration. Care should be exercised to avoid sterile glove tears, since these types of bullets are extremely sharp. Once a bullet is removed, the surgical technologist should place it in dry, clean gauze in a plastic specimen container and pass it off the sterile field to the perioperative nurse. Using the chain-of-custody procedures, the perioperative nurse should label the container appropriately and dispose of the bullet according to established institutional policies.

Deep Vein Thrombosis Prophylaxis. Because of the prolonged immobilization anticipated for the trauma patient, along with the frequency of orthopedic or lower extremity surgery, trauma patients are at high risk for developing venous thromboembolic events (VTE). Placement of a sequential compression device (SCD) preoperatively is ideal. These pneumatic compression devices assist in decreasing the possibility of deep vein thrombosis (DVT), and their effect is optimized when applied before surgical intervention. Preoperative placement is subject to the physician's preference; clinical research regarding similar devices and demonstrated product effectiveness is ongoing. The incidence of DVT and pulmonary embolism (PE) in trauma patients varies widely according to current literature. Meier and colleagues (2007) conducted a meta-analysis of trauma literature that estimated 11.8% of trauma patients develop a DVT and 1.5% develop a PE. The incidences are higher where there is severe head injury, pelvic fracture, and older age.

Currently, in patients with traumatic brain injury, the only recommended prophylaxis is SCD because of concerns with the use of heparin leading to bleeding complications. Subsequently, an inferior vena cava filter (VCF) may be inserted in high-risk patients to prevent pulmonary embolus. Risk factors for PE include prolonged immobility, multiple pelvic and lower extremity fractures, previous history of PE, severe head trauma,

and incomplete spinal cord injury with paralysis. VCFs have success rates of 98% in preventing PE from lower extremity DVT (Meier et al, 2007). However, the placement of a VCF is associated with inferior vena cava obstruction and recurrent DVT. Contraindication to pharmacologic prophylaxis is generally limited to a short period after the initial trauma, and long-term vena cava filtration is rarely necessary (Research Highlight).

Anesthesia Implications. Depending on institutional protocol, the anesthesia team may be directly involved in resuscitation of the trauma patient immediately after arrival at the ED. The anesthesia provider maintains the airway and intubates the patient if necessary. A critically injured patient may be transferred directly to the OR, whereas some interventions may be performed in the ED of a trauma center. These interventions vary from insertion of an ICP monitor to an emergent exploratory thoracotomy.

However, if diagnostic evaluation can be accomplished without intubation and sedation, the patient may be conscious upon arrival in the OR. A trauma patient is assumed to have a full stomach; thus these patients are at high risk for aspiration and resultant pneumonia. Under the direction of the anesthesia provider, the perioperative nurse applies cricoid pressure (Sellick maneuver) (Figure 27-6). This pressure is maintained over the cricoid area until the cuff on the endotracheal (ET) tube is inflated and tube placement verified by the anesthesia provider. This type of intubation is often referred to as a "crash induction."

In addition, the patient may require intubation for protection of the airway before radiologic examination of the cervical spine. If the cervical spine is not cleared or if the radiographic screening examination is not performed before intubation, ET intubation is done while cervical spine precautions (i.e., in-line intubation) are maintained. The anesthesia provider may decide to use rapid-sequence intubation (RSI). RSI involves administration of 100% oxygen, an analgesic, and a neuromuscular relaxant; application of cricoid pressure; and insertion of a cuffed ET tube. Etomidate (Amidate) is the most commonly used induction agent (Emergency Nurses Association, 2007). It acts in about 1 minute and lasts about 5 minutes. It is often used in trauma patients because it does not cause an increase in ICP or worsening of hypotension. Succinylcholine (Anectine) is the most frequently used neuromuscular relaxant. The perioperative nurse can facilitate RSI by ensuring availability of all intubation and resuscitation equipment, assisting with monitoring devices, and confirming correct ET-tube placement (Box 27-3).

In injuries of the face where midface fractures are present, nasal intubation and nasogastric tube placement are avoided.

RESEARCH HIGHLIGHT

Early Placement of Optional Vena Cava Filters

Trauma patients are at increased risk for developing thromboembolic events such as deep vein thrombosis. Standard anticoagulant therapy may not be suitable for certain traumas, such as brain injuries. In this study, investigators evaluated 34 patients who had a prophylactic vena cava filter (VCF) implanted. Those included in the study were high-risk patients with contraindications to pharmacologic prophylaxis for more than 5 days because of traumatic brain injury. The OptEase VCF was used on all patients and was placed infrarenally. Of the patients, 27 (or 84%) had their filters retrieved with no related mortality. Five (16%) patients had VCFs that were permanently implanted. One patient developed early inferior vena cava occlusion and DVT occurred 14 days after VCF placement. One patient developed symptomatic pulmonary embolus 5 days after VCF retrieval. The researchers concluded that early VCF placement may benefit patients in whom pharmacologic intervention is contraindicated.

Modified from Meier C et al: Early placement of optional vena cava filter in high-risk patients with traumatic brain injury, *Eur J Trauma Emerg Surg* 33(4): 407-413, 2007.

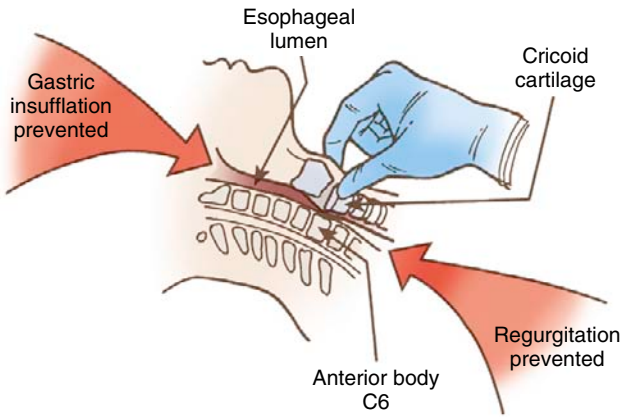

FIGURE 27-6 Application of cricoid pressure. Thumb and forefinger are used to depress cricoid cartilage, causing it to impinge on the lumen of esophagus and sealing it closed against the anterior body of C6. As a result, gastric insufflation secondary to positive-pressure ventilation (bag-valve-mask apparatus) from above, as well as regurgitation of stomach contents from below, is largely prevented. *C6*, Sixth cervical vertebra.

BOX 27-3

Rapid-Sequence Intubation Steps

Preparation	Assist anesthesia care provider as needed. Ensure all equipment is available.
Preoxygenation	Administer 100% oxygen.
Pretreatment	Assist anesthesia care provider in medication administration, as indicated (atropine, lidocaine, etomidate).
Paralysis with induction	Anesthesia is induced (midazolam, fentanyl), patient loses consciousness, and neuromuscular agent is administered (succinylcholine).
Protection and positioning	Use Sellick maneuver to provide cricoid pressure. Must be applied continuously and until anesthesia care provider asks to have pressure released to avoid aspiration.
Placement with proof	Inflate cuff; check placement with exhaled carbon dioxide detector and by listening to lungs with stethoscope.
Postintubation management	Secure tube, verify ventilator settings, and monitor per routine.

Modified from Emergency Nurses Association (ENA): *Trauma nursing core course,* ed 6, Des Plaines, Ill, 2007, Author.

Tube placement in the brain through a fracture of the cribriform plate is a well-known complication. To avoid this, oral ET intubation is the technique of choice. The anesthesia provider places an oral gastric tube to achieve stomach decompression. An oral intubation on a conscious patient is often necessary because anesthetics and muscle relaxants can result in the loss of any remaining airway in the presence of facial trauma.

Large-bore IV access used with rapid-infusion fluid warmers may be employed in the ED. These fluid warmers can deliver high volumes of crystalloid solution at body temperature. Use of the fluid warmer may continue during the intraoperative phase to facilitate volume replacement and help maintain normothermia. A number of factors may influence a trauma patient's response to fluid loss. These factors include age, severity of injury, type and location of injury, time lapse from injury to treatment, prehospital fluid therapy, prehospital use of a pneumatic antishock garment, and medications taken for chronic conditions. Fluid resuscitation should be initiated when early signs of blood loss are suspected. A classification system can be useful in determining the needs of the patient (Table 27-7).

Pregnancy. The normal physiologic changes that occur during pregnancy increase the challenge of evaluation and treatment when these individuals are victims of trauma. Cusick and Tibbles (2007) note that while the incidence of trauma in pregnant patients is low, it is still the leading cause of obstetric mortality. A trend noticed in this study identified more severe abdominal injuries and less severe head injuries in the pregnant patient. It is most important to remember that two patients are being treated. The key to resuscitation of the fetus is to resuscitate the mother. One of the first physiologic changes to note is that the pregnant trauma patient has a much larger circulatory volume (Table 27-8). The cardiac output may be increased by as much as 40%. Oxygen requirements are increased. Heart rate increases over the pre-pregnant state. The usual clinical indicators of hypovolemic shock are unreliable in the pregnant trauma patient (Table 27-9). The team must assume that the pregnant trauma victim is in shock until proven otherwise. Early aggressive treatment is essential. The uterus is enlarged and no longer a pelvic organ, and it elevates the bladder out of the pelvis as well. Supine position for the pregnant patient can result in a decrease in cardiac output as a result of compression of the inferior vena cava. If the patient is close to term, cardiac output can be reduced by as much as 30% as a result of compression on the inferior vena cava. Consequently, patients who are 20 weeks or more into their pregnancy should be placed in the left lateral decubitus position to avoid a hypotensive episode and maintain blood flow to the uterus and placenta. If this is not possible, manual displacement of the uterus by lateral abdominal pressure should be attempted. As a result of the physiologic changes just described, the pregnant patient is at risk for aspiration. Rapid-sequence induction, along with the Sellick maneuver, is the preferred method for intubation.

Ultrasound studies are conducted to determine viability of the fetus when possible. In the event of a ruptured uterus, a cesarean delivery and hysterectomy may be required if the fetus is viable. Neonatal resuscitation is of the utmost importance immediately on delivery of the fetus.

Pregnant patients requiring surgery also need fetal assessment performed intraoperatively. Any fetal movement should be noted. In addition, fetal monitoring is continuous. This includes fetal heart rate and uterine contractions. Fetal monitoring provides information on the condition of the fetus and the response to uterine contractions, if present. Fetal heart rate can usually be obtained after 10 weeks of gestation. Abnormalities in fetal heart rate can be an early sign of maternal compromise because the pregnant uterus is viewed as a nonessential peripheral organ in states of hypovolemic shock. The study by Cusick and Tibbles (2007) also noted that the presence of disseminated intravascular coagulation (DIC) was associated with fetal mortality. Personnel qualified in the interpretation of fetal heart rate patterns must be present. This expertise may be provided by the obstetric nursing staff.

TABLE 27-7

Estimated Fluid and Blood Losses Based on Patient's Initial Presentation*

	Class I	Class II	Class III	Class IV
Blood loss (ml)	Up to 750	750-1500	1500-2000	>2000
Blood loss (% blood volume)	Up to 15%	15%-30%	30%-40%	>40%
Pulse rate (beats/min)	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate (breaths/min)	14-20	20-30	30-40	>35
Urine output (ml/hr)	>30	20-30	5-15	Negligible
Central nervous system (CNS)/ mental status	Slightly anxious	Mildly anxious	Anxious, confused	Confused, lethargic
Fluid replacement (3:1 rule)	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

*The guidelines are for a 70-kg man. They are based on the 3:1 rule. This rule derives from the empiric observation that most patients in hemorrhagic shock require as much as 300 ml of electrolyte solution for each 100 ml of blood loss. Applied blindly, these guidelines can result in excessive or inadequate fluid administration. For example, a patient with a crush injury to the extremity may have hypotension out of proportion to his or her blood loss and require fluids in excess of the 3:1 guidelines. In contrast, a patient whose ongoing blood loss is being replaced by blood transfusion requires less than 3:1. The use of bolus therapy with careful monitoring of the patient's response can moderate these extremes.

Modified from American College of Surgeons: *ATLS program for doctors,* ed 7, Chicago, Ill, 2004, Author; Boswell SA, Scalea TM: Initial management of traumatic shock. In McQuillan KA et al, editors: *Trauma nursing: from resuscitation through rehabilitation,* ed 4, St Louis, 2009, Saunders.

TABLE 27-8

Maternal Adaptation During Pregnancy and Relation to Trauma

System	Alteration	Clinical Responses
Respiratory	↑ Oxygen consumption	↑ Risk of acidosis
	↑ Tidal volume	↑ Risk of respiratory mismanagement
	↓ Functional residual capacity	↓ Blood-buffering capacity
	Chronic compensated alkalosis	
	↓ $Paco_2$	
	↓ Serum bicarbonate	
Cardiovascular	↑ Circulating volume, 1600 ml	Can lose 1000 ml of blood
	↑ Cardiac output	No signs of shock until blood loss >30% of total volume
	↑ Heart rate	↓ Placental perfusion in supine position
	↓ Systemic vascular resistance (SVR)	Point of maximal impulse, fourth intercostal space
	↓ Arterial blood pressure	Heart displaced upward to left
Renal	↑ Renal plasma flow	↑ Risk of stasis, infection
	Dilation of ureters and urethra	↑ Risk of bladder rupture
	Bladder displaced forward	
Gastrointestinal	↓ Gastric motility	↑ Risk of aspiration
	↑ Hydrochloric acid production	Passive regurgitation of stomach acids if head lower than stomach
	↓ Competency of gastroesophageal sphincter	
Reproductive	↑ Blood flow to organs	Source of ↑ blood loss
	Uterine enlargement	Vena caval compression in supine position
Musculoskeletal	Displacement of abdominal viscera	↑ Risk of injury, altered rebound response; altered pain referral
	Pelvic venous congestion	↑ Risk of pelvic fracture
	Cartilage softened	Center of gravity changed
Hematologic	Fetal head in pelvis	↑ Risk of fetal injury
	↑ Clotting factors	↑ Risk of thrombus formation
	↓ Fibrinolytic activity	

Modified from Dorman KF: Obstetric critical care. In Lowdermilk DL, Perry SE, editors: *Maternity & women's health care,* ed 9, St Louis, 2007, Mosby.

TABLE 27-9

Signs of Hypovolemic Shock in Pregnancy

	Circulating Blood Volume Deficit	
	Early (20%)	**Late (25%)**
Pulse rate	<100 beats/min	>100 beats/min
Respiratory rate	12-20 breaths/min	>20 breaths/min
Blood pressure	Normal	Hypotensive
Skin perfusion	Warm, dry skin	Cool, ashen skin
Capillary refill time	<2 sec	>2 sec
Level of consciousness	Alert	Agitated, lethargic
Urine output	>30-50 ml/hr	<30-50 ml/hr
Fetal heart rate (normally 120-160 beats/min)	High, low, late decelerations	High, low, absent, late decelerations

Perimortem (postmortem) cesarean delivery may be performed in the event of the sudden death of the mother and the presence of a viable fetus.

Pediatric Trauma Patients. Special considerations related to the care of infants and children who have sustained a trauma are described in Chapter 25. Table 25-4 details a modified Glasgow Coma Scale for children.

Elderly Trauma Patients. As the number of adults older than 65 years continues to grow, so does the number of elderly patients requiring surgical intervention related to trauma. The physiologic effects of aging combined with the preinjury health status of many elderly patients significantly affect their ability to respond to initial treatment for traumatic injuries and subsequent surgical intervention. Consequently, the mortality for elderly trauma patients is significantly higher than that in younger patients with the same level of injury. Preexisting medical conditions, medication use, decreased physiologic reserves, and the physical and psychologic stress experienced during surgical interventions place elderly trauma victims at increased risk for perioperative complications (Plummer, 2009). (See Chapter 26 for the physical and psychologic changes that occur in elderly patients.)

Bariatric Trauma Patients. There has been a notable increase in admissions of bariatric patients in all healthcare facilities. Bariatric medicine is defined as the care of the extremely obese patient, as measured by body mass index (BMI). The World Health Organization (WHO) defines obese as a BMI greater than 30 and severely obese as a BMI greater than 40 (Muir and Archer-Heese, 2009). The obese patient often has several co-morbid conditions, including cardiac disease, hypertension, respiratory disease, diabetes, osteoarthritis, and stress incontinence. Because of their size and their decreased self-esteem the needs of bariatric patients are different from those of other patients. Societal prejudice against obesity is well established.

RISK REDUCTION STRATEGIES

Special Considerations for the Bariatric Trauma Patient

Bariatric trauma patients (e.g., those weighing more than 350 pounds) present special challenges to the surgical team. Morbidly obese trauma patients have an eight times greater risk of dying from their injuries than patients who are of normal body weight (Szczensiak, 2009). Several strategies must be developed to reduce risk to the patient and the healthcare team. The facility should be cognizant of the needs of bariatric patients and have policies and protocols established to facilitate effective and safe care.

Once the OR is notified of the arrival of a bariatric trauma patient, the perioperative nurse and surgical technologist must consider the planned procedure and the availability of necessary equipment, including a bariatric OR bed, foot board, and side extensions as well as long surgical instruments. A large blood pressure cuff will also be necessary for accurate blood pressure monitoring so that hemodynamic changes are quickly observed and treated.

As with all trauma patients, airway maintenance is a prime consideration. The bariatric patient often has a history of sleep apnea and is unable to lie flat for any length of time. The nurse should pad the head of the OR bed so that the patient's head is elevated as much as possible. In addition, the nurse should be prepared to assist the anesthesia care provider with intubation and also ensure that the difficult airway cart is available. The bariatric trauma patient is at increased risk for aspiration. The nurse can assist with airway protection by performing the Sellick maneuver at the anesthesia provider's direction.

Protection from positioning injury is a critical risk reduction strategy that the perioperative nurse should provide for the bariatric patient. Whenever feasible, it is best to have the patient move from the transport vehicle to the OR bed; if not, adequate personnel should be available to assist with the transfer and positioning so that both the patient and the surgical team can avoid injury. The increased adipose tissue of the bariatric patient does not protect the patient from pressure sores; the nurse must pad all bony prominences and pressure points well. Pillows collapse easily under a heavy load, so foam supports should be used. Shear injury can easily occur; therefore the nurse must check the patient's position and remove blankets or other materials under the patient if they are preventing a smooth surface.

All trauma patients are at increased risk for DVT. Bariatric patients have an even greater risk for developing this complication. The nurse should obtain the appropriate size of stockings and compression sleeves; these must be placed carefully, without any folds.

Skin breakdown, tissue injury, and dermatitis between the obese patient's layers of adipose tissue are very common. The perioperative nurse must retract skin folds while prepping to ensure the area is clean and well-prepped. If a limb is to be prepped, help should be obtained; another person or a sling may be used. Because one leg is 16% of body weight, it may weigh as much as 62 pounds; if not held securely, the weight of the limb can cause knee or ankle dislocation.

Care must also be taken in the placement of the ESU dispersive pad. Because of the increased amount of adipose tissue, the nurse may consider applying two dispersive pads to prevent the concentration of electrical current in a single area.

The bariatric trauma patient is at increased risk for retention of foreign bodies related to the size of the abdominal and other cavities. The perioperative nurse and surgical technologist must scrupulously count all sponges and instruments on the surgical field.

Finally, the nurse must have self-awareness and insight into any personal prejudice against the obese and act as an advocate for the patient. Comments about the patient's weight are not appropriate, and the nurse plays a role in reminding members of the team to monitor their verbal and nonverbal communications when providing care for bariatric patients.

Modified from Bell S: Current issues and challenges in the management of bariatric patients, *J Wound Ostomy Continence Nurs* 32(6):386-391, 2005; Ide P et al: Perioperative nursing care of the bariatric surgical patient, *AORN J* 88(1):30-58, 2008; Muir M, Archer-Heese G: Essentials of a bariatric patient handling program, *Online J Issues Nurs* 14(1), 2009; Szczensiak SL: Trauma in the bariatric patient. In McQuillan KA et al, editors: *Trauma nursing: from resuscitation through rehabilitation,* ed 4, St Louis, 2009, Saunders.

Studies show that nurses are often less attentive to the needs of the obese patient and are often worried about the possibility of personal injury related to positioning the patient. Sharma (2005) states that diagnosis can be very difficult in the absence of routine symptoms; CT and MRI scans are often not possible because of the limitations of the equipment. The use of ultrasonography may be limited because of distortion caused by the thickness of the abdominal wall. There are many strategies that the perioperative nurse may use to decrease risk for this patient group (Risk Reduction Strategies).

Invasive Emergency Department Interventions. If a patient has shown a very recent deterioration of vital signs, either en route to the hospital or on arrival at the ED, the surgeon may elect to perform an emergency thoracotomy in the ED. A left-sided approach is usually performed because this allows rapid access to the heart for external cardiac massage and exposure of the great vessels for clamping in the event of severe blood loss (Figure 27-7). The incision can be extended

FIGURE 27-7 Emergency exploratory thoracotomy performed in the emergency department.

RAPID RESPONSE TEAM

The Ohio State University Medical Center (OSUMC) conducted a 2-week trial of the in-house "stat" nurse position. Nurses accepted into this position need prior experience in critical care with a demonstrated ability for critical thinking. At OSUMC the role of the stat nurse includes assisting with patient transport to and from diagnostic tests, helping nurses perform difficult intravenous starts, responding to cardiac arrest and trauma calls, assisting with procedural sedation, and serving as a clinical resource for staff. The stat nurse, typically a non–emergency department (ED) professional, rarely takes the lead in patient care but rather acts as an assistant to the ED nurse. In a trauma situation, the stat nurse serves as an extra hand by setting up needed equipment, transporting blood specimens to the laboratory, and comforting family members as needed. The ability to provide an experienced critical care nurse in the trauma setting has had a positive impact on both patient care and staff morale.

Modified from Sinclair TD: The role of the rapid response nurse: hospital wide and in trauma resuscitations, *J Trauma Nurs* 13(4):175-177, 2006.

to the right side by cutting across the sternum. This procedure can be used to gain control in hemorrhage of the great vessels, to access the heart, or, in a grave situation, as a final effort to save a life. The procedure is used more often in penetrating injuries where a laceration to a ventricle or other potentially treatable, life-threatening injury may be present.

Because of the perioperative nurse's knowledge of surgical instrumentation and procedures, his or her assistance in this procedure in the ED is often required. In some facilities, perioperative nurses may assist the rapid response team in this role (Rapid Response Team box). Rapid access to the heart and great vessels is the goal. The patient is then transported to the OR for additional interventions once hemorrhage is controlled.

In a similar fashion, an exploratory laparotomy can be initiated in the ED to control abdominal hemorrhage, especially when a splenic rupture is suspected and the patient is severely compromised.

If all other techniques of airway access are unsuccessful, the surgeon performs a cricothyrotomy. The surgeon makes a vertical incision through the skin, and incises the cricothyroid membrane. An ET or tracheostomy tube can be inserted through the membrane to create an airway. In the event a tube is not immediately available, a large-bore needle can be inserted into the membrane and the catheter left in place. This provides a temporary airway access measure but is inadequate to effectively ventilate the patient without a jet oscillating ventilator.

Successive Surgical Interventions. Often the multiple trauma patient requires a multitude of surgical procedures—either specialty-related or as a stepwise progression in the primary treatment of the initial injury. Initially the trauma patient is critically ill and requires intensive care facilities. When surgery is scheduled, the perioperative nurse may need additional assistance in transport of the patient as transport monitoring of the ECG, arterial line, and blood pressure is performed. Oxygen administration and mechanical ventilation with an Ambu bag are necessary for the intubated patient. Acalculous cholecystitis is often a secondary complication of the trauma patient's postoperative course that requires cholecystectomy. Fixation of initially undiscovered fractures, debridements, secondary wound closures, flap constructions, and other reconstructive procedures make up the majority of follow-up procedures. Depending on the patient's condition, some procedures may be performed after discharge on an outpatient basis (Ambulatory Surgery Considerations).

AMBULATORY SURGERY CONSIDERATIONS

Outpatient Follow-up Procedures

Because of the extensive nature of some traumatic injuries, many trauma patients need further surgeries. Often follow-up procedures are performed on an outpatient basis. The perioperative nurse's care and planning for these patients must include an awareness of the physiologic and psychologic effects of the previous trauma. Preoperative teaching should include an assessment of the knowledge acquired by the patient and caregiver(s) from previous admission as well as the coping strategies they have been using. Maintaining the same routine as much as possible will help with the psychologic adjustment to yet another procedure. Pain assessment by the perioperative nurse is critical and must consider the patient's current medication use, including the duration of use as well as the medication's effectiveness. It is imperative to consider that this procedure will likely change the focus and severity of the pain and that additional or different medications may be necessary postoperatively.

Modified from Association of periOperative Registered Nurses (AORN): Preoperative patient care in the ambulatory setting guideline. In *Perioperative standards and recommended practices,* Denver, 2009, The Association.

Evaluation

The evaluation of the patient should reflect the effectiveness of the interventions. Did the patient remain free from untoward complications? Was there progress toward the expected outcomes as described in the perioperative plan of care? The following are examples of evaluation statements in relation to the sample plan of care:

- The patient demonstrated a decreased level of anxiety; he or she verbalized less apprehension, maintained eye contact, and was able to comply with requests even though anxiety persisted.
- The patient remained hemodynamically stable; fluid resuscitation was undertaken, blood pressure and pulse rate measurements were adequate considering the patient's status, and the H&H values were within acceptable ranges.
- The patient achieved and maintained normothermia in the OR.
- The patient reported reasonable relief from pain during preparatory maneuvers in the OR.
- The airway was maintained, and induction of anesthesia proceeded without complication.

On completion of the procedure or procedures, the perioperative nurse is afforded an opportunity to further assess the trauma patient as well as evaluate the plan of care implemented. If the patient sustained numerous injuries and remains critically injured, the PACU may be bypassed and the patient may be transferred directly to the ICU. The perioperative nurse should accompany the patient, along with the anesthesia provider, to the ICU. Once the anesthesia report is given, the perioperative nurse can provide a wealth of information to the critical care nurse. At this point, family members may have been contacted or are present, allowing more specific medical history information to be obtained. However, the mechanism of injury and events surrounding the trauma are still significant. A high index of suspicion remains during postoperative care of the patient sustaining multiple injuries. Attention can be diverted from a less significant injury in the presence of a highly visible or obvious trauma. Once the obvious trauma undergoes intervention, pain or discomfort from other injuries becomes more apparent. In the care of a patient with neurologic deficit, physical assessment and continued evaluation are essential because patient self-report is nonexistent.

The nurse should also report the status of progress in the secondary assessment. Any additional laboratory work or interventions that have yet to be completed should be discussed. It is imperative in a thorough examination to view the back of the patient in an effort to locate all injuries.

Additional diagnostic procedures may be required after completion of the surgical procedure if the patient's condition is stable. The perioperative nurse may be requested to accompany the patient to the diagnostic department with the anesthesia provider. In addition, respiratory care personnel may assist in patient transport and maintenance of the airway.

Patient and Family Education and Discharge Planning

Traumatic injury to a family member or significant other occurs without warning. Patients may be traveling or visiting out of town or state at the time of injury. Families or friends involved in a motor vehicle collision may be triaged to several different facilities based on severity of injury or age. A family member or significant other may not be contacted until several hours or even days after the injury. Sometimes the patient's identity either is unknown or must be kept confidential to prevent further harm. Both the patient and the family member are truly victims of traumatic injury. Consequently, patients and family members are in a time of crisis.

Some families may handle the crisis with ease, whereas others become dysfunctional. Coping strategies may be inappropriate at times as the patient and family attempt to reestablish patterns of function. A family system already taxed before the event may be overwhelmed with the additional stress of a sudden traumatic event. On the other hand, family members may wish to be present during resuscitation efforts. Family presence requires a facilitator to explain procedures and the accompanying sights, sounds, and smells that may occur. Nurses base their decisions on medical concerns, which may be very different than patient and/or family concerns. In trauma situations, nurses do not know their patient's preferences and may even be unaware that differences in opinion exist. Care may be improved when understandable terms are used to explain the situation, to provide realistic expectations, and to relay when clinicians will be available to answer questions (Murray, 2008).

The perioperative nurse must be prepared for a variety of responses, both from the patient and from the family or significant others. Interaction with the patient before surgical intervention may be impossible because of the severity of the injury, prior intubation, or hemodynamic instability. The perioperative nurse will need to offer brief, simple instructions and explanations if the patient is conscious. These may include the following:

- Background noise as caregivers prepare for emergent intervention
- Perception of cold within the OR room
- Placement of safety and restraining straps, armboards, warming devices, and pneumatic compression stockings, for example
- Invasive interventions, such as additional IV access or arterial line monitoring

A reassuring touch or holding the patient's hand may be the only communication possible. Touch, placement of warm blankets, a gentle squeeze of the hand, and softly spoken words of reassurance are important comfort measures.

In accordance with hospital policies and procedures, the perioperative nurse may call the surgical waiting room with periodic updates on the patient's condition. The information shared is subject to the surgeon's discretion and is usually concise in nature, such as, "At this time the extent of injury is unknown; his/her condition is critical." When implemented, these contacts with family members are appreciated because frequently they were unable to see or speak with the patient before surgery.

All of the patient's injuries and possible subsequent complications may not be known at the time of operative intervention. The multiply injured patient frequently requires rehabilitation or an extended stay in a skilled nursing facility before discharge to home. In addition to coping with physical changes, some patients may experience posttraumatic stress disorder (Research Highlight). Continued therapy, such as neuropsychology (for cognitive impairment) or occupational and physical therapy, may be provided on an outpatient basis. Consequently, information regarding recovery and rehabilitation is limited on admission to the hospital. Many facilities have access to or provide support groups for patients and families related to the type of injury and its subsequent lifelong effects (Patient and Family Education).

End-of-Life Care

Unfortunately, some accidental injuries result in death. Many facilities have a chaplain or social worker available to assist family members during this time of crisis. These caregivers assist in the initial family contact and provide immediate support. Providing end-of-life care for patients and family is relevant, even in trauma situations. Trauma is different in that the patient and family do not have a prior relationship with the healthcare team. This makes it difficult for the team to know and/or understand the wishes and values of the patient and family. Jacobs and colleagues (2005) believed that there was a need to develop guidelines for end-of-life care that incorporates aspects of trauma into a model. The American Trauma Society (ATS) sponsored a Trauma Leadership Forum (TLF) to identify specific problems related to trauma and end-of-life issues.

RESEARCH HIGHLIGHT

Propranolol and the Prevention of Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) may be defined as the reexperiencing of a traumatic event that is accompanied by symptoms. Most research to date has been focused on treatment to reduce symptoms but currently some researchers are studying prevention of PTSD with the use of drugs to blunt its effects. Medications such as propranolol (a beta-blocker) have been shown to attenuate the memory of emotions associated with traumatic events. Current treatments include various forms of psychotherapy, but these methods can take months or even years to help the patient and are not routinely effective. There is a period shortly after a trauma in which the memory is encoded in the brain; the strength of the memory is directly related to the release of stress hormones such as adrenaline. Some research has shown that administration of a beta-blocker for a time before or after the trauma effectively decreases the strength of the memory. However, debate exists regarding the ethics of eliminating or decreasing a person's memory. In one study, participants were given a placebo or a beta-blocker and then asked to watch some stories. The placebo group had much stronger memory and response to the emotional story but both groups had equal recall of the emotionally neutral story. The future may see the use of beta-blockers in the ED to treat patients recently involved in a traumatic event but the ethical concerns about the risks and benefits of pharmacologic intervention need to be addressed first.

Modified from Henry M et al: Propranolol and the prevention of post-traumatic stress disorder: is it wrong to erase the sting of bad memories? *Am J Bioeth* 7(9):12-20, 2007.

PATIENT AND FAMILY EDUCATION

Psychoeducation for Survivors of Trauma

Psychoeducation that focuses on long-term effects of trauma helps by making symptoms understandable and manageable for the survivor and helps to minimize responses. The knowledge that a stress response is autonomic makes it more understandable and may give the survivor a sense of control over these responses. Education about the physiologic basis for symptoms such as mood instability, flashbacks, and depression allows the survivor to realize they are symptoms and not personal failings. Trauma education for the healthcare team assists them in assessing a person's behavior more accurately, intervening more appropriately, and showing more empathy. A second goal is to help family members understand normal responses, offer coping strategies, and identify responses that may indicate more help is required. Phoenix (2007) discusses three phases of response to traumatic events. The first, the impact phase, occurs at the scene and includes feelings of disorientation and responsibility for the event. During phase 2, or the immediate postevent phase, the survivors may experience denial, shock, flashbacks, and/or nightmares. Intense anger is normal at this phase and awareness of this may help survivors and their families avoid conflict or misunderstanding. Phase 3 is the prolonged recovery phase, during which memories should become less extreme over the first few months after the event. Nurses can assist survivors and their families by providing them with a range of coping strategies. Individual or group support systems, including spiritual, assist all involved toward recovery.

Modified from Phoenix BJ: Psychoeducation for survivors of trauma, *Perspect Psychiatr Care* 43(3):123-131, 2007.

A result of one of the forums was TELOS (Trauma End-of-Life Optimum Support), the primary goal of which is to standardize care given to trauma victims and their families from incident through the dying process. Healthcare professionals are obligated to support healthy survival as well as peaceful dying. According to Jacobs and colleagues (2005), "Even if the healing for certain patients is death, the dying process leading to ultimate healing, ought to be supported with compassion, care, comfort, and respect." This standard prompts the healthcare team, from the ED through the OR, to support the patient and family with honesty and truthfulness.

Critical Incident–Stress Debriefing

When the end result of a traumatic injury is death, it can be particularly difficult for the perioperative team, since most surgical interventions are of a curative or restorative nature. In many emergency medical systems, a critical incident–stress debriefing team exists. It is composed of mental health professionals and specially trained volunteers who are also professionals and peers in the healthcare field. Police officers, firefighters, paramedics, ED nurses, and ICU nurses may also be on the team. In the event of a particularly tragic death of a patient, the team can be contacted, and a meeting with that patient's care providers is arranged. The benefit of this team is enhanced when intervention is timely for the care providers. Opportunity for them to discuss their feelings and emotions is provided and encouraged as each provider discusses feelings related to personal participation in the care of the patient. Gray and Litz (2005) emphasize that critical incident–stress debriefing teams enhance coping mechanisms and can provide a healthy professional growth from what may otherwise be considered a tragedy.

Surgical Interventions

DAMAGE CONTROL SURGERY

Damage control surgery is a well-recognized surgical strategy that sacrifices complete, immediate repair to adequately address the physiologic impact of trauma and surgery. Damage control surgery is a series of operations performed to accomplish definitive repair of abdominal injuries with consideration of the patient's physiologic tolerance. The focus is on control of hemorrhage and contamination to stop bleeding and control any intestinal, biliary, or urinary leak into the abdominal cavity. Indications for the potential need for damage control surgery include hemodynamic instability, hemorrhagic shock, coagulopathy, hypotension, tachycardia, tachypnea, inaccessible major anatomic injury, concomitant major injury, and altered mental status.

Abdominal packing is the foundation principle of damage control surgery, first reported in the early twentieth century. Later reports detailed survival of patients with severe liver injuries that were packed. In 1981 a report described operative

management that included initial abandonment of laparotomy, use of intraabdominal packing, correction of coagulopathy and metabolic acidosis, and later reoperation for definitive repair (Germanos et al, 2008). The term "damage control" was first used in 1993 along with a detailed approach. The components are stop bleeding, close perforations; continue resuscitation, emphasizing correction of coagulopathy, acidosis, and hypothermia; plan reoperation for definitive repair.

There are five decision-making stages for damage control.

- *Stage 1*—Patient selection and decision to perform damage control: The emphasis is on early recognition for potential damage control surgery, including rapid transport to the hospital and early decisions related to control of hemorrhage.
- *Stage 2*—Operation and intraoperative reassessment of laparotomy: This consists of control of hemorrhage and contamination with rapid packing and temporary abdominal closure.
- *Stage 3*—Physiologic restoration in the intensive care unit: The focus here is restoration of physiologic status, which may include rewarming and fluid replacement.
- *Stage 4*—Return to OR for definitive procedures: The focus is on removal of packing, repair of injuries, and closure. Indications for emergency reoperation include massive ongoing bleeding, evidence of bowel leak or ischemic organ, and presence of abdominal compartment syndrome.
- *Stage 5*—Abdominal wall closure/reconstruction: It is not always possible to close the abdominal wall in stage 4, necessitating further repair.

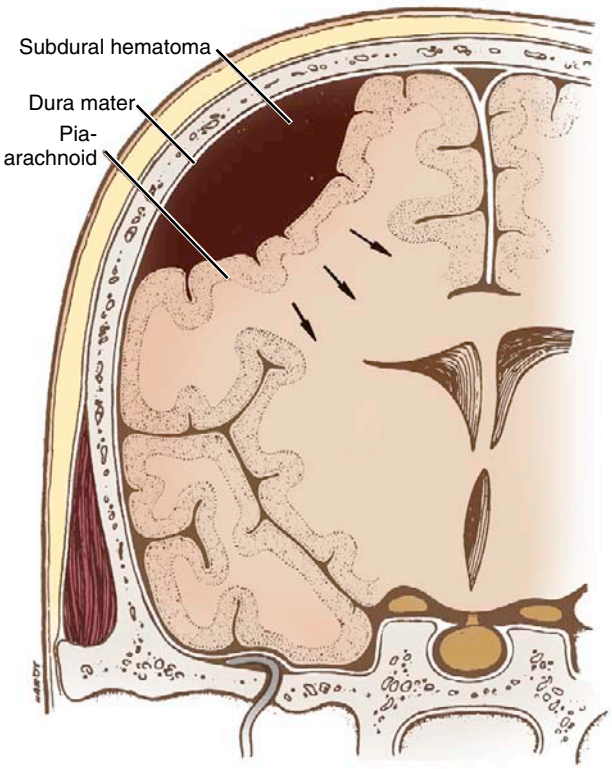

FIGURE 27-8 Subdural hematoma causing increased intracranial pressure with shifting of tissue.

INJURIES OF THE HEAD AND SPINAL COLUMN

Trauma to the head is responsible for half of all trauma deaths. Brain injury occurs either as a direct result of the trauma to the tissue or as a complication. Often, forces of energy from the impact are tolerated by the rigid skull, but the soft tissue of the brain is traumatized, resulting in the formation of subdural (Figure 27-8), epidural, or intracerebral hematomas. Blood clots are classified by their location in the brain and range from mild to life-threatening. A clot under the skull but on top of the dura is an epidural hematoma, which often results from a tear in an artery under the skull. A clot under the skull and dura but outside the brain is a subdural hematoma, often resulting from a tear in a vein or from a cut on the brain itself. An injury to the brain itself, a contusion, is an intracerebral hematoma, a result of a skull fracture or other blood clot causing swelling inside the brain. In addition, cerebral swelling can result in herniation of the brain despite treatment (Figure 27-9).

A baseline neurologic examination is extremely important. The pupils are examined, and the presence or absence of posturing is noted. The Glasgow Coma Scale (see Table 20-3) provides a universally accepted mechanism to assess the baseline data for the trauma team. However, in the presence of alcohol or drug intoxication or chemical paralysis, the scale cannot be used. For patients with a score of 8 or less, intubation with controlled ventilation is the immediate treatment of choice. In the highly combative patient, intubation may also be performed to allow adequate assessment of the extent of injury.

Previously, ICP hyperventilation was routinely used to decrease ICP in the initial management of patients with neurologic deterioration. No studies have shown improved outcomes for these patients, and other methods of assessment have shown that hyperventilation can cause significant constriction of cerebral vessels and may reduce cerebral blood flow to an ischemic level. One study has shown long-term improvement when hyperventilation was not used. Occasionally, hyperventilation may be necessary with persistently high ICP unresponsive to other treatment modalities.

An osmotic diuretic, such as mannitol, can be used in the treatment of ICP. Osmotic effects take place in 15 to 30 minutes (Hodgson and Kizior, 2009) and instigate an osmotic gradient to extract water from neurons. Osmotic diuretics such as mannitol have proven benefits in lowering ICP without reducing cerebral blood flow. They are given by bolus administration to create an acute reduction phase in ICP. These agents are excreted in the urine and cause a rise in serum and urine osmolality. Patients with serum osmolalities higher than 320 mOsm/kg (Kulaylat and Dayton, 2008) are at risk of acute tubular necrosis. Hypovolemia should be avoided with the infusion of isotonic fluids as necessary. Because such agents act quickly, fluid intake and output and the potential for fluid and electrolyte imbalances mandate close hemodynamic monitoring (Surgical Pharmacology). Elevating the head of the bed 30 degrees and keeping the patient's head midline (to promote venous drainage) can also be beneficial.

Skull fractures usually do not require operative intervention when there is no displacement and the fracture is linear. Depressed fractures or the presence of bone in the brain frequently requires elevation and debridement (Figure 27-10). Hematoma evacuation is based on its location as well as the size and number of hematomas present. Before performing a craniotomy or drilling a burr hole, the CT scan, the neurologic

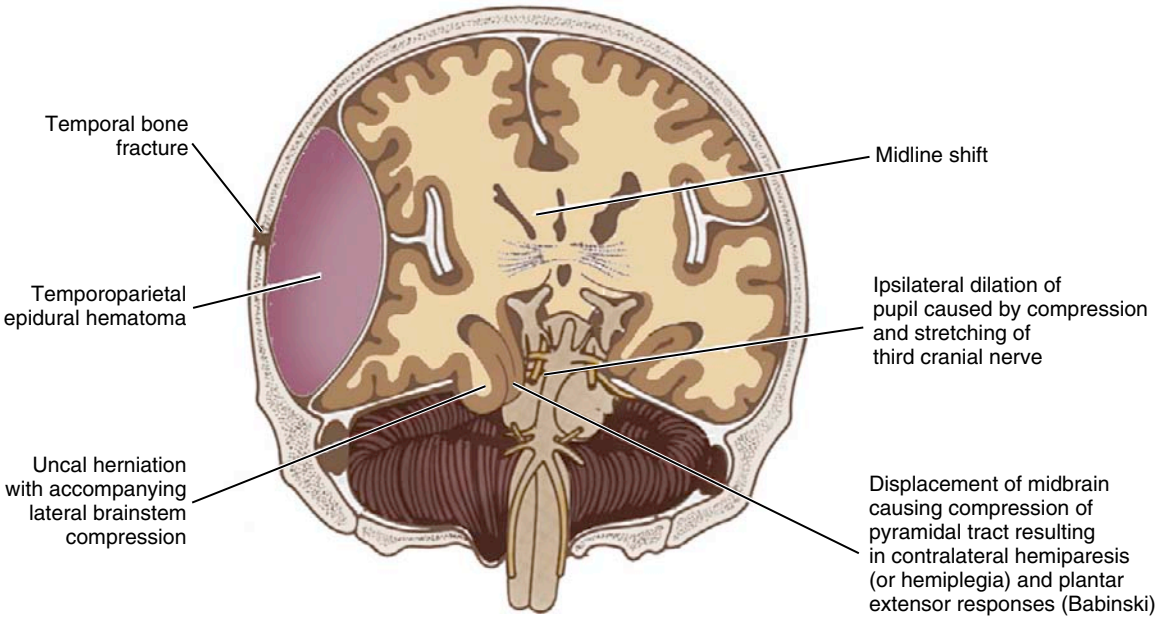

FIGURE 27-9 Cross section showing herniation of lower portion of temporal lobe (uncus) through tentorium caused by temporoparietal epidural hematoma. Herniation may occur also in cerebellum. Note mass effect and midline shift.

SURGICAL PHARMACOLOGY

Commonly Used Medications and Head Trauma

Trauma patients may have situations arise with the diagnosis of head trauma that require immediate attention at the scene, in the emergency department, and in the OR and ICU. With injury to the brain, swelling may occur quickly, requiring a host of aggressive decisions to manage increasing intracranial pressure (ICP). Increased ICP may result in changes in the patient's stability that make survival a priority, including instituting mechanical ventilation, monitoring intraventricular stability, and administering medications necessary to maintain hemodynamic stability. Familiarity with the medications frequently used with head trauma patients is vital.

Medication	Usual Dosage	Nursing Implications	Rationale for Use
BENZODIAZEPINES			
Midazolam (Versed)	0.05-0.1 mg/kg IV, may be repeated prn, not to exceed 6 mg for infants or 10 mg for children	Monitor patient for hypersensitivity. Monitor for hypotension, cardiorespiratory depression.	Use for sedation with patients having increased ICP, especially if on mechanical ventilation Adverse reactions can occur if patient not ventilated
Lorazepam (Ativan)	*Adult:* 4 mg/kg IV over 2-5 min, repeat in 10-15 min prn, not to exceed 8 mg/12 hr *Pediatric:* 0.05-0.1 mg/kg IV over 2-5 min, may be repeated in 10-15 min	Assess for continuing seizure activity. Monitor for hypotension, cardiorespiratory depression, CNS depression.	Long-acting benzodiazepine; used as anticonvulsant for immediate control of seizure activity
ANTICONVULSANTS			
Phenytoin (Dilantin)	*Adult:* Loading dose for status epilepticus: 15-20 mg/kg IV once or in divided doses, followed by 100-150 mg dose at 30-min intervals *Pediatric:* Loading dose 15-20 mg/kg IV once or in divided doses	Assess patient for seizure activity, description and duration of activity. Assess patient for hypotension during administration and do not exceed 50 mg/min for IV infusion. Monitor for interaction with other medications because it interacts and may precipitate in presence of some medications or fluids.	Prophylactic measure for patients at increased risk for seizure activity following head trauma May act on motor cortex to inhibit spread of seizure activity Preferred to phenobarbital because it does not cause as much CNS depression

Commonly Used Medications and Head Trauma—cont'd

Medication	Usual Dosage	Nursing Implications	Rationale for Use
DIURETICS			
Furosemide (Lasix)	*Adult:* 20-80 mg IV; may increase dose, not to exceed 600 mg/day *Pediatric:* 1-2 mg/kg IV every 6-12 hr	Monitor for hypotension. Note extent of diuresis. Watch for changes from initial assessment.	Loop diuretic helpful in decreasing ICP Influences CSF formation by affecting sodium-water movement across blood-brain barrier and shows preferential excretion of water over solute in distal tubule
Mannitol (Osmitrol)	*Adult:* 1.5-2 g/kg IV as 20% solution over 30 min *Pediatric:* 0.5-1 g/kg IV initial dose; 0.25-0.5 mg/kg IV every 4-6 hr	Careful evaluation of cardiovascular status: sudden increase in extracellular fluid may lead to fulminating CHF. If used every 4-6 hr, serum osmolality should be monitored and dose held if it exceeds 320 mOsm/kg.	Osmotic diuretic that lowers blood viscosity and produces cerebral vasoconstriction with normal cerebral blood flow; ICP decrease occurs subsequent to decrease in cerebral blood volume
BARBITURATES			
Thiopental (Pentothal sodium)	*Adult:* 75-250 mg/kg IV; repeat prn *Pediatric:* Induction 4-7 mg/kg IV	Monitor for myocardial depression, decreased cardiac output, and hypotension. Contraindicated with severe hypovolemia, unstable hemodynamics, inability to manage airway.	Use as an adjunct in management of elevated ICP Facilitates transmission of impulses from thalamus to cortex of brain, resulting in imbalance in central inhibitory and facilitatory mechanisms
Phenobarbital (Luminal)	*Adult:* 300-800 mg followed by 120-240 mg/kg IV at 20-min intervals until seizures controlled or total dose of 1-2 g administered *Pediatric:* Loading dose 15-20 mg/kg IV in single or divided doses	Monitor respiratory and cardiac function during loading dose; may cause drowsiness.	Adjunct for seizure control in patients with head trauma
NEUROMUSCULAR BLOCKERS			
Vecuronium (Norcuron)	*Adult:* 0.1 mg/kg IV *Pediatric:* Loading dose 0.08-0.1 mg/kg IV	Effect should be titrated to peripheral nerve stimulator. Concomitant administration of steroids may result in prolonged blockade despite withdrawal of agent.	Therapy directed at controlling ICP with multiple medications, including neuromuscular blockers Used as adjunct to sedative or hypnotic agent Facilitates endotracheal intubation and mechanical ventilation
Cisatracurium (Nimbex)	*Adult:* 0.10-0.2 mg/kg bolus; maintain at 2.5-3 mcg/kg/min *Pediatric:* 1 yr-23 mo: 0.15 mg/kg over 5-10 sec 2 yr-12 yr: .1-.15 mg/kg over 5-10 sec Infusion 3 mcg/kg/min; may titrate to 2 mcg/kg/min	Monitor blood pressure, heart rate, peripheral nerve stimulation, muscle twitching, and blood gases.	Used for control of refractory ICP, mechanical ventilation, and ease of endotracheal intubation Used as adjunct to sedative or hypnotic agent
SEDATIVE/HYPNOTIC/ AMNESIC			
Propofol (Diprivan)	100-200 mcg/kg/min *For general anesthesia:* *Adult:* 5 mcg/kg/min IV infusion for 5 min; titrate in 5-10 mcg/kg/min increments for desired sedation. Maintain at 5-50 mcg/kg/min or possibly higher	Monitor for hypotension, respiratory depression, decreased cerebral blood flow. Elderly or debilitated patients have increased risk of cardiorespiratory effects including hypotension, apnea, airway obstruction, and/or oxygen desaturation. May be used in pediatrics but with caution secondary to propofol infusion syndrome	Sedation for mechanically ventilated patient; titrated to achieve desired level of sedation Short-acting agent used for induction of general anesthesia; provides no analgesia

status of the patient, the morbidity or mortality associated with the procedure, and the presence of other injuries or underlying medical problems, if known, are evaluated. An ICP monitor may be placed in the patient who is at risk for increased ICP. Chapter 20 discusses neurosurgical procedures.

The patient with a cervical spine injury at or near C3 to C5 is at great risk for respiratory difficulties because this is the area of diaphragmatic innervation. There is also the possibility of swelling above the area of injury, and the perioperative nurse should be alert for the potential of respiratory distress even if it is not initially present. A 24- to 48-hour dose of methylprednisolone (Solu-Medrol), calculated by body weight, is considered to decrease initial cord swelling.

The standard indicators of possible cord injury are absence of rectal tone and bradycardia in the presence of hypotension. The body's normal response is to increase heart rate in the presence of decreased blood flow or hypotension. These responses are not present in injury of the spinal cord, and vagal control results in bradycardia.

Injuries involving the spinal cord can range from complete transection, without hope of recovery, to a contusion of the cord. Fractures or dislocation of a vertebra can result in the

protrusion of small pieces into the spinal canal. This is known as a *burst fracture*. Several vertebrae may be fractured or have fractured components. Generally, in compression fractures, if the loss of vertebral height is more than 20%, surgical treatment may be indicated. Spinal bracing can be considered an option if the compression is less than 20% and no neurologic signs or symptoms are present. Cerebral arteriography may be used to screen patients with cervical vertebral fractures for blunt vertebral artery injuries (BVIs). Patients who sustain blunt trauma with unilateral headache or posterior neck pain, particularly if it is sharp, sudden, and severe, should be screened for BVIs and treated with anticoagulant therapy if not contraindicated (Inamasu and Guiot, 2006).

Treatment of spinal column fractures can involve surgery. Stabilization of the fracture may be necessary, depending on the severity of the injury. For cervical spine fractures, traction may be used initially to reduce the fracture, followed by surgical intervention as soon as the patient's condition permits. Internal fixation devices are discussed in Chapter 19.

INJURIES OF THE FACE

Motor vehicle crashes account for about 60% of maxillofacial injuries. Mandibular fractures alone are highly associated with assault as the MOI. In the patient who presents with facial injury, the airway must be secured. This requires ensuring patency and removing any items that pose the threat of aspiration. If a midface fracture is present, the anesthesia provider avoids nasogastric tube placement and nasotracheal intubation. A tracheostomy may need to be performed before initiation of the operative procedure. Control of scalp or facial hemorrhage can be achieved through a pressure dressing until surgical intervention is possible, since exsanguinations can occur. Treatment of the fracture may be delayed until the immediate life threats have been successfully managed. Goals of operative intervention are to reduce and immobilize the fracture, prevent infection, and restore facial cosmesis and function.

Facial fractures can be categorized into Le Fort I, II, or III (Figure 27-11). A Le Fort I fracture is the most common maxillary fracture. It involves a horizontal interruption of the anterior and lateral wall of the maxillary sinus. Le Fort II is a pyramidal fracture along the maxilla and lacrimal bones and through the infraorbital rim. Le Fort III is otherwise known as *craniofacial disjunction*. The midface is completely disengaged from the cranial base, resulting from a fracture across the frontomaxillary sutures. Specific information regarding these injuries is in Chapter 21.

INJURIES OF THE EYE

Injuries to the eye can result from blunt or penetrating types of trauma. Penetrating objects in the globe are stabilized and not removed until the patient is in the OR. These injuries threaten loss of vision because of the injury itself, inflammation, or infection. Blunt injury to the eye can result in hematomas and accompanying fractures. A blow-out fracture is the result of a blunt force to the eye that pushes soft tissue through the thin bony orbital floor. The patient has recession of the eye into the orbit and loses the ability to gaze upward. Surgical repair is often indicated. Chapter 17 discusses ophthalmic procedures.

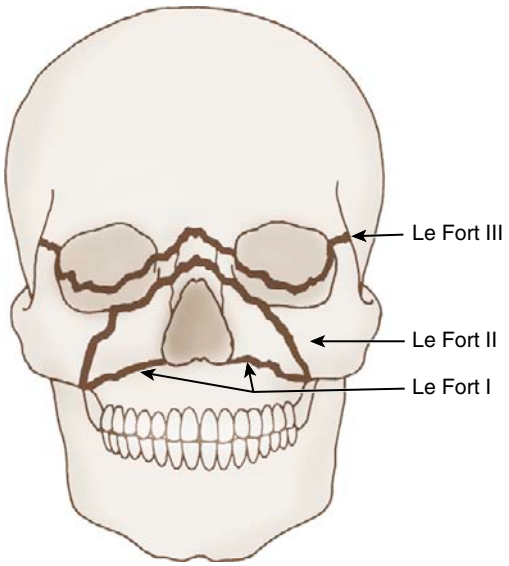

FIGURE 27-11 Le Fort classification of maxillary fractures.

INJURIES OF THE NECK

Injury to the neck and soft tissue structures is most commonly a result of penetrating trauma. The neck can be divided into three zones with respect to injury and consequence. Zone I is the base of the neck below the clavicles. Anatomic structures located in this region are the great vessels and aortic arch, innominate veins, trachea, esophagus, and lungs. Zone II is the area in the middle of the neck between the clavicles and the mandible. Structures located in this area include the carotid artery, internal jugular vein, trachea, and esophagus. Zone III is located between the angle of the mandible and the base of the skull. The primary target of evaluation in these injuries is vascular structures.

Zone II injuries may necessitate an otorhinolaryngology specialist. Penetrating injuries to the larynx and trachea can be primarily repaired. Blunt force to the larynx can result in a fracture and impose immediate airway obstruction. These patients require immediate tracheotomy followed by repair of the fracture when it is unstable or displaced. Chapter 18 provides specific information concerning otorhinolaryngologic procedures.

INJURIES OF THE CHEST AND HEART

Trauma to the chest area is the primary cause of death in approximately 25% of trauma victims. Blunt trauma is most often associated with high-speed motor vehicle crashes. Penetrating traumas may be associated with violent crimes. Penetrating injuries at or immediately below the nipple line or level of the scapular tips are evaluated for both chest and abdominal involvement. Diaphragmatic injury is also a possibility.

Deceleration injury, such as that occurring from a fall or from striking the steering wheel in a motor vehicle crash, may cause contusions of the chest wall, fractures of the ribs or sternum, contusions of the heart or lungs, or rupture of the aorta and other major vessels. Rib fractures are also associated with a hemothorax or pneumothorax. A flail-chest segment may result when two or more adjacent ribs are broken in two or more places. This results in paradoxical chest wall movement

as a result of loss of bony support; that is, the affected segment of the chest wall will move in the opposite direction. If respiratory distress and diminished breath sounds are present, a chest tube is indicated immediately; an autotransfusion chest drainage device is also considered. Chest tube output must be closely monitored intraoperatively because accumulation of 1000 to 1500 ml of blood is an indication for chest exploration. Penetrating wounds, as a result of either gunshot or stab injuries, may cause hemothorax and pneumothorax as well. Lacerations or perforation of the lung, heart, great vessels, trachea, esophagus, and bronchus is possible.

Myocardial contusion usually involves the right ventricle and can be evidenced by dysrhythmias on patient arrival or shortly thereafter. The patient is monitored on a telemetry unit, and surgical intervention is not required. Rupture of a heart valve can occur, depending on the timing of the contusion in relation to the phase of the cardiac cycle. If valve rupture has occurred, surgical repair is necessary. Heart sounds should be evaluated during the secondary assessment to document the presence or absence of murmurs. Heart valve rupture can occur as a late complication of myocardial contusion. Pericardiocentesis is performed for signs and symptoms of pericardial tamponade (Figure 27-12), which include jugular venous distention, muffled heart sounds, and a narrowing pulse pressure. Patients may present to the OR for a pericardial window either emergently or during the recovery phase.

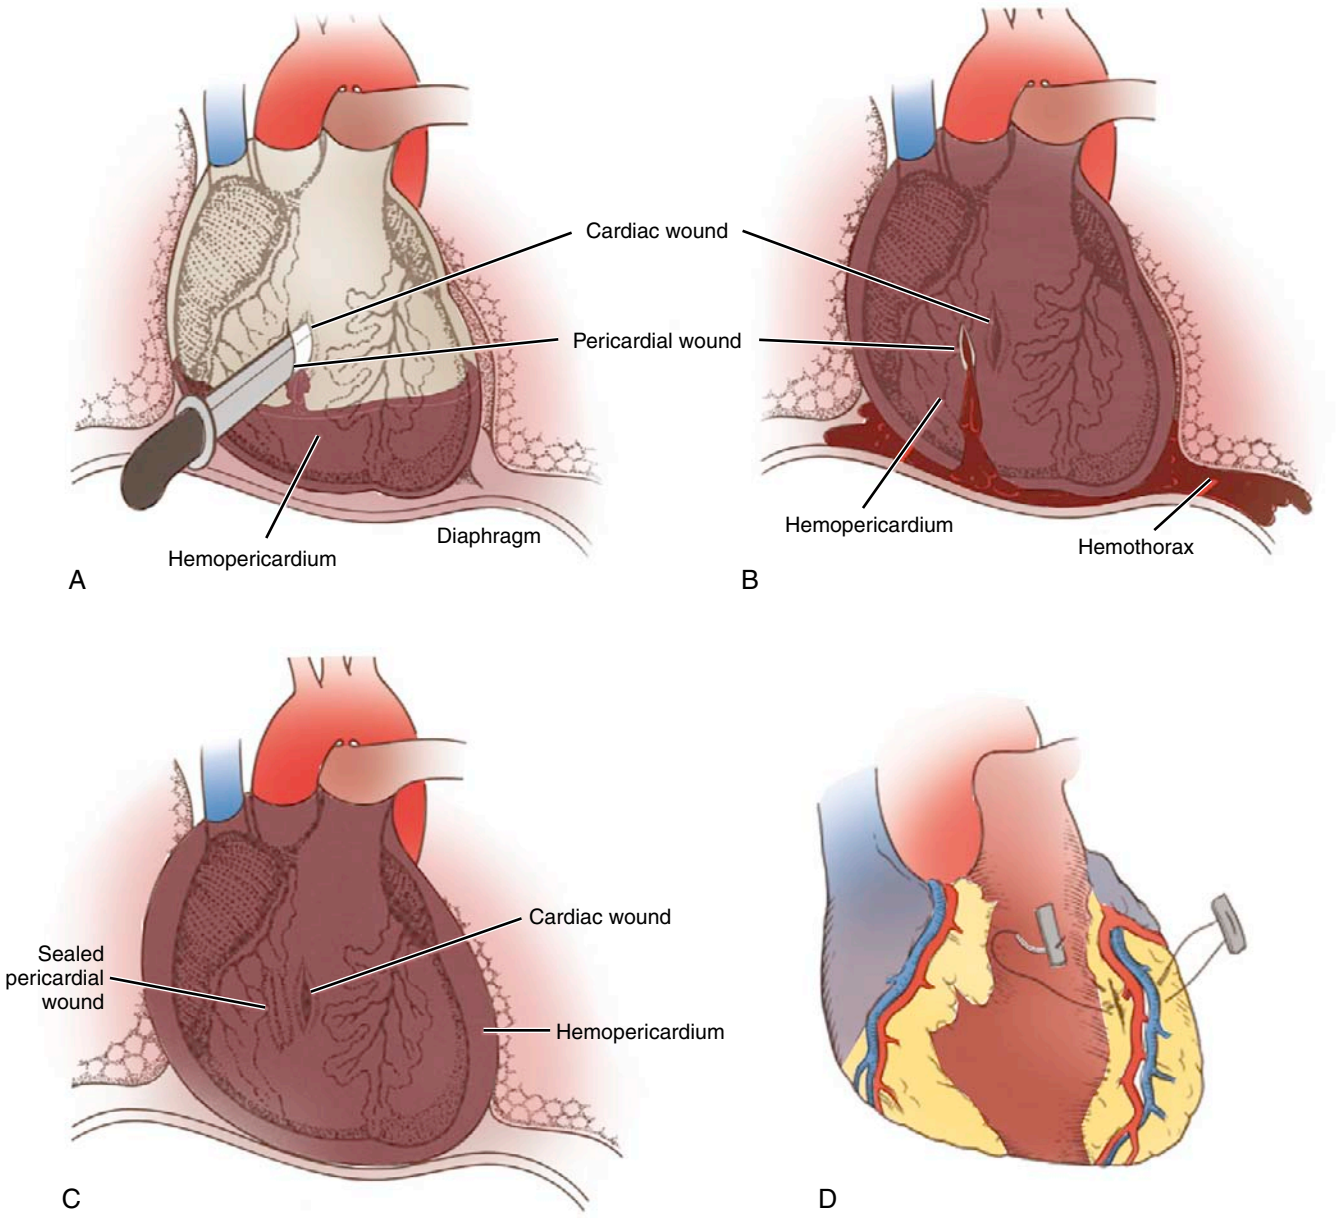

FIGURE 27-12 **A**, Cardiac injury with pericardial disruption. **B**, Bleeding from heart through pericardial tear into pleural space. **C**, Self-sealing of pericardial wound resulting in pericardial tamponade. **D**, Sutured cardiac wound.

An emergency thoracotomy may be indicated in the patient with penetrating trauma to the chest in full arrest or pulseless electrical activity on ECG. If a laceration to the heart is suspected and the patient is rapidly deteriorating, a thoracotomy may be performed in the ED. The laceration may be primarily repaired and the patient transferred to the OR for irrigation, wound debridement, and closure. Otherwise, surgical intervention is initiated in the OR. Wounds located across the mediastinum accompanied by hemodynamic instability, massive penetrating lung injuries, and disruption of the trachea, bronchus, or esophagus also require surgical intervention. Rupture of the thoracic aorta is another injury requiring surgical intervention and includes the use of extracorporeal bypass. This injury is an obvious life threat but may be difficult to diagnose. An arch aortogram is indicated in trauma patients who may have sustained such an injury. Rupture of the thoracic arch is associated with first rib or sternal fractures. Chapters 22 and 24 provide additional information about associated surgical procedures in thoracic and cardiac surgery, respectively.

INJURIES OF THE ABDOMEN

The spleen is the most common organ injured in blunt trauma, and the liver, because of its large size, is the most common organ injured in penetrating trauma. Historically, initial efforts were aimed at performing splenectomy with splenic injury. However, because of the role of the spleen in the body's defense against infection, the surgeon makes every effort to control hemorrhage in the spleen and avoid its removal. Treatment is determined by the condition of the spleen and of the patient. Injury to the spleen occurs with deceleration injuries, resulting in fracture of the organ because of its multiple fixation points. Splenic injury may be associated with fractures of the left tenth through twelfth ribs. The patient may exhibit left shoulder pain (Kehr's sign), upper left quadrant tenderness, abdominal wall muscle rigidity, spasm or involuntary guarding, and/or signs and symptoms of hemorrhage and hypovolemic shock. Splenic injuries (Table 27-10) range from laceration of the capsule to ruptured subcapsular hematomas or parenchymal laceration. The most serious injury is a severely fractured spleen or vascular tear, producing massive blood loss and splenic ischemia. Rupture of the spleen can be immediate or delayed. Splenic lacerations may be treated nonoperatively by close monitoring and bed rest or operatively for lacerations of a more severe nature. The surgeon creates a midline incision, which allows for exposure of all abdominal contents. Topical hemostatic agents are also used with success, as well as suturing and the argon laser in some instances. In some cases, angiographic embolization may be attempted. A laceration involving the splenic hilum or complete shattering of the organ usually results in splenectomy.

The severity of hepatic injury ranges from controlled hematoma to severe vascular injury of the hepatic veins or hepatic avulsion (Table 27-11). Because liver tissue is so friable and has an extensive blood supply as well as blood storage capacity, hepatic injuries often result in profuse hemorrhage and require surgical control of bleeding. The patient usually exhibits upper quadrant pain, abdominal wall muscle rigidity, involuntary guarding, rebound tenderness, hypoactive or absent bowel sounds, and signs of hemorrhage or hypovolemic shock. Nonoperative treatment is indicated in minor capsular and subcapsular injuries. This can be accomplished with bed rest and close monitoring. Topical hemostatic agents and suturing are used in management of minor injuries. Fibrin glue is also used in some institutions as a topical hemostatic agent. More severe injuries with active expanding hematomas or lobe disruption require surgical exploration and may necessitate hepatic resection or ligation of associated vasculature. With massive hemorrhage, control of bleeding is the primary concern. Packing with laparotomy sponges may be indicated, along with manual compression of the organ if intraoperative hypotension becomes severe. A pressure dressing may be applied and the wound closed temporarily until associated coagulopathies, hypothermia, and hemodynamic instability can be corrected. The patient is usually returned to the OR within 24 to 72 hours postoperatively or when his or her condition permits further exploration and removal of the sponges.

Injuries to the gastrointestinal system are also associated with abdominal trauma. Bowel injuries may be missed on abdominal CT scan during the initial diagnostic period. The small bowel is frequently injured because deceleration may

TABLE 27-10

Splenic Injury Scale

Grade	Type of Injury	Description of Injury
I	Hematoma	Subcapsular: <10% of surface area
	Laceration	Capsular tear: <1 cm parenchymal depth
II	Hematoma	Subcapsular: 10%-50% of surface area; intraparenchymal: <5 cm in diameter
	Laceration	Capsular tear: 1-3 cm; parenchymal depth that does not involve a trabecular vessel
III	Hematoma	Subcapsular: >50% of surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma; >5 cm or expanding
	Laceration	>3 cm parenchymal depth or involving parenchymal vessels
IV	Laceration	Laceration involving segmental or hilar vessels, producing major devascularization (>25% of spleen)
V	Laceration	Completely shattered spleen
	Vascular	Hilar vascular injury that devascularizes spleen

Modified from Hoyt DB et al: Management of acute trauma. In Townsend CM et al, editors: *Sabiston textbook of surgery,* ed 18, Philadelphia, 2008, Saunders.

TABLE 27-11

Liver Injury Scale

Grade	Type of Injury	Description of Injury
I	Hematoma	Subcapsular: <10% of surface area
	Laceration	Capsular tear: <1 cm parenchymal depth
II	Hematoma	Subcapsular: 10%-50% of surface area; intraparenchymal: <10 cm in diameter
	Laceration	Capsular tear: 1-3 cm parenchymal depth; <10 cm in length
III	Hematoma	Subcapsular: >50% surface area of ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma: <10 cm or expanding
	Laceration	>3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25%-75% of hepatic lobe or 1-3 of 8 Couinaud segments
V	Laceration	Parenchymal disruption involving >75% of hepatic lobe or >3 of 8 Couinaud segments within a single lobe
	Vascular	Juxtahepatic venous injuries (i.e., retrohepatic vena cava/central major hepatic veins)
VI	Vascular	Hepatic avulsion

Modified from Hoyt DB et al: Management of acute trauma. In Townsend CM et al, editors: *Sabiston textbook of surgery,* ed 18, Philadelphia, 2008, Saunders.

lead to shearing, which causes avulsion or tearing. The most commonly affected areas of the small bowel are areas relatively fixed or looped. Associated with any perforation of the gastrointestinal tract is a chance for peritonitis and sepsis or compartment syndrome from increased pressure. Crystalloid resuscitation and capillary leakage contribute to tissue swelling. The resulting abdominal edema creates a pressurized compartment that must be explored to render relief to the compromised organs.

If the abdomen is difficult to close, alternative wound closure techniques may be used to prevent the occurrence of abdominal compartment syndrome. One such method is to use a silo-bag closure, in which heavy plastic is trimmed to fit and sutured to skin edges (Figure 27-13). A sterile absorbent drape may also be placed inside the abdomen to absorb fluid.

In the event of a penetrating injury, the trajectory of the missile or the implement is examined, and organs within the area are considered potentially injured. Exploration is indicated, and the components of the gastrointestinal system are thoroughly examined for any perforations, contusion, hemorrhage, or compromise of vasculature, such as a mesenteric hematoma. Once the injury is identified, suturing, stapling, or segmental excision may be indicated. Chapter 10 discusses gastrointestinal surgery and Chapter 11 addresses surgery of the liver, biliary tract, pancreas, and spleen.

Diagnostic laparoscopy is frequently used for direct visualization of abdominal organs to decrease the need for open abdominal exploration. This procedure allows the surgeon to effectively evaluate the presence of any injury and develop an appropriate plan of treatment in the stable patient. However, there is some concern that bowel injuries may not always be identified. Some therapeutic interventions may also be performed through the laparoscope so that the more invasive open approach is avoided. Increased intraabdominal pressure required in laparoscopic insufflation may create an adverse ventilatory effect. In the presence of abdominal vein injury with low pressures, CO_2 could leak into the vasculature and result in CO_2 emboli to the heart or lungs. Tension pneumothorax may be created in patients with a diaphragmatic injury. Consequently, indications for these procedures in the trauma setting continue to be evaluated.

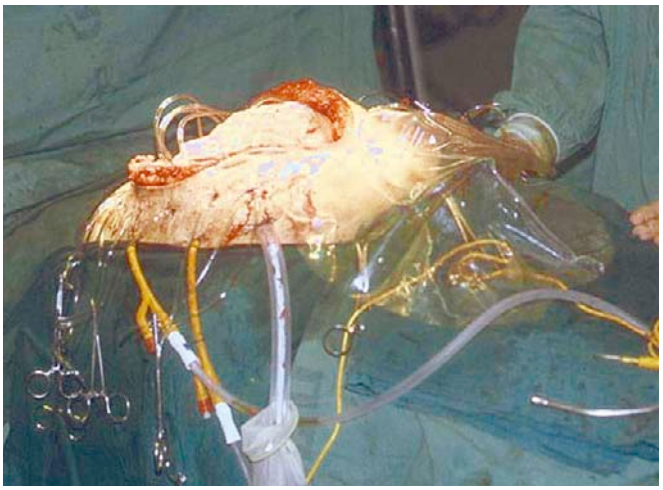

FIGURE 27-13 Alternative technique using plastic for temporary closure of the abdomen.

INJURIES OF THE GENITOURINARY SYSTEM

Laceration of the kidney is closely associated with fracture of the ribs and transverse vertebral processes (Table 27-12). Because the kidney is retroperitoneal, the presence of bleeding may not be observed on diagnostic peritoneal lavage. Renal contusions often produce hematuria. Gross clots may also be seen in more serious injury, but it should be noted that hematuria is not present in a complete avulsion injury. Management of renal contusions can be nonoperative with monitoring of hematuria. Lacerations involving the collecting system, severe crush injuries, or pedicle injuries necessitate surgical intervention (Figure 27-14). Nephrectomy may be indicated with severe injury of the pedicle or massive hemorrhage.

Rupture of the bladder and urethral injury are most often associated with pelvic fractures. Both blunt trauma and penetrating trauma are causative factors. The type of bladder injury is a direct result of the amount of urine present in the bladder at the time of injury. Blunt forces applied to a full bladder result in an intraperitoneal rupture. This type of rupture is closely associated with alcohol consumption because of alcohol's

TABLE 27-12

Renal Injury Scale

Grade	Type of Injury	Description of Injury
I	Contusion	Normal urinalysis except possible microscopic or gross hematuria
	Hematoma	Subcapsular, no parenchymal laceration
II	Hematoma	Perirenal, confined to renal retroperitoneum
	Laceration	>1 cm depth of renal cortex
III	Laceration	>1 cm parenchymal depth of renal cortex
IV	Laceration	Extends through cortex, medulla, and collecting system
	Vascular	Involves main renal artery or vein
V	Vascular	Completely shattered kidney Includes avulsion of renal hilum, which devascularizes kidney

FIGURE 27-15 Complete urethral injury as demonstrated on urethrogram.

diuretic effect. Pelvic fracture is associated with an extraperitoneal bladder rupture. Most often these patients present with gross hematuria. A small extraperitoneal rupture may be managed by urinary catheter drainage. A large extraperitoneal rupture and intraperitoneal rupture require surgical intervention. A suprapubic cystostomy tube may be placed, and the bladder is repaired. Pelvic fracture reduction and fixation are also performed.

Urethral injuries require exploration and primary repair. These types of injuries are more common in the male because the male urethra is longer and less protected than the female urethra (Figure 27-15). A fall or straddle type of injury is usually responsible. This injury is detected by the presence of blood at the urinary meatus. In these instances an indwelling urethral catheter should not be inserted. Blood at the urinary meatus may indicate a tear in the anterior urethra. A retrograde urethrogram may be performed to evaluate for extravasation of urine and potential injury. Suspicion of a pelvic fracture raises the index of suspicion of a concomitant urethral injury. Chapter 14 provides additional information on urologic procedures.

SKELETAL INJURIES

Trauma to the skeletal system usually results in contusion or fracture. After stabilization of the patient, radiographs are taken of any body part that is distorted, edematous, painful, or highly suspicious for fracture or dislocation. Treatment of fractures is aimed at restoring function with a minimum of complications. Immobilization of fractures can be accomplished by casting, bracing, splinting, application of traction, or hardware fixation. Femur fractures in particular can be associated with a high risk of hemorrhage and require traction before surgical repair. Closed and open reductions, application of internal

and external fixators, and some types of traction may be performed in the OR. The perioperative nurse involved in care of the trauma patient must have a working knowledge of orthopedics. Fractures must be repaired in a timely manner to avoid untoward complications; however, immediate life threats are corrected first. Open fractures are at an increased risk of infection. Chapter 19 contains information on the surgical procedures used in fracture management.

Pelvic fractures may pose an additional challenge to the perioperative team. Fractures within the pelvic ring are associated with significant internal blood loss and shock. Systemic peripheral vascular resistance is increased. A method to quickly minimize or tamponade blood loss in severe pelvic fractures is the application of a pneumatic antishock garment (PASG) or PASG trousers to provide stabilization of the fracture and reduce associated hemorrhage. The use of PASG trousers may be effective in patients who are 20 to 40 minutes away from the hospital and have unstable pelvic fractures and decompensated shock (Salomone et al, 2005). If a pneumatic garment is applied, the patient may be transported to the OR with the trousers still inflated. The perioperative nurse must be familiar with deflation procedures. The attending anesthesia provider directs deflation in collaboration with the surgeon. Blood pressure and other vital signs are closely monitored. The abdominal compartment is deflated first. Deflation continues slowly while IV fluids are infused to maintain blood pressure. A 5 mm Hg drop in blood pressure requires fluid resuscitation of approximately 200 ml before deflation of the next compartment. If the patient remains stable, each leg compartment is deflated slowly, one at a time.

Some trauma centers apply external fixator devices in the ED during initial resuscitation. A pelvic C-clamp, sheet wrap, or a commercially available support binder may be used for initial stabilization of pelvic fractures. Severe hemorrhage associated with the fracture may be controlled by arterial embolization performed in the radiology department if surgical intervention for fracture fixation must be delayed.

Soft tissue injuries of an extremity are subject to compartment syndrome. This is a result of swelling of the soft tissues and muscles encased in the fascia. With a significant amount of swelling, pain is increased and the surrounding circulation may be compromised. The patient may experience a decrease in motor and sensory function. This injury must be treated surgically by a fasciotomy. Incising the fascia allows space for tissue swelling. Several days later, the patient returns to the OR for closure, which may require skin grafting for complete coverage.

HYPOTHERMIA

When trauma is involved, hypothermia often begins at the time of injury, related to heat loss through conduction and convection. A core body temperature of 32° C (89.6° F) is associated with a nearly 100% mortality rate (Moore, 2008). Moore (2008) reviewed a study designed to determine if trauma nurses check the patient's temperature during the secondary assessment. Only 40% of the patients had their temperature checked and of these 33% were hypothermic. Starting hypothermia prevention at the trauma scene and continuing measures to prevent hypothermia throughout surgery and into the ICU continue to be the recommended best practice.

For purposes of definition, generalized hypothermia is considered to be present when the core temperature is below 36° C (96.8° F). (See Chapter 9 for discussion of the prevention of inadvertent hypothermia in adult surgical patients.) Hypothermia can be classified into three types. *Mild hypothermia* is a core temperature between 32° and 36° C (89.6° and 96.8° F). These patients may appear gray and are cool to the touch. Some alterations in level of consciousness can be present. If the patient's clothing is wet, the nurse should remove it and cover the patient with warm blankets. Treatment is aimed at passive rewarming of the patient by means of warm ambient room temperature, warm fluids, and infrared radiant energy lights. *Moderate hypothermia* is characterized as core temperatures between 30° and 32° C (86° and 89.6° F). Warmed fluids are given by IV line and also by gastric or peritoneal lavage. In addition, a warming blanket, such as a forced air–warming device, may be used. Immersion in a Hubbard tank filled with warm water has also been successful. An irritable myocardium may cause dysrhythmias to be present. Shivering may or may not be present. If the patient is intubated, warmed, humidified gases can be administered. *Severe hypothermia* is diagnosed in the patient with a temperature below 30° C (86° F). The heart rate and the respiratory rate are greatly decreased. This patient is comatose, often appears deceased, and requires active rewarming processes. It is advisable to warm the core first to avoid complications associated with rewarming. This can best be accomplished by using cardiopulmonary bypass (CPB), which directly warms internal vital organs, including the heart. The patient should be handled gently during transfers to avoid further tissue injury and stimulation of an irritable myocardium.

In the trauma patient, hypothermia may be potentiated by hypovolemia, hypotension, and shock. Cold hemoglobin cannot release oxygen to tissue as readily as normothermic hemoglobin and decreased circulating volume related to hemorrhage reduces oxygen delivery to the tissues. The combination of hypothermia, acidosis, and coagulopathy is known as the trauma triad of death (Solheim, 2008). The three parts of the triad have a complex relationship; each may be influenced by the other and often results in high mortality if not interrupted. In hypoperfusion, cells burn glucose for energy (lactic acidosis), which increases total blood acidity (metabolic acidosis). Hypoperfusion may also halt the coagulation cascade (coagulopathy), thus triggering the triad. Hypothermia also affects other body systems already compromised by the trauma. At a core temperature of less than 30° C (86° F), atrial fibrillation is common; when the core temperature is below 25° C, the heart automatically converts to ventricular fibrillation (Moore, 2008). Cerebral blood flow is highly sensitive to hypothermia and the patient may appear to be dead. Resuscitation measures are ceased if the patient is rewarmed to at least 35° C (97° F) and cardiac functions remain nonexistent.

THERMAL INJURIES

Heat and cold exposure injuries require prompt initial management in the ED setting. Some institutions transfer pediatric burn patients and severely burned adult patients to a burn center for treatment once the patients' conditions are stabilized. In addition to treatment of the site of injury to decrease further tissue damage, fluid management is of the utmost importance in

these patients. After hemodynamic stabilization of the patient, burn and frostbite wounds usually require a series of procedures. These patients may have multiple surgical debridement procedures before skin grafting and cosmetic interventions. Restoration of function is important. Circumferential burns may restrict the neurovascular structures during eschar formation. Chest burns with eschar may restrict movement of the chest wall and ventilatory function. An escharotomy (incision of the eschar) may be performed to alleviate the constriction. If necessary, this procedure may be performed at the bedside and the perioperative team may be asked to assist.

ORGAN AND TISSUE PROCUREMENT

As previously noted, trauma primarily affects young people. In the event that resuscitation efforts or surgical interventions are not successful, the patient may be declared dead. Depending on the cause of death and preexisting medical conditions, the patient may be an organ-donor candidate. Both federal and state laws mandate that local organ-procurement facilities are notified of potential donors and that families are informed that organ donation exists as an option. Organ-donation agencies can be contacted early and will assist in assessing the potential donor, as well as providing a protocol for donor management once the patient is declared dead. Brain death criteria for organ donation began around 1968, attributed to the Harvard Ad Hoc Committee on Brain Death. Most organ donations in this country are from patients who experience brain death. In 1980 the Uniform Declaration of Death Act offered an additional option: cardiopulmonary death, defined as irreversible cessation of circulatory and respiratory function. This may present an ethical dilemma to some perioperative nurses. With brain death, the physician declares the patient dead in the intensive care unit (ICU) and the family is offered an opportunity to say goodbye. The patient arrives in the OR on a ventilator, which is deactivated when the organs have been retrieved. In cardiopulmonary death, the physician accompanies the patient to the OR, the ventilator is deactivated, the staff wait for cessation of circulatory and respiratory function, and death is declared at that time (Saver, 2007). Definitions of brain and cardiopulmonary death are not uniform throughout the United States. The perioperative nurse should be familiar with the state's definitions of brain and cardiopulmonary death and the institution's criteria for the declaration.

Once a patient is declared dead and becomes a potential organ donor, the patient's family does not incur any financial costs acquired from that point. The patient is not disfigured in any way that will interfere with bereavement rituals.

A transplantation coordinator assists in managing the organ-donor patient in the ICU setting until the procurement teams arrive. The perioperative nurse must prepare for the organ-procurement procedure. The harvesting of organs and tissue may take several hours and additional members of the perioperative team. Different organ-procurement agencies will provide a surgical team, but additional scrub and circulating personnel are needed. The transplantation coordinators actively seek tissue and organ recipients during the harvest procedure. Most organ-transplantation agencies contact the institution and provide follow-up information regarding the ultimate success of the transplantation procedures and information about the recipients.

The heart is removed first, followed by the lungs, pancreas, liver, and kidneys. Tissue dissection is performed in such a manner as to allow for optimal organ transplantation. Sterile technique remains important. In addition, traffic control is of concern during these procedures. Traffic should be limited to essential personnel. Bone, skin, and corneas can also be removed. Some procurement agencies remove bone and corneas in the morgue rather than in the OR.

CHAPTER 28

Interventional Radiology

KATHLEEN A. GROSS

Interventional radiology (IR) is the medical specialty devoted to advancing patient care through the innovative integration of clinical and imaging-based diagnosis and minimally invasive therapy (Society of Interventional Radiology [SIR], 2005). Interventional radiology procedures offer many advantages for the appropriate patient and are commonly performed because they are less invasive when compared to surgical procedures.

The specialty of radiology is subdivided into many modalities—namely, diagnostic radiology, computed tomography (CT), positron emission tomography (PET), nuclear medicine, ultrasound, interventional radiology, and magnetic resonance imaging (MRI). Procedures vary from diagnostic procedures to therapeutic and/or palliative procedures. Today, combinations of imaging are frequently employed in the imaging environment. Imaging studies, including CT, MRI, diagnostic imaging, and interventional radiology, play an important role in the determination of patient care and treatment. The interventional radiologist uses all available information to determine a minimally invasive treatment approach.

The list of reasons for IR continues to grow as less invasive means are preferred by patients, providers, and payors. An interventional procedure is performed by a team of healthcare providers, namely, the interventional radiologist(s), radiology nurse(s), and interventional radiology technologist(s). Interventional radiologists may work collaboratively with other specialists, including vascular surgeons, urologists, or gastroenterologists, to perform a procedure. Anesthesia providers may also be involved in the periprocedural care of the patient. The specialty of IR is certified by the American Board of Medical Specialties. Notable milestones in IR are noted in the History box.

RADIOLOGY NURSING

Introduction to Radiology Nursing

Records show that nurses worked in radiology departments as early as 1911 at the Massachusetts General Hospital. In 1935 the Johns Hopkins Hospital established a radiation department, staffed by two technologists and one registered nurse, and a diagnostic department, staffed by one nurse (Po, 2005). Advances in technology, alterations in practice, changes in patient acuity, establishment of regulatory mandates, and trends for nurses to become more involved in imaging areas led to an increase in the need for radiology nurses and supported the evolution of the specialty.

The practices of radiology nurses, whether performed at a free-standing clinical site or in a hospital, should be in accordance with the standards of radiology nursing established by the American Nurses Association and the Association for Radiologic and Imaging Nursing (ARIN) as well as other established guidelines for nursing. Every nurse should practice within his or her scope of professional practice as guided by the state board of nursing, national association, regulatory agencies, and institutional policies and procedures.

Patient safety is paramount to the practice of radiology nursing. The emphasis for the interventional radiologist to be involved in longitudinal patient care (American College of Radiology [ACR], 2005) helps to support the roles and value of nursing in the imaging areas. While there is no specific academic educational preparation for the role of radiology nursing to date, prior experience in critical care nursing, emergency nursing, or postanesthesia care unit nursing is of great value to the practice of radiology nursing. Specific radiologic nursing competencies should be current for all activities performed. Orientation with a preceptor and continuing on-the-job training is essential. Certifications in advanced cardiac life support (ACLS) and pediatric advanced life support (PALS) are recommended.

The nurse must possess strong critical thinking skills and knowledge to make quick, accurate patient assessments and initiate treatments per the radiologist. Although the ability to work independently is key to this role, the nurse must be capable of working with a team of imaging professionals to meet the needs of the patient. Intellectual curiosity, self-study, and involvement are key to becoming a more qualified, competent radiology nurse. Nursing initiative has always been an important attribute in advancing the specialty of radiology nursing throughout its history.

Facilities

Most interventional radiology procedures are performed in the hospital setting with patients registered as either inpatients or outpatients. There are also some free-standing interventional radiology centers in the United States. The number of clinics designed for preprocedure and postprocedure care for interventional radiology patients is increasing. Facilities designated for interventional radiology have specific requirements for radiographic equipment, patient precare and postcare areas, medical/surgical supplies and nonradiographic equipment, staffing, and physiologic monitoring equipment (Figure 28-1) (ACR, 2005).

A few interventional procedures, such as venous line placement, thoracentesis, paracentesis, or simple percutaneous drainage, may be performed at the bedside in critical care areas using ultrasound guidance if the acuity of the patient or other

HISTORY

Milestones in Radiology

In 1895 Wilhelm Röentgen, a physics professor at the University of Würzberg, Germany, discovered "X-Light" or x-rays as they are known today. Physicists, physicians, and photographers became involved in this new discovery. The popular press also spread the word about "the new light." Poetry was written about this new phenomenon and cartoons appeared in popular literature. An evacuated glass tube with an anode and cathode and a generator were all that were needed to produce an image; thus "bone portraits" became popular in studios that were established in larger cities. The operator became known as a "skiagrapher." The x-ray pictures were known as "skiagrams."

X-rays were rapidly integrated into the medical field. X-rays were used to locate bullets in soldiers during the British River Wars on the Nile in 1896. The first angiographic study was done by Haschek and Lindenthal in Vienna in 1896. This postmortem exam was performed using an injection of mercury compounds. Grubbé used x-rays to treat cancer in 1896. The medical use of x-rays lead to other discoveries, such as x-ray epilation and other harmful effects, including erythema, dermatitis, loss of digits, and death. By 1898 lead was being used for protection and limits to exposure were in use. Rooms especially designed for taking x-rays were found in many hospitals in the United States by 1905. Ventriculography was developed in 1918, pneumoencephalography in 1919, and arteriography in 1927. Dyke is known as the first neuroradiologist and practiced in New York in 1930. In 1904 Hickey introduced the term "radiograph" and talked about the "interpretation" of the radiograph in a standardized manner.

As the field of interventional radiology evolved, the following milestones were observed:

1964
Angioplasty
1966
Embolization therapy to treat tumors and spinal cord vascular malformations by blocking blood flow
1967
The Judkins technique of coronary angiography, the technique still most widely used around the world today
Closure of the patent ductus arteriosus, a heart defect in newborns in which there is a vascular opening between the pulmonary artery and the aorta
Selective vasoconstriction infusions for hemorrhage, now commonly used for bleeding ulcers, gastrointestinal (GI) bleeding, and arterial bleeding
1969
The catheter-delivered stenting technique and prototype stent
1970s
Percutaneous removal of common bile duct stones, occlusive coils
1972
Elective arterial embolization for GI bleeding, which was adapted to treat massive bleeding in other arteries in the body and to block blood supply to tumors
1973
Embolization for pelvic trauma
1974
Selective arterial thrombolysis for arterial occlusions; now used to treat blood clots, stroke, DVT, for example
Transhepatic embolization for variceal bleeding
1977-1978
Embolization technique for pulmonary arteriovenous malformations and varicoceles
1977-1983
Bland embolization and chemoembolization for treatment of hepatocellular cancer and disseminated liver metastases
1980
Cryoablation to freeze liver tumors
Development of special tools and devices for biliary manipulation
1980s
Biliary stents to allow bile to flow from the liver, saving patients from biliary bypass surgery
1981
Embolization technique for spleen trauma
1982
TIPS (Transjugular Intrahepatic Portosystemic Shunt) to improve blood flow in damaged livers from conditions such as cirrhosis and hepatitis C
Dilators for interventional urology, percutaneous removal of kidney stones
1983
The balloon-expandable stent (peripheral) used today
1985
Self-expandable stents
1990
Percutaneous extraction of gallbladder stones
Radiofrequency ablation (RFA) technique for liver tumors
1990s
Treatment of bone and kidney tumors by embolization
RFA for soft tissue tumors, for example, bone, breast, kidney, lung, and liver cancer

Modified from Society of Interventional Radiology: *Milestones pioneered by interventional radiologists,* available at www.sirweb.org/about-us/historyIR.shtml. Accessed January 2, 2009.

factors limit the ability to transport the patient to a procedure area for imaging. Interventional magnetic resonance imaging (iMRI) procedures and intraoperative MRI procedures require strict attention to safety issue (see www.acr.org for information on MRI safety).

Radiology Nurse Roles and Responsibilities

The role of the nurse varies according to the individual site and modality in which the nurse practices, as well as the level of expertise of the nurse (e.g., radiology nurse generalist or radiology advanced practice registered nurse).

Nursing roles and responsibilities in the imaging areas are multifold (Box 28-1). Many of these responsibilities revolve around the Joint Commission National Patient Safety Goals. The nurse functions as a provider, role model, patient advocate, and resource in the radiology area. The nurse documents patient care and events. One of the most common aspects of the nurse's role is that of providing sedation and analgesia for diagnostic and therapeutic procedures. Competency in this role should be verified and in accord with current standards. The nurse often assumes responsibility for risk management, performance improvement, and continuing education within

the area. All the roles of the nurse are directed at improving patient outcomes in the radiology area. On-call responsibilities are often assumed with the position of radiology nurse.

Nursing Care of the Interventional Radiology Patient

Assessment. In addition to the standard assessment techniques used with all perioperative patients, nurses caring for patients in IR settings must review information about the patient's renal status and obtain a thorough history that would uncover any other contraindications or any risk factors for the use of contrast media. This information may not be easily obtainable in an emergency situation or when the patient is unconscious or unable to communicate effectively, which can result from a variety of factors. The history should note any circumstances that would increase the patient's risk of a reaction, such as any history of prior reaction, asthma, or significant heart disease. Seafood allergy should no longer be considered a risk factor (Beaty et al, 2008) (Research Highlight). The elderly often have co-morbidities that need to be considered before contrast media use. The very young patient may be at higher risk for a reaction. Other conditions that may place the patient at risk include sickle cell disease, myasthenia gravis, and severe debilitation. The emotional status of the patient is considered relevant to the occurrence of adverse reactions and may affect the severity of reactions. Thyroid disease may increase the risk of delayed hyperthyroidism. Patients who have undergone interleukin II therapy may experience a delayed flulike syndrome. The radiologist should be notified of any patient with thyroid cancer because the use of contrast media may be contraindicated in these patients.

FIGURE 28-1 Angiographic procedure in radiology suite.

Preprocedure medication assessment is essential in the interventional radiology setting. If preprocedure telephone calls are made to outpatients, it is helpful to request the patient to provide a list of medications, including dosage (or actual containers that can then be returned to a family member), so that an accurate list can be obtained for medication reconciliation on the day of the procedure. All over-the-counter medications and herbal supplements should also be included in the medication assessment. Particular attention should be given to any prescription, over-the-counter, or herbal medications that influence prolongation of coagulation. When the nurse obtains the patient's medical history, special attention is directed to medications that may increase the risk of reaction to contrast media, such as beta-adrenergic blocking agents, which may place the patient at risk for a reaction or increase the severity of a reaction. Calcium channel blockers may interfere with the correction of hypotension should a contrast medium reaction occur. Metformin and medications containing metformin should be discontinued at the time of the study and withheld for 48 hours (Box 28-2) because of the increased risk for lactic acidosis when combined with contrast media. Renal function should be assessed before the resumption of metformin or any of the metformin combination drugs.

BOX 28-1

Interventional Radiology (IR) Nurse Duties

In addition to standard perioperative nursing duties, nurses practicing in the IR setting perform the following activities. NOTE: This list is not exhaustive. The role of the radiology nurse will vary according to expertise, practice developments, and facility.

- Participate in radiation safety measures for patient and staff.
- Understand occupational radiation exposure concepts/monitoring.
- Practice ALARA.
- Practice the principles of MRI safety.
- Practice the principles of radionuclide exposure/protection.
- Conduct a targeted assessment relative to the examination/procedure (e.g., NPO status, distal pulses, neurologic assessment, ability to lie prone if applicable).
- Screen patient for any procedure contraindications (e.g., abnormal clotting studies, renal insufficiency, or MRI contraindications) and communicate findings.
- Assess patient for contrast administration (e.g., premedications, contraindications, risk factors).
- Assist with hemostasis (use hemostasis devices or monitor arterial closure by device).
- Transfer patient to same or higher level of care with appropriate hand-off communication.
- Insert PICC lines and perform other procedures (if credentialed and competency is current).
- Know safe handling of chemotherapy agents if used for procedures.
- Have a basic understanding of special equipment (e.g., radiofrequency ablation equipment, Doppler ultrasound devices, electrosurgical devices).

Modified from the *RNCB survey of radiologic nursing practice,* Radiological Nursing Certification Board, 2008.

RESEARCH HIGHLIGHT

Seafood Allergy and Contrast Media Reactions

Allergies to seafood and shellfish have long been considered a contraindication to the use of iodinated contrast media in radiologic procedures. Research has shown that in patients with true allergies to seafood and shellfish the IgE-mediated response is to the actual proteins within the fish—not to the iodine content of the fish. Despite these findings, some physicians continue to consider this type of allergy as increasing the risk of contrast media reactions.

Researchers conducted a survey to determine if radiologists considered seafood allergy a risk factor for contrast media reaction. They surveyed 231 radiologists and interventional cardiologists at 6 Midwestern universities. The survey consisted of 8 yes/no questions about how practitioners assessed for seafood allergy and the actions they took in relation to administration of contrast media in the presence of seafood allergy.

The response rate to the survey was 48.9% (113 respondents). Analysis of the survey results indicated that 69% of responders inquire about a history of seafood allergy before contrast media administration and 37.2% of responders would withhold contrast media or recommend premedication on the basis of a history of seafood allergy.

While this survey was informal and therefore limited in terms of validity of results, it did corroborate the misconception about the relationship between seafood allergy and contrast media reaction. More than one third of the responders noted that they would either withhold contrast media or premedicate the patient if a history of seafood allergy was present; approximately two thirds of the responders still question patients about seafood allergy as part of the pre–radiology assessment. This study demonstrates there is a need for continuing education for physicians about the relationship between seafood allergy and contrast media administration.

Modified from Beaty AD et al: Seafood allergy and radiocontrast media: are physicians propagating a myth? *Am J Med* 121:158e1-158e4, 2008.

BOX 28-2

Medications Containing Metformin

- Actoplus Met (pioglitazone and metformin HCl)
- Advandamet (rosiglitazone maleate and metformin HCl)
- Fortamet (extended release metformin HCl)
- Glucophage, Glucophage Forte, or Glucophage XR (metformin HCl)
- Glumetza (metformin HCl extended release)
- Glucovance (glyburide metformin HCl)
- Glybofen (metformin and glyburide)
- Janumet (sitagliptin phosphate and metformin)
- Metaglip (glipizide and metformin HCl)
- PrandiMet (repaglinide and metformin HCl)
- Riomet (metformin HCl liquid)

Modified from Hodgson BB, Kizior RJ: *Saunders nursing drug handbook 2010,* St Louis, 2010, Saunders; Skidmore-Roth L: *Mosby's drug guide for nurses with 2010 update,* ed 8, St Louis, 2010, Mosby.

The patient's height and weight, a brief history of the present illness, and significant past history, including renal or clotting problems and allergies (including latex, contrast medium allergy, or tape allergies), are obtained. Any history or suspected problems with sleep apnea should be noted and further action taken if needed, including possible anesthesia service consultation by the radiologist. Anxiety related to the procedure can be addressed. Anxiety may be related to the procedure diagnosis and not necessarily the procedure. Claustrophobia can be a significant issue for patients undergoing procedures such as CT or MRI, or any interventional radiology procedure in which sterile draping around the head, face, and neck is needed. Reassurance that sedation and analgesia will be available may help to significantly allay fears. The value of complementary or alternative (CAM) therapies, such as verbal relaxation techniques, music distraction, and therapeutic presence, should not be overlooked. The nurse provides clear verbal instructions (and written instructions, if time allows) regarding preprocedure lab work or special studies; the time, date, and place to arrive on the day of the procedure; NPO status; medication list instructions (as described in the previous paragraph) or actual containers (per institution policy); insurance information; advance directives; and a contact number should further questions or needs arise. Patients should be advised how to take certain medications (e.g., blood pressure or cardiac medications) the morning of the procedure, usually with only a sip of water. Patients with diabetes should be given clear instructions about how to manage their morning serum glucose levels. Some medications may be held for 48 hours before and up to 24 hours after myelography. It is sometimes necessary for patients to provide copies of x-rays/CT scans/MRI films and/or reports on the day of the procedure, and if this is the case patients should be reminded to have these available. Patients should also be notified of the need for transportation home after the procedure, if applicable. The availability of amenities within the facility should be explained to the patient/family member, as well as an anticipated time of confinement. Facility brochures with parking instructions and information sheets can be mailed to patients if time allows. Special needs or anticipated problems can be ascertained and corrective or preventive action initiated at the time of the preprocedure phone call. Gaining the patient's trust and cooperation is essential to a successful procedure. All preoperative preparation is aimed at making the patient's procedure day experience be as stress-free as possible. Baseline vital signs including a pain assessment should be done on admission and documented. The patient's current weight should be verified. Procedure tables vary according to weight limits. When in doubt or the patient's stated weight is not believable, an actual weight should be obtained. This should be done with sensitivity, especially in regard to the obese patient. Accurate weight assessment is also important for medication dosages, especially in the pediatric population. If angiography is to be performed, initial pulse assessments (presence/absence and quality) should be performed and marked. This may necessitate the use of a portable or handheld Doppler device. Intravenous access should be obtained for most procedures. Intravenous access is needed both for administration of periprocedural medications and hydration fluids and for treatment of untoward reactions such as vagal responses, allergic reactions, or hemorrhage. A nursing neurologic assessment, including notation of difficulty with speech, visual disturbances, facial weakness, and any motor or sensory loss in the extremities, should be

completed before neuroangiography procedures. This assessment is used for comparison during the procedure and during the recovery period along with distal pulse assessment. Timing of preprocedure antibiotics should be according to the guidelines of The Joint Commission and other facility and professional association established guidelines.

Patient teaching should include some basic information about the procedure table and room. Interventional procedure tables and CT tables are narrow and not well-padded. The nurse informs the patient that the room lights may be turned off or dimmed when imaging is complete and that monitoring and equipment sounds may be heard throughout the procedure, especially when only light sedation and analgesia is needed. Patients should also be informed that personnel may leave the room briefly during the acquisition of some images but that the patient will be observed and voice communication will be maintained during this time.

The American College of Radiology (2007a) *Practice Guideline on Informed Consent for Image-Guided Procedures* states consent should be obtained for many invasive procedures requiring the insertion of needles or catheters, for any incisional procedures, and for those procedures requiring sedation. The document further notes that consent for intravenous contrast medium may be omitted but this decision should be obtained based on state law, institutional and departmental policy, and surrounding community practice. Radiation-induced cancer risk is not generally part of the consent because of the necessity of the procedure, but the radiologist should be ready to answer the patient's questions (Marx, 2008). For procedures involving high-risk radiation exposure (e.g., certain stent placements, transjugular intrahepatic portosystemic shunt (TIPS), neurologic and visceral embolizations), the patient should be specifically informed of the risk of skin injury from radiation (Marx, 2008).

Nursing Diagnosis. Nursing diagnoses related to the care of patients undergoing IR procedures might include the following:

- Risk for Impaired Comfort
- Anxiety related to the procedure
- Deficient Knowledge related to procedure and postprocedure period
- Ineffective Breathing Pattern related to pain or conscious sedation
- Ineffective Tissue Perfusion related to sedation, procedural fluid imbalance, or postprocedure bleeding
- Risk for Injury related to radiation exposure

Outcome Identification. Outcomes for the selected nursing diagnoses could be stated as follows:

- The patient will experience relief of pain, verbalize relief of pain, and demonstrate less autonomic responses to pain.
- The patient will verbalize decreased anxiety.
- The patient will verbalize understanding of the procedure and postprocedure expectations.
- The patient's airway will be maintained and oxygen saturation will be within normal limits.
- The patient will maintain vital signs within acceptable limits, maintain peripheral pulses as expected, and demonstrate no evidence of excessive bleeding.
- The patient's skin remains intact, is nonreddened, and is free from blistering.

Planning. Planning care for the patient undergoing an IR procedure consists of the standard elements of perioperative care as well as special considerations for radiation exposure and safety. A Sample Plan of Care for a patient undergoing an interventional radiology procedure is shown on p. 1221.

The use of fluoroscopy (real-time radiography) with ionizing radiation allows for visualization of catheters and guidewires during interventional radiology procedures. The potential benefit of the specific procedure should always be weighed against the risks of radiation exposure. Appropriate utilization is a desired goal (Table 28-1). The linear-no-threshold (LNT model) risk model's presumption is that any radiation is hazardous and the risk increases with exposure. This concept may not apply to doses less than 100 millisievert (mSv) per year (yr) as the risk to health is considered so minimal. Injuries from radiation are described as stochastic or deterministic (Box 28-3).

Today there is growing professional interest and concern about radiation exposure because of the increased incidence of radiation-induced skin injury cases documented by the U.S. Food and Drug Administration. New interventional procedures may require prolonged fluoroscopic guidance (e.g., percutaneous transluminal coronary angioplasty, vertebroplasty, endograft repair of abdominal aortic aneurysms, and uterine artery embolization), and repeated interventional procedures may make the patient more vulnerable to injury (Table 28-2). The radiation risk to the patient involves more than skin dosage. Different tissues vary in their sensitivity to radiation. Cataract development may be influenced by exposure to radiation.

Pregnancy is a contraindication for radiation exposure (unless unusual life-threatening exception exists). Fetal radiation dose calculation may be required to assess fetal vulnerability in the case of discovery of an unknown or undisclosed patient pregnancy. The risk from radiation exposure is the greatest during organogenesis and the first trimester. Children are more sensitive to radiation than adults. Personnel should inform their employer if they are pregnant, and appropriate radiation protection actions should be taken.

All staff members are responsible for patient and staff safety. Everyone receives natural background radiation. Geographic location can affect the amount received. In the x-ray suite, lights to signal "x-ray in use" should be at room entrances. The room doors should be closed during procedures with the exception of necessary brief exits or entrances. Staff should be familiar with the location of the emergency stop button for radiation exposure. Sources of x-ray exposure in the procedure room include primary radiation (through imaged area), secondary radiation (scatter), and leakage radiation. When the operator remembers to control the dose to the patient he/she also controls the dose received by the operator (Klein et al, 2009). The "As Low As Reasonably Achievable" (ALARA) principle should be used. The obese patient may need a higher radiation dose in order to obtain quality images (Uppot, 2007). The Health Physics Society Position Statement entitled *Ionizing Radiation-Safety Standards for the General Public* (2009) states "The Health Physics Society supports the establishment of an acceptable dose of radiation of 1 mSv/y (100mrem/y) above the annual natural radiation background. At this dose the risk of radiation-induced health effects are either nonexistent or too small to be observed."

SAMPLE PLAN OF CARE

NURSING DIAGNOSIS
Risk for Impaired Comfort

OUTCOME
The patient will experience relief of pain, verbalize relief of pain, and demonstrate less autonomic responses to pain.

INTERVENTIONS
- Assess characteristics of pain: location, severity on a scale of 1-10, type, frequency, precipitating factors, relief factors.
- Eliminate factors that precipitate pain.
- Offer analgesics per physician's orders.
- Teach patient to request analgesics before pain becomes severe.
- Explore nonpharmacologic methods for reducing pain/promoting comfort.

NURSING DIAGNOSIS
Anxiety related to the procedure

OUTCOME
The patient will verbalize decreased anxiety.

INTERVENTIONS
- Monitor the patient's level of anxiety by assessing the patient's state of alertness, ability to comprehend, and ability to comply with requests.
- Facilitate family's presence.
- Assist the family in identifying coping mechanisms; facilitate and support their use.
- Reassure patient and family during interactions by touch (when welcomed) and empathetic verbal and nonverbal communication.
- Explain IR environment to patient and what to expect to assist in reduction of anxiety.
- Discuss patient's postoperative appearance (e.g., drains, tubes, equipment) with the patient and family.

NURSING DIAGNOSIS
Deficient Knowledge related to the procedure and postprocedure pain

OUTCOME
The patient will verbalize understanding of the procedure and postprocedure expectations.

INTERVENTIONS
- Assess patient's desire to learn.
- Assess preferred learning mode (e.g., auditory, visual) and literacy level.
- Provide orientation to the preprocedure unit, procedural area, and postprocedure unit.
- Provide health teaching and written instructions.
- Plan and share necessity of learning outcomes with patient.

NURSING DIAGNOSIS
Ineffective Breathing Pattern related to pain or conscious sedation

OUTCOME
The patient's airway will be maintained and oxygen saturation will be within normal limits.

INTERVENTIONS
- Note risk factors for respiratory compromise.
- Assess for signs/symptoms of respiratory distress.
- Administer oxygen as ordered.
- Monitor respiratory rate, pulse oximetry, and capnography (when available) parameters.

NURSING DIAGNOSIS
Ineffective Tissue Perfusion related to sedation, procedural fluid imbalance, or postprocedure bleeding

OUTCOME
The patient will maintain vital signs within acceptable limits, maintain peripheral pulses as expected, and demonstrate no evidence of excessive bleeding.

INTERVENTIONS
- Monitor patient's vital signs and assess cardiac rhythm.
- Assess peripheral pulses.
- Observe for signs of bleeding.
- Assess the patient for the underlying cause and contributing factors.
- Correct the underlying cause.
- Maintain patency of all IV and other invasive lines.
- Provide psychosocial support for patient and family members.

NURSING DIAGNOSIS
Risk for Injury related to radiation exposure

OUTCOME
The patient's skin remains intact, is nonreddened, and is free from blistering.

INTERVENTIONS
- Implement protective measures to prevent injury caused by radiation sources.
- Minimize time of exposure to radiation.
- Maximize distance from radiation source if possible.
- Evaluate patient for signs and symptoms of radiation injury.

Staff education on radiation exposure and protection is essential. Personnel should be familiar with the three principles of radiation protection: time, distance, and shielding. Fluoroscopy time should be limited as much as possible. Digital subtraction angiography (DSA) and cineangiography produce high dose-rates. Fluoroscopy time is often noted by equipment that produces an audible sound after 5 minutes of fluoroscopy and staff should be aware of this warning. Some equipment may have a feature that shows actual fluoroscopy time on a screen. Last-image-hold is a technique that radiologists can use to limit fluoroscopy time. Loop-replay will also allow for review of an image without additional exposure time. The "road map" technique, or roadmapping, is of value during interventional procedures. Pulsed fluoroscopy reduces the absorbed dose. Collimators are used to reduce the area of exposure. Changing the angle of the x-ray beam is also an important way to reduce the amount of radiation to a specific area by changing the beam's entry point. Multimodality guidance (e.g., ultrasound with fluoroscopy for nephrostomy or venous access procedures) can be used to limit radiation exposure (Dendy, 2008).

Distance is key to providing protection during fluoroscopy because radiation exposure follows the inverse square law. (For example, the exposure at 2 meters from the source will be only one fourth as much as the exposure at 1 meter's distance.) Another important concept to follow is that "The patient should be positioned as far from the x-ray tube and as close to the image intensifier as possible for optimal image quality and

TABLE 28-1

Radiation Units of Measure

Measured Quantity	SI Unit	Conventional Unit	Equivalents
Dose: amount of energy absorbed per unit mass	Gray (Gy)	Rads (1 Gy = 100 rads)*	1 Gy = 1 J/kg
Dose equivalent: amount of biologic damage from a radiation dose (= dose × "quality factor"†)	Sievert (Sv)	Rem (1 Sv = 100 rem)	Sv = Gy × QF†
Activity: radioactive emission per unit mass	Becquerel (Bq) = 1 disintegration/sec	Curie (Ci) = 3.7×10^{10} disintegrations/sec	1 Ci = 3.7×10^{10} Bq

*For external β-ray, γ-ray, or x-ray exposure, 1 rad = 1 rem.
†Quality factor (QF) adjusts for the amount of biologic damage caused by a given radiation type: the QF of x-rays, γ-rays, and β-rays is 1; the QF of α-radiation is 20 for internal exposure; and the QF of neutrons ranges from 3 to 20 depending on the energy. Particulate radiation, such as α-radiation and neutrons, is more densely ionizing per unit length of tissue exposed than nonparticulate radiation, such as x-rays and γ-rays. The former, more injurious forms of radiation (e.g., α, neutrons) are assumed to have a high linear energy transfer (LET), while x-rays and γ-rays are referred to as low LET radiation.
Modified from Chambers JA, Purdue GF: Radiation injury and the surgeon, *J Am Coll Surg* 204:128-139, 2007.

BOX 28-3

Glossary of Common Interventional Radiology Terms

Angiography: An x-ray exam of the arteries and veins to diagnose blockages and other blood vessel problems; uses a catheter to enter the blood vessel and a contrast agent (x-ray dye) to make the artery or vein visible on the x-ray.
Balloon angioplasty: Opens blocked or narrowed blood vessels by inserting a very small balloon into the vessel and inflating it. Used by IRs to unblock arteries in the legs or arms, kidneys, brain, or elsewhere in the body.
Biliary drainage and stenting: Uses a stent (small mesh tube) to open up blocked ducts and allow bile to drain from the liver.
Biologic variation: Differences between individuals in threshold dose or degree of response to radiation; may be idiopathic or due to underlying disease; different portions of patient's skin also differ in radiosensitivity.
Centipoise (cps): a unit of measure that describes the viscosity of a liquid
Chemoembolization: Delivery of cancer-fighting agents directly to the site of a cancer tumor while depriving the tumor of its blood supply; currently being used mostly to treat cancers of the endocrine system and liver cancers.
Contrast media: Substance used to enhance the contrast and visibility of blood vessels, fluids, and other structures in the body during medical imaging.
Deterministic effect: Radiation effect characterized by a threshold dose; injury does not occur unless threshold dose is exceeded; once threshold dose is reached, severity of injury increases with increasing dose; examples include hair loss and cataracts.
Dose fractionation: Delivery of radiation over time (e.g., days or weeks); occurs in interventional radiology when same patient has multiple procedures on different days.
Embolization: Delivery of clotting agents (e.g., coils, plastic particles, gel, foam) directly to an area; used to stop bleeding or to block blood flow to a problem area, such as an aneurysm or a fibroid tumor in the uterus.
High-osmolality contrast media (HOCM): Composed of salts that dissociate into cations (sodium or meglumine) and anions (diatrizoate, iothalamate, or metrizoate).
Ionic: Ions held together by a bond.
Low-osmolality contrast media (LOCM): Not composed of salts; does not dissociate.
Osmolality: Number of particles in solution per kilogram of water; concentration of osmotically active particles.
Radiofrequency ablation: Use of radiofrequency (RF) energy to kill cancerous tumors.
Stochastic effect: Radiation effect in which probability of occurrence increases with increasing dose; severity of effect is independent of total delivered dose; example is radiogenic cancer.
Threshold dose: Minimum radiation dose at which a deterministic effect can occur (threshold will vary somewhat among individuals).
Transient erythema: Mild observable skin reaction to radiation; has threshold dose of 2 Gy and resembles a sunburn; subsides by 48 hours after exposure and is frequently not noticed by patient.

Modified from Society of Interventional Radiology: *Common IR terms fact sheet,* available at www.sirweb.org/news/newsPDF/facts/Common_IR_Terms_fact_sheet.pdf. Accessed June 4, 2009; Miller DL et al: Minimizing radiation-induced skin injury in interventional radiology procedures, *Radiology* 225: 329-336, 2002.

minimal radiation dose" (Mauro et al, 2008.) Magnification of an image decreases the area exposed but causes an increase in dose to the area viewed (Marx, 2008). Hands should be kept away from the beam. Nonessential personnel should stand at least 6 feet away from the patient when fluoroscopy is in use. Nurses should attempt to provide nursing interventions when the beam is off if possible and limit close-proximity exposure for urgent patient needs only.

Shielding is the third method of protection. Lead aprons with a minimum of 0.5 mm of lead should be worn by staff for protection. Maternity aprons are available. Proper care of lead aprons is essential to extend the life of the apron, to provide maximum protection to the user, and to protect the patient from contaminants such as blood and body fluids. Thyroid shields are used to reduce radiation exposure to the thyroid gland (Figure 28-2). Lead aprons and thyroid shields should

TABLE 28-2

Potential Clinical Effects of Radiation Exposures to the Skin and Eye Lens

	Effects	Threshold Dose (Gy)	Time of Onset
Skin	Early transient erythema	2	2-24 hr
	Main erythema reaction	6	≈1.5 weeks
	Temporary epilation	3	≈3 weeks
	Permanent epilation	7	≈3 weeks
	Dermal necrosis	>12	>52 weeks
Eye	Lens opacity (detectable)	>1-2	>5 years
	Lens/cataract (debilitating)	>5	>5 years

In NIH publication no. 05-5286; *Interventional fluoroscopy reducing radiation risks for patients and staff,* March 2005.

FIGURE 28-2 Radiation protection devices, including protective apron, thyroid shield, and dosimeter.

be stored by hanging them vertically or they can be laid flat, if appropriate, when not in use. They should not be folded. Cracks in the lead decrease protection from radiation exposure (Box 28-4). Institutional policies and procedures for monitoring of lead aprons should be followed, including a labeling system that allows for tracking and routine maintenance. Lead aprons can contribute to musculoskeletal injury and low back pain (Risk Reduction Strategies box). Leaded eyeglasses provide protection against cataract development for the equipment operator and personnel adjacent to the operator. Sterile lead gloves are available for use but may not be used for a variety of reasons, including cost and comfort. Institutional policies should be followed during radioactive "seed" implants,

BOX 28-4

Care of Lead Aprons

- Hang apron by both shoulders.
- Handwash apron with mild soap and water; rinse with a damp cloth. Aprons should be kept clean and free of dry blood and other fluids.
- Hang to air-dry.
- Check apron for defects as required by State Radiation Control Boards. This is usually an annual requirement.
- Do not fold lead apron over chair.
- Do not lay apron over processor or any other source of heat.
- Do not puncture the apron with any sharp objects.
- Do not put the lead apron through the laundry or clean it with chemicals.
- Do not throw the apron on the floor or crinkle it in any way.
- Take care when having the lead apron repaired.
- Have the apron repaired by a professional in the lead business because someone unfamiliar with the proper technique can ruin the apron by sewing through the lead and thus rendering it unsafe.

Modified from *Care of lead aprons: Davis lead aprons,* available at www.apronco.com/servcare.htm. Accessed February 3, 2009.

RISK REDUCTION STRATEGIES

Preventing Occupational Low Back Pain in the Imaging Environment

- Wear lightest apron available that meets shielding requirements.
- Do not borrow an apron that is not sized appropriately for height and shape.
- Obtain a two-piece apron that shifts some weight off the shoulders to the hips, or use a belted apron or one with an internal frame to take weight off the shoulders.
- Use overhead or mobile x-ray barriers whenever possible to reduce exposure and need for apron use.
- Place shielding around the patient to reduce scatter radiation and need to wear apron.
- Maintain an upright posture; avoid bending forward or sideways.
- Avoid maintaining one position for a long time.
- Use antifatigue pads on the floor; wear well-padded shoes.
- Maintain optimal neck position, neutral to slightly flexed.
- Avoid trunk twisting when reaching for objects.
- Consider arrangement of IR room, tables, monitors, other equipment.
- Ensure there is sufficient staff to assist with patient transfers on and off the procedure table. Obtain assistive transfer devices and encourage staff to use them.
- Practice healthy living habits, attempting to maintain a work environment that minimizes stress.

Modified from Naito NA: *Occupational back pain in the interventional radiologist,* Society of Interventional Radiology Annual Meeting Program, New Orleans, La, 2005.

including a "Radioactive" warning sign on the room door and use of lead aprons by personnel.

Fixed shielding (in walls or doors), table-side lead apron drapes, ceiling-suspended lead acrylic shields, and movable lead acrylic shields provide additional protection for staff.

EVIDENCE FOR PRACTICE

Strategies to Manage Radiation Dose to Patients and Operators

IMMEDIATE	LONG-TERM
OPTIMIZE DOSE TO PATIENT	
Use proper radiologic technique: ◆ Maximize distance between x-ray tube and patient. ◆ Minimize distance between patient and image receptor. ◆ Limit use of electronic magnification. Control fluoroscopy time: ◆ Limit use to necessary evaluation of moving structures. ◆ Employ last-image-hold to review findings. Control images: ◆ Limit acquisition to essential diagnostic and documentation purposes. Reduce dose: ◆ Reduce field size (collimate) and minimize field overlap.	Include medical physicist in decisions: ◆ Consider machine selection and maintenance. ◆ Incorporate dose-reduction technologies and dose-measurement devices in equipment. ◆ Establish a facility quality improvement program that includes an appropriate x-ray equipment quality assurance program, overseen by a medical physicist, which includes equipment evaluation/inspection at appropriate intervals.
MINIMIZE DOSE TO OPERATORS AND STAFF	
Keep hands out of the beam. Use movable shields. Maintain awareness of body position relative to the x-ray beam: ◆ Horizontal x-ray beam: operator and staff should stand on the side of the image receptor. ◆ Vertical x-ray beam: the image receptor should be above the table. Wear adequate protection: ◆ Wear protective, well-fitted lead apron. ◆ Wear leaded eyeglasses.	Improve ergonomics of operators and staff: ◆ Train operators and staff in ergonomically good positioning when using fluoroscopy equipment; periodically assess their practice. ◆ Identify and provide the ergonomically best personal protective gear for operators and staff. ◆ Urge manufacturers to develop ergonomically improved personal protective gear. ◆ Recommend research to improve ergonomics for personal protective gear.
DOSIMETRY RECORDS AND FOLLOW-UP	
Measure and record patient radiation dose: ◆ Record fluoroscopy time. ◆ Record available measurements: dose area product (DAP), cumulative dose, skin dose. ◆ Inform patients who have received high doses to examine the x-ray beam entrance site for skin erythema. Develop methods to quantify late effects: ◆ Design medical records to clearly document the number and types of interventional procedures received by the patient. ◆ Maintain a database of all patients with procedure and dose information. ◆ Review dose information to identify patients with high doses (>2 Gy) for follow-up.	

Modified from *Interventional fluoroscopy: reducing radiation risks for patients and staff,* NIH publication no. 05-5286, March 2005.

Patient shielding should be considered. All patient body parts not being imaged (e.g., hands) should be out of the field of view during fluoroscopy.

Personnel radiation monitoring is an important part of radiation exposure safety. Optically stimulated luminescence (OSL) personal radiation dosimeters are typically used on the trunk (under the apron) and at the collar level (outside the apron). Personal radiation dosimeters should not be left on aprons as this would cause inaccurate readings when an apron or thyroid shield is worn by other than the intended user. Monitors are usually exchanged and monitored on a monthly basis. Staff should be aware of and strictly follow the institution's policies and procedures and governing laws (Evidence for Practice).

Implementation. To provide effective perioperative care of the patient undergoing an IR procedure the nurse implements those actions that relate to the patient's nursing diagnoses and contribute to achievement of identified outcomes. During this phase of care the nurse will obtain and use appropriate equipment and supplies and perform interventions related to patient positioning, prepping, monitoring, and medication administration.

EQUIPMENT. In addition to x-ray equipment (e.g., ultrasound devices) other essential equipment includes power injectors for precise timing and rate of injection of contrast media (Figure 28-3), torque devices to guide catheters, and vascular closure devices to assist hemostasis. Tourniquets are needed for peripherally inserted central catheter (PICC) line placement and venography procedures. Portable handheld Doppler devices or other ultrasound equipment may be required for vascular procedures. An electrosurgical unit may be used during procedures where a pocket is created for device insertion. Other special equipment is needed for procedures such as inferior vena cava filter placement, diskography, kyphoplasty, and radiofrequency ablation. Laser equipment may be used for angioplasty cases. Laser safety includes education of staff, use of protective equipment, and special preparation of the procedure room. Any equipment that is used for interventional MRI (iMRI) procedures should meet the current MRI safety standards and be nonferrous (nonmagnetic).

FIGURE 28-3 Power injector used to deliver contrast medium.

FIGURE 28-4 Catheters and guidewires.

SUPPLIES AND INSTRUMENTATION. A variety of specialty items are used for IR procedures. A Seldinger needle (18 gauge, 2¾ inches) is commonly used for groin access. A finer needle (or micropuncture set) is used when other considerations exist, such as when there is increased risk for bleeding, axillary or brachial artery puncture is planned, or a pediatric case is being performed. The radiologist may have a specific preference based on other factors. Minor instrument trays may be used to create pockets for implantable devices.

A sheath is commonly inserted at the arterial or venous puncture site. The sheath has several functions. Most importantly, it is used to protect the puncture site and vessel from damage. This is especially true in interventional procedures that involve multiple guidewire and catheter exchanges. Heparinized saline flush may be infused through the sidearm (port) of the sheath. For thrombolysis procedures or when a sheath is left in place for another pending procedure, it may be sutured to the skin and covered with a sterile dressing per the radiologist's preference.

Guidewires are available in a variety of lengths, diameters, and stiffness (Figure 28-4). A 0.035-inch J or straight wire is often used. There are steerable and nonsteerable guidewires as well as introducing and exchange guidewires. Guidewires may have a hydrophilic coating. There are guidewires with long, floppy tips that allow access past difficult vessels. The type of guidewire selected will depend on its purpose and the preference of the radiologist. Guidewires can be dislodged during catheter exchange and caution should be used at this time. Guidewires have a right and wrong end for insertion.

Catheters are available in a variety of lengths and shapes, each with a specific advantage (see Figure 28-4). Catheters are sized by the French system. Flow rates will vary among the catheter types and sizes. A pigtail catheter can deliver a larger amount of contrast medium because of additional side holes, as compared to the standard catheter with one end hole. Multihole straight catheters are available. Catheters can be referred to as selective or nonselective. Examples of selective catheters include the Cobra, Berenstein, Headhunter, and Simmons (Sidewinder) catheters. Microcatheters (co-axial catheters) are used for access to very small vessels. Catheters may also have balloons that can be inflated for angioplasty purposes. Meticulous catheter technique is needed to prevent inadvertent air in the line and coagulation of blood in the catheter. Before an injection is done, the placement of the catheter tip is often verified by using fluoroscopy. A test injection using a small amount of contrast material may be done. The type of contrast dye and its volume and flow rate are determined by the radiologist before injection.

Pressure bags, used with high-pressure tubing and connectors, are needed for vascular interventional procedures. Three-way stopcocks are placed on the flush line. A Tuohy-Borst adaptor is used to form a seal around guidewires and catheters. The Tuohy-Borst sidearm can be used as a port for injection. Vascular snares are devices that are used to retrieve foreign bodies. Heparinized saline flush bags and a closed system for discard of flush, contrast medium, or blood will also be needed for a procedure. Stents and catheters equipped for balloon angioplasty may be needed for vascular procedures. Percutaneous mechanical thrombectomy devices will be used in cases in which pharmaceutical thrombolysis cannot be done or as an adjunct treatment for thrombolysis. This will also be used for some dialysis graft interventions.

Coils, embolic agents, or sclerosants may be needed for procedures designed to occlude a vessel. Because tube tracts frequently need to be dilated for initial tube placement, dilators of all sizes are needed. Urinary, biliary, or other drainage tubes may be held in place by sutures or by a variety of commercial tube holders. Drainage bags, stopcocks, and connecting tubing are needed for drainage catheter placement. Drainage bags with leg straps may be used. Some patients with nephrostomies will also prefer to have a larger drainage bag for use overnight. A variety of suture materials will be needed for pocket closure following device placements such as a portacath or cardiac device. Sterile specimen containers and sterile slides should be available for biopsy or drainage procedures. Solutions and fixatives for specimen storage should be available. Chest tubes, collection systems, and wall suction are needed for pneumothorax interventions. Vacuum bottles will be needed for paracentesis or thoracentesis procedures.

MEDICATIONS. Medication assessment, administration, monitoring, and performance improvement often constitute a large part of the nurse's productive time. An accurate medication history is essential to providing safe patient care. A variety of medications are administered in the IR setting. The perioperative nurse must be familiar with the medications used in this setting including their indications, dosages, and side effects.

Anticoagulants. The diagnostic or therapeutic procedure may necessitate the administration of heparin or other anticoagulant or antiplatelet medications (e.g., aspirin, dipyridamole, ticlopidine) because vascular injury can lead to thrombus development. Heparin is often used to prevent acute thrombosis and ischemic episodes. Heparin's short half-life makes it a good choice for periprocedural anticoagulation. Its effect can be reversed with protamine sulfate. The nurse notes the time heparin is given because the anticoagulation status of the patient will influence when a repeat dose may be needed or when an arterial sheath can be safely removed. An activated coagulation time (ACT) may be determined to evaluate the need for additional intraprocedural heparin administration in certain cases or to assess the effectiveness of anticoagulation before a sheath is removed. The perioperative nurse may be involved in point-of-care testing for the ACT. An intravenous infusion of heparin may be started for thrombolysis or angioplasty cases. Standard mix bags of heparin are practical and convenient to use. Heparin is a high-alert medication—the concentration of heparin should be checked. For example, premix bags with 25,000 units of USP heparin in 500 ml of 0.45% normal saline (0.45NS) may be used for the intravenous infusion of heparin during thrombolysis or angioplasty cases. Heparin flush premix bags (e.g., 1000 units of USP heparin in 500 ml of 0.9NS) may be used for sheath or catheter flushing and should not be confused with other concentrations. The thrombin inhibitor bivalirudin (Angiomax) may be used during stent procedures instead of heparin.

After most venous access lines are placed, heparin is instilled. The specific type of line (e.g., dialysis catheter, portacath, triple-lumen central line, or PICC) will dictate the amount and strength of heparin needed. Manufacturer guidelines for the device and hospital policy for line management should be followed. Certain types of lines, such as Groshong catheters, may not require heparin. Low-molecular-weight heparin (LMWH), heparin, or other medications may be used for venous thromboembolism prophylaxis following the procedure.

Heparin is contraindicated in the patient with hypersensitivity or the patient with bleeding. Thrombocytopenia and heparin-induced thrombocytopenia (HIT) can develop. Aspirin or other antiplatelet drugs can be given to prevent embolic or ischemia events caused by coagulation problems. A wide variety of platelet aggregation inhibitors, anticoagulants, and vitamin K antagonists are used.

Thrombolytics. Small amounts of a thrombolytic drug can be instilled into portacaths and aspirated to ensure patency of the device. Intravascular thrombolytic agents are used to dissolve a thrombus so normal vascular patency can be achieved. Thrombolytic drugs activate the conversion of plasmin to plasminogen and break down fibrin. Thrombolytic drugs work best on a fresh clot. Thrombolytic drugs cause a systemic lytic state and hemorrhage is a possible complication. The patient should be screened for both relative and absolute contraindications for thrombolytic therapy. During thrombolytic infusion procedures the patient should be monitored in a critical care setting.

Vasodilators and Vasoconstrictors. Nitroglycerin, a short-acting vasodilator, is used to prevent or treat vascular spasm caused by the wire or catheter during interventional procedures (e.g., percutaneous transluminal angioplasty). It is prepared as a 100-mcg dose and administered directly into the affected vessel by the radiologist. Papaverine delivered as a bolus and then by infusion has been used for nonocclusive mesenteric ischemia. Tolazoline hydrochloride (Priscoline) is another vasodilator that has been used intraarterially during angiography.

Vasopressin (Pitressin), a vasoconstrictor, may be given as an intraarterial infusion for gastrointestinal bleeding. Vasopressin has an antidiuretic hormone (ADH) effect.

Miscellaneous Medications. Amobarbital sodium (Amytal) is used during cerebral arteriography in Wada's test to evaluate neurologic function.

Because of its platelet inhibition properties, aspirin is often given before and after a percutaneous transluminal angioplasty procedure. Aspirin may also be administered after endovascular laser treatment.

Chemotherapy agents are used during transcatheter liver chemotherapy procedures. The pharmacy from which the chemotherapy agents are prepared should know in advance of the need and approximate time of need. Imaging staff members should be aware of chemotherapy handling and disposal precautions and follow facility policies and procedures.

Diphenhydramine (Benadryl) is used for a variety of reasons, including as a sedative adjunct, as a treatment for contrast reaction urticaria, and, in rare circumstances, as a local anesthetic.

Glucagon is used to decrease peristaltic activity of the bowel during angiography and during gastrointestinal tube placement. The lyophilized form of glucagon needs to be reconstituted with the diluent provided just before use. Glucagon 1 mg is given intravenously. (NOTE: Glucagon is supplied in 1- and 10-mg vials. Be careful not to confuse the two.)

The antioxidant *N*-acetylcysteine (Mucomyst) is an off-label use medication for the prevention of contrast-induced nephropathy, although this has not been conclusively proven effective. It is usually administered 600 mg twice daily on the day before the procedure and on the day of the procedure. Other regimens have been recommended.

Radioisotopes may be given via a lumbar puncture. Staff from the nuclear medicine department should be notified when the patient is scheduled for the procedure.

Secretagogue, 10% calcium gluconate, may be given during diagnostic angiography for gastrinomas or insulinomas.

Thrombin (Gentrac, Inc., Middleton, Wisc, for Johnson & Johnson; or Jones Medical Industries, St Louis, Mo) may be used for direct percutaneous injection for pseudoaneurysm repair. With ultrasound guidance this may be used in combination with direct pseudoaneurysm compression.

EMBOLIC AND SCLEROSING AGENTS. Embolic materials induce mechanical obstruction within a vessel and formation of thrombus via platelet activation and activation of the patient's clotting mechanism. The size of the vessel to be embolized and the need for embolization to be permanent or temporary will affect the choice of agent. Some clinical indications for use of embolic agents include upper and lower gastrointestinal bleeding, pelvic embolization (e.g., posttrauma, uterine fibroid embolization, postpartum hemorrhage), severe hemoptysis, pseudoaneurysm, arteriovenous (AV) fistula, and preoperative solid organ embolization (e.g., renal, splenic). An inflammatory response may be initiated with certain agents. Nontarget embolization is a possible complication. Postembolization syndrome (PES) is expected in some situations, such as after uterine fibroid embolization.

Embolic agents can be categorized by the nature of their occlusive action, either temporary or permanent. Temporary agents include absorbable gelatin sponge, Gelfoam sponge powder, starch microspheres, oxidized cellulose, and collagen fiber preparations. Gelfoam may be cut into small pledgets or "torpedoes" and injected via a catheter, or cut into small pieces and mixed with saline and contrast medium to form a "Gelfoam slurry" for injection via a catheter. Gelfoam activates platelet aggregation and the clotting cascade. It also causes inflammation of a vessel wall. Collagen fiber preparations cause mechanical obstruction in a vessel or inflammation to occur. Gelfoam may be used for the purpose of devascularization before surgery or for control of bleeding. Gelfoam may be placed into a needle tract following a biopsy to prevent bleeding from the biopsy site.

A vascular plug or coils may be used. Coils may consist of Dacron fibers to promote thrombosis. Coils may be used in combination with another material such as Gelfoam. Coil size is very important to prevent migration from the intended site. Coils are usually packed tightly to prevent recanalization of the vessel. Surgical silk and polypropylene suture material have been used for embolization but the lack of radiopacity is a drawback. Permanent nonreabsorbable materials for small vessel use include polyvinyl alcohol particles or sponges, trisacryl gelatin microspheres, particulate agents, and tissue adhesives. Cyanoacrylate glue and coils have been used for embolization of brain arteriovenous fistulas. Ethiodol, an oil-based contrast agent, is sometimes used during embolization procedures to allow visualization of the extent of the embolization. Thrombin activates the conversion of fibrinogen to fibrin. It may be used to treat iatrogenic pseudoaneurysms following femoral artery catheterization.

Sclerosing materials cause direct destruction of the vascular endothelium. Examples include absolute alcohol, sodium tetradecyl sulfate, and ethylene–vinyl alcohol co-polymer. Chemical pleurodesis for pleural effusions has been accomplished with tetracycline. Doxycycline suspended in saline or contrast medium has been used for sclerotherapy of seromas. Sclerosing agents may involve a "dwell" time followed by drainage. Injection of a sclerosant into a pocket may cause discomfort for the patient and a local anesthetic may be injected. The topical antiseptic povidone-iodine has been used as a sclerosing agent to eradicate persistent pockets. After catheter drain placement and initial treatment in the interventional radiology department, outpatients are often given instillation, dwell time, and drainage instructions.

ANALGESIA AND SEDATION. While some simple interventional procedures, such as PICC line placement, can be performed using only a local anesthetic, most interventional procedures require sedation and analgesia. In addition to the normal perioperative assessment parameters, the nurse providing care in the IR setting should be familiar with the patient's American Society of Anesthesiologists (ASA) status (see Chapter 4) and be able to assess additional factors specific to the risk of developing complications related to sedation (Patient Safety).

The nurse works under the direction of a radiologist credentialed for sedation and analgesia administration per the institution's policy and procedure. Advanced cardiac life support (or pediatric advanced life support in the event of a pediatric case) should be a requirement for all providers. Pharmacologic antagonists, medications, and intravenous fluids to correct vasovagal or other blood pressure problems as well as resuscitation medications should be readily available. Oxygen and suction and resuscitation equipment should also be readily available before the patient is given medications for sedation and analgesia.

Physiologic monitors (continuous electrocardiography, blood pressure [BP], pulse oximetry, and capnography, if available) with audible alarms should be in place when sedation and analgesia are given. Pulse oximetry can be used to monitor the patient's respiratory status but it should not be the sole indicator of respiratory status. Respiratory rate and ventilation are both important vital signs to monitor for the prevention of oversedation or untoward response. Capnography is an

PATIENT SAFETY

Nursing Assessment and Actions for the Patient Receiving Intravenous (IV) Moderate Sedation/Analgesia

A primary responsibility of the nurse providing care in the IR setting is the administration of sedation and analgesia. In addition to being familiar with the agents used for sedation, the nurse must be well versed in assessment and in the actions to take if complications related to the agents occur.

Before administering sedation agents the nurse should assess the following about the patient:

- Relevant physical examination findings
- Current medications
- Allergies and sensitivities
- Current medical problems such as hypertension, diabetes, cardiopulmonary disease, liver disease, and renal disease
- History of sleep apnea
- Smoking history
- Alcohol intake history
- Recreational drug use
- Presenting medical problems
- Baseline vital signs
- Level of consciousness
- Emotional state
- Communication ability
- Perceptions of sedation/analgesia and the procedure itself

STEPS TO FOLLOW WITH INADVERTENT DEEPENING OF SEDATION WITH LOSS OF AIRWAY

- Check patient; stimulate patient quickly to affirm deepening of sedation with loss of airway.
- Call for help early (rapid response team or code blue team). Use all available members of the team to correct situation.
- Provide supplemental oxygen/increase oxygen flow (if apneic or inadequate respirations, provide bag-valve-mask ventilation). (Ensure oxygen is flowing to patient.)
- Improve head position (per advanced life support guidelines).
- Use oral or nasal airway (trained provider).
- Provide bag-valve-mask ventilation (with oxygen source).
- Consider reversing sedation and analgesia.
- Insert protected airway device, laryngeal mask airway, endotracheal tube (by trained provider).

Modified from Shabanie A: Conscious sedation for interventional procedures: a practical guide, *Tech Vasc Interv Radiol* 9:84-88, 2006; Association of periOperative Registered Nurses (AORN): *Perioperative patient care in the ambulatory surgery setting,* Denver, 2007, The Association.

excellent adjunct to monitor the patient's respiratory status especially in procedures where ventilatory function assessment is compromised, such as when the patient is in a prone position. Careful observation of the patient, knowledge of all the procedure-related events, and trending of all vital signs are key to successful sedation and analgesia in the imaging setting.

Supplemental oxygen should be started before the initiation of sedation (Shabanie, 2006). The provider should be familiar with both the risks and benefits of oxygen use. The team should be knowledgeable about fire potential in the radiology area when oxygen is in use and be aware when other elements of the fire triangle are present.

Sedation and analgesia help to allay fear and facilitate patient cooperation throughout the procedure. Anxiety can enhance pain perception and lead to undesired physiologic responses, as well as movement during the procedure. Imaging procedures require that a patient lie quietly on the procedure table to prevent motion artifact on the images. Breathing instructions may be given to the patient just before filming in certain situations. Therefore analgesia and sedation need to be adjusted to the procedure. For example, if respiration control is desired, the patient should be awake enough to cooperate but comfortable enough to tolerate the procedure. Some procedures, such as a diskogram, require that a patient be able to communicate the amount of pain felt with each disk injection and rate it in comparison to the usual pain. If the patient is oversedated, he or she may not be able to respond or the response may not be accurate. During the course of some procedures, the radiologist may need to perform a more painful maneuver, such as tract dilation before tube advancement during percutaneous nephrostomy tube or drainage tube placement. These maneuvers may require additional analgesia and sedation. There should always be good communication between the radiologist and nurse administering sedation and analgesia so that painful procedures are avoided or minimized whenever possible. The amount and type of analgesia and sedation are highly dependent on patient and procedure factors (Surgical Pharmacology). Each patient's perception and response to pain is different, based on their physiologic response, cultural response, and history of previous radiology procedures. A visual analogue scale can be used to evaluate the patient's level of pain before, during, and after the procedure. The experienced nurse will know when additional sedation and analgesia are typically required and proceed accordingly so valuable time is not lost during the procedure.

In circumstances where the services of an anesthesia provider are needed, the perioperative nurse should assist the provider as needed because the anesthesia provider is often working in an unfamiliar setting. Providing anesthesia in imaging settings is not easily accomplished. Cases involving anesthesia services are typically scheduled in advance per hospital policy, and the availability of an anesthesia provider on short notice may be a limiting factor. A recent study showed how difficult it was to estimate anesthesia times for interventional radiology (IR), computed tomography (CT), and magnetic resonance (MR) imaging procedures and also developed useful guides for scheduled or elective procedures for all three areas (Research Highlight).

Providers find the anesthesia experience less satisfying than that accomplished in the OR where turnover times are more controlled (Arnold and Roberts, 2008). Dedicated anesthesia services for radiology departments are present in some locations. Working around multiple pieces of imaging equipment may interfere with patient contact. The possibility of hypothermia should be considered because of the usual room temperatures in the imaging areas. Anesthesia assistance may be needed for deepening sedation beyond the control of the imaging team. In cases where a general anesthetic is given the nurse should alert the postanesthesia care unit of the estimated time of arrival and ensure that all equipment needed for transport is available.

CONTRAST MEDIA. Since the beginning of radiographic imaging, contrast media have been used to enhance visualization of anatomic structures. Contrast agents can be positive or negative in effect. A negative contrast agent (e.g., carbon dioxide or air) attenuates (absorbs) the x-ray beam less than surrounding tissue. A positive contrast agent (e.g., the water-soluble intravascular agents discussed in this chapter and the various preparations of barium) attenuates the beam more than surrounding tissue. Contrast media are very useful in detecting diseased or abnormal tissues/organs because these appear different than normal tissues/organs after contrast injection. Contrast media can also be used to visualize a specific structure, such as a blood vessel, part of the urinary tract, or a cavity (Box 28-5). Visualization caused by contrast injection is affected by several issues. Iodine concentration is directly related to the radiopacity produced by the contrast medium. Other factors affecting visualization are the amount and speed of delivery of the contrast agent, blood flow and hemodilution of the area, and the size of the vessel being imaged. Thus iodine concentration, volume of contrast medium, and timing of the injection are critical to imaging.

In 1923 practitioners at the Mayo Clinic observed bladder opacification on abdominal x-rays from patients who had been given oral and intravenous sodium iodide for the treatment of syphilis. This accidental discovery lead to the quest for development of safe iodinated intravenous contrast media. The toxicity of sodium iodide prevented it from being a suitable contrast agent. The early efforts were focused on creating a contrast agent suitable for diagnostic intravenous urograms. Uroselectan was first used in 1929 and then refined as Uroselectan B.

In the mid-1950s sodium diatrizoate (distributed as Urografin, Renografin, and Hypaque) was introduced and used as the primary contrast medium for urologic and intravascular procedures. Sodium diatrizoate, a high-osmolality ionic contrast medium (HOCM), was far from ideal. This HOCM dissociated in solution, yielding an anion and cation that produced undesirable side effects, including vascular pain, nausea and vomiting, cardiovascular changes (e.g., bradycardia), and disturbances in the blood-brain barrier. Iothalamate (Conray), a high-osmolality contrast medium similar in composition to diatrizoate, was better tolerated, especially neurologically, but not as well tolerated by the cardiovascular system. The osmolality of diatrizoate and iothalamate is high (1500 to 2100 mOsm/kg of water). The osmolality of blood is 296 mOsm/kg of water. Many of the harsh side effects, such as pain on injection and nausea and vomiting, were attributed to this difference in osmolality. Metrizamide, a low-osmolality contrast medium (LOCM), was released in 1969. Metrizamide was unstable in solution and needed to be produced as a freeze-dried powder with a special diluent. In the late 1970s metrizamide replaced

SURGICAL PHARMACOLOGY

Medications Used for Sedation and Analgesia (and Antagonists)

The recommendations included here are generally acceptable guidelines and may require modification for individual patients at the discretion of the physician. Dosages provided are generally acceptable but may need to be reduced in a given patient to avoid serious cardiorespiratory depression or other undesired side effects. Furthermore, many of these medications have synergistic respiratory depressant effects; when administered in combination, lower dosages may be required.

Drug	Dose	Total	Onset	Duration	Nursing Considerations
BENZODIAZEPINES (SEDATIVES)					
Diazepam (Valium)	2-10 mg into rapidly infusing IV line; may repeat at 5-min intervals	0.1-0.2 mg/kg	1-5 min	15-60 min; may be greatly increased in pts >60 y/o	Patient should remain supine until effects of medication are absent and risk of hypotension has passed. Hepatic or renal insufficiency increases duration of effect.
Midazolam (Versed)	<60 y/o: 1.0-2.5 mg over 5 min (wait 2 min to evaluate) Titrate in small increments at 2-min intervals	Total maximum dose 2.5-5 mg	1-5 min	20-30 min	Too much or too little may cause cerebral hypoxia, agitation, combativeness. Hepatic insufficiency increases duration of effect; 30% dose reduction with concomitant use of opiate agonists or CNS depressants.
	>60 y/o, debilitated, or chronically ill: 0.5 mg (wait 3 min to evaluate) Titrate 0.5-mg increments at 2-3 min intervals	Total maximum dose 3.5 mg			Implement 50% dose reduction with concomitant use of opiate agonists or CNS depressants.
Lorazepam (Ativan)	44 mcg/kg 15-20 min before procedure	Total maximum dose 2 mg 15-20 min before procedure	5-15 min, peak unknown	24-48 hr	Use with caution in geriatric patients, debilitated, renal/hepatic disease. Dizziness, drowsiness, orthostatic hypotension can occur. Prepare immediately before use; has short-term stability. Monitor respirations q 5-15 min if given IV (rapid injections may cause cardiac arrest) and CNS changes. Check Y-site compatibilities. Give IV after diluting; give at 2 mg or less over 1 min.
OPIATE AGONISTS (NARCOTICS)					
Morphine	1-2 mg at 3-5 min intervals	Up to 0.1-0.15 mg/kg	1-5 min	3-5 hr	If respirations are 12/min or less, hold next dose. Hepatic or renal insufficiency increases duration of effect.
Fentanyl (Sublimaze)	Bolus of 1-2 mcg/kg, then 1 mcg/kg every hour.	1.5-2 mcg/kg	1-5 min	0.5-1 hr	Hepatic insufficiency increases duration of effect.
Hydromorphone (Dilaudid)	0.5-1 mg (titrate to effect)	Maximum 2 mg IV every 4-6 hr	15-30 min (peak 0.5-1 hr)	4-5 hr	Increased effects caused by alcohol, opiates, sedatives/hypnotics, antipsychotics, skeletal muscle relaxants. Check IV compatibilities. If direct IV route used, dilute.

RESEARCH HIGHLIGHT

Predicting Anesthesia Times

Although the majority of IR procedures are accomplished with sedation, some procedures may require the presence of an anesthesia provider. Because anesthesia providers do not routinely practice in the IR setting, calculations related to anesthesia time may be incorrect. In this study, researchers evaluated anesthesia billing data and logbooks from diagnostic radiology and interventional radiology departments and current procedural terminology (CPT) codes from computerized tomography (CT) and magnetic resonance imaging (MRI) procedures in an effort to predict anesthesia time for imaging procedures. This information was found not particularly useful in predicting anesthesia time. Anesthesia time was more accurately assessed by expert judgment. The authors noted that radiology suites are not as interchangeable as ORs and suggested that completion times should be estimated and used to assist with scheduling interventional radiology procedures.

Modified from Dexter F et al: Predicting anesthesia times for diagnostic and interventional radiological procedures, *Anesth Analg* 102:1491-1500, 2006.

oil-based contrast media (e.g., Pantopaque) for use in myelography. Ioxaglate (Hexabrix), an ionic dimer contrast medium, was developed and is still in limited use today. Ioxaglate is contraindicated for myelography and radiculography because of its ionicity.

By the late 1970s a second generation of low-osmolality nonionic contrast media was introduced. Iohexol (Omnipaque), iopamidol (Isovue), ioversol (Optiray), iopromide (Ultravist), and ioxilan (Oxilan) were nonionic monomers. All of the second-generation LOCM were lower in osmolality and were better tolerated then metrizamide (Amipaque). Efforts to further reduce osmolality created the newest contrast media, the nonionic dimers iotrolan and iodixanol. Iotrolan has been removed from the market because of concerns about delayed cutaneous reactions. Iodixanol (Visipaque), the newest agent, is a nonionic dimer and carries six atoms of iodine on each molecule of contrast agent. The osmolality of iodixanol is 290 mOsm/kg of water, which is better tolerated by the body. The nonionic dimer iodixanol causes the least discomfort when injected into the body. The viscosity (11 centipoise [cps] at 37° C) of iodixanol is higher than that of the other contrast media. Viscosity is affected by both the iodine concentration and the temperature of the contrast medium. Warming reduces the viscosity of contrast media. The delivery of contrast media through catheters is therefore facilitated by warming it to body temperature.

Once injected, contrast medium moves throughout the extracellular space of the body. No metabolism of the contrast medium occurs. Contrast medium is cleared primarily by passive glomerular filtration. The renal tubules do not reabsorb any contrast agent. The half-life of contrast media is believed to be about 1 hour in patients with normal renal function. Another important pharmacokinetic property of contrast agents is that protein binding is minimal. No immunoglobulin E (IgE) antibodies are associated with contrast injection. The injection of contrast agents can cause organ-specific or system-specific changes (Box 28-6).

Physiologic Response to Contrast Media.. The physiologic response to intravenous injection of contrast media is multifold. Contrast media have an osmotic diuretic effect. Following contrast injection there is movement of contrast agent from the intravascular space to the interstitial fluid followed by elimination through renal clearance. Cardiac, pulmonary, and peripheral vascular changes have been noted. Heart rate may be affected. Disturbances in electrical conduction (e.g., bradycardia) may occur during cardiac angiography. Peripheral vascular resistance may decrease and peripheral vasodilation may occur. Contrast media cause the release of histamine from the mast cells within the lung. Pulmonary edema resulting from contrast agent administration is rare. Because contrast media have an irritant effect on the vascular endothelium of blood vessels, the patient may notice a sensation of heat following injection of contrast medium. This effect is less pronounced with LOCM and iso-osmolality contrast medium (IOCM) than with HOCM.

Medical problems that affect or disrupt the blood-brain barrier may place the patient at risk for seizure following contrast media injection. Contrast media inhibit the clotting mechanisms of the body by inhibiting platelet aggregation and limiting the clotting cascade. HOCM affect these processes more than LOCM or IOCM. This fact influences catheter technique

BOX 28-6

Organ-Specific or System-Specific Adverse Effects from Contrast Media

Adrenal Glands
- Hypertension (in patients with pheochromocytoma after intra-arterial injection)

Brain
- Headache, confusion, dizziness, seizure, rigors, lost or diminished consciousness or vision

Gastrointestinal Tract
- Nausea, vomiting, diarrhea, cramping

Heart
- Hypotension
- Dysrhythmia (asystole, ventricular fibrillation, ventricular tachycardia)
- Pulseless electrical activity (PEA)
- Acute congestive heart failure

Kidney
- Oliguria
- Hypertension
- Contrast-induced nephrotoxicity (CIN)

Pancreas
- Swelling/pancreatitis

Respiratory System
- Laryngeal edema, bronchospasm
- Pulmonary edema

Salivary Glands
- Swelling/parotitis

Skin and Soft Tissue
- Pain, swelling, flushing, erythema, urticaria, pruritus
- Compartment syndrome (from extravasation)

Thyroid
- Exacerbation of thyrotoxicosis

Vascular System
- Hemorrhage
- Thrombophlebitis

Modified from American College of Radiology: *Manual on contrast media, version 6,* 2008, available at www.acr.org/SecondaryMainMenuCategories/quality_safety/contrast_manual.aspx. Accessed September 6, 2009.

during angiography. Meticulous flushing is imperative. Complement activation is believed to be a consideration in contrast reactions.

Biphasic renal flow has been described following contrast administration. This involves a transient increase in blood flow and then a longer period of decreased blood flow to the kidneys. Contrast media–induced nephrotoxicity (CIN) can occur as a result of this physiologic change. CIN is diagnosed when no other specific cause of renal decline can be noted after the administration of contrast medium. The ACR

BOX 28-7

Formulas to Estimate GFR

COCKCROFT-GAULT FORMULA:

$$\text{Creatinine clearance, male (ml/min)} = \frac{140 - \text{age} \times \text{lean body mass (kg)}}{\text{Serum creatinine (SCr) (mg/dl)} \times 72}$$

Creatinine clearance, female = CrCl (male) × 0.85

MODIFICATION OF DIET IN RENAL DISEASE (MDRD) FORMULA:

GFR (ml/min per 1.73 m^2) = 175 × SCr (mg/dl) (exp[-1.154])
× age (exp[-0.203]) × 0.742 (if female) × 1.21 (if African American)

Modified from Al-Ghonaim M, Pannu N: Prevention and treatment of contrast-induced nephropathy, *Tech Vasc Interv Radiol* 9:42-49, 2006.

(2007b) states that there is no standard definition for CIN, but others define CIN either as an acute drop in glomerular filtration rate (GFR) estimated from a rise in serum creatinine level occurring within 72 hours of contrast exposure in the absence of another renal insult (Solomon et al, 2007) or as an absolute increase in serum creatinine level (0.5 or 1.0 mg/dl), a change in serum creatinine level that is a 25% to 50% increase over the baseline level, or a decrease in the estimated GFR (Bettman, 2008).

The patient's state of hydration and the existence of any preexisting renal insufficiency affect the likelihood of CIN. Patients with normal renal function tolerate contrast administration well given certain guidelines are observed. Because serum creatinine level is affected by many factors including age, gender, muscle mass, race, nutritional status, and diet, it is not the best indicator of renal function or GFR. This is a special concern among the elderly (Detrenis et al, 2007). Serum creatinine level has been used in the past to assess renal function because of the ease of obtaining a simple blood specimen and the rapid turnaround time to obtain results. Creatinine clearance has become the best current option to assess GFR before contrast agent administration. The GFR is estimated from the serum creatinine level by use of the Cockcroft-Gault formula or the Modification of Diet in Renal Disease (MDRD) formula (Box 28-7).

The development of CIN may be influenced by the type of injection—intravenous or arterial. The list of risk factors that have been studied includes emergency procedures, preexisting renal insufficiency, dehydration, diabetes mellitus (especially those patients with preexisting renal insufficiency), cardiovascular disease (hypertension, congestive heart failure), intraprocedural hypotension, diuretic use, advanced age, hyperuricemia, concurrent use of nephrotoxic drugs (e.g., cisplatin, gentamicin, tobramycin, vancomycin, amikacin), surgery, cholesterol emboli syndrome, use of nonsteroidal anti-inflammatory drugs (NSAIDs), and administration of large volumes of contrast media. Drugs that decrease renal perfusion (e.g., angiotensin-converting enzyme inhibitors, diuretics, and NSAIDs) may contribute to the development of CIN. The most notable predictor of CIN is believed to be underlying renal insufficiency. Careful patient selection is advised before contrast medium is given. It is important to note that risk factors are additive and interactive.

The pathophysiology of CIN is not fully known. Tumlin and colleagues (2006) cite three contributing factors: vasoconstriction, oxidative stress, and direct tubular toxicity. CIN presents clinically as acute renal failure and is usually nonoliguric, but oliguria can occur. Serum creatinine level may increase from day 1 to day 7 after contrast medium is used and then return to baseline in 1 to 2 weeks. Renal dialysis is needed in rare cases only. CIN is considered a "marker" for those with overall poor outcomes (Mauro et al, 2008).

It is important to identify the at-risk patient and determine the level of risk. Alternatives to a contrast study should be considered. An unenhanced (no contrast) examination or alternative modality may be used to obtain the necessary information. Carbon dioxide may be used as an alternative to water-soluble contrast media for certain angiographic studies.

CIN preventive measures have been developed. Hydration with normal saline alone or in combination with sodium bicarbonate has been used. The antioxidant *N*-acetylcysteine (NAC) has been used. Administration of oral NAC has been recommended on the day before and on the day of the contrast media study (ACR, 2007b). Other medications (including mannitol, furosemide, theophylline, fenoldopam) have been tried in the past without conclusive results. The ACR recommends hydration as the best preventive measure against CIN. Oral hydration is recommended if appropriate for the patient; intravenous hydration is recommended before and after the procedure if oral hydration is not possible. The use of LOCM or IOCM is recommended for patients with renal insufficiency (ACR, 2007b). McCullough and Soman (2005) advocate the use of iodixanol as the preferred contrast medium for high-risk patients. Preventive dialysis is not recommended for prevention of CIN; if hypotension occurs, preventive dialysis may be detrimental (Meschi et al, 2006). Hemofiltration is only recommended for patients with chronic renal disease who need cardiovascular procedures (Marenzi et al, 2006).

Contrast Media Reactions. Reactions to contrast media can occur and the risk varies according to several patient- and contrast-related factors. A prior reaction to contrast media is the single best predictor of a subsequent reaction but this may not always be the case (Mauro et al, 2008). Reactions are categorized as mild, moderate, or severe (Box 28-8). These categories are not necessarily distinct. A significant reaction can have the appearance of a minor reaction at the onset.

BOX 28-8

Categories of Contrast Media Reactions

MILD

Signs and symptoms appear self-limited without evidence of progression, including:

- Nausea, vomiting
- Cough
- Warmth
- Headache
- Dizziness
- Shaking
- Altered taste
- Itching
- Pallor
- Flushing
- Chills
- Diaphoresis
- Rash, hives
- Nasal stuffiness
- Edema of the eyes and face
- Anxiety

Treatment: Requires observation to confirm resolution and/or lack of progression, but usually no treatment is indicated. Patient reassurance is helpful.

MODERATE

Signs and symptoms are more pronounced. Moderate degree of clinically evident focal or systemic signs or symptoms, including:

- Tachycardia/bradycardia
- Hypertension
- Generalized or diffuse erythema
- Dyspnea
- Bronchospasm, wheezing
- Laryngeal edema
- Mild hypotension

Treatment: Clinical findings in moderate reactions frequently require prompt treatment. These situations require close, careful observation for possible progression to a life-threatening event.

SEVERE

Signs and symptoms are often life-threatening, including:

- Laryngeal edema (severe or rapidly progressing)
- Unresponsiveness
- Cardiac arrest
- Convulsions
- Profound hypotension
- Clinically manifested dysrhythmias

Treatment: Requires *prompt* recognition and aggressive treatment; manifestations and treatment frequently require hospitalization.

Modified from American College of Radiology: *Manual on contrast media,* version 6, 2008, available at www.acr.org/SecondaryMainMenuCategories/quality_safety/contrast_manual.aspx. Accessed September 6, 2009.

Careful observation of the patient and early recognition and treatment intervention are imperative. The overall rate of reaction to nonionic contrast media is small. The ACR (2008) estimates the rate for serious reactions is 1 to 2 per 1000 patients. Severe reactions to contrast media are not IgE-mediated or immunologic in nature. Because of this they are described as anaphylactoid reactions. These are also referred to as idiosyncratic reactions because they are unpredictable. The clinical manifestations of an anaphylactoid reaction are the same, however, as those of an anaphylactic reaction in which there is an allergen-IgE response and release of mast cell mediators. The majority of serious reactions occur "immediately or within 20 minutes" after the contrast injection (ACR, 2008). Increased capillary permeability and constriction of bronchial smooth muscle cells are present. Facial and laryngeal edema, urticaria, bronchospasm, and hypotension may lead to a life-threatening situation if not recognized and treated promptly.

Nonidiosyncratic (sometimes referred to as chemotoxic reactions) are predictable. Reassurance may be all that is needed for the patient experiencing a vasomotor reaction. Nausea and vomiting are usually transient. If a vasovagal reaction (with symptomatic bradycardia and hypotension) occurs, simply raising the patient's legs to increase intravascular volume can be of value. The vasovagal response may be reversed with fluids and atropine if bradycardia persists.

Delayed reactions are extremely uncommon but can occur from 1 hour to several days after injection of contrast media (Brockow, 2009). Past treatment with interleukin-2 may be associated with a delayed cutaneous reaction. Iodine "mumps" and syndrome of acute polyarthropathy may be other examples of delayed reactions (ACR, 2008). Most patients recover from contrast reactions without long-term sequelae (Wang et al, 2008). All contrast reactions should be well documented and patients should be advised to inform their primary care providers and referring physicians of any problems with procedures involving contrast media (Patient and Family Education).

Careful observation and preparation to respond to an emergency situation are necessary at all times. All patients should be observed for the possibility of a contrast reaction after injection and intravenous access should remain until there is reasonable assurance that a reaction will not occur. Patients with known or suspected past reactions to contrast media may be pretreated (Box 28-9). Premedication does not guarantee that a reaction will not occur. The injection of contrast media should be discontinued at the first sign of a reaction and a quick assessment performed. Intravenous fluids to secure intravenous access should be given via tubing that does not contain residual contrast media. All personnel in the area should be knowledgeable about reactions and know their role in the treatment of reactions (Rapid Response Team box).

Contrast Media Extravasation. Extravasation occurs when contrast medium is injected into or leaks into soft tissue. It can cause tissue damage as a result of the toxicity of the agent or through pressure (e.g., compartment syndrome). The risk for

PATIENT AND FAMILY EDUCATION

Discharge Instructions for Contrast Media Injection

Always provide the patient and the caregiver *verbal* and *written* instructions. Provide them with the name and telephone number of the physician or nurse to call if questions arise.
Review the physician's explanation of postdischarge care and evaluate the patient's response to the instructions provided.

GENERAL INSTRUCTIONS AFTER INJECTION OF CONTRAST MEDIA

- Increase your fluid intake over the next 24 hours to help your kidneys pass the contrast media (x-ray dye).
- Call your physician if any of the following occur:
  - You have any worsening of the pain or symptoms you were having before the procedure.
  - The place where the contrast media was injected, or the catheter was put into your skin, begins to bleed or swell, or it becomes more painful.
  - Your arm, leg, or foot becomes cool or cold.
  - You have slurred speech, balance problems, or trouble using your arm or leg.
  - You develop a rash, itching, sweating, or trouble breathing.

INSTRUCTIONS FOR CONTRAST MEDIA REACTIONS

- Call the radiology nursing station if your symptoms do not resolve, or you develop new symptoms such as hives or a rash, itching, prolonged or frequent vomiting, chest tightness, shortness of breath, dizziness, or swelling.
- Take the medications prescribed to treat your reaction. Oral antihistamines, such as diphenhydramine (Benadryl), may make you too drowsy to drive or operate machinery safely. They can affect concentration and interfere with children's learning in school. These medications should be taken only as long as directed.
- If you do not respond to the treatment prescribed for your reaction, it is important that you see a medical professional for re-evaluation.
- Do not attempt to treat or "wait out" severe reactions at home. Go immediately to a hospital emergency department.
- If no one is available to drive you right away, call an ambulance for emergency medical transport.
- Obtain and wear a MedicAlert bracelet and carry an identification card describing your allergy.
- Inform healthcare providers about your allergy before any procedures are performed.
- Follow up with your healthcare provider to let him or her know about your reaction. At this follow-up appointment, he or she can evaluate your recovery from the reaction and adjust any medications.

INSTRUCTIONS FOR CONTRAST MEDIA EXTRAVASATION

- Keep the area elevated higher than your heart.
- Use a cold pack or warm compresses, as instructed, on the area for the next 4 hours.
- Avoid any tight-fitting clothing/jewelry near the affected site.
- Call your physician if the pain gets worse, or the swelling does not improve after 24 hours.

Modified from Canobbio MM: *Mosby's handbook on patient teaching,* ed 3, St Louis, 2006, Mosby; *Medical treatment for drug allergy,* available at www.emedicinehealth.com/drug_allergy/page8_em.htm. Accessed September 6, 2009; *Mosby's nursing consult: patient education instructions; cardiac catherization, CT scanning, intravenous pyelogram,* 2008, St Louis, Mosby.

BOX 28-9

Premedication Options for Contrast Allergy

1. Prednisone 50 mg by mouth at 13 hours, 7 hours, and 1 hour before contrast media injection, *plus* diphenhydramine (Benadryl) 50 mg intravenously, intramuscularly, or orally 1 hour before contrast medium injection.
2. Methylprednisolone (Medrol) 32 mg by mouth 12 hours and 2 hours before contrast media injection. An antihistamine (as in option 1) can also be added to this regimen.

Modified from American College of Radiology: *Manual on contrast media,* version 6, 2008, available at www.acr.org/SecondaryMainMenuCategories/quality_safety/contrast_manual.aspx. Accessed September 6, 2009.

extravasation is increased when a power injector is used or the patient has certain medical conditions (e.g., circulatory problems of an extremity, history of radiation or surgery).

Extravasation of contrast medium should be prevented by establishing a reliable peripheral injection site and assessing the site before injection of the contrast agent. Commercial extravasation detector devices are available but they should not be a substitute for patient site assessment, observation, and communication. The nurse should instruct the patient to report any burning, stinging, or tight feeling that occurs with the injection of the contrast agent, and if complaints occur they should be investigated. The patient may not be aware of the occurrence of an extravasation or may not be able to report symptoms; examples of such patient populations include infants or young pediatric patients, patients with limited mental ability, or patients with a decreased level of consciousness (e.g., from sedation or medical condition) or inability to communicate. Extravasation may appear as "blush" when intraarterial images are taken, as in the example of a diagnostic study for gastrointestinal bleeding.

An extravasation should be brought to the attention of the radiologist immediately after it occurs. Treatment is based on the nature of the extravasation. Close follow-up is indicated for any extravasation because the initial evaluation may not reveal the extent of the problem (ACR, 2008). Treatment options are per the radiologist's preference, with limb elevation and warm or cold compress application being the most frequently used therapies. Surgical consultation is advised for significant

RAPID RESPONSE TEAM

Contrast media reactions represent an area where quick recognition of the problem and rapid intervention can prevent escalation of a serious condition. Perioperative nurses working in the IR setting must be familiar with the signs and symptoms of a contrast media reaction so they can respond rapidly to the situation. The information below outlines the steps to take in managing contrast media reactions in adults and children.

Symptom	Adult Management	Pediatric Management
Urticaria	1. Discontinue injection if not completed. 2. No treatment needed in most cases. 3. Give H_1-receptor blocker: diphenhydramine PO/IM/IV 25-50 mg. *If severe, or widely disseminated, give alpha agonist: epinephrine SubQ (1:1000) 0.1-0.3 ml (=0.1-0.3 mg) if no cardiac contraindications.*	1. No treatment needed in most cases. 2. Give H_1-receptor blocker: diphenhydramine PO/IM/IV 1-2 mg/kg up to 50 mg. *If severe, or widely disseminated, give alpha agonist: epinephrine SubQ (1:1000) 0.01 ml/kg.*
Facial or laryngeal edema	1. Give O_2 6-10 L/min (via mask). 2. Give alpha agonist: epinephrine SubQ (1:1000) 0.1-0.3 ml (=0.1-0.3 mg) or, especially if hypotension evident, epinephrine (1:10,000) slowly IV 1-3 ml (=0.1-0.3 mg). Repeat as needed up to a maximum of 1 mg. *If not responsive to therapy or if there is obvious acute laryngeal edema, seek appropriate assistance (e.g., rapid response or code team).*	1. Give O_2 6-10 L/min (via mask, face tent, or blow-by stream). Monitor ECG, O_2 saturation, and blood pressure. 2. Give alpha agonist: epinephrine SubQ or IM (1:1000) 0.01 ml/kg, up to 0.3 ml/dose. Repeat in 3-5 min as needed. 3. Give H_1-receptor blocker: diphenhydramine IM/IV 1-2 mg/kg, up to 50 mg. 4. Give beta-agonist inhalers (metaproterenol, terbutaline, albuterol) 2-3 puffs; repeat as necessary.
Bronchospasm	1. Give O_2 6-10 L/min (via mask). Monitor ECG, O_2 saturation, and blood pressure. 2. Give beta-agonist inhalers (metaproterenol, terbutaline, albuterol) 2-3 puffs; repeat as necessary. If unresponsive to inhalers, use SubQ, IM, or IV epinephrine. 3. Give epinephrine SubQ or IM (1:1000) 0.1-0.3 ml (=0.1-0.3 mg); or especially if hypotension evident, epinephrine (1:10,000) slowly IV 1-3 ml (=0.1-0.3 mg). Repeat as needed up to maximum of 1 mg. *Seek appropriate assistance (e.g., rapid response or code team) for severe bronchospasm, or if O_2 saturation <88% persists.*	Same as treatment for laryngeal edema.
Hypotension with tachycardia	1. Elevate legs 60 degrees or more (preferred) or place in Trendelenburg's position. 2. Monitor ECG, O_2 saturation, and blood pressure. 3. Give O_2 6-10 L/min (via mask). 4. Rapidly infuse large volumes of Ringer's lactate or normal saline. *If poorly responsive, give epinephrine (1:10,000) slowly IV 1 ml (=0.1 mg). Repeat as needed up to maximum of 1 mg. If still poorly responsive, seek appropriate assistance (e.g., rapid response or code team).*	1. Give O_2 6-10 L/min via mask. Monitor ECG, O_2 saturation, and blood pressure. 2. Elevate legs 60 degrees or more (preferred) or place in Trendelenburg's position. 3. Keep patient warm. 4. Give IV or IO normal saline or Ringer's lactate 20 ml/kg over 5-10 min. Bolus infusion over 10-20 min in patients with myocardial dysfunction. *Seek appropriate assistance (e.g., rapid response or code team).*
Hypotension with bradycardia (vagal reaction)	1. Elevate legs 60 degrees or more (preferred) or place in Trendelenburg's position. 2. Give O_2 6-10 L via mask. Monitor ECG, O_2 saturation and blood pressure. 3. Rapid IV administration of large volumes of Ringer's lactate or normal saline. 4. If patient does not respond, give atropine 0.6-1 mg IV slowly. Repeat up to a total dose of 0.04 mg/kg. 5. Seek appropriate assistance (e.g., rapid response team or code team)	1. Give O_2 6-10 L/min via mask. Monitor ECG, O_2 saturation, and blood pressure. 2. Elevate legs 60 degrees or more (preferred) or place in Trendelenburg's position. 3. Keep patient warm. 4. Give IV or IO normal saline or Ringer's lactate 20 ml/kg over 5-10 min. Bolus infusion over 10-20 min in patients with myocardial dysfunction. 5. Give atropine IV 0.02 mg/kg if patient does not respond quickly to steps 2-4. Minimum initial dose of 0.1 mg. Maximum initial dose of 0.5 mg (infant/child) or 1.0 mg (adolescent). 6. Atropine dose may be doubled for second administration. *Seek appropriate assistance (e.g., rapid response or code team).*

IM, Intramuscular; *IO,* intraosseous; *IV,* intravenous; *PO,* orally; *SubQ,* subcutaneous.

Modified from American College of Radiology: *Manual on contrast media,* version 6, 2008, available at www.acr.org/SecondaryMainMenuCategories/quality_safety/contrast_manual.aspx. Accessed September 6, 2009.

extravasations. Compartment syndrome can develop following severe reactions and requires immediate management.

UNIVERSAL PROTOCOL AND STANDARD PRECAUTIONS. The nurse is often the person responsible for ensuring that the *Universal Protocol for Preventing Wrong Site, Wrong Procedure, Wrong Person Surgery* is observed in the procedure areas. The "Time Out" must involve the whole team and be done just before the procedure is initiated. Special positioning for the radiology procedure and multiple procedures involving position changes may become sources of confusion so vigilance is advised.

Personal protective equipment should be worn according to facility policy and procedure. All standard Universal Precautions and infection control measures should be observed in the procedure area. If the patient has recently undergone a nuclear medicine scan, the half-life of the isotope tracer should be known. It may be necessary to dispose of contaminated drapes and supplies per nuclear medicine disposal policies.

POSITIONING. The patient's position on the procedure table will be determined by the type of procedure to be performed. It is important that the patient is transferred safely onto the procedure bed and that a reasonably comfortable position is arranged. The nurse pads all bony prominences and places pillows to relieve pressure points. For procedures such as nephrostomy tube placement or kyphoplasty, the patient will be positioned prone. The prone position may be difficult for elderly or acutely ill patients to achieve without assistance. Care should be taken to assist the patient and not to rush because injuries to skin or joints or intravenous displacement can occur. Care should also be taken so that tension is not placed on any existing drainage tubes. Ostomy bags may need to be emptied before placing the patient in a prone position. All sponges, wedge pillows, or other devices that are used for positioning should be kept out of the field of view for imaging. It is important to ask the patient if the position will be comfortable to maintain for the length of the procedure. Assure the patient that sedation and analgesia will be given, if that is the case, after appropriate positioning and placement of monitors. The nurse carefully plans the placement of the monitoring equipment and connecting cables so they will not interfere with the imaging area of interest. For example, when lateral abdominal filming is anticipated the right leg electrocardiogram lead and cable will need to be out of view. Placement of monitoring equipment should not interfere with the best possible access to the patient for monitoring or emergency reasons. If the electrosurgical unit is to be used, the nurse places the grounding pad in an area that will not be in the field of view. Equipment used for physiologic monitoring and resuscitation of the patient in the magnetic resonance imaging setting must be MRI compatible.

PROCEDURES. Interventional procedures fall into several categories (Box 28-10), but most are initiated with the Seldinger technique. This technique, developed in 1953 by the Swedish radiologist Dr. Sven-Ivar Seldinger, involves a guidewire (leader) fed through a puncture needle (Figure 28-5). The Seldinger technique changed interventional radiology because it provided a less invasive and safer means of access to vessels. After sterile preparation and draping, a local anesthetic is administered over the intended entry site, usually the groin for an angiogram that uses the retrograde femoral artery approach. A small dermatomy is made just before the puncture. A needle (Seldinger 18-gauge, 2¾-inch or other) with stylet is used to gain vascular access and then the stylet is removed. A pulsatile backflow of blood will be noted with arterial access. A guidewire is advanced, after which the needle is removed while the vessel is compressed. A sheath can then be placed over the guidewire and a catheter can be advanced. The guidewire is then removed.

A puncture can be either a single-wall puncture or a double-wall vessel puncture. For vascular access the location of the puncture is crucial. In the case of groin access, the femoral artery puncture is made over the middle third of the femoral head well below the inguinal ligament. The femoral head helps with compression of the artery after access is removed. Punctures that are too high (above the inguinal ligament) can result in bleeding after access is discontinued. Low arterial punctures have been associated with pseudoaneurysm formation. Fluoroscopy over the femoral head helps to confirm the location of access. Obesity may make identification of anatomic landmarks difficult; in these patients a portable Doppler may be useful. Doppler is also helpful when the patient's pulse is not easily palpable. A high brachial artery puncture or axillary artery puncture may be done if femoral artery puncture is not possible or desired. The presence of radial and ulnar pulses and their quality should be documented before the procedure, similarly to documentation for distal extremity pulses for a femoral artery puncture. A translumbar puncture is rarely used. Hemorrhage, distal embolization, and pseudoaneurysm development are potential complications of an arterial puncture.

The Seldinger technique may also be used during other interventional procedures such as a percutaneous abscess drainage procedure, percutaneous nephrostomy, or chest tube placement.

Biopsy specimens obtained during procedures should be labeled per institutional policy and protocols. Specimen preparation, requirements for fixative additives, and handling should be done in accordance with established policy and procedures. A cytology technologist may be requested to be present during the procedure to determine if adequate tissue has been obtained.

Evaluation. During the evaluation phase of care the nurse determines if the outcomes established for the patient were met and revises outcomes and interventions as necessary. The evaluation period provides opportunities to improve nursing interventions through careful reflection and analysis of outcomes. The following are possible evaluation statements relating to the Sample Plan of Care (see p. 1221):

- The patient verbalized an acceptable level of pain as defined with a 1 to 10 pain scale.
- The patient demonstrated a decreased level of anxiety, verbalized less apprehension, maintained eye contact, and was able to comply with requests even though anxiety persisted.
- The patient verbalized understanding of the procedure and described the actions to take after discharge.
- The patient's airway was maintained and oxygen saturation was within preprocedure baseline limits.
- The patient's vital signs were within acceptable limits, peripheral pulses returned to baseline, and there was no evidence of excessive bleeding.
- The patient's skin was intact with no reddened areas or lesions.

BOX 28-10

Types of Interventional Procedures

ARTERIAL DIAGNOSTIC AND THERAPEUTIC PROCEDURES
- Arteriography for diagnostic or therapeutic purpose
- Aortoiliac interventions (stent placements), angioplasty
- Carotid interventions
- Endovascular repair (peripheral to abdominal aortic aneurysm (AAA) repair, arterial)
- Embolotherapy (for perioperative planning, trauma, other)
- Thrombolytic therapy for arterial disease
- Stroke intervention
- Peripheral interventions
- Renovascular disease interventions
- Neurointerventional disease management (cerebral aneurysm, arteriovenous malformations)

VENOUS DIAGNOSTIC AND THERAPEUTIC PROCEDURES
- Venous access placement (portacath, triple-lumen catheters, midline catheters, peripherally inserted central catheters)
- Venous reflux and varicose vein management
- Hemodialysis access and catheter maintenance
- Portal hypertension management (TIPS)
- Inferior vena caval filter placement (permanent and temporary) and removal
- Thrombolytic therapy
- Venous sampling (e.g., parathyroid, adrenal, renal vein)
- Retrieval of foreign body

NONVASCULAR DIAGNOSTIC AND THERAPEUTIC PROCEDURES
- Abscess drainage or seroma tube placement
- Chest tube placement
- Percutaneous gastrostomy tube (G-tube) or gastrojejunostomy tube (GJ-tube) placement
- Percutaneous jejunostomy feeding tube (J-tube) placement
- Cecostomy tube placement
- Gastrointestinal stent placement
- Percutaneous biliary tube placement
- Percutaneous nephrostomy tube placement
- Ureteral stent placement
- Percutaneous nephrolithotomy
- Varicocele interventions
- Lacrimal procedures (balloon dilation, stent placement, stone removal)
- Biopsies of solid organs (e.g., liver, kidney, prostate, bone, lung, or breast)

BONE AND SPINAL DIAGNOSTIC AND THERAPEUTIC PROCEDURES
- Myelograms
- Diskograms
- Lumbar punctures (for pressure measurement, spinal fluid collection, or isotope injection)
- Vertebral augmentation procedures (vertebroplasty, kyphoplasty)
- Selective nerve blocks
- Facet injections
- Stellate ganglion blocks
- Epidural steroid injection
- Periradicular therapy

GYNECOLOGIC PROCEDURES
- Uterine artery embolization
- Uterine fibroid embolization
- Fallopian tube cannulation
- Pelvic congestion intervention

ONCOLOGY PROCEDURES

Embolotherapy
- Chemoembolization of the liver
- Transarterial placement of yttrium-90 microspheres (90Y)
- Tumor ablation with radiofrequency (RFA)/thermal, cryotherapy, other
- Brachytherapy delivery

MISCELLANEOUS OTHER PROCEDURES
- Botox® therapeutic use (for psoas spasm or piriformis syndrome), or for cosmetic reasons
- Trauma interventions
- Pleurodesis
- Paracentesis
- Thoracentesis

At the conclusion of an angiographic procedure the nurse may be involved in ensuring hemostasis of the puncture site and applying dressings. Hemostasis is obtained by manual pressure, compression devices, vascular closure suture, or collagen plug. Additional medication for analgesia, administered either locally or intravenously, may be needed before manual or compression device hemostasis. The time the catheter and/or sheath are removed should be noted. Compression should be firm but should not obliterate the distal pulses. In addition to vital signs, distal pulses should be assessed during this period. A loss of pulse could indicate distal embolism or vascular spasm, and the radiologist should be notified immediately. The color and temperature and neurosensory status of the extremity should be observed. The nurse should also monitor the patient for signs of hematoma formation at the puncture site or retroperitoneal hemorrhage. Manual pressure should be applied if hemorrhage and hematoma formation are suspected. After hemostasis is achieved, the affected extremity should be kept still for a length of time, as determined by the type of closure performed. Any signs or symptoms of stroke should be reported immediately. Pseudoaneurysm formation, nerve damage, and infection, although rare, can occur after arterial puncture.

The patient will be transported to a recovery area and monitored according to the amount of sedation and analgesia received, pain level, vital signs, and other discharge assessment criteria per the specific procedure and postanesthesia recovery room criteria. The type of interventional procedure performed will determine other variables that will be monitored, including distal pulses for angiography; neurologic, motor, and sensory signs for the lower extremities after vertebroplasty; or urine output following nephrostomy. Patients who have undergone biopsies should be monitored for signs of bleeding. After lung biopsy blood-tinged sputum may be present. Hemoptysis or signs of pneumothorax should be reported immediately. Patients who have undergone liver biopsy may complain of pain radiating to the shoulder.

The inpatient can be transferred according to facility policy, usually when vital signs are stable and pain has been managed. Neurointerventional procedure patients may be transferred to an intensive care setting after the procedure.

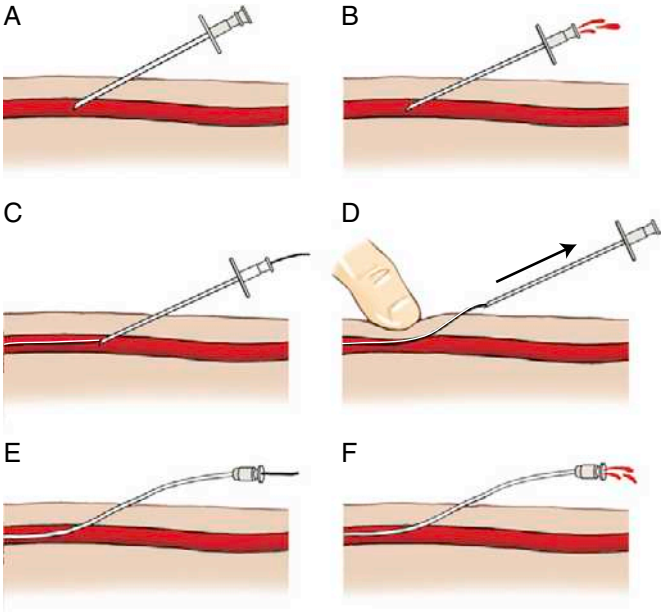

FIGURE 28-5 Seldinger technique. **A**, Insertion of needle. **B**, Placement of needle in lumen of vessel (inner cannula removed). **C**, Insertion of guidewire. **D**, Removal of needle (guidewire remains in place). **E**, Threading of catheter over guidewire. **F**, Removal of guidewire.

Outpatients will need to meet criteria similar to those for other surgical procedures per facility policy (Ambulatory Surgery Considerations). Discharge instruction forms should be procedure specific. Items to be included in the discharge instructions are activity restrictions, possible complications and when/who to call for help, diet, medications, specific care related to procedure, driving restrictions, signs of infection, and follow-up care plan/appointment. Patients who have had arterial punctures should be given precise instructions on actions to take in case of hemorrhage or other puncture site complication. Patient and family teaching with return demonstrations for procedures such as tube care should be done. Instructions regarding care of drainage bags and required flushing of tubes are essential. Sterile technique demonstration is critical in many instances, including PICC line care. Teaching videos, patient information booklets developed by a device's manufacturer, and facility-developed handouts will be useful in patient teaching. A uniform postprocedure phone call form will prompt the nurse to ask the appropriate questions. Postprocedure phone calls for outpatients are made the day after the procedure when possible or as soon thereafter per policy and procedure. These calls generate information not only about outcomes and possible complications but also about the patient's perceived satisfaction with the procedure and nursing care provided. This information will be useful for performance improvement data collection for outpatient nursing care.

Some outpatient procedures may require a 23-hour observation stay as a result of pain, unforeseen procedure events, or changes in the patient's condition. A planned 23-hour stay may be arranged in advance. For example, the patient may be hospitalized for symptoms of postembolization syndrome, which occurs after the blood supply is interrupted to an organ, as expected in the case of uterine fibroid embolization. Pain, nausea (and possible vomiting), fever, and an increased white cell count are expected signs and symptoms. The nursing report should include information about the procedure, all procedure-specific instructions, and information about possible equipment needed, such as wall suction after chest tube placement. Documentation of the entire procedure and reports should be completed per facility policy.

AMBULATORY SURGERY CONSIDERATIONS

Discharge Assessment/Summary

- Physician order to discharge patient has been provided.
- Patient has stable vital signs (resembling baseline vital signs), including Spo_2 level.
- Patient shows no evidence of respiratory depression.
- Patient is oriented per baseline to person, place, and time.
- Patient can take fluids, if appropriate, without nausea.
- Patient can void, if a procedure-specific criterion.
- Patient can ambulate with/without assistance as appropriate, and has no dizziness.
- Pain has been addressed/managed.
- Bleeding is not present; drainage is per procedure expectation.
- Written discharge instructions including medication reconciliation with phone number to call have been given to patient. (Patients are informed how to obtain necessary supplies, if applicable.)
- A responsible person is available to escort patient to home/stay with patient.

CHAPTER 29

Integrated Health Practices: Complementary and Alternative Therapies

SUSAN M. CRAIG

HISTORY AND BACKGROUND

Any accurate presentation of the history of medicine in the United States needs to include influences from the botanic cultural traditions of Asia, India, Europe, and the First Nations. Our current medical system, called *biomedicine,* began to dominate sometime in the mid-1800s with the discovery that microorganisms were responsible for disease and pathologic damage and that antitoxins and vaccines could improve the body's ability to oppose the effects of pathogens. Armed with this knowledge, scientists and clinicians began to refine surgical procedures and treat previously serious and fatal infections.

As biomedicine dominated the healthcare system, it became the mainstream or "conventional" approach, establishing the standards for diagnosis and treatment of illness. By the 1990s, however, consumer faith and trust in this conventional system began to falter and many Americans sought complementary or alternative treatments for their healthcare. Complementary and alternative medicine (CAM) has grown to constitute a significant percentage of American healthcare dollars and visits. This growth is sustained by the trend for patients to be more empowered healthcare consumers and the availability of media information about the many alternatives to the mainstream, traditional Western biomedical approach to medicine.

Myths and misconceptions initially prevented the investigation and development of promising therapies outside the biomedical regimen. In response to growing consumer pressure, anecdotal evidence, and a small body of published scientific results, the U.S. Congress established the Office of Alternative Medicine (OAM) within the office of the Director, National Institutes of Health (NIH), in 1992. This office was given responsibility for (1) facilitating fair, scientific evaluation of alternative therapies that showed promise in health promotion and (2) reducing barriers to the acceptance and utilization of those alternative therapies that showed promise.

In 1998 the OAM became the National Center for Complementary and Alternative Medicine (NCCAM, 2009a). This expansion into a center allowed more substantial funding for and initiation of research projects, providing more sound information about CAM therapies and systems. The annual budget for NCCAM has grown significantly, as has the sophistication of research designs of studies being funded by the center. The NCCAM adheres to guidelines set forth in public policy as noted in Box 29-1.

Many CAM therapies and interventions stem from a philosophy of wholeness, with intent to treat the entire person (body-mind-spirit) (Evidence for Practice). This is in contrast to the current "gold standard" of randomized, control-led clinical trials, which may not be the best, or indeed appropriate, way to measure the effectiveness of many CAM therapies. Conventional scientists and physicians and the proponents of CAM often debate about the appropriate forms of research to determine efficacy and safety of alternate therapies. A reason for this disparity stems from divergent theoretic models. The *comprehensive approach* takes into account multidimensional factors that may not easily or appropriately be studied independently. The comprehensive approach is more congruent with the philosophic underpinnings of most CAM. The *biomedical approach,* on the other hand, is concerned with a disease orientation, suggesting that a specific agent or variable is responsible for a specific disorder or illness.

The NCCAM has categorized the many CAM modalities into five major domains: alternative medical systems, mind-body interventions, biologically based therapies, manipulative and body-based methods, and energy therapies. Numerous treatments and systems are within each category. The remainder of this chapter discusses the major domains and provides examples of each.

MAJOR CATEGORIES OF COMPLEMENTARY AND ALTERNATIVE MEDICINE

Alternative Medical Systems

An estimated 10% to 30% of human healthcare is delivered by practitioners such as surgeons and nurses who have been trained in the mainstream, traditional Western biomedical model. The remaining 70% to 90% involves care given in a healthcare system that is based on alternative traditions—self-care based in folk practice or many practices that range somewhere between alternative and traditional healthcare. Many of these therapies are culturally, ethnically, spiritually, or religiously derived (Figure 29-1). Among the diverse values, beliefs, and practices found in the many cultural groups in the

EVIDENCE FOR PRACTICE

Evaluating Complementary and Alternative Medicine Therapies

In a recent survey of 31,000 Americans, the Centers for Disease Control and Prevention (CDC) estimated that 36% use some form of complementary and alternative medicine (CAM). In discussing the use of CAM with perioperative patients, nurses have a unique opportunity to advise patients on best practices to adopt when considering the use of CAM therapies. Nurses should include the following advice when counseling patients about choosing CAM therapies:

- Take charge of your health by being an informed consumer. Investigate the therapy to determine what studies have been done on its safety and effectiveness.
- The internet is a good source to find information about CAM. In evaluating information on the internet you should always ask the following questions:
  - Who runs the web site? Is it a government, university, or reputable medical or health-related association? Is it sponsored by a manufacturer of products, drugs, and so on? It should be easy to clearly identify the sponsor.
  - What is the purpose of the site? Is it to educate the public or sell a product? The purpose should be clearly stated.
  - What is the basis of the information? Is it based on scientific evidence with clear references?
  - How current is the information? Is it reviewed and updated frequently?
- If you do not have access to the internet, contact the NCCAM Clearinghouse at 1-888-644-6226 for assistance.
- Visit your local library or medical library to search for scientific information about CAM.
- Discuss CAM with your healthcare provider before making any decision about care. Ask questions about any possible interactions with medications you currently take or therapy you are undergoing. If your physician cannot answer your questions, he or she may be able to refer you to someone who can.
- Before taking herbal supplements:
  - Talk to your physician before starting to take herbal supplements.
  - Talk to a licensed pharmacist if you have questions about the supplement, and discuss any potential reactions with any prescription or nonprescription medications (over-the-counter [OTC] medications) you currently take.
  - Read labels carefully. Buy only supplements that are approved by the American Botanicals Council's Commission E.
  - Buy products from a reputable herbal company. Be cautious about products for sale through magazines, TV, radio, or the internet.

Modified from *Are you considering using complementary and alternative medicine (CAM),* available at http://nccam.nih.gov/health/decisions/consideringcam.htm. Accessed June 9, 2009.

United States are those relating to health, illness, professional healthcare, and folk healthcare (Box 29-2). They include well-known and respected Asian systems of medicine. Many Asian medicine techniques or systems are widely known here in the United States. The most well-known and popular of these include herbal medicines, massage, energy therapy, acupressure, acupuncture, and qi gong. This alternative medicine system has a wide range of applications from health promotion to the treatment of illness. A significant aspect of Asian medicine is an emphasis on diagnosing and treating disturbances of *qi* (pronounced "chee"), or vital energy, and restoring its proper balance (Micozzi, 2006).

Ayurveda is a traditional system from India that strives to restore the innate harmony of the individual while placing equal emphasis on body, mind, and spirit. Ayurvedic practitioners use many products and techniques to cleanse the body and restore balance. Key foundations are universal connectedness (e.g., that all living and nonliving things are joined together; health will be good if one's mind and body are in harmony; disease arises when a person is out of harmony with the universe); the body's constitution or *prakriti (e.g., the person's unique physical and psychologic characteristics and how the person functions to maintain health); and life forces or doshas.* Each person has a combination of three doshas; each dosha has a particular relationship with a bodily function and can be upset for a variety of reasons. Treatment is tailored to each person's constitution and predominant dosha. Practitioners expect patients to be active participants because many ayurvedic treatments require changes in diet, lifestyle, and habits (NCCAM, 2009b).

Native American, Middle Eastern, Tibetan, Central and South American, and African cultures have developed other traditional medical systems (Micozzi, 2006). Other examples of complete alternative medicine systems are naturopathic and homeopathic medicine systems. Homeopathic medicine is based on the principle that "like cures like" (i.e., a substance that in large doses produces the symptoms of a disease will in a very diluted dose cure the patient). Small doses of plant extracts and minerals specially prepared are given to stimulate the body's defense mechanisms and encourage healing processes. A careful evaluation of symptoms enables the practitioner to determine a patient's specific sensitivity and to select the appropriate remedy.

Naturopathic medicine emphasizes health restoration as well as disease treatment based on the belief that disease is a manifestation of alterations in the body's natural healing processes. Naturopathic physicians use multiple modalities, including clinical nutrition and diet; acupuncture; herbal medicine; homeopathy; spinal and soft tissue manipulation; physical therapies involving ultrasound, light, and electric currents; therapeutic counseling; and pharmacology (Pizzorno and Snider, 2006).

Mind-Body Interventions

A growing scientific movement has explored the mind's ability to affect the body. The clinical application of this relationship is categorized as *mind-body medicine.* Some mind-body interventions (e.g., behavioral-cognitive therapy), formerly categorized as CAM therapies, have been assimilated into conventional mainstream medicine. Progressive relaxation techniques, biofeedback, meditation, and cognitive-behavioral approaches have a well-documented theoretic basis with supporting scientific evidence. Other mind-body interventions still considered CAM include hypnosis, music, dance, art therapy, prayer, and mental healing.

Biologically Based Therapies

The CAM category of biologically based therapies includes biologically based and natural-based practices, products, and interventions, some of which overlap with mainstream

BOX 29-1

Ten Guiding Principles for Legislative and Administrative Recommendations

Following are 10 guiding principles from the White House Commission on Complementary and Alternative Medicine Policy (WHCCAMP) for legislative and administrative recommendations that will ensure public policy maximizes the potential benefits of complementary and alternative medicine (CAM) to all citizens.

EXECUTIVE SUMMARY

The WHCCAMP was established by Executive Order No. 13147 in March 2000. The order states that the commission is to provide the President, through the Secretary of Health and Human Services, with a report containing legislative and administrative recommendations that will ensure public policy maximizes the potential benefits of CAM to all citizens. The report of the commission is to address the following:

- The coordination of research to increase knowledge about CAM products
- The education and training of healthcare practitioners in CAM
- The provision of reliable and useful information about CAM practices and products to healthcare professionals
- Guidance regarding appropriate access to and delivery of CAM

The commission's 20 presidentially appointed members represented an array of healthcare interests, professional backgrounds, and knowledge. Healthcare expertise was provided by both conventional and CAM practitioners.

Based on its mission and responsibilities, the commission endorsed the following 10 guiding principles to shape the process of making recommendations and to focus the recommendations themselves:

1. *A wholeness orientation in healthcare delivery.* Health involves all aspects of life—mind, body, spirit, and environment—and high-quality healthcare must support care of the whole person.
2. *Evidence of safety and efficacy.* The commission is committed to promoting the use of science and appropriate scientific methods to help identify safe and effective CAM services and products and to generate evidence that will protect and promote the public health.
3. *The healing capacity of the person.* People have a remarkable capacity for recovery and self-healing, and a major focus of healthcare is to support and promote this capacity.
4. *Respect for individuality.* Each person is unique and has the right to healthcare that is appropriately responsive to him or her, respecting preferences and preserving dignity.
5. *The right to choose treatment.* Each person has the right to choose freely among safe and effective care or approaches, as well as among qualified practitioners who are accountable for their claims and actions and responsive to the person's needs.
6. *An emphasis on health promotion and self-care.* Good healthcare emphasizes self-care and early intervention for maintaining and promoting health.
7. *Partnerships as essential to integrated healthcare.* Good healthcare requires teamwork among patients, healthcare practitioners (conventional and CAM), and researchers committed to creating optimal healing environments and to respecting the diversity of all healthcare traditions.
8. *Education as a fundamental healthcare service.* Education about prevention, healthy life-styles, and the power of self-healing should be made an integral part of the curricula of all healthcare professionals and should be made available to the public of all ages.
9. *Dissemination of comprehensive and timely information.* The quality of healthcare can be enhanced by promoting efforts that thoroughly and thoughtfully examine the evidence on which CAM systems, practices, and products are based and make this evidence widely, rapidly, and easily available.
10. *Integral public involvement.* The input of informed consumers and other members of the public must be incorporated in setting priorities for healthcare and healthcare research and in reaching policy decisions, including those related to CAM, within the public and private sectors.

CAM is a heterogeneous group of medical, healthcare, and healing systems other than those intrinsic to mainstream healthcare in the United States. Although "complementary and alternative medicine" is the term used in this report, the commission recognizes that the term does not fully capture all the diversity with which these systems, practices, and products are being used by consumers, CAM practitioners, and mainstream healthcare institutions.

From the White House Commission on Complementary and Alternative Medicine Policy: *Executive summary,* available at www.whccamp.hhs.gov/es.html. Accessed June 6, 2009.

medicine's use of dietary supplements. Herbal, orthomolecular, individual biologic therapies and special dietary treatments are encompassed in biologically based therapies.

Herbs are plants or parts of plants that contain and produce chemical substances that act on the body (Figure 29-2). Some diet therapies are believed to promote health and prevent and/or control health. Proponents of diet therapies include religious factions such as Seventh Day Adventist, or Jewish Kosher. Veganism, vegetarianism, raw food diets, and diets promoted by Drs. Atkins, Pritikin, and Weil are other examples of therapeutic nutrition. Orthomolecular therapies use differing concentrations of chemicals or megadoses of vitamins aimed at treating disease. Many biologic therapies are available that are not currently accepted by mainstream medicine, such as the use of cartilage products from cattle, sheep, or sharks for treatment of cancer and arthritis or the use of bee pollen to treat autoimmune and inflammatory diseases.

Manipulative and Body-Based Methods

Methods that are based on the movement or manipulation of the body include chiropractic, osteopathy, and massage. Touch and manipulations with the hands have been used in healing and medical practice since the beginning of the history of medicine. At one time, the physician's hands were considered the most important diagnostic and therapeutic tool. This remains true today, despite sophisticated diagnostic equipment and modalities (Box 29-3). Manual healing methods are based on the principle that dysfunction of a part of the body often affects secondarily the function of other discrete, possibly indirectly connected body parts. Theories have developed for correction of these secondary dysfunctions by realigning body parts or manipulating soft tissues. Chiropractic science is concerned primarily with the relationship between structure (spine primarily) and function (nervous system primarily) of

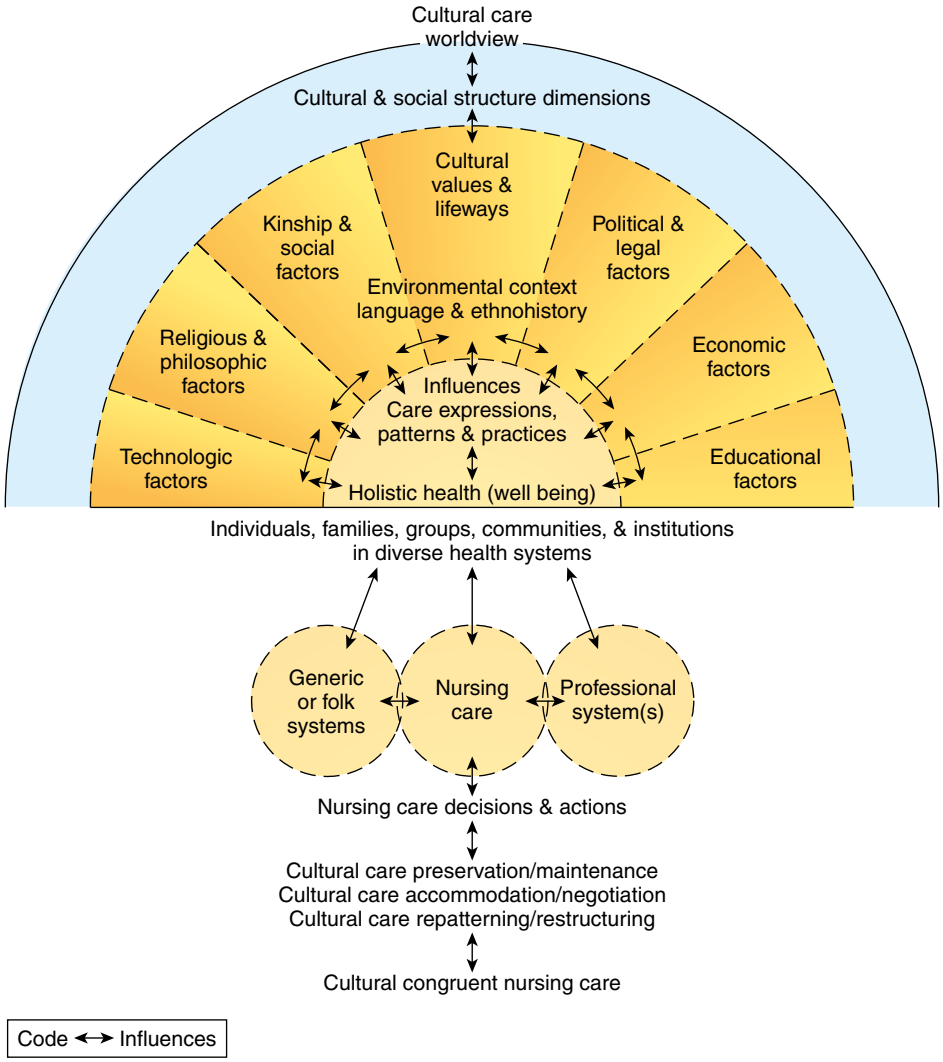

FIGURE 29-1 The Leininger Sunrise Model. From a holistic, worldview stance, the Sunrise Model serves as a map depicting the cultural, social, and environmental dimensions affecting individuals, families, communities, and institutions.

the human body to preserve and restore health. Osteopathic medicine incorporates an extensive body of work that supports the use of osteopathic techniques for both musculoskeletal and nonmusculoskeletal problems. Massage therapy is one of the oldest methods known in the practice of healthcare. Many different massage techniques are aimed at helping the body heal itself through the use of manipulation of the soft body tissues.

Energy Therapies

Energy therapies have been categorized into two groups: biofield therapies (those that focus on fields believed to originate within the body) and electromagnetic fields (those that originate from other sources). The existence of energy fields that originate within and around the body has not yet been definitively proven. However, many studies have examined the experiences of recipient or practitioner and the outcomes of this type of energy therapy. Examples of therapies with a biofield basis include acupuncture, reiki, qi gong, therapeutic touch (TT), and healing touch. Therapies that involve electromagnetic fields use unconventional pulsed fields, magnetic fields, alternating current fields, or direct current fields. These therapies have been clinically applied with patients who have arthritis, cancer, and pain (Kolthan, 2009).

COMPLEMENTARY AND ALTERNATIVE MEDICINE USE AND SURGERY

Energy Therapies

Patients have choices in how to manage their healthcare. However, surgery is the most invasive of all options (History box). As healthcare consumers become more knowledgeable about their health they may seek complementary modalities to augment traditional Western medical therapies. To use the term *alternative* is actually misleading. Many progressive medical facilities embrace a holistic patient focus, exploring and integrating nontraditional healing modalities to support an individualized surgical experience. Biofield therapies represent a nonpharmacologic anxiolytic for surgical patients that may be integrated with an allopathic treatment plan.

HISTORY

The Historical Basis for Complementary Therapies in Nursing

The philosophical basis for complementary therapies has been present since the inception of nursing as a profession. Florence Nightingale emphasized the need to create a supportive environment to foster healing and advocated the use of music in the healing process. The medical condition of a patient has always been just as important as the "rest" of the patient as nurses strive to address emotional needs and individual patient concerns. In this excerpt from a 1918 textbook, the following recommendations are provided for preparing the surgical patient:

> The general preparation of the patient begins from the time that the surgical condition is recognized. Patients should be treated in such a manner as to maintain, and indeed increase, their confidence in a successful solution of their trouble. Anything tending toward discouragement should be obviated. As a rule, the nearer the individual's normal manner of living is imitated, the more satisfactory the result. If the patient is not ill enough to be confined to bed it is well for him to walk about, read, go to the toilet, take his own bath, and at the time set for the operation walk to the OR. By so doing not only is the patient's mind kept active but especially in hospital work a not inconsiderable amount of nurse's time saved. Nervous patients should be insured a good rest the night prior to the operation by the administration of a sedative, preferably a combination of the bromids. Any concomitant disease should receive appropriate treatment.

Modified from Fowler RS: *The operating room and the patient—a manual of pre- and post-operative treatment,* Philadelphia, 1918, Saunders; Snyder M, Lindquist R: An overview of complimentary/alternative therapies. In Snyder M, Lindquist R, editors: *Complimentary and alternative therapies in nursing,* ed 5, New York, 2006, Springer.

Many ancient cultures refer to a human biofield (Table 29-1) or "life force." Sometimes referred to as "energy work," biofield therapeutics are a range of interventions sharing common beliefs. First is the existence of a "universal force" or "healing energy" arising from God (as the person understands this being), the cosmos, the earth, or another supernatural source. Second, the human biofield, as part of the "universal field," is dynamic, open, complex, and pandimensional. Human biofields are constantly changing, interacting with each other, the environment, and the universal force field. Third, the ability to use one's biofield for healing is considered to be universal, although few people are aware of it without specific training. Last, practitioners intend to positively affect the patient's biofield, either by direct contact or by using the hands in proximity, similar to the ancient practice of "laying on of hands" (Keegan and Shames, 2005) (Table 29-2).

Therapeutic Touch (TT). TT is the contemporary interpretation of several ancient healing modalities. Dolores Krieger and Dora Kunz developed TT in the early 1970s. The practice, like others that form part of the body of CAM, consists of learned skills for the conscious manipulation of human energies. In practice it is not necessary for the practitioner (healer) to actually touch the recipient (healee), because the energy field can be "felt" several inches away from the physical body. TT describes a process of healing with clear definitions of the required skills and knowledge for successful practice. Explanations of the assumptions, the concepts, and the background of the practice, based on Keegan and Shames (2005), follow.

ASSUMPTIONS

- *A human being is an open energy system.* This assumption implies that the transfer of energy is natural and continuous. When a practitioner transfers energy to a healee using TT, it is without effort and guided by conscious, mindful action. The practitioner adds intentionality within a compassionate context.

BOX 29-2

Cultural Characteristics Related to the Balance of "Hot" and "Cold"

A naturalistic or holistic approach often assumes that there are external factors (some good, some bad) that must be kept in balance if we are to remain well. The balance of "hot" and "cold" is a part of the belief system in many cultural groups, such as the Arab, Chinese, Filipino, and Hispanic cultures. To restore a disturbed balance (i.e., to treat) requires the use of opposites (e.g., a "hot" remedy for a "cold" problem). Different cultures may define "hot" and "cold" differently. It is not a matter of temperature, and the words used might vary; for example, the Chinese have named the forces yin (cold) and yang (hot). Western medicine cannot ignore the naturalistic view if many of its patients are to have appropriate treatment for illness as well as disease.

HOT CONDITIONS AND THEIR CORRESPONDING TREATMENTS

Hot Conditions	Cold Foods	Cold Medicines and Herbs
Fever	Fresh vegetables	Orange flower water
Infection	Tropical fruits	Linden
Diarrhea	Dairy products	Sage
Kidney problem	Meats such as goat, fish, chicken	Milk of magnesia
Rash	Honey	Bicarbonate of soda
Skin ailment	Cod	
Sore throat	Raisins	
Liver problem	Bottle milk	
Ulcer	Barley water	
Constipation		

COLD CONDITIONS AND THEIR CORRESPONDING TREATMENTS

Cold Conditions	Hot Foods	Hot Medicines and Herbs
Cancer	Chocolate	Penicillin
Pneumonia	Cheese	Tobacco
Malaria	Temperate-zone fruits	Ginger root
Joint pain	Eggs	Garlic
Menstrual period	Peas	Cinnamon
Teething	Onions	Anise
Earache	Aromatic beverages	Vitamins
Rheumatism	Hard liquor	Iron preparations
Tuberculosis	Oils	Cod liver oil
Cold	Meats such as beef, water fowl, mutton	Castor oil
Headache	Goat's milk	Aspirin
Paralysis	Cereal grains	
Stomach cramps	Chili peppers	

Modified from Seidel HM et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2006, Mosby.

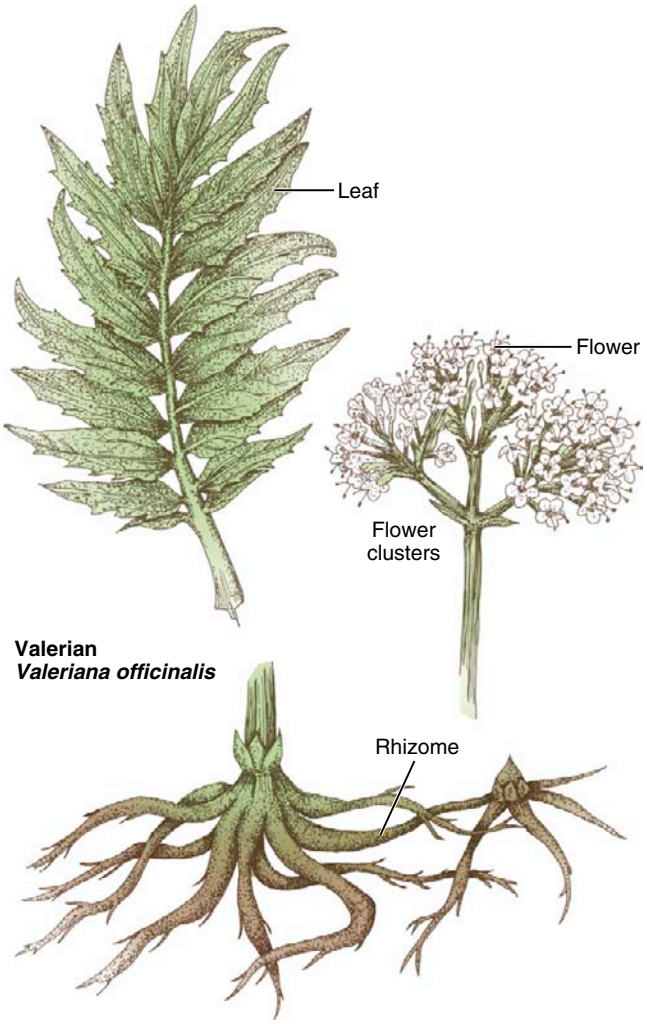

FIGURE 29-2 Valerian is a perennial plant cultivated throughout the world. Its reported uses include treatment of nervous disorders such as anxiety, restlessness, and insomnia. The plant rhizomes and roots are used to produce valerian in the forms of capsules, crude tea, extracts, and tinctures and in combination with products containing other herbs.

- *A human being is bilaterally anatomically symmetric.* Symmetry is apparent in several anatomic systems, most clearly seen in the skeleton. This symmetry is the rational basis for the inference that there is also a pattern in the underlying human energy field. This provides the background for the TT practitioner's assessment of the healee's energy state.
- *Illness is an imbalance in an individual's energy field.* With TT, the practitioner manipulates the energy field by directing or modulating using the sense of touch much like the other four major senses of the body. All these senses are able to act from a distance without direct connection. The human energy field extends a few inches away from the body surface, and the practitioner senses fine energetic cues such as changes in pattern.
- *Humans have natural abilities to transform and transcend their conditions of living.* These functions are, in a sense, prerequisites for healing to occur.

BOX 29-3

The Use of Palpation in Physical Examination

Palpation involves the use of your hands and fingers to gather information through the sense of touch. Certain parts of your hands and fingers are better than others for specific types of palpation. The palmar surface of the fingers and finger pads is more sensitive than the fingertips and is used whenever discriminatory touch is needed for determining position, texture, size, consistency, masses, fluid, and crepitus. The ulnar surface of the hand and fingers is the most sensitive area for distinguishing vibration. The dorsal surface of the hands is best for estimating temperature; of course, this estimate provides only a crude measure and is best used to detect temperature differences in comparing parts of the body.

Touch is in many ways therapeutic, and palpation is the actuality of the "laying on of hands." It is the moment at which we begin our physical invasion of the patient's body. Our much-repeated advice that your approach be gentle and your hands be warm is not only practical but also symbolic of your respect for the patient and for the privilege the patient gives you.

Modified from Seidel HM et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2006, Mosby.

TABLE 29-1

Biofield Terms and Source Culture

Term	Source Culture
Ankh	Ancient Egyptian
Bioenergy	American, European
Ki	Japanese
Life force	General use
Oki, Orenda, Ton, Wakan	American Indian: Huron, Iroquois, Dakota, Lakota
Pneuma	Ancient Greek
Prana	Sanskrit, Ancient Hindu Indian
Qi	Chinese
Subtle energy	American, European
Sila	Inuit
Tane	Hawaiian

Modified from Cassidy CM: Social and cultural factors. In Micozzi MS, editor: *Fundamentals of complementary and integrative medicine,* ed 3, St Louis, 2006, Saunders.

CONCEPTS AND CONSTRUCTS

- *Laying on of hands.* This is a healing practice found in multiple ancient cultures as well as contemporary religious groups.
- *Vital energy fields.* All persons share a unity with nature and all living things, which includes universal energies. Most Eastern and ancient cultures have words and concepts for this phenomenon; the Western culture does not. This concept was derived from Chinese, Indian, and Native American cultures and other ancient religions; it supports or demonstrates some of the theories of quantum physics and of nurse theorist Martha Rogers, but it is not derived from these sources.
- *Energy transfer.* This is described as a method by which one individual can transfer or send energy to another.

TABLE 29-2

Comparisons of Selected Biofield Therapies

Therapy	Practice Initiated	Developers	Hand Placement	Theoretic Basis and Intent
Healing Touch	1981	American Holistic Nurses Association	Both on and off the body	Uses elements of Healing Science and Therapeutic Touch in conjunction with crystal and dowsing to treat whole person and specific disorders.
Qi gong	Traditional	Chinese	At meridian points or short distance from the body	Qi follows meridians and body patterns to heal biologic disorders.
Reiki	Traditional 1800s 1936	Buddhist Japan—Hawayo Takata United States—Mikao Usui	A few standardized hand placements on the physical body	Spiritual energy from universe is channeled by "masters" to heal spiritual body, which in turn heals physical body.
Therapeutic Touch	1972	Dolores Krieger and Dora Kunz	Primarily off the body 2-4 inches	Aligning Kunz's Human Energy Field Model with Martha Rogers' Science of Unitary Human Beings, the centered practitioner assesses, directs, and modulates biofield energy to achieve relaxation response for healing of whole person.
Reflexology	Traditional	Ancient method of treatment for ailments dating back to Egyptians and beyond	Application of pressure to sites on foot, hands, ears, and so on that correspond with organs and nerves to cause a reflex arc of stimulation to area in need	Promotes balance and wellness through nerve stimulation.

Modified from Engebretson J, Wardell D: Energy-based modalities, *Nurs Clin North Am* 42:243-259, 2007; National Center for Complementary and Alternative Medicine: *Energy medicine: an overview,* available at http://nccam.nih.gov/health/whatiscam/energy/energymed.htm. Accessed June 12, 2009.

- *Energy congestion.* When energy is not flowing from head to toe but seems to be localized, or *stuck* at a certain level of the body, it is considered congested. Although energy flow is not only head to toe, this is considered the major flow pattern.
- *Energy imbalance.* When the energy field does not appear to be symmetric, there seems to be some disturbance or difference in the field on one side and not the other.
- *Inner practitioner.* With TT, persons in the role of practitioner have to be more than masters of techniques—they must become masters of themselves. This concept, like the laying on of hands, was derived from multiple sources including cultural and religious and the martial arts, as well as personal observation and experience.
- *Intentionality.* This concept addresses the focused and inner intent to help another achieve the maximum level of wholeness or well-being that he or she is capable and desirous of attaining.
- *Centered consciousness.* This concept describes the act of self-searching—going within to explore the deeper levels of oneself. Centered consciousness is a concept derived from ancient cultures and religions.

BACKGROUND. To work within biofields, the practitioner uses a model or map to focus the healing energy. Chakras, or energy centers, described by the Upanishads in the Vedas, the oldest literature of the East Indian people, are often used as a reference point. Although the most detailed descriptions are in the Upanishads, the attributes are found in the teachings of other cultures as widely geographic as the Sufis of the Middle East to the First Nations, particularly from the North American Southwest (Figure 29-3).

TT practice lends itself well to the fast-paced surgical environment. The skills learned through study of TT provide a trained practitioner with the ability to center quickly and use intention to calm both himself/herself and others nearby in stressful situations. Research design, methods, techniques, and sample sizes are considerations for future studies into how biofield therapeutics may benefit surgical patients. Replicating past studies, as well as new research based on physiologic data and quantitative studies, is necessary (Research Highlight). It has become evident that the concepts involved in energy therapies need consistent definitions. If the concepts do not have preestablished definitions, they cannot be quantified or measured in meaningful ways. However, interest is high and research continues in an effort to better understand a phenomenon that seems to provide meaningful relief to the patient as well as to often-stressed nurse (or other healthcare) colleagues.

Perioperative Medical Hypnotherapy

Use of medical hypnotherapy in hospitals and clinics for perioperative care is becoming more common. Patients are seeking an active role in their treatment and are better informed regarding surgical options. Participating in perioperative medical hypnotherapy allows patients to take shared responsibility for their healing process, giving them a measure of control, because all hypnosis is self-hypnosis. Meaningful and active

RESEARCH HIGHLIGHT

Therapeutic Touch (TT) and Human Cell Growth

As part of 2-year in vitro study at the University of Connecticut Health Center, researchers determined that TT stimulates the growth of human cells in culture. This research examined culture growth of fibroblasts, osteoblasts, and tenocytes discarded from podiatry procedures of healthy patients. The study compared the effects of TT provided by three experienced TT practitioners and sham TT (provided by a "sham healer," an individual who had no knowledge of TT) against untreated control cultures. Researchers measured the cell growth and determined that TT produced a statistically significant difference in the fibroblast cell proliferation. In measuring osteoblast growth they determined that TT did produce significant cell proliferation compared to the control, but not to the sham treatment. In the tenocytes' grouping, TT produced significant cell proliferation in comparison to both the control and the cells treated by the sham practitioner. Although this study was limited in scope, it does provide the basis for further exploration into practices involving the human biofield and the mechanisms by which organisms respond.

Modified from Groncowicz GA et al: Therapeutic touch stimulates the proliferation of human cells in culture, *J Altern Complement Med* 14(3): 233-239, 2008.

	English Name	Situation
1	Root or basic chakra	At the base of the spine
2	Spleen or splenic chakra	Over the spleen
3	Navel or umbilical chakra	At the navel, over the solar plexus
4	Heart or cardiac chakra	Over the heart
5	Throat or laryngeal chakra	At the front of the throat
6	Brow or frontal chakra	In the space between the eyebrows
7	Crown or coronal chakra	On the top of the head

FIGURE 29-3 Chakras.

participation empowers a patient to enter into anesthesia and surgery with confidence.

Surgery is a life-changing event, and each perioperative medical hypnotherapy patient is unique. The initial assessment serves to determine goals and explore questions relative to emotional as well as physical concerns. The hypnotherapist, working within the patient's belief system, helps acknowledge areas of the patient's concern as a multidisciplinary partnership of healing is forged in a patient-centered manner.

As the hypnotherapist guides the patient into relaxation and induces hypnosis, both therapist and patient journey into the body, together addressing predetermined issues. Fear of the unknown, preprocedure anxiety, changes in body image, anticipated pain or nausea, loss of organs, and transplantation of new organs are some examples of issues that may be addressed in the perioperative setting (Gurgevich, 2007).

Hypnosis compassionately allows a patient to explore emotions without judgment or expectation of those feelings. The practice of emotional awareness, of being present with feelings, and of holding those feelings sacred can bring a sense of peace and healing insights during a time of profound stress, such as that experienced by many surgical patients. Predetermined suggestions or affirmations may increase confidence in the healthcare team, increase compliance with the treatment plan, decrease blood loss, maintain intraoperative homeostasis, reduce the need for sedation or pain medication, decrease postoperative nausea or vomiting, and increase patient satisfaction (Valente, 2006).

Postoperative hypnotherapy sessions reinforce continued participation of patients in their healing process. This may take the form of establishing metabolic gauges in the "control room" or a symbolic shield of protection, holding or sending color, light, or a certain feeling of safety to a specific part of the body. It may be expressing gratitude to and confidence in the medical and nursing community. Follow-up sessions allow both patient and hypnotherapist to evaluate attainment of preoperative goals, consider postoperative outcomes, and explore issues relevant to the ongoing healing process.

Guided Imagery

Another therapy closely related to hypnosis is guided imagery. Imagery, or thinking in pictures, is the natural language of the unconscious mind and is used by the autonomic nervous system as a primary mode of communication. The autonomic nervous system controls unconscious body functions such as heart rate, immune function, digestion, blood flow, smooth muscle tension, and pain perception (Figure 29-4). Guided imagery for surgical patients may be in the form of pre-scripted tapes that lead the patient through relaxation exercises and provide healing suggestions. In other instances, the perioperative nurse may assist the patient with guided imagery through the use of a calming, monotone voice; a smooth speaking delivery; and the use of relaxing images, such as a place in nature. The perioperative nurse coaches the patient to see, feel, smell, sense, and hear the imagined scene. Benefits of guided imagery with surgery patients may include the following (Ignatavicius, 2010):

- Decreased anxiety
- Decreased pain perception
- Faster recovery
- Increased sense of control

Aromatherapy in Perioperative Services

Aromatherapy involves the therapeutic use of fragrance (e.g., aromatic plant extracts and essential oils) applied to the patient's body through inhalation or topical methods, or rarely

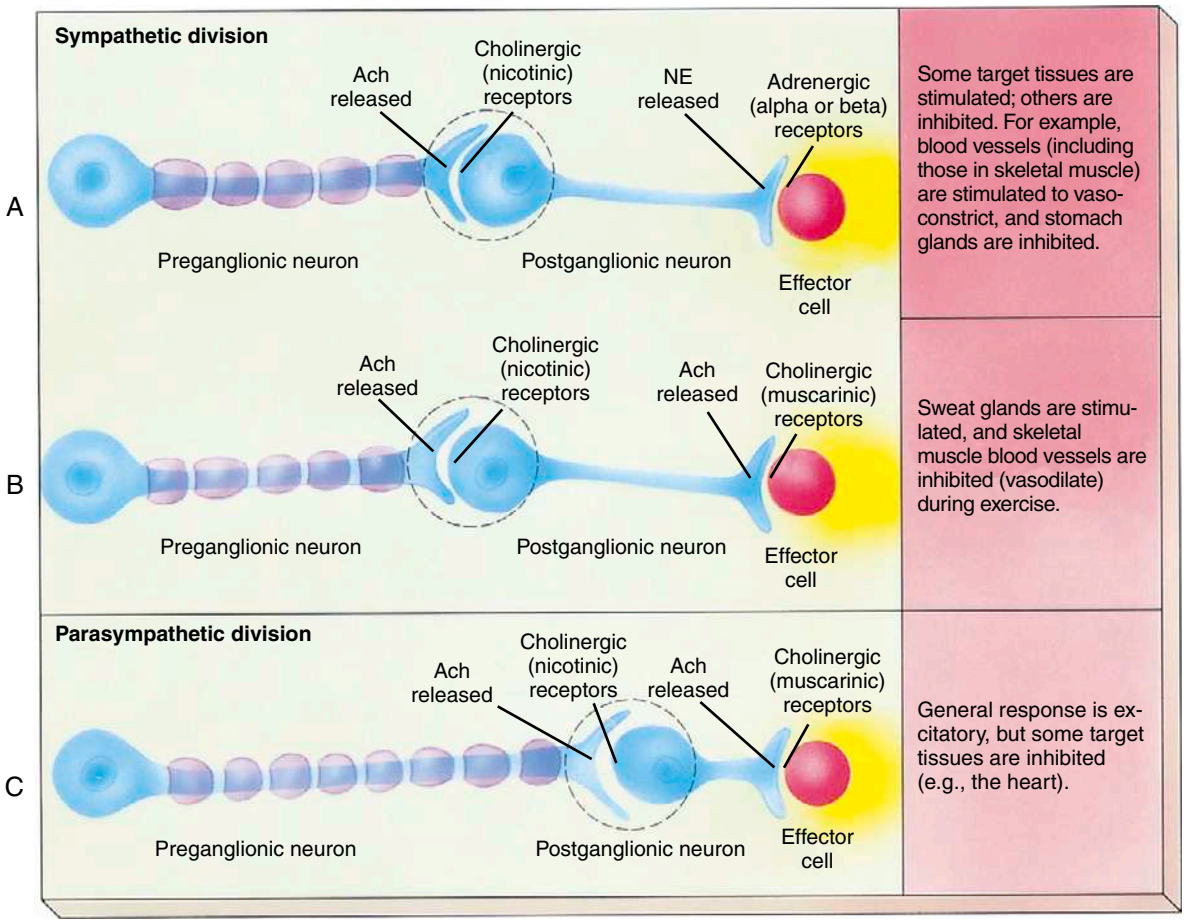

FIGURE 29-4 Locations of neurotransmitters and receptors in the autonomic nervous system. In all pathways, preganglionic fibers are cholinergic, secreting acetylcholine *(Ach)*, which stimulates nicotinic receptors in the postganglionic neuron. Most sympathetic fibers are adrenergic (**A**), secreting norepinephrine *(NE)*, thus stimulating alpha- or beta-adrenergic receptors. A few sympathetic postganglionic fibers are cholinergic, stimulating muscarinic receptors in effector cells (**B**). All parasympathetic postganglionic fibers are cholinergic (**C**), stimulating muscarinic receptors in effector cells.

ingestion. Long before Western medicine, use of aromatherapy and herbs was part of physicians' practice and prescriptive use and was taught in all of the original Nightingale schools (Radzyminski, 2007). Clinical aromatherapy is gaining acceptance with consent and participation of patients. It is practiced by certified clinical aromatherapy practitioners (CCAPs), knowledgeable about the specific properties of essential oils and how they interact with patients and the therapeutic environment. CCAPs use clinical-grade essential oils in a controlled way for specific, measurable outcomes. These may affect the patient on a psychologic, physiologic, or cellular level. The choice of essential oil is based on the chemistry of that essential oil and its proven effects (Table 29-3).

As pharmacology combines medications to potentiate effect, aromatherapy may act synergistically with traditional treatment; or it may be offered in concert with other complementary modalities to relieve discomfort, thereby reducing dosages of analgesics or sedatives. Potential uses for perioperative services include reducing anxiety for patients and their families in the waiting area and ameliorating nausea and vomiting during the immediate postoperative phase (Steflitsch and Steflitsch, 2008).

The nursing process of aromatherapy begins with obtaining consent for use of aromatics and collecting pertinent information. Assessment of the patient, the physical environment, and the team of caregivers defines the healing environment. Along with review of the medical and nursing histories, allergies, vital signs, and laboratory values, subjective data are relevant, such as how to offer treatment. The plan of therapy may include direct inhalation (on a cotton ball or through a diffuser), compresses, topical application, or massage. As with all nursing interventions, postprocedure follow-up with the patient is imperative to assess efficacy of this intervention.

Additional well-designed research is required to provide data substantiating the value of clinical aromatherapy as another component of holistic perioperative nursing practice.

Music and Surgery

The therapeutic and healing properties of music have been recognized throughout history. Music is recognized as a way to decrease the physiologic and behavioral anxiety found in most individuals awaiting surgical procedures, and has been validated through many research and evidence-based studies and reviews (Sendelbach et al, 2006; Klassen et al, 2008).

TABLE 29-3

Essential Oils and Their Properties

Property	Essential Oils
Antiemetic	Chamomile, lavender, lemon, peppermint, ginger
Antiseptic	Bergamot, clove, eucalyptus, lavender, juniper, thyme, tea tree
Anxiolytic	Benzoin, bergamot, chamomile, jasmine, lavender, neroli, rose, sandalwood, verbena, ylang-ylang
Analgesic	Lavender, West Indian lemongrass, peppermint, Turkish oregano, Brazilian mint
Sedating	Bergamot, chamomile, jasmine, lavender, neroli, rose, ylang-ylang
Stimulating	Basil, black pepper, eucalyptus, peppermint, rosemary
Antiinflammatory	German chamomile, rosemary, black pepper, helichrysum

From Mantle F, Tiran D: *A-Z of complementary and alternative medicine,* London, 2009, Churchill Livingstone; Steflitsch W, Steflitsch M: Clinical aromatherapy, *J Men Health* 5(1):74-85, 2008.

Music has been shown to increase metabolism; increase or decrease muscular energy, breathing rate, blood volume, pulse rate, and blood pressure; and lower sensory stimuli thresholds. Music can touch patients deeply and thus transform their anxiety and discomfort into relaxation and healing.

Anxiety and pain are common perioperative nursing diagnoses identified in the sample plans of care in Unit II (Surgical Interventions) in this book. Because anxiety and pain lead to increased stress and stress may cause detrimental physiologic reactions, many nursing interventions are undertaken to reduce patients' anxiety. Music is a nursing intervention that is easy to administer, relatively inexpensive, and noninvasive.

Music is therapeutic if used in a manner that enables its elements and their influences to aid in integration of the body, mind, and spirit of the patient during the treatment of an illness or disability. When selecting music to invoke physiologic and psychologic changes, it is important to note the attributes of music. Factors that need to be considered are the various elements of music (e.g., tempo, mode, pitch, rhythm, harmony, melody); listener characteristics (e.g., age, language, culture, education, musical preferences); and the mode of delivery (e.g., headphones, speakers). Slow, quiet music without lyrics tends to lower the physiologic responses associated with stress and anxiety. Fast tempos tend to increase tension, while slow tempos can cause suspense. A tempo of 60 to 72 beats/min appears to promote relaxation and decrease anxiety, as theorized by matching the normal heart rate of humans. Research also demonstrates the importance of patient-selected music that is familiar, desirable, and meaningful, which often leads to positive responses from patients. The use of headphones blocks unpleasant environmental sounds, a common occurrence in busy preoperative holding areas and OR suites. Compact disks or MP3 players provide consistent, uninterrupted music, which is critical towards the success of the ongoing therapeutic reactions that music affords. Best of all, music therapy can be used preoperatively, intraoperatively, and postoperatively.

Anticipation of surgery commonly produces anxiety. The preoperative waiting period may be more stressful and anxiety-provoking for some patients than the anticipated surgical intervention. High levels of anxiety cause negative physiologic manifestations, such as elevated blood pressure, that can lead to postoperative complications, such as increased cardiac workload. High levels of preoperative anxiety may result in postoperative complications such as depression, fear, and anger, and the use of music during the preoperative phase can decrease anxiety and significantly lessen complications in the postoperative phase of recovery. Emotions are altered, apprehension and tension are reduced, and sympathetic stimulation and adrenocortical activation are more controlled. Therefore changes in vital signs, such as elevated blood pressure and increased heart rate, are minimal. Studies have verified that patients listening to music had a significant decrease in anxiety and pain when compared with patients in a control group who did not listen to music (Klassen et al, 2008).

Patients undergoing surgery in which local or regional anesthetics are administered have an acute awareness of the environment found within the OR. The OR may appear threatening, with unfamiliar machines, equipment, noises, and smells. Physical positioning and exposure of body parts intensify anxiety. Unfamiliar sounds, bright lights, and technical language add to the stressors of the surgical experience. During surgery, patient-selected music reduces anxiety by providing the patient some autonomy through self-selected musical choices, while distracting the patient from what is happening within the environment. The music not only blocks the various sounds in the room but also provides an escape through imaginative thought. Researchers support the idea that musical vibrations have an effect on the subconscious mind. Older patients have reported comfort and strength by listening to hymns and other music of spiritual or psychologic support. Daydreaming, imagery, escape, and fantasizing are common to listeners. This creates a release of tension and is a way of focusing attention away from threats. Intraoperative music may decrease the patient's anxiety and consequently minimize the need for patient-controlled conscious sedation and analgesia. Music can have a positive effect during general anesthesia when delivered through headphones or earpieces, as long as care is exerted to prevent pressure points and volume increases.

The subject of patient awareness during anesthesia and surgery continues to receive much attention (see Chapter 7). Auditory functioning may be largely intact, especially in patients undergoing cardiac, trauma, or cesarean section procedures. As many as 1% to 2% of all patients may experience awareness during general anesthesia and while most do not experience pain, up to 36% of patients who experience recall do report some pain (Orser et al, 2008). Much of the extensive literature regarding intraoperative recall is anecdotal. As a result, understanding the confluence of factors relevant to patient recall or wakefulness is limited. The use of intraoperative music delivered by way of a headset can facilitate a more pleasant surgical experience if recall or awareness becomes an issue.

Pain is a common problem in the postanesthesia care unit (PACU). Pain results in negative respiratory, cardiovascular, gastrointestinal, renal, neuroendocrine, and autonomic nervous system consequences for patients. The traditional means to providing pain relief in the PACU has been through medications. Because the effect of medications differs from person to

person, experts have suggested that a combination of pharmacologic and nonpharmacologic therapies has a greater potential for providing optimal pain relief (Tse et al, 2005).

Music has a long history as an adjunct to healing and pain control. Soothing music is a potential pain-management strategy. Reduced anxiety and the ability to relax are components of comfort. Soothing music can decrease anxiety, improve relaxation and comfort, and improve emotional status.

The noise levels of the OR and PACU contribute to the discomfort of patients (Nightingale, 1859). The level of noise typically encountered during the surgical experience is potentially harmful to patients because of the undesirable effects of a release of stress hormones on the cardiovascular system, including increased vasoconstriction, heart rate, and blood pressure. Noise also increases psychologic stress and discomfort, and patients' ability to cope is reduced. Soothing music delivered through a headset can block out external noises and can serve as a distraction from the noise of the PACU.

When using music as a nursing intervention to promote physiologic and psychologic well-being, the nurse prepares both the patient and the environment. The nurse should inform the patient of the purpose of the music experience and interview the patient about musical preferences, allowing the patient to listen to portions of selected music to ensure the music will afford the therapeutic purpose. The use of music therapy is documented in the medical record. A library of different types of music selections should be available. When compiling these collections, it is important that attention is given to the tempo, rhythm, melody, and harmony of the music (as noted earlier). In addition to implementing the music intervention, nurses must monitor patients' responses to ensure that intended outcomes are achieved, making adjustments as necessary.

Psychoneuroimmunology

A great deal of change has transpired in healthcare as sophisticated techniques have been developed to define intricate biologic systems and the underlying connections among these systems. Psychoneuroimmunology theory and research have insights for all complementary and alternative therapies (Micozzi and Amri, 2006) as well as perioperative nursing.

Psychoneuroimmunology studies the relationship between the brain and immune function. Thus perioperative nursing interventions that seek to reduce stress influences have the potential to improve immune system function. This involves how perioperative nurses communicate with patients as well as our behaviors, the attitudes we convey, the language we use, and our very presence (Table 29-4).

Early animal conditioning studies showed links on a molecular level (immune regulators: neurotransmitters and hormones) that act to stimulate nerves or trigger physiologic changes. Further, the perception of stress is known to lead to a reduced ability to fight infection. Because measurement of immune function is a complicated process, much remains to be learned about the precise mechanism of how psychosocial or emotional factors affect susceptibility to disease.

Herbs and Surgery

The use of herbal and botanic products is common today. Surveys estimate that 22% to 32% of patients having surgery use herbal medicines or supplements (Ang-Lee et al, 2005). However, many patients do not communicate this information to their conventional medical physicians or nurse caregivers, because they are unsure of the reaction of conventional caregivers to their use of alternative substances.

TABLE 29-4

Languaging for Nurses

Positive, Therapeutic Language	Negative, Toxic Language
We're giving you the medication that will let you gently go to sleep.	We're going to put you to sleep now.
We are well trained in how to take care of you.	Don't be afraid.
I'll be with you the entire time to make sure you stay asleep and comfortable.	Don't worry; you won't wake up during surgery.
Focus your energy on healing.	Don't give up.
You might feel pressure; some people don't feel anything.	This isn't going to hurt. Just a little bee sting.

Modified from Eslinger MR: The power of suggestion, languaging for nurses, AHNA beginnings, *Am Holist Nurs Assoc* 29(2):22-23, 2009.

Botanicals are marketed as food supplements in the United States. Manufacturers are not allowed to make claims about health benefits for these products because they are not FDA-approved. Since 1994, when the Dietary Supplement Health and Education Act (DSHEA) was passed, the definition of dietary supplements has broadened. A product that contains a vitamin, mineral, herb, amino acid, or other botanic or dietary substance used to supplement the diet is considered a dietary supplement; this includes concentrates, metabolites, constituents, extracts, and combinations of listed ingredients. These supplements are no longer subject to premarket safety evaluations by the FDA. Once a supplement is marketed, under the DSHEA, the FDA can restrict its use only if it can be shown that the product is unsafe.

There are no regulations establishing criteria for purity, manufacturing procedures, or identification of ingredients for these supplements. Therefore the potential exists for high variability in the potency of different batches of the same botanic product. In addition, impurities and unknown substances may also be present in these products. Because herbal products are so readily available and have such widespread media attention, many people think that they can safely self-medicate (Patient and Family Education). Another mistaken assumption is that dietary supplements are safer than prescribed or over-the-counter drugs.

Botanicals may initiate a pharmacologic response within the body and therefore should be considered as medications from a medical or nursing perspective (Risk Reduction Strategies). Many herbal products have actions that could be dangerous during surgery. Some herbal supplements may accentuate the toxicity of anesthetics or interfere with drug metabolism or clearance (Surgical Pharmacology). Herbal supplements may also have a role in the perioperative setting and are an important consideration for nurses (Research Highlight).

Coagulation Interactions. Anesthesia providers are concerned about the potential increased risk of instability intraoperatively resulting from inhibition of coagulation with the use

PATIENT AND FAMILY EDUCATION

Advising Patients about CAM

Nurses have traditionally acted as guides for patients as they navigate through the healthcare system, providing counseling and advice. When providing education to patients about CAM, the nurse should consider the overwhelming amount of information available via the internet and popular media. The internet is a popular source of information regarding the use of herbal and dietary supplements and other CAM therapies, but caution must be used in evaluating the validity of the information that is accessed. Nurses can use the following tips from the National Institutes of Health (NIH) to educate their patients on accessing reliable information from the internet. These tips are also useful for nurses to use when evaluating consumer information from the internet.

CONSIDER THE SOURCE—USE RECOGNIZED AUTHORITIES

- Know who is responsible for the content.
- Look for an "about us" page. Check to see who runs the site: Is it a branch of the federal government, a nonprofit institution, a professional organization, a health system, a commercial organization, or an individual?
- There is a big difference between a site that says, "I developed this site after my heart attack" and one that says, "This page on heart attack was developed by health professionals at the American Heart Association."
- Web sites should have a way to contact the organization or webmaster. If the site provides no contact information, or if you cannot easily determine who runs the site, use caution.

FOCUS ON QUALITY—ALL WEBSITES ARE NOT CREATED EQUAL

- Does the site have an editorial board? Is the information reviewed before it is posted?
- This information is often on the "about us" page, or it may be under the organization's mission statement or be part of the annual report.
- Determine if the board members are experts in the subject of the site. For example, a site on osteoporosis whose medical advisory board is composed of attorneys and accountants is not medically authoritative.
- Look for a description of the process of selecting or approving information on the site. It is usually in the "about us" section and may be called "editorial policy," "selection policy," or "review policy."
- Sometimes the site will have information "about our writers" or "about our authors" instead of an editorial policy. Review this section to find out who has written the information.

BE A CYBERSKEPTIC—QUACKERY ABOUNDS ON THE WEB

- Does the site make health claims that seem too good to be true? Does the information use deliberately obscure, "scientific" sounding language? Does it promise quick, dramatic, miraculous results? Is this the only site making these claims?
- Beware of claims that one remedy will cure a variety of illnesses, that it is a "breakthrough," or that it relies on a "secret ingredient."
- Use caution if the site uses a sensational writing style (lots of exclamation points, for example).
- A health web site for consumers should use simple language, not technical jargon.
- Get a second opinion! Check more than one site.

LOOK FOR THE EVIDENCE—RELY ON MEDICAL RESEARCH, NOT OPINION

- Does the site identify the author? Does it rely on testimonials?
- Look for the author of the information, either an individual or an organization. Good examples are "Written by Jane Smith, R.N.," or "Copyright 2003, American Cancer Society."
- If there are case histories or testimonials on the web site, look for contact information such as an email address or telephone number. If the testimonials are anonymous or hard to locate (e.g., "Jane from California"), use caution.

CHECK FOR CURRENCY—LOOK FOR THE LATEST INFORMATION

- Is the information current?
- Look for dates on documents. A document on coping with the loss of a loved one does not need to be current, but a document about the latest treatment of AIDS needs to be current.
- Click on a few links on the site. If there are a lot of broken links, the site may not be kept up-to-date.
- Beware of bias—What is the purpose? Who is providing the funding?

ASK WHO PAYS FOR THE SITE

- Check to see if the site is supported by public funds, by donations, or by commercial advertising.
- Advertisements should be labeled. They should say "Advertisement" or "From our Sponsor."
- Look at a page on the site, and see if it is clear when content is derived from a noncommercial source and when an advertiser provides it. For example, if a page about treatment of depression recommends one drug by name, see if you can tell if the company that manufactures the drug provides that information. If it does, you should consult other sources to see what they say about the same drug.

Modified from *MedlinePlus guide to healthy web surfing,* available at www.nlm.nih.gov/medlineplus/healthywebsurfing.html. Accessed June 13, 2009.

of ginger, ginseng, feverfew, ginkgo, and garlic (Skidmore-Roth, 2010). One difficulty with analyzing case reports is the lack of laboratory analysis of the purported botanicals. In some reported cases in which prolonged or excessive bleeding occurred, the patient had been taking multiple herb supplements and drugs. Many plants contain anticoagulant components, including ginger, ginseng, feverfew, and others; however, it is unknown if the danger posed is clinically significant.

Sedative Interactions. Some botanicals have significant sedative actions. Anesthesia providers are concerned about the potential for valerian and St. John's wort to prolong or

RISK REDUCTION STRATEGIES

Potential Herb-Pharmaceutical Interactions

Although many complementary therapies are relatively safe and pose little risk to the patient, certain herbal medications have the potential for causing harm through unfavorable interactions with medications used in and out of the perioperative setting. The nurse plays a vital role in performing a thorough medication history to identify potential herbal-pharmaceutical interactions and providing education to the patient about the possible consequences of combining herbs with prescribed and over-the-counter medications.

Herb	Pharmaceutical	Unfavorable Herbal Interaction
Garlic, feverfew, ginger	Warfarin	May increase anticoagulant effect
Astragalus and licorice	Corticosteroids, cyclosporine	Immunosuppressive effects may be inhibited
Echinacea	Corticosteroids	Immunosuppressive effects may be inhibited
	Anabolic steroids, methotrexate, or other hepatotoxic drugs	Hepatotoxicity
Hawthorne	Digoxin	May potentiate effect
Siberian ginseng	Warfarin	May inhibit anticoagulation
	Digoxin	May interfere with assays
All ginsengs, yohimbe	MAOIs Phenelzine and others	May cause headaches, tremors, and insomnia
Licorice	MAOIs Phenelzine and others	May act as inhibitors and potentiate effects
	Digoxin	May cause hypokalemia
Chromium	Hypoglycemics	May decrease insulin requirements and potentiate effects
Chamomile, feverfew, and St. John's wort	Iron	May inhibit iron absorption
Borage, evening primrose oil	Phenobarbital Phenytoin	May lower seizure thresholds
Ephedra (banned by U.S. FDA)	Cardiac glucosides or halothane	Cardiac dysrhythmias
	MAOIs, guanethidine	Enhanced sympathomimetic effects
	Oxytocin	Hypertension, potentiates contractile effects
Gingko	ASA, NSAIDs, warfarin, or heparin	Increased bleeding risk
Valerian	Sedative/hypnotic or anesthetic agents	Potentiated or prolonged effects
St. John's wort	Cyclosporine	Posttransplant complications
	MAOIs, steroids, warfarin, sympathomimetics, antidepressants	Alters drug metabolism for unpredictable results
Goldenseal	Oxytocin	Potentiates contractile effect

ASA, Aspirin; *FDA,* Food and Drug Administration; *MAOIs,* monoamine oxidase inhibitors; *NSAIDs,* nonsteroidal antiinflammatory drugs.
Modified from Skidmore-Roth L: *Mosby's handbook of herbs & natural supplements,* ed 4, St Louis, 2010, Mosby; Mills S, Bone, K: *The essential guide to herbal safety,* Philadelphia, 2005, Churchill Livingstone.

potentiate the sedative effect of anesthetic agents. Valerian has been associated with central nervous system (CNS) depression and muscle relaxant effects in animals; large doses of valerian may contribute to delirium and high-output cardiac failure on emergence from general anesthesia. Although St. John's wort has been found to inhibit the binding of naloxone, to date no cases have been reported of excessive sedation when combined with narcotics. In addition, there is concern about the monoamine oxidase inhibitor (MAOI) activity of St. John's wort, although no cases of MAOI effects in humans have been reported (Skidmore-Roth, 2010).

Cardiovascular Interactions. Hypertension and cardiac dysrhythmias are potential adverse events that may result from the sympathetic stimulation that occurs during intubation and surgery. Ephedra has been associated with cardiovascular effects, including hypertension, palpitations, tachycardia, stroke, and seizures. The long-term use of licorice may cause hypertension, dysrhythmias, or hypokalemia, which can potentiate muscle relaxants and cause adverse cardiovascular effects (Skidmore-Roth, 2010).

Because the use of botanic supplements may increase the risk of adverse herb-drug interactions, patients should be counseled to discontinue herbs preoperatively. Generally surgeons recommend that patients stop taking any herbal supplement at least 2 weeks preoperatively (Ang-Lee et al, 2005). Most patients, however, do not see an anesthesia provider until the day of surgery or a few days before surgery; so the implementation of this recommendation is challenging. Clinical research is insufficient to quantify the actual dangers of these herbal supplements. However, because individuals vary in their absorption, distribution, and clearance of the drugs administered during anesthesia, adding unknown chemicals into an already complex and fast-acting mix of drugs is likely an unnecessary risk.

Integrative Health Therapies and Perioperative Nursing

A variety of factors influence the perioperative patient's experience. Well-informed healthcare consumers increasingly choose a blend of traditional and nontraditional healing modalities with sensitivity to cultural, spiritual, and health education needs. Public involvement and legislative policy decisions are just beginning to equalize emphasis between the traditional biomedical model of care and a holistic comprehensive focus. Integrating health and wholeness incorporates elements

SURGICAL PHARMACOLOGY

Herbs: Effects and Precautions/Recommendations

The use of herbal supplements has become increasingly popular as people become more educated consumers and take a more active interest in their health. Because herbal supplements and other nutriceuticals are available without prescription, patients may not reveal their use of these therapies unless specifically questioned. The perioperative nurse must always consider the possibility that the patient is taking supplements and assess for their use. As with other medications the patient may be taking, the nurse is responsible to know the potential for interaction with medications used in the perioperative period. The information that follows offers a source for broadening the perioperative nurse's knowledge of commonly used herbal supplements.

Herb (Scientific Name) and Other Names	Uses and Desired Effects	Potential Side Effects	Precautions and Recommendations
Garlic *(Allium sativum)* Clove garlic Ajo Poor man's penicillin	Antioxidant; antibiotic; lowers low-density lipids (LDLs) to prevent atherosclerosis; has antihypertensive, antiplatelet, and antithrombolytic properties	May prolong bleeding or clotting time, potentiate effects of antihypertensive or anticoagulant drugs	Large doses (>5 cloves) may cause gastrointestinal (GI) upset, garlic breath/flatus. Discontinue use at least 7 days preoperatively.
Ginkgo *(Ginkgo biloba)* Duck foot Kew tree Maidenhair tree Silver apricot Fossil tree	Antioxidant; anticlotting; enhances blood flow (especially to brain); reduces cellular lesions, retinal edema; treats symptoms of peripheral vascular disease and dementia; inhibits platelet-activating factors; used to enhance brain function and memory; treats headaches, depression, vertigo, and tinnitus	Headache, GI upset, palpitations, dizziness, or skin reactions	Causes increased bleeding risk by inhibiting platelet activity, lowering fibrinogen levels, and decreasing plasma viscosity. May potentiate anticoagulant therapy. Discontinue use at least 36 hr preoperatively.
Ginseng American ginseng *(Panax quinquefolius)* Chinese ginseng or Korean ginseng *(Panax ginseng)* Siberian ginseng *(Eleutherococcus ginseng)*	Antioxidant; enhances memory and immune function; increases stamina; decreases fatigue; reduces stress response; lowers blood glucose level; inhibits clotting	Usually mild and dose-related: nervousness, dizziness, mastalgia "Ginseng abuse syndrome" (>15 g/day) = insomnia, hypotonia, and edema Siberian ginseng may falsely elevate digoxin levels; potentiate monoamine oxidase inhibitors (MAOIs)	Contraindicated for patients with hypoglycemia, hypertension, and cardiac disorders. Avoid with other stimulants; may lead to tachycardia or hypertension. May decrease effectiveness of warfarin (decreased international normalized ratio [INR]). May cause postmenopausal bleeding. Discontinue use at least 7 days preoperatively.
Ephedra *(Ephedra sinica)* Ma huang Mexican or Mormon tea Dessert tea Natural ecstasy Natural fen-phen Ephedrine Chinese joint fir	Stimulant; bacteriostatic; antitussive; decongestant; bronchodilator; used for weight loss	Hypertension (HTN), tachycardia, dysrhythmias, cardiac arrest, myocardial infarct, nausea, vomiting, decreased GI motility, mydriasis, diuresis, anxiety, constipation, dizziness, headache, insomnia, psychosis, urine retention, seizure, stroke, uterine contractions	Do not use with cardiac glycosides, guanethidine, MAOI medications. Do not use for patients with anxiety, HTN, glaucoma, enlarged prostate, or heart disease. Discontinue use at least 24 hr preoperatively. Limit use to 7 days.
Echinacea *(Echinacea purpurea, E. pallida, E. angustifolia)* Purple coneflower	Antiinfective; antiinflammatory; enhances immune function; may prevent or minimize symptoms and duration of common cold, upper respiratory infection (URI); enhances wound- and burn-healing process	May activate T-cells Cross-allergic reaction Immune suppression if taken long term	Discontinue as far in advance preoperatively as possible. Should not be used by patients with autoimmune diseases. Should not be used by patients with allergy to sunflower. Avoid use for transplant patients or those with liver dysfunction.

Continued

SURGICAL PHARMACOLOGY

Herbs: Effects and Precautions/Recommendations—cont'd

Herb (Scientific Name) and Other Names	Uses and Desired Effects	Potential Side Effects	Precautions and Recommendations
St. John's wort *(Hypericum perforatum)* Amber touch-and-heal Goatweed Klamath weed	Anxiolytic; antidepressant (mild to moderate symptoms), may take 4-6 wk for effect; relieves dyspepsia and insomnia; mechanism: inhibits uptake of neurotransmitters	Photosensitization, skin irritation, restlessness, fatigue May prolong effects of anesthesia and potentiate meperidine or other narcotics Possible peripheral neuropathy, serotonergic crisis	May alter metabolism of other drugs: cyclosporine, warfarin, steroids, protease inhibitors. Do not combine with ephedra. Discontinue use at least 5 days preoperatively.
Cayenne *(Capsicum annuum)* Hot chili pepper Paprika	External use: muscle spasm or soreness Internal use: GI disorders	External: skin irritation, especially if used longer than 2 days Internal: lower GI discomfort; overdose may cause hypothermia	Avoid use preoperatively.
Feverfew *(Tanacetum parthenium)* Featherfew Midsummer daisy	Antipyretic; relieves arthritis, fever, headache, and migraine pain; increases fluidity of respiratory mucus; promotes menses and uterine contractions	Oral lesions, GI tract irritation Rebound headache with sudden cessation Hypersensitive reaction in those allergic to ragweed, asters, chrysanthemums, or daisies May increase clotting time	Causes increased bleeding risk. Avoid use preoperatively.
Goldenseal *(Hydrastis canadensis)* Orange or yellow root Ground raspberry Tumeric root Eye root	Antibacterial, antiinflammatory properties; diuretic (no sodium excreted); laxative; improves immune function; aids digestion; regulates menses	Hypotension, nausea, vomiting, abdominal cramping May exacerbate edema or hypertension May potentiate effects of insulin	May cause electrolyte imbalance, seizures, respiratory paralysis. Avoid use preoperatively.
Valerian *(Valerian officinalis)* All heal Setwell Vandal root	Mild anxiolytic, muscle relaxant, hypnotic and sedative; may ease symptoms of benzodiazepine withdrawal	Headache, excitability, nausea, visual disturbance Potentiates sedative/hypnotics Long-term use may increase anesthesia tolerance Sudden cessation may cause withdrawal symptoms	Potentially prolongs anesthesia recovery time. Treat withdrawal symptoms with benzodiazepines. If possible, taper dose over 1-2 wk preoperatively. If not, continue use until surgery.
Ginger *(Zingiber officinale)* African ginger Black ginger	Prevents nausea caused by motion sickness, pregnancy, chemotherapy, and anesthesia; antispasmodic	Heartburn Inhibition of platelet aggregation	Causes increased bleeding risk. Avoid use preoperatively.
Kava kava *(Piper methysticum)* Awa, kawa Intoxicating pepper Tonga	Anxiolytic; mild sedative; muscle relaxant; sleep aid	Adverse effect on motor reflexes and judgment	Potentiates sedative/hypnotics. Discontinue use at least 24 hr preoperatively.
Licorice *(Glycyrrhiza glabra)* Sweet root	Antipyretic; antiviral; demulcent; expectorant; beneficial for chronic fatigue, allergies, asthma, bronchitis, depression, emphysema, herpes, and hypoglycemia; treats gastritis and gastric and duodenal ulcers	May cause headache, muscle flaccidity, lethargy, edema, HTN, hypokalemia, or other electrolyte imbalance, and electrocardiogram (ECG) changes (prolonged QT interval) Pseudoprimary aldosteronism a possible complication	Contraindicated for chronic liver conditions, renal insufficiency, hypertonia, or existing hypokalemia. Avoid use for more than 7 consecutive days.

SURGICAL PHARMACOLOGY

Herbs: Effects and Precautions/Recommendations—cont'd

Herb (Scientific Name) and Other Names	Uses and Desired Effects	Potential Side Effects	Precautions and Recommendations
Saw palmetto *(Serenoa repens)* Sabal cabbage palm	Relieves benign prostatic hypertrophy; has antiandrogenic and antiexudative properties	Headache, increased appetite	Causes additive effects with other hormone therapies.
Dong quai *(Angelica polymorpha)*	Relieves menstrual disorders; increases effects of ovarian and testicular hormones	Dizziness, headache, nausea, miscarriage, dermatitis, GI upset, photosensitivity	Avoid use in pregnancy.
Huang qi *(Astragalus membranaceous)*	Antibacterial; increases production of white blood cells (WBCs); immunostimulant; cardiotonic; energy tonic (strengthens *wei qi*); regulates water metabolism	Inhibits platelet aggregation and fibrinolysis	Causes increased bleeding risk.
Black cohosh *(Cimicifuga racemosa)* Rattle root Squaw root	Antihypertensive; lowers cholesterol; reduces mucus production; induces labor to aid in childbirth; relieves menopausal symptoms (hot flashes)	May lead to premature labor if used in pregnancy	Avoid use in pregnancy.
Senna *(Cassia senna)*	Stimulating laxative	Abdominal cramping; affects absorption in GI system	Causes potential electrolyte imbalance.
Vitamin E (D-α-tocopherol)	Antioxidant used for cardiovascular disease	Reduced platelet adhesion and aggregation	Causes increased bleeding risk.
Yohimbe *(Pausinystalia yohimbe)*	Increases blood flow (particularly to genitalia) and libido	Anxiety, hallucinations, HTN, elevated heart rate, headache, dizziness, flushing	Avoid use by patients with psychologic or renal disorders.
Hawthorn *(Crataegus oxyacantha)* May bush May blossom Whitethorn	Antihypertensive; dilates coronary blood vessels; improves cardiovascular function (inotropic and beta-blocking effect); lowers cholesterol	Nausea, fatigue, sweating, headache, hypotension, mild central nervous system (CNS) depression	Use caution with cardiac glycosides, CNS depressants, antihypertensives, and nitrates.

RESEARCH HIGHLIGHT

The Use of Ginger to Prevent Postoperative Nausea and Vomiting

Postoperative nausea and vomiting (PONV) are significant problems for many patients administered general anesthetics. This complication not only is distressing for the patient but also, if uncontrolled, can result in additional complications such as wound dehiscence, fatigue, dehydration, and electrolyte imbalances. The PONV phenomenon has been widely studied, yet the development of a universally effective and consistent solution has not been achieved. Complementary therapies may offer an additional option for patients with PONV.

Researchers in Thailand conducted a review and meta-analysis of 5 randomized trials with a total of 363 patients from existing literature to determine the effectiveness of a fixed dose of ginger compared to a placebo in the treatment of PONV. Ginger has long been used in China as a treatment for nausea and vomiting. Researchers postulate that the antiemetic properties are due to its antiserotonin-3 effects on the central nervous system and the gastrointestinal system.

Patient ages ranged from 31 to 46 years and the surgery types were primarily endoscopic in nature. In the studies, the treatment group received 1 g of ginger and the control group received a placebo 1 hour before anesthesia was induced. Analysis of the results showed that ginger was significantly better than placebo for the prevention of PONV. The incidence of PONV was 35% lower in the patients treated with ginger when compared to the control group.

Researchers concluded that ginger is an effective therapeutic option in the prevention of PONV, but the exact role of ginger as an antiemetic warrants additional study.

PATIENT SAFETY

Encouraging the Patient/Physician Relationship

Perioperative nurses can encourage safety in patients who use CAM by promoting the National Center for Complementary and Alternative Medicine (NCCAM) *Time to Talk* education campaign. The goal of the campaign is to ensure safe and coordinated care for patients while helping to minimize the risks of interaction with any conventional therapy in which the patient may be engaged. The campaign also seeks to inform and educate patients so they are empowered to make better healthcare decisions and more effectively manage their health. Nurses can provide the following tips from NCCAM to patients as a starting point for discussing CAM with their providers:

- When completing patient history forms, be sure to include all therapies and treatments you use. Make a list in advance. Also note any medical specialists or CAM practitioners you see. Take the list with you whenever you visit a healthcare provider.
- Tell your healthcare providers about all therapies or treatments—including over-the-counter and prescription medicines as well as herbal and dietary supplements.
- Take control. Do not wait for your providers to ask about your CAM use.
- If you are considering a new CAM therapy, ask your healthcare providers about its safety, effectiveness, and possible interactions with medications (both prescription and over-the-counter).

AMBULATORY SURGERY CONSIDERATIONS

Supporting CAM in the Ambulatory Surgical Setting

As advocates using the holistic approach, perioperative nurses play an important role in supporting the patient who desires to use CAM in the perioperative setting. It is important to balance the use of conventional and nonconventional interventions in respecting the patient's wishes and providing safe care. Many CAM interventions are well suited to the ambulatory setting, including music therapy, aromatherapy, and energy interventions. The nurse must ensure that any healthcare personnel who wish to treat the patient in the perioperative setting do so under the institution's policies and procedures. The nurse should document any use of CAM in the perioperative nursing record along with the patient's response.

In the educator role, the nurse may be able to partner with patients to empower them to research the safety and efficacy of the techniques they are using. The preoperative assessment offers a prime opportunity for the nurse to identify possible safety risks for the perioperative patient. Whenever possible the preoperative assessment should be conducted a few days before the planned surgical procedure to allow ample time to gather data and begin patient teaching in a controlled, unhurried setting versus the typical fast pace that occurs on the patient's day of admission to the ambulatory surgery setting. The nurse can use this time to educate patients about the impact of CAM therapies in the perioperative period and beyond. By obtaining information in advance about the patient's use of these medications, the nurse can impact safe care by advising the patient to consult with the surgeon and modify the treatment regimen to avoid anesthetic complications.

The preoperative assessment also allows a forum to educate patients about the need to obtain reliable information about CAM. In discussing the patient's use of CAM, the nurse should remind the patient that results should be supported by clinical trials and that information on the internet may be commercial in nature rather than scientific (see Patient Education box on p. 1251). Patients who use CAM should also be encouraged to notify their physician if any side effects occur.

Modified from Dossey BM, Guzzetta CE: Holistic nursing practice. of self-responsibility for wellness and self-awareness to inner changes on the part of the patient.

A collaborative partnership of professionals involved in an individual's care optimizes resources that promote comprehensive, effective, less-invasive/nonpharmacologic adjuncts to allopathic medical treatment (Patient Safety). Perioperative nurses using available resources on interactions among prescriptions, dietary supplements, and herbals ensure preoperative medication safety. Seeking out and participating in appropriate research methodologies are essential for grounding the diverse components of our practice in evidence-based knowledge.

Documenting integrated care may involve noting herbals or the dietary supplement regimen the patient followed preoperatively. The nurse should also note whether these were discontinued and, if so, when. Nurse energy work practitioners who comply to a patient's request for energy treatment may refer to the North American Nursing Diagnosis Association (NANDA International) diagnosis "Potential Energy Field Disturbance" when comfort measures such as TT, healing touch, or reiki are provided by the perioperative nurse.

Integrative health therapies have a place in each perioperative nurse's practice (Ambulatory Surgery Considerations). Nursing history demonstrates a philosophic attitude of altruism and compassion, founded in creating an environment of healing. Awareness of how vital self-care practices are to sustaining a caregiver role may ultimately benefit our practice. Self-care learning and meditative experiences may come full circle by enhancing the caregiver's therapeutic use of self through presence, compassion, and holistic assessment skills.

CHAPTER 30

Workplace Issues and Staff Safety

REBECCA M. PATTON

The goals of healthcare are to reduce the burden of illness, injury, and disability and to improve the health and functioning of patients. Unsafe working environments jeopardize those twin goals, through unintended consequences for patients, care providers, and organizations (Nelson, 2006). Perioperative nurses play a critical role in making the workplace environment safer. They strive daily to keep the OR safe for patients, other members of the perioperative staff, and themselves.

Employers create a climate of safety for their employees and patients by providing a framework of institutional support. Factors that affect the safety climate include management commitment to safety, healthcare worker involvement in safety decisions, implementation of measures to reduce safety hazards in the work environment, opportunity for feedback on safety improvements, and individual accountability.

Yet, even with strong institutional support, OR nurses and surgical technologists face daily challenges to their well-being and the effectiveness with which they can do their jobs. Routine occupational activities, such as lifting patients and equipment, can cause back injuries and musculoskeletal disorders, while unsafe working environments can lead to occupational injuries from slips, trips, and falls. In addition, nurses and surgical technologists regularly face low-level but repeated exposures to numerous hazardous materials, including residues from medications, anesthetic gases, sterilization chemicals, radiation, latex, cleaning chemicals, and disinfection agents. Nurses and surgical technologists also risk injuries from sharps and exposure to bloodborne pathogens, hazardous chemicals, and workplace violence.

ERGONOMICS

Perioperative nurses and surgical technologists routinely face a wide array of occupational hazards that place them at risk for work-related musculoskeletal injuries, a frequent and costly occupational issue in nursing (Association of periOperative Registered Nurses [AORN], 2007). More than any other work-related injury or illness, musculoskeletal disorders (MSDs) are responsible for lost work time, the need for protracted medical care, and permanent disability among healthcare workers (American Nurses Association [ANA], 2008b). The extent of musculoskeletal injuries among nurses should be no surprise, given that nurses lift an estimated 1.8 tons per shift (Edlich et al, 2005).

Studies of back-related workers' compensation claims reveal that nursing personnel have the highest claim rates of any occupation or industry (ANA, 2003). Back injuries affect approximately 38% of all nurses (ANA, 2008b), and an estimated 12% of nurses who leave the profession each year do so because of back injuries (ANA, 2009).

The high incidence of MSDs among nurses is the cumulative effect of repeated patient handling events, often involving unsafe loads. Nurses and surgical technologists often lift, transfer, or reposition patients on OR beds and transport vehicles, and assist with prepping with their arms outstretched or their bodies bent forward in awkward postures and positions, increasing the risk for injury (de Castro, 2004). Several factors influence the level of risk, including the patient's weight, the transfer distance, the extent of the workspace, instrument temperature, unpredictable patient behavior, and awkward positions such as stooping, bending, and reaching (Nelson, 2006; Nelson et al, 2009).

Work in the perioperative environment particularly requires an unavoidable constant—moving and lifting large quantities of patient equipment and instrumentation daily. Nurses and surgical technologists also face risk of injury by standing on floor lifts and platforms while holding instruments and equipment. An ergonomically healthy workplace can decrease or prevent injury to its workforce.

SAFE PATIENT HANDLING AND MOVEMENT

Concentrated efforts to address workplace safety for nurses have been under way for some time. In 2005 the American Nurses Association (ANA) partnered with the Association of periOperative Registered Nurses (AORN), the National Institute for Occupational Safety and Health (NIOSH), and the James A. Haley Veterans Administration Medical Center (VAMC) in Tampa, Florida, to form the Workplace Safety Task Force. Its aim was to prepare a safe patient handling algorithm guidance document to support ergonomically healthy workplaces. The task force began by identifying high-risk tasks specific to perioperative nurses that could be addressed with specific ergonomic tools. These tasks included transferring patients on and off OR beds, repositioning patients on the OR bed, lifting and holding patients' extremities, standing for long periods of time, holding retractors for long periods of time, lifting and moving equipment, and sustaining awkward positions. The task force developed seven ergonomic tools, or *algorithms,* to guide workplace safety in the perioperative setting. These clinical tools incorporate current ergonomic safety concepts, scientific evidence, and the use of technology, such as safe patient handling equipment (AORN, 2007).

What is an algorithm? An algorithm is a set of rules for solving a problem in a finite number of discrete steps. In this

case, the algorithm is an ergonomic tool designed to help make decisions in performing various healthcare tasks. The tool directs the caregiver through a series of questions (see the diamond boxes in Figure 30-1) and provides optimal responses for action—specifically, whether assistive equipment should be used, what type of equipment would best support the task, and how many caregivers are needed to perform the task safely. The purpose of the set of algorithms is to standardize practice based on research and task analysis, rather than to allow each caregiver to rely solely on his or her own training and experience to make decisions (Nelson, 2006).

The ergonomic tools should be used in the context of an assessment and plan of care for each patient. The plan of care is designed to communicate decisions about the patient's safe handling practices among all staff likely to participate in these tasks.

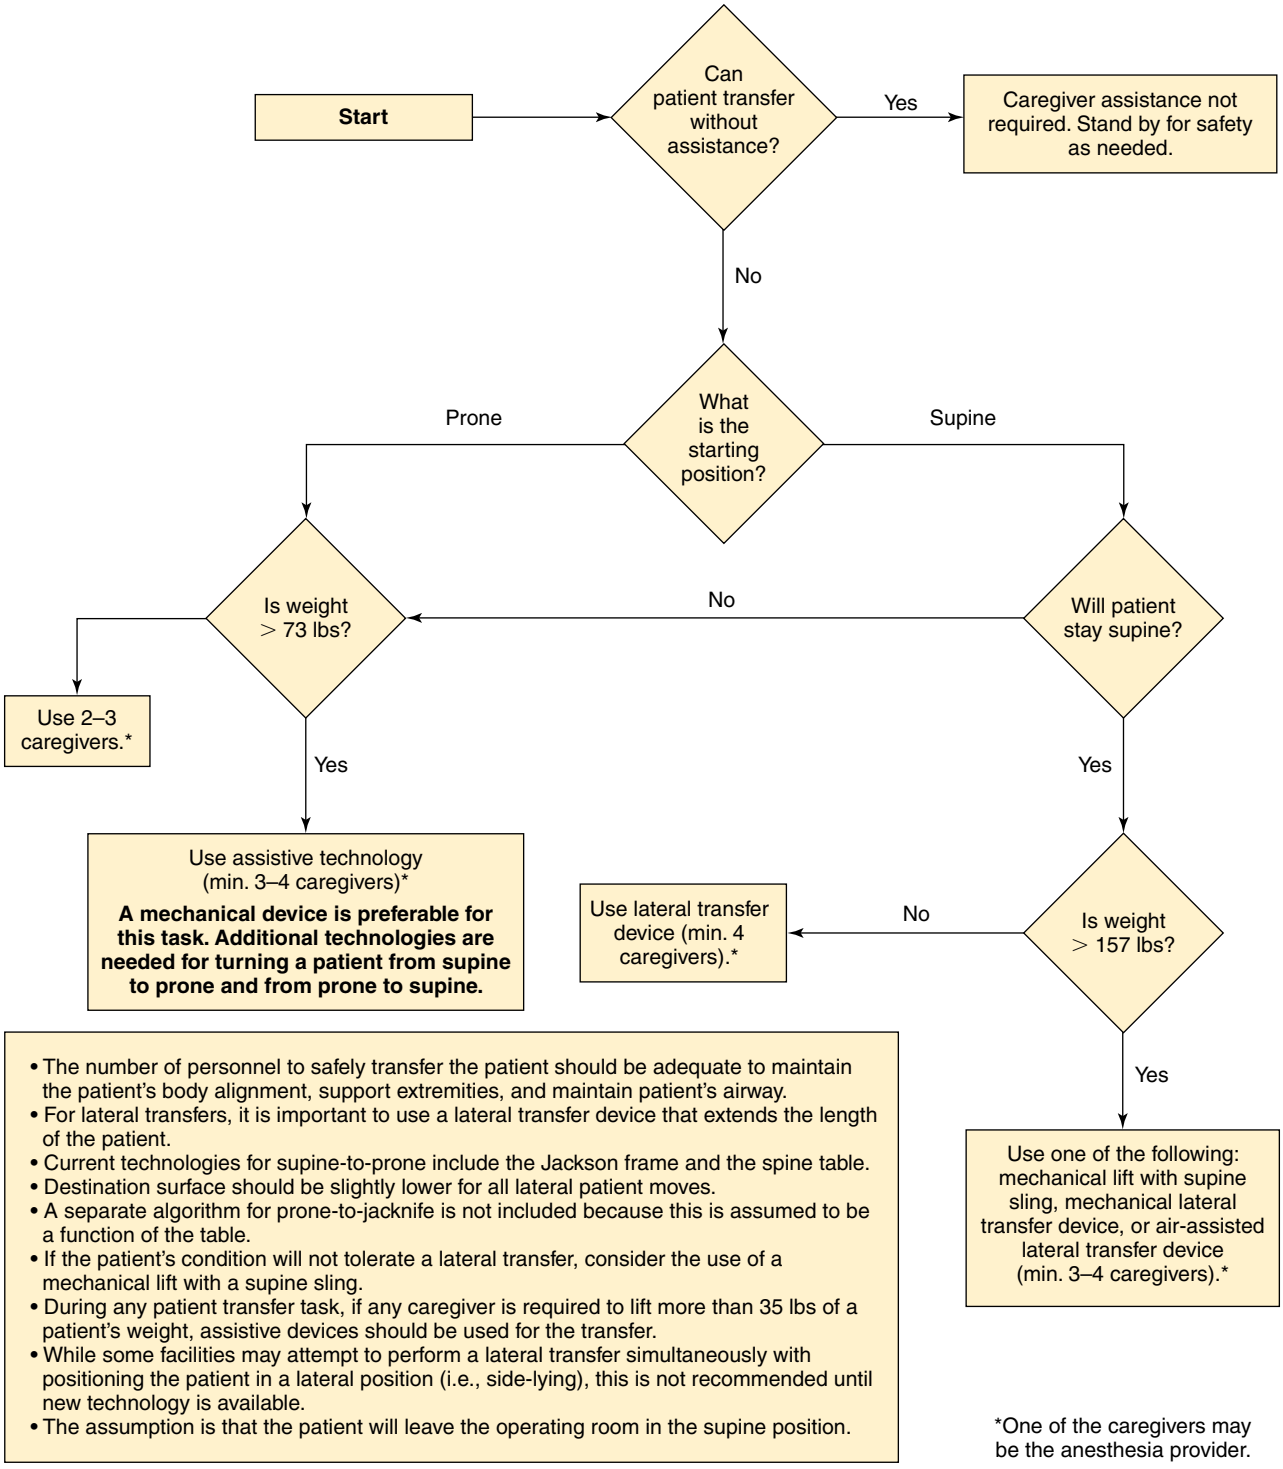

FIGURE 30-1 Lateral transfer from stretcher to and from the OR bed.

Seven Ergonomic Tools for Safe Patient Handling and Movement

This section explains the seven ergonomic tools for safe patient movement and handling.

1. *Ergonomic tool #1: Lateral transfer from stretcher to and from the OR bed* is shown in Figure 30-1. Lifting and moving patients occurs frequently in perioperative settings, with patients being transferred to and from transport carts and the OR bed. Many patients are completely or partially dependent on assistance with moving because of anesthesia (AORN, 2007). Lifting and moving patients is a hazardous patient care activity. Fully 38% of nurses have suffered injuries related to moving, lifting, or repositioning patients, and about one half of nurses have experienced chronic pain that they associate with these activities (Peter D. Hart Research Associates, 2006).
2. *Ergonomic tool #2: Positioning and repositioning the patient on the OR bed into and from the supine position.* Healthcare providers must often reposition patients, once they are on the OR bed, to provide appropriate exposure of the surgical site. They frequently lift and maneuver the patient while simultaneously placing a positioning device. Ergonomic Tool #2 provides guidelines for repositioning the patient in a safe manner.
3. *Ergonomic tool #3: Lifting and holding legs, arms, and head for prepping in a perioperative setting.* OR nurses often must lift or hold patients' limbs during skin preparation. Ergonomic Tool #3 is a table that provides calculations to determine whether it is safe for only one caregiver to lift the weight of various limbs and the safe length of time the limbs can be lifted.
4. *Ergonomic tool #4: Prolonged standing.* This tool provides relief to OR nurses and surgical technologists, often required to stand in one place for long periods of time during surgery. Prolonged standing can cause acute and chronic back, leg, and foot pain, as well as fatigue.
5. *Ergonomic tool #5: Retraction.* OR team members must sometimes hold retractors for long periods of time to expose the surgical site. This tool considers whether a self-retaining retractor can safely be used and, if not, how to determine an optimal working height and posture for the retracting team member (assistant in surgery, such as a physician's assistant [PA] or registered nurse first assistant [RNFA]).
6. *Ergonomic tool #6: Lifting and carrying supplies and equipment.* Members of the OR team lift and carry many types of supplies, instrument trays, and equipment. This tool uses the NIOSH lifting index (described below) to predict the risk of back pain from lifting specific objects in the OR.
7. *Ergonomic tool #7: Pushing, pulling, and moving equipment on wheels.* This tool makes recommendation on the number of people required to safely push or pull equipment on wheels; it is especially useful for prescribing safe movement of hospital and OR beds.

The use of assistive devices is recommended for situations where manual lifting puts the caregiver at substantial risk of injury. According to ANA's *Handle with Care* Campaign, the development of patient care ergonomics programs that include the use of assistive patient handling equipment and devices has essentially rendered "manual" patient handling unnecessary. A growing selection of equipment and devices makes available technology suitable for the variety of patient handling tasks performed by nurses (de Castro, 2004). Box 30-1 lists a number of such patient handling devices currently available. Figure 30-2 illustrates the ceiling lift device in use in the OR.

Evidence of the efficacy of safe patient handling techniques is now widespread. In one study conducted by the NIOSH on resident handling in nursing homes, a safe handling and movement program reduced resident-handling workers' compensation injury rates by 61%, lost workday injury rates by 66%, and restricted workdays by 38% (Nelson, 2006).

NIOSH Lifting Equation

The recommendation to use lifting devices for moving patients arises from a body of research that demonstrates that mechanical lifting equipment, as part of a program to promote safe patient handling, can significantly reduce musculoskeletal injuries among healthcare workers. In 1981 NIOSH developed

BOX 30-1

Categories and Descriptions of Safe Patient Handling Equipment and Devices

Inflatable lateral-assist devices	Flexible mattress inflated with air to create a cushioned layer for patient transfer
Friction-reducing lateral-assist devices	Boards made with smooth, low-friction material used for patient transfer
Mechanical lateral-assist devices	Height-adjustable stretchers used for patient transfer
Transfer chairs	Chairs that convert into stretcher, eliminating the transfer from a horizontal plane (bed or stretcher) to a seated position
Powered full-body sling lifts	Portable or ceiling-mounted lift devices to lift and transfer highly dependent patients
Powered stand-assist and repositioning lifts	Lift with arm and/or back slings to assist patients with some weight-bearing ability
Bed improvements to support transfer or repositioning	Beds that convert directly into chairs or equipped with shearless pivot that minimizes slipping toward foot of bed when head is raised
Sliding boards	Boards made of smooth, rigid, low-friction material for seated bed-to-chair or chair-to-toilet transfers that act as a supporting bridge
Stand-assist and repositioning aids	Secure devices, either free-standing or attached to beds, to help support patients to lift themselves

FIGURE 30-2 Ceiling lift.

a lifting equation to calculate recommended weight limits for specified two-handed, manual lifting tasks (Waters, 2007). Although the equation was not originally recommended for the lifting of humans, the equation has been revised and is now recommended for many patient lifting activities under certain conditions (e.g., the patient can follow directions, the amount of weight the caregiver handles can be estimated). The Revised NIOSH Lifting Equation (RNLE), promulgated in 1991, provides a mathematical equation to determine the recommended weight limit (RWL) and lifting index (LI) for selected two-handed manual lifting tasks. The RWL is defined for a specific set of task conditions and represents the weight of the load that nearly all healthy workers could perform over a substantial period of time (e.g., up to 8 hours) without an increased risk of developing lifting-related low-back pain (AORN, 2007).

The concept behind the Lifting Equation is to start with a recommended weight that is considered safe for an ideal lift and then to reduce the weight as the task becomes more stressful (e.g., the distance of the load from the worker increases, the duration of the task increases, type of handhold varies) (AORN, 2007). In general, the revised equation yields a recommended 35-lb maximum weight limit for use in patient handling tasks. When the weight to be lifted exceeds this limit, assistive devices should be used (Waters, 2007).

The formula produces a recommended weight limit that can be used to determine the lifting index. This lifting index may then be used to identify potentially hazardous lifting jobs or to compare the relative severity of two jobs for the purpose of selecting the better option. The equation has also been used to provide recommendations for lifting objects such as lead aprons, sterile packs, body positioning devices, and instrument pans or trays (AORN, 2007).

SLIPS, TRIPS, AND FALLS

Although slips, trips, and falls (STFs) may occur in many places throughout a hospital or ambulatory surgery center, the OR is of special interest because it is the site where critical patient care occurs. An STF that disables a worker is expensive in terms of both direct and indirect costs, but a disabling fall of an OR team member may adversely affect a patient as well. A fall in the OR can cause direct patient injury, disrupt the surgical procedure, contribute to surgical errors, and delay the current surgery as well as other scheduled surgeries while other staff attend to or replace the injured staff member (Brogmus et al, 2007).

STFs remain the second leading cause of serious injury among hospital workers (Hughes, 2009), accounting for the largest proportion of injuries to healthcare workers who lost time from work (Collins et al, 2008). Hospitals are responsible for slip, trip, and fall incidence rates 67% higher than those in other U.S. private industries (Collins et al, 2008). STFs account for nearly 14% of all workers' compensation costs (Brogmus et al, 2007). The average cost to an employer when a worker experiences a fall is $12,470 (Hughes, 2009).

STF Causes and Prevention

STFs are caused by many factors, including wet floors, uneven floor surfaces, low-profile equipment and cords, cluttered or poorly lit walkways, and improper footwear. Historically, STF incidents have been considered largely nonpreventable, and blame has been laid more often than not on carelessness of the fall victim (Collins and Bell, 2009). Research has shown, however, that a comprehensive STF-prevention program can significantly reduce workers' compensation claims. To a large degree, STFs are preventable (Bell et al, 2008).

Wet Floors. In one 10-year study, STFs resulting from liquids (e.g., water; fluid; and slippery, greasy, and slick spots) were the most common cause (24%) of STF workers' compensation claims (Bell et al, 2008). Anticipatory planning to avoid wet spots, however, can reduce the rate of falls. Providing lids for all cups or other open containers being transported helps to avoid spills. Installing paper-towel holders in high-spill areas, such as near scrub sinks, nursing stations, and elevators, helps employees to clean up spills promptly (Hughes, 2009).

Wet floors should be signaled by placing highly visible "Caution: Wet Floor" signs, preferably 4 feet tall and with flashing lights, in areas that have been recently mopped (Hughes, 2009). Housekeeping staff should be equipped with beepers so that they can be quickly alerted to spill areas. In a NIOSH study, employees were able to call a housekeeping hotline to report a spill and were encouraged to use pop-up caution signs placed throughout the hospital to cover spills until housekeeping arrived. The hospital also purchased highly visible yellow absorption towels that employees could toss onto a spill until it was cleaned (Bell et al, 2008).

In the OR, liquids on the floor can make an otherwise slip-resistant surface hazardous (Brogmus et al, 2007). Using a

dripless, brush-free gel solution for surgical hand scrubs minimizes water splashes. In addition, when used at the surgical site, gel-based skin preps are less likely to run than liquid prep solutions. They are also less likely to pool under patients or to drip and pool on the floor or OR bed (Brogmus et al, 2007).

Pads can be used to temporarily cover a spill that occurs in an OR because fluids spilled during surgery are hazardous (Hughes, 2009). Fluid solidifiers usually are composed of a granulated substance that can be sprinkled onto a spill or poured into a container with fluid. Fluid solidifiers absorb liquid and solidify the fluid into gel. Adding a fluid solidifier in a liquid medical-waste container or on a fluid spill on the floor serves to control fluid and to reduce the risk of slips and falls (Brogmus et al, 2007). Effective containment also includes adequate waste containers for the planned procedure and readily available waste-control supplies, including absorptive products.

Uneven Floor Surfaces. One NIOSH study found that, while 36% of same-level incidents occurred because of floor contaminants such as wet floors, the remainder (64%) of the falls on the same level occurred at transition areas, such as from dry to wet, on uneven surfaces, or from one type of floor surface to another (Collins et al, 2006). Hospitals should ensure that there are no uneven surfaces, including thresholds, on floors. In stairwells with potentially low visibility, the nosing on the top and bottom steps can be painted to provide visual cues.

Unobstructed Pathways. Pathways must be kept clear, particularly of low-profile equipment and cords that can be easily overlooked in patients' rooms, hallways, ORs, or other care areas (Hughes, 2009). If possible, cords should not cross walkways; if this is impossible, cords should be covered or taped. Extension cords are also often found under desks and at nursing stations; where feasible, cord organizers, cord clamps, or retractable cord holders should be used to minimize these tripping hazards.

Keeping pathways clear is especially difficult in the OR, where multiple cables and cords are used in surgical procedures. Newer ORs are equipped with articulated ceiling-mounted booms that help keep cords off the floor and systems that integrate cables into the OR bed. Cords and cables in older ORs should be routed so that they do not stretch across walking paths, and they should be secured by bundling, taping, or braiding. Routing and securing cords makes it easier to check that all necessary cords are properly connected, and doing so makes it less likely that a patient will be injured or the procedure prolonged because someone trips on a cord (Brogmus et al, 2007).

Low-standing equipment and supplies are potential tripping hazards. These include buckets, rolling stools or step stools, support structures for equipment, and supply containers. OR staff often have to navigate around IV tubing and poles. The Occupational Safety and Health Administration (OSHA) suggests marking mobile equipment such as stools with a bright color or a taped X to make them more visible and distinguishable from the floor (OSHA, 2008c). Also, even though protective and absorptive mats play a safety role, they too can pose a tripping hazard. Slip-resistant absorptive mats should be used, and soiled absorptive mats should be removed. A mat that is oversaturated can swell and become a slipping and tripping hazard (Brogmus et al, 2007).

Failures in teamwork and communication can lead to surgical errors. One study found that when preoperative briefings occurred such errors decreased by more than 50%. In a recent study (Berenholtz et al, 2009), a majority of surgical team members who participated in a study of 37,133 briefings and debriefings using a standard 1-page tool said the process improved communication and teamwork. On average, the briefing took 2.9 minutes, and the debriefing took 2.5 minutes. Planning reduces critical events and errors, as well as risks to patients and OR personnel. After considering the layout of equipment, tubes, and cords and the team's response to trips and spills (Brogmus et al, 2007), any concerns held by the perioperative nurse or surgical technologist can be addressed during the preoperative briefing.

Lighting. Lighting throughout the healthcare facility must be adequate to visualize pathways, particularly stairways, when supplies or other items are being carried (Hughes, 2009). Adequate lighting is of specific and critical importance in the OR. Advancements in surgical technology, such as minimally invasive surgery (MIS) procedures, have increased the use of LED monitors in the OR. This increasingly requires dimming general room lighting while leaving the surgical site highly illuminated. Not only does this leave the rest of the OR dimly lit, but also the high illumination on the surgical site makes adapting one's vision to the dimmer room lighting more difficult (Brogmus et al, 2007). Dimmer lighting, of course, tends to heighten the risks of not seeing tripping hazards or fluids on the floor.

Proper Footwear. Proper footwear minimizes the risk of STFs. Lessons can be learned from industries, such as food service and commercial fishing, in which antislip footwear is standard (Hughes, 2009). Slip-resistant shoes are perhaps most effective at eliminating falls from slips. Specialized footwear is estimated to reduce the risk of slips and falls by 50% (Staal et al, 2004). In addition to being slip resistant, shoes should fully surround the foot and provide support (Hughes, 2009). Further, shoes should meet, and preferably exceed, the wet and dry test minimums of the U.S. footwear industry, should be comfortable, should be appropriate for both on- and off-the-job use, and should be affordable (Staal et al, 2004). Other research has suggested that the use of slip-resistant shoes by employees is encouraged when employers provide shoes or a payroll deduction for approved shoe purchases (Collins and Bell, 2009).

Programmatic STF Prevention and Reduction

Given the diverse age, job duties, and experience of healthcare workers, an STF program is critical to create a safe work environment. During program development, each healthcare facility should conduct a hazard vulnerability analysis to study the facility's unique set of hazards so they can be appropriately addressed in a workplace safety program that includes targeted STFs (Hughes, 2009).

A comprehensive prevention program can significantly reduce injuries. NIOSH researchers, in one study, compared injury rates and workers' compensation costs for a 10-year period before, during, and after the implementation of interventions. They found a 58% reduction in workers' compensation claims for slips, trips, and falls in the postintervention period (Bell et al, 2008). One key component of a successful STF prevention

program is to educate workers about the importance of STF prevention and to encourage every employee to take personal responsibility for eliminating STF hazards. Whether this involves personally cleaning spills or cordoning off an area to alert fellow employees while waiting for housekeeping staff to arrive, a successful STF program requires that all hospital staff share responsibility for prevention (Collins and Bell, 2009).

SHARPS SAFETY AND BLOODBORNE PATHOGENS

Scope and Significance of Problem

In the high-risk perioperative environment, healthcare workers routinely face exposure to bloodborne pathogens (BBPs) and percutaneous injuries (PIs). According to the Centers for Disease Control and Prevention (CDC), hospital-based personnel sustain 385,000 needlesticks and other sharps-related injuries each year—an average of more than 1000 sharps injuries daily (CDC, 2008b). The OR, with 33% of injuries, has the highest proportion of PIs relative to those sustained in all other hospital settings (Research Highlight). When applied to the CDC's estimate for annual number of hospital PIs in the United States, this translates to 128,000 OR PIs each year (Davis, 2006). In an international study, needlestick injuries per 1000 full-time equivalents (FTEs) for medical-surgical unit nurses were 146 in the United States, 209 in Canada, 157 in the United Kingdom, and 488 in Germany. Nurses working in the OR and/or other perioperative settings had sharp device injury rates double those of nurses in other specialties in the United States and Canada—255 and 569 injuries per 1000 per year, respectively (Clarke et al, 2007).

RESEARCH HIGHLIGHT

Inoculation Volume Delivered by Suture Needles

Needlestick injury is a common occurrence in the OR. Most data about seroconversion from needlesticks are based on hollow-bore needles and inoculation volumes of pure blood delivered by suture needles. Data are lacking, however, on contaminant transmission in less viscous body fluids that are not prone to coagulation and the effect of layers of gloves on contaminant transmission.

For this study, an enzyme-colorimetry assay was used to quantify the volume of inoculation delivered by suture needles coated with a water-like contaminant through various types and layers of surgical gloves. They found that one glove layer removed 97% of the contaminant from tapered suture needles and 65% from cutting needles. Additional layers of gloves did not significantly improve contaminant removal from tapered needles.

For cutting needles, however, two layers of gloves removed 91% of the contaminant, which was significantly better than one glove. Three gloves did not afford significant additional protection. There were no statistically significant differences between glove types.

This research supports using double-gloves for maximum safety. A single layer of gloves removes contaminant from tapered needles as effectively as multiple layers, but for cutting needles, double-gloving offers superior protection.

Adapted from Lefebvre DR et al: An enzyme-mediated assay to quantify inoculation volume delivered by suture needlestick injury: two gloves are better than one, *J Am Coll Surg* 206:113-122, 2008.

Although the hepatitis B virus (HBV), the hepatitis C virus (HCV), and the human immunodeficiency virus (HIV) are the pathogens most commonly transmitted during patient care, injuries from needles and other sharp devices used in healthcare and laboratory settings are associated with the transmission of approximately 20 pathogens (CDC, 2008b). In one study of the prevalence of BBPs in an urban, university-based general surgical practice, testing revealed that 38% of all operations involved patients infected with a BBP: 26% were infected with HIV, 4% with HBV, 35% with HCV, and 17% with both HIV and HCV (Davis, 2006). The risk of transmission after a needlestick or sharps injury is estimated to be 6 to 30 out of every 100 people for HBV, 3 to 10 out of every 1000 people for HCV, and 1 out of every 300 people for HIV.

Exposure to bloodborne pathogens occurs during all phases of the perioperative process. The American College of Surgeons (ACS) estimates that cuts or needlestick injuries occur in 1% to 15% of all operations (ACS, 2005). Risk of a sharps injury increases during more invasive, longer procedures that result in higher blood loss. Fatigue resulting from working extended hours in combination with the fast pace of the perioperative environment may also contribute to increased risk of PIs (AORN, 2009a). Other factors that may contribute to surgical PIs include frequent handling of sharp instruments, prolonged contact of surgical personnel with open surgical sites, presence of relatively large quantities of blood (Jagger et al, 1998), unsafe needle handling techniques, assignment of incision closure to relatively inexperienced staff, and failure to use a neutral zone for passing sharps between personnel (Davis, 2006).

Although injuries from hollow-bore needles constitute the majority of percutaneous injuries in the healthcare field overall, the pattern of injuries inside the OR is somewhat different. Suture needle injuries (SNIs) are by far the predominant cause of PIs in the surgical setting, accounting for as many as 77% of these injuries (AORN, 2009a), and are also the leading cause of occupational exposure to bloodborne pathogens among OR professionals (Davis, 2006).

Box 30-2 provides information on bloodborne pathogens and legislation.

Preventing Injuries During Surgery

Surgery involves precise, regimented actions that require planning, communication, and teamwork. These same elements can be employed to mitigate inherent hazards associated with sharp devices in the perioperative setting (AORN, 2009a). AORN has developed a list of risk reduction strategies that OR nurses can use to protect themselves from exposure injuries in surgery. Care in setting up the surgical work area includes placement of sharp items, constant awareness of the location of sharps and other sterile team members during surgery, and careful disposal of sharps after surgery. Such care contributes to ensuring a surgical environment that is safe for all participants. These risk reduction strategies are presented in the following sections.

Safe Handling Practices for Surgical Sharps. Observing safety precautions during all phases of surgery, from setup to cleanup, reduces the number of injuries and exposures for all OR personnel.

BOX 30-2

Bloodborne Pathogen Legislation

Protecting healthcare workers from bloodborne pathogens was largely neglected until the global AIDS epidemic of the 1980s. The CDC, the first federal agency to respond, in 1987 issued guidelines for Universal Precautions to protect workers at risk of exposure to blood or body fluids of patients.

In 1991 OSHA issued a rule for Occupational Exposure to Bloodborne Pathogens, based on the concept of Universal Precautions. The Needlestick Safety and Prevention Act, enacted in 2000, directed OSHA to revise its Bloodborne Pathogens Standard. OSHA subsequently revised its final rule to include a special focus on needlestick and other percutaneous exposures to bloodborne pathogens. OSHA's Bloodborne Pathogens Standard now requires that engineering and work-practice controls be used to eliminate or minimize exposures to blood and other potentially infectious materials (OPIMs), including human body fluids, tissue, or organs; and HIV- or HBV-containing cell or tissue cultures.

In particular, the Standard requires that sharps injuries in the surgical area be eliminated or minimized through the use of such measures as safe needles and other sharps devices; blunt-tip suture needles; needleless IV connectors; proper containers for sharps; a "No Pass Zone" for surgical instruments; and a method to pass equipment safely between surgeon and assistants. The Standard also recommends the use of scalpel blades with safety features; the use of alternative cutting methods, when appropriate; and the use of mechanical (self-retaining) retraction devices. Other requirements include wearing appropriate personal protective equipment (PPE), such as gloves, gowns, face shields or masks, and shoe covers, if blood or OPIM exposure is anticipated and adhering to the following practices regarding contaminated needles and sharps: contaminated needles and other sharps should not be bent, recapped, sheared, or broken; and they should be discarded immediately.

One unique feature of the Needlestick Safety and Prevention Act was the required participation of healthcare workers in evaluating and selecting safety-engineered needles and sharps; further, employers were mandated to document evaluation and implementation of safety-engineered devices. Employers were also required to maintain a sharps injury log to document the types of devices causing injuries and an explanation of the circumstances of each incident.

There is convincing evidence that this legislation, particularly as it pertains to safety-engineered devices, has been successful. U.S. researchers identified reductions in injury rates that have been attributed to the passage of federal sharps legislation in 2000 and more vigorous enforcement of safety guidelines. In an international study, researchers concluded that sharps injury rates were lowest in the United States, where the use of safety-engineered devices is highest and where federal regulation has a positive impact on nurse safety. Within the United States, a study at Memorial Sloan-Kettering Cancer Center (MSK) in New York explored the effects of adopting safety-engineered devices. After adoption, there was an overall reduction in sharps injuries of 58%, with a 71% reduction in injuries from hollow-bore needles and a 75% reduction in injuries among nurses, the occupational group that typically sustains the highest proportion of injuries. The same study found, however, that surgical settings are least likely to adopt safety-engineered devices, such as blunt suture needles and shielded scalpel blades.

Modified from Jagger J et al: The impact of U.S. policies to protect healthcare workers from bloodborne pathogens: the critical role of safety-engineered devices, *J Infect Pub Health* 1:62-71, 2008; Occupational Safety and Health Administration: *Hospital eTool, surgical suite module, bloodborne pathogens (BBPs),* 2008, available at www.OSHA.gov/SLTC/etools/hospital/surgical/surgical.html#BloodbornePathogens. Accessed April 6, 2009; Clarke SP et al: Sharp-device injuries to hospital staff nurses in 4 countries, *Infect Control Hosp Epidemiol* 28:473-478, 2007.

During preparation for surgery:

- Organize the work area (Mayo stand, back table) so that sharps are always pointed away from the person setting up.
- Establish a separate area, a "neutral zone," to place a reusable sharp for safe handling during the procedure; include identification and agreement about this neutral zone in the preoperative briefing.
- Use standardized sterile field setups throughout the surgical services department.

During the procedure:

- Use neutral or hands-free techniques for passing sharp items, instead of passing hand to hand.
- Give verbal notification when passing a sharp device.
- Be aware of other sterile team members in and near the area when handling a sharp device.
- Keep track of, and account for, all sharp items throughout the procedure.
- Keep hands away from the surgical site when sharp items are in use (i.e., suturing, cutting).
- Use gloves and an instrument to pick up sharp items (e.g., suture needles, hypodermic needles, scalpel blades) that have fallen on the floor.

During postprocedure cleanup:

- Inspect the surgical setup used during the procedure for sharps.
- Transport reusable sharps in a closed, secure container to the designated cleanup area.
- Inspect the sharps container for overfilling before discarding disposable sharps in it.
- Do not place hands or fingers into a container to dispose of a device.
- Keep hands behind the sharp tip when disposing.

The Risk Reduction Strategies box provides information on requirements for the most effective sharps disposal containers.

The Neutral Zone. The "neutral zone" has been defined as a location on the surgical field where sharps are placed in a predesignated sterile basin or tray or on a magnetic pad, from which the surgeon or assistant can retrieve them. After use, the items are placed back in the neutral zone, and the scrub person retrieves them. This technique eliminates hand-to-hand passing of sharps between the surgeon and the scrub person, so that no two individuals touch the same sharp at the same time. In one study, when this hands-free technique (HFT) was

RISK REDUCTION STRATEGIES

Requirements for Sharps Disposal Containers

- Durable, closable, leakproof, and puncture resistant
- Appropriate size for user and type of sharps
- Container designed for "letter-drop" of sharps
- Lids allow sharps to enter by gravity without need for additional manipulation
- Within horizontal reach of healthcare team members (close to the point of use) who dispose of sharps
- Container, level of fullness (full line), proper warning labels (biohazard labels), and color coding (orange, orange-red) must remain visible to healthcare team members
- Self-closing lids to prevent overfill if container is not see-through to observe fill line
- Ease of assembly and operation, including one-handed disposal

used at least 75% of the time during the procedure, there was a 59% decrease in exposure incidents during procedures in which the blood loss was at least 100 ml (Stringer et al, 2002). As it reduces the chance of accidental needle punctures and cuts, use of the neutral zone to transfer sharps has been recommended by the ACS and AORN (Berguer and Heller, 2004), as well as by OSHA (Davis, 2006).

The following suggestions make the most valuable use of the neutral zone:

- A magnetic pad or basin may be used to create the neutral zone; if a basin is used, it should be placed on the field and not held by the scrub person.
- Dedicate the neutral zone to sharps only; these include suture and hypodermic needles, scalpels, and other sharp instruments.
- The scrub person and surgeon or assistants should confer on the best placement of sharps in the neutral zone.
- Place only one sharp at a time in the neutral zone.
- Announce the transfer of a sharp before placing it in the neutral zone (such as "knife down"); after announcement, orient the sharp in the correct position in the neutral zone (i.e., place it such that the person picking it up does not have to alter its position in his or her hand).
- Include identification of the neutral zone during hand-off communications to relief scrub persons.

PERSONAL PROTECTIVE EQUIPMENT

The use of personal protective equipment (PPE) has proven very effective against transmission of pathogens in the OR. For prevention of infection among OR nurses, two practices are particularly useful: double-gloving and the use of eye protection.

Double-Gloving

Glove barrier failure commonly occurs in the perioperative setting. The frequency of glove perforation during surgery has been studied extensively and found to range from 8% to 50% (Misteli et al, 2009). Glove failures can be caused by punctures, tears by sharp devices, or spontaneous failures; all these failures expose the wearer to bloodborne pathogens. Studies have demonstrated that glove perforations often occur after an average of 40 minutes of use during surgical procedures. When two pairs of gloves are worn, in most instances only the outer glove perforates when punctured by a sharp device. In addition, research demonstrates that when two pairs of gloves are worn and a puncture occurs, the volume of blood transferred from a solid sharp device (e.g., suture needle) is reduced by as much as 95%. AORN advises double-gloving during invasive procedures, noting that 18 clinical trials have demonstrated that double-gloving minimizes the risk of exposure to blood and that double-gloving reduces by as much as 87% the risk of exposure to blood and body fluids if the outer glove is punctured (AORN, 2009b).

Eye Protection

In one study of blood exposures in OR personnel, blood contact with the mucosa of the eyes was the most common type of exposure from splashing or spraying, accounting for 45% of incidents (compared with only 7% and 5% of cases occurring to the mucosa of the nose or mouth, respectively) (Jagger et al, 1998). This finding suggests that barrier protection for the nose and mouth is more consistently worn by OR personnel than eye protection. As it is now well documented that the conjunctivae serve as a transmission route for HIV and HCV, it is recommended that all OR members, regardless of proximity to the surgical site, wear protective eyewear as routinely as surgical masks (Jagger et al, 1998).

BLUNT SUTURE NEEDLES

Suture needle injuries (SNIs) are the predominant cause of PIs in the surgical setting. Straight suture needles pose the highest risk of injury per needle use, but the majority of SNIs occur during suturing of fascia or muscles with unprotected, curved sharp suture needles (Davis, 2006). According to the ACS, blunt suture needles permit suturing of fascia and other structures with minimal risk of injuring the surgeon, even when the surgeon's glove is punctured. All published studies to date have demonstrated that the use of blunt suture needles can substantially reduce or eliminate needlestick injuries from surgical needles. The ACS supports the universal adoption of blunt suture needles as the first choice for fascial suturing to minimize or eliminate needlestick injuries from surgical needles (ACS, 2005). The use of blunt suture needles has also been officially endorsed by AORN and the Council for Surgical and Perioperative Safety (Box 30-3).

Eliminating exposure to hazards cannot be accomplished in a "once and done" manner. Often, several diverse steps must be taken simultaneously. These might be as different as hazard-proofing a room, changing the type of equipment used, and changing staff behavior by asking each team member to wear a particular type of protective garment. The Evidence for Practice box explains this approach as the Hierarchy of Controls model.

RESPONDING TO EXPOSURE

OSHA regulations require healthcare organizations to protect their workers and to have a sharps injury and bloodborne pathogen exposure control plan (ECP). By law, the plan must be written, communicated to all workers in the perioperative setting, and uniformly supported and enforced by perioperative

BOX 30-3

Blunt Suture Needles

The blunt needle does not have a sharp point; it dissects tissue as it is used, causing less tissue trauma than a conventional sharp-pointed needle. The risk of needlestick injury is significantly reduced. The following organizations support the use of blunt needles in surgery:

- The American College of Surgeons: Issued a statement on blunt suture needles, noting that the College supported "the universal adoption of blunt suture needles as the first choice for fascial suturing to minimize or eliminate needle-stick injuries from surgical needles" and recommending that "blunt suture needles should be available in various sizes and with a range of suture adequate for different surgical applications."
- The Council on Surgical and Perioperative Safety (CSPS): Endorsed use of blunt suture needles as a recommended sharps safety measure.
- NIOSH: Strongly encouraged the use of blunt-tip suture needles to decrease percutaneous injuries to surgical personnel (NIOSH, 2008).
- AORN: In its recommended practice for prevention of transmissible infections, AORN notes that the use of blunt suture needles is a method for reducing injuries caused by needles.

Adapted from American College of Surgeons: Statement on sharps safety, *Bull Am Coll Surg* 92(10), 2007, also available at www.facs.org/fellows_info/statements/st-58.html; Association of periOperative Registered Nurses (AORN): Recommended practices for prevention of transmissible infections in the perioperative practice setting. In *Perioperative standards and recommended practices*, Denver, 2009, The Association; Council on Surgical and Perioperative Safety: *The CSPS endorses that all measures to prevent sharps injuries will be used, inclusive of: double-gloving, use of blunt suture needles, hands-free technique or neutral zone, and the universal adoption of all sharps safety measures in perioperative care is recommended,* adopted July 15, 2007, available at www.cspsteam.org/information/information1.html. Accessed February 5, 2009.

EVIDENCE FOR PRACTICE

Hierarchy of Controls

The Hierarchy of Controls model defines a method to control exposure to occupational hazards as a fundamental approach to protect workers. The hierarchy is used to determine a feasible and effective set of controls and can be summarized as follows:

- Elimination
- Substitution
- Engineering controls
- Administrative controls
- Personal protective equipment (PPE)

The concept of the hierarchy is that the control methods at the top of the preceding list are potentially more effective and protective than those at the bottom. Elimination and substitution, while most effective at reducing hazards, also tend to be the most difficult to implement in an existing process. Administrative controls and PPE are frequently used with existing processes where hazards are not particularly well controlled, but these methods for protecting workers have proven less effective than other measures and require significant effort by workers to achieve success.

Blood exposure prevention practices can be prioritized following the principles of the Hierarchy of Controls prevention model. In the hierarchy for sharps injury prevention, for example, the first priority is to eliminate and reduce the use of needles and other sharps, where possible. The next step is to isolate the hazard, thereby protecting workers from an otherwise exposed sharp, through the use of an engineering control. When these strategies are not available or will not provide total protection, the focus shifts to work-practice controls and personal protective equipment. Active involvement of the OR team and hospital management is essential because decisions about supplies, immunizations, and training, among other considerations, require continuous team efforts.

From CDC, NIOSH: *NIOSH safety and health topic: engineering controls,* Cincinnati, 2009, available at www.cdc.gov/niosh/topics/engcontrols/. leadership. At a minimum, the following must be included in the ECP:

- Determination of employee exposure
- Implementation of exposure control methods, including:
  - Universal Precautions
  - Engineering and work-practice controls
  - Personal protective equipment
  - Housekeeping
- Hepatitis B vaccination
- Postexposure evaluation and follow-up
- Communication of hazards to employees and training
- Recordkeeping
- Procedures to evaluate exposure incidents (ANA, 2002)

If You Sustain an Injury

If a needlestick or other occupational contact (e.g., splashing or spraying) that could result in a bloodborne pathogen exposure does occur, the injured person should begin the following procedures *immediately.*

Immediate Response

- Wash with soap and water all wounds and skin sites that have been contacted by blood or body fluids. Flush mucous membranes with water (CDC, 2001).
- Alert your supervisor and initiate the injury reporting system used in your workplace.

- Identify the source patient; this patient should be tested for HIV, HBV, and HCV infections. Your workplace will begin the testing process by seeking patient consent.
- Immediately report to employee health, the emergency department (ED), or the designated facility.
- Get tested immediately and confidentially for HIV, HBV, and HCV infections.
- Get postexposure prophylaxis (PEP) using CDC guidelines when the source patient is unknown or tests positive for HIV or HBV (currently, there is no PEP for HCV). PEP medications for HIV should be started within 2 hours of exposure. PEP can be started after 2 hours from exposure; however, you should be evaluated as soon as possible after injury.
- Document the exposure in detail, for your own records as well as for the employer and for workers' compensation purposes. Employers must maintain a sharps injury log (described under EPINet below) (ANA, 2002).
- Obtain an immediate evaluation and risk assessment.
- Initiate a postexposure treatment plan, including counseling, education, and follow-up testing.

Follow-Up

- Obtain confidential postexposure testing at 6 weeks, 3 months, 6 months, and (depending on the risk), 1 year.
- Undergo monitoring and follow-up of PEP.
- Take precautions to prevent exposing others until follow-up testing is complete (ANA, 2002).

EPINet

The Exposure Prevention Information Network (EPINet) is a voluntary surveillance system used to record and track PIs and blood and body fluid contacts. The EPINet system consists of a Needlestick and Sharp Object Injury Report (Figure 30-3); Blood and Body Fluid Exposure Report (Figure 30-4); and software to enter and analyze data from the forms (International Healthcare Worker Safety Center [IHWSC], 2008a). Since its introduction in 1992, more than 1500 hospitals in the United States and overseas have acquired EPINet.

The federal Needlestick Safety and Prevention Act of 2000 and the 2001 revised Bloodborne Pathogens Standards require healthcare facilities to maintain a sharps injuries log. The log must include, at a minimum, the type and brand of device involved in the exposure incident, the department where the exposure occurred, and an explanation of how it occurred. EPINet data can be used to help facilities target high-risk devices and products, identify injuries that may be prevented with safer medical devices, and evaluate new technology designed to prevent needlesticks. Data can also be used by institutions to share and compare information and successful prevention measures (International Healthcare Worker Safety Center, 2008b).

A CULTURE OF SAFETY

A healthcare institution's culture of safety profoundly impacts its success or failure in reducing employees' blood exposure risk. For sharps safety in particular, success factors include effective systematic review of exposure data, workers' perceptions of exposure risk, availability and use of safety devices, and comprehensive education on bloodborne pathogen exposure risk and safety device use (CDC, 2008b).

Protecting Yourself

You can take significant measures toward ensuring your personal safety and avoiding injuries from sharps if you do the following: Adopt and incorporate safe habits into daily work activities when preparing and using sharp devices. Observe local, state, and federal (OSHA) regulations. Comply with methods to protect yourself from disease transmission (e.g., get the hepatitis B vaccination). Participate in education about bloodborne pathogens, and follow recommended infection prevention practice. Know the location in your department of the exposure control plan. Finally, follow the exposure control policy if injured, including *immediate* reporting of the incident and commencement of exposure response procedures (AORN, 2009a).

WASTE ANESTHETIC GASES

Scope and Significance of Problem

Surgical anesthesia was first used in the United States when diethyl ether was administered to a patient in 1942 (OSHA, 2000). Since then, many anesthetic agents have been administered to patients to provide freedom from pain during surgical procedures. Advances in anesthetic agents have eliminated the risk of explosion caused by anesthetic agents such as diethyl ether, cyclopropane, and ethylene (OSHA, 2000). Developments in chlorofluorocarbon chemistry have resulted in halogenated, nonflammable, volatile agents; these have reduced the risk of explosion and flammability, but nonetheless are responsible for an occupational hazard and risk estimated to expose 200,000 healthcare professionals (OSHA, 2000). Those OR workers at occupational risk include anesthesia care providers, perioperative nurses, surgical technologists, postanesthesia care unit (PACU) nurses, and others who work in settings where anesthetics are administered (CDC, NIOSH, 2007).

Waste anesthetic gases (WAGs) are small amounts of gases that may leak either from the patient's anesthetic breathing circuit into the OR air while anesthesia is being administered or from exhalation of the patient during recovery. Both mechanisms of exposure create risks for OR personnel. Therefore OR workers must know the risks, potential health effects, and precautions that should be taken.

OR personnel are more prone to being exposed to WAGs in facilities either with no automatic scavenging systems or with no automated ventilation, in facilities with anesthesia systems in poor working order, or in recovery areas such as the PACU with inadequate systems. Where scavenging and ventilation systems are in place, OR personnel nevertheless can be exposed when leaks occur in the anesthetic breathing circuits because of poor maintenance of tubing, connectors, or valves, or because of circuits with loose connections. Gases can also escape during connection and disconnection of the system. In addition, poor-fitting patient masks or endotracheal tube connections can cause gases to escape into the air, making induction of anesthesia another occasion when gas leakage places OR personnel at risk (CDC, NIOSH, 2007). Other mechanisms of potential exposure include defects in rubber and plastic tubing and hoses; selected anesthesia techniques; improper practices such as gas flow control valves being left open after use; liquid anesthetic spills; and improperly inflated tracheal

FIGURE 30-4, cont'd Blood and body fluid exposure report for the OR.

tubes, which can allow WAGs to escape into the ambient OR air (OSHA, 2000).

PACU personnel are exposed to WAGs from patients who have received anesthetics and then are admitted to the PACU or another postanesthesia recovery area. These postoperative patients eliminate anesthetics through their respiratory tracts by simply exhaling. Because of PACU nurses' close proximity (i.e., in the nurses' breathing zone) to their patients while providing monitoring, they are being exposed to varying concentrations of anesthetic agents (OSHA, 2000). In contrast to the OR, ambient air in the PACU may contain multiple WAGs, which include nitrous oxide, halothane, enflurane, isoflurane, desflurane, and sevoflurane (OSHA, 2000). Detection of the levels of WAGs without monitoring air samples in the breathing zone is very deceiving because one study found that less than 50% of the population were able to detect the presence of halothane until the concentrations were above 125 times the NIOSH-recommended exposure limit (OSHA, 2000).

Exposure to high concentrations of waste anesthetic gases can result in headaches, fatigue, irritability, nausea, drowsiness, liver and kidney disease, and difficulties with judgment and coordination (CDC, NIOSH, 2007). Some studies show that long-term exposure to low concentrations of WAGs appears to have no adverse health effects, while other studies have shown links to miscarriage, genetic damage, and cancer for perioperative personnel (and their spouses), with further links to birth defects in their children (CDC, NIOSH, 2007). In light of these latter studies, responsible approaches to limit exposure to WAGs are needed (OSHA, 2000).

A list of strategies designed to help healthcare workers reduce their exposure to WAGs is presented in the Risk Reduction Strategies box.

CHEMICALS

Chemicals are used in OR settings for many purposes, including sterilization and disinfection of equipment, cleaning, specimen preservation, and anesthesia. Some commonly used chemicals found in ORs include ethylene oxide, aqueous glutaraldehyde, formalin, formaldehyde, peracetic acid, and methyl methacrylate. Exposure to chemicals can occur through several routes. Toxic exposure effects can be limited to the site of exposure or result in a systemic effect. The following are the three main routes of exposure to toxic chemicals (OSHA, 2005):

1. *Inhalation* is the introduction of toxic chemicals, radioisotopes, or pathogens via the respiratory tract. Gases or vapors of volatile liquids are the most commonly inhaled chemicals, although it is possible to inhale chemicals as aerosols or dusts. Chemical agents inhaled are generally quickly absorbed because of the vascularity and large surface area of lungs, with symptoms of exposure manifesting within 1 to 3 days after exposure.
2. *Skin contact or absorption through mucous membranes* is slower than inhalation. Mucous membranes include mouth, eyes, and nose. Nonintact skin integrity can also lead to exposures.
3. *Ingestion* is the least common route of exposure. Ingestion may be the result of unintentional exposures from the hand (including nail biting) or mouth, such as swallowing saliva containing trapped airborne particles.

The amount of chemical absorbed by the body can vary, depending on duration of exposure, concentration of the chemical, time of exposure, and environmental factors (OSHA, 2005). Toxicity can be acute or chronic. Acute toxicity usually results from an accidental spill of a chemical substance. Exposure is sudden and results in an emergency. Chronic toxicity results from repeated exposure to low levels of the chemical over a prolonged period (CDC, 2008a).

Exposure limits for many chemicals used in healthcare help to provide a safe environment. Exposure limits published by OSHA are the only legally recognized regulatory limits (CDC, 2008a). OSHA defines a permissible exposure limit (PEL) as the amount of exposure to a chemical permitted as a time-weighted average (TWA), based on an average concentration for an 8-hour workday and a 40-hour workweek, to which workers can be repeatedly exposed without adverse health effects (CDC, 2008a). Recommended exposure limits

RISK REDUCTION STRATEGIES

Steps to Reduce Exposure to Waste Anesthetic Gases (WAGs) before Beginning Anesthesia

- Inspect the anesthetic delivery system before each use, looking for irregularities or breaks in the system.
- Check the patient's breathing circuit for negative-pressure and positive-pressure relief as part of daily machine checklist.
- Activate the room or local ventilation system.
- Ensure scavenging equipment is properly connected.
- Connect the gas outlet to central scavenging system.
- Start the gas flow after the laryngeal mask or endotracheal tube is in place.
- Fill vaporizers under a ceiling-mounted hood with an active evacuation system before or after the procedure.
- Be certain that uncuffed endotracheal tubes create a completely sealed airway.
- Use the lowest anesthetic gas flow rates possible for proper functioning of the anesthesia delivery system and for patient safety.
- Avoid very high anesthetic gas flow rates to prevent leaks because high flow rates generate more waste anesthetic gases than low flow rates.
- Do not deliver anesthetic by open-drop method (i.e., dripping liquid, volatile anesthetic onto gauze).
- Make sure the mask, if used, fits the patient well. Have several sizes available to select the proper-fitting mask for the patient.
- Before disconnecting a patient from a breathing system, eliminate residual gases through the scavenging system as much as possible.
- Turn the gas off first before turning off the breathing system.

Adapted from CDC, NIOSH: *Waste anesthetic gases: occupational hazards in hospitals,* Publication No. 2007-151, Cincinnati, 2007, Author.

(RELs) are occupational exposure limits developed and recommended by NIOSH, providing protection over a working lifetime. NIOSH uses a TWA for up to a 10-hour workday during a 40-hour workweek (CDC, NIOSH, 2005). A short-term exposure limit (STEL) is a designated value that should not be exceeded anytime during the workday, based on a 15-minute TWA (CDC, NIOSH, 2005). For example, for glutaraldehyde, the NIOSH REL is 0.2 parts per million, with an OSHA PEL of zero (CDC, NIOSH, 2005).

Responsibility to inform workers about chemical hazards and to use control measures, including providing PPE, rests with the employer. The OSHA Hazard Communication Standard (29 CFR 1910.1200, 1915.99, 1917.28, 1918.90, 1926.59, and 1928.21) requires all manufacturers and importers of hazardous chemicals to develop Material Safety Data Sheets (MSDSs) for all chemicals and mixtures of chemicals (OSHA, 2009). Employers must make these data sheets readily available to all employees who work with the products to which they could be exposed (CDC, 2008a).

The purpose of the OSHA Standards is to ensure that all hazards of chemicals produced or imported are evaluated and that information concerning hazards is transmitted to employers and employees. This transmittal must be accomplished by comprehensive hazard communication programs that must include container labeling and other forms of warning, MSDSs, and employee training (OSHA, 2009). MSDSs initially were written as tools for workers with health and safety roles in the chemical industry. With the expansion of the federal and state right-to-know regulations, however, the need for information on the MSDSs expanded to the healthcare industry.

A typical MSDS includes the following sections:

- Material identity, including chemical and common names
- Hazardous ingredients
- Cancer-causing ingredients
- List of physical and chemical hazards and characteristics
- List of health hazards, including acute and chronic effects
- Whether the material is listed as a carcinogen by OSHA, the International Agency for Research on Cancer, or the National Toxicology Program
- Limits to which a worker can be exposed
- Routes of entry
- Specific target organs likely to be damaged with exposure, and medical problems exacerbated by exposure
- Precautions and safety equipment
- Emergency and first aid procedures
- Firefighting information
- Procedures for cleanup of leaks and spills
- Safe handling precautions
- Identity of the organization responsible for the MSDS, date of issue, and emergency phone number

An additional source of information about chemical exposures is the *NIOSH Pocket Guide to Chemical Hazards,* which offers useful information about several hundred chemicals. This guide, Publication No. 2005-149 (CDC, NIOSH, 2005), can also be found at www.cdc.gov/niosh/npg/.

It is important that healthcare workers are aware of chemicals they are exposed to in their work settings and take necessary precautions to use PPE and other means to eliminate or reduce their occupational risks. Measures may include attending training provided by the employer and being familiar with information about occupational exposures, such as the chemicals inventoried on their work unit. These inventories should be located on each unit and be easily accessible.

Another form of chemical exposure in perioperative settings is exposure to hazardous drugs. Hazardous drugs are defined by NIOSH using the definition developed in 1990 by the American Society of Hospital Pharmacists as meeting one or more of the following characteristics in humans or animals (CDC, NIOSH, 2004):

- Carcinogenicity
- Teratogenicity or other developmental toxicity
- Reproductive toxicity
- Organ toxicity at low doses
- Genotoxicity
- Structure and toxicity profiles of new drugs that mimic existing drugs determined hazardous by the above criteria

Exposure can result from handling of hazardous drugs as well as working near the sites where they are used. The drugs can be in the air, on surfaces in the work area, on medical equipment, or in the urine or feces of patients. Healthcare workers functioning with or near hazardous drugs can experience skin rashes, infertility, miscarriages, birth defects of offspring, and cancers such as leukemia (CDC, NIOSH, 2004). Currently, no NIOSH REL or OSHA PEL is established for hazardous drugs; however, there are OSHA guidelines, Environmental Protection Agency (EPA) regulations, and CDC and National Institutes of Health (NIH) guidelines (CDC, NIOSH, 2004). Work practices and training are important to minimize occupational risks of hazardous drug exposure.

Related to hazardous drug exposure and chemical risk are reproductive hazards found in perioperative patient care settings, with implications for both males and females. Occupational exposure to reproductive hazards can result in effects before or after conception, with different outcomes. Before conception, exposure effects include reduced fertility, unsuccessful fertilization, implantation problems, fetal abnormality, reduced libido, or menstrual dysfunction. Maternal exposure can result in low-birth-weight infants, birth defects, developmental difficulties, behavioral difficulties, cancer, or even fetal demise (OSHA, 2008d). Male workers who suffer workplace exposure can introduce harm to a woman's reproductive system and offspring (OSHA, 2008d). Awareness of reproductive hazards, prevention strategies, and work practices to minimize risks is instrumental in dealing with reproductive hazards in the workplace.

Currently, there are also new bioengineered drugs that target specific locations in the human body. These are evolving and potentially creating new hazardous risks to healthcare workers.

As healthcare facilities become more environmentally sensitive, they take more steps to reduce chemical exposures by eliminating or reducing the use of chemicals, seeking safer alternatives for substances such as cleaning agents, using engineering controls such as ventilation, and using chemical storage to isolate chemicals (Health Care Without Harm [HCWH], 2006).

UNIVERSAL AND STANDARD PRECAUTIONS

Universal Precautions

In 1985, in response to growing numbers of individuals testing positive for HIV, the CDC published a set of recommendations for the use of *Universal Precautions*. Reports of hospital

personnel becoming infected with HIV after a needlestick or skin exposure to a patient's blood created an urgent need for new and better measures to protect personnel. Recognizing that many patients with bloodborne infections are undiagnosed, the CDC's Universal Precautions, for the first time, applied Blood and Body Fluid Precautions (one of the categories in the later 1993 *Guidelines for Isolation Precautions in Hospitals*) to all individuals, regardless of infection status (CDC, 1996). Universal Precautions expanded the Blood and Body Fluid Precautions by recommending masks and eye protection to prevent mucous membrane exposure, in addition to routine use of barrier protection, such as gowns and gloves. Universal Precautions also emphasized prevention of needlestick injuries and use of ventilation devices during resuscitation.

The CDC continued to recommend Universal Precautions until 1987, when a new system of isolation called *Body Substance Isolation* (BSI) was proposed. BSI directed isolation of *all* moist and potentially infectious body substances (i.e., blood, feces, urine, sputum, saliva, wound drainage, and other body fluids) for all individuals, regardless of their infection status. This was accomplished primarily with the use of gowns and gloves. With multiple similarities and differences between Universal Precautions and BSI isolation, confusion reigned.

Standard Precautions

By the early 1990s the controversy regarding Universal Precautions and BSI had escalated. There was considerable confusion about which body fluids required special care under either Universal Precautions or Body Substance Isolation. There were also concerns about the need for additional precautions to prevent airborne, droplet, and contact transmission of other infectious agents. With this need in mind, the CDC developed a single set of precautions incorporating the major features of Universal Precautions and BSI (CDC, 1996). These precautions became *Standard Precautions,* designed to reduce the transmission risk of bloodborne and other pathogens. Additional precautions, based on routes of transmission for patients known or suspected to be infected or colonized with highly transmissible or epidemiologically significant pathogens, are included in the CDC document.

Standard Precautions aim to reduce transmission of microorganisms from recognized and unrecognized sources of infection. Standard Precautions should be applied to all patients receiving care, regardless of their diagnosis or presumed infection status. They are considered the first, and most important, tier of precautions; as such, they are a primary strategy for successful infection prevention and control. Standard Precautions apply to: (1) blood; (2) all body fluids, secretions, and excretions (except sweat), regardless of whether they contain visible blood; (3) mucous membranes; and (4) nonintact skin. Perioperative personnel historically have relied on numerous types of precautions to protect themselves and others from bloodborne pathogens and other infectious diseases (History box). Consistent application of these precautions and frequent handwashing by all members of the perioperative team serve to protect the healthcare provider and to minimize cross-infection of pathogens among patients (Research Highlight) (Refer to Chapter 3 for further discussion of Standard- and Transmission-Based Precautions).

HISTORY

The Origins of Hand Hygiene

While handwashing with soap and water has been a measure of personal hygiene for generations, the concept of cleansing hands with an antiseptic agent probably did not emerge until the nineteenth century. In 1846 Ignaz Semmelweis observed that women whose babies were delivered by students and physicians in the First Clinic at the General Hospital of Vienna consistently had a higher death rate than those whose babies were delivered by midwives in the Second Clinic. He noted that physicians who went directly from the autopsy suite to the obstetrics ward had a disagreeable odor on their hands, despite washing their hands with soap and water upon entering the obstetrics clinic. Semmelweis postulated that the puerperal fever that affected so many parturient women was caused by "cadaverous particles" transmitted from the autopsy suite to the obstetrics wards via the hands of students and physicians. In 1847 he insisted that students and physicians clean their hands with a chlorine solution between the treatment of each patient in the clinic. The maternal death rate in the First Clinic subsequently dropped dramatically and remained low for years (Boyce and Pittet, 2002).

Today, hand hygiene remains the most important factor in preventing the spread of infection. Many studies have shown that bacteria that cause healthcare-associated infections (HAIs) (formerly referred to as "nosocomial" or "hospital-acquired") are most frequently spread from one patient to another on the hands of healthcare workers. The most common infections are caused by staphylococci and multidrug-resistant pathogens, such as MRSA (methicillin-resistant *Staphylococcus aureus*), VRE (vancomycin-resistant *Enterococcus*), and resistant gram-negative rods. Nearly 20,000 patients die each year as a direct result of these infections. Patients may become ill with bloodstream infections, surgical site infections, urinary tract infections, and pneumonia. Nurses and other healthcare workers are exposed to bacteria by doing simple tasks such as moving patients in bed, measuring a blood pressure or pulse rate, or simply touching equipment.

Hands must be washed whenever they contact blood, body fluids, secretions, excretions, and contaminated items, whether or not gloves are worn. Hands are washed immediately after gloves are removed, between patient contacts, and when otherwise indicated to avoid transfer of microorganisms to other patients or environments. Sometimes it is necessary to wash hands between tasks and procedures on the same patient to prevent cross-contamination of different body sites. A plain (nonantimicrobial) soap should be used for routine handwashing. When special circumstances such as hyperendemic conditions occur, an antimicrobial soap or antiseptic hand rub (waterless antiseptic agent) should be used. Hand rub antiseptic agents are most effective when hands are clean before agents are applied. For effectiveness, a sufficient amount of the agent must be used in accordance with manufacturers' written instructions.

RESEARCH HIGHLIGHT

Use of a Hand Hygiene Device

Hand hygiene is perhaps the single most important strategy to reduce healthcare-associated infections (HAIs), but compliance remains low. Researchers in this study from Dartmouth-Hitchcock Medical Center hypothesized that improvements in compliance with intraoperative hand hygiene would reduce transmission of bacteria to surgical patients and reduce the incidence of HAIs. To test their hypothesis, researchers used the Sprixx GJ device (Harbor Medical Inc., Santa Barbara, Calif)—a personal alcohol-based sanitizer dispenser with tracking electronics that prompted anesthesia providers to perform hand hygiene every 6 minutes and documented its use. The device is clipped to clothing and is operated with one hand.

Use of the device reduced bacterial contamination in the anesthesia workspace and on peripheral intravenous tubing. HAIs were reduced from 17.2% (control group) to 3.8% (device group). Intravenous tubing contamination was identified in 32.8% of cases in the control group and 7.5% in the device group. There were no significant differences in risk factors between groups. The researchers therefore concluded that improved hand hygiene compliance in the OR through the use of a hand sanitation strategy reduces the risk of intraoperative bacterial transmission and HAIs.

Adapted from Koff MD et al: Reduction in intraoperative bacterial contamination of peripheral intravenous tubing through the use of a novel device, *Anesthesiology* 110:978-985, 2009.

IMMUNIZATIONS AND INFECTIOUS DISEASE EXPOSURE

Contact with infected patients or infectious material puts healthcare workers at risk for occupational-acquired infection. Hospital-acquired and healthcare-associated transmission of disease is well documented (CDC, 1997). Many diseases and infections can be prevented through immunizations and vaccines. It is therefore essential for nurses and other healthcare workers to prevent infections by establishing and maintaining their immunity in cooperation with their employers. Healthcare organizations providing direct patient care should develop a comprehensive immunization program for workers. Healthcare workers are found to be at risk for acquiring or transmitting HBV, influenza, measles, mumps, rubella, varicella (CDC, 1997), and pertussis (CDC, 2006b).

HBV is a major infectious risk for healthcare workers as a result of percutaneous and permucosal exposure to blood or other potentially infectious material (CDC, 1997). Through a joint advisory notice in 1987, the Departments of Labor and Health and Human Services initiated rulemaking to regulate exposure to HBV. The resulting federal standard issued in December 1991 mandated that hepatitis B vaccine be made available at the employer's expense to all healthcare workers occupationally exposed to blood or other potentially infectious materials (CDC, 1997). It is important for healthcare workers to have a hepatitis B antibody titer to evaluate their immune response to a vaccine series. Once immunity is documented, there is no need for booster doses even if titer levels drop.

Seasonal influenza and its complications are responsible for more than 36,000 deaths and more than 200,000 hospitalizations each year (ANA, 2008a). Despite the well-documented seriousness of seasonal influenza cases, according to the CDC less than 50% of healthcare workers are vaccinated annually (ANA, 2008a). Influenza has been transmitted to healthcare workers from patients, and healthcare workers who are clinically or subclinically infected with influenza can transmit seasonal influenza to patients or others (CDC, 2006a). Studies have demonstrated seasonal influenza antibodies in healthcare workers who did not recall even having a respiratory tract infection. By receiving the seasonal influenza vaccination, healthcare workers protect themselves, their patients, and their families.

Inactivated influenza vaccine and live attenuated influenza vaccine (LAIV) are currently available for workers in the healthcare professions. LAIV is approved only for nonpregnant healthy persons ages 5 to 49 years (CDC, 2006a). Healthcare workers caring for severely immunocompromised patients should not receive LAIV. Instead, the inactivated influenza vaccine is the preferred vaccine when workers come in direct contact with this group of patients (CDC, 2006a). Workers can secure guidance on which vaccine to take from their occupational or employee health department.

In January 2007 The Joint Commission (TJC) issued a standard requiring accredited organizations to offer influenza vaccinations to staff, including volunteers and licensed independent practitioners with close patient contact (ANA, 2008a). Accredited organizations are required to establish annual immunization programs to educate employees about influenza and offer the vaccine on site (ANA, 2008a).

Healthcare-associated infections (HAIs) with measles, mumps, and rubella have all been documented. The risk for measles infection in healthcare workers is estimated to be 13 times greater than that for the general population (CDC, 1997). Previously, birth before 1957 was considered acceptable evidence of measles immunity. However, serologic studies of healthcare workers have discovered that 5% to 9% of those born before 1957 are not immune to measles (CDC, 1997).

Healthcare-associated infections from varicella zoster virus (VZV) have also been well documented. Patients who are at increased risk for varicella infection are pregnant women; premature infants born to susceptible mothers; infants born at less than 28 weeks' gestation or who weigh less than 1000 grams, regardless of maternal immune status; and immunocompromised persons of all ages (including persons who are undergoing immunosuppressive therapy, have malignant disease, or are immunodeficient) (CDC, 1997). Sources of healthcare-associated varicella infection include patients, hospital employees, and hospital visitors who are infected with either varicella or zoster (CDC, 1997).

Generally, a reliable history of chickenpox is a valid measure of VZV immunity. That reliability was serologically tested, and it was found that, among adults, 97% to 99% of persons with a positive history of varicella were seropositive (CDC, 1997). In addition, adults with negative or uncertain histories are seropositive (range: 71% to 93%) (CDC, 1997). Serologic testing of healthcare workers with a negative or unknown history of varicella has been shown to be cost-effective (CDC, 1997).

Recent increases in rates of pertussis (an acute, infectious cough illness) among healthcare workers led to a recommendation in 2006 that they receive one dose of tetanus, diphtheria, and pertussis (Tdap) (CDC, 2006b). Pertussis rates among healthcare workers were found to be nearly double those in the general population in a Canadian study (CDC, 2006b).

Immunity to pertussis wanes 5 to 10 years after childhood immunization, leading to susceptibility to pertussis among adults (CDC, 2006b). Costs for an outbreak and exposure investigation in a healthcare setting are estimated to be from $74,870 to $174,327 per outbreak (CDC, 2006b). The recommended schedule of Tdap is one single dose to replace one dose of Td for active boosting of tetanus, diphtheria, and pertussis if the worker received the last dose of Td more than 10 years earlier, with additional doses being received every 10 years (CDC, 2006b). A healthcare worker who has not had a previous dose of Tdap may receive a dose 2 years from the last dose of Td or as soon as feasible (CDC, 2006b).

Routine immunization of healthcare workers against tuberculosis, HAV, meningococcal disease, typhoid fever, or vaccinia is not currently recommended by the Advisory Committee on Immunization Practices (CDC, 1997). However, based on job responsibilities and risks at the employer's facility, other immunizations may be recommended or required. There is currently no vaccination for HCV. It remains imperative that healthcare workers follow recommended bloodborne pathogen precautions.

Should an exposure to an infectious or communicable disease occur in the clinical area, chemoprophylaxis may be available. Healthcare workers should report the exposure to their occupational health department or other provider according to the facility's procedures and receive proper follow-up. Infectious exposures outside the workplace should also be reported for the protection of patients and co-workers. Postexposure work restrictions may range from restricting contact with high-risk patients to furlough for healthcare workers without immunity.

Exposure of healthcare workers to diphtheria, pneumococcal disease, or tetanus is not significantly more than that of the general population; therefore healthcare professionals should elect to receive these immunizations from their primary care providers (CDC, 1997). In addition to immunization records maintained by the employer for healthcare workers, healthcare workers should also maintain accurate records of all their immunizations and exposures, including any prophylaxis or laboratory studies.

Immunizations are part of a comprehensive workplace infection control program. Guidance for development of a program is available from OSHA, CDC, and the Department of Health in the state in which the facility is located. The recommended and required vaccinations vary by state and depend on legislation at either the state or the federal level. To further evaluate compliance with recommended or required vaccinations, healthcare workers should consult with the occupational or employee health department at their workplace.

RADIATION SAFETY

Radiologic imaging studies are invaluable diagnostic and treatment tools. Radiation presents environmental safety concerns for patients and staff. Many surgical procedures use radiologic studies performed immediately before, during, or after surgery, increasing the potential for radiation exposure. X-rays of all frequencies can damage tissues and may produce long-term effects. The effects of radiation are dose-dependent and cumulative: the larger the dose or the more frequent the exposure, the greater the risk of the effects of radiation.

Sources of radiation exposure in the OR include (1) ionizing sources—portable radiography (x-ray) machines and portable fluoroscopy units (C-arm)—and (2) nonionizing sources—lasers (laser safety is discussed more extensively in Chapter 7). Ionizing radiation is used in diagnostic, interventional, and therapeutic procedures, but can damage living tissues and may produce long-term effects (AORN, 2009c). Expanding use of x-ray imaging during interventional surgery has dramatically increased exposure of many OR personnel to ionizing radiation in recent years (Chapter 28 discusses interventional radiology departments and procedures). Acute exposure to ionizing radiation can result in dermatitis and reddening of the skin (erythema) at the point of exposure, while large, full-body exposures can lead to radiation poisoning, symptoms of which may include nausea, vomiting, diarrhea, weakness, and death. Ionizing radiation at high doses may also lead to cancer and mental retardation in children of mothers exposed during pregnancy, and it has been linked to other health effects such as heart disease and stroke (ANA, 2007).

In radiation protection, the guiding philosophy is ALARA—As Low As Reasonably Achievable. Typically, reducing the patient dose also reduces the dose to healthcare workers. Therefore performing optimized procedures is an important aspect of radiation protection. Optimization includes performing only medically necessary studies and performing them sufficiently well that they do not need to be repeated (Brateman, 1999).

In diagnostic radiology, the main source of occupational dose is radiation that scatters as the x-ray beam passes through the patient, particularly from fluoroscopically guided procedures. Healthcare workers who do not protect themselves from scatter radiation are especially at risk when performing interventional procedures, given significantly increased exposure time and close proximity during the procedure (AORN, 2009c). Personnel stand near patients for long times, and angulated geometrics with C-arm equipment may result in high personnel doses from backscatter. For all procedures, time, distance, and shielding affect dose levels sustained (Brateman, 1999).

Accordingly, guidelines for radiation safety are based on the principles of time, distance, and shielding. When exposed to radiation at a constant rate, the total dose equivalent received depends on the length of time exposed. If the distance from the point source of radiation is doubled, exposure is quartered. Passage through materials also reduces the amount of radiation (AORN, 2009c).

Members of the surgical team should avoid unnecessary exposure to radiation sources and comply with practices that reduce potential exposure. Personnel present in the OR must maintain the greatest practical distance (at least 6 feet) from the radiation source or remain behind leaded shielding when ionizing radiation is used during surgery. Personnel assisting with radiologic procedures should not hold the patient manually for a study because of the risk of exposure by the direct beam (AORN, 2009c). Members of the sterile scrub team should wear protective devices and move as far from the radiation source as possible, while still adhering to aseptic technique. Nonessential personnel should leave the room.

Protective equipment reduces the intensity of radiation exposure. Radiation safety devices include mobile rigid shields on wheels; ceiling-suspended transparent barriers; flexible leaded aprons (e.g., wraparound), vests, skirts, thyroid shields,

and gloves; and leaded safety eyeglasses with side shields (AORN, 2009c). AORN recommends that personnel who may have to stand with their back to the radiation beams wear wraparound aprons to decrease their risk of exposure, and that personnel nearest to the radiation beam shield their upper chest and neck, and upper legs.

OSHA has established enforceable, health-based limits on occupational exposure to ionizing radiation and provides a series of guidelines that hospitals can use to protect staff from excess radiation exposure. OSHA also requires that employees working with radiation sources be monitored for exposures and be informed of their levels of exposure at least once a year (ANA, 2007).

OSHA also recommends that film badges or an equivalent be used for long-term monitoring. A film badge is a passive dosimeter for personal exposure monitoring that should be worn whenever an employee works with x-ray equipment, radioactive patients, or radioactive materials. Depending on the work setting, dosimeters may be worn at collar, chest, or waist level. Personnel who work in high-dose fluoroscopy settings may be asked to wear two badges for additional monitoring. Ring badges (used to measure beta and gamma doses to the hand) should be worn on the hand closest to radiation sources (OSHA, 2008a).

Leaded garments should be handled carefully and examined regularly to ensure the integrity of shielding; they should not be folded during storage, and they should undergo regular radiologic testing. Staff-development programs on radiation safety should be conducted periodically to reinforce radiation safety practices and to correct misconceptions or unrealistic practices relating to radiation exposure and monitoring.

The American College of Radiology (ACR) recommends that facilities adopt the following safety measures to protect personnel:

- Implement a radiation-exposure monitoring program, as required by the Nuclear Regulatory Commission or appropriate state agencies.
- Perform systematic inspection of interlock systems.
- Provide appropriate room shielding.
- Perform routine leak testing of all sealed sources, as required by regulatory agencies.
- Furnish appropriate safety equipment for use of sealed sources (ACR, 2004).

LATEX ALLERGY

Natural rubber latex allergy is a serious medical problem for a growing number of patients and a disabling occupational disease among healthcare workers. Latex allergy develops from exposure to natural rubber latex and plant cytosol, used extensively to manufacture medical gloves and other devices, as well as numerous consumer products. Allergic reactions to latex range from skin disease to asthma and anaphylaxis that can result in chronic illness, disability, career loss, hardship, and death (ANA, 1997).

Historically, latex has been the material of choice for surgical gloves because it is flexible and maintains tactile sensitivity for the wearer. Although natural rubber latex has been a common component in thousands of medical and consumer products for many years, latex sensitivity is a relatively new problem for patients and healthcare personnel. Clinicians were aware of contact dermatitis from chemicals in rubber as early as the 1930s; however, they did not recognize systemic allergic reactions to latex proteins until the 1970s. Latex allergy erupted in the United States shortly after the CDC introduced Universal Precautions in 1985. Today, researchers hypothesize that the latex allergy outbreak is the result of multiple factors, including increased latex exposure and deficiencies in manufacturing processes, among others. Latex allergy affects between 8% and 12% of workers in all health disciplines. However, it affects only about 1% of the general population (ANA, 1997).

Individuals can experience three types of reactions to latex. *Irritant contact dermatitis* is the most common type of reaction and is characterized by dry, reddened, itchy, or cracked hands. Irritant contact dermatitis is not a true allergic reaction. *Allergic contact dermatitis* (also called *chemical contact dermatitis*) is a delayed cell-mediated type IV localized allergy caused by chemicals used to manufacture rubber products. The most common contact sensitizers are the accelerators: thiurams, mercaptobenzothiazoles (MBTs), and carbamates (ANA, 1997). Allergic contact dermatitis is a delayed reaction, usually appearing 6 to 48 hours after exposure. Symptoms are similar to those from irritant contact dermatitis (i.e., pruritus, edema, erythema, vesicles, drying papules, crusting and thickening of the skin), except that the reaction may extend beyond the actual point of contact.

A *true latex allergy* is a type I IgE-mediated hypersensitivity reaction that involves systemic antibody formation to proteins in products made from natural rubber latex. Natural rubber latex contains up to 240 potentially allergenic protein fragments, and different persons may be sensitized to different combinations of latex allergens. Synthetic latexes are not involved in latex allergy (ANA, 1997). A true latex allergic response is immediate, IgE-mediated, and anaphylactic. The onset of anaphylactic reaction usually occurs within minutes of contact with the proteins, with symptoms that may include generalized urticaria, wheezing, dyspnea, laryngeal edema, bronchospasm, tachycardia, angioedema, hypotension, and cardiac arrest. Many serious anaphylactic reactions have occurred when a latex product (e.g., surgical gloves) directly contacts mucous membranes during surgical procedures. This situation permits a rapid introduction of latex antigen directly into the vascular circulation.

Traditionally, it was assumed that sensitization to latex resulted only from cutaneous absorption in healthcare workers or from direct mucosal contact during clinical treatment. Recent studies confirm that latex protein allergens effectively bind to glove powder and, when airborne, can remain suspended for prolonged periods. Inhalant exposure is an additional risk factor for sensitization to latex allergens.

Healthcare professionals should employ the following strategies to reduce their risk of allergic reaction to latex:

- Use powder-free gloves that are low in protein and chemical allergens (ANA, 1996).
- Use nonlatex gloves for activities that are not likely to involve contact with infectious materials (OSHA, 2008b).
- Be aware that hypoallergenic gloves do not reduce the risk of latex allergy, although they may reduce reactions to chemical additives in the latex (CDC, NIOSH, 1997).
- When wearing latex gloves, do not use oil-based hand creams or lotions, which can cause glove deterioration (ANA, 1996).

- After removing latex gloves, wash hands with a mild soap and dry thoroughly (CDC, NIOSH, 1997).
- Learn to recognize the symptoms of latex allergy, including skin rashes; urticaria; flushing; pruritus; nasal, eye, or sinus symptoms; asthma; and shock (CDC, NIOSH, 1997).

Institutions need to develop strategies for limiting healthcare workers' occupational exposure to latex. If a latex-free environment cannot be created, the goal is to create a latex-safe environment, in which all reasonable efforts are made to remove high-allergen and airborne latex sources. This includes switching to low-allergen, powder-free gloves. Cornstarch powder on powdered latex gloves is an efficient allergen carrier and contributes to airborne contamination, especially in ORs and invasive-procedure rooms where glove use is high. The use of low-allergen, powder-free gloves reduces airborne latex allergen sources to below detectable levels, reducing occupational exposure. In addition, appropriate latex-free gloves should be provided for healthcare workers with known latex sensitivity or for procedures in which patients have known sensitivity or allergy.

Box 30-4 provides valuable information on latex allergy.

WORKPLACE VIOLENCE

Violence in the workplace impacts patient care and healthcare workers and undermines a culture of safety. The Occupational Safety and Health Act of 1970 assures every working person a safe and healthful workplace, free from recognized hazards that may cause death or serious physical harm. NIOSH and OSHA define *workplace violence* as any physical assault, threatening behavior, or verbal abuse occurring in the workplace (ANA, 2006). The World Health Organization (WHO) defines workplace violence as the intentional use of power, threatened or actual, against another person or group in work-related circumstances that either results in or has a substantial likelihood to result in injury, death, psychologic harm, maldevelopment, or deprivation (WHO, 2002).

The U.S. Bureau of Labor Statistics reported in 2007 there were 27.3 assaults and violent acts per 10,000 full-time workers in the healthcare sector (U.S. Bureau of Labor Statistics, 2009). In 2006 the healthcare sector led all other industries in workplace violence, with 45% of all nonfatal assaults against workers resulting in lost workdays in the United States (U.S. Bureau of Labor Statistics, 2007). OSHA has no federal standard on workplace violence (ANA, 2006).

Workplace violence can occur in various forms, from bullying and verbal abuse to physical abuse and even homicide. Patients are the main perpetrators of physical violence, while staff are the main perpetrators of psychologic violence (ICN, 2007).

Prevention of workplace violence can best be accomplished after conducting an analysis of workplace risk factors and incidence rates at the facility. Risk factors and solutions include environmental, work-practice, and training solutions (ANA, 2006). Environmental risk factors include the availability of guns or other weapons among patients and visitors; presence of mentally ill patients with little or no follow-up care; availability of medications or money; unrestricted movement of the general public throughout facilities; presence of gang members, drug or alcohol abusers, trauma patients, or distraught family members; and poorly lit parking areas (ANA, 2006). Work practices contributing to workplace violence include long waits in emergency or clinic areas; low staffing levels; isolated work with patients during examinations or treatment; and lack of staff training in recognizing and managing aggressive behavior (ANA, 2006). Victims are often untrained or newly hired staff nurses (ANA, 2006). Perpetrators often have a history of violent behavior and have been diagnosed with psychosis, substance abuse disorders, or dementia (ANA, 2006).

Workplace violence can be prevented and is never acceptable. Environmental solutions include controlled access doors, metal detectors, alarm systems, panic buttons, handheld noise devices, and cell phones; lockable staff areas, such as lounges and bathrooms; curved mirrors and adequate lighting; and well-lit parking areas (ANA, 2006). Work practices that help prevent workplace violence include identification of high-risk patients, including flagging charts, both hard copy and electronic; proper training of staff; avoidance of employees working alone, particularly in secluded areas; easy and effective processes for reporting suspicious behavior, harassment, threats, or violent assaults; careful supervision of the movement of psychiatric patients within the facility; and use of a team approach to prevent workplace violence (ANA, 2006). Training should include review of prevention policies, reporting procedures, support systems, and action plans; identification of risk factors that cause or contribute to violence; early identification of warning signs of escalating behavior; tools for diffusing violent situations; and review of system and policy failures (ANA, 2006).

Workplace bullying, which is now increasing in healthcare settings, is another form of workplace violence. The International Labour Organization (ILO) defines *bullying* as offensive behavior through vindictive, cruel, malicious, or humiliating attempts to undermine individuals or groups of employees (International Centre for Human Resources in Nursing [ICHRN], 2009). Colleagues, employers, management, patients, patients' families, or visitors can be responsible for bullying in the healthcare setting. Behaviors can be exhibited as sadistic or aggressive behavior over time; exclusion from meetings; reduced opportunities for advancement; humiliation; ridicule; private or public unwarranted criticism; changing work responsibilities unreasonably or without justification; deliberately withholding information to affect work performance; punishing others for being competent; and overworking or overloading to punish (ICHRN, 2009).

Harmful effects of bullying include a decline in the quality of patient care delivery; poor staff relations; low morale; increase in stress and stress-related illness; feelings of shock, disbelief, shame, guilt, anger, fear, and powerlessness; depression; self-blame with decreased self-confidence that can endanger patients; sleeplessness and loss of appetite; increased cost to employers and the healthcare system; increased absenteeism and use of sick time; poor performance; reduced productivity; loss of creative problem-solving capacity; and attrition (ICHRN, 2009).

Bullying risk factors in the workplace include stress, tension, and frustration; poor management skills; inadequate or absent policies; lack of training to recognize or cope with bullying; shift work and demanding workloads; working alone (ICHRN, 2009); and lack of reporting systems or punishment of perpetrators (Hughes, 2008).

BOX 30-4

Latex Allergy

Latex allergy is an immunoglobulin E (IgE)-mediated reaction to proteins retained in finished natural rubber latex products.

ETIOLOGY AND INCIDENCE

Latex is the milky sap of the rubber tree *Hevea brasiliensis*. This natural rubber product contains proteins. Latex allergy is the reaction to certain proteins in the latex rubber. These allergies emerged in the 1990s as one of the most pervasive problems in healthcare. It remains a serious and growing problem, and healthcare workers are at increasing risk to acquire latex allergies. It is currently estimated that an allergy caused by repeated exposure to latex protein allergens develops in approximately 1 in 10 healthcare professionals; indeed, 53% of healthcare workers reported some reaction to latex gloves when surveyed. Children with spina bifida and individuals with chronic illnesses who require frequent operations are especially susceptible to latex allergy.

PATHOPHYSIOLOGY

The amount of latex exposure necessary to produce sensitization or an allergic reaction is unknown. Increasing exposure to latex proteins increases the risk of developing allergic symptoms. Although latex-containing products have only 2% to 3% protein, this protein is thought to be the allergen in type I hypersensitive individuals. The precise protein responsible for causing allergic contact dermatitis latex type I hypersensitivity remains unknown and may differ among individuals.

RISK FACTORS BY OCCUPATIONAL STATUS

- Healthcare professionals: surgery personnel, emergency care workers, and obstetrics workers are at highest risk
- Children with spina bifida or others with conditions requiring frequent operations
- Persons with congenital urogenital abnormalities requiring indwelling catheters
- Employees in the rubber industry
- Persons with history of other IgE-dependent allergies (e.g., rhinitis, asthma, or food allergies) with a positive skin test

CLINICAL MANIFESTATIONS

Clinical signs include local skin redness, dryness, and itching after contact with latex. Inhalation of particles results in respiratory symptoms, such as rhinitis, sneezing, itchy eyes, scratchy throat, or asthma. More severe manifestations include anaphylaxis with bronchospasm, laryngeal edema, respiratory distress, or respiratory failure.

COMPLICATIONS

Complications may include anaphylactic shock, and respiratory and cardiac arrest leading to death.

DIAGNOSTIC TESTS

History

Diagnostic significance in an individual's history includes atopic history, hives under rubber or latex gloves, hand dermatitis related to gloves, allergic conjunctivitis after rubbing eyes following hand contact with latex, swelling around mouth after dental procedures or inflation of a balloon, and vaginal burning after pelvic examination or contact with latex condom.

Immunologic Evaluation

Immunologic evaluation comprises skin prick, intradermal, and patch contact skin tests and serologic testing (e.g., radioallergosorbent test [RAST] or enzyme-linked immunosorbent assay [ELISA]). The FDA has approved a standardized latex reagent for skin testing for research only, not for public use.

THERAPEUTIC MANAGEMENT

Medications

Medications include epinephrine for reaction (may be autoinjector and carried by individual), β-agonist inhaler, prednisone, and other anaphylactic life-supporting medications.

General

Immediate assessment and interventions for acute reaction include cardiac monitoring and, if needed, respiratory support.

Prevention and Promotion

For latex-sensitive individuals:

- Avoid latex products.
- Avoid environments with high levels of circulating aeroallergens (e.g., ORs, ERs, blood banks).
- Wear MedicAlert bracelet or tag.
- Carry autoinjector for use at first signs of anaphylaxis.

To address this serious issue, on January 1, 2009, TJC instituted a new leadership standard (LC.03.01.01) that addresses disruptive and inappropriate behaviors (Hughes, 2008). Hospitals and organizations are required to have a code of conduct defining acceptable and disruptive or inappropriate behaviors (Hughes, 2008). Under this standard, leaders are expected to create and implement a process for managing disruptive and inappropriate behaviors (Hughes, 2008).

Workplace violence in any form negatively impacts healthcare workers and patients. It harms workers professionally and personally, and it alters the quality of care provided to patients. The perioperative area is not excluded from the impact or incidence of workplace violence. Nurses and other healthcare workers in this setting must be educated and trained to recognize workplace violence in all forms, including lateral violence (violence between co-workers), in order to create a safe working environment that promotes teamwork and collaboration in the perioperative setting (Research Highlight).

RESEARCH HIGHLIGHT

Measuring Teamwork in the OR

Teamwork is a major component of OR efficiency, quality of care, and patient safety. The Joint Commission has reported breakdowns in communication as a leading cause of adverse events and errors. While surgical departments across the United States work on initiatives to prevent negative outcomes, they seek reliable tools to measure improvements in OR teamwork that demonstrate that their initiatives are effective. The goals of this study were to test the reliability and validity of a teamwork climate scale in the OR and to provide benchmarking information on OR teamwork climate by hospital and caregiver type. The researchers designed a Safety Attitudes Questionnaire and administered it to OR personnel in 60 U.S. hospitals—222 surgeons, 1058 OR nurses, 564 surgical technologists, 170 anesthesiologists, and 121 certified registered nurse anesthetists (CRNAs). The response rate was 77.1%, with OR nurses having the highest response rate (79%) and CRNAs the lowest (67%).

The teamwork climate domain of the survey included the following six items:

1. Difficulty speaking up
2. Conflict resolution
3. Nurse-physician collaboration
4. Feeling supported by others
5. Asking questions
6. Heeding nurse input

In analyzing their data, researchers found strong evidence for grouping individual-level respondents to the hospital OR level. OR teamwork climate variability was greater between than within hospital OR levels, and a consistent pattern occurred across the hospitals studied. Thus the response according to caregiver types (e.g., between surgeon and nurse) had discrepant attitudes about teamwork with each other. Surgeons and anesthesiologists were more satisfied with physician-nurse collaboration than nurses were. OR nurses and CRNAs did not reciprocate the high ratings of teamwork climate given by physicians.

This research validates that assessment of teamwork climate is possible using the same questionnaire used in the study. The findings of this study add a research tool for assessing teamwork in the OR and include greater detail to more general reports of discrepant attitudes about collaboration between physicians and nurses.

Pharmacology Index

A
Absorbable gelatin sponge, 859-860, 1227
Acetaminophen, 284
Acetazolamide sodium, 623
Acetylcholine chloride, 621
Activase. *See* Tissue plasminogen activator
Adenosine, 1033, 1143
Adrenalin. *See* Epinephrine
Alfentanil (Alfenta), 125, 1032
Amidate. *See* Etomidate
Amiodarone, 1143
Amobarbital sodium (Amytal), 1226
Ampicillin, 306
Amrinone, 1032
Amvisc. *See* Sodium hyaluronate
Anaprox. *See* Naproxen sodium
Ancef. *See* Cefazolin
Anectine. *See* Succinylcholine
Ardeparin, 743
Aristocort. *See* Triamcinolone acetonide
Aspirin, 284
Ativan. *See* Lorazepam
Atracurium, 125, 1032
Atropine sulfate, 127, 621, 1032, 1143
Avitene. *See* Collagen hemostat

B
Bacitracin, 675, 901, 1033
Balanced salt solution, 622, 650
Benadryl. *See* Diphenhydramine
Benzocaine, 674
Benzocaine/tetracaine/butamben, 674
Betamethasone sodium phosphate and betamethasone acetate suspension, 622
Bivalirudin, 1033
B&O suppository, 490
Brethine. *See* Terbutaline
Bretylium (Bretylol), 1033
Brevital. *See* Methohexital
Brevital sodium. *See* Sodium methohexital
Bupivacaine, 126, 135, 138, 407, 621
Buprenorphine (Buprenex), 285
Butorphanol, 285

C
Calan. *See* Verapamil
Calcilean. *See* Heparin
Calciparine. *See* Heparin
Calcium chloride, 1032, 1143
Carbachol, 621
Carbocaine. *See* Mepivacaine
Cefadyl, 1033
Cefazolin, 622, 1033
Ceftazidime, 622
Celecoxib, 284
Celestone. *See* Betamethasone sodium phosphate and betamethasone acetate suspension
Cephalosporins, 1033
Cervidil. *See* Dinoprostone
Cetacaine. *See* Benzocaine/tetracaine/butamben
Chloroprocaine, 126
Choline magnesium trisalicylate, 284
Cisatracurium, 125, 1207
Clindamycin, 306
Cocaine, 622, 674
Codeine, 285
Collagen hemostat, 859
Cortisporin Otic Suspension. *See* Neomycin and polymyxin B sulfates and hydrocortisone
Coumadin. *See* Warfarin
Cyclopentolate (Cyclogyl), 621
Cytotec. *See* Misoprostol

D
Danaparoid, 743
Dantrolene (Dantrium), 140-141
DDAVP. *See* Desmopressin
Decadron. *See* Dexamethasone
Demerol. *See* Meperidine hydrochloride
DepoDur, 125
Depo-Medrol. *See* Methylprednisolone acetate suspension
Desflurane, 122, 124, 1032
Desirudin, 743
Desmopressin, 1033
Dexamethasone, 622
Dexmedetomidine, 127
Diamox. *See* Acetazolamide sodium
Diazepam, 126, 1033, 1229
Diflunisal, 284
Digoxin, 1033
Dilantin. *See* Phenytoin
Dilaudid. *See* Hydromorphone
Dinoprostone, 469
Diphenhydramine, 1226
Diprivan. *See* Propofol
Disalcid. *See* Salsalate
Dizac. *See* Diazepam
Dobutamine (Dobutrex), 1032, 1143
Dolobid. *See* Diflunisal
Dolophine. *See* Methadone
Dopamine hydrochloride, 1032, 1143
Doxacurium, 1032
Doxycycline, 953
Droperidol, 277
Duranest. *See* Etidocaine

E
Endosol. *See* Balanced salt solution
Enflurane, 124, 1032
Enoxaparin, 743
Ephedrine, 1032
Epinephrine, 138, 368, 621, 675, 1032, 1143
Ertapenem, 306
Estrace cream. *See* Estradiol cream
Estradiol cream, 471
Ethrane. *See* Enflurane
Etidocaine, 621
Etodolac, 284
Etomidate, 126, 1198

F
Faslodex. *See* Fulvestrant
Fenoprofen calcium, 284
Fentanyl, 125, 1032, 1229
Flomax. *See* Tamsulosin
FloSeal. *See* Gelatin matrix
Flumazenil, 1230
Fluorescein, 622
5-Fluorouracil, 622, 645
Fluothane. *See* Halothane
Flurbiprofen, 284
Forane. *See* Isoflurane
Fortaz. *See* Ceftazidime
Fulvestrant, 596
Furosemide, 1033, 1207

G
Garamycin. *See* Gentamicin sulfate
Gelatin matrix, 859
Gelfoam. *See* Absorbable gelatin sponge
Gentamicin sulfate, 306, 622
Glucagon, 1226
Glycerin, 622
Glycopyrrolate, 127, 1032
Glyrol. *See* Glycerin
Gonioscopic Prism Solution. *See* Hydroxyethylcellulose
Goniosol. *See* Hydroxypropyl methylcellulose

H
Halothane, 124, 1032
Healon. *See* Sodium hyaluronate
Helistat. *See* Collagen hemostat
Heparin, 743, 981, 1033, 1226
Herceptin. *See* Trastuzumab
Hexabrix. *See* Ioxaglate
Homatropine hydrobromide, 621
Hyaluronidase, 621
Hydromorphone, 285, 1229
Hydroxyethylcellulose, 621
Hydroxypropyl methylcellulose, 621

I
Ibuprofen, 284
Inocor. *See* Amrinone
Instat. *See* Collagen hemostat
Insulin, 1033
Intropin. *See* Dopamine hydrochloride
Iodixanol, 1230
Iodopovidone, 953
Ioxaglate, 1230
Iprivask. *See* Desirudin
Isoflurane, 124, 1032
Isoproterenol (Isuprel), 1032
Isoptin. *See* Verapamil
Isopto Carbachol. *See* Carbachol
Isopto Homatropine. *See* Homatropine hydrobromide
Isopto Hyoscine. *See* Scopolamine hydrochloride

K
Keflex, 1033
Keflin, 1033
Kefzol. *See* Cefazolin
Kenalog. *See* Triamcinolone acetonide
Ketamine (Ketalar), 126
Ketoprofen, 284
Ketorolac, 284

L
Lanoxin. *See* Digoxin
Lapatinib, 596
Lasix. *See* Furosemide
Levophed. *See* Norepinephrine
Levorphanol (Levo-Dromoran), 285
Lidocaine/lidocaine hydrochloride, 126, 138, 407, 621, 674, 1033, 1143
Linezolid, 54
Lodine. *See* Etodolac
Lorazepam, 1032, 1206, 1229
Lorcet. *See* Hydromorphone
Lovenox. *See* Enoxaparin
Lymphazurin, 605

M
Mafenide acetate, 901
Magnesium salicylate, 284
Magnesium sulfate, 470, 1143
Mandol, 1033
Mannitol, 622, 1033, 1205, 1207
Marcaine. *See* Bupivacaine
Maxitrol ointment or suspension. *See* Neomycin and polymyxin B sulfates and dexamethasone
Meclofenamate sodium (Meclomen), 284
Meperidine hydrochloride, 285, 897
Mepivacaine, 621

Metformin, 1218-1219
Methadone, 285
Methohexital, 1032
Methotrexate, 470
Methylene blue, 471, 490
Methylergonovine maleate (Methergine), 469
Methylprednisolone acetate suspension, 622
Metoclopramide, 280
Metrizamide, 1228, 1230
Metronidazole, 306
Miconazole nitrate cream, 471
Midazolam, 116, 126, 1032, 1093, 1206, 1229
Milrinone, 1032
Minocycline, 953
Miochol-E. *See* Acetylcholine chloride
Miostat. *See* Carbachol
Misoprostol, 471
Mitomycin, 622
Mivacurium (Mivacron), 125
Monistat. *See* Miconazole nitrate cream
Morphine liposomal. *See* DepoDur
Morphine sulfate, 125, 285, 897, 1032, 1229
Motrin. *See* Ibuprofen
Mucomyst. *See N*-acetylcysteine
Mupirocin, 675
Mutamycin. *See* Mitomycin
Mydfrin. *See* Phenylephrine
Mydriacyl. *See* Tropicamide

N

N-acetylcysteine, 1226, 1232
Nalbuphine, 285
Nalfon. *See* Fenoprofen calcium
Naloxone (Narcan), 281, 1033, 1143, 1230
Naproxen (Naprosyn), 284
Naproxen sodium, 284
Naropin. *See* Ropivacaine
Nasal Bactroban. *See* Mupirocin
Nebcin. *See* Tobramycin
Neomycin and polymyxin B sulfates and dexamethasone, 622
Neomycin and polymyxin B sulfates and hydrocortisone, 675
Neosporin ointment. *See* Polymyxin B/neomycin/bacitracin
Neostigmine, 127
Neo-Synephrine. *See* Phenylephrine
Nesacaine. *See* Chloroprocaine
Nifedipine, 1033
Nimbex. *See* Cisatracurium
Nitric oxide, 1033
Nitroglycerin, 1032, 1226
Nitroprusside (Nipride), 1032
Nitrous oxide, 124
Norcuron. *See* Vecuronium
Norepinephrine, 1032
Nubain. *See* Nalbuphine
Numorphan. *See* Oxymorphone

O

Occucoat. *See* Hydroxypropyl methylcellulose
Ondansetron, 278
Ophthaine. *See* Proparacaine hydrochloride
Orudis. *See* Ketoprofen
Osmitrol. *See* Mannitol
Osmoglyn. *See* Glycerin
Oxaprozin, 284
Oxidized regenerated cellulose, 859-860
Oxycodone, 285
Oxymetazoline hydrochloride, 675
Oxymorphone, 285
Oxytocin, 469

P

Pancuronium (Pavulon), 126, 1032
Papaverine hydrochloride, 982, 1033, 1226
Parecoxib sodium, 280, 743
Pentazocine, 285
Pentothal. *See* Thiopental
Percocet. *See* Oxycodone
Percodan. *See* Oxycodone
Phenobarbital, 1207
Phentolamine, 1032
Phenylephrine, 621, 1032
Phenytoin, 1206
Pilocarpine hydrochloride, 621
Pipecuronium, 1032
Pitocin. *See* Oxytocin
Pitressin. *See* Vasopressin
Polymyxin B/bacitracin, 622, 901
Polymyxin B/neomycin/bacitracin, 622
Polysporin ointment. *See* Polymyxin B/bacitracin
Pontocaine. *See* Tetracaine hydrochloride
Precedex. *See* Dexmedetomidine
Primacor. *See* Milrinone
Procainamide (Pronestyl), 1033
Procardia. *See* Nifedipine
Proparacaine hydrochloride, 621
Propofol, 126, 128, 137, 1032, 1207
Propranolol, 1204
Prostaglandin E_1 (Prostin VR), 1032
Prostigmine. *See* Neostigmine
Protamine sulfate, 981, 1033

  ascending, 297–298, 298f
  blood supply of, 297–298, 298f
  descending, 297–298, 298f
  sigmoid, 346f, 347–348
  surgical procedures of
    abdominoperineal resection, 348–350, 349f
    colectomy. *See* Colectomy
    colostomy. *See* Colostomy
    ileoanal endorectal pull-through, 350–352, 351f–353f
    resection, 346f
    right hemicolectomy and ileocolostomy, 345–347
    sigmoid colon resection, 346f, 347–348
    transverse colectomy, 346f, 347
  transverse, 297–298, 298f
  wall of, 298
Colonoscope, flexible, 205f
Colonoscopy, 321–322
  definition of, 321–322
  preprocedural instructions for, 311b
Color bars, 217b
Color reproduction, 217b
Colostomy, 343, 1105–1107, 1106f
  operative procedure, 343, 344f
Colpomicroscopy, 425
Colposcopy, 425
Columella, 659, 687
Common bile duct
  anatomy of, 357, 359f
  description of, 296
  open exploration of, 378–379
Common peroneal nerve, 153, 154f–155f
Communication
  clinical documentation as form of, 23–25, 27f–29f, 30b
  hand-off, 26b, 30, 31b
  safety and, 23
Compartment syndrome
  abdominal, 1192–1193, 1193f
  definition of, 1192
  patient positioning and, 167b, 171
  prevention of, 167b
  signs and symptoms of, 1192, 1193t
  soft tissue injuries and, 1214
Complement assay, 301t
Complementary and alternative therapies, 1219–1220
  alternative medical systems, 1240–1241
  ambulatory surgery, 1256b
  aromatherapy, 1247–1248, 1249t
  background on, 1240
  biofields, 1244, 1245t–1246t
  biologically based therapies, 1241–1242, 1245f
  body-based methods, 1242–1243, 1249t
  categories of, 1240–1243
  cultural characteristics of, 1244b
  diet, 1242
  energy therapies, 1243–1256
  evaluation of, 1241b
  guided imagery, 1247, 1248f
  herbs, 1242, 1245f, 1250–1252, 1252b
  history of, 1240, 1244b
  hypnotherapy, 1246–1247
  integrative health therapies, 1252–1256
  legislative and administrative recommendations for, 1242b
  manipulative methods, 1242–1243
  mind-body interventions, 1241
  music, 1248–1250
  patient education about, 1251t
  psychoneuroimmunology, 1250
  therapeutic touch, 1244–1246, 1246t, 1247b
Complete blood count, 301t–303t, 941t, 1017t
Composite dressings, 264t–265t
Composite grafts, 906
Composite video output, 217b
Comprehensive Geriatric Assessment, 1162
Compression fracture, 745–746, 746f
Compression garments, 892–893
Computed tomography, 668, 845, 1013, 1191–1192, 1192t
Computer-assisted surgery, 223
Condensation, 68
Conduction system
  description of, 1006, 1006f
  disturbances of
    implantable cardioverter-defibrillator for, 1080f, 1081
    myocardial pacing electrodes for, 1080–1081
    pacemaker for, 1078–1079, 1079f
    surgery for, 1077–1081
    transvenous pacing electrodes for, 1079–1080, 1079f
Conductive hearing loss, 666t, 684
Condylomata acuminata
  of penis, 499
  of vagina, 433, 433f
Confusion, 1166–1167
Congenital diaphragmatic hernia, 473, 474f, 1112–1113, 1113f
Congenital heart disease, 1145–1156
Conjoined tendon, 407
Conjunctiva
  anatomy of, 610, 612f
  surgery of, 637
Conscious sedation/analgesia, 118, 137–138
Constipation, 289
Contact dermatitis
  allergic, 98, 1278
  irritant, 98, 1278
Contact precautions, 56, 64
Contaminated wound, 257, 369, 1196
Contamination
  airborne, 89
  definition of, 49b
Continuous bladder irrigation, 491–492
Continuous epidural analgesia, 139
Continuous passive motion, 737f
Continuous positive airway pressure, 702
Continuous suture, 183, 185f
Continuous wave Doppler, 977
Continuous-flow resectoscope, 515–516, 516f
Contractility, 1015b
Contrast media, 1228–1236
  seafood allergy and, 1219b
Cooper ligament
  anatomy of, 397–398
  hernia repair, 407–408, 409f–410f
Coping, 1203
Coracoclavicular suture fixation, 750
Core needle biopsy
  of breast, 602
  of prostate gland, 514
Cornea
  anatomy of, 612, 612f–613f
  layers of, 612, 612f
  refractive power of, 613f
Corneal surgery, 637–640
  pediatric, 1141
Coronary anastomoses, 1056f–1057f
Coronary arteries, 1002–1003, 1005f
Coronary artery bypass grafts
  aortic valve replacement and, 1066
  with arterial and venous conduits, 1054–1057
  off-pump, 1051
  practice guidelines for women undergoing, 1009b
  with reversed saphenous vein, 1057f
Coronary artery disease
  description of, 1002–1003
  inflammation's role in, 1010
  risk factors for, 1010, 1010b
Coronary circulation, 1002–1003, 1005f, 1039–1040
