## Introduction

### Overview of the Developmental History of LPL

Lipoprotein lipase (LPL, EC 3.1.1.34) is an extracellular and multifunctional water-soluble enzyme that is produced by many tissues and plays a key role in lipid metabolism and transport especially in the catabolism of triglyceride-rich lipoproteins. It catalyzes the hydrolysis of a variety of acyl esters including the triacylglycerols (TAGs) of circulating very low-density lipoproteins (VLDL) and chylomicrons to provide free fatty acids and 2-monoacylglycerols for tissue utilization (e.g. for energy production or synthesis of other lipids) (Bensadoun, 1991). The discovery of the first LPL dated back to 1943 has been believed to be made by Paul Hanh who found that an intravenous injection of heparin abolished the lipaemia associated with a fatty meal (Hahn, 1943). Subsequent studies revealed the critical role of LPL as a clearing factor for the overall lipid transport and metabolism with apolipoprotein-CII (apoC-II) as the activator (Scanu, 1966), and the interactions of apolipoprotein-AV with the LPL to accelerate the hydrolysis process through guiding VLDL and chylomicrons towards LPL. To date, a lot of important roles of LPL, either catalytic or non-catalytic function, have been identified, and the consequences of LPL abnormalities including LPL overexpression or deficiency have been well documented such as the close association with a number of pathophysiological conditions such as atherosclerosis, chylomicronemia, obesity, Alzheimer's disease, diabetes, infection, and impairment in bone marrow myelopoiesis. Most of the disorders caused by LPL are associated with its genetic mutations. Currently, gene therapy places a focus on treating LPL deficiency e.g. the AAV1-LPLS447X gene therapy that has been found positive in humans (Gaudet et al., 2012).

### Occurrence and Structure of LPL

The activity of LPL has been reported in adipose, lung, cardiac, and skeletal muscle tissues as well as lactating mammary glands, brain, kidney, and macrophages of humans (Chajek-Shaul et al., 1985; Stegmayr, 2014) and animals such as rabbit, duck, goat, cattle, rat, chicken, bovine and sheep (Mahoney et al., 1982; Borensztajn, 1987).

LPL belongs to the lipase gene family of proteins comprising endothelial lipase, hepatic lipase, pancreatic lipase, and *Drosophila* yolk proteins (i.e., YP1, YP2, and YP3). This enzyme family has a high TAG esterase activity with varied phospholipase activity, although *Drosophila* yolk proteins lack lipase activity and obvious LPL functionality (even though share sequence similarity with LPL) (Pistillo et al., 1998).

LPL catalyzes the hydrolysis of TAGs, diacylglycerols (DAGs), phosphatidylcholines (PCs), and phosphatidylethanolamines (PEs) in plasma TAG-rich lipoproteins (Jackson et al., 1983). LPL is a polypeptide with 839 amino acids with four functional sites: (1) a glycosaminoglycan binding site that immobilizes LPL to the endothelial cell surfaces; (2) a binding site for the physiological activator of LPL catalysis, apoC-II; (3) an active or catalytic site; (4) a lipoprotein interfacial lipid-binding site. The lipolytic active site with conserved Ser-132, Asp-156 and His-241 triad inside the large N-terminus domain is important for lipolysis (McIlhargey et al., 2003). Advanced characterization techniques such as X-ray crystallography, nuclear magnetic resonance (NMR), analytical ultracentrifugation and isothermal titration calorimetry have been used to study the structure–function relationship of LPL and LPL's interaction with regulatory factors. Most recently, new models of LPL structure have been generated using disulfide mapping, computational modeling, and the data derived from the single-molecule Forster resonance energy transfer (sm-FRET) (Hayne et al., 2018).

### LPL Synthesis and Translocation

#### The Synthesis, Activation, and Secretion of LPL

In general, LPL is synthesized and secreted in the form of a glycosylated homodimer within the parenchymal cells of various tissues, and then translocated through the extracellular matrix to the luminal surface of vascular endothelial cells. LPL is first synthesized as an inactive monomer proenzyme in the rough endoplasmic reticulum (ER) and then turns into its active form after glycosylation in the presence of lipase maturation factor 1 (LMF1). That is, native LPL monomers in a head-to-tail subunit orientation are commonly converted to the noncovalent active homodimer prior to transport. The mechanism of glycosylation-related LPL activation is still under investigation, and different inhibitors seemed to exert different impacts: using tunicamycin as the inhibitor to block completely glycosylation resulted in an inactive non-secretable form of LPL whilst using menonsine as the inhibitor to glycosylation resulted in a slightly active non-secretable form of LPL (Chajek-Shaul et al., 1985). The monomers tend to aggregate rather than re-associate e.g. through rapid dissociation to misfolded monomers in the absence of LMF1 in the ER, and undesirable dissociation was found to cause loss of enzyme activity (Ben-Zeev et al., 2011). The active LPL enters the Golgi apparatus, with a part of the active LPL binding to a sortilin-related receptor with type-A repeats (SorLA) for further modifications, sorting, and packaging, and the rest of the active LPL binding to heparan sulfate-proteoglycans (HSPG) on the parenchymal cell surface. Some of the synthesized LPL

undergo degradation e.g. the lysosomal degradation prior to their secretion, probably as a result of the cell/tissue-specific differences in the turnover rate of LPL.

### Translocation of LPL

LPL has been thought to bind to the HSPGs on the luminal surface of the endothelial cells where the hydrolysis of TAG-rich lipoproteins normally takes place (Obunike et al., 2001). Recent studies indicated that the role of a glycosylphosphatidylinositol-anchored protein named “glycosylphosphatidylinositol-anchored high-density lipoprotein-binding protein 1” (GPIHBP1) as the binding site for LPL in the capillary lumen, a “platform for lipolysis”, should also deserve attention (Meneghetti et al., 2015). The exact mechanism of LPL transport remains unclear, although transcytosis of LPL across endothelial cells involving parenchymal heparan sulfate-proteoglycans (HSPGs) and the VLDL receptor has been believed the characteristic process. LPL can be released from the parenchymal HSPGs via the catalysis by the heparanase from the endothelial cells, which may either enter the circulation or bind to the oligosaccharides and transport to the endothelial cells due to the polarity of endothelial cells. The endothelial cells release two forms of heparanase: active and the latent form. The active form releases LPL from the myocyte surface whilst the latent form stimulates intracellular LPL through RhoA activation mediated by HSPGs (Li et al., 2014). Sub-endothelial matrix isolates and stabilizes the LPL, Fig. 1 summarizes the synthesis, activation, secretion, and translocation of LPL.

### Functions of LPL

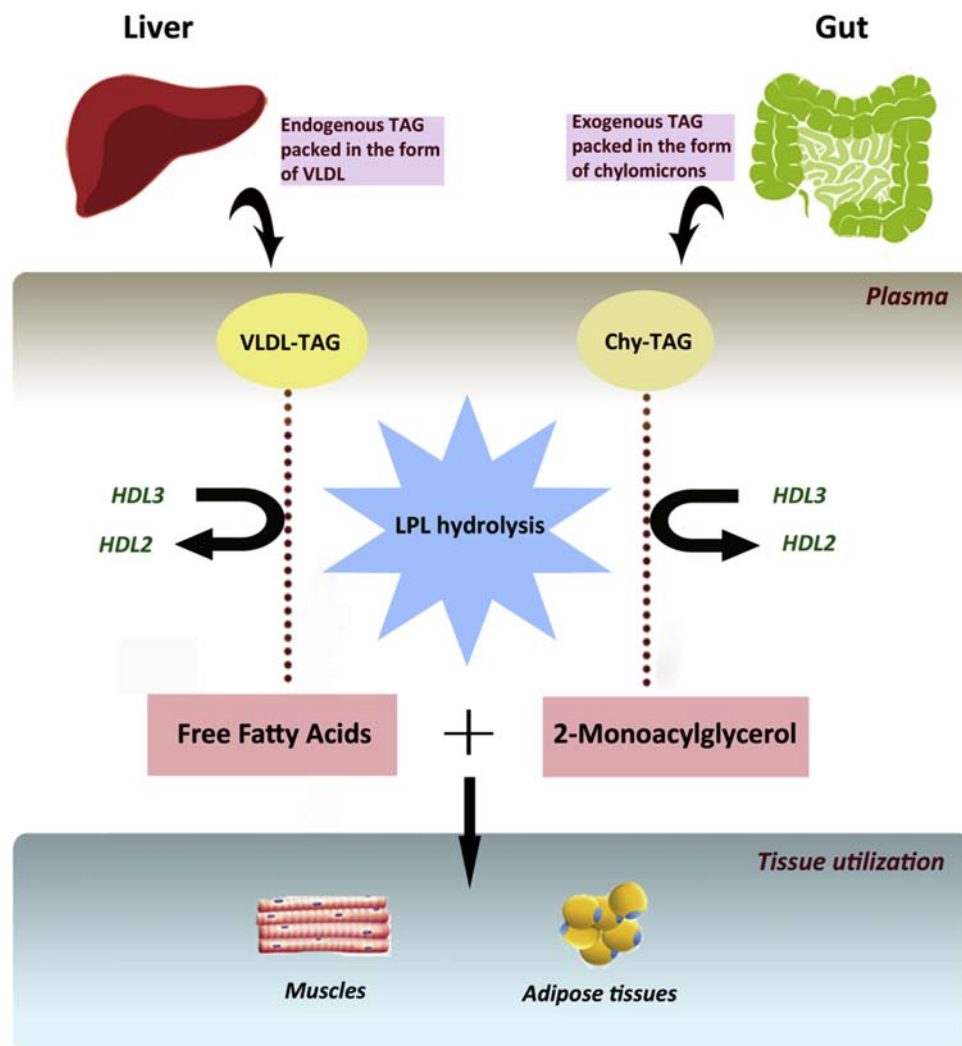

LPL is a rate-limiting enzyme that plays a major role in lipid metabolism and transport e.g. VLDL and chylomicron catabolism and transport of phospholipids, apolipoproteins, and cholesterol among lipoprotein particles. LPL exerts dual functions as triglyceride hydrolase and ligand/bridging factor for receptor-mediated lipoprotein uptake. VLDL can be converted to IDL and then to LDL via LPL catalysis. The hydrolysis of the TAG component of chylomicrons and VLDL catalyzed by LPL results in non-esterified fatty acids and 2-monoacylglycerol, which are utilized by different tissues in many ways e.g. the non-esterified fatty acids produced can be re-esterified for storing energy in the form of the TAG. LPL can simultaneously bind to both the lipoproteins and the cell surface receptors or proteoglycans to form bridges in the absence of another catalyst, allowing accumulation and cellular uptake of lipoproteins.

### LPL-Catalyzed Hydrolysis of VLDL-TAG and Chy-TAG

The exogenous and endogenous TAGs are transported and distributed in the circulation in the form of large multi-molecular lipoprotein particles. The exogenous dietary TAGs and fat-soluble vitamins are packed into the chylomicrons synthesized by the mucosal cells of the intestine, while the endogenous TAGs secreted by the liver are packed in the form of VLDL. Chylomicrons

**Figure 1** A diagram representing the synthesis, activation, secretion, and translocation of LPL. After synthesis and activation in the ER, LPL enters the Golgi apparatus where it is either secreted or undergo lysosomal degradation following which LPL binds to the HSPGs and translocated to the abluminal side of endothelial cells. Finally, LPL is transported to the luminal surface via transcytosis process where it carries out hydrolysis with the help of GPIHBP1. Adapted from Li et al. (2014).

**Figure 2** The metabolism of lipoproteins involving LPL and the resultant formation of free fatty acids and 2-monoacylglycerol for tissue utilization.

and VLDL enter the blood circulation by which TAGs are distributed to tissues (Fig. 2). The lipoproteins can deliver lipids to specifically target tissues in which apolipoproteins can act as either a cofactor for cell surface lipases (such as LPL) or a ligand for cell surface receptors. Thereby, monitoring lipoproteins can prevent unnecessary dispersal of lipids during transport through exchange or diffusion.

Besides the well-known catalyst role for TAG hydrolysis, LPL has a range of other physiological functions: LPL expressed in heart and skeletal muscles mainly catalyzes the lipolysis of plasma lipoproteins and produces free fatty acids for oxidation (providing energy); LPL also transports cholesterol and vitamin E to the neurons thus assists in recycling and scavenging of lipids released from the degenerating nerve; More recently, hypothalamic LPL has been found to assist in ceramide distribution, glucose metabolism and regulation of body weight.

### Mechanistic Action of LPL on Lipid Interface or Phospholipids

Phospholipids consist of two fatty acids chain and are the key component of almost all the biological membranes (including cells and cellular components). The intake of PL is estimated to be 1%–10% of total fat consumption. Foods such as eggs, fish, shellfish, animal organs, lean meats, dairy products, cereal grains and oilseeds contain a high PL content, while some leafy vegetables, fruits, and tubers also contain small amounts of PL. The fatty acid composition of PLs varies with their origin. PC is the most common PL in foods with other PLs such as PE, phosphatidylserine (PS) and phosphatidylinositol (PI) present at much lower levels. Moreover, PLs are commonly used ingredients/additives in food, pharmaceutical, nutraceutical and cosmetic industries for manufacturing products like dairy foods, baked goods, chocolate, and confectionery.

PLs are digested and absorbed in the small intestine in ways different from TAGs. Unlike TAG, PLs do not need bile salts for emulsification and lingual or gastric lipases for hydrolysis, and can form micelles by themselves in the digesta and be hydrolyzed

directly by enzymes in the small intestine (where they are almost absorbed and then enter in plasma lipoproteins and red blood cells). PC is the most common PL present in the intestinal lumen and represent the second most abundant lipid in the digestive tract after TAGs, with other PLs like PE, PS, and PI of much lower contents (Murru et al., 2013). In the lumen, chemical breakdown of most PLs via hydrolysis at the sn-2 position is mainly catalyzed by pancreatic phospholipase A2 (PLA<sub>2</sub>) and other lipases secreted by the pancreas, to yield free fatty acids and lyso-PLs. Both components are then taken up by mucosal cells. The type of PL including fatty acid chain length and unsaturation number determines PL's digestion, absorption, transport, and metabolism e.g. PLs containing medium-chain fatty acids tend to be absorbed better than those with long chain fatty acids (Ramirez et al., 2001). Lyso-PLs and some free-FAs may be re-esterified to newly-formed PLs (while some free FAs may bind to for new TAGs) and enter the bloodstream incorporated into the surface layer of chylomicrons. A small proportion of PLs may also incorporate into very low-density lipoproteins (VLDL). In the meantime, co-occurring TAG-rich particles are incorporated into the core of chylomicrons and then degraded, resulting in a proportion of chylomicron PLs especially PC to be transferred to the high-density lipoprotein (HDL) (a process takes place within 5–6 hours of PLs ingestion with about 20% of intestinal PLs being incorporated directly into HDL) (Burri et al., 2012) (Burri et al., 2012). Via HDL, PLs are then transferred into cells of different tissues and organs such as brain, liver, muscle, kidneys, heart, and lung including blood cells such as platelets and erythrocytes (Burri et al., 2012; Hussain, 2014). Accordingly, PLs may deliver health-beneficial polyunsaturated fatty acids more efficiently than TAGs.

Phospholipids are capable of shield other lipid species from aqueous environments via the formation of a mixed monolayer with proteins such as apolipoproteins. Moreover, LPL can catalyze the hydrolysis of TAGs and DAGs, PCs, and PEs in plasma triacylglycerol-rich lipoproteins, as well as in emulsion-like systems (McLean et al., 1986). Thus, it is of high interest to examine the interactions with LPL with PLs. However, very few studies have been performed to examine the interaction of LPL with PLs, because the detailed molecular organization of the lipoprotein substrate for LPL has not been elicited. Only a few studies investigated this aspect and in which PC was used singly as the major lipid component of the surface of the lipoprotein. McLean, Larsen et al. (1986) studied the interaction of LPL with a nonhydrolyzable PC, 1,2-ditetradecyl-rac-glycero-3-phosphocholine (C14-ether-PC) using physical methods: Analysis of LPL by circular dichroism spectroscopy revealed that its conformation contained 35%  $\alpha$ -helix, 30%  $\beta$ -pleated sheet and 45% other structures, and no significant change was found in LPL's conformation upon addition of C14-ether-PC vesicles. Addition of LPL to sonicated C14-ether-PC vesicles containing entrapped carboxy fluorescein caused the release of less than 15% of the vesicle contents in 20 min, indicating that LPL hardly disrupt the bilayer structure of the lipid (as observed by freeze-fracture electron microscopy, Fig. 3). However, the addition of apolipoprotein A-I to such a vesicle preparation caused the release of more than 80% of the vesicle contents. Further, at a low ionic concentration (0.1–0.25 M NaCl) significant aggregation of intact vesicles was observed by light scattering and electron microscopy (Fig. 3B (as indicated by arrows)). Other studies also found that vesicle aggregation could be prevented and reversed by 1 M NaCl or heparin, and LPL may bind as a dimer to the surface of a lipid interface e.g. the endothelial cell surface (Garfinkel et al., 1983) and to heparin and lipid droplet (Olivecrona et al., 1985), without causing dramatic changes in lipid bilayer or protein structure.

The function of LPL and its activation by apoC-II were studied with monomolecular films of 1,2-didodecanoyl-*sn*-glycero-3-phosphoglycerol as a substrate. The enzymatic velocity and specific activity of the interface-bound enzyme showed a bell-shaped curve as a function of lipid packing, in the presence and absence of apoC-II. Above the critical surface pressure of 20 dyn cm<sup>-1</sup>, LPL alone was found not able to hydrolyze a monolayer of 1,2-didodecanoyl-*sn*-glycero-3-phosphoglycerol, but could readily penetrate the phospholipid interface up to surface pressures exceeding 40 dyn cm<sup>-1</sup>, without any effect by apoC-II (Fig. 4). Below the critical surface pressure of 20 dyn cm<sup>-1</sup>, apoC-II merely increased the turnover number of LPL by 4-fold. Lambert et al. (2000) reported that the longer the carboxyl-terminal fragment of apo C–II was, the greater was the activation. The PL hydrolysis activity

**Figure 3** Freeze-fracture electron microscopy of C14-ether-PC vesicles with and without LPL: (a) C14-ether-PC vesicles in 0.25 M NaCl (500  $\mu$ g of PC/mL); (b) C14-ether-PC vesicles (500  $\mu$ g of PC/mL) plus LPL (250  $\mu$ g/mL) in 0.25 M NaCl; (c) sample B in 1 M NaCl. The final glycerol concentration was 25%. Magnification: (a) and (b) 30840  $\times$ ; (c) 31480  $\times$ ; scale bar = 0.1  $\mu$ m. Adapted from McLean et al. (1986).

**Figure 4** Action of lipoprotein lipase (LPL) on monolayer of phospholipids (PLs), in the presence of low or high pressure, in low-pressure monolayer packing is loose, easily access the substrate without apolipoprotein C-II (apoC-II), and in high pressure, difficult access the substrate without apoC-II, and apoC-II assists in the penetration of PL monolayer layer. Lipid binding sites: red triangles; apoC-II binding sites: yellow Zig-Zag; substrate: Cyan; apoC-II activator: Blue, curved arrow.

**Figure 5** A model action of lipoprotein lipase (LPL)-dimer on chylomicrons: (A) LPL-dimer and apoC-II activator approaching the substrate; (B) LPL-dimer act on the phospholipid (PL) monolayer, but cannot access the substrate, when apoC-II binds to LPL and gets access to the substrate; (C) when activator apoC-II dissociates to the LPL, it loses activity or the hydrolysis stops; (D) Finally, LPL-dimer leaves the substrate.

represented, in the presence of apo C-II, 36% of the TAG hydrolysis activity. PL hydrolysis is less dependent on the activator than TAG hydrolysis (100% and 300% of increase with apo C-II for PC and TAGs, respectively). The mechanism of hydrolysis activated by apoC-II or the synthetic apo C-II fragments seems to be the same as that for TAGs, as each synthetic apo C-II fragment present the same percentage activation in comparison with the whole apoC-II, irrespective of the substrates. The carboxyl-terminal 30 amino-acid fragment of intact apo CII can activate LPL, suggesting that other elements beyond the carboxyl-terminal 30 amino-acid fragment are necessary for the binding of apo C-II to LPL and its full activation. Moreover, expression of LPL with catalytic activity can be regulated by the physical state of the substrate interface. ApoC-II can affect this regulation. The requirement for the presence of PL-associating residues in apoC-II would be due to that the activator either alters PL structure or changes the orientation of LPL at the interface. Further, if apoC-II could change PL structure, the presence of the lipid binding region between residues 43 and 50 would probably affect LPL activation at low lipid packing. The two proposed activation mechanisms — increased turnover and assisted penetration are by no means mutually exclusive. Under certain conditions, they may well be working simultaneously, with the latter likely being a prerequisite for the former to occur. It is worth noting the hypothesis that LPL is not interacting directly to PLs, LPL assisted by lipoprotein apoC-II which gives more grip on lipoprotein particles (such as chylomicrons) during hydrolysis of substrate and apoC-II interacts with PLs via amphipathic interactions, which would afford greater stability to LPL (Fig. 5). In summary, the presence of two cooperative activation mechanisms would secure the catalytic efficiency of LPL under dynamically changing interfacial conditions during the hydrolysis (Vainio et al., 1983)

## Conclusions

LPL is an important and versatile enzyme that influences human metabolism and health. The understanding of the synthesis, structural characteristics, physiological and physical behaviors and modes of catalytic action (including substrate specificity, cofactor requirements, and working system/location) of LPL would support LPL monitoring and utilization. Although PLs are generally considered a minor component of foods, PLs are key components of cellular membranes. The interactions of both bioactive substances, LPL, and phospholipids, thus represent an important research topic, and the obtained knowledge would benefit the food, pharmaceutical, nutraceutical and cosmetic industries.

# Reactivity of Lipid Oxidation Products in Foods – Is Malondialdehyde a Reliable Marker?

Angelique Vandemoortele and Bruno De Meulenaer, NutriFOODchem Unit, Department of Food Technology, Safety and Health (Partner of Food2Know), Faculty of Bioscience Engineering, Ghent University, Ghent, Belgium

## Introduction

Lipid oxidation is one of the major causes of food quality deterioration responsible for the generation of off-flavors (rancidity) and undesirable changes of color, texture and nutritive value. In some foods, a limited amount of lipid oxidation is desirable because it leads to the generation of desirable aroma substances; such as 2,4-decadienal, hept-4-enal and non-2-enal (Zehentbauer and Rein-eccius, 2002). Furthermore, the oxidation of unsaturated lipids results in the generation of toxic compounds which have been associated with cardiovascular diseases, as well as cancer, atherosclerosis, aging, etc (Negre-Salvayre et al., 2008; Ayala et al., 2014).

It is generally accepted that lipid oxidation starts with the transformation of unsaturated lipids by oxygen-active species to lipid hydroperoxides, which are considered as the primary lipid oxidation products. These lipid hydroperoxides can be generated via three different pathways: (1) via a free radical chain mechanism or autooxidation; (2) via photooxidation, requiring the presence of visible light and a photosensitizer (e.g. riboflavin, chlorophyll); or (3) via an enzymatic reaction requiring the presence of lip-oxygenases. Hydroperoxides are unstable molecules. They may induce oxidation reactions and generate the formation of lipid radi-cals that may further support the oxidation process or may be converted to a variety of so-called secondary lipid oxidation products, including carbonyl compounds (aldehydes, ketones, oxo-fatty acids) alcohols, epoxides, dimers, polymers, among others (Belitz et al., 2009; Schaich, 2005). Typically, carbonyl compounds have been related to rancidity and used as markers for lipid oxidation (Ross and Smith, 2006; Panseri et al., 2011; Pignoli et al., 2009), although recently Mubiru et al. revealed the unexpected high content of epoxy fatty acids in a variety of fresh oils with a low hydroperoxide value suggesting that some of the lipid oxidation markers already used for decades are potentially not always reliable (Mubiru et al., 2013). A typical example of such an oxidation marker used to assess lipid oxidation in foods and other biological matrices is malondialdehyde (Requena et al., 1996; Del Rio et al., 2005).

Malondialdehyde (MDA) is generally recognized for its generation during the oxidation of  $\omega$ -3 and  $\omega$ -6 fatty acids. It is a three carbon dialdehyde mainly present as its enol in aqueous and organic solutions (George and Mansell, 1968; Xu et al., 2015). Though, in aqueous solutions, MDA can exist in various forms depending on the pH (as shown in Fig. 1). The pK<sub>a</sub> of the enolic OH group is 4.46. Therefore, under neutral and alkaline conditions the predominant form of MDA is the enolate anion, whereas at acidic pHs, MDA mainly exists in its undissociated enol in equilibrium with the dicarbonyl form (Esterbauer et al., 1991). Besides, the Z-isomer of the enol can stabilize itself via the formation of an intramolecular hydrogen bond resulting in a chelated form

Figure 1 Behavior of MDA in aqueous solutions.

(Freitag et al., 2007). However, in aqueous solutions the relative stability of the intramolecular hydrogen bond diminishes because of competing hydrogen bond formation with the solution (Xu et al., 2015; Freitag et al., 2007). Hence, in aqueous solutions the reactivity of MDA depends on the pH, in contrast to oils in which MDA is produced. In oil-in-water (O/W) emulsions, however, MDA can partition between the oil and aqueous phase depending on the nature of its molecular environment (e.g. the used emulsifier type, droplet size, oil content, etc.) (Berton-Carabin et al., 2014; Osborn and Akoh, 2004; McClements and Decker, 2000; Lethuaut et al., 2002). Vandemoortele et al. showed that, after spiking MDA into the aqueous phase, 36% of the MDA was translocated to the oil and/or interface of the O/W emulsion (Vandemoortele and De Meulenaer, 2015; Vandemoortele et al., 2017).

Several methods have been developed to assess the MDA content, including spectrophotometric or fluorimetric techniques, high performance liquid chromatography (HPLC), gas chromatography and immunological techniques (Del Rio et al., 2005). The most common method for MDA determination in foods is the spectrophotometric measurement of the pink-colored fluorescent MDA-thiobarbituric acid (TBA) complex (Botsoglou et al., 1994). However, the spectrophotometric TBA method has been criticized because of the lack of sensitivity, since TBA reacts not only with MDA but also with many other compounds (e.g. carbohydrates, amino acids, pyridines, other secondary lipid oxidation products, etc.), resulting in considerable overestimation of the MDA content (Mendes et al., 2009; Papastergiadis et al., 2012). Therefore, chromatographic techniques (e.g. HPLC-fluorescence detection) are preferred to quantify the MDA content due to their high separation power, specificity and accuracy (Grotto et al., 2009). The aim of this review is to evaluate critically the general applicability of MDA as marker for assessing lipid peroxidation in foods. Thereby, no summary will be made about the plurality of methods for analyzing the MDA content in foods, as it has been reported before (Del Rio et al., 2005; Grotto et al., 2009; Barriuso et al., 2013). Though, the focus will be on the stability of MDA in foods and the subsequent consequences for the MDA determination via HPLC-fluorescence detection of MDA-TBA adducts (the TBA-MDA assay).

## Reactivity of MDA

### Aldol Self-condensation and Hydrolytic Cleavage of MDA

MDA can undergo aldol self-condensation and hydrolytic cleavage under physiological conditions (aqueous medium, pH near neutrality, room temperature) (cf. Fig. 2). The aldol self-condensation of MDA leads to the formation of acid labile dimers and

#### A Aldol self-condensation of MDA

#### B Hydrolytic cleavage of MDA

**Figure 2** Reaction mechanism of (A) the aldol self-condensation and (B) hydrolytic cleavage of MDA.

oligomers and is restricted to pH 5–7 (Esterbauer et al., 1991; Gómez-Sánchez et al., 1990; Janero, 1990). MDA condensation products have been reported to be approximately equipotent to MDA with respect to their mutagenicity (Niedernhofer et al., 2003; Riggs and Marnett, 2001). Moreover, these condensation products of MDA are suspected to be involved in protein modifications (Esterbauer et al., 1991; Janero, 1990), complementary to MDA as will be discussed in detail below. In addition, hydrolytic cleavage of MDA can occur (pH 4–7), generating formic acid and acetaldehyde (Vandemoortele et al., 2017; Gómez-Sánchez et al., 1993). Multiple studies have shown that acetaldehyde is mutagenic and even carcinogenic (Seitz and Meier, 2007; Salaspuuro, 2009). Its interaction with a variety of proteins resulted in the formation of protein-acetaldehyde adducts that may interfere with the biological functions of the modified protein (Tuma et al., 1996; Thiele et al., 2001). Vandemoortele et al. reported that both the aldol self-condensation and hydrolytic cleavage of MDA can occur in a lipid medium. Moreover, the aldol self-condensation of MDA was very dependent on the storage and operating temperature of the oil and increased dramatically with increasing temperature. About 1.5% and 68% of the added MDA underwent aldol self-condensation at 4 and 40 °C, respectively, after 24 h. Though, no temperature effect was observed on the hydrolytic cleavage of MDA in oil (which accounted for 7% loss). Surprisingly, greater hydrolytic cleavage was found in a lipid medium than in an aqueous buffer (pH 6.8) (cf. about 3% of the added MDA). In aqueous buffer (pH 6.8), the main reaction route was the aldol self-condensation of MDA (cf. 5% of the added MDA at 4 and 40 °C) (Vandemoortele and De Meulenaer, 2015; Vandemoortele et al., 2017).

### Interaction Between MDA and Food Proteins

Lipid peroxidation and protein oxidation are often addressed together. Oxidative damage to protein may be induced indirectly by reaction with lipid oxidation products in general, and by lipoperoxidation-derived  $\alpha,\beta$ -unsaturated aldehydes in particular. These aldehydes are able to bind spontaneously to proteins, causing protein modification (e.g. cross-linking, aggregation) and generation of adducts (termed “advanced lipid peroxidation end products” or “ALE”) (Domingues et al., 2013).

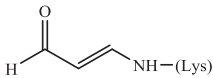

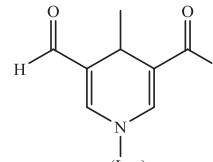

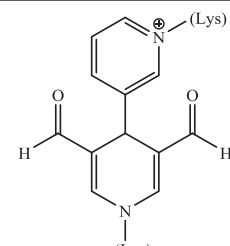

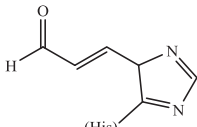

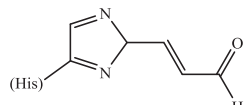

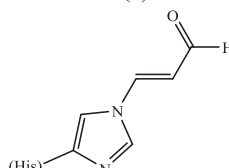

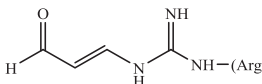

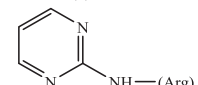

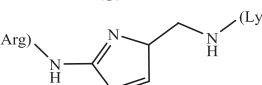

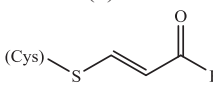

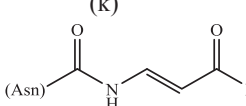

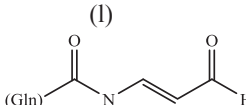

The interaction of different proteins with MDA under physiological conditions has been shown to generate potentially various toxic adducts and cause cross-linking of proteins (Domingues et al., 2013; Uchida et al., 1997; Refsgaard et al., 2000). Table 1 provides an overview of the different MDA-protein adducts.

The predominant derivatives resulted from the reaction of MDA with proteins have been identified as MDA-lysine adducts. The reaction of MDA with the free amino groups of lysine residues leads to the formation of imines, specifically N<sup>ε</sup>-(prop-2-enal)lysine derivatives or enaminals (a) (Uchida et al., 1997; Ishii et al., 2008). These adducts have been detected as the major forms in which endogenous MDA is excreted in rat and human urine (Draper et al., 1984; Draper et al., 1988). Because of the bifunctional nature of MDA, nucleophilic addition of a second free amino group of lysine can occur, generating a 3-amino-1-iminopropene cross-link (b) (Slatter et al., 2000). Formation of such iminopropene cross-links in an *in vitro* reaction has been reported for polylysine and human low-density lipoprotein (Requena et al., 1997). In the presence of alkanals, MDA addition can generate fluorescent adducts, 4-substituted 1,4-dihydropyridine-3,5-dicarbaldehyde derivatives (DHP-type adducts), with lysine. For example, MDA and acetaldehyde (derived from MDA cleavage *in vitro*) can react with each other in a concerted manner forming 4-methyl-1,4-dihydropyridine-3,5-dicarbaldehyde (c) (Tuma et al., 1996; Mooradian et al., 2001). These DHP-type adducts can induce further cross-linking, leading to the formation of another fluorescent adduct containing dihydropyridine and pyridinium rings (pyridinium DHP (d)), although, these pyridinium DHP adducts were not detected on protein or peptide level (Itakura et al., 1996).

In addition to these adducts, MDA may provide many other derivatives upon reaction with the side-chain groups of histidine, arginine, cysteine, asparagine and glutamine as well as the N-termini of peptides. Modification of the imidazole group of histidine by MDA to various imine derivatives (e–g) has been reported (Slatter et al., 2004; Zhao et al., 2012). Besides, MDA imine formation at the side chain of arginine (h) has been identified on peptide level (Zhao et al., 2012). Also the conversion of the guanidine group of arginine to a 2-aminopyrimidine residue by MDA (i) under strong acidic conditions has been described in peptides and proteins (Foettinger et al., 2006). Moreover, Slatter et al. reported the feasibility of a MDA-derived cross-link formed between arginine and lysine, giving 2-ornithinyl-4-methyl(1<sup>ε</sup>-lysyl)1,3-imidazole (j) (Slatter et al., 2004). Buttkus demonstrated that MDA could react with the sulfhydryl groups of cysteine (k) (Buttkus, 1969). A decrease in the sulfhydryl groups of soy proteins was found upon the increase of the MDA level (ratio MDA/free sulfhydryl groups: 0.0025–2.5 mol mol<sup>−1</sup>) (Wu et al., 2009). The reactivity of asparagine and glutamine with aldehydes is expected to be low due to the reduced nucleophilicity of the amino group in the carboxamide residue. Nevertheless, MDA imine formation at the side chain of both amino acid residues (l, m) was detected (Zhao et al., 2012).

Interaction of MDA with food proteins during processing and storage can lead to a decrease in the nutritional quality of proteins (e.g. damage to amino acid residues) and a change in their physicochemical properties. Progressive conjugation or cross-linking by MDA can cause protein browning, protein denaturation, polymerization, aggregation, and loss in solubility (Wu et al., 2009; Traverso et al., 2004; Adams et al., 2008). Protein aggregation can lead to a decrease in proteolytic susceptibility and also affect the digestibility of proteins (Chen et al., 2013; Obando et al., 2018). Further, enzymes containing reactive amino acid groups can be inactivated (Tironi et al., 2002). Protein immunogenicity and allergenicity could also be reduced due to MDA-induced conformational changes (Song et al., 2015; Nikolić et al., 2017). Thus, MDA-protein interaction is of biological importance because of the induced profound alteration in protein biochemical properties and correlation to chronic diseases such as atherosclerosis (Duryee et al., 2010), Alzheimer's disease (Pizzimenti et al., 2013), diabetes (Slatter et al., 2000), etc.

**Table 1** Structures of MDA-modified amino acid residues identified in various proteins and model systems

Lysine (Lys, K)	   
Histidine (His, H)	  
Arginine (Arg, R)	  
Cysteine (Cys, C)	
Asparagine (Asn, N)	
Glutamine (Gln, Q)	

Besides some immunological methods (Khan et al., 2002; Wang et al., 2012; Bevan et al., 2003), lacking sensitivity and accuracy, only the analytical method of Requena et al. (1997) revealed two MDA-lysine adducts (a, b), although its applicability for food matrices needs to be assessed.

### Interaction Between MDA and Other Food Constituents in Food

Analogous to amino compounds, MDA interacts with other food compounds such as phenolic compounds, ascorbic acid, nitrite, DNA and phospholipids.

Phenolic antioxidants are widely used to protect lipids from oxidation by acting as free radical scavengers and chelators (Yin et al., 2012; Racicot et al., 2012). In addition, these compounds are able to act as lipid-derived carbonyl scavengers. Carbonyl-phenol adducts are produced with phenolic compounds that have either aromatic carbons or hydroxyl groups with a high nucleophilicity. This reaction occurs mainly with *m*-diphenols such as resorcinol, phloroglucinol, epicatechin, theaflavin, hesperetin (Hidalgo and Zamora, 2014; Hidalgo et al., 2017). The interaction between phenolic compounds and MDA or other reactive carbonyl substances such as propanal, pentanal, hexanal, acrolein, pent-2-enal, oct-2-enal, and 4-hydroxy-non-2-enal (HNE) have been reported (Hidalgo et al., 2017; Zhu et al., 2009a,b). Zhu et al. (2009a) proposed that green/black tea polyphenols might directly trap MDA, a phenomenon similar to that occurring between black tea polyphenols and methyl glyoxal (Lo et al., 2006; Sang et al., 2007). However, at present, the structures of MDA-phenol adducts have not yet been proposed. Based on the reaction

**Figure 3** Proposed structures of MDA-phenol adducts. Only the portion of the phenolic compound that takes part in the reaction has been shown. Adapted from Zamora, R., Hidalgo, F.J., 2018. Carbonyl-phenol adducts—an alternative sink for reactive and potentially toxic lipid oxidation products. *J. Agric. Food Chem.* 66, 1320–1324.

mechanism proposed for alk-2-enals and *m*-diphenols (Hidalgo and Zamora, 2014; Zamora and Hidalgo, 2016, 2018), these structures may be as those shown in Fig. 3.

Like phenolic compounds, ascorbic acid can also function as a nucleophile (which is less appreciated compared to its antioxidant action). The formation of Michael adducts between ascorbic acid and lipoxidation products such as HNE and acrolein has been demonstrated (Fodor et al., 1983; Sowell et al., 2004, 2005). Currently, no interaction between ascorbic acid and MDA has been reported. Though, a similar adduct as acrolein (Fodor et al., 1983) can be expected for MDA-ascorbic acid reaction (as shown in Fig. 4).

MDA can react with nitrite in an acidic medium (pH 1.3–6), even at room temperature. Nitrite is an important additive in cured meat due to the induced characteristic cured-meat color, antioxidant activity and antimicrobial effect (Kolodziejaska et al., 1990). However, the presence of residual nitrite in meat samples could lead to nitrosation of MDA (which cause limitations of the TBA-MDA method in cured meat) (Fernandez et al., 1997; Ulu, 2004). Nevertheless, the TBA-MDA assay has still been used for analyzing the MDA content in cured meat despite the potential nitrosation (Moawad et al., 2012; Sharma et al., 2012; Berardo

**Figure 4** Suggested reaction mechanism between ascorbic acid and malondialdehyde. Based on Fodor, G., Arnold, R., Mohacsi, T., Karle, I., Flippen-Anderson, J., 1983. A new role for L-ascorbic acid: Michael donor to  $\alpha$ ,  $\beta$ -unsaturated carbonyl compounds. *Tetrahedron* 39, 2137–2145.

**Figure 5** Mechanism proposed for MDA nitrosation in aqueous solutions. Adapted from Garcia-Rio, L., Mejuto, J.C., Parajó, M., Pérez-Lorenzo, M., 2008. First kinetic discrimination between carbon and oxygen reactivity of enols. *J. Org. Chem.* 73, 8198–8205.

et al., 2016). In Fig. 5, the possible mechanism underlying MDA nitrosation in aqueous solution is presented, although this mechanism is still under discussion since no MDA-nitrite adducts have been isolated so far.

The mutagenicity of MDA has been linked to its reaction with DNA bases. Indeed, MDA can interact with nucleic acid bases to form multiple adducts (as shown in Fig. 6) (Niedernhofer et al., 2003; Marnett, 1999). Among the various MDA-DNA adducts produced *in vitro*, the pyrimido[1,2- $\alpha$ ]purin-10(3H)-one ( $\text{M}_1\text{G}$ ) is probably the major adduct followed by  $\text{N}^6$ -(3-oxopropenyl)deoxyadenosine ( $\text{M}_1\text{A}$ ) with  $\text{N}^4$ -(3-oxopropenyl)deoxycytidine ( $\text{M}_1\text{C}$ ) only found in trace amounts (Marnett, 1999; Guéraud et al., 2010). Further, the amine-containing head groups of phospholipids (e.g. phosphatidylserine or phosphatidylethanolamine) can also form adducts with MDA (Bhuyan et al., 1986). In the last decade, the latter interaction has not gained much attention in contrast to the action of phospholipids as antioxidants.

### Consequences of the Reactivity of MDA in View of Its Use as Lipid Oxidation Marker in Food

Since MDA represents a secondary lipid peroxidation product and sensitive analytical methods are available for its isolation and quantification, MDA has been considered as an excellent marker for lipid peroxidation of  $\omega$ -3 and  $\omega$ -6 fatty acids in foodstuffs. However, as discussed in detail in above paragraphs, MDA is a highly reactive substance towards not only various compounds in food but also itself. The commonly used MDA-TBA assay would measure only the free MDA content. It remains unknown whether or not the various MDA adducts and reaction products are stable under the harsh test conditions used in the TBA-MDA assay. MDA bound to proteins would definitely not be determined by this method because proteins (including those bound with MDA) are mostly excluded prior to TBA derivatization (to avoid interference). Attempts have been made to measure the

**Figure 6** Structure of MDA-DNA adducts.

MDA bound to proteins including the treatment via alkaline hydrolysis prior to TBA derivatization (Grintzalis et al., 2013; Tukozkan et al., 2006; Jung et al., 2016). During this treatment, MDA would mainly exist in its anionic form (which is much less reactive than its undissociated enol) (Chuaqui-Offermans and Chuaqui, 1983). However, the stability of MDA during such alkaline hydrolysis and the degree of protein hydrolysis are still concerns (Grintzalis et al., 2013; Tukozkan et al., 2006; Jung et al., 2016; Mendonça et al., 2017; Carboneau et al., 1991). The ignorance of the occurrence of free amino acids after this hydrolysis step and their interaction with MDA would lead to incorrect analysis results of MDA content, even in acidic medium (cf. arginine). In the study of Grintzalis et al., the proteins were first precipitated with trichloroacetic acid before the alkaline hydrolysis, although resolubilization of precipitated protein is often difficult (Nandakumar et al., 2003). As for MDA, little is known about the stability of the reaction products between MDA and co-existing food components during MDA analysis. Consequently, the MDA determination in a particular food using the conventional TBA-MDA assay is likely inaccurate and the results are greatly affected by the food ingredients and food physico-chemical properties (cf. pH and temperature).

Proteins and peptides can act as multifunctional antioxidants to inhibit lipid oxidation in foods by inactivating reactive oxygen species, scavenging free radicals, chelating prooxidative transition metals, reducing hydroperoxides and altering food physical properties (Elias et al., 2008). Several studies evaluated the antioxidant potential of proteins and peptides by the TBA-MDA assay (Pena-Ramos and Xiong, 2001; Peña-Ramos and Xiong, 2002, 2004; McCarthy et al., 2001a,b; Kęska et al., 2017). The resultant antioxidant activities of protein and peptides would likely be overestimated, because the MDA-protein interaction is not a reaction truly based on an antioxidant mechanism (it does not inhibit lipid oxidation but instead, masks the extent lipid oxidation). Similar conclusions can be made for ascorbic acid (Shalata and Neumann, 2001), phospholipids (Hidalgo et al., 2005) and phenolics (Ahn et al., 2002; Brettonnet et al., 2010). Hence, high reactive MDA as a general oxidation marker for lipid peroxidation in foods and as a measure for antioxidant activity is of concern. Further research is needed to examine the stability of MDA adducts during the TBA-MDA assay and amounts of the MDA oligomers and MDA-protein adducts.

### Consequences of the Reactivity of MDA With Respect to Food Safety

Modern diets contain significant amounts of oxidized lipids due to the inclusion of fried, cooked, and emulsified lipids, unsaturated fats and other lipid-containing foods, as well as the increasing proportion of prepared meals. Papastergiadis et al. studied the dietary exposure to MDA for the Belgian population by combining food consumption data with the determination of free MDA in foods specifically available in Belgium. On the basis of the threshold of toxicological concern, they indicated no risk to human health related to the consumption of such foods for the vast majority of analyzed consumers (Papastergiadis et al., 2014). The total dietary exposure to MDA for humans cannot be estimated based on the measured of free MDA content in foods, otherwise, the risk associated with the presence of potentially toxic MDA adducts along with the products derived from cleavage and aldol self-condensation would be neglected (Vandemoortele et al., 2017). Besides, MDA can be formed during gastric digestion (Steppeler et al., 2016; Larsson et al., 2016; Tullberg et al., 2016; Gorelik et al., 2008a), and in fact, its postprandial absorption and accumulation in the human plasma, most likely in the forms of MDA-lysine adducts, were reported (Gorelik et al., 2008b, 2013; Sirota et al., 2013; Giron-Calle et al., 2002). Giron-Calle et al. found that  $N^{\epsilon}$ -(prop-2-enal)lysine (**a**) can be absorbed from the gut and would then reach many organs, although this finding was based on the *in vivo* digestion of radioactive labeled MDA-lysine adduct rather than the MDA-modified food proteins or peptides. Moreover, MDA adducts can also be formed during the digestion process and then react further with co-existing food components (which may help to prevent the absorption of MDA during digestion). Actual consequences of the resultant MDA-containing species would be on a case-by-case basis, which represents another stream of future research.

# Protein-Lipid Interactions and the Formation of Edible Films and Coatings

Victor N Enujiugha and Ajibola M Oyinloye, Federal University of Technology, Akure, Nigeria

## Introduction

The need to protect consumer health, as well as environmental concerns, led to exploitation of natural food grade materials in food packaging. Such biodegradable films extend shelf life by acting as selective barriers against moisture and oxygen. They also reduce lipid oxidation by controlling oxygen transmission and volatile compounds which are effective in producing undesired odor and flavour (Koushki et al., 2015). Polysaccharides, proteins, and lipids or a combination of these have been used to prepare biodegradable edible films. In general, the main film-forming materials are polysaccharides (i.e. starch, carrageenan, pectin, alginate, carboxymethylcellulose and chitosan), proteins (i.e. wheat gluten, whey protein isolate, caseinate and soy protein), and lipids (i.e. waxes and fatty acids) (Falguera et al., 2011). Among these materials the inherent properties of proteins make them excellent components for producing edible films. Edible films can be used for versatile food products to reduce loss of moisture, restrict absorption of oxygen, lessen migration of lipids, improve mechanical handling properties, provide physical protection, and/or offer an alternative to the commercial packaging materials (Enujiugha et al., 2013). Composites and mixtures of these films have shown more remarkable functionality in terms of barrier properties and food freshness preservation, when compared to individual biopolymer-based films. An example is the combination of proteins and lipids to form biodegradable edible films and coatings, whereby the low water vapour resistance of protein films is compensated for by the wiper-repelling properties of the incorporated lipids.

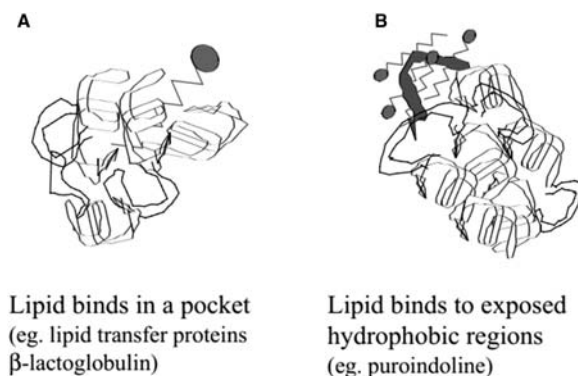

Protein-lipid films are formed as a result of endothermic polymerization of heat denatured proteins or lipoprotein monomers at the liquid surface promoted by surface dehydration (Enujiugha et al., 2013). Heat treatment leads to a change in the three-dimensional structure of proteins and results in exposing sulphhydryl groups and hydrophobic side chains. During film formation, lipid acts as a surfactant which moves to the air/water interface and interacts with proteins by hydrophobic interactions. The protein creates a continuous network structure wherein the lipids are dispersed as droplets. Covalent bonding of lipids to proteins through lipolization offers unique opportunities for film formation with improved properties. Lipid addition reduces significantly the water vapour permeability of protein-based films (Handa et al., 1999a,b; Enujiugha et al., 2013).

Foods are living tissues before and shortly after harvest with specific membrane functions at the cellular level. Within the cell, the mechanism by which a protein interacts with lipids has significant biological consequences, because it determines the specificity and affinity of membrane binding as well as possible effects of the protein on the morphology and dynamics of the membrane (Zhao and Lappalainen, 2012). Processing and preservation of food materials have obvious effects on the cellular activities, and at this level, the interaction of proteins with lipids deals more with the disturbance of the original structure by exposing of the hydrophobic core of the molecule. According to Bourtoom (2009), modifying properties of protein by chemical and enzymatic methods, combining with hydrophobic material or some polymers, or by using a physical method primarily focuses on improving the mechanical strength and moisture barrier properties. In this technical review, the underlying mechanisms of protein-lipid film formation are examined and the applications of the films in food systems x-rayed, with a view to enhancing packaging quality. The potential of edible films to control water transfer and to improve food quality and shelf life is key to the currently increasing attention given to their applications in food systems.

## The Mechanisms of Protein-Lipid Interactions

The hydrophobicity of a protein determines, to a large extent, the value of its interfacial tension, which usually changes as the number and density of hydrophobic residues increase. Proteins generally are amphiphilic molecules, that is, possessing both hydrophobic and hydrophilic regions within their structures. They are commonly surface active and form adsorbed layer at the boundary or interface between the hydrophilic and hydrophobic phases. It is therefore noteworthy that increased surface hydrophobicity of a protein has been associated with increased rates of adsorption. In a study of the physical, thermal and structural properties of amaranth flour films, Tapia-Blácido et al. (2007) observed that there was a strong association between the lipids and the proteins, and consequently established that the presence of both proteins and lipids in the flour films had an important effect on film solubility and also on the color and opacity of the films.

Fillery-Travis et al. (2000) stated that native proteins are able to bind lipid in two main ways, either in a cavity or binding, or through less well defined hydrophobic patches which lie close to the surface of the protein (Fig. 1). For example, the milk whey protein  $\beta$ -lactoglobulin binds a wide variety of aliphatic components in its binding site, including lipids, while, on the other hand, the cereal nonspecific lipid transfer proteins seem to have an important functional role at interfaces, and are known to bind lipids in a central pocket. Apart from the naturally occurring lipid-binding sites, new binding sites can be induced by processing using heat or pressure, or as a consequence of the pH and ionic strength of a food system (Fig. 2). Thus, the proteins may unfold to reveal the more hydrophobic sites normally only present in the centre of the protein, or the conditions may cause dimeric proteins to dissociate to reveal the hydrophobic faces normally buried in the dimer interface (Fillery-Travis et al., 2000). Heating of soymilk, for example, has been found to lead to a change in the three-dimensional structure of the soy proteins and results in

**Figure 1** Modes of lipid binding in native interfacially active food proteins. (A) proteins which bind lipids in a pocket. (B) proteins which bind lipid through exposed hydrophobic regions. From Fillery-Travis, A., Mills, E.N.C., Wilde, P., 2000. Protein-lipid interactions at interfaces. *Grasas Y Aceites* 51 (1–2), 50–55.

**Figure 2** Processes which introduce lipid-binding regions in proteins through dissociation and unfolding of native proteins. From Fillery-Travis, A., Mills, E.N.C., Wilde, P., 2000. Protein-lipid interactions at interfaces. *Grasas Y Aceites* 51 (1–2), 50–55.

exposing sulphhydryl groups and hydrophobic side chains. The protein creates a framework in the protein-lipid film structure, while lipids are dispersed in it as droplets within the protein network (Enujiughu et al., 2013).

Zhao and Lappalainen (2012) reported that the interactions between proteins and lipids can be studied using isolated and model membranes or food matrices in vitro. They observed that proteins can interact with lipids through an unspecific association, for example, by inserting an amphipathic  $\alpha$ -helix into the bilayer, and through electrostatic interactions between the protein and lipid head groups. There are many possible ways by which proteins interact with lipids in real food systems. For example, in the study of physical and molecular properties of egg-white lipid films, Handa et al. (1999a,b) observed that oleic acid increased tensile strength and elongation, and surface sulphhydryl group concentrations in egg white solutions. They suggested that reducing the water vapour permeability of hydrophilic egg white films would probably require cross-linking treatments (e.g., Maillard reaction) that promote covalent bonds other than S–S bonds.

The respective contents of proteins and lipids seem to exert an effect on the productivity of protein-lipid films (Enujiughu et al., 2013), with poor productivity occurring in systems with low protein-lipid ratio under 1.00. This is especially the case with traditional soybean food (yuba) which is a cream-yellow bland flavoured surface film of high nutritional value formed during the heating of soymilk. Furthermore, time and temperature of protein denaturation usually affect the solubility, tensile properties and oxygen permeability of resultant edible protein-lipid films. During the film-formation, lipids act as surfactants which move to the air/water interface and interact with proteins by hydrophobic interactions.

A composite film made of a protein and a lipid can be divided into laminates (in which the lipid is a distinct layer within or atop the biopolymeric films) and emulsions (in which the lipid is uniformly dispersed throughout the biopolymeric film). Both the laminate and emulsion films offer advantages (Enujiughu et al., 2013). The laminate films are easier to apply with regard to the temperature, due to the distinct natures of the support matrix and lipid. During the casting of the lipid onto the protein film,

the temperatures of the film and lipid can easily be controlled separately. When producing the emulsion films, the temperature of the emulsion must be above the lipid-melt temperature but below the temperature for solvent volatilization of the structural network. The main disadvantage of the laminated films, however, is that the preparation technique requires four stages; two casting and two drying stages. This is why the laminated films are less popular in the food industry despite their being good barriers against water vapour. The preparation of the emulsion films requires only one casting and one drying stage, but the finished films are still rather poor barriers against water vapour, since the water molecules still permeate through the non-lipid phase (Enujiughu et al., 2013). The reason for this is the nonhomogeneous distribution of lipids. However, they have the advantages of exhibiting good mechanical resistance, and to require a single step during the manufacture and application process, against one step per layer for multilayer films. It has been shown that for emulsion-based films the smaller the lipid globule size is, and the more homogeneously distributed they are, the lower the water vapour permeability.

## Properties of Protein-Lipid Films

The properties of protein-lipid films include the physical properties (color and opacity; solubility, as total soluble matter; film thickness; moisture content), the mechanical properties (tensile strength; Young's modulus; elongation at break), barrier properties (water vapour permeability; oxygen permeability) and molecular properties (surface and total sulphhydryl groups; electrophoretic patterns; protein content; concentration of saturated and unsaturated fatty acids) (see Table 1). Properties such as tensile properties, water vapour resistance and gas permeability are usually affected by film structure and the nature of protein-lipid interactions.

Water vapour permeability comprises sorption, diffusion and adsorption and is largely governed by the interactions between the polymer and the water molecules. Water permeation through a film usually occurs through the hydrophilic part of the film, thus the relation of the hydrophilic/hydrophobic portions influences water vapour permeability. Polymers with high hydrogen bonding produce films that are susceptible to moisture, while polymers with hydrophobic groups make excellent barriers to moisture (Souza et al., 2010). Water vapour permeability is also dependant on the pore size of the film, and tends to increase with polarity, degree of unsaturation and degree of ramification of the lipids. Gas permeabilities of edible films and coatings depend on several factors such as the integrity of the film, the ratio between crystalline and amorphous zones, the hydrophilic–hydrophobic ratio and the polymeric chain mobility. Oxygen is known to cause food oxidation, inducing several unwanted changes such as odor, color and flavor, as well as nutrients deterioration. Therefore, films providing a proper oxygen barrier can help improve food quality and extend shelf life. Carbon dioxide, on the other hand, is formed in some foods due to deterioration and respiration reactions, and therefore has to be removed from the package to avoid food deterioration and/or package destruction (Souza et al., 2010).

Tensile strength and elongation-at-break are frequently used to characterize the mechanical properties of films. Tensility is the maximum tension supported by the film until the moment it collapses, while elongation is a measure of the flexibility of the film and defines the ability of the film to deform in place before it collapses. Factors, such as film composition, temperature, relative humidity and storage time, affect tensile properties. Films containing low-molecular-weight proteins have higher chain mobility of the matrix. Film formation generally takes place through the development of a three-dimensional network of protein molecules by ionic, hydrogen, hydrophobic and disulphide bonds (Gounga et al., 2007). Young's modulus is also an important property, as it measures the stiffness of a solid material. Edible films show elastic deformation, whereby they revert to original shape after an exerted force is lifted.

**Table 1** Comparison of physical and mechanical properties of selected protein-lipid films

Properties	<i>Amaranth flour</i>	<i>Pistachio globular protein—stearic acid</i>	<i>Hake protein—thyme oil</i>	<i>Egg white—Oleic acid</i>

Fatty acids are characterized by their chain length and unsaturation degree and both have influence, as increasing chain length of fatty acids results in lower water vapour permeability of emulsion films. The longer the hydrophobic tail of these molecules, the lower the film water solubility, and as a consequence, the lower the moisture transfer rate. [Fernández et al. \(2007\)](#) examined the effect of the unsaturation degree and concentration of fatty acids on the properties of whey protein isolate-based edible films and found that surface tension was significantly decreased by adding unsaturated fatty acids (oleic and linoleic acid), whereas the greatest effect on water vapour permeability reduction was achieved with stearic acid. Unsaturated fatty acids have one or more double bonds, thereby causing a sharp bends in the carbonyl chain. Increasing unsaturation degree reduces the contact between acyl chains, which lowers the melting temperature. Stearic acid plays a key role in controlling the physical and mechanical properties of films and any increase in the ratio of this component could increase the consistency coefficient, shear thinning behavior, elasticity, rate of drying and flexibility of edible films ([Rezvani et al., 2013](#)).

Covalent disulfide (S–S) bonds are considered important for film formation with proteins containing cysteine and/or cystine amino acids, as they are involved in network formation. In the work of [Handa et al. \(1999a\)](#), concentration of surface sulfhydryl (SH) groups was increased ( $P < 0.05$ ) (3.81–19.45 mM/g protein) with both pH and heating, presumably due to protein denaturation and cleavage of disulfide (S–S) bonds. Concentration of surface SH groups correlated ( $P < 0.05$ ) with film tensile strength ( $r = 0.70$ ), elongation at break ( $r = 0.86$ ), and film total soluble matter ( $r = -0.94$ ). Most likely, surface SH groups formed S–S bonds through air oxidation and/or sulfhydryl/disulfide interchange, thus contributing to film formation.

Visual characteristics of biodegradable films such as gloss, color, and transparency can affect consumer acceptability and even food quality. In a study by [Zahedi et al. \(2010\)](#), the color of control pistachio globulin protein film was yellow and the color intensity depended on film thickness. The addition of fatty acids increased the film opacity, and the opacity increased significantly ( $P < 0.05$ ) as fatty acid level increased.

## Development of Edible Films and Coatings

Edible films and coatings potentially increase food shelf life, improve their quality. They provide the potential to control transport of moisture, oxygen, aroma, oil, and flavor compounds in food systems. Also, edible films and coatings can be used as carriers of food additives, such as antimicrobials, flavors, antioxidants, nutrients and colorants, to enhance preservation, physicochemical and organoleptic properties of food. Such films and coatings provide mechanical integrity and physical protection for food products which are susceptible to injury during transport. The contribution of charge is highlighted by the observation that surface viscoelasticity reaches a maximum when the pH is close to a proteins' isoelectric point, i.e., its net charge is zero. By increasing the overall charge on a dispersed phase (lipid) droplet through the charge of the adsorbed protein the dispersion can be stabilised by the electrostatic repulsion of the droplets hindering their close approach ([Enujiugha et al., 2013](#)).

The efficiency of an edible film against moisture transfer cannot not be simply improved by addition of hydrophobic lipid materials unless the formation of a homogenous and continuous lipid layer inside the hydrocolloid matrix is achieved ([Karbowski et al., 2007](#)). As a result, optimization of film composition and its rheological behavior is one of the most important steps in edible films production. The coating surface is influenced by rheological behavior of components, mechanism of application and changes in properties associated with transition from liquid to solid state. As most coating systems are pseudoplastic, viscoelastic and thixotropic, their rheological state is strongly dependent on the coating process which involves shear in different magnitude. The application of homogenization to the initial biopolymer-oil mixture is required, to obtain a uniform droplet distribution with small-sized droplets so as to increase the tortuosity factor and improve the water barrier performance of the film. In a study by [Matsakidou et al. \(2013\)](#), homogenization of the film-forming oil bodies dispersion led to size reduction and improved to some extent the surface related characteristics of the films although their moisture barrier and the tensile properties were not significantly affected.

Edible films are formed through extrusion, co-extrusion, spreading, casting, roll coating, drum coating, pan coating or laminating techniques. Edible coatings, on the other hand, are mainly applied using spraying, drum coating, spray fluidization, pan coating or falling film techniques. Film-forming mechanisms of biopolymers include intermolecular forces such as covalent bonds (e.g., disulphide bonds and cross-linking) and/or electrostatic, hydrophobic or ionic interactions ([Souza et al., 2010](#)). Physical modifications of edible films and coatings include lamination, formation of composites, addition of particles or emulsions, perforation, over-coating, annealing heat curing, orientation, radiation, ultrasound treatment and electric field treatments. For edible coatings, knowledge of the surface properties of the coating-forming solutions is crucial for the characterization of their performance.

The development of films with a uniform and compact layer can be an important achievement toward the improvement of various film properties, such as their permeability to gases ([Souza et al., 2010](#)). Scanning electron microscopy is frequently used to evaluate film homogeneity, layer structure, pores and cracks, surface smoothness and thickness, while X-ray diffraction is mainly used to evaluate the degree of crystallinity of the films. Coatings can be obtained either by dipping the product into, or by brushing or spraying it with solution containing film ingredients, so as to deposit the film directly on food surface, or by creating standalone film from solution or through thermoformation for subsequent covering of food surface. Thermoformation is rarely used to create edible films, because most edible components cannot be molded at elevated temperatures without causing irreversible structural changes to the material. Direct application of any lipid to a hydrophilic or wet surface results in weak adhesion at the film–food interface. Dual-coating is one possible solution to this problem, as it provides protection against more than one permeate through use of different laminate layers.

## Conclusion

Proteins and lipids have been shown to interact in many different ways to form effective edible films and coatings. Such composite protein-lipid films are capable of combining the effective structural and oxygen barrier properties of protein films with the high moisture barrier characteristics of lipids. However, the film-forming conditions and the composition and structural variations of the constituent lipids affect film performance and properties, with regard to aesthetics and keeping quality of packaged food systems. An understanding of the mechanisms of the interaction of proteins with lipids helps in elucidating the important properties of the resultant films and coatings.

# Protein Ingredients in Low- and Intermediate-Moisture Systems<sup>☆</sup>

Thom Huppertz, NIZO, Ede, The Netherlands

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Proteins play a crucial role from nutritional and physicochemical perspectives in a wide array of food products. In some cases, proteins are included as part of the materials in which they naturally occur, e.g., the use of milk to prepare cheese or yoghurt, but in many cases, proteins are included in products in the form of (partially) purified protein ingredients. While in some cases this can be done in the form of concentrated liquid protein ingredients, in most cases, dried protein ingredients will be used. Drying of protein ingredients can be beneficial from the perspective of extending shelf life and reducing volumes for transport and standardization. However, some undesirable effects are also observed during production and storage of these protein ingredients, most notably a loss of solubility and a concomitant loss of functionality, as well as a reduction in nutritional value, because of the Maillard reaction and other modifications of amino acids. Therefore, despite low moisture content and water activity ( $a_w$ ) in these low-moisture systems (LMSs), considerable changes will still occur in protein ingredients. Although the use of most protein ingredients typically involves reconstitution and rehydration of proteins in high-moisture systems, some protein ingredients are also used in intermediate-moisture systems (IMSs), most notably high-protein bars. As in the LMS, considerable interactions can still occur in the IMS even though proteins are not fully hydrated. In this article, the behavior of proteins and protein ingredients in the LMS and IMS will be described and discussed, with particular emphasis on milk protein ingredients.

## Water Relations in Protein Ingredients

When considering protein ingredients in the LMS and IMS, insights into how water is bound and distributed within the ingredients are necessary. Insights into such phenomena can be gained from moisture sorption isotherms, which describe the relationship between  $a_w$  and equilibrium moisture content (EMC). In general, sorption isotherms of proteins can be described well based on the sum of the main individual components, i.e., typically proteins and carbohydrates contribute heavily to moisture sorption, whereas fat does not (Foster et al., 2005). Moisture sorption isotherms for milk protein concentrate (MPC) samples containing 35%–90% protein in the dry matter are shown in Fig. 1.

**Figure 1** Moisture sorption isotherms at 40 °C for milk protein concentrate (MPC) samples containing 35%, 60%, 80%, and 90% protein in the dry matter.

<sup>☆</sup> Change History: August 2017. T Huppertz added Abstract, Keywords, and Figures 1 and 2.

Change History: September 2017. This is an update of Thom Huppertz, Protein Ingredients in Low- and Intermediate Moisture Systems, In Reference Module in Food Science, Elsevier, 2016, ISBN 9780081005965, <https://doi.org/10.1016/B978-0-08-100596-5.21081-0>.

Moisture sorption by proteins can be separated into three zones (Kinsella et al., 1986): at low  $a_w$  values, i.e.,  $a_w < \sim 0.3$ , most water occurs as structural/hydrogen-bonded water and hydrophobic hydration water, which are strongly bound by the polar, charged, and hydrophilic residues of proteins. This water is typically considered to be nonfreezable and not available for chemical reactions and requires intense drying conditions for removal. At  $a_w$  values between 0.3 and 0.7, proteins can sorb the so-called multilayer water (which is less strongly bound than the monolayer water but is more firmly bound than free water) and some capillary water (which is physically held in capillaries, voids, clefts, cavities, or crevices in  $a_w$  range of 0.5–0.7). Multilayer water refers to layers of hydrogen-bonded water surrounding structural water, thus can be considered as the continuous transition from the monolayer to free water. At  $a_w > 0.7$ , free water is also found, primarily in the forms of capillary water in  $a_w$  range of 0.7–0.95 (which is held in large capillaries, voids, and crevices within structures) and hydrodynamic hydration water (which is loosely associated with the proteins at  $a_w > 0.99$ ). This free water behaves the same as bulk water.

Because moisture sorption and desorption induce some structural changes in proteins and powder particles, hysteresis is sometimes observed in moisture sorption isotherms between the adsorption and desorption isotherm (especially when the desorption isotherm lies above the adsorption isotherm). This is particularly important when using moisture adsorption isotherms for predicting the drying behavior of products. In cases where a large hysteresis loop is observed between adsorption and desorption, notable variations in drying behavior (e.g., the degree of dryer fouling or powder stickiness) can occur when only adsorption isotherms are used as input parameters. Hysteresis can also influence the chemical and physical changes in stored foods, e.g., decrease the accessibility of the polar residues of proteins. Typically, EMC at a given  $a_w$  is higher in the desorption isotherm than in the adsorption isotherm (Al-Muhtaseb et al., 2002). Hence, moisture adsorption of a protein powder during storage does not restore the same situation at a given  $a_w$  that existed during desorption.

In addition to moisture sorption by proteins, sorption by carbohydrates is also important for protein-containing ingredients, particularly in ingredients where carbohydrates are present at high concentrations. For example, in milk powder containing 50%–55% carbohydrate in the form of lactose, the carbohydrate forms a continuous amorphous matrix in which the rest of the constituents are suspended. The extremely high viscosity of this amorphous (glassy) phase ensures that it behaves like a solid, but an increase in  $a_w$  or in temperature results in plasticization of the amorphous phase and the transition from a glass to a highly viscous phase that has been described as sticky and rubbery. The critical temperature above which this change occurs can be determined by differential scanning calorimetry and is referred to as the glass transition temperature ( $T_g$ ). In this viscous phase, crystallization of carbohydrates may occur. Furthermore, reducing carbohydrates are more prone to participate in reactions such as the Maillard reaction when temperatures are above the glass transition temperature.

## Changes During Storage of Protein Ingredients

As outlined in the introduction, a number of changes can occur during storage of protein ingredients, most notably the loss of solubility and (chemical) modification of amino acid residues. Solubility is a key functional property for any application of protein ingredients. Whereas ingredients containing a significant amount of carbohydrate typically have good solubility and maintain the solubility during storage, many high-protein ingredients are prone to loss of solubility during processing and storage. Among the milk protein ingredients, milk protein concentrates and micellar casein isolate are particularly well known to lose solubility easily (Anema et al., 2006; Havea, 2006; Gazi and Huppertz, 2015). Solubility of milk protein concentrates during storage is shown in Fig. 2. Both milk protein concentrates and micellar casein isolate are prepared by membrane filtration of milk and lead to powdered products containing a high concentration of casein in the micellar form. Although being remarkably heat-stable during heating of fresh milk, casein micelles tend to have poor stability in more concentrated systems, particularly when both temperature and  $\text{Ca}^{2+}$  activity are high but pH is low (Crowley et al., 2014; Gazi and Huppertz, 2015). This manifests itself in the aggregation of casein micelles during drying, in a manner similar to heat-induced coagulation; this aggregation leads to a network of casein micelles, which has poor solubility. Development of insolubility during drying can be reduced through careful selection of appropriate processing conditions and product properties (De Castro-Morel and Harper, 2003). Further aggregation and development of insolubility can occur during storage of milk protein concentrates (Anema et al., 2006; Havea, 2006; Gazi and Huppertz, 2015). Insolubility becomes more severe with increasing storage time and temperature as well as with elevated water activity. Protein analysis of the soluble and insoluble phases revealed that, like during processing, casein micelles could lose solubility during storage whereas the other constituents (lactose, salts, and whey proteins) remain soluble. The progressive insolubility of such ingredients results primarily from the noncovalent interactions between casein micelles; aggregation of casein micelles appears to be more extensive on the surface of the particles than in the core. Higher heat load on the surface of particles during drying along with depletion of lactose to a greater extent on the surface of particles compared with the core of the particles could certainly contribute (Kelly et al., 2015). It should further be considered that on drying, the environment of the particles changes considerably. The hydrophilic aqueous phase is replaced by a more hydrophobic air phase; as a result, protein interactions are promoted. Higher degree of insolubility development during storage and at a higher  $a_w$  and temperature can be related to the increased mobility, and thus propensity to aggregation, for the proteins. If the interactions are noncovalent, solubility can be reattained in most cases when sufficient shear and time (especially, hydration time) are applied. However, when the interactions are covalent, irreversible protein aggregation can occur.

Chemical modifications can occur during storage of protein ingredient powders. The Maillard reaction is probably the most studied chemical reaction, particularly for milk protein ingredients. The Maillard reaction requires the presence of a reducing carbohydrate along with accessible lysine residues. As part of the Maillard reaction, the so-called Amadori compounds (mainly

**Figure 2** Solubility as a function of storage time (unit: day) at 20, 37, and 50 °C for milk protein concentrate (MPC) samples containing 35%, 60%, 80%, and 90% protein in the dry matter. Data from Gazi, I., Huppertz, T., 2015. Influence of protein content and storage conditions on the solubility of caseins and whey proteins in milk protein concentrates. *Int. Dairy J.* 46, 22–30.

lactulosyl-lysine for most milk products) are formed, which can undergo further reactions including dehydration and deamination to form other intermediates, by-products, and advanced Maillard reaction products. These advanced Maillard reaction products include many heterocyclic compounds, and melanoidins are formed in the final stage via polymerization causing browning (Van Boekel, 1998). The rate of the Maillard reaction increases with increasing temperature and  $a_w$ , although at a high  $a_w$ , the rate of the Maillard reaction can decrease again (Morgan et al., 2005; Gonzales et al., 2010). Because of the browning effect and loss of the essential amino acid lysine, Maillard reactions in protein ingredients are generally considered undesirable, although controlled glycation of proteins can improve certain protein functionality. Studies have shown that glycation of proteins can improve emulsifying and foaming properties, solubility, and heat stability.

Another reaction involving lysine can occur during storage of protein powders, which is the formation of isopeptide bonds as a result of dephosphorylation of phosphoserine. A dehydroalanine side chain is then formed, which can cross-link with adjacent lysine residues to yield lysinoalanine (LAL). Histidine and cysteine may also form cross-links with the dehydroalanine side chain. The reaction is promoted by heat treatment (i.e. a greater reaction rate at a higher temperature). Owing to the requirement for phosphoserine, the formation of isopeptide bond is limited to the proteins containing phosphoserine residues, most notably caseins, and other products such as milk protein osteopontin and egg protein phosvitin. During storage of caseinates at temperatures above 30 °C, LAL formation rates can exceed 100 ppm/month. The LAL level is considerably lower in Ca-caseinate than in Na- or K-caseinate. The interaction of Ca with phosphoserine, which also occurs in milk powder, milk protein concentrate, and micellar casein, is likely the contributor to reduce LAL formation. Other modifications of amino acids in protein ingredients include the oxidation of methionine to methionine sulfoxide and the oxidation of tryptophan (Higgs and Boland, 2009).

## Application of Protein Ingredients in Intermediate-Moisture Systems

IMSs ( $a_w$  0.3–0.7) involving protein ingredients have also gained considerable interest since the early 2000's. This can be attributed primarily to the rapidly expanding market for high-protein bars. The high-protein bars usually contain milk and/or plant proteins, carbohydrate syrup, and fat as the main ingredients. Water activity of these products is typically in the range of 0.5–0.7. One of the main issues associated with these products is bar hardening, which occurs mostly during storage. The behavior of protein ingredients is the primary cause of bar hardening.

Insights into the behavior of protein ingredients in the IMS have been primarily gained from model systems mimicking consumer protein bars. Such systems contain protein ingredients with/without carbohydrate syrups and/or polyols. Bar hardening in these model systems was found to increase with storage time and temperature. Irrespective of what model system was used, elevated bar firmness was observed with increasing protein content. Considerable differences, however, are found between models involving different protein ingredients (single use or in combinations). Both protein type and powder properties can strongly affect bar hardening. With respect to protein type, proteins with reasonably high solubility such as whey proteins (particularly protein hydrolysates) tended to produce soft bars (Zhou et al., 2008; Hogan et al., 2012, 2016; Rao et al., 2016). Protein hydrolysates, however, may present sensory issues such as those associated with excessive Maillard-induced browning. As a result, the amount of protein hydrolysate used in protein bars is limited (Childs et al.,

2007). The firmest bars are likely attained when protein ingredients with low solubility are used. In terms of milk protein ingredients, bars produced with micellar casein, milk protein concentrate, or caseinate were found firmer than those with whey protein concentrate, isolate, or hydrolysate (Hogan et al., 2012). Remarkably firm bars are feasibly produced when insoluble protein ingredients such as acid or rennet casein are used. In addition to protein type, powder properties are also important factors that influence bar hardening. For example, powders with a high  $a_w$  tend to reduce hardening in bars (Hogan et al., 2012), whereas powders with a higher particle density and lower amount of occluded air likely yield softer bars. Agglomeration of powder particles would reduce bar hardening. Compared with the influence of proteins on bar hardening, the effect of the carbohydrate fraction in bar is limited.

Accordingly, on mixing the different ingredients of a protein bar, a notable gradient in  $a_w$  is established between the protein powder and carbohydrate syrup. As a result, sorption of the aqueous phase (i.e., the carbohydrate syrup) into the protein powder particles takes place. This results in an increase in the volume fraction of protein particles because part of the continuous phase becomes “entrapped” in the serum phase of the bar system. The volume fraction of powder particle can further increase if the powder particles swell on sorption of the aqueous phase. If the volume fraction of powder particle becomes sufficiently high, interactions between powder particles can occur, giving rise to bar hardness of protein bars (Hogan et al., 2012). Over time, fusion of interactive protein particles into a continuous mass, not unlike the fusion of *para*-casein micelles in cheese curd, can occur. To monitor protein bar hardness, controlling the volume fraction of protein powder and the interactions between powder particles is essential. The volume fraction of protein powder correlates negatively with particle density but positively with occluded air. Furthermore, the polydispersity of the particle size distribution can also affect bar hardness, as the maximum volume fraction attainable before the system is “full” would be higher. The same phenomenon was observed for bimodal particle size distributions. These findings partially explain why protein bars prepared with blends of protein ingredients often exhibit lower hardness than those prepared with a single type of protein ingredient. Blends of protein ingredients typically contain mixtures of protein ingredients with different water solubility. Protein hydrolysates and whey proteins typically exhibit higher solubility than casein-based or vegetable protein-based ingredients. (Partial) dissolution of proteins not only causes a reduced powder volume fraction but also leads to increased serum phase viscosity.

## Conclusion

As outlined above, understanding the behavior of proteins and protein-based ingredients in the LMS and IMS is crucial. It enables the production of soluble and functional protein ingredients and retention of their desirable properties during storage. Protein ingredients are the key ingredient in high-protein bars. In these food systems, the sorption behavior of protein powder particles and the interactions between the powder particles are the key to controlling bar hardness. In both LMS and IMS, it is crucial to ensure that proteins are not fully hydrated, and desirable sorption behavior and particle interactions occur in very different environments of LMS and IMS. Careful consideration of these environmental changes is required to control and optimize protein interactions in low- and intermediate-moisture food products.

## Glossary

**Full width at half maximum** The width of a spectrum curve measured between those points on the y-axis which are half the maximum amplitude.

**Long-range molecular order** The long-range ordered array of double helices, often referred to as crystallinity, which is often determined by X-ray diffraction.

**Self-assembly** A process in which a disordered system of pre-existing components forms an organized structure or pattern as a consequence of specific, local interactions among the components themselves, without external direction.

**Short-range molecular order** The ordered array of double helices at a short-range scale, which is measured usually by FTIR and Raman spectroscopy.

**Starch gelatinization** A process of breaking down the intermolecular bonds of starch molecules in the presence of water and heat, allowing the hydrogen bonding sites (the hydroxyl hydrogen and oxygen) to engage more water.

**Starch retrogradation** A process in which disaggregated amylose and amylopectin chains in a gelatinized starch paste reassociate to form more ordered structures during cooling and storage.

**Thermodynamically incompatible** Two or more (incompatible) polymers cannot achieve uniform dispersion at the molecular level, and phase separation between them often occurs even in concentrated systems.

## Introduction

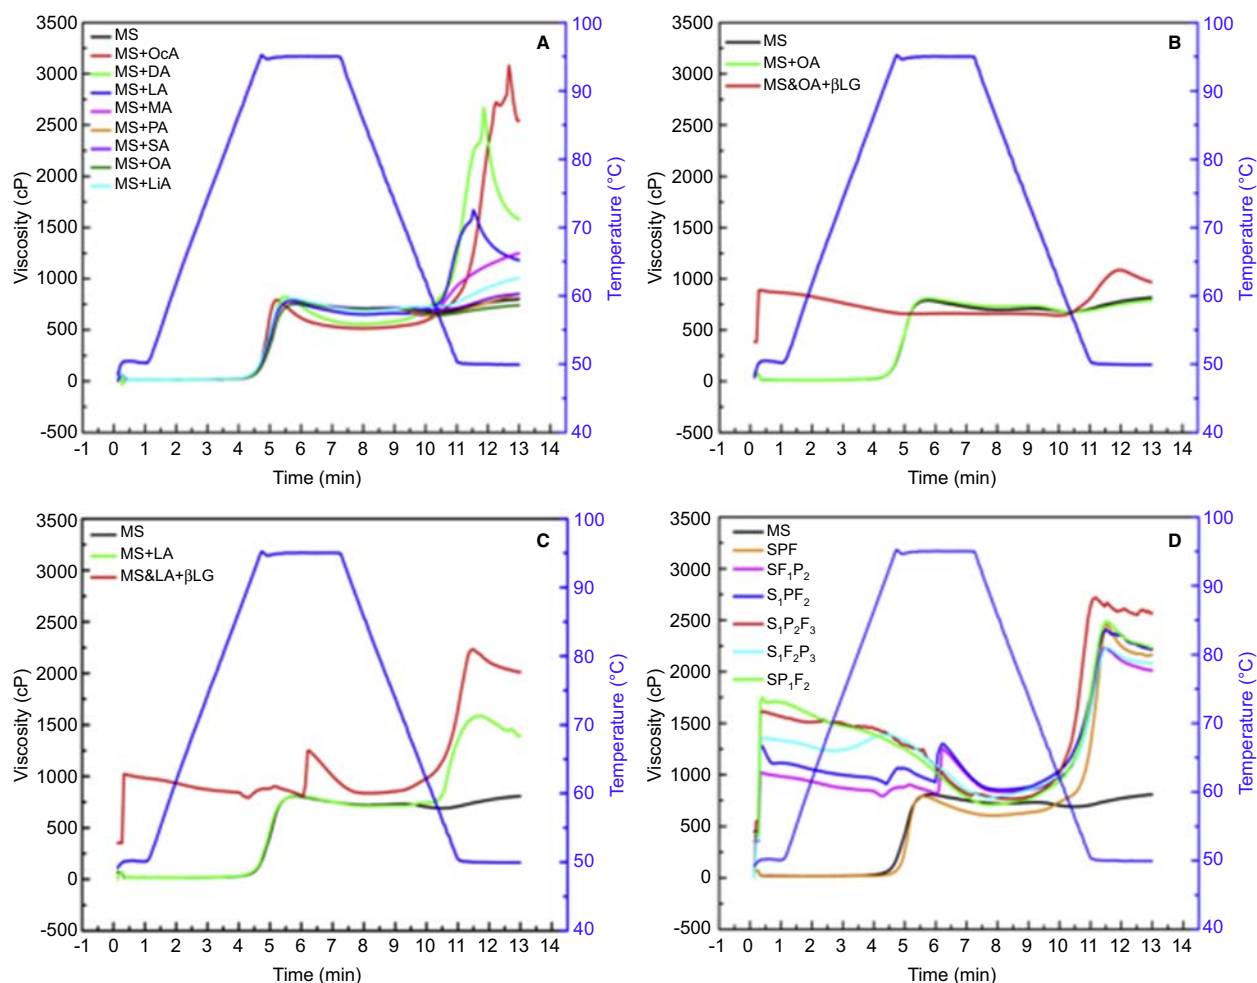

Starch, lipids and proteins are three major macronutrients in human diet that provide the human body with energy (calories). These three components often occur together in many food systems, especially the starchy foods. During food processing, each macronutrient undergoes a series of changes. Such processing-induced changes and associated interactions among these macronutrients have a direct impact on the quality of final food products such as flavor, mouth-feel, texture, shelf-life and nutritional value (Parada and Santos, 2015; Wang and Copeland, 2013). The interactions among starch, proteins and lipids are very complex including their binary interactions and ternary interactions. Understanding how these interactions occurred during food processing may help to optimize processing parameters to create food products with desired microstructure and functionality.

Binary interactions among the starch, lipids and proteins have been studied extensively, and their effects on the properties of starch and derived finished foods were found. Starch-lipid complexes naturally occur in native starch or are formed during food processing and storage (Ai et al., 2013; Tang and Copeland, 2007; Wang et al., 2016c), and the formation of such complexes reduces swelling power and starch solubility, retards the gelatinization and retrogradation of starch and slows the enzymic digestion rate (Copeland et al., 2009; Putseys et al., 2010; Wang and Copeland, 2013). Protein-lipid interactions occurring in real foods can act as emulsifiers at the interfaces (Rodríguez Patino et al., 2001), mainly via hydrophobic interactions, and electrostatic and/or polar interactions (Cornell and Patterson, 1989; Ioffe et al., 2007). Starch and protein are two thermodynamically incompatible macromolecules (Polyakov et al., 1997). The interactions between protein and starch such as those in wheat flour may afford desirable health benefits, for example, protein network-coated starch granule in white flour exhibit decreased glycemic response and digestibility (Jenkins et al., 1987).

To fully understand the functionality and digestibility of starch and other macronutrients in foods containing starch, lipids and proteins, not only binary interactions but also ternary interactions have been examined. A number of studies have confirmed the occurrence of a ternary starch-lipid-protein complex during food processing, which led to alterations in starch pasting and gelatinization, the digestion rate and extent of the three macronutrients, as well as the rheological properties of the finished foods (Parada and Santos, 2015; Zhang et al., 2003). More importantly, both starch-lipid complexes and starch-lipid-protein complexes were found to possess the capacity to carry sparingly soluble small molecules in the lumen of the amylose helices not occupied by the hydrophobic carbon chain of lipids. Such a capacity enables the potential of starch-lipid or starch-lipid-protein complexes in the delivery and release of hydrophobic bioactive substances contained in functional foods and health products (Bhopatkar et al., 2015).

## The Formation of the Ternary Starch-Lipid-Protein Complexes

The starch-lipid-protein complex formed between starch, proteins, and fatty acids (FAs) was discovered by Zhang et al. who studied the pasting properties of sorghum flour, which was believed to account for the viscosity peak for sorghum flour during rapid

**Figure 1** RVA profiles of starch with different fatty acids (octanoic acid (OAcA), decanoic acid (DA), lauric acid (LA), myristic acid (MA), palmitic acid (PA), stearic acid (SA), oleic acid (OA) and linoleic acid (LiA) and  $\beta$ -lactoglobulin). (A) maize starch (MS) with different fatty acids in one cycle; (B) MS, MS-OA (in one cycle) and MS-OA (in one cycle) +  $\beta$ LG (in the second cycle); (C) MS, MS-LA (in one cycle) and MS-LA (in one cycle) +  $\beta$ LG (in the second cycle); (D) MS- $\beta$ LG-LA in different mixing sequences. Starch control, SPF in one cycle,  $SF_1P_2$ ,  $S_1PF_2$ ,  $S_1P_2F_3$ ,  $S_1F_2P_3$ ,  $SP_1F_2$  (S, P, and F, are for starch, protein and lauric acid, respectively). Wang et al. (2017). Reproduced with permission from ACS publications.

viscosity analysis (RVA) cooling stage by self-assembling amylose molecules along with lipids and proteins. A model starch-rich system containing normal starch, soluble proteins and FAs showed a RVA pattern different from that of normal starch but similar to that of sorghum flour (Zhang and Hamaker, 2000). Addition of long chain FAs alone (e.g. palmitic, oleic and linoleic acids) to starch can only cause an increase in starch pasting viscosity at the cooling stage (Fig. 1A), whereas, the addition of  $\beta$ -lactoglobulin ( $\beta$ -LG) to these starch-FA pasting systems led to the occurrence of a viscosity peak during the cooling stage of the following RVA run (Fig. 1B). Interestingly, the addition of  $\beta$ -LG to the pasting systems containing starch and short chain FAs can further increase the viscosity peak during the second RVA run (Fig. 1C) (Wang et al., 2017). However, the addition of whey protein to the system containing starch alone caused no effect on starch pasting behavior. Accordingly, the formation of starch-protein-lipid complexes during RVA pasting has been believed to be a common phenomenon that might occur during thermal processing of starchy foods (Wang et al., 2017; Zhang and Hamaker, 2003).

The addition sequence of starch, proteins and lipids during RVA runs is critical for the formation of a ternary complex, and as a consequence, viscosity would change during the cooling stage of the RVA protocol (Fig. 1D). For example, the addition of lauric acid (LA) together with  $\beta$ -lactoglobulin ( $\beta$ -LG) after starch alone was pasted in the RVA (i.e.  $S_1PF_2$ ) or addition of LA after the pasting of starch along with  $\beta$ -LG ( $SP_1F_2$ ) would result in higher viscosity, compared with the addition of LA in the first RVA run ( $SF_1P_2$ ) or second RVA run ( $S_1P_2F_3$ ). Adding LA in the third run ( $S_1P_2F_3$ ) led to the highest viscosity peak. The systems with  $\beta$ -LG added in the second ( $SF_1P_2$ ) or third RVA run ( $S_1F_2P_3$ ) exhibited a smaller viscosity peak, compared with the system in which all three components were mixed together (SPF). The prior mixing of starch and  $\beta$ -LG could promote the formation of a ternary complex whilst the addition of LA in the RVA cycle before adding  $\beta$ -LG did not. The emulsifying action of  $\beta$ -LG likely contributed

to the complex formation among starch,  $\beta$ -LG and LA, but a prior interaction of starch with LA could make  $\beta$ -LG a less effective emulsifier causing weaker interactions between starch,  $\beta$ -LG and LA (Wang et al., 2017).

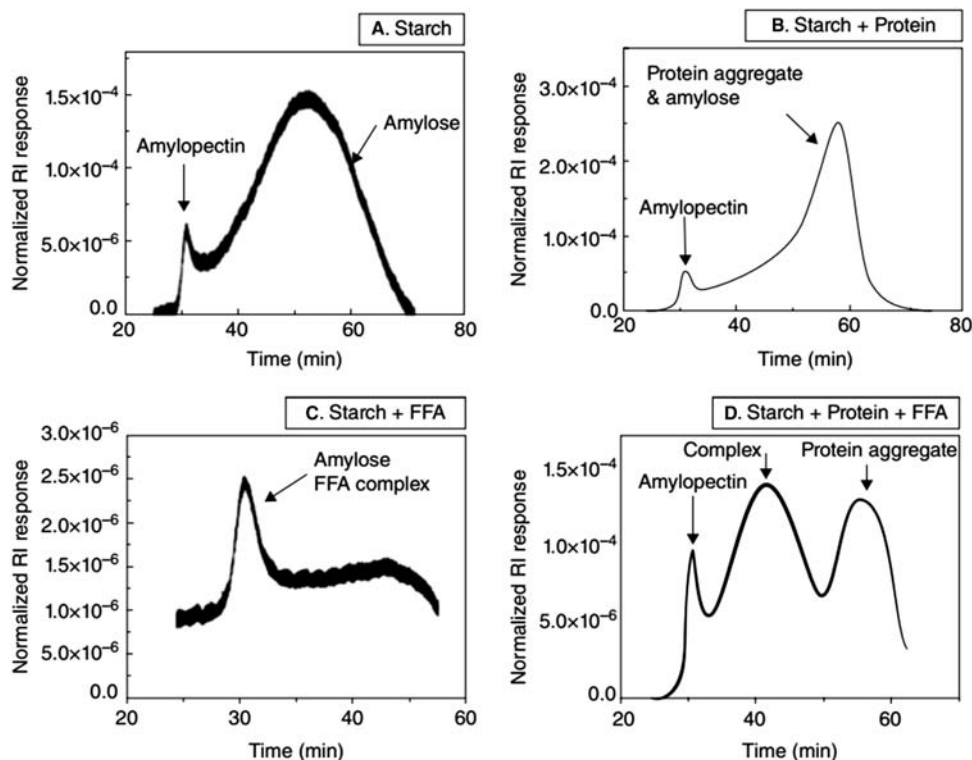

### Identification of the Ternary Complex of Starch, Proteins and Lipids

The starch-lipid-protein complex can be identified by high-pressure size exclusion chromatography (HPSEC) with multi angle laser scattering (MALLS)—detector (Shah et al., 2011; Shah, 2009; Zhang et al., 2010; Zhang et al., 2003) and FTIR spectroscopy (Wang et al., 2017). For pure starch, two HPSEC peaks are typically found (the smaller peak corresponding to amylopectin molecules while the larger one derives from amylose molecules) (Fig. 2A). In comparison, a very small amylopectin peak and a prominent amylose cum protein peak were found for the starch-protein mixture (Fig. 2B). SEC profiling revealed only a void volume peak for the starch-FA mixture (Fig. 2C, indicating the formation of an insoluble amylose-lipid complex), but three distinct peaks for the ternary system (Fig. 2D, corresponding to the amylopectin molecules, ternary complex, and protein aggregate or protein-lipid complex (Zhang et al., 2010, 2003). The molecular mass and the radius of gyration of the ternary complex were  $\sim 10^6$ – $10^7$  Da and 20–100 nm, respectively, as estimated by MALLS/HPSEC (Shah et al., 2011; Zhang et al., 2010).

The identification of starch-lipid-protein complex by FTIR is demonstrated in Fig. 3 which contains spectra of native starch, the three-component mixture and samples obtained after RVA pasting. In comparison with maize starch (MS), two additional absorptions at  $1710\text{ cm}^{-1}$  and  $2846\text{ cm}^{-1}$  were found in the FTIR spectra of MS-LA complex (assigned to vibration of carbonyl groups and C–H asymmetric stretching vibration of FA's methylene groups, respectively), with a concomitant shift of the absorption peak around  $1705\text{ cm}^{-1}$  (corresponding to the carbonyl group of LA) to a higher value of  $1710\text{ cm}^{-1}$  (Guillen and Cabo, 1997; Koca et al., 2007; Safar et al., 1994). Moreover, the absorption band at  $1710\text{ cm}^{-1}$  was absent in the spectra when the MS- $\beta$ LG-LA complex was formed due to its attenuating effect on the IR absorbance of the carbonyl group of LA (Wang et al., 2017).

### Changes in Thermal Properties Caused by the Starch-Lipid-Protein Complex

Differential scanning calorimetry is used to analyze the thermal transition parameters of systems containing starch, lipid and proteins, by which the melting and formation of starch-lipid complex or starch-protein-lipid complex were examined. Upon heating of the MS- $\beta$ LG-LA mixture, three endothermic transitions were observed including melting of LA (around  $43^\circ\text{C}$ ), starch

**Figure 2** High pressure size exclusion chromatography (HPSEC) results of different materials: (A) starch control, (B) starch + protein, (C) starch + FFA, and (D) starch + protein + FFA. Shah et al. (2011). Reproduced with permission from Elsevier.

**Figure 3** FTIR spectra of MS, three-component mixture, binary and ternary complex samples. Wang et al. (2017). Reproduced with permission from ACS publications.

gelatinization (65–75 °C) and melting of starch-lipid complex (95–105 °C) (Fig. 4A). Compared with MS, a greater enthalpy change was found for both MS-LA and MS-βLG-LA samples indicating the formation of starch-lipid complex during DSC heating. During the DSC cooling stage, an exothermic transition was observed at 65–80 °C, with the enthalpy changes following the order of MS < MS-LA < MS-βLG-LA (Fig. 4B). These results indicated the formation of an MS-βLG-LA complex during cooling and a more ordered structure of the MS-βLG-LA complex compared with the MS-LA sample. On an immediate DSC reheating of the cooled samples, a small endothermic transition for MS, MS-LA and MS-βLG-LA samples occurred at 90–105 °C. The greatest enthalpy changes for MS-βLG-LA sample further confirmed the more ordered structure of MS-βLG-LA complex compared to the MS-LA complex (Wang et al., 2017).

### The Ordered Structure of the Ternary Starch Lipid-Protein Complex

The ordered structure of starch can be characterized by various analytical techniques, including X-ray diffraction, small-angle X-ray scattering, solid state NMR, FTIR and Raman spectroscopy. X-ray based methods are the only commonly used means to analyze quantitatively and qualitatively the long-range crystalline structure in starch. In contrast, there are a number of methods available

**Figure 4** DSC curves of MS, binary and ternary mixtures. (A) First heating and reheating process. (B) Cooling process. Wang et al. (2017). Reproduced with permission from ACS publications.

to measure the short-range double helical order in starch, for example, NMR, FTIR and Raman spectroscopy. During food processing, the long- and short-range ordered structures of native starch are disrupted, and the gelatinized starch chains regain an ordered structure during subsequent cooling and storage. Such changes vary with the quantity of water (excess or limited amount) as well as the nature of the heating and subsequent cooling processes (Wang and Copeland, 2013; Wang et al., 2015). The formation of a ternary starch-lipid-protein complex during food processing could affect these structural changes of native starch.

### Long-Range Ordered Structure

The long-range ordered structure of starch is often measured by X-ray diffraction technique by which four major types of diffraction patterns of starch, A-, B-, C- and V-type, can be characterized. Starch-lipid complexation can give rise to a typical V-type pattern with two major diffraction peaks at 13 and 20° (2 $\theta$ ). After pasting of starch-LA and starch- $\beta$ LG-LA mixtures in the RVA, four diffraction peaks at 2 $\theta$  values of 12.8 and 19.8° (assigned to V-type amylose-fatty acid crystallites), and 21.3 and 24.2° (assigned to fatty acid aggregates) can be clearly seen in the diffraction profiles of their freeze-dried samples (Fig. 5A). Further, the intensities of peaks at 12.8° and 19.8° were much stronger for the ternary complex than for MS-LA complex, suggesting the presence of V-type crystallites and more ordered structures in MS- $\beta$ LG-LA complex (Wang et al., 2017; Zhang and Hamaker, 2004).

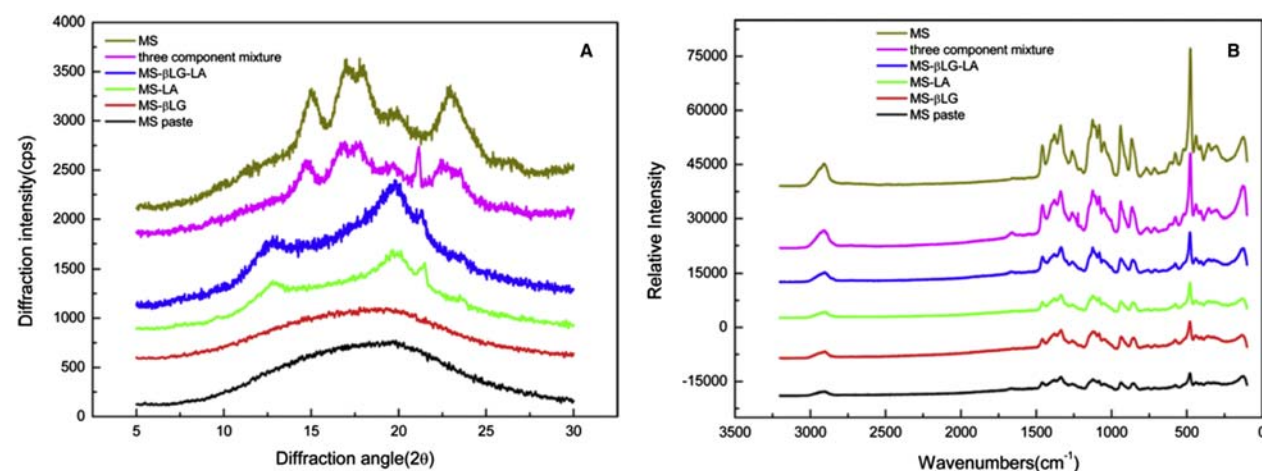

### Short-Range Ordered Structure

The short-range molecular order of double helices in starch can be characterized by Raman spectroscopy (Mutungi et al., 2012; Wang et al., 2016d), and measured based on the full width at half maximum (FWHM) of the band at 480 cm<sup>-1</sup> i.e. a smaller FWHM value indicates a greater degree of structural order (Wang et al., 2016b,d). Native MS sample typically exhibits very intense bands at 480, 865, 943, 1264 and 2900 cm<sup>-1</sup> whilst weaker bands are normally presented in the spectra of gelatinized starch and MS- $\beta$ LG-LA three-component mixture (Fig. 5B). Of the RVA samples, the Raman band intensity ranks in the order of MS- $\beta$ LG-LA complex > MS-LA complex > MS- $\beta$ LG sample. After RVA pasting, the FWHM value of gelatinized starch (22.31) was higher than those of MS-LA and MS- $\beta$ LG-LA samples (16.37 and 16.18, respectively). All these results confirmed the greater short-range ordered structure of the MS- $\beta$ LG-LA complex sample (Wang et al., 2017).

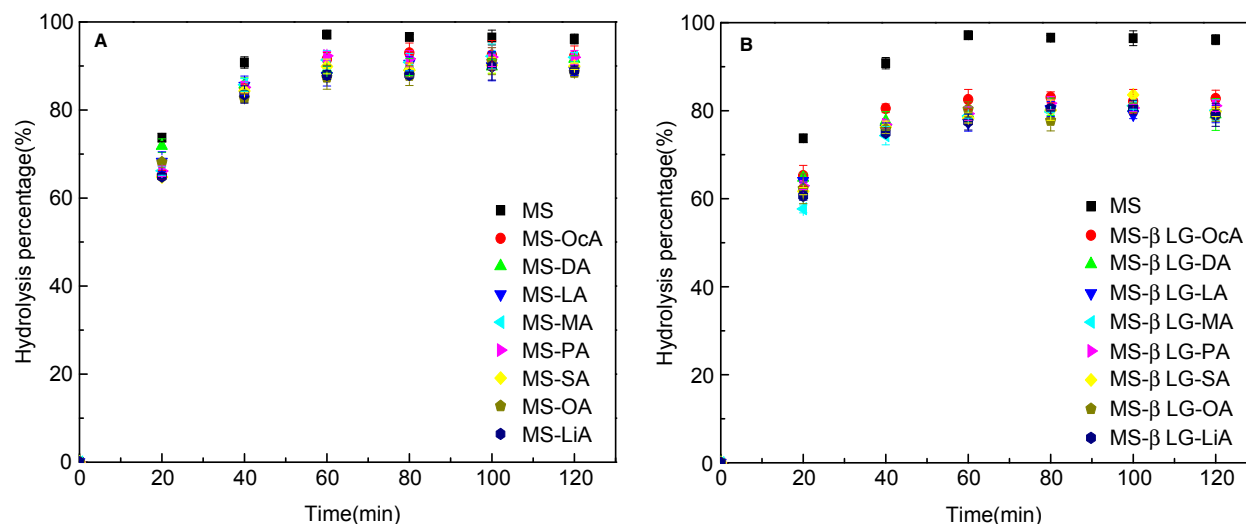

### Digestibility of the Ternary Complex by Amylolytic Enzymes

Carbohydrates including starch are the main energy source in human diet. Thus, the rate and extent of starch digestion to produce glucose for absorption into the bloodstream are of great interest. Native starch is attacked slowly by amylolytic enzymes due to its granular structure, but the susceptibility of the hydrothermally processed starch to enzymatic breakdown would be considerably increased. Treatments of starch such as retrogradation or modification of starch such as complexation with lipids were found to reduce the susceptibility to enzymatic hydrolysis (Copeland et al., 2009; Wang and Copeland, 2013; Wang et al., 2015). The processing-induced formation of ternary complex such as starch-protein-lipid complex could influence the *in vitro* digestibility of starch and *in vivo* glycemic response of starchy foods (Parada and Santos, 2015).

Native MS paste, and the MS-FA and MS- $\beta$ LG-FA complexes obtained after RVA pasting, behave differently during *in vitro* enzymatic digestion (Fig. 6): 90% of MS paste was digested by amylase and amyloglucosidase after a 40-min incubation. Compared with MS paste, the digestion extent of the binary MS-FA complexes at each time points was slightly lower with the digestion after 2 h close to 90% (Fig. 6A). When MS paste, MS-FA and MS- $\beta$ LG-FA complexes were compared, the ternary complex exhibited lower

**Figure 5** XRD patterns (A) and LCM-Raman spectra (B) of maize starch (MS), three-component mixture, and binary and ternary complex samples. Wang et al. (2017). Reproduced with permission from ACS publications.

**Figure 6** *In vitro* starch hydrolysis of pasted MS, MS-FA (A) and MS-βLG-FA (B) complex samples. (Unpublished data from our laboratory).

digestion percentages at each time point with the final digestion reaching about 80% (Fig. 6B). The fact that ternary complexes have a higher resistance to amylolysis than binary complexes is likely owing to the higher structural order and greater steric hindrance resulting from the presence of protein in the ternary complexes.

### The Use of Ternary Complex as Self-Assembled Nanocapsule to Carry Sparingly Soluble Functional Molecule(s)

In the starch-lipid-protein ternary complex, there are still sufficient spare spaces in the lumen of the amylose helices to accommodate the sparingly soluble small molecules (Liu et al., 2009). This characteristic enables the ternary complex as a high potential carrier for the delivery and release of hydrophobic bioactive substances. 1-Naphthol, an insoluble small molecule, has been successfully incorporated into the nanoparticle of ternary complex, and is located in the lumen of amylose helix along with FA molecules (Bhopatkar et al., 2015). Similarly, 5-fluorouracil (5-FU) used to treat cancer could also be incorporated into the hydrophobic lumen of the amylose helix of the ternary nanoparticle (Zhang et al., 2015).

### Conclusions

Mixing starch, FAs and proteins under heating and cooling conditions can induce complex interactions and result in confounding effects including desirable outcomes e.g. amylose-FA complexation, FA aggregation into micelles, melting/solidification of FA, starch retrogradation, protein-starch, protein-FA and starch-protein-FA interactions. The ternary complexes formed among starch, proteins and lipids would have a higher degree of ordered structure compared with the starch-lipid binary complex. The MS-βLG-FA complexes exhibit more resistance to enzymatic digestion than the MS-FA complexes. Further, the starch-lipid-protein complex can be used as carriers for the entrapment of hydrophobic bioactive substances to improve their delivery and release in the human body. Future studies should be directed towards the investigations on the structures and functionality of starch-lipid-protein complexes to obtain a better understanding of how the ternary complexes are formed during food processing and their effects on the quality and nutritional value of final food products.

### Glossary

**Complex coacervation** is a liquid–liquid phase separation phenomena caused by the complexation between macroions of opposite charge in aqueous solution, by which the insoluble complex formed deposit onto an interface or sediment as a bottom phase.

**Electrophoretic mobility** is the ratio between the observed velocity of migration of a charged solute and the applied electric field strength in a given medium.

**Isoelectric point (pI)** the isoelectric point of a protein is the pH at which the net charge of the molecule is zero, i.e., the protein has a neutral charge.

**Maillard reaction** is a cascade of consecutive and parallel complex reactions initiated between an amino group on a protein, peptide, or amino acid and the  $\alpha$ -hydroxy carbonyl moiety on a reducing sugar; at its initial phases the Maillard reaction produces two intermediate products, the Amadori and Heyns products; in the final stage, melanoidins and brown pigments are formed.

**Steric stabilization** refers to the stabilization of colloidal particles involving non-ionic macromolecules that are attached to the particle surface. Each particle becomes surrounded by a layer of solvated polymeric molecules and, when approaching, two particles overlap and penetrate these polymer layers, in such a way that the increased polymer concentration in the overlapping region and the osmotic pressure favour the solvent transportation to this area, causing the particles be repelled away from each other again. At the same time, the polymer molecules have their conformation restricted in the overlapping area, which leads to entropy decreasing and, consequently, to a repulsion potential.

**Zeta potential** is the electric potential that develops between the surface of a solvated particle and the liquid solvating medium, measured at the shear plane, i.e., at the boundary between the edge of the solvated layer and the bulk liquid; it is also known as the electrokinetic potential and is measured in millivolts.

### Introduction

Oil-in-water (O/W) food emulsions are dispersed systems in which oil, generally a triglyceride oil, is dispersed in small droplets into a continuous aqueous phase. Common examples of O/W food emulsions include milk, cream, mayonnaise, salad dressings, sauces, and soups. In spite of their intrinsic thermodynamic instability, emulsions may be kinetically stabilized in the presence of surfactants that lower interfacial tension, help breaking up larger droplets into smaller ones, and prevent coalescence. Surfactants may be classified, regarding their molar mass, as small amphiphilic molecules - such as monoacylglycerols and phospholipids -, or as polymeric surfactants, mainly represented by proteins (Walstra, 2003).

Proteins, as well as polysaccharides to some extent, have significant advantages over monomeric surfactants because they present several adsorption sites that can anchor simultaneously onto the oil-water interface, forming viscoelastic films around the dispersed droplets with improved resistance to mechanical stresses, in addition to providing steric stabilization. These attributes turn them the preferred emulsifiers in many food systems. Even so, new and very suitable amphiphilic structures can be produced from interactions between proteins and polysaccharides, with the resulting complexes being able to replace the synthetic low molar mass emulsifiers. These association colloids do not require special legislation and may have textural and stability advantages. The interfacial functionality in emulsions is achieved not only from the direct adsorption on the oil–water interface during emulsification, but also from the established associative interactions with the stabilizing protein layer after the emulsion formation (Benichou, Aserin, and Garti, 2002; Dickinson, 2003). To better understand the role of protein-polysaccharide interactions in stabilizing O/W emulsions, it is useful to examine the mechanisms by which proteins alone exert their interfacial activity.

### Proteins as Interfacial Stabilizing Agents

The ability of proteins to act as emulsifiers is related to their amphiphilic character, which in turn derives from the number of polar and nonpolar surface groups present in the polypeptide chain. The number of neutral, anionic, and cationic amino acids present in a protein molecule depends on the protein type and source, and on the extraction process, whereas the exposed hydrophilic and lipophilic groups may also be affected by the solvent properties (pH, ionic strength), temperature, and denaturation extent. A

greater number of hydrophilic sites increase the protein solubility, which positively affects the diffusion toward the oil-water interface during emulsion production. On the other hand, the presence of lipophilic groups is important to allow the protein adsorption on the oil side of the interface, which leads to formation of a viscoelastic interfacial film (Damodaran, 1996; Lam and Nickerson, 2013).

Proteins are polyelectrolytes, i.e., they contain electrically charged groups, including both positively (basic) and negatively (acidic) charged ones. The surface charge of polyelectrolytes may be described by the zeta potential, or electrokinetic potential, which is related to the electrophoretic mobility and gives a measure of the net charge on the surface of the macromolecule. Important properties of colloidal systems are determined by the electrical charge on the particle surface, as the electrical potential distribution determines the interaction energy between the particles and this, in many situations, determines if the particles will be stable in suspension or, otherwise, will undergo coagulation and subsequent destabilization (Hunter, 1981). In proteins, the zeta potential varies as a function of pH and changes from high positive charge at low pH, passing through neutrality at the isoelectric point (pI) of the protein, and attaining highly negative values at alkaline conditions (Fig. 1). Knowledge of the pH that corresponds to the protein pI, which may be affected by the ionic strength of the aqueous medium, is important to determine the conditions of stability/instability of protein stabilized O/W emulsions, since at  $\text{pH} \approx \text{pI}$  the protein molecules will present a net zero charge and, in the absence of a sufficiently thick protein layer or of a complementary stabilization mechanism, probable droplet aggregation will take place (McClements, Bai, and Chung, 2017).

At this point it is important to distinguish between the roles played by emulsifiers and stabilizers. The emulsifying agent is responsible for rapidly and substantially lowering the interfacial tension at the oil-water interface, permitting formation of large interfacial area due to a great number of small dispersed droplets, which requires adsorption of the amphiphilic molecules onto the droplet surface at a sufficient concentration. Once the fine emulsion has been produced, the aggregation/flocculation and coalescence of droplets must be prevented in order to attain long-term stability. This is possible by the action of stabilizers whose performance is based on steric and electrostatic phenomena; the short-range steric interactions are important for preventing coalescence, while the electrostatic interactions, which are short-to-long range in nature, work by hindering droplet flocculation. In order to provide steric stabilization it is desirable that, in addition to the hydrophobic groups that will keep permanently attached to the oil droplets' surface, the macromolecular structure at the oil-water interface presents a large fraction of hydrophilic chain segments that will protrude from the surface and increase the thickness of the stabilizing layer. At the same time, if this macromolecular structure contains charged groups that contribute to increasing the net repulsive electrostatic interactions, it would help to prevent aggregation of adjacent droplets caused by the attractive van der Waals forces (Dickinson, 2003; Ozturk and McClements, 2016).

Proteins alone may be unsuitable to fulfil all the requirements to providing extended stability to emulsions, as the interfacial coverage formed around oil droplets by protein molecules is often not thick enough. In addition, the functional properties of proteins may be lost due to aggregation and precipitation that occur under acidic conditions near their isoelectric point, at high concentrations of electrolytes (high ionic strength), at high temperatures, and in the presence of organic solvents. In order to overcome these adverse factors, promising alternatives to enhance the emulsion stabilizing properties of proteins are showing to be feasible by taking advantage from their potential interactions with charged polysaccharides (Semenova, 2017; Akhtar and Ding, 2017).

**Figure 1** Typical behavior of zeta potential of proteins and polysaccharides as a function of pH.

## Nature of Protein–Polysaccharide Interactions

Proteins and polysaccharides may interact forming supramolecular complexes by two possible mechanisms: electrostatic interactions or covalent bonding. Both types of supramolecular structures will be able to combine the surface activity of proteins, which will adsorb onto the oil–water interface of the dispersed droplets, with the ability of polysaccharides to interact with the proteins and to increase the thickness of the stabilizing layer. In addition, the polysaccharides possess hydrophilic chain segments that will protrude from the surface enhancing steric stabilization, as well as binding great amounts of water and thus contributing to emulsion stabilization by increasing the viscosity or even causing gelation of the continuous aqueous phase. Both types of protein–polysaccharide interactions will be discussed as follows.

### Electrostatic Complexes Between Proteins and Polysaccharides

When mixed in a solution, protein and polysaccharides may interact with each other or remain freely dispersed, depending mainly on their surface charge and on the physical–chemical properties of the solvating medium, including pH and ionic strength. The biopolymer interactions can lead to two possible situations: segregative phase separation or associative phase separation. The segregative phase separation prevails when the biopolymers have similar electrical charges or they are neutral, and occurs when the biopolymer concentration exceeds a certain critical level. On the other hand, the biopolymers may associate with each other through relatively strong attractive electrostatic interactions. In turn, the resulting molecular complexes from these attractive interactions may be soluble, i.e. they remain dispersed in the solution with no macroscopic phase separation, or otherwise may be insoluble, leading to the formation of a sediment phase rich in biopolymers and an aqueous phase that is depleted in biopolymers (Moschakis and Biliaderis, 2017).

The insoluble supramolecular structures resulting from associative electrostatic interactions are known as complex coacervates and require two polymers with opposite charges - a polyanion and a polycation, whereas soluble complex formation may occur between an overall positively charged protein presenting a negative charge patch and a cationic polysaccharide (Kayitmazer, 2017). Even though, in most of the conventional situations, an anionic polysaccharide is used in combination with a protein bearing positive charge below its isoelectric point. The negative charge of polysaccharides is commonly due to the presence of carboxyl or sulfate groups. The only naturally occurring cationic polysaccharide is chitosan and in this case electrostatic interaction will take place with a protein at a pH above its pI. Regarding the ionic strength effect, in general, increasing salt concentration has a negative effect on polyelectrolyte complexation and above a critical salt concentration the attractive interaction is inhibited (Moschakis and Biliaderis, 2017; Evans, Ratcliffe, and Williams, 2013).

Both soluble electrostatic complexes, as well as the complex coacervates may be applied as emulsifiers/stabilizers in O/W food emulsions, although the insoluble complex coacervates have been mostly used to produce biopolymer-based particles, mainly to microencapsulation.

It has been recognized that even non-surface-active polysaccharides could contribute to interfacial stabilisation of an O/W emulsion if it can form an outer steric stabilising layer by electrostatic complexation with a protein adsorbed on the oil droplet interface (Fig. 2a) (Dickinson, 2013). Nevertheless, there are different approaches for producing protein–polysaccharide stabilized O/W emulsions and the resulting functionality of the complexes may vary depending on the production route adopted. Both biopolymers can be initially complexed in the absence of an oil phase, which will only be added at the end of the process then producing the so-called mixed emulsions. Alternatively, in the layering, bilayer, or double-layer approach, the protein forms the inner adsorbed layer on the primary emulsion droplets and a polysaccharide dispersion is subsequently added to the system to induce the formation of a complexed polysaccharide outer layer. The double-layer method is the most commonly used at industrial scale, despite it has been shown that the stability of a mixed emulsion prepared with soluble sodium caseinate – dextran sulfate complexes was greater than that of a bilayer emulsion prepared with the two-step method, in which bridging flocculation was observed (Jourdain, Leser, Schmitt, Michel, and Dickinson, 2008; Schmitt and Turgeon, 2011; Evans, Ratcliffe, and Williams, 2013).

**Figure 2** Schematic representation of oil droplets stabilized by (a) protein–polysaccharide electrostatic complexes and (b) protein–polysaccharide conjugates.

## Protein–Polysaccharide Conjugates

The most promising example of protein-polysaccharide complexes involving covalent bonding with good performance on emulsion stabilization is the Maillard-type conjugates, in which a polysaccharide is attached to a protein via the Maillard reaction and forms a permanently bonded conjugate. The Maillard reaction is a complex series of nonenzymatic reactions initiated between the amino groups of proteins and the reducing end carbonyl groups of polysaccharides (Troise, 2018; Oliveira, Coimbra, Oliveira, Zuñiga, and Rojas, 2016; Yaylayan, 1997). The protein-polysaccharide conjugates produced through the Maillard reaction have demonstrated ability of stabilizing O/W emulsions even under stressing conditions, such as high ionic strength, low pH, and along thermal and freeze-thaw processing. The improved emulsifying properties appear as a consequence of the enhanced steric stabilization provided by the bulky hydrophilic polysaccharide moiety attached to the protein (Fig. 2b). In fact, the parameter that most significantly improves emulsifying properties of protein-polysaccharide conjugates is the increasing molecular weight of the polysaccharide chain (Chen, Ji, Qiu *et al.*, 2018; Akhtar and Ding, 2017; Akhtar and Dickinson, 2007).

It is interesting to note the existence of naturally occurring protein-polysaccharide conjugates, including  $\kappa$ -casein that contains small side chains consisting of 3 or 4 sugar moieties that are thought to be crucial in stabilizing colloidal casein micelles in milk. Another typical example is gum Arabic that is largely applied as emulsifier/stabilizer in soft drinks and in beverage emulsions, and in which the proteinaceous fraction makes about 2% of the total polysaccharide. The relatively small fraction of proteins present in these few natural conjugates has contributed to the interest of generating alternative glycosylated proteins to induce the Maillard reaction (Ettelaie, Zengin, and Lishchuk, 2017).

The most used method for producing protein-polysaccharide conjugates is through dry thermal processing, although wet-heating has also been explored. In a typical process under dry heating conditions, the selected protein (mostly caseins, whey, albumin, soy or pea proteins) and polysaccharide (usually dextran, maltodextrin, or galactomannans) are mixed in a solution at the desired proportion, subjected to pH adjustment to slightly alkaline values, and freeze-dried. The powder is then heated at a controlled temperature and relative humidity for a given period. Heat energy input is essential for the Maillard reaction development and the rate reaction increases with temperature, which is typically set around 60 °C – 80 °C. Water activity has a major impact on the reaction rate that is maximal at water activity in the range of 0.3 to 0.7. The reaction time, of at least a few hours, must be carefully controlled in order to avoid the formation of the potentially harmful advanced glycation end-products that occurs at the advanced stages of the Maillard reaction (Ettelaie, Zengin, and Lishchuk, 2017; Oliveira, Coimbra, Oliveira, Zuñiga, and Rojas, 2016). Alternatively, wet-heating methods have been tested to produce protein-polysaccharide conjugates aiming to maximize the contact between protein and polysaccharide, as well as eliminating the freeze-drying step that is energy and time consuming. Recent approaches have included utilization of a spinning disc reactor (SRD) and microwave heating (Akhtar and Ding, 2017; Nasrollahzadeh, Varidi, Koocheki, and Hadizadeh, 2017).

## Conclusion

Independently of the mechanism by which proteins and polysaccharides interact forming supramolecular complexes, their complementary properties of emulsifying and stabilizing O/W emulsions have nourished plenty of research work aiming to clarify the various aspects of interest regarding their understanding and applications, which include thermodynamics, functional properties, processing approaches, and others. This will certainly enable the increasing tailored use of protein-polysaccharide pairs to improve food stabilization, enhancement of textural properties, and creation of reduced-fat food systems, microencapsulation of bioactive compounds, as well as other potential applications.

### Glossary

**High pressure processing** This is a non-thermal technology for food preservation and food manufacture that found an early application in the food industry for extending the shelf life of foods.

**Storage ( $G'$ ) and loss ( $G''$ ) moduli** These are the indication of the hydrogel's ability to store deformation energy in an elastic and viscous manner and show solid-like property and liquid-like property respectively.

### Introduction

Proteins are a very important group of food component of the human diet, as they are essential to the maintenance of muscle mass, immune responses, cell signaling and repair of damaged cells (Lin et al., 2017). They also contribute to color and flavor developments in foods. However, the structures of single protein formed gels or films are always fragile. Proteins combined with other biopolymers, e.g., polysaccharides or proteins, to form functional complexes are widely used for improving the functionalities of proteins. In complex food systems, the interactions between proteins and other macromolecules will inevitably take place in a variety of ways. These interactions can potentially have great influences on the structures and properties of food products.

High pressure processing (HPP) is one of the promising non-thermal preservation techniques and has the advantage of satisfying the increasing consumer demand for food products having highly retained sensory and nutritional qualities during food processing in industrial settings (Knorr, 1996). HPP could extend the shelf life of food and improve the safety of food products (Knorr, 1996). In addition, HPP could also induce modification of macromolecular arrangements during protein denaturation, starch gelatinization, or other interactions between food ingredients (Devi et al., 2013a). The extent of macromolecular rearrangements caused by HPP is dependent on macromolecule's intrinsic properties, physicochemical environment, applied pressure level and temperature, duration of pressure treatment (Michel and Autio, 2002). This chapter discusses the changes in rheological properties, gel properties, surface/interfacial properties and structure owing to the interactions between proteins and other macromolecules (e.g., proteins, polysaccharides) induced by HPP.

### Changes in the Interactions Between Proteins and Proteins Induced by HPP

Applying HPP to protein molecules in solution can have a strongly disruptive effect on electrostatic and hydrophobic interactions causing denaturation and aggregation of proteins (Galazka et al., 2001). High pressure effects on proteins are mainly related to the rupture of non-covalent interactions between and/or within protein molecules, and the subsequent reformation of intra- and inter-molecular bonding. Many quaternary structures show complex behaviors, such as dissociation, followed by aggregation of subunits or precipitation upon a high pressure treatment (Apichartsrangkoon and Ledward, 2002). Changes in secondary structures occur at a very high pressure and likely lead to irreversible denaturation. Interactions of proteins at the oil-water or air-water interfaces can help maintain the stability of emulsions or foams, whilst the interactions between protein molecules in aqueous solutions are essential to the formation of protein gels and films (Lin et al., 2017). The protein-protein interactions induced by HPP can bring new functional properties of food products. Protein-protein interactions have been well investigated with the objectives of examining structure-function relationships, improving food quality, and developing new products. HPP is one of the useful technologies to enable changes in protein-protein interactions.

### Changes of Rheological Properties

Protein-protein interactions and the resulting changes of rheological properties (e.g., viscosity and flow behavior) depend greatly on the type of protein, protein concentration and applied pressure. In the study on the gluten and soy mixtures treated at 700 MPa by HPP (Apichartsrangkoon and Ledward, 2002), both high temperature and pressure were found to increase the strength of storage ( $G'$ ) and loss ( $G''$ ) moduli of all the gluten-soy mixtures, especially the mixtures having high gluten concentrations. The  $\tan \delta$  values, which are the ratios of loss ( $G''$ ) to storage moduli ( $G'$ ), were low for all the soy protein-rich samples, although the samples containing high amounts of gluten exhibited higher  $\tan \delta$  values at frequencies in the range 1–10 Hz. The HPP treatments affect

neither the flow behavior of gelatin alone, nor that of the skim milk-gelatin mixtures made with  $\sim 0.4\%$  weight/weight (w/w) gelatin. However, at a gelatin concentration  $\sim 0.4\%$  w/w, the mixtures treated with 300 and 450 MPa exhibited a peculiar flow behavior. The viscosity remarkably increased in the milk-gelatin mixtures prepared with a high milk solid concentration (15% and 20% w/w) following a HPP treatment at 300 MPa, whereas, HPP at 600 MPa caused a decline in viscosity (Hemar et al., 2010).

### Changes of Gel Properties

Gels are a kind of special decentralized systems in which molecules are connected to each other to form a network structure under certain conditions. Gaps in the networks may be filled with liquid or gas as a dispersed phase (Lin et al., 2017). Mixing different proteins to form gels is a good way to improve the sensory and nutritional properties of foods. The concentration of one protein in protein-protein mixtures should be high enough to act as a filler to fill the gaps in the networks formed by the other protein. In addition, pressure and temperature may influence the protein-protein gel properties. Mixed systems subjected to HPP in aqueous solutions had higher  $G'$  values than the mixed systems (e.g. whey protein and gelatin) subjected to HPP in the form of gels (Devi et al., 2014). The cooling profile of  $G'$  in mixed solutions was similar to that of the gelatin solution treated by HPP, which indicates that HPP could lead to a high degree of gelatin continuity (Devi et al., 2014). Confocal imaging analyses confirmed that the gelatin was in a continuous phase whilst whey protein aggregated in discontinuous inclusions within the mixed systems treated by HPP (Devi et al., 2014). High pressure applications at temperatures below the thermal denaturation of whey protein (i.e.,  $<65^\circ\text{C}$  at pH 6.8) permitted gelatin to maintain its continuity within the mixed systems (Devi et al., 2014). The microstructure of the mixed gel (whey protein and gelatin) at 600 MPa for 30 min was different from the single gel, possibly due to an associative phase separation (Devi et al., 2014). The  $G'$  value of mixed gel was still higher than that for the pure whey protein gels (Devi et al., 2014).

### Changes of Surface/Interfacial Properties

The surface/interfacial properties include the emulsification and foamability. Vegetable proteins (e.g., soybean protein, pea protein and gluten) and dairy proteins (e.g., casein and whey) are widely used as emulsifiers. There is a growing interest in mixing vegetable proteins with animal proteins or utilizing vegetable proteins instead of animal proteins for emulsification (Karaca et al., 2011). The thermal stability of mixed protein-stabilized emulsions can be increased due to protein-protein interactions. However, emulsions stabilized by mixed proteins are still sensitive to certain extreme conditions (e.g., some HPP treatments) (Lin et al., 2017).

High pressure-low temperature (HPLT) and HP (high pressure) treatments led to a decreased emulsion stability for emulsions derived from whey protein (WPI) solutions independent from a pH treatment, while the foaming stability was increased for these samples (Baier et al., 2015). The large flocs, which were induced in samples containing a high amount of micellar casein (MC), influenced greatly the rheological behaviors of these samples, while exerting no specific effect on foam and emulsion stability (Baier et al., 2015). HPLT treatments of MC-rich samples always led to the formation of some very large flocs which had a major influence on the functionalities. The treatments on mixtures could lead to varied results in comparison to pure dispersions which indicate the high influence of interactions between MC and WPI (Baier et al., 2015). The emulsifying capacity decreased after a HPP treatment at 200 MPa on myofibrillar proteins-egg white mixtures (Barrios-Peralta et al., 2012).

### Changes of Structure

Protein-protein interactions in protein solutions may lead to phase separation, synergistic interaction and aggregation (Firoozmand and Rousseau, 2015). In most cases, a mixture of two proteins will lead to phase separation, e.g., coagulation and segregation. When phase separation occurs, two proteins form independent phase-separated networks thus preventing the assembly of a uniform network structure (Sarbon et al., 2015). A mixture of two oppositely charged proteins can result in aggregation induced by electrostatic attraction. Synergistic interactions can lead to more desirable products with a uniform structure than those formed by each individual protein alone (Lin et al., 2017). Very complicated changes in structure owing to protein-protein interaction can be observed during HPP (Devi et al., 2013b).

The type of protein has an enormous effect on protein-protein interactions in solutions treated by HPP. The structures of the gluten-soy mixtures were very firm at 700 MPa and  $60^\circ\text{C}$ , exhibiting solid-like behaviors and a highly permanent cross-link density (Apichartsrangkoon and Ledward, 2002). The detected variations in structural modification of the gluten-soy mixtures were mainly due to the gluten rather than soy protein. Disulphide bonds contributed to the final structure of gluten-soy mixtures treated at a high temperature; however, other non-covalent bonds may also be involved. In the presence of gelatin, the state of the dissociated casein micelles is different to that of in the presence of skim milk alone. This was due to ruptured aggregates and phase separation as confirmed by confocal laser scanning microscopy (Devi et al., 2013b). Application of an intermediate to high pressure (300–600 MPa) results in changes in microstructure of the mixture depending on the milk solid content (Devi et al., 2013b). It appeared that milk solids occurring at levels of industrial interest ( $<20\%$  w/w) would lead to enhanced gelatin structure formation at refrigeration temperature during HPP (Devi et al., 2013b).

Pressure is also one of the most important factors that can significantly influence the protein-protein interactions in solutions treated by HPP. If the pressure applied is 150 MPa, extensive dissociation of the casein micelle does not occur and only the phase separation was observed in the skim milk-gelatin mixtures (Hemar et al., 2010). When the gelatin concentration is not lower than the critical concentration at which a gelatin gel is formed, the casein submicelle network would be entrapped in the gelatin network

(Hemar et al., 2010). If the gelatin concentration is lower than the critical concentration, then the system behaves as in good solvent conditions and the submicelle clusters can rearrange upon decompression. When the hydrostatic pressure applied is higher than 450 MPa, the submicelles do rearrange into more compact submicelle aggregates (Hemar et al., 2010).

## Changes in the Interactions Between Proteins and Polysaccharides Induced by HPP

Two main types of food macromolecules, proteins and polysaccharides, are often present together in a wide range of food products. Proteins and polysaccharides have a profound effect on the shelf life and texture of food products. Proteins are commonly recognized for their emulsifying and foaming properties whereas polysaccharides are known for their water-holding characteristics. Polysaccharides are used in admixture to proteins mainly to enhance stability of dispersed systems. Most high molecular weight polysaccharides are hydrophilic in nature and do not adsorb to the air–water interface. However, they can strongly enhance the stability of protein foams. The changes in protein-polysaccharide interactions under various conditions can be examined by measuring the rheological properties of resultant food fluids. Proteins and polysaccharides can form fine complexes via covalent bond(s) and/or non-covalent bond(s) (Ji et al., 2015). The covalent bonding, in this case, takes place during the Maillard reaction (Liu et al., 2012). The non-covalent bonds include hydrogen bond and electrostatic attraction. Generally, uncharged polysaccharides can form complexes with proteins mainly via hydrophobic interactions, whereas for ionic polysaccharides, complexes mainly are formed via electrostatic interactions (Lin et al., 2017). HPP can also influence the interaction between proteins and polysaccharides; hence, increasing interests have been attracted to the effect of HPP on systems containing mixed proteins and polysaccharides.

### Changes of Rheological Properties

HPP can cause changes in the rheological properties of protein-polysaccharide mixtures and the changes depend on the type, concentration, ratio of polysaccharide and protein, applied pressure and time. HPP treatment of sweet potato protein (SPP) in the presence of guar gum (GG) showed improvement in viscosity (Khan et al., 2015). The effects of HPP (800 MPa and 20 °C for 20 min) on the rheology of LMP (low methoxy pectin)/MC (micellar casein) mixtures depend on their concentrations and ratio (Abbasi and Dickinson, 2002a). The mixed gels subjected to high pressure displayed increasing  $G'$  and  $G''$  throughout the MC concentration range (0.5%–12% w/w) (Abbasi and Dickinson, 2002a). The enhancement of  $G'$  was likely due to either the intensified interaction between the positively charged parts of casein micelles and the negatively charged polygalacturonan chains, or the attachment of  $\text{Ca}^{2+}$  into the gap between the pectin backbones under pressure. However, the  $G'$  recovered at a high percentage of MC (12%–14% w/w), possibly because a network of caseins was developed upon pressure release (Abbasi and Dickinson, 2002a). An enhancement of  $G'$  was also found for skim milk powder (SMP) dispersions supplemented by LMP following HPP, especially when LMP (0.5% w/w) was mixed with SMP dispersions with MC ranging in 2%–8% and at 800 MPa (at 20 °C for 20 min) (Abbasi and Dickinson, 2002b). High pressure homogenization reduced the viscosity of hydroxypropyl cellulose (HPC)-casein complexes regardless of the molecular weight of HPC (Ye and Harte, 2014).

### Changes of Gel Properties

Proteins and polysaccharides are gelling agents mainly responsible for gelation, and for this reason, they play important roles in the food industry. Gels formed by mixed polymers usually have better mechanical properties than those formed by a single polymer due to the interactions between different polymers (Hou et al., 2015). The properties and concentration of polysaccharides would have great influences on the structures and properties of protein-polysaccharide gels. In addition, pressure, time and temperature can also influence the properties of a protein-polysaccharide gel.

High-pressure homogenization (HPH) delayed gelling of some mixed systems (e.g. peanut protein isolate (PPI)-chitosan, PPI-xanthan gum and PPI-guar gum mixtures), through the rupture of the molecular chains of PPI and polysaccharides (Jiao et al., 2018). A stronger gel network was formed for the PPI-xanthan gum mixed system as compared to that of PPI-guar gum mixtures, and the solid-like structure of the former system was unaffected by heating (Jiao et al., 2018).

The exudation of pressure-induced  $\beta$ -lactoglobulin gels (12% w/w and pH 7) could be prevented by incorporating 0.1% w/w of certain polysaccharides, i.e., LMP (low methoxy pectin), HMP (high methoxyl pectin), or Na-alginate (Dumay et al., 1999). When the concentration of polysaccharide is too high (i.e., 1% w/w), either no gel was formed (for  $\beta$ -lactoglobulin + Na-alginate), or a gel with poor water retention was obtained (for  $\beta$ -lactoglobulin + LMP), following 30 min treatments at 450 MPa and 25 °C.

The gelifying effect was studied through pressure treatments, at room temperature or 50 °C, on mixed systems of whey protein/polysaccharide ( $\kappa$ -carrageenan, xanthan gum and HMP) (Fernandes and Raemy, 1996). At room temperature,  $\kappa$ -carrageenan was the most efficient gelifying agent in whey protein/polysaccharides systems; however, it was no longer the case at 50 °C. A higher pressure did not always lead to a stronger gel. Xanthan gum and HMP were as efficient as  $\kappa$ -carrageenan at 50 °C. Large protein lumps enclosed by a pectin-rich phase were observed following an intense HPP treatment at 800 MPa. Due to the phase separation of protein and pectin, the concentrated pectin phase was probably the cause for the rise in viscosity of pressure treated mixtures whilst the protein network was developed during protein gelation (Fernandes and Raemy, 1996).

### Changes of Surface/Interfacial Properties

Emulsions stabilized by proteins combined with polysaccharides usually show better heat stability than those stabilized only by proteins. Generally, polysaccharides cannot adsorb onto the surface of oil droplets and accordingly cannot stabilize emulsions. However, they can improve the stability of emulsions in association with proteins. Among vegetable proteins, soy protein isolate (SPI) is the most frequently used protein as a foaming stabilizer due to its favorable foaming ability and potential health benefits (Lin et al., 2017). Interactions between proteins and polysaccharides at interfaces can enhance the foamability of proteins adsorbed onto interfaces (Baeza et al., 2005). HPP can also cause changes in the interfacial properties of protein-polysaccharide mixtures (Galazka et al., 2001).

The effects of dynamic high-pressure homogenization (HPH) on the interfacial and foaming properties of SPI and Methocel (E4M and E15) with different molecular weights were studied (Martínez et al., 2011). The obtained results showed that the interactions between SPI and polysaccharides apparently favored the foam overrun of untreated mixed systems. This interactive effect was promoted using HPH particularly in the case of E15 at 300 MPa. The effect of SPI-E4M was less pronounced than that observed for E15. Thus, the molecular weight of PS was a very important factor for the interaction with SPI under these high pressure conditions.

High pressure treatment of 11S globulin (11S) and  $\iota$ -carrageenan ( $\iota$ -CAR) or  $\kappa$ -carrageenan ( $\kappa$ -CAR) mixtures was found causing a remarkable improvement in emulsifying efficiency and emulsion stability (Galazka et al., 1999b). When  $\iota$ -CAR was added to 11S, the mixture gave a higher surface tension value ( $\gamma$ ) than did the untreated 11S alone. High pressure treatment of the 11S +  $\iota$ -CAR mixture led to lower  $\gamma$  values than native 11S, but a higher  $\gamma$  than pressure processed 11S alone. The tension data shown for the 11S +  $\iota$ -CAR mixtures are indicative of complexation between the protein and polysaccharide in the bulk solution, which perturbs the dynamic equilibrium of protein between bulk and interface in favor of the bulk. High-pressure treatment (200 MPa for 20 min) induces the formation of a more viscous steric stabilizing layer in a strongly time-dependent manner. The presence of  $\iota$ -CAR added to native 11S globulin at a low ionic strength was found to give emulsions with smaller droplets (whose size decreased with increasing polysaccharide concentration and degree of pressure treatment) (Galazka et al., 2001).

HHP treatment of sweet potato protein (SPP) in the presence of guar gum (GG) increased the stability of emulsions and decreased the creaming rate as compared to the control (Barrios-Peralta et al., 2012). Protein-starch interaction could increase the emulsifying capacity at pressures over 350 MPa for 3–5 min and the emulsifying capacity also increased in samples with agar (Barrios-Peralta et al., 2012).

The influence of high pressure (200–600 MPa) on surface tensions and surface shear viscosities of protein layers adsorbed at pH 6.5 or 8.0 from the mixtures of sulfated polysaccharides with  $\beta$ -lactoglobulin, bovine serum albumin (BSA) or ovalbumin (OVA) was studied (Galazka et al., 2001). The experimental interfacial tension for  $\beta$ -lactoglobulin + dextran sulphate (DS) indicated weak electrostatic complexation, whereas mixtures of BSA or OVA with DS were likely associated with strong protein-polysaccharide complex formation in bulk solutions. While the interactions of proteins with the polysaccharides might have only a small influence on the surface viscosities of the adsorbed proteins, they behaved like the strongest interaction for the most sulfated polysaccharide (DS). The pressure processing induces the dissociation of reversible electrostatic protein-polysaccharide complexes, and during the pressure treatment the protein was partly denatured and thus causing more charged groups exposed. When pressure is released, electrostatic protein-polysaccharide interactions could be strongly restored, as a result, re-complexation of the unfolded protein with polysaccharide is possible (Galazka et al., 2001).

### Changes of Structure

Thermodynamic incompatibility between proteins and polysaccharides often leads to separation, but two separate network structures formed by segregation can still form a rigid structure by physical or chemical force-driven intertwining. Properties of proteins and polysaccharides (e.g., charge density, molecular weight and branched chain) and their concentrations or ratio have a big influence on the protein-polysaccharide network structures (Lin et al., 2017). Pressure, time and temperature used during HPP can also influence the structure of protein-polysaccharide.

$\beta$ -Lactoglobulin at pH 7 in the presence or absence of dextran sulphate (DS) was subjected to a combined pressure and temperature treatment (pressures up to 280 MPa, temperature up to 60 °C and time up to 30 min) (Galazka et al., 1996). The treatments with combinations of moderate pressures and temperatures can result in distinct structures. Even under moderate processing conditions, it is still possible to optimize the processing parameters to obtain significant structural changes that potentially lead to functional advantages. The presence of DS could apparently reduce the degree of BSA unfolding induced by pressure but not for  $\beta$ -lactoglobulin, suggesting that DS either protected the protein against pressure-induced unfolding or enabled the pressure-denatured protein to regain some secondary structures.

Addition of a polysaccharide (DS or  $\iota$ -carrageenan) to the native protein at a low ionic strength leads to no change in fluorescence intensity (Galazka et al., 1999a). The presence of DS in the thermally processed samples appeared to inhibit the formation of aggregates. Under pressurization ovalbumin could form electrostatic complexes with DS or  $\iota$ -CAR at a low ionic strength and pH  $\leq$  7.0. As with BSA, the strength of protein-polysaccharide complex appeared to be dependent on the charge density of sulphate group on the polysaccharide (DS,  $\iota$ -CAR), and the extent of the interaction between ovalbumin and DS or  $\iota$ -CAR was enhanced during the pressure treatment at pH 6.5 (Galazka et al., 1999a). It seemed that protein-polysaccharide complexation would have protected the protein against pressure-induced aggregation (Table 1).

**Table 1** Selected examples of changes in the interactions between proteins and other macromolecules induced by HPP

HPP, WP(), MC, SPP, PPI, GG, LMP, HLP, HPC, BSA, OVA, DS and SMP represent high pressure processing, whey protein(isolate), micellar casein, sweet potato protein, peanut protein isolate, guar gum, low methoxy pectin, high methoxy pectin, hydroxypropyl cellulose, bovine serum albumin, ovalbumin, dextran sulphate and skim milk powder respectively.

## Conclusion

The desired characteristics of food products such as structure, stability and textural attributes can be achieved through mixing polysaccharides and/or proteins, and monitoring the strength and nature of the interactions between the mixed biopolymers. Interesting effects may take place when HPP is applied to mixtures of macromolecules (polysaccharides and/or proteins) owing to their interactions under pressure and during decompression. HPP can induce modification of macromolecular structures and interactions of food biopolymers, causing changes that can potentially have great influences on the properties of food products. Thus, HPP can be used as a processing approach for manipulating properties of mixtures of proteins–proteins and proteins-polysaccharides. HPP may produce new ingredients and products (e.g., emulsifiers, stabilizers, foams or gels) containing protein–protein and protein-polysaccharide complexes for food industry.

# Different Catalytic Activities of Microbial L-Glutaminases Against Bitter Amino Acid Phenylalanine in the Production of Kokumi $\gamma$ -Glutamyl Peptides

Juan Yang, Dongxiao-Sun Waterhouse, and Chun Cui, South China University of Technology, Guangzhou, China

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Gamma-glutamyl transpeptidation** The transfer of  $\gamma$ -glutamyl moieties from molecules such as glutathione (GSH), glutamine (Gln) or other  $\gamma$ -glutamyl compounds to an acceptor such as an amino acid, a peptide or water to form  $\gamma$ -glutamyl peptides or glutamate.

**Gamma-glutamyl-peptides** These are peptides in which an amide linkage occurs between the  $\gamma$ -carboxyl group of glutamic acid and the amino group of another amino acid.

**Kokumi** A Japanese expression ("rich taste") to describe a complicated sensory sensation of food that is detected through calcium channels on the tongue involving calcium-sensing receptor (CaSR) but not perceived as an independent taste quality, encompassing continuity, mouthfulness, thickness, taste-enhancing and persistent/long-lasting characteristics.

**L-Glutaminase** An amidohydrolase that mainly catalyzes the hydrolysis of  $\gamma$ -amido bond of L-glutamine (Gln) to produce L-glutamic acid, with some also catalyzing the transfer of  $\gamma$ -glutamyl moieties from Gln to other amino acids or peptides to form  $\gamma$ -glutamyl peptides.

## Introduction

The sensation of flavor plays an important role in food choice, dietary behaviors and even human development. Quite a lot of valuable nutrients and bioactives are naturally bitter or have unpalatable tastes including aromatic, basic or branched-chain amino acids and some short peptides such as aspartic acid, glutamic acid, isoleucine, leucine, methionine, phenylalanine, tyrosine, tryptophan and valine. While masking their unpleasant tastes through encapsulation is used in some cases, nonencapsulation approaches especially those based on food component interactions are often more desirable (Sun-Waterhouse and Wadhwa, 2013). Using bitter taste blockers for food formulation is a popular nonencapsulation approach but presents limitations related to the lack of universal bitter blocker. Thus, in situ taste improvement that can be included as part of the manufacturing process is preferred e.g. Gamma-glutamyl transpeptidation to improve the taste of bitter or bad-tasting peptides and amino acids generated in aged, fermented and hydrolyzed foods (Yang et al., 2017).

$\gamma$ -Glutamyl peptides including  $\gamma$ -glutamyl dipeptides or tripeptides such as  $\gamma$ -Glu-Val,  $\gamma$ -Glu-Met,  $\gamma$ -Glu-Glu,  $\gamma$ -Glu-Gln,  $\gamma$ -Glu-Gly,  $\gamma$ -Glu-Leu,  $\gamma$ -Glu-His,  $\gamma$ -Glu-Cys-Gly and  $\gamma$ -Glu-Val-Gly, are usually found in edible beans (Dunkel et al., 2007), cheese (Toelstede et al., 2009; Toelstede and Hofmann, 2009; Sgarbi et al., 2013; Roudot-Algaron et al., 1994) and soy sauces (Frerott and Chen, 2013).  $\gamma$ -Glutamyl peptides may possess antinociceptive, anticancer, antiplatelet, antiatherosclerotic, detoxifying and lipid-lowering effects (Kim et al., 2017; Keusgen, 2002; Ichinose et al., 1987; Main et al., 2012). These peptides are useful antioxidants and pro-therapeutics for Parkinson's disease, as they are quite stable in the body as their  $\gamma$ -glutamyl linkage cannot be cleaved by normal peptidases until at the location where specific enzymes such as  $\gamma$ -glutamyltranspeptidases are expressed. Besides the biological effects,  $\gamma$ -glutamyl peptides play important roles in sensory properties of foods and exhibit kokumi-imparting properties upon addition of a small amount. Kokumi is often listed together with the five basic tastes (sweet, salty, sour, bitter and umami), and describes a complicated taste sensation of food associated with continuity, mouthfulness, thickness, taste-enhancing and long-lasting characteristics. Moreover,  $\gamma$ -glutamyl peptides can be produced on a large scale via an enzymatic  $\gamma$ -glutamyl transpeptidation process, and  $\gamma$ -glutamyltransferases (EC 2.3.2.2) can catalyze the  $\gamma$ -glutamyl transfer from a  $\gamma$ -glutamyl donor (e.g. glutathione (GSH), glutamine (Gln) or other  $\gamma$ -glutamyl compounds) to a  $\gamma$ -glutamyl acceptor (e.g. other amino acids or peptides) to form  $\gamma$ -glutamyl peptides (Chen et al., 2015; Speranza and Morelli, 2012; Suzuki et al., 2002a,b,c, 2004, 2007). These two types of enzymes often possess several catalytic activities for the following reactions: 1) only hydrolysis (in which the  $\gamma$ -glutamyl moiety is transferred to a water molecule yielding glutamic acid), 2) only transfer reaction (in which the  $\gamma$ -glutamyl moiety is transferred to the acceptor is an  $\text{NH}_2$ -group containing compound), 3) hydrolysis of glutamine prior to a transfer reaction with some acceptors, 4) transfer reaction prior to hydrolysis (hydrolysis is largely suppressed by suitable acceptor in favor of a transfer reaction), and 5) autotranspeptidation (when the free  $\text{NH}_2$ - group of a donor acts as an acceptor itself). For example, the glutaminases from *Pseudomonas nitroreducens* (GPN) (Itoh et al., 2012) and *Aspergillus oryzae* (GAO) (Tomita et al., 1989) have transpeptidase activity and can catalyze the synthesis of L-theanine and a large number of  $\gamma$ -glutamyl peptides, respectively. GPN can catalyze the hydrolysis of glutathione prior to  $\gamma$ -glutamyltransfer to glycylglycine and also the  $\gamma$ -glutamyl transfer to ethylamine or methylamine with suppressed hydrolysis of glutamine. Thus, a series of  $\gamma$ -glutamyl peptides are normally produced during the enzymatic synthesis e.g.  $\gamma$ -Glu- $\gamma$ -Glu-Tau was found as a by-product of the  $\gamma$ -Glu-Tau synthesis catalyzed by  $\gamma$ -glutamyl transpeptidase (GGT) (Suzuki

et al., 2002c);  $\gamma$ -glutamyl-glutamine and other poly-glutamylated species were identified during the GGT-catalyzed synthesis of  $\gamma$ -glutamyl-peptides (Morelli et al., 2014).

### Biochemical Characteristics and Catalytic Activities of Microbial L-Glutaminases

L-Glutaminase has been in the spotlight since the discovery of its antitumour properties. Decades of research have been directed toward searching its sources, characterizing, utilizing and improving its catalytic properties. The enzyme naturally occurs as a family of species with varying enzymatic activities and biochemical characteristics and can be found in the whole biological world including human beings and microorganisms (bacteria, yeast and fungi). Most microbial species produce L-glutaminase at a neutral or slightly alkaline pH under mild conditions (25–37 °C). For the microbial L-glutaminases, L-glutamine is the main substrate, with D-glutamine, L-asparagine or D-asparagine at a lower concentration also as a substrate in some cases. In food industry, efforts have been made toward the exploration of their novel properties in specific food matrices and under food manufacturing conditions (e.g. desirable temperature, pH and salt tolerance). In particular, the catalytic activity of L-glutaminase for the synthesis of glutamic acid has been optimized in a range of food applications including soy sauce fermentation.

### Biochemical Characteristics and Transpeptidase Activity of Glutaminase

Glutaminases sourced from different microorganisms differ in molecular weight, optimal pH for stability and catalysis, optimal temperature for stability and catalysis, and substrate specificity (Tachiki et al., 1996; Yano et al., 1988; Koibuchi et al., 2000; Ye et al., 2013). Most L-glutaminases are monomers with some bacterial L-glutaminases as dimers and tetramers, and have molecular weight in the range of 40–148 kDa and high stability at 40–50 °C. The glutaminases from *Bacillus amyloliquefaciens* (GBA), GAO and GPN have a molecular mass of about 35 kDa, 82–113 kDa, and 40 kDa, respectively. The optimum pH and temperature for catalysis are 6.5 and 60 °C for GBA, 9.0 and 37–45 °C for GAO, and 9.0 and 30 °C for GPN. Different glutaminases exhibit varied salt-tolerance (which is an important aspect especially for food applications involving high salt conditions). For example, GAO can be significantly inhibited by high salt concentrations (e.g. 17%–18% salt concentration during soy sauce fermentation), whilst GBA still exhibits high activity (68% of the original activity) in the presence of 20% NaCl.

In terms of transpeptidase activity, GBA and GAO were found to possess transpeptidase activity i.e. 100 and 10 U/g, respectively, at the optimal pH of 10.0 and optimal temperature of 37 °C (Yang et al., 2017). The two enzymes can catalyze a  $\gamma$ -glutamyl transfer reaction to yield Phe-containing  $\gamma$ -glutamyl peptides in the presence of Gln and Phe i.e.  $\gamma$ -Glu-Phe and  $\gamma$ -Glu- $\gamma$ -Glu-Phe (by GAO), or  $\gamma$ -Glu-Phe,  $\gamma$ -Glu- $\gamma$ -Glu-Phe,  $\gamma$ -Glu- $\gamma$ -Glu- $\gamma$ -Glu-Phe,  $\gamma$ -Glu- $\gamma$ -Glu- $\gamma$ -Glu- $\gamma$ -Glu-Phe and  $\gamma$ -Glu- $\gamma$ -Glu- $\gamma$ -Glu- $\gamma$ -Glu- $\gamma$ -Glu-Phe (by GBA). Like any other enzyme, the specific activity of glutaminase is closely related to its degree of purity (which greatly depends on the purification method). GBA was found to have a final specific activity of 1.92, 25.70, 93.70, and 196.20 U/mg that corresponded to each purification step of a progressive purification process: supernatant after centrifugation at 12 000  $\times$  g for 10 min (to remove microorganisms), fraction coming out from the DEAE-Sepharose FF anionic exchange chromatography column, fraction from the hydroxyapatite column, concentrate after sephacryl S-200 (Ye et al., 2013). However, the glutaminases from *Escherichia coli* and *Pseudomonas aeruginosa* seemed to have no activity toward the transfer of  $\gamma$ -L-glutamyl-*p*-nitroanilide to Gly-Gly.

### Synthesis of $\gamma$ -Glutamyl Peptides in the Presence of Phe by GBA or GAO

Glutaminases of different microbial sources under the same enzymatic synthesis conditions (including type and concentration of substrates, pH, temperature, enzymatic activity, reaction time and method for inactivation of enzyme), can lead to different profiles of  $\gamma$ -glutamyl peptides. When GBA or GAO at 0.05 U/mL, the synthesis reaction was run at 37 °C for 2 h with substrate water solutions containing Gln and Phe (both at 200 mM, pH 10.0), yielding various Phe-containing  $\gamma$ -glutamyl peptides. The concentrations of  $\gamma$ -[Glu] $_n$ -Phe products differed between the two cases of GBA and GAO i.e.  $\gamma$ -Glu-Phe,  $\gamma$ -[Glu] $_2$ -Phe,  $\gamma$ -[Glu] $_3$ -Phe,  $\gamma$ -[Glu] $_4$ -Phe and  $\gamma$ -[Glu] $_5$  were 61.59, 27.64, 14.09, 1.50 and 0.13 mM, respectively, whereas, for GBA, only  $\gamma$ -Glu-Phe and  $\gamma$ -[Glu] $_2$ -Phe (20.31 and 3.10 mM, respectively) were detected for GAO (Yang et al., 2017). In both cases, a lower yield was likely achieved for the  $\gamma$ -[Glu] $_n$ -Phe product with a higher molecular weight. Such differences in the yield and type of  $\gamma$ -[Glu] $_n$ -Phe products indicated that GBA appeared to be more efficient than GAO in catalyzing the transfer of a  $\gamma$ -glutamyl group to a tripeptide or a higher molecular weight peptide. The synthesis of Phe-containing  $\gamma$ -glutamyl peptides is summarized in Fig. 1 (Yang et al., 2017).

A “Ping-Pong” kinetic mechanism was possible, causing the formation of a covalently bonded  $\gamma$ -glutamyl acyl-enzyme intermediate involving hydrogen bonding and charge interactions, then the intermediate reacted with Phe or existing peptides as acyl-acceptor substrates to yield a  $\gamma$ -glutamyl peptide (Itoh et al., 2012). GBA and GAO were found to exhibit a difference in affinity for acceptors such as Phe and  $\gamma$ -Glu-Phe, with GAO exhibiting a lower affinity than GBA for the acceptors (Fig. 2). The superiority of GBA and or GAO in the production of Phe-containing  $\gamma$ -glutamyl peptides can be evaluated through measuring the Michaelis-Menten constants ( $K_m$ ) for the synthesis of  $\gamma$ -[Glu] $_n$ -Phe and hydrolysis of  $\gamma$ -[Glu] $_n$ -Phe, respectively. For the  $K_m$  of the synthesis reaction, GBA or GAO, substrate (Phe or  $\gamma$ -[Glu] $_{(n<5)}$ -Phe), and donor substrate (Gln) were at 0.0025 U/mL, 5–50 mM, and 50 mM, respectively, with the reaction pH, temperature and time being 10.0, 37 °C and 30 min. For the  $K_m$  of the hydrolysis reaction, the same reaction pH, temperature, time and GBA or GAO (0.0025 U/mL) were used (Yang et al., 2017). For the transpeptidation, the  $K_m$  values generally increased with an elevated number of  $\gamma$ -glutamyl residue within the acceptor, and were 47.88 and 153.92 mM with Phe as the acceptor, 84.89 and 236.47 mM with  $\gamma$ -Glu-Phe as the acceptor, for GBA and GAO, respectively. Unlike

**Figure 1** A scheme for the synthesis of Phe-containing  $\gamma$ -glutamyl peptides. G-E refers to glutaminase.

**Figure 2** The  $K_m$  value (mM) of GBA and GAO for the synthesis and hydrolysis of  $\gamma$ -[Glu]<sub>n</sub>-Phe ( $n = 0-5$ ). GBA and GAO refer to L-glutaminases from *Bacillus amyloliquefaciens* or *Aspergillus oryzae*.

GBA, GAO could not catalyze the transfer of  $\gamma$ -glutamyl moiety to the tripeptide ( $\gamma$ -[Glu]<sub>2</sub>-Phe) or peptides with the number of  $\gamma$ -glutamyl residues higher than 2. Moreover, the  $K_m$  values (4.81–40.75 mM) for the hydrolysis catalyzed by GBA were lower than that for the synthesis catalyzed by GBA. All these findings suggest that GBA had a greater affinity than GAO for Phe and  $\gamma$ -Glu-Phe in the transpeptidation reaction. GBA was superior to GAO in the synthesis of Phe-containing  $\gamma$ -glutamyl peptides, and the transfer of  $\gamma$ -glutamyl moiety to a  $\gamma$ -[Glu]<sub>n</sub>-Phe became more difficult with increasing number of  $\gamma$ -glutamyl residues in the molecule (Yang et al., 2017).

### Sensory Characteristics of $\gamma$ -Glutamyl Peptides

$\gamma$ -Glutamyl peptides possess very interesting sensory properties. They can modulate the calcium sensing receptor (CaSR) in humans (which is an extracellular seven-transmembrane-spanning, G protein-coupled receptor (GPCR)).  $\gamma$ -Glutamyl peptides have a minimal flavor in water and exhibit only an unspecific, slightly astringent taste at high taste threshold concentrations. But as other kokumi substances, they modify the five basic tastes (especially sweet, salty and umami tastes), in particular, when added in a small amount to an umami solution or foods containing savory compounds such as sodium chloride and L-glutamic acid, they can substantially enhance the thickness, continuity, complexity, mouthfulness and palate length of the food. The important structural elements for  $\gamma$ -glutamyl peptides with a high CaSR activity have been proposed i.e. the presence of an N-terminal  $\gamma$ -L-glutamyl

residue, a moderately sized, aliphatic, neutral substituent of L-configuration at the second residue, and a C-terminal carboxylic acid, preferably with glycine occurring as the third constituent (Amino et al., 2016).

$\gamma$ -[Glu]<sub>(1 ≤ n ≤ 5)</sub>-Phe peptides were reported to exhibit astringency in water but kokumi properties in commercial soy sauce and model chicken broth (Yang et al., 2017). In detail,  $\gamma$ -[Glu]<sub>n</sub>-Phe in water (5 mM, pH 6.5) was astringent, with the threshold concentrations corresponding to n = 1, 2, 3, 4 and 5 as 2.5, 3.34, 3.58, 3.69 and 3.92 mM, respectively. However, when these  $\gamma$ -[Glu]<sub>n</sub>-Phe products were added at 2 mM separately to commercial soy sauce, enhanced continuity and umami taste were detected (p < 0.05), and all these fortified commercial soy sauce systems had a long-lasting taste and mouthfeel similar to that of an umami solution involving the peptide-associated Maillard reaction (Liu et al., 2015; Ogasawara et al., 2006). The kokumi-imparting properties of  $\gamma$ -[Glu]<sub>(1 ≤ n ≤ 5)</sub>-Phe peptides were also found in a model chicken broth (at 2 mM). The threshold concentrations in the commercial soy sauce and model chicken broth were all in the range of 0.78–1.42 mM. Interestingly,  $\gamma$ -[Glu]<sub>(n > 1)</sub>-Phe compounds (n > 1) had similar sensory characteristics to that of  $\gamma$ -Glu-Phe (n = 1), even though the taste-enhancing scores of  $\gamma$ -[Glu]<sub>(n > 1)</sub>-Phe were slightly lower than that of  $\gamma$ -Glu-Phe. The taste score in water and the taste-enhancing scores in commercial soy sauce and model chicken broth all decreased progressively with an increasing number of  $\gamma$ -glutamyl residues. The taste effect of the  $\gamma$ -[Glu]<sub>n</sub>-Phe would become weaker with an increased molecular weight. Similar findings were found with other  $\gamma$ -glutamyl peptides such as  $\gamma$ -Glu-Val-Gly and  $\gamma$ -Glu-Cys-Gly,  $\gamma$ -Glu-Cys- $\beta$ -Ala,  $\gamma$ -Glu-Leu, and  $\gamma$ -Glu-Val (Ueda et al., 1997; Ohsu et al., 2010; Miyaki et al., 2015).

## Conclusion

Microbial L-glutaminases hold the promise of catalyzing the production of  $\gamma$ -glutamyl peptides as bioactive flavor enhancers. Their potential as the biocatalyst for in situ taste improvement of foods with processing-induced bitter peptides or amino acids would enhance their applications in the food industry. Further, different species of glutaminases exhibit their distinct catalytic behaviors and lead to different profiles of  $\gamma$ -glutamyl peptides. For a specific type of  $\gamma$ -glutamyl peptide targets, one glutaminase may be superior to the other(s) owing to the intrinsic properties of the enzyme.

GBA, GAO and GPN all possess transpeptidase activity and thus can be used to yield specific  $\gamma$ -glutamyl peptides by altering substrates and optimizing reaction conditions. For the synthesis of Phe-containing  $\gamma$ -glutamyl peptides through transpeptidation using the same Gln and Phe as substrates, GBA was more suitable than GAO based on their K<sub>m</sub> values for the transpeptidation reaction. Under the same reaction conditions, the use of GAO or GBA would lead to different species of  $\gamma$ -[Glu]<sub>n</sub>-Phe at varied concentrations:  $\gamma$ -Glu-Phe and  $\gamma$ -Glu- $\gamma$ -Glu-Phe for GAO, and  $\gamma$ -Glu-Phe,  $\gamma$ -Glu- $\gamma$ -Glu-Phe,  $\gamma$ -Glu- $\gamma$ -Glu- $\gamma$ -Glu-Phe,  $\gamma$ -Glu- $\gamma$ -Glu- $\gamma$ -Glu-Phe,  $\gamma$ -Glu- $\gamma$ -Glu- $\gamma$ -Glu- $\gamma$ -Glu-Phe for GBA. These exciting findings encourage future research toward the discovery and development of novel glutaminases including those salt- and thermo-tolerant species for a broad spectrum of food applications.

## Introduction

Tannins are plant secondary metabolites, and believed to play a role in plant defense against bacteria, fungi, pests and herbivores. There are two main classes of tannins, hydrolysable tannins and non-hydrolysable tannins (condensed tannins). Condensed tannins are also called proanthocyanidins, and are oligomers and polymers of flavan-3-ols. They have a wide variety of structure arising from the presence of several constitutive units and linkage positions, substitution, especially with galloyl groups, and varying degrees of polymerization. Proanthocyanidins are the major group of tannins in foods and beverages, and are particularly abundant in fruits such as blackthorn chokecherry, bird cherry, quince and persimmon fruits and in beverages such as tea and wine. Tannins play an important role in the perception of plant-based foods and beverages. In those foods, tannins induce a complex sensation, called astringency.

## The Proposed Molecular Mechanisms for the Origin of Astringency

Astringency is a trigeminal sensation, described as a drying-out, roughening, and puckering sensation felt in the mouth. It is generally described as a tactile sensation. Tannins have also the ability to bind to and precipitate proteins. Therefore, astringency is thought to result from the interaction between tannins and salivary proteins. Astringency and the affinity of tannins for proteins depend on the structural features of tannins and increase with chain length and degree of galloylation (Canon et al., 2010; Poncet-Legrand et al., 2006; Sarni-Manchado et al., 2002).

However, the molecular mechanisms for the origin of astringency are still not fully understood. Two main hypotheses have been proposed to explain the mechanical origin of astringency. One postulates that the precipitation of salivary proteins, in particular of PRPs, by tannins reduces the lubricating properties of saliva, leading to the perception of an increase of oral friction. The second hypothesis proposes that tannins reduce the lubricating properties of the mucosal pellicle, a thin layer of salivary proteins covering the oral epithelium, leading to an increase of the friction forces at the surface of the oral mucosa. In this hypothesis, PRPs play a role in the protection of the mucosal pellicle *via* their ability to bind tannins (Gibbins and Carpenter, 2013). It is supported by the increase of perceived astringency of tea after removal of saliva (Nayak and Carpenter, 2008). Moreover, recent results, obtained in a model of oral mucosa, have shown that tannins can aggregate the mucosal pellicle. The size of the aggregates depended on the structure of the tannin, while their formation was precluded by the presence the basic PRP (*bPRP*), IB5 (Ployon et al., 2018). In parallel, measurements on the surface of the oral mucosa have revealed an increase of the friction force after the aggregation of the mucosal pellicle (Ployon et al., 2018). A two-stage mechanism, involving adsorption of tannins on the mouth epithelium as the salivary proteins become depleted, has been proposed (Guinard et al., 1986). In these two hypotheses, PRPs appear as major actors in the astringency sensation. Therefore, interactions between PRPs and tannins are of particular interest to understand the molecular bases of astringency sensation.

## The Interactions Between PRPs and Tannins

### Three Different Stages of PRP-Tannin Interactions

The secretion of PRP, and especially of basic PRPs (*bPRPs*), whose known function is to bind tannins, is likely the first line of defense for herbivores against dietary tannins. For instance, in rats and mice, a tannin-rich diet induces the secretion of PRPs in their saliva (Mehansho and Carlson, 1983; Mehansho et al., 1985), allowing their survival. Moreover, PRPs are particularly prone to the interaction with tannins (Hagerman and Butler, 1981). The high affinity of PRPs for tannins is attributed to their particular structure. PRPs do not fold into a well-defined three-dimensional structure but show extended random coil conformations (Boze et al., 2010), except for small polyproline helix segments. They belong to the family of intrinsically disordered proteins (IDPs), which defy the classical structure-function paradigm (Tompa, 2006). The most widely accepted model of PRP-tannin interactions is composed of three different stages as the tannin concentration increases: (i) tannins, which are multidentate ligands, bind to several sites on the free protein, (ii) the stoichiometries of the complexes increase and tannins cross-link different protein molecules, (iii) the resulting multimeric aggregates grow until precipitation (Canon et al., 2013b).

### Interactions of Human Salivary PRPs, IB5 or IB9<sub>37</sub>, With Three Different Tannins

A human salivary PRP, named IB5, and its interactions with tannins have been particularly studied. IB5 is a small bPRP of 73 residues. Its sequence contains 8 clusters of 2–5 proline residues and presents 5 tandem repeats of KPQGPP(P) (Fig. 1A). Small angle X-ray scattering (SAXS) (Boze et al., 2010), circular dichroism (CD) (Canon et al., 2011), nuclear magnetic resonance (NMR) (Pascal et al., 2009), and mass spectrometry (MS) (Canon et al., 2009) experiments have shown that IB5 has a random coil structure and undergoes transition from disorder to order upon the interaction with epigallocatechin gallate (EGCG) (Canon et al., 2011). The study of a smaller truncated PRP, IB9<sub>37</sub>, has also shown that structural rearrangements of the peptide chain occur during its binding to tannins. Charlton et al. (1996) were the first to propose that the peptide chain of PRPs may wrap around the tannin, in order to explain that IB9<sub>37</sub> and IB5 have a higher affinity for tannin than a peptide composed of a single proline-rich repeat (Charlton et al., 1996).

MS experiments have also revealed that the interaction between IB5 and EGCG could lead to the appearance of soluble non-covalent complexes with several stoichiometries (Canon et al., 2009). A multitechnique approach based on SAXS and MS demonstrated that at least three molecules of EGCG per protein are required to form PRP-EGCG aggregates (Canon et al., 2013b), a result in agreement with previous results obtained by NMR (Charlton et al., 2002). Comparison of different tannins showed that the stability of the non-covalent complexes depends on the number of tannin hydroxyl groups. This observation suggests that PRP-tannin interactions involve hydrogen bonds. Specific hydrophilic interactions between two proline-rich peptides (IB7<sub>14</sub> and IB9<sub>37</sub>) and tannins were also observed using NMR (Cala et al., 2012; Cala et al., 2010b). Fragmentation and titration experiments suggested the presence of 8 binding sites on IB5, corresponding to the number of proline clusters. NMR confirmed the involvement of proline residues in the interactions between IB5 or proline-rich peptides and tannins. However, the precise binding site of tannins could not be determined. The absence of a well-defined structure, the numerous repeated sequences and the coexistence in solution of numerous supramolecular edifices with different stoichiometries, make that the structural study of PRP-tannin interactions represents a challenge for classical techniques of structural biology, such as crystallography or NMR. In order to determine the binding site of tannins, we introduce a new technique of ion fragmentation based on the coupling of MS and synchrotron radiation. We applied this technique to the study of the interaction between IB5 and B2 3'-OG (epicatechin-(4b-8)-epicatechin-3-O-gallate). It generates numerous fragments of the protein, while preserving the non-covalent interaction between IB5 fragments and B2 3'-OG. The comparison of the two patterns of fragmentation (i.e. IB5 alone Vs IB5·B2 3'-OG), allowed to identify the fragments of sequence binding to B2 3'-OG and thus to determine its binding site onto IB5. The segment 'KPQGPPPPQGG' of the IB5 sequence constitutes the binding site. It contains a larger cluster of proline present into IB5 structure. In the cases of IB7<sub>14</sub> and IB9<sub>37</sub>, all tannin dimers and trimers tested bound to the same three binding sites, corresponding to PP (Pro-Pro) and GG (Gly-Gly) clusters, but with different strengths. Tannins having extended conformation and longer chain length showed a higher binding force.

Regarding these different observations, it seems important to know if, as for shorter IB9<sub>37</sub>, tannins with different structures bind onto the same site on IB5. Therefore, we recently apply the new methods of MS fragmentation using vacuum-ultraviolet (VUV) to localize the binding site of two others tannins: a monomer, EGCG, and another dimer, B2 ((epicatechin-4b-8)-epicatechin) (Canon et al., 2015). Fig. 1B presents the structure of the different tannins.

MS spectra of the mixtures containing IB5 and one of the three tannins, show ions with several charge states corresponding to the free IB5 and to the IB5·*n*Tannins non-covalent complexes with different stoichiometries. Ions corresponding to [IB5·1Tannin+7H]<sup>7+</sup> were then selected and activated by synchrotron radiation at 16 eV.

**Figure 1** (A) Sequence of the IB5 human salivary protein (B) Molecular structures of the epigallocatechin gallate (EGCG) (epicatechin-4b-8)-epicatechin (B2) and epicatechin-(4b-8)-epicatechin-3-O-gallate (B2 3'OG).

**Figure 2** (B) Dissociative photoionization (DPI) tandem mass spectra at 16 eV of the selected precursors  $[(\text{IB5} \cdot \text{tannin}) + 7\text{H}]^{7+}$ .

Fig. 2 presents the resulted mass spectra, in which are present the precursor ions, the  $[\text{M} + 7\text{H}]^{8+ \bullet}$  radical cation and fragment ions. The radical cation was produced upon the photoionization of the precursor ions. Activation at photon energies above the ionization threshold generated fragments through dissociative photoionization (DPI), with abundant formation of sequence ions of various natures (Giuliani et al., 2014). This regime of fragmentation has been previously reported to provide a higher sequence coverage than other techniques of activation, such as collision induced dissociation, electron capture dissociation or photodissociation (Canon et al., 2013a). Comparison of the 16 eV DPI MS/MS spectra of  $[\text{IB5} \cdot \text{1Tannin} + 7\text{H}]^{7+}$  with that of the bare protein ( $[\text{IB5} + 7\text{H}]^{7+}$ ) revealed the appearance of new fragments while others were not present anymore. The new ions correspond to the fragments of the peptide chain linked to the tannins, while ions of the corresponding bare fragments were not present anymore. Fig. 3 presents the fragments identified for the fragmentation of the bare proteins and of those linked to tannins for the fragmentation of the different non-covalent complexes. Analysis of all fragments linked to the tannins allowed to establish a map of the protein sequence containing the binding site of each tannin. Comparison of the different maps revealed that all tannins were bound to the following sequence 'QPQAPPAGKPQGPPPPQGG'.

This indicates that, as for the interaction with proline-rich peptides, tannins bound onto the same binding site. This sequence contains two clusters of proline and one of them is the longest cluster of proline into IB5 sequence. This part of the protein probably folds into a PPI (Pro–Pro I) or a PPII (Pro–Pro II) helix in solution (Simon et al., 2003). It probably provides a rigid section that facilitates the initiation of the binding. Indeed, it has been proposed that preformed structural element could facilitate the binding of intrinsically unstructured proteins (IUPs; also called intrinsically disordered proteins, IDPs) with their partners (Fuxreiter et al., 2004). This segmented is located between two clusters of glycine and alanine residues, which form flexible hinges allowing the establishment of additional hydrogen bonds (Chatterjee et al., 2005). These observations allows to propose a model of the interaction between PRP and tannins, in which clusters of proline form rigid regions, providing anchoring points to initiate the binding. Moreover, the carbonyl functional group in tertiary amides of proline residues is a more effective hydrogen bond acceptor than that in primary and secondary amides (Haslam, 1993). Flexible regions allowing the reeling of the peptide chain and the establishment of additional contact points for linking to these anchoring sections. This model is in agreement with the results obtained based on

**Figure 3** Fragmentation patterns of IB5 alone (A) and in association with B2 3'OG, B2 and EGCG (B). The binding sites identified for the tannins on the backbone are indicated by a box.

ion mobility indicating that a transition from extended to compact structures may occur (Canon et al., 2011), which also agrees with earlier findings obtained by NMR and circular dichroism (Pascal et al., 2009). Furthermore, molecular modeling of the interaction between IB9<sub>39</sub> and tannins indicates structural rearrangements of the peptide backbone (Cala et al., 2012). Such structural rearrangements do not seem to occur to shorter proline-rich peptides (Cala et al., 2010a; Simon et al., 2003). The model and associated observations may explain that the full PRP, IB5, has a higher affinity for tannins than a proline-rich peptide (Charlton et al., 1996). Interestingly, this model of the interaction involving preformed structural elements that initiate the binding and are linked by flexible hinges, which allow the establishment of additional interaction points, is rather common in the binding of IDP with their partners (Fuxreiter et al., 2004). Such a mode of interaction allows IDPs to bind to different partners and seems appropriate to the tannin-scavenging function of bPRPs, which have to adapt to a large variety of tannin structures.

## Conclusions

bPRPs are believed to be the first line of defense of mammals toward dietary tannins, as they are only present in the saliva of mammals for consuming tannins and their only known function is to bind tannins. To fulfill this function, PRPs have to adapt to a wide variety of structures exhibited by tannins. The present results indicate that two dimers (B2 and B2 3'OG) and one monomer (EGCG) bind to the preformed polyproline helix that forms a rigid contact point for initiating the binding. At the same time, the surrounding flexible hinges allow the structural transition and the establishment of additional hydrogen bonds. Thus, PRPs are likely to wrap around tannins, explaining that their interaction with tannins is stronger than the one of small proline rich-peptides. It should allow PRP to scavenge tannins more efficiently in order to protect the organism against their antinutritional effect, as well as the mucosal from aggregation. As astringency is thought to be triggered by the aggregation of the mucosal pellicle, it is likely that the presence of bPRPs in saliva precludes this sensation when tannin concentration is low. When tannin concentration is high and

that at least three tannins per protein are bound, aggregates are formed and grow in size with tannin concentration up to their precipitation. After PRP depletion, the mucosal pellicle is not anymore protected toward tannins leading to its aggregation, and subsequent increase of the friction and perception of astringency.

## Introduction

In living plants, polyphenols, secondary metabolites, and macromolecules such as proteins and polysaccharides are usually compartmentally separated. During food and beverage processing, the plant cells de-compartmentalize under shearing and thermal forces. Polyphenols are released from vacuoles and bind to proteins and polysaccharides, notably those of the cell walls, and can also be oxidized by polyphenoloxidase (PPO). Various phenomena occur such as adsorption, oxidation, solubilization, and migration, leading to the emergence of new structures and new biological functions during processing, resulting from the establishment of physical and chemical associations. They will have an impact on technological, organoleptic and nutritional qualities of foods.

The polyphenols most involved in interactions with macromolecules are the tannins. The term 'tannin' has been employed classically to designate the molecule of plant origin capable of transforming fresh hide into leather. Tannins are widely widespread in plant and plant-based foods, in particular in fruits and vegetables, and derived beverages such as wine, tea, cocoa, beer and cider (Scalbert and Williamson, 2000). The term tannin includes two families of compounds: hydrolysable tannins and condensed tannins. Hydrolysable tannins consist of simple phenolic acids such as gallic acid (gallotannins) or hexahydroxydiphenic acid (ellagitannins) esterified to polyols, typically glucose (Fig. 1A and B).

Condensed tannins, also known as proanthocyanidins, are polymers and oligomers of flavan-3-ol units. Proanthocyanidins may differ by the nature of the constitutive units, by their mean degree of polymerization (mDP) which is the number average of constitutive units (varying between 2 and more than 100), and by the type of linkage (Cheynier, 2005; Fig. 2). They are divided into several classes based on hydroxylation of the constitutive units and the nature of the linkages. Their most common constitutive units are (epi)-catechins and (epi)-gallocatechins, leading to procyanidin and prodelphinidin structures, respectively. Flavan-3-ol subunits are most frequently linked through B-type bonds, that is, C4–C8 or C4–C6 interflavanic linkages. A-type proanthocyanidins are linked by an additional C2–O–C7 or C2–O–C7 ether bond producing doubly bonded proanthocyanidins.

Tannins are widely studied due to their health benefits that are ascribed to their ability to act as antioxidants (Hagerman et al., 1998). Tannins may exert their positive health effects either due to their antioxidant activity within the gastrointestinal tract producing local effects or due to bioactivity of their absorbable metabolites from colonic fermentation that may produce systemic effects in various organs (Serrano et al., 2009). Tannins contribute also to the organoleptic properties of plant-based foods, especially by their astringency, bitter taste, color, and by their participation to haze formation of various food products (Le Bourvellec and Renard, 2012).

Tannins interact with macromolecules either by non-covalent bonds, primarily driven by hydrogen bonding and hydrophobic interactions, or by covalent binding after polyphenol activation either by oxidation, i.e. as quinones, or as carbocations, resulting from proanthocyanidin cleavage under hot acidic conditions (Beart et al., 1985). Tannin macromolecule interactions has been the subject of many reviews in recent years (Zhu, 2017; Renard et al., 2017; Jakobek, 2015; Bordenave et al., 2014; Le Bourvellec and Renard, 2012; Hanlin et al., 2010). These reviews conclude that these interactions are dependent on both the structural characteristics of tannins and the physical properties and chemical composition of macromolecules, as well as the experimental and environmental conditions. In this context, we aim to synthesize the state of the science on the impact of tannin structures, i.e. molecular weight, constitutive units, substitution especially with galloyl groups, interflavanic bonds, conformation and flexibility, hydrophobicity on their interactions with macromolecules.

## Proanthocyanidins

### Molecular Weight

In general, increasing the molecular weight of proanthocyanidins increases the binding between macromolecules, i.e. proteins and polysaccharides, and proanthocyanidins (Girard et al., 2018; Ropiak et al., 2017; Ma et al., 2016; Barros et al., 2014; White et al., 2011; Cala et al., 2010a; Bindon et al., 2010; Bautista-Ortin et al., 2014; Le Bourvellec et al., 2004b, 2005; de Freitas and Mateus, 2001; Renard et al., 2001).

The NMR data and molecular modeling of wine proanthocyanidins binding further show that proanthocyanidin trimer (C2) exhibits a greater affinity to salivary peptide IB7 than four proanthocyanidin dimers (B1-4) (Cala et al., 2010a). Nephelometric and turbidimetric studies on glutenins, gliadins, BSA and gelatin also show that aggregation increases with increasing degree of polymerization (Girard et al., 2018; Ropiak et al., 2017). By Isothermal Titration Calorimetry (ITC) Kilmister et al. (2016) show that the calculated change in enthalpy ( $\Delta H$ ) and association constant ( $K_a$ ) between BSA and proanthocyanidin oligomers increase as the oligomer size increase. A positive relationship between the degree of polymerization of proanthocyanidins and salivary protein affinity is also revealed by Ma et al. (2016).

**Figure 1** Structure of the  $\beta$ -penta-O-galloyl-D-glucose (A) and of vascalagin (B).

**Figure 2** Structure of B-type.

Proanthocyanidins with higher degree of polymerization are also selectively adsorbed by cell-wall from various origins (Renard et al., 2001; Le Bourvellec et al., 2004b; Bindon et al., 2010; Bautista-Ortin et al., 2015), and by cell wall polysaccharides such as pectins (White et al., 2011), xyloglucans (Le Bourvellec et al., 2005) or cellulose (Le Bourvellec et al., 2005), and starch (Barros et al., 2014; Le Bourvellec et al., 2005), with the proanthocyanidins remaining in solution being low molecular weight polymers. Molecular weight of the proanthocyanidins also directly affect their binding to starch: the higher the molecular weight, the stronger the binding to amylose and the higher the resistant starch formation (Barros et al., 2014). An exception to the grape cell wall selective binding of large-size proanthocyanidins has been found for very large molecular mass proanthocyanidins (>15,000 g/mol) from skin of red grapes, which appear to be excluded from bindings when cell-wall porosity is low (Bindon et al., 2010).

Associations between proanthocyanidins and macromolecules, i.e. proteins and polysaccharides can be related to a tanning effect. This tanning effect is a function of both the presence of functional groups, i.e. hydroxyl groups and aromatic rings, able to form hydrogen bonds and hydrophobic interactions, and of the molecular weights, i.e. the size of the tannin (McManus et al., 1985). Therefore, larger proanthocyanidin molecules have more binding sites for the associations as they act as multidentate ligands able to bind simultaneously to more than one site of the macromolecule.

## Constitutive Units

### B-Ring Hydroxylation Pattern and Stereochemistry of the Proanthocyanidin Subunits

With regards to the B-ring substitution pattern proanthocyanidins could be divided in two groups: procyanidins, formed via the condensation of the flavan-3-ols catechin and epicatechin, are dihydroxylated, while prodelphinidins, formed via the condensation of the flavan-3-ols gallocatechin and epigallocatechin, are trihydroxylated. Catechin and gallocatechin are *cis*-flavan-3-ols whereas epicatechin and epigallocatechin are *trans*-flavan-3-ols.

Increasing the hydroxylation pattern of proanthocyanidins, i.e. from procyanidins to prodelphinidins, increases their ability to bind proteins (Helsper et al., 1993; Aerts et al., 1999). The dimer gallocatechin-C4-C8-epigallocatechin inhibits trypsin activity three times as much as the dimer catechin-C4-C8-epicatechin (Helsper et al., 1993). Moreover, increasing the prodelphinidins/procyanidins ratio, with concomitant increase of B the ring hydroxylation and of the molecular weight increases their capacity to complex with proteins (Aerts et al., 1999). Prodelphinidins have one more hydroxyl group than procyanidins and form more hydrogen bonds with proteins, increasing the strength of the interactions.

Trypsin inhibition activity of procyanidin dimers ranks in the order B2 > B4 > B3 (Helsper et al., 1993). NMR binding studies of four different procyanidin 4–8 dimers and the human saliva protein fragment IB7 also demonstrate that affinities are ranked: B2 > B4 > B1 > B3. The tendency to procyanidins diastereoisomers to adopt the extended versus the compact rotamer determines their relative binding affinities to IB7 in aqueous solution (Cala et al., 2010a,b). The extended conformation must facilitate the approach or/and the binding of the proanthocyanidin to the peptide: the more the extended conformation is preferred, the higher the affinity towards the peptide is. However, Bohin et al. (2012) and de Freitas and Mateus (2001) show that procyanidin B1 displays a better affinity for  $\beta$ -casein and salivary proline-rich proteins than procyanidin B2. Moreover, using a diverse panel of proanthocyanidins Ropiak et al. (2017) find no significant correlation between the procyanidin/prodelphinidin and *cis/trans*-flavan-3-ol ratios and BSA aggregation determined by turbidimetry. Besides, BSA tryptophan fluorescence quenching is positively correlated with procyanidin and *cis*-flavan-3-ols whereas BSA secondary structure is positively correlated with prodelphinidins (Ropiak et al., 2017). Hence, the effect of procyanidin monomer composition and conformation on their binding affinity for proteins might also be protein-dependent and method-dependent.

Cell wall material from grape flesh binds up to 47% and 57% w/w of total seed and skin proanthocyanidins respectively (Bindon et al., 2010). Both prodelphinidins and procyanidins are present in grape skins, whereas only procyanidins are present in seed. However, due to the complexity of skin and seed extracts (skin proanthocyanidins have a mDP of 17 and a percentage of trihydroxylation of 25 whereas seed procyanidins have a mDP of 7 and a percentage of galloylation of 17) it is not possible to conclude on the effect of the hydroxylation pattern (Bindon et al., 2010).

The stereochemistry of flavan-3-ol units also influence proanthocyanidin interactions with cell wall polysaccharides. Thus, proanthocyanidins comprising catechin as extension units have higher affinity to cell wall polysaccharides than proanthocyanidins composed mainly of epicatechin. A polymer composed of catechin forms a right-hand helix, whereas epicatechin forms a left-hand helix (Fletcher et al., 1976). The presence of catechin within the proanthocyanidin molecule may form a kink in the polymer increasing the number of reactive sites that are exposed on the outer side a helical conformation. Interactions with cellwalls are modulated by flavan-3-ol subunit composition: the presence of catechin leads to changes in proanthocyanidins conformation, with a more open and flexible conformation that may facilitate the formation of hydrogen bonds and hydrophobic interactions (Le Bourvellec et al., 2004b).

### Galloylation

The addition of ester-bonded gallic acid to proanthocyanidins plays a significant role in their macromolecules binding capacity (Soares et al., 2018; Bindon et al., 2010; Soares et al., 2007; Poncet-Legrand et al., 2006; Le Bourvellec et al., 2004b; de Freitas and Mateus, 2001; Sarni-Manchado et al., 1999; Ricardo da Silva et al., 1991).

Increasing the degree of galloylation of proanthocyanidins increases their ability to precipitate proteins (Soares et al., 2007, 2018; Poncet-Legrand et al., 2006; de Freitas and Mateus, 2001; Sarni-Manchado et al., 1999; Ricardo da Silva et al., 1991). The results of ITC and saturation transfer difference NMR indicate that the association constant ( $K_a$ ) between salivary proline-rich protein is higher for procyanidin B2 3'-O-gallate than for procyanidin B2 (Soares et al., 2018). Affinity of galloylated condensed dimers and trimers for proline-rich proteins is greater than that of ungalloylated analogues (Ricardo da Silva et al., 1991).

Proanthocyanidins with higher degree of galloylation are selectively adsorbed by apple and grape cell walls (Bindon et al., 2010; Le Bourvellec et al., 2004b). However, for grape cell walls, gel permeation chromatography has shown that the role of proanthocyanidins galloylation can be explained by the variation in size of galloylated material, as opposed to specific selectivity of cell wall galloylated proanthocyanidins (Bindon et al., 2010).

Three factors may explained the increased affinity observed for galloylated proanthocyanidins:

- 1) increased number of sites to form hydrogen bonds and hydrophobic interactions between proanthocyanidins and macromolecules;
- 2) increased hydrophobic character of proanthocyanidins as demonstrated by measuring the partition coefficients of monomeric and oligomeric flavan-3-ols between *n*-butanol and water (Plumb et al., 1998) which favors binding to macromolecules (Le Bourvellec and Renard, 2012);
- 3) greater structural flexibility to proanthocyanidins facilitating their binding to macromolecules.

## Interflavanic Bonds

### C4–C8 vs C4–C6

B-type proanthocyanidin subunits are mainly linked by two kinds of interflavanic bond, C4–C8 or C4–C6.

Procyanidin dimers linked through a C4–C8 interflavanic bond, such as procyanidin B3, have greater tannin specific activity for proline-rich proteins than their counterpart with a C4–C6 interflavanic bond, procyanidin B5 (de Freitas and Mateus, 2001), suggesting that the C4–C8 linkage promotes a more open configuration. However, Ricardo da Silva et al. (1991) find the opposite, i.e. proanthocyanidin dimers linked through a C4–C6 linkage bind more strongly with proteins than dimeric proanthocyanidins with a C4–C8 linkage. Santos Silva et al. (2017) confirm this result showing that procyanidin B6 (C4–C6 linkage) has a greater affinity for salivary proteins than procyanidin B3 (C4–C8 linkage). Discrepancies observed could be due to proanthocyanidin configuration and/or proteins used. However, further investigation concerning to interflavanic linkage is required.

To our knowledge no data are available in the literature concerning the impact of proanthocyanidins C4–C8 or C4–C6 interflavanic linkage on their binding with cell walls or polysaccharides.

### B-type vs A-type

Proanthocyanidins can be differentiated into B-type or A-type depending on their interflavanic linkages, the latter differing from the former by at least one double linkage consisting of a C–C bond and an additional ether bond (Fig. 2A and B).

Proanthocyanidin A2 has a higher trypsin inhibitor activity than proanthocyanidin B2 (Helsper et al., 1993). Proanthocyanidin A1 displays a higher affinity for  $\alpha$ -casein than proanthocyanidin B1 (Bohin et al., 2012). Cranberry proanthocyanidins, which are A-type, inhibit  $\alpha$ -amylase more strongly than grape proanthocyanidins which are B-type (Barret et al., 2013). The effect of the additional ether bond could be attributed to their higher hydrophobicity (McRae et al., 2010). However, cranberry proanthocyanidins have also a higher degree of polymerization than grape proanthocyanidins. A synergy between size and structural complexity could explain the results obtained.

Only indirect evidence supports the existence of interactions between A-type proanthocyanidins and the cell walls (White et al., 2011). To our knowledge, no study of the impact of the structure of A-type proanthocyanidins on their interaction with cell walls is available in the literature.

## Proanthocyanidin Oxidation

Proanthocyanidins are not substrates of PPO (Le Bourvellec et al., 2004a; Goodenough and Lea, 1979), but they can be oxidized by a coupled oxidation/reduction reaction involving primary *o*-quinones formed by PPO catalysis (Cheynier and Ricardo da Silva, 1991). Proanthocyanidins oxidation leads to both intra and intermolecular reactions. Intramolecular reaction results in the formation of new covalent bonds such as A-type linkages, reducing the proportion of acid-labile interflavanic bonds, thus limiting the configurational freedom of the macromolecules. Intermolecular reaction creates large macromolecules as evidenced by increased weight average degree of polymerization (Mouls and Fulcrand, 2012; Poncet-Legrand et al., 2010).

Oxidation of proanthocyanidins doubles their capacity to inhibit polyphenol oxidase (Le Bourvellec et al., 2004a). This effect could be due to the higher degree of polymerization of oxidized proanthocyanidins and to the presence A-type interflavanic bond inducing a higher hydrophobicity. However, ITC investigation of the interactions between poly-L-proline and grape or aged wine tannins, i.e. oxidized tannins, reveals that aged wine tannins have a lower protein affinity compared to grape tannins. The compact conformation of aged wine tannins may have limited their capacity to bind the poly-L-proline and the overall proanthocyanidin structure may be more important than hydrophobicity (McRae et al., 2010). Further investigation concerning oxidation effect is required by using well defined proanthocyanidins, because degrees of polymerisation, A-type linkages, and degree of molecular flexibility could explain the discrepancies observed. Moreover, initial concentration and degree of polymerization influence behaviour of proanthocyanidins upon oxidation: branched versus linear polymers are obtained, which have differences in their flexibility and hydrophobicity (Vernhet et al., 2014).

Oxidation of proanthocyanidins also increases their binding with cell walls (Le Bourvellec et al., 2009; Bautista-Ortin et al., 2014). The oxidation effect could be related to the increase of the degree of polymerization of proanthocyanidins as larger proanthocyanidins have more potential binding sites for the interactions.

## Hydrolyzable Tannins

### Tannin Molecular Weight

Like proanthocyanidins, it is generally accepted that hydrolyzable tannins with a higher molecular weight bind more strongly to macromolecules (Shimozu et al., 2017; Dobrev et al., 2014; Tang et al., 2003; Beart et al., 1985; McManus et al., 1985).

The size exclusion chromatography and polyacrylamide gel electrophoresis data show that isorugosin ellagitannin dimers exhibit a greater affinity for BSA than the monomer (Shimozu et al., 2017). ITC analysis confirms that for each ellagitannin monomer-dimer pair tested (vascalagin vs roburin A; pedunculagin vs oenothien B and pentagalloyl glucose vs gemin A) the dimer binds more strongly than the monomer (Dobrev et al., 2014).

Using thin layer chromatography [Tang et al. \(2003\)](#) show that the affinity of ellagitannins and gallotannins for cellulose is positively correlated with their molecular mass.

### Galloylation

Increasing the degree of galloylation of hydrolyzable tannin also increases their ability to bind macromolecules ([Tang et al., 2003](#); [Beart et al., 1985](#); [McManus et al., 1985](#)).

In the simple galloyl-D-glucose series, increasing the number of galloyl ester groups increases the protein binding capacity ([Tang et al., 2003](#); [Beart et al., 1985](#); [McManus et al., 1985](#)). This is attributed to an increase both of the number of hydroxyl group and aromatic ring able to interact with the protein.

[Tang et al. \(2003\)](#) also show that the affinity of ellagitannin and gallotannins for cellulose is positively correlated with the number of galloyl groups.

### Conformational Mobility and Flexibility

The flexibility of hydrolyzable tannin molecule is an important factor as well. Structurally flexible hydrolysable tannins bind more strongly to macromolecules than the more rigid molecules ([Karonen et al., 2015](#); [Deaville et al., 2007](#); [Hofmann et al., 2006](#); [Richard et al., 2006](#); [Frazier et al., 2003](#); [Tang et al., 2003](#)).

Vascalagin and castalagin bind much less effectively to proteins than their structural analogue  $\beta$ -penta-O-galloyl-D-glucose ([Beart et al., 1985](#); [McManus et al., 1985](#); [Hofmann et al., 2006](#); [Richard et al., 2006](#); [Tang et al., 2003](#)). Moreover, [Frazier et al. \(2003\)](#) show that tara gallotannins have a stronger affinity for BSA than myrabolan gallo- and ellagitannins. [Deaville et al. \(2007\)](#) and [Tang et al. \(2003\)](#) also observe that gallotannins have a stronger affinity for BSA and collagen than ellagitannins. Gallotannins are flexible and can easily change their conformation by intramolecular rotations whereas introduction of intergalloyl covalent linkages in the ellagitannins limits their capacity for conformational change, thus lowering their protein affinity. Using a series of oligomeric ellagitannins, [Karonen et al. \(2015\)](#) show by ITC that the binding constant of the monomer ( $K_a = 1.8 \times 10^4 \text{ M}^{-1}$ ) was higher than those for the dimer ( $K_a = 5.7 \times 10^3 \text{ M}^{-1}$ ) and trimer ( $K_a = 7.6 \times 10^3 \text{ M}^{-1}$ ) and similar to those for hexameric and heptameric ellagitannins ( $K_a = 1.7 \times 10^4 \text{ M}^{-1}$ ), thus the monomer to the trimer deviated from the overall trends. The differences observed are due first to the presence of an additional free galloyl group in the monomer and to the loss in the dimer structure of conformational flexibility and freedom, which affects its ability to bind to protein. Thus, hydrolysable tannins galloylation and flexibility may act in synergy in this case.

Ellagitannins show also much weaker interactions with cellulose than gallotannins having similar molecular mass, the same number of galloyl groups, and the same number of hydroxyl groups ([Tang et al., 2003](#)). Thus, interactions between hydrolyzable tannin and cellulose are also strongly dependent on the flexibility of galloyl groups, and the conformational restriction of ellagitannins limits their interactions with cellulose.

### Hydrophobicity

An inverse relationship is found between the strength of association with macromolecules and the solubility in water of hydrolyzable tannins ([Santos Silva et al., 2017](#); [Dobreva et al., 2014](#); [Tang et al., 2003](#)).

Vascalagin which is more hydrophilic than its stereoisomer castalagin has a lower affinity to salivary proteins ([Santos Silva et al., 2017](#)). [Dobreva et al. \(2014\)](#) also show using ITC that the more hydrophobic ellagitannins bind more strongly to BSA. Moreover, by evaluating the hydrothermal stability of sheepskin collagen treated with hydrolyzable tannins [Tang et al. \(2003\)](#) have shown that the hydrothermal stability of collagen is increases after polyphenol treatment and such effects are also positively correlated with the hydrophobicity of hydrolyzable tannins.

The strength of interaction between ellagitannins and gallotannins and cellulose is also positively correlated with hydrolysable tannin hydrophobicity ([Tang et al., 2003](#)).

### Conclusions

Some key structural characteristics namely molecular weight, the presence of galloyl groups, the conformation and the hydrophobicity that influence the ability of both proanthocyanidins and hydrolyzable tannins to interact with macromolecules are commune. However, some of structural characteristics are specific to each phenolic class:

- for proanthocyanidins: B vs A-type linkages, C4–C8 vs C4–C6;
- for hydrolysable tannin: gallotannins vs ellagitannins.

Some conflicting results appear in the literature: the polyphenol-macromolecule interactions also depend on the type of macromolecules as well as the experimental conditions and methods used.

In comparison to tannin-protein interactions, less is known regarding the interaction between tannin and polysaccharides and especially hydrolysable tannins and polysaccharides whereas they are both present simultaneously in many plant and food ([Okuda](#)

and Ito, 2011). Besides, polysaccharides play a role in regulating selective extraction of polyphenols from fruit to juice (Renard et al., 2017) and a role of “polyphenol carrier” by non-digestible polysaccharides has been described as an “essential physiological function” of polysaccharides (Saura-Calixto, 2011).

Because of a knowledge gap, mainly due to difficulties in tannin analysis, an in-depth study of the impact of certain structural characteristics of proanthocyanidins and hydrolysable tannins on their ability to interact with polysaccharides is still needed:

- for proanthocyanidins: impact of procyanidin/prodelphinidin ratio, C4–C8 vs C4–C6 and A-type vs B-type linkages.
- for hydrolysable tannins: interactions with cell walls and the different cell wall polysaccharides, i.e. pectins and xyloglucans, and starch.

# A Molecular Thermodynamics Approach to Capture Non-specific Flavour–Macromolecule Interactions

Seishi Shimizu<sup>a,\*</sup>, Steven Abbott<sup>b,c</sup>, and Nobuyuki Matubayasi<sup>d,e</sup>, <sup>a</sup>University of York, York, United Kingdom; <sup>b</sup>University of Leeds, Leeds, United Kingdom; <sup>c</sup>Steven Abbott TNCF Ltd, Ipswich, United Kingdom; <sup>d</sup>Osaka University, Osaka, Japan; and <sup>e</sup>Kyoto University, Kyoto, Japan

## Introduction

This short article provides an accessible practical guide to a new method for quantifying, from experimental measurements (Damodaran and Kinsella, 1981b; Hansen, 1997; Kuhn et al., 2006; Kuhn et al., 2008; Wang and Arntfield, 2016), how flavour molecules interact with food macromolecules and their assemblies. A serious problem of the traditional approach based on binding models (Wyman and Gill, 1990), is that it involves many unrealistic assumptions (Shimizu et al., 2017a; Shimizu et al., 2017b), such as the stoichiometric binding of flavour on binding sites distributed on macromolecular surfaces. The major shortcoming of such an assumption is the inability to grasp the non-specific and dynamic nature of the interactions. In contrast, the novel theory, which is rigorous, free of assumptions and surprisingly easy to handle, enables us to achieve this goal (Shimizu, 2004; Shimizu et al., 2017b). The fact that it works at the intuitive molecular level, rather than in terms of abstract thermodynamics, is a further advantage.

The need is to work out flavour-macromolecule interactions at the molecular level from typical experimental measurements, such as (a) dialysis equilibria using semi-permeable membranes (Arora and Damodaran, 2010; Damodaran and Kinsella, 1981a, 1981b; Guichard and Langourieux, 2000; Muresan, van der Bent and De Wolf, 2001; O'Neill, 1996; O'Neill and Kinsella, 1987b), (b) headspace vapour pressure measurements (Andriot et al., 1999, 2000; Fabre et al., 2002; Jung and Ebeler, 2003; Kuhn et al., 2006; O'Neill and Kinsella, 1987a; van Ruth, 2001; van Ruth and Villeneuve, 2002) and (c) denaturation temperature changes induced by flavour molecules (Burova et al., 2003; Tolstoguzov, 2003). The advantages of the new approach is clear; unlike the classical models, there is no need any longer to assume (i) specific binding sites for flavour molecules and water on macromolecular surfaces; (ii) stoichiometric binding reactions between flavour (f) and the binding site (s),  $f + s \rightarrow fs$ ; and (iii) equal binding constant for all the binding sites (Shimizu et al., 2017a; Shimizu et al., 2017b). Such unrealistic assumptions have led to many paradoxes and controversies in wide-ranging disciplines, including protein thermodynamics, colloid and surface science, and solution chemistry; the confusion could only be resolved by abandoning the unrealistic assumptions (Shimizu, 2004; Shimizu and Boon, 2004). As a further bonus, confusing ideas about “water structure” vanish from the approach, because the interactions are overwhelmingly direct: macromolecule to flavour molecule rather than macromolecule via some ill-defined chain of water structure to flavour molecule.

The new approach is based on the well-established fluctuation solution theory (FST) also called Kirkwood-Buff (KB) theory (after the early pioneers of this approach), though its application to biological macromolecules has been established only recently (Shimizu et al., 2017a; Shimizu, 2004; Shimizu, Stenner & Matubayasi, 2017b). With this method, flavour-macromolecule interactions can be quantified:

- (1) without any models and assumptions, and are derived directly from the first principles of molecular thermodynamics;
- (2) truly as non-specific, dynamic and long-ranged interactions through the use of molecular distribution functions;
- (3) via a remarkably simple methodology for going from experimental data to theoretical analysis.

Thus, replacing and updating the theoretical foundation has led to the following realizations and new possibilities that were beyond the reach of the classical binding models (Shimizu et al., 2017a):

- Prevention of misidentifying the true molecular mechanism, such as misinterpreting flavour-macromolecule repulsion as the increase of macromolecular hydration.
- Possibility to relate, collate and compare the data obtained from different experimental techniques in a unified rigorous theory.
- Quantifying non-specific interactions even from historic data, by considering binding models merely as fitting equations from which we can extract what is really going on.
- Comparing, via the same type of molecular-based theory, flavour-macromolecule interaction with other additives such as co-solutes, denaturants, stabilizers etc. which in turn provide interactions that modulate gelation and denaturation. Similarly, the same approach is used to describe the solubilisation of hydrophobic molecules (such as flavour) into aqueous solution.

In the following, we shall demonstrate how the new approach drastically simplifies the analysis of experimental data, and brings in long-awaited clarity in the interpretation. For brevity, we focus exclusively on the realistic case when the flavour and biological macromolecules are both dilute. For a generalization beyond this limit, which is straightforward, please refer to our recent review on this topic (Shimizu et al., 2017a).

## Quantifying Non-specific Interactions via the Kirkwood-Buff Integral

Like any other interactions in the solution phase, flavour-macromolecule and flavour-water interactions can be defined most generally and rigorously (but also in a way that fits with our intuitions) in terms of the radial distribution function (RDF) which is a descriptor of how many molecules of type  $i$  are at any given distance from molecules of type  $j$ . The stronger the affinity between  $i$  and  $j$  the higher RDF becomes overall, whereas the more excluded  $j$  from  $i$  the lower RDF becomes overall. In the former scenario, the integrated RDF (called the KB integral, see Fig. 1) is less negative or even positive, whereas in the latter it is negative (Abbott et al., 2017; Shimizu et al., 2017b). These integrals are shown as  $G_{ij}$ . So, in the case of Protein interactions with Flavour molecules, this would be  $G_{PF}$  or  $G_{FP}$ , since the ordering is not important. Our previous tutorial review on solubilization by hydrotropes (Abbott et al., 2017) features a large set of free interactive “apps” to assist an intuitive understanding of KBIs and RDFs.

The negative contribution to KBIs, which even a strong positive contribution from the affinity in the solvation shall cannot overcome, comes from the excluded volume effect, i.e., the inability of two molecules to overlap (Fig. 1). Although excluded volume can be described in terms of abstract numbers such as entropy, its interpretation in terms of the RDF is more direct and insightful. In the cases where there is especially strong affinity between  $i$  and  $j$  sufficient to overcome the excluded volume effect, KBI becomes large and positive. KBI, on the contrary, is large and negative for molecules that are mutually incompatible (Abbott et al., 2017; Shimizu et al., 2017b).

## Analysing Fresh Experimental Data

What follows is necessarily somewhat theoretical. However, for those who simply want access to the results, we have provided an “app”, <https://www.stevenabbott.co.uk/practical-solubility/kb-flavours.php>, that carries out all the analyses, showing the input data and the calculated values. The user can choose from a number of published datasets or load their own data once they have placed it into the simple format required by the app.

## Headspace Analysis

Let us consider an aqueous solution as a system consisting of water (W), protein (P) and flavour (F) molecules. Flavour molecules are volatile, and their solubility in water is relatively low. The question is how the vapour-water partition coefficient of the flavour molecule  $K_{vw} = c_F/c_F^{vap}$  ( $c_F$ : molar concentration of flavour molecule in the aqueous phase;  $c_F^{vap}$ : in the vapour phase) is affected by the presence of protein molecules. This question can be answered using the competition between the flavour-water and flavour-protein KBIs as (Shimizu, 2004; Shimizu and Matubayasi, 2014; Shimizu et al., 2017b)

$$\left( \frac{\partial \ln K_{vw}}{\partial c_P} \right)_{T,P,c_F \rightarrow 0; c_P \rightarrow 0} = G_{FP} - G_{FW} \quad (1)$$

**Figure 1** The physical meaning of the macromolecular-flavour Kirkwood-Buff integral (KBI), defined as  $G_{PF} = \int dr 4\pi r^2 [g_{PF}(r) - 1]$ , where the radial distribution function (RDF),  $g_{PF}(r)$  (red), depends on macromolecule-flavour distance  $r$ , and tends to 1 at large separation. The regions with  $g_{PF}(r) < 1$  signifies the less-than-bulk distribution of the flavour, which contributes negatively to the KBI, whereas the regions with  $g_{PF}(r) > 1$  signifies the more-than-bulk distribution of the flavour, which contributes positively to the KBI. The large negative contribution to KBI from small  $r$  is due to the excluded volume (i.e., the macromolecule and flavour molecules cannot overlap), if there is repulsion between the flavour and the macromolecule. See our previous tutorial review (Abbott et al., 2017) as well as the accompanying app <https://www.stevenabbott.co.uk/practical-solubility/rdf.php> for the interactive and intuitive understanding of the concept.

**Figure 2** A schematic explanation of the strategy to calculate the macromolecule-flavour affinity, characterised in terms of the KBI  $G_{FP}$ , from experimental data. The gradient of  $\ln K_{vw} = \ln (c_F/c_F^{vap})$  (vapour-solution partitioning determined from headspace measurements) against the macromolecular concentration  $c_P$  yields the KBIs. See main text for further explanations. An interactive web-based app (Shimizu et al., 2017a) for data analysis is available at <http://www.stevenabbott.co.uk/practical-solubility/kb-flavours.php>.

Eq. (1) immediately leads to the following set of procedures to determine the KBI difference,  $G_{FW} - G_{FP}$ :

- (i) Change and record protein concentration  $c_P$ ;
- (ii) At each protein concentration, measure
  - (a) the vapour phase flavour concentration  $c_F^{vap}$  from the headspace vapour measurements;
  - (b) the solution phase flavour concentration  $c_F$ ;
  - (c)  $K_{vw} = c_F/c_F^{vap}$  from (a) and (b)
- (iii) The slope (Fig. 2) yields  $G_{FW} - G_{FP}$ .

$G_{FW}$  and  $G_{FP}$  can both be determined independently. This requires an additional piece of information, i.e., the partial molar volume of the flavour molecule,  $V_F$ , from which  $G_{FW}$  can be determined directly using

$$V_F = -G_{FW} + RT \kappa_T \approx -G_{FW} \quad (2)$$

where the term containing  $\kappa_T$ , isothermal compressibility, makes a negligibly small contribution (Shimizu, 2004; Shimizu and Matubayasi, 2014; Shimizu et al., 2017b).  $V_F$  can be determined, in principle, from density measurements of the aqueous flavour solutions (Chalikian, 2003). However, this approach may not be suitable in practice because most flavour molecules have low aqueous solubility. Hence the reliable alternative is to estimate  $V_F$  using empirical formulae based on group additivity (Lepori and Gianni, 2000), which is quite good enough for the purpose.

## The Use of a Semi-permeable Membrane to Quantify Protein-Flavour Interactions

Now we consider protein molecules in dilution inside the semi-permeable membrane (Shimizu et al., 2017a; Timasheff, 2002b). Outside the semi-permeable membrane, we inject the flavour molecule, which can go through the semi-permeable membrane, but protein molecules stay inside the membrane. If we could measure the concentration of the species  $F$  both in the bulk phase ( $c_F$ ) and inside the semi-permeable membrane ("vicinity" concentration,  $c_F^{vic}$ ) at the protein concentration  $c_P$ , we could obtain the KBI directly from the following definition (Shimizu et al., 2017a):

$$G_{PF} = \frac{1}{c_F} \frac{c_F^{vic} - c_F}{c_P} \quad (3)$$

However, it is impossible in practice to determine  $c_F$  and  $c_F^{vic}$  directly from experiments. Instead, what is measurable experimentally is the increment of (or decrease in) flavour molecule concentration that accompanies the introduction of protein molecules inside the membrane (Timasheff, 2002a). Such an approach follows the well-established protocol for determining ligand binding on proteins using a semi-permeable membrane (Wyman and Gill, 1990). Such a measurement leads to the amount of flavour molecules bound to a mole of protein

$$\Gamma = \left( \frac{\partial m_F}{\partial m_P} \right)_{T,P,\mu_F} \quad (4)$$

where  $m_i$  is the molality of the species  $i$ . Molecular thermodynamics shows that this quantity can be expressed in terms of KBI as

$$\Gamma \simeq c_F (G_{PF} - G_{PW}) \quad (5)$$

under the approximation that flavour molecules are much smaller in general than proteins (Shimizu et al., 2017a).

To evaluate  $G_{PF}$ , we need to obtain  $G_{PW}$  via the partial molar volume of the protein in pure water,  $V_P$ , via  $G_{PW} = -V_P$ .  $V_P$  can either be measured experimentally using density meter or estimated from the molecular weight (Chalikian, 2003; Chalikian and Filfil, 2003).

## Recycling Old Literature Data

KBIs can be obtained directly from old papers that report the flavour-macromolecule binding constant  $K$  and the number of binding flavour sites  $n$ . This is despite the unrealistic assumptions that classical binding models employ (Shimizu et al., 2013; Shimizu et al., 2017b), yet it can serve as an excellent model for the fitting of experimental data (Arora and Damodaran, 2010; Damodaran and Kinsella, 1981a, 1981b; Guichard and Langourieux, 2000; Muresan et al., 2001; O'Neill, 1996; O'Neill and Kinsella, 1987b).

Old literature focuses predominantly on the amount  $\Gamma$  of flavour molecules bound to a mole of protein (Wyman and Gill, 1990), assuming  $n$  flavour-binding sites on the surface of a protein, each of which binds the flavour molecule with the binding constant  $K_b$ , as

$$\Gamma = \frac{nK_b c_F}{1 + K_b c_F} \quad (6)$$

Because it is often impossible to re-analyze historical data, we propose a practical way out to obtain KBIs from them (Shimizu et al., 2017a). This can be achieved by using the binding model (Eq. 6) as a fitting equation for  $\Gamma$ . From Eqs. (5) and (6), we obtain

$$G_{PF} - G_{PW} = \frac{nK_b}{1 + K_b c_F} \quad (7)$$

To evaluate  $G_{PF}$ ,  $G_{PW}$  can be obtained from the experimental or estimated partial molar volume of the protein in pure water,  $V_P$  (Chalikian and Filfil, 2003), using  $G_{PW} = -V_P$ , as before.

## Consequence of Flavour Binding on Macromolecular Stability

The presence of flavour, even in dilution, strongly affects protein denaturation temperature and sol  $\rightarrow$  gel transition temperature. The addition of flavour molecules commonly increases the transition temperatures drastically, which means there is a marked difference in flavour-macromolecule affinity between native ( $n$ ) and denatured ( $d$ ) states, or gel ( $g$ ) and sol ( $s$ ) states. Leaving the in-depth treatment to our recent review (Shimizu et al., 2017b), here we summarise the results. The change of free energy  $\Delta\mu_P^*$  that accompanies gel melting,  $g \rightarrow s$ , can be linked to the KBI difference,  $\Delta G_{PF} = G_{PF}^{(s)} - G_{PF}^{(g)}$  and  $\Delta G_{PW} = G_{PW}^{(s)} - G_{PW}^{(g)}$ , as

$$\frac{1}{RT} \left( \frac{\partial \Delta\mu_P^*}{\partial c_F} \right)_{T, P, c_P \rightarrow 0; c_F \rightarrow 0} = \Delta G_{PW} - \Delta G_{PF} \quad (8)$$

and the free energy change (the left hand side) can be obtained directly from the gel melting temperature ( $T_{g \rightarrow s}$ ) and  $\Delta H_{g \rightarrow s}$  the enthalpy change accompanying gel melting, as

$$\frac{\Delta H_{g \rightarrow s}}{RT^2} \frac{\delta T_{g \rightarrow s}}{\delta c_F} = \Delta G_{PW} - \Delta G_{PF} \quad (9)$$

The same approach is applicable also to protein denaturation,  $n \rightarrow d$ .

For practical purposes, the flavour concentration dependence of the melting temperature is sufficient for the determination of KBIs, when combined with the melting enthalpy in water (Burova et al., 2003; Tolstoguzov, 2003). In addition, compared to  $\Delta G_{PF}$ ,  $\Delta G_{PW}$  has been shown to be negligible, due to the usual smallness of the volume changes that accompany denaturation or gelation (Shimizu and Boon, 2004; Shimizu et al., 2017b). Eq. (9) can therefore be simplified further as

$$\frac{\Delta H_{g \rightarrow s}}{RT^2} \frac{\delta T_{g \rightarrow s}}{\delta c_F} \simeq -\Delta G_{PF} \quad (10)$$

This means that  $\Delta G_{PF}$  is determinable directly from the plot in Fig. 3.

## Concluding Remarks

That flavour molecules interact with food macromolecules in a non-specific manner has long been known. However, the lack of an appropriate theoretical language for non-specific interactions has forced the non-specific interaction to be modelled stoichiometrically, and hence unrealistically. This has made the experimental analysis of flavour-macromolecule interactions more complicated than it should ever be.

**Figure 3** A schematic explanation of the strategy to calculate the change of macromolecule-flavour affinity, characterised in terms of the KBI difference  $\Delta G_{PF}$ , from experimental data. The gradient of the gel-melting temperature ( $T_{g \rightarrow s}$ , or similarly the denaturation temperature) against the flavour concentration  $c_F$  yields the KBIs. See main text for further explanations. An interactive web-based app (Shimizu et al., 2017a) for data analysis is available at <http://www.stevenabbott.co.uk/practical-solubility/kb-flavours.php>.

Based on the principles of molecular thermodynamics (Shimizu, 2004; Shimizu et al., 2017b), non-specific interactions can now be captured and quantified directly from experiments without unrealistic assumptions. The analysis has been simplified drastically by making the stoichiometry assumption redundant. The collective and statistical nature of flavour-macromolecule affinity can now be captured in terms of the KB integrals. Such experimentally-determined KBIs enable us not only to quantify the interactions between different species but also their relative contributions to macromolecular solvation and transitions. Such a clarification has led to significant insights, such as the abandonment of the popular “water structure” hypothesis (Abbott et al., 2017; Shimizu et al., 2017b).

To make this short article as accessible as possible, we have focused exclusively on the simplest and most common case, i.e., the flavour and biological macromolecules are both dilute. However, systems beyond the dilute limit can be analysed equally straightforwardly through the general theory presented in our recent reviews (Abbott et al., 2017; Shimizu et al., 2017a; Shimizu et al., 2017b).

# Flavor Enhancement Induced by Taste–Odor Interactions

Guowan Su, Dongxiao Sun-Waterhouse, Yaqi Zhao, Weiwei He, and Mouming Zhao, South China University of Technology, Guangzhou, China

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Flavor** is a complex sensory impression which describes the overall perception generated after local processing and central integration (in the brain) of the signals resulting from the individual and combined effects of aromatics, taste sensations, trigeminal nerve stimulation and chemical feeling factors evoked by a substance in the oral cavity, including aroma/odor (detected by the olfactory epithelium in the nose), taste (detected by taste buds on the tongue), pain/irritation/hotness/temperature (detected by the trigeminal sensors in the mouth and nose), and mouthfeel/texture (detected by the force sensors in the mouth).

**Taste** is a sensory modality involving the oral perception of food-derived chemicals/substances, and describes the sensation produced when a substance on contact with the mouth and throat and reacts chemically with the taste receptor cells located on taste buds in the oral cavity, especially on the tongue. Several taste qualities have been defined or proposed including sweet, sour, salty, bitter, umami, astringent, pungent and kokumi, with the first five being more recognized. Umami and kokumi are Japanese words and represent ‘delicious taste’ and ‘rich taste’, respectively. Both can enhance the sensation of other tastes/flavors in different ways and to different extents. Umami is the sensation perceived upon the consumption of a food containing glutamate and ribonucleotides like inosinate and guanylate, whereas, Kokumi is a complicated sensation and describes continuity, mouthfulness, thickness, taste-enhancing and persistent/long-lasting characteristics associated with substances like calcium, protamine, glutathione and L-histidine.

**Smell or odor** is detected by the olfactory epithelium of the nose. The sense of smell gives rise to perception of odor via the mediator, the olfactory nerve. An odor/scent, pleasant or unpleasant, is caused by one or more volatilized molecules (chemical stimuli) at a low concentration and perceived by the sense of olfaction. The term “aroma” is often used to describe a pleasant odor, and sometimes the terms “odor” and “aroma” are used to represent the orthonasal olfactory perception and the retronasal olfactory perception, respectively. Like the sense of taste, the sense of smell is also a chemical sense although smell can work at a remarkably large distance as compared to taste. The smell process involves the travel of vaporized odor molecules in the air to reach the nostrils, dissolution of these molecules in the mucus, detection by olfactory receptor neurons in the olfactory epithelium underneath the mucus, transmission of the obtained sensory signal(s) to the olfactory bulbs located at the back of the nose (where the sensory receptors as part of the brain would send the signals to the brain centers).

## Introduction

Food sensory attributes such as smell, taste, colour and texture play vital roles in food preference, eating habits and life enjoyment. Among the sensory attributes, the flavor of food is the key determinant of food quality and acceptance. Flavor is an integrated sensation of food reflecting chemical and trigeminal nerve stimulation evoked by taste and odor substances. The perception of flavor is driven largely by smell and taste, with some contributions from trigeminal and tactile sensations, and visual and auditory cues. Compared to any other of senses such as taste and touch, the sense of smell is a lot more sensitive (up to 10,000 times more sensitive) and the recognition of smell is far quicker (almost immediate).

Food is a complex system consisting of nutrients and flavor compounds in a great variety (such as proteins, fats, sugars, non-volatile acids, volatile acids and carbonyl compounds). The volatile flavor compounds typically include aldehydes, ketones, alcohols, acids, esters, furans, pyrazines, amides and sulfur compounds. After all these substances are blended and processed into a certain format of food, a rich and characteristic flavor would be produced and perceived by humans.

## Contributions Made by Peptides Towards Taste or Flavor

Peptides are commonly found, as intermediates of protein synthesis and decomposition, in various foods such as meats, vegetables, pickled foods, dairy products and other types of food. Peptides are important nutrients and health-promoting bioactive substances that are mostly digestible and absorbable. They play important roles in food flavor and texture/mouth-feel through imparting their own sensory and other physico-chemical characteristics, and enhancing, and/or masking the sensory properties of food.

Umami peptides can be directly isolated from or obtained after hydrolysis of gluten (Schlichtherle-Cerny and Amadò, 2002), fish (Maehashi et al., 1999), ham (Aristoy and Toldrá, 1995; Sentandreu et al., 2003) and soy sauce (Lioe et al., 2006, 2007). Aspartame (Magnuson et al., 2007) and alitame (Kim and Shin, 2001) have already been developed as food sweeteners. The perception of the flavor of taste peptides is comprehensive. Peptides may exhibit complex taste profiles, and can make direct and indirect contributions

to the basic taste qualities of foods including sourness, sweetness, umami, bitterness, and saltiness. It was found that Arg-Pro, Gly-Arg-Pro and Arg-Pro-Gly were perceived with strong bitterness (Otagiri et al., 1985). Dipeptides (Gly-Asp, Ala-Glu and Glu-Leu) were reported to exhibit sour and umami tastes simultaneously (Roudot-Algaron et al., 1994). Furthermore, the eleven-amino acid peptide (Ala-Pro-Pro-Pro-Pro-Ala-Glu-Val-His-Glu-Val) was found to have an acid inhibitory function (Okumura et al., 2004).

### Interactions Between Taste Peptides and Other Tastants Co-existing in Foods

Taste peptides may exhibit a synergistic effect with other co-existing flavor substances (such as sodium glutamate, sodium inosinate, disodium guanylate, sodium succinate, sodium acetate and acidulant), or significantly enhance or alter their original flavor characteristics. Accordingly, the special flavor characteristics of taste peptides can be utilized not only for improving food palatability, but also as a safe substitute for high sodium condiments.

It is worth noting that a concrete taste substance may not only impart a certain taste or several tastes, but also influence the perception of other substances in a different taste type. Taste–taste interactions have been explored widely in sensory research, molecular biology investigations on taste receptors, and human psychophysical studies. Previous research showed that bitterness could be masked by umami substances (Noguchi et al., 1975). Taking umami taste as an example, intracellular  $\text{Ca}^{2+}$ -flux signal induced by salicin could be significantly suppressed by five umami soybean peptides (Glu-Asp, Glu-Glu, Glu-Ser, Asp-Glu-Ser and Glu-Gly-Ser) in hTAS2R16-expressing cells via bitter taste receptor(s) in a time-dependent manner, and in a noncompetitive mode (Kim et al., 2015). Park et al. (2002) reported that 0.3% NaCl could enhance the umami and sweetness of synthesized oligopeptides with the amino acid sequence originated from a Vietnamese fish sauce. It was also reported that sucrose and monosodium glutamate had positive effects on the umami taste of the octapeptide subfraction extracted and isolated from puffer fish muscle (Zhang et al., 2012).

Tastants such as sugar, salt or monosodium glutamate in small amounts can enhance the overall flavor of foods. Moreover, these compounds can interact with the food aroma compounds (Friel et al., 2000). The intensity of perceived apple and lemon flavors was found higher in the presence of a sour taste (Cayeux et al., 2003). The congruency between olfactory and gustatory stimuli seems to be an important criterion for taste-referred aroma enhancement in a food product. Taste-induced enhancement of aroma significantly depends on the consonance of aroma and taste stimuli e.g. the enhancing effect detected during the interaction of fruitiness and sweetness or sourness (Frank and Byram, 1988).

### Odor-Induced Flavor Enhancement

The aromas of food products are derived from a variety of volatile aroma substances, most of which have no or little nutritional value and possess poor thermostability. Food aroma and taste play important roles in appetite control: aroma and taste alone or in combination can influence appetite sensation and food intake. Aromas also indirectly improve the digestion and absorption of nutrients. The perception of aroma is more sensitive and complex than taste perception. Aroma perception is highly correlated with the molecular structure of aroma and takes effect even at a very low concentration (i.e. 1–1000 ppm). The threshold values and concentrations of aroma substances are important parameters that determine the ultimate effect of aroma.

Certain tasteless substances (especially volatiles) could also influence taste perception. Aroma is well-known for its considerable contribution to the perception of taste even in trace amount. The “odor-induced changes in taste perception” phenomenon have been examined in quite a few studies. However, minimal efforts have been made in examining odor-induced taste peptide enhancement.

Specific odor-induced influences take place in the perception of salt taste. Sodium salt is a commonly used condiment, which is indispensable for the human body. However, excessive consumption of sodium salt may lead to a number of diseases such as hypertension, cardiovascular disease, kidney disease and other serious diseases. High intake of sodium salt would affect the disease resistance of human cells and aggravate the burden of kidneys. It is of high importance to explore solutions to reduce the amount of sodium salt in foods without compromising food taste. Utilizing the interactions between odor and taste substances represents a feasible approach for reducing the intake of sodium salt. The enhancement of saltiness is related to the consistency of odor and the concentration of salt in aqueous solutions or solid foods. Research showed that the intensity of perceived salty taste was significantly increased by the sardine aroma when the salt concentration was at a low- or medium-level, but no significant change in salty taste was found at high salt concentrations (Nasri et al., 2011). Similarly, specified odors may induce enhancement of saltiness in low salt solutions, suggesting an approach through which the amount of sodium chloride in food can be reduced without losing any intensity of salty taste (Lawrence et al., 2009). Nasri et al. (2013) found that the effect of odor-taste interactions on potassium chloride was stronger than on sodium chloride. Accordingly, odor-sour-salty ternary systems may allow a desirable flavor improvement based on the same mechanism as that for odor-induced taste enhancement in real food systems. In solid cheese models, comté cheese and sardine odors were found to play a significant role in the enhancement of saltiness of either flavored or unflavored cheese (Lawrence et al., 2011). Syarifuddin et al. (2016) also indicated that odors could compensate for taste insufficiency in low-salt, low-sugar and low-oil cheese model through cross-modal interactions. Emorine et al. (2015) reported that the effect of ham odor-induced saltiness enhancement was independent of salt and aroma diffusion. It is known that the ham with an uneven salt distribution was saltier ( $P < 0.01$ ) than that with homogeneous salt distribution, but the unevenly distributed ham odor

could affect neither the perception of taste nor the perception of odor. Djordjevic et al. (2004) confirmed that soy sauce odor-induced saltiness enhancement and strawberry odor-induced sweetness enhancement were centrally mediated and also resulted from taste-smell interactions.

The well-selected odor, even at a subthreshold level, can markedly enhance the perception of taste. The effect of sweet-congruent odor on sweetness perception was detected by Labbe and Morgenegg (2007) using a continuous flow system with a constant sucrose concentration but different odor concentrations. The authors indicated that at a supra-threshold level, ethyl butyrate and maltol would have the highest and lowest sweetening properties, respectively. At a subthreshold level, ethyl butyrate could significantly enhance the sweetness of the sucrose solution, whilst maltol did not, probably due to the different odorant-tastant associations and respective sensitivity. The concentration of ethyl butyrate is not in direct proportion to the enhancement of sweetness at a subthreshold level, but an opposite trend was detected at a supra-threshold level. The odor-induced sweetness enhancement is correlated with the concentration of a sweet substance. Symoneaux et al. (2015) confirmed that enhancement of cider's sweetness would occur when the sugar content was in the range of 35–40 g L<sup>-1</sup>.

Caporale et al. (2004) found that the presence of cut grass odor was beneficial for inducing a higher intensity of bitterness and longer duration in virgin olive oil even when diverse stimuli were upheld. McCabe and Rolls (2007) observed that a higher intensity of pleasant flavor was achieved if vegetable aroma was combined with sodium glutamate. Moreover, integration of vegetable aroma and sodium glutamate was found to facilitate a greater stimulation of the medial orbitofrontal cortex and pregenual cingulate cortex than the sum of respective stimulation provided by vegetable aroma or sodium glutamate, as revealed by functional magnetic resonance imaging. Niimi et al. (2014) found that at the low- and middle-aroma concentrations, cheese flavor was increased with the concentration of monosodium glutamate, but decreased in the system with aroma at a high concentration. Cheese aroma could significantly enhance the perception of umami and bitterness, but had no effect on the intensity of sweetness, saltiness or sourness. Therefore, the perceptible interaction between taste and aroma of cheese was influenced by the type of taste and the concentration of aroma. The same type of odor-induced flavor enhancement may lead to totally different results in varied food systems. In a cocoa beverage, cocoa and vanilla odors would induce enhancement on bitterness and sweetness, respectively. But surprisingly, vanilla odor did not enhance sweetness, on the contrary, enhanced the bitterness of caffeinated milk (Labbe et al., 2006).

Odor-induced changes in taste perception was mediated centrally (Caporale et al., 2004), and correlated with chemical reactions and physical interactions between taste and odor components as well as their subsequent interactions with taste receptors (Sun-Waterhouse and Wadhwa, 2013). Based on the obtained psychophysical and neuroanatomical results, the cerebral cortex activity of the coordinated odor-taste combination was extremely higher than that of the incongruent integration, involving insula, frontal operculum, anterior cingulate cortex, and orbitofrontal cortex (Seo et al., 2013). Flavor perception results from the central integration, which depends on the previous experience with congruent taste-odor integration. Dynamic stability of taste attractors in gustatory cortical was regulated by feedback signals from orbitofrontal cortex to gustatory cortical, resulting in an enhancement or inhibition of taste perception caused by certain aroma (Shimemura et al., 2016). Another reason for such odor-induced taste enhancement could be the cognitive link between the taste and aroma features. Aromas may possess certain taste attributes. For example, vanilla odor tends to be associated with sweet perception, whilst sardines odor is likely related to salty perception (Lim et al., 2014). Thus, the congruency of taste and odor in taste-odor interaction is especially important (Small and Prescott, 2005). Lawrence et al (2011) reported that the carrot odor, which was not related to saltiness, did not enhance saltiness (Lawrence et al., 2011). When studies are carried out on such odor-induced taste enhancement, one should pay attention to a “dumping” effect (the taste rating is extended in the absence of related attributes e.g. the perceived olfactory enhancement on the taste scale was evaluated with no olfactory intensity scale available) (Lim et al., 2014). In these cases, reaction deviation should be considered and included.

## Conclusion

Taste, odor or aroma are commonly used terms in describing food sensory attributes. The relationships between these attributes, and between them and other sensory attributes, are rather complicated, which represents an ongoing and challenging research topic. This article highlights the importance of understanding the interactions among various taste and odor substances in improving both the sensory attributes and the healthiness of human diet and food, as well as the feasibility to utilize the approaches based on odor-induced taste enhancement for reducing the amounts of undesired or even harmful food additives in the final consumer foods.

## Introduction

Proteins in foods can form complexes with other food components, including polyphenols, which lead to vital changes in their structural, functional and nutritional properties (Shahidi, 2000; Ozdal et al., 2013; Bordenave et al., 2014; Shahidi and Ambigaipalan, 2015). Understanding of these changes as a result of interactions with phenolic compounds is essential in light of their scientific, industrial, and economic significance.

Phenolic compounds are plant secondary metabolites and are derived from phenylalanine and, to a lesser extent, tyrosine (Fig. 1) (Shahidi, 2000). Their chemical structures have an aromatic ring attached to one or more hydroxyl groups, including their functional derivatives (Shahidi and Ho, 2005). Due to the indigestion of plant foods these phenolic compounds can be found in animal tissues and non-plant materials (Shahidi, 2000). Plant phenolics may act as natural pesticides, providing protection against ultraviolet rays and also involved in pigmentation in plant foods, among others (Shahidi and Nacz, 2003; Martinez-Gonzalez et al., 2017). Generally, phenolic compounds can be classified into simple phenols, hydroxybenzoic acid and hydroxycinnamic acid derivatives, flavonoids, stilbenes, lignans and hydrolyzable as well as condensed tannins, the latter also known as proanthocyanidins (Nacz and Shahidi, 2006; Shahidi and Ambigaipalan, 2015; Martinez-Gonzalez et al., 2017). Proanthocyanidins exist as oligomers and polymers of flavonoids like flavan-3-ols whereas hydrolysable tannins are often found as glycosylated gallic acid (Ferreira and Li, 2000; Shahidi, and Ambigaipalan, 2015). More than 8000

**Figure 1** Phenolics compounds originating from phenylalanine and tyrosine. Adapted from Shahidi and Nacz (2003).

phenolic compounds have been identified in plant-based materials such as fruits, vegetables, cereal grains, legumes and oilseeds, among others (Ozdal et al., 2013). The simple phenols mainly include monophenols such as *p*-cresol, thymol and orcinol mainly isolated from fruits (Naczki and Shahidi, 2006; Ozdal et al., 2013). Diphenols such as hydroquinones are considered as the most widespread simple phenols (Shahidi and Ho, 2005). In addition, polyphenols present in foods may further be categorized according to their carbon atoms in conjunction with the basic phenolic skeleton (Ozdal et al., 2013). Hydroxybenzoic acids possessing the general structure C6–C1 (such as gallic, vanillic, syringic, and ellagic acids) and hydroxycinnamic acids which have C6–C3 (*p*-coumaric, caffeic, ferulic, sinapic, and chlorogenic acids) are the two main classes of phenolic acids, the latter being more common in food products compared to the former (Shahidi and Ho, 2005; Shahidi and Ambigaipalan, 2015).

The other prominent subclass of polyphenols is the flavonoids and they are ubiquitously found in plants. They have the general formula of C6–C3–C6 with flavonoid skeleton which consists of two benzene rings linked by a 3 carbon heterocyclic ring (Shahidi and Naczki, 2005; Martinez-Gonzalez et al., 2017). Flavonoids are further divided into subgroups such as flavones, flavanones, flavonols, flavanonols, isoflavones, flavanols (catechins), and anthocyanidins according to the substitution of the heterocyclic ring (Strat et al., 2016). Flavanols, also known as flavan-3-ols, are hydroxylated at C3 in the heterocyclic ring and often exist in the monomeric form or as oligomers/polymers (Strat et al., 2016). The compounds (+)-catechin (+C), (–)-catechin (–C), (–)-epicatechin (EC) are the major dietary flavanol monomers (Jakobek, 2015). Flavonols are different from flavones by possessing a hydroxyl group in the 3-position and can be regarded as 3-deoxyflavonol (Shahidi and Ambigaipalan, 2015). Flavonols are referred to as 3-hydroxyflavonones or dihydroflavonols and differ from flavonones by having a hydroxyl group in the 3-position (Shahidi and Naczki, 2003).

Phenolic compounds containing two benzene rings separated by an ethane bridge are called stilbenes and found abundantly in higher plants (Shahidi and Ho, 2005). Lignans are dimers of phenylpropanoid (C6–C3) units linked by the central carbons of their side chains and four major groups of linear lignans are formed according to their oxygenation such as lignans (butane derivatives), lignolides (butanolide derivatives), monoepoxylignans (tetrahydrofuran derivatives) and bipheoxylignans (Shahidi and Naczki, 2003). Coumarins are another group of polyphenols derived from lactones of *cis*-*O*-hydroxycinnamic and can be found in the free form or as glycosides, especially in the plant kingdom (Shahidi and Naczki, 2003). In general, most of the dietary polyphenols have been subjected to numerous *in vivo* and *in vitro* studies to demonstrate their interactions with macro- and micronutrients (Bordenave et al., 2014). All these interactions are influenced by various parameters, including temperature, pH, ionic strength, type and nature of the protein and phenolic compounds that are involved in the formation of bonding or complexes (Ozdal et al., 2013). The mechanism and type of these interactions also play a vital role as they influence the functional properties of both the protein and the phenolic compounds (Jakobek, 2015). Upon oxidation, phenolic compounds gain strong affinity towards macronutrients. Various studies have investigated the bioaccessibility and bioavailability of dietary phenolic compounds (Jakobek, 2015). From a nutritional point of view, bioavailability of phenolic compounds is the most important parameter in the evaluation of their physiological effects. Therefore, it is imperative to consider the nature and the significance of these interactions and their subsequent effects on food systems as a whole.

### Formation of Protein–Phenolic Interaction

Basically, four types of interactions are reported for phenolics and proteins and these are hydrogen bonding, ionic (electrostatic) interaction, covalent bonding and hydrophobic interaction (Bordenave et al., 2014; Ozdal et al., 2013; García-Estévez et al., 2017; Fernandes et al., 2017). Among them, hydrophobic and hydrogen bondings account for the main driving force for all these interactions (Jia et al., 2016). According to Shahidi and Naczki (2003), phenolics form complexes at both low and high concentrations of proteins due to the formation of hydrophobic interactions. This is further explained by hydrogen bonding via hydroxyl groups in the phenolic compounds and the carbonyl groups of the peptide bonds of proteins (Loomis and Battaile, 1966).

Interactions between protein and phenolic compounds can be found in different occasions such as phenolic compounds attached to the storage and physiologically active proteins present in plants, interactions of plant phenolic compounds with proteins present in food matrices, during digestion with enzymes in the gastrointestinal tract, after the digestion during absorption they may interact with plasma proteins and finally there may be a possibility to interact with the target tissues or organs in the human body.

Formation of these interactions can be divided into three stages. At initial stage after the addition of polyphenol, several polyphenol molecules may bind with the proteins; then higher amount of polyphenol can induce the formation of polyphenol-coated dimers, thus causing precipitation and finally with increasing the number of molecules larger complexes may be formed (Tang et al., 2017). These aggregates can either be soluble or insoluble (Bandyopadhyay et al., 2012). The interaction of the –OH groups of polyphenols with the protein chain or hydrophobic stacking of the aromatic groups of the protein and polyphenols lead to the formation of aggregates.

Hydrophobic interactions can occur between two aromatic rings where one could be hydrophobic amino acid (Le Bourvellec and Renard, 2012). This is also known as stacking interaction. Protein concentrations have a direct influence on this hydrophobic interaction as hydrophobic monolayer is formed at low protein concentrations while at high concentrations more hydrophobic surface layer is formed due to the complexation of polyphenols and proteins. This process also includes the cross-linking of protein molecules. Aggregation and precipitation occur as a consequence of all these steps. Ionic bonding or electrostatic forces

between the hydroxyl group of the phenol compounds and amino groups of protein residues takes place in such interactions (Martinez-Gonzalez et al., 2017).

Furthermore, Kroll et al. (2003) proposed five potential types of interaction between phenolics and proteins, namely hydrogen bonding,  $\pi$ -bonding, as well as hydrophobic, ionic, and covalent linkages. Compared to covalent linkages, non-covalent linkages are weaker since they do not involve sharing of electron pairs (Nagy et al., 2012; Jakobek, 2015). Most of these non-covalent interactions are reversible and are assumed to be stabilized by hydrogen bonding (Yuksel et al., 2010; Jia et al., 2016). In contrast, covalent bonds form irreversible interactions.

Reversible complexation takes place in a two-stage process, in the first stage the polyphenol and the co-substrate, are in equilibrium with soluble complexes via various non-covalent forces (Luck et al., 1994). In a second stage these soluble complexes may aggregate and precipitate from the solution upon which the position of this equilibrium changes. The precipitated complexes may then redissolve and this whole process is reversible under favorable conditions (such as absence of oxygen, metal ions, acid or base). The maximum protein–polyphenol interaction occurs at the isoelectric point of the protein (Trigueros et al., 2014) or optimum pH for the complex formation which is described as the pH at which maximum precipitation occurs (Naczek et al., 1996).

Different phenolic compounds can form complex with active groups of protein. In particular, natural phenolic compounds are prone to interact with active groups in protein molecules. This may affect biological, nutritional and functional properties of proteins including changes in surface hydrophobicity, solubility, gelling, emulsification, and antioxidant properties of the protein molecule (Ozdal et al., 2013; Bordenave et al., 2014; Jakobek, 2015; Shahidi and Ambigaipalan, 2015; Jia et al., 2016; Martinez-Gonzalez et al., 2017; Czubinski, and Dwiecki, 2017). As proteins are affected by their interactions with phenolic compounds, the biological activity and functionality of phenolics are also affected by their interactions with proteins.

### Protein Interactions With Phenolic Acids

Phenolic acids as low molecular weight plant phenols and are considered as important native food components with a wide range of structures and functions. Phenolic acids generally have one or more aromatic rings bearing one or more hydroxyl groups and in particular, presence of aromatic ring with hydroxyl group and carboxylic acids in phenolics increases their affinity to conjugate with major food components (Alu'datt et al., 2016). Unique array of phenolic acids which include derivatives of hydroxybenzoic and hydroxycinnamic acids are found to form complexes with proteins (Shahidi and Zhong, 2010; Shahidi and Chandrasekara, 2013). The interaction of phenolic acids with proteins occurs mainly by hydrogen bonds involving the hydroxyl groups of polyphenols and polar groups of proteins, as well as hydrophobic contacts between the planar ring surfaces of phenolic compounds and the rings of proline residues (Ferrer-Gallego et al., 2017). Moreover, the process of protein hydrolysis may weaken the protein–phenolic complexes by reducing the interactions between these compounds and by increasing the availability of the nucleophilic sites of peptides and of phenolic compounds (Guimarães Drummond e Silva et al., 2017) in millets (Chandrasekara and Shahidi, 2011), coffee beans (Narita and Inouye, 2011), flaxseed (Guimarães Drummond e Silva et al., 2017), salivary proteins (Ferrer-Gallego et al., 2017) and myofibrillar protein (Cao and Xiong, 2015).

### Protein Interactions With Flavanoids

Flavonoid–protein interactions are widely investigated with polyphenols such as flavan-3-ols, flavonols and proanthocyanidins (Xiao, and Kai, 2012; de Freitas and Mateus, 2012; Bordenave et al., 2014; Watrelot et al., 2016; Chaudhury et al., 2017). The formation of flavonoid–protein complexes is usually promoted by the food matrix (Czubinski, and Dwiecki, 2017). Protein–flavonoid complexation is mainly due to non-covalent interactions between the compounds of interest. These non-covalent interactions between flavonoids and proteins can further be divided into chemically specific or non-specific (Bordenave et al., 2014). Most of the specific bindings are between flavonoids and globular tertiary structure of protein such as hemoglobin or milk immunoglobulins (Xi, and Guo, 2007; Xiao et al., 2011).

Flavonols and flavones also have the potential to form specific non-covalent interactions with proteins. Hydrogen bonds between the hydroxyl groups of the polyphenol ligands and the catalytic residues of the binding site can directly be linked to the inhibitory activity of the flavonoids over human digestive enzymes (Lo Piparo et al., 2008). Flavonoids interact with dietary proteins and digestive enzymes irreversibly in the gut and are assumed to be transported in vivo bound to plasma proteins (Brunet et al., 2002). Non-specific, non-covalent interactions of flavonoids and proteins have often been detected in salivary proline-rich proteins (PRP), BSA, ovalbumin and casein (Bordenave et al., 2014). Moreover, higher affinity of PRPs is expected for PRP compared to BSA and other globular proteins as PRP possess a randomly coiled structure and globular proteins lack proline which is considered to be an important feature for polyphenol binding (de Freitas and Mateus, 2012).

Complexation of flavonoids with salivary PRPs is also reported to result in astringency. For example, complexation of oligomeric flavonoids, such as proanthocyanidins, and salivary PRP create aggregates that precipitate (Bordenave et al., 2014). Compared to oligomeric flavonoids, interaction between monomeric flavonoids and salivary protein form complexes that do not precipitate (likely soluble complexes) but result in astringency perception (de Freitas and Mateus, 2001). London interactions between the non-polar polarizable aromatic rings of flavonoids and non-polar polarizable parts of protein side chains operate in both of these scenarios either forming soluble or insoluble complexes (Bordenave et al., 2014).

## Protein Interactions With Stilbenes

Stilbenes, such as resveratrol (3,5,4-trihydroxystilbene), interact with different types of proteins and this complexation influences the binding sites, structure and the conformational changes of proteins. The protein-phenol complexation includes hydrophobic and amphiphilic ligands and may lead to structural transition of proteins. Particularly, structure-affinity relationships and the physicochemical properties-affinity relationships of phenol–protein interactions were found to be important in both food and pharmaceuticals (Bordenave et al., 2014).

## Protein Interactions With Lignins

Lignins are complex substances with aromatic rings, formed via polymerization of a mixture of the three monolignols *p*-coumaryl, sinapyl and coniferyl alcohols (Shahidi and Naczek, 2003). The phenolic group in the lignin is considered as an excellent hydrogen donor. It can interact with functional groups of proteins including carboxyl, hydroxyl, and amino groups to form covalent and hydrogen bonds (Pradyawong et al., 2017). In other words, they can interact with the side-chain of amino acids via quinone intermediates (Cong et al., 2013). Plant cell wall-localized proteins complex with the wall structural components, mainly lignins (Cassab, 1998). Particularly, amino acids with nucleophilic side chains can covalently attach to lignin (Cong et al., 2013). Moreover, it has been suggested that lignin interacts with protein to form a protein-lignin complex or network by hydrophobic interactions, and ionic and hydrogen bonds (Pradyawong et al., 2017). Lignins enhance the tensile strength, thermal stability, and Young's modulus by cross-linking with proteins (Doherty et al., 2011; Salas et al., 2012; Xiao et al., 2013). Understanding the nature of lignin–protein interactions is of fundamental importance as it plays a critical role in lignin-based value-added products such as bio-based adhesives.

## Protein Interactions With Coumarins

Coumarins are lactones of *cis*-*O*-hydroxycinnamic acid that exist in the free form or as glycosides (Shahidi and Naczek, 2003). Compared to other phenolic compounds, coumarins and their interaction with other macromolecules including proteins were studied mainly under anti-diabetic candidates (Ali et al., 2016), antibiotic agents (Gormley et al., 1996; Marcu et al., 2000) and other health beneficial components. Hydrophobic binding sites of these proteins were found to determine the capacity of binding aromatic and heterocyclic compounds to them and strong bindings of hydroxycoumarin derivatives that improved their therapeutic activities.

## Protein Interactions With Tannins

The defining characteristic of tannins is their ability to precipitate protein molecules (Hagerman et al., 1998). The interaction between proteins and tannins influences the appearance and taste of foods and beverages (Shahidi and Naczek, 2003; Ozdal et al., 2013), the function of ecological (Hagerman and Butler, 1991) and agricultural (Kumar and Singh, 1984) systems. Tannins interact with proteins mainly through hydrogen bond formation between the phenolic donor and the peptide acceptor (Hagerman et al., 1998; Nie et al., 2017). The nature of tannin/protein interactions is either covalent or non-covalent, based on whether the molecules were irreversibly bound to each other or not. In addition, as a consequence of the type of bonding, complexes formed can either be soluble or insoluble (Soares et al., 2012). There is an optimum tannin/protein ratio for which maximum precipitation occurs. It has been observed that the quantity of insoluble precipitates is lower for both higher and lower tannin/protein ratios. Besides, as protein structure plays an essential role in complex formation (Hagerman et al., 1998), binding sites of the proteins are important. For example, if protein has a fixed number of binding sites and tannin has more than one binding site, even though there is excess tannins, the final result is dictated by the number of binding sites in the protein. All the sites in proteins would be occupied by tannins and due to that tannin could not find available binding site for another protein when it is attached at one end. This results in smaller particles and less precipitation (less haze).

Proline-rich proteins (PRP) form strong hydrogen bonds with tannins (Hagerman et al., 1998; Soares et al., 2012). Conformation of these interactions of PRP are flexible and increase the accessibility of hydrogen bonding sites (Hagerman et al., 1998; Watrelot et al., 2017). The association between tannin and PRP is suggested to have face-to-face stacking of aromatic groups onto proline residues while interaction with globular proteins may involve only surface exposure of aromatic residues (de Freitas and Mateus, 2001). Complexation of tannins and salivary PRPs is due to their involvement in inducing the astringency in food products including wine, teas and some dairy products (Scollary et al., 2012; Thongkaew et al., 2014). These processes of creating complexation between polyphenol and protein is commonly utilized in food processing industries such as wine making which improves the haze stability and taste (Sarni-Manchado, and Cheynier, 2002; Nguela et al., 2016). Interactions of tannins with peptides and proteins also possess biological importance as they influence the absorption, metabolism and bioactivities of polyphenols in the human body including inactivation of digestive enzymes. Moreover, they may be responsible for plant defence mechanisms against predators (Sarni-Manchado and Cheynier, 2002).

**Table 1** Potential effects of phenol–protein interactions on nutritional and health related properties of foods

Property of the food	Source of food protein	Phenolic compound	Changes in functionality or modification	References
Allergic potential	peanut proteins	dietary polyphenols	direct inhibition of mast cell mediator release suppression of T cell proliferation, inhibition of cytokine secretion	Nowak-Węgrzyn and Sampson (2011) and Srivastava et al. (2002)
	milk and peanut proteins	green tea catechins	Increase the resistance of allergenic proteins towards the enzymatic hydrolysis	Astwood et al. (1996); Maleki et al. (2000)
	Egg white protein	green tea polyphenol	polyphenol decrease the allergenicity of egg white protein and modulate immunoreactivity	Foegeding et al. (2017)
Anti-inflammatory properties	milk protein	green tea polyphenol	accelerate protein gelation rate and produced firm $\beta$ -lactoglobulin gels improve the antiproliferative bioactivity of the polyphenols	Schneider et al. (2016); von Staszewski et al. (2011)
Emulsifying properties	zein protein	tannic acid	stabilize emulsions by a pickering emulsion gel mechanism	Zou et al. (2015)
	$\beta$ -lactoglobulin	green tea polyphenols	improve the stability of emulsion by producing surface active particles	von Staszewski et al. (2011)
Foam formation	$\beta$ -lactoglobulin whey protein isolate	catechin phenolic compounds from cranberry, blackcurrant and muscadine grape juices	improve foam formation and stability enhance foam formation and stability compared to whey protein isolate alone	Sarker et al. (1995) Schneider et al. (2016)

### Potential Effects of Protein–Phenol Interaction on Nutrition and Health

Protein–phenol interactions influence the sensory properties and as well as nutritional composition of the foods at the molecular level (Foegeding et al., 2017). These associations are likely to impact the functional properties of foods as they enhance the protection against chronic and degenerative diseases (Bordenave et al., 2014). Growing consumer interest and demand for foods rich in biologically-active, health-protective properties have encouraged the food application of protein-polyphenol complexation. Use of proteins as encapsulating agent for polyphenols (Foegeding et al., 2017), for stabilizing protein foam structures (Prigent et al., 2009), use of protein–polyphenol interactions to stabilize, deliver and improve biological activity of phenolic compounds (Bordenave et al., 2014) are some of the efforts made to functionalize food with protein-phenol combination and taking advantage of their association. However, according to nutritional view point, nutritional quality and bioavailability of phenolic compounds as well as proteins may be significantly effected by the protein-phenol complexation (Table 1) and thus rational design of food products would ensure efficient utilization of phenol–protein interactions.

### Methods Used for Analysis of Phenolic–Protein Interactions and Their Limitations

Analysis of the interactions between proteins and phenolic compounds is important as it has direct influence on nutritional and functional properties of food products. Most of the frequently used analytical methods to investigate protein–phenol interactions is based on spectroscopic methods. UV–Vis spectroscopy is an ideal technique to investigate molecular nature of the interactions of phenols and proteins. Generally, spectrophotometric methods are considered as common, easy, practical, and qualitative methods to observe conformational changes in proteins and can also be used for selective determination of phenolic compounds in the presence of other substances (Avan et al., 2016; Zhang et al., 2017). In addition, microscopic, thermodynamic, electrophoretic, chromatographic, and bioinformatics analyses are other analytical methods reported for this purpose (Ozdal et al., 2013; Rohn, 2014; Jakobek, 2015; Czubinski and Dwiecki, 2017). Fluorescence spectroscopy (FLU) and calorimetric studies (isothermal titration calorimetry and differential scanning calorimetry) are considered as ideal methods for investigating the interaction between polyphenols and digestive enzymes. However, main challenges are still associated with the development of effective methods that could be used for both quantitative and qualitative determination of protein–phenol interactions.

### Conclusion

Protein–phenol interactions can lead to both favourable and adverse effects on structure, functional and nutritional properties of proteins as well as phenolic compounds. The consequences of these interactions play an important role in influencing the functional properties and sensory attributes of food components. The protein-phenol complexation may be reversible or irreversible. Protein-phenol associations may be via covalent bonding or non-covalent interactions. Contradictory results have been reported for bioavailability of the phenolic compounds, factors affecting the degree of the interactions and determination

methodologies for protein-phenol complexation. Further studies are needed to provide a deeper understanding and also to explore this complex phenomenon in order to clarify the controversial observations already reported in the literature.

## Introduction

Flavonoids possessing three ring chemical structure (C6—C3—C6) are ubiquitous in plants such as cereals, legumes, vegetables, and fruits as their secondary metabolites. In plants, flavonoids perform pivotal roles such as controlling auxin transport, defending against external predators, and acting as UV filters (Kitamura, 2006). Recently, there has been an increasing interest in flavonoids by both researchers and consumers due to their remarkable bioactivities such as anticancer, anti-inflammation, and anti-virus as well as reducing cardiovascular disease and type-2-diabete (Lin et al., 2000; Panat et al., 2016; Watanabe et al., 2007; Kang et al., 2013; Chtourou et al., 2016).

Proteins, which are assemblies of 20 different kinds of amino acids, are essential macromolecules for the life. Proteins are involved in a variety of functions in plant metabolism such as the regulatory function which decides the influx of compounds to the inside of cell or organelle at the surface of membrane or vice versa and play the structural role in which proteins help make the rigid formation of cellulose fiber at the cell wall. In addition, proteins serve as the main nutritional storage sources that are used for the development and growth of seeds. Proteins act similar roles in biological systems; that is, they act as a building material for tissues (collagen), render catalytic activity (enzymes), or are involved in the mechanisms for muscle movement (myosin and actin) (Foegeding, 2015).

In foods, a variety of macronutrients and micronutrients are present together, which causes numerous chemical interactions during storage and food processing. Among them, flavonoid-protein interaction is a common chemical reaction, leading to major changes in physico-chemical characteristics of proteins. For example, the interaction of flavonoid and protein affects solubility, thermal stability, and digestibility of proteins (Labuckas et al., 2008; Rawel et al., 2001). In addition, the structural changes of essential amino acids by the reaction with flavonoids influence to the nutritional quality of proteins (Kroll et al., 2003). The flavonoid-protein interaction also affects the antioxidant potential and the bioactivity of flavonoids mostly in a negative way due to the loss of hydroxyl groups upon the formation of covalent or non-covalent interaction between flavonoids and proteins (Duarte and Farah, 2011; Burg-Koorevaar et al., 2011; Serafini et al., 2009; Blauz et al., 2008). For instance, the interaction of milk proteins with flavonoids in coffee/tea decreases the antioxidant capacities of flavonoids in ABTS radical cation scavenging capacity and ferric reducing antioxidant power (FRAP) assays (Sanchez-Gonzalez et al., 2005; Ziyatdinova et al., 2010). Furthermore, the complexation of walnut proteins, mostly glutelin and globulin, with walnut flavonoids reduced the DPPH radical scavenging ability of flavonoids. The binding of milk proteins with flavonoids in cocoa also suppressed the antioxidant potential as revealed in ABTS radical cation scavenging capacity, ferric reducing antioxidant power (FRAP) assays, and DPPH radical scavenging ability (Belščak et al., 2009; Labuckas et al., 2008).

The interaction between flavonoids and proteins has been well investigated using several advanced techniques such as infrared (IR) spectroscopy, fluorescence spectroscopy, electronic absorption spectroscopy, and nuclear magnetic resonance (NMR) spectroscopy, which exploits the property of elementary particles such as electron, nucleus and photon based on the quantum mechanics. For example, the interaction of  $\alpha$ - and  $\beta$ -caseins with tea flavonoids such as (+)-catechin, (–)-epicatechin, (–)-epigallocatechin and (–)-epigallocatechin gallate observed by using Fourier-transform infrared spectroscopy (FTIR), fluorescence spectroscopy, and electronic absorption spectroscopy (Hasni et al., 2011). Therefore, such advanced techniques are successfully employed for understanding the interaction of flavonoids and proteins.

Electron paramagnetic resonance (EPR) spectroscopy is also a useful means for the determination of chemical reaction between molecules. However, the limitation of this technique is related to the fact that it is only applicable to the radical or resonance possessing molecules, thus EPR spectroscopy could only be used for monitoring the reaction of flavonoids with free radicals such as 2,2-diphenyl-1-picrylhydrazyl (DPPH). Hence, this allows one to evaluate electron donating potential of flavonoids. Thus, EPR spectroscopy has successfully been used to determine the antioxidant potential of plant-based foods such as lentils, millets, and fruit seeds (Yeo and Shahidi, 2017; Alshikh et al., 2015; Chandrasekara and Shahidi, 2010; Ayoub et al., 2016) and could potentially be used to determine changes in their reactivity upon complexation with proteins.

## Chemistry of Flavonoid-Protein Interaction

Flavonoids and proteins can chemically interact during food processing and storage by forming reversible and irreversible interactions. The reversible interaction of flavonoid-protein is formed via non-covalent bonds such as hydrogen bond, hydrophobic interaction and van der Waals forces (Charlton et al., 2002a,b; Jobstl et al., 2004; Poncet-Legrand et al., 2006; Prigent et al., 2003; Richard et al., 2005, 2006; Siebert, 2006). This weak interaction can be readily broken by a relatively low level of energy. Conversely, the irreversible interaction, which is covalently bound, is not dissociated even under alkali or acidic hydrolysis. The formation of irreversible covalent bond accompanies a complex reaction mechanism, which is initiated by the oxidation of flavonoids. The oxidation of flavonoids, especially two hydroxyl groups of the B-ring in flavonoids, leads to the formation of o-quinone (O'Connell and Fox (1999)). The o-quinone can then react with thiol and amino groups of proteins through the nucleophilic 1, 4-Michael

**Table 1** Analysis of flavonoid-protein interaction using advanced techniques

Analytical technique	Flavonoid	Protein	References
Infrared (IR)	rutin	gelatin	Yan et al. (2011)

addition which subsequently leads to the formation of irreversible covalent bond between flavonoids and the proteins (Le Bourvellec and Renard, 2012). The irreversible interaction between flavonoids and proteins has been reported in the literature. For instance, Rawel et al. (2002) demonstrated the irreversible interaction of soyprotein with apigenine, kaempferol, quercetin and myricetin. In addition, O'Connell and Fox (1999) and Tantoush et al. (2011) explored the irreversible covalent bond between  $\beta$ -lactoglobulin and sour cherry flavonoids. However, most of the research work on the determination of covalent bond between flavonoids and proteins have been carried out in an indirect way such as protein precipitation using turbidimetry and nephelometry, thus this chapter concentrates more on non-covalent interactions that are usually determined by advanced techniques such as IR, fluorescence and electronic absorption spectroscopy, as well as NMR (Table 1).

## Analysis of Flavonoid-Protein Interaction by Advanced Techniques

### Infrared (IR) Spectroscopy

Infrared spectroscopy is a simple and feasible technique widely used in diverse areas including food science. This advanced technique exploits the fact that the specific movement of molecules such as rotation and vibration absorbs in the infrared wavelength range through the resonance. Infrared is defined as electromagnetic radiation having wavelengths in the range of 0.8–1000  $\mu\text{m}$  ( $14000\text{--}10\text{ cm}^{-1}$ ), which is relatively longer than visible, ultraviolet, and X-ray. The energy of infrared wavelength can be absorbed by the molecular movements such as rotation and vibration as mentioned earlier. For instance, the oscillation (stretching frequency) at the hydroxyl group of a molecule absorbs wavelength at  $3610\text{--}3670\text{ cm}^{-1}$ . Thus, IR spectroscopy allows one to identify functional groups and their changes during chemical reaction. The interaction of flavonoid-protein leads to the alteration of functional groups such as hydroxyl and amide due to the covalent or non-covalent interaction between them. This can be detected using IR spectroscopy.

Yan et al. (2011) found the complexation of gelatin with rutin using Fourier-transform infrared spectroscopy FTIR. Hasni et al. (2011) demonstrated the complexation of  $\alpha$ - and  $\beta$ -caseins with tea flavonoids using FTIR, in which they reported two casein amid bands, namely band I at  $1656\text{--}1652\text{ cm}^{-1}$  for C=O stretching and band II at  $1544\text{--}1500\text{ cm}^{-1}$  for C–N stretching, then found the shift of these bands after the complexation of flavonoid with casein. Wu et al. (2011) studied the complexation of (–)-epigallocatechin (EGC) and  $\beta$ -lactoglobulin using FTIR; they also observed the shift of amide I (mainly C=O stretch) and II band (C–N stretch coupled with N–H bending mode), i.e. amide I band moved from  $1639.37$  to  $1641.30\text{ cm}^{-1}$  and the amide II band moved from  $1541.01$  to  $1542.93\text{ cm}^{-1}$ . They concluded that the band shift may be due to the alteration in secondary structure of  $\beta$ -lactoglobulin upon complexation with (–)-epigallocatechin (EGC). In another study, the complexation of whey protein with quercetin was also measured by FTIR; the electrostatic interactions such as hydrogen bond between whey proteins and quercetin contributed to the stabilization of ketone groups and peptide bonds and these were reflected in the changes of FTIR spectrum. That is, band I at  $1648\text{--}1649\text{ cm}^{-1}$  for the C=O stretching vibrations and band II at  $(1536\text{--}1547)\text{ cm}^{-1}$  for the N–H bending vibrations were shifted upon complexation of whey protein with quercetin (Mehanna et al., 2014).

### Fluorescence Spectroscopy

Fluorescence is defined as the emission of wavelength by a molecule after excitation by light and electromagnetic radiation. Individual molecules possess their own intrinsic energy level (ground state) and they are excited by absorbing specific strength

**Figure 1** The excitation of a molecule by absorbing wavelength and yielding fluorescence.

of energy which can elevate to the upper energy level. The excited unstable molecules tend to be stabilized by releasing energy via rotation, vibration, and translational motion. Furthermore, some molecules release energy in a wavelength (normally lower energy level than the excitation wavelength), and the released wavelength is via fluorescence (Fig. 1). Fluorescence spectroscopy observes the changes of excitation wavelength of target fluorescence compounds, which is induced by the alteration of electron density of the molecules, hence it has been widely used for the investigation of chemical interaction between molecules including flavonoid-protein complexation.

The binding of flavonoid-protein has been successfully explored by using fluorescence spectroscopy. The alteration of the quantum yield of fluorescence provides useful information about the chemical interaction between molecules (Tayeh et al., 2009). For example, the intrinsic tryptophan fluorescence such as Trp-37, Trp-66 in  $\alpha_{s1}$ -casein and Trp-109 in  $\alpha_{s2}$ -casein is used for the detection of chemical interaction of casein protein with flavonoids (Kumosinski et al., 1993). Rawel et al. (2002) reported the interaction of soyprotein (Soy glycinin) with apigenine, kaempferol, quercetin and myricetin using fluorescence spectroscopy in which the intensity of the emission wavelength of soyprotein at 338 nm was decreased after interaction. Hasni et al. (2011) studied the interaction of  $\alpha$ - and  $\beta$ -caseins in milk with tea flavonoids such as (+)-catechin, (–)-epicatechin, (–)-epigallocatechin and (–)-epigallocatechin gallate by using intrinsic fluorescence of tryptophan in casein; they determined the binding constant between flavonoids and caseins, and the results showed a higher constant value in (–)-epigallocatechin and (–)-epigallocatechin gallate than (+)-catechin and (–)-epicatechin due to the presence of more hydroxyl groups. Moreover, the shifted emission band observed after complexation also allowed more detailed explanation of the interaction. The downward shift was found in catechin- $\alpha$ -casein and epicatechin- $\alpha$ -casein complex (from 350 nm to 334 and 343 nm) due to the tightening of protein structure by hydrogen bonding. Fluorescence spectroscopy was also employed to determine the binding of quercetin, rutin, and isoquercetin with proteins such as human serum albumin, bovine serum albumin, and soy glycinin through the alteration of excitation and emission energy levels (Rawel et al., 2005).

### Electronic Absorption Spectroscopy

Electronic absorption spectroscopy, referred to as UV/Visible spectroscopy, is routinely used in analytical chemistry. The principle of electronic absorption spectroscopy relates to the absorption of UV/visible wavelength by the chromophore of molecules; that is, an electron in the chromophore such as  $\pi$ -bond absorbs the photon having UV/visible wavelength through resonance and this leads to the excitation of the electron to the higher energy level. Especially, the electron in the outer shell of molecules is responsible for the absorption of UV/visible wavelength, which is longer and low energy wavelength than X- and  $\gamma$ -ray. Thus, electronic absorption spectroscopy is a useful means to detect the changes of electronic state of molecules resulted from the interaction with other molecules such as flavonoid-protein interaction.

Until now, the electronic absorption spectroscopy has been successfully adopted in understanding the interaction of flavonoid and protein. Zsila et al. (2003) found a strong bathochromic shift of approximately 30 nm upon the interaction of quercetin to the human serum albumin at 374 nm. Besides, the band broadening at that wavelength was also observed upon complexation, which occurs by the interactions between molecules such as dipole-dipole, H-bond, and ionic interaction, hence it is explained as the non-covalent interaction of quercetin to the amino acid residue of human serum albumin. Kanakis et al. (2011) studied the interaction of  $\beta$ -lactoglobulin with (–)-epigallocatechin (EGC); they found the changes of spectrum upon complexation of  $\beta$ -lactoglobulin with (–)-epigallocatechin (EGC). Hasni et al. (2011) found the interaction of milk  $\alpha$ - and  $\beta$ -caseins with tea flavonoids using UV-visible spectroscopic method by yielding the binding constant from the reciprocal plot and the result showed that the stability of casein-catechin and casein-epicatechin was similar due to the same number of hydroxyl groups, however the complexation of casein with (–)-epigallocatechin (EGC) and (–)-epigallocatechin gallate (EGCG), possessing more hydroxyl groups, revealed a better stability than the catechin- and epicatechin-casein complexation.

### Nuclear Magnetic Resonance (NMR) Spectroscopy

NMR spectroscopy that exploits the magnetic characteristic of certain atomic nuclei is a representative means to identify the chemical structure of molecules. The nuclear magnetic resonance provides key information about the structure, dynamics, reaction

state, and chemical environment of molecules; thus, the nuclei spin of atom in molecule is influenced by neighboring atom(s) and the surrounding environment, leading to scrutinizing the chemical structure of target molecules (Le Bourvellec and Renard, 2012). The chemical shift, which is the resonant frequency of a nucleus compared to the standard compound in a magnetic field, is varied depending on the electron shielding from an atom or functional groups in molecule. Thus, the chemical interaction of flavonoid with protein, which accompanies the alteration of electron shielding, can be explored using NMR spectroscopy by monitoring the alteration of chemical shift. The NMR spectroscopy allows accurate determination of interaction sites, mechanism of interaction, and even the dissociation constants upon the interaction of flavonoids and proteins (Murray et al., 1994; Charlton et al., 2002a,b; Baxter et al., 1997; Wroblewski et al., 2001). The interaction of flavonoids and protein have been widely investigated by using NMR. For example, Delius et al. (2017) studied the interaction between salivary proline-rich proteins and flavonoids by  $^1\text{H}$ -NMR spectroscopy, in addition Baxter et al. (1997) investigated the interactions of flavonoids and a salivary proline-rich protein using NMR in which they found that flavonoids with more hydroxyl groups interact with the salivary proline-rich protein in a multidentate fashion as well as self-polymerization. On the other hand, beyond the advantages of NMR spectroscopy such as giving precise binding sites, the number of bonding sites, and the interaction of molecules with environments (i.e., complexation of flavonoid-protein), it has a serious drawback in the application of NMR spectroscopy. That is, the sample for the application to the NMR should be prepared in a high concentration to gain good resolution of peaks for the correct interpretation. However, many flavonoids and proteins have a low solubility at high concentrations, especially in aqueous medium, which makes it difficult to apply to the NMR system.

## Conclusion

The interaction between flavonoids and proteins is responsible for the formation of both reversible and irreversible interactions. The reversible interaction of flavonoid-protein is produced through non-covalent bonds such as hydrogen bond, hydrophobic interaction and van der Waals forces, whereas irreversible interactions occur by covalent bonding that is not dissociated by even alkali or acid hydrolysis process. The structural changes upon interaction of flavonoids with proteins have been successfully investigated using advanced techniques such as infrared (IR) spectroscopy, fluorescence spectroscopy, electronic absorption spectroscopy, and nuclear magnetic resonance (NMR) spectroscopy. Each technique has its own advantages and disadvantages in the application for the analysis of flavonoid-protein interactions, thus it is imperative to consider the condition of samples prepared and research environment to obtain the required results.

# Covalent Interactions Between Proteins and Phenolic Compounds

Sascha Rohn, University of Hamburg, Hamburg, Germany

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Phenolic compounds are secondary plant metabolites that plants use for coloring, UV shielding, as phytoalexins, or repellents (Friend, 1979; Dixon and Paiva, 1995). As part of the human diet, they are hypothesized to affect human health either in a positive way or in some cases lead to adverse implications (Scalbert et al., 2005; Crozier et al., 2009). However, in most studies chemical transformations of phenolic compounds during plant food preparation have not been considered carefully, and compounds are often regarded as pure isolates, even inert. In realistic scenarios and because of high reactivity of phenolic compounds, their interaction with other compounds present cannot be excluded. Often such interactions already take place in the plant, as endogenous mechanism for activating or inhibiting a certain function (e.g., glycosylation for enhancing solubility and transport). However, due to the high number of other compounds present, a whole bunch of nontargeted reactions should be considered as well. With regard to food processing - conditions of higher temperature, or certain treatments affecting the plant cell structure (e.g., peeling, cutting) - even more reaction products can be expected, as compounds "meet" each other that have been not related in the untreated plant before. In the further course, after consumption of a plant-based food, interactions and reactions in the human body are possible, as well.

Among the primary compound classes, proteins seem to be the most interesting ones, as they can interact with phenolic compounds on different occasions. From a chemical point of view, protein-phenol interactions can occur in different ways. Similar to the typical protein-protein interactions, hydrogen and ionic bonding, hydrophobic and aromatic interactions are key mechanisms. Moreover, covalent bonds are of special interest, as such bonds are mainly irreversible and influence the (chemical) properties of both reaction partners enduringly.

## The Covalent Reaction of Phenolic Compounds With Proteins

A key step of the reaction of phenolic compounds with proteins is the capability of the phenolic compounds to be easily oxidized enzymatically or nonenzymatically (Cilliers and Singleton, 1991; Friedman, 1996) and being therefore highly reactive (Fig. 1). Primarily, the resulting ortho- or para-quinoid structures are reacting with other quinones to produce dark melanin pigments (Nicolas et al., 1994; Friedman, 1997; Robards et al., 1999). This is valid for most of the phenolic compounds. In case of mono-hydroxyl phenolic compounds such as ferulic or coumaric acid, the reaction proceeds via the formation of semiquinones. The free radicals can then participate in nonenzymatic reactions, including polymerization, hydration, and disproportionation (Thurston, 1994; Selinheimo et al., 2007). But also during thermal treatments (i.e., during food processing), the formation of quinones is a key element and will lead to (smaller) degradation products that may also serve as substrates for follow-up reactions such as polymerization (browning) (Buchner et al., 2006). All the previously mentioned reactions are prerequisites for generating electrophilic species capable of underlying a nucleophilic (Michael-type) addition (Fig. 1). In case of the proteins, they provide nucleophilic side chains as preferred reaction partners. Especially  $\epsilon$ -amino groups of lysine residues, thiol groups, or the indole group of tryptophan are the most reactive ones. In one of the earliest investigations, Mason and Peterson (1955) reported that the reaction of the quinone proceeds rapidly at a neutral pH, as demonstrated for proline and nucleoprotamine. Besides, imidazole and disulfide groups have

**Figure 1** Oxidation of a catechol moiety as a prerequisite for the formation of reaction products. Reprinted from Food Research International, vol. 65, Part A, Rohn, S., November 2014. Possibilities and Limitations in the Analysis of Covalent Interactions between Phenolic Compounds and Proteins, pp. 13–19, with permission from Elsevier. Permission was requested and publisher (Elsevier) agreed (License Number 4207161081661).

also been reported to be reaction partners (Vithayathil and Murthy, 1972; Loomis, 1974; Matheis and Whitaker, 1984a,b; Kroll et al., 2003).

### Where Does This Happen?

A review of the literature reveals the following locations or categories for the interactions of phenolic compounds: (1) interactions in the plant with storage and physiological active proteins; (2) interactions of plant phenolic compounds with food proteins during food processing, resulting in changes of food texture; (3) interactions may further occur with food proteins or enzymes in the course of digestion in the gastrointestinal tract; (4) during digestion, proteins/enzymes secreted in the gastrointestinal tract may serve as the interaction partners, as well; (5) after absorption, plasma proteins can be the target; and finally (6) interactions possibly occur with proteins in target tissues/organs in the human body.

### Physicochemical Consequences

From the point of view of the chemical structure, the conformation of a protein is influenced by the posttranslational modifications. As described above, such reactions almost occur nontargetedly, which means that depending on the initial protein structure/conformation, the most accessible protein side chains react primarily, before the protein refolds and uncovers to further generate possible reaction sites. This further means that every protein might be affected specifically depending on the conditions (phenolic substrates, pH value, temperature, amino acid sequence, isoelectric point). A prediction of the degree of derivatization seems to be impossible, which is a severe aspect when one tries to characterize/analyze such protein derivatives. A change in the protein structure leads to a corresponding change in the hydrophobic–hydrophilic properties of the protein derivatives, which is accompanied by a change in the solubility and a shift of the isoelectric point. These changes in turn may influence certain technofunctional properties (e.g., emulsion-, foaming properties) (Prigent et al., 2003; Gonzalez-Perez et al., 2002; Gonzalez-Perez and Vereijken, 2007).

With regard to color, it has been shown with smaller reaction products that the implementation of the aromatic rings leads to a color shift. Under conditions of autoxidation of caffeic acid esters and in presence of an amino compound the formation of benzacridine derivatives was observed (Namiki et al., 2001). The reduced form of the derivative was found to be yellow and further with characteristic products of green and blue color (Namiki et al., 2001; Yabuta et al., 2001). Several green trihydroxy benzacridine derivatives were identified during the alkaline sunflower meal extraction. There, the presence of chlorogenic acid in the meal leads to the formation of *o*-quinones (Bongartz et al., 2016). Larger reaction products turn brown as observed during alkaline sunflower protein processing (Sabir et al., 1974).

### Protein Cross-linking

When taking a look at the reaction mechanism, it is obvious that the phenolic compounds remain reactive after the addition to a protein side chain. This means that they are able to be oxidized again, and depending on the structural/conformational characteristics of the protein, a second binding of a further protein molecule can occur (Fig. 2). This protein cross-linking leads to dark-colored protein complexes of high molecular weight (Sabir et al., 1974).

**Figure 2** Protein cross-linking as a result of the reaction of oxidized phenolic compounds with protein side chains, followed by a second enzymatic or nonenzymatic reoxidation of the phenolic compounds. Permission was requested and publisher (Elsevier) agreed (License Number 4207161081661).

## Nutritional Consequences

### Phenolic Compounds

Resulting from their reaction with proteins, properties of the phenolic compounds might be affected as well, e.g., the antioxidant activity of the phenolic compounds declined as a result of the covalent attachment to the protein (Rohn et al., 2004, 2005).

### Proteins

The derivatization of proteins (with phenolic compounds) influences the biological activity of proteins/enzymes (Alberghina, 1964; Rohn et al., 2001, 2002, 2004, 2005). Indispensable amino acids such as lysine and tryptophane are preferred reaction partners; thus a loss of nutritional quality of the proteins can be observed (Davies et al., 1978; Petzke et al., 2005; Rohn et al., 2006). For example, a rat growth and nitrogen balance study showed that a protein derivatization with chlorogenic acid affected the nutritional quality of beta-lactoglobulin (Petzke et al., 2005). Proteolytic digestion of such protein derivatives showed that at a lower degree of derivatization, the tryptic degradation was adversely affected, whereas the peptic digestion declined with increasing modification. In vitro experiments illustrated that the digestion of derivatized lysozyme with enzymes of the gastrointestinal tract was adversely affected (Rawel et al., 2001a).

### Phenolic Polymers or Phenol-Protein Reaction Products?

As planned by nature, the phenolic compounds preferably react with themselves prior to the reaction with the amino group. Usually this leads to dark-colored melanins observed during the enzymatic browning of plant tissues. In the presence of nucleophilic amino groups and taking the mechanism proposed by Namiki and coworkers into account, a dimerization of phenolic compounds prior to their interaction with proteins during heating and at alkaline pH values seems to be a precedent reaction (Namiki et al., 2001; Yabuta et al., 2001). This was also already shown for chlorogenic acid in simple model mixtures with selected amino acids (Prigent et al., 2003). With regard to proteins and protein cross-linking, complexity can be even higher as more or less oligomerized phenolic compounds might serve as substrates for the reaction with the proteins. Consequently, three types of reaction products have to be considered (Fig. 3A–C): In the first case, there are simple reaction products, where single phenolic compounds are bound to single specific amino acid side chains (Fig. 3A). Secondly, the phenolic compounds form oligomers of varying molecular weight before being bound to the amino acid residues (Fig. 3B). Finally, there is protein cross-linking that can occur via monomeric or even

**Figure 3** (A–C) Different reaction product profiles. Simple reaction products, where single phenolic compounds are bound to single specific amino acid side chains (A); mixed reaction products consist of bound oligomers besides monomers (B); complex cross-linked proteins and variations thereof (C). Reprinted from Food Research International, vol. 65, Part A, Rohn, S., November 2014. Possibilities and Limitations in the Analysis of Covalent Interactions between Phenolic Compounds and Proteins, pp. 13–19, with permission from Elsevier. Permission was requested and publisher (Elsevier) agreed (License Number 4207161081661).

oligomeric phenolic structures. Further, the occurrence of neoformed disulfide bridges is also possible due to the various redox reactions of the phenolic compounds and the transformation of the protein structure/conformation (Fig. 3C).

Recently, two types of covalent protein–phenol reaction products have been described in honey. With the use of size-exclusion chromatography it was possible to reveal that oligomerization of phenolic monomers seems to occur prior to protein binding (Brudzynski et al., 2013). As obvious, a mix of all kinds of reactions might be possible under realistic conditions of food processing, which makes the analysis of phenol–protein reaction products a huge challenge.

### Analysis of the Phenol–Protein Reaction Products

Analysis of phenol–protein adducts is quite challenging, as the phenolic compounds remain reactive after the addition to the protein. Understanding the conditions required for the formation of covalent bonds or the biological consequences of the covalent modification is hindered by the lack of suitable analytical methods for evaluating the reaction products and the paucity of methods to purify the products for a complete characterization (Hagerman, 2012). Strategies and methodologies are not yet satisfactory.

Similar to the analysis of posttranslational modifications determined in biochemistry and physiology (e.g., glycosylations, phosphorylations), the analysis of nontargeted reaction products of phenolic compounds and proteins is challenging. It could be rated as an even greater challenge, because most of the biochemical posttranslational modifications are catalyzed by specific enzymes that can be taken into account for analyzing the reaction products. In case of phenol–protein reactions occurring during food processing, consumption, and digestion with multiple influencing factors described earlier (oxidation conditions, chemical structure of the substrates, pH value, temperature, protein sequence and structure, etc.), the obtained products are of a far higher variety.

From simple adducts to more complex intermediates up to cross-linking products, an analytical strategy has to be developed, which fits the specific goals of analysis. When investigating protein–phenol adducts, there are several possibilities. From all the aspects mentioned so far, it seems to be of further interest in knowing to which extent a protein is modified.

Indirect methodologies focus on the estimation of modified amino acids, analyzing the extent of phenolic compound bound, or evaluation of the resulting change in the properties of both compounds. For example, there are numerous (coloring) reagents to determine free amino groups in a protein. One of the approaches appropriate for phenol–protein adducts is the derivatization with trinitrobenzenesulfonic acid in a sodium dodecylsulfate solution of the samples (Adler-Nissen, 1972). For modified whey proteins, it has been shown that the amount of free amino groups declines resulting from the modification with different plant phenolic compounds (Rawel, Kroll and Hohl, 2001b; Rohn et al., 2001). From such data it is possible to give a rough estimation on the degree of modification. With regard to nutritional value, it is possible to determine the amount of (bio)available lysine (James and Ryley, 1986). For the analysis of modified thiol groups there are also several methods available, e.g., the total thiol groups can be determined by a fluorescence method, using monobromobimane as a derivatization reagent (O’Keefe, 1994). Similar to the analysis of free amino groups, a reaction of phenolic compounds does also lead to a decline in the amount of free thiol groups. Application of denaturing and reducing reagents such as sodium dodecylsulfate and dithiothreitol leads to full unfolding of the modified protein and allows evaluating if disulfide bridges have been involved in the reaction. Denaturation and fluorescence measurement can also be used for the estimation of a tryptophan modification (Jackman and Yada, 1989). A possible reaction of oxidized phenolic compounds with the heterocyclic N-atom of tryptophan has also been discussed previously (Hurrell and Finot, 1984).

The consequences of covalent reactions between phenolic compounds and proteins can be evaluated at hand of a series of changes in selected protein properties (Kroll et al., 2003). Chromatographic and electrophoretic behaviors (e.g., changes of the isoelectric point) are affected. The hydrophobic–hydrophilic properties and solubility are also modified, and these in turn may influence certain functional properties (e.g., emulsion-, foaming properties) of the protein derivatives (Prigent et al., 2003; Gonzalez-Perez et al., 2002; Gonzalez-Perez and Vereijken, 2007).

Direct analysis is used to identify the specific binding site in a protein structure. Information about specific binding sites in the protein sequence to predict, correlate, or even model resulting effects on the protein conformation with the corresponding change of its properties would be very valuable. However, there are certain limitations. As already described, main reasons are the complexity of reaction products formed and the remaining reactivity of both reaction partners: proteins and phenolic compounds. Several analytical techniques, such as capillary electrophoresis, electrospray mass spectrometry, high-performance affinity chromatography, NMR spectroscopy, fluorescence quenching, and multispectroscopic methodologies, have been developed to characterize protein–phenol interactions (Le Bourvellec and Renard, 2012; Xiao and Kai, 2012). However, identification of specific binding sites of small molecules within a protein sequence and the corresponding conformational position is still challenging. Innovative approaches are necessary to combine the abovementioned techniques. This has to be done in parallel by using more than one methodology to evaluate/correlate the data sets. A further option is the direct coupling of two techniques (“hyphenation”). A very good example for the latter approach and a promising alternative tool for the analysis of phenol–protein interactions is high-performance thin-layer chromatography (HPTLC). A few years ago, coupling of TLC and MALDI-TOF-MS was already successfully applied to analyze (unmodified) peptides (Gusev et al., 1995a,b). One-dimensional (1D) and two-dimensional (2D) HPTLC were already successfully applied to mapping of peptides (Pasilis et al., 2008a,b). Intact proteins and protein derivatives can be separated to a certain extent, as well (Biller et al., 2015).

Due to the possibility of developing HPTLC plates in two dimensions using two different solvent systems, 2D HPTLC enables protein or peptide separation with high resolution. In addition to the first dimension, which already can give good separation, a development in the second dimension can be added. Proteins/peptides, which are similar in polarity and molecular weight, may be detected as one band in 1D HPTLC. During 2D HPTLC such a band of several analytes can be separated, and each peptide can be detected as a single spot, which is similar to 2D gel electrophoresis but with far higher separation possibilities. The influence of the reaction between selected phenolic compounds on the proteins or the peptide profile in terms of quantity, polarity, UV activity, and antioxidant activity prior to or after proteolytic digestion can be studied with HPTLC. When modified proteins or peptides are separated, there are different possibilities for their detection on the plate. Usually, various staining reagents can be applied to reveal specific properties of the peptides. To observe changes in color and UV activity, detection under visible and UV wavelengths is performed. Staining with fluorescamine and ninhydrin is particularly used for peptide detection. Antioxidant activity of peptides or even modified peptides can be measured with solutions of stable radicals (Tschersch et al., 2013).

## Conclusions and Outlook

Reactions between phenolic compounds and proteins might severely influence the properties of both compound classes. Although covalent modifications occur only to a small extent, specific protein functions in plants, food, or the human body might be significantly affected. The consequences such as toxicological risks, when such protein derivatives are consumed or when such protein derivatives are formed in the human organisms, are not clearly understood and evaluated, yet. When comparing with reactions such as the Maillard reaction, which is also a very complex cascade of reactions, there may be health risks as well as advantages.

Analysis of the reaction products is challenging, as the reaction product mixture is quite complex depending on simple or complex modifications with protein cross-linking, where it is not sure, yet, how the cross-linking develops (e.g., in phenolic compound containing melanoidins). With regard to the kind of phenolic compound (small phenolic acids, flavonoids, or complex procyanidins or tannins), the more complex the phenolic compound, the more complex the reaction products will be. However, the oxidation of a catecholic moiety has to be the primary step. The phenolic compounds remain reactive during the course of reaction, and oligomers or degradation products of the phenolic compounds can be substrates for follow-up reactions. Analytical techniques have been highly improved in the last decade but are still inefficient to identify the binding sites at hand of strategies of traditional protein chemistry. Proteomics (*bottom-up* or *top-down* approaches) is also not fully applicable. Innovative strategies have to be developed, which not only focus on the protein but also taking into account the properties of the phenolic reaction partner. This does not necessarily mean that more modern devices have to be developed. Instead, the combination of traditional and hyphenated techniques, such as the coupling of HPTLC with mass spectrometry, might initiate a *neoproteomics* approach, directly targeting the phenol–protein reaction products.

# Interactions Between Proteins and Polyphenols in Beer

Haifeng Zhao and Dongxiao Sun-Waterhouse, South China University of Technology, Guangzhou, China

© 2019 Elsevier Inc. All rights reserved.

## Glossary

Haze in beer is essentially the variably-sized suspended particles that scatter light. Substances such as proteins, polyphenols (tannins), polysaccharides, yeast cells, bacteria, and foreign material can all contribute to the haze in beer. Two forms of postpackaging haze are often observed: chill haze (which results from precipitated proteins in a cooled beer) and permanent haze (which is visible in beer at room temperature). Hop haze is a permanent haze as a result of aggressive dry-hopping. Haze in beer may indicate bacterial infection (which is often accompanied by off-flavors).

## Introduction

Beer is one of the most widely consumed beverages worldwide because of its unique sensory attributes (including clear frothy appearance and fresh taste) as well as high nutritional value. With a few notable exceptions, consumers generally expect packaged beer to be clear and bright, thus beers should remain clear until they are purchased and consumed. However, as beer is inherently unstable, haze may develop inevitably during a long period of storage, and its formation is a quality indicator of physical instability. Despite the importance of both biological and flavour stability, the shelf life of beer is determined mainly by its physical stability (Steiner et al., 2010). The formation of haze or turbidity in clear and bright beer is regarded as not only a serious quality defect but also a potential hazard, thereby would decrease the likelihood of repeat purchasing of the product (Robinson et al., 2004). Nowadays, the brewers aim to delay the onset of haze so that any haze produced is imperceptible until after beer's intended shelf life.

## Haze Formation in Beer

Beer is a complex mixture of more than 450 constituents including proteins, carbohydrates, polyphenols, fatty acids, nucleic acids, amino acids, etc (Steiner et al., 2011). Some of these ingredients in bright beer tend to aggregate and form haze with different particle sizes and appearances. Glenister (1975) classified the haze particles in beer as native particles, process particles, and foreign particles according to the source of haze, whereas, Bamforth (2011) divided haze into precipitates, bits, haze, and invisible haze in the light of the size of haze. Among the contributors to haze formation, protein–polyphenol interaction is believed to be the most frequent cause (Bamforth, 1999; Siebert, 2006). There are two forms of postpackaging haze in beer, “chill haze” and “permanent haze” (Nadzeyka and Altenhofen, 1979). Chill haze develops when beer is chilled to 0 °C, which involves a reversible non-covalent association of small-polymerized polyphenols with proteins. When the beer is warmed to 20 °C, this haze can be redissolved into beer and the beer becomes clear and bright again. Permanent haze is present in beer at all practical temperatures, which initially results from non-covalent bonding between polypeptides and polyphenols, and soon after, covalent bonds are formed to yield non-reversible insoluble complexes (Siebert et al., 1996a). It is worth noting that both types of protein–polyphenol haze would normally develop and eventually exist in beer even when it is properly stabilized.

## Proteins Responsible for the Haze Formation in Beer

Beer contains two types of proteins: those must be retained (because of their role in foaming), and those should be eliminated or minimized (otherwise causing haze). Approximately 500 mg/L of proteinaceous substances occur in the form of polypeptides within the 5–100 kD size range, and are the products of barley proteins that have been modified chemically and enzymatically during brewing (Steiner et al., 2010). There is often far more proteins in beer than what is needed to form a haze (as low as 2 mg/L for haze formation) (Bamforth, 1999; Chapon, 1994; Steiner et al., 2010). The proteins in beers are considered as the main contributors to haze formation, and protein composition and the extent of protein modification (e.g. glycation, coagulation and aggregation) throughout malting and brewing are of particular importance. Indeed, the haze isolated from beers consists of about 40%–75% of proteins, polyphenols (in combination with proteins) and 2%–15% of carbohydrates (Steiner et al., 2010). Generally, the haze active (HA) proteins found in beer are derived from barley hordein, and their contributions to haze formation depend greatly on their proline content. The proline residues are involved in the sites where the polyphenols are attached to the protein. HA proteins also contain considerable glutamine residues, and adjacent proline and glutamine tend to enable unusually strong binding to polyphenols (Siebert, 2009). Asano et al. (1982) found that proteinaceous fractions responsible for chill haze in beer were derived mainly from malt hordein, and had molecular weights of 1–40 kDa and appreciable amounts of proline. Loisa et al. (1971) suggested that the acidic proteins originated from the albumins and globulins of barley were responsible for chill haze formation. Nadzeyka and Altenhofen (1979) proved that proline and glutamic acid-rich hordeins with the molecular weight within 10–30 kDa were the main initiators of haze development. Outtrup (1989) emphasized the importance of hydrophobic amino acid

residues in proteins that contributed to the formation of haze, and thought that the polypeptides in beer mostly related to physical instability were those derived from the hordein of barley and rich in proline and glutamine. Some researches proposed that polypeptides with an isoelectric point between 3 and 5 and relatively high molecular weights are particularly haze-active (Matsuzawa and Nagashima, 1990; Mussche, 1990). Moreover, 3%–7% of beer glycoproteins have been found to be involved in haze formation, with the most important glycoproteins in the size of 16.5 kD and 30.7 kD, and with a characteristic compositions of proline, glutamic acid, and hexose (Leiper and Miedl, 2009).

### Polyphenols Responsible for the Haze Formation in Beer

Phenolic compounds represent a group of chemical substances containing at least one phenol unit, which can be divided into monophenolic compounds (including phenolic acids or their decarboxylation products), non-flavonoid polyphenols (including stilbenes, chalcones, lignans and (hydrolyzable) tannins), and flavonoids and condensed tannins (such as flavones, flavonols, flavanols, flavanones, flavan-3-ols and condensed flavan-3-ols (proanthocyanidins)) (Aron and Shellhammer, 2010; Callemien and Collin, 2010; de Freitas and Mateus, 2012). Phenolic components in beer originate from malt and hop. Although hop is normally added much less (100 times lesser) than malt, hop contributes about 30% of total beer polyphenols and is the exceptional source of catechins and proanthocyanidins. It is worthy to note that not all the beer polyphenols are involved in physical instability and participate in haze formation, and oxidized flavonoids can have a strong influence in this aspect. Also, the structures of phenolic compounds could evolve during beer production and storage. HA-polyphenols should be able to effectively crosslink HA-proline-rich proteins to form a stable network causing precipitation (Siebert, 2006). It has been shown that the binding of phenol to protein depends to a great extent on the number and location of the hydroxyl groups on an aromatic ring (McManus et al., 1985). Polyphenols with a higher degree of polymerization are found to be more haze-active than those with a lower molecular weight, with one aromatic ring bearing two hydroxyl groups being sufficient for their interactions with proteins (Gramshaw, 1967; Siebert and Lynn, 1998). Polymerization degree appears to be a more determinant factor than the number of hydroxyl groups (Mulkey and Jerumanis, 1983). Accordingly, monophenols are hardly attached to proteins, and metadiaphenols have weak affinities for proteins, whereas, *ortho*-diphenols and vicinal triphenols exhibit moderate and relatively strong binding affinities, respectively (Siebert, 2006). Indeed, Mulkey and Jerumanis (1983) found that the haze-forming activity of polyphenols increased with molecular complexity (trimers > dimers > monomers). Moreover, Asano et al. (1984) reported that the flavan-3-ol monomers, (–)-epicatechin and (+)-catechin and (+)-gallocatechin, can bind to but do not crosslink with HA proteins, and phenolic acids had no haze-forming capacity. Interestingly, oxidized flavanols can initiate chill haze and, once condensed or polymerized into proanthocyanidins, they participate in the formation of permanent haze. In fact, flavanoids in beer are known constituents of permanent haze, and proanthocyanidin oligomers possess two or more binding sites within the same molecule, allowing their crosslinking with HA proteins. Trimer, tetramer and higher proanthocyanidin oligomers are difficult to survive over the course of the brewing process, whilst the proanthocyanidin dimers such as procyanidin B3 and prodelfinidin B3 have been shown as the main haze-active polyphenols in beer (Siebert and Lynn, 1998).

### Interactions Between Proteins and Polyphenols in Beer

Beer contains smaller amounts of haze-active polyphenols than haze-active proteins, and haze more likely occurs near pH 4.0 than at pH 3.0 or above pH 4.2. According to Siebert (2009), the basic mechanism underlying the interaction between proteins and polyphenols is that a polyphenol molecule with at least two binding sites attaches to two proteins and bridges are then formed between the polyphenol and two proteins to yield a 3-membered structure. Additional polyphenol molecules are able to form an attachment with this 3-membered structure, followed by further binding to additional protein molecules. This construction process would continue until the complex eventually grows so large that it is no longer soluble in beer. Some authors claim that the protein–polyphenol interaction is reversible at least initially (rather than covalent bonding) because heating can often disperse such initial protein–polyphenol hazes. Moreover, both hydrogen bond acceptors and non-polar solvents (but not salt) are found to interfere with haze formation in beer (Asano et al., 1982; Siebert et al., 1996b). As a result, hydrogen bonding and hydrophobic effect (but not ionic bonding) play an important role in the protein–polyphenol interaction (Siebert and Lynn, 2008). Protein–polyphenol interaction in a model or real beer system is mostly influenced by the concentrations of proteins, polyphenols, polysaccharides, alcohol content, oxygen, pH, temperature, ionic strength and the presence of metal ions (Siebert et al., 1996a,b). Siebert et al. (1996a,b) have conducted a detailed study on protein–polyphenol interaction in model system, in which the amount of haze was found to increase up to a peak and then decline when protein (polyphenol) content remained constant and polyphenol (protein) concentration was increased. An increase of pH would also cause a similar change in the amount of haze formed (which would increase firstly, and then decline), and the pH at which a maximum haze occur is much lower than the isoelectric point of gliadin. Meanwhile, Siebert et al. (1996a,b) noticed that alcohol had little effect on haze formation at the normal pH of beer, and the intermediate protein/polyphenol ratios resulted in the largest particles. In addition to such influencing factors investigated by Siebert and Lynn (2001), parameters such as oxygen, shaking, temperature, light, polysaccharides and (heavy)

metals will significantly contribute to colloidal instability caused by interactions between proteins and polyphenols (Callemien and Collin, 2010; Leemans et al., 2003; Collin et al., 2013). Temperature has a significant influence on haze formation in beer as an increase in temperature raises the rate of the protein–polyphenol reactions. Thus, pasteurization or storage at a higher temperature would accelerate haze formation (Stewart, 2004). Oxidation or the presence of oxygen has a great effect on beer haze formation, oxidation probably promotes the polymerization of polyphenols that cross-link with proteins to form haze (Bamforth, 1999). Indeed, monomeric polyphenols, such as catechin, would exhibit a higher potential to initiate haze when they are polymerized through oxidation (O'Rourke et al., 1998). Metal ions, particularly ferrous ion, can promote the formation of colloidal haze because the free radicals generated by Fenton and Haber-Weiss reactions in beer would attack proanthocyanidins to produce oxidation products with higher affinities for proteins (Kaneda et al., 1990). In addition, movement of beer accelerates haze formation because of rapid interaction of colloids, and light encourages oxidation and consequently causes haze formation (Callemien and Collin, 2010; Stewart, 2004). A number of polysaccharides have been associated with beer hazes or flocs, which include starch, mannan and beta-glucans (Siebert, 2009).

## Conclusion

In this review, we provide an overview of the current status of research on the interaction between proteins and polyphenols in beer and associated mechanisms. So far, the physical instability of beer is under control in both research and industrial settings. However, much research effort is still needed to maximize the nutritional profile of beer, especially nutrients like proteins and the health-promoting polyphenols, whilst minimizing haze formation.

## Overview

Polyphenols are secondary metabolites of plants and consist of one or more aromatic rings with one or more hydroxyl substitutions. They include different sub-classes such as flavanones, flavones, flavan-3-ols, flavon-3-ols, isoflavones, and anthocyanidins according to the differences in oxidation levels and substitutions on the heterocyclic pyran ring (C-ring) (Huvaere and Skibsted, 2015). Besides the main differences in carbon skeleton, modifications on primary and secondary structural elements (e.g. glycosylation, acylation, methylation etc.) causes great differences in structure and biological functions leading to complexity in polyphenol studies. Among polyphenols, flavonoids and phenolic acids have important places in human diet and are most abundantly found in fruits, vegetables, cocoa, coffee, tea, wine and beer. The intense research focus on polyphenols over the last decades is mainly due to their possible health promoting effects. The health benefits of polyphenols have been reported to result from the antioxidative and radical scavenging properties of these compounds which eventually prevent the formation of free radicals and resultant oxidation and damage that are associated with neuro-degenerative and cardiovascular diseases and common chronic diseases including cancer (Wang et al., 1996). On the other hand, bioavailability of phenolic compounds and their metabolites is affected by several factors such as food processing conditions and interactions with other molecules (salivary proteins, digestion enzymes etc.) (Cheynier, 2005). Bioavailability of polyphenols were reported to be higher when they are consumed with food rather than in form of supplements (Williamson, 2017). Therefore, their interactions with macromolecules in food are critical for nutrition studies.

The interactions of polyphenols with proteins have been extensively studied. Milk proteins are classified into two main groups namely caseins and whey proteins. Caseins are characterized with high proline content and amorphous structure. Main casein fractions found in milk are  $\alpha_{s1}$ -casein,  $\alpha_{s2}$ -casein,  $\beta$ -casein and  $\kappa$ -casein. These fractions in milk are held together by hydrophobic interactions, H-bonds and calcium phosphate bridges to form casein micelles.  $\beta$ -Lactoglobulin,  $\alpha$ -Lactalbumin, bovine serum albumin (BSA), and immunoglobulins are major whey proteins in milk and contain varying number of disulfide bonds which contribute to a compact spherical shape. Although the amount of whey proteins in milk is much lower than that of caseins, the nutritional and functional properties make whey proteins valuable components of milk. Milk protein-polyphenol studies initially gained attention due to some dietary habits such as consumption of tea or coffee with milk. Moreover, there is a growing interest in natural bioactive delivery systems in pharmacological studies. Special structural/functional characteristics and nutritional importance of milk proteins make them appropriate candidates as delivery tools for polyphenols. From the food science and technology point of view, the nature and consequences of milk protein-polyphenol interactions are critical for functional dairy product formulations. Utilization of polyphenols for improving techno-functional properties of dairy products has been under consideration in the last 20 years. Although the interactions of polyphenols with milk proteins in model systems and various dairy matrices have been recently reviewed and discussed in detail (Yildirim-Elikoglu and Erdem, 2017), the competitive binding of polyphenols to other macromolecules in complex dairy product matrices needs to be investigated. In addition, the conflicting findings have been revealed from a number of studies due to a wide range of structural differences and methods used to evaluate the binding. Development of standard methods for the determination of interactions and consequences of binding reactions seems essential for future studies.

## Mechanism of Interactions in Model Systems

Polyphenols can react with proteins both reversibly and irreversibly. Irreversible interactions involve covalent bond formation upon enzymatic or nonenzymatic oxidation of phenolic compounds to *o*-quinones which may lead to protein cross-linking. Contrarily, weak interactions such as hydrophobic, H-bonding and van der Waals attractions are responsible for reversible protein-polyphenol reactions. Over the years, a number of studies on milk protein-polyphenol interactions have been reported in model systems and the mechanisms behind these interactions were investigated. The majority of the studies pointed out the non-covalent interactions between milk proteins and polyphenolic compounds (Wu et al., 2011; Yuksel et al., 2010; Prigent et al., 2009; Ojha et al., 2012; Kanakis et al., 2011), while covalent interactions were less frequently reported (Gallo et al., 2013; Rawel et al., 2001).

Whey proteins in milk are of special interest especially as delivery tools for bioactive compounds due to their nutritious value, low cost and availability. A wide variety of phenolic compounds including phenolic acids, flavonoids, phytoalexins and extracts of polyphenol-rich foodstuffs have been studied extensively for molecular interactions with  $\beta$ -Lactoglobulin. The predominating forces between  $\beta$ -Lactoglobulin and polyphenols were reported to be H-bonding, hydrophobic interactions and van der Waals attractions (Wu et al., 2011; Ojha et al., 2012; Jauregi et al., 2016). On the other hand, irreversible covalent bond formation between  $\beta$ -Lactoglobulin and cocoa polyphenols was also reported (Gallo et al., 2013).  $\alpha$ -Lactalbumin, the second pre-dominant whey protein in milk, has been studied to a lesser extent. Noncovalent interactions were reported between complexes formed between

$\alpha$ -Lactalbumin and kaempferol, genistein, resveratrol, curcumin or green tea polyphenols (Mohammadi and Moeeni, 2015a, 2015b; Al-Hanish et al., 2016). BSA is a large globular protein and reported to bind various small compounds including fatty acids, flavor compounds and some surfactants. This protein is widely preferred for bioactive compound binding studies due to the homology between human serum albumin (HSA) and BSA. Binding of tea polyphenols, including oligomeric tannins and procyanidins, to BSA have been studied extensively (Lei et al., 2017; Watrelot et al., 2015; Karonen et al., 2015). Similar to other whey proteins, BSA and polyphenol interactions were reported to be dominated by hydrophobic interactions and electrostatic attractions which might be stabilized by H-bond formation (Bourassa et al., 2010; Fu et al., 2016; Papadopoulou et al., 2005; Kitson, 2004).

The interactions between casein micelles and polyphenols are of special interest for the evaluation on consumption behaviors of polyphenol-rich products along with milk. Besides nutritional studies, casein micelles and individual casein fractions have also been studied for the evaluation of polyphenol binding as an alternative approach for bioactive compound/drug delivery systems. Caseins found in milk are characterized with a high proline content and flexible structures which make them amenable for polyphenol binding. Various polyphenolic substances were reported to bind to caseins predominantly via hydrophobic effects and H-bridges (Moeiniafshari et al., 2015; Bohin et al., 2012; Mehranfar et al., 2013). Although the binding affinity and characteristics have been reported to depend on several factors, weak attractions dominate the interactions between polyphenols and milk proteins, whereas irreversible interactions are rarely identified under specific conditions.

### Effect of Structural Features and Environmental Conditions on Binding

The nature and strength of polyphenol binding to proteins have been reported to be affected by a number of factors among which the chemical structures of proteins and polyphenols are of great importance.

The conformation and structure of proteins greatly affect the binding properties of polyphenols. In general, proteins with a regular secondary structure show lower affinity to polyphenols compared to randomly structured proteins. Besides, amino acid composition of protein molecule is known to affect its interactions with polyphenols. Proteins with more prolyl residues and proline repeats possess strong affinity to polyphenolic substances due to the attraction forces between proline and the hydroxyl group of polyphenols (Murray et al., 1994). Therefore, caseins in milk have a great potential as delivery tools for polyphenols. Especially,  $\beta$ -casein could bind to several phenolic compounds with high affinity because of the high number of proline residues and hydrophobic nature of  $\beta$ -casein (Hasni et al., 2011; Bourassa et al., 2013). However, the amino acid composition and prolyl residues might not be the critical factors in some cases where other factors play more significant roles.  $\beta$ -Lactoglobulin has three possible binding sites for small ligands and these ports were reported to bind various polyphenols strongly (Riihimäki et al., 2008; Hemar et al., 2011; Gholami and Bordbar, 2014). Free cysteine (Cys) residue in  $\beta$ -Lactoglobulin was also able to react with polyphenols and alkylation of Cys residue may hinder binding (Gallo et al., 2013).  $\alpha$ -Lactalbumin is a metalloprotein which is known for its ability to bind several metal cations. The binding of several polyphenols (such as curcumin, resveratrol, genistein and kaempferol) to  $\alpha$ -Lactalbumin was reported in literature. The hydrophobic cleft of BSA showed high affinity to some polyphenols. Additionally, the neighborhood of Tyr-134 residue on the surface was reported to be a possible binding site for polyphenols. Although sophisticated molecular methods have revealed specific sites on milk proteins with higher affinity, nonspecific protein-polyphenol complexation also occurs especially for caseins lacking a defined globular tertiary structure.

The type and chemical structure of polyphenols also significantly affect the characteristics of polyphenol-protein interactions. A number of studies revealed that the affinity of polyphenols for protein binding is enhanced with increasing molecular weight and bulkiness of the polyphenol (Soares et al., 2007). Besides molecular weight, differences in hydroxylation, methylation and glycosylation may also change the binding affinity of polyphenols. Methylation of the polyphenols may cause a slight inhibitory effect on their reactions with milk proteins (Xiao et al., 2011). Similarly, glycosylation was reported to affect these interactions in a negative way which might be due to steric hindrance and hydrophilic character of the attached carbohydrate group. However, a number of studies showed that an increase in the number of hydroxyl groups on polyphenol structure (ring A or ring C) significantly promotes the binding reactions (Kanakakis et al., 2011; Hasni et al., 2011; Xiao et al., 2010). The small changes in molecular structure may have an important consequence in binding characteristics and biological functions of polyphenols.

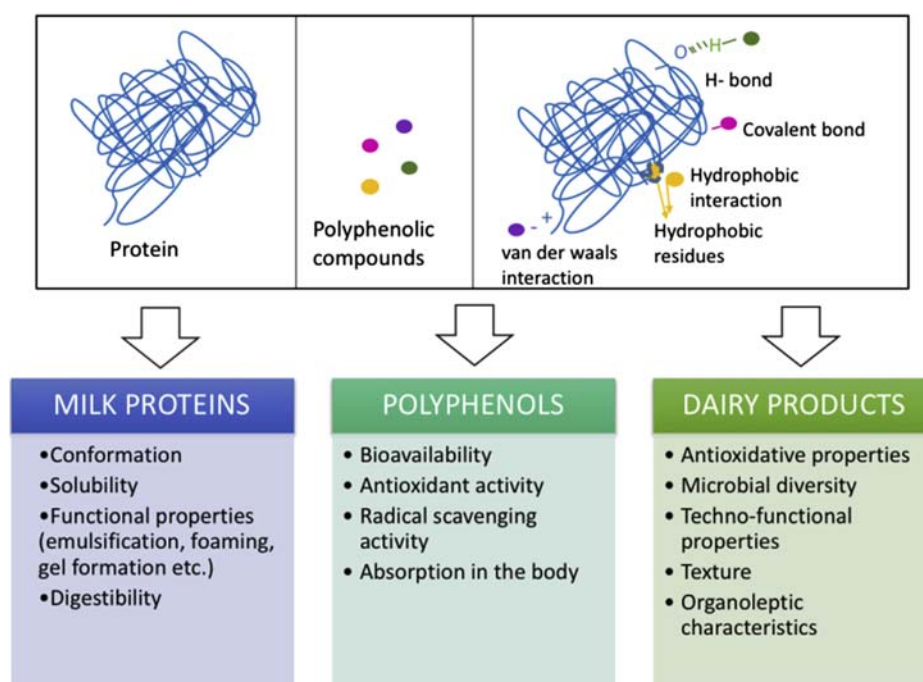

Although the structural differences of reacting molecules play a key role in protein-polyphenol reactions, environmental factors such as temperature, pH and ionic strength may also affect these interactions. The pH of the reaction environment becomes critical especially when the electrostatic interactions are pre-dominating. Polyphenols were reported to bind stronger to proteins when the pH closes to the isoelectric point of the protein molecule (Wang et al., 2007). High temperature is generally considered to improve binding affinity of polyphenols unless the temperature is near or above the denaturation point of proteins. In case of thermal denaturation, conflicting results were obtained for milk proteins. A group of researchers claimed that exposure of hydrophobic ports due to protein denaturation leads to stronger interactions between epigallocatechin gallate (EGCG) and BSA (Wang et al., 2007), whereas, other studies revealed an impaired binding to quercetin or chlorogenic acid after heat denaturation of BSA (Rawel et al., 2005). In addition, denaturation of  $\beta$ -Lactoglobulin was reported to promote the binding of polyphenols (Liang and Subirade, 2012). As seen from these contradictory results, the effect of thermal denaturation could be varying with the type of polyphenols and/or dominating interactions. Therefore, making a general estimation on temperature-dependent protein-polyphenol interactions does not seem possible.

## Consequences of Binding

Binding reactions of milk proteins and polyphenols can lead to significant alterations in the properties of proteins and polyphenols or polyphenol-enriched dairy product characteristics, as illustrated in Fig. 1. Irreversible interactions between proteins and polyphenols have been reported to cause more pronounced changes though irreversible interactions are less common compared to weak interactions. One of the most frequently reported effects of polyphenol binding on proteins is the change in the secondary or tertiary structure of the protein molecule. Changes in structural features of milk proteins may affect further binding reactions of proteins. The alterations in protein structure caused by polyphenol binding seem to be affected by factors such as structure, concentration and binding affinity of polyphenols, pH of the reaction environment, and the state of the protein molecule (native or denatured), which leads to conflicting results (Stojadinovic et al., 2013; Zorilla et al., 2011).

Some researchers could not find any differences in the conformations of BSA,  $\beta$ -Lactoglobulin and  $\beta$ -casein upon binding to several flavonoids (Papadopoulou et al., 2005; Bohin et al., 2012; Gholami and Bordbar, 2014). On the other hand, partial stabilization (Wu et al., 2011; Kanakis et al., 2011; Skrt et al., 2012) and destabilization (Kanakis et al., 2013) of milk proteins resulted from changes in their secondary or tertiary structures when interacted with polyphenols have been recently reported. Besides structural changes, milk protein-polyphenol interactions may also lead to alterations in functional properties of proteins, some of which are essential for the production of dairy products. Formation of protein aggregates upon interactions with polyphenols, due to the occurrence of crosslinking bridges mainly via H-bonds, have been revealed by several studies. Therefore, the solubility of proteins is considered to be reduced by their interactions with polyphenols. On the other hand, a study using a model system to evaluate the solubility of BSA and  $\alpha$ -Lactalbumin asserts that the solubility of proteins remained unchanged upon binding to phenolic acids (Prigent et al., 2003). Enhanced foaming ability and foam stability of whey proteins such as  $\beta$ -Lactoglobulin,  $\alpha$ -Lactalbumin and BSA were also discussed upon their binding to polyphenols (Prigent et al., 2009; Sarker et al., 1995). From the nutritional point of view, digestibility of milk proteins when consumed/interacted with polyphenols is of significant importance. However, the effect of polyphenol binding on digestion of milk proteins has been evaluated to a lesser extent. The susceptibility of  $\beta$ -Lactoglobulin to *in vitro* gastric and pancreatic digestion was reported to be altered upon its interactions with polyphenols.

As perceived responsibility for the main health benefits, antioxidative properties of polyphenols have been one of the most important aspects for protein-polyphenol studies. *In vitro* and *in vivo* antioxidant assays can be used for evaluation of any changes induced by protein-polyphenol interactions. Recent studies have revealed that the observed effects of polyphenols were lower than expected due to their low absorption and transformation to the metabolites that do not act as powerful antioxidants. Therefore, most of the biological functions of polyphenols proven in *in vitro* studies, might not be observed *in vivo*. The majority of *in vitro* studies revealed the masking effect of noncovalent interactions between milk proteins and polyphenols on the antioxidant and radical scavenging activities (Ryan and Petit, 2010; Staszewski et al., 2011). *In vivo* approaches pointed out two opposite consequences of polyphenol binding for bioavailability and absorption of polyphenols: either a negligible effect or a diminishing effect (Serafini et al., 1996; Langley-Evans, 2000; Roura et al., 2007; Keogh et al., 2007). The conflicting findings might arise from

**Figure 1** Schematic representation of binding forces between milk proteins and polyphenols and possible related changes.

different methodologies used for the evaluation of biological activities of polyphenols. Although a lot of effort has been made in order to reveal the effects of milk protein-polyphenol interactions on the bioavailability of polyphenols, understanding these mechanisms at the molecular level with a description is still lacking.

## Interactions in Complex Dairy Matrices

The interactions between different polyphenols and individual milk proteins have been extensively studied in model systems. However, complex dairy matrices require more extensive studies, as other macromolecules could interfere with polyphenol-protein interactions. Moreover, the dynamic nature of dairy product matrices is a limiting factor for proper elucidation of these interactions leading to conflicting results. Use of polyphenols as fortification agents for a variety of dairy products has been proposed formerly (O'Connell and Fox, 2001). The studies were primarily based on the improvement of food structure, quality and novel functional properties of food formulations.

Research on the interactions between milk protein and polyphenols has been mainly conducted on the effects of the binding on biological activities of polyphenols and antioxidative properties of functional dairy products rather than the mechanistic understanding of binding in complex matrices. Improvements of radical scavenging activity and antioxidative properties of several dairy products such as yogurt and cheese were reported through fortification with polyphenols (Najgebauer-Lejko et al., 2011; Rashidinejad et al., 2013; Han et al., 2011; Trigueros et al., 2014). Polyphenol-protein interactions were found to improve the thermal stability of caseins probably via the interactions of *o*-quinons with amino acid residues to prevent, eventually, protein aggregation (O'Connell et al., 1998). However, yogurt samples upon polyphenol addition had poor gelation properties and increased syneresis which could mainly result from the alterations in the strength and nature of the bonds and subsequent formation of a three dimensional network. The formation of covalent bonding (mainly S-S bridging) during acidification was found to decrease when polyphenols were present in yogurt formulations (Vega and Grover, 2011). Interestingly, addition of polyphenols to drinking yogurt samples resulted in different behaviors for differently formulated yogurts, which reveals the importance of the interactions between molecules, other than milk proteins and polyphenols, in complex matrices (Sun-Waterhouse et al., 2013). The rennet-coagulation properties were also reported to be altered in the presence of polyphenols due to protein-polyphenol interactions (Haratifar and Corredig, 2014), although detailed information on the effects of these interactions on coagulation process and associated mechanisms is needed. The textural analysis of Cheddar cheese enriched with green tea extracts revealed a firmer structure, as compared to the control cheese, pointing out enhanced para-casein micelle interactions during coagulation of the enriched cheese. Furthermore, the primary proteolysis, resulting mainly from the residual chymosin and plasmin activities, seemed to be promoted as well (Giroux et al., 2013).

## Conclusions

The possible interactions between milk proteins and polyphenols may lead to a number of changes in several properties of the interacting molecules and the dairy products fortified with phenolics. Generally, weak noncovalent attractions dominate the interactions between polyphenols and milk proteins. The binding affinity and characteristics of such interactions are affected by a number of factors. Model system studies carried out with molecular methodologies revealed the mechanisms behind these reactions. However, due to the high structural diversity of polyphenols and proteins, conflicting findings have been obtained. Investigation and consequences of these reactions in dairy products would be even more complicated due to the presence of other possible interactions and the complex dynamic nature of these matrices. The widely discussed alterations caused by polyphenol-protein interactions include structural/functional changes in protein structure and antioxidative properties of polyphenols. However, these changes might depend on other environmental influences and structural parameters of dairy products as well. Despite the extensive studies on polyphenols and milk proteins, the structural mechanisms associated with the obtained consequences of these interactions are not clearly known yet. More research using different approaches would be essentially required in order to predict the potential of using polyphenols as ingredients for dairy products in technological and nutritional aspects.

### Glossary

**$\beta$ -Lactoglobulin** One of the most abundant milk proteins that was proposed to be a transport protein for various small molecules.

**Calyx site** A large barrel-shaped hydrophobic core of  $\beta$ -lactoglobulin that was proposed to be the main binding site for hydrophobic molecules.

### Introduction

$\beta$ -Lactoglobulin is a globular protein that is present in the milk of many mammalian species including ruminants, such as cows and sheep, and some non-ruminants, such as pigs and horses (Kontopidis et al., 2004; Sawyer and Kontopidis, 2000).  $\beta$ -Lactoglobulin is the major whey protein in milk. For example, it accounts for about 10% of the total milk proteins in cow's milk. Surprisingly,  $\beta$ -lactoglobulin is not present in the milk of humans and other species including some rodents, rabbits, camels and llamas.

Although  $\beta$ -lactoglobulin was discovered and isolated more than 80 years ago, to date, no functions have been conclusively ascribed to the protein (Kontopidis et al., 2002; Pérez and Calvo, 1995).  $\beta$ -Lactoglobulin has been proposed to be a transport protein for various small molecules. These include, but are not limited to, fatty acids, polyphenols and retinols. The purpose of this review is to summarise recent studies on the binding between  $\beta$ -lactoglobulin and its proposed ligands. The review focuses on binding interactions with  $\beta$ -lactoglobulin in its native structure at physiologically relevant temperatures. Heat-induced aggregates or adducts between  $\beta$ -lactoglobulin and small molecules are out of scope of the review.

### Structure of $\beta$ -Lactoglobulin

Bovine  $\beta$ -lactoglobulin contains 162 amino acids with a molecular weight of 18.4 kDa (Brownlow et al., 1997; Kontopidis et al., 2004).  $\beta$ -Lactoglobulin exists as a dimer (Fig. 1) at pH 2.5 to 7.5 in the presence of salts (which represents almost all the conditions of food systems and manufacturing) (Mercadante et al., 2012). Genetic polymorphism of  $\beta$ -lactoglobulin has been reported (Threadgill and Womack, 1990). For example in cow's milk, the most common variants of bovine  $\beta$ -lactoglobulin are variants A and B. The differences between the two variants are the two mutations that occur at positions 64, in which an aspartic acid (variant A) is replaced by a glycine (variant B), and 118, in which a valine residue (variant A) is replaced by an alanine (variant B). Structurally, bovine  $\beta$ -lactoglobulin contains one  $\alpha$ -helix and nine antiparallel  $\beta$ -strands ( $\beta$ A– $\beta$ I). Eight of these strands ( $\beta$ A– $\beta$ H) form the cylindrical shape central calyx of the protein (Fig. 1). The structure of  $\beta$ -lactoglobulin is further stabilised by two disulphide bonds that occur between Cys66 and Cys160, and between Cys106 and Cys119.

$\beta$ -Lactoglobulin does not have a compact hydrophobic core (Kontopidis et al., 2002, 2004). The two hydrophobic walls of the calyx cylinder are approximately 15 Å in length and have a volume of 315 Å<sup>3</sup>. This structure was proposed to be the main binding site for small compounds with high hydrophobicity (Fig. 1). A pH-triggered dynamic mechanism that involves the opening and closing of the loop on top of the calyx (between  $\beta$ E and  $\beta$ F) was proposed in order to control the binding and release of ligands. Apart from the internal core of the calyx, two other binding sites have also been proposed (Fig. 1). These two binding sites are located at the dimer interface and in the hydrophobic region between  $\alpha$ -helix and the  $\beta$ -barrel of the protein. These sites may be important for the binding of hydrophilic molecules, although the binding pockets remain undetermined.

### Binding Between $\beta$ -Lactoglobulin and Small Molecules With High Hydrophobicity

The binding interactions between hydrophobic ligands (such as fatty acids and fat soluble vitamins) and  $\beta$ -lactoglobulin are well characterised.

#### Fatty Acids

Oleic acid was the first ligand of  $\beta$ -lactoglobulin to be reported (Davis and Dubos, 1947). Since then, the binding of different fatty acids to  $\beta$ -lactoglobulin has been studied extensively. A high substrate promiscuity was observed. Recent studies have focused on the structural basis of fatty acid's binding to the protein.

**Figure 1** Dimeric structure of  $\beta$ -lactoglobulin. The three ligand binding sites are highlighted in blue. These include the calyx site, the dimer interface, and the hydrophobic groove between the  $\alpha$ -helix and the  $\beta$ -barrel. The EF loop was proposed to act as a pH-sensitive gate to the calyx site.

### Structural Basis for Fatty Acid Ligand Binding

Several studies have been conducted to understand the relationship between the structure of the fatty acid ligands and their binding potency to  $\beta$ -lactoglobulin. To date, over 50  $\beta$ -lactoglobulin structures were reported in the protein data bank (PDB), and many of these structures were co-crystallised with long chain fatty acids. These structures showed that the aliphatic chain of fatty acid ligands binds to the calyx core in a linear conformation, and the carboxylic group of the fatty acids interacts with the polar residues (i.e. Lys60, Glu62 and Lys69) of the protein (Loch et al., 2012, 2013a,b). However, this binding mode is not universal for all fatty acids. Structural and computational studies showed that, depending on the aliphatic chain length, the interaction(s) between the carboxyl group of the fatty acid ligands and the polar amino acids on the top of the calyx may not always survive (Qin et al., 1998; Evoli et al., 2014; Deepa et al., 2017). This is likely due to the competition between the polar interactions of fatty acid's carboxyl group and the protein, and the hydrophobic interactions of fatty acid's aliphatic chain and protein's calyx core (Loch et al., 2011). By using X-ray crystallography and taking caprylic and capric acids as examples, it was found that the shorter fatty acid caprylic acid binds, through its carboxylic group, to the upper part of the calyx near the polar residues, whilst the longer fatty acid capric acid is bound deeper in the calyx through hydrophobic interactions (but does not interact with the polar residues at the top of the calyx) (Loch et al., 2011). The importance of hydrophilic and hydrophobic interactions in the binding of fatty acid ligands with  $\beta$ -lactoglobulin was also confirmed through molecular dynamics studies (Bello et al., 2012). This competition between hydrophobic and polar interactions also appears to have an impact on the binding affinity of the fatty acids. Using electron paramagnetic resonance (EPR) spectroscopy and spin-labelled stearic acids, Guzzi et al. showed that binding affinity is correlated to the length and size of the fatty acid hydrocarbon chain. In particular, the highest affinity is observed when the fatty acid hydrocarbon chain fills fully the hydrophobic calyx cavity of  $\beta$ -lactoglobulin (Guzzi et al., 2012).

### Number of Binding Sites

The main binding site for fatty acid ligands in  $\beta$ -lactoglobulin is the calyx core, which was demonstrated by X-ray crystallography in 1999 (Wu et al., 1999). Molecular modelling studies also showed that the calyx is the main binding site for fatty acid ligands (Evoli et al., 2014). Several surface binding sites have also been proposed, although the number of such surface sites was not well defined. Molecular modelling studies showed that at least two binding sites are located on the surface of  $\beta$ -lactoglobulin, although these sites were predicted to bind fatty acid ligands with lower affinities than the calyx site (Evoli et al., 2014). Le Maux et al. reported that  $\beta$ -lactoglobulin may have more than 7 binding sites in its native form, and even more when it is in its covalent dimeric or oligomeric forms by using isothermal titration calorimetry (ITC) and intrinsic fluorescence (Le Maux et al., 2013). Incredibly, using ITC, Fang et al. showed that  $\beta$ -lactoglobulin may have 32 binding sites for fatty acid ligands (Fang et al., 2015). Overall, computation and experimental evidence suggests that these external sites may be involved in transient and relatively short-lived  $\beta$ -lactoglobulin-fatty acid interactions, which may be related to the functions of the protein as fatty acid transporter.

### Conformational Change Upon Fatty Acid Ligand Binding

No major global structural changes of  $\beta$ -lactoglobulin upon fatty acid binding were observed experimentally or computationally (Fang et al., 2015; Bello et al., 2012). However, local changes may occur upon fatty acid binding. Such changes are inferred from a recent study by Liu et al. (2017), in which  $\beta$ -lactoglobulin was able to interact with both fatty acids and curcumin at the same time. More importantly, the authors showed that the presence of fatty acids appeared to enhance the binding affinity of

curcumin, thus inferring localised conformation change. However, experiments also showed that the formation of curcumin-fatty acid- $\beta$ -lactoglobulin ternary complexes did not cause changes in the secondary structure of the protein. Further experiments are needed to understand fully this synergetic behaviour (Liu et al., 2017).

## Lipid-Soluble Vitamins

### Vitamin A<sub>1</sub> (Retinol)

One of the proposed biological roles of  $\beta$ -lactoglobulin was the transport of retinol. Retinol is a fat-soluble vitamin that participates in the regulation of important cellular functions including cell growth, proliferation and differentiation (Sawyer and Kontopidis, 2000). The binding of retinol to  $\beta$ -lactoglobulin was found to be pH dependent. At pH 7, at which  $\beta$ -lactoglobulin is a dimer, there are two apparent binding sites for retinol (which are the calyx and the surface sites), whilst at pH 2, there is only one set of binding sites at the surface of the protein for retinol (Ahmadi et al., 2015). Interestingly, the binding of retinoid was found to induce a change in the secondary structure of the protein, with a decrease in  $\beta$ -sheet and an increase in turn structure, which, as a result, destabilises the protein (Belatik et al., 2012). Further experiments are needed to understand the significance of such conformational, oligomeric and/or structural changes.

### Vitamin D

Vitamin D<sub>3</sub> is a fat-soluble vitamin found to bind to both the calyx and surface hydrophobic pocket of  $\beta$ -lactoglobulin. The binding of vitamin D<sub>3</sub> to  $\beta$ -lactoglobulin appeared to improve the stability of the vitamin when the vitamin is exposed to UV light (Diarrassouba et al., 2014). The resistance of  $\beta$ -lactoglobulin-vitamin D<sub>3</sub> complex to protease-catalysed denaturation was also increased. The authors also showed that the  $\beta$ -lactoglobulin-vitamin D<sub>3</sub> complex has led to improved bioavailability of vitamin D<sub>3</sub>, as the complex managed to cross cell membranes (Diarrassouba et al., 2014). These findings are useful in food applications, offering the possibility for using the  $\beta$ -lactoglobulin-vitamin D<sub>3</sub> complex to improve the intake of vitamin D<sub>3</sub> (Diarrassouba et al., 2014).

### Vitamin E

$\alpha$ -Tocopherol, or vitamin E, is a fat-soluble vitamin that was found to bind to both the surface and calyx sites of  $\beta$ -lactoglobulin at neutral pH. However, at acidic pHs,  $\alpha$ -tocopherol is released from the internal cavity but is still bound to the surface of  $\beta$ -lactoglobulin (Liang and Subirade, 2012). The interaction of  $\beta$ -lactoglobulin with lipophilic  $\alpha$ -tocopherol did not disrupt the secondary or tertiary structures of  $\beta$ -lactoglobulin.  $\beta$ -Lactoglobulin appeared to increase the solubility of  $\alpha$ -tocopherol by forming a  $\beta$ -lactoglobulin- $\alpha$ -tocopherol complex (Liang et al., 2011).  $\beta$ -Lactoglobulin was also found to protect  $\alpha$ -tocopherol against decomposition (Liang et al., 2011). Similar to vitamin D<sub>3</sub>, this study shows the potential for  $\beta$ -lactoglobulin to act as a carrier to improve the intake and bioavailability of the vitamin.

## Binding of $\beta$ -Lactoglobulin to Polyphenols

The binding of polyphenols to  $\beta$ -lactoglobulin has been intensively studied due to the antioxidant activity of the polyphenols against reactive oxygen species. The binding site for a polyphenol was proposed to be located in the hydrophobic calyx of  $\beta$ -lactoglobulin and on the surface of the  $\beta$ -lactoglobulin. Similar to the binding of fatty acid ligands, the hydrophobic interaction in the calyx is often considered specific and generally has high affinity, whilst the interaction at the surface is generally weaker and nonspecific.

### Structural Basis of Polyphenol Binding to $\beta$ -Lactoglobulin

The structural basis of the binding of polyphenol to  $\beta$ -lactoglobulin has been studied extensively both experimentally and computationally. Polyphenols are often found to bind inside or at the entrance of the calyx cavity of  $\beta$ -lactoglobulin through a combination of hydrophobic interactions, hydrogen bonding and  $\pi$ - $\pi$  stacking interactions (Cheng et al., 2017; He et al., 2016; Wu et al., 2013a,b). pH may influence where the polyphenolic ligand binds to  $\beta$ -lactoglobulin, the centre or surface of the calyx site. By using curcumin as a model system, Li and co-workers found that at pH 6.0 (Li et al., 2013), curcumin tended to bind on the external surface of the calyx, whilst at pH 7.0 it tended to bind inside the central cavity. This is apparently due to the dynamic opening and closing of the loop at the top of the calyx site. At the neutral pH, the loop between  $\beta$ E and  $\beta$ F is in the opening conformation. This enables hydrophobic polyphenols to access to the internal calyx cavity. At acidic pH, however, the Glu89 residue is protonated. This shifts the EF loop to the closed conformation. The closing of the gate stops the polyphenol molecule from entering the core structure, thus the molecule tends to bind on the external surface of the calyx at such pHs (Li et al., 2013).

Polyphenols were also found to bind to the surface cleft of  $\beta$ -lactoglobulin (Wu et al., 2013a,b). For example, resveratrol, a natural polyphenolic compound that is commonly found in red wine and grapes, was found to bind to the outer surface of  $\beta$ -lactoglobulin near Trp19 and Arg124 at both neutral and acidic pHs (Liang et al., 2008; Liang and Subirade, 2012).

Not surprisingly, the structure of the polyphenols may have an effect on their binding affinity to  $\beta$ -lactoglobulin. For example, the position of the hydroxyl groups was found to be important. Hydroxylation at the 3-position would increase the affinity of the phenolic acids whilst hydroxylation at the 2- or 4-positions may have a negative effect (Wu et al., 2017). One potential application

of  $\beta$ -lactoglobulin is to deliver bioactive polyphenolics. A thorough understanding of the structural–activity relationship at the calyx site of  $\beta$ -lactoglobulin would facilitate the development of such applications.

### Protein Dynamics Upon Polyphenol Binding

The binding of polyphenols to  $\beta$ -lactoglobulin appears to cause changes to the protein's structure. For example, the binding of cyanidin-3-O-glucoside, a polyphenol that binds the  $\beta$ -lactoglobulin calyx site, causes a decrease in  $\alpha$ -helix and an increase in  $\beta$ -sheet of the protein, as revealed by UV–vis spectroscopy, fluorescence spectroscopy and circular dichroism analyses (Cheng et al., 2017). In contrast, the binding of epicatechin to  $\beta$ -lactoglobulin appeared to cause little change in the protein's  $\alpha$ -helix content, and the  $\beta$ -sheets were altered in a manner that implies the transition from dimer to monomer. The authors argued that this finding reflects the binding of epicatechin to the dimerisation interface of the  $\beta$ -lactoglobulin dimer, although further experiments are needed to prove conclusively this hypothesis (Nucara et al., 2013). A thorough understanding of the structure of polyphenols, their binding sites on  $\beta$ -lactoglobulin, and whether the binding interaction causes a conformational change, is important, in order to use  $\beta$ -lactoglobulin as a carrier for these bioactives.

### Applications of Polyphenol- $\beta$ -Lactoglobulin Complexes

The ability for  $\beta$ -lactoglobulin to complex with polyphenols has led to several potential applications in the food industry. It was found that the polyphenol- $\beta$ -lactoglobulin complex is more stable to pepsin and pancreatic digestion in the gastrointestinal tract, thus enhancing the protein's stability to digestion. However, this strong complex can also mask the total antioxidant capacity of the polyphenol (Stojadinovic et al., 2013). A similar observation was made by Libardi et al. using vanillin as an antioxidant (Libardi et al., 2011). A balance between stability and antioxidant capacity is important to tune the application of the polyphenol- $\beta$ -lactoglobulin complex.

Interestingly, the  $\beta$ -lactoglobulin-catechin complex showed decreased allergenicity compared to  $\beta$ -lactoglobulin on its own, even though the overall structure of the protein remained unchanged (Wu et al., 2013a,b). Further research in the structure–activity relationship of  $\beta$ -lactoglobulin, in the absence and presence of polyphenol binding, may enable us to find out the cause of  $\beta$ -lactoglobulin-induced allergenicity.

### Binding of $\beta$ -Lactoglobulin to Water-Soluble Small Molecules

Apart from hydrophobic molecules and polyphenols, many studies have shown that  $\beta$ -lactoglobulin also binds and interacts with polar, or water-soluble, molecules. We summarise recent studies on water-soluble vitamins and lactose as below.

#### Water-Soluble Vitamins

Folic acid is a vitamin that is essential for a variety of physiological processes. However, folic acid is unstable and readily decomposes under UV irradiation. It was postulated that the binding of folic acid to  $\beta$ -lactoglobulin may enhance the stability of the vitamin. The binding of folic acid to  $\beta$ -lactoglobulin was therefore investigated by UV–visible light absorption and scattering, fluorescence and molecular docking techniques. Folic acid was found to bind to the hydrophobic surface groove between the  $\alpha$ -helix and the  $\beta$ -barrel of  $\beta$ -lactoglobulin. Fluorescence analysis showed that the  $\beta$ -lactoglobulin-bound folic acid has increased photostability and thermal stability (Liang and Subirade, 2010, 2012; Liang et al., 2013). This indicates the potential of  $\beta$ -lactoglobulin in carrying and delivering water-soluble vitamins.

#### Lactose

The binding of lactose, which is the most abundant sugar in milk, to  $\beta$ -lactoglobulin was studied by molecular docking (Domínguez-Ramírez et al., 2013). Lactose is known to modify covalently the lysine residues of  $\beta$ -lactoglobulin at higher temperatures, a process that is known as glycation or glycosylation. However, the interaction of lactose with  $\beta$ -lactoglobulin at room temperature in the protein's native state remains unclear. The molecular docking study showed that lactose did not bind to  $\beta$ -lactoglobulin in its monomeric form, however, binding interactions were possible with  $\beta$ -lactoglobulin in its dimer form. Lactose did not bind to the calyx core, a result that is not surprising due to the hydrophobic nature of the calyx core. Instead, it was predicted that the dimeric interface of  $\beta$ -lactoglobulin is the most likely binding site for lactose. The docking model suggests that lactose forms hydrogen bonds with residues from both monomers of  $\beta$ -lactoglobulin (K141 and H146 from one monomer, and D137 and R148 from the other monomer). Nevertheless, it is worth noting that the binding of lactose to  $\beta$ -lactoglobulin at room temperature still needs to be confirmed experimentally.

## Conclusions

$\beta$ -Lactoglobulin is the second most abundant protein in milk. However, its function remains poorly defined, and the mapping of its small molecule interactome is incomplete.  $\beta$ -Lactoglobulin appears to be promiscuous in its ligand selectivity, and is able to interact with a large number of hydrophobic and hydrophilic molecules. This review covered recent studies about the binding of fatty acids, fat-soluble vitamins, polyphenols, as well as some water-soluble bioactive molecules. The ability for  $\beta$ -lactoglobulin to interact and bind different molecules has enabled the development of different applications in the food industry. For example, recent studies showed that  $\beta$ -lactoglobulin has promising potential as a carrier for bioactives in food applications. We hope this review will stimulate interest in further reading and research into this area.

## Introduction

In last decades, the global trend has been shifted from synthetic materials to natural sources (the so-called 'back to nature'). There is an increasing consumer demand for healthy diets and nutritious foods which leads to a huge commercial market for functional foods. Functional foods are foods that can provide health promoting benefits beyond their nutritional value. Food fortification is one of the major approaches for developing functional food products. This process increases the content of one or more nutrients and bioactive substances, whether or not they are normally present in the food, for the purpose of correcting and/or improving the nutritional quality of the food and provide desired biological benefit(s) with minimised risk to health (Allen et al., 2006).

Phenolic compounds with more than 6000 identified substances represent the largest group of secondary metabolites in plant foods. Increasing interests in these compounds is largely related to their impacts on the organoleptic and nutritional qualities of fruits and vegetables, their roles in plant growth and metabolism and, more recently, their physiological activities in humans (Kroll et al., 2003). Functional foods with elevated levels of antioxidants including phenolic compounds are of high demand because of their health-promoting functions such as antioxidative, hepatoprotective, antibacterial, anti-inflammatory and anticancer activities to reduce the risk of chronic diseases (Siro et al., 2008; Yildirim-Elikoglu and Erdem, 2017). However, food fortified with phenolic compounds may lead to changes in the nutritional, chemical and rheological properties of the fortified food. Phenolics are able to interact with food matrix components which affect the biological impact of the fortified food (Umar Lule and Xia, 2005; Seczyk et al., 2015).

In this chapter, chemistry behind protein-phenolic interactions is summarized along with the factors affecting the interactions between proteins and phenolic compounds. Changes resulting from protein-phenolic interactions in proteins and phenolic compounds are also reviewed. Furthermore, processing effects on protein-phenolic interactions and characterization of the formed polyphenol-protein complex will also be described.

## Chemistry Behind Protein-Phenolic Interactions

Phenolic compounds, as the major secondary metabolites in plant foods, comprise more than 8000 identified substances (Guo et al., 2009). They have a common structural feature, an aromatic ring bonded to at least one hydroxyl group (Kroll et al., 2003), and are classified according to the number of carbon atoms in their structure. Flavonoids, phenolic acids, and less common stilbenes and lignans, are phenolic compounds occurring in plants (some common phenolic acids and flavonoids are shown in Fig. 1A and B) (Crozier et al., 2009; Czubinski and Dwiecki, 2017).

Phenolic compounds in food undergo chemical changes during food processing and can interact with protein macromolecules during food production and processing, and even after food consumption (i.e. during digestion in the gastrointestinal tract) (Buitimea-Cantúa et al., 2017; Le Bourvellec and Renard, 2012; Parada and Aguilera, 2007). The molecular weight and structural flexibility of a phenolic compound, as well as the number of hydroxyl groups and type of side chain have been identified as the key factors that affect phenolic-protein interactions (Buitimea-Cantúa et al., 2017; Czubinski and Dwiecki, 2017). Phenolic compounds with a higher molecular weight and a higher abundance of hydroxyl groups (providing more than one site for interaction) are thought to have a higher affinity for protein (Dubeau et al., 2010; Frazier et al., 2010; Jakobek, 2015; Xiao et al., 2011). Phenolic-protein interactions can be grouped into non-covalent interactions (reversible) and covalent interactions (mostly irreversible) (Prigent, 2005; Rawel and Rohn, 2010; Ozdal et al., 2013). Five types of non-covalent interactions were reported, including hydrogen bonds, electrostatic interactions, hydrophobic interactions, van der Waals interactions, and  $\pi$  bonds (Ali, 2013; Frazier et al., 2010; McRae and Kennedy, 2011; Poncet-Legrand et al., 2006; Prigent, 2005; Rawel and Rohn, 2010; Siebert, 2006). Among these, hydrophobic interactions and hydrogen bonds are the primary non-covalent forces that mediate phenolic-protein interactions. Amino acids, including alanine, valine, isoleucine, leucine, methionine, phenylalanine, tyrosine, tryptophan, cysteine and glycine, may interact with phenolic compounds through hydrophobic interactions. Moreover, phenolic compounds are excellent hydrogen donors that form hydrogen bonds with the carboxyl group of proteins (Jongberg et al., 2015; Mulaudzi et al., 2012; Xiao et al., 2011). Consequently, hydrogen bonds may take place between the nitrogen or oxygen molecule of amino acids (e.g., lysine, arginine, histidine, asparagine, glutamine, serine, threonine, aspartic acid, glutamic acid, tyrosine, cysteine and tryptophan) and the hydroxyl groups of phenolics (Ali, 2013; Prigent, 2005; Rawel and Rohn, 2010). Interestingly, the ability of phenolic compound to produce a quinone radical mediates the formation of a covalent bond (Jongberg et al., 2015). Under alkaline conditions and in the presence of oxygen, the phenolic compounds are susceptible to enzymatic and non-enzymatic oxidation reactions causing the generation of highly reactive quinone radicals. As the second step of oxidation, the quinone undergoes condensation reactions (reacting with another quinone) to form a dimer, a high molecular weight brown colored pigment named as tannin, which can further react with amino acids in a polypeptide chain through covalent bonding

**Figure 1** Structures of the major phenolic acid (A), and flavonoid (B) compounds.

(Felton et al., 1989). As the third step, the dimers are re-oxidized and crosslinked to another polypeptide chain (Arts et al., 2001; Buchner et al., 2006). A schematic representation of the mechanism of phenolic-protein interactions is given in Fig. 2. Examples of non-covalent and covalent phenolic-protein interactions are provided in Table 1.

### Factors Affecting the Interactions Between Proteins and Phenolic Compounds

While there exist a variety of factors that influence protein-phenolic interactions including environmental factors such as temperature, pH, salt concentration and presence of certain reagents (Kroll et al., 2003; Ozdal et al., 2013), type of protein and structure of phenolic compound have been reported as the two main factors (Czubinski and Dwiecki, 2017)

#### Type of Protein

The hydrophobicity, isoelectric point and amino acid sequence of proteins influence strongly their binding affinity to phenolic compounds (Prigent et al., 2003). For instance, bovine serum albumin (BSA), which is more hydrophobic than  $\alpha$ -lactalbumin and lysozyme, exhibited higher binding affinity to chlorogenic acid (Naczek et al., 1996). Additionally, proteins that have relatively higher molecular weights may exhibit higher affinity for phenolics (Hagerman, 1989). The size of polypeptides and proteins also played a role in their affinities for polymeric proanthocyanidin (Siebert, 1999).

#### Structure of Phenolic Compounds

Phenolic compounds may differ in their molecular weight, degree of hydroxylation, methylation, glycosylation and hydrogenation, all of which play a role in the formation of protein-phenolic complexes. Polyphenols with higher molecular weights likely have

**Figure 2** Proposed reactions of a phenolic acid compound with amino side chains of polypeptides (Strauss and Gibson, 2004).

a higher binding affinity to proteins (Dubeau et al., 2010). Compared with some low molecular weight phenolics, protocatechuic acid and caffeic acid showed the strongest binding affinity for BSA whilst *p*-hydroxybenzoic acid had the lowest (Bartolome et al., 2000). The monoglycoside forms of flavonoids had stronger binding affinities for milk proteins compared to their polyglycoside forms. For quercetin and its glycosides, the aglycone form caused a stronger interaction with BSA (Martini et al., 2008). Methylation was reported to decrease the binding affinity of flavonoids for milk proteins, whereas, hydroxylation of the rings A and B in flavones and flavonols improved the binding affinity. Hydrogenation of flavonoids on their C2 = C3 double bonds led to reduced binding affinities for milk proteins (Xiao et al., 2011).

### Other Factors

Temperature is an important environmental factor that influences the binding affinities of phenolic compounds for proteins. The binding affinity of 5-O-caffeoylquinic acid for 11S protein of sunflower seed and BSA decreased with increased temperature (Prigent et al., 2003; Sastry and Rao, 1990). This was associated with the changes in hydrogen bonding between phenolic compounds and proteins (Sastry and Rao, 1990).

Another influencing environmental factor is pH. Increased precipitation of protein-polyphenol complexes was observed at pH values close to the isoelectric point of protein, due to a lower solubility of these complexes at this pH. Thus, the optimum pH for precipitation is close to protein isoelectric point, which varies among different proteins (Naczek et al., 1996, 2006). Higher binding

affinities of crude tannin canola extract for BSA, fetuin, gelatine and lysozyme, and also, ferulic acid and chlorogenic acid for BSA, were observed all at pHs near the isoelectric points of the proteins (Naczek et al., 1996; Rawel et al., 2005). However, binding of (–)-epicatechin to BSA was not affected by pH (Charlton et al., 2002; Frazier et al., 2006; Papadopoulou et al., 2005).

Protein-phenolic interactions may also be influenced by other environmental factors such as type and concentration of salt. High salt concentrations may lead to dissociation of oligomeric proteins, causing reduced amounts of binding points. Accordingly, increased salt concentration caused a decrease in binding strength of chlorogenic acid to 11S protein of sunflower seed (Sastry and Rao, 1990).

## Changes Resulting From Protein-Phenolic Compound Interactions

### Changes in Protein Properties

#### Structural Properties

The effects of protein-phenolic compound interactions on the structural properties of proteins can be studied using techniques such as differential scanning calorimetry (DSC), circular dichroism (CD), sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), Matrix-Assisted Laser Desorption/Ionization–Time-of-Flight–Mass Spectrometry (MALDI-TOF-MS), etc. Changes in the secondary and tertiary structures of protein may be reflected as percent changes in  $\alpha$ -helix,  $\beta$ -strand,  $\beta$ -turn and unordered structures (Ali, 2013). The conformation of caseins ( $\alpha$ - and  $\beta$ -caseins) was altered upon their interactions with tea polyphenols ((+)-catechin, (+)-epicatechin, (+)-epigallocatechin and (+)-epigallocatechin gallate (EGCG)), with large percent reductions in  $\alpha$ -helix and  $\beta$ -sheet structures and an increase in random coil structure (Hasni et al., 2011). In the presence of tea polyphenols,  $\beta$ -lactoglobulin conformation was changed to obtain greater structural stabilization with percent increases in  $\beta$ -sheet and  $\alpha$ -helix structures (Kanakis et al., 2011).

Protein-phenolic interactions could also cause the formation of high molecular weight fractions (Ali, 2013; Ozdal et al., 2013). Prigent et al. (2003) reported an increase in molecular weight upon the interaction of  $\alpha$ -lactalbumin or lysozyme with chlorogenic acid. Interactions between soy proteins and phenolic compounds like chlorogenic acid, caffeic acid or gallic acid also resulted in high molecular weight fractions (Rawel et al., 2002). Furthermore, the interaction with phenolic compounds could enhance thermal stability of proteins (Madhan et al., 2005; Tsai and She, 2006) and decrease surface hydrophobicity (Ali, 2013).

#### Effects on Functional Properties

The overall quality and sensory attributes of foods may be affected by functional properties of proteins (Ali, 2013) such as solubility, foaming ability, emulsification, antioxidative capacity, elasticity, color and flavor binding properties.

Protein solubility determines the functionality of proteins in food systems and is affected by phenolic compounds. Several studies reported a decreased solubility of proteins including lysozyme, walnut proteins and potato proteins as a result of their interactions with phenolic compounds (Prigent et al., 2003; Relkin and Shukat, 2012; Van Koningsveld et al., 2002), possibly due to the induced cross-linking of proteins, and altered net charges and hydrophilic/hydrophobic properties of protein molecules (Rawel et al., 2002). The covalent (irreversible) interactions of proteins with phenolic compounds were found to enhance the network formation in gelation gels with improved mechanical strength and higher thermal stability (Strauss and Gibson, 2004). Proteins that are modified with phenolic compounds can be applied as emulsifying agents in food systems, to decrease emulsion stability and increase size of oil droplets (Aewsiri et al., 2009).

#### Effects on Nutritional Properties and Digestibility

The nutritional value of food proteins depends on several factors including protein source, amino acid composition, ratio of essential amino acids, sensitivity to hydrolysis during digestion, processing conditions, etc (Ali, 2013). Several studies reported decreased nutritional value and digestibility of proteins after their interactions with phenolic compounds (Emmambux and Taylor, 2003; Kroll et al., 2003; O'Connell and Fox, 1999; Rawel et al., 2002; Rubanza et al., 2005). The interaction of milk proteins with caffeic acid during heating caused a decrease in the amount of available lysine and thiol groups (O'Connell and Fox, 1999). This has been linked to the occurrence of quinones resulting from caffeic acid oxidation and the subsequent formation of complexes with amino acids (Kroll et al., 2003). Reduced contents of lysine, cysteine and tryptophan were observed after the interactions of soy protein with several phenolic compounds such as chlorogenic acid, gallic acid, caffeic acid and quercetin (Rawel et al., 2002). The presence of condensed tannins in high-tannin sorghum would cause decreased sorghum protein digestibility (possibly due to the complexation of sorghum condensed tannins with the major sorghum protein, kafirin) (Emmambux and Taylor, 2003). Similarly, sea buckthorn procyanidins can cause the precipitation of proteins and inhibition of digestive enzymes, thereby changing the digestibility of proteins (Arimboor and Arumugan, 2011).

### Changes in Phenolic Compound Properties

#### Effects on Antioxidant Properties

The antioxidant activity of phenolic compounds may be affected by their interactions with proteins. A number of relevant studies have been published with most focusing on the interactions of phenolics from tea, coffee and cocoa with milk proteins (Ozdal et al., 2013). The interactions of tea phenolics including epigallocatechin gallate (EGCG) and gallic acid with  $\beta$ -casein significantly

reduced their antioxidant potential (Arts et al., 2002). Black tea with milk had a lower total polyphenol content than that without milk (Sharma et al., 2008). Addition of increasing amounts of milk to tea was negatively related to total antioxidant capacity (Ryan and Petit, 2010). The catechin-protein interactions could be strong causing reduced antioxidant capacity in milk chocolate, due to decreased recovery of catechin from the food matrix (Belscak et al., 2009). Masking effect of milk on antioxidant potential of different coffee brews was also reported (Niseteo et al., 2012; Sanchez-Gonzalez et al., 2005; Ziyatdinova et al., 2010).

### Effects on Bioavailability

Protein-phenolic interactions can affect the bioavailability of phenolic compounds. Consumption of coffee with milk resulted in a decreased amount of adsorbed chlorogenic acid into the bloodstream (Duarte and Farah, 2011). Interestingly, the bioavailability of cocoa phenolics was found unaffected by milk proteins under certain conditions (Roura et al., 2007). The plasma concentrations of cocoa polyphenols were not influenced by the presence of milk powder although the absorption of cocoa polyphenols was slightly (but not significantly) increased (Keogh et al., 2007). Burg-Koorevaar et al. (2011) also did not find a difference in plasma catechin concentrations upon consumption of tea with or without milk. The addition of bovine, soy or rice milk to tea samples increased the *in vitro* recovery of total tea catechins, whilst no significant difference was detected in *in vivo* (in humans) catechin bioavailability of tea samples with or without milk (Green et al., 2007). Similarly, no significant effects of milk proteins on *in vivo* bioavailability of tea and coffee phenolics were reported (Hollman et al., 2001; Leenen et al., 2000; Reddy et al., 2005; Renouf et al., 2010). In terms of blueberry polyphenols, their interactions with milk proteins led to a lower *in vivo* antioxidant potential and decreased caffeic acid absorption (Serafini et al., 2009). Contradictory results were obtained regarding the effects of milk proteins on the bioavailability of cocoa polyphenols e.g. decreased absorption of (–)-epicatechin into the bloodstream was attributed to its interaction with milk proteins (Serafini et al., 2003), whilst no effect of milk on flavanol absorption was reported (Schramm et al., 2003; Schroeter et al., 2003).

### Processing Effect on Protein-Phenolic Interactions

Besides the effect of food matrix, processing also initiates and changes the protein-phenolic interactions, and the stability and bioaccessibility of bioactive compounds. Such processing-induced effects are affected by food type, nature and location of phenolic compounds in food, and type, intensity and duration of processing (Chandrasekara et al., 2012; Rodriguez-Roque et al., 2015). Quite a lot of studies investigated protein-phenolic interactions and delivery of bioactive compounds in functional bread and dairy products, while some examined commercially available food products fortified with plant extracts. Swieca et al. (2013) enriched the bread with phenolics by partial replacement of flour with onion skin (OS) during dough preparation. The authors found that the phenolic contents in baked bread dough at 230 °C for 30 min, although increased with the level of onion skin supplement, were significantly lower than expected (the amount initially added) due to the masking effect of protein-phenolic interactions. The degree of this masking effect depended on the amount of added OS, and *in vitro* protein digestibility exhibited a reduction from 78.4% (for control breads) to 55% (for breads with a 4% OS supplement). Under the same processing conditions, Swieca et al. (2014) found that enrichment of bread with quinoa leaf (QL) phenolic-rich increased its total phenolic content and antioxidant activity with such increases all lower than expected, possibly due to the inhibition of reactive groups of phenolics by bread proteins via interactions. The authors also reported significant decreased protein digestibility caused by QL phenolics with the lowest occurring to bread fortified 3% QL phenolics.

Zhu et al. (2016) added black tea extracts (up to 175 mg gallic acid equivalent/gram wheat flour) to wheat flour to prepare Chinese Steam Bread (CSB). Black tea extract supplement significantly increased CSB phenolic content and antioxidant activities of in a tea extract concentration-dependent manner, although the increases in phenolics, flavonoids and antioxidant activities of CSB extracts were less than a half of the original black tea extracts. Thermal breakdown during steaming process, oxidation throughout the production, redox interactions and binding between tea polyphenols and gluten proteins all were possible contributors.

Sivam et al. (2011) enriched breads were produced by replacing the same amount of flour with apple, blackcurrant and kiwifruit phenolic extracts (APE, BPE and KPE, respectively) (at 3% w/w) in the presence or absence of apple pectin. The total extractable phenolic contents of fortified breads after baking were largely retained after bread making possibly due to the protection of the phenolic compounds against degradation by wheat proteins. The type of phenolics would affect their binding to wheat proteins resulting in different impacts on the final products. Sivam et al. (2012) further reported that addition of BPE and pectin caused altered conformations and extractability of wheat flour proteins in model bread systems (which simulated real finished breads): decreases in  $\beta$  turns and  $\alpha$ -helix structures but moderately increased intermolecular H bondings, and reduced amounts of unextractable HMW proteins.

Gazzola et al. (2012) studied the roles of proteins, polysaccharides, and phenolics in haze formation in white wine. Chitinases and thaumatin-like protein (TLP) proteins and total polyphenols derived from Chardonnay wine were purified and then added to the base wine. After a heating/cooling cycle (70 °C for 1 h and 25 °C for 15 h), there was only a limited effect of phenolics on Chitinases' aggregation behavior. The phenolics had varied effects on isoforms of TLP protein and the resulting aggregation behavior was likely affected by the types of proteins and molar ratio of phenolic/protein.

The effects of addition of pea protein isolate (PPI) and green tea extract (GTE) on rice-substituted fried noodle were investigated (Song and Yoo, 2017). Adding PPI caused decreased dough viscosity parameters of the substituted rice noodle, whilst addition of

PPI together with GTE recovered these values remarkably and had a positive effect on cooking loss of substituted noodles. The researchers concluded that the protein-phenolic interaction occurring to co-addition of GTE and PPI has a great potential for the fried rice-substituted noodle production in terms of higher antioxidant activity and desirable textural properties.

Fortification of milk products with polyphenols has been a desirable approach for bioactive compound delivery. Veena et al. (2015) reported that the addition of *Asparagus racemosus* (shatavari) extract led to a pH decrease thereby increasing the heat stability of enriched milk but decreasing rennet coagulation time.

Rodriguez-Roque et al. (2015) reported that the concentration and bioaccessibility of phenolic compounds in fruit juice-based beverages increased or did not change after high-intensity pulsed electric fields (HIPEF) or high-pressure processing (HPP) treatments, due to the interactions of phenolics with other food components released, breakdown of cell wall structure, or increased activities of enzymes (which would take part in phenol biosynthesis). In contrast, thermal treatment reduced the bioaccessibility of most phenolic compounds. Fortification the fruit juice-based beverages with bovine milk or soy milk might lead to a decrease in antioxidant activity of phenolics possibly owing to with their interactions with milk proteins.

The effects of adding blackcurrant extracts and pure cyaniding, before and after fermentation, on drinking yoghurt were studied by Sun-Waterhouse et al. (2013). A significantly increased total extractable phenolic content (up to 4 times higher) of fortified yoghurts obtained via the pre-fermentation approach, as compared to that via the post-fermentation approach, indicates enhanced extractability of polyphenols via fermentation. The properties of fortified drinking yoghurts including rheological behaviours such as elastic property ( $G'$ ) of yogurt samples were affected by the type of polyphenol added, type of pectin used in the yoghurt formulation, and method for polyphenol addition (pre- or post-fermentation), via specific intermolecular interactions.

Han et al. (2011) and Rashidinejad et al. (2015) investigated the effects of various natural extracts and their individual phenolic compounds on cheese making properties and final product characteristics. They found that the free radical scavenging activity of cheese samples fortified with phenolics was found higher than control cheeses, and phenolics changed the coagulation properties of milk proteins mainly due to the decrease in pH or milk protein-phenol interactions.

In summary, phenolic fortification may improve the health-promoting properties of food products, however, the interactions of phenolic compounds with food components especially proteins could influence antioxidant efficiency and protein digestibility.

## Characterization of Polyphenol-Protein Complex Formation

To understand the changes in bioavailability and digestibility caused by phenolic-protein interactions, it is important to characterize proteins and polyphenols in the same food system at molecular level. A range of techniques based on different mechanisms have been used for this purpose and compliment each other in terms of providing information related to the interaction between protein and phenolics.

### Fluorescence Quenching

Fluorescence quenching method helps to study non-covalent binding between proteins and phenolics based on the decrease of the quantum yield of fluorescence from a fluorophore induced by a variety of molecular interactions with quencher molecule. Fluorescence quenching can be dynamic (owing to collisional encounters between the fluorophore and quencher), or static (owing to the formation of a ground-state complex between the fluorophore and quencher) (Lakowicz, 1999; van de Weert and Stella, 2011). Stern-Volmer equation is a tool to determine quenching constants to measure the binding affinity between the phenolics and proteins. Fluorescence quenching method is widely used, however, this technique does not provide any direct information about the molecular changes of proteins nor polyphenols (Bandyopadhyay et al., 2012). Zhang et al. (2014) used this technique to determine the binding constants, binding sites and types of binding force between milk whey protein and some phenolic acids, and found that the mechanism was of static quenching by complex formation.

### Circular Dichroism Spectroscopy

The three dimensional structure of proteins is changed upon binding to polyphenols, and CD spectroscopy gives information about the change in secondary structure in the far UV region (190–250 nm) and the tertiary structure in the near UV region (250–390 nm). He et al. (2016) reported that via binding to malvidin-3-O-glucoside (MG), the secondary structure of  $\beta$ -lactoglobulin was changed: a decrease in  $\alpha$ -helix, turn and random coil while an increase in  $\beta$ -sheet.

### Fourier Transform Infra-Red Spectroscopy

FT-IR spectroscopy measures effectively and efficiently the wavelength and intensity of the absorption of IR radiation by a sample (e.g. a very small amount of proteins), thus, is a reliable tool for examining protein chain conformation and hydrophobic contact in the polyphenol-protein complex. Sivam et al. (2012) aimed to develop fruit polyphenol-enriched breads and detected, using FT-IR, the changes in bread gluten conformations related to Amide I and II bands caused by blackcurrant polyphenol fortification.

### Mass Spectrometry

Mass spectrometry can identify the complexes formed between phenolics and proteins, via separating the charged particles according to their mass (more exactly of the mass/charge ratio, noted  $m/z$ ) (Chen and Hagerman, 2004). This technique requires a very small amount of sample, and can give information about the mechanism and stoichiometry of the adduct(s) formed although it is worth noting the possible difference between the adducts detected in a gas phase by MS and that specifically in solutions (Sarni-Manchedo and Cheynier, 2002). Using ESI-MS, Dias et al. (2016) identified the sequence of peptide fractions of wheat gliadin and demonstrated the binding between a food tannin (procyanidin B3) and wheat-derived peptide fractions.

### Dynamic Light Scattering

Contrary to other protein precipitation methods, DLS is a technique operating at a nano scale to provide information about size and shape (sphere or rod) of a sample (including the aggregates resulted from interactions), based on the relaxation rate of particles that scatter light in solution. The limitation of this technique is closely associated with the degree of turbidity of a sample (Le Bourvellec and Renard, 2012). Using DLS, Karefyllakis et al. (2017) reported a neutral pH caused the formation of sunflower protein isolate-chlorogenic acid (SFPI-CGA) adducts via hydrogen bonding-facilitated self gathering.

### Nuclear Magnetic Resonance

NMR spectroscopy determines the chemical structure of molecules by measuring the resonance of protons under a magnetic field and can give precise information about the structural basis for phenolic-protein interactions (Le Bourvellec and Renard, 2012). Both solution and solid-state NMR can be used for this purpose. Polyphenols can interact with salivary proline rich protein (PRP) fragments, and a stronger interaction was detected by NMR between larger and more complex polyphenols and PRPs (Charlton et al., 2002).

### Size Exclusion Chromatography

Size exclusion chromatography (SEC) is a simple and efficient method to display the binding and size of the water-soluble protein-phenolic complexes (Sun-Waterhouse et al., 2011). However, this technique has limitations related to the interaction of polyphenols with the gel filtration material and the dilution with eluents (Bartolome et al., 2000). Using SEC, Swieca et al. (2013) determined the protein-phenolic interaction in breads enriched with extracts from quinoa leaves (QL).

### High Performance Liquid Chromatography/Reversed Phase-HPLC

HPLC/RP-HPLC can determine phenolic profiles, therefore, this kind technique with/without coupling with MS has been used to monitor the changes in phenolic profiles before and after the interactions of phenolics with other food components (Awad et al., 2002; Soares et al., 2012). Soares et al. (2012) showed that the interactions of tannins, procyanidin trimer or pentagalloylglucose (PGG) with acidic proline rich proteins (PRPs) affected acidic salivary solution, and each tannin interacted differently with each group of proteins.

### SDS-PAGE

SDS-PAGE is probably the most common technique used to separate proteins according to their molecular weight and differential rates of migration through a gel under the influence of an electrical field. Using SDS-PAGE, Veena et al. (2015) found the high molecular weight products formed between *A. racemosus* (shatavari) and milk proteins via interaction.

### Isothermal Titration Calorimetry

Among the techniques for examining binding, ITC is the only one capable of measuring both the magnitude of the binding affinity and the magnitude of the enthalpic and entropic components. It provides a direct and quantitative measurement of the net interaction between phenolic and protein (Pascal et al., 2007) although this technique requires high quantities of samples (Le Bourvellec and Renard, 2012). Using ITC, the binding interactions of green tea flavonoids and milk proteins was examined and the interaction between catechin and  $\beta$ -casein was non-covalent (Yuksel et al., 2010).

### Turbidimetry and Nephelometry

Insoluble protein-phenolic complexes have been mostly studied by protein precipitation. Both turbidimetry and nephelometry are based on light scattering properties of insoluble aggregates (Hamilton, 2014). Turbidimetry measures light transmitted through a suspension of particles and can be used to determine the ability of phenolics to bind proteins (Le Bourvellec and Renard, 2012). Nephelometry also measures light scattered by particles in a suspension and does not require high phenolic concentrations, as this technique is able to neglect the light absorption and has solvated particles' refraction index almost identical with that of the

solution (Le Bourvellec and Renard, 2012). These two techniques do not tell about the number, morphology and structure of aggregates.

## Conclusions

Both covalent (irreversible) and non-covalent interactions (reversible) occur between protein and phenolic compounds. Most published studies focused on non-covalent interactions (reversible) mainly due to the lack of suitable methodologies for quantitating the covalent bonds between molecules. Main factors affect protein-phenolic interactions, and include type of protein, structure of phenolic compounds and environmental factors such as temperature, pH, salt concentration and present of certain reagents/substances. Even though the exact mechanisms of how proteins would influence phenolics remain unknown, many studies have been conducted on the changes in the structural and functional properties of resulting foods. While the fortification of phenolics could improve the health-promoting properties of food products, the interactions of the fortified phenolic compounds with food components especially proteins may have a desired or undesired impact on antioxidant efficiency and protein digestibility. Thus, more in-depth studies are needed on the protein-phenolic interactions in different matrices and under different processing conditions, in order to guide the development of phenolic-enriched functional food products with enhanced nutritional and health benefits.

# The Potential Role of Polyphenol–Enzyme Interactions on Human Health

Gordon J McDougall, The James Hutton Institute, Dundee, Scotland, United Kingdom

## Introduction

Many reports implicate polyphenols (PPs), some abundant in foods, in inhibition of enzyme-catalysed reactions that could influence human health. Indeed, recent computationally-driven analysis has modelled the PP-protein “interactome” (Lacroix et al., 2018) in which over 350 different PPs were found to interact with over 5500 specific proteins resulting in nearly 12000 interactions. However, a substantial proportion of PP-enzyme inhibition reports involve screening for inhibitory effectiveness with crude extracts and using *in vitro* assays under non-physiological conditions or concentrations. Traditionally, PP-protein interactions have had negative connotations for biochemists who have striven to remove polyphenols during enzyme purification and assays (Pierpoint, 1996). Also, certain PPs (e.g. proanthocyanidins, PACs) in plant feeds have been noted for their anti-nutritional effects due to non-specific inhibition of digestive processes (Butler, 1992). Therefore, it is important to set out certain criteria for judging the relevance of potential PP-enzyme interactions.

1. **Specificity:** The interaction between polyphenol and enzyme must be reasonably specific, and not a non-specific effect on multiple enzymes.
2. **Dose** – The interaction between the polyphenol and enzyme must occur at a dose that can be safely reached through intake of a food, product or pharmacological extract.
3. **Bioavailability** – The polyphenol component must be available in the same location at the target enzymes, e.g. the gut to inhibit digestive enzymes, the bloodstream to influence Angiotensin Converting Enzyme or the extracellular matrix to inhibit metalloproteases.

Using these rather inter-dependent criteria as a guide, I assessed the relevance of potential PP-enzyme interactions and have split the review into those occurring with non-digestive enzymes and then digestive enzymes. I have not considered inhibition of enzymes which could be due to general antioxidant activity of PPs acting on redox-active enzymes (such as (e.g.) peroxidase, catalase, lipoxygenase, tyrosinase and polyphenol oxidase), although these may be important in other areas, especially such as in food and drink. Also, I have not considered the many occasions where PPs have been shown to have interactions with cell receptors and thereby influence intracellular protein kinase cascades implicated in the control of disease progression (Aiyer et al., 2012; Kim et al., 2014) through (say) remodelling of gene expression. As this is a short commentary, I also refer the reader to previous reviews on the definition and structure of PPs (e.g. Del Rio et al., 2013; McDougall, 2017) and their bioavailability and metabolism (Del Rio et al., 2013; D’Archivio et al., 2010; Hu et al., 2017).

## Non-digestive Enzymes

### Acetylcholine Esterase (AChE)

Decreased acetylcholine concentrations appear critical in the development of dementia in neurodegenerative diseases, such as Alzheimer’s disease (Loizzo et al., 2008) and therefore AChE inhibition may be a useful therapeutic step. Crude PP-rich extracts can inhibit AChE *in vitro*, but often at physiologically-unachievable doses. Common dietary flavonols (quercetin and myricetin) gave IC<sub>50</sub> values ~ 15 µM (Xie et al., 2014). However, rosmarinic acid potently inhibited AChE activity *in vitro* [Ki at 40 pM (Gulcin et al., 2016)], which approaches the measured range in rat brain (Li et al., 2007). AChE activity was reduced after supplementation of mice with PP-rich wild blueberry extract (Papandreou et al., 2009) but probably due to reduced gene expression.

### Monoamine Oxidase (MAO)

Inhibition of MAO activity can reduce breakdown of specific amine neurotransmitters (e.g. norepinephrine, serotonin, and dopamine) and MAO inhibitors have been used to treat depression and Parkinson’s disease (Volz and Gleiter, 1998). Flavonoids inhibited MAO *in vitro* with low µM IC<sub>50</sub> values (Nabavi et al., 2017). Anthocyanidins, their 3-glycosides and quercetin were also effective with IC<sub>50</sub> values around 30 µM (Dreiseitel et al., 2009). Although various studies have garnered evidence that serum-available phenolic metabolites can cross blood-brain-barrier models (e.g. Figueira et al., 2017), whether these specific PPs could reach the brain and be effective *in vivo* is debatable. Nevertheless, supplementation with PP-rich black currants was shown to reduce serum MAO activity in healthy adults (Watson et al., 2015).

### Xanthine Oxidase (XO)

XO converts purines to uric acid but also produces superoxide and XO activity has been associated with various disease states (e.g. Pachter et al., 2006). Flavonoids (e.g. chrysin and genistein) gave *in vitro* IC<sub>50</sub> values ~ 1 µM, lower than the known inhibitor, allopurinol (Lin et al., 2015) whereas more common dietary flavonols, kaempferol and quercetin, were 10–25 fold less potent.

However, different studies gave lower IC<sub>50</sub>s and found that quercetin 4'-glucuronide, a known serum-bioavailable metabolite (Mullen et al., 2006), was as effective as quercetin with a  $K_i \sim 0.25 \mu\text{M}$  (Day et al., 2000).

### Angiotensin Converting Enzyme (ACE)

Inhibition of ACE, a dipeptidyl carboxypeptidase commonly found in vascular endothelial cells, prevents conversion of angiotensin I to angiotensin II, a vasoconstrictor that raises blood pressure (Hugel et al., 2016). Synthetic ACE inhibitors can control hypertension but have drawbacks, so natural ACE inhibitors are of interest. Flavonoids inhibit ACE *in vitro* (IC<sub>50</sub>s luteolin 23  $\mu\text{M}$ , quercetin 43  $\mu\text{M}$  and rutin 63  $\mu\text{M}$ ; Guerrero et al., 2012). Different assay formats influence potency as quercetin and quercetin-3-glucuronide had IC<sub>50</sub> values of  $\sim 150$  and 30  $\mu\text{M}$ , respectively, using purified ACE but at  $\sim \text{nM}$  concentrations using cell-based assays (Balasuriya and Rupasinghe, 2012). Grape-seed PAC extracts gave IC<sub>50</sub> values  $< 20 \text{ nM}$  (Godoy et al., 2012) whereas purified epicatechin octamer (EC8) had an IC<sub>50</sub> of  $\sim 40 \text{ nM}$ , compared with EC5 at 2.4  $\mu\text{M}$  (Afonso et al., 2013). Feeding PP-rich blueberries to rats reduced circulating ACE activity (Wiseman et al., 2011) and a human study showed significant effects of Aronia supplementation on ACE levels (Sikora et al., 2014). However, in both cases, the reduction was probably due to reduced gene expression.

### Matrix Metalloproteinases (MMP)

Inhibition of MMP by PPs may reduce metastasis in cancers (Sang et al., 2006), through prevention of extracellular matrix remodelling. Although direct inhibition can be relatively potent, it is more probably likely that PPs *in vivo* cause down-regulation of MMP expression. Intriguingly, Urolithin A, a major colonic metabolite of ellagitannins known to be serum-bioavailable, reduced MMP activity in cultured cancer cells at sub- $\mu\text{M}$  levels (Zhao et al., 2018).

### 3-Hydroxy-3-Methylglutaryl CoA Reductase (HMGCR)

Inhibition of HMGCR by statins controls cholesterol levels through reducing the rate-limiting HMG-CoA to mevalonate step (Willey and Elkind, 2010). However, decreased flow through this pathway may also influence inflammation, nitric oxide synthesis, coagulation and neurological diseases. Epigallocatechin gallate (EGCG) potently inhibited HMGCR *in vitro* ( $K_i \sim \text{nM}$ ; Cuccioloni et al., 2011) due to high-affinity binding at the nicotinamide adenine dinucleotide phosphate (NADPH) co-factor site and bioavailable EGCG levels may compete with NADPH *in vivo*. Molecular docking identified that curcumin also had high affinity for the active site (Islam et al., 2015). Whether HMGCR inhibition by PPs occurs *in vivo* is uncertain as PPs may pre-dominantly influence HMGCR gene expression.

## Enzymes Involved in Digestive Processes

### Protein Digestion

PPs inhibit proteolytic enzymes *in vitro* including pepsin (Martinez-Gonzalez et al., 2017), trypsin (Gonçalves et al., 2007), and chymotrypsin (Wu et al., 2013). Trypsin inhibition by PACs increased with increasing size through both specific and non-specific protein binding (Goncalves et al., 2011a,b). Effects on protein digestion *in vivo* are rarer but studies in pigs noted decreased ileal protein digestibility by grape tannins (Myrie et al., 2008). Recently, a phenolic-rich extract of artichoke, apple and plum also reduced ileal digestibility of protein in mini-pigs (Dufour et al., 2018). Reduced protein digestion could be deemed a negative nutritional outcome but enhanced protein residence in the small intestine may have beneficial effects on appetite and satiety (Fromentin et al., 2012; van Avesaat et al., 2017). However, further *in vivo* studies are required to confirm these findings.

### Lipid Digestion

PPs inhibit pancreatic lipase (PL) *in vitro* (Buchholz and Melzig, 2015) and inhibition of PL through drugs such as Orlistat is clinically proven to reduce fat digestion and uptake (Sjöström et al., 1998). Studies with different sources implicate different PP components: Galloylated catechins (including EGCG) and theaflavins from teas gave  $\mu\text{M}$  IC<sub>50</sub> values (Rahim et al., 2015) and modelling indicated that galloyl groups enhanced potency by direct interactions with active site residues (Clisan et al., 2017). Caffeoyl quinic acids from (e.g.) coffee also act at the active site (Hu et al., 2015), albeit at IC<sub>50</sub> values  $\sim 1 \text{ mM}$ . PACs inhibit PL through non-competitive inhibition (Wang et al., 2014) and ellagitannins from berries (McDougall et al., 2009) act through non-specific astringent effects. Various *in vivo* studies have confirmed that PP intake reduced fat uptake (e.g. boysenberry; Mineo et al., 2015), tea intake (Hsu et al., 2006), galloylated catechins (Ikeda et al., 2005), EGCG (Grove et al., 2012) and theaflavins (Jin et al., 2013) but also apple PACs (Sugiyama et al., 2007). Chronic exposure to PPs could lead to compensatory increases in lipase levels as noted with condensed tannins in rats (Griffiths, 1986). However, inhibition of lipase is only one of many mechanisms whereby polyphenols could influence obesity (e.g. Hsu and Yen, 2007) and this seems a fertile future research area.

## Carbohydrate Digestion

PPs can inhibit both  $\alpha$ -amylase and  $\alpha$ -glucosidase *in vitro*, the main enzymes required for breakdown of starch to glucose *in vivo* (Hanhineva et al., 2010). Inhibitory effects on  $\alpha$ -glucosidase include specific effects on maltase and sucrase activities (Williamson, 2013). Inhibitory potency range encompasses gut-achievable levels ( $\mu$ M to mM) and mechanisms include active site binding (flavonoids/amylase; Lo Piparo et al., 2008; kaempferol/glucosidase; Peng et al., 2016), mixed mode inhibition (tea PPs/amylase; Sun et al., 2016) to less-specific protein aggregation (PACs and amylase; Goncalves et al., 2011a,b). Inhibitory effectiveness approaches levels caused by known inhibitors such as acarbose (e.g. Boath et al., 2012).

Certain PPs also inhibit glucose transporters at the gut lumen which may cause synergistic effects on blood glucose levels (Williamson, 2013). Indeed, PPs and PP-rich foods reduced blood glucose levels after starch and sucrose intake in humans and animals (Coe and Ryan, 2016) but their variable effectiveness may be influenced by dose, trial design and food interactions (Dominguez-Avila et al., 2017). Akin to the lipase situation, chronic exposure to PPs could lead to compensatory enhanced secretion of pancreatic enzymes but recent work has shown that chronic exposure to oleuropein-rich olive leaf extract inhibited sucrase activity and glucose transport in a model gut cell system but also reduced sucrase mRNA expression and the proportion of sucrase present at the cell surface (Pyner et al., 2017).

In a related area, inhibition of gut dipeptidyl-peptidase IV (DDP4) activity by PPs present in PP-rich foods could increase the longevity of incretin hormones [i.e. glucagon-like peptide-1 (GLP-1) and glucose-dependent insulintropic polypeptide (GIP)] which are intimately involved in glycaemic control and already targeted by pharmacological agents (Lacroix and Li-Chan, 2016).

## Conclusion

Even within the limited scope of this commentary, there are many examples of PP-enzyme inhibition that could have beneficial effects on human health. Given the less limited availability of PPs in the gut, many of these relate to digestive enzymes and this is an area that fully deserves further attention. However, given the continuing interest in the health benefits of PP intake (e.g. Del Rio et al., 2013), it is very likely that other examples of PPs inhibiting novel enzymes will arise, such as the recent report that the flavonol, myricetin, can potently inhibit gastric  $H^+$ ,  $K^+$ -ATPase activity (Miyazaki et al., 2018) and may thereby function as a natural proton pump inhibitor.

Bridging the gap between human and animal studies that confirm beneficial effects on blood glucose levels, lipid digestion and uptake or *in situ* proteolysis and studies that uncover the mechanisms whereby individual PPs can cause these effects, is crucial. Understanding if PP intake can provide acute or chronic benefits is also important to design PP-rich extracts/foods for specific (e.g.) hyperglycaemic effects. Of course, adding to this complexity is the considerable inter-individual response to PP intake noted in recent work (Manach et al., 2017).

## Overview of Structure-function Relationship of $\alpha$ -Lactalbumin

$\alpha$ -Lactalbumin ( $\alpha$ -LA) is the second most important milk protein, accounting for 20%–25% of the whey proteins and about 3.4% of total milk proteins. According to the description provided by Chrysina et al. (2000),  $\alpha$ -LA molecule consists of a single polypeptide chain of 123 amino acids, with a molecular mass of 14,200 Da and 3D structure homologous to the lysozyme family. The  $\alpha$ -LA tertiary structure has two domains: the larger  $\alpha$ -domain including three major  $\alpha$ -helices of the protein (residues 5–11, 23–24 and 86–98) and two short  $3_{10}$  helices (residues 18–20 and 115–118), and the smaller  $\beta$ -domain with three stranded antiparallel  $\beta$ -sheets (residues 41–44, 47–50 and 55–56), one short  $3_{10}$  helix (residues 77–80) and loops (Al-Hanish et al., 2016). The  $\alpha$ -LA structure is stabilized through four disulfide bonds, and there is no free thiol group available (Gao et al., 2008).

Each  $\alpha$ -LA molecule has a single strong calcium binding site, also called “calcium binding loop”, which is placed in a deep cleft in between  $\alpha$  and  $\beta$  domains (Mohammadi and Moeeni, 2015), and partly contains the  $\alpha$ -helix H3 and  $3_{10}$  helix h2 (N’Negue et al., 2006). The calcium ion is coordinated to the  $\beta$ -carboxyl groups of three aspartic acid residues (Asp<sup>82</sup>, Asp<sup>87</sup> and Asp<sup>88</sup>), two backbone carbonyl oxygens (Lys<sup>79</sup> and Asp<sup>84</sup>), and two water molecules (Acharya et al., 1991; N’Negue et al., 2006). Farkas et al. (2005) explained that calcium binding plays an important role in stabilizing the native state of  $\alpha$ -LA. For instance, the temperature required to induce  $\alpha$ -LA unfolding registered a shift from about 20 °C, corresponding to the apo-form, to nearly 70 °C for the Ca<sup>2+</sup>-bound protein. Stănciuc et al. (2012) studied the effect of pH and temperature on the fluorescence of apo- $\alpha$ -LA, and showed that the protein is sensitive to both environmental factors. The heat-induced denaturation followed a third-state model when unfolding at pH 2.0, and *all-or-none* transitions were registered at pH 4.5 and 7.0. The protein structure appeared more flexible at acidic pH values, favoring the exposure of the hydrophobic residues.

Because the  $\alpha$ -LA molecule has several partially unfolded intermediate states and is known to be present in molten globule form under various conditions, it was extensively used as model for studying the protein folding and unfolding patterns (Chaudhuri and Chattopadhyay, 2014). At low pH values,  $\alpha$ -LA undergoes conformational changes toward the molten globule state, a specific conformation that retains its secondary structure domains but loses its stable tertiary structure. Ryu et al. (2012) studied the pH-induced conformational changes of  $\alpha$ -LA and suggested sequential changes from pre-molten globule to molten globule state at pH 4.75 and 2.75. The first changes were observed in the  $\beta$ -sheet structures, followed by  $\alpha$ -helices alteration at lower pH values.

$\alpha$ -LA has multiple biological and pharmaceutical functions. It has an important *in vivo* role in lactose biosynthesis in mammary gland, as a specificity modifier of galactosyltransferase (Permyakov and Berliner, 2000). In partially disordered states,  $\alpha$ -LA has the ability to interact with membranes (Halskau et al., 2002). The potential of interacting with membranes is of significant relevance, since the complexation of  $\alpha$ -LA with oleic acid may form the HAMLET (Human Alpha-lactalbumin Made LEthal to Tumor cells) complex (Svensson et al., 2000, 2003; Brinkmann et al., 2013) which has antimicrobial properties and is tumoricidal against a spectrum of cancer cells while exhibiting far lower toxicity towards differentiated cells.

Milk proteins are widely used as carriers for drugs/bioactive compounds. Several studies indicated the ability of apo  $\alpha$ -LA to interact with different hydrophobic compounds, such as carotenoids (Dumitraşcu et al., 2016; Ursache et al., 2017), retinol (Livney, 2010), vitamin D3 (Delavari et al., 2015), hydrophobic peptides, model lipid membranes, fatty acids (Barbana et al., 2006; Kehoe and Brodtkorb, 2014), and epigallocatechin-3-gallate (Al-Hanish et al., 2016).

## Carotenoids

Carotenoids are intensely yellow to red colored liposoluble pigments synthesized by plants and micro-organisms. The structures of all carotenoids are based on a common 40-carbon linear terpene. Carotenoids are classified into carotenes that are hydrocarbons without oxygen, and xanthophylls that contain one or more oxygen atoms (Bhosale and Bernstein, 2007).

Carotenoids are present in many foods, particularly in fruit, vegetables, and fish (El-Agamey et al., 2004; Yuan et al., 2013). Humans consume a wide variety of carotenoids, with  $\beta$ -carotene, lycopene, lutein, zeaxanthin,  $\beta$ -cryptoxanthin, and  $\alpha$ -carotene accounting for 90% of the circulating carotenoids (Bhosale and Bernstein, 2007). Although other carotenoids, such as violaxanthin and neoxanthin, are also common in the human diet, they do not appear to be absorbed. Because of their antioxidant activities, such as oxygen radical scavenging and singlet oxygen quenching abilities, carotenoids have significant functional properties (Elliott, 2005; Stahl and Sies, 2005).

Among the carotenoids, considerable attention has been paid to the  $\beta$ -carotene, which has a polyene chain with 11 conjugated double bonds and a  $\beta$ -ring at each end of the chain (Knockaert et al., 2012).  $\beta$ -Carotene is one of the most effective vitamin A precursors, and provides additional potential health benefits, as an efficient cancer prevention agent, ulcer inhibitor, life extender, and heart attack inhibitor (von Lintig, 2010; Chen et al., 2014).

Due to their highly conjugated double bonds, carotenoids are rather unstable to oxygen, light, and heat. In their natural forms, carotenoids are insoluble in water and slightly soluble in oil at room temperature (Rodríguez-Huezo et al., 2004). One way to enhance the solubility of carotenoids relies on the formation of complexes with proteins or lipids (Pillbrow et al., 2012). Moreover,

carotenoids microencapsulation by using milk proteins has been proposed as an effective method for increasing their stability and their transportation while facilitating their functionality in delivery systems (Dumitraşcu et al., 2016)

### Fluorescence Spectroscopy-Based Evidences on Carotenoids- $\alpha$ -Lactalbumin Binding and Thermal Stability of the Resultant Complex

Fluorescence spectroscopy is a spectral technique widely used to characterize proteins and track conformational changes. The natural fluorescence of proteins is mainly attributed to tryptophan (Trp), phenylalanine, and tyrosine residues. The fluorescent properties of Trp are the most widely exploited. The detection of native and unfolded states of proteins is based on the indole side chain of Trp, whose emission spectrum is very sensitive to the polarity of its environment. Therefore, additional molecular events taking place on the same time scale might interfere with the emission properties of Trp (Efink, 1991). Fluorescence intensity of Trp residues can be measured as a function of excitation or emission wavelengths, or as a function of quencher or time. The emission maximum of Trp residues provides important information regarding solvent accessibility. The spectral properties of Trp residues include: (1) if emission maximum ( $\lambda_{\text{max}}$ ) is near 350 nm, residues are considered to be completely exposed to solvent; (2) if  $\lambda_{\text{max}}$  is close to 340 nm, residues are partially exposed to protein surface; (3) if  $\lambda_{\text{max}}$  is in the 315–330 nm range, residues are buried within the protein but interacting with neighboring polar groups; (4) if  $\lambda_{\text{max}}$  is close to 308 nm, residues are fully buried in a non-polar environment.

There are four Trp residues in each  $\alpha$ -LA molecule. As indicated by Chrysina et al. (2000), the Trp residues participate either in defining the aromatic cluster II (Trp<sup>26</sup>, Trp<sup>60</sup> and Trp<sup>104</sup>), or in the aromatic cluster I (Trp<sup>118</sup>). In its native state,  $\alpha$ -LA has intrinsic fluorescence mainly associated to Trp<sup>60</sup> which is exposed to the solvent. When  $\alpha$ -LA is heated alone in the temperature range of 25–70 °C, minor changes appear in Trp fluorescence or  $\lambda_{\text{max}}$  of  $\alpha$ -LA (Figs. 1 and 2). The heat-induced changes in  $\alpha$ -LA at the neutral pH and temperatures up to 70 °C are reversible (McGuffey et al., 2007).

Fluorescence spectroscopy is also frequently applied to study the interaction between proteins and any target compound. Dumitraşcu et al. (2016) studied the mechanism of carotenoids binding through thermal treatment of  $\alpha$ -LA, while Ursache et al. (2017) reported on the thermal stability of the  $\alpha$ -LA-carotenoid complexes obtained at 25 °C. When  $\alpha$ -LA is heated first and then quenched with carotenoids, fluorescence intensity of Trp decrease with increasing concentration, indicating that despite their high hydrophobicity, carotenoids possess significant affinity for  $\alpha$ -LA. This behavior is associated with Trp movement from non-polar toward polar environment. The fluorescence intensity of Trp decreases under both tested conditions, but to a greater extent when the protein was first heated and then quenched with carotenoids. The heat treatment also caused significant differences in  $\lambda_{\text{max}}$  values. When compared with  $\alpha$ -LA and  $\alpha$ -LA-carotenoids complex at 25 °C, the protein quenching with carotenoids resulted in red shifts of at least 6 nm (Fig. 2), indicating a higher amount of exposed Trp for the interaction with polar groups.

Maximum Trp emission in the heated  $\alpha$ -LA subjected to quenching with carotenoids was blue shifted in the temperature range of 25–70 °C, whereas heating the  $\alpha$ -LA and  $\alpha$ -LA-carotenoids complex, in the same temperature range, resulted in no major change in  $\lambda_{\text{max}}$  (Fig. 2). For all the studied experimental set-ups, heating at temperatures over 80 °C caused red shifts of  $\lambda_{\text{max}}$ , indicating the interaction of Trp residues with polar groups (Dumitraşcu et al., 2016).

Stern-Volmer equation is often used to measure whether quenching process is static or dynamic (Dumitraşcu et al., 2016). Quenching experiments can be performed with quenchers such as KI and acrylamide, which allow the detection of the fluorescence of Trp residues with different degrees of exposure. Regardless of the applied heating conditions, quenching titrations with

**Figure 1** Fluorescence intensity of  $\alpha$ -lactalbumin ( $\alpha$ -LA) alone or in the presence of carotenoids added before or after heating. After the results presented by Dumitraşcu et al. (2016) and Ursache et al. (2017).

**Figure 2** Maximum emission of  $\alpha$ -lactalbumin ( $\alpha$ -LA) alone or in the presence of carotenoids added before or after heating. After the results presented by Dumitraşcu et al. (2016) and Ursache et al. (2017).

acrylamide generated higher  $K_{SV}$  values than with KI. The KI quenches the fluorescence of Trp residues located at or near the molecule surface, whereas acrylamide would target both exposed and partially exposed Trp residues (Ursache et al., 2017).

Quenching titrations can be performed with ligands that show the ability of protein to bind different compounds. Quenching experiments were performed on heated  $\alpha$ -LA with carotenoids. Based on the linearity of the Stern-Volmer plots, regardless of carotenoids being added before or after heat treatment of the protein, the quenching is static and the complex formed by carotenoids and  $\alpha$ -LA is in the ground state.

### Molecular Modelling Details on the Interaction Between $\beta$ -Carotene and $\alpha$ -Lactalbumin in Thermal Treatment

Different studies aiming to understand the molecular architecture of proteins alone or in complex with different ligands, relied on the use of various experimental techniques. One way to overcome the limitation of an experimental technique in providing atomic level details on the interactions between different molecules is to complement molecular modelling studies.

$\beta$ -Carotene was found as one of the major compounds in the carotenoid extract from sea buckthorn used by Dumitraşcu et al. (2016) and Ursache et al. (2017) in their investigations on the carotenoids- $\alpha$ -LA complex. The *in silico* investigations were used to examine the particularities of the  $\alpha$ -LA- $\beta$  carotene complex equilibrated at different temperatures as well as the interaction between  $\beta$ -carotene and the preliminarily heated protein. To provide comprehensive insights on the interaction and stability of the  $\alpha$ -LA- $\beta$  carotene complex, molecular docking and molecular dynamics approaches were successfully combined.

When studying the thermally induced structural rearrangements of the unbound  $\alpha$ -LA molecule, Dumitraşcu et al. (2016) showed a significant reduction in the amounts of amino acids involved in defining strands (from 9.8% at 25 °C to 3.3% at 90 °C) and  $3_{10}$  helix (from 7.4% at 25 °C to 2.5% at 90 °C) motifs. Thermal destabilization of the helix was mainly motivated by the dynamics of the hydrogen bonding pattern. The conformation of the aromatic cluster II hosting most of the Trp residues of the molecule (Chrysina et al., 2000) was altered at a high temperature due to significant molecular rearrangements resulting in changes of fluorescent residues exposed to the solvent, and formation of new native-like antiparallel G1 beta bulge, linking Tyr<sup>50</sup>, Gln<sup>54</sup> and Ile<sup>55</sup> residues, and four inverse beta turn motifs involving consecutive residues (Ser<sup>69</sup>-Asn<sup>71</sup>, Ser<sup>70</sup>-Ile<sup>72</sup>, Ile<sup>75</sup>-Cys<sup>77</sup> and Cys<sup>120</sup>-Lys<sup>122</sup>) compacted within 7 Å. In the molecular dynamics set-up proposed by Dumitraşcu et al. (2016), when the protein was heat treated alone, partial folding occurred, as indicated by the total protein surface evolution (6648.6 Å<sup>2</sup> at 25 °C and 6527.86 Å<sup>2</sup> at 90 °C). When the  $\alpha$ -LA molecule was subjected to the thermal treatment in the presence of  $\beta$ -carotene, Ursache et al. (2017) reported the slight relaxation of the protein structure at a high temperature (total protein surface increased up to 6904.8 Å<sup>2</sup> at 90 °C). In the latter case, the molecular structure appeared to be better organized at a high temperature, preserving the  $\alpha$ -helical content with about 80% of the strands specific to the native protein. Superposition of the protein molecules equilibrated at 90 °C using the two different set-ups proposed by Dumitraşcu et al. (2016) and Ursache et al. (2017) resulted in a backbone based root mean square deviation (RMSD) of 3.12 Å.

Regardless of the set-up used in the molecular modeling investigations, the reduction of the affinity was found between protein and  $\beta$ -carotene with increasing temperature. Lower interaction energy and higher interface area between the two components of the complex were reported when thermally treating the complex assembled at room temperature ( $\alpha$ -LA- $\beta$  carotene interaction energy of -175.40 kJ/mol and interface area of 484.7 Å<sup>2</sup> at 90 °C; Ursache et al. (2017)), suggesting better affinity compared to the complex obtained through docking the ligand onto the preliminary heat treated whey protein ( $\alpha$ -LA- $\beta$  carotene interaction energy of -127.19 kJ/mol and interface area of 333.7 Å<sup>2</sup> at 90 °C; Dumitraşcu et al. (2016)). Careful analysis of the forces contributing to the stability of protein-ligand complex showed that London dispersion forces prevail over the short range Coulomb interactions in both cases.

**Figure 3**  $\beta$ -Carotene binding by  $\alpha$ -lactalbumin ( $\alpha$ -LA) equilibrated at 25 °C (A) 60 °C (B) and 90 °C (C). The image was prepared using the Visual Molecular Dynamics (VMD) software (Humphrey et al., 1996).  $\alpha$ -LA is represented in silver using Surf style, while the ligand is represented in orange (25 °C), red (60 °C) and cyan (90 °C) in Licorice style. The amino acids involved in the interaction with the ligand are presented in Table 1.

**Table 1** The amino acid composition of  $\beta$ -carotene binding sites of  $\alpha$ -lactalbumin ( $\alpha$ -LA)

Temperature	Molecular modeling set-up	
	Thermal treatment of $\alpha$ -LA followed by docking with $\beta$ -carotene (Dumitraşcu et al., 2016)	Molecular docking of $\beta$ -carotene on $\alpha$ -LA followed by thermal treatment Ursache et al. (2017)
25 °C	Glu <sup>1</sup> , Gln <sup>2</sup> , Leu <sup>3</sup> , Glu <sup>11</sup> , Asp <sup>84</sup> , Thr <sup>86</sup> , Asp <sup>87</sup> , Met <sup>90</sup>	Glu <sup>1</sup> , Leu <sup>3</sup> , Glu <sup>11</sup> , Leu <sup>12</sup> , Asp <sup>83</sup> , Thr <sup>86</sup> , Asp <sup>87</sup> , Ile <sup>89</sup> , Met <sup>90</sup>
60 °C	Phe <sup>31</sup> , His <sup>32</sup> , Thr <sup>33</sup> , Tyr <sup>36</sup> , Glu <sup>49</sup> , Ile <sup>59</sup> , Tyr <sup>103</sup> , Trp <sup>104</sup> , Leu <sup>105</sup> , Ala <sup>106</sup> , Leu <sup>110</sup>	Glu <sup>1</sup> , Gln <sup>2</sup> , Leu <sup>3</sup> , Thr <sup>4</sup> , Glu <sup>7</sup> , Val <sup>8</sup> , Glu <sup>11</sup> , Leu <sup>12</sup> , Ile <sup>89</sup> , Lys <sup>93</sup>
90 °C	Leu <sup>15</sup> , Lys <sup>16</sup> , Val <sup>21</sup> , Ser <sup>22</sup> , Leu <sup>23</sup> , Glu <sup>25</sup> , Glu <sup>113</sup> , Lys <sup>114</sup>	Glu <sup>11</sup> , Leu <sup>12</sup> , Asp <sup>14</sup> , Leu <sup>15</sup> , Leu <sup>52</sup> , Leu <sup>85</sup> , Thr <sup>86</sup> , Asp <sup>88</sup> , Ile <sup>89</sup> , Met <sup>90</sup>

The ability of a protein to recognize and bind ligands is highly influenced by the surface properties. The exposure of different hydrophobic and hydrophilic patches on the protein surface vary with tertiary and secondary structure, and with the environmental conditions. Due to the temperature related expansion of the cavities located on top of protein surface, different binding sites, sharing no common residues, have been reported by Dumitraşcu et al. (2016) through docking the  $\beta$ -carotene molecule to the heat treated  $\alpha$ -LA (Fig. 3 and Table 1). On the other hand, when the complex was thermally treated, it appeared that the amino acids Leu<sup>12</sup> and Ile<sup>89</sup> from  $\alpha$ -LA played a central role in binding the  $\beta$ -carotene in the temperature range of 25–100 °C (Fig. 4). Both residues belong to two different  $\alpha$ -helices, which were the most stable elements of the globular protein structure. Indeed, no significant changes in the organization of the Asp<sup>87</sup>-Lys<sup>98</sup> helix was registered with increasing the temperature from 25 °C to 100 °C. In case of the Lys<sup>5</sup>-Leu<sup>12</sup> helix, the Leu<sup>12</sup> migrated toward a  $\beta$ -turn motif when the  $\alpha$ -LA- $\beta$  carotene complex was heated at 70 °C and 80 °C, because of the changes in the relative orientation of the side chains causing the alteration of the hydrogen bond pattern.

When the complex was heated, the increase of temperature resulted in the increase of the amount of hydrophobic amino acids interacting with the  $\beta$ -carotene molecule. In addition to the hydrophobic amino acids Leu<sup>3</sup>, Leu<sup>12</sup> and Ile<sup>89</sup>, which were in contact with  $\beta$ -carotene molecule at 25 °C, the following residues were found to establish hydrophobic contacts with the ligand at 100 °C: Val<sup>8</sup>, Leu<sup>15</sup>, Leu<sup>23</sup>, Trp<sup>26</sup>, Leu<sup>52</sup> and Leu<sup>85</sup> (Fig. 4). Since the ligand carried no electric charge, in both studied molecular modeling set-ups, the hydrophobic contacts were responsible for stabilizing the  $\alpha$ -LA- $\beta$  carotene complex. The involvement of the electrostatic interactions, which were considered to play a crucial role in rendering specific the protein-ligand binding, was limited to the eventual  $\pi$ - $\pi$  and cation- $\pi$  interactions (Dumitraşcu et al., 2016).

## Conclusions

The computer-assisted techniques used for simulating molecular behavior have been proven to be very efficient in complementing the experimental observations on carotenoids- $\alpha$ -lactalbumin complexes by fluorescence spectroscopy. Thermal treatment at high temperatures affects the stability of the complex. The fundamental knowledge of the atomic-level events responsible for the molecular behavior might allow tracking the origins of the macroscopically observed behaviors, leading to practical solutions for laboratory-scale experiments, or even for efficient technological processing at industrial scale of food ingredients.

**Figure 4** Details on the  $\alpha$ -lactalbumin- $\beta$  carotene docking models at 25 °C and 100 °C. (A) Superposition of the complexes prepared using the Visual Molecular Dynamics (VMD) software.  $\alpha$ -Lactalbumin ( $\alpha$ -LA) is represented in New Ribbons style in *mauve and gray*, whereas the ligand is represented in Licorice style in *blue and red*, at 25 °C and 100 °C, respectively. (B) Hydrophobic contacts established between  $\alpha$ -LA amino acids (represented through *arcs* radiating towards the ligand atoms they are in contact with) and  $\beta$ -carotene molecule at 25 °C and 100 °C. The representation was prepared using LigPlot+ (Laskowski and Swindells, 2011).

## Introduction

### Bulk Composition of Whole Milk

Whole milk, skim milk, and infant formula emulsions are regularly spray dried to powder form at large industrial scale for preservation with increased stability against oxidative rancidity, reduced bulk volume for economy of transportation, and easier processing as ingredient in food products (Vega and Roos, 2006; Schuck, 2002). While the exact composition of bovine whole milk can vary considerably, on average it has a solid content of 12%–13% w/w and, as presented in Table 1, the major components are lactose with an approximate content of 40% w/w in dry matter, fat with 32% w/w, and protein with 28% w/w (neglecting minerals and vitamins). The milk fat is dispersed inside the aqueous continuous phase in form of spherical fat globules of 0.1–10  $\mu\text{m}$  in diameter (Michalski et al., 2002). The globules are stabilized by a surrounding layer of fat globule membranes, which are composed of a complex combination of phospholipids, lipoproteins, other proteins, organic acids, bound water, traces of metals, and enzymes (Singh and Gallier, 2016). About 80% of the total protein content in bovine milk is made of caseins. These phosphoproteins are held together in form of submicron-sized micelles by hydrophobic interaction and calcium ions (Müller-Buschbaum et al., 2007). In studies that investigate milk model emulsions, native casein is often replaced by sodium caseinate as emulsifier. It is produced from precipitated casein by the addition of sodium hydroxide and is soluble in water without developing a micelle structure (Jost, 2002). The remaining protein fraction in milk consists of whey proteins, which are primarily comprised of  $\alpha$ -lactalbumin and  $\beta$ -lactoglobulin. Whey protein is also known as milk serum protein due to its greater water solubility than that of casein.

### Powder Surface Composition After Spray Drying

The main components at the surface of spray-dried milk powder usually differ substantially in proportion from the bulk composition of the original milk emulsion because of an overrepresentation of fat at the surface. The surface layer of fat is unwanted, as the chemical surface composition strongly influences the functional powder properties, with surface fat leading to several detrimental effects on the product characteristics (Vignolles et al., 2007). This includes enhanced lipid oxidation during storage and thus faster expiration (Granelli et al., 1996; Hardas et al., 2000; Keogh et al., 2001), reduced reconstitution behavior (Fäldt and Bergenstahl, 1996b; Millqvist-Fureby et al., 2001), and greater stickiness (Kim et al., 2005a; Nijdam and Langrish, 2006). This can cause a deteriorated product quality for the end user, as well as lower production efficiencies due to significant product losses and the requirement of additional processing steps, such as coating with lecithin. Furthermore, an enrichment of protein at the surface of particles from low-fat milk emulsions is sometimes observed. Although being less of a concern for skim and whole milk, in powders that contain particularly high proportions of native casein, the rehydration behavior can also be detrimentally affected by too much surface protein as a result of a network formation between the casein micelles (Schuck et al., 2007; Havea, 2006; Mimouni et al., 2010). It is therefore of great interest to identify the segregation mechanism that induces the surface fat formation or other component segregation processes during spray drying of milk powders. A better understanding will help to find technical solutions to establish more desirable surface compositions. Moreover, knowledge about the chemical surface formation in drying milk droplets is relevant for modeling purposes of industrial applications to predict the functional product properties and to optimize spray dryer designs.

**Table 1** Composition of bovine whole milk (Bylund, 2003)

Species	Concentration (% w/w)
Water	87.5
Lactose	4.8
Fat	3.9
Protein, total	3.4
Casein	2.71
$\alpha_{s1}$ -casein	1.04
$\alpha_{s2}$ -casein	0.27
$\beta$ -casein	1.05
$\kappa$ -casein	0.34
Whey protein	0.65
$\alpha$ -lactalbumin	0.13
$\beta$ -lactoglobulin	0.33
Miscellaneous	0.19
Fat globule membrane proteins	0.04
Minerals, vitamins	0.8

An analysis of the whole manufacturing process of milk powder has indicated that spray drying is the determining step, whereas the following fluidized bed and handling stages have a negligible influence on the surface composition (Kim et al., 2009b). As such, the studies on the surface formation of milk particles reported in literature have mostly focused on the spray drying process itself. It has been attempted to explain the component segregation by mechanisms occurring during the drying stage between droplet generation and completion of the spray drying process (segregation induced by diffusivity, surface activity, and crust formation), or prior to this during disintegration of the feed emulsion into individual droplets (segregation induced by atomization). It is still under debate which of those mechanisms is in fact the predominating driving force, with the respective studies providing either one specific segregation concept as explanation (Table 2) or a combination of two or more (Table 3).

## Chemical Surface Composition of Milk Particles

### Presence of Surface Fat and Effect of Spray Drying Conditions

In general, Tables 2 and 3 show that there is a wide agreement in the observation of a dominant presence of surface fat on convectively dried milk powder, which could not be prevented by variation of the drying parameters or spray dryer type. For milk (model) emulsions with fat contents similar to whole milk, the particles were found to be covered by an almost consistent fat layer that occupied more than 90% of the outmost surface area (Kim et al., 2003; Murrieta-Pazos et al., 2012; Foerster et al., 2016a,b). This corresponds to a fat surface overrepresentation of approximately three times in relation to the feed bulk composition. Skim milk (model) emulsions and milk protein concentrates were observed to also translate into a fat accumulation on the powder surface with 3.5%–45.9% surface fat for fat contents of 0.6%–1.5% in the bulk (Kim et al., 2009a; Nikolova et al., 2014; Kelly et al., 2015; Murrieta-

**Table 2** Summary of studies on component segregation in droplets consisting of milk protein and fat: organized by concepts provided as explanation—part 1: only one concept per study

Concept	System	Surface composition (XPS)	Analysis	Author
Diffusivity	Aqueous solution of sucrose/caseinate in agar gel matrix	20% protein overrepresentation	XPS	Meerdink and Van't Riet (1995)
Diffusivity	Industrial spray dried skim and whole milk	Overrepresentation of fat (whole milk: 98% on surface/29% total, skim milk: 18% on surface/1% total), also enrichment of protein near the surface	XPS, free fat extraction	Kim et al. (2003)
Diffusivity	Single droplet drying of whole and skim milk	Hydrophobic surface due to surface fat	Dissolution behavior	Fu et al. (2011)
Diffusivity	Spray drying of skim milk in pilot scale	Overrepresentation of fat (5.8%–7.4% on surface/0.9% total) and protein (43.0%–49.8% on surface/36.9% total), slight increase in component segregation with longer drying times	XPS	Nikolova et al. (2015a, 2014)
Surface activity	Spray drying of lactose/soybean oil/whey protein or sodium caseinate	Overrepresentation of fat for whey protein, better fat encapsulation with sodium caseinate (whey protein: 45% on surface, caseinate: 3% on surface/30% total)	XPS	Fäldt and Bergenståhl (1996a, 1995)
Surface activity	Spray drying of sucrose/whey protein or sodium caseinate	Overrepresentation of protein (up to 50%–58%/0.5%–1% total)	XPS	Adhikari et al. (2009)
Surface activity	Spray drying of phosphor-caseinate/lactose/milk fat	Overrepresentation of fat (14.5%–18.7% on surface/0.4% total)	XPS	Gaiani et al. (2006)
Surface activity/hydrophobicity	Spray drying of milk protein concentrate with various protein contents	Overrepresentation of fat (3.5%–10.2% on surface/0.6%–1.4% total) and protein (62.7%–97.2% on surface/35.4%–85.8% total)	XPS	Kelly et al. (2015)
Crust formation	Industrial spray dried skim and whole milk	Overrepresentation of fat (whole milk: 93.3% first 5 nm, 58.6% first $\mu\text{m}$ /28.4% total, skim milk: 45.9% first 5 nm, 22.8% first $\mu\text{m}$ /1.5% total) and slight overrepresentation in protein for skim milk (45.1% first 5 nm, 34.4% first $\mu\text{m}$ /38.5% total)	XPS, EDX, free fat extraction	Murrieta-Pazos et al. (2012)

EDX, energy dispersive X-ray analysis; XPS, X-ray photoelectron spectroscopic analysis

**Table 3** Summary of studies on component segregation in droplets consisting of milk protein and fat: organized by concepts provided as explanation—part 2: combinations of concepts

<i>Concept</i>	<i>System</i>	<i>Surface composition (XPS)</i>	<i>Analysis</i>	<i>Author</i>
Diffusivity, surface activity	Spray drying of lactose and fat with casein or whey protein	Overrepresentation of fat for all powders and of protein for many powders, less fat enrichment for casein instead of whey protein and for higher temperatures	XPS	Gaiani et al. (2010)
Diffusivity, surface activity	Spray drying of lactose/rapeseed oil/whey protein	Overrepresentation of fat (55%–65% on surface/30% total)	XPS, free fat extraction	Millqvist-Fureby et al. (2001)
Surface activity, crust formation	Spray drying of whole and skim milk	Overrepresentation of fat (significant) and protein (less distinct)	XPS	Nijdam and Langrish (2005, 2006)
Surface activity, crust formation	Spray drying of walnut oil and skim milk (with Tween 80 or maltodextrin)	Overrepresentation of fat (85.6%–92.5% on surface/50% total)	XPS, free fat extraction	Shamaei et al. (2016)
Diffusivity, surface activity, crust formation	Single droplet and spray drying of milk model emulsions at various fat contents and of milk protein concentrate	Overrepresentation of fat (milk emulsion with e.g., 76%–87% fat on surface/29%–42% total, milk protein concentrate: 17%–27% on surface/1.5% total)	XPS	Chew et al. (2015, 2014)
Surface activity, crust formation, atomization	Spray drying of whole and skim milk (lab and pilot scale), compared with commercial powders	Overrepresentation of fat in form of thin patches on all powders (e.g., commercially dried skim milk: on surface 16.5%/0.7% total, pilot scale: similar, laboratory scale: less surface fat)	XPS, CLSM	Fyfe et al. (2011)
Diffusivity, surface activity, crust formation, atomization	Spray drying of whey protein/sunflower oil/maltodextrin	Overrepresentation of fat (17.7%–34.1% on surface/10% total) and protein (19.8%–42.7% on surface/10% total)	XPS	Xu et al. (2013)
Diffusivity, surface activity, crust formation, atomization	Industrially spray-dried powders of skim and whole milk	Overrepresentation of fat (whole milk: >90% on surface/26% total, skim milk >18% on surface/1% total), slight protein overrepresentation for skim milk (42% on surface/35% total)	XPS	Kim et al. (2009a,b)
Diffusivity, surface activity, atomization	Spray drying of skim milk	High fat overrepresentation and lower protein overrepresentation, surface fat content already high directly after atomization	XPS, flash-freezing of atomized droplets	Wu et al. (2014)
Diffusivity, surface activity, atomization	Spray and single droplet drying of low-fat and regular-fat model milk	High fat overrepresentation and lower protein overrepresentation, surface fat content already high directly after atomization	XPS, CLSM, flash freezing of atomized droplets	Foerster et al. (2016a,b),

CLSM, confocal laser scanning microscopy; XPS, X-ray photoelectron spectroscopic analysis

Pazos et al., 2012; Fyfe et al., 2011). This corresponds to a surface overrepresentation of 6–30 times in comparison with the bulk composition. Nevertheless, in contrast to whole milk particles, it has been shown that the surface of skim milk and milk protein concentrate powders is not dominated by fat because of the low overall fat proportion. The remaining surface area of low-fat milk powders was found to primarily consist of protein (42.0%–62.7% on the very surface for 35.0%–38.5% in the bulk), indicating a slight surface enrichment in protein during drying. Independent from the overall fat content, a distinct lack in lactose

has been consistently reported for all milk powders that were subject of the studies listed in [Tables 2](#) and [3](#), with lactose being sometimes almost completely absent from the outmost surface region ([Gaiani et al., 2006](#); [Nijdam and Langrish, 2006](#)).

To some degree, within the above described range of surface compositions, the exact amount of fat and protein at the particle surface has been reported to be influenced by the drying conditions. [Fyfe et al. \(2011\)](#) studied commercial skim and whole milk powders as well as powders obtained from laboratory- and pilot-scale spray drying. Comparison of the powders showed that there was a difference in surface composition depending on the spray dryer type, albeit always featuring a distinct fat overrepresentation and, for skim milk powders, a moderate protein overrepresentation. Commercial milk powders consisted of more fat and less protein at the surface than the powders produced with laboratory and pilot spray dryers. It remained unclear if this can be ascribed to a larger particle size and higher feed solid content of the industrial drying processes or to the differences in atomization techniques applied. Some studies have indicated that the final particle surface composition will conform more with the bulk composition if the drying rate is increased, for instance by means of a higher drying temperature or a smaller droplet size as influenced by the atomization pressure ([Nikolova et al., 2015a](#); [Gaiani et al., 2010](#); [Kelly et al., 2002](#)).

Furthermore, the properties of the feed emulsion can affect the surface composition. A higher droplet viscosity and earlier crust formation due to an increased feed solid content have been reported to reduce the extent of component segregation during drying of skim milk ([Wu et al., 2014](#); [Kim et al., 2009b](#)). The fat encapsulation efficiency was improved by a stronger reduction in fat globule size during homogenization in studies conducted by [Kim et al. \(2009b\)](#) and [Millqvist-Fureby \(2003\)](#), whereas the surface composition data sets provided by [Xu et al. \(2013\)](#) and [Keogh and O'Kennedy \(1999\)](#) did not demonstrate such a statistically significant relationship for the range of droplet sizes investigated. [Gaiani et al. \(2010\)](#) and [Fäldt and Bergenståhl \(1996a\)](#) observed an influence of the kind of milk protein employed as emulsifier. The use of casein, particularly in the presence of lactose, resulted in less surface fat than the use of whey protein, presumably due to casein's greater surface activity and resistance to denaturation under heat ([Vega and Roos, 2006](#)).

### Analysis Techniques of Component Distribution

X-ray photoelectron spectroscopic (XPS) analysis, also referred to as electron spectroscopy for chemical analysis in this context, is the prevailing method to quantify the chemical surface composition of milk particles. In this sensitive surface analysis technique, the powder samples are irradiated with an X-ray beam of a well-defined energy level under high vacuum, and electrons are emitted if their binding energy is surpassed by the photon energy. Detection of the number of emitted electrons and their respective kinetic energy, which is characteristic for each chemical element, yields the sample composition and the chemical state of the elements. [Fäldt et al. \(1993\)](#) suggested a transformation of the obtained elemental particle surface concentrations, i.e., the relative amounts in carbon, nitrogen, and oxygen, into the surface percentages that are covered by lactose, protein, and fat by means of a matrix linearization based on each component's representative structural formula. This approach has been widely adapted in literature, and the surface compositions presented in [Tables 2](#) and [3](#) were determined in this manner. [Nikolova et al. \(2015b\)](#) discussed the possibility of a distortion of the XPS analysis toward higher carbon contents as a result of organic pollution inside the vacuum chamber and therefore proposed a modified approach where the linearization matrix is derived from experimental measurements of XPS spectra for lactose, protein, and lipid standard samples. Either way, it is generally accepted that component compositions derived from XPS atomic spectra should be considered as semiquantitative estimations only. In addition, it needs to be noted that XPS analysis accounts only for the first few nanometers of the sample surface (about 0–10 nm), with the exact sampling depth being difficult to quantify because of the surface curvature of the milk particles. As such, it only describes the outmost surface layer of the analyzed powders, which does not allow a conclusion about the overall amount of free surface fat, especially for high-fat milk powders.

The total amount of free surface fat, often expressed by the encapsulation efficiency of a powder sample, is frequently quantified by surface fat extraction. In this method, the mass of extracted fat is determined by measuring the sample weight before and after extraction with a nonpolar, organic solvent, such as hexane or petroleum ether. In terms of powder concentration, duration of the extraction process and intensity of the contact between powder and solvent during mixing, no standard procedure has been established yet and the techniques reported in literature vary considerably among each other, as summarized by [Vega and Roos \(2006\)](#). The amount of extracted fat further depends on the particle size and porosity ([Twomey et al., 2000](#); [Vignolles et al., 2007](#)). A significant amount of extractable fat is believed to not originate from the particle surfaces, but from inner free fat that is extracted from the inside of the particles through pores and cracks, in particular at relatively intense mixing and long exposure times to the solvent ([Buma, 1971](#); [Buchheim, 1982](#)). For this reason, the results from fat extraction of milk powder samples might most often represent the amount of free fat instead of the amount of free surface fat ([Kim et al., 2005b](#)). As a consequence, free (surface) fat extraction might provide a more suitable technique than XPS to quantify the total amount of surface fat, but is typically limited to a qualitative comparison among samples analyzed with the same extraction technique, rather than giving robust absolute values.

Other, less-frequently employed analysis methods include confocal laser scanning microscopy (CLSM) for the protein and fat distribution inside the whole particle ([Taneja et al., 2013](#)), transmission electron microscopy (TEM) for protein–lipid or protein–protein interactions ([Mckenna et al., 1999](#)), and energy dispersive X-ray (EDX) analysis of the atomic surface composition at a sampling depth of about 1  $\mu\text{m}$  ([Murrieta-Pazos et al., 2012](#)). As these analysis techniques describe the particle composition at different distances from the extreme surface, often various combinations are employed to obtain a comprehensive insight into the component distribution, such as XPS measurements together with free fat extraction and CLSM investigation ([Vignolles et al., 2009](#)) or XPS and EDX analysis ([Murrieta-Pazos et al., 2012](#)).

## Potential Segregation Mechanisms

### Diffusivity

As illustrated in **Fig. 1B**, Meerdink and van't Riet suggested that the component segregation could occur due to differences in the components' diffusivities (Meerdink, 1994; Meerdink and Van't Riet, 1995), a concept that has been adopted in a series of subsequent studies (Kim et al., 2003; Fu et al., 2011; Chew et al., 2014; Nikolova et al., 2015a). As water evaporates from the droplet surface, radial gradients in the component concentrations are formed and cause the components to diffuse toward the inside of the droplet. Because the diffusivity of a species increases with decreasing hydrodynamic radius, the outer droplet region might become depleted in the smaller, faster diffusing components, such as lactose. As a first approximation of the binary diffusion coefficient of a species in liquid medium, there is an inverse proportionality between the hydrodynamic radius of the species and its diffusivity according to the Stokes–Einstein equation (Cussler, 2009). In homogenized, bovine whole milk, the radius is in the range of 100–10,000 nm for lipid globules (Leman et al., 1989; Michalski et al., 2002), 50–300 nm for casein micelles (Dewan et al., 1974; Müller-Buschbaum et al., 2007), and 0.1–1 nm for lactose (Bylund, 2003). Thus, the diffusivity of lactose is two to five orders of magnitude greater than the diffusivity of the fat globules. The longer the drying process takes (for instance the lower the drying temperature or the higher the initial water content), the stronger might the diffusivity effect influence the component segregation (Kentish et al., 2005; Nikolova et al., 2015a; Vehring et al., 2007).

### Protein Surface Activity and Fat Hydrophobicity

Furthermore, the surface composition of milk powder might be influenced by the components' interaction with the air–water interface (**Fig. 1C**). Milk protein's surface activity has mostly been used as explanation of the protein surface overrepresentation observed in several studies. Milk proteins and particularly casein, due to its relatively flexible molecule structure, feature a high degree of surface activity as a result of an amphiphilic nature (Leman et al., 1989). Thus, their adsorption at the air–water interface has been widely reported, with the movement to the interface being primarily controlled by diffusion, although other factors such as convection as a result of temperature and pressure gradients can also have an influence (Graham and Phillips, 1979; Landström et al., 1999). Fäldt and Bergenstahl observed a migration of milk protein to the surface of drying emulsion droplets consisting of soybean oil, lactose, and either whey protein or sodium caseinate (Fäldt and Bergenstahl, 1996a, 1995) and explained this by the protein's surface activity. This concept has been adopted in other studies (Gaiani et al., 2006; Adhikari et al., 2009). Additionally, as the adsorbed protein is bound to the air–water interface, this impacts the gradient in protein concentration inside the droplet and counteracts any concentration driven diffusion processes away from the surface (compare to section **Diffusivity**). Similarly, the hydrophobic nature of milk fat might attenuate diffusion away from the droplet surface toward the inside of the droplet for fat globules that have already accumulated at the air/water interface (Fu et al., 2011). Furthermore, it has even been suggested that the hydrophobicity causes fat globules to migrate from the droplet center toward the surface (Kelly et al., 2015).

**Figure 1** Explanations proposed in literature for the component segregation in drying milk droplets: Schematics of (A) atomization concept, (B) diffusivity concept, (C) protein surface activity and fat hydrophobicity concept, (D) crust formation concept.

### Crust Formation Concept

It has additionally been proposed that the final particle surface composition might be subject to the crust formation and the solubility of the dissolved protein and lactose solutes (Fig. 1D), as first discussed by Charlesworth and Marshall (1960) and later adopted by others on dairy droplets (Kim et al., 2009b; Wang and Langrish, 2009). These reports argued that the precipitated solutes, once part of the solidified crust, do not participate in the diffusion process anymore. Assuming a decreasing water concentration from the droplet center to the surface due to evaporation, saturation concentrations, and consequent precipitation are first reached near the droplet surface. A lower solubility of one component could thus lead to an enrichment near the surface in comparison with the other components.

Furthermore, it has been suggested that on advanced solidification of the drying droplet the fat phase might move through the crust's network of cracks and pores as driven by overpressure imposed by internal vacuoles and capillary forces (Nijdam and Langrish, 2005). As a result of mechanical stress during drying or atomization, the fat globule membranes might become ruptured to some extent and the lipid phase could hence spread freely inside the drying particle and on its surface at the elevated temperatures of the spray drying process, thus forming a consistent fat surface film (Xu et al., 2013).

### Atomization Concept

As Tables 2 and 3 illustrate, the component segregation in drying milk droplets has primarily been presumed to take place during the drying stage of the spray drying process, with different combinations of the three concepts described above being most often presented as potential driving forces.

However, a smaller number of reports have considered the possibility that an atomization-induced segregation mechanism might take place prior to the drying stage (Fig. 1A). In a study by Fyfe et al. (2011), a pilot-scale spray dryer resulted in a considerably greater fat overrepresentation on skim milk particles' surfaces in comparison with the same powders produced with a laboratory-scale spray dryer, despite both instruments employing the same atomizer type and drying air temperature profile. It was speculated whether this observation can be ascribed to an influence of the different pressure and shear levels during atomization on the disintegration process of the feed emulsion film. Xu et al. (2013) investigated powders that were produced with a bench-top spray dryer from emulsions consisting of sunflower oil, maltodextrin, and whey protein. An increasing fat content on the particle surface with larger fat globule size of the emulsions after homogenization was found. This was explained by liquid fat leakage and consequent spreading of a thin fat film at the particle surface caused by rupture of the fat globule membranes, which become less stable with larger globule sizes. The rupture was supposed to take place either during atomization as a result of shearing or during the drying stage as a result of differential stress on the membranes as they shrink at constant fat globule volume. Kim et al. (2009b) reported respective surface fat contents of more than 90% and 18% on whole milk and skim milk particles that had been dried at a drying air inlet temperature of 205 °C. Because of the intense heat exposure and the consequent fast solidification and immobilization of the components during the drying stage, it was concluded that the surface fat must have already been formed, at least in part, during the preceding atomization stage.

As it is difficult to draw reliable conclusions about the impact of the atomization step from the powder characteristics after completed spray drying, Wu et al. (2014) and Foerster et al. (2016a) compared the surface composition of atomized droplets immediately after atomization, as obtained by cryogenic flash freezing, with the one of the corresponding spray-dried particles. Their work showed that the surface fat on the skim and whole milk particles was caused by the atomization stage for the range of emulsions and spray dryers investigated. After atomization the milk droplets featured surface fat contents of 9%–13% and 83%–92% v/v fat for feed emulsions of 0.5% and 44.2% v/v fat (dry matter basis), respectively, and the surface fat contents remained relatively unchanged throughout the following drying stage (Foerster et al., 2016a). Foerster et al. (2016a), along the argumentation of Kim et al. (2009b), proposed that the atomization-induced fat accumulation on freshly generated milk droplets might originate from the impact of the dispersed fat phase on the disintegration behavior of the emulsion feed. A perforation mechanism was provided as explanation where the milk emulsions preferably disintegrate along the fat globules, causing the fat globules to cover the surface as soon as individual droplets have been formed. This hypothesis was based on earlier photographic investigations of the break-up behavior of emulsions as a function of oil content (Dombrowski and Fraser, 1954; Zakarlan and King, 1982).

### Relevant Mathematical Modeling Approaches

Mathematical simulation of the component distribution in drying milk droplets promises further insight into the segregation mechanism and a useful tool for the theoretical prediction of powder properties at certain drying conditions. A number of modeling approaches on the convective drying of droplets are available in literature, such as models that incorporate the concept of the characteristic drying curve (Keey, 1991; Langrish and Kockel, 2001; Harvie et al., 2002; Tran et al., 2016) or the lumped reaction engineering approach (Chen and Putranto, 2013; Lin and Chen, 2005). The former approach divides the drying process into a perfect shrinkage stage (shrinkage proportional to volume reduction as governed by a constant evaporation rate) and a second stage defined by a falling evaporation rate, whereas the latter approach utilizes empirical correlations between the overall droplet moisture content and the water vapor pressure at the surface as well as the droplet diameter. Although in their simplest form these approaches only incorporate a global mass balance without computation of concentration gradients, some basic models allowing

spatiotemporal resolution of one or more species concentrations emerged from these in the 1970s and 1980s and were further refined in recent times. The majority of models discussed in the following section was developed for description of food material droplets during spray drying and was validated against the drying kinetics obtained from single droplet drying experiments. Their accuracy is usually limited by the difficulty of finding reliable formulations for the influence of the forming crust on the droplet shrinkage rate, on the effective diffusivities of water and the components due to a rising viscosity and mass transport resistance of the solidified material, and on the partial vapor pressure at the surface and thus on the evaporation rate (Kentish et al., 2005).

### Approaches With a Spatiotemporal Water Mass Balance

The earliest spatiotemporal approaches modeled water concentration profiles in drying skim milk droplets (Cheong et al., 1986; Ferrari et al., 1989; Sano and Kee, 1982; Wijnhuizen et al., 1979). An evaporation term was set as outer boundary condition and Fick's second law of diffusion was incorporated along the droplet radius for the water mass balance. The challenge to describe the effective diffusivity and evaporation rate more accurately was addressed in ensuing models. A work by Seydel et al. (2004) described the formation of hollow salt particles by simulating the radius-dependent change in particle density, which was unique in its attempt to account for component precipitation by means of a population balance that was solved independently from the mass and energy balances. Handscomb et al. (2009) formulated a model that aimed to predict shrinkage and shell thickening rates by balancing capillary contraction forces with the structural strength. The complexity of the crust properties and their effect on evaporation and shrinkage was further highlighted in a study by Vehring et al. (2007) on the drying of a protein-in-water droplet. Using the Peclet number, the model predicted the drying time until commencement of precipitation to stop the simulation at that point, because from then on a sufficient accuracy in simulating the declining evaporation rate was considered to be not feasible. Particularly, the effective diffusion coefficient of moisture through a solidified porous crust medium is difficult to predict with reasonable precision from theoretical equations (Perré, 2014).

### Approaches With Spatiotemporal Binary Mass Balances

Adhikari and coworkers have been pioneering the simulation of binary component migration in drying droplets to work toward the prediction of the surface composition (compare to Table 4), presenting a model on fruit juice samples (Adhikari et al., 2003, 2004, 2007). Lumping together the juice components into one averaged component, a pseudo-binary system was formulated. The model was based on a discretization of the spatial coordinate, which was divided into equally long increments. Each of the increments represented a spherical disk with homogeneous composition under radial symmetry assumption. Diffusive fluxes were calculated from the differences in concentration and length between the centers of adjacent disks according to Fick's first law of diffusion. The increasing evaporation resistance was incorporated via estimation of the moisture-dependent water activity in the surface disk and perfect shrinkage was assumed. The differential equations were solved with the method of lines (Iserles, 2009). After the simulated drying kinetics had been compared with suspended single droplet drying experiments for validation, the model was applied on spray drying conditions to predict the particle stickiness from the glass transition temperature.

Gopireddy and Gutheil (2013) utilized a description of the diffusion resistance imposed by the solid surface layer and water activity correlations to account for the retardation caused by solidification. Solving a set of differential diffusion and energy equations with a finite difference approach, in this way the concentration profiles of mannitol or polymer solutions during the early stages of single droplet drying were simulated.

### Approaches With Spatiotemporal Multicomponent Mass Balances

To date, only a few models can be found in literature that allow theoretical prediction of the concentration profiles of more than one component (see Table 4). A computation of the component distribution requires a spatiotemporal resolution of the mass balances, either as a set of simple ordinary differential equations by spatial discretization or as a set of partial differential equations. A global energy balance is typically sufficient under the assumption of a uniform temperature profile. This has been validated by dimensionless analysis (Biot numbers well below unity) for spray drying applications and even for significantly larger droplets in single droplet drying configurations (Chen and Peng, 2005; Patel et al., 2005). Furthermore, radial symmetry is generally assumed.

A spatiotemporal multicomponent model by Wang and coworkers was applied to resemble the spray drying process of an aqueous lactose/caseinate solution by variation of the Reynolds number and drying air temperature over time (Wang and Langrish, 2009; Wang et al., 2013). Spatial discretization of the droplet radius comparable to the above described work by Adhikari and coworkers, under the assumption of perfect shrinkage, allowed a simple incorporation of precipitation by comparison between the saturation concentration of each component and the calculated concentration in each disk at each time step. Also the protein surface activity was incorporated into the mass balance of the surface disk. Therefore, the model stands out in respect to its applicability on the component segregation during convective drying of milk droplets. The component diffusivities were expressed as temperature-dependent functions, but lacked an influence of the water concentration. The water evaporation rate was governed by an additional term in the water mass balance of the surface disk as a function of local water activity, which was estimated from the components' individual moisture-dependent water activity correlations. As available isotherms describing how the presence of solids affect the water activity have been either generated from liquid phase or fully formed solids, however, using either one to describe the entire drying process may not provide a precise description of the evaporation rate. The model was validated via

**Table 4** Modeling approaches that can be applied for prediction of the surface composition of binary or multicomponent droplets during drying: overview of included segregation mechanisms, consideration of the influence of solidification and experimental validation

comparison of the simulated surface composition with particles obtained from spray drying experiments. A surface overrepresentation of protein, which was decreasing with higher drying temperature, was predicted. From a sensitivity study it was concluded that the difference in component diffusivities and the protein surface activity were the major driving forces for component segregation, while the components' solubility imposed a subordinate influence.

Three other models were less comprehensive, but nevertheless interesting in their unique approach. Meerdink and Van't Riet (1995) described the component segregation during drying of small sucrose/sodium caseinate solution slabs. The model contained Maxwell–Stefan partial differential equations with concentration-dependent diffusion coefficients. Since measuring and approximation tools for Maxwell–Stefan multicomponent diffusion coefficients in concentrated aqueous solutions are lacking, the parameters of the diffusivity equations had to be fitted so that the simulated concentration profiles agreed with the experimental results. In the modeling work by Porowska et al. (2015) on drying whey protein/sucrose droplets, the phenomena taking place during crust formation were largely disregarded. The focus was laid on the surface activity of the whey protein, and it was supposed that the adsorption process would halt upon commencing shell formation. The protein surface activity was described with the aid of experimental determination of the dynamic surface tension as a function of protein bulk content and time. Also noteworthy, despite not being a spatially resolved model, Chen and coworkers presented an analytical continuum approach to simulate the solid formation in the outermost layer of a drying water droplet with dissolved lactose, fat and milk protein (Chen et al., 2011, 2013; Xiao and Chen, 2014). Under the assumption that the concentration only changes in a thin surface region, an explicit equation for the surface composition was obtained. Protein surface activity was not covered by this model. The Stokes–Einstein equation was introduced in an extended form to account for the concentration dependency of the effective component diffusivities.

Putranto et al. (2017) utilized the same modified Stokes–Einstein equation for a model on drying low-fat milk droplets. It accounted for the protein's surface activity as a boundary condition. Spatiotemporal balances for energy, momentum and mass of water, lactose, protein, and fat formed a set of partial differential equations that was solved with the method of lines. A realistic description of the influence of solidification on the water diffusivity, evaporation rate, and particle shrinkage was aspired by incorporation of semiempirical drying and shrinkage kinetics, which were obtained from suspended single droplet drying experiments and expressed via the reaction engineering approach. As such, the model required some experimental work to obviate the need for a perfect shrinkage assumption and for approximations of the effective water diffusivity. A new single droplet drying technique was employed for result validation, which allowed tracking of the changes in chemical surface composition over time. The experimentally and theoretically obtained surface concentrations agreed reasonably well, but better agreement might have been impeded as solute precipitation and the influence of the fat's hydrophobic nature on the component distribution had not been implemented. From the experimental study also the initial surface composition of the droplets was known, which was used as initial condition for the component mass balances of the simulation. The study highlighted the influence of the atomization stage on the component distribution in drying milk droplets. Accordingly, it was concluded that the use of experimentally observed initial surface compositions after droplet generation are critical for an accurate simulation of the component distribution in spray-dried milk particles.

## Concluding Remarks

The surface composition of milk powder imposes a critical influence on its functional properties. It is widely accepted that a strong overrepresentation of fat, in comparison with the bulk composition, emerges on the surface during spray drying at both industrial- and laboratory scale with detrimental impact on the powder quality. However, the surface formation process is far from being thoroughly understood. Four different processes might potentially affect the component segregation in drying milk droplets; the components' diffusivities, the components' interaction with the air/water interface (protein's surface activity and the lipid phase's hydrophobicity), the crust formation/precipitation process, and the atomization process. As the degree of influence of each of these mechanisms is still under debate, further experimental work is required to test and validate the different concepts. While the subordinate enrichment of protein is most often perceived to take place during drying due to its lower diffusivity than lactose and primarily due to its surface activity, the atomization stage seems to have a critical impact on the formation of surface fat. Some promising modeling approaches have been published in recent times that are, in principle, capable of simulating the component distribution of drying milk droplets. These should be further developed to account for all of the four potential segregation mechanisms for a better understanding of the surface formation and a more accurate prediction of the powder properties.

## Glossary

**Oxidative stress** Describes an imbalance between the pro-oxidant action of reactive oxygen species (ROS) and a biological system's ability (endogenous antioxidant defenses) to readily detoxify the reactive intermediates or to repair the resulting damage in molecules of biological significance (lipids, proteins, DNA, etc.).

**Antioxidants** Are molecules that inhibit the oxidation of other molecules. They may neutralize free radicals or ROS by accepting or donating electron(s), or hindering the formation of ROS by, for instance, acting at low concentrations as radical scavenger, hydrogen donor, electron donor, metal chelator and peroxide decomposer, with the resulting oxidized molecule not able to propagate the chain reaction to other biomolecules (thus terminating the chain reactions).

## Nomenclature

3-NT 3-nitrotyrosine  
4-HNE 4-hydroxy-nonenal  
APOPs advanced protein oxidation products DNA: deoxyribonucleic acid  
CAT catalase  
DLHMB DL-2-hydroxy-(4-methylthio) butanoic acid  
GPx glutathione peroxidase  
GR glutathione reductase  
GSH glutathione  
GSSG oxidized glutathione  
HMSeBA 2-hydroxy-4-methylselenobutanoic acid  
MDA malondialdehyde  
Met methionine  
NO nitric oxide  
NO<sub>2</sub><sup>-</sup> nitrite  
OH• hydroxyl radical  
PUFA polyunsaturated fatty acids  
RNS reactive nitrogen species  
ROS reactive oxygen species  
Se selenium  
SeCys selenocysteine  
SOD superoxide dismutase  
SeMet selenomethionine  
T-AOC total antioxidant capacity

## Introduction: Oxidation as a Threat to Meat Quality and Safety

The application of antioxidants in the meat industry is a common practice. Yet, the consequences of muscle lipid and protein oxidation are traceable throughout the food chain, from farm to fork (Estévez, 2015). Hence, a better understanding of the mechanisms implicated in redox reactions is required in order to put forward efficient and safe antioxidant solutions.

Redox reactions are fundamental in all biological systems as assorted functions and biochemical processes (i.e. the energetic metabolism) depend on the oxidative degradation of fuel molecules, although as a result, the formation of reactive oxygen substances (ROS) is unavoidable (Kohen and Nyska, 2002). Under physiological conditions, the balance between pro-oxidants and the endogenous antioxidant defences guarantees the homeostasis and molecules with relevant biological functions are protected against ROS. However, a disproportionate imbalance towards pro-oxidants leads to uncontrolled oxidative damage to cellular components, known as oxidative stress (Kohen and Nyska, 2002). The impact of ROS is now recognized to be as harmful

as that exerted by reactive nitrogen species (RNS) (which interact cooperatively to cause oxidation including nitrosation in muscle lipids and proteins). While oxidative stress occurs in live animals under diverse circumstances (subject to pathological or heat stress, intake of oxidized feed, etc.), a pro-oxidative environment takes place in *post-mortem* muscles with oxidative reactions being considerably enhanced upon animal slaughter owing to the collapse of the endogenous antioxidant defences (Bekhit et al., 2013). Provided with insufficient antioxidant resources such as reducing compounds (tocopherols, sulphur compounds, etc.) and antioxidant enzymes (catalase, glutathione reductase, etc.), meat lipid and proteins would then confront oxidative threats during handling, processing, storage and culinary preparation, prior to consumption (Estévez, 2015). Oxidative and nitrosative reactions are known to take place during the three digestion phases (gastric, intestinal and colonic), with the nature and intensity of these reactions depending on external (diet composition and food combination) and internal (microflora, physiological responses, etc.) factors (Van-Hecke et al., 2017).

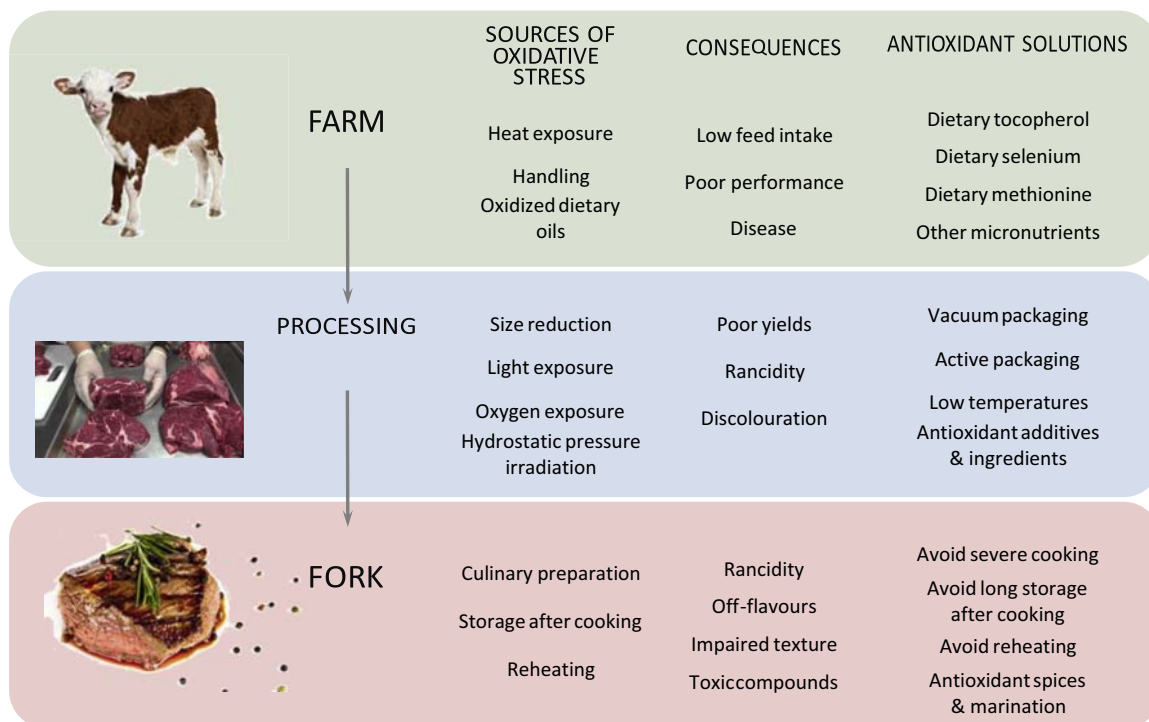

The adverse effects of meat oxidation vary with factors such as the process between farm and fork, the target (whether lipids and/or proteins are oxidized), and the severity the damage to meat components (Soladoye et al., 2015). If oxidative stress is manifested in live animals, compromised animal welfare, low production rates and poor meat quality would be possible. For meat products, oxidation-induced impairments of their sensory properties include (i) the onset of unpleasant flavours and odours (e.g. rancid, fishy), (ii) increase of hardness due to protein oxidation, and (iii) discolouration caused by co-oxidation of pigments (Bekhit et al., 2013; Soladoye et al., 2015). Oxidation of muscle proteins may also affect their functionalities causing reduced water-holding ability, fat emulsification and formation of gels (Utrera and Estévez, 2012). As a result, the nutritional value of meat is negatively impacted owing to losses of antioxidant vitamins, essential fatty acids (especially polyunsaturated fatty acids) and essential amino acids (i.e. lysine, tryptophan, etc.). Moreover, the repeated intake of oxidized lipid and protein products poses a threat to consumer's health (Estévez and Luna, 2017). Harmful species such as malondialdehyde (MDA), 4-hydroxy-nonenal (4-HNE), protein carbonyls and carboxylic acids, advanced protein oxidation products (AOPs) and dityrosines, may be formed during processing, or subsequently produced during digestion and exposure to the intestinal and luminal oxidative stress, inflammation and various other pathological conditions (Estévez and Luna, 2017; Estévez et al., 2017). Specific tryptophan and tyrosine oxidation products (kynurenines and dityrosines, respectively) have recently been identified as red or white meat discriminating metabolites in colonic digests (Rombouts et al., 2017). Recent scientific evidences support the implication of lipid oxidation products and N-nitroso-compounds in the formation of DNA adducts upon the consumption of processed red meat (Hemeryck and Vanhaecke, 2016). Besides their local impacts in the gut, certain low-molecular weight oxidation products may be absorbed and distributed through the bloodstream to impair the biological functions of specific organs such as the liver, kidney, pancreas and brain, as indicated by some animal studies (Estévez et al., 2017).

### Animal Handling and Feed Manipulation

The oxidative stress suffered by animals is a significant cause of the onset/development of assorted pathological conditions that eventually affect animal welfare and production rates (Fellenberg and Speisky, 2006). Likewise, many infections, physiological and metabolic disorders cause impaired redox status and then oxidative stress (Lykkesfeldt and Svendsen, 2007). Lykkesfeldt and Svendsen (2007) indicated that, at least, theoretically, oxidative stress can easily be prevented through the use of antioxidants although such a therapy remains controversial. From a technological perspective, the impact of oxidative stress on meat quality (Estévez, 2015) implies the necessity of applying antioxidant solutions at the farm to support the improvement of production rates and animal welfare, especially the animals such as pigs and domestic birds that are frequently exposed to oxidized feeds and heat (Zhang et al., 2011).

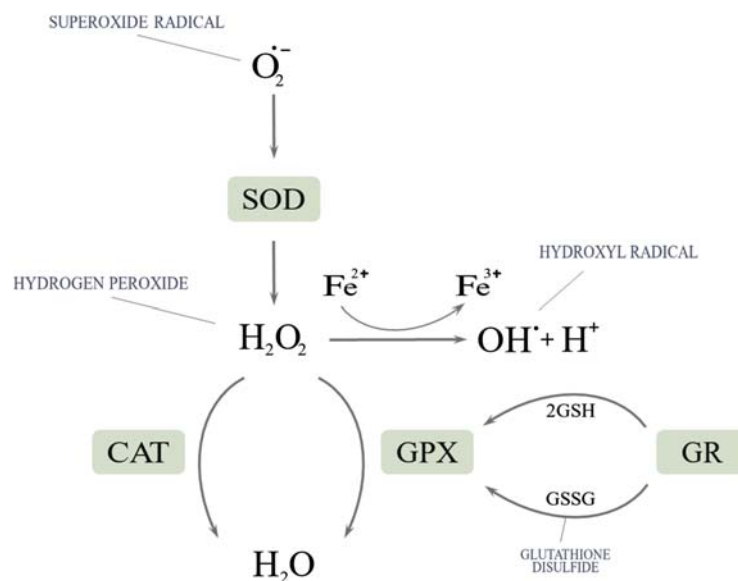

Further, the antioxidant status of livestock can be optimized by diet, and through which the oxidative stability and quality of corresponding animal meat would be improved. In practice, an efficient antioxidant strategy can be built on two essential pillars: i) monitor fatty acid composition, avoid high PUFA rates and oxidized feeds, and ii) supplement with  $\alpha$ -tocopherol, organic selenium, sulphur amino acids and arguably, ascorbate, phytochemicals and other microelements (zinc, copper, magnesium, etc.). Interestingly, dietary antioxidants have been found to alleviate negative influence of external oxidative stress on pigs and broilers (e.g. those heat-induced) (Ismail et al., 2013). The supplementation with  $\alpha$ -tocopherol (100–200 mg tocopherol/kg feed), a key component of endogenous antioxidant defences of skeletal muscle and a main contributor to the oxidative stability of biological membranes, is a common practice to improve chicken, pork and beef quality (Chan and Decker, 1996; Sales and Koukolová, 2014). The positive effects of  $\alpha$ -tocopherol supplementation have been profusely documented, including the promotion of higher oxidative stability in fresh meat during storage (Buckley et al., 1995), protection against discoloration (Sales and Koukolová, 2014), and reduction of the oxidation of PUFAs, cholesterol and proteins in processed meat products (Gobert et al., 2010; Botoglou et al., 2012). It is worth mentioning that low levels of oxidation are usually associated with reduced rancidity, improved sensory properties and consumer acceptability (Sohaib et al., 2016; Albertí et al., 2017). These positive effects have been achieved through the supplementation with  $\alpha$ -tocopherol acetate or via feeding animals with natural materials naturally rich in tocopherols such as pasture (Descalzo and Sancho, 2008), acorns (Ventanas et al., 2007), chestnuts (Pugliese et al., 2009) and olive leaf (Botoglou et al., 2012) (Fig. 1).

Dietary selenium (Se) supplementation has also been found to increase the oxidative stability of meat plausibly by promoting the concentration of glutathione peroxidase (GPx) in muscle. GPx is known to work cooperatively with catalase (CAT), glutathione reductase (GR), superoxide dismutase (SOD) and glutathione (GSH) to neutralize radical and non-radical pro-oxidant species in

**Figure 1** Sources and consequences of oxidative stress as well as potential antioxidant solutions at three key stages of the meat production and supply chain.

meat systems (Fig. 2). Se may be supplemented as inorganic Se (mainly as selenite or selenate) or organic Se (in the form of selenomethionine, SeMet). The latter may be used in the form of Se-yeast or SeMet preparations (Surai and Finislin, 2016). SeMet, a naturally occurring amino acid, is widely recognized to be more efficient than inorganic Se in terms of prompting bioavailability and antioxidant protection (Surai and Finislin, 2016). SeMet is converted, via *in vivo* transsulfuration, to selenocysteine (SeCys), and then to selenide that is critical for the synthesis of selenoproteins such as GPx. A hydroxyl analog of SeMet, 2-hydroxy-4-methylselenobutanoic acid (HMSeBA) has been recently proposed to be a highly efficient and bioavailable form of SeMet (Jlali et al., 2014). The benefits of supplementation of organic Se to the quality of poultry meat and chicken products are well documented (as reviewed by recently Estévez, 2015), although the effects of such a supplementation on mammals remain unclear.

**Figure 2** Cooperation of glutathione peroxidase (GPx) with catalase (CAT), glutathione reductase (GR), superoxide dismutase (SOD) and glutathione (GSH) to neutralize radical and non-radical pro-oxidant species in meat systems.

Recent studies on pork yielded contradictory results: some revealed certain positive effects of Se supplementation on oxidative stability, color and water holding capacity (Li et al., 2011; Calvo et al., 2016; Batorska et al., 2017), whilst others did not find any beneficial effect (Lisiak et al., 2014) or even reported some adverse effects at doses of 0.5 mg inorganic selenium/kg feed (Schwarz et al., 2017). Scarce studies on beef quality agree on the protective effect of Se supplementation on myoglobin oxidation and beef color stability (O'Grady et al., 2001). Give the location of selenoproteins such as GPx in the cytoplasm, the effective protection of selenoproteins on myoglobin and other sarcoplasmatic and myofibrillar proteins against ROS seems a more plausible hypothesis than that related to other endogenous antioxidant defences such as tocopherols. In addition to the supplementation with SeMet, adjusting the concentrations of sulphur amino acids in livestock feeds using DL-Met or its hydroxyl equivalent (DL-2-hydroxy-(4-methylthio) butanoic acid, DLHMB) is also recommended as an alternative effective approach for antioxidant protection. Supplementing DL-Met above recommendations by the National Research Council (NRC) (>0.38%) would lead to high antioxidant protection of broiler and pig muscles thus improving meat quality traits such as color and cooking losses (Castellano et al., 2015; Zhai et al., 2016).

Phytochemicals are used in animal nutrition, which aligns with in the global trend against antibiotic growth promoters and towards natural products for animal welfare and production. Phytochemicals refer to assorted materials from the plant kingdom (e.g. spices, herbs, fruits, nuts, fresh leaves, essential oils, plant extracts, etc.). They are natural sources of phytochemicals (phenolic acids, polyphenols, terpenes, vitamins, etc.) and have displayed abilities to improve the growth rate, nutrient digestibility and gut health of livestock. Providing farm animals with this '5-vegg-a-day' Mediterranean-like diet is proven to display immunomodulation and antimicrobial activities, technological benefits at the farm (gas production), and even impact sensory properties on animal products (e.g. astaxanthin on meat color) (Estévez, 2015). Hong et al. (2012) reported that feeding 125 ppm of oregano essential oil, anise and citrus peel powder leads to more tender breast muscles and juicier thigh muscles compared to the control group. Supuka et al. (2015) used the agrimony extract (*Agrimonia eupatoria* L., 0.2%) and its combination with a sage extract (*A. eupatoria* L. + *Salvia officinalis* L., 0.1% + 0.1%) for water supplementation during the fattening period of broiler chickens, to lower ( $P < 0.05$ ) SOD activity in blood and the amount of thiobarbituric acid reactive substances in thigh meat during 8-day chilling storage. Cherian et al. (2013) significantly enhanced muscle lipid stability in broilers fed with 2% and 4% sweet wormwood (*Artemisia annua* L.). Sun et al. (2014) found that lycopene supplementation (20, 40, and 80 mg/kg) significantly increased fertilization rates in hens with increased SOD, total antioxidant capacity, and reduced glutathione to oxidized glutathione ratio GSH/GSSG in serum and liver and significantly decreased total cholesterol and increased high density lipoprotein cholesterol and triiodothyroxine.

### Food Formulation: Classic Antioxidant Additives

After slaughter and upon the resolution of the *rigor mortis*, the biochemical environment in *post-mortem* meat is genuinely full of pro-oxidants owing to the collapse of physiologically controlled cell functions causing formation of ROS, release of hydrolases, and occurrence of myoglobin, non-heme iron and other promoters of oxidative reactions (Estévez, 2011). The reactions between such reactive and susceptible species (e.g. PUFA, cholesterol, certain amino acid residues in sarcoplasmatic/myofibrillar proteins and vitamins), are facilitated during the operations intended to transform raw meat into processed muscle foods (Soladoye et al., 2015). Undesirable factors like light exposure, oxygen exposure, irradiation, size reduction and heat treatment would expedite the oxidation of muscle lipids and proteins. In this scenario, only limited amounts of endogenous antioxidant defenses are available in the meat system to counteract the oxidative threat, namely, membrane tocopherols, enzymes (like SOD, CAT and GPx), thiol-based antioxidant molecules (glutathione, taurine, isotaurine, etc.) and other water-soluble molecules with antioxidant properties such as ascorbate, carotenoids, etc. Therefore, the use of antioxidant additives during meat processing becomes a common practice to improve antioxidant protection.

Non-meat ingredients and additives such as nitrite, ascorbate, phosphates, non-muscle proteins and peptides, and assorted seasonings have been profusely reviewed (Honikel, 2008; Weiss et al., 2010; Varvara et al., 2016; Xiong, 2017). It is worth mentioning that some of the chemical additives typically used in the formulation of meat products are redox-active compounds, thus, their involvement in oxidative reactions is possible. The antioxidant action of nitrite may be based on a number of mechanisms including its combination with molecular oxygen and metal chelation (Honikel, 2008). However, nitrite ( $\text{NO}_2^-$ ), displays pro-oxidant actions owing to its ability to abstract an electron from a sensitive molecule and hence, initiate oxidative reactions [Reaction 1].

Ascorbate (A) is known as an efficient scavenger of radical species (Buettner and Jurkiewicz, 1996), and also exhibits pro-oxidant properties by reducing transition metals such as iron and perpetuating the formation of hydroxyl radicals ( $\text{OH}^\bullet$ ) through the Fenton reaction [Reaction 2].

Nevertheless, the combination of nitrite and ascorbate additives usually leads to an overall positive outcome as the formation of reaction products such as nitric oxide (NO) [Reaction 3] and eventually lipid radicals (LOO•) scavenging, through which lipid oxidation is inhibited [Reaction 4].

Although the abilities of nitrite and ascorbate to control lipid oxidation are previously recognized, recent studies have re-examined their effects on protein oxidation during meat processing. Villaverde et al. (2014a) reported that nitrite alone had a negligible effect on protein oxidation but induced the formation of a specific marker of nitrosative stress, namely 3-nitrotyrosine (3-NT), and that ascorbate was efficient in inhibiting the formation of 3NT via a dose-dependent anti-nitrosative effect to enable the antioxidant action of nitrite. The same authors found pro-oxidant actions of nitrite on meat proteins during sausage fermentation and abilities of ascorbate to counteract the oxidative and nitrosative damage of nitroso compounds on meat proteins (Villaverde et al., 2014b). Berardo et al. (2016) reached a similar conclusion after studying the effect of nitrite and ascorbate on dry-fermented sausages. Further, the antioxidant effects of phosphates have been reported, which were linked to their chelating abilities, inhibition of pro-oxidant action of transition metals, and controlling lipid oxidation and warmed-over flavours (Cheng and Ockerman, 2007).

### Food Formulation: Novel Antioxidant Alternatives

Currently, there are increasing consumer interest in the so-called 'natural' ingredients, especially plant materials, their extracts, essential oils or phytochemicals as natural antioxidant alternatives to conventional additives in meat products (Kumar et al., 2015; Fernandes et al., 2016). Ben Slima et al. (2017) recently proposed the partial replacement of nitrite curing agent (i.e. down to 50 mg/kg) with probiotic *Lactobacillus plantarum* TN8 in beef sausages, leading to decreased pathogenic bacteria counts, low oxidation rates and human health hazards. Vossen et al. (2012) used dog rose as a functional ingredient in frankfurters (without adding ascorbate and nitrite), and found a positive antioxidant effect on lipids and proteins. Fermented rooibos (*Aspalathus linearis*) could retard lipid oxidation in nitrite-free ostrich salami Cullere et al. (2013). A 2% grape pomace improved the oxidative and color stability of nitrite-reduced cooked beef sausages (Riazi et al., 2016), and acid whey and mustard seed suppressed lipid oxidation of nitrite-free organic fermented sausages (Karwowska et al., 2015). It is worth noting that some of the currently used approaches are not reducing the overall concentration of nitrate/nitrite in the product but replacing nitrate/nitrite with certain vegetable sources naturally containing nitrate/nitrite (Ko et al., 2017). Caution must be taken in using certain plant phenolics alone or in combination with nitrite/ascorbate, as unexpected pro-oxidant effect may appear. Lin et al. (2017) observed an acceleration of lipolysis and lipid oxidation in pepperoni sausages treated with green tea extract (0.05%) and sodium nitrite (0.009%).

Additional antioxidant protection is increasingly demanded for ready-to-eat muscle foods. Extensive technological processing applied to these products e.g. pre-heating and cold storage-reheating would considerably promote oxidative reactions, leading to final products with elevated amounts of potentially harmful compounds (MDA, protein carbonyls, oxidized cholesterol, etc.) and impaired sensory properties (Utrera et al., 2012; Feng and Ahn, 2016; Akcan et al., 2017a; Ferreira et al., 2017). In these products, addition of antioxidant additives/ingredients of natural origin (plant materials, spices, essential oils, fruits, etc.) is preferred with/without the need of additional packaging strategy for oxygen exclusion. However, Ferreira et al. (2017) observed that 200 mg/kg gallic acid equivalents of acorn (*Quercus ilex* L.) extract was effective in inhibiting basal lipid and protein oxidation in ready-to-eat chicken patties independently of the packaging system (normal vs. reduced oxygen level). Hawberry (*Crataegus monogyna* Jacq.) extracts (200 and 800 gallic acid equivalents) were also found efficient against lipid oxidation in ready-to-eat pork patties (Akcan et al., 2017b). Moreover, non-muscle proteins and hydrolysates have been introduced to provide antioxidant protection as well as additional technological, sensory and nutritional benefits to processed meat products (Lafarga and Hayes, 2017; Sohaib et al., 2017). Plasma and dairy protein hydrolysates have been found efficient in enhancing the oxidative stability and other quality properties of processed meat products (Seo et al., 2016; Kumar et al., 2016). Bacteriocin BacTN635 exhibited protective effects against lipid and protein oxidation in refrigerated turkey sausages (Smaoui et al., 2017).

It is worthy to stress the scientific and technological interest in using muscle foods as vehicles to deliver dietary antioxidant compounds to humans. Antioxidants can be used from farm (the livestock) to the fork (final consumer) including the intermediate stages of food processing and storage. Such an antioxidant approach may not be limited to antioxidant properties but other health benefits associated with these bioactive compounds such as antimicrobial (phytochemicals), antihypertensive (peptides), odorants (terpenes from essential oils), anti-inflammatory, etc. However, the effectiveness of plant-derived antioxidants as well as their safety (despite the fact of having a 'natural' origin) need to be thoroughly examined before being used in meat processing plants. Although the antioxidant benefits of the assorted plant materials and derived antioxidants are reported in the scientific literature (reviewed by Karre et al., 2013; Falowo et al., 2014; Shah et al., 2014), the adverse (pro-oxidant) effects of phytochemicals on foods and human health have also been documented (Halliwell, 1994; Cando et al., 2014; Van-Hecke et al., 2016).

The dose and means of delivery seem critical for ensuring the effectiveness and safety of plant-derived antioxidants. These antioxidants comprise phenolic acids (hydroxybenzoic and hydroxycinnamic), phenolic diterpenes (i.e. rosmanol, carnosol, carnosic acid), flavonoids (flavones, flavonols, flavanols and flavanones), condensed tannins (i.e. proanthocyanidins) and volatile terpenes (i.e. thymol, carvacrol) (Brewer, 2011). They are sourced from plumb, grapeseed, cranberry, pomegranate, bearberry, pine bark, oregano and rosemary (Karre et al., 2013; Riaz et al., 2016; Ghaderi-Ghahfarokhi et al., 2016; Fernandes et al., 2017). Table 1 summarises some recent and significant applications of antioxidants including those from plant kingdom in processed meat products. Both antioxidant and pro-oxidant actions have been reported (Utrera and Estévez, 2013; Cao et al., 2016). It is worth noting that certain compounds are able to prevent lipid oxidation but may not be effective in inhibiting protein oxidation (Estévez, 2011). The impact of plant phenolics on the oxidative stability of meat proteins is determined by the interactions between the active moieties of phytochemicals (hydroxyl or quinone groups) and the amino acid residues. These interactions are dependent on the amount and chemical state of the phenolic compound as well as the size, conformity, overall charge and oxidative status of the protein (Estévez, 2011).

### Innovative Means of Antioxidant incorporation in Processed Meat Products

While direct addition of antioxidant preparations in the form of a powder or extract to comminuted meat products is simple and feasible (Fernandes et al., 2018), marination, spraying and injection with antioxidants have also been tested for whole meat products (Rimini et al., 2014). Bioactive compounds and antioxidant additives have been incorporated in microcapsules (Sickler et al., 2013), edible films (Akcan et al., 2017a), polyethylene terephthalate (PET) trays (Contini et al., 2014) and chitosan nanoparticles (Hu et al., 2015). Regarding marination, Rimini et al. (2014) evaluated the effects of a mixture of thyme and orange oils (EO) on the quality characteristics and oxidative stability of chicken meat (breast and wing). These authors noticed that both fresh and frozen EO breasts and EO wings were less susceptible to lipid oxidation compared to the control breasts and wings. Incorporation of cinnamon oil into chitosan nanoparticles that are included in low density polyethylene films could retard lipid oxidation in pork meat, indicating the synergistic antioxidant effects of cinnamon oil and chitosan (Hu et al., 2015). Regarding the antioxidant-releasing packaging materials, one of the main benefits, as compared to the direct addition of antioxidants to meat products, is that active materials may act as a source of antioxidants to be released to the meat products at controlled rates during storage (Mastromatteo et al., 2010). The antioxidant films containing 3% eugenol improved the efficacy of vacuum packaging and stabilized raw beef patties against oxidation (Park et al., 2012). Contini et al. (2014) also showed that antioxidant active packaging with citrus extract was effective in reducing the lipid oxidation of cooked turkey meat during storage along with maintaining its sensory characteristics (particularly tenderness) and overall acceptability. Akcan et al. (2017a) reported that the lipid oxidation in cooked meatballs during frozen storage at  $-18^{\circ}\text{C}$  for 60 days was effectively retarded by the incorporation of whey protein isolate-based edible films containing natural antioxidant extracts from laurel (*Laurus nobilis* L.) or sage (*S. officinalis*) into the edible films. Baldin et al. (2016) assessed the addition of microencapsulated jabuticaba extract (as the natural antioxidant source) to fresh sausage and noticed that the extract at 2% and 4% led to reduced lipid oxidation of fresh pork sausages during 15 days of storage.

**Table 1** Recent and significant applications of alternative antioxidant sources including those from plant kingdom in processed meat products

Antioxidant source	Dose	Application method	Meat system	References
Rosemary extract	150 ppm carnosol/kg fat	Direct addition	Frozen chicken nuggets	Rocío Teruel et al. (2015)
Lactic acid bacteria isolate	$10^7$ cfu/kg	Inoculation	Experimental sausage	Chen et al. (2015)
Thyme	2%	Edible films	Cooked cured ham	Ruiz-Navajas et al. (2015)
Mustard seed	1%	Direct addition	Nitrite-free fermented sausage	Karwowska et al. (2015)
<i>Myrciaria cauliflora</i>	2%–4%	Microencapsulation	Pork sausage	Baldin et al. (2016)
Thyme essential oil	0.1%	Nanoencapsulation	Beef burgers	Ghaderi-Ghahfarokhi et al. (2016)
Grape pomace	2%	Direct addition	Nitrite-reduced meat emulsions	Riaz et al. (2016)
Blackcurrant extract	1%	Direct addition	Vacuum packed sausages	Nowak et al. (2016)
<i>Rosa canina</i> L.	500 mg GAE/100 g	Brine injection	Boiled ham	Armenteros et al. (2016)
Camel milk casein hydrolysate	0.03%–0.09%	Direct addition	Goat meat emulsion	Kumar et al. (2016)
Chestnut leaves extract	2000 ppm	Microencapsulation	Dry-cured sausage	Munekata et al. (2017)
<i>Laurus nobilis</i> & <i>Salvia officinalis</i>	2%–4%	Edible films	Cooked meatballs	Akcan et al. (2017a)
Hawberry	200–800 ppm GAE	Direct addition	Ready-to-eat patties	Akcan et al. (2017b)
Cinnamon essential oil	0.1%	Nanoencapsulation	Beef burgers	Ghaderi-Ghahfarokhi et al. (2017)
<i>Lactobacillus plantarum</i> TN8	7 log CFU/g	Inoculation	Nitrite-reduced beef sausages	Ben Slima et al. (2017)
Acorn extract	200 ppm GAE	Direct addition	Ready-to-eat patties	Ferreira et al. (2017)
Bacteriocin BacTN635	500–1000 AU/g	Direct addition	Refrigerated turkey meat sausage	Smaoui et al. (2017)
Borage extract	0.5%–10%	Sprayed	Lamb leg chops	Bellés et al. (2017)
Lotus rhizome powder	1%–3%	Direct addition	Cooked pork sausages	Ham et al. (2017)
Tea	1%–3%	Biocomposite film	Minced beef meat	Ashrafi et al., (2016)
<i>Origanum vulgare</i>	5–8 mg/kg	Direct addition	Sheep sausage	Fernandes et al. (2018)

Ghanderi-Ghanhfarokhi et al. (2017) also observed that encapsulated cinnamon essential oil effectively retarded lipid oxidation and improved the consumer acceptability of beef patties.

## Conclusions

Antioxidant solutions are commonly applied to control lipid and protein oxidation at every stage from farm to fork. While some antioxidant strategies are well-established such as the use of dietary tocopherols and formulation with antioxidant additives, novel solutions to the oxidation of proteins and lipids in processed meat are requested by consumers who demand safer and effective strategies. Accordingly, more integrative antioxidant solutions should aim to protect the livestock, the muscle food and the consumer, to minimize the negative consequences on human health of intake of oxidation products. The combination of phytochemical antioxidants with novel packaging strategies would guarantee the quality and safety of processed meat products.

## Introduction

Seafood is recognized as a healthy component of human diet due to its high eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) contents (Wang et al., 2006). A number of health benefits have been associated with EPA/DHA intake and fish consumption such as reduced risk of coronary heart disease (CHD), certain cancers, rheumatoid arthritis and depression, as well as improved visual and cognitive development (Ruxton et al., 2004). However, fatty fish is extremely susceptible to oxidation due to the presence of polyunsaturated fatty acids. Lipid oxidation will lead to the development of unpleasant odor, rancid taste and discoloration (Frankel, 2005). Secondary oxidation products resulted from lipid oxidation can further initiate reactions to modify proteins, amino acids and vitamins causing loss of protein functionality and nutritional quality (Soladoye et al., 2015). Synthetic antioxidants such as butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), and *tert*-butyl hydroquinone (TBHQ) have been widely used in the 19th century to reduce/prevent quality loss due to lipid oxidation in seafood (Boyd et al., 1993). But the use of BHA and BHT in foods was later found harmful and have been restricted because of their carcinogenesis potential (Saito et al., 2003). In addition to carcinogenicity, BHA and BHT have been reported to be cytotoxic (Saito et al., 2003) and have adverse effects on the kidney, liver as well as lung tissues (Siman and Eriksson, 1996). Hence, the use of antioxidants from natural sources such as plant phenolics is encouraged.

Plant phenolics are secondary metabolites containing one or more phenolic ring, which are produced by plants as a part of defense response to ultraviolet radiation or aggression by pathogens (Beckman, 2000; Parr and Blowell, 2000). Studies showed that long-term consumption of diets rich in plant polyphenols could allow protection against some cancers, diabetes, cardiovascular diseases, neurodegenerative diseases and osteoporosis (Arts and Hollman, 2005). Plant phenolics include phenolic acids, flavonoids, lignans, stilbenes and tannins (Arts and Hollman, 2005). Plant phenols are good antioxidants, and their modes of antioxidative action depend on the chemical structure of individual phenolic compounds (Bendary et al., 2013). The mechanisms by which phenolic antioxidants retard lipid oxidation include (1) scavenging reactive oxygen species that initiate peroxidation, (2) quenching  $\cdot\text{O}_2^-$  and preventing the formation of peroxides, and (3) preventing the generation of the reactive oxygen molecule and decomposition of lipid peroxides by metal chelation (Fig. 1). Various factors are reported to affect the phenolic composition and also the antioxidant activity of plant extracts such as genotype, climatic conditions, growing environment, processing, post-harvest storage and solvent used for phenolic extraction (Howard et al., 2003; Kevers et al., 2011). Many purified phenolic compounds and plant phenolic extracts have demonstrated their abilities to retard oxidation of lipids and proteins in different kinds of seafood. This chapter reviews in detail plant phenolic extracts and their roles in retarding lipid or protein oxidation in seafood products.

## Lipid and Protein Oxidation in Seafood

Lipids and proteins fractions in fish meat are easily prone to oxidative deterioration due to rapid depletion of endogenous antioxidants after the death of fish especially during post-mortem handling and storage (Jacobsen et al., 2008). The mechanism of lipid oxidation involves three stages: initiation, propagation and termination (Frankel, 1985). During initiation, lipid or alkyl radicals ( $\text{L}\cdot$ ) are formed in the presence of catalysts (such as oxygen, light, heat and metal ions) and irradiation. These radicals then react with oxygen to form peroxy radicals ( $\text{LOO}\cdot$ ), which abstract hydrogen atom from other lipids to form hydroperoxides leading to the generation of a new lipid radical ( $\text{L}\cdot$ ) and the cycle continues. During the termination step, the interaction of alkyl and peroxy radicals leads to the formation of non-radical products such as aldehydes, alkanes and conjugated dienes (Frankel, 1985). The rate and extent of lipid oxidation is influenced by factors such as fatty acid composition, concentrations of pro-oxidants and antioxidant(s), endogenous ferrous iron, enzymes, pH, temperature and oxygen available (Underland, 2001). Iron and oxygen play influencing roles in the lipid oxidation of fish muscle. Iron in fish muscle may occur in associated forms (e.g. heme pigments, non-heme iron complexed to proteins (ferritin) or as low molecular weight metabolites (Richards and Hultin, 2002). Reducing compounds occurring in the seafood tissue such as ascorbate can convert the inactive ferric iron to the active ferrous iron. There are also enzyme systems that use reducing equivalents from NAD(P)H to reduce ferric iron. Iron is also part of the active site of specific enzymes like lipoxygenase (which may participate in lipid oxidation) (Banerjee, 2006). Thus, the iron derived from the above-mentioned sources can activate molecular oxygen and promote lipid oxidation (Richards and Hultin, 2002). Reducing the pH also enhance lipid oxidation in fish muscle, due to increased autooxidation of Hb at a decreased pH and subsequent release of iron (Tsuruga et al., 1998).

**Figure 1** Schematic Diagram of Lipid Oxidation and the Antioxidant Mechanisms of Plant Phenolics (PP).

Protein oxidation is defined as covalent modification of proteins either by reactive oxygen species (ROS) or via the interaction with secondary lipid oxidation products (Shacter, 2000). Oxidation of proteins is believed to proceed via a free radical chain reaction similar to that of lipid oxidation, although more complex pathways and a wider range of oxidation products may be involved in lipid oxidation (Davies and Dean, 2003). Protein oxidation begins with the abstraction of hydrogen atoms from a protein (PH) via ROS to form a protein carbon-centered radical ( $P^{\bullet}$ ). This protein radical, in the presence of oxygen, is converted into an alkylperoxyl radical ( $POO^{\bullet}$ ) and ultimately to an alkylperoxide ( $POOH$ ) by obtaining a hydrogen atom from another susceptible molecule (Fig. 2). Subsequently, alkoxy radical ( $PO^{\bullet}$ ) and its hydroxyl derivative ( $POH$ ) are produced when they react with ROS (such as  $HO_2^{\bullet}$ ) or reduced forms of transition metals ( $Fe^{2+}$  or  $Cu^{+1}$ ). Finally, carbonyl groups and acyl radicals are formed when these alkoxy residues undergo  $\beta$ -scission or fragmentation reaction via cleavage of peptide bonds (Lund et al., 2011). Moreover, protein oxidation also occurs when lipid oxidation products (such as hydroperoxides, aldehydes, reducing sugars and ketone) interact with nitrogen or sulfur centers of reactive amino acid residues of protein (Viljanen, 2005) (Fig. 3). Protein fragmentation can occur as a result of a free radical attack of glutamyl, aspartyl and prolyl side chains (Hawkins and Davies, 2001). Oxidative modifications of proteins and amino acids can lead to the formation of cross-linked protein derivatives, alteration of side chains amino acids and oxidative cleavage of peptide chains, and as a result, cause changes in protein functionalities (e.g. solubility, water holding capacity, viscosity, and emulsification) and muscle quality (Xiong, 2000).

A number of simplified model systems are available for studying the efficacy of antioxidant molecules. The most common model systems used to study the antioxidant activity of plant phenolics or extract against lipid/protein oxidation in seafood products are bulk fish oil, fish oil-in-water emulsions, and fish muscle systems. Bulk fish oils are homogeneous systems in which the affinities of antioxidants towards the air-oil interfaces determine their effectiveness against lipid oxidation with polar antioxidants being especially efficient in this system (Frankel, 1998). Emulsions may involve oil-in-water emulsions or water-in-oil emulsions. The nonpolar antioxidants are more efficient than polar antioxidants in oil-in-water emulsion because they locate more efficiently at the oil-water interface (Cuvelier et al., 2000). The behaviors of phenolic antioxidants in emulsions are influenced by several factors including pH, emulsifier, and the interaction of phenolic antioxidants with emulsifier and iron (Sorensen et al., 2008). Fish muscle or fish mince is a complex system containing lipids, proteins, antioxidants (e.g. endogenous  $\alpha$ -tocopherol and ascorbic acid) and pro-oxidants (heme proteins such as hemoglobin and myoglobin, free and bound iron). The lipid oxidation in fish muscle/mince is complex and various factors such as fatty acid content, concentrations of pro-oxidants and antioxidants, and harvest, post-harvest and processing conditions, all influence the oxidation process (Underland, 2001).

## Plant Extracts in the Prevention of Lipids and Protein Oxidation in Seafood Products

### Extracts From Herbs

Herbs have historically been used in cooking, and can not only enhance flavor but also impart health-promoting properties including antioxidant properties (Harborne and Williams, 2000). They are rich in phenolic compounds.

#### Rosemary Extract

Among the plant antioxidant extracts, rosemary extract is one of the most common extracts used in food industry. The antioxidant effect of rosemary extract is attributed to its diterpene phenolics, carnosic acid, and derived oxidation products carnosol, rosmanol and galdosol (Frankel et al., 1996; Wang et al., 2011). Fish oil supplemented with 0.2 mg/g carnosic acid was better than tocopherol in retarding lipid oxidation in fish oil (Wang et al., 2011). Rosemary extract at different concentrations was reported to prevent lipid oxidation efficiently in mackerel oil (Tsimidou et al., 1995), Menhaden oil (Bhale et al., 2007) and Cod and Pollack liver oil (O'Sullivan et al., 2005). A strong synergistic effect was also reported between  $\alpha$ -tocopherol and rosemary extract in preventing lipid oxidation in sardine oil model system at 30 °C and in frozen Bonito mince. The mechanism underlying this synergistic effect was proposed as the regeneration of  $\alpha$ -tocopherol by the rosemary constituents (Wada and Fang, 1992).

Frankel et al. (1996) found that rosemary extract and its constituent's carnosic acid and carnosol efficiently retarded the lipid oxidation in bulk fish oils, but failed to prevent lipid oxidation when tested in fish oil-in-water emulsions. The reason behind this was proposed as the orientation of hydrophilic carnosic acid and carnosol at the air-oil interface thereby protecting the bulk oil from oxidation. A reduction of protection offered by rosemary extract and its constituents in oil-in-water emulsion might be due to the partitioning of antioxidants into the aqueous phase (Frankel et al., 1996; Erdmann et al., 2015). Synergist effects between fish protein and rosemary extracts in the prevention of lipid oxidation were also reported in fish muscle emulsions, which were likely attributed to the partitioning behavior of antioxidants to the fish muscle and the protective effect of fish proteins in inhibiting carnosic acid oxidation (Medina et al., 2003).

Rosemary extracts have shown excellent antioxidant properties in the refrigerated and frozen storage of rainbow trout and salmon muscle (Akhthar et al., 1998; Tironi et al., 2009), horse mackerel and Mediterranean hake (Vareltzis et al., 1997), Cooked fish fake (Boyed et al., 1993), Sardine mince (Serdarolu and Felekolu, 2005) and coated fried Escollar fish fillets (Sarabi et al., 2017). Though being effective in safeguarding the omega-3 fatty acid and red color of salmon muscle, rosemary extracts could not prevent protein alterations (Tironi et al., 2009). The antioxidant activity of these extracts was greater than  $\alpha$ -tocopherol in modified atmospheric packaging (MAP) and vacuum packed Gilt head bream fillets and Sardines, respectively (Giménez et al., 2004; Ozogul et al., 2010). After marinated with rosemary extracts, deep water pink shrimp had a longer shelf life under chilled storage (extended to >75 days) (Cadun et al., 2008). Pressure-induced seafood gels are more prone to oxidation. Rosemary extract was found to

**Figure 3** Mechanisms Involved in the Formation of Protein Carbonyls (A) Metal Catalyzed Oxidation of Basic Amino Acid Side Chains. (B) Peptide Backbone Cleavage or Peptide Scission. (C) Binding to Lipid Peroxidation Products Such as 4-Hydroxy-2-Nonenal (HNE) (D) Reaction with Reducing Sugars. (E) Binding to Lipid Peroxidation Products Such as Malondialdehyde. Adopted from Xiong, Y.L., 2000. Protein oxidation and implications for muscle food quality. In: Decker, E., Faustman, C., Lopez-Bote, C.J. (eds), *Antioxidants in Muscle Foods: Nutritional Strategies to Improve Quality*. John Wiley and Sons, New York, pp. 85–111.

prevent the high pressure/thermal induced lipid oxidation in gels made from the flesh of mackerel with fortified rosemary extract and omega-3 unsaturated fatty acids (Pérez-Mateos et al., 2002). Active packaging materials incorporated with rosemary extracts were found highly efficient in retarding lipid oxidation of smoked rainbow trout (Emir Çoban and Pelin-Can, 2013). The overall mechanisms related to the antioxidant activity of rosemary phenolics may be metal chelation and ability to donate hydrogen to free radicals by the  $-OH$  groups in the aromatic rings (Brewer, 2011).

### Extracts of Oregano and Other Herbs

Culinary herbs such as oregano, thyme and parsley impart antioxidant activities in seafood products. The primary antioxidant constituents of these herbs are carvacrol and thymol (Milos et al., 2000). Tsimidou et al. (1995) compared the antioxidant activity of oregano with red chilies, bay leaf and rosemary extracts in mackerel oil stored at 40 °C in the dark. They found that Oregano at 0.5% was as effective as BHA or 0.5% rosemary extract in retarding lipid oxidation in mackerel oil. Similarly, Jimenez-Alvarez et al. (2008) evaluated the antioxidant effect of oregano, parsley, and olive mill wastewaters on bulk oils and oil-in-water emulsions enriched with 5% tuna oil. The olive mill wastewater was found highly effective in retarding lipid oxidation in both bulk fish oil and an oil-in-water emulsion. Hydroxytyrosol and caffeic acid are the main antioxidant phenolics present in olive mill wastewater and parsley respectively (Shan et al., 2005; Visioli et al., 1999).

In the chilled storage of anchovy and Chilean jack mackerel, incorporation of aqueous extracts of oregano, thyme, and rosemary leaves into ice showed a significant decrease in lipid oxidation (Quitral et al., 2009; Bensid et al., 2014). Oregano and thyme oil added to a coating medium exhibited a protective effect against lipid oxidation in ready-to-eat squid rings (Sanjuas-Rey et al., 2012). Oregano essential oil added at 0.8% to salted Sea bream fillets functioned synergistically with MAP to counteract the increased thiobarbituric acid reactive substances (TBARS) (Goulas and Kontominas, 2007). A combination of oxygen absorber

and oregano essential at 0.4% could reduce lipid oxidation significantly in rainbow trout fillets stored at 4 °C (Mexis et al., 2009). Similarly, 0.1% thyme essential oil and dried thyme showed a synergistic effect with MAP on swordfish fillets (Kykkidou et al., 2009) and vacuum packed Tuna flesh, respectively, in terms of protecting lipids against oxidation (Selmi and Sadok, 2008). The main antioxidant constituents in thyme are thymol and carvacrol. The ethyl acetate extracts of *Majorana syriaca*, which is commonly used as a flavoring agent in the Middle East, were able to prevent, in a dose-dependent manner, both the lipid oxidation and microbial growth in the chilled storage of yellowfin tuna mince (Al-Bandak et al., 2009). Thymol and carvacrol were reported to be the constituents responsible for the observed antioxidant activity (Al-Bandak and Oreopoulou, 2007).

It is worth mentioning the incorporation of plant phenolic extracts to seafood-derived edible/biodegradable packaging films was found to be effective in reducing lipid oxidation. Fish skin gelatin films incorporated with the essential oil from basil had a higher antioxidant activity than plai and lemon (Tongnuanchan et al., 2014). Ahamad et al. (2012) also reported that wrapping of Seabass slices with gelatin film incorporated with 25% (w/w) lemongrass essential oil (LEO) significantly enhanced the prevention from lipid oxidation.

## Spice Extracts

### Clove and Cinnamon Extracts

Aroma extracts from dried clove buds were as effective as  $\alpha$ -tocopherol in the prevention of cod liver oil oxidation (Lee and Shibamoto, 2001). Though preventing lipid oxidation of silver carp fillets under chilled storage, clove bud extracts were less pronounced in controlling protein oxidation (Shi et al., 2014). The greatest protection against lipid oxidation in gutted and beheaded anchovy was achieved when they were stored in ice containing clove (0.02% w/v) (Bensid et al., 2014). Similarly, gelatin and chitosan-based edible coatings incorporated with cinnamon essential oil at 2% protected trout fillets efficiently against lipid oxidation during refrigerated storage (Andevani and Rezaei, 2011; Ojagh et al., 2010). Cinnamaldehyde and eugenol are the primary compounds in cinnamon responsible for this bioactivity.

### Ginger and Garlic Extracts

Application of fresh ginger paste or garlic extract before hot smoking was found to inhibit substantially lipid oxidation and extend the shelf life of catfish (*Clarias gariepinus*) (Kumolu-Johnson and Ndimele, 2011) and sardines (Guiñares et al., 2013). Similarly, a dried or fresh form of garlic and ginger reduced TBARS formation during the chilled storage of liquid smoked silver carp (Frank et al., 2014). A combination of 1% essential oil and 20% aqueous extract of ginger could inhibit the oxidation of fish oil-in-water emulsion. Emir Çoban (2013) found that addition of 1% ginger oil to fish finger significantly reduced the TBARS formation during the refrigerated storage. Ginger essential oil was found more efficient than garlic or rosemary essential oils in reducing TBARS formation during the refrigerated storage of fish sausages (El-Sherif and El-Ghafour, 2016). The primary compounds occurring in the ginger extracts were sesquiterpenoids including zingiberene, copaene and monoterpenoids such as camphane and geranial (Kumari et al., 2014). Alliin, allicin and allyl cysteine occurring in garlic are the compounds responsible for the detected antioxidant effects (Chung, 2006).

## Other Spices

Other spices are also known for their antioxidant and antibacterial activities in seafood products. The polyphenolic compounds derived from some common spices include curcumin (turmeric), capsaicin (chili) and kaempferol (cumin and fennel) (Shan et al., 2005; Hinneburg et al., 2006). Ramanathan and Das (1993) found that dried spices were more effective antioxidants than fresh spices for cooked groundfish. Among the fresh spices, ginger and turmeric were more potent than garlic and onion in suppressing lipid oxidation. Among dried spices, cloves showed the highest antioxidant activity, followed by cinnamon, cumin, black pepper, fennel and fenugreek. Kiin-Kabari et al. (2011) found that the extracts from three African spices, *Piper guinensis* (uziza), *Xylopiia aethiopicum* (okada) and *Myrustica monodora* (ehuru), were effective in preventing lipid oxidation in smoked-dried catfish stored for six weeks, with *P. guinensis* (uziza) being the most efficient antioxidant. Javanese turmeric and red ginger essential oils enriched cassava starch-based edible coating was found to delay significantly lipid oxidation in frozen patin fillets (Utami et al., 2016).

The extracts from Galangal, a spice used in Thai cuisine, were found to prevent hemoglobin-mediated lipid oxidation of washed mince at pH 6.5 (Buaniaw et al., 2010). Washing the sea bass fillet having a low preformed lipid hydroperoxide (LHP) content with a galangal extract solution (0.2% w/v GAE) could effectively inhibit the TBARS formation throughout the storage, although this approach was inefficient to retard lipid oxidation in longtail tuna (*Thunnus tonggol*) with a significant amount of preformed LHPs. Preventing the formation of deoxyhemoglobin (a potent pro-oxidant) was likely the principal mechanism for this phenomenon (Buaniaw et al., 2010).

## Extracts From Teas

Green tea extracts (GTEs) are available in the market and well believed to prevent lipid oxidation in seafood products. GTEs were reported to exhibit a higher antioxidant activity in cod and pollack liver oil compared to other plant extracts such as Black clove oil,

white clove oil, mustard and oregano (O'Sullivan et al., 2005). However, GTE could exhibit a pro-oxidant effect in refined, bleached and deodorized seal blubber oil and menhaden oil due to the pro-oxidant effect of their chlorophyll constituents, whereas, dechlorophyllized GTE had an excellent antioxidant activity in both oils (Wanasundra and Shahidi, 1998). The primary antioxidant constituents in tea are catechins. Among the four catechins, epicatechin gallate was the most effective followed by epigallocatechin gallate, epigallocatechin and epicatechin. The epicatechin gallate seemed more effective than TBHQ (Wanasundara and Shahidi, 1996). Zhu et al. (2009) indicated that the green and black tea extracts and their constituents could trap peroxidation-derived reactive carbonyl substances such as acrolein and reduce the peroxidation of seal blubber oil at high temperatures. GTEs were also found to protect against oxidation in the fish muscle and mince during refrigerated and frozen storage (Tang et al., 2001, Alghazeer et al., 2008). Glazing the fresh bonito fillets with GTEs with different degree of fermentation could be an efficient way to protect fillets against lipid and protein oxidation with green tea and pouching tea at 5% being more effective than black tea (Lin and Lin, 2005). Seto et al. (2005) found that among the hot water extracts of five Taiwanese tea (Longjing-type green tea, Shy Jih Chuen oolong tea, Tungting oolong tea, Pouchong tea and black tea), the extracts of Tungting oolong tea and Longjing-type green tea were highly effective in suppressing pro-oxidation of meat and skin extracts of blue sprat. The detected antioxidant activity correlated well with the content of catechins (especially epigallocatechin gallate), but did not correlate with the content of total polyphenols (Seto et al., 2005).

### Extracts From Vegetables and Their By-products

Vegetables are rich in polyphenolic compounds, and their consumption is desirable because of their health benefits and high potential in prevention of many chronic diseases. Pezeshk et al. (2011, 2013) studied the effect of extracts of shallot or a combination of shallot and turmeric extracts on the refrigerated vacuum packed rainbow trout. Immersion of live fish before gutting or gutted fish in 1.5% shallot extract had the same effect in delaying oxidative deterioration under the refrigerated storage (Pezeshk et al., 2011). The combination of shallot and turmeric extracts led to a greater protection against lipid oxidation of vacuum packaged rainbow trout (Pezeshk et al., 2013). Moreover, Farvin et al. (2012) found that potato peel extract can be a useful source of natural antioxidants and could retard lipid oxidation in omega 3 PUFA-containing system, irrespective of the presence of oxidation inducers or activators such as heat, iron or hemoglobin (Farvin et al., 2012; Habeebullah et al., 2010). The authors evaluated the antioxidative effect of both the ethanolic and water extracts of two varieties of potato peel in bulk fish rapeseed oil and oil-in-water emulsions. The study found that the phenolic composition and antioxidant activity varied with potato species and extraction medium. The peel extract from "Sava" variety potato had a higher phenolic content than that of "Bintje", and ethanol was more efficient than water in extracting polyphenolic compounds. The ethanolic extracts of "Sava" showed a higher antioxidant efficacy in bulk fish-rapeseed oil and oil-in-water emulsion where the oxidation was likely induced by heat and  $\text{Fe}^{2+}$ , respectively. Water extracts showed no antioxidant activity in bulk oil (Fig. 4) but a pro-oxidative effect in the oil-in-water emulsion, which might result from the low total phenolic content and absence of certain phenolic acids such as caffeic, salicylic and coumaric acids in the water extract (Habeebullah et al., 2010). The authors also found that the ethanolic extracts of potato peels provided the highest protection against lipid and protein oxidation in horse mackerel mince. The causes proposed for the higher antioxidant activity of the ethanolic extracts of potato peel extracts were radical scavenging activity, metal chelating activity, reducing properties and tocopherol sparing properties of different phenolic compounds occurring in the extracts (Habeebullah et al., 2010).

### Fruit and Fruit By-product Extracts

#### Grape By-products

The primary antioxidant components in grape seed extracts are flavonoids and stilbenes like resveratrol (Hao et al., 2009). Extracts from grape by-products could inhibit lipid oxidation in a variety of fish lipid-containing systems. Pazos et al. (2005a) studied the phenolic fractions containing flavanol monomers, oligomers (procyanidins) and glycosylated flavonols from grape seed extracts, and found that in terms of retarding lipid oxidation, monomers were more effective in bulk fish oil whilst the oligomers were more efficient in oil-in-water emulsions and fish muscle. The authors concluded that an optimal combination of procyanidins, degree of polymerization and percentage of galloylation were the critical factors that determine the efficacy of grape phenolics in different systems. A grape phenolic extract was found to prevent the lipid oxidation in frozen mackerel and horse mackerel mince through preserving the endogenous antioxidants such as  $\alpha$ -tocopherol, ubiquinone-10 and total glutathione (Pazos et al., 2005a, 2005b). Glazing with a grape seed extract before a frozen storage could inhibit the lipid oxidation in bonito fillets (Yerlikaya and Gokoglu, 2010). Spraying the extract containing grape procyanidins and hydroxytyrosol on the horse mackerel fillets before freezing seemed more effective in lowering lipid oxidation than glazing (Pazos et al., 2006). Washing the fillets with water before spraying the phenols-rich extract could synergistically improve the effectiveness of these phenolic compounds, especially for the grape procyanidins, possibly due to a better distribution of procyanidins onto the fillet surface by the residual water in the fillet (Pazos et al., 2006). Crude grape dietary fiber often contain natural antioxidants such as procyanidins, catechins and other flavonoids (Saura-Calixto, 1998), and addition of white and red grape fiber (at 2 or 4%) could inhibit oxidation in the frozen horse mackerel mince (Sanchez-Alonso et al., 2007; Sanchez-Alonso and Borderias, 2008).

Besides flavonoids, grapes and grape-derived product extracts also contain stilbenes. Stilbenes include resveratrol (3,5,4'-trihydroxystilbene), pterostilbene (a dimethylated derivative of resveratrol), piceid (a resveratrol glucoside) and viniferins (resveratrol oligomers) (Fremont, 2000). Medina et al. (2010) have evaluated the antioxidant activity of

**Figure 4** Antioxidant activity of potato peel in bulk oil where oxidation is induced by heat. (A) Peroxide value and (B) anisidine value. The prefix “E” represents ethanol extract and “W” represents water extract. The numbers indicates the concentration in ppm. Adopted from Habeebullah, S.F.K., Nielsen, N.S., Jacobsen, C., 2010. Antioxidant activity of potato peel extracts in a fish-rape seed oil mixture and in oil-in-water emulsions. *J. Am. Oil Chem. Soc.* 87, 1319–1332.

Resveratrol, and its acylated and glycosylated derivatives in a bulk fish oil, oil-in-water emulsion and fish muscle system, and found that resveratrol was effective in retarding lipid oxidation in all the systems studied. Resveratrol and piceid (glycosylated resveratrol) showed high antioxidant activity in an oil-in-water emulsion. Lipophilization or glycosylation of resveratrol did not improve its antioxidant activity in either emulsions or bulk fish oil, mainly due to their localization at the interior of oil droplet or in the aqueous phase rather than the oil-in-water interface.

#### Apple Peel Extracts

Polyphenols obtained from frozen and dried apple peels were reported to stabilize omega-3 polyunsaturated fatty acid-rich fish oil (Sekhon-Loodu et al., 2013). The major constituents of these extracts were flavanols, quercetin-3-O-glycosides and phenolics such as phloridzin, phloretin, cyanidin-3-O-galactoside, chlorogenic acid and epicatechin. Compared to the initial crude apple peel extracts, fractionated polyphenols showed greater inhibition of lipid oxidation compared to  $\alpha$ -tocopherol and BHT

(Sekhon-Loodu et al., 2013). An apple skin extract prepared from “Northern spy” cultivar could inhibit lipid oxidation in the aqueous eicosapentaenoic acid (EPA) emulsions and bulk fish oil. This extract could reduce the oxidation induced by heat, UV light and peroxy radicals, and interestingly, removal of sugars and organic acids from the crude ethanol extract of apple skin enhanced the antioxidant properties (which were comparable to  $\alpha$ -tocopherol and BHT) in both the emulsion and bulk fish oil systems (Rupasinghe et al., 2009).

### Berries and Associated Products

Berry extracts were found to protect omega-3 containing lipids. Luther et al. (2007) reported that among Chardonnay and black raspberry seed extracts, black raspberry seed flour extract was more powerful in suppressing lipid oxidation and rancidity development in fish oil under accelerated oxidative conditions. A garden strawberry leaf extract at 5% was reported to lower lipid oxidation in fish oils (Raudonite et al., 2011). In terms of antioxidant efficacy, proanthocyanidins showed less antioxidant activity against the hemoglobin-induced oxidation in washed cod muscle compared to other polyphenolics in cranberry extract such as phenolic acids, anthocyanins and flavanols (Lee et al., 2006). The decreasing order of the effectiveness of preventing TBARS formation in washed cod muscle was phenolic acids > flavanols > anthocyanins > proanthocyanidins. The component that was efficient in inhibiting Hb-mediated lipid oxidation has tentatively been identified as quercetin (Lee et al., 2006). In another study, a flavanol-rich fraction from cranberry juice powder also showed excellent protection on cod mince against hemoglobin-induced oxidation (Sanchez-Alonso et al., 2007). Presoaking the fillets in a quince (*Cydonia oblonga* Miller) polyphenolic extract efficiently inhibited lipid oxidation in mackerel fillets during refrigerated storage. The protective effect of the quince extract was attributed to the radical scavenging activity of procyanidin B dimer and hydroxycinnamic acids in the extracts (Fattouch et al., 2008).

### Seaweed Extracts

Seaweeds are gaining increasing attention as a potential antioxidant source. Polyphenolic compounds such as phenolic acids, catechins, flavonoids and phlorotannins have been identified from different species of seaweeds (Yoshie-Stark et al., 2003; Koivikko et al., 2005). Recently, marine macroalgal extracts have been extensively studied for their usefulness as antioxidants in fish muscle or fish oil enriched food products. Antioxidant activity of several brown and red algal species was reported to be responsible for their protection on fish oil (Athukorala et al., 2003; Siriwardhana et al., 2004). The antioxidant capacity of seaweed varies with species, location of collection, concentrations of individual phenolic compounds, pigments, polysaccharides and extractant medium. Kindleysides et al. (2012) evaluated the antioxidative effect of lipid extracts from two brown (*Ecklonia radiata* and *Macrocystis pyrifera*) and two red species (*Champia* sp. and *Porphyra* sp.) in an elevated temperature (60 °C) storage of Hoki (*Macruronus novaezelandiae*) oil. They found that the brown seaweed extracts outperformed the red seaweed extracts, and the most effective seaweed extract in the prevention of Hoki liver oil oxidation was *E. radiata*, followed by *Champia* sp., *M. pyrifera* and *Porphyra* sp. extracts.

Different seaweed extracts offered protection against oxidation of fish oil emulsions (Farvin and Jacobsen, 2015; Hermund et al., 2015). The absolute ethanol and 50% ethanol extracts of red seaweed *Polysiphonia fucoides* had higher antioxidant activities than those of *Fucus serratus* in 5% oil-in-water emulsions with and without added iron (Farvin and Jacobsen, 2015). Although a higher amount of phenolic compounds were extracted with absolute ethanol compared to 50% ethanol, the latter exhibited higher antioxidant properties in emulsions (which were comparable to that of BHT). Besides phenolic compounds, protein and polysaccharides were present in the 50% ethanolic extracts. The absolute ethanolic extracts of both seaweed species showed a pro-oxidant effect. Babakhani et al. (2016) observed a similar effect for the ethanolic extract of the red seaweed *P. fucoides* in retarding the lipid and protein oxidation in mackerel muscle mince. The extract, although protecting the loss of  $\alpha$ -tocopherol and tryptophan residues and prevented carbonyl formation, had minimal effect on protein oxidation. Hermund et al. (2015) found that the ethyl acetate fraction of Icelandic *F. vesiculosus* was the most efficient in preventing lipid oxidation in fish oil enriched milk emulsions and mayonnaise. Water, ethanolic and acetone extracts of Icelandic *F. vesiculosus* were reported to prevent fish oil-enriched mayonnaise from oxidation (Honold et al., 2016) and skin care emulsions (Poyato et al., 2017). Radical scavenging and metal chelating activities of the phenolics and carotenoids present in these extracts would be responsible for the prevention from oxidation. Phlorotannin-enriched solvent extracts of *Fucus vesiculosus* was reported to protect against Hb-mediated lipid oxidation for the washed cod muscle (Wang et al., 2010) and Granola bars fortified with fish oil in water emulsion (Hermund et al., 2016).

### Other Plant Extracts

Antioxidant activities of other plant extracts against oxidation in seafood have also been investigated. Carob seed peel was found effective against lipid and protein oxidation in minced horse mackerel (Albertos et al., 2015). Crude brown lead seed with chlorophyll showed protective effect on minced mackerel in a dose-dependent manner (Benjakul et al., 2013). An ethanolic extract of Kiam wood at 0.1%, (w/w) retarded the hemoglobin-induced lipid oxidation in washed seabass mince and also in menhaden oil (Maqsood and Benjakul, 2013). The defatted soy flour extract was very effective at 5% level in preventing the oxidation of menhaden oil and over 60% of DHA and EPA retained when the oil was heated at 150 °C for 30 min (Yue and Xu, 2010). Similarly, a cactus pear fruit (*Opuntia ficus-indica*) extract was reported to inhibit the lipid oxidation in fish oil and

fish oil-in-water emulsion in a dose-dependent manner (Siriwardhana and Jeon, 2004). A flax-seed extract inhibited the secondary oxidation products and hence rancidity in frozen whole mackerel (*Scomber scombrus*) (Stodolnik et al., 2005). Further, food packaging films incorporated with phenolic extracts from barley husk could increase the oxidative stability of packed salmon flesh (de Abreu et al., 2010). Lyophilised water extracts of borage leaves at a concentration of 340 ppm could be as effective as that of BHT at 200 ppm in preventing dry fermented sausage enriched with n-3 PUFA from lipid oxidation (de Ciriano et al., 2009).

## Conclusion

Plant extracts are extensively used as antioxidant sources to protect the biologically important long-chain polyunsaturated fatty acids in seafood products against oxidation. The antioxidative/prooxidative nature of the plant extracts is complex. The concentrations of antioxidant molecules in the obtained extracts vary with factors such as genotype, environmental conditions, plant parts, extraction medium employed. Further, detailed studies are needed to characterize the co-existing constituents present in the extracts before one makes concluding statements on the beneficial effect(s) of particular extracts. Some substances co-extracted, such as alkaloids from the potato peels and kainic acid (a potential neurotoxin compounds) from some seaweeds, may cause health-related problems to the consumers.

## Overview

The nature of protein-phenolic interactions in plant-based food systems (e.g., soybean, flaxseed and sorghum seeds) can be classified into two groups as reversible or irreversible interactions (Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2013, 2017d). Reversible protein-phenolic interactions may form insoluble complexes in solutions through non-covalent interactions such as hydrogen bonds, Van der Waals interactions and hydrophobic interactions. Irreversible protein-phenolic interactions may lead to a new molecular structure resulting in increased solubility of proteins and phenolic compounds in solution through their interactions via covalent bonds, non-disulfide linkages, and cross-linking (Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2013, 2017d). The functionality of protein-phenolic complexes and their nutraceutical properties are determined by the stability, structure, amino acid composition and ratio, distribution and ratio of positive to negative charge of the proteins, as well as by the complexity of the phenolic compounds (e.g., the number of phenolic rings and presence of different functional groups) (Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2013, 2014, 2017d). Interactions of phenolics and proteins with lipids present in foods may also occur (Jakobek, 2015).

The stability and conformation of proteins in terms of their primary, secondary, tertiary and quaternary structures may affect the affinity of phenolic compounds for conjugation with proteins and therefore influence the nutraceutical properties of resultant complexes. Moreover, the presence of one or more aromatic rings and hydroxyl groups in the chemical structure of phenolic compounds can enhance their binding affinity for different sites of the protein molecular structure (Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2013, 2014, 2016a, 2017a, 2017d).

Protein-lipid-phenolic interactions in food materials may occur naturally or develop during food processing, handling and storage (Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2013, 2014, 2016a,b, 2017a, 2017d). Other interactions may occur *in vivo*, for instance in the gastrointestinal tract. The main types of interactions responsible for the stability of protein-phenolic complexes are hydrogen bonding and hydrophobic interactions, while the interactions involving lipids are mostly based on hydrophobic interactions (Alu'datt, 2006; Le Bourvellec and Renard, 2012; Ozdal et al., 2013; Jakobek, 2015; Alu'datt et al., 2013, 2016b, 2017d).

## Phenolic Composition and Properties of Flaxseed and Soybean

Phenolics are secondary metabolites produced by plants and found in numerous plant-based foods such as those that contain flaxseed and soybean. Phenolics have extremely diverse chemical structures (e.g., one or more phenolic groups and various functional groups), which contribute to their biological activities (Shahidi and Ambigaipalan, 2015; Alu'datt et al., 2017b). Phenolics can be formed from their precursors, phenylalanine and tyrosine amino acids, through shikimate and acetate pathways (Alu'datt, 2006; Bravo, 1998; Alu'datt et al., 2017b, 2017d). The major features of phenolics in plant foods are their contribution towards color and flavor, as well as their biological and pharmaceutical properties (Alu'datt, 2006; Alu'datt et al., 2013, 2014, 2017b, 2017d).

Flaxseed (*Linum usitatissimum*) has a wide range of food and non-food applications (Alu'datt, 2006; Alu'datt et al., 2016b, 2017b, 2017d), as this plant material is a rich source of health-promoting compounds, both nutrients and non-nutrients, including unsaturated fatty acids (e.g., omega-3 fatty acids), phenolics, proteins, lignin and dietary fiber (Cunneane and Thompson, 1995; Alu'datt et al., 2013, 2014, 2017b).

One main class of health-promoting constituents of flaxseeds are phenylpropanoids, including *o*-coumaric, *p*-coumaric, *p*-hydroxybenzoic, ferulic, sinapic and vanillic acids, which occur in either free forms or bound with carbohydrates (Alu'datt, 2006; Alu'datt et al., 2013, 2016b, 2017b, 2017d). Phenylpropanoids play a key role in the biosynthesis of naturally-occurring phenolics. The main bound phenolic-carbohydrate complexes are *p*-coumaric acid glycosides and ferulic acid glucosides (Johnsson et al., 2000; Alu'datt, 2006; Alu'datt et al., 2017b, 2017d). The total content of esterified, free and bound phenolic compounds in dehulled defatted flaxseed meal was 81.0, 73.9 and 7.2 mg/100 g, respectively (Dabrowski and Sosulski, 1984).

Phenolic compounds may be responsible for objectionable off-flavor and undesirable sensory properties such as brown color and bitter taste in flaxseed and derived food products (Arai et al., 1966; Alu'datt, 2006; Alu'datt et al., 2017b, 2017d). The total content of phenolic acids in flaxseeds was reported to be in range of 355–442 mg/100 g (Varga and Diosady, 1994; Alu'datt,

2006; Alu'datt et al., 2017b) and 800–1000 mg/100 g (Oomah et al., 1995; Alu'datt et al., 2017b), out of which the insoluble bound phenolic compounds accounted for 26%–29% (Varga and Diosady, 1994) and 48%–66% in the esterified form (Oomah et al., 1995). Flaxseed is considered as a relatively good source of lignans compared to other plant foods and flaxseed lignan is composed of two cinnamic acid units (Pszczola, 2002). The main lignan present in flaxseed is secoisolariciresinol diglucoside (SDG), which has demonstrated several roles in supporting human health, for instance, anti-carcinogenic, cardioprotective, phyto-estrogenic and antioxidant effects (Westcott and Muir, 2000; Clifford, 2000; Anon, 2001; Alu'datt, 2006; Shahidi and Ambigaipalan, 2015; Alu'datt et al., 2017b). The content of SDG in flaxseed ranges from 1% to 3% in defatted meals (Bakke and Klosterman, 1956; Thompson, 1994; Johnsson et al., 2000; Alu'datt et al., 2017b). Matairesinol is another type of lignin, which is present in flaxseed albeit in a relatively low amount compared to SDG (Mazur and Adlercreutz, 1998; Alu'datt et al., 2017b). Other lignans found in flaxseed in low amounts include isolariciresinol, SDG isomer and pinorensinol diglucoside (Bambagiotti-Alberti et al., 1994; Meagher et al., 1999; Qiu et al., 1999; Alu'datt et al., 2017b).

The three major cultivars of soybean are *Glycine max*, *Glycine ussuriensis* and *Glycine gracilis*. Asian countries have the highest dietary consumption of soybean in the world. Soybean has been used, since ancient times, as both human food and animal feed due to its high contents of oil and proteins compared to other plant foods (Alu'datt et al., 2016b, 2017b). In addition, the high contents of bioactive compounds such as phenolics, dietary fiber, functional peptides and vitamins in soybean lead to the role of soybean as a functional food and an important source of nutraceutical ingredients in the food and healthcare industries (Alu'datt, 2006; Alu'datt et al., 2013, 2016b, 2017b, 2017d).

Numerous studies have reported the roles of bioactive plant-derived compounds in promoting human health due to diverse biological activities such as estrogenic, anti-carcinogenic, anti-mutagenic, antioxidant and prebiotic activities (Alu'datt, 2006; Alu'datt et al., 2013, 2016b, 2017b, 2017d; Cardona et al., 2013). The presence of phenolic compounds in soybean, in the free and bound forms together with other food constituents, can cause objectionable and undesirable sensory properties affecting the flavor and color of soybean and its products (Alu'datt, 2006; Alu'datt et al., 2017b, 2017d). The main phenolics present in soybean, namely, isoflavones, are rather complex. Several health benefits of isoflavones have been reported (Messina et al., 1994; Alu'datt et al., 2017b), although they can also contribute bitterness and astringency to soy food products. The main isoflavones present in soybean are genistein, daidzein, glycitein as well as their conjugate derivatives, e.g., aglycones, glucosides, acetylglucosides and malonylglucosides (Wang and Murphy, 1994; Alu'datt et al., 2017b). Such derivatives include malonyl-daidzein, malonyl-glycitein, malonyl-genistein, acetyl-daidzein, acetyl-glycitein and acetyl-genistein (Gyorgy et al., 1964; Ingham et al., 1981; Kudou et al., 1991; Barnes et al., 1994; Hoeck et al., 2000; Hosny and Rosazza, 2002; Alu'datt et al., 2017b). The isoflavone content in soy ranges between 47.2 and 420 mg/100 g (Wang and Murphy, 1994, 1996; Simonne et al., 2000). The major isoforms of isoflavones present in soy foods contain glucosides that are hydrolyzed by colonic bacteria *in vivo*, leading to an increased solubility of the aglycone isoflavone (Barnes et al., 1994). Isoflavones and other phenolics of soybean have a strong natural affinity to attach to proteins (Alu'datt, 2006; Alu'datt et al., 2013, 2014, 2016b, 2017e).

For soybean flour, the contents of free phenolics and free phenolic acids were 73.6 mg/100 g and 0.23 mg/g, respectively (Dabrowski and Sosulski, 1984; Alu'datt et al., 2017b). For defatted soy flour, the major identified free phenolic compounds are syringic acid (Arai et al., 1966; Alu'datt et al., 2017b), ferulic acid, syringic acid and vanillic acid (Maga and Lorenz, 1974; Alu'datt et al., 2017b), and *o*- and *p*-coumaric acids and ferulic acids (How and Morr, 1982; Alu'datt et al., 2017b).

## Nature of Protein–Phenolic Interactions in Flaxseed, Soybean and Derived Food Systems

In recent years, plant phenolics and other bioactive compounds have spurred tremendous interest in the food and health industries. The properties of phenolic compounds have been extensively applied in the food and drug industries mainly because of their antioxidant properties (Alu'datt, 2006; Alu'datt et al., 2013, 2017d). The chemical structures of phenolic compounds allow an affinity towards proteins via conjugation and precipitation (Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2013, 2017d). Phenolic compounds can bind to proteins and decrease their solubility (Alu'datt, 2006; Le Bourvellec and Renard, 2012; Ozdal et al., 2013; Alu'datt et al., 2014, 2017d). Reduced protein solubility can decrease the digestibility and biological utilization of proteins (Myer and Gorbet, 1985). Phenolic compounds have been found to bind to proteins in fruit juice, wine and beer, causing haze formation and turbidity (Siebert, 1999; Alu'datt, 2006; Alu'datt et al., 2017d). The enzymatic and non-enzymatic oxidation of phenolic compounds (Haslam, 1989; Alu'datt, 2006; Alu'datt et al., 2017d) may promote their interaction with some amino acids and decrease the activity of digestive enzymes such as trypsin and lipases resulting in decreased digestibility (Milic et al., 1968; Alu'datt, 2006; Alu'datt et al., 2017d). Several studies have reported tannin-protein interactions, which are influenced by many factors such as temperature, pH, structural complexity of the phenolic compound, and the size and amino acid composition of the protein (Serafini et al., 1997; Alu'datt, 2006; Alu'datt et al., 2017d).

## Formation, Characteristics and Importance of Protein–Phenolic Interactions

The conjugation of bovine serum albumin (BSA) with ferulic acid, caffeic acid and (+)-catechin has been reported, which was suggested to affect BSA antioxidant activity (Hagerman, 1989). Haslam et al. (1999) reported that the hydroxyl groups in phenolics led to an affinity, via conjugation, for the amino and carbonyl groups of proteins through hydrogen bonding. In addition, lysine and

cysteine have a strong affinity for oxidized phenolics through covalent linkages, which contributes to the conjugation of sunflower proteins with chlorogenic acid (Sastry and Rao, 1990; Bianco et al., 1997; Siebert, 1999). Non-polar or hydrophobic interactions may also occur through the aromatic ring of phenolics and the non-polar hydrocarbons of the protein molecules (Bartolome et al., 2000; Alu'datt, 2006; Alu'datt et al., 2013, 2017d). Interactions between proteins and phenolics fall into two main types, namely, reversible and irreversible interactions (Haslam et al., 1999; Alu'datt et al., 2013, 2017d; Ozdal et al., 2013).

The main requirement for irreversible protein-phenolic interactions is the presence of oxygen and polyphenol oxidases (PPO) (Mole and Waterman, 1986; Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2017d), which can cause darkening of some products, for instance the browning of cut fruits and vegetables. The main requirements for reversible protein-phenolic interactions involve weak, non-covalent interactions such as hydrophobic interactions, hydrogen bonds and solvation which cause the formation of protein-phenolic complexes (Haslam et al., 1999; Alu'datt, 2006; Alu'datt et al., 2013, 2017d; Ozdal et al., 2013).

The chemical structure of proteins allows them to conjugate with other compounds, including phenolics, lipids, carbohydrates and other proteins (Alu'datt, 2006; Alu'datt et al., 2013, 2014, 2017d; Ozdal et al., 2013). Phenolic compounds can also conjugate with glycosylated proteins (Haslam et al., 1999), and precipitate proteins at a pH close to their isoelectric points (Siebert, 1999). Alu'datt et al. (2013 and 2017d) proposed mechanisms explaining the affinity of phenolics to interact with proteins, lipids and carbohydrates in soybean and flaxseed.

Several factors determine the strength and affinity between proteins and phenolics, including molecular size, number of phenolic rings, protein flexibility and conformation, and number of hydrophilic moieties (Murray et al., 1994; Haslam et al., 1999; Alu'datt, 2006; Alu'datt et al., 2013, 2014, 2017d). Tannins are a major constituents of certain plants, including some common consumer plant-based foods and beverages (Murray et al., 1994; Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2017d). Tannins are classified into two groups, namely the hydrolysable tannins, which are esters (usually with D-glucose) of gallic acid and its derivatives, and the condensed or non-hydrolysable tannins (e.g., proanthocyanidins), which are oligomers of the flavan-3-ol skeleton, e.g., epicatechin (Bravo, 1998; Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2017d). Tannins have a wide range of biological effects including inhibition of some digestive enzymes and non-hemic iron absorption, alteration of food taste by inducing astringency, and reduction of food nutritional value by interfering with nutrient digestion and absorption (Haslam, 1989; Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2017d). Protein-phenolic interactions involving tannins have been found in sorghum, a staple and nutritionally significant food in several countries. It has been shown that the presence of condensed tannins in sorghum decreased the *in vitro* and *in vivo* protein digestibility via inhibition of digestive enzymes (Nguz and Huyghebaert, 1998; Nyamambi et al., 2000; Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2017d). Likewise, the ability of phenolic compounds to precipitate kafirin and prolamin proteins of sorghum has been studied extensively. Sorghum condensed tannins can bind irreversibly to kafirin, which plays an important role in decreasing protein digestibility in sorghum with a high tannin content causing haze formation (Emmambux and Taylor, 2003).

Soy glycinin and soy trypsin inhibitors can interact with chlorogenic, caffeic acid, cinnamic and gallic acids. Soy flavonoid compounds, including flavone, apigenin, kaempferol, quercetin and myricetin, can also interact with soybean proteins. Such derivatizations can reduce the nutritional value of soybean proteins due to the decreased availability of lysine, cysteine and tryptophan residues (Wang and Murphy, 1994; Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2017d). Tannins, in general, can interact with proteins and form both soluble and insoluble complexes, which is largely responsible for the anti-nutritional effects observed in animals, particularly non-ruminants fed tannin-rich diets (Martin-Tanguy et al., 1977; Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2017d). The formation of tannin-protein complexes depends on the size, conformation and charge of protein molecules, and the size, length and flexibility of tannins (Shahidi and Naczki, 1995; Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2017d). Globular proteins, such as ribonuclease, lysozyme and cytochrome C, tend to have a low binding affinity towards tannins, while proteins with open conformational structures such as gelatin have a high affinity for binding with tannins (Hagerman and Butler, 1981; Alu'datt, 2006; Alu'datt et al., 2017d). These complexes with tannin can further interact with essential amino acids and other nutrients, causing decreased bioavailability (Ohlson and Anjou, 1979; Alu'datt, 2006; Ozdal et al., 2013; Alu'datt et al., 2017d). The precipitation of tannin-protein complexes is pH sensitive (Hagerman and Butler, 1978). Naczki et al. (1996) reported that the solubility of such complexes reached the lowest level at pH 0.3–3.1. In such complexes, BSA, fetuin, collagen and pepsin could precipitate at a pH range of 3.0–5.0. Tannins may need to possess at least three flavanol subunits to be effective as protein precipitating agents. Dimers are less effective precipitating agents with simple flavanols unable to precipitate proteins (Artz et al., 1987).

The interactions of simple phenolic compounds with proteins have been investigated in model systems. Smyk and Drabent (1989) reported that BSA-phenolic complexes were favored under neutral and basic pH conditions. Zadernowski (1987) reported that BSA binds via an ester bond to sinapine. Condensed tannins extracted from canola hull samples were found to precipitate 3.0–59.0 mg of BSA per gram of hulls (Leung et al., 1979). Mehansho et al. (1987) reported that the mammalian response to the interaction of salivary proline-rich proteins with dietary tannins could lead to an astringent taste associated with the interactions between polyphenolic compounds in food and salivary proline-rich proteins (Luck et al., 1994; Baxter et al., 1997).

The affinity of tannins towards proteins depends on the chemical and structural properties of the proteins and tannins as well as the properties of their surrounding milieu (e.g., temperature, pH and ionic strength), all of which determine the involvement of hydrophobic interactions, hydrogen bonds and other types of interactions (Oh et al., 1980; Hagerman and Butler, 1980; McManus et al., 1985; Hagerman, 1989; Alu'datt, 2006; Alu'datt et al., 2017d).

One of the main consequences of protein-phenolic interactions is the generation of dark color and unpleasant taste(s) (like bitterness and astringency) in some plant protein-based foods, with the involvement of various mechanisms including hydrogen

bonding, ionic bonding, electrostatic interactions, hydrophobic interactions and covalent linkages (Alu'datt, 2006; Alu'datt et al., 2013, 2014, 2016a,b, 2017d). For example, thimasidic acid can conjugate with proteins at pH 7.0 or 8.5 and room temperature through hydrophobic interactions (Rubino et al., 1996).

The ability of proteins to interact with phenolics through hydrogen bonding is due to a combination of factors including the presence of the hydroxyl groups in the main structure of phenolics and the carbonyl group in the peptide linkage of proteins. These interactions may also occur in the oxidation stage of quinines which can interact with the reactive functional groups on the amino acids of proteins (Loomis and Battaile, 1966; Alu'datt, 2006; Alu'datt et al., 2017d). Phenolic-protein complexes may also form via hydrophobic interactions (Shahidi and Naczki, 1995; Shahidi and Ambigaipalan, 2015). To our knowledge, protein-phenolic interactions do not occur via ionic interactions under normal physiological pH conditions (Butler et al., 1984).

The characteristics of phenolics such as relatively low boiling points and flavor-imparting/altering ability have led to a broad range of applications in the food flavor industry (Alu'datt, 2006; Alu'datt et al., 2013, 2017b, 2017d). Recently, many studies have reported the interactions of phenolic flavor compounds with lipids, salts, carbohydrates, proteins and other phenolics (Alu'datt, 2006; Alu'datt et al., 2013, 2014, 2016a,b, 2017b, 2017d). Siebert et al. (1996a,b) investigated the biological and pharmacological effects of these interactions. As observed in citrus, the chemical nature of flavonoids may affect the volatility of flavor compounds. The volatility of ethyl benzoate and 2,3-diethylpyrazine in citrus decreased in the presence of flavonoids, with no effect on the volatility of limonene (King and Solms, 1981, 1982).

One of the effects of protein-phenolic interactions on plant food proteins is to alter the nutritional properties of proteins and their products by affecting their digestibility and absorption (Bravo and Saura-Calixto, 1998; Alu'datt, 2006; Alu'datt et al., 2013, 2017d). Plant phenolics have the affinity for digestive enzymes to conjugate in the human gastrointestinal system, causing reduced digestibility of proteins, carbohydrates and lipids (Quesada et al., 1996; Alu'datt, 2006; Jakobek, 2015; Alu'datt et al., 2013, 2014, 2016a,b, 2017d). Many studies reported that the inhibitory activity of phenolics towards amylolytic enzymes, by which the digestibility of dietary carbohydrates would be reduced, with a beneficial reduction of the postprandial glycemic response (Thompson et al., 1984; Alu'datt, 2006; Jakobek, 2015; Alu'datt et al., 2013, 2016a,b, 2017d).

A few studies reported the effect of phenolic interactions with proteins on the functional and bioactive properties of food products (Alu'datt, 2006; Alu'datt et al., 2013, 2014, 2017d). Martin-Carron et al. (1997) found that the presence of phenolics and condensed tannins increased fecal lipid excretion in an animal model. Consumption of food and food products with grape tannins, tannic acid and tea catechins was further shown to decrease the blood levels of high density and low density lipoproteins (Muramatsu et al., 1986; Martin-Carron et al., 1997).

## **Extraction and Analysis of Free, Bound and Total Phenolics in Flaxseed and Soybean**

The free and bound phenolics in proteins and byproducts of flaxseed and soybean can be determined according to the Folin-Ciocalteu colorimetric method, as described by Hoff and Singleton (1977) and modified by Alu'datt (2006) and Alu'datt et al. (2013 and 2016b). Several organic solvents and water have been reported to extract free and bound phenolics from plant materials (Shahidi and Naczki, 2004; Alu'datt, 2006; Alu'datt et al., 2017c, 2017d). Shahidi and Naczki (2004) reported that the best solvent for extracting free phenolics from plants is methanol. Free phenolics were extracted from protein isolates of flaxseed and soybean at both room temperature and 60 °C (Alu'datt, 2006; Alu'datt et al., 2013, 2016b). Bound phenolics were extracted from protein isolates of flaxseed and soybean by acid or basic hydrolysis, followed by methanol extraction at room temperature (Alu'datt, 2006; Alu'datt et al., 2013, 2016b). Various analytical techniques have been used to characterize the profiles of extracted free phenolics from different plant materials, including high-performance liquid chromatography (HPLC), thin layer chromatography (TLC), gas chromatography (GC), nuclear magnetic resonance (NMR), capillary electrophoresis (CE) and capillary zone electrophoresis (CZE) (Montedoro et al., 1992a,b; Pirisi et al., 2000; Alu'datt, 2006; Alhakmani et al., 2013; Wong-Paz et al., 2015; Liu et al., 2016; Alu'datt et al., 2013, 2016b). Protein-phenolic and protein–lipid–phenolic complexes in flaxseed and soybean can be identified and characterized using HPLC and mass spectrometry (Alu'datt, 2006).

## **Distribution of Free and Bound Phenolics in Proteins Isolated From Soybean and Flaxseed**

The total content of free and bound phenolics in protein isolates from defatted soybean (3.42 mg/g) was found to be higher than in the protein isolates from full-fat soybean (1.96 mg/g) (Alu'datt, 2006; Alu'datt et al., 2013). The content of bound phenolics in protein isolates from full-fat and defatted flaxseed (0.70–1.91 mg/g) was higher than in protein isolates from full fat and defatted soybean (0.37–0.39 mg/g) (Alu'datt, 2006; Alu'datt et al., 2013). These authors further showed that the profiles of free phenolics in soybean and flaxseed protein isolates were different from those of bound phenolics. The antioxidant activity of free phenolics was higher than that of bound phenolics from isolated proteins of soybean and flaxseed (Alu'datt, 2006; Alu'datt et al., 2013). Protein–phenolic and protein–lipid–phenolic interactions were present in soybean and flaxseed, respectively.

Alu'datt (2006) and Alu'datt et al. (2013) reported that the major free phenolics identified in the protein isolates from soybean were hydroxybenzoic acid, gallic acid, sinapic acid, syringic acid, *p*-coumaric acid, ferulic acid, quercetin, hesperidin and caffeic acid.

The major bound phenolic compounds in soybean protein isolates were syringic acid, hesperidin and *p*-coumaric acid. [How and Morr \(1982\)](#) identified free phenolics in soy protein isolate as *p*-coumaric, *o*-coumaric, syringic, ferulic and genistic acids.

In flaxseed protein isolates, the free phenolics identified were syringic, hydroxybenzoic, protocatechuic, *p*-coumaric, gallic, ferulic and caffeic acids, while the bound phenolics were hydroxybenzoic, gallic, caffeic, syringic, *p*-coumaric and ferulic acids ([Alu'datt, 2006](#); [Alu'datt et al., 2013](#)). The bound phenolic contents of protein isolates from full-fat and defatted flaxseed were positively correlated with the antioxidant activity values. In comparison, the bound phenolic contents of protein isolates from full-fat or defatted soybean were weakly positively correlated with the antioxidant activity. A weak positive correlation was also noted between the free phenolic content and antioxidant activity for the protein isolates from full-fat flaxseed. The free phenolic contents in protein isolates from defatted flaxseed, full-fat soybean and defatted soybean were positively correlated with corresponding antioxidant activities ([Alu'datt et al., 2013](#)).

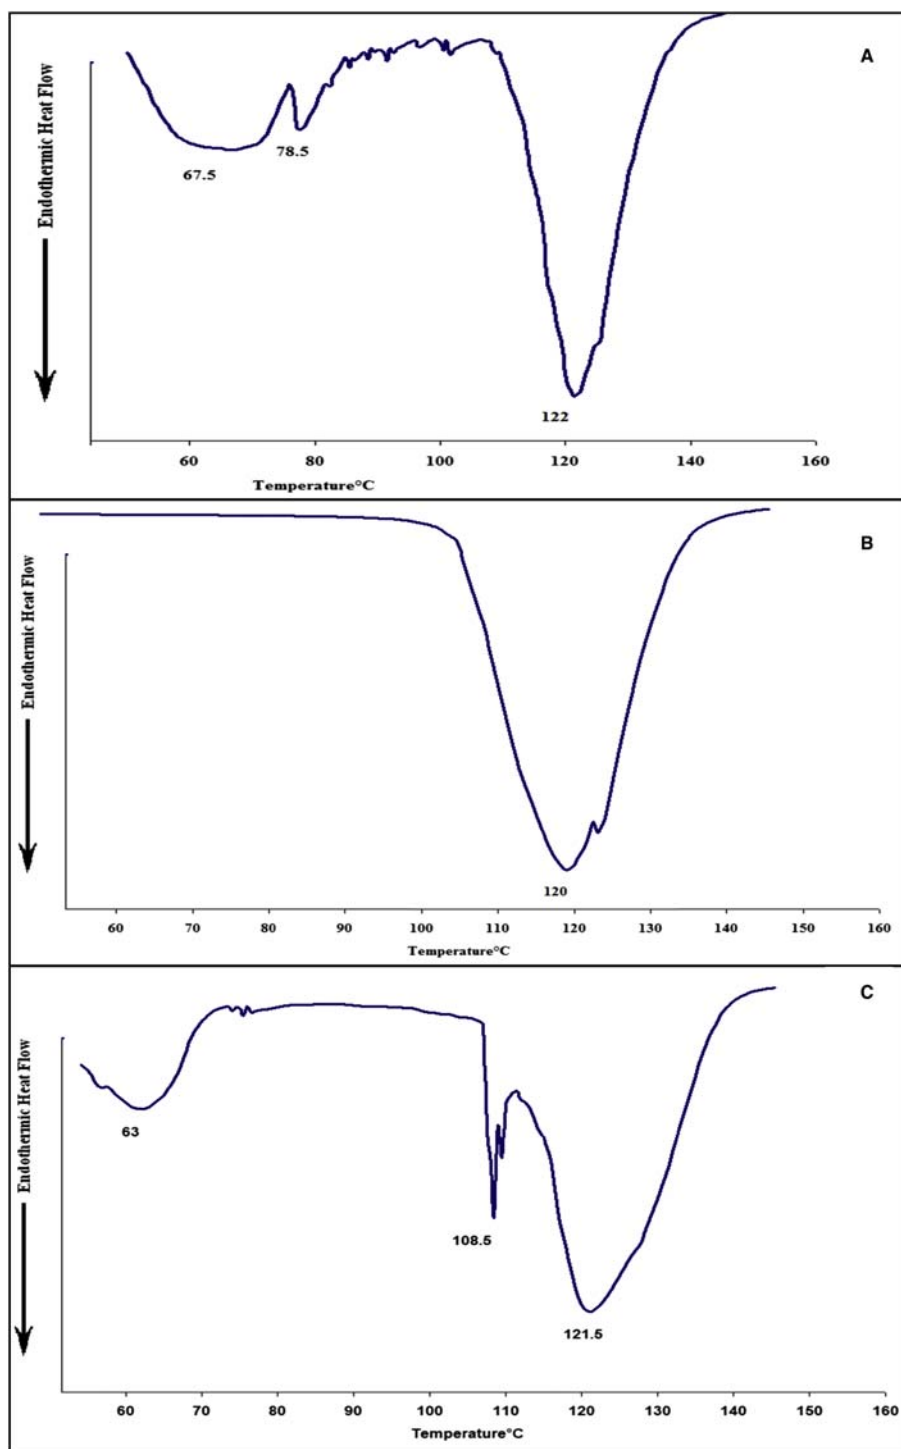

[Alu'datt et al. \(2016b\)](#) reported that the content of bound phenolics in residues obtained after protein isolation from flaxseed was higher (56%–62%) than the content of free phenolics in flaxseed. In contrast, the free phenolic content in residues obtained after protein isolation from soybean was higher than the content of bound phenolics. In the supernatant obtained after protein precipitation from soybean and flaxseed, the free phenolic content was higher than that of bound phenolics ([Alu'datt et al., 2016b](#)). The main free phenolics found in the residue and supernatant obtained after isolation of soybean proteins were ferulic acid, quercetin, hesperidin, *p*-coumaric acid gallic acid, caffeic acid, *p*-hydroxybenzoic acid, sinapic acid and syringic acid ([Alu'datt et al., 2016b](#)). These researchers found that there were no bound phenolics in supernatants obtained after isolation of soybean proteins. The main bound phenolics identified in residues obtained after isolation of soybean proteins were ferulic acid, *p*-hydroxybenzoic acid, sinapic acid, *p*-coumaric acid and syringic acid ([Alu'datt et al., 2016b](#)). The main free phenolics identified in the flaxseed supernatants and residues obtained after isolation proteins were *p*-coumaric acid, syringic acid, gallic acid, caffeic acid, hydroxybenzoic acid, protocatechuic acid, ferulic acid and sinapic acid ([Alu'datt et al., 2016b](#)). The main bound phenolics in flaxseed supernatants and residues obtained after isolation proteins were sinapic acid, ferulic acid, *p*-hydroxybenzoic acid, *p*-coumaric acid and caffeic acid ([Alu'datt et al., 2016b](#)). Protein-lipid-phenolic interactions in flaxseed were thought to occur through sinapic acid ([Alu'datt et al., 2013, 2016b](#)).

### Effect of the Removal of Phenolics on Antioxidant Activity, Water Holding Capacity, Rheological and Thermal Properties of Isolated Proteins From Soybean and Flaxseed

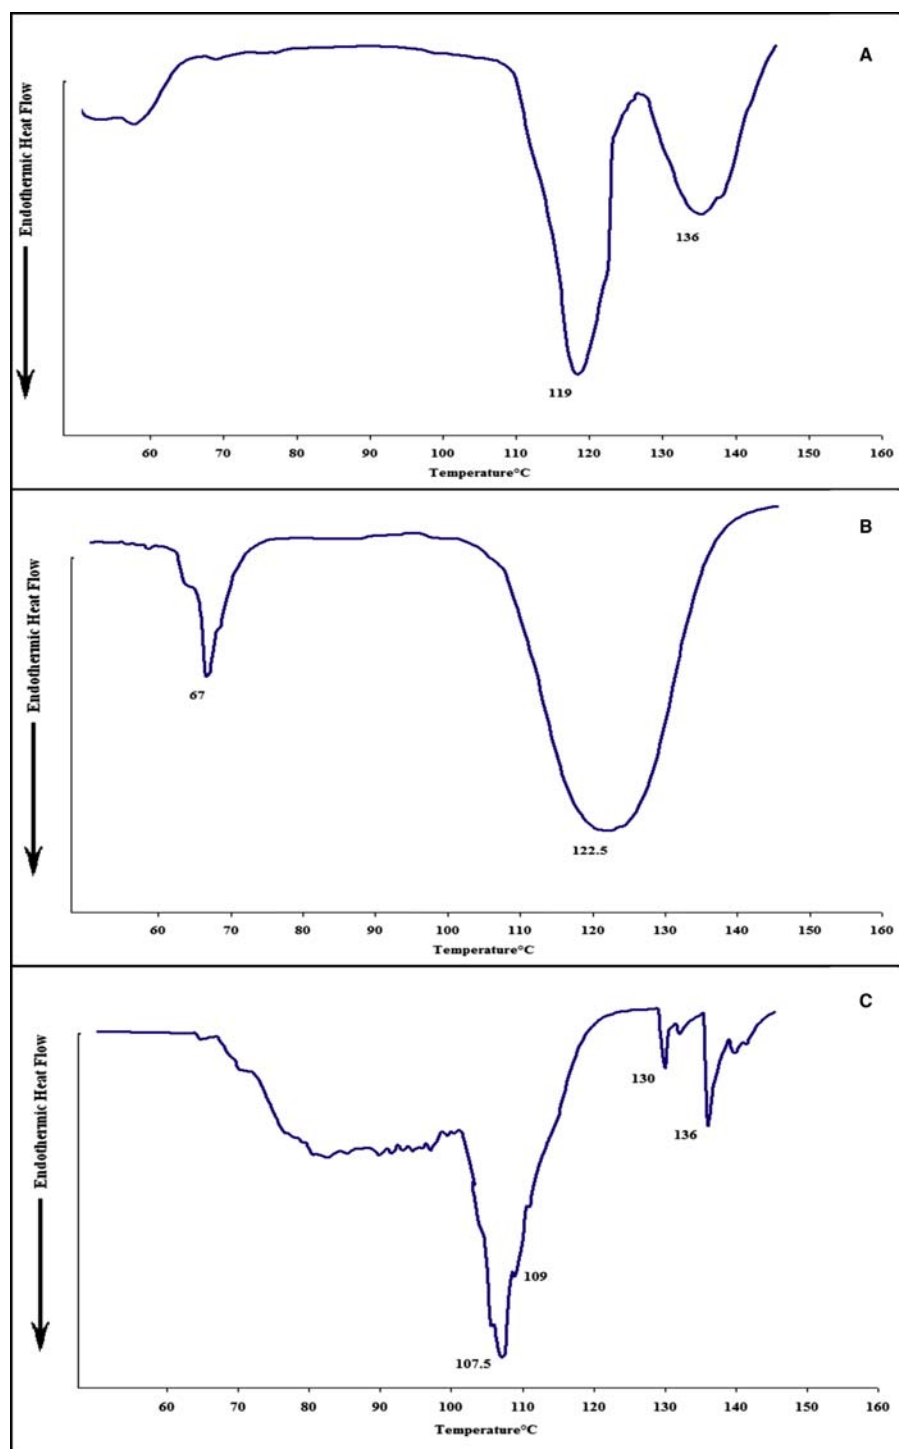

The effects of phenolic removal on isolated proteins from defatted and full-fat soybean and flaxseed were demonstrated by differential scanning calorimetry (DSC) ([Figs. 1–4](#); [Alu'datt, 2006](#); [Alu'datt et al., 2014](#)). The removal of free and bound phenolics from protein isolates of defatted soybean lowered the thermal stability of glycinin ([Fig. 1](#)). However, the sole removal of free phenolics from protein isolate from full-fat soybean led to a higher thermal stability of glycinin compared to the removal of both free and bound phenolics ([Fig. 2](#); [Alu'datt, 2006](#); [Alu'datt et al., 2014](#)).

In defatted soybean, the removal of both free and bound phenolics from isolated proteins also led to lower gel viscosity, greater elasticity and lower water holding capacity (WHC), compared to the initial isolated proteins without any phenolics removed ([Alu'datt, 2006](#); [Alu'datt et al., 2014](#)). In full-fat soybean, the removal of free phenolics caused an increase in gel viscosity, WHC, and thermal stability of glycinin compared to the removal of both free and bound phenolics ([Alu'datt, 2006](#); [Alu'datt et al., 2014](#)). In flaxseed, the removal of both free and bound phenolics from isolated proteins from either full-fat or defatted flaxseed caused a decrease in WHC, viscoelastic properties and thermal stability compared to the removal of free phenolics only ([Alu'datt, 2006](#); [Alu'datt et al., 2014](#)). For protein isolates from full-fat flaxseed, defatted flaxseed, full-fat soybean and defatted soybean, the effect of phenolic removal on WHC was as follows: 70.0, 63.0, 77.0 and 99 for protein isolates after removal of free phenolics, respectively, and 86.0, 93.0, 99.0 and 88.0 for protein isolates after removal of both free and bound phenolics, respectively, as compared to 59, 98, 74.0 and 98.0 for protein isolates before removal of phenolics. The aforementioned effects can be ascribed to the ability of phenolics to interact with proteins and form different types of complexes with high to low polarity ([Papadopoulou and Frazier, 2004](#); [Alu'datt, 2006](#); [Alu'datt et al., 2013, 2014, 2016a, 2016b, 2017d](#)), which will influence their bioavailability. The bioavailability of phenolics and their complexes with proteins depends on many factors, including phenolic chemical structure, co-existing food constituents and their composition, and genetic factors ([Scalbert and Williamson, 2000](#); [Alu'datt, 2006](#); [Alu'datt et al., 2017b, 2017d](#)). The presence of protein-phenolic complexes also influences the physiological properties and bioavailability of certain macro- and micro-nutrients ([Serafini et al., 1997](#); [Wollgast and Anklam, 2000a,b](#); [Alu'datt, 2006](#); [Jakobek, 2015](#); [Alu'datt et al., 2013, 2017d](#)).

[Fig. 5](#) shows the antioxidant activity of free and bound phenolics from isolated proteins from full-fat and defatted flaxseed and soybean meals ([Alu'datt, 2006](#); [Alu'datt et al., 2013](#)). The antioxidant capacity of protein-phenolic complexes in different plants such as soybean and flaxseed was found to be different from that of free phenolics ([Riedl and Hagerman, 2001](#); [Alu'datt, 2006](#); [Alu'datt et al., 2013, 2016b, 2017d](#)). [Alu'datt \(2006\)](#) and [Alu'datt et al. \(2016b\)](#) reported substantial antioxidant activities derived from the bound phenolics in residue and supernatant obtained after protein isolation from full-fat flaxseed and soybean, while minimal antioxidant activity was found for the bound phenolics in residues and supernatants obtained after protein isolation from defatted flaxseed and soybean ([Alu'datt, 2006](#); [Alu'datt et al., 2016b](#)). The contents of bound phenolics in residues and supernatants obtained after protein isolation from flaxseed and soybean showed strong positive correlations with corresponding antioxidant activity of phenolics. In comparison, the contents of free phenolics from supernatant and residue obtained after protein

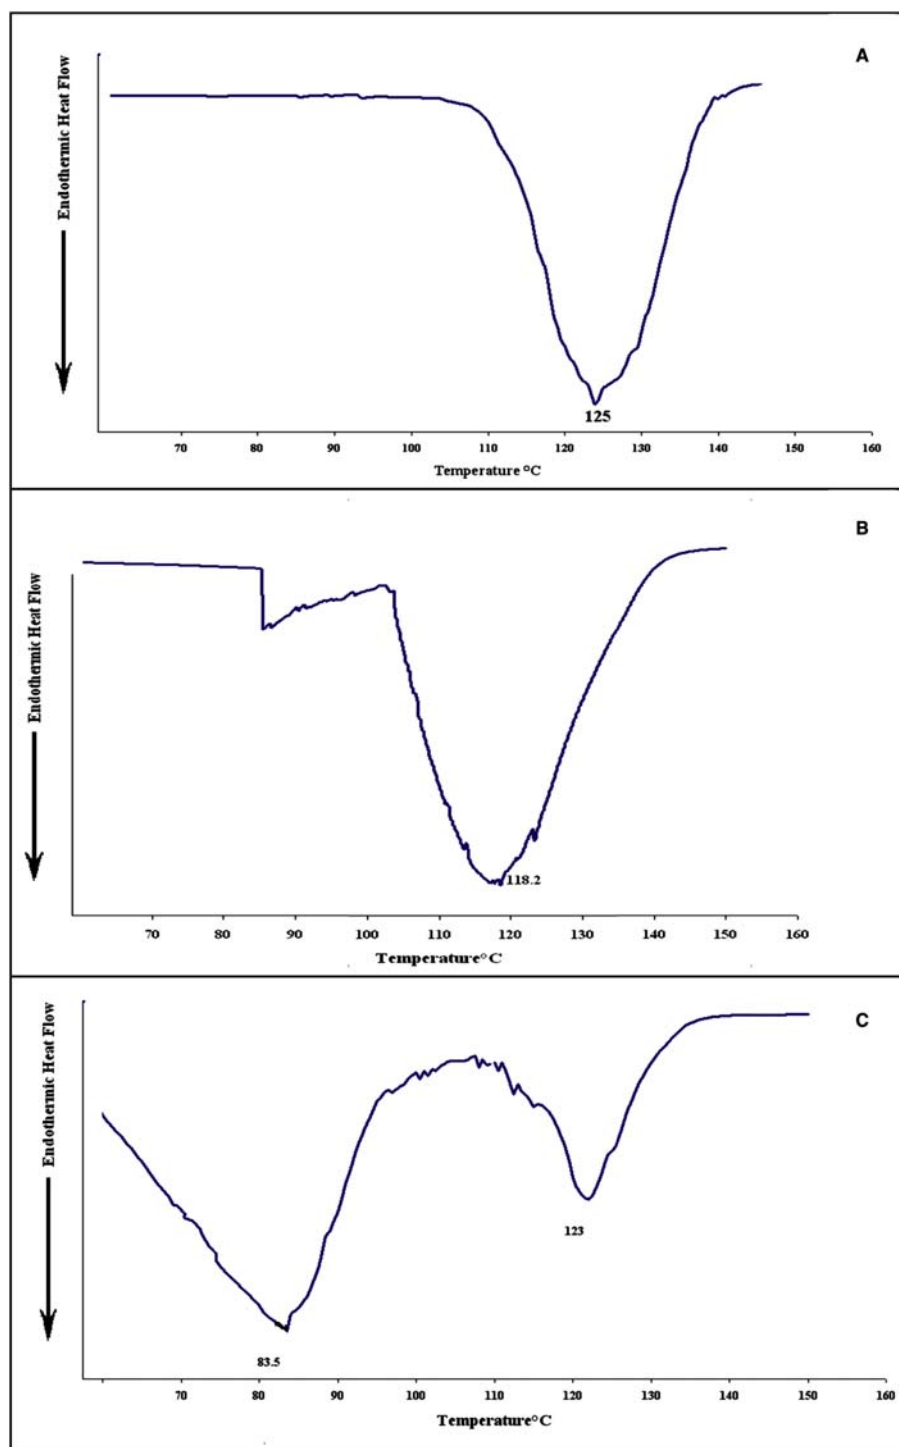

**Figure 1** Effect of the removal of free and bound phenolics from isolated proteins from defatted soybean on thermal stability assessed by differential scanning calorimetry (A) before removal free phenolics, (B) after removal of free phenolics, (C) after removal of free and bound phenolics (Alu'datt, 2006; Alu'datt et al., 2014).

**Figure 2** Effect of the removal of free and bound phenolics from isolated proteins from full-fat soybean on thermal stability assessed by differential scanning calorimetry (A) before removal free phenolics, (B) after removal of free phenolics, (C) after removal of free and bound phenolics (Alu'datt, 2006; Alu'datt et al., 2014).

**Figure 3** Effect of the removal of free and bound phenolics from isolated proteins from defatted flaxseed on thermal stability assessed by differential scanning calorimetry (A) before removal free phenolics, (B) after removal of free phenolics, (C) after removal of free and bound phenolics (Alu'datt, 2006; Alu'datt et al., 2014).

**Figure 4** Effect of the removal of free and bound phenolics from isolated proteins from full-fat flaxseed on thermal stability assessed by differential scanning calorimetry (A) before removal free phenolics, (B) after removal of free phenolics, (C) after removal of free and bound phenolics (Alu'datt, 2006; Alu'datt et al., 2014).

**Figure 5** Antioxidant activity of extracted free and bound phenolics from isolated proteins from full-fat and defatted flaxseed and soybean meals (Alu'datt, 2006; Alu'datt et al., 2013).

isolation from flaxseed and soybean only showed a weak positive correlation with antioxidant activities (Alu'datt, 2006; Alu'datt et al., 2016b). Alu'datt et al. (2017e) found that the contents of free, bound and total phenolics in sonicated protein isolates from soybean were lower than in non-sonicated protein isolates. They indicated that sonication increased the efficiency of the extraction of bound phenolics from soybean protein isolates.

## Conclusion

Protein-rich plants like soybean and flaxseed and their dietary products are of high nutritional importance worldwide. Their regular consumption is increasingly associated with appreciable health-promoting effects beyond their nutritional roles. In this respect, the protein-phenolic interactions that involve plant proteins have attracted a great deal of interest in the food and healthcare industries. Interactions with lipids may contribute additional beneficial effects. The interactions of phenolics with proteins and lipids in edible seeds (including fresh beans and pulses), cereals, fruits, vegetables, herbs and their derived food products warrant further research to better understand how such complexes form and exert their beneficial physiological effects *in vivo* and contribute to health promotion and disease prevention. Further research will also help elucidate how these complexes contribute to important functional properties in food matrices. Advancements in this field will support the development of novel food and non-food products with enhanced properties.

# Interactions Between Dietary Antioxidants and Plant Cell Walls

Catherine MGC Renard, INRA, Avignon, France

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Pectin** one of the major polysaccharide in primary plant cell walls and food additive E440, pectin is characterized by its high content of galacturonic acid, forming either homogalacturonan chains or rhamnogalacturonans. The carboxylic acids of galacturonic acids may be methylesterified, and the degree of methylation determines the conditions for gelification.

**Proanthocyanidins** oligo or polymeric flavan-3-ols; they are divided in various subclasses, the most common being procyanidins, which are composed exclusively of catechin or epicatechin subunits, and prodelphinidins, which include gallocatechin or epigallocatechin subunits. Proanthocyanidins are also known as condensed tannins.

**Carotenoids** C40 tetraterpenoid pigments presenting highly unsaturated carbon chains. Carotenes (like lycopene,  $\beta$ -carotene or  $\alpha$ -carotene) are strictly hydrocarbons; xanthophylls (like lutein, zeaxanthin, b-cryptoxanthin) are oxygenated.

**chromoplasts** plastids that accumulate carotenoid pigments, resulting in the yellow-red colours of ripe fruit, some flowers and roots, or senescent leaves.

## Introduction

“Antioxidant” is a generic terms that covers very diverse chemical structures with a common property, namely molecules that may prevent the oxidation of other molecules. This can involve different mechanisms: acting as electron donors, reducing reactive oxygen species, complexing transitions metal ions or regenerating other antioxidants such as tocopherols (vitamin E) (Dangles, 2012). Antioxidants, whether synthetic or of natural origin, are used in the food industry to prevent degradation of products leading to destabilization of emulsions (by protein oxidation for example), off-tastes (and toxic by-products, for example by lipid oxidation), or off-colours (oxidation of polyphenols). However “antioxidant” has become a household term for a diversity of natural plant molecules (dietary antioxidants) which were believed to participate to prevention of some degenerative diseases by contributing to the oxidative balance in vivo. This includes notably some vitamins (vitamin C, E), provitamin A and other carotenoids, and polyphenols. Many more secondary plant metabolites may have some antioxidant activity as assessed by the common colorimetric assays. This was a seductive simple hypothesis for the health effects of fruit and vegetables, which has been largely disproved. The scientific consensus is now that some of these molecules (or their metabolites) can interact at minute concentrations with specific sites in the body, which may lead to positive health effects for some, but detrimental for others if taken in excess (Bjelakovic et al., 2012), and which are in any case not related to their antioxidant property. It is only in the gastric compartment that dietary antioxidant properties may be relevant, as dietary antioxidants may be present in millimolar concentrations and exert protective actions on other food components (Dangles, 2012).

Three classes of dietary antioxidants have been specifically studied for their interactions with the plant cell walls: polyphenols, carotenoids, and ascorbic acid, with very different mechanisms and consequences. Polyphenols may bind to the cell wall components; this is a major factor in extraction of polyphenols to some beverages, notably wine, with consequences on their colour, bitterness and astringency (Le Bourvellec and Renard, 2012; Renard et al., 2011, 2017; Bindon et al., 2010a, 2012). This binding also decreases their bioaccessibility but ensures that a high load of polyphenols reaches the colon where they may be metabolised in bioavailable and active metabolites (Del Rio et al., 2010; Jaganath et al., 2006; Aura et al., 2005, 2013; Appeldoorn et al., 2009). Bio-encapsulation of the lipophilic intracellular carotenoids by the hydrophilic cell walls decreases their bioaccessibility and notably explains the very low efficiency observed for provitamin A carotenoids from raw fruit and vegetables (Van Buggenhout et al., 2010; Lemmens et al., 2009, 2010, 2011; Tiback et al., 2009; Colle et al., 2013; Mutsokoti et al., 2016, 2017; Palmero et al., 2014; Edwards et al., 2002). Ascorbic acid, in spite of its antioxidant reputation, actually appears to act as prooxidant and degrade cell wall polysaccharides (Airianah et al., 2016; Fry, 1998; Fry et al., 2001).

## General Mechanisms

Five mechanisms can be involved in interactions between dietary antioxidants and the plant cell walls: protection of plant cells, limit to diffusion (of soluble molecules or enzymes), bio-encapsulation, affinity for specific molecules, and chemical reactions (Fig. 1).

**Figure 1** The five mechanisms involved in interactions between dietary antioxidants and plant cell walls.

## The Plant Cell Wall

The plant cell wall is an organite that surrounds plant cells; its main roles are support for the plant organs and exchange with the external medium. It defines the shape and size of cells and is responsible for intercellular adhesion within a plant tissue. In foods commonly consumed by Humans, type I cell walls are dominant: They are thin, hydrophilic and highly hydrated. They are composed primarily of polysaccharides, with load-bearing cellulose microfibrils, embedded in an amorphous matrix composed mainly of pectins and hemicelluloses (xyloglucans, mannans, arabinoxylans) (Carpita and Gibeau, 1993). Pore size in the plant cell walls have been estimated to be about 3–4 nm (Carpita et al., 1979), i.e. while small water-soluble molecules may diffuse through plant cell walls, proteins above 10–20 kDa are restricted. Pectin is responsible for tensile strength of the cell wall, and is also extensively used as a gelling agent or stabilizer in foods. It is also the plant cell wall component which changes the most with ripening (Brummell, 2006; Goulao and Oliveira, 2008; Redgwell et al., 1997) or processing (Ng and Waldron, 1997), and its degradation may increase pore size, while its reticulation (typically by calcium after partial demethylation) increases resistance (Cybulska et al., 2011; Muller and Kunzek, 1998). Plant cell walls are also the main origin of dietary fibers in Human foods. They determine the texture of fruit and vegetable-based foods (Waldron et al., 1997): plant cell walls are responsible for the cohesion and structure of intact fruit or vegetable pieces, cell wall “ghosts”, more or less aggregated, produce the texture of pureed fruit and vegetables (Espinosa-Munoz et al., 2013; Leverrier et al., 2016), and solubilized polysaccharides, mainly pectins, or microfibrillar complexes have gelling and thickening properties (Chan et al., 2017).

## Protection of Plant Cells

This is a mechanical effect linked to the *in vivo* role of cell walls. It has not been studied specifically for dietary antioxidants, but one may assume that they will be affected similarly to macrocomponents. Soft plant foods (e.g. tomato, ripe fruits ...) are swallowed as millimetric or centimetric pieces. Median particle sizes of 2 mm are reported for raw carrots or olives, and 1 cm for tomato or ripe papaya (Jalabert-Malbos et al., 2007; Peyron et al., 2004). Within these pieces plant cells are intact and intracellular components are still compartmented. This delays their liberation in the gut as action of gastrointestinal enzymes and peristalsis actually have limited efficiency in plant tissue breakdown or plant cell lysis: recognizable shredded carrots and intact plant cells have been reported after digestion in ileostomic patients (Faulks et al., 2004; Livny et al., 2003; Tydeman et al., 2010). In simulated gastric digestion conditions, raw carrots lose less than 10% of their dry weight (mainly sugars) in weakly acidic conditions (pH 5.3, i.e. start of digestion) but up to 60% in acidic conditions (pH 1.8) (Kong and Singh, 2011); this is accompanied by swelling of plant cell walls, probably due to degradation of pectins. Size of particles, either after processing (grinding) or mastication, and the proportion of open cells is thus an important factor in bioaccessibility.

## Limit to Diffusion

Once plant cells are lysed (degradation of the plasmalemma and intracellular membranes), the plant cell walls constitute a barrier with a limited porosity; as such they slow the diffusion of water-soluble molecules and the ingress of enzymes to the plant tissue (Kong and Singh, 2004; Mandalari et al., 2008). There is little scientific information on this phenomenon during food processing, and almost none during digestion. Diffusion and leaching has been modelled for glucosinolates in cabbages, as they may either diffuse and leach as such (e.g. during processing in a large amount of water) or be degraded by myrosinase to isothiocyanates (Volden et al., 2008; Nugrahi et al., 2015). As myrosinase is present in the same tissues but different cells than glucosinolates, enzymic degradation depends on cell lysis followed by diffusion and leaching (Verkerk and Dekker, 2004), and is affected differentially by processing and cooking methods.

Much more attention has been devoted to the effect of dietary fibers as a limit to bioaccessibility in the gut: dietary fibers increase the viscosity of the gastrointestinal liquid, and this acts *per se* to slow diffusion of all molecules, including digestive proteases, lipases or amylases (Capuano, 2017; Kumar et al., 2012; Gidley, 2013). This has been highlighted for the glycaemic index: increased viscosity of the chyme slows down gastric emptying, it slows starch digestion by limiting amylase binding to their substrate, and it slows diffusion of glucose to the gastrointestinal mucosa. Though rarely specifically studied, these mechanisms are also involved in bioaccessibility of dietary antioxidants, and their relevance has been shown for carotenoids (Carrillo et al., 2017; Mutsokoti et al., 2015; Palmero et al., 2016).

## Bio-Encapsulation

Bio-encapsulation describes the mechanisms by which the plant cell walls (among others) as such act as a barrier between fat-soluble dietary antioxidants and the outer medium. For carotenoids and vitamin E, a lipid continuum is needed between the cell and the fat phase of the food to allow integration during digestion in mixed micelles (Castenmiller and West, 1998; Castenmiller et al., 1999; Kopeck and Failla, 2017; Desmarchelier and Borel, 2017; Fernandez-Garcia et al., 2012; Rodriguez-Amaya, 2010; Schweiggert and Carle, 2017). The plant cell walls prevents establishment of this continuum, and its degradation, either chemical or mechanical, allows rupture of this barrier. This will be detailed below for carotenoids, for which this mechanism and the effects of food processing on bioaccessibility have been extensively studied.

### Affinity for Specific Molecules

Polyphenols are highly reactive molecules that bind to macromolecules (Le Bourvellec and Renard, 2012). Though this is mostly known for proteins, with perception of astringency (Schwarz and Hofmann, 2008; Zanchi et al., 2008; de Freitas and Mateus, 2012; McRae and Kennedy, 2011) or inhibition of (digestive) enzymes (Rohn et al., 2001, 2002), they also have affinity for polysaccharides such as constitute the plant cell walls (Renard et al., 2017; Bindon et al., 2010a,b, 2012; Braham et al., 2017; Watrelot et al., 2013, 2014; Bindon and Kennedy, 2011; Bindon and Smith, 2013; Cerpa-Calderon and Kennedy, 2008; Carn et al., 2012). Affinity constants are much lower than for proteins, but the plant cell walls constitute a quantitatively major component of the plant tissues in which polyphenols are present. Impact of binding of polyphenols to plant cell walls has mostly been studied for tannins, and will be presented below.

### Chemical Reactions

Vitamin C is a small, water-soluble molecule and as such may diffuse almost freely from plant tissues, with only limited hindrance by plant cell walls. However it has been demonstrated to exert a pro-oxidant effect and cleave the cell wall polysaccharides, with consequences on texture (Airianah et al., 2016; Fry, 1998; Fry et al., 2001).

## The Interactions Between Polyphenols and Plant Cell Walls

Mechanisms of these interactions are described in Chapter “Interactions between polyphenols and macromolecules”. This paragraph will mostly focus on consequences of the interactions in terms of food processing and digestion.

### Polyphenols

Polyphenols are a very diverse class of molecules (Fig. 2), and their antioxidant properties are linked to the presence of ortho-diphenol groups (Dangles, 2012). Polyphenol intake in a typical Western diet is mostly from beverages (Manach et al., 2004): tea (with flavan-3-ols such as epigallocatechin gallate), chocolate (with procyanidins i.e. oligomers of catechin and epicatechin), coffee (with caffeic acid and its quinic esters chlorogenic acids), wine (with complex structure derived from proanthocyanidins and condensation of anthocyanins, or stilbenes such as resveratrol). Fruit and vegetables have a lower contribution, in which proanthocyanidins, flavonols, anthocyanins (characterized by their red colour), or hydroxycinnamic acids are the most common classes. All these polyphenols are located in the vacuoles of the plant cells.

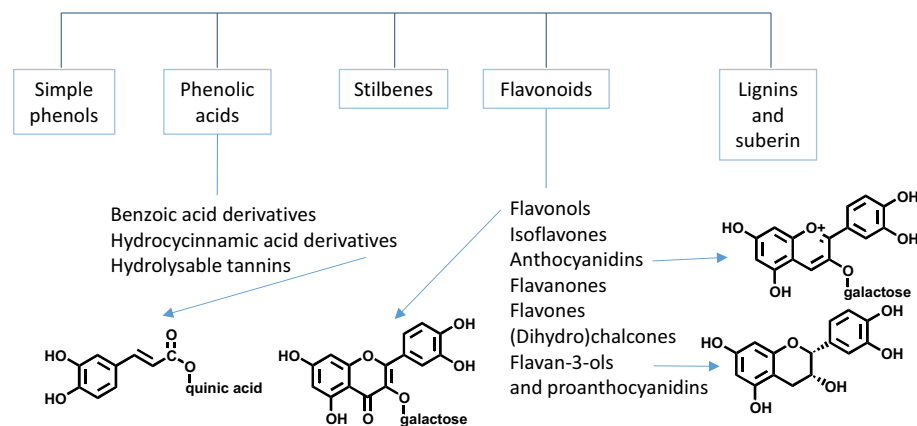

### Investigated Impacts

Polyphenols, initially present in the vacuoles, bind spontaneously and non-covalently to macromolecules, including the plant cell wall polysaccharides (Le Bourvellec and Renard, 2012). This binding gives rise to polyphenol – plant cell wall complexes whenever the plant cells are lysed or ruptured, either physically (e.g. grinding, pressing) (Le Bourvellec et al., 2007), by physical phenomena that lead to loss of membrane integrity (e.g. heating (Le Bourvellec et al., 2011; Le Bourvellec et al., 2013; Le Bourvellec et al., 2012), pulsed electric fields, power ultrasound and others) or by senescence. These interactions have mostly been studied in relation with the extractability of polyphenols to beverages, and in particular to wine by the groups of Smith, Kennedy & Bindon (Bindon et al., 2010a,b, 2012; Bindon and Kennedy, 2011; Bindon and Smith, 2013), Gidley at University of Queensland (Phan et al., 2015, 2017; Liu et al., 2017; Padayachee et al., 2012), and Gomez-Plaza (Bautista-Ortin et al., 2015; Bautista-Ortin et al., 2015; Bautista-Ortin et al., 2014; Bautista-Ortin et al., 2016) or to apple juice by Le Bourvellec & Renard (Renard et al., 2011, 2017; Le Bourvellec et al., 2007). The main focus was on proanthocyanidins (or condensed tannins), because of their role in wine or cider body and astringency, and on anthocyanins, because of their role in wine colour.

These polyphenol – cell wall complexes are also the major source of “non-extractable polyphenols” such as studied by Perez-Jimenez & Saura-Calixto (Perez-Jimenez et al., 2013; Arranz et al., 2010), and are indeed a very common artefact explaining detection of polyphenols in plant cell walls or “antioxidant polysaccharides” by numerous authors.

A special notice should be taken for the existence in the cell walls of polysaccharides which are biosynthetically esterified by hydroxycinnamic acids, primarily ferulic acid. Feruloylated arabinoxylans are present in cereals (with higher concentrations in the bran) (Saulnier and Thibault, 1999) and feruloylated pectins in some Chenopodiaceae such as sugar-beet (Saulnier and Thibault, 1999; Fry, 1983) or quinoa (Renard et al., 1999). They can contribute to antioxidant properties of derived foods, with marked effect of particle size. However it should be kept in mind that presence of feruloylated polysaccharides is the exception and not the rule for primary plant cell walls. Lignin would also be an unextractable polyphenol, but it is not normally encountered in significant amounts in Human foods as lignin deposition is a sign of plant cell wall secundarization leading to hard textures, such as in wood, straw or bran.

Classification and typical structures of major food polyphenols

**Figure 2** Chemical formulae of some major dietary antioxidants in plant foods.

### Transfer of Polyphenols From Plant Tissue to Beverages

The main technological impact of the interactions between polyphenols and cell walls (or other polysaccharides) concerns proanthocyanidins and the extraction of juices. There is a marked discrepancy between the amounts of proanthocyanidins present in the fruits and the low concentrations often found in the juices or musts (Renard et al., 2011; Brahem et al., 2017; Le Bourvellec et al., 2007; Bautista-Ortin et al., 2015; Guyot et al., 2003). Not only the concentrations but also the structures are different: the extracted proanthocyanidins generally have much lower degrees of polymerization. There has been attempts to link the evolution of cell walls (notably in grape skin) with the extraction of tannins (Bindon et al., 2010a, 2012; Bautista-Ortin et al., 2015a,b, 2016). In pear or apple, which are simply pressed after grinding, the extraction decreases with increased maturity levels (Brahem et al., 2017). In wine phenomena are more complex due to the importance of the diffusion of polyphenols from skin or seed during maceration and fermentation (Bindon et al., 2010, 2012; Bindon and Kennedy, 2011).

### Bioaccessibility and Colonic Fermentation

Bioaccessibility of polyphenols in relation to their health effects is also impacted by binding to plant cell walls (Saura-Calixto et al., 2007). Many polyphenols have low to very low bioavailabilities even in pure form (Landete, 2012), and binding to plant cell walls or to plant cell wall components such as pectin further decreases their bioaccessibility. However there is strong evidence that the colonic fermentation metabolites (Dall'Asta et al., 2012) play a major role in the health effects of many polyphenols (Jaganath et al., 2006). For flavonoids, colonic fermentation metabolites, notably ring fission metabolites such as hydroxyphenyl- $\gamma$ -valerolactones, are efficiently absorbed. Presence of plant cell walls facilitates colonic fermentation of polyphenols, probably by providing substrates for bacterial growth (Aura et al., 2005; Perez-Jimenez et al., 2013; Bazzocco et al., 2008; Saura-Calixto, 2010). Therefore it is likely that the interactions between polyphenols and plant cell walls are favorable rather than detrimental when taking into account the whole picture and the whole gut.

### Structure–Affinity Relationships

The affinity of polyphenols for plant cell walls increases with molecular weight (specially for oligo and polymeric proanthocyanidins) and number of hydroxyl groups of the polyphenols (Le Bourvellec et al., 2004; Le Bourvellec and Renard,

2005; Renard et al., 2001). Galloylation increases the affinity, but less than molecular weight increase, as observed by comparing prodelphinidins and procyanidins (Le Bourvellec et al., 2004). The nature of the interactions is not totally elucidated yet: both hydrophobic and hydrogen bonds are involved for proanthocyanidins (Le Bourvellec and Renard, 2012; Watrelot et al., 2013, 2014; Le Bourvellec et al., 2004). In addition for anthocyanins ionic bonds might form between the positively charged anthocyanins and the negatively charged pectins (Padayachee et al., 2012; Buchweitz et al., 2012a,b). Concerning plant cell wall polysaccharides, highest affinities are found for pectins, and specially highly methylated pectins (Watrelot et al., 2013), but cellulose is also involved (Phan et al., 2015, 2016, 2017).

## Bio-Encapsulation of Carotenoids by Plant Cell Walls

### Carotenoids

Common dietary carotenoids are highly hydrophobic C40 tetraterpenoid pigments (from yellow to red) (Fig. 2) (Saini et al., 2015). They are subdivided in 2 classes: carotenes, which are exclusively hydrocarbons ( $\beta$ -carotene and lycopene are the main molecules in foods) and xanthophylls, which are oxygenated (such as lutein). They are located in the plant cells inside plastids: they are found in chloroplasts of leaves and accumulate in chromoplasts of fruit and vegetables where they are embedded within a complex organisation of lipids and proteins with very diverse substructures (crystalline, globular, fibrillar, membranous, tubular) (Schweiggert and Carle, 2017; Schweiggert et al., 2012). Their antioxidant properties are linked to the polyene chain and the presence of functional groups (hydroxyl or carbonyl) in the terminal ring (Kopeck and Failla, 2017; Rodriguez-Amaya, 2010).

### Bioaccessibility of Carotenoids

Carotenoids are better absorbed from processed fruit and vegetables, and many investigations have been carried out in the last ten years to understand the mechanisms (Castenmiller and West, 1998; Desmarchelier and Borel, 2017; Nagao, 2014). There are many barriers to dissolution of carotenoids from within a plant matrix, which explain why very low bioaccessibilities are reported. To become bioaccessible, they must be liberated from the food matrix to dissolve in the fat phase of the gastro-intestinal lumen. This is a prerequisite for their incorporation in bile salt mixed micelles produced by digestion of triglycerides and phospholipids, and which may reach the intestinal mucosa for absorption. An important point is that the effects of bio-encapsulation also vary with the carotenoid, and in particular with its hydrophobicity. In the same food matrix, xanthophylls are generally much more bioaccessible than carotenes.

Carotenoids bioavailability is further influenced by many factors which will not be treated here, such as the carotenoid itself and its conformation, the presence of other effectors such as naringenin, and the host's nutritional status and genotype (Humans have difference expression of receptors for carotenoids) (Desmarchelier and Borel, 2017; Borel, 2003; Borel et al., 2005; Reboul et al., 2006).

Carotenoids are found in diverse physical forms inside plastids, where they may be dissolved in lipids but also form more of less complex aggregates or associate with proteins. Next, the hydrophilic cell walls of the individual cell but even more of the neighbouring cells forming a plant tissue constitute natural barriers with a porosity which is not compatible with the size of the lipid droplets. Carotenoids liberation from plant tissues is thus limited by their structural features and by at least two levels of bio-encapsulation, by substructures of the plastids and by cell walls. In the next paragraph only encapsulation by the cell walls will be detailed, as it has been demonstrated that cell breakage is the most efficient step in increasing bioaccessibility. This has been studied in detail notably by Hendrickx and Van Loey's group in relation with diverse food processing techniques.

### Food Processing and Bioaccessibility of Carotenoids

Thermomechanical processes appear to be the most efficient to increase carotenoid bioaccessibility (Lemmens et al., 2011; Livny et al., 2003; Knockaert et al., 2011). Bioaccessibility decreases as the tissue structure increases: enriched oils > chromoplast fractions > small cell clusters > large cell clusters (Palmero et al., 2013). Decreasing the size of cell clusters facilitates carotenoids bioaccessibility, which has been demonstrated with raw carrot tissues to be proportional to the available surface of the particles (Lemmens et al., 2010; Tydeman et al., 2010). Heat treatments also generally lead to increased bioaccessibility of carotenoids, though some conflicting observations are reported for example for lutein from spinach (Faulks et al., 2004) or when intact cell ghosts are generated (Tydeman et al., 2010a, b). The sequencing of homogenization and cooking (homogenization prior to or after cooking) has contrasting impacts: for example while homogenization prior to cooking leads to higher bioaccessibility from sweet potato (Bengtsson et al., 2009, 2010), cooking prior to homogenization increases bioaccessibility for tomato (Page et al., 2012). Heat treatments rupture the natural barriers to carotenoid bioaccessibility and enhance cell cluster dissociation. This has been explained by pectin degradation, which may lead to cell breakage, facilitates cell separation and increases cell wall porosity. Ripening of fruits, which is also characterized by softening caused by pectin degradation, also increases carotenoid bioaccessibility (Ornelas-Paz et al., 2008; Victoria-Campos et al., 2013). By contrast, high pressure processing decreases carotenoid bioaccessibility (Gupta et al., 2011; Barba et al., 2017). High pressure processing better preserves tissue structure, by favouring pectin reticulation through action of endogenous pectinmethylesterases that liberate free galacturonic acids which form a calcium network, thus strengthening cell walls and intercellular adhesion (Van Buggenhout et al., 2009; Duvetter et al., 2009).

Recent experiments with non-thermal food processing technologies mitigate the importance of bio-encapsulation by more or less intact plant cell walls for carotenoid bioaccessibility. High pressure homogenization consists in forcing a fluid through a narrow valve. This generates strong shear stresses, cavitation and turbulence that rupture cell walls and decrease the size of particles in plant tissue suspension below that of intact cells. However, high pressure homogenization only has slight effects on carotenoid bioaccessibility, and even decreases the bioaccessibility of carotenoids added in oil (Mutsokoti et al., 2015; Palmero et al., 2016; Knockaert et al., 2012; Panozzo et al., 2013; Svelander et al., 2011). This was also observed when high pressure homogenization was applied to oil droplets in pectin-containing suspensions, specially with pectins of low degree of methylation (Aschoff et al., 2015; Sriwichai et al., 2016; Verrijssen et al., 2016). A similar effect i.e. decrease of bioaccessibility in spite of cell rupture is observed with ultrasound treatments (Anese et al., 2015). This phenomenon was ascribed to formation of a fibrillar network or gel during food processing. Thus, plant cell walls and their solubilised pectins may decrease bioaccessibility of carotenoids which were not initially encapsulated in plant cells, by formation of a new network or more generally by increased viscosity slowing the complex mechanisms by which carotenoids are transferred to mixed micelles.

## Conclusion

Because most dietary antioxidants are of plant origin, they can come in contact with plant cell walls at various stages: during processing, where plant cell walls act to limit their extractability, during digestion, where plant cell walls or their derived dietary fibers limit bioaccessibility, or during colonic fermentation where both are modified by the gut microbiota. Sequestration and protection can both be found.

Although the first decade of the XXI<sup>st</sup> century has seen increased awareness of these interactions, and more generally of the role of food structure on nutrition, there are still many unanswered questions. Major complexity is linked to the nature and diversity of the plant cell walls. Although the main cell wall constituents are by now well identified, their precise structures and interactions are still only basically understood. For example, knowledge on plant cell wall porosity and its evolution relies on very few data. Different plant cell walls are synthesized in different plant species, varieties and tissues, and they evolve differently during growth, maturation and senescence, to say nothing of food processing. All of this will affect their physicochemical properties (porosity, hydrophobicity, swelling) and capacity to interact with antioxidants.

### Introduction

Since the free radical theory of ageing was proposed by Harman (1956), a broad range of investigations have been conducted on the relationship between oxidative damage and various degenerative diseases and have led to various publications in the scientific literature. Reactive oxygen species (ROS), including superoxide anion radical ( $O_2^{\cdot-}$ ), singlet oxygen ( $^1O_2$ ), hydrogen peroxide ( $H_2O_2$ ) and the highly reactive hydroxyl radical ( $\cdot OH$ ), are formed as natural by-products of the normal metabolism of molecular oxygen. ROS behave like a double-edged sword in the prevention and promotion of some diseases. Normally ROS exist in all aerobic cells in a physiological balance with biochemical antioxidants, and are essential signalling molecules of certain normal biological and physiological processes such as cellular responses to noxia, immune responses, and defences against infectious agents. Excessive ROS production in the absence of adequate antioxidant defences would lead to an imbalance between prooxidant load and body's antioxidant defence causing nutritional and physiological oxidative stress. Over accumulation of ROS cause oxidative damages to cellular membranes, structure and biomolecules such as proteins, lipids, carbohydrates and DNA, resulting in many degenerative diseases or disorders such as inflammation, cardiovascular diseases, cancers ischaemia-reperfusion injury and ageing. Therefore, in the past decades, a great deal of interest has been directed towards searching potent antioxidants, particularly those naturally occurring species such as polyphenols like flavonoids, that have the ability to minimize or prevent oxidative damages by preventing or inhibiting ROS formation and by quenching the generated ROS. Efforts have also been made to promote the health-promoting properties and counteract the disadvantages of polyphenols in practical applications, through exploring effective preservation of polyphenols or examining desired synergies between antioxidants under simulating or real handling, manufacturing and digestive conditions.

### Chemical Structure and Antioxidant Activity of Flavonoids

Flavonoids consist of a large group of secondary plant metabolites that are mainly synthesized from the aromatic amino acid phenylalanine (via the shikimic acid pathway) and acetic acid or their derivatives. So far, more than five thousand of flavonoid compounds have been identified. Flavonoids have received increasing attention mainly owing to their intrinsic structures and properties. Flavonoids contain three phenolic rings (two benzene rings, A and B rings; one heterocyclic pyrane ring, C) and present a unique benzo- $\gamma$ -pyrone structure (Fig. 1). The differences in substitution on three rings (e.g. the type, number, distribution and orientations in space) lead to various flavonoid derivatives with distinct structures and properties such as those commonly included in human diets like flavonols, flavones, anthocyanidins, flavanols (catechins), flavanones and isoflavones. Flavonoids occur as glycoside and methylated derivatives besides aglycones with the majority as glycosides in plants (e.g. arabinosides, galactosides, glucosides, rhamnosides and xylosides), except for catechins (i.e. mainly in the form of aglycones) (Smith et al., 2000). The chemical structures of flavonoids determine their modes of molecular action such as delocalization of electrons, rearrangements of molecules, ROS scavenging, intra-/inter-molecular hydrogen bonding, metal ion chelation, steric effects and electronic properties. The geometry and electronic properties are greatly affected by the position of OH groups in flavonoids. O-Methylation of the hydroxyl groups of flavonoids generally leads to reduced radical scavenging capacity. Procyanidins with a higher degree of polymerization tend to exhibit greater effectiveness against various radical species.

Epidemiological, animal and clinical studies have linked the consumption of flavonoid-rich diet with a reduced risk of cardiovascular diseases, and indicated the underlying mechanisms involving the potent antioxidant capacity, improved endothelial function, anti-thrombotic effect and lipid-lowering property of various flavonoids. Dietary flavonoids act as important endogenous antioxidants to mediate cardioprotective effects (Stangl et al., 2007), as shown in chemical-based and cellular assays as well as *in vivo* experiments. Certain flavonoids exhibit higher antioxidant activity than some commonly known antioxidants such as vitamins C and E (Prior and Cao, 2000). The biological behaviours and activities of flavonoids depend on their chemical structures (including basic structure, configuration, number and distribution of hydroxyl groups and type and degree of substitution of functional groups) as well as physicochemical characteristics such as molecular size, solubility,  $pK_a$  and lipophilicity. Poor solubility of flavonoid aglycones in water, along with their short residence in the intestine and low absorption, presents minimal risks to humans in terms of irritancy, allergenicity and toxicity. Flavonoid glycosides generally have greater absorption than corresponding aglycones e.g. the absorption of quercetin glucosides could be twice as much as quercetin in humans (Hollman et al., 1995). The dietary flavonoids liberated from foods, depending on chemical structures, may be absorbed from the small intestine or transported to the colon to undergo molecular changes before absorption. Oligomeric flavonoids may be broken down to monomers or dimers under the acidic environment in the stomach. Hydrophilic flavonoid glycosides such as quercetin glucoside may be transported across the small intestine by the intestinal  $Na^+$ -dependent glucose cotransporter (SGLT1), hydrolysed by  $\beta$ -glucosidases (e.g. lactase phloridzin hydrolase) outside the brush border membrane of the small intestine, or hydrolysed by microflora in the colon (Day et al., 2000;

**Figure 1** Basic structure of flavonoids (A) and the chemical structures of six primary groups of polyphenols (B).

Hollman et al., 1999; Scheline, 1973). Isoflavones probably exhibit the highest bioavailability among the flavonoid family (Spencer et al., 2000).

The bioactivities of flavonoids and associated mechanisms of action depend on not only their native form (aglycones or glycosides) but also their metabolites resulting from phase 1 and/or phase 2 metabolisms. Aglycones of flavonoids usually exhibit greater antioxidant capacity but lower bioavailability compared to their corresponding glycosides. The flavonoid products derived from phase 2 metabolism often exhibit lower antioxidant activity compared with the initially ingested flavonoids. The pathological mechanisms are involved in the antioxidant actions of consumed flavonoids through 1) upregulating or protecting the endogenous antioxidant defences e.g. inducing antioxidant enzymes; 2) inhibiting pro-oxidant enzymes such as oxidases; 3) inhibiting redox sensitive transcription factors; 4) mitigating oxidative stress caused by nitric oxide; 5) suppressing lipid peroxidation in the local biological environment; 6) complementing and/or enhancing antioxidant properties of small molecule antioxidants (Babu et al., 2006; Cabrera et al., 2006; Chan et al., 1997; Khan et al., 2006; Procházková et al., 2011; Suzuki et al., 2006; Vinson and Zhang, 2005). Further, the necessity of balance between the antioxidant and prooxidant characteristics of flavonoids enables them as multitarget agents to exert effective biological activities. Only a small proportion of flavonoids' therapeutic properties probably result from their direct antioxidant properties, with the majority of efficacy likely due to their pro-oxidant action and direct interaction with target biomolecules (Chen et al., 2000; Clifford, 2004; Crozier et al., 2009). Flavonoids can bind cellular targets with high sequence selectivity such as those planar molecules with an extended aromatic core (like quercetin) can bind to and stabilize human telomeric G-quadruplex DNA Tel7 or Tel22 sequence via end-stacking ( $\pi$ - $\pi$  stacking) and external binding (Tawani and Kumar, 2015). Flavonoids containing a 1,2-diphenol (catechol moiety), 1,4-diphenol (hydroquinone moiety) or 1,2,3-triphenol (galloyl moiety) would undergo oxidation upon ingestion and for flavonoid quinones. These flavonoid quinones possess electrophilic properties and can readily react with the thiols in protein Cys residues to form cysteinyl flavonoid adducts and induce cytoprotective proteins, which represents a major mechanism for their anti-inflammatory and anticancer effects (Awad et al., 2003; Crozier et al., 2009; van Zanden et al., 2003). Some flavonoids, although do not contain a catechol, hydroquinone or galloyl moiety, can still induce cytoprotective proteins and exhibit anti-inflammatory and anti-cancer properties, through transforming to intermediates like 1,2-diphenols by phase 1 enzymes and then further oxidized into quinones (Sahin et al., 2012; Yu et al., 2012). Further, flavonoids are well known natural pigments that can undergo excited-state intramolecular proton transfer (ESIPT) (via an intramolecular hydrogen bond between the C=O and 3-OH groups) and exhibit dual fluorescence behaviours and chromophore frame-based selective binding to proteins (Xiao et al., 2011). The ESIPT in flavonoids is a microenvironment-dependent process e.g. considerably sensitive to the external hydrogen-bonding interference from the surrounding environment.

### Insight Into the Antioxidant Interactions Involving Some Common Flavonoids

Various flavonoids co-exist in Nature and in human diets. The bioactivity of a natural mixture or a formulated combination of flavonoids is determined mainly by individual chemical structure and their mass ratio (rather than individual activity) as well as the interactions among these phenolic compounds. Flavonoids may interact with one another, or with other water-soluble and lipid-soluble substances because of their amphiphilicity, prior to consumption and after ingestion, digestion and absorption. Such interactions are rather complicated considering the diversity and complexity of the flavonoids in human daily diets and the variations in individual's metabolic conditions along with the whole digestion and absorption process. Therefore, the detected health-promoting properties of flavonoid-rich diets in *in vitro* or *in vivo* studies resulted from different interactive effects, additivity, synergism or antagonism, which reflect the combined effect owing to the interaction of two or more flavonoids is equal, greater and lesser than the theoretical sum of the separate effect of each flavonoid, respectively. Some examples of such interactions between flavonoids are provided as follows.

#### Quercetin and Other Flavonoids

Quercetin (3,5,7,3',4'-pentahydroxyflavone) is a member of the flavonol family and has two aromatic rings (A and B) linked by an oxygen heterocycle (ring C) (Fig. 2). It accounts for approximately 60%–75% of total flavonoid intake (Sampson et al., 2002).

**Figure 2** Chemical structure of quercetin.

Accumulating evidence has shown that quercetin is a powerful antioxidant with a potent antiradical property towards hydroxyl/peroxyl radicals and superoxide anions, and possesses a range of biological effects including anti-inflammatory, antineoplastic and cardio-protective activities. The antioxidant properties of quercetin are greatly attributed to its ability to decrease the amount of ROS by inhibiting ROS formation and promoting ROS removal, through mechanisms such as inhibition of various ROS-generating enzymes, chelation of metals involved in ROS generation, down-regulation of expression of relevant enzymes, up-regulation of expression of endogenous synthesizing enzymes, inducing of the synthesis of ROS-removing enzymes, and/or direct ROS scavenging action via single-electron transfer and hydrogen atom-donation. Both synergic and antagonistic effects were found for the combinations of quercetin and other flavonoids. Quercetin, epicatechin, rutin and resveratrol in red grape exhibited a dose-dependent synergy in antiradical effect towards ONOO<sup>-</sup> (Iacopini et al., 2008). The combination of 25 µM catechin and 5 µM quercetin, although using either alone had no effect on platelet function, could act synergistically to inhibit platelet adhesion to collagen and collagen-induced platelet aggregation by virtue of their antioxidant effect (Pignatelli et al., 2000). In the ferric reducing antioxidant power (FRAP) assay, the combined use of epicatechin and quercetin-3-β-glucoside exhibited the greatest synergistic effect whilst myricetin along with quercetin resulted in an antagonistic effect. Quercetin and epicatechin may provide a synergistic neuro-protection against ischaemic injury via activation of Akt- and Ca<sup>2+</sup>-mediated signalling pathways (Nichols et al., 2015). A negative synergistic effect on the antiradical activity was reported for an ethanol solution containing catechin, resveratrol and quercetin (Pinelo et al., 2004). No synergistic interaction but additive effects on vascular function were found between quercetin and catechin in systemic and pulmonary vascular smooth muscle (Menendez et al., 2010). Strong antagonistic effects were found on *in vitro* radical scavenging capacity when quercetin-3-glucoside was paired with the five anthocyanins (Hidalgo et al., 2010).

### Flavonoids and Tocopherols

Tocopherols (also called methylated phenols) belong to the vitamin E family and occur in α, β, γ and δ forms (which differ in the number and position of methyl groups on the chromanol ring). They are lipid-soluble antioxidants and can effectively prevent oxidative damage to lipids. Once being oxidized to tocopheroxyl radicals, tocopherols can be regenerated by ascorbate alone or in co-operation with certain flavonoids like quercetin. Green tea catechins and procyanidins were found to regenerate α-tocopherol via one-electron reduction of α-tocopheroxyl radicals (Pazos et al., 2007). Catechins might reduce the consumption of α-tocopherol to retain α-tocopherol as a scavenger within cell membranes while scavenging the aqueous peroxy radicals near the membrane surface (Zhu et al., 1999). In terms of the structure-activity relationship of the tocopherol-regeneration reaction by catechins (EC, ECG, EGC, and EGCG), Mukai et al. (2005) found that anionic character of catechins was positively correlated to the reaction rates of catechins, with the monoanions at catechol B- and resorcinol A-rings as well as dianions at pyrogallol B- and gallate G-rings exhibiting the highest free radical scavenging activity.

The bioactivity outcome of the interactions between flavonoids and tocopherols varies with the flavonoid species possessing different chemical structures and degree of lipophilicity. Significant antioxidant synergisms were found between α-tocopherol and catechin monomers or oligomers (procyanidins) in antioxidant assays (Arnous et al., 2001; Vinson et al., 2001). Quercetin in combination with vitamins (C and E) significantly ameliorated cadmium-induced oxidative stress and anomalies in renal biochemical and histological indices (Milton et al., 2010). The presence of flavonoids in the macrophages could conserve the content of α-tocopherol while delaying the onset of lipid peroxidation (Middleton et al., 2000). Tea catechins can take part in vitamin E recycling to complement some functions of glutathione antioxidant that is essential for cellular protection (Zhu et al., 1999).

### Interactions of Some Flavonoids Presented in the Same Fruit

Epidemiological studies have shown a strong association between the consumption of whole fruits with a range of potential health benefits. Thus, it is of interest to understand what natural polyphenols in fruits may exert such biological effects, and whether or not these purified antioxidants act alone or in a combination and behave in the same way. Recently, antioxidant extracts have been obtained from certain flavonoid-rich fruits, or dietary flavonoids that naturally occur in these fruits have been isolated, for the examinations on the possible interactions of flavonoids. For example, tart cherry (*Prunus cerasus*) fruit is rich in a variety of flavonoids antioxidants (such as cyanidin derivatives, kaempferol, quercetin and isorhamnetin and their derivatives), and the health benefits of tart cherries are likely associated with interactions of these compounds (Seymour et al., 2008). The pairs of antioxidant compounds exhibiting the highest antioxidant capacity and strong synergism included kaempferol and melatonin at a dose ratio of 2:1, and cyanidin 3-rutinoside and isorhamnetin 3-rutinoside at a dose ratio of 1:4, whereas, other pairs of antioxidants had lower antioxidant capacities and exhibited either additive or negative effect (Kirakosyan et al., 2010). Grapes are berries rich in natural antioxidants, among which the polyphenol compounds exhibit a range of health benefits. Extracts were produced from grape seed (GSD, which contained polygalloyl polyflavan-3-ol accounting for 47.16% of GSD's total phenolic content) and from grape skin (GSK, which contained anthocyanins, flavonols, polygalloyl polyflavan-3-ol and hydroxycinnamic acids accounting for 28.18% of GSK's total phenolic content). *In vitro* incubation experiments with human platelets and *ex vivo* feeding studies in dogs found that maximal antiplatelet benefits were achieved only when GSD and GSK were combined, whilst the concentration of GSD or GSK exerted little or no effect on platelet activity when either extract was used alone (Shanmuganayagam et al.,

2002). Accordingly, the combined use of these two extracts can provide the health benefits of grape polyphenols at a relatively low daily dose compared to use of one extract alone.

## Conclusion

Flavonoids are one of the most studied phytochemicals due to their diverse health benefits. Flavonoids have varying chemical structures. Such structural differences determine their biological behaviours and the interactions among flavonoids or between flavonoids and other non-flavonoid antioxidants from the same whole fresh foods like fruits. The bioactivities of flavonoids depend on not only their native state (aglycones or glycosides) but also their metabolites. The findings associated with the structure-bioactivity relationships and interactive effects of flavonoids obtained previously were mostly based on purified or isolated flavonoids. These results could only provide some evidence of a more basic character, but probably not transferable for real food matrices. Therefore, more investigations are required on the interactions of bioactive substances including flavonoid–flavonoid or flavonoid–non-flavonoid interactions in a near native state to obtain a better understanding of the health benefits associated with the consumption of flavonoid-rich diets. Future design of new dietary supplements or fortified foods should select the combination of flavonoids with the most desirable properties.

# Polyphenol Interactions and Food Organoleptic Properties

Susana Soares, Nuno Mateus, and Victor de Freitas, Faculdade de Ciências da Universidade do Porto, Porto, Portugal

## Introduction

Polyphenols are present in all vegetables, fruits and derived foodstuffs, e.g. coffee, beer, tea and wine. These compounds are referred as the phytonutraceuticals of the century due to important biological properties linked to their intake, e.g. cardiovascular protection and antioxidant activity (Valavanidis and Vlachogianni, 2013).

Besides health-promoting properties, polyphenols are also associated with some sensory properties of foodstuffs, namely colour and taste. Regarding colour, anthocyanins are one of the most important natural pigments but they present a problem due to their high instability. Regarding taste, polyphenols are responsible for some unpleasant organoleptic properties, namely astringency and bitterness. Astringency is a tactile sensation defined as dryness, tightening and puckering sensations perceived in the oral cavity during the ingestion of astringent molecules, mainly tannins, alums and some metal ions. It is desired if these molecules are in balanced levels for some food products such as red wine, being a parameter of wine quality, but it is unpleasant when perceived in excess. Currently, oral astringency onset is mainly explained by the precipitation of salivary proteins by tannins. Bitterness is a taste and so it is perceived via activation of specific bitter taste receptors (TAS2Rs) by some polyphenols. Usually, excessive bitterness is also undesirable.

Polyphenols are widely known to interact with many different compounds, both with food compounds, such as carbohydrates, lipids and proteins, as well as with biological compounds, namely proteins. Interactions between polyphenols and molecules from food are mostly based on non-covalent hydrophobic interactions but in the cases of interactions between polyphenols and proteins or/and carbohydrates, hydrogen bonds also contribute significantly. Furthermore, some covalent bonds may also occur under certain food processing conditions. All these interactions can influence the overall sensory perception of foodstuffs and consumer acceptance. This article revisits the current knowledge about these interactions at a molecular level, how these interactions could affect the sensory properties, e.g. taste, colour, texture, with the purpose to modulate them toward increasing consumer acceptance and intake of healthy foodstuffs rich in polyphenols.

## Polyphenols

Polyphenols are usually divided into two major groups: flavonoids and non-flavonoids. Flavonoids share a common flavanic core (Fig. 1) and are further divided into several classes such as flavanols [(epi)catechin], flavonols (e.g. myricetin and quercetin), anthocyanins (e.g. malvidin-3-glucoside), flavanones, flavones and isoflavones; non-flavonoid compounds include phenolic acids, phenols and stilbenes. These classes differentiate according to the degree of unsaturation and degree of oxidation of the heterocyclic pyranic ring C (Fig. 1). Flavonoids are the most relevant and widely present polyphenols in the human diet ( $\frac{2}{3}$  of ingested polyphenols are flavonoids) (Scalbert and Williamson, 2000). Among flavonoids, the most consumed groups are flavanols and anthocyanins (Rasmussen et al., 2005).

Flavanols differ in the stereochemistry of C3 of ring C and pattern of hydroxylation of ring B (Fig. 1). They share a structural unit of (epi)catechin and can range from monomers to polymers (proanthocyanidins). Conversely to other flavonoids classes, flavanols usually occur as aglycone molecules without sugar molecules.

Anthocyanins are the main pigments in many flowers and fruits (e.g. grapes) responsible for the great diversity of colours (i.e. red, violet and blue) found in nature and in some foodstuffs. In aqueous solution, the colour of anthocyanins is dependent on their structure and also strongly affected by the pH (Brouillard and Lang, 1990). At acidic pHs (pH~1), anthocyanins are present in their flavylium cation form which has a red colour. As the pH increases, anthocyanins can be present in other different forms yielding from the violet quinonoidal base to the non-coloured hemiketal form or to the *trans*-chalcone forms which present a yellow colour (Pina, 1998).

**Figure 1** Structure of the flavanic core common to flavonoids.

Another common designation to some polyphenols is tannins. Tannins comprise a group of usually structural complex polyphenols that share the ability to interact with proteins. Tannins are usually divided in two major subgroups: condensed and hydrolysable tannins. Condensed tannins (proanthocyanidins) are polymers of flavanols, usually gallo- or (epi)catechin units, which can form very complex and high-molecular weight structures. Hydrolysable tannins are further divided into gallotannins and ellagitannins. They are esters of gallic acid or hexahydroxydiphenic acid, respectively, with a polyol, usually glucose.

In summary, polyphenols present a high structural diversity and possess a significant number of hydroxyl groups and planar rings, which makes them susceptible to a wide range of interactions. Therefore, polyphenols can interact with one another and with other types of molecules that surround them.

## Interactions Between Polyphenols and Other Food Compounds

Lipids, proteins and carbohydrates are major food compounds often found together with polyphenols in the same food matrices. An excellent review on these interactions and their biological effects was published by Jakobek (2015). Herein, these interactions will be focused on a sensory perspective.

### Interaction With Food Lipids

Lipids affect flavour perception by their effects on aroma, taste and mouthfeel. Surprisingly, only a few studies have investigated the effect of dietary lipid–polyphenol interactions on taste. Dietary fats go through a digestion process that starts with mastication in which lipids are often transformed into emulsions. The particle size of fat droplets present in these emulsions is important since it influences the rheological properties, texture, shelf life and appearance (Dapčević Hadnadev et al., 2013). The association of polyphenols with milk fat globules has been widely studied. Several studies have been focused on the interaction associated with tea catechins and this interaction as shown to affect the size and the surface properties of milk fat globules (Rashidinejad et al., 2016). In general, the globules seem rougher and larger in size in the presence of catechins, and sharp and rough particles are known to cause more friction than rounder particles (De Wijk and Prinz, 2006).

Considering dietary lipids, it is inevitable to refer oxidation, which is an expected process in fat rich products, such as olive oil, leading to deterioration that can become more pronounced during oil storage. Initially, lipids are radically oxidized to hydroperoxides, which are odourless and tasteless. However, cleavage of these products gives rise to various volatile compounds, known as secondary oxidation products, which are responsible for typical unpleasant sensory characteristics of fat-rich foodstuffs. Oxygen, light, temperature, metals, pigments, unsaturated fatty acid composition, as well as the quantity and kind of natural antioxidants, are all factors that can influence the free radical mechanism of the autoxidation process but in a different manner. The addition of phenolic extracts to olive oil to improve oxidative stability is not straightforward as expected, especially in the presence of hydrocolloids, where their interactions with hydrocolloids can exert a significant influence and lead to different creaming rates, turbidity and rheological behaviours, but can also have pro-oxidant effects under certain conditions (Caporaso et al., 2016). Shishikura et al. (2006) studied the emulsification process of a model emulsion from olive oil and phosphatidylcholine, *in vitro*, and the influence of polyphenols on this process. It was found that green and black tea polyphenols affected the emulsions by increasing droplet size and decreasing specific surface area. Phosphatidylcholine possesses hydrophilic heads which face the exterior of the emulsion droplet. Polyphenols have many hydroxyl groups and may interact with phosphatidylcholine creating complexes. Furthermore, polyphenols may have acted as a linker between complexes to form complex aggregates, thus increasing droplet size.

### Interaction With Food Carbohydrates

Food is also usually rich in carbohydrates and the interaction of some of these compounds with polyphenols is well reported. The first ideas that some polyphenols interact with carbohydrates arise to explain fruit ripening process and subsequent loss of astringency. This interaction has also been the justification to explain the decrease of anthocyanins extracted during red wine making process.

Fruit ripening process includes several physicochemical and sensory changes, namely texture changes where fruits become softer and smoother, with reduction of astringency and bitterness (Prasanna et al., 2007). A typical example of these changes is persimmon. One hundred years ago, Lloyd and co-workers (Lloyd, 1911) suggested that the decrease in persimmon astringency was related to the loss of tannins' solubility due to their interaction with carbohydrates presented in tannin-rich cells. Recent evidence revealed that during grape ripening, tannins bind to cell wall carbohydrates (Braidot et al., 2008). Texture changes during fruit ripening result from the enzymatic degradation of structural carbohydrates of cells wall, namely pectins, hemicellulose and cellulose, and also storage carbohydrates (Prasanna et al., 2007), causing the release of small soluble fragments of carbohydrates. So, another hypothesis for reducing astringent sensation is that these small, soluble fragments would be able to inhibit the interaction of tannins with salivary proteins (Luck et al., 1994) via two mechanisms (Luck et al., 1994; Ozawa et al., 1987; Mateus et al., 2004) (Fig. 2): (i) carbohydrates form ternary complex protein–polyphenol–carbohydrates, which increase solubility in an aqueous medium; (ii) molecular association occurs in solution between carbohydrates and polyphenols hence competing for salivary protein aggregation.

**Figure 2** Possible mechanisms to explain the effect of carbohydrates on restraining the formation of tannin/protein aggregates (Mateus et al., 2004).

Polydextrose (Ares et al., 2009) and carboxymethylcellulose (Troszynska et al., 2010; Smith et al., 1996) can be used to reduce the astringent properties of aqueous tannin solutions and polyphenol-rich plant extracts. Arabic, guar and xanthan gums also demonstrated a significant capability to reduce astringent sensation (Troszynska et al., 2010). In general, pectins are the most effective carbohydrates in restraining the interaction between tannins and proteins (Le Bourvellec et al., 2005; de Freitas et al., 2003; Soares et al., 2012), and their high affinities to tannins resulting from their ability to develop a gel-like network and form hydrophobic pockets to encapsulate procyanidins (Le Bourvellec et al., 2005). Whereas, filamentous and globular polysaccharides, like cellulose and xyloglucan, would bind procyanidins weakly. Another common trait is that acidic carbohydrates seem to have a more significant effect on decreasing astringency than neutral carbohydrates from the same origin (Vidal et al., 2004). Besides influencing astringency perception, the tannin-carbohydrate interaction also affects the physical properties of carbohydrates e.g. the interaction between amylopectin and tea polyphenols favours gelatinization by decreasing the gelatinization temperature and enthalpy of starch (which is possibly related to easier hydration of starch granules).

Besides tannins, anthocyanins were found to interact with carbohydrates. During wine making, the extent and yield of anthocyanin extraction depend not only on their concentration but also the carbohydrate composition of grape cell wall (Busse-Valverde et al., 2011). In fact, Romero-Cascales and co-workers found that the anthocyanin concentration in the grapes is not directly correlated with the final concentration in the resulting red wine and the barrier effect of carbohydrates polymers is likely the reason (Romero-Cascales et al., 2005; Ortega-Regules et al., 2006). Several studies with model carbohydrates (e.g. cellulose and cellulose-pectin mixtures) or those isolated from grape cells walls have shown their high affinity to anthocyanins and their effect on anthocyanins extraction (Padayachee et al., 2012). In general, acylated anthocyanins have greater affinity to carbohydrates than non-acylated forms. The physicochemical characteristics of carbohydrates, namely porosity, monosaccharide composition and hydrophobicity affect their interaction with anthocyanins. Differences in the galactose and arabinose contents along with variations in the cellulose and pectin esterification degree (the lower esterification, the greater interaction) affect the interaction with anthocyanins (Ortega-Regules et al., 2006; Buchweitz et al., 2013; Kopjar et al., 2009). Further, anthocyanins occur in different forms with different hue and intensity in colour (otherwise, colourless) at different pHs. In nature, copigmentation interactions can occur which promotes the stability of the flavylium form of anthocyanins and associated colour of anthocyanin-rich foodstuffs. Interaction between anthocyanins and pure carbohydrates (e.g. pectins, arabic gum or  $\beta$ -cyclodextrin) have been examined mostly on the pectin copigmentation effect i.e. a slight stability enhancement of anthocyanins colour (Chung et al., 2016; Howard et al., 2013). This effect was mostly ascribed to the intermolecular association between the carbohydrate and anthocyanins mainly through hydrogen bonds and hydrophobic interactions (Fig. 3) (Fernandes et al., 2014).

In summary, the studies discussed here showed that different polyphenols could bind to different food carbohydrates. Depending on the compounds these interactions could have positive and negative effects. The interaction of tannins with food carbohydrates can lead to an astringency and bitterness modulation while anthocyanins interaction with carbohydrates could lead for, on one hand, to a lower extraction yield, and therefore lower colour intensity on the final product, and on the other hand to stabilization and enhancement of anthocyanins colour.

## Interaction With Proteins

### Food Proteins

Plant phenolic compounds are known to interact with proteins producing changes in the food (e.g. biological value (BV), colour, taste).

Polyphenols are known to interact with proteins causing changes in food, e.g. biological value, colour and taste. In some foods, proteins and polyphenols can form soluble complexes with sizes similar to colloidal particles, causing turbidity of beverages and limited shelf life. In beer, wine and juice production, polyphenols may induce the development of protein precipitates causing undesired sensory properties in consumers' perception (Siebert, 1999; Siebert et al., 1996). Most of the studies on the interaction of polyphenols with food proteins examined milk proteins, soy proteins, myoglobin (meat protein), lysozyme (egg-white protein)

**Figure 3** Schematic representation of some interactions established between anthocyanins and a low methoxylated pectin model involving hydrophobic interaction and H bonding. Pectin molecule is depicted with sticks coloured in dark grey (Fernandes et al., 2014).

and gelatin. Beside noncovalent interactions like  $\pi$ - $\pi$  bonding (aromatic interaction), hydrogen bonding, hydrophobic or ionic interactions (Siebert, 1999; Siebert et al., 1996), it has been assumed that covalent bonding is likely to play an important role in protein-polyphenol interactions (Rawel et al., 2001; Beart et al., 1985).

Beside noncovalent interactions like p-p-bonding (aromatic interaction), hydrogen bonding, hydro-phobic or ionic interactions (Valavanidis and Vlachogianni, 2013; Scalbert and Williamson, 2000), it has been assumed that covalent bonding is likely to play an important role in protein-phenol interactions.

Polyphenols, in general, interact with globular proteins and can cause structural and conformational changes in proteins. Interaction of milk proteins with tea polyphenols induces structural changes in both whey proteins and ( $\alpha$ - and  $\beta$ -) caseins (Hasni et al., 2011; Kanakis et al., 2011). This interaction leads to reduced protein digestibility and altered antioxidant activity although no change in polyphenol structure (Stojadinovic et al., 2013; Xiao et al., 2011), as well as reduced tea astringency. An extensive study on the interactions of fifty-five dietary polyphenols with milk proteins revealed that the binding was strongly influenced by the structural features of polyphenols (Xiao et al., 2011). Methylation and methoxylation as well as glycosylation of flavonoids decreased the affinities to milk proteins. Hydroxylation on the rings A and B of flavones and flavonols enhanced slightly the interaction, whilst hydroxylation on the ring A of flavanones significantly improved the affinities. Galloylation of catechins significantly increased the affinity by 100–1000-fold. Glycosylation of resveratrol decreased its affinity for milk protein. Esterification of gallic acid increased its binding affinity. Soy proteins, especially soy glycinin and soy trypsin inhibitor, were shown to react with several phenolic acids (gallic, chlorogenic and caffeic acids), flavones (flavone and apigenin) and flavonols (kaempferol, quercetin and myricetin) giving protein derivatives. The secondary and tertiary structure of the proteins is changed as a result of these interactions, influencing their surface properties and making them hydrophilic in nature (Rawel et al., 2002). In the same way, myoglobin also suffers structural changes upon interaction with *o*-, and *p*-hydroxyphenols, *p*-quinone and gallic acids (Kroll and Rawel, 2001), causing lower digestion by tryptic,  $\alpha$ -chymotryptic, peptic and pancreatic proteases. Lysozyme is also modified upon its covalent attachment to certain phenolic compounds (*m*-, *o*-, *p*-dihydroxybenzenes, ferulic and gallic acid) (Rawel et al., 2001). The derivatization was accompanied by the reduction of solubility over a broad pH range and increase of hydrophobicity, with the isoelectric points shifted to lower pH values and high molecular weight fractions formed. Furthermore, the peptic digestion of the derivatized lysozyme was adversely affected, whereas the tryptic, chymotryptic and pancreatic hydrolysis seemed in favour.

Besides modifications on the biological value of these proteins due to reduced digestibility, changes in protein hydrophilic/hydrophobic properties are induced by the interaction with polyphenols causing altered protein solubility and different functional and sensory properties of food (e.g. emulsion- and foaming properties, gel building, etc.) (Rohn et al., 2006). Strong interactions occur between polyphenols and proteins with flexible and open structures (usually with a high proline content, e.g. gelatin) (Asano et al., 1982; Oh et al., 1980; Hagerman and Butler, 1981; Frazier et al., 2010). Gelatin is a mixture of polypeptides derived from collagen and often used as wine fining agent. In fact, fresh wine is a turbid, complex and physicochemically unstable hydroalcoholic solution. Its limpidity, which is highly appreciated and required by consumers, is achieved through several processes like natural sedimentation, filtration and centrifugation. Still, a limpid wine has to remain that way during the period of bottle ageing and storage. In white wine production, chemical oxidation of catechins and proanthocyanidins is the main source of browning, affecting the colour, aroma and taste of white wine (Spagna et al., 2000). Accordingly, clarification and stabilization of wines are mainly achieved through addition of proteins, a process known as “fining.” Protein components in gelatin bind to wine polyphenols to form complexes which would precipitate out of solution and thereby potential browning is minimized (Spagna et al., 2000; Sarni-Manchado et al., 1999). Maury et al. (2001) characterized the fining abilities of a commercial gelatin (average molecular

weight 25,000 Da) and gelatin fractions (16,000–190,000 Da) for tannin removal. Selective precipitation occurred between gelatin and highly polymerized or galloylated tannins, and more polymerized tannins was precipitated by the 16,000 Da gelatin than by the 190,000 Da gelatin. In addition, the gelatin-treated wines were significantly less astringent than the unfined wine. Another study also reported the significant differences caused by various hydrolysed gelatins in wine chemical composition and polyphenol profile, and a preference for the treated wines over untreated ones (Karamanidou et al., 2011).

It has been shown that the protein-polyphenol binding increases with the molecular size of the polyphenol molecule (de Freitas and Mateus, 2001) and is affected by polyphenol conformational flexibility (Haslam et al., 1992). The above-mentioned studies indicate that some structural features of polyphenol molecules are important for this kind of interaction: (i) molecular weight, (ii) structural flexibility and (iii) number of OH groups.

### Salivary Proteins

The most recognized mechanism for astringency perception involves the interaction between tannins and salivary proteins. In 1954 Bate-Smith (Bate-Smith, 1954) proposed that astringency results from the interaction of tannins with salivary proteins in the oral cavity, mainly proline-rich proteins (PRPs), and since this idea has been generally accepted and supported by numerous studies in the literature (Sun et al., 2013; Rinaldi et al., 2012; Kallithraka et al., 1998; Bennick, 2002; Mehansho et al., 1987; Soares et al., 2011). Moreover, some studies reported the differences in reactivity of several families of salivary proteins. HPLC and SDS-PAGE analyses demonstrated that when all the major families of salivary proteins were presented in a competitive assay, which simulated the oral cavity, condensed tannins interacted firstly with acidic PRPs and statherin, then with histatins, glycosylated PRPs and finally basic PRPs (Soares et al., 2011). It seems that *in vivo* astringency intensity and development with time may be related to the modifications of different salivary proteins. In the case of a low concentration of tannins for the first exposure to PRPs, the precipitation of acidic PRPs and statherin correlated with the intensity of astringency. However, for higher concentrations of tannins upon subsequent exposures, the relative astringency likely correlated to gPRPs precipitation. These results were reported for the first time that the several families of salivary proteins could be involved in different stages of astringency development (Soares et al., 2011; Brandão et al., 2014).

In summary, polyphenol–protein interactions might potentially influence the availability of certain amino acids and protein structure, which could affect the functionality and digestibility of proteins. However, the extent of this influence depends on the origin and nutritional quality of proteins, and food processing conditions and other co-existing food nutrients. Furthermore, polyphenols bind to salivary proteins inducing the perception of astringency in the oral cavity, whilst the binding of polyphenols to some other (food) proteins can modulate this perception. So, at the end, interaction of polyphenols with proteins, as one of the most important interactions, is very complex with many positive and negative effects thus its characterization requires many different areas of knowledge.

### Concluding Remarks

Studies discussed here show that polyphenols are able to interact with other food compounds. The referred interactions have many side effects on sensory properties. Most of the current discussion focused on colour and taste. Also, the effects of these interactions, positive or negative, depend on the end use. Although polyphenol–lipid interactions have scarce data, it seems that this interaction can affect lipid emulsion properties; Polyphenol-carbohydrate interactions can lead to an astringency and bitterness modulation as well as affect anthocyanin colour; Polyphenol-protein interactions can affect astringency and also affect some functionalities of proteins in food. Literature review revealed that most studies on these interactions are only focused on the bioavailability of the involved compounds. More studies are needed to investigate other sensory properties that could be influenced by these interactions such as food texture and pleasantness, especially in relation to the interaction with food lipids.

# Effects of Interactions Between Antioxidant Phytochemicals and Coexisting Food Components on Their Digestibility

Sukanya Thuengtung and Yuki Haru Ogawa, Chiba University, Matsudo City, Japan

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Antagonistic effect** The effect of two or more substances that the combined effect is less than the algebraic sum of the individual effect of each substance.

**Digestibility** The proportion of a foodstuff absorbed from the digestive tract into the bloodstream. This is measured as the difference between food intake and output, including excretion of feces.

**Digestive tract** The system composed of the gastrointestinal tract along with the accessory organs that break down food into smaller components and then digestible molecules for the human body to absorb and assimilate. The digestive tract includes mouth, salivary glands, esophagus, stomach, pancreas, liver, gallbladder, small intestine, large intestine, and rectum.

**Phytochemicals** Nonnutritive plant chemicals that play important roles in human health through providing protective properties such as antioxidant and antiinflammatory effects to reduce the incidence of certain chronic diseases.

**Synergistic effect** The joint action of two or more substances to create a combined effect greater than the algebraic sum of the individual effect of each substance. A synergistic effect can be beneficial or harmful.

## Introduction

Antioxidant phytochemicals are secondary plant metabolites found in plants such as cereal grains, fruits, vegetables, and spices, among which polyphenols and carotenoids are two major groups that have demonstrated various beneficial effects on human health, including preventive properties on certain chronic diseases such as diabetes and obesity (Zhang et al., 2015). Polyphenols are compounds that contain one or more aromatic rings connected to at least one hydroxyl group. More than 10,000 polyphenols have been identified and they can be classified differently; for example, according to the number of phenol rings. Flavonoids, stilbenes, and phenolic acids are among the major groups of polyphenols in nature. Polyphenols may be soluble in polar solvents such as water, ethanol, and methanol. Their solubility depends on hydroxyl group, molecular size, and length of hydrocarbon (Franco et al., 2008). Carotenoids are compounds found in orange and red fruits and vegetables that play important roles in human health. More than 600 types of carotenoids have been identified from natural sources with about 40 types found in the human diet containing basic structures of 40-carbon terpenoids linked to isoprene (Kiokias et al., 2016). Most carotenoids are slightly soluble in oil at room temperature and readily soluble in nonpolar organic solvents such as acetone and chloroform, with exceptions like crocin that can be dissolved in water (Alavizadeh and Hosseinzadeh, 2014; Kiokias et al., 2016).

The consumption of foods containing antioxidant phytochemicals leads to many health benefits to humans (Li et al., 2014). However, several factors would affect the digestibility and bioavailability of phytochemicals in foods, of which chemical interactions are important factors that influence food metabolites in the human body (Chitindingu et al., 2015).

## Sources and Structures of Antioxidant Phytochemicals

Most natural antioxidant phytochemicals have been found in cereal grains, herbs, microalgae, beans, fruits, vegetables, and tea, including edible and wild flowers. Vegetables and cereal grains, especially pigmented rice, soybean, broccoli, and cowpea, are important sources of polyphenols (Li et al., 2014). Most polyphenols in cereal grains exist in a bound form in the aleurone layer, pericarp, and embryo cell walls (Abdel-Aal et al., 2006; Liu, 2007) and in flesh and peels of various fruits and vegetables (Boyer and Liu, 2004; Xu, 2012). Citrus fruits, tomato, papaya, and carrot contain important dietary sources of carotenoids, in particular, lycopene and  $\beta$ -carotene (Kiokias et al., 2016; Xu, 2012; Zhang et al., 2015). Thus, cereal grains, fruits, and vegetables are large food groups that are rich in polyphenols and carotenoids.

Flavonoids occur in the forms of aglycone, glycosides, and methylated derivatives and can be divided into six subclasses: anthoxanthins (including flavones and flavonols), flavanones, flavanonols, flavans, anthocyanidins (including derived anthocyanins), and isoflavonoids (including isoflavones). Phenolic acids normally occur in a bound form, which can be divided into two major groups: hydroxybenzoic acids (e.g., *p*-hydroxybenzoic, vanillic, syringic, gallic, and protocatechuic acids) and hydroxycinnamic acids (e.g., caffeic, *p*-coumaric, sinapic, and ferulic acids). Hydrocarbons (carotenes; e.g.,  $\alpha$ -carotene,  $\beta$ -carotene, and lycopene) and their oxygenated derivatives (xanthophylls; e.g., lutein, bixin, and capsanthin) are the major subclasses of carotenoids in fruits and vegetables.

## Health-Promoting Effects of Foods Rich in Antioxidant Phytochemicals

The overproduction of free radicals in humans can generate oxidative stress and cause severe damage to biomolecules of cells and tissues, resulting in various chronic diseases such as cardiovascular disease, obesity, cancers, and diabetes (Zhang et al., 2015). Many studies have shown that the intake of food rich in antioxidant phytochemicals would lead to reduced risk of chronic diseases (Kim et al., 2013; Munirah et al., 2012). The consumption of whole grain along with three or more servings of fruits and vegetables exhibited positive effects on glycemic control, blood lipid profile, and body weight of diabetic patients (Munirah et al., 2012). The study involving 38 healthy volunteers demonstrated that a daily consumption of red and black cabbage in a portion of 300 g could increase the plasma carotenoid concentration resulting in decreased lipid hydroperoxide levels and oxidized low-density lipoprotein (Bacchetti et al., 2014). The consumption of black rice containing high concentrations of anthocyanins for 8 weeks has caused the reduction of weight gain and cellular lipids in an animal study (Kim et al., 2013). Quercetin could reduce body weight gain along with improved sensitivity and glucose intolerance in mice (Dong et al., 2014). Moreover, antioxidant phytochemicals may exert direct impacts on the enzymes that intrinsically occur inside the human body and contribute to food component digestion and absorption. Citrus fruits containing significant amounts of antioxidant phytochemicals exhibited  $\alpha$ -glucosidase inhibitory activity in *in vitro* study (Girones-Vilaplana et al., 2014). In addition, anthocyanins in purified form showed suppressive effects against porcine pancreatic  $\alpha$ -amylase, and cyanidin-3-glucoside seemed to be the most effective compound (Sui et al., 2016). A previous study (Akkrachiyasit et al., 2010) reported that cyanidin or cyanidin-3-glucoside (1.0  $\mu$ M) combined with acarbose (3.12  $\mu$ M) exhibited a synergistic inhibition of pancreatic  $\alpha$ -amylase. A study of 14 chili pepper varieties revealed the synergism among their phytochemical components such as carotenoids, phenolics, and capsaicinoids to reduce the sugar level via inhibition of  $\alpha$ -amylase activity (Sricharoen et al., 2017). The study of tomato leaf extracts also revealed the synergism of flavonoids, phenolic acids, and chlorogenic acid to inhibit both  $\alpha$ -amylase and  $\alpha$ -glucosidase enzymes (Figueiredo-González et al., 2016). Hydrogen bonding between the hydroxyl groups of polyphenols and the catalytic residues of the active site of the digestive enzyme could lead to inhibition of the  $\alpha$ -amylase and  $\alpha$ -glucosidase enzymes (de Sales et al., 2012). The inhibition of certain digestive enzymes such as those related to the absorption of carbohydrates and lipids may be beneficial, as a decrease of the levels of glucose and undesired lipids in the blood would be possible for patients with diabetes.

## Digestibility of Antioxidant Phytochemicals and the Influence of Their Interactions With Coexisting Food Components

Carotenoids, flavonoids, and phenolic acids are antioxidant phytochemicals that are presented in a wide range of plant-based food. They have been recognized as potential bioactive compounds that play important roles in human health and prevention or treatment of a chronic disease (Xu, 2012; Zhang et al., 2015; Palafox-Carlos et al., 2011). Moreover, food microstructure, type of macromolecules in food (carbohydrates, lipids, and protein), food source, and chemical interactions between phytochemicals and other phytochemicals or biomolecules are factors that influence the digestibility and bioavailability of the antioxidant phytochemicals (Palafox-Carlos et al., 2011; Parada and Aguilera, 2007; Chitindingu et al., 2015). Therefore, recent studies have focused on the effects of chemical interactions on the digestibility of carotenoids, flavonoids, and phenolic acids.

### Flavonoids

Generally, most flavonoids in food are found in glycoside form that is attached with a sugar moiety (Palafox-Carlos et al., 2011). Flavonoid glycosides can be digested into monomer molecules via mastication and enzymatic actions during the oral and stomach processes. From this step, the sugar residue attached with flavonoids can be absorbed in the small intestine first, resulting in the release of individual flavonoids (aglycones). The flavonoids (aglycones) are unstable under the neutral small intestine conditions, so a significant portion of aglycones cannot be digested and absorbed in the small intestine (Palafox-Carlos et al., 2011; Pinto et al., 2017).

The presence of dietary fiber could be an influencing factor that affects the digestibility and bioavailability of flavonoids in the small intestine. Dietary fibers can interact with flavonoids via electrostatic and dipolar interactions, van der Waals attraction, and hydrogen bonding, resulting in restricted flavonoid digestion and absorption in the small intestine (Eastwood and Morris, 1992). Hence, undigested flavonoids would be passed through to the large intestine where they are cleaved by colonic microflora and are either absorbed into the circulatory system or utilized to exert the antioxidant activity in the intestine environment (Del Rio et al., 2009). The consumption of foods and/or beverage containing both flavonoids and dietary fiber has been found causing restricted flavonoid digestion and absorption in the small intestine, as flavonoids' interaction with dietary fibers and their subsequent entrapment by fibers would retard their hydrolysis by digestive enzymes in the small intestine, as shown in Fig. 1 (Palafox-Carlos et al., 2011). Saura-Calixto and Díaz-Rubio (2007) reported that dietary fiber presented in wine could obstruct the bioavailability of polyphenols during the upper part of digestive tract; therefore, these polyphenols could be entrapped within the dietary fibers until reaching the large intestine. The molecular interactions such as electrostatic interactions or polar-polar interactions between apple-sourced flavonoids and dietary fiber (like cellulose membrane) might decrease the digestibility of these phytochemicals in the digestive tract (Bouayed et al., 2011).

**Figure 1** The digestibility and bioavailability of polyphenols contained in foods rich in dietary fibers. Reproduced from Palafox-Carlos, H., Ayala-Zavala, J.F., González-Aguilar, G.A., 2011. The role of dietary fiber in the bioaccessibility and bioavailability of fruit and vegetable antioxidants. *J. Food Sci.* 76 (1), 6–15.

### Phenolic Acids

Phenolic acids are mostly presented in bound form and/or attached to the plant cell walls. Generally, phenolic acids can be digested and absorbed in the upper part of gastrointestinal tract in aglycone form (Konishi et al., 2006; Lafay and Gil-Izquierdo, 2008). Hydroxybenzoic acids, such as gallic acid, are easily digested and absorbed through gastrointestinal tract. Hydroxycinnamic acids in free form such as ferulic acid, caffeic acid, and chlorogenic acid can also be rapidly digested and absorbed in the gastrointestinal tract by conjugating with the intestinal and/or hepatic detoxification enzymes (Lafay and Gil-Izquierdo, 2008).

Most of phenolic acids can be found in cereal grains, and the cell wall polysaccharides in grains such as arabinoxylans could interact with the phenolic acids in bran and aleurone layers, resulting in retarded digestibility of phenolic acids in the upper part of gastrointestinal tract. This might be due to the esterification of phenolic acids with one or more arabinose and xylose, which are mostly not absorbed in the small intestine; instead, pass through to the large intestine where they can be hydrolyzed by colonic bacterial enzymes (Palafox-Carlos et al., 2011). However, some phenolic acid esters can be cleaved by the esterase in the gastrointestinal tract and converted to the free form of phenolic acids that may be digestible in the gut depending on their molecular size (Chandrasekara and Shahidi, 2012; Palafox-Carlos et al., 2011). Furthermore, the binding of some phenolic acids such as hydroxycinnamic acids to macromolecules such as proteins via hydrophobic and electrostatic interactions also decrease the bioavailability of phenolic acids (Budryn et al., 2016). The decreased starch digestibility associated with increased phenolic acids and proteins in the bread made with sprouted wheat flour as compared with that of normal wheat flour was proposed to result from the phenolic acid–bread matrix interaction (Świeca et al., 2017).

### Carotenoids

Carotenoids are predominantly hydrophobic and lipophilic compounds and are associated with lipids in chloroplasts; thus their digestion would mainly take place in the small intestine where significant amounts of lipases occur (Kiokias et al., 2016; Palafox-Carlos et al., 2011). Certain carotenoids are also able to attach to some water molecules in forms of conjugates with bile salts, forming micelles and solubilized carotenoids (Palafox-Carlos et al., 2011). Their bioavailability is associated with the degree of digestion to release carotenoids from the food matrix, formation of lipid micelles in the small intestine, absorption of carotenoids in the intestinal mucosal cells, and transport of carotenoids to the lymphatic system (Berni et al., 2015).

**Figure 2** The digestibility and bioavailability of carotenoids contained in foods rich in dietary fibers. Reproduced from Palafox-Carlos, H., Ayala-Zavala, J.F., González-Aguilar, G.A., 2011. The role of dietary fiber in the bioaccessibility and bioavailability of fruit and vegetable antioxidants. *J. Food Sci.* 76 (1), 6–15.

Carotenoids are usually digested and absorbed along with dietary lipid in the intestinal tract, which depends on the type, molecular size, and isomeric configuration (*cis* or *trans*) of carotenoids (Britton, 1995). Dietary fibers are well known for their abilities to retard the digestion and absorption of certain macronutrients such as some carbohydrates, proteins, and lipids. Dietary fibers can interact with carotenoids dissolved in oil or in a crystalline form through noncovalent interactions, resulting in unavailability of carotenoids for digestion and absorption (Zaripheh and Erdman, 2002). Dietary fibers can influence the bioavailability of carotenoids through increasing the viscosity of the whole digestive system to restrict enzymatic actions in the pancreas and to reduce the intestinal enterocyte contacts (Fig. 2) (Palafox-Carlos et al., 2011). Carotenoids can also link to the lipid component of lipoproteins via hydrophobic interactions, which facilitate carotenoid's function and transport in an aqueous environment (Britton, 1995). Interactions between carotenoids and proteins via hydrophobic effects were also found in citrus fruits that promote the bioavailability of carotenoids (Turner and Burri, 2013). Therefore, the bioavailability of carotenoids from foods depends on both their respective chemical structures and food matrix characteristics.

## Conclusion

Many studies reported the chemical interactions between antioxidant phytochemicals and other coexisting substances such as dietary fibers, lipids, and proteins and the effects of these interactions on the digestibility and bioavailability of phytochemicals in the digestive system. The interactions include electrostatic interactions, van der Waals attractions, hydrogen bonding, and hydrophobic interactions, as well as covalent interactions; e.g., those in esterification. Dietary fibers would likely present an antagonistic effect on polyphenols and carotenoids, whereas carotenoid and lipoprotein might work in a synergistic way.

## Glossary

**Biopolymers** Are biomacromolecules that possess biological functions owing to their hierarchical structures (primary, secondary, tertiary or quaternary structure) and chemical composition of their building blocks (i.e. monomeric units), and include carbohydrates (mostly polysaccharides), proteins and nucleic acids. Their structures and functional properties depend on environmental conditions such as temperature, pH, surrounding media and co-existing substances (including salts and other additives).

**Biopolymeric nanocomposites** Refer to a type of deagglomerated, well-dispersed and multiphased biopolymer material with beyond usual chemical, physical, mechanical, thermal, optical or electrical properties, in which nanostructures (structures containing nano-scale repeating distances between different phases) and/or nanomaterials (matrices with at least one phase having one, two or three dimensions at a nanoscale, including those containing nanoparticles) are present.

**Self-emulsifying nano-/micro-emulsions** Are a thermodynamically stable colloid system of two or more immiscible liquids (emulsions) in which droplets within the nano-/micro-meter range are formed using hydrophilic biopolymers capable of gelling in the continuous minority emulsion phase, thereby simultaneously emulsifying and stabilizing the colloidal system in the absence of additives such as surfactant, co-surfactant or stabilizer.

## Introduction

Advances in layer-by-layer (LbL) assembly methods for polyelectrolyte complexes (PECs) over the past three decades (Decher, 1997) has resulted in the widespread utilization of multilayered polyelectrolyte assemblies for various applications, in particular bioactive delivery. Biocompatible PECs in the form of biopolymeric stacks formed via the interactions between polyanions and polycations have recently gained special attention. These multilayered systems can be fabricated using a multitude of natural biopolymers (e.g. chitosan, sodium alginate, carboxymethyl cellulose and certain active peptides) and their individual properties tuned during fabrication to deliver intricate composite architectures for the encapsulation and delivery of bioactive substance(s). Since these composites consist of biocompatible polysaccharides and proteins, the polymer composites also possess high biocompatibility as bioactive carriers. Chitosan (Park et al., 2006) and alginate (Zhou et al., 2013) are two biopolymers that chemically resemble extracellular matrix components.

Polysaccharides are commonly used as gelling agents and exhibit varying solubility and viscoelasticity in water. Under appropriate conditions, they can be dissolved or dispersed in a solution owing to the disruption of hydrogen bonding networks that exist in the solid state. Subsequently, their polymer chains cross-link via covalent or noncovalent interactions, eventually yielding a three-dimensional (3-D) polymeric network in solution that occupies the whole volume of the liquid to which they were added. Intermolecular interactions also contribute to these gelling processes, and include ionic or ion dipole bonding (electrostatic attraction and polar covalent bonding), hydrogen bonding, van der Waals attraction, hydrophobic interaction and covalent bonding. Intermolecular association of polysaccharides is stable only when the chain length exceeds a minimum critical value (mostly 15–20 residues) required for the cooperative nature of interaction (Bertoft, 1993). Factors that influence the solubility and gelation of polysaccharides include intrinsic parameters such as molecular weight (MW) (e.g. large MW polysaccharides typically have low dissolution rates), molecular structure (e.g. degree of regularity in conformation, crystallinity, branching or packing density), charge (e.g. charged polysaccharides associated typically have a higher solubility than neutral polysaccharides), type of polysaccharide, as well as external environmental conditions such as temperature, pH, pressure and the presence of co-factors (e.g. counterions or cosolutes) that affect the interactions between polysaccharides and water. Certain counterions with appropriate radius and charge form junction zones in polymeric networks promoting the associations between polysaccharide molecules thus leading to the formation of unique structures, whereas co-solutes with low MW (e.g. sugars) compete with the polysaccharides for water and impact the gelling properties.

Chitosan is a linear positively charged polysaccharide composed of  $\beta(1\rightarrow4)$  linked D-glucosamine residues with varying numbers of randomly located N-acetyl-glucosamine units. It is obtained by alkaline hydrolysis or enzymatic N-deacetylation of the abundant natural biopolymer chitin. Chitin serves a structural function in insect and crustacean cuticles in a similar way to the cellulose in plants and collagen in animals. Chitosan as a raw material exhibits excellent nontoxicity, biocompatibility, biodegradability, and antimicrobial and wound healing properties (Nguyen et al., 2013). The  $-\text{OH}$  and  $-\text{NH}_2$  ( $-\text{NH}_3^+$ ) groups of chitosan can induce strong intramolecular and intermolecular interactions, resulting in the complexation of various negatively charged substrates such as carbohydrates, proteins, lipids, cells and microorganisms (associated with antimicrobial properties of

chitosan) (Kenawy et al., 2007) as well as hydrophobic interactions with substances like neutral lipids (Tao et al., 2013). Chitosan's N-acetylglucosamine residues can interact with and form conjugates with certain specialty proteins including growth factors or receptors thus enabling the development of carriers with additional advantages that retain the properties of these special proteins (Prabaharan and Mano, 2006). The degree of deacetylation (DD) greatly affects its stability, crystallinity, swelling degree, mechanical strength, bioactivity and (bio)-degradation behavior (Cao et al., 2005). Naturally sourced chitosans are neither 100% acetylated nor 100% deacetylated but instead, exist as a copolymer composed of two types of monomer building blocks with different acetyl contents. Commercial chitosans typically have a DD of 70%–95% and MWs ranging from 50 to 2000 kDa. The MW, DD, intermolecular hydrogen bonding degree, distribution of acetyl groups, time for deacetylation, rigidity of D-glucosamine structure, degree of crystallinity, concentration, viscosity, temperature and pH all influence chitosan's solubility. To prepare chitosan solutions free of agglomeration, it is common to mix a plasticizer (e.g. water or glycerol) with the chitosan, followed by the slow addition of a weak acetic acid solution (at pH < its pKa (6.3)) under agitation. Under these conditions, the amino groups (NH<sub>2</sub>) of chitosan become protonated (–NH<sub>3</sub><sup>+</sup>) forming a polycation (i.e. chitosan is completely protonated at pH 4.5 and below) (Pillai et al., 2009). The critical concentration (C\*) for chitosan chain entanglement in acetic acid is around 0.1% (w/w) (Montembault et al., 2005).

Alginate is a negatively charged polysaccharide composed of two uronate sugars,  $\alpha$ -L-guluronic acid (G) and  $\beta$ -D-mannuronic acid (M) and obtained mainly from brown seaweed. Alginates occur as copolymers with different weight fractions, length and distribution of G and M blocks, which endows alginate gels with varying physicochemical properties (e.g. different gel-forming capacities due to varying flexibility of GG, MM or MG units). Alginates are versatile encapsulants for intestinal delivery systems in functional food and biomedical applications (Shinde et al., 2014) due to their pH sensitivity, chemical and mechanical stability, gel barrier function, good cell-affinity and biological functions (e.g. muco-adhesive and appetite-regulating properties) (Georg et al., 2012). In particular, alginate oligomers, which are broken down via acidic/enzymatic hydrolysis or depolymerization from parent alginate molecules, exhibit excellent prebiotic effects (Wang et al., 2006) and offer increased antioxidant activity (Kelishomi et al., 2016). Commercial alginates typically have an average MW of 200,000 (although up to 500,000 is possible), degree of polymerization (DP) of 180–930 and pKa of 3.4–4.4. The stability of alginate depends on intrinsic factors (e.g. G/M ratio, DP and MW) and external conditions (e.g. pH, temperature and presence of contaminants). Cleavage of the glycosidic linkages between alginate's sugar monomers is possible under acidic (especially at pH 3–4) and alkaline conditions. Acid hydrolysis is due to the tendency to form six-membered rings via intramolecular catalysis involving non-dissociated carboxyl groups. A change in alginate's polymeric structure can lead to different gelation mechanisms and gels with varying properties. For example, chains rich in L-alginate form transparent and brittle gels whilst chains rich in D-alginates yield turbid gels with low elastic moduli. Alginate is compatible with many other biopolymers including polysaccharides like pectin, starch and chitosan in many formulations (Sun-Waterhouse et al., 2014; Wang et al., 2013).

Both chitosan and alginate can assume interconnected porous microstructures in water to encapsulate/immobilize bioactive substance(s) whilst also allowing controlled diffusion of nutrients, soluble factors and metabolic wastes. At appropriate pHs, they are ionized in aqueous-based media and carry opposite electric charges allowing their interactions to form PECs through the positively charged amino groups of chitosan and the negatively charged carboxylic acid groups of alginate. Various types of chitosan-alginate PECs can be prepared in solutions depending on the exact conditions, including random composites, LbL assembled multilayers and precipitates.

### Creation of Polyelectrolyte Stacks With Different Structures and Geometries

Polyelectrolyte multilayers (PEMs) with different internal architectures can be fabricated to encapsulate efficiently and release precisely various bioactive substances (including small or big molecular compounds and active substances like enzymes and cells), through selecting chitosan and alginate biopolymers with specific MW, DD/DP, G/M ratio, concentration ratio, rheological properties and existing form (charged or neutral forms), and tailoring the assembly of two polymers (e.g. substrate, starting layer, outermost/terminal layer and layer thickness). Understanding the specific molecular and polymeric interactions is important for producing stimuli-responsive delivery systems with effectively incorporated bioactives for subsequent release after consumption.

### Fabrication Methods or Processes

Electrospinning is an established technique for producing 3-D porous nanofibrous structures from biopolymer solutions, and can also be used to create multi-layered fibrous structures. During a typical electrospinning process, a high electric potential is applied between a spinneret and a collector to create an electrically charged jet of a polymer solution, and the polymer jet is solidified and deposited on the collector. The electrospun nanofibers are then fused together to form layers of nonwoven meshes or scaffolds by using different collection methods or set-ups (e.g. electro-centrifuge spinning, rotary jet-spinning or rotating mandrel), by adjusting the gap between two collectors or by stretching the mesh post electrospinning. Among various electrospinning processes, the co-axial electrospinning approach is generally preferred for the construction of multilayered PECs as it does not require an additional crosslinking step (Waterhouse et al., 2017). To prepare chitosan-alginate multilayer fibres, chitosan and alginate polymer solutions are pumped through a two capillary spinneret and the polymer jet is ejected in the form of core-sheath fibers and collected as core-shell fibers. Bioactive substance(s) can be incorporated into the core or even the shell. Manipulating the electrospinning set-up and the properties of polymer solutions (e.g. concentration, ionic strength, pH and viscosity) allows precise tuning of the characteristics of electrospun multi-layered PEC products.

Polymerized high internal phase emulsions (PolyHIPEs) represent another approach to form multilayers of highly porous chitosan and alginate PolyHIPE matrices. A typical PolyHIPE fabrication process involves the dropwise addition of an internal emulsion phase into the continuous phase containing polymerizable monomers and surfactant(s) until the total volume ratio of internal to continuous phase exceeds 0.74, followed by polymerization or solidification of HIPE via mild chemical and/or physical crosslinking and final removal of liquid via freeze-drying or Soxhlet extraction (Hayman et al., 2005). Polysaccharides contain many functional groups, thus allowing mutual interactions between different types of polymers and specific modifications of individual polymers prior to polyHIPE fabrication, in order to tailor the attributes of polyHIPEs (e.g. increased pore size and pore interconnectivity as well as improved mechanical strength and biodegradation post-delivery). Grafting a designed peptide sequence on the surface or adding to the backbones of a natural polymer can make the polymer an amphiphilic entity which can function as the matrix for polyHIPEs (thereby avoiding the use of stabilizers like surfactants which are harmful to living cells), whilst acting simultaneously as the emulsifier for emulsion templating and as the stabilizer to maintain large droplet/pore size (i.e. self-emulsifying HIPEs for polyHIPEs). For example, short peptide-chitosan copolymers with thermoresponsive properties can be created through grafting oligo(amino acid) side chains onto chitosan. The oligo(amino acid) side chains including oligo-/polyproline with hydrophilic and hydrophobic domains, negatively charged oligo-glutamic acid, positively charged oligolysine and oligoarginine, can disrupt the intermolecular hydrogen bonding between the  $-\text{NH}_2$  and  $-\text{OH}$  groups of chitosan and thereby improve emulsion stability and solubility at physiological pH and temperatures. An additional coating of the polyHIPEs may be required to improve adhesiveness between layers of alginate-based polyHIPEs and chitosan-based polyHIPEs for freestanding stacked assemblies, depending on the influence of the grafted peptides.

Layer by layer (LbL) processes involving the stepwise deposition of building blocks onto planar surfaces or core materials are commonly used to construct multilayers of PECs (Iler, 1966). Stacks of chitosan-alginate biopolymer layers can readily be deposited on planar substrates via successive dip coating cycles in chitosan and alginate solutions. The LbL technique also provides the possibility to create complex layer geometries e.g. planar template built onto differently patterned flat surfaces, and colloidal template built onto core materials with appropriate 3-D structures (Fig. 1) under very mild conditions for incorporating bioactive substances. For multilayers on a planar template, cleaned flat hydrophilic surfaces (e.g. glass, silica or mica) are typically used as substrates. The deposition of the first layer is accomplished by dipping the charged substrate into a polymer solution with opposite charge (e.g. positively charged chitosan solution for negatively charged silica glass) for a specified time period, following by rinsing to remove non-bound free polymers and air drying. The coated substrate is then immersed in a solution of the oppositely charged biopolymer (e.g. alginate), rinsed and then air dried. The process is repeated until a predetermined PEM thickness is achieved (e.g. 50 or 100 layers). For layers deposited over a colloidal template (including spherical, quasi-spherical or cylindrical geometries), the layers of PECs (e.g. chitosan and alginate) are deposited by alternating addition of polycations and polyanions to particle dispersions (including nano-biopolymer particles or bioactive molecules e.g. chitosan particles), followed by washing and centrifugation to remove excess polymers. During the LbL process for colloidal PEMs, the competition of the coagulation process of partly covered particles with the formation of a defined monolayer around the particle (the so-called “supersaturation”) needs to be monitored, which is typically achieved through reducing the MW of coating polymer particles (e.g. tens of nanometres to several micrometres) or controlling the adsorption rate of polymers to be greater than that of particle collision. The PEM deposition process can be monitored by electrophoresis. The properties of LbL assemblies derive from their preparation history: planar layers are often dried after each deposition step whilst colloids are not (to reduce unwanted aggregation), as well as variations in parameters used during fabrication including concentrations and pH of the polymer solutions, type of supporting medium and washing steps.

In addition, it is possible to increase the complexity of multilayered architectures (Fig. 1) via (1) complexation/condensation of polyelectrolytes in the presence of nonspecific ion linkers such as biological electrolytes (e.g.  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$ ) prior to or during the deposition of each layer to form close-packed raft-like networks (Wong et al., 2003); (2) removal of the colloidal cores of PEMs

**Figure 1** Scheme showing polyelectrolyte multilayers built on different templates (planar or colloidal; hollow or filled) and with different layer patterns.

using a core sacrificial method to create hollow core structures following the formation of the multi-layered coatings (Zhao et al., 2007); (3) creation of nano-sized particles with encapsulated insoluble core bioactives inside the PEMs with controlled ultrasonication, distributive or dispersive mixing (Ariga et al., 2011). Stacking PEMs at different angles can also create complicated carrier architectures such as hexagonal arrays, moiré or grid patterns.

### Local Molecular Interactions and Structural Complexity

The kinetics of PEM deposition impacts PEM final properties. The PEM architecture is created mostly by electrostatic interactions (Waterhouse et al., 2017) and/or hydrogen bonding (Kharlampieva et al., 2009), with significant contributions from repulsive forces, entropic forces, hydrophobic interactions and van der Waals interactions (Song et al., 2009; Kotov, 1999). The electrostatic build-up may cooperate with other processes e.g. Langmuir–Blodgett transfer (Ruths et al., 2000) or specific binding mechanisms (Cassier et al., 1998). The formation of multilayers is governed by the absolute charge density of the component polymer chains, and also affected by the type and concentration of salts (i.e. ionic strength), dielectric constant of solvent, pH or temperature of deposition solutions, deposition time, presence or absence of counterions, ratio of different the polymers, and type, concentration, MW, stoichiometry, degree of ionization, outer surface properties, internal interfaces and entanglements of each polymer. Charge neutrality and charge reversal are essential for the subsequent deposition of multilayers and continuous layer growth, and can be achieved via intrinsic charge compensation and/or extrinsic charge compensation for strong or weak PECs. Charge renormalization may occur in PEMs owing to the strong coupling between electrostatics and chemical dissociation equilibria at the growth surface as well as the adsorption and physical binding of counterions at the surface. Strong electrostatic forces can decelerate equilibration causing very slow growth dynamics. The desorption of a full PEC chain and consequently deconstruction of PEMs may also be possible, due to local molecular interactions (e.g. under conditions where electrostatic interactions are weakened sufficiently) (Kovacevic et al., 2002). This is especially true for weak PECs where dissociation equilibria exist in multilayers. Secondary interactions could dominate under conditions when electrostatic interactions are strongly screened (e.g. at high salt concentrations) or when solvent molecules are released from the hydration shell layers (Büscher et al., 2002).

Polyelectrolyte multilayers on substrates generally comprise three distinct zones: A “precursor zone” at the substrate interface (which is influenced by substrate/polymer interactions), a “core zone” (in which the regular layer-by-layer growth occurs and component polymer layers are mostly compensated and balanced), and finally an “outer zone” (where the chains mostly assume a loop-like conformation with the last/outermost layer possessing excess charge and determining the stimuli-response). Polymer chains in the terminating layer are much more mobile than those in the “core zone” owing to their charge imbalance and lesser steric restriction. This outermost layer greatly governs the properties of PEM surfaces (e.g.  $\zeta$  –potential) and even the whole PEM). The attributes of the substrate affect the first few layers in the “precursor zone” e.g. the amount of adsorbed polymer is smaller on a flat and hard surface (owing to stratification of polymer flexible chains) compared to a rough and soft surface with the same surface charge density ( $\sigma$ ). Significant overlap between the segments of adjacent layers (“interpenetration” or “interdigitation”) can occur driven by complexation of positive and negative charges. The thickness of the “precursor zone” is generally smaller for strong PECs than for weak PECs. An approximate linear growth of layer thickness with layer number is usually found in the “core zone” while a significantly smaller thickness is observed for the “precursor zone”, although factors such as the density and total layer number of the PEM structure, pH and ionic strength affect the thicknesses of these zones (Lavallo et al., 2002).

The biopolymers in each layer of PEMs are mainly in the form of hydrophilic hydrogels created by absorbing water to approximately 20% of their dry weight which results in swelling and the formation of the 3-D gel structure. When the polymer concentration increases, electrostatic repulsion between oppositely charged monomers is eventually screened. At sufficiently high concentrations, PECs behave like charge-neutral polymers and interpenetrate at a critical overlap concentration  $c^*$ , leading to progressive overlap of their chains with the dynamics of each chain restricted/hindered by co-existing chains (as a result of entangled and non-entangled inter-chain interactions). The dual swelling and responsivity characteristics enable hydrogels to be bioactive carriers with high sensitivity to various stimuli including pH, temperature, ionic type and strength. The pH responsivity of PEMs derives from ionized groups on the PEC polymers, which is closely associated with their pKa values and the pH of medium (e.g. anionic alginate is ionized at pH above its pKa whilst cationic chitosan is ionized below its pKa). For PEMs in contact with solutions of a defined pH value, the difference between the external pH and the internal pH controls the dissociation of weak polymers in the layers by regulating the distribution of free protons between the solution and the layer interior (Rmaile and Schlenoff, 2002). In particular, the dissociation of weak PECs in PEMs can be varied by changing the external conditions even after deposition (Rmaile and Schlenoff, 2002).

In the absence of salt, the individual polymers used to construct PECs will be flexible and exist in a stretched configuration (rod-like chains) in dilute solutions owing to long-ranged unscreened electrostatic repulsions. In the presence of salt, these PECs adopt a coil-shaped structure with a lower extent of interpenetration. When present in excess, the PECs behave like neutral polymer chains and generally assume a swollen coiled configuration (isotropic conformation) owing to the electrostatic exclusion volume effect which causes a decreased accessibility of the outer layer segments to the next adsorbing layer. If PEMs fabricated in salt-free solutions are transferred to a salt solution, the PEM structure will inevitably swell due to counterion incorporation. Small salt ions entering the layers will compete for the polymer charges and occupy particular binding sites, causing a decrease in extent of complexation between polymer chains of opposing charge and thereby a looser layer arrangement (facilitating extra water uptake). A decrease of film roughness due to segmental rearrangements is expected in concentrated salt solutions. Further, the response of PEMs to ion gradients is of relevance for ion exchange and ion transport, which will vary with ion concentration, solution pH and specific layer chemistry. Charge overcompensation can occur irrespective of ionic strength. Slight charge overcompensation often

occurs to flat adsorbing chains at low ionic strength. Strong overcompensation is possible for polymer chains with a large fraction of loops and tails on the surface at high ionic strength, as adsorption is no longer dominated by electrostatics (both self-repulsion and attractive interactions are greatly screened), instead, by short-range attractive potentials (Joanny, 1999). At low surface charges, minimal ion adsorption takes place.

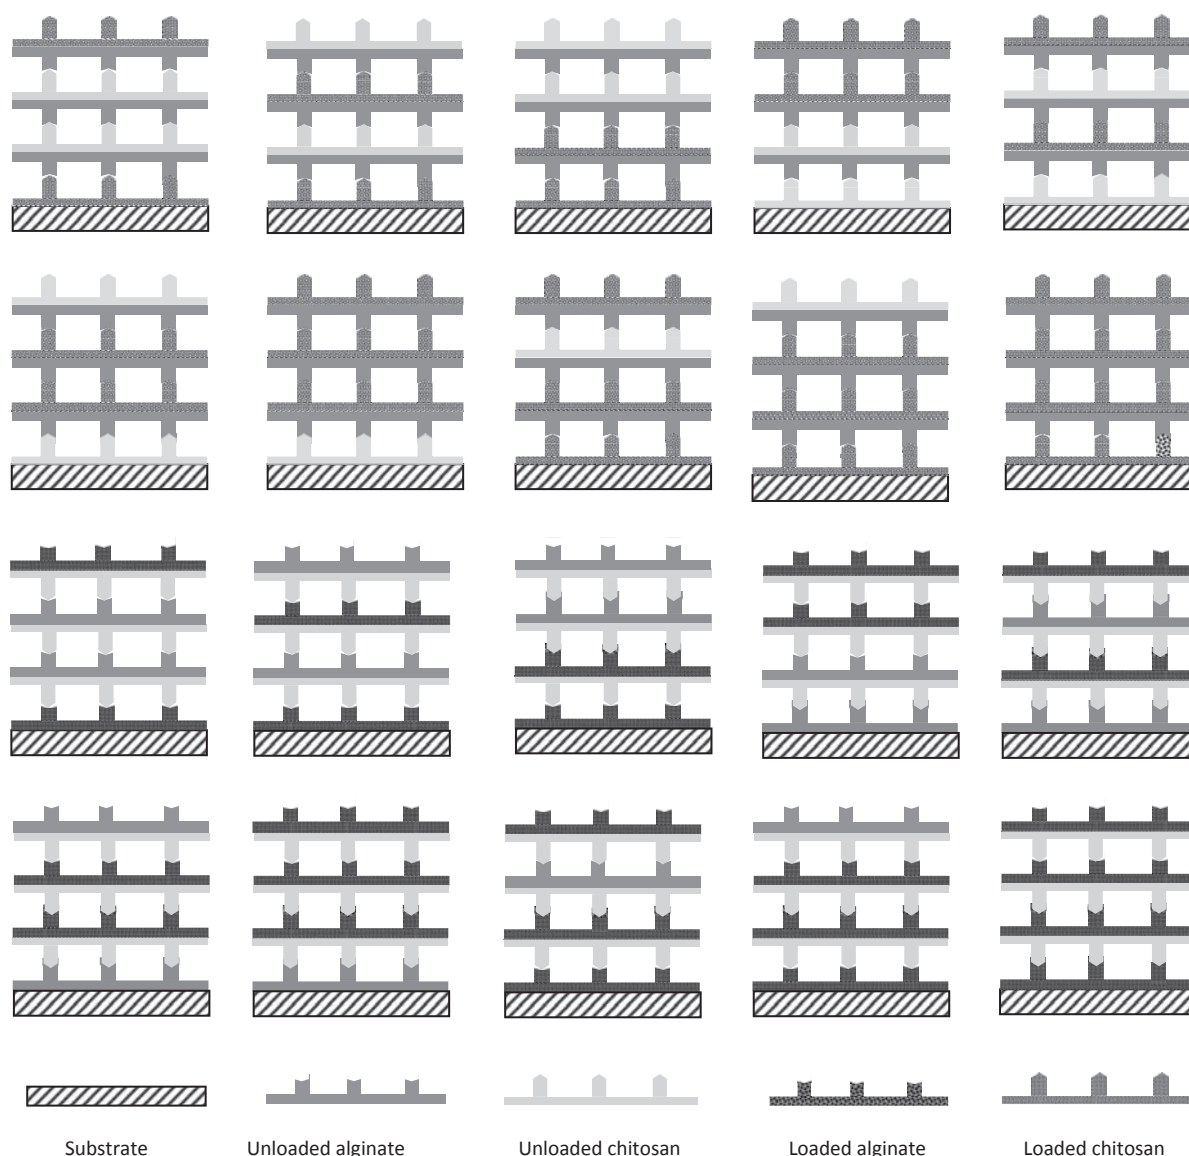

### Bioactive Release From Biopolymeric Stacks in Response to Stimuli

Different release mechanisms are employed to achieve tailored delivery of encapsulated bioactive(s). Modified release, as compared with immediate passive release, refers to a delayed, extended and/or targeted release of the desirable amount of bioactive to the intended body site at a specified time. Controlled release and sustained release are the two major mechanisms of extended release (although similarity is found between them), and can be realized through judicious choice of the carrier constituents and their properties and interactions. Controlled release targets liberation of bioactive(s) at a predetermined and nearly constant rate over a specific period (often following the zero-order release kinetics). Sustained release systems are designed to liberate continuously the bioactive(s) over a specific period at a predetermined rate (but not a constant rate, typically not less than two-fold decrease in dosing frequency over the release period) to achieve reduced side effects (often following first-order release kinetics). A wide range of delivery systems can be fabricated based on different modes of action for releasing the encapsulated bioactive substance(s). Amongst these, matrix-based or reservoir diffusion mechanisms can be utilized according to the spreading action of the encapsulated bioactive substance as it migrates from a confined region upon environmental changes (i.e. exposure to stimuli). Whilst both mechanisms are based on the changing physicochemical properties (e.g. swelling) of the encapsulation matrix surrounding the bioactive(s) and the osmotic differences between the solvent media inside and outside the encapsulation matrix, the matrix-based systems utilize pore opening of the encapsulation matrix whereas the reservoir systems depend on a permeable barrier. Moreover, degradation-controlled release mechanisms including bulk erosion, surface erosion or combinations thereof are also used in bioactive release systems. These approaches involve the inclusion of a polymer with a predetermined rate of degradation, dissolution and/or deformation (e.g. a single or multiple, early or late, short or long, and weak or severe erosion). The bioactive release profile can be tailored through monitoring not only the releasing rate, but also the starting time, high/low dosage, or "pause-restart" ("ON"/"OFF") of release, according to the chemical reactions and subsequent physical changes among the encapsulation system components (e.g. triggered evaporation or penetration) in response to one or more imposed stimuli. Fig. 2 illustrates the possible release profiles of three differently designed PEMs systems based on chitosan-alginate stacks for delivering the same bioactive substance. For a specific amount of the same bioactive, a range of loading methods can be developed based on its amount and distribution throughout the layers (Fig. 3), which would further complicate the bioactive release profile. All these release mechanisms can be implemented in PEM delivery systems including those for chitosan-alginate PECs.

Surface functionalization is critical to endowing bioactive delivery systems with specifically designed stimuli-responsive switches and/or targetable ligands as gatekeepers for achieving on-demand controlled release or exerting improved therapeutic properties while minimizing adverse effects. The surface properties of multi-layered carriers are especially important. The surface represents the point where exogenous substances make contact (e.g. living cells prefer hydrophilic surfaces in the native aqueous environment). Often the surfaces for bioactive delivery systems are designed to have timely degradation kinetics to harmonize with the metabolism or local physiological environment. For PEMs, the surface charge is mostly determined by the ionization and dissociation of functional groups (such as the carboxylic or sulphate groups) and depend on the chemical structures of PECs and local ionic

**Figure 2** Bioactive release behaviors of chitosan-alginate multi-layered films with tailored architectures. Multilayers with a low (Design 1), medium (Design 2) or high (Design 3) loading of bioactives uniformly distributed throughout all the layers of film.

**Figure 3** Schematic representation of the structures formed by chitosan-alginate polyelectrolyte stacks with different bioactive loading locations.

environment. Thus, any variation of local environment would alter the surface charge and relative motion of neighboring polymers, as well as the architecture and properties of PEMs. Accordingly, PEMs can readily be created to possess responsive properties to exogenous stimuli e.g. Magneto-stimulus (Wang et al., 2009), photo-stimulus (Angelatos et al., 2005), ultrasound-stimulus (Mourad and Webster, 1999), electro-stimulus (Yabutani et al., 2014), thermo-stimulus (Richardson et al., 2016), as well as endogenous stimuli (e.g. enzymes) (Constantine et al., 2003), pH (Zhao and Li, 2008), redox potential (Luo et al., 2011), charge (e.g. a tumor protease triggered charge switch) (Gjetting et al., 2014), and certain substances including glucose (Qi et al., 2009), glutathione (Kim et al., 2010), antigen (Caruso et al., 1997), lectin (Zhang et al., 2008), folate receptor (Rieger et al., 2007) and biotin-conjugates (Endo et al., 2011).

Specific processing steps may change the structure of PEM systems, e.g. different agitation methods may lead to different positioning of either polymer chains within the PEC and/or PEM network. For a particular PEM carrier with a specific bioactive loading, there may exist batch-to-batch variations associated with the encapsulation effectiveness, actual location and distribution of loaded bioactive(s), maximal biocompatibility and specific release profile. The controllable responses of the inner layer stacks and the outer zone of PEMs to the surrounding environments afford PEMs with different dynamic properties e.g. nanocarriers can be tuned to have a long circulation time in the blood (Yang et al., 2010). Further, the two types of polymer molecules in PEM shells (e.g. alginate and chitosan) can be tuned to impart directly a desirable impact on the activities of encapsulated bioactive through interacting with the active molecules present in their environment, leading to a beneficial synergy of the whole bioactive-loaded PEM carrier, for example, a stable chitosan-alginate PEM carrier with multiresponsive attributes and multifunctional ligands.

With the incorporation of functional modules into hierarchical PEM structures, an auto-modulated bioactive delivery with ON/OFF responses based on a number of cooperative mechanisms can be constructed.

## Conclusion

The encapsulating and release properties of polymer electrolyte multilayers are governed by the nature of component polymers, the concentration ratio of the component polymers and the physics and chemistry of the interactions between the individual polymer chains and environmental factors. The PEM fabrication history (including substrate and processing methods), along with the location and concentration of incorporated bioactive substance(s) are also important. The self-assembly of PEM carriers requires a case-by-case approach, wherein the end goal drives PEM development. In the design of PECs stacks, the nature (e.g. internal stoichiometry and conformation) and pharmacokinetics of the target bioactive substance as well as its intended time-related release amount should be considered. The number, thickness of layers, terminal layer and carrier configuration of PEMs, along with the viscoelastic properties (e.g. viscosity, shear or elastic modulus), surface composition and charge of the outermost layer as affected by environmental conditions (pH, temperature, ion type and strength), all determine the stability, bioactive release behavior and biodegradation of the delivery system and even the functionality of intended bioactive substance. In all cases, irreversible changes in the bioactive substance of interest and its pharmacokinetics as a therapeutic should be avoided.

# Interactions Between Food Ingredients and Nanocomponents Used for Composite Packaging

Adam Ekielski, Department of Production Management and Engineering, Warsaw University of Life Sciences, Warsaw, Poland

## Introduction

Global sales of nanomaterial based products to the food and beverage packaging sector has been significantly rising in recent years (Ravichandran, 2010). Nanotechnology has offered wide range of alternatives with improved performance in food packaging. The typical components of packaging formulation include barrier-forming polymers, oxygen scavenger, moisture control agents, anti-microbials, and UV protective agents. The development or selection of individual packaging formulation depends on the nature of the food to be packed; for example, dry powder and crispy foods would need a strict control on moisture, otherwise caking of dry powder or softening of crisp food may take place. On the other hand, excess moisture loss from some food items can lead to desiccation. The moisture, if not regulated, can also cause microbial growth or increase the rate of oxidation in combination with other factors. Similarly, oxygen can trigger the oxidative reactions and promote the growth of certain microbes, which finally results in spoilage or deterioration of food quality causing foul odors, unacceptable color change, change in flavor, reduction in nutritional values, etc. Bionanocomposites have offered greener alternatives to traditional packaging materials i.e. providing similar packaging function while being environmentally benign. These bionanocomposites can then be tuned into active and smart packaging with additional functions (as shown in Table 1). Polymers commonly used in nanoparticle composites include low density polyethylene (LDPE), gelatin, isotactic polypropylene and polylactic acid polymers. Examples of nanoparticle composites include Ag/LDPE, CuO/LDPE, TiO<sub>2</sub>/LDPE and ZnO/LDPE composites, as well as ZnO/gelatin, Ag/OMt-LDPE, Ag/poly(3-hydroxybutyrate-co-18 mol%-3-hydroxyvalerate), ZnO/PLA, ZnO/graphene oxide/PLA. Foods are often made up of a variety of components such as water, carbohydrate, fats, protein and minerals which are arranged in different structural patterns/forms. To understand the interactions between packaging (nanocomponents) and a food, the migration of particles from packaging composite into the food should be considered. In literature, there are quite a lot of reports on the occurrence of particle migration, but most of them haven't found strong evidence to the possibility of the human exposure. Also, the synergistic or antagonistic effect of food components caused by their action deserve attention.

## Nanoparticles and Migration Issues

### Silver (Ag) Nanoparticles

Silver usually shows action against those bacteria which, otherwise, have developed resistance against antibiotics (Emamifar, 2011). The proposed mechanisms underlying the antimicrobial activity of Ag nanoparticles include the generation of reactive oxygen species (ROS) (which induces oxidative stress and causes degradation of cell membrane structure), and the release of ions from the surface of nanoparticles resulting in death of the microbes (due to their binding to the cell membrane) (Emamifar et al., 2011; Sharma et al., 2015). Silver ions that are released from the surface of nanoparticles are also found to interact with the thiol groups present in cell proteins, inducing bacterial inactivation, condensation of DNA molecules, and loss of their replication ability (Emamifar et al., 2011; Sharma et al., 2015). A recent study concluded that the total amount of silver released from the food

**Table 1** Classification of nanocomponents used in food packaging

Classification of nanocomponents of food packaging based on function		
<b>Sensors (in active and smart packaging)</b>		
Detection of time/temperature abuse over storage		
Detection on micro-organisms and deterioration of food quality		
Microwave doneness		
Moisture control		
Gas indicators		
Freshness indicators		
<b>Active components based on functions</b>		
Food storage	Ag	Anti-bacterial action
Packaging film	Ag, SiO <sub>2</sub> , Mg, ZnO	Barrier properties
Nano screens	Colloidal precious metals	Removal of pathogens
UV protection	TiO <sub>2</sub>	UV absorption
Prevention of oxidative damage	ZnO	Free radical scavenging
Nano reinforcement	Nanoclays, Nanocellulose,carbon nanotubes, silica	Reinforcement of composite properties
Antimicrobial properties	Modified clays, Ag, ZnO	Microbial-Growth inhibition

containers to which consumer would expose is low, in comparison to the background silver exposure of general population. Since natural background concentrations are only known for ionic silver, the exposure to silver nanoparticles can not directly be compared with a safe background level (von Goetz et al., 2013). Another study observed that the amount of migrated nanosilver increased with storage time and temperature (Huang et al., 2011). Bott et al. studied the potential of silver nanoparticles (Ag-nanoparticles) that may migrate from food contact polyolefins into food, and then suggested that such migration would not lead to significant exposure to consumer (Bott et al., 2014a). In another study conducted by Jokar and Abdul Rahman, it was found that a higher silver concentration in the nanocomposite, higher temperature, and higher acidity of contact liquid would promote the silver ion release from the nanocomposite films. This migration of silver ions from nanocomposites followed the first order diffusion kinetics (Jokar and Abdul Rahman, 2014). Another sensitivity analysis showed that silver migration from the nanocomposite to the food surface was influenced most by the percentage fill, followed by the storage time and storage temperature of composite packaging (Cushen et al., 2013). A comprehensive study on marketed packaging revealed silver migration for all samples studied, with the total silver migration values ranging between 1.66 and 31.46 ng/cm<sup>2</sup> (lower than the permitted limits). The size and morphology of the silver nanoparticles changed among different samples, and migration of other nanosized materials was also observed (Echegoyen and Nerín, 2013). An investigation was carried out at 40 °C for 10 days to examine four brands of commercially available plastic food packaging, the total amount, particle size and concentration of silver, and the migration rates into three different food simulants (Milli-Q grade water, 10% ethanol, and 3% acetic acid). In this study, the total content of silver in the containers was found in the range of 13–42 µg/g. The highest migration was shown by the 3% acetic acid food simulant for all four brands of packages, with total silver released up to 3.1 ng/cm<sup>2</sup> after 10 days. This study concluded that silver has the potential to migrate into food, especially when in contact with more acidic substances (Mackevica et al., 2016). Some negative results about the migration issue of Ag nanoparticles under abnormal conditions (no migration in normal conditions) were observed by Addo Ntim et al. (2015).

### Cupric (CuO) Nanoparticles

CuO nanoparticles are used in products used for human care and in the household because of their bactericidal properties. CuO nanoparticles release copper (Cu) ions into solution; high toxicity of ions is associated with their high redox activity. Free Cu ions can produce hydroxyl radicals on the external surface of the cells, destroying the cell membrane. Excessive heavy metal(s) can also lead to breakage of protein chains. In a study on migration of Cu nanoparticles, significant migration of nanoparticles from polyethylene composite packaging to a food material was found. Simulation models for accurate assessment of the extent of such migration was feasible, although the varied background levels of copper in the food matrices would make the prediction of trace nanocopper migration more difficult (Cushen et al., 2014).

### Silica (SiO<sub>2</sub>) Nanoparticles

Silica nanoparticles (unmodified) are commonly used for reinforcement in packaging composites. Some studies reported that the presence of grafted polymers on the surface of silicon dioxide improved the tailorability of the composites by affecting the tensile properties and interfacial interactions (Wu et al., 2002; Zhang and Rong, 2003). In the study conducted by Wu et al. (2002), silica was found to improve tensile properties of the composite material, when added to polypropylene matrix. Xiong et al. (2008) also obtained similar results that tensile properties of a starch-based composite were improved after the addition of silica nanoparticles. Vladimirov et al. incorporated silicon dioxide in an isotactic polypropylene (iPP) matrix using maleic anhydride grafted polypropylene (PP-g-MA) as a compatibilizer. Silicon dioxide was also reported to increase storage modulus of the iPP matrix, thus making the material stiffer while improving oxygen barrier properties (Vladimirov et al., 2006). Jia et al. prepared nanocomposites of polyvinyl alcohol and silica by radical copolymerization of vinyl silicon dioxide nanoparticles and vinyl acetate. The nanocomposites could improve the thermal and mechanical properties as compared to the pure polyvinyl alcohol, probably due to strong covalent interactions between silicon dioxide and the polymer matrix (Jia et al., 2007). Further, Tang et al. prepared biodegradable films composed of starch, polyvinyl alcohol, and silicon dioxide, and the relative amount of silica was found to affect directly the tensile properties and water resistance of the films (Tang et al., 2008). Due to their high affinity, SiO<sub>2</sub> nanoparticles can be hazardous to health. nanoparticles can enter the human body via three routes: products containing nanoparticles (16%), skin (58%) and the respiratory system (25%). The safety of nanoparticles-containing systems used in the food industry must be tested thoroughly and considerable work in this aspect has been conducted. However, the interaction between nanoparticles and food has not yet been well investigated. On the other hand, food ingredients can also affect the absorption and toxicity of nanoparticles. SiO<sub>2</sub> can react with saccharides, proteins, fatty acids and minerals. Maximum 4.6% of saccharides, 1.7% of fatty acids, and 1.6% of minerals were found absorbed on nanoparticles. Weak interaction of SiO<sub>2</sub> with the proteins was found. In a European Food Safety Authority (EFSA) study on silica, it was observed that the substance silicon dioxide does not raise a safety concern for the consumer in the currently authorized conditions of use (EFSA, 2014). A study demonstrated an approach to track nanomaterials from source-to-sink and establish a baseline occurrence of nano-scale SiO<sub>2</sub> in foods and wastewater treatment plants (Yang et al., 2016). In a study by Go et al. (2017), the interactions between food additive silica nanoparticles and food matrix components such as saccharides, proteins, lipids, and minerals, were investigated. The results showed that zeta potential and hydrodynamic radius of silica nanoparticles were affected by all the food matrices, although their solubility was not affected. However, quantitative analysis of the interactions revealed that a small portion of food matrices interacted with silica nanoparticles and such interactions were

dependent on the type/nature of food component. Additionally, minor nutrients could also affect the interactions, as shown by greater nanoparticles interaction with honey as compared to that with a mixture of simple sugars with equivalent amounts of fructose, glucose, sucrose, and maltose (Go et al., 2017). Further study on the effect of the presence of food components on the oral absorption of nanoparticles along with their interactions, revealed that oral absorption of nanoparticles ( $3.94 \pm 0.38\%$ ) was greater than that of bulk materials ( $2.95 \pm 0.37\%$ ), possibly due to intestinal transport by microfold (M) cells. Oral absorption profile of silica nanoparticles was highly affected by the presence of sugar or protein, resulting in a high glucose absorption rate, probably due to their surface interaction on nanoparticles (Lee et al., 2017).

### Zinc Oxide (ZnO) Nanoparticles

Zinc oxides in the form of nanoparticles are widely used. The antibacterial activity of zinc oxide is known to increase with a decrease in particle size and such an action can be stimulated by visible light (Mishra et al., 2017). The additional UV-absorbing property would cause reduced UV damage and thereby improved composite stability (Martirosyan and Schneider, 2014). Additionally, zinc oxide is recommended as a generally recognized as safe (GRAS) material by FDA. Zinc oxide nanoparticles can induce disorganization of the cellular membrane due to their accumulation (Sharma et al., 2015; Emamifar, 2011). Jin et al. (2009) studied several approaches for applying zinc oxide nanoparticles to food systems. A recent study investigated the combined toxicity of zinc oxide nanoparticles (ZnO nanoparticles) and vitamin C (Vc, ascorbic acid). The results showed that Vc increased the cytotoxicity significantly compared with ZnO nanoparticles alone. When the cells were exposed to ZnO nanoparticles at a concentration less than  $15 \text{ mg L}^{-1}$ , or to Vc at a concentration less than  $300 \text{ mg L}^{-1}$ , there was no significant cytotoxicity. However, when  $15 \text{ mg L}^{-1}$  of ZnO nanoparticles and  $300 \text{ mg L}^{-1}$  of Vc were introduced together to the cells, cell viability decreased sharply indicating significant cytotoxicity (Wang et al., 2014). In another study, six nanosilver-labelled products and five silver ion ( $\text{Ag}^+$ )-labelled products were used to investigate the migration of Ag from food-contact plastics, including nanosilver into various food simulants. Migrations of Ag and Zn were the highest in 4% acetic acid, and such migrations also occurred in water and 20% ethanol. Big differences were not observed in the migration ratio between nanosilver products and  $\text{Ag}^+$  products. Ultrafiltration experiments revealed that Ag migrated from nanosilver products into 4% acetic acid was in its ionic form, while Ag migrated into water and 20% ethanol was in its nanoparticle form (Ozaki et al., 2016). Emamifar et al. (2011) prepared LDPE films containing Ag and ZnO nanoparticles through melt mixing in a twin-screw extruder. The packaging made from nanosilver-containing nanocomposite film showed a more pronounced antimicrobial effect, as compared with nano-ZnO during 112 days storage of inoculated orange juice. However, LDPE + 5% P105 packages showed a significant antimicrobial activity compared with others (Emamifar et al., 2011).

### Titanium Dioxide ( $\text{TiO}_2$ ) Nanoparticles

Titanium dioxide is another compound that has been approved by FDA for uses in human food, drugs, cosmetics and food packaging. Bactericidal property of  $\text{TiO}_2$  has been reported against *Escherichia coli*, *Salmonella choleraesuis*, *Vibrio parahaemolyticus*, *Listeria monocytogenes*, *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Diaporthe actinidiae* and *Penicillium expansum*.  $\text{TiO}_2$ -coating has also been used for food preparations or packaging equipment (Emamifar, 2011). Chawengkijwanich and Hayata developed a titania coated packaging film and tested its antimicrobial ability against *E. coli* via both *in vitro* and in actual tests, under the conditions of two different particle sizes and two types of illumination at different intensities. They showed that both UV-A alone, and titanium dioxide coated OPP (oriented polypropylene) film combined with UV-A, reduced the number of *E. coli* cells *in vitro*, although the reduction of *E. coli* cell numbers was greater for titanium dioxide coated OPP film combined with UV-A (Chawengkijwanich and Hayata, 2008). In a study on the migration into food simulants of titanium nitride (TiN) nanoparticles incorporated at three different levels in low density polyethylene (LDPE) films was carried out under severe test conditions. The study concluded that due to the usual size, shape and aggregation of nanoparticles in plastic nanocomposites, nanomaterials were likely immobilized in food contact plastics, thus the possibility of exposure to the consumer was negligible (Bott et al., 2014b). The migration of Ti from nano- $\text{TiO}_2$ -PE films used for food packaging into food simulants under different temperature and migration time conditions was further investigated. It was found that increasing the additive content in the film promoted the migration of nanoparticles, via dissolution from the surface and cut edges of the solid phase (film) into the liquid phase (food simulant) (Lin et al., 2014). Faust et al. (?) found that  $\text{TiO}_2$  isolated from the candy coating of chewing gum and commercially available  $\text{TiO}_2$  food grade additive samples were of the anatase crystal structure. Through the use of two independent techniques (by which the effects of gravity and subsequent  $\text{TiO}_2$  sedimentation were removed), disruption of the microvilli was found independent of sedimentation, and food grade  $\text{TiO}_2$  exposure resulted in the loss of microvilli from the Caco-2BBE1 cell system as a result of a biological response (not a physical artifact of *in vitro* exposure) (Faust et al., 2014). In another study, the effect of the interactions between the  $\text{TiO}_2$  and biomolecules on oral absorption was investigated and the intestinal transport pathway was also assessed using 3-dimensional culture systems. The obtained results demonstrated slightly higher oral absorption of f- $\text{TiO}_2$  (food grade) nanoparticles compared to g- $\text{TiO}_2$  (general grade) nanoparticles, which could be related to their intestinal transport mechanism by M cells. However, most of the nanoparticles were eliminated from the body through feces. Additionally, the biokinetics of f- $\text{TiO}_2$  nanoparticles was found to depend on their interaction(s) with biomolecules, and their dispersibility was affected by surface chemistry (Jo et al., 2016).

### Nanoclays

Nanoclays are commonly used in nanocomposite form with packaging polymers and usually forms intercalated or exfoliated type of composites. The exfoliated nanocomposites are known to exhibit the best properties because of the improved interactions between polymer and clay. A commonly used clay for food packaging nanocomposites production is Montmorillonite (MMT) with general formula  $M_x(Al_{4-x}Mg_x)Si_8O_{20}(OH)_4$ . MMT exhibits excellent reinforcing filler abilities in the range between 50 and 1000 (Uyama et al., 2003). According to Nielsen (1967), the improvement in barrier properties of nanocomposites is probably due to the increasing tortuosity of the diffusive path for permeants (such as moisture, oxygen, microbes etc.), presenting a longer path for them to travel for diffusion through the film. Other authors (Adame and Beall, 2009; Mirzadeh and Kokabi, 2007) further reiterated this theory. The mineral clays have also been investigated as biocide carriers for inorganic biocides such as silver, zinc, copper, magnesium, etc (Patakfalvi and Dékány, 2004; Patil et al., 2005). Nanoclays have also been functionalized to be used as antimicrobial agents (Thostenson et al., 2005). The aminopropyl functionalized magnesium phyllosilicates (AMP clay) were found to inhibit strongly the growth of microorganisms such as *E. coli*, *S. aureus* and *C. albicans* (Rhim et al., 2013). In a nanoclay migration study, a bionanocomposite consisting of polylactide (PLA) with 5% Cloisite30B (a derivatized montmorillonite clay) was used as a filler, and the particles ranging from 50 to 800 nm in radius migrated into the 95% ethanol (which was used as a food simulant). No clay mineral could not be detected in the full hyphenated AF(4)-MALS-ICP-MS system and absence of clay mineral in migrate was concluded (Schmidt et al., 2009). Farhoodi et al. (2014) prepared poly(ethylene terephthalate) (PET)/clay (Cloisite 20A) nanocomposite samples and they observed that the migration process was dependent on storage time and temperature. The molar ratio of aluminum and silicon in the acidic aqueous solution  $(Al/Si)_{aq}$  used for migration testing to the ratio in the solid phase of prepared nanocomposites  $(Al/Si)_{solid}$  was about 23% higher for the samples stored at 45 °C (Farhoodi et al., 2014).

### Nanocellulose

Two types of reinforcement can be generated from cellulose, namely CNFs (Cellulose Nano-fibrils) and CNCs (Cellulose Nano-crystals) (Azizi Samir et al., 2005). CNFs are actually the bundles of molecules, elongated and stabilized by hydrogen bonding. The diameters of microfibrils are in nanosize range, around 2–20 nm, and lengths are in the range of micrometer. The length of the cellulose nanocrystals ranges from 500 nm to 1–2 µm, and diameter from 8 nm to 20 nm or less, resulting in high aspect ratios. The CNC can be isolated from CNF by acid hydrolysis. Acid hydrolysis works by removing the amorphous parts of the fibrils by dissolving them in acid (usually sulphuric acid), leaving the crystalline regions intact (De Azeredo, 2009). De Azeredo (2009) studied the effect of cellulose nanofibers on the physical properties of mango puree edible films and found that cellulose nanofibers, when used as filler, increased effectively the tensile strength and young's modulus of mango puree films (De Azeredo, 2009). Helbert et al. (1996) explained this effect of cellulose nanofibers on the modulus: an increase in modulus is due to not only the geometry and stiffness of the nanofibers but also the formation of a fibrillary network within the polymer matrix (Helbert et al., 1996). Cellulose nanofibers seem to link through hydrogen bonds. No migration of nanocellulose has ever been reported.

### Carbon Nanotubes

Another important group of reinforcing agents are carbon nanotubes. Carbon nanotubes have extraordinarily high aspect ratios and elastic modulus (Zhou et al., 2004). According to Lau and Hui (2002), carbon nanotubes can have theoretical elastic modulus and tensile strength values up to 1 TPa and 200 GPa, respectively. In a study by Kim et al. (2008), carbon nanotubes were functionalized with carboxylic acid groups on their surfaces to enhance the intermolecular interactions between the poly(ethylene-2,6-naphthalene) matrix and carbon nanotubes. Carbon nanotubes showed an improvement in thermal stability as well as tensile strength and modulus of poly(ethylene-2,6-naphthalene), even at a concentration as low as 0.1 wt%. Polyvinyl alcohol, polyamide and polypropylene are other polymers whose tensile strength/modulus could be improved by the addition of carbon nanotubes (Bin et al., 2006; Chen et al., 2005; Manchado et al., 2005; Zeng et al., 2006). In a recent study (reference?), carbon black nanoparticles was assessed in terms of the possibility to migrate out of plastic materials used in the food packaging industry. Two types of carbon black were incorporated in low density polyethylene (LDPE) and polystyrene (PS) at 2.5% and 5.0% loading (w/w), respectively, for migration studies. The samples were exposed to different food simulants according to European Union Plastics Regulation 10/2011, simulating long-term storages for aqueous and fatty foodstuffs. At a detection limit of 12 µg kg<sup>-1</sup>, carbon black did not migrate from the packaging material into food simulants. The experimental findings are in agreement with theoretical considerations based on migration modelling. From both the experimental findings and theoretical considerations, it can be concluded that carbon black does not migrate into food once it is incorporated into a plastics food contact material (Bott et al., 2014c).

### Conclusions

The interactions between packaging nanocomponents and foods have mainly been studied on the particle migration from packaging to food. The migration of nanoparticles from packaging to food has largely been assessed in terms of the safety for human

exposure. The chemical nature of food component including surface activity and propensity to bind nanoparticle affect both the nanoparticles and food of interest. For example, flavonoids (compounds with proven antioxidant properties) and some lipids and proteins (substances with significant surface activity) show strong tendency to bind nanoparticle surface. Although many studies can be found on food additive nanoparticles and food components, inside and outside the GIT (gastrointestinal tract), the number of studies on the impact of migrated particle on food is fairly few. More investigations in this direction are required to obtain a more comprehensive understanding of this issue.

### Introduction

Food packaging systems have traditionally been used to contain the food and isolate it from environmental factors that affect their quality and therefore can arrive intact to the consumer from the place where they are produced (Valdés et al., 2015). However, the food industry has been given to the search for new packaging systems in view of increasing environmental concerns for synthetic packaging; as well as the growing consumer demand for more natural foods. As an option, biopolymers have emerged as food packaging materials due to their versatility and biodegradability, which could be helpful to solve the environmental problems caused by wastage of plastic packaging. Therefore, biodegradability is not only a functional requirement but also an important environmental attribute. Among biopolymers, polysaccharides are frequently used as innovative packaging materials by their ubiquitous presence in nature. Particularly, pectin is a polymeric chain of hydrophilic nature, with excellent oxygen, aroma, and lipid barrier ability as well as good gelling properties (Espitia et al., 2014). This last characteristic gives to pectins the ability to form edible films and coatings used as biodegradable packaging. Pectin provides film integrity and can trap different antimicrobials to formulate antimicrobial packaging, which could protect foods against contamination with spoilage and/or pathogenic microorganisms, maintaining safety and quality.

### Antimicrobial Packaging

Nowadays, demands of high-quality and safety foods became the major challenge of food industry, which has been continuously explored novel food processing technologies to achieve this goal (Miranda et al., 2016). In this sense, microbial contamination became a major concern because food is more susceptible to present some kind of spoilage when it finally reaches the consumer. This represents great economic losses throughout the food chain and health sector by foodborne diseases. Some alternatives have been used to assure safety of food products; however, the main way to isolate food from deteriorating and/or contaminating conditions is through packaging (Sung et al., 2013). Antimicrobial packaging (obtained by adding antimicrobial substances to packaging materials) has emerged as a novel development in the field of food processing that can significantly reduce pathogen survival and extend shelf life by facilitating the release of antimicrobials from the packaging (Sung et al., 2013).

Among the main materials used to formulate food packaging, plastics derived from petroleum have been by far the most used. They are cheap, present good aesthetic quality, and possess excellent physicochemical properties (Rhim et al., 2013). However, due to nondegradability of plastics and the environmental impact problem that the disposal of these wastes causes, research has been focused in the use of biopolymers obtained from natural sources (Siracusa et al., 2008): proteins (gluten, collagen, wheat and milk proteins, carrageenan, etc.), lipids (fatty acids, monoglycerides, waxes, etc.), and polysaccharides (starch, cellulose derivatives, chitosan, alginates, carrageenan, pectin, etc.) (Tang et al., 2012; Galgano et al., 2015).

Polysaccharides have been widely used as food packaging materials by their ubiquitous presence in nature, as well as by their low cost, film-forming ability, and good mechanical and gas barrier properties (Valdés et al., 2015). Among them, pectin has been used to formulate edible films and coatings and have shown good gelling properties and gas permeability, in addition to carrying antimicrobial additives, even when it has poor water barrier properties (Espitia et al., 2014). Pectin in combination with antimicrobials has served as antimicrobial packaging, controlling growth of spoilage and pathogenic microorganisms such as *Escherichia coli* O157:H7, *Staphylococcus aureus*, *Listeria monocytogenes*, *Salmonella Typhimurium*, *Alttrernaria alternata*, *Salmonella Choleraesuis*, among others (Ayala-Zavala et al., 2013; Alvarez et al., 2014; Rodriguez-Garcia et al., 2016).

As mentioned before, antimicrobial packaging is created by an “activation” of packaging material using compounds with antimicrobial activity. Some antimicrobials mostly used for this purpose include organic acids, enzymes, bacteriocins, plant extracts, essential oils (EOs), and their main components (Mauriello, 2016). The purpose of incorporating antimicrobial agents in polymeric matrices such as pectin aims to reduce the necessary concentrations of antimicrobial compounds to kill or inhibit the growth of microorganisms. The main mode of action is the gradual diffusion of the active compound from the package to the food surface; in addition, this gradual release prevents inactivation of the antimicrobials (Galgano et al., 2015).

### Pectin Sources, Structure, and Properties

Pectins are an important water-soluble biopolymer present all around us, which constitute about one-third of the cell wall of higher plants (Srivastava and Malviya, 2011). There are a lot of fruits that are good sources of high-quality pectins, such as apples, citrus fruits, papaya, peach, among others (Faravash and Ashtiani, 2007; Guo et al., 2012; Sharma et al., 2015; Yadav et al., 2015). Although pectin is commonly found in most plant tissues, the number of sources that can be used for commercial manufacture of pectin is limited. This is due to the smaller proportions of pectin found in plants, which is related to their dilution in great

amounts of tissues and their degradation due to rapid metabolic changes (Matsumoto and Otagaki, 1990). On each plant or fruit, the content of pectins is variable and depends on the age, ripening stage, and environmental conditions (Navarro and Navarro, 1985). Pomace from apples, citrus albedo, sugar beet pulp, and sunflower rinds have been proposed as by-products from the agricultural and food industries to obtain pectic substances with contents over 15% on dry basis (Giovanetti et al., 2012). However, apple pomace (10–20% of pectin) and citrus peel (30–35% of pectin), obtained from juice industry, are the two main raw materials used for industrial extraction of pectins (Kumar and Chauhan, 2010). Other plant materials reported as sources for pectin extraction are listed in Table 1.

Structurally, pectin is a heteropolysaccharide constituted by  $\alpha$ -(1, 4)-galacturonic acids with various degrees of methylation of carboxylic acid residues and/or amidated polygalacturonic acids (White et al., 1999). Pectin structure can be divided in two main regions: a “smooth” region composed by homogalacturonan and a “hairy” region constituted by rhamnogalacturonan I (RG I) and rhamnogalacturonan II (RG II) (Willats et al., 2001; Fig. 1). HG is a linear homopolymer of  $\alpha$ -(1, 4)-linked galacturonic acids that comprises about 65% of pectin. The other pectic polysaccharides are considerably more complex in structure than HG (Mohnen, 2008); for example, RG I consists of a backbone of galacturonic acids interrupted by residues of L-rhamnose attached

**Table 1** Plants materials as sources of pectins

Source	Yield (%)	References

**Figure 1** Structure compounds of pectin: homogalacturonan, rhamnogalacturonan I, and rhamnogalacturonan II (Gutierrez-Pacheco et al., 2016).

by  $\alpha$ -(1, 2) bonds to which a variety of different glycan chains (principally arabinan and galactan) are attached and represents about the 20–35% of pectin structure (Willats et al., 2006; Mohnen, 2008). On the other hand, RG II has a backbone of HG, with complex side chains (mainly rhamnose, arabinose, and some sugars such as apiose and methylfucose) attached to galacturonic acid residues (Ridley et al., 2001).

Depending of the degree of esterification (DE), pectin can be classified as high methoxyl pectin (HMP) and low methoxyl pectin (LMP) (Espitia et al., 2014). HMPs have over 50% of their carboxyl groups esterified ( $DE > 50$ ), while LMPs have a  $DE < 50$ . The DE depends on the source of pectin and extraction method, influencing the gelation ability of pectin. This property has gained a lot of attention because it strongly determines the physical characteristics of pectins such as their capability to form films, which can be used as food packaging material (Videcoq et al., 2011). In the next section, some studies about the use of pectin in combination with antimicrobials to formulate antimicrobial packaging are illustrated, as well as their effect on food matrices.

## Pectin as Antimicrobial Packaging Material

Naturally, pectin is a nonantimicrobial material; however, due to its functional properties, it has been used as a carrier material to inhibit the growth of spoilage and pathogenic microorganisms. Some authors have reported the use of pectin films or coatings incorporated with antimicrobials such as enzymes, metals, EOs, plant extracts, bacteriocins, among others. Some studies about the use of pectin as an antimicrobial packaging against isolated strains and tested in food matrices are considered in the following sections.

## Antimicrobial Activity of Pectin Against Isolated Food Bacteria

The antibacterial activity of edible films based on pectin and apple puree incorporated with oregano, cinnamon, or lemongrass EOs was tested against *Escherichia coli*, being oregano incorporated films the most effective (inhibition zone = 1.4 mm) followed by lemongrass (1.2 mm) and cinnamon EOs (1.1 mm) (Rojas-Graü et al., 2006). Similarly, pectin films incorporated with oregano EO also have been effective against *E. coli* O157:H7, *S. Choleraesuis*, *S. aureus*, and *L. monocytogenes* showing inhibitory zones of 16.3, 18.1, 20.8, and 21.3 mm, respectively (Alvarez et al., 2014). On the other hand, Du et al. (2009) tested pectin–tomato puree films incorporated with oregano, allspice, or garlic EOs against *E. coli*, *Salmonella enterica*, and *L. monocytogenes*. The results indicated that the antibacterial activities against the three pathogens were in the following order: oregano oil > allspice oil > garlic oil. EOs antibacterial activity has been attributed to individual chemical compounds presented in their composition; for example, the activity of oregano EO has been attributed mainly to their terpenes carvacrol and thymol. On the other hand, eugenol and cinnamaldehyde are mainly responsible for the antibacterial activity of cinnamon and clove EOs (Burt, 2004). For this reason, the major constituents of EOs have been used as antimicrobials in active packaging films made of pectin.

Edible films based on pectin and tomato puree incorporated with carvacrol (0.75% and 1.0%) showed antibacterial activity against *E. coli* O157:H7, with inhibition zones of 14.1 and 43.4 mm<sup>2</sup> (Du et al., 2008). Similarly, Otoni et al. (2014) found that cinnamaldehyde (2% wt) nanoemulsions incorporated in pectin–papaya puree films showed antibacterial activity against *E. coli*, *S. enterica*, *L. monocytogenes*, and *S. aureus* with inhibition zones up to 104.72, 257.06, 176.67, and 648.59 mm<sup>2</sup>, respectively. Pectin also has been combined with alginate and lemongrass EO (0.1%, 0.2%, 0.3%, and 0.4% v/w) and proved against *E. coli* O157:H7 showing inhibition zones of 50, 69.9, 78.9, and 94.0 mm<sup>2</sup>, respectively (Maizura et al., 2007).

The bacteriocin nisin has been extensively used as potential natural preservative in the food industry. However, the antimicrobial activity of nisin is reduced when it is applied directly in foods due to its binding with other food components and enzymatic inactivation (Aasen et al., 2003). For this reason, encapsulation of nisin into polymeric matrices such as pectin has emerged as an efficient approach to overcome this problem (Khaksar et al., 2014). Nisin-loaded pectin–inulin particles were effective against Gram-positive bacteria (*Arthrobacter* sp. and *Bacillus subtilis*), killing between  $1 \times 10^9$  and  $7 \times 10^9$  cells. A lower antibacterial activity was detected against Gram-negative bacteria (*Klebsiella* sp. and *E. coli*), where about  $2\text{--}3 \times 10^7$  cells did not survive. Overall, the effectiveness of nisin-loaded pectin–inulin particles was mostly dependent of the DE of pectin (Krivorotova et al., 2016). The particles with low DE or not esterified demonstrated the higher activity as compared to particles of high DE. Due to the high efficiency of nisin loading and similar antimicrobial activity comparing to nisin–pectin particles, combination of pectin and inulin has potential to be used in the food industry (Krivorotova et al., 2016).

Moreover, pectin–polylactic acid composite films incorporated with nisin were tested against *L. monocytogenes*. Developed composite films were tested in three different media, brain heart infusion (BHI) broth, orange juice, and liquid egg white showing reductions of *L. monocytogenes* of 2.1, 3.7, and 4.5 log CFU mL<sup>-1</sup>, respectively. The use of pectin and polylactic acid in combination with nisin has potential as antimicrobial food packaging to reduce postprocess contamination (Jin et al., 2009b). Pectin also has been chemically modified with fatty acids such as linoleate, oleate, and palmitate as antibacterial agents. Chemically modified pectins exhibited the greatest inhibitory effect against *S. aureus* and *E. coli* with inhibition zone values between 50% and 70%, compared with no-modified pectin (Calce et al., 2014). On the other hand, pectin films when combined with silver nanoparticles showed strong antibacterial activity against *E. coli* and *L. monocytogenes*, with inhibition zones of  $8.4 \pm 1.2$  and  $3.9 \pm 0.8$  mm, respectively (Shankar et al., 2016).

## Antimicrobial Activity of Pectin in Food Matrices

Edible films containing plant antimicrobials are gaining importance as potential treatment to extend products' shelf life and reduce risk of pathogen growth on contaminated food surfaces.

Cinnamaldehyde or carvacrol was incorporated within pectin–apple puree edible films and its antibacterial activity was tested against *S. enterica* and *E. coli* O157:H7 on chicken breasts and *L. monocytogenes* on ham. On chicken breasts, pectin films incorporated with carvacrol (3%, 1.5%, and 0.5%) reduced the bacterial populations by 3, 1.6–3, and 0.8–1 log CFU g<sup>-1</sup> at 4°C, respectively. On the other hand, cinnamaldehyde incorporated films (3% and 1.5%) induced 1.2–2.8 and 1.2–1.3 log CFU g<sup>-1</sup> reductions at the same temperature, respectively. On ham, carvacrol films induced greater reductions of *L. monocytogenes* than cinnamaldehyde films at all concentrations tested (0.4–2.2 log CFU g<sup>-1</sup>) (Ravishankar et al., 2009). A similar study, probed the antibacterial activity of edible films based on pectin and apple, carrot or hibiscus incorporated with carvacrol or cinnamaldehyde against *L. monocytogenes* on contaminated ham and bologna. Results showed that films with carvacrol exhibited better antimicrobial activity against *L. monocytogenes* than films with cinnamaldehyde, with developed films being more effective on ham than on bologna (Ravishankar et al., 2012).

Pectin apple–based edible films containing carvacrol and cinnamaldehyde were evaluated against antibiotic-resistant (D28a and H2a) and susceptible (A24a) *Campylobacter jejuni* strains on chicken at 4 or 23°C for 72 h. At 4°C, cinnamaldehyde-incorporated films caused variable reductions for all strains, ranging from 0.2 to 2.5 log CFU g<sup>-1</sup> and 1.8 to 6.0 log CFU g<sup>-1</sup> at 1.5% and 3.0%, respectively. Films with ≥1.5% cinnamaldehyde reduced populations of all strains to below detection at 23°C at 72 h. On the other hand, films with 3% of carvacrol caused a 0.5 log CFU g<sup>-1</sup> reduction for both A24a and D28a, and by 0.9 log CFU g<sup>-1</sup> for H2a at 4°C, while at 23°C the reductions were below detection for A24a and H2a, and by 2.4 log CFU g<sup>-1</sup> for D28a. Reductions ranged from 1.1 to 1.9 log CFU g<sup>-1</sup> and 0.4 to 1.2 log CFU g<sup>-1</sup> with 1.5% and 0.5% of carvacrol at 23°C, respectively (Mild et al., 2011). The differences in antibacterial activities between cinnamaldehyde and carvacrol may be due to the fact that both antimicrobials operate by different mechanisms. It is hypothesized that carvacrol disintegrate the bacterial outer membrane, releasing cytoplasmic constituents and consequently changing the passive permeability of the cell, whereas cinnamaldehyde reacts chemically with the membrane surface resulting in cell death (Burt, 2004; Mild et al., 2011; Rodriguez-Garcia et al., 2015).

The antimicrobial activity of pectin edible films incorporated with nisin and its combination with an ionizing radiation treatment was used against *L. monocytogenes* on a ready-to-eat turkey meat. Results showed that pectin–nisin films without irradiation reduced *L. monocytogenes* by 1.76 log CFU cm<sup>-2</sup>. Moreover, the combination of pectin–nisin films with irradiation resulted in a 3.95 and 5.35 log CFU cm<sup>-2</sup> reduction at 1 and 2 kGy, respectively; indicating a synergistic effect on *Listeria* viability on the surface of ready-to-eat turkey meat (Jin et al., 2009a). Both, in vitro and in vivo studies have showed the potential of pectin to formulate antimicrobial packaging, which despite the chemical structure and nature of aforementioned compounds showed an inhibitory effect against different food pathogens.

## Conclusion

Pectin has shown potential to be used as antimicrobial packaging material because of its excellent film-forming properties and good barrier properties, which has enabled it to serve as a carrier of many types of antimicrobials, from EOs to bacteriocins. Although some of these studies have shown promising results, more research are needed about the effect of antimicrobials on the physico-chemical characteristics of the packaging material as well as the feasibility of its application on a large scale. Moreover, since many of the studies have been carried out using commercial pectins, there are still many sources of pectin that need to be exploited for food applications.

## Starchy Food, a Complex Food

The so-called “starchy foods” are products having a high starch fraction, where other constituents (biopolymers among others) are present forming a complex edible matrix. Some examples of starchy foods are bread, pasta, baked products, etc., and in general are a very important source of dietary energy worldwide. All these foodstuffs are matrices built mainly by starch, proteins, and lipids, but type of ingredients and processing conditions affect their microstructure (microscopic arrangement), which in turn can affect their organoleptic and nutritional properties, among other (e.g. shelf life) (Aguilera, 2005). In this way, current evidence suggests that the knowledge of binary interactions among starch, lipid, and protein is neither sufficient to understand the properties of food matrix and its actual effect on starch digestibility, since really the three constituents are present together in food. In fact, since synergistic or not lineal effects derived from ternary interaction among starch, lipid, and protein may be present, extrapolation of observations done in binary systems would be not the most suitable way to explain the physical and nutritional properties of foods (Zhang and Hamaker, 2003, 2004, 2005; Zhang et al., 2003, 2010; Jacobs et al., 2009). However, detailed studies about microstructure of ternary (or more complex systems) are scarce so far, mainly due the complexity of such systems, which result in a poor reproducibility of systems and research protocols. In addition, current evidence suggests that a linear relationship between food microstructure and digestibility or glycemic response (nutritional effect) is not always clearly found due to genetic or physiological differences among consumers, which finally determine the actual nutritional effects of foods (Cummings and Englyst, 1995; Englyst and Englyst, 2005).

## Digestibility of Starch

Starch is a complex carbohydrate produced by plants to store energy generated through photosynthesis. It is constituted by glucose units which form two types of biopolymers: amylose, which is linear (glucose with  $\alpha$ -1,4 bonds), and the amylopectin, which has branches and a much higher molecular weight (glucose units are linked by two types of bonds:  $\alpha$ -1,4 in the linear sections, and  $\alpha$ -1,6 in the branching points). Both polymers are joined forming discrete granules of different sizes, shapes, and amylose/amylopectin ratio, depending on the botanic origin (Sajilata et al., 2006; Copeland et al., 2009). Starch is especially abundant in legumes, tubercles, and cereals; all these are highly consumed by human beings worldwide, hence it is considered as their main energy source (Copeland et al., 2009).

In human being, starch consumed is digested at both the level and in the small intestine by the sequential action of  $\alpha$ -amylases (salivary and pancreatic), and the concerted action of enzymes such as the Maltase–Glucoamylase (MGAM) complex and the Sucrose–Isomaltase (SI) complex (Nichols et al., 2009; Santos et al., 2012). The final process of starch digestion into free glucose is completed in the small intestine brush border, with glucose efficiently absorbed in the small intestine and transported to the blood stream.

The starch that is not fully digested into glucose in the small intestine passes to the large intestine, where it may be fermented by the microbiota, thus producing short-chain fatty acids that have been related to beneficial health effects (Cummings and Englyst, 1995; Dona et al., 2010). The starch digested into glucose and having effect on postprandial glycaemia, is called “digestible,” whereas the starch passing to the large intestine is known as “resistant.” Digestible starch, on its turn, is divided into rapidly and slowly digestible starch. Slowly digestible starch produces more moderate changes in the postprandial glycaemia (concentration of glucose in the blood after a meal), whereas rapidly digestible starch leads to rapid changes in the glycaemia, even similar to that caused by simple sugars, characterized by a fast increase in blood glucose concentration up to maximal high levels (Englyst et al., 1992). Current classification of starch based on its *in vitro* digestibility under “small intestine conditions” is the following:

- Very rapidly digestible starch (VRDS): Starch hydrolyzed within 1 min (Chung et al., 2006).
- Rapidly digestible starch (RDS): Starch hydrolyzed within 20 min (Englyst et al., 1992).
- Slowly digestible starch (SDS): Starch digested during the period between 20 and 120 min (Englyst et al., 1992).
- Resistant starch (RS): Starch not hydrolyzed within 120 min (Englyst et al., 1992).

From some decades ago a great interest in food that when consumed leads to a lower glycemic response has been generated; that is, a lower change in blood glucose concentration after food ingestion (postprandial period). This interest is based on the growing scientific evidence, suggesting that exaggerated postprandial glycemic response would be a risk factor for several chronic non-transmissible diseases, such as diabetes and cardio-vascular diseases (FAO/WHO, 1998; Brand-Miller, 2003; Thomas and Wolever, 2003; Jakobsen et al., 2010; Larsen et al., 2010). The postprandial glycemic response (commonly referred as glycemic index or glycemic load) of a great variety of foods is known; their values may be considered as referential (Foster-Powell et al., 2002; Dona et al.,

2010). Several *in vitro* methods have been developed to estimate glycemic response; they may significantly differ in their methodology and not always (in fact, almost never) predict *in vivo* glucose homeostasis precisely since such methods do not include the high number of factors that take place in the physiological responses to carbohydrate-rich food (Priebe et al., 2008; Woolnough et al., 2008).

### **Role of Food Microstructure in Starch Digestion**

Starch digestibility and glycemic response depend on several factors that can be measured (considering that digestibility is only one of factors affecting the glycemic response), with the two main groups identified as: those related to the food characteristics (for example, composition and structure), and those related to the consumer (for example, physiological state and genetic background) (Cummings and Englyst, 1995).

Among the factors related to food, food microstructural and mechanical properties (which are affected in turn by microstructure) may act at various levels, affecting the rate of starch digestion (Parada and Aguilera, 2011a; Turgeon and Rioux, 2011). It has been observed that in the mouth the size reduction of food, its disintegration, and the rate of starch hydrolysis depend on the chewing time as well as the physical characteristics (determined by microstructure) of ingested food (Hoebler et al., 1998). Gastric emptying may also be delayed by the occurrence of microstructures (which are more difficult to be disintegrated inside the stomach, thus affecting the rate of the whole digestion process in the intestine). Furthermore, the matrix where starch is in the intestine and the compound intimately interacting with the starch may retard or even prevent its contact with the digestive enzymes, hence reducing its digestibility.

Additionally, the degree of gelatinization/retrogradation of starch, which is probably the main “structural” factor affecting digestibility, is a function of food processing and storing conditions and can highly affect the proportion of total digestible starch. When the gelatinized starch (with an amorphous structure; e.g. after cooked in water excess) is rapidly digested, the molecules in native crystalline state (present in raw foods) or retrograded (starch chains that, after to be in an amorphous state by gelatinization, interact among themselves during storage at low temperatures forming crystalline zones) are digested slowly or simply not digested (Fardet et al., 1998; Mora-Escobedo et al., 2004; Parada and Aguilera, 2011a).

Finally, it should be noted that although microstructure is well known to affect starch digestibility, appropriate characterization and quantification of interactions among different food constituents, in addition to compositional analysis, remain very challenging and are crucial for a successful food design (Aguilera, 2005; Jacobs et al., 2009).

### **Interaction Between Main Components of Starchy Food and Resultant Starch Digestibility**

Most of starchy foods, such as pasta, bread, etc., are formed mainly by starch, protein (mainly gluten if wheat flour is used), and lipids (mainly triglycerides), and these contents may be simply determined using standardized methods. Nonetheless, the information on the contents of these components is not sufficient to explain the digestibility of a product (Mourot et al., 1988; Riccardi et al., 2003). In many cases, this difference is derived from the microstructure formed during the manufacturing process; however, information about how these three ingredients interact in food, and the real effect of the structures on starch digestibility, are still scarce (Zhang and Hamaker, 2003, 2005).

Food constituents interact forming structures showing particular properties, which have been deeply studied in binary systems, such as starch–lipids (Tang and Copeland, 2007); nevertheless, in ternary or more complex systems, information is still rather limited (Zhang and Hamaker, 2003; Zhang et al., 2010). For example, the complex amylose–lipid is known to form two types of structures: I and II. The structure type I melts at a temperature, from 10 to 30 °C, lower than the melting temperature of the structure type II. Similarly, the structure type II may be detected by x-ray crystallography; whereas the structure type I is not detectable through this technique, which suggests that this type is probably in an amorphous state. Amylose may form structures of both type I and II, whereas amylopectin will probably bind to a lipid only through individual chains.

The type of starch–lipid formed structure depends on the lipid type and the conditions under which the complex is formed. Lipids with charged head groups have a lower tendency to form type II structures (Eliasson and Wahlgren, 2004). In other cases, both types I and II have been reported to be dependent on how the complexes are formed. Complexes of type I are dominant if their formation occurs rapidly and at low temperatures (between 70 °C and 80 °C), whereas, the most ordered complexes type II are favored if the complex formation happens at high temperatures (Eliasson and Wahlgren, 2004). In general, many other factors can also affect the formation of the starch–lipid complex, such as monoacyl chain length, polar head of the lipid, water content, type of starch, and food processing.

Complexes between amylose and lipids (fatty acids, lysophospholipids, and monoacylglycerides) may significantly modify the properties and functionality of starch; for example, starch solubility is reduced in water, rheological properties of pasta are altered, swelling capacity is reduced, gelatinization temperature is increased, retrogradation is retarded, and susceptibility to enzymatic hydrolysis is reduced (Copeland et al., 2009).

In a study on the effect of superficial components of starch granules (non-carbohydrate surface components), Debet and Gidley (2006) classified starch as fast swelling starch (e.g. waxy maize, potato, etc.), slow swelling starch (which may be transformed into fast swelling starch by extraction of superficial lipids and proteins e.g. wheat, maize, etc.), and limited swelling starch (which is not

affected by protein/lipid extraction e.g. high amylose maize/potato). In addition, Noisuwan et al. (2011) observed that milk proteins, located in the interface or in empty spaces (channels, holes, etc.) of starch granules (rice), may restrict water diffusion inside the granules during its gelatinization. This outcome shows us how “small” changes in non-carbohydrate components can significantly modify starch properties e.g. dependence on its origin/nature/structure.

On the other hand, there are studies about how gluten proteins may form matrices covering starch granules, thus preventing both their gelatinization and contacts with digestive enzymes; all of which make digestibility more difficult (Li et al., 2007; Auger et al., 2008; Parada and Aguilera, 2011b). Pasini et al. (2001) observed in bread that at high cooking temperatures ( $>180^{\circ}\text{C}$ ), *in vitro* digestion of wheat protein is significantly limited due to the formation of protein aggregates having high molecular weight stabilized by strong irreversible interactions, different from disulfide (SS) bonds and/or hydrophobic bonds that may be present in processes at low temperatures ( $<100^{\circ}\text{C}$ ). In addition, it has been observed that an “adequate” kneading/mixing maximizes the formation of a protein matrix (gluten) through the action of disulfide bonds. However, if an excessive kneading/mixing is carried out, the matrix loses firmness when the bonds break and glutenin particles are dissociated into smaller fragments, which would influence the accessibility of digestive enzymes, and would enhance starch digestibility (Parada and Aguilera, 2011b). Hence, the processing (mechanical, thermic, etc.) may affect the interaction level among protein molecules, affecting digestibility of the whole system.

As said above, there is little information about microstructures of the ternary systems formed by starch, protein, and fatty acids and their effect on starch digestibility. Starch and proteins are two important biopolymers whose interaction is inherently difficult; Nevertheless, the presence of free fatty acids (FFAs) has been observed to favor the formation of ternary complexes, where possibly three different structural elements may take effect: formation of complexes starch-FFA, formation of complexes protein-FFA, and the disulfide bond-linked protein aggregate (Zhang et al., 2003; Zhang and Hamaker, 2005).

Since interactions among food components mandatorily affect the rheological (and/or textural) properties of food, several studies focused on rheological behaviors of model systems have been carried out to investigate such interactions. For example, Zhang and Hamaker (2003) studied interaction between sorghum starch, serum protein, and FFAs (20:2:1, p/p/p) by means of a rapid visco-analyzer (RVA). The authors observed the presence of a noticeable peak in viscosity (during cooling phase) when the three components are present in the system, which is different from the event of the binary systems constituted only by starch and protein or FFAs (i.e. where the viscosity peak was not observed or was significantly lower). In addition, it was observed that both the addition sequence of to the components of the ternary system and the fatty acid used (probably related to the unsaturation degree) affected peaks. For clarity, it should be taken into account that when isolated starch is in an aqueous solution and heated beyond the gelatinization temperature under agitation, viscosity increase until reaching a maximum value due to granule swelling (gelatinization); after that, viscosity decreases if agitation continues due to granule fragmentation; finally, when the solution is cooled, the viscosity increases again, but now by the retrogradation (interaction between starch chains). Exact values of viscosity highly depend on starch type and other component of the system (proteins, lipid, salts, sugar, etc.).

Regarding role of proteins in the formation of complexes, it has been observed, also in model systems, that the presence of serum protein diminishes the formation of the starch-FFA complex; Nevertheless, the crystalline order of this complex (V type crystals) was better defined. These changes were related to the formation of a ternary complex of starch, FFA, and protein, since the movement of basic structural elements of the complex amylose-FFA would be restricted, thus helping the formation of more ordered complexes and diminishing the opportunity to form new complexes between amylose and FFAs (Zhang and Hamaker, 2004).

In another study, Zhang et al. (2010) concluded that FFAs may act as a bond between amylose and protein molecules, which are thermodynamically incompatible, and whose functional carboxyl groups are essential for the formation of a stable ternary complex. The authors suggest that electrostatic interactions among carboxyl groups, possessing negative charge, of FFAs and the poly-ionic protein are the basis for the self-assembly of the complex.

Concerning the effect of lipids on the digestibility and glycemic response of starch, the lower glycemic response observed when lipids are ingested with starchy food (which may be related to various factors such as delay in gastric emptying), the higher insulin response, lower glucose absorption in the small intestine, and a lower accessibility to the digestive enzymes (Latgé et al., 1994; Fardet et al., 1999; Henry, 2009). Fardet et al. (1999) studied the effect of lipids on the accessibility of  $\alpha$ -amylase in a wheat-based food. The authors observed that, depending on the food and the lipid emulsion used, the presence of lipid might not affect, decrease, or slightly enhance starch digestibility without presenting large differences in any case. These and other results suggest that lipid can act at both a molecular (interaction at molecular level) and “meso-structural” level (where probably the digestibility is more affected by resultant texture than by fine molecular architecture, although evidently the latter affects the former).

Also, lipid (via starch-lipid interaction) may prevent gelatinization by inhibiting hydration of amylopectin chains, and retard retrogradation, which affects starch digestibility (Henry, 2009).

Regarding processing, it affects the textural/physical properties of food, thus affecting starch digestibility and finally glycemic response (Lee et al., 2005). Many studies have been conducted to investigate how processing and storing conditions affect starch digestibility and glycemic response. Specifically concerning potato, it has been observed that any process involving heating above the gelatinization temperature would cause very high glycemic responses, similar to those reached by glucose; while a storing period at low temperatures significantly decrease the response due to the retrogradation process; some variations may be observed depending on the actual experimental conditions (Kingman and Englyst, 1994; Soh and Brand-Miller, 1999; Garcia-Alonso and Goñi, 2000; Foster-Powell et al., 2002; Fernandes et al., 2005; Tahvonon et al., 2006). Again, the challenge lies in the understanding of the details at both the structural and compositional levels, and the advanced analysis technologies (as modern microscopy techniques) are particularly helpful.

## Impact of Consumer Characteristics on Final Glycemic Response

In order to have a full understanding of postprandial glycemic response, knowing food characteristics appears to be insufficient. The knowledge of consumer characteristics including genetic background and metabolic status is crucial. In general, variability of glycemic response among individuals after a carbohydrate-rich meal is known to be larger than within-subjects variability (Frost and Dornhorst, 2002). This variability (among individuals) can be explained by several intrinsic factors such as health status and genetic profile (Cummings and Englyst, 1995), and some other extrinsic factors such as degree of particle breakdown resulted by mastication (which can affect significantly the outcome analysis) (Ranawana et al., 2010).

Probably, diabetes is one of diseases that is the most relevant in relation to glycemic response. As defined by the American Diabetes Association (2010), Diabetes is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. In type 2 diabetes, the most common type of diabetes, insulin deficiency is caused by a combination of pancreatic  $\beta$ -cell defect coupled with insulin resistance, and frequently accompanied by inadequate glucagon suppression after meals, increased hepatic glucose output, and decreased amplification of insulin secretion mediated by gut hormones responsible for the incretin effect, such as GLP-1 or GIP (DeFronzo, 2004).

Although many genetic loci have been previously implicated in type 2 diabetes (Hiveert et al., 2011), there is no clear evidence of interaction between food microstructure (or type of food components' interaction) and genetic susceptibility to type 2 diabetes. In this context, genetic variation of salivary  $\alpha$ -amylase emerges as a possible genetic marker related to glycemic response to food microstructure. Some evidence (related with the action time) suggests that although salivary  $\alpha$ -amylase is not relevant for total starch digestibility, it could affect the final postprandial glycemic response. The action of salivary  $\alpha$ -amylase on starch digestion and glycemic response is relatively not so important compared with the effect of pancreatic  $\alpha$ -amylase or other enzymes on carbohydrate digestion in the small intestine, given its short action owing to the inhibition caused by low pH in the stomach (Frayn, 2010; Woolnough et al., 2010). The salivary  $\alpha$ -amylase is encoded by the AMY gene that shows a particular type of genetic polymorphism called copy-number variation (CNV), which means that the number of functional gene copies may range from 2 diploid copies of the AMY1 gene (1 of paternal and 1 of maternal origin) to as many as 16 copies (Perry et al., 2007). Interestingly, a positive correlation between AMY1 CNV and  $\alpha$ -amylase concentration or activity in saliva has been found, whereas CNV of AMY1 gene has been found in different populations, probably due to genetic adaptation during human groups' evolution associated with different diets (Perry et al., 2007; Santos et al., 2012).

It has been reported that high endogenous salivary  $\alpha$ -amylase activity due to high AMY1 copies would be associated with improved glycemic homeostasis (resulting in lower glycemic response) following starch ingestion in healthy adults with normal body weights. Such a theory is supported by some evidence (Mandel and Breslin, 2012) that individuals having low activity of salivary  $\alpha$ -amylase (a low CNV of AMY1 gene) may be at greater risk of glucose intolerance after ingesting starch-rich diets compared with the subjects with high levels of endogenous salivary  $\alpha$ -amylase. It is suggested that the early release of starch digestion products in the oral cavity may provide signals to the body to prepare for incoming starch and ensuing glucose through vagal activation, resulting in an early insulin release that can be termed "pre-absorptive insulin release" (PIR, also known as cephalic-phase insulin release) (Mandel and Breslin, 2012). This type of pre-absorptive secretion has been clearly characterized in the cephalic release of other hormones such as pancreatic polypeptide (Teff, 2010). It has been described that, although PIR is weak and probably represents only a minor proportion of secreted insulin, PIR may have an important influence on glycemic response (Åhrén and Holst, 2001). Butterworth et al. (2011) suggest that sweet receptors in the upper sections of the gastrointestinal tract could detect any maltose formed from starch by salivary amylase, and if coupled with the release of a number of signaling peptides, such as GLP-1 and PYY, influence CNS-mediated control of gastric emptying, insulin secretion, and appetite. In the case of maltose generated in the mouth, there could also be a feed-forward effect in such a way that after its detection by receptors in the gastrointestinal tract, the signals could be interpreted as a warning that a starch-containing meal has been consumed, leading to increased secretion of pancreatic amylase for digesting the unexpected starch load. Moreover, it has been observed that starch hydrolysis in the mouth also depends on the initial food structure as well as the breakdown of solid food (Hoebler et al., 1998), suggesting that food microstructure could also affect PIR.

It has been observed that the consumption of slowly digestible starch does not always result in a lower glycemic response, and does not lead to the widely accepted consensus on such phenomenon (i.e. a low starch digestion should generate a lower glycemic response). The explanation is probably that if glucose enters the circulation at a slower rate, less insulin is secreted to keep glucose concentrations beneath an acceptable limit, resulting in a slower uptake of glucose into tissues, and a high glycemic response (Eelderink et al., 2012a,b). This fact, together with the possible effects of PIR described above, supports the idea that the food having a small fraction of very rapidly digestible starch could help to achieve a lower glycemic response than the food without this fraction due to the early secretion of insulin. Evidence obtained by our research group suggests that, although the role of early starch digestion in the mouth in glycemic response is a plausible possibility, the differences between consumers could most likely be found only among very different persons (high difference in CNV of AMY1 gene) and/or foods with clearly different digestibility, due the high intrinsic variability of the whole system and the capacity of the body to regulate the glycemic homeostasis (Mandel and Breslin, 2012; unpublished results of our group).

## Non-starch Components of Food and Satiety

The structural effect of proteins not only affects the stomach emptying rate and starch digestion, but also helps to regulate postprandial glycaemia through the regulation of food intake and satiety. Several mechanisms have been proposed to explain the satiety effect of proteins: increase in the concentrations of hormones involved in satiety signals, increase in energy expenditure, variation in amino acid concentrations, and increase in the process of gluconeogenesis. It has been found that high-protein foods cause high sensory-specific satiety and decreased feeling of hunger than the same type of foods with low protein contents (Lang et al., 1999; Turgeon and Rioux, 2011). Hence, this structural effect of proteins should also be considered when the nutritional properties of food related to the control of glycaemia are studied.

Fat is a major contributor to overall energy intake, however fat with satiating properties could potentially reduce energy intake. In this line, several lipids have been found to exert satiating effects. Maher and Clegg (2018) have recently reviewed the potential mechanisms whereby some lipids show this property. The authors state that the lipid with the highest potential to enhance satiety is Medium-Chain Triglycerides (MCT) and short-chain fatty acids (SCFA) can also promote satiety, but oral administration has been linked to poor tolerability rather than satiety. The authors also indicated that data on the appetite effects of conjugated linoleic acid (CLA) are limited but do suggest potential. Others lipids with satiating effects are diacylglycerol (DAG), *n*-3 PUFA, and small particle lipids.

## Conclusions

Basic interactions of food constituents are known and have been studied, however, information about ternary or more complex systems, as well as their effect(s) on starch digestibility, is still limited and the obtained results are not easy to be analyzed and understood due to intrinsic complexity of the entire system: "components and food"-*"human metabolism"*-*"actual nutritional effect"*. In addition, there is evidence to suggest that the presence of fatty acids (along with their type) and processing conditions, may affect the physical properties of protein and starch-based systems. Further, intrinsic differences among individuals need to be considered *in vivo* to determine the actual effect of food microstructure and components on the glycemic response of starch-rich foods when consumed by different individuals (affecting glycemic homeostasis and satiety, for example).

# Encapsulation Systems Containing Multi-Nutrients/Bioactives: From Molecular Scale to Industrial Scale

Geoffrey IN Waterhouse and Dongxiao Sun-Waterhouse, The University of Auckland, Auckland, New Zealand

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Bioactive substances** herein refer to non-nutrient constituents including compounds (e.g. carotenoids, flavonoids and phytosterols), enzymes and microorganisms that occur in small quantities in foods but can interact with one or more component(s) of a living organism, tissue or cell by imparting probable biological effects (including beneficial physiological, behavioral, and immunological functions beyond the basic nutritional value of the product). Certain nutrients capable of promoting health or preventing diseases are not included in this category.

**In situ matrix encapsulation** is a delivery approach, in which encapsulation is integrated as a part of normal food processing, and a finished food matrix with tailored structure is used as a “natural” encapsulation system for target substance(s).

## Introduction

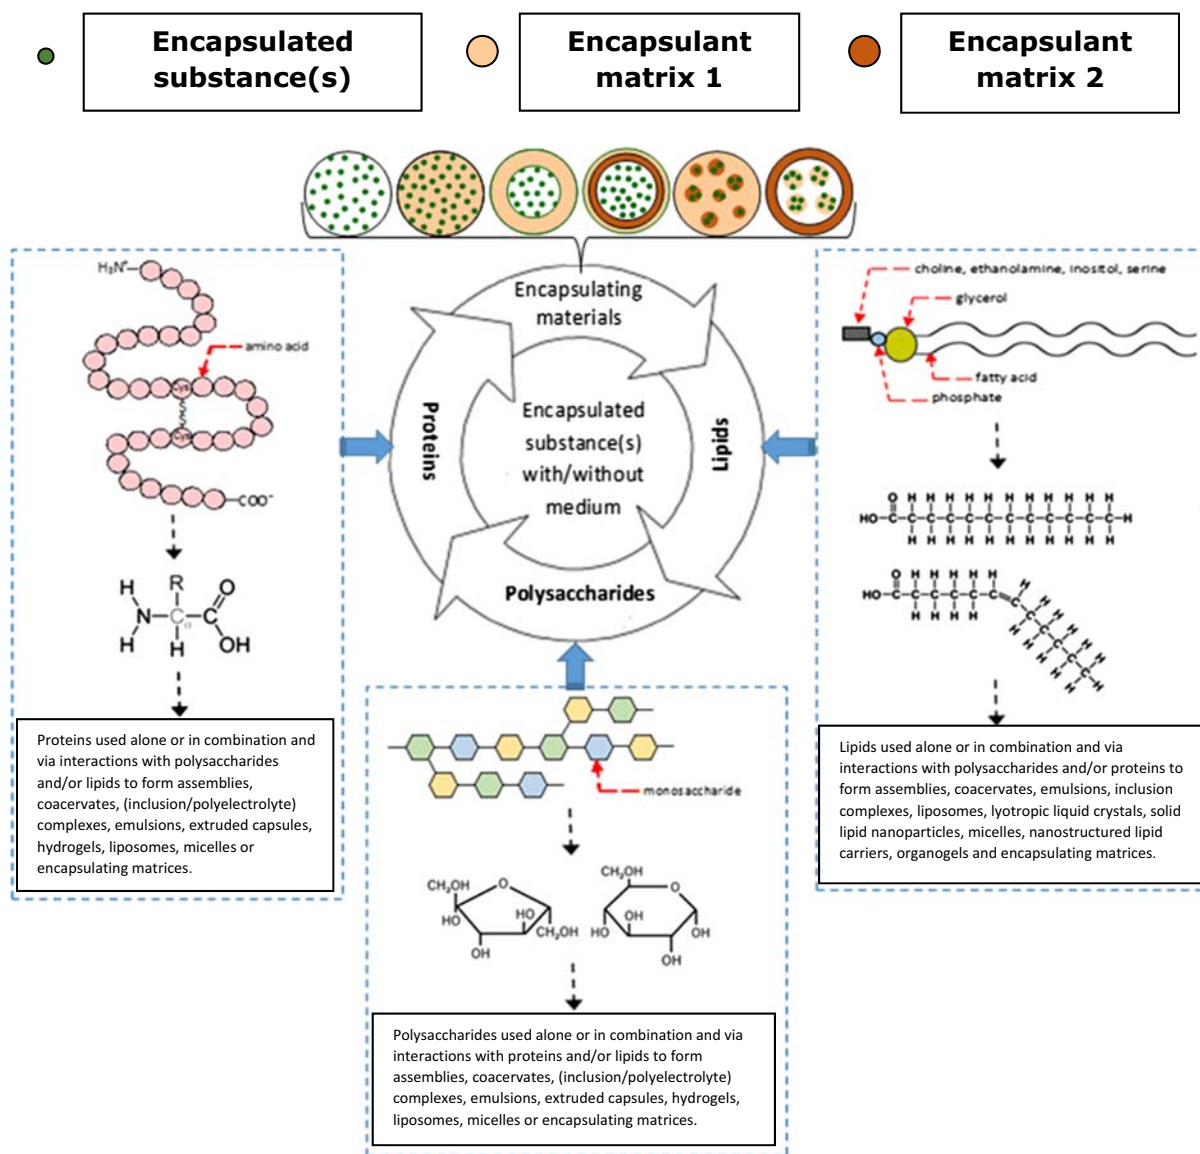

Increased consumer awareness of the close relationship between diet and good health, together with growing recognition of the specific health benefits of individual nutrients and bioactive substances, motivate attempts to increase the stability, bioaccessibility and bioavailability of these bioactives in foods and various dietary supplements. Consumer foods are complex matrices that differ enormously in chemical composition, molecular arrangements and physical state, and contain diverse components including natural food ingredients, additives and different water/lipid contents. Direct fortification of foods with highly demanded nutrients or bioactive substances (including “functional ingredients” with positive effects on overall well-being and/or specific health benefits) presents huge challenges associated with maintaining product quality and food acceptance from a technical perspective, as well as potentially reduced bioavailability of target bioactives due to unwanted interactions or degradation during processing. This has led to the search for efficient delivery systems for highly demanded substances in both academic and industrial research settings.

Nutrients and bioactive substances encompass micro- or macro-molecules such as proteins (including enzymes), carbohydrates, lipids, phenolics, carotenoids, vitamins and minerals. Besides their nutritional significance, many of these substances play dominant or contributing roles in food molecular dynamics and structure. However, many have low solubility in aqueous-based or oil-based foods and poor transmembrane permeability through gastric or intestinal membranes, whilst being very susceptible to deterioration under particular external influences. They can induce desirable or undesirable food component interactions via chemical and physical mechanisms under the stresses imposed during food processing, handling, ingestion and digestion. Hence, the utilization efficiency of fortifying food ingredients is important for preserving biological functionality of desired nutrients and bioactive substances, whilst maintaining overall food quality and sensory acceptability for consumers (Sun-Waterhouse and Wadhwa, 2013).

Encapsulation is a physicochemical or mechanical process to entrap/enclose one or more substances within a protective barrier (i.e. a shell or a matrix), “temporarily isolating” the substance(s) from external environments for a pre-determined period or until the target site of action inside the human body is reached. Encapsulation can serve as an independent process to produce “encapsulated ingredients” or can be integrated into normal food processing. Accordingly, encapsulation allows immobilization, stabilization, protection, dose management, structuration, release and functionalization of nutrient/bioactive substance(s) for a more precise delivery with greater palatability, efficacy and safety at the point of use. Encapsulation systems are also called “delivery systems” or “carriers” interchangeably, and can be grouped based on their scale i.e. macroencapsulation (>1 mm), microencapsulation (100 nm–1 mm) and nanoencapsulation (1–100 nm). Components in a delivery system or encapsulation matrix can be selected from various validated nutrients and bioactives from plants, animals and microbes e.g. carbohydrates, proteins, lipids, phytochemicals, minerals, enzymes, cells and microorganisms, to maximize their respective amounts for human consumption. The determination of how, when and where these substances are included into the delivery systems and final fortified foods requires smart design and state-of-the-art technologies to optimize the interactions among co-existing formulation components in response to changing environments.

## Carrier Materials (“Encapsulants”)

Encapsulation systems should be designed to engage nutrients or bioactive substances as components of the carrier’s shell or matrix barrier to maximize the nutritional advantages and health benefits of the whole encapsulation system. Carbohydrates, proteins, lipids, water and surfactant(s) are the common ingredients used to create carriers with different structures, conformations,

**Figure 1** Schematic representation of molecular interactions and carrier dynamics in various encapsulation systems involving the three major food components.

topologies, shapes and sizes (Fig. 1) e.g. multi-layered planar sheets, fiber webs, microclusters, hydrogel beads, nano-/micro-particles, emulsions, liposomes, colloidomes and micelles are all commonly employed carrier systems.

Carbohydrates are mono-, di-, oligo- and poly-saccharides and encompass a wide range of compounds with different molecular structures. Polysaccharides are important nutrients (e.g. dietary fibers) and versatile biopolymers that can adopt shapes of varying sizes, including neutral polysaccharides (e.g. cellulose, starch, dextran, agarose and guar gum) or ionic polysaccharides (e.g. anionic alginate, pectin, xanthan and carrageenan, and cationic chitin and chitosan). Their HCOH repeating segments make them highly hydrophilic, but their CH residues give rise to some hydrophobic features. The hydrophilic groups result in desirable solubility in polar media and confer temperature stability (compared to proteins and lipids). When the molecular weight is high (i.e. from monomers to dimers, oligomers or polymers), the influence of hydrophobic domains increases forming three-dimensional (3-D) hydrophobic cavities e.g. toroid structure with hydrophilic exterior and almost hydrophobic interior (cyclodextrins) or helical structures (e.g. modified species with amphiphilic characteristics) to entrap hydrophobic guest molecules. In practice, cellulose or starches and their derivatives, plant exudates and extracts, and microbial and animal polysaccharides are often used to construct emulsions, inclusion complexes, coacervates and polymeric extruded capsules. Some oligo-/poly-saccharides exhibit unique favorable properties e.g. Gum Arabic, sugar beet pectin and galactomannans naturally possess high emulsifying and film-forming properties, and inulin or alginate (after depolymerization) exhibit good prebiotic effects.

Proteins and derived peptides are food components with high nutritional value and sourced from meat, fish, egg, milk, wheat, soy, corn and pea. They possess high reactivity and surface activity thus are superior encapsulants for the development of carriers such as emulsions, coacervates and polymeric extruded capsules. The building blocks of peptide chains include hydrophobic amino acids (e.g. alanine, glycine, leucine, isoleucine, phenylalanine, proline, methionine, tryptophan and valine) and polar amino acids (asparagine, cysteine, glutamine, serine, threonine and tyrosine). Proteins in native state or after modification (e.g. via aggregation or denaturation) are biopolymeric amphiphiles and can self-organize and co-assemble with other molecules. Intrinsic block-wise distribution (i.e. long hydrophobic domains with hydrophilic patches) and large polymer size (especially the open structure of proline-rich proteins) promote protein amphiphilic behaviors. At a pH below or above protein's isoelectric point (pI), protein solubility increases due to positive or negative surface charges, respectively. This makes protein microstructures (e.g. filamentous or particulate gels) and properties essential for encapsulation (e.g. surface charge, particle size and hydrophobicity) sensitive to changes in pH, temperature, pressure, shear and/or ionic strength, which opens opportunities for tailoring protein self-assembly to create suitable polymer architectures for binding to/co-assembling target encapsulated substances. Certain native or modified oligopeptides are amphiphilic and can self-assemble via driving forces including  $\pi$ - $\pi$  stacking, electronic interactions and disulphide bonding with additional contributions from hydrogen bonding, hydrophobic effect and van der Waals interactions.

Food lipids mainly comprise triacylglycerols, phospholipids and sterols and take the form of either a liquid oil or solid fat at room temperature. As macro-molecules or matrix media for heat or mass transfer, lipids exhibit distinct physico-chemical characteristics that impact enormously on food's physiological, nutritional and sensory properties. Fats, fractionated or hardened fats, polar lipids, fatty acids and fatty alcohols, mono-/di-glycerides, waxes (insect and plant waxes e.g. beeswax, candelilla wax and carnauba wax), and lipid-polymer conjugates are versatile materials for encapsulation. The carboxylic acid group ( $pK_a = 4.5$ ) of a fatty acid afford a range of chemical reactions e.g. linking to an alcohol via an ester linkage or forming a complex via ionic interaction making lipids more water-soluble and promoting self-assembly. Unique physical properties of certain lipids such as melting over a wide range of temperatures and crystallizing in different polymorphic forms including the most important  $\alpha$  and  $\beta$  forms, make them excellent encapsulants e.g. lipids with melting points well above the human body temperature are desired for lipid nanoparticle carriers targeting sustained release. Phospholipids and monoglycerides are commonly used emulsifiers and can form self-assembled structures comprising submicrometre regions (diameter as 10–50 Å) with various polarities that can host hydrophilic, amphiphilic and lipophilic molecules in the form of liquid or solid carriers for controlled release. The use of more unsaturated phospholipids (e.g. phosphatidylcholine from egg or soybean) or more saturated phospholipids (e.g. dipalmitoylphosphatidylcholine with long acyl chains) to form lipid membranes results in differences in degrees of fluidity, charge, stability and permeability.

Water is a critical food component that provide a hydrophilic matrix medium, act as a reactant and plasticizer, and participate in substance transportation, chemical reactions, and textural, rheological or thermomechanical alterations during food manufacturing and digestion. Bioactive substances for encapsulation including polyphenols, carotenoids, organosulfur compounds and vitamins have vastly different chemical structures and play crucial roles in human health promotion and disease prevention or treatment. Polyphenols comprise molecules from simple compounds (e.g. phenolic acids) to polyphenolic species. Carotenoids are oxygenated or non-oxygenated hydrocarbons with extensive conjugated double bonds and different polarities (e.g. nonpolar  $\beta$ -carotene and lycopene, or polar lutein). These bioactives can also interact with the biomolecules from encapsulant(s) or surrounding environment. The polarity of polyphenols facilitates their activities at water-lipid interfaces and interactions with medium components (e.g. water and triglycerides) depending on polyphenol partition coefficient and applied processing conditions. Furthermore, polyphenols can influence the conformation of proteins and starches in a favorable way e.g. form hydrophobic domains/pockets for encapsulation via inclusion mechanisms.

## Molecular Interactions

The processing properties and biological functions of foods depend on the events at molecular level, as well as the structural arrangement of large molecules at different hierarchical levels e.g. secondary conformation and 3-D networks. Multicomponent systems are sensitive to the delicate balance of intra- and inter-molecular forces i.e. covalent bonds (via which the atoms bound by an electron pair such as C–C, C–N, C=O, C–H, C–N–C and S–S), and non-covalent bonds (which exist within and between molecules e.g. electrostatic forces, hydrogen bonds, hydrophobic interactions, steric repulsive forces, van der Waals interactions). Although individual non-covalent bonds are weak, their cumulative effect can be substantial leading to various structural and functional properties. Ionic bonding is the attraction between opposite charges e.g.  $-\text{NH}_3^+$  and  $-\text{COO}^-$ , which is closely associated with solvent and salt effects in a matrix. Electrostatic repulsion occurs between functional groups with the same type of electric charges (both positive or both negative from polar residues e.g. carboxyl, amino, imidazole and guanido groups, which can be disrupted by pH changes and salts). Hydrogen bonding typically involves a hydrogen shared between two electronegative atoms (e.g.  $\text{N}-\text{H}\cdots\text{O}=\text{C}$  of hydroxyl, amide and phenol groups), which can be affected by dimethylformamide, guanidine hydrochloride or urea. Hydrophobic interactions involve apolar groups (e.g. long aliphatic chains and aromatic groups) and can be disrupted by detergents or organic solvents. Van der Waals interactions are relatively weak attractions between molecules and driven by induced electrical interactions between two or more atoms/molecules in the vicinity. Molecular interactions and organization largely account for macroscopic properties while non-covalent interactions likely dictate microstructure. The balance of forces is such that self-assembly occurs enabling the amplification of small segmental interactive effects into large-scale intermolecular effects to form supramolecular structures (e.g. aggregates and arrays). Further, interfacial effects play an important role for many complex condensed structures with a high surface-area-to-volume ratio. At the nanoscale, the influence of gravity is considerably reduced

while surface interactions play dominant roles and endow the material with distinct physicochemical characteristics for encapsulation (compared with the corresponding bulk material).

The nature of a food component determines its behavior in response to its environment (Sun-Waterhouse et al., 2012). Naturally occurring carbohydrates, proteins and lipids present limitations in terms of their processing, encapsulation and release properties. Besides chemical/physical/enzymatic modification of these materials, the combined use of these biomolecules is an effective approach to compensate individual weakness whilst improving a specific property (e.g. low resistance to acidic media) or imparting additional benefits (e.g. the use of Hi-maize starch to overcome the low stability of alginate gel in the presence of high affinity ions like phosphate or citrate while enhancing alginate's microbial viability-promoting properties) (Iyer and Kailasapathy, 2005). Almost all proteins are affected by acid or base and can react with many different substances including polysaccharides, sugars, oil, water, polyphenols and carotenoids. Their carboxylic acid and amine groups play major roles in inter-molecular or inter-peptide interactions, solubilization, hydration and surface events, while their apolar residues also contribute. Protein hydration is affected by hydrophilic polysaccharides, lipids and salts, along with environmental conditions (e.g. pH and temperature). Hydrophobic proteins can effectively decrease surface tension and bind lipophilic substances like lipids and emulsifiers. Polysaccharides are well known for their high hydrophilicity (owing to the large number of hydroxyl groups), although they also exhibit hydrophobic character. Such amphiphilic properties are desirable for encapsulation and cell adhesion, especially for certain oligo-/poly-saccharides e.g. cyclodextrins. Like proteins, polysaccharides are excellent gelling agents and can bind up to 100 times their own weight of water to form solid-like 3-D network to adsorb substances for encapsulation. The combined use of polysaccharides and proteins can create chemically or physically cross-linked hydrogels in water e.g. polysaccharide mixed gels and pectin-casein gels. Disulfide and hydrogen bonds, ionic or hydrophobic interactions, or their combinations are involved in gelation and the resulting properties depend on the nature of biopolymer(s) and applied thermodynamic conditions. These gel structures (hydrogels) are appropriate barrier matrices for encapsulation while offering additional benefits. Protein-soluble fiber conjugates in a heated food system could lead to increased antioxidant activity via the Maillard reaction between proteins and fiber polysaccharides. Starch can interact with protein to form complexes during gelatinization, with protein stability greatly affected by hydrophobic forces. Carbohydrate-lipid complexation is also possible. Starch tends to associate with polar lipids, saturated monoglycerides and free fatty acids (FFAs), whilst protein binds unsaturated monoglycerides. Interestingly, the incorporation of protein into an amylose-lipid structure can yield a water-soluble amylose-FFA-protein ternary complex, a nanoscaled self-assembly supramolecule with a molecular weight of  $10^6$ – $10^7$  Da. These complexes are carriers for lipophilic molecules, in which the amphiphilic FFA acts as the bridge via hydrophobic interactions between amylose's helical structure and FFA's aliphatic tail, and ionic interactions between FFA's charged negatively carboxyl group and polyionic proteins at an appropriate pH and salt concentration (Zhang and Hamaker, 2003). The so-called "co-factors" also play important roles e.g. cross-linkers like phenolics are required for some biopolymer architectures; calcium ions induce the gelation of pre-denatured whey proteins, alginate and pectin; activators and inhibitors are associated with encapsulant's emulsifying and film-forming properties; surfactants (e.g. phospholipids), co-surfactants (e.g. sugar esters) and co-solvents (e.g. alcohols and polyols) are used to optimize the emulsification of emulsions. Processing aids are sometimes needed for encapsulation such as solvents, plasticizers, drying aids, density modifiers and anticaking agents. The type, amount, timing of addition, duration of performance of co-factors depend on the encapsulant used, encapsulation technology, production approaches and production capacity (batch or continuous production), and the intended food application for the encapsulation system.

Multicomponent barriers are created using proper combinations of the aforementioned substances to deliver specific release kinetics e.g. immediate, sustained or triggered release. The underlying modes of action include simple or tailored diffusion (based on the differences in concentration gradients and translation diffusion coefficient between the system interior and surrounding environment), swelling or shrinking (via manipulating the pore size of biopolymer matrix with a diffusion process often involved), fragmentation (based on the fracture properties of selected encapsulant(s) and the applied stress, which is often followed by quick diffusion), and erosion (via chemical, physical, mechanical or enzymatic degradation of the outer layer of the matrix). The encapsulant molecules can undergo self-alteration (e.g. swelling, bulk or surface erosion) or interact with other molecule(s) in the vicinity when a specific environmental change is applied e.g. a change in a material's physicochemical properties or controllable degradation induced by a change in enzymatic activity, light intensity/wavelength, magnetic/ultrasonic/electric/electronic signal, pH, pressure, redox potential, solvent composition, temperature, and osmotic/mechanical force. Hence, the encapsulation systems are fabricated with single, dual or multiple responses to external physical, chemical and biological stimuli, and the encapsulated substances are delivered following different release kinetics such as zero-order release (by which encapsulated substances are released the moment the encapsulation system arrives at its destination i.e. a particular site of human body or a particular step of human metabolism), first-order release (by which the encapsulated substances are released at a pre-defined time or condition and at an exponentially decreasing rate with time), or triggered release (by which encapsulated substances are released upon a change of environment).

## Encapsulation Methods

Recent advancements in material science, processing and biotechnology enable various encapsulation systems to be created in both research and commercial settings. Their fabrication may be through mechanical processes (mostly based on a top-down approach, in which larger systems are broken down to homogeneously small sized particles or droplets), physicochemical processes (mostly based on a bottom-up approach, in which molecular building blocks are assembled into structured systems e.g. microemulsions,

micelles and certain polymeric nanoparticles), or a mixed approach (in which molecular assembly and comminution processes are integrated together to form multilayer emulsions, liposomes and biopolymeric nanoparticles). The carriers are tailored to possess essential encapsulating and release properties as well as other desirable characteristics e.g. biocompatibility, biodegradability, taste masking, extended shelf life, convenient handling and intake.

A range of techniques are available to create encapsulation systems. Typically these involve physicochemical approaches or processing approaches. A successful commercial encapsulation process often requires the integration of these two types of approaches. The physicochemical approaches include assemblies, biopolymeric inclusion complexes, coacervates (simple/complex), co-extrusion, co-crystallization, emulsions, granulates, hydrogels, liposomes, matrix encapsulation, micelles, polyelectrolyte complexes, polymerization (dispersion, interfacial, emulsification or *in situ*), lyotropic liquid crystals (LLCs), solid lipid nanoparticles (SLNs), nanostructured lipid carriers (NLCs) and structured lipids (organogels). The processing approaches include centrifugal extrusion, centrifugal suspension-separation coating, co-extrusion, coacervation, dripping and jet breakup, electrospinning, electrospray, electrostatic extrusion, emulsification, fluid bed coating, freeze drying, hot melt extrusion, layer-by-layer deposition, melt extrusion, melt injection, microwave drying, molecular inclusion, pressure extrusion, spinning-disk coating, spray-bed drying, spray chilling, spray cooling, spray congealing (spray melt dispersion), spray-freeze-drying, spray drying and vacuum drying. Various processing approaches can be used throughout the carrier fabrication while physicochemical-based inputs are often required (e.g. during polymerization, coacervation and solidification). Stabilization is usually the last step of encapsulation involving chemical (polymerization), physical (evaporation, solidification or coalescence) and/or physicochemical (gelification) mechanisms. Based on structural characteristics (Fig. 1), the encapsulation systems are grouped: (1) reservoir type (like those created by co-extrusion or spray coating technology), (2) matrix type (like those created by emulsification, spray drying or extrusion technology), and (3) coated matrix type (having the combined features of reservoir and matrix types). The selection of an encapsulation method depends on the type and nature of bioactive substance of interest, its intended functionality and end use (e.g. its delivery site in humans, and dietary format as a functional food ingredient or dietary supplement for direct intake). The size of carriers ranges from tens of nanometers to tens of millimeters, but generally a specific size range is common for each encapsulation method. Physical processes generally lead to larger sized units. Emulsification allows a particle size ranging from 0.2 to 5000  $\mu\text{m}$ . Spray drying and spray coating generate similar particle sizes (10–3000  $\mu\text{m}$ ). Extrusion gives particles sized 200–8000  $\mu\text{m}$  and co-extrusion offers a narrower range (150–5000  $\mu\text{m}$ ). Nano-scale carriers are available in the forms of (bio)polymeric nanoparticles, nano-complexes, liposomes, micelles, nanotubes and particulates (Sun-Waterhouse *et al.*, 2015).

Co-extrusion is a physical technique used to produce core-shell microcapsules/microbeads, by which a liquid, dispersion, slurry or emulsion is extruded through a stationary, centrifugal, vibrating or submerged coaxial inner nozzle while the wall materials are passed through the outer nozzle. This technology allows continuous carrier fabrication (production rates as high as several thousand pounds per hour) and creation of multiple coating layers (using extrusion nozzles with multiple concentricity for slow and controlled release). The physicochemical properties of shell and core solutions are critical to forming particular core-shell morphologies and minimizing droplet agglomeration and shell breakage. Typical requirements include surface tension and viscosity in the range of 10–72 dyne/cm and 1–1000 cP (2000 cP in some cases), respectively, along with a matching density (0.7–1.3 g/cm<sup>3</sup>) between the shell and core. Microbeads containing multi-nutrients/bioactives have been developed to deliver bioactive compounds and probiotic bacteria in water- or oil-based media such as those using alginate as the key encapsulant (Sun-Waterhouse *et al.*, 2011; Shinde *et al.*, 2014). The microbead shell can be created using a polysaccharide or combination of polysaccharides (alginate-pectin or alginate-starch) (Sun-Waterhouse *et al.*, 2014; Wang *et al.*, 2013). Some bioactives can be incorporated in the core or shell although the resulting carrier properties and end applications are usually quite different (Waterhouse *et al.*, 2014).

Spray drying is a widely used as an encapsulation process in the food industry due to its continuous operation and cost-effectiveness (typically 15–30 s drying time). The resulting bioactive carriers in powder form possess advantages in terms of storage stability and convenience. Smart pretreatments of the feed solution containing conventional or non-conventional encapsulants prior to spray drying can impart important benefits e.g. pre-warming briefly at 50 °C, or tailoring the feed formulation by monitoring the functions imparted by enzyme species, dietary fibers, proteins and antioxidants naturally occurring in the plant extract and dairy ingredients (Sun-Waterhouse and Waterhouse, 2015; Waterhouse *et al.*, 2017). *In situ* one-step encapsulation by spray drying under mild conditions for large-scale production of “nanosized core coated with micron-sized outer network” powders is feasible, through utilizing the polymerization of biopolymer encapsulants and agglomeration of powder particles during spray drying process (Sun-Waterhouse *et al.*, 2013, 2015). This technical breakthrough is of high significance to the food industry as it minimizes the potential hazards associated with nanoparticles e.g. accidental inhalation of powder into the lung during manufacturing, and mistransit or premature absorption of nanosized substances along the gastrointestinal tract before reaching the target absorption site.

Lipid-containing encapsulation systems include emulsion, micelles, liposome, LLCs, SLNs, NLCs and oleogels. Unlike solid particles, emulsion droplets and liposomes have mobile and deformable surfaces. An emulsion is a mixture of two or more immiscible liquids in which one is present as minute droplets distributed throughout another. Micro-/nano-emulsions have very high surface area to volume ratios thus are useful ‘liquid transport vehicles’ for almost any substance irrespective of their solubilities in any food systems. Emulsions with different arrangements (e.g. water-in-oil in water (w/o/w) versus oil-in-water in oil (o/w/o), or Pickering emulsions versus inverse Pickering emulsions) have immiscible multiphases to encapsulate large quantities of target substances (e.g. prebiotics, phytochemicals or proteins) mainly in the inner phase with some at the interface. Micelles and microemulsions are often grouped into the same carrier category due to their nature as surfactant aggregates containing

water, oil, surfactant, co-surfactant and salt, although they differ in droplet dimensions and complexity of aggregates. Micelles generally refer to aggregates made of surfactant only and dispersed in water, whilst microemulsions are much bigger aggregates with large oil cores (for oil-in-water systems) or water cores (for water-in-oil systems) surrounded by a surfactant monolayer. Different types of micelles can be created using surfactants or amphiphilic materials including amphiphilic copolymers to encapsulate almost any kind of bioactive substance: Normal/regular micelles are used in aqueous media to encapsulate substances with low water-solubility, reverse micelles are used in a nonaqueous medium for delivering hydrophilic species, and unimolecular micelles containing hydrophilic and hydrophobic regions in the same amphiphilic block copolymer (i.e. self-assembly of one molecule into a micelle) can be used for both hydrophobic or hydrophilic substances in either media. Micelles made with reverse thermo-responsive polymers undergo phase change from the solid state (enabling encapsulation of target substance) to a gel structure (enabling sustained release of encapsulated substance) when the environmental temperature rises from room temperature (for micelle fabrication) to the body temperature (after ingestion). A liposome is a spherical vesicle with at least one phospholipid bilayer and the same aqueous phase on both sides of the lipid bilayer. Liposomes can be modified to possess varying chemical compositions and physical properties for encapsulating substances with different solubilities. Polyphenols like those in green tea can be well protected in liposomes before fortification into foods (otherwise causing severe bioactive loss e.g. almost all unencapsulated green tea polyphenols lost in the whey fraction during functional cheese making) (Rashidinejad et al., 2014). Single- or multi-layered emulsions and unilamellar or multilamellar liposomes can be constructed involving combinations of lipids, surfactants, carbohydrate or protein polymers (e.g. phospholipids, glycolipids, mikfat, chitosan, xanthan, caseins and whey). Surface-active proteins influence the interfaces of emulsions and liposomes during formation, disintegration or aggregation of system units. Carbohydrates like starch, microcrystalline cellulose and xanthan gum can act as rheological modifiers or impart additional coating(s), thereby reducing and slowing the diffusion of encapsulated substances inside these carriers. Thus, the type and mass ratio of polar lipids, proteins and carbohydrates, as well as the type, intensity and input method of energy (e.g. microfluidization and sonication), all influence the characteristics of emulsions or liposomes and encapsulation efficiency. High energy input often leads to large numbers of tiny vesicles with increased surface area.

Besides self-assembled liquid lipid systems, lipid solid-containing carriers (e.g. LLCs, SLNs, NLCs and oleogels) deserve attention. The particle growth process during carrier fabrication is critical to final carrier's properties. In LLC systems, amphiphilic lipids such as glycerol dioleate, glycerol monooleate, oleyl glycerate and phytanyl glycerate can form semi-permeable crystal structures with cubic, hexagonal or lamellar mesophases, equipped with different controlled release mechanisms to improve bioactive bioavailability e.g. 20–100 times greater bioavailability for water-soluble peptides (Kim et al., 2015). SLN and NLC systems are constructed using physiological lipids or lipids with “generally recognized as safe” (GRAS) status by water-based technologies (no organic solvents involved) to encapsulate both lipophilic and hydrophilic substances at high concentrations (as compared to polymeric nanoparticle carriers). Unlike SLN carriers, NLC systems are colloidal carriers with a solid lipid core comprising a nanostructured mixture of solid and liquid lipids, thus overcoming some of the drawbacks of SLNs e.g. low payload and potential expulsion during storage. NLC systems with specially required properties can be created by altering the composition of the lipid blend and processing variables e.g. Mixing solid lipids with liquid lipids (oils) endows NLC carriers a lower melting point but still a solid matrix at body temperature (compared to the systems with solid lipids alone). The drawbacks of SLN carriers are an inherently low incorporation rate of substances in the lipid crystalline structure, unpredictable gelation tendency and complex polymorphic transition dynamics. NLC systems face the same challenges as all other colloidal nanoparticle carriers i.e. their potential interaction with the reticulo-endothelial system (which may be mitigated by increasing their hydrophilicity and/or controlling their size to be not larger than 200 nm). Oleogels are unique carriers where solid lipids (oleogelators) at lower concentrations (<10% weight/weight) are dispersed in bulk liquid oil and form 3-D network through molecular-level self-organization driven by van der Waals forces, hydrogen bonding, steric entanglements, ionic interactions or covalent bonding (Das-sanayake et al., 2011). High-melting lipids are used as oleogelators e.g. small molecules saturated fatty acids (which crystallize to form colloidal or fibrillar networks) and hydrophobic polymers like ethylcellulose (which self-assembles under appropriate processing conditions). The type and concentration of gelators, along with the nature of bulk liquid oil and processing variables (heating, stirring and cooling conditions), determine oleogel structure and mechanical strength and subsequent susceptibility to lipolysis and release of encapsulated molecules. For all these discussed lipid-based carriers, oxidation of unsaturated acyl chains and hydrolysis of ester bonds, along with unpredictable change in physical properties related to gelation and polymorphic transition, are the major considerations to stable product development. The degree of unsaturation of unsaturated lipids determines their susceptibility to oxidation and phase transition temperature, while their fatty acid chain lengths influence barrier thickness and diffusion rate of solutes. Saturated fatty acids, although less likely causing membrane degradation, tend to be more rigid compared to their unsaturated counterparts. The fatty acid composition, position and chain length of phospholipids affect both the stability and barrier permeability of derived carriers. Accordingly, a combined use of various lipid materials (e.g. inclusion of saturated fatty acids, phytosterols, cholesterol and hydrogenated lipids), incorporation of antioxidants like tocopherols, and/or addition of biopolymeric coatings and Pickering particles at the interface/surface of lipid carriers, can improve carrier structural integrity and stability.

### **Challenges for Industrial-Scale Encapsulation: Monitoring Factors Beyond Molecular Interactions**

Despite the proliferation in scientific publications about encapsulation over the past few decades, only a few encapsulation systems have been successfully applied industrially, with spray drying and extrusion accounting for over 80% of market success stories. Safety considerations in line with legal requirements should be addressed throughout the industrial manufacturing of encapsulation systems either for direct consumption or further incorporation into foods to eliminate toxicity and minimize side

effects on non-targeted body sites, in addition to other criteria such as delivery efficiency, bioefficacy, cost, application restrictions and environmental sustainability. The materials, ingredients and additives used must be biodegradable and food grade (with GRAS approval). Many substances used in academic research may be not allowed for food applications. Biopolymers that appear on the GRAS list of the Food and Drug Administration (FDA) of the United States of America (USA) include agar, alginate, carob bean gum, carrageenan, cellulose, cornsilk, dextran, dextrans, guar gum, methylcellulose, pectin and starch. Some GRAS approved materials may not be suitable for products intended for frequent intake e.g. concern has recently been raised regarding the healthiness of maltodextrin (a conventional drying aid for spray drying) owing to its high glycemic index ([Brand-Miller et al., 2013](#)). Further, the whole carrier fabrication process, as with any other normal food processing step, must be monitored according to good manufacturing practices (GMPs), and under processing conditions approved by the regulations of intended countries for sale e.g. those of the US FDA, Health Canada, European Food Safety Authority (EFSA) and Food Standards Australia New Zealand (FSANZ), or processed in a way that allows classification as Kosher or halal.

During scale up of carrier fabrication and the production of carrier-containing foods, predictable or unpredictable technical issues may occur (as with any other processing scale-up). It is not uncommon that an encapsulation system successfully developed on a laboratory scale fails when scaled up to industrial scale. Industrial scale encapsulation systems mainly involve spray drying, spray chilling, fluid-bed coating, melt injection, particularization, crystallization, emulsion, liposome, coacervation, melt infusion and extrusion technologies. Some of these are “in-situ matrix encapsulation” methods (in which encapsulation is integrated as part of the normal food processing, and a finished food matrix with tailored structure is used as a “natural” encapsulation system for target substance(s)). Understanding the advantages and disadvantages of each encapsulation technology as well as their limitations in industrial settings is the key to achieving a successful lab-to-industry scale up. e.g. Low production capacity along with large but inhomogeneous particle size occur with extrusion, whereas inconsistent and large droplet size was found in industry scale emulsions. Large scale layer-by-layer (LbL) assembly of multilayered carriers especially those weak polyelectrolyte stacks could be challenging, as the processes established in laboratories tend to be time consuming and not practical for high volume production expected in large scale industrial operations. Maintaining a constant size distribution for encapsulated substances can be easily achieved using laboratory-scale droplet devices, but quite often it is difficult or impossible to achieve a similar size distribution and emulsification outcome by applying the same mixing method to the large volume of carrier matrix in industrial manufacturing which involves many additional variables. From the industrial perspective, fully enclosed systems such as capsules, spheres or lipidic droplets (e.g. emulsions or liposomes) with a complete physical barrier (such as membranes, films or coatings) may not be favorable when used as food ingredients for further consumer food applications. Instead, “in-situ matrix encapsulation” is more desirable considering cost-effectiveness and operational feasibility resulting from less processing steps, high utilization of existing equipment, increased safety and ingredient compatibility, acceptance and preference by a wider range of consumers, legal and cultural/religion constraints. The nature of the food matrix, existing form of food components (including the substance for encapsulation), stage of food processing at which the target substance is added, and food processing conditions all influence the ultimate success of “in-situ matrix encapsulation” approaches.

Molecule behaviors and polymer physics play important roles in scaling up of encapsulation systems. Intra-/inter-molecular interactions, charge distribution, molecular dynamics, molecule or particle interactions, macromolecular crowding, polymer chain dynamics and statistics in large-scale systems all differ when compared to small laboratory-scale encapsulation systems. Comparing laboratory-scale to industry-scale production, at least four aspects would be changed: (1) distance-dependent molecular interactions and matrix effects (e.g. charge screening/shielding and steric hindrance effects); (2) geometry effects and space confinement; (3) magnitude and degree of inhomogeneity for applied energy and stresses (e.g. those associated with temperature, pH, shear, pressure, air/O<sub>2</sub> and light distribution); (4) undefined and unquantified salts introduced (e.g. those associated with water source, tap water or reverse osmosis water used in industries versus distilled or Milli-Q water used in laboratories). Difference in the applied conditions would affect food components differently. There exist unspecific dilution effects along with intricate reptation dynamics and long-range behavior of unscreened electrostatic interactions encountered for large volumes involved in commercial manufacturing. Also, different container/pipe confinement effects on biopolymers may be present in industrial tanks compared with laboratory vessels. High shear stresses may be imposed during industrial fabrication considering the need of pumping products long distances through pipes (as compared to the transfer of small amounts of mass using small spatulas or short glass/rubber tubing in laboratories). Some local microenvironments around the force applying spot may be overpowered by mixing and shearing stress, causing unpredictable perturbation (under small amplitude of stress), disruption and cracking (under large amplitude of stress) or even breakdown (under excessive stress) of carrier architectures. At the interface of two phases of self-assemblies, co-occurrence of lipophilic, amphiphilic and aqueous domains along with concentration effects could arise, which may initiate or enhance certain chemical and physical interactions causing an unusual outcome. Many biopolymers carry different types and densities of electric charges. The altered carrier architecture may lead to new opportunities for neighboring counterions to interact, thereby causing counterion condensation (due to the tendency of macroscopic electro-neutrality) and subsequent development of structures very different from the initially created architecture. Further, processing speed is a critical factor in industrial scale-ups. Higher processing rates are expected for industrial applications compared to those commonly used in laboratory settings. It remains unclear how to estimate the speed of certain processes involving complicated kinetics e.g. self-assembly as a process moving down a free energy gradient. The free energy landscapes along the paths towards self-assembled products are not fully explored. All these challenges encountered during scaling up carrier fabrication would also be encountered when the carriers are incorporated as ingredients into consumer finished foods. The lack of technologies and means for in-situ or real-time monitoring the compositional and structural changes on nano- and micro-scales create further challenges to optimizing scale up processes.

## Conclusion

Nutrients and bioactive substances with different physico-chemical and nutritional properties can be protected or delivered via various encapsulation systems, with choice of an encapsulation system influencing the release and bioefficacy of the carrier product or final consumer food product. Encapsulation is feasible and beneficial in terms of meeting modern consumers' demands for convenient dietary products with multiple nutritional advantages and specific biological function(s). The ultimate aim for using encapsulation in commercial manufacturing is regulatory approval and consumer acceptance. The bottleneck in the development of complex carrier systems and their use as ingredients in consumer food applications relates to the availability and optimization of matrix materials and specialty equipment for carrier fabrication (especially in an industrial context). Detailed knowledge about molecular interactions and biopolymer dynamics in response to food processing conditions, as well as pharmacokinetics of biological active compounds (both target encapsulated substance and other nutrients and bioactives co-existing in the same carrier), are all essential for developing industrial-scale encapsulation technologies for nutrients and bioactives. Particular care needs to be taken when attempting to upscale laboratory encapsulation research to industrial scale production.

## Chemical Composition and Structure of Green Tea Polyphenols

Tea, made from the leaves of the *Camellia senensis* plant in the family Theaceae, is now the second most consumed beverage world-wide after water. The whole tea processing includes plucking, wilting, disruption, fermentation, fixation, yellowing, shaping, drying and aging steps. Shortly after tea leaves are picked, the wilting process starts involving enzymatic oxidation or browning. There are six common tea varieties: white, yellow, green, oolong, black and post fermented teas. Green tea (unfermented), black tea (fermented) and oolong tea (semi-fermented) that account for about 20%, 78% and 2% of global tea consumption, respectively, and are produced after different extents of fermentation (Yang and Pan, 2012). Fresh tea leaves subject to only plucking, fixation, shaping and drying steps yields green tea, involving almost immediately steaming or panning to prevent fermentation via inactivating intrinsic oxidase activities. An extra yellowing step to the green tea product is needed for the production of yellow tea thus yellow tea is commonly considered as a semi-fermented tea. Black tea is obtained by allowing the oxidation and polymerization of tea catechins during fermentation by the endogenous polyphenol oxidase and peroxidase to form oligomeric and polymeric derivatives. Oolong tea is considered one type of tea between green tea and black tea. Its production involves some basic steps resembling those in black tea production such as withering, rolling, shaping and firing, although unique timing, temperature and physical stress are required throughout the manufacturing process, e.g. freshly picked tea leaves are subject to withering under strong sun, intentional “bruising” by shaking, and partial oxidation/semi-fermentation (often terminated via steaming or pan-frying). White tea is also categorized as a semi-fermented tea. Its production is somewhat similar to that for oolong tea but does not require bruising, oxidation and curing steps. Epidemiological, laboratory and human intervention studies have revealed that regular consumption of tea is linked to many health benefits including antioxidant, anti-inflammatory, hepatoprotective, anti-mutagenic, anti-cancer, anti-neurodegenerative, anti-diabetic and anti-obesity effects (Adhami and Mukhtar, 2007; Chantre and Lairon, 2002; Ibrahim et al., 2015; Pan et al., 2016; Zou et al., 2010).

Green tea has a complex chemical composition and constituents typically include: proteins (15%–20% dry weight), consisting of enzymes and amino acids (e.g. aspartic acid, arginine, glutamic acid, glycine, leucine, lysine, serine, theanine, threonine, tryptophan, tyrosine and valine); carbohydrates (5%–7% dry weight), consisting of dietary fibers (e.g. cellulose and pectins) and free sugars (e.g. glucose, fructose and sucrose); minerals and trace elements (17 species, 5% dry weight, e.g. aluminium, calcium, copper, iron, magnesium, manganese, phosphorus, potassium, selenium, sodium and zinc); lipids (trace amounts) e.g. linoleic acid,  $\alpha$ -linolenic acids and sterols (stigmasterol); vitamins (small or trace amounts A, B<sub>1</sub>, B<sub>2</sub>, B<sub>3</sub>, B<sub>6</sub>, C, E and folate); alkaloids (caffeine, theophylline and theobromine); pigments (chlorophyll and carotenoids); volatile substances (up to 38 species such as aliphatic/aromatic aldehydes, alcohols, esters, lactones and hydrocarbons). Green tea contains polyphenols (up to 30% of the dry weight) including flavanols, flavandiol and phenolic acids, with the major monomeric flavanols (also called catechins) as: (+)-catechin (C), (–)-catechin gallate (CG), (–)-epicatechin (EC), (–)-epicatechin gallate (ECG), (–)-epigallocatechin (EGC), (–)-gallocatechin (GC), (–)-gallocatechin gallate (GCG) and (–)-epigallocatechin gallate (EGCG). The catechins share the same basic structural feature, i.e. two close parallel aromatic rings and a third aromatic ring vertical to the two parallel rings, but differ in the number and distribution of hydroxyl groups on the B-ring, the type of configuration (*cis*- or *trans*-isomers), and the presence or absence of a galloyl moiety. In addition to variables such as origin, variety, growing conditions and collection timing, the handling history and preparation method also affect the composition of GTPPs in the final dietary product. A typical cup of brewed green tea contains 20%–45% (dry weight) catechins. EGCG is the most abundant catechin in green tea, accounting for 38%~40% dry weight of tea and about 16.5 wt% in the water extractable fraction of tea. Commercial products derived from green tea are mainly green tea extracts in a liquid or powder form, with a standardized green tea extract containing about 90% total polyphenols and one green tea capsule equivalent to approximately five cups of green tea.

## Metabolism, Biotransformation and Bioavailability of Green Tea polyphenols

Proven biotransformation of tea polyphenols in the intestinal, hepatic and microbial metabolism has heterogeneous and complex influences on their bioavailability and bioactivities. Metabolic transformation of GTPPs affects their absorption, distribution, metabolism, excretion and toxicity, which is a process based on personalized responses. The metabolism of GTPPs has been

investigated using both animal and human models, and its pathways include methylation, glucuronidation, sulfation and ring-fission in the liver, kidneys and gastrointestinal tract. The major metabolism pathways of GTPPs are illustrated in **Fig. 1**. EGC and EGCG may be readily methylated by catechol-O-methyltransferase (COMT) to form 4'-O-methyl-(–)-EGC and 4''-O-methyl-(–)-EGCG or 4',4''-O-dimethyl-(–)-EGCG, respectively. Although variations were found between animals and between animal and human models, the influencing role of EGCG concentration in final type of methylated metabolite has been confirmed: the dimethylated species predominate at low EGCG concentrations whilst the monomethylated form could prevail at high EGCG concentrations (Lu et al., 2003). A number of products result from glucuronidation catalyzed by a group of UDP-glucuronosyltransferases (UGT) (including at least six EGCG and EGC glucuronides such as EGCG-4''-O-glucuronide and EGC-3'-O-glucuronide). The type and concentration of obtained glucuronides depend on the types of parent catechins, *in vivo* models and tissues collected for analysis. The glucuronidation of EGCG was much greater than that of EGC. The efficiency of enzymatic catalysis in microsomes follows these orders: mouse intestine > mouse liver > human liver > rat liver > rat small intestine for EGCG-4''-O-glucuronide, whereas, mouse liver > human liver > rat liver > rat or mouse small intestine for EGC-3'-O-glucuronide. Enzymatic-catalyzed sulfation of GTPPs takes place with sulfotransferase family (SULTs) being the major catalysts (such as SULT1A1 in human liver and intestine and SULT1A3 in human intestine). SULTs can distinguish and respond to small molecules, e.g. the most abundant isoform SULT1A1 can bind catechins like EGCG via one specific noninteracting allosteric-binding site that is physically separated from the other binding site for nonsteroidal anti-inflammatory agents (Cook et al., 2016). The sulfation of EC likely takes place in cytosol of human liver and intestine whilst EGCG mostly in human liver cytosol. Microbial actions greatly account for the gastrointestinal metabolism of GTPPs. This is especially true for the human colon where microbial catalytic and hydrolytic activities are very high and GTPPs can be broken down via ring fission into simple compounds such as 5-(3',4',5'-trihydroxyphenyl)- $\gamma$ -valerolactone, 5-(3',4'-dihydroxyphenyl)- $\gamma$ -valerolactone, 5-(3',5'-dihydroxyphenyl)- $\gamma$ -valerolactone, 4-hydroxybenzoic acid, 3,4-dihydroxybenzoic acid, 3-methoxy-4-hydroxybenzoic acid and 3-methoxy-4-hydroxy-hippuric acid (Wan, 2013). Depending on the biotransformative pathways (which vary on a case-by-case basis), the biotransformation process may inactivate or break down some polyphenols while activating or generating more active metabolites than parent compounds. It is worth noting the possible interplay between the different steps and pathways e.g. glucuronidation on the B-ring or D-ring of EGCG may suppress the methylation on the same ring, whilst glucuronidation on the A-ring of EGCG or EGC likely has no influence on methylation. Therefore, understanding of biotransformation of GTPPs will help optimize the design of future intervention and epidemiological studies and associated result interpretation.

### Health Benefits of Green Tea Polyphenols and the Challenge in Determination and Utilization

Epidemiological, cellular, animal and human intervention studies have indicated many potential health benefits of tea polyphenols and its major constituent EGCG. However, these different *in vitro* and *in vivo* studies have not yet achieved consistent and conclusive results in terms of the efficacy and dose for all the illness and diseases of interest. In 2004–06, the US Food and Drug Administration (FDA) concluded that “there is no credible evidence to support qualified health claims for green tea or green tea extract reducing the risk of heart disease” and “it is highly unlikely that green tea reduces the risk of breast cancer or prostate cancer” (FDA, 2005, 2006). For example, an animal trial revealed the potential of high green tea consumption to cause oxidative DNA damage of hamster pancreas and liver (Takabayashi et al., 2004). An epidemiological study on the protective effect of green tea against breast cancer has been inconsistent (Zhang et al., 2007). Human studies in China reported a significant low incidence of pancreatic cancer upon high green tea consumption, whilst the studies in Japan implied an opposite trend (Zeng et al., 2014). Not all the reasons for the inconsistency are well defined. While the composition, dose, times, preparation and consumption patterns of the treatment, individual and local bias, or even lifestyle are possible contributors, stability and bioavailability of tea polyphenols could be critical factors.

GTPPs are very unstable and reactive owing to their chemical structures, thus, highly susceptible to chemical, physical and biological stress factors during food processing, distribution, storage, ingestion and digestion. Temperature, oxygen, pH, light and metal ions are the significant influencing factors. In aqueous solutions, GTPPs are readily oxidized to form quinone products via temporary semiquinone intermediates. GTPPs are especially unstable in alkaline or neutral pH solutions, and an increased oxidation rate corresponds an elevated pH. Green tea would lose approximately 10%–15% of catechins when brewed in boiling water for 15 min. EGCG in tea or in a purified form would undergo epimerization upon autoclaving at 120 °C for 20 min (Chen et al., 2001).

Low bioavailability of GTPPs and certain adverse effects associated with very high GTPP concentration have been unresolved issues. After oral administration of 20 mg green tea solids/kg body weight, the maximum plasma concentrations ( $C_{\max}$ ) of human subjects were 0.17, 0.73 and 0.43  $\mu$ M, respectively, for EGCG, EGC and EC (Renouf et al., 2011). This finding indicates the irrelevance of quite a lot *in vitro* results associated with tea polyphenols such as bioactivities like antioxidant capacity, as their *in vivo* concentrations would never be so high irrespective of plasma or tissue. Molecular and cellular mechanisms associated with poor

**Figure 1** The metabolism pathways of green tea catechins. COMT, catechol-O-methyltransferase; UGT, UDP-glucuronosyltransferase; SULT, sulfotransferase.

bioavailability of GTPPs have been proposed including loss or inactivation owing to metabolic transformation or degradation, low cellular uptake due to poor hydrophobicity to cross cellular membranes, and active efflux by the multidrug resistance-associated protein 2. The chemical structures of GTPPs lead to poor membrane permeability but highly reactive nature, thus, both auto-oxidation and *in vivo* modifications (e.g. severe and unspecific degradation by gut microorganisms, and increased hydrophobicity due to acetylation of their phenolic alcohol groups) as well as significant efflux from cells would take place. When GTPPs are consumed at very high concentrations, adverse impacts would be possible, e.g. an oral dose of EGCG ranging in 750–500 mg/kg body weight led to hepatotoxic effects in CF-1 mice (Lambert et al., 2010). At high doses, the naturally antimicrobial GTPPs could become undesirable for certain vulnerable populations due to their non-specific inhibition or even killing of desired microbiome in the human gastrointestinal tract (Vossoughinia et al., 2014). Prolonged supplementation of tea polyphenols may cause altered bile acid synthesis, increased hepatic oxidative stress and inflammatory hepatic injury in mice fed high cholesterol diets (Hirsch et al., 2016). Accordingly, optimizing the interplay of dose and bioavailability of GTPPs is probably the most critical aspect for maximizing the health benefits of GTPPs.

## Nanoparticle-Based Encapsulation of Green Tea Polyphenols

Strategies aiming at improving GTPP bioavailability, preserving their structural integrity and masking their undesired tastes have been developed. Among which, encapsulation is a promising approach.

Nanoencapsulation is defined as a technology to pack solids, liquids or gaseous materials in miniature, sealed particles with diameters ranging from 1 to 1000 nm. This technology has recently been used for encapsulating polyphenols. Compared with free polyphenols and microencapsulated polyphenols, polyphenol nanoparticles appear to have higher stability, greater bioavailability and more precise site-specific delivery. Colloidal complexes of methylcellulose and EGCG would exhibit a sustained EGCG release, i.e. 60% liberation at the intestinal pH after 2 h (Patel et al., 2011). Electrospray-enabled nanoencapsulation of catechins could improve the release and permeability of catechins, especially at lower core-to-wall ratios (1:50 or 1:10) compared to catechins in free form (Bhushani et al., 2017). In addition, some pH-responsive and magnetic-responsive nanoparticle systems have been developed by incorporating pH/magnetic-responsive polymers in nanoparticles. Self-assembled nanoparticles composed of chitosan (CS) and an edible polypeptide, poly( $\gamma$ -glutamic acid) ( $\gamma$ -PGA) were prepared for the delivery of tea catechins, which were pH-responsive and demonstrated different tea catechins release profiles in simulated gastrointestinal tract (GI tract) media (Tang et al., 2013). The release of green tea polyphenols from nanoparticles may be based on time specific, site specific and/or stimulus specific.

Modification of the surface of coating material (e.g. via functionalizing with ligands such as albumin, hyaluronic acid, biotin, folate, transferrin, monoclonal antibodies) can further improve the delivery efficiency of encapsulated GTPPs to specific organs/tissues for intended treatments of many cancers. EGCG-loaded PLGA-PEG nanoparticles functionalized with small molecules like the prostate-specific membrane antigen (PSMA) inhibitor were found to exhibit *in vitro* efficacy against PSMA-expressing prostate cancer cells (Sanna et al., 2011). Some nanoparticle-based delivery systems for delivering GTPPs are discussed briefly as follows.

Chitosan-based solid nanoparticles are commonly used carriers for nanoencapsulation of GTPPs. This is mainly attributed to its versatile functionalities, such as biodegradability, biocompatibility, non-toxicity, low allergenicity, simple nanoparticle preparation process, good mucosal surface adhesive properties, and bacteriostatic properties. Moreover, the positive charge carried by chitosan enables interaction with negatively charged polymers, macromolecules and polyanions resulting in sol-gel transition stages. The reactive hydroxyl and amine groups on the backbone of chitosan facilitate chemical modifications to form a variety of chitosan-based nanoparticles. In the gastrointestinal tract, oxidation/degradation of GTPPs encapsulated in chitosan nanoparticles was significantly reduced, and such chitosan nanoparticles can penetrate across small intestinal epithelium via either paracellular or transcellular route thereby improving *in vitro* intestinal absorption of GTPPs. Grafting specific ligands onto chitosan not only retains the original properties of chitosan but also endows with tumor-targeting activity. GTPPs-loaded chitosan nanoparticles have been produced via ionotropic gelation with chitosan and sodium tripolyphosphate. It would likely require fourfold longer time for EGCG encapsulated in chitosan-tripolyphosphate nanoparticles to degrade 50% of its initial amount, compared with EGCG in a free form (Dube et al., 2010). Folate conjugated EGCG-loaded chitosan nanoparticles were also prepared via ionic gelation using the folic acid modified carboxymethyl chitosan and chitosan hydrochloride as carriers (Liang et al., 2014). In addition to chitosan, other food grade natural and synthetic biopolymers can be used to fabricate biopolymer-based nanoparticles including carbohydrates (i.e. maltodextrins, starches, corn syrup solids and pectin), proteins (i.e. milk and/or whey proteins and gelatin), and glycoprotein-polysaccharide complexes (i.e. gum arabic).

Liposomes are small, well rounded structures with the bilayer amphiphilic lipid membrane and an aqueous core, and created using biodegradable, biocompatible, nontoxic, low immunogenic phospholipids such as phosphatidylcholines. They can be grouped into 1) unilamellar liposome vesicles with a single bilayer or multilamellar liposome vesicles with two or more bilayers, based on the number of bilayers within the single liposome; 2) small (20–100 nm) or large unilamellar liposome vesicles (10  $\mu$ m) based on size. Liposomes can encapsulate hydrophilic compounds in their internal water core and hydrophobic compounds into the membrane, thereby are used for deliver GTPPs at higher bioactive loading (higher loading efficiency) compared to other

lipid-based delivery systems such as solid lipid nanoparticles and emulsions. Catechin-loaded liposomes can be prepared using egg phosphatidylcholine, cholesterol or anionic surfactant in the presence of 15% ethanol (Fang et al., 2006). Attention should be paid to the drawbacks of liposomes associated with physical and chemical instability especially in acidic conditions (e.g. those of gastrointestinal tract). They would undergo degradation via oxidation of unsaturated acyl chains and hydrolysis of ester bonds causing leakage of encapsulated bioactive substance(s). Also, differences in the number of hydroxyl groups on the B-ring and the stereochemical structure of the C-ring cause different degrees of hydrophobicity and affinity for lipid bilayers, e.g. more *cis*-type than corresponding *trans*-type GTPPs would be incorporated into liposomes (Kajiya et al., 2001).

Solid lipid nanoparticles (SLNs) are considered as an alternative carrier to colloidal systems such as liposomes, emulsions and polymeric nanoparticles, and combine the advantages of these traditional carriers. SLNs consist of spherical outer solid lipid particles in the range of 10–1000 nm and a monolayer coating of phospholipids. The solid lipid core contains dissolved or dispersed bioactive substances such as GTPPs and the surface of SLN consists of emulsifiers. The crystallinity of the lipid matrix is very important. The difference in polymorphic transition of SLN's solid lipid matrix would affect the release or activity of encapsulated compounds, and polymorphic transitions may occur right after SLN preparation and during SLN storage. SLNs have high long-term stability and are commonly prepared through high shear, ultrasonication or high speed homogenization, solvent emulsification/evaporation, supercritical fluid technology and spray drying process, EGCG-loaded solid lipid nanoparticles (EGCG-SLNs) can be prepared using the emulsion-solvent evaporation method and physiological lipid matrix, resulting in additional structural reinforcement of the nanoparticle assemblies, along with advantages of low acute and chronic toxicity but good biocompatibility (Radhakrishnan et al., 2016). EGCG-SLN can exhibit 8.1 times greater inhibitory effect on the proliferation of MDA-MB 231 human breast cancer cells and 3.8 times greater inhibition on DU-145 human prostate cancer cells than EGCG in free form (Radhakrishnan et al., 2016).

## Conclusion

Green tea is consumed globally in different dietary forms. Regular consumption of GTPPs exhibit diverse and significant benefits to general or specific health. Nanoparticle-based encapsulation techniques hold great promise for addressing issues related to GTPPs' poor stability, solubility and bioavailability encountered in food, cosmetic and medical applications. However, there is still much more to do in terms of optimizing the performance of nanoparticle-based delivery systems for GTPPs. Despite the well-recognized high bioavailability and efficacy of nanoencapsulated phytochemicals, there is a need to determine the actual magnitude and pharmacological mechanisms of GTPPs encapsulated in nanoparticles as compared to GTPPs in free form in order to address newly emerging safety issues associated with the potential "local overdose" effect for nanotechnology-enabled encapsulation systems. Also, the success of GTPPs as therapeutic agents depends on the optimized synergies with other co-existing compounds in the tea extracts (e.g. caffeine and certain minerals like zinc and chromium), other dietary components present in the same treatment regime or accompany meals (e.g. proteins, sugars and ascorbic acid, which may introduce additional molecular interactions with GTPPs and make contribution to energy metabolism), and even other lifestyle habits (unadjusted confounding factors).

## Overview

Nanotechnology focuses on the engineering, characterization, modification and development of biological and non-biological structures at the scale of 1 to 100 nm. These biological and non-biological compounds have revealed some unique properties and the research on the field is thus gaining momentum rapidly. Since the beginning of the 20th century, food industry has shown an increasing interest to nano-technological products focusing on improving safety, shelf-life and nutrient delivery of the food products (Weiss et al., 2006; Chen et al., 2006).

The possibility to mimic the nature towards engineered food nano-structures with enhanced properties has offered numerous potential applications in the food industry. Examples of nano-technological advances proposed by researchers in the food sector include:

- **Food processing.** Nanotechnology provides the aid of improving product shelf-life, texture and taste preservation during food processing. These nano-entities are used as food additives and are suggested to enhance food quality for a longer period of time (Singh et al., 2017).
- **Food Safety.** One of the most promising sectors of food industry involves the introduction of nanotechnology for food preservation and safety *via* packaging. Several nano-materials have been proposed from pathogens' nano-sensors to polymer nano-composites to combat product contamination, degradation of nutritional value, environmental and other risks (Duncan, 2011).
- **Bioactives' delivery.** The interest of the researchers as well as the food industry focuses on the fabrication of the so called "functional foods" using nano-carriers to promote targeted delivery and enhanced bioavailability of bioactive compounds. Following the consumers' demand for a healthier diet, scientists are providing solutions towards healthier "smart" foods *via* nanotechnology (Singh, 2016).

In summary, during the last decades scientists have introduced nanotechnology to improve many aspects of a food product. In this chapter we will focus on the general concepts, challenges and potential applications of food nano-dispersions proposed as vehicles of bioactive compounds. The most potent advantages of the aforementioned carriers of bioactive molecules include the increased solubility of therein molecules which subsequently leads to their enhanced bioavailability. Moreover, soft nano-dispersions mimic biological membranes already existing in the human body and are able to protect the encapsulated molecules from environmental stress such as pH alterations or proteolytic degradation. Finally, entrapped bioactives may be more efficient as food additives as they are protected from thermal or mechanical stress occurring during the processing of the final food product.

## Types of Soft Nano-Dispersions

In the present chapter attention will be paid to the most common nano-structures proposed in the food industry. These colloidal nano-dispersions are formed from water, oil and emulsifiers and are the most promising carriers of bioactive molecules.

It is well known that water and oil are two immiscible liquids with a high surface tension of 30–60 mN/m gradually leading to phase separation. When these liquids are mixed using mechanical means, a so-called "emulsion" is formed that will eventually break down into two phases post mixing. To overcome the aforementioned problem, scientists have proposed the addition of surface active agents (surfactants) that decrease the surface tension between the two phases leading to a slower collapse of the system. For the food industry these surfactants are food grade amphiphilic molecules called "emulsifiers" and will be analyzed below.

## Nanoemulsions

Conventional emulsions are optically opaque metastable colloids containing droplets from a few nanometers to 100  $\mu\text{m}$  (Leal-Calderon et al., 2007). These systems, as mentioned above, have a high surface tension and need external energy to induce their formation. In the last decades, food scientists have proposed nanoemulsions as a means to replace conventional emulsions for food applications. There has been much of a debate for the size limits of the nano-droplets ranging from 100 nm (McClements and Rao, 2011), 200 nm (Huang et al., 2010) to 500 nm (Anton et al., 2008). Nevertheless, these systems are in most cases almost transparent, a characteristic that is beneficial compared to conventional emulsions due to their slight alteration of food color

and organoleptic characteristics. One of the most important advantages of nanoemulsions is the relatively high shelf-life due to the nano-droplets' resistance to gravitational separation (Rao and McClements, 2011). Depending on the composition of the immiscible liquids, nanoemulsions are distinguished in water-in-oil (W/O) and oil-in-water (O/W) ones. In the first case, the continuous phase is oil with water droplets dispersed in it while the polar heads of the emulsifiers are facing the water core. In the second case, the reverse situation is taking place with the aqueous medium being the continuous phase and the non-polar part of the emulsifier laying towards the inside "entrapping" the oil molecules.

In order for nanoemulsions to be formed, an energetic barrier has to be overcome thus energy input is required. There are two types of methods proposed for the emulsification involving either high or low amounts of energy (Acosta, 2009). High energy input refers to techniques like microfluidization, high pressure homogenization and sonication. These methodologies provoke disruption of the droplets under homogenization thus decreasing their size (McClements and Rao, 2011; Jafari et al., 2008). The second type of methodologies is based on a spontaneous formation of smaller droplets due to alterations in the composition of the nanoemulsion. Most frequently, the emulsifier is solubilized in the solvent (water or oil). Spontaneous emulsification is based on the diffusion of one phase to another when these phases are brought into contact. Another low energy emulsification technique includes the alteration of the emulsifiers' molecular geometry towards phase inversion by altering the composition (Phase inversion composition) or the temperature (Phase inversion temperature) of the nanoemulsion. In the recent years, even though the low energy emulsification methodologies are gaining momentum the vast majority of applications involve the former type of emulsification due to ease of preparation and handling at an industrial scale.

Due to the fact that nanoemulsions are only kinetically stable, they are susceptible to gradual phase separation. These destabilization phenomena have been extensively studied in order to reverse or delay the nanoemulsions' collapse and are distinguished in reversible and irreversible instabilities (Figs. 1 and 2). The first case includes creaming or sedimentation depending on the type of nanoemulsion. For both phenomena, the nanoemulsions' droplets aggregate *via* flocculation retaining their initial size and shape (McClements, 2015). On the other hand, irreversible instabilities include coalescence and Ostwald ripening and refer to phenomena that lead to gradual phase separation (Leal-Calderon et al., 2007). Coalescence is caused due to collision of the nanoemulsion droplets when an energy barrier is overcome. Coalescence is the most "violent" disruption mechanism as size evolution is self-accelerated leading to a fast collapse of the system (Leal-Calderon and Cansell, 2012). Ostwald ripening is caused when the droplets are not highly monodispersed. Differences in the size lead to differences in the Laplace pressure that eventually cause a diffuse transfer gradient from smaller to larger droplets. In 1962, Higuchi and Misra proposed the addition of a solute to the droplets in order to cause osmotic pressure mismatch (Higuchi and Misra, 1962). In that way, they were able to compensate the effect of Ostwald ripening thus retarding phase separation.

### Microemulsions

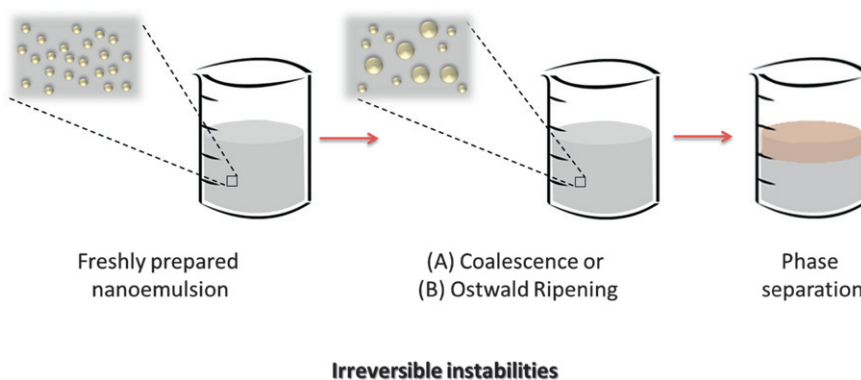

Microemulsions, also known as swollen micelles, are nano-structures that self-aggregate due to micellar formation, which is a thermodynamically favorable state (Shinoda and Kunieda, 1977). Despite their name, microemulsions droplets range from 5–50 nm and opposite to nanoemulsions no external energy is required for their formation. This is a major difference between these soft nano-dispersions that will be discussed extensively below. Even though microemulsions were reported from the 1940s, the most widely accepted definition was given almost forty years later from Danielsson and Lindman. According to this definition: "a microemulsion is a system of water, oil and an amphiphile, which is a single optically isotropic and thermodynamically stable liquid solution" (Danielsson and Lindman, 1981). Microemulsions are macroscopically transparent liquids due to the fact that the dispersed droplets are smaller than the wavelength of light. Microemulsions are also mainly distinguished in O/W and W/O depending on the continuous phase. A system containing oil droplets dispersed in an aqueous phase is called O/W microemulsion whereas the reverse composition is leading to a W/O microemulsion. For the case of microemulsions, a third case that almost equal amounts of water and oil are solubilized in a macroscopically transparent liquid could occur and is called "bicontinuous microemulsion".

In order to determine the limits of the monophasic region of a microemulsion, a ternary phase diagram is usually utilized. The phase behavior of water-oil-emulsifier is visually assessed at different composition points eventually constructing an illustration of

**Figure 1** Reversible instabilities occurring in nanoemulsions.

**Figure 2** Irreversible instabilities occurring in nanoemulsions.

**Figure 3** Typical ternary phase diagram representation at constant temperature and pressure.

the phase regions at constant pressure and temperature (Lawrence and Rees, 2000). A typical phase diagram is shown in Fig. 3. Briefly, every corner of the triangle represents the pure component whereas every axis is the binary mixture of the relative components. Every point inside the equilateral triangle represents a specific composition of water, oil and emulsifier and thus different phases can be optically distinguished. For compositions approaching the water–oil axis, phase separation is induced due to the lack of sufficient amounts of emulsifier. On the other hand, for compositions close to the emulsifier edge, lamellar structures are favored due to the high ratio of emulsifier compared to water or oil.

As mentioned above, the microemulsion region represents a one-phase area where systems are macroscopically transparent. The construction of the ternary phase diagram is frequently a time-consuming tool as the equilibration becomes slower with approaching to the multi-phase region (Garti, 2003). The typical protocol followed for the construction of a phase diagram includes the formation of binary mixtures (usually in the ratios of 1:9 to 9:1) followed by the gradual titration of the third component at constant temperature and pressure conditions (Kalaitzaki et al., 2013).

The addition of one or more components has been proposed in order to increase the monophasic region and decrease the amount of emulsifier needed. There systems are represented with the so-called “pseudo-ternary” phase diagrams. In these cases, one or more triangle edges represent a mixture of components that has been shown to enhance microemulsion formation. Garti and his team proposed the addition of alcohols and/or food-grade short polyols for the increase of the monophasic ( $L_2$ ) region due to the destabilization of liquid crystals (Garti et al., 2001; Yagmur et al., 2002).

### Nanoemulsions versus Microemulsions

In order to distinguish between the two aforementioned soft nano-dispersions mainly proposed for the food industry, one should consider the fundamental differences concerning systems’ thermodynamics. For the case of nanoemulsions, an energetic barrier needs to be overcome for the formation of the nanodroplets. A nanoemulsion could therefore be kinetically stable after the energy input in the sense that the energy barrier between droplet formation and phase separation is high enough. On the other hand, for the case of microemulsions, the formation of micellar droplets is the thermodynamically favorable state, thus occurring spontaneously. Consequently, the shelf-life of a microemulsion concerning the structural characteristics of therein droplets is higher than those of a nanoemulsion.

Another important difference between the two systems concerns the emulsifiers typically used for the droplets formation. Often, the amphiphilic molecules used for the formation of micelles tend to form different shapes depending on the molecules geometry and packing parameters. On the other hand, nanoemulsion droplets have the tendency to be spherical due to the relatively large Laplace pressure (McClements, 2012).

Finally, the two types of soft nano-dispersions differ in the amount of emulsifier needed for the formation. Because of the external energy input in the case of nanoemulsions, a relatively small amount of emulsifier is required for the droplet formation. On the other hand, microemulsion formation requires a larger amount of emulsifier which has to exceed the Critical Micellar Concentration (CMC) for spontaneous formation to occur.

For the food industry, the cost, the legislation restrictions on the amount of emulsifier used, the possible off-taste effect and the shelf-life of the final product, are the parameters taken into consideration for the selection of the appropriate bioactives' nano-carrier.

The most commonly used emulsifiers in the food industry are low cost and food-grade amphiphilic molecules derived from foods such as proteins, phospholipids, and polysaccharides. Synthetic emulsifiers are also being used but in most cases the legislation restrictions are strict, thus synthetic molecules are often used in mixtures with naturally occurring amphiphiles (Leal-Calderon et al., 2007).

Other types of soft nano-dispersions such as complex formulations of nanostructured multilayer emulsions or nano-liposomes have been also proposed as efficient vehicles for bioactive nutrient delivery (Weiss et al., 2006; Reza Mozafari et al., 2008)

## **Nano-Dispersions and Bioactive Molecules**

Numerous studies have proposed nano- and/or microemulsions as soft carriers for nutrient or drug delivery applications. Due to their aforementioned unique physicochemical properties as well as the use of naturally occurring emulsifiers these systems are ideal for encapsulation of bioactive ingredients as they tend to protect therein molecules from environmental stress (pH, oxidation, proteolytic degradation etc.) (Leal-Calderon and Cansell, 2012; Flanagan and Singh, 2006). They are also able to enhance their solubility and, in some cases, their bioavailability under gastrointestinal conditions.

In the recent years, another cutting-edge perspective in the food chemistry and engineering is gaining momentum concerning the design of novel foods with health benefits. The tendency of the consumers as well as the increasing demand of today's way of life for healthier foods has lead food scientists to the design of "functional foods". A definition given by the Institute of Medicine's Food and Nutrition Board (IOM/FNB) refers to functional foods as "any food or food ingredient that may provide a health benefit beyond the traditional nutrients it contains. Nevertheless, the European Commission's Concerned Action on Functional Food Science in Europe (FuFoSE) along with the International Life Science Institute (ILSI) of Europe give the following definition: "a food product can be considered functional if together with the basic nutritional impact it has beneficial effect on one or more functions of the human organism thus either improving the general and physical conditions or/and decreasing the risk of evolution of diseases".

Numerous bioactive molecules of natural origin have been proposed for encapsulation in delivery matrices in order to increase their effective bioavailability in the gastrointestinal tract. For instance, lipophilic molecules, such as omega-3 fatty acids have been claimed to protect from cardiovascular, immune, mental and other disorders thus providing high nutritional value. Due to their hydrophobic character, omega-3 fatty acids show low-solubility in water leading to precipitation and low bioavailability. To this respect, nano-carriers have been proposed as ideal matrices for the incorporation and delivery of these fatty acids as they are able to solubilize them at higher amounts and increase thus, their bioavailability under gastrointestinal conditions (Garg et al., 2006).

Another type of naturally occurring molecules that have been proven to function more efficiently in a delivery system rather than in "free" state, are antioxidants. By definition, antioxidants are "substances used to preserve food by retarding deterioration, rancidity, or discoloration due to oxidation" (Shahidi et al., 1992). On the other hand, due to the fact that oxidation occurs, also, in the human body being involved in aging, cancer, degenerative diseases and others, these molecules are crucial for human health. Interestingly, Porter and his team observed that hydrophilic antioxidants are more effective when present in lipophilic media, whereas the opposite behavior occurred for hydrophobic antioxidants which were more efficient in emulsions rather than oils (Porter, 1993). The so called "polar paradox" has been extensively studied ever since, in order to understand the mechanism of the antioxidants' activity under various conditions (Laguerre et al., 2015; Shahidi and Zhong, 2011). Nowadays, the most acceptable theory for naturally occurring polar scavengers is that they tend to migrate to oil-water interfaces. Consequently, the protection of the molecules from oxidation under storage conditions as well as the increased molecules' efficacy, make nano-formulations a very promising solution to the aforementioned challenges. Indeed, it is currently known that in nature self-organization of monomers in nano-associations take place in bulk oils entrapping moisture and solubilized polar scavengers. More specifically, it has been proven that the minor amphiphilic components of vegetable oils such as phospholipids, sterols etc. self-form nano-structures in bulk oils entrapping hydrophilic bioactives (Sotiroudis et al., 2005; Chaiyasit et al., 2007; Xenakis et al., 2010; Papadimitriou et al., 2013). Even though the mechanism of radical scavenging is not yet fully understood, scientists, in an attempt to mimic nature, have extensively studied the beneficial effect of nano-dispersions as antioxidants' carriers either experimentally, or using molecular dynamics approaches (Chatzidaki et al., 2015, 2016a; Laguerre et al., 2008; Chatzidaki et al., 2017)

Proteins or peptide molecules are another type of compounds that could be beneficial to human health, nevertheless they are susceptible to proteolytic degradation when incorporated into foods and/or human gastrointestinal tract. Depending on the structural characteristics of a peptide (molecular mass, characteristic amino acid sequence etc), scientists could determine their functionality. Peptides or amino acids are also very sensitive to thermal processes or pH instabilities and could lose their effectiveness during food processing, storage or transportation (Chatterton et al., 2006). Some peptides are also being used from

the food industry as naturally occurring antimicrobial agents and have been studied for their efficacy under encapsulation conditions with promising results (Chatzidaki et al., 2016b).

## Food Nano-Dispersions and Final Product Issues

Nowadays, it is evident that ingested nanoparticles increase the permeability limits thus enhancing the absorption of therein bioactive molecules (Fröhlich and Roblegg, 2012; Constantinides, 1995). Nevertheless, due to the complexity of these systems, their potential toxicity should be thoroughly investigated. On the other hand, formulation of soft materials at the nano-scale is a practice mimicking natural processes to minimize the free energy needed. To this respect, self-assemblies resembling the naturally occurring aggregates of phospholipids, proteins etc. should not pose a high risk to the body compared to inorganic nanoparticles. Unfortunately, there are no specific differentiation regulations between soft nano-dispersions and metal or polymeric nano-particles. Moreover, there are no reported limitations concerning the uptake of these nano-materials or their potential toxicity levels. Although the FDA suggests that "size is not an issue", the Institute of Food Science and Technology (IFST), an independent authority for food quality is rather critical on food nanomaterials declaring that they should be considered as potentially harmful unless specified testing proves otherwise. Also, it suggests the classification of nano-materials to the E-numbering using the subscript "n" for their use at the labeling of the final product (Weiss et al., 2006). On the other hand, the European Food Safety Authority (EFSA) has issued a guidance on risk assessment of nanomaterials in the food and feed chain (EFSA, 2011). The European Commission (EC) is planning modifications to the current regulations to include nano-foods in a case-by-case basis. To this respect, EFSA elaborates an update of the guidance of 2011, to help the EC in its final decisions.

Although there is a scientific evidence that nanotechnology could strongly enhance the beneficial characteristics of our nutrition while suppressing possible weaknesses, consumers' opinion remain skeptical. While public perception on science and nanotechnology is positive for other industrial fields such as biomedicine or pharmacy, public acceptance of nano-engineered foods remains at its infancy (Macoubrie, 2004). Since there are no specified regulations for nanofoods, a database for these products currently released in the European market has been established since 2012 (Hansen et al., 2016). To date, the database contains information about 3038 products, 128 of which refer to nano-engineered food and beverages currently in the European food market (www.nanodb.dk). Some food products containing nanomaterials that are already in the market or patented are summarized in Table 1.

On the other hand, the rising consumers' demand for healthier foods with respect to their increased nutritional characteristics, is an emerging driving force for industrial research and development towards nano-structured food products (Singh et al., 2017; Tiju and Morrison, 2006).

## Conclusions

Food grade soft nano-dispersions are currently being used as a cutting-edge technology to overcome solubility and bioavailability of bioactive molecules. Moreover, they serve as effective carriers to protect specific molecules from environmental stress during food processing and storage. In an attempt to mimic naturally occurring self-assemblies at the nanoscale, scientists are currently using these nano-dispersions as vehicles to encapsulate bioactive molecules that are crucial for human health. The two major formulations of soft nano-carriers are nanoemulsions and microemulsions with the latter containing smaller droplets than the former type. More specifically, nanoemulsions are only kinetically stable and need external energy for the droplet formation whereas

**Table 1** Nano-materials currently patented or already released in the food market

Name	Patent/Product	Type of nanoformulation	Description	Source
Solgar Nutri Nano	Product	Microemulsion	Encapsulation of CoQ-10 and Alpha Lipoic Acid	<a href="http://nanodb.dk/en/product/?pid=3009#prettyPhoto">http://nanodb.dk/en/product/?pid=3009#prettyPhoto</a>
Nano Melatonin	Product	Nanoemulsion	Encapsulation of Melatonin	<a href="http://www.phfsa.com/en/products/nutritional-drugs/neurology/nano-melatonin-patented/">http://www.phfsa.com/en/products/nutritional-drugs/neurology/nano-melatonin-patented/</a>
Edible microemulsions with encapsulated plant extracts as dressing type products	GR Patent GR1008863 (B)	Microemulsion	Encapsulation of plant extracts	<a href="https://worldwide.espacenet.com/publicationDetails/biblio?FT=D&amp;date=20161006&amp;DB=&amp;locale=en_EP&amp;CC=GR&amp;NR=1008863B&amp;KC=B&amp;ND=4">https://worldwide.espacenet.com/publicationDetails/biblio?FT=D&amp;date=20161006&amp;DB=&amp;locale=en_EP&amp;CC=GR&amp;NR=1008863B&amp;KC=B&amp;ND=4</a>
Mustard oil nanoemulsion and preparation method thereof	CN103315956 (A)	Nanoemulsion	Decrease of the volatilization of the mustard oil and alleviation of its pungent smell	<a href="https://worldwide.espacenet.com/publicationDetails/biblio?II=2&amp;ND=3&amp;adjacent=true&amp;locale=en_EP&amp;FT=D&amp;date=20130925&amp;CC=CN&amp;NR=103315956A&amp;KC=A">https://worldwide.espacenet.com/publicationDetails/biblio?II=2&amp;ND=3&amp;adjacent=true&amp;locale=en_EP&amp;FT=D&amp;date=20130925&amp;CC=CN&amp;NR=103315956A&amp;KC=A</a>

microemulsions are formed spontaneously and thus are thermodynamically stable. To this respect, depending on the final product and the bioactive encapsulated, food processing could involve minor energy input hence being environmentally sustainable.

On the other hand, due to the consumers' skepticism on food nanotechnology, the final products currently released in the food market are relatively limited. Since there is strong evidence on the beneficial characteristics of nano-carriers for bioactive molecules, informative campaigns on nano-foods should be adopted from food companies and stakeholders.

## Introduction

The production of innovative functional food products has been the focus of food industry in response to the on-going trend towards the consumption of healthy foods, with additional properties (e.g., antioxidant, anti-inflammatory and anti-cancer), apart from their nutritional value (Guiné et al., 2016; Simões et al., 2017; Ramos et al., 2017; Weiss et al., 2008; Dordević et al., 2014). Such properties can be accomplished by the incorporation of bioactive compounds (i.e., nutraceuticals) that are often added to food or beverages. Bioactive compounds are functional molecules that have significant health benefits when consumed or applied. Vitamins, antioxidants, prebiotics, probiotics, antimicrobials, enzymes, among others, can be used and incorporated into food products to enhance their functional properties, or to increase their shelf-life. However, such compounds can have inadequate water solubility and/or low cellular absorption. A strategy that has been used to overcome this issue is the application of micro- and nanotechnologies, in particular, for the protection (i.e. from the adverse conditions of the surrounding environment, such as temperature, pH and ionic strength), control release and bioavailability enhancement of bioactive compounds (Simões et al., 2017; Ramos et al., 2017; Weiss et al., 2008; Robles-García et al., 2016).

At the micro ( $10^{-6}$  m) and nano ( $10^{-9}$  m) scale, materials have different behaviors and may acquire novel functional properties, when compared with those in the bulk state, due to e.g., the higher surface area-volume ratio observed at these scales (Simões et al., 2017; Madalena et al., 2016). Such feature can be explored through micro- and nanosystems that can be produced and tailored to encapsulate bioactive compounds, thus increasing their oral bioavailability (Robles-García et al., 2016). Since these micro- and nanosystems are intended to be applied to food products, they must be generally recognized as safe (GRAS). Therefore, proteins (e.g., whey, soy and egg proteins), polysaccharides (e.g., chitosan, alginate, gum arabica and pectin) and lipids (e.g., vegetable oils, phospholipids and triacylglycerol) are being used to produce micro- and nanosystems for the encapsulation and controlled release of bioactive compounds (Simões et al., 2017; Ramos et al., 2017; Aditya et al., 2017). These bio-based materials can be used to produce controlled delivery micro- and nanosystems due to their ability to form gels, particles/capsules and emulsions, as well as bonds with bioactive compounds (Simões et al., 2017). For instance, whey proteins have the ability to conjugate a large variety of bioactive compounds through either primary amino groups or ionic and hydrophobic binding. This behavior allows protection of labile compounds from degradation, while permitting a release in a specific site (e.g., small intestine for absorption) at a controlled delivery rate – i.e. by swelling behavior of gel in response to environmental stimuli (e.g., pH, temperature and/or electric fields) – thus allowing an improved bioavailability of such compounds (Ramos et al., 2017). Even though these bio-based materials can form stable controlled release systems, they are intended to be applied to food products that are further ingested and submitted to the harsh conditions of the human gastrointestinal (GI) tract. Consequently, understanding the interactions of such controlled delivery micro- and nanosystems with food components and subsequently their behavior under GI conditions is of utmost importance (Madalena et al., 2016). It is also crucial to assess the toxicity of such systems, in particular nanosystems since they are at a sub-cellular scale and may induce cellular damage or produce some unwanted phenomena (e.g., tissue bioaccumulation, inflammatory response and systemic exposure) (Simões et al., 2017; Rossi et al., 2014).

Therefore, this chapter covers the most commonly used bio-based and bioactive micro- and nanosystems (i.e., bioactive compounds encapsulated into micro- and nanosystems) for food applications, as well as of possible interactions established between different nanosystems. Moreover, some applications of such systems in commercialized food products are also depicted. Fig. 1 represents the main topics discussed in this chapter.

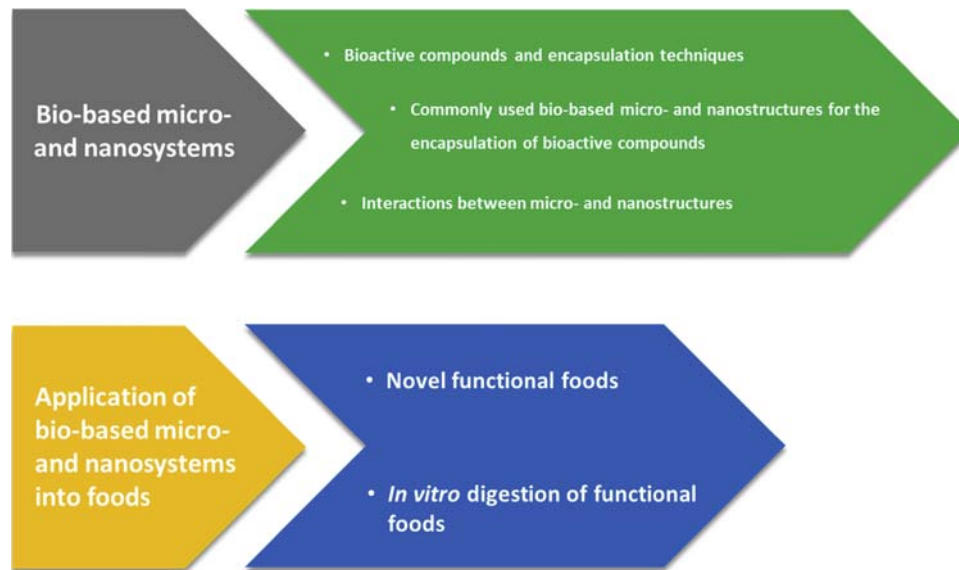

## Bio-Based Micro- and Nanosystems

### Bioactive Compounds and Encapsulation Techniques

Bioactive compounds are functional ingredients that occur in Nature, are part of the food chain, and can provide additional beneficial properties to food products (Biesalski et al., 2009). Vitamins (e.g., vitamin B<sub>2</sub> and vitamin E) (Madalena et al., 2016; Yang and McClements, 2013), polyphenols (e.g., curcumin and quercetin) (Pinheiro et al., 2016; Souza et al., 2013), probiotics (e.g., *Lactococcus lactis* ssp. *Cremoris* and *Lactobacillus rhamnosus* GG) (Ramos et al., 2016; Ying et al., 2012), minerals (e.g., iron and magnesium) (Zimmermann, 2004; Bonnet et al., 2009), fatty acids ( $\omega$ -3 and  $\omega$ -6) (Chen et al., 2017; Xu et al., 2013), among others, can be applied for this purpose. These compounds can have poor water solubility, and present low digestion stability and GI absorption, and may be influenced by external environmental conditions (e.g., temperature, light, oxygen, metallic ions, enzymes and water exposure), thus influencing their final performance and purpose. This can lead to their degradation that changes the

\* (corresponding author)

**Figure 1** Schematic representation of the chapter content structure.

overall properties of the final food product (i.e., presence of off-color, off-flavors and toxic degradation residues) (Simões et al., 2017; Đorđević et al., 2014; Jia et al., 2016). The encapsulation of bioactive compounds can overcome these challenges and two strategies can be used to achieve this purpose – top-down and bottom-up approaches (Simões et al., 2017).

The top-down strategy implies the mechanical processing of bulk materials to reduce their size and molding their shape. Consequently, precise tools must be used to achieve the desired final material characteristics. An example of this approach is the development of micro- and nanoemulsions by high-pressure homogenization (Fig. 2-1). Sample grinding and extrusion (Fig. 2-2) are also alternative top-down strategies for the encapsulation at the micro- and nanoscale. However, this strategy has

## Top-down Strategies

## Other Techniques

### 1 - High Pressure Homogenization

### 2 - Co- Extrusion

### 3 - Complex Coacervation

### 5 - Spray Drying

### 6- Fluid Bed Coating

### 4- Freeze Drying

**Figure 2** Schematic representation of the most used encapsulation techniques. Adapted from Simões, L.S., Madalena, D.A., Pinheiro, A.C., Teixeira, J.A., Vicente, A.A., Ramos, Ó.L., 2017. Micro- and nano bio-based delivery systems for food applications: in vitro behavior. Adv. Colloid Interface Sci. 243, 23–45.

some limitations from an economical point of view (i.e., expensive equipment, operability and maintenance costs) (Simões et al., 2017; Joye and McClements, 2014). The bottom-up strategy comprehends the application of self-assembly methodologies, at the molecular level, by inducing changes to the surrounding environmental conditions (e.g., temperature, pH and ionic strength). This approach allows a more accurate control over particle size and shape and is more energy efficient, when compared with top-down approaches (Joye and McClements, 2014).

Choosing an appropriate encapsulation technique depends on the nature of the bioactive compound and encapsulating structure (i.e., hydrophilic or lipophilic affinity). For instance, emulsions can be used to entrap lipophilic compounds (e.g., curcumin) (Simões et al., 2017; Jia et al., 2016). Pinheiro et al. (2016) produced curcumin nanoemulsions stabilized with lactoferrin and lactoferrin/alginate biopolymers by high pressure homogenization, which allow increasing curcumin bioactivity and bioavailability. Although, other techniques (Fig. 2-3:6) can be used to encapsulate bioactive compounds (e.g., coacervation, spray drying, freeze drying, inclusion and fluid bed coating) (Simões et al., 2017).

### Commonly Used Bio-Based Micro- and Nanosystems for the Encapsulation of Bioactive Compounds

Bio-based micro- and nanosystems are being widely used as delivery vehicles for controlled release of bioactive compounds. These structures can be produced using bio-based materials, such as proteins, polysaccharides and lipids, or their combination, to form different structures (e.g., capsules, hydrogels and emulsions) intended for the encapsulation of bioactive compounds – please see Table 1 (Simões et al., 2017; Cerqueira et al., 2014).

Capsules (Fig. 1) are colloidal structures that can be used to entrap bioactive compounds on their hollow aqueous or oil core, surrounding them with a wall material that can be made of bio-based materials. This structure can be produced at macro-, micro- and nanoscale. Despite the advantages of producing capsules at microscale (e.g., the preparation techniques employed and their scale-up), some limitations exist regarding their applicability. Capsules at microscale tend to present a heterogenous size distribution (i.e., high polydispersity) and low thermodynamic stability (Simões et al., 2017). On the other hand, capsules at the nanoscale (i.e., size below 100 nm) exhibit low polydispersity, high thermodynamic stability, high long-term kinetic stability, fast release kinetics of bioactive compounds and better mucus adsorption in the small intestine (Simões et al., 2017; Weiss et al., 2008). Although, due to their lower diameter, particles at the nanoscale can require complex techniques that may increase the cost of their production and scale-up, as well as require more sophisticated characterization methodologies (Jarzębski et al., 2017). Several techniques can be used to produce nanocapsules, which can include ionic pre-gelation/coacervation, polymerization (e.g., emulsion polymerization and dispersion polymerization) and dispersion of preformed polymers (e.g., nanoprecipitation, spontaneous emulsification, self-assembly, salting-out and supercritical fluid) (Cerqueira et al., 2014). Kamburova et al. (2017) produced nanocapsules from natural polymers as chitosan and pectin to entrap indomethacin (Table 1). Since chitosan and pectin polymers have opposite charges, the indomethacin was adsorbed to nanocapsules using a self-assembly layer-by-layer methodology. The authors established that the coating thickness was proportional to the number of deposited layers and observed a prolonged release rate of indomethacin from nanocapsules, as a result of its encapsulation.

Hydrogels are three-dimensional networks that are composed by hydrophilic or amphiphilic polymeric molecules that form intermolecular interactions through covalent and non-covalent bonds (e.g., hydrogen bonds, van der Waals interactions and physical entanglements). These structures are mainly formed by gelation processes that typically include linking of polymeric chains, thus leading to a progressively larger embranchment of molecules and to the formation of a three-dimensional network (this process is called as “sol”). Continuous networking through intermolecular interactions increases the ramification of polymeric chains, thus leading to a decrease in the network solubility. The transition from aggregation to a continuous building process is called “sol–gel transition” and the continuous building process is known as “gelation”. Hydrogels are formed when the building process terminates and the critical point where gel is achieved is called “gel point” (Simões et al., 2017; Ramos et al., 2014). These structures are mainly used due to their ability to swell and retain large amounts of water without disrupting their network. This feature is possible due to the presence of e.g., hydroxyl, amino and carboxyl groups in the network structure, which makes them suitable carriers for bioactive compounds (Ramos et al., 2017). Nanohydrogels of lactoferrin-glycomacropeptide (Lf-GMP) were

**Table 1** – Micro- and nanosystem examples for controlled delivery applications and their respective production technique

Micro- and nanosystems	Material	Bioactive compound	Production technique	References

		–		Mantovani et al. (2017)

successfully used for the encapsulation of bioactive compounds with different chemical nature, such as caffeine (hydrophilic) and curcumin (hydrophobic) (Table 1) (Bourbon et al., 2016). Chitosan, alginate and pullulan nanohydrogels were also produced to protect 5-fluorouracil (Table 1) from *in vitro* digestion conditions (Liu et al., 2016) and stable structures (i.e., in water and physiological conditions) (Di Meo et al., 2015), respectively.

Emulsions are structures composed by two immiscible phases that can be classified as oil-in-water (O/W), water-in-oil (W/O), liquid-in-liquid or solid-in-solid emulsions. Their stability may depend on many aspects, as follows: (i) the type of emulsifier/surfactant used to stabilize the emulsion; (ii) the homogenization conditions; (iii) the solvents and co-solutes present; (iv) the surfactant-to-oil ratio; and (v) the emulsion composition. Therefore, when submitted to high temperatures, pH variations and ionic strength changes, emulsions can exhibit weak physical stability during transportation, storage or application (Simões et al., 2017; Lu et al., 2016). However, micro- and nanoemulsions currently exhibit a good coalescence stability likely due to the decrease of the van der Waals attractive forces between droplets, with a concomitant decrease in particle size. In this sense, micro- and nanoemulsions can be used as suitable functional carriers for lipophilic compounds (e.g., essential oils, polyphenols, fatty acids, antioxidants, antimicrobials and some vitamins) (Simões et al., 2017). Micro- and nanoemulsions are often produced using high-energy methodologies that require the use of specific equipment, such as high-pressure valve homogenizers, sonicators and microfluidizers. The high mechanical energy produced by the equipment enables the production of stable oil droplets. Micro- and nanoemulsions can also be produced using low energy techniques that rely on the intrinsic physicochemical characteristics of the surfactants and oily and water phases used (Simões et al., 2017; Jia et al., 2016). Soybean and linseed oil were previously used to produce O/W micro- and nanoemulsions, using stabilizers (e.g., whey protein fibrils and Tween 20, respectively) and high-pressure homogenization techniques to entrap bioactive compounds (e.g., astaxanthin and lycopene) (Table 1), thus protecting them from the harsh conditions of the *in vitro* GI conditions (Sotomayor-Gerding et al., 2016), and maintaining their stability during storage (Mantovani et al., 2017).

### Interactions Between Micro- and Nanosystems

Micro- and nanosystems can establish covalent and non-covalent bonds (e.g., electrostatic, steric, van der Waals, hydration and intermolecular hydrophobic interactions, and hydrogen bonds) with other systems, bioactive compounds and/or food components, thus allowing the improvement of the existent properties of food ingredients or even the creation of innovative ones. For instance, protein molecules can be tailored to form different food structures, depending on the extent of protein association. This allows developing protein-protein, polysaccharide-protein and lipid-biopolymer complexes in order to take advantage of the synergistic effects between both materials (Ramos et al., 2017; Liu et al., 2017).

Protein-protein non-covalent interactions (e.g.,  $\beta$ -lactoglobulin and  $\alpha$ -lactalbumin interaction) can be influenced by pH (electrostatic interaction), temperature (intermolecular hydrophobic interactions by exposing apolar residues), hydration (repulsive forces due to high hydration levels), protein conformation (steric interactions) and protein molecular weight and size (van der Waals interactions increase with the increase in protein size). Protein covalent interactions are formed when a reaction between free sulphydryl and disulfide groups occurs, which is responsible for protein aggregation and further gelation. This kind of complexation enables the functionalization of protein matrices by modulating their rheological properties. Therefore, it is possible to control the release rates of bioactive compounds that can be entrapped in this kind of structures (Ramos et al., 2017). Oancea et al. (2017) developed  $\beta$ -lactoglobulin ( $\beta$ -lg) microparticles to encapsulate anthocyanins from sour cherries. The protein matrix was developed by dissolving pure  $\beta$ -lg in Tris-HCl buffer with a pH of 7.7, far from the isoelectric point of  $\beta$ -lg (i.e., pH of 5.2) to promote repulsive electrostatic intermolecular interactions. The protein mixture suffered a heating treatment in order to promote a protein destabilization/denaturation, thus exposing the  $\beta$ -sheets present in the  $\beta$ -lg secondary structure and permitting the establishment of electrostatic interaction with the anthocyanins and its encapsulation (Liu et al., 2016). Furthermore, this study also concluded that  $\beta$ -lg prevented anthocyanin degradation during *in vitro* gastric digestion, and its release in the small intestine.

Protein-polysaccharide interactions can also take place to promote the synergy between both structures and thereby improving their functional properties. This kind of interaction can be achieved through chemical (not used in the food industry due to regulatory concerns), physical and enzymatic processes (Ramos et al., 2017; Liu et al., 2017; Damodaran et al., 2007). The Maillard reaction is often used to prepare protein-polysaccharide complexes under monitoring temperature, time, moisture, pH, heating, dry-heating or the use of novel processing technologies, such as pulsed electric field conditions. Briefly, deprotonated amino groups from protein molecules and polysaccharide carbonyl groups can react with each other (i.e., through covalent bonding) to form a N-glycosylamine and one water molecule. The N-glycosylamine can then be rearranged to form the Amadori product (i.e., 1-amino-1-deoxyketose), which is a more stable ketone that can lead to the formation of protein-polysaccharide conjugations. If the reaction takes place under controlled conditions (i.e., temperature, moisture, pH and time), the interaction between proteins and polysaccharides can have enhanced emulsifying, heating stability, antioxidant and antimicrobial properties (Liu et al., 2017; de Oliveira et al., 2016; Semenova, 2017). Mengibar et al. (2017) assessed the emulsifying and antioxidant properties of the Maillard reaction residues from soluble chitosans (with different molecular weights) with  $\beta$ -lg, emphasizing the importance of choosing the appropriate biopolymer (according to its physico-chemical properties), to formulate novel functionalized food products. The authors concluded that the Maillard reaction with high molecular weight chitosans (39 and 56 kDa) resulted in the gelation of the final product. On the other hand, the Maillard reaction with low molecular weight chitosans (1.3 kDa) resulted in the formation of soluble functional residues with significantly higher antioxidant activity.

Micro- and nanoemulsions are often used to protect lipophilic bioactive compounds from environmental conditions, while tensioactive compounds (i.e., surfactants) can be used to stabilize micro- and nanoemulsions, preventing from flocculation and coalescence. Biopolymers can also be used with surfactants in order to increase the repulsive intermolecular interactions between droplets (i.e., influence of repulsive steric forces), resulting in an increased emulsion stability. Proteins, for example, can compete with surfactants in the oil-water interface (i.e., competitive adsorption), as well as interact with surfactants resulting in protein unfolding (i.e., increase in hydrophobicity) or protein precipitation (with charge neutralization leading to an increase in the surface activity of surfactant-protein complex) (Damodaran et al., 2007; Hasenhuttl and Hartel, 2008).

## Application of Bio-Based Micro- and Nanosystems Into Foods

Micro- and nanotechnologies applied in the food industry have been widely studied and reported in the last few decades. Consequently, novel food-grade controlled delivery micro- and nanosystems were developed to be further applied to food products. Therefore, it is very important to understand the interactions of such systems with food matrices and their digestibility (Simões et al., 2017; Wilde et al., 2016). In this section, food products containing micro- and nanosystems that were recently developed are listed, and information regarding to the digestion of such functional food products is provided.

### Novel Functional Foods

Consumer awareness towards the consumption of fortified, healthy food products is gradually increasing in nowadays society. This results in an increased effort from the food industry players to develop novel food formulations with additional functional properties. Consequently, recent developments in food science point to the application of encapsulated bioactive compounds in commercialized food products (Simões et al., 2017; Cerqueira et al., 2014; Gultekin-Ozguven et al., 2016). For instance Gultekin-Ozguven et al. (2016) encapsulated black mulberry extract into anionic liposomes coated with chitosan through layer-by-layer deposition. The resulting mixture was spray-dried to be further applied into chocolate formulations (i.e., natural and alkalized cocoa liquors) at different conching temperatures (i.e., 40, 60 and 80 °C). The authors concluded that it is possible to fortify dark chocolate with encapsulated anthocyanins, although the fortification efficiency depends on the pH and processing temperatures.

Encapsulating delivery systems can also be used to mask off-flavors, as well as the astringency and bitterness which some bioactive compounds can produce. Wilde et al. (2016) used  $\beta$ -lg to encapsulate allicin, the main thiosulphate in garlic, responsible for its taste and smell. The authors incorporated the nanosystem entrapped with allicin into a coffee-based beverage and assessed the sensory profile of this food product. They concluded that the encapsulation of allicin into  $\beta$ -lg masked the characteristic flavor of garlic in the tested food matrix.

Rivero et al. (2013) took a different approach and developed chitosan films loaded with propionic acid to extend the shelf-life of pastry dough. The authors concluded that chitosan films loaded with propionic acid had a significant antimicrobial effect, which makes this system a good sustainable, food-grade alternative to conventional synthetic films and chemical preservatives.

Therefore, food-grade micro- and nanosystems can be used to functionalize food products, through the controlled release of bioactive compounds, to mask off-flavors and unwanted organoleptic characteristics (e.g., smell and taste) that are associated to the application of some bioactive compounds, as well as to extend the shelf-life of food ingredients through the controlled release of antimicrobial and antifungal bioactive compounds.

### In vitro Digestion of Functional Foods

The digestion of food is a complex, yet an important assessment to understand the behavior of controlled delivery nanosystems in the GI tract. Therefore, *in vitro* digestion models can be used to make this assessment since they do not raise any ethical issues and they are an unexpensive alternative to *in vivo* models (Simões et al., 2017; Madalena et al., 2016). Several *in vitro* digestion models were developed in the last few years with different functionalities; some of them are more simple and static (Gultekin-Ozguven et al., 2016), while others are more complex and dynamic (Pinheiro et al., 2016) taking into account the peristaltic movements of the GI tract during digestion. This kind of models (static and dynamic) can be used to study the digestion of functionalized food, fortified with controlled delivery systems, as well as the bioavailability of bioactive compounds incorporated into food matrices. In addition to the development of fortified dark chocolate with black mulberry extract, Gultekin-Ozguven et al. (2016) studied the *in vitro* digestion of this functionalized food product and determined the effect of liposomes encapsulation in anthocyanin activity, under GI conditions. The authors reported that the encapsulation of anthocyanins in liposomes improved their bioavailability by protecting them from the acidic gastric conditions and by allowing their release in the small intestine due to the presence of bile salts (responsible for the disruption of the liposomes). Amine et al. (2014) evaluated the protective effect of alginate microsystems on the survivability of *Bifidobacterium longum* in Cheddar cheese during *in vitro* digestion. The authors concluded that microencapsulated *B. longum* had higher survivability during gastric digestion when compared with that in free form.

Micro- and nanosystems can in fact be applied to food products to promote the protection of bioactive compounds during digestion, thus improving their bioavailability. Despite the increased number of publications regarding the application of micro- and nanosystems in food products, systematic studies on regulation and legislation of the application of these systems are still

lacking, in particular of those at nanoscale, thus, more studies must be conducted to understand the possible interactions or undesired reactions that may occur in food matrices.

## Concluding Remarks

Micro- and nanotechnologies have a significant impact on the food industry through the development of novel food products with additional functional properties, resulting from an increased public awareness towards the consumption of healthy food products. However, at the nanoscale, materials tend to have distinct characteristics (e.g., higher volume/surface area ratio) which results in improved or even novel functionalities. This indicates that nanotechnology is a very promising option and published research efforts corroborate this statement. However, some challenges must be addressed (e.g., potential cytotoxicity) through *in vitro* or *in vivo* studies. Another important bottleneck is the understanding of the possible interactions of nanosystems with food matrices; there is an enormous lack of research in this field. In addition, there is a growing interest in understanding the behavior of such micro- and nanosystems when incorporated into real food products under GI conditions. For this purpose, *in vitro* GI models have been used since they are inexpensive and practical, do not raise any ethical concerns, and, in fact, some simulate closely the GI conditions of the human digestion. Several studies infer that micro- and nanoencapsulation protect the bioactive compounds from the harsh gastrointestinal conditions and consequently increase their bioavailability. But, it is important to point out that more knowledge is required regarding the digestion of functional foods using *in vitro* GI systems mainly due to the complexity of the food matrix and the constraints of existing experimental methodologies. There is still a long way to go, more fundamental and applied research are needed to prove that these functional food products are safe for public consumption and can be commercialized.

## Glossary

**Oleogels** Sub-group of organogels where the continuous liquid oil phase is structured into a gel with the help of a dispersed continuous network of either self-assembled structures, crystalline particles, aggregated inorganic particles or polymeric strands.

**Oleocolloids** A broad range of oil continuous soft matter systems comprising colloids at an interface of complex fluids and phase-separated states of matter such as oleogels; biphasic colloids (indirect emulsions and oleofoams); complex colloids such as foamed oleogels and oil-in-water-in-oil (O/W/O) emulsions; and layered structural matrixes embedding a large volume of liquid oil (oleofilms).

**Self-Assembly** A process by which individual molecules form defined molecular assemblies such as aggregates or clusters.

**Self organization** A process by which the self-assembled aggregates or clusters create higher-ordered structures (network).

## Introduction

Oleogels are a sub-group of oleocolloids where a continuous liquid oil phase is structured into a gel through self-assembly and hierarchical organization of oleogelators. These oleogelators or oil structuring agents are low molecular weight molecules that can assemble into a continuous space-filling network which is capable of physically immobilizing liquid oils into 'gel-like' structures. In most cases, a single oleogelator is used to design oleogels (which are often referred to as monocomponent gels). Although this is an interesting strategy, monocomponent gels suffer from certain drawbacks such as requirement of relatively higher concentration of oleogelator and limited tunability of gel properties such as optical clarity, melting range, rheological properties and storage stability. Alternatively, multi component oleogels (mixed gels) which are based on synergistic interactions of two or more materials offer the flexibility of creating oleogels with desired properties at a low total structurant concentration. A low concentration of structurant ensures incorporation of a large proportion of liquid oil in reformulated food products (resulting in the improvement of fatty acid profile) and, the flexibility of altering macrostructural properties (by simply changing the proportion of components) may further broaden their applicability in different product formats.

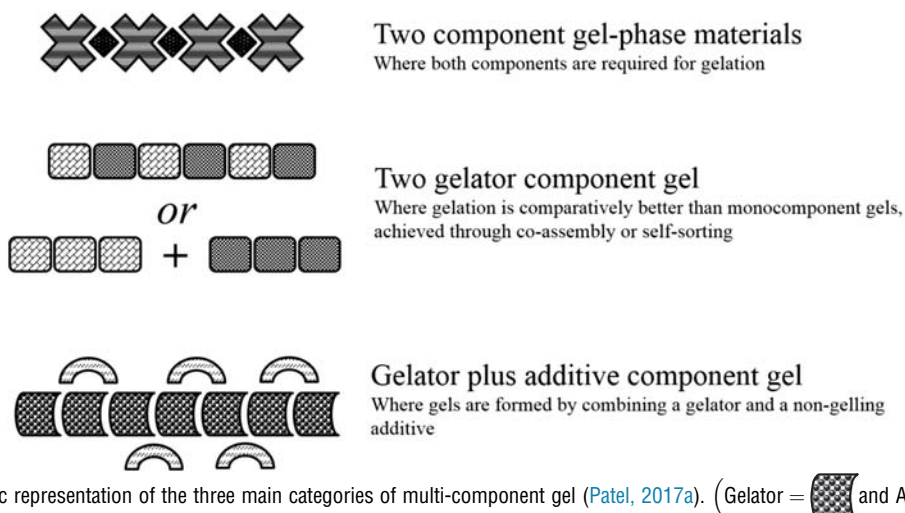

The simplest of these mixed gels are ones in which two components are added to the liquid oil in order to exploit their synergistic interactions to alter the formation of microstructure as well as the structural framework that supports the gel. The three general classes of these kind of gels (Fig. 1) include: (a) two component gel-phase material gels where both components are required for gelation as the individual components cannot form gel on their own (in other words, the two components form gelator *in-situ*, interacting *via* non-covalent forces to form a complex that is the gelator); (b) two gelator component gels where both components are themselves gelators (having properties of forming structured materials) and when used in combination, they are capable of organizing into assembled structures either together (co-assembled) or independent of each other (self-sorting), and (c) gelator plus additive component gels which are formed by a combination of a gelator and a non-gelling additive. The non-gelling additive can impact either the self-assembling properties of gelator or promote an effective spatial distribution of building blocks formed by gelator or strengthen the network linkages among the formed building blocks (Patel, 2017a).

Some selected examples of edible gels prepared from combination of food components are discussed briefly in the following text.

## Two Component Gel-Phase Material Gels

### Phosphatidyl Choline-Tocopherol Oleogels

When phosphatidyl choline (PC) or  $\alpha$ -tocopherol are individually added to vegetable oil, they do not yield to any structural organization, but their mixture (at 1:1 ratio) leads to the formation of solid-like structures (*in-situ* formation of building blocks) (Niki-foridis and Scholten, 2014). Due to its molecular structure (small polar group and large hydrophobic tail), PC likes to pack itself into spherical reverse micelles. However, these spherical structures are incapable of organizing into a spanning network.

**Figure 1** Schematic representation of the three main categories of multi-component gel (Patel, 2017a). (Gelator =  and Additive = .

Incorporation of  $\alpha$ -tocopherol (which has a complementary structure, i.e. large hydrophobic group and a small polar head) leads to the formation of cylindrical micelles that have the ability to grow into a space-filling network which leads to gel formation. Mixed gels with thermoreversible properties can be created at a total solid mass of 25% weight (wt) but these gels display a high sensitivity to shear (Nikiforidis and Scholten, 2014). The requirement of high concentration and shear sensitivity of these gels may limit their practical applications in food structuring.

### Lecithin-Sorbitan Tristearate Oleogels

Individually both lecithin (Lec) and sorbitan tristearate (STS) are incapable of forming oil gels at concentration between 6 and 20 % wt in absence of a polar solvent. However, when mixed in specific ratios between 40:60 to 60:40, Lec:STS can form firm gels at a total concentration as low as 4 %wt (Pernetti et al., 2007). The crystalline units formed in these systems are based on STS, while Lec plays an important role in influencing both the morphology of the crystalline units as well as the network junctions among the formed units. The gel however has limited use as hardstock fat replacer as it starts softening at temperature above 15 °C and undergoes complete collapse at 30 °C (Pernetti et al., 2007).

### Lecithin-Sucrose Esters Oleogels

Lec is also known to show synergistic interactions with sucrose esters (SEs) resulting in the formation of structured units (reverse worm-like micelles) in organic solvent such as *n*-decane (Hashizaki et al., 2009). Formation of these units and the subsequent continuous network results in gel formation. This interaction was reported for hydrophilic SEs (HLB > 10) and the functionality of Lec-SEs combination was found to be influenced both by concentration of Lec and the hydrophobicity of SEs (Hashizaki et al., 2009).

It was recently shown that synergistic interactions of Lec and SEs are also seen in edible vegetable oil (rapeseed oil) when hydrophobic SEs (HLB 1 and 2, also called as sucrose oligoesters) are mixed with Lec at a total structurant concentration of 10 %wt (Bin Sintang et al., 2017c; Patel, 2017b). It was hypothesized that the presence of Lec interrupts the extensive hydrogen bonding among SEs molecules and prevents the aggregation induced contraction seen in mono component gels of SEs. This is in contrast to the reported study done in *n*-decane where Lec micelles were the structuring units and SEs played the role of an additive that modified the morphology of micelles by interacting with the phosphate groups of Lec (Hashizaki et al., 2009).

## Two Gelator Component Gels

### Phytosterols-Oryzanol Oleogels

Mixed component oleogels of  $\beta$ -sitosterol and  $\gamma$ -oryzanol are undeniably one of the most extensively studied oleogel systems. On their own both components form crystalline particles in vegetable oils, but when mixed at certain proportions they co-assemble to form nanoscale tubular structures. Depending on the concentration, these nanoscale tubules aggregate to form a 3-D network that can physically immobilize liquid oil through capillary forces to form a viscoelastic gel. Aside from  $\beta$ -sitosterol, other related phytosterols such as dihydrocholesterol, cholesterol and stigmasterol can also produce gels with  $\gamma$ -oryzanol. Structurally, the presence and position of hydroxyl group was found to be critical for gel formation while the composition of alkyl group did not appear to have

any major impact on the gelling properties of phytosterols (Bot and Agterof, 2006). Both  $\beta$ -sitosterol and  $\gamma$ -oryzanol are reported to have an effect on cholesterol absorption due to the similarity in their chemical structures (Rong et al., 1997; Ikeda et al., 1988). This lipid lowering bioactivity makes these components even more attractive for oil structuring in lipid-based food products.

### Fatty Acid-Fatty Alcohol Oleogels

Fatty acid (stearic acid) and fatty alcohol (stearyl alcohol) mixtures were among the first components used for creating mixed component gels to be potentially used for edible applications (Gandolfo et al., 2006). The synergistic effect in these systems was previously explained based on mixed crystal formation (co-crystallization) which results in finer crystal sizes as well as an altered crystal morphology (needle-like for mixtures versus platelet-like for individual components) (Gandolfo et al., 2006; Schaink et al., 2007). However, a recent study claims that the synergistic effect is not linked to the changes in crystal sizes but rather linked to the increase in the crystalline mass as well as its spatial distribution in the solvent (Blach et al., 2016).

### Phytosterol-Monoglyceride Oleogels

Phytosterols (PS) and monoglycerides or monoacylglycerols (MAGs) are lipidic materials that form well-defined crystalline particles in liquid oils. Crystalline particles formed by MAGs can connect together to form a 3D network that results in oleogel formation. However, these oleogels are usually soft in nature (low firmness) and MAGs are prone to polymorphic transition over time, resulting in the formation of grainy crystals. On the other hand, PS crystallize as large flat-crystals and thus, form weakly structured oleogels that are prone to phase separation caused by aggregation-induced contraction of crystalline phase. Surprisingly, by combining MAGs with PS at certain proportions (and a total gelator concentration of 10 %wt), a synergistic enhancement in the rheological properties of oleogels was observed due to the formation of finer crystalline particles with completely different morphology compared to MAG and PS crystals (Bin Sintang et al., 2017a). Based on the data from several characterization techniques, it was concluded that the synergism was not based on co-crystallization owing to a large difference in the molecular structures of the two components (Bin Sintang et al., 2017b). Instead, a self-sorting behavior was noticed as both components crystallize independent of each other to form characteristic structuring units (fibrous and spherulitic crystals) that contribute to a synergistic enhancement in the rheological property of the gel (Patel, 2017a). In addition, the presence of different structuring units prevents aggregation of crystalline mass (which is an issue in the monocomponent gels) leading to a better spatial distribution of mass in the bulk liquid oil phase.

### Gelator Plus Additive Component Gels

#### Stearic Acid Oleogels

Stearic acid has been reported to form oleogels on its own when used at concentration close to 20%wt. Structuring in these gels comes from network of crystalline particles which are predominantly shaped as plate-like. Uvanesh and co-workers have demonstrated that non-gelling additives such as Span 60 (sorbitan monostearate) and Tween 20 (polyethylene glycol sorbitan monolaurate) can significantly influence the properties of stearic acid oleogels by modulating the crystallization behavior of stearic acid (Uvanesh et al., 2016a,b). Span 60 was shown to promote the crystallization of stearic acid which in turn resulted in significant decrease in the crystal size and microarchitectural changes from plate-like to fibrous mesh-like structures (Uvanesh et al., 2016a). Incorporation of Tween 20 resulted in molecular rearrangement and ordering of stearic acid molecules by influencing the polymorphic transition of stearic acid (Uvanesh et al., 2016b).

### Conclusion

Oleogelation is an emerging approach and has the potential to contribute significantly towards solving some long-standing challenges in the area of food structuring. However, one of the main bottlenecks in the field of oleogelation is finding oleogelators that are effective at low concentrations and have required regulatory approval for use in edible products. By exploring the synergistic interactions of known food-grade materials, a range of mixed gels can be created. The flexibility of tuning the rheological and physical properties of such gels (by changing the proportions of individual components and the total gelator concentration) makes them quite attractive for commercial applications. There is however a lack of information on the influence of formulation matrix and product conditions on synergistic interactions among gelators. Therefore, an in-depth analysis to understand this aspect is needed to fully exploit the potential of this class of oleogels.

## Introduction

Over the last two decades, the concept of using functional foods for health promotion has been confirmed by several *in vitro*, animal and human studies. Among the food-derived ingredients, proteins are drawing a lot of attention due to their functionality as essential biopolymers and also their distinct biophysicochemical characteristics such as biocompatibility, amphipathicity and the presence of modifiable moieties. Development of encapsulation system using food-derived proteins has become a major research endeavour to facilitate efficient delivery of functional compounds and probiotic organisms (McClements, 2015). Hence, proteins such as gelatin, collagen, zein, casein and whey proteins represent some of the most investigated groups of ingredients for food and biotechnological applications as delivery systems (Gomez-Guillen et al., 2011; Livney, 2015; McClements, 2015; Raikos and Ranawana, 2017; Rajendran et al., 2016).

The size of a protein-based delivery system in the intestinal environment is critical in ensuring biorecognition, bioavailability, bioadhesion and stability (Santos et al., 2013). Acosta (2009) provided a comprehensive review, using thermodynamic and mass transfer principles, on the essence of nanosize of delivery systems in enhancing their bioavailability and bioadhesion relative to their larger sized counterparts. The decrease in size of delivery systems can increase their surface area-to-volume ratios as well as physicochemical interactions with a corresponding effect on the global characteristics of the delivery system in the human gastrointestinal tract (Cerqueira et al., 2014).

To date, various techniques developed to produce protein-based nanodelivery systems include nanoemulsification, coacervation, antisolvent precipitation, electrospraying and electrospinning (Rajendran et al., 2016). McClements (2015) recently discussed critical parameters that are essential in the development of food-grade nanodelivery systems. There are several considerations required to develop nanoencapsulation systems, including safety, commercial viability, food matrix compatibility, robustness, performance, and labelling requirements (Fig. 1). This chapter discusses the fundamental basis of protein-based nanodelivery systems, together with the key characteristics of the produced nanodroplets/nanoparticles and their drawbacks, for tailored design to suit their final applications in food products.

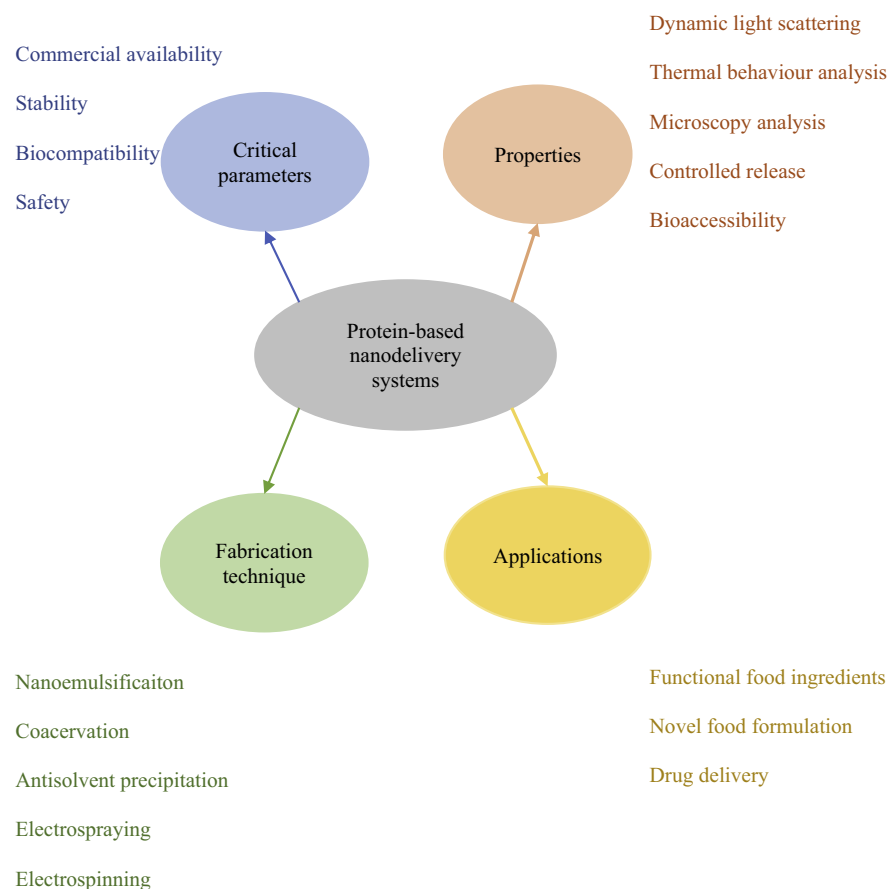

## Preparation and Characterization of Protein-Based Nanodelivery Systems

### Nanoemulsification

Nanoemulsification is a technique that involves dispersion of immiscible liquids and is commonly employed in the production of nanoparticle droplets that are thermodynamically stable, bioavailable, and optically isotropic. Nanoemulsions have a number of potential advantages over conventional microemulsions, including better stability against particle agglomeration and gravitational separation (Tadros et al., 2004), weaker light scattering effects (Mason et al., 2006) and increased bioavailability of some encapsulated lipophilic compounds (Acosta, 2009). Like the conventional oil-in-water (O/W) emulsions, protein-based O/W nanoemulsion can also be prepared using high-energy approaches including high-pressure homogenisation, microfluidisation and ultrasonication (McClements and Rao, 2011). Dynamic light scattering technique is usually used to test the size distribution of the nanoemulsion while the morphology of the nanodroplets/nanoparticles can be revealed by various microscopic techniques including confocal laser fluorescence, scanning electron, atomic force, and transmission electron microscopy.

### Nanoemulsions Prepared by High Pressure Homogenisation

The high pressure method is the most commonly used homogenisation method in the contemporary food industry and for producing fine O/W microemulsions from coarse emulsion prepared with high shear mixers (Schubert and Engel, 2004). As large O/W droplets pass through the narrow valve of the high pressure homogeniser, the O/W droplets are broken down into smaller ones due to the intensively disruptive forces. Generally, the size of droplets decreases with increase in homogenisation pressure and number of passes. By using extremely high homogenisation pressures and multiple passes, sometimes O/W nanoemulsion can also be produced. It should be emphasised that the amount of emulsifier must be sufficient to adsorb onto the O/W interface during homogenisation to prevent re-coalescence of the nanodroplets (Jafari et al., 2008). A study reported the preparation of whey protein-based nanoemulsion using medium-chain triglycerides containing  $\beta$ -carotene with a final emulsion droplet size below 200 nm at the homogenisation pressure of >80 MPa with 3 passes (Mao et al., 2010). Moreover, the delivery of fenofibrate in nanoemulsions of sizes ranging from 100–250 nm was achieved using soy and whey protein isolate as emulsifiers (He et al., 2011). In the study, a more rapid absorption of the nanoencapsulated fenofibrate was observed *in vitro* compared to the unencapsulated compound.

**Figure 1** Protein-based nanodelivery systems: critical considerations for development, physicochemical properties, fabrication technique and their applications.

### Nanoemulsions Prepared by Microfluidisation

Microfluidisation works similarly as homogenisation. The O/W coarse emulsion droplets are also forced to pass through a narrow channel to facilitate the droplets disruption during the process. However, this channel is differently designed, compared to the high pressure homogenisation valve, to produce emulsions with smaller droplets size and narrower size distribution. Using this method, [Dagleish et al. \(1997\)](#) found that protein fractions influence the nanoemulsion droplet size distributions. Moreover, [Klein et al. \(2010\)](#) reported that O/W droplet size in canola O/W nanoemulsion stabilised by whey protein isolate, prepared by microfluidisation, remained unchanged during 30 days of storage. Like high pressure homogenisation, O/W emulsion produced by microfluidisation tends to exhibit a decreased size with increase in pressure, number of passes, emulsifier concentration, and continuous/disperse phase ratio.

### Nanoemulsions Prepared by Ultrasonication

Ultrasonication is a method that uses high intensity ultrasonic waves to disrupt oil and water phase to create small O/W emulsion droplets. This method has been widely used in the nanoemulsification of food-derived products. Like homogenisation and microfluidisation, smaller O/W emulsion droplet size tends to be formed by increasing the energy input (ultrasonic wave intensity), and/or the residence time ([Maa and Hsu, 1999](#)). Using this method, [Mahdi Jafari et al. \(2006\)](#) encapsulated *d*-limonene oil in whey protein concentrate-based O/W nanoemulsion with droplet size below 250 nm. The emulsion size was found to be dependent on process parameters such as emulsifier concentration, *d*-limonene oil-to-water phase ratio, ultrasonic intensity and residence time. Therefore, desired emulsion size can be prepared by adjusting the ultrasonication condition, and this was applied in determining the optimum ultrasonication condition beyond which the emulsion size either increased or remained unchanged with further processing ([Mahdi Jafari et al., 2006](#)).

To date, high pressure homogenisation, microfluidisation and ultrasonication have been widely used for preparing nanoemulsions for food, pharmaceutical and agricultural applications. The fundamental basis of nanoemulsification is simple, but it should be emphasised that the size of nanoemulsion droplets/particles also depends strongly on the characteristics of the oil and protein used. It is usually easier to produce small droplets using the oil phase with low viscosity and/or interfacial tension such as flavour and essential oil, compared to the one with high viscosity and/or interfacial tension, for example, medium and long-chain

triglycerides. This is because, at low viscosity or interfacial tension, the restoring forces holding the droplets can easily be overcome by the homogenizer disruptive forces (McClements and Rao, 2011).

### Coacervation

Coacervation is a method of inducing phase separation by formation of insoluble liquids known as coacervates in a colloidal system. Driven by change in entropy in colloidal systems, this phenomenon can be induced by altering the pH, temperature, dielectric constant and/or ionic strength of the protein mixture (McClements, 2015). Depending on the numbers of polymers used, coacervation can be termed as simple or complex; the former occurs through the surface energy change of the proteins whereas the latter is by means of interactions of oppositely charged colloids at various conditions. The major advantage of coacervation is the ability to regulate the process conditions to produce nanoparticles of desired sizes. Wang et al. (2008) reported the nanoencapsulation of capsaicin into gelatin-based particles with the size of about 100 nm via simple coacervation. In the work of Xing et al. (2005), complex coacervates between gelatin and gum acacia were used to encapsulate tannins into nanoparticles with spherical morphology and mean diameters of 300–600 nm. The mean drug loading content and encapsulation efficiency of the nanocapsules were 20.8% and 81%, respectively. A good dispersion was observed and the particle distribution and morphology were greatly influenced on addition of hydrolysable tannins because of hydrophobic and hydrogen bonding effects. Gelatin is almost the only protein successfully used in nanoparticle production by coacervation, but the increasing vegetarian and/or vegan population limits its food application. Therefore, there is a need to develop non-gelatin based protein delivery systems when using the coacervation technique.

### Antisolvent Precipitation

Antisolvent precipitation occurs via the addition of a non-solvent to a solution to enhance desolvation and production of the active solute of interest (Joye and McClements, 2013). Thorat and Dalvi (2012) described the general steps in the precipitation of nanoparticles by antisolvent precipitation as: 1) mixing of the solution and antisolvent; 2) generation of supersaturation; 3) formation of nucleation and its growth by coagulation and condensation; and 4) particle agglomeration in the uncontrolled system. The properties of formed nanoparticles such as size, morphology and purity are significantly dependent on the flow rate of the antisolvent, magnitude and uniformity of supersaturation (Thorat and Dalvi, 2012). The precipitation methods involve the use of miscible organic antisolvents, heat treatment and application of shear force and/or lyophilisation (Jarzebski and Malinowski, 1995). Although various antisolvent precipitation methods have been successfully developed for pharmaceutical applications, they are fraught with significant bioprocessing concerns such as exposure to oxygen, high shear force, recovery of solvent for reuse, and high temperatures (Thiering et al., 2000).

As a result, gas antisolvent precipitation, where the fluid near its critical or supercritical conditions is used as the antisolvent, has been developed. The process has a competitive advantage over the traditional methods (Yeo et al., 1993). Using antisolvent precipitation, zein was used as a carrier to prepare lysozyme nanoparticles of sizes around 100 nm, by optimising the zein concentration, solvent type and CO<sub>2</sub> flow rate (Zhong et al., 2008). Interestingly, ultrasonication has been used to enhance mass transfer during protein nanoparticle precipitation (Chattopadhyay and Gupta, 2002). This technique can potentially be used in the development of a delivery system with protein as the shell material. However, zein is one of the few protein candidates currently available for this technique due to its solubility in organic solvents miscible with CO<sub>2</sub> and insolubility in water.

### Electrospraying

Electrospraying is an electro-hydrodynamic atomisation method that allows for easy tailored (in terms of architectural form, morphology and composition) nanoformulations from a broad spectrum of precursors such as biopolymers and cells (Jaworek, 2008; Jayaraman et al., 2015). Using an electrical field, it allows for the breakdown of a conductive liquid jet, flowing through a capillary nozzle, into fine droplets with high monodispersity. Hence, the droplet size formed via electrospraying technique only depends on the solution flow rate and charge acquired due to voltage variation (Dasgupta and Ranjan, 2018). In the study by Torres-Giner et al. (2010), docosahexaenoic acid (DHA) was encapsulated in ultrathin zein-based delivery system of 500 nm particle size, and the nonencapsulated DHA exhibited improved oxidative stability at elevated storage temperature and/or relative humidity. Likewise, López-Rubio and Lagaron (2012) produced glycerol in whey protein isolate-based nanocapsule and found that pH affects the surface tension of whey protein solution and consequently the size of the formed nanocapsule. Surface tension of 47.0, 43.3, 42.1, 43.5 and 45.3 mN/m were calculated at pH 4.5, 5.5, 6.4, 7.3 and 8.0, respectively. Surprisingly, smaller protein capsules were not formed in solution with lower surface tension; instead, larger protein capsules were observed. This is an indication that other parameters, such as conductivity of the solution, may play a major role in size determination. Furthermore,  $\beta$ -carotene was electrosprayed into whey protein capsule and this improved its stability against photo-oxidation (López-Rubio and Lagaron, 2012). This demonstrates the direct shielding/protective effect of the protein shell. Recently, Gomez-Estaca et al. (2012) reported the formation of curcumin-rich zein nanoparticles using electrospraying technique. In addition to zein concentration, optimization of the flow rate and applied voltage resulted in nanoparticles in the size range of 80–130 nm, with encapsulation efficiency of over 85%. Despite the prospects, there are some challenges in using electrospraying technique, including low throughput and product yield typically in the range of milligrams/hour (Jayaraman et al., 2015).

## Electrospinning

Electrospinning works on a similar principle as electrospraying but occurs at a higher voltage leading to the formation of polymer nanofibers (Frenot and Chronakis, 2003). In electrospinning, the main processing factors are voltage, solution flow rate, concentration, molecular weight of the polymer, and nozzle-to-ground distance (Dasgupta and Ranjan, 2018). Several nanofibre systems have been developed for the delivery of bioactive compounds including phytochemicals, probiotics, growth factors and hormones (Dong et al., 2009; Zhang et al., 2006). For instance, nanoencapsulation of  $\beta$ -carotene was achieved in electrospun zein fibres with a mean cross-section of 1140 nm and this resulted in improved oxidative stability of the bioactive compound (Fernandez et al., 2009). Similarly, curcumin-loaded zein nanofibers with an average diameter of 310 nm were developed by electrospinning (Brahatheeswaran et al., 2012). In the study, loaded curcumin was well encapsulated within the nanofibre as no aggregates were found on the surface. Also, an increase in fluorescence was reported after encapsulation and curcumin was found to retain its antioxidant property on release. The thermal stability of zein-curcumin nanofibre increased with an increase in curcumin amount, as pure curcumin has higher thermal stability than zein. Initial burst release followed by sustained release was also observed, which is a characteristic of drug release from a polymer-based matrix. The zein-nanofibre exposed a good surface of attachment that can enable the growth of fibroblast making it a promising candidate for drug/nutraceutical delivery and for soft tissue engineering. However, the major bottleneck in using electrospinning is the difficulty of large-scale production of nanofibers with diameters under 50 nm (Wang et al., 2013).

## Binding, Digestion and Bioaccessibility of Protein-Based Nanodelivery Systems

### Binding and Encapsulation

Various types of protein nanoparticles have been engineered from whey, gelatin, collagen, zein, casein (Gomez-Guillen et al., 2011; Livney, 2015; Penalva et al., 2015; Pérez-Masiá et al., 2015; Raikos and Ranawana, 2017; Shen et al., 2018),  $\beta$ -lactoglobulin, lactoferrin (Chapeau et al., 2016), potato protein (David and Livney, 2016), soy protein (Lee et al., 2016), fish protein (Stephansen et al., 2015), and cruciferin (Akbari et al., 2017; Wang et al., 2018). The proteins can be employed in the food, pharmaceutical and medical industry as delivery vehicle for efficient capping, protection and release of bioactive compounds. Protein has inherent structural and physicochemical properties that enhance binding and hence encapsulation of molecules, ligands and ions. For instance, caseins spontaneously bind with calcium and calcium phosphate nanoparticles through their serine-phosphate residues. Alpha-lactalbumin easily binds calcium while lactoferrin is known to bind ferric ion (Fox and McSweeney, 2003).  $\beta$ -Lactoglobulin can bind epigallocatechin (Livney, 2010), vitamin D (Forrest et al., 2005), omega-3 fatty acid (Zimet and Livney, 2009), retinol (Fox and McSweeney, 2003), and resveratrol (Liang et al., 2008). The binding is usually facilitated by hydrophobic interaction, hydrogen bonding or van der Waals attraction. In a recent study, encapsulation and loading efficiency ranges of 68.1–72.0 and 5.4%–6.2%, respectively with particle sizes of 217–227 nm were reported for acylated rapeseed cruciferin protein loaded with curcumin (Wang et al., 2018). Stability study indicates increase in particle size and decrease in encapsulation efficiency with time due to the diffusion of curcumin out of the nanoparticle matrix. Moreover, casein-folic acid nanoparticles stabilized with cationic lysine and arginine, prepared by coacervation, had 95%–97% yield and 40% encapsulation efficiency, with decreases in particle size, polydispersity index and zeta potential when compared with unstabilized casein nanoparticles (Penalva et al., 2015). Furthermore, the nanoparticles stabilized with lysine and arginine were reported to be stable for at least 48 h and 16 h, respectively. Affinity of bioactive compounds to the proteins is important in achieving high encapsulation efficiency, but this can also influence the release of the compounds *in vivo*. Some examples of various types and properties of protein-based nanodelivery systems are presented in Table 1.

### In Vitro Release Studies

Protein has demonstrated efficient binding of bioactive compounds and there is need to consider the release of various encapsulated nutraceutical into the target regions of the human body. Protein nanoparticles digest rapidly and can permeate the mucus layer and epithelium cells of the intestine (McClements, 2018). The small size of the nanoparticle can increase the bioavailability, chemical stability and absorption of bioactive compounds encapsulated within the matrix. The nanoparticle may release any encapsulated agent more rapidly during digestion in the gastrointestinal tract due to their small size and large surface area. Some studies reported efficient release of bioactive compounds encapsulated in protein nanodelivery systems as a result of inherent structural and physicochemical properties of proteins. For instance, caseins can easily undergo proteolytic cleavage due to their open structures, a result of their high proline content and low contents of  $\alpha$ -helix and  $\beta$ -sheet secondary structures. Moreover, acid-soluble calcium-phosphate bridging in casein can facilitate target-activated release mechanism for offloading encapsulated compounds in the stomach (Fox and McSweeney, 2003). Likewise, bovine serum albumin binds small molecules in the blood and offloads them in their target locations (Li and Yao, 2009). Recently, *in vitro* release of curcumin from acylated rapeseed cruciferin protein nanoparticles was demonstrated in simulated gastric fluid (SGF) and intestinal fluid (SIF) within 6 h of exposure (Wang et al., 2018). Initial burst release of about 70% in the first 2 h and sustained release of about 75% after 2 h was observed in the SIF. In the SGF treatment, only about 10% of curcumin was released in the first 1 h followed by slow and up to 25% release after 6 h. Acidic nature (pH 1.2) of the system compared to the isoelectric point of chitosan (pI 6.5) contributed to the slow curcumin release in the SGF. Burst release of curcumin in the SIF in the first 2 h at pH 6.8 was due to deprotonation of the amine group of chitosan giving rise to a weaker polysaccharide-protein interaction. A pH-dependent release of folic acid encapsulated with casein nanoparticles was demonstrated using a similar digestion model (Penalva et al., 2015). No folic acid was released in the SGF (pH 1.2) with pepsin

action due to strong binding of the vitamin inside the protein network. Burst release was equally observed at 2 h followed by slow and sustained release in the SIF. This is likely because of the electrostatic repulsion between folic acid and casein at neutral pH.

The interactions can also depend on the protein type and complexity of the matrix. For instance, kinetics of *in vitro* release of curcumin from electrospun zein nanofibre into cell culture media showed initial burst release of about 80% between 5 and 20 h, followed by constant release of about 90% for the nanofibre loaded with 10 wt% curcumin (Brahatheeswaran et al., 2012). The initial burst release is as a result of diffusion of curcumin adsorbed at the outer region of electrospun zein nanofiber, whereas the steady release after 20 h was due to slow diffusion of water molecules into the covered nanofiber, which limited the release of capped curcumin. Larger molecules have also been successfully released from protein nanoparticles. Stephansen et al. (2015) demonstrated the control release of insulin encapsulated with electrospun fish sarcoplasmic protein nanoparticles in simulated intestinal fluid. The encapsulating agent shielded insulin from chymotrypsin-catalysed degradation, which is expected to enhance its bioavailable amount. In contrast, whey protein-stabilized astaxanthin was resistant to pepsin, but trypsin digested the complex leading to the release of astaxanthin (Shen et al., 2018). The rate, extent and trigger mechanism of release of protein-encapsulated components depend on protease activity, temperature, pH, dilution, and ionic strength of the gastrointestinal environment. These factors are critical especially when delivering sparingly water-soluble components with the goal of controlling their release within the mouth, stomach, or small intestine (McClements and Rao, 2011).

### Bioaccessibility and Uptake Studies

Protein-based nanomaterials do not only bind, encapsulate and protect bioactive compounds but also control their release, uptake and transport across cells, thereby reducing the risk of toxicity associated with burst release. For instance, acylated cruciferin-chitosan nanoparticles loaded with curcumin had higher permeability coefficient in cultured Caco-2 intestinal cells, and lower effect on cell viability compared to free curcumin (Wang et al., 2018). The latter may be due to the delayed release of curcumin from the curcumin nanoparticles, among other factors. Properties of the nanoparticles, e.g. surface charge, are critical to the bioaccessibility and uptake of protein-based nanoparticles. Akbari et al. (2017) demonstrated that uptake of negatively charged cruciferin/calcium nanoparticles by Caco-2 cells was far higher than that of positively charged cruciferin/chitosan nanoparticles. Uptake and transport of the nanoparticles was not affected by the mucus secreted by a Caco-2/HT29 cells co-culture, which demonstrate that they are potentially biostable. As demonstrated for cruciferin-curcumin (Wang et al., 2018), an increase in cellular uptake of coumarin was recorded for the digested nanoparticles in simulated gastrointestinal fluids, and this was more with cruciferin/chitosan than cruciferin/calcium nanoparticles (Akbari et al., 2017). Likewise, Stephansen et al. (2015) reported the permeability of insulin encapsulated with electrospun fish sarcoplasmic protein nanoparticles across Caco-2 cells. The protein-based delivery agent was also found to be biocompatible, and insulin uptake in Caco-2 cell was pH-dependent. However, overall insulin transport was not affected by its increased release from the protein nanoparticles, and insulin binding and structural properties were not affected after cell permeation. Lastly, capping astaxanthin with whey protein isolate and polymerized whey protein enhanced its apparent permeability coefficient in Caco-2 cells by 10- and 16 folds, respectively (Shen et al., 2018). If translated *in vivo*, this observation can result in the use of lower amounts of bioactive compounds in food products to achieve beneficial health effects in humans.

### Drawbacks of Protein-Based Nanodelivery Systems

Protein-based nanoparticles have demonstrated efficient binding, encapsulation, protection and controlled release of bioactive compounds. However, there are drawbacks associated with the use of proteins in producing nanomaterials. Allergenicity can occur in some individuals due to the ability of some proteins to elicit immune response. Proteins from egg, soybean, fish, cow's milk, etc. can be allergenic (Hefle et al., 1996), and this would impede their use for producing nanodelivery agents. Protein abundance, resistance to digestive enzymes, and processing may also lead to allergenicity (Bannon, 2004). Furthermore, high specific surface area associated with the small size of nanoparticles could lead to adsorption of digestive or metabolic enzymes, which may consequently interfere with their normal gastrointestinal function (McClements and Xiao, 2017). Also, changes in thermodynamic environment after adsorption of some proteins to the nanoparticle surface can cause denaturation thereby affecting the activity of many digestive enzymes. As a result of the small size associated with nanoparticles, rapid digestion and burst release in the intestinal medium may also lead to adverse effects. Currently, there is no standardized analytical technique for assessing the potential toxicity of protein-based nanoparticles and further studies is required in this area.

### Concluding Remarks

Various techniques have been developed to produce food protein-based nanoencapsulation systems for the delivery of nutraceutical compounds. This chapter was focused on the prospects and drawbacks of nanoemulsification, coacervation, antisolvent precipitation, electrospraying and electrospinning techniques in the production of protein-based nanoparticles, as well as the major characteristics of fabricated nanodroplets/nanoparticles. It is worth noting that due to the uniqueness and complexity of proteins, it is difficult to have predetermined set of standard conditions for different protein nanodelivery systems. Hence, the design and processing of the nanoparticles should be on a case-by-case basis. Furthermore, fabrication conditions for laboratory and industrial

scale applications can also vary significantly. Proteins are easily digested in the gastrointestinal tract making them promising candidates for controlled delivery of drugs/nutraceuticals. Some considerations are required to develop protein-based nanodelivery systems that can be commercialised, such as availability of raw materials, biocompatibility, safety, performance of the entrapped bioactive compounds, efficient gastrointestinal release, and stability of the protein nanoparticles when incorporated into food products.

## Glossary

**Phytochemicals** Bioactive components produced by plants through primary or secondary metabolism. When orally consumed in forms of fruits, vegetables, nuts, grains, herb extracts, or dietary supplements, these compounds exert health-promoting effects. And the rate and extent to which they are absorbed and become available to the action site determine their health-promoting efficiency or bioefficacy. Major categories of phytochemicals include carotenoids, flavonoids, indoles, isothiocyanates, phenolic compounds, phytosterols, saponins, vitamins, bioactive peptides, etc.

## Introduction

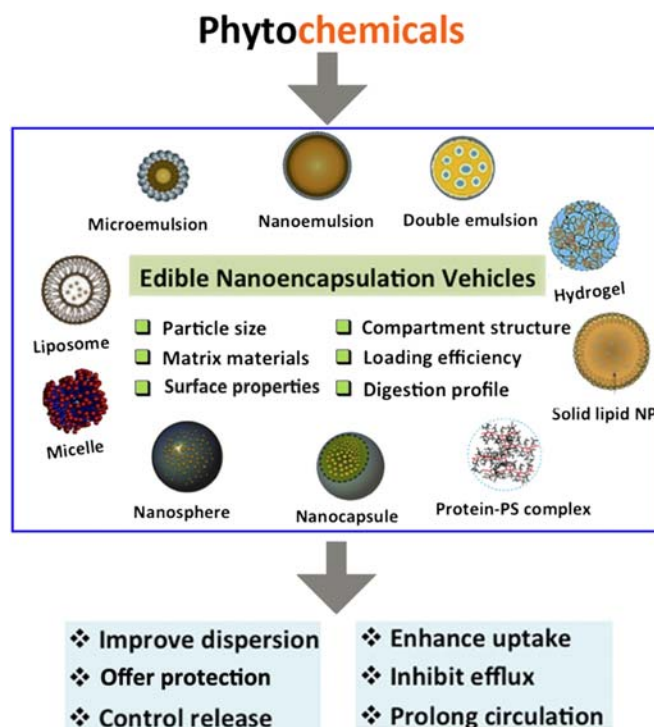

The term “phytochemicals” defined here refers to naturally occurring bioactive compounds found in vegetables, fruits, spices, nuts, grains, and other plants that have health-promoting properties. The major categories of phytochemicals include phenolic acids, carotenoids, flavonoids, isoflavones, indoles, phytosterols, saponins, monoterpenes, bioactive peptides, etc. (Swamy and Sinniah, 2015; Khan et al., 2015; Jiang et al., 2015; Erdem et al., 2015). Although synthesized by plants in low concentrations, a high intake of phytochemicals via frequent consumption of dietary vegetables, fruits, nuts, and herbal extracts usually leads to reduced risk for diseases and enhanced health benefits (Ta and Arnason, 2016; Lu et al., 2016; Chang et al., 2016). The rate and extent to which they are absorbed and become available to the action site determine their health-promoting efficiency or bioefficacy. In reality, the actual quantities of phytochemicals or their metabolites entering the systemic circulation often fall in the micromolar range (which are far less than their initial amounts for oral ingestion), causing their bioefficacy to be limited (Palles et al., 2013). Thus, there is an increasing interest in developing novel encapsulation and delivery strategies for these phytochemicals. Edible delivery vehicles (EDVs), which are constructed using “generally recognized as safe” (GRAS) ingredients (various lipids, polysaccharides, proteins, and synthesized biodegradable polymers featured on the “GRAS” list) with defined shape, size, and compartment structure, are thus proposed as encapsulation and delivery reservoirs for phytochemicals to improve their bioefficacy.

EDVs in forms of biopolymeric nanoparticles, protein–polysaccharides coacervates, emulsions, hydrogels, and inclusion complexes are among the most commonly utilized carriers for phytochemicals. Such EDVs exert effects on (1) the dispersion and gastrointestinal stability; (2) the digestion and release profile; (3) the transportation efficiency across endothelial layer to systemic circulation; (4) the systemic circulation and target distribution; (5) the microflora metabolism process of phytochemicals. Encapsulating phytochemicals within appropriate ENVs would increase their bioefficacy due to one or more of the following effects: (1) protection of sensitive phytochemicals from degradation during storage and gastrointestinal digestion; (2) enhancement in solubility; (3) prolonged contact time with the intestinal wall; (4) enhanced penetrability through mucus and permeability across intestinal walls; (5) improved cellular uptake efficiency; (6) prolonged residence time within the blood; (7) optimized release rate and duration as well as delivery location; (8) optimized interactions with gut microflora.

While the interactions among the building materials of EDVs play key roles in the controlled fabrication of EDVs, the interactions between building blocks and encapsulated phytochemicals determine the loading efficiency, stability, and release profiles of phytochemicals. This article focuses on interactions favoring the establishment of various edible delivery systems and the encapsulation of phytochemicals. Their respective application status as delivery vehicles is also briefly discussed (Fig. 1).

## Biopolymeric Nanoparticles

Biopolymeric nanoparticles are polymer- or lipid-based carriers that have particles sized from 10 to 1000 nm. Compared with inorganic nanoparticles, biopolymeric nanoparticles are biodegradable, less immunogenic, and nontoxic. Building materials include

**Figure 1** Edible encapsulation vehicles for oral delivery of phytochemicals. Copyright © 2017, American Chemical Society. All rights reserved.

naturally occurring proteins, such as albumin, collagen, gelatin, silk sericin or fibroin, zein, and kafirin, or polysaccharides, such as alginate and chitosan. Synthetic biodegradable polymers, including polyalkylcyanoacrylate, poly (lactic-co-glycolic acid), and polyanhydride, are also good candidates for biopolymeric nanoparticles. In addition, lipid-based nanoparticles, referred to as solid lipid nanoparticles, are constructed from physiological lipids and surfactants.

Dominant interactions favoring the biopolymeric nanoparticle formation vary among fabrication methods (Sundar et al., 2010). For instance, alginate nanoparticles can be obtained by producing a water-in-oil reverse microemulsion followed by inducing gelation with calcium ions, where physical cross-linking among polysaccharide chains plays a major role in sustaining the nanoparticle matrix. The use of oppositely charged proteins and polysaccharides to form nanoparticles via a complex coacervation method involves mainly electrostatic interactions. Alcohol-soluble proteins such as zein and kafirin proteins can be fabricated into nanoparticles through an antisolvent precipitation method, where hydrophobic interactions among protein chains dominate the self-assembly process. It is worth to mention that, during the particle formation process, covalently conjugating nanoparticle matrixes with cross-linking reagents (such as glutaraldehyde and formaldehyde) is a commonly utilized technique because it actively manipulates the density, biodegradability, and subsequent release profile of nanoparticles.

Interactions between surface materials of nanoparticles and specific surface coating materials occurring during the surface modification process endow biopolymeric nanoparticles with versatile functionalities. Take the layer-by-layer assembly process for an example, a typical assembly cycle involved the dispersion of nanoparticles into a coating material solution with opposite charge, electrostatic attractive interactions occurring at the interface lead to one deposit layer onto the surface. And subsequent coating is carried on by initiating another cycle of electrostatic attractive interactions between the deposited membrane and the other oppositely charged coating material. Repeating a number of the coating cycles leads to nanoparticles with desired coating thickness and surface chemistry. In this scenario, positively charged chitosan and poly-L-lysine are two of the most commonly utilized external surface coating candidates for nanoparticles because they endow nanoparticles with positive charge that promotes nonspecific binding between nanoparticles and the epithelium, thus enhancing the absorption through the tight junction. Apart from the non-covalent weak interaction, covalent bonding happened between the surface material and address tags such as monoclonal antibodies or peptides, yielding nanoparticles with target delivery feature.

Biopolymeric nanoparticles have long been utilized as efficient delivery vehicles for sustained, controlled, and target release of phytochemicals. Nanoparticles can be structured as nanospheres or nanocapsules (Roger et al., 2011), and phytochemicals are generally loaded through physical interactions within the particle matrix. In the former case, phytochemicals can be entrapped or adsorbed to the particle matrix and distribute evenly within the nanosphere. In the latter case, phytochemicals are physically encapsulated within the aqueous or lipid core. With regard to the release mechanisms, phytochemicals may diffuse out due to

the hydration of nanoparticles, that is, once the nanoparticles are swollen to a point where they stretch, phytochemicals diffuse out from the polymeric matrix. Also, nanoparticles may release phytochemicals via an erosion-dominant diffusion process as the particle matrixes degraded due to the enzymatic degradation during oral digestion process. Usually, nanoparticulate encapsulation is particularly suitable for phytochemicals that suffer to premature degradation or have poor solubility in the human gastrointestinal tract such as curcumin, quercetin, epigallocatechin gallate, and resveratrol, due to their high surface to volume characteristics. By manipulating the particle formation process and/or incorporating target ligands on the surface of the as-prepared biopolymeric nanoparticles, nanoparticles can perform sustained release manner and/or targeted delivery of phytochemicals, all add to the charm of nanoparticulate encapsulation of phytochemicals.

### Protein–Polysaccharide Coacervates

“Complex coacervation” commonly refers to the formation of a dense macroion-rich phase caused mainly by an electrostatically driven liquid–liquid phase separation process. Among the polyanion–polycation interactions that lead to the formation of complex coacervations, electrostatic interactions between oppositely charged residues of proteins and polysaccharides are studied most extensively (Corredig et al., 2011). The size of protein–polysaccharide coacervates may range from 0.1 to 100  $\mu\text{m}$  with their soluble precursors less than 200 nm in diameter. To form the soluble complexes, specific pH values are adjusted so that the electrostatic repulsion forces are minimized and associated interactions between charged patches of molecules are favored. During the complex formation process, hydrogen bonding and hydrophobic interactions also play a role in stabilizing the coacervates. The shift balance of the abovementioned three forces determines the final conformation of protein–polysaccharide coacervates (Turgeon et al., 2007). And the chemical nature of biopolymers (such as molecular weight, charge, distribution of charges), the mole ratio between polymers and their respective concentration, as well as environmental conditions, all exert effects on the force balance.

Because the structure of protein–polysaccharides coacervates is sensitive to environmental changes, especially the pH value and ionic strength, complex coacervates have been utilized as stimuli responsive delivery vehicles for phytochemicals. For application scenarios where sustained release is preferred, stronger coacervates are achieved by initiating cross-linking reactions among coacervate components (Chen et al., 2012). Another application of protein–polysaccharide coacervates lies in their ability in serving as emulsion stabilizer (Li and McClements, 2011). Herein, the emulsion interface can either be stabilized through emulsifying the oil phase with aqueous complex coacervates or via emulsification of the oil phase with the aqueous dispersion of one biopolymer followed by adsorption of the second biopolymer to induce the formation of interfacial complex coacervates (Raikos, 2010). In such cases, complex coacervates do not encapsulate phytochemicals directly (phytochemicals are encapsulated within the dispersed phase instead) but contribute to the smart delivery of phytochemicals by tuning the interfacial stability of emulsions triggered by environmental stimuli.

### Emulsions

Emulsion is a mixture of two or more liquids (usually oil and water) that are initially immiscible such as oil-in-water, water-in-oil, and derived multiple emulsions. Under mechanical turbulence and with the aid of surface-active compounds, one liquid (the dispersed phase) is dispersed into the other (the continuous phase). Interactions between emulsifiers and the water–oil interface play critical roles in the formation and stability of emulsions.

Emulsifiers can be classified according to their relative molecular weight into three categories: small molecular weight surfactants, surface-active macromolecules, and colloidal particles. Small molecular weight surfactants, for instance, lecithin, monoglycerides, and diglycerides, stabilize emulsion interface via migrating onto the interface and reducing interfacial tension between two phases. Because small molecular weight surfactants contain both hydrophobic tails and hydrophilic heads, their interactions with the interface are thermodynamically favored: the water-insoluble hydrophobic tails extend into the oil phase, whereas the water-soluble head groups remain in the water phase. On the contrary, interactions among surfactant molecules happen at places other than interface, for example, interactions among excessive surfactants in the bulk aqueous phase, result in formation of micelles and destabilization of emulsion.

Surface-active macromolecules, usually proteins and polysaccharides, stabilize emulsion droplets by creating a viscoelastic film over the dispersed phase, which prevent droplets from coalescence or flocculation via steric hindrance and repulsive electrostatic interactions. Interactions between proteins and the interface is also thermodynamically favorable because the hydrophobic residues of protein backbone orient toward the oil phase, following protein structural rearrangement at the interface (Chen and Dickinson, 1995). Key parameters determining the interaction strength between a protein and the oil–water interface lie in molecular flexibility and surface hydrophobicity (Dickinson, 2010). Again, the interactions between interfacial proteins and components in the aqueous phase can destabilize the emulsion. For instance, increase in ionic strength in aqueous phase exerts masking effect on the charged, adsorbed proteins and thus destabilize emulsion droplets through flocculation (Chen and Dickinson, 1995).

Colloidal particles, usually in the size of 100–2000 nm, can also stabilize emulsions (referred as Pickering emulsions). To stabilize Pickering emulsions, colloidal particles should remain stable in both oil and water phases while having a proper partial

**Figure 2** Emulsion droplets stabilized by colloidal particles via limited coalescence process. Phytochemicals can be loaded either within the colloidal particles or within the internal oil phase.

wettability (Xiao et al., 2016). Due to their large particle size, once migrating onto the emulsion interface, the energy required for detaching colloidal particles from emulsion interface will be several orders of magnitude higher than the kinetic energy for their Brownian motion, thus the attachment of colloidal particles at emulsion interface is regarded as an irreversible process. This is essentially different from the dynamic equilibrium process in cases of small molecular weight surfactant-stabilized and surface active macromolecule-stabilized emulsions. After absorbed onto the interface, colloidal particles stabilize emulsion interface by the physical barrier effect via a “limited coalescence” process (Fig. 2): During emulsification process, a large excess of oil–water interface (compared with the amount that can be covered by the presence of colloidal particles) is produced. As the agitation process is stopped, the partially protected droplets start to coalesce to reduce the surface area of oil–water interface until the interface is sufficiently covered by a rigid layer of colloidal particles. In this way, the colloidal particle layer prevents adjacent emulsion droplets from coalescence.

After the formation of emulsions, their stability and rheological properties are correlated largely to interactions between emulsion droplets, either via repulsive or attractive forces, which in turn depend on the structure and composition of the interfacial layer of emulsion. Emulsions (100 nm–100  $\mu$ m), nanoemulsions (10 nm–100 nm), and microemulsions (2–10 nm), especially in the oil-in-water type of structure, are widely used for the encapsulation and delivery of lipophilic phytochemicals. In case of a Pickering emulsion, phytochemicals can be encapsulated within the internal oil droplets, and the colloidal particle layer also serves as an encapsulation reservoir if phytochemicals are loaded within colloidal particles prior to emulsification. For instance, curcumin was encapsulated within the zein–chitosan particle layer prior to emulsification to achieve an antioxidant Pickering emulsion (Wang et al., 2015). A striking benefit of using emulsions to deliver lipophilic phytochemicals is that when orally digested, lipophilic phytochemicals migrate into micelles formed by free fatty acids after the digestion of the lipid phase, which facilitates the dispersion and subsequent cellular transportation process (Xiao et al., 2015). When fabricated as water-in-oil-in-water emulsions, they can be utilized as a protective carrier of sensitive hydrophilic phytochemicals, dual-delivery vehicle for both oil-soluble and water-soluble phytochemicals (Xiao et al., 2017a; Kaimainen et al., 2015).

## Hydrogels

Hydrogel, a coherent three-dimensional network of at least two components, behaves mechanically like a solid and is capable of retaining a significant amount of water within its structure. Popular building materials for food application-oriented hydrogels include collagen, gelatin, whey protein isolates, starch, alginate, caseinate, pectin, etc. While the water holding property arises from hydrophilic functional groups of the hydrogel matrix, their resistance to dissolution arises from cross-linked polymeric network. The cross-linked junctions can be either permanent or transient depending on their physical or chemical nature. In the former case, hydrogels with tailored properties such as biodegradability desired mechanical strength and response to stimuli can be synthesized through polymerization via interactions between hydrophilic monomers and cross-linkers. In the latter case, cross-linked junctions can arise from polymer chain entanglements; crystallite formation; or chemical and physical interactions such as ionic interactions, hydrogen bonding, or hydrophobic interactions. Particularly, protein-based hydrogels can be formed via a heat- or cold-induced gelation process. Electrostatic interactions, hydrophobic interactions, and disulfide bonding contribute differently in respective aggregation and gelation processes during heat-induced gelation (Alting et al., 2002). Cold-induced gelation takes place via two consecutive steps: protein aggregates are first formed by heating a protein solution and then gelation is induced via the addition of calcium or by lowering the pH.

Hydrogels are usually sensitive to environmental conditions particularly temperature, pH, ionic strength, pressure, and solvent composition. Thus particular advantages of encapsulating phytochemicals within a hydrogel matrix involve the protection effects during storage and the controlled release profiles in response to specific environmental triggers. When encapsulating phytochemicals within a hydrogel matrix, hydrophilic phytochemicals are mixed directly with the polymer solution prior to hydrogel formation and hydrophobic phytochemicals are typically incorporated into emulsified lipid droplets prior to the hydrogel formation.

Hydrogen bonding and steric hindrance effect between phytochemicals and the polymer skeleton of hydrogel contribute to the holding effect. Thus, the release of phytochemicals occurs through mechanisms such as a simple diffusion process, swelling and diffusion process, disintegration and diffusion process, with the chemical nature of phytochemicals (polar or nonpolar), polymer concentration, and gel viscosity affecting the rate of diffusion (Eros et al., 2003). Recent research practices in which beta-carotene and curcumin-enriched lipid droplets were entrapped within hydrogel matrixes have proven the protective effect and controlled release function of the systems (Xiao et al., 2017b; Zhang et al., 2016). In application scenarios where a slow release kinetic is demanded, a chemical cross-linking process following the regular gelation process can be carried out to increase the polymer junction and shrink the pores.

## Inclusion Complexes

Inclusion complexation refers to the entrapment of smaller molecules inside the hollow cavity of a larger molecule. Cyclodextrins (CDs) are the most commonly utilized components for the formation of such cavities. Naturally occurring CDs are a group of cyclic oligosaccharides derived from starch with six ( $\alpha$ -CD), seven ( $\beta$ -CD), eight (commonly  $\gamma$ -CD), ten ( $\epsilon$ -CD), or more glucose residues linked by  $\alpha$ -(1–4) glycosidic bonds in a cylinder-shaped structure (Karoyo and Wilson, 2015). Its central cavity is made hydrophobic by the glycosidic oxygen, while the hydroxyl groups located on the external edges making its outer surfaces hydrophilic. Various methods had been developed for the fabrication of inclusion complexes including kneading, solid dispersion, spray/freezing drying, and coevaporation (Pereva et al., 2016).

A whole range of interactions, including the van der Waals interactions, entropy-driven hydrophobic interactions, hydrogen bonding and electrostatic interactions, have been identified and are vital to sustaining the CDs derived inclusion complexes (Joshi et al., 2016). The same interactions exist between the inclusion complex and guest phytochemicals. The encapsulation efficiency is a combined result of the hydrophobicity of phytochemicals and relative size of the inclusion complex and the guest phytochemicals. After oral digestion, phytochemicals are usually released from the matrix through a Fickian or non-Fickian diffusion process. Benefits of encapsulating phytochemicals within an inclusion complex include improved water solubility, enhanced stability, decreased decomposition rate in GI tract, shortened time lag to reach plasmatic peak, etc. (Singireddy and Subramanian, 2016). Bioavailability enhancement of hydrophobic phytochemicals, such as curcumin, quercetin, myricetin, and capsaicin, has been found when the phytochemicals were encapsulated within an inclusion complex (Marques, 2010; Miskolczy et al., 2016; Mangolim et al., 2014).

## Conclusion

Understanding the dominant interactions among building blocks of EDVs and phytochemicals occurring during the encapsulation and release processes will guide the rational design of EDVs with controlled sizes, surface properties, matrix effects, and compartment structures. EDVs with different structural characteristics, such as polymeric nanoparticles (nanospheres and nanocapsules), protein–polysaccharide complex coacervates, emulsions, CD inclusion complexes, and polymeric hydrogels, can thus be designed to encapsulate various phytochemicals with different loading processes, encapsulation efficiency, release profile after oral ingestion, and application potentials.

## Introduction

The use of bioactive compounds in foods has been gaining increasing interest over the last years due to the fact that these ingredients can provide health benefits to consumers, beyond nutrition. This category includes vitamins, polyphenols, probiotics, peptides, essential fatty acids, and minerals, among others. However, preserving the health-promoting properties of bioactive compounds along the food supply chain, and also during the transport in the gastrointestinal tract, is still challenging.

Encapsulation technologies constitute an actual path to protect bioactive compounds from adverse environmental conditions (e.g., light, moisture, and oxygen) through the entrapment of core materials within a wall polymer (e.g., polysaccharides and protein-based materials). This strategy allows the improvement of the stability of bioactive compounds, the delivery of compounds at a controlled rate, masking of unwanted odor or taste, and/or improvement of the properties of raw materials (solubility and dispersibility, among others) for easier handling. Different methods have been used to encapsulate bioactive compounds including spray drying, emulsification, coacervation, liposome entrapment, inclusion complexation, nanoprecipitation, and freeze drying, among others (de Vos et al., 2010). However, some of these techniques involve harsh processing conditions (e.g., high temperature and solvents use), which can significantly reduce the functionality of the bioactive compounds (Ghorani and Tucker, 2015). In this context, electrospinning and electrospraying technologies are becoming simple and attractive alternatives to encapsulate sensitive bioactive food ingredients. Nevertheless, the application of electrospinning and electrospraying technologies in the field of food processing engineering remains less explored.

## Principles of Electrospinning and Electrospraying Technologies

Electrospinning and electrospraying are one-step technologies that utilize high electrostatic potentials to draw polymer solutions (or polymer melt) into fibers or particles, respectively. The typical setup for electrospinning and electrospraying is mainly constituted by four components: (1) a high-voltage source (1–50 kV) usually operated in direct current mode (although alternating current mode is also possible), (2) a syringe pump, (3) a spinneret (typically a hypodermic syringe needle), and (4) a grounded collector either a flat plate or a rotating drum (Fig. 1; Bhushani and Anandharamakrishnan, 2014).

In both electrospinning and electrospraying, polymer solutions (or polymer melt) are pumped at a fixed solution flow rate to a capillary spinneret, forming a droplet in the needle tip. When the electrical voltage is applied to the spinneret, the droplet becomes charged and experiences an electrostatic repulsion, forming into a conical geometry known as a 'Taylor cone.' Once the electrical voltage exceeds a critical value at which the repulsion forces overcome the surface tension of the droplet from the tip of the Taylor cone, electrospun fibers are formed if the solution concentration or the molecular chain entanglement in the liquid is high, and the polymer ejects from the Taylor cone and travels toward the collector as a stable jet. On the other hand, if the solution concentration is low, aerosol droplets are produced due to the liquid jet breakup. These highly charged droplets are deposited on the collector as

**Figure 1** Schematic representation of the electrospinning process.

<sup>☆</sup> *Change History:* This is an update of Alex López-Córdoba, Jose Maria Lagarón and Silvia Goyanes, Fabrication of Electrospun and Electrosprayed Carriers for the Delivery of Bioactive Food Ingredients, In Reference Module in Food Science, Elsevier, 2016, ISBN 9780081005965. March 2018 Alex López-Córdoba, Jose Maria Lagarón and Silvia Goyanes updated the text, figures and references.

micro- or nanoparticles. One important advantage of electrospinning and electrospraying is that the evaporation of the solvent occurs during the process and no heating is needed, which makes these technologies suitable for dealing with thermally sensitive materials (e.g., probiotic bacteria).

The most relevant factors that affect the fabrication of electrospun fibers or electrosprayed particles are the solution properties (e.g., conductivity, viscosity, and surface tension), the instrumental parameters (e.g., applied electrical field, solution flow rate, and the distance between the tip of the needle and the collector), and the ambient conditions (e.g., temperature and humidity). By changing these parameters, the size and the morphology of the encapsulation structures obtained can be tailored for specific applications (Fig. 2).

### Food-Grade Materials for Electrospinning and Electrospraying

Polymers from natural sources are the preferred materials for the encapsulation of bioactive food ingredients by electrospinning and electrospraying because these have the advantages of being nontoxic, edible, and biocompatible. Moreover, many of them can be dissolved using GRAS (generally regarded as safe) substances (e.g., water or ethanol), avoiding the use of toxic solvents. Proteins (e.g., whey protein isolate, whey protein concentrate, soy protein isolate, egg albumen, collagen, gelatin, zein, and casein) and polysaccharides (e.g., chitosan, alginates, cellulose and its derivatives, and dextran) have been the wall materials most frequently used for encapsulation of bioactive ingredients by electrospinning and electrospraying.

Pérez-Masiá et al. (2014) studied the ability to form fibers or particles from aqueous solutions of selected hydrocolloids such as dextran (molecular weight (Mw)  $\sim 70\,000$ ), maltodextrin (Mw  $\sim 1300$ ), resistant starch (Mw  $\sim 1700$ – $2700$ ), pullulan (Mw  $\sim 100\,000$ ), fructooligosaccharides (Mw  $\sim 330$ – $8100$ ), whey protein concentrate from milk (Mw  $\sim 20\,000$ – $70\,000$ ), and a soy protein isolate (Mw  $\sim 30\,000$ – $350\,000$ ). Only dextran, pullulan, and whey protein were able to form capsules (sizes about  $1\,\mu\text{m}$ ). This fact was attributed to their higher molecular weight, which led to a significant viscosity increase when increasing the hydrocolloid concentration in the dispersion. As an exception, the soy protein, despite its high molecular weight (Mw  $\sim 30$

**Figure 2** Examples of different morphologies obtained by electrospinning/electrospraying.

**Figure 3** SEM image of capsules obtained from 10% (w/v) soy protein solutions after denaturation. From Pérez-Masiá, R., Lagaron, J., López-Rubio, A., 2014. Development and optimization of novel encapsulation structures of interest in functional foods through electrospraying. *Food Bioprocess Technol.* 7(11), 3236–3245, reprinted with permission.

000–350 000), did not lead to the capsule formation, probably due to the presence of strong inter- and intramolecular forces, which impeded chain entanglements in its globular structure. In this case, the electrosprayability of the solutions was improved by the denaturation of the protein through a thermal treatment (Fig. 3). It was stated that denaturation leads to protein unfolding and exposure of the functional groups, which could improve intermolecular interactions, both between the different protein chains and with the solvent, resulting in increased viscosity (Pérez-Masiá et al., 2014). On the other hand, the effect of the addition of gums (guar gum or xanthan gum) and/or surfactant (Span 20) was also analyzed as a strategy to improve the electrosprayability of the hydrocolloids (Pérez-Masiá et al., 2014). This approach led to important changes in the solution properties (conductivity, viscosity, and surface tension) allowing to obtain capsules from all wall materials.

In several studies, the use of synthetic polymers, such as polyvinyl alcohol (PVOH) and polyethylene oxide, as spinning aids has been also reported (Sousa et al., 2015; Wongsasulak et al., 2014).

Compatibility between active compounds and polymer carriers is a key factor to consider when choosing materials for encapsulation by electrospinning or electrospraying. Active compound loading capacity is determined mainly by several driving forces such as hydrophobic interaction, electrostatic interaction, hydrogen bonding,  $\pi$ - $\pi$  stacking and van der Waals force (Li and Yang, 2015). Other factors affecting active compound loading capacity are loading space, preparation methods, crystallinity and glass transition temperature (T<sub>g</sub>) of carrier materials (Li and Yang, 2015).

Variations in composition or chemical modifications such as cross-linking or the addition of functional groups into loading sites have been used as strategies in order to generate specific attractive or repulsive active compound-carrier interactions, thus controlling the retention and release of bioactive compounds (Deng et al., 2017; McClements, 2018). If there is a strong attraction between the bioactive compounds and polymers, then the bioactive will tend to be retained inside the carrier, but if there is no attraction or a repulsion then the bioactive compounds will tend to be released (McClements, 2018). Also, the sign or magnitude of the interactions between bioactive ingredient and carrier materials can be altered by changing environmental conditions (such as pH, ionic strength or temperature), which can be used to develop triggered release mechanisms (McClements, 2018).

## Encapsulation of Functional Food Ingredients by Electrospinning and Electrospraying Technologies

Different strategies are available for encapsulation purposes using electrospinning and electrospraying. The direct dissolution of the active components in the polymeric carrier is the most common encapsulation approach. Using this path, the bioactive component is randomly distributed throughout the fibers or the particles. Another strategy is the fabrication of core-sheath structures using a couple of capillary tubes where a smaller one (inner) is inserted concentrically inside the bigger (outer) capillary (Fig. 4). The active component is fed through the inner capillary spinneret, while the polymer solution is extruded through the outer capillary spinneret simultaneously in order to acquire core-sheath structures (Yao et al., 2016). This approach is highly versatile because the core fluid does not need to be electrospinnable.

Core-sheath structures can also be fabricated by emulsion electrospinning using a single feeding capillary. In this approach, the immiscible solutions are mixed into an emulsion and then electrospun or electrosprayed. In order to avoid phase separation, vigorous mixing of the polymer and core materials and the incorporation of an emulsifying agent are almost always necessary. This technique shows high encapsulation efficiency of immiscible drugs as well as their sustained release. Some examples of recent studies using electrospinning or electrospraying to encapsulate bioactive compounds of interest in the food area are out-lined below.

Antioxidants are considered attractive ingredients to encapsulate because these compounds are frequently used in the food industry in order to prevent the spoilage of oxidation-sensitive foods (e.g., baked goods, biscuits, mayonnaise, meat products,

**Figure 4** Schematic representation of coaxial electrospinning device setup.

nuts, oils, and fats). The use of antioxidants from natural sources is preferred due to the association of synthetic additives with the generation of adverse health effects. Several studies have been carried out dealing with the fabrication of electrospun fibers and electrospayed particles containing natural antioxidants. For instance, the entrapment of gallic acid within zein electrospun fibers was first reported by [Neo et al. \(2013\)](#). In this work, electrospinning proved to be an efficient tool for one-step preparation of gallic acid-loaded zein electrospun fibers, yielding a loading efficiency of almost 100%. The active fibers were examined using Attenuated total reflectance-Fourier transform infrared (ATR-FTIR) spectroscopy method, finding interactions between gallic acid and zein at the molecular level which promoted the compatibility between the active compound and the polymer carrier. Despite such interaction, gallic acid has retained its antioxidant activity.

Curcumin, besides being a commonly used natural food dye, exhibits numerous biological activities, including antioxidant, anti-inflammatory, antiviral, antibacterial, and antifungal properties. However, the use of curcumin in foods is limited due to its low water solubility and photostability. Recently, [Gómez-Estaca et al. \(2015\)](#) reported the fabrication of electrospayed gelatin microspheres containing curcumin. The encapsulation process allows increasing the antioxidant activity, the water solubility, and the bioavailability of curcumin. Moreover, encapsulated curcumin was better dispersed into a jellified fish product than commercial curcumin (i.e., a nonencapsulated ingredient) ([Fig. 5](#)). Recently, [Deng et al.](#) evaluated the effect of different surfactants (non-ionic Tween 80, anionic sodium dodecyl sulfonate (SDS) and cationic cetyltrimethyl ammonium bromide (CTAB)) on the release behavior of curcumin from gelatin electrospun nanofibers ([Deng et al., 2017](#)). Tween 80 and CTAB greatly improve the release of curcumin into polar solvents, resulting in a higher radical scavenging activity and a stronger antimicrobial activity, while the addition of SDS provoked chemical interactions which do not favor the release of curcumin. Fourier transform infrared spectroscopy and differential scanning calorimetry analysis suggested that gelatin and SDS intimately interacted via electrostatic and hydrophobic interactions.

$\alpha$ -tocopherol is a form of vitamin E that is well known for its ability to act as a hydroperoxyl radical scavenger, therefore playing an important role in protecting the organism against oxidative damage. [Wongsasulak et al. \(2014\)](#) reported the fabrication of

**Figure 5** Photographic images of control fish gel (A), fish gel supplemented with commercial curcumin (B), and fish gel supplemented with 10% curcumin-loaded gelatin microparticles obtained by electrospaying (C). Curcumin content for B and C gels was 0.05 g/100 g of fish mince. From [Gómez-Estaca, J., Gavara, R., Hernández-Muñoz, P., 2015. Encapsulation of curcumin in electrospayed gelatin microspheres enhances its bio-accessibility and widens its uses in food applications. \*Innov. Food Sci. Emerg. Technol.\* 29, 302–307, reprinted with permission.](#)

composite electrospun fibers based on zein/poly(- ethylene oxide)/chitosan blends embedding  $\alpha$ -tocopherol (a hydrophobic bioactive compound). A non-polar surfactant, Tween 40, was added to facilitate manipulation of the composite and the gastro-mucoadhesivity was tested using porcine gastric mucosa. The presence of  $\alpha$ -tocopherol significantly enhanced the mucoadhesivity of the nanofibers, thereby aiding in improved bioaccessibility and bioavailability. Mucoadhesion is considered a highly effective delivery method to conserve the functional properties of a bioactive compound delivered to the gastrointestinal tract. In this process, the attachment first arises from molecular chain diffusion/interpenetration between the polymeric molecules of the mucoadhesive material and mucin glycoprotein (solid main component of the mucosa), followed by molecular bonding (e.g., ionic interaction, covalent bonds, hydrogen bonding, dipole-dipole interactions, as well as hydrophobic interaction) between the mucoadhesive material and the mucin glycoprotein (Wongsasulak et al., 2014).

Lycopene, a naturally occurring red carotenoid pigment found in tomatoes and other fruits, is another antioxidant which is well-known because of its potential to reduce the risk of chronic diseases such as cancer and coronary heart disease. However, lycopene presents several unsaturated bonds in its molecular structure, which makes it very susceptible to oxidants, light and heat. Moreover, it has a very low water solubility, which limits its industrial applicability in aqueous-based systems. Pérez-Masiá et al., 2015 addressed these limitations through the encapsulation of lycopene by electrospaying assaying dextran, a whey protein concentrate (WPC), and chitosan as wall materials (Pérez-Masiá et al., 2015). Since lycopene is a poorly water-soluble compound and WPC and dextran are water dispersible polymers, emulsion and coaxial electrospaying were used in these cases. For chitosan, an acetic acid solution was used, where lycopene could be easily dissolved and, thus, uniaxial electrospaying was carried out. The antioxidant-containing electrospayed capsules were compared with those obtained through the traditional spray drying process. In overall, electrospaying process allow to obtain higher encapsulation efficiencies than the spray drying method, mainly when emulsion electrospaying was carried out and WPC was used as wall material (encapsulation efficiency  $\sim 75\%$ ). This behavior was attributed to the high temperature involved in the spray drying process which led to a partial degradation of the antioxidant. When chitosan was used as a matrix to encapsulate lycopene through both techniques (electrospaying and spray drying), the acid conditions needed in this case in order to dissolve the polymer affected lycopene stability and very poor encapsulation efficiencies were found ( $\sim 2\%$ ).

Acetuno-Medina et al. (2015b) studied the encapsulation of two bioactive compounds, quercetin and ferulic acid, within amaranth protein isolate/pullulan electrospun fibers. In general, quercetin was released in a most sustained manner during in vitro digestion than ferulic acid. At the end of the in-vitro intestinal digestion stage, the amount of quercetin and ferulic acid released corresponded to 82% and 99%, respectively. This behavior was attributed to the composition of the polymeric matrix (i.e., the ratio between amaranth protein isolate and pullulan) and to the interactions of the bioactives themselves with the encapsulating matrices.

**Figure 6** Chemical structures of cyclodextrins ( $\alpha$ -CD,  $\beta$ -CD and  $\gamma$ -CD) and schematic representation of formation of inclusion complexes (B). Adapted from Kayaci, F., Ertas, Y., Uyar, T., 2013. Enhanced Thermal Stability of Eugenol by Cyclodextrin Inclusion Complex Encapsulated in Electrospun Polymeric Nanofibers. J. Agric. Food Chem. 61(34), 8156–8165, reprinted with permission.

Folic acid is a water-soluble vitamin that is vital for a variety of physiological functions in humans. However, this bioactive compound undergoes degradation reactions when it is exposed to light, temperature, moisture, acid or alkaline medium, and oxygen atmosphere. In order to overcome these disadvantages, the entrapment of folic acid into electrospun nanofibers and electro-sprayed particles has been suggested as viable alternative. Aceituno-Medina et al. (2015a) reported the fabrication of folic acid-loaded protein isolate/pullulan electrospun fibers with high encapsulation efficiency (>95%). The encapsulation strategy led to enhanced thermal stability and photostability of folic acid. In another study, the encapsulation of folic acid in both a whey protein concentrate matrix and a commercial resistant starch was also carried out by electro-spraying, finding that the folic acid stability was also improved (Perez-Masia et al., 2015).

Probiotics are widely used bioactive food ingredients due to their health-related benefits. However, the survival of probiotic bacteria into food formulations can be affected by several factors (e.g., pH and temperature). López-Rubio et al. (2012) studied the feasibility of using the electro-spraying technique to encapsulate bifidobacterium strains in whey protein concentrate and pullulan.

Whey protein concentrate provided higher protection for the probiotic bacteria than pullulan, extending the survival of the cells even at high relative humidity.

The formation of inclusion complexes of cyclodextrins with bioactive compounds has been proposed as a strategy to enable the encapsulation of bioactive compounds within electrospun or electro-sprayed nanostructures. Cyclodextrins ( $\alpha$ -CD,  $\beta$ -CD, and  $\gamma$ -CD) possess hydrophobic cavities of different sizes, which render them capable of forming inclusion complexes with a range of hydrophobic compounds (Fig. 6). This means that cyclodextrins can be used as formulation aids to increase the aqueous solubility and enhance the stability of guest molecules. For example, Kayaci et al. (2013) reported the fabrication of PVA nanofibers containing inclusion complexes of cyclodextrins ( $\alpha$ -CD,  $\beta$ -CD, and  $\gamma$ -CD) with geraniol (a natural component of plant essential oils that presents several bioactive properties such as antioxidant, anti-inflammatory, and anticancer properties). Higher complexation efficiency was obtained when  $\gamma$ -CD was used, and, therefore, these complexes were chosen to be incorporated within PVOH nanofibers by electrospinning. This strategy allows obtaining a higher thermal stability and a prolonged durability of geraniol.

## Conclusions

Electrospinning and electro-spraying technologies have proven to be an excellent method for the encapsulation of bioactive food ingredients. These processes have the advantages of being simple and easily adaptable. Moreover, through the control of the solution properties and the optimization of the processing variables, a huge variety of micro- or nanocarriers with unique properties may be engineered. The large-scale production and successful commercialization of electrospun fibers or electro-spraying particles are still in their infancy, despite that industrial equipment of electrospinning and electro-spraying is available. Therefore, close linkages between the scientific community and the industrial sector are highly necessary in order to identify and commercialize more application for these technologies in micro- and nanoencapsulation of bioactive food ingredients.

## EDITOR BIOGRAPHIES

---

### EDITORS IN CHIEF

**Laurence Melton**

Professor Laurence Melton was the Inaugural Professor of Food Chemistry at the University of Auckland, New Zealand, where he set up degrees in Food Science and Wine Science. He has been a Principal Investigator for the Riddet Centre of Research Excellence for Food Research. Formerly he was Professor of Food Science at the University of Otago, at Dunedin, N.Z. and earlier a scientist at Unilever's Colworth House in Bedfordshire, UK. His major research interest is how food macromolecules interact to give foods their structure (e.g. the complex mixture of polysaccharides that comprise plant cell walls (dietary fibres) and the interaction of proteins and polysaccharides such  $\beta$ -lactoglobulin and pectins). He has published over 300 scientific papers and reports. Currently he is an Editor for Food Chemistry and Emeritus Professor at the University of Auckland. He wrote "As a teenager I was training to be an electrician but I thought it would be more exciting to be a chemist because there could be fires and explosions. And there were some. However, what kept me motivated over 50 years was the excitement of discovering stuff by doing research."

**Fereidoon Shahidi**

Professor Fereidoon Shahidi is a University Research Professor at the Memorial University of Newfoundland, Canada. He is highly respected for his research in such areas as marine products and functional foods.

**Peter Varelis**

Dr Peter Varelis is an applications chemist with Shimadzu Scientific Australia where he manages a team of chemists. Prior to joining Shimadzu he was a principal scientist and team leader at Food Standards Australia New Zealand. He trained as an organic chemist and has more than 20 years of research experience in both government and industry. His research interest is the application of mass spectrometry to the analysis of organic compounds that have implications for human health and nutrition. Peter obtained his PhD from the University of Western Australia. He was research professor at the Illinois Institute of Technology and principal research scientist with the Commonwealth Scientific and Industrial Research Organization in Australia. From 2007 through to 2011, Peter was a theme leader with the National Centre for Food Protection and Defense.

## SECTION EDITORS

**Rotimi Aluko**

Dr Rotimi Aluko, a Certified Food Scientist is a Professor in the Department of Food and Human Nutritional Sciences at the University of Manitoba, Winnipeg, Canada. He also serves as the Assistant Director of the Richardson Centre for Functional Foods and Nutraceuticals, Winnipeg. He obtained a PhD (Food Science) degree in 1996 from the University of Guelph, Ontario, Canada. His work focuses on the structure-function properties of bioactive proteins and peptides with special focus on oilseeds and pulses. In addition to over 170 journal article publications, Dr Aluko holds two patents on the antihypertensive properties of plant seed protein-derived peptides. Dr Aluko has trained over 70 people in various areas of food chemistry and human nutrition. He is a 2017 “Highly Cited Researcher” in the Agricultural Sciences category, which is recognition given to researchers with peer-reviewed journal citations in the top 1% in the world. Dr Aluko is a Fellow of the Canadian Institute of Food Science & Technology, the Institute of Food Technologists and the American Oil Chemists’ Society. He currently serves as the Editor-in-Chief for the *Journal of Food Biochemistry* and an Associate Editor for *Current Topics in Nutraceutical Research*.

**John Birch**

John teaches Food Science undergraduate and postgraduate courses specializing in food chemistry, food processing and food quality management and safety.

His research area is on physicochemical composition and properties of food components, increasing value of secondary food processing products and their contribution to consumer health and wellness. Students research on value-added oilseed products, transesterification of oils with phenolic acids (to produce antioxidants), bioactive peptides, alternative protein sources to traditional farming practices, fish oil composition, stabilization and analysis of oxidative products, biofuel production from primary wastes, nanoencapsulation of bioactives, frying oil stability and lipid derived flavour in meat. Analytical instruments: HPLC, GC, GCO, PTRMS, GC-MS, NMR, DSC, TGA and access to specialized University instruments.

**Danae Larsen**

Danae Larsen, PhD, is a Food Science Consultant in Zurich, Switzerland. She has worked in various sectors of the food industry and academia, having held research positions in the School of Chemical Sciences and the Department of Chemical and Materials Engineering at the University of Auckland, New Zealand and at the Centre for Organismal Studies, Heidelberg University, Germany. Her research interests include, food structure, oral processing pathways, molecular biology, sensory perception, product development and the role of textural complexity in satiation and satiety.

**Michael Rogers**

Dr Rogers operates one of only three TIM-1 simulated GI tracks in Canada and the only one where physical properties of foods can be measured directly in the system. His research area focuses on lipid digestion kinetics of processed foods, with particular interest in developing infant formula that have similar digestion kinetics to human breast milk. Dr Rogers' joined the University of Guelph after holding faculty positions at Rutgers University and University of Saskatchewan, he was also the Director of the Gastrointestinal physiology laboratory at the New Jersey of Food, Nutrition & Health. He currently holds a Tier II Canadian Research Chair in Food Nanotechnology studying how to make high fat foods healthier. For his work on lipid structure and food nanostructures he has recently been awarded The Young Scientist Research Award from the American Oil Chemists' Society and has been appointed as a Fellow of the Early Career Scientists' Section of the International Academy of Food Science and Technology. He holds two patents, 70 peer reviewed manuscripts and more than 40 technical presentations.

**Richard Stadler**

Richard Stadler is Head of the Nestlé Institute for Food Safety and Analytical Sciences, based in Lausanne, Switzerland. His current research interests include food process contaminants, new analytical approaches in food safety, exploring digital solutions to identify and mitigate food chain risks. He is a member of several editorial boards of scientific journals, as well as Editor of the Journal "Food Additives & Contaminants". He is chairman of two expert groups in FoodDrinkEurope, and permanent guest in the "Senate Commission on Food Safety" of the German Research Foundation (DFG). He has published more than 120 scientific papers/book chapters in international journals, and is lecturer at the ETH Zürich.

**Dongxiao Sun-Waterhouse**

Dr Dongxiao Sun-Waterhouse is a Fellow of the New Zealand Institute of Food Science & Technology, a Chief Expert of the Guangdong Institute of Food Science and Technology, and Chair of the “Functional/Wellness Foods & Nutrition Working Group” of the International Commission of Agricultural and Biosystems Engineering. She also holds Chair Professorships at the South China University of Technology and Shandong Agricultural University. She has a wealth of experience working in the food industry, academia, research institutes and a food safety authority. Her R&D expertise encompasses food chemistry and biomaterials, food processing/manufacturing and food safety, industrial biotechnology, functional foods and nutrition. Her particular research strength is the smart use of food component interactions in food systems, as well as formulation and processing synergies, for wellness/functional food development and bioactive delivery. She has been actively involved in applied research and industrial consulting nationally and internationally to improve commercialisation outcomes. Dongxiao is a Section Editor of Elsevier's *Encyclopedia of Food Chemistry* and an Editorial Board member of the journal *Food Chemistry*. She has also acted as a conference convenor, conference chair, scientific advisory board member or organizing committee member for a number of international conferences.

## CONTENTS OF VOLUME 3

---

<i>Contributors to Volume 3</i>	<i>xv</i>
<i>Contents of all Volumes</i>	<i>xxi</i>
<i>Preface</i>	<i>xxxv</i>
 Fruit and Vegetable Texture: Role of Their Cell Walls <i>José A Mercado, Antonio J Matas, and Sara Posé</i>	 1
Atomic Force Microscopy (AFM) and X-Ray Micro-Computed Tomography (Micro-CT): Applications in Cell Wall Imaging of Softening Fruit <i>Jovyn K T Frost and Roswitha Schröder</i>	8
Legume Microstructure <i>Duc Toan Do and Jaspreet Singh</i>	15
Meat Structure During Processing <i>Hanne Christine Bertram</i>	22
The Structure and Properties of Eggs <i>Danaé S Larsen</i>	27
Crustacean By-products <i>Fatih Özogul, Imen Hamed, Yesim Özogul, and Joe M Regenstein</i>	33
Microstructure of Dairy Fat Products <i>P R Ramel and A G Marangoni</i>	39
The Structure and Properties of Ice Cream and Frozen Desserts <i>H Douglas Goff</i>	47
The Structure and Rehydration Properties of Dairy Powders <i>Irina Boiarkina and Brent Young</i>	55
Structure and Properties of Chocolate <i>Monica H Caparosa and Richard W Hartel</i>	61
Traditional African Bread and the Physicochemical Properties of Unfermented Flatbreads <i>Geremew Bultosa</i>	66
Traditional African Bread: Physicochemical and Sensory Properties of Fermented Breads <i>Geremew Bultosa</i>	81

Indian Flatbreads: How Structure Influences Properties <i>Shabir Ahmad Mir and Manzoor Ahmad Shah</i>	90
Tofu and Soy Products: The Effect of Structure on Their Physicochemical Properties <i>Qing Zhang and Wen Qin</i>	96
The Structure of Meat Analogs <i>Pavan Kumar, Nitin Mehta, Om Prakash Malav, Akhilesh Kumar Verma, Pramila Umraw, and Matli Krishna kanth</i>	105
Nanomaterials in Food: An Overview <i>Stéphane Dubascoux and Yves Wyser</i>	110
Delivery of Epigallocatechin-3-Gallate by Bovine Alpha-Lactalbumin Based on Their Non-covalent Interactions <i>Tanja Cirkovic Velickovic, Dragana Stanic-Vucinic, Ayah Al-Hanish, Jelena Mihailovic, Ivana Prodic, Simeon Minic, Marija Stojadinovic, Milica Radibratovic, and Milos Milcic</i>	118
Food Structure, Rheology, and Texture <i>L Day and M Golding</i>	125
Applications of Microrheology to Food Systems <i>Susav Pradhan, Catherine P Whitby, and Martin A K Williams</i>	130
Intrinsically Disordered Proteins: Polymers Without Structure but With Great Potential for Applications in Food Science <i>Davide Mercadante</i>	134
Structured Lipid Functionality and Application <i>Xun Ang, Siew-Young Quek, and Hong Chen</i>	141
Application of Electrospinning as Bioactive Delivery System <i>Siew Young Quek, Joshua Hadi, and Hartono Tanambell</i>	145
Food Texture, Oral Processing and Satiation: Examining Their Relationship <i>Danaé S Larsen</i>	150
Food Sensory Perception Influenced by Structure and/or Food–Saliva Interactions <i>Xinmiao Wang and Jianshe Chen</i>	154
How Food Structure and Processing Affect the Bioavailability of Nutrients and Antioxidants <i>Sui Kiat Chang</i>	158

# CONTENTS OF ALL VOLUMES

---

## VOLUME 1

Acids and Bases in Food <i>Iris J Joye</i>	1
Anthocyanins <i>Celestino Santos-Buelga and Ana M González-Paramás</i>	10
Aromas <i>Keith R Cadwallader</i>	22
Artificial Sweeteners <i>Runu Chakraborty and Arpita Das</i>	30
Betalains <i>Delia B Rodriguez-Amaya</i>	35
Carotenoids <i>Luxsika Ngamwonglumlert and Sakamon Devahastin</i>	40
Clarifying Agents <i>Harsh P Sharma, Aditya Madan, and D C Joshi</i>	53
Dietary Fiber (Psyllium, $\beta$ -Glucan) <i>Lilian E Figueroa and Marina Dello Staffolo</i>	61
Diglycerides <i>Reed A Nicholson and Alejandro G Marangoni</i>	70
Egg Proteins <i>Snigdha Guha, Kaustav Majumder, and Yoshinori Mine</i>	74
Enzyme Applications in Food Processing: Traditional Uses to New Developments <i>Takuji Tanaka</i>	85
Encyclopedia of Food Chemistry: Fat replacers <i>Michael A Rogers</i>	96
Flavor Enhancers and Modifiers <i>Nicole J Gaudette</i>	101

Flavors (Bittering Agents, Astringent Flavors, Pungency, Menthol) <i>Paul Hughes</i>	104
Galactomannans (Guar, Locust Bean, Fenugreek, Tara) <i>Vassilis Kontogiorgos</i>	109
Gases and Vapors Used in Food <i>Loong-Tak Lim</i>	114
Gelatin <i>Soottawat Benjakul and Phanat Kittiphattanabawon</i>	121
Hardstock Triglycerides <i>Dongming Tang</i>	128
Medium Chain Triacylglycerides <i>Fernanda Peyronel</i>	132
Milk Proteins <i>Ryan Hazlett, Christiane Schmidmeier, and James A O'Mahony</i>	138
Bioavailability of Minerals (Ca, Mg, Zn, K, Mn, Se) in Food Products <i>Mitra Nosratpour and Seid Mahdi Jafari</i>	148
Monoglycerides: Categories, Structures, Properties, Preparations, and Applications in the Food Industry <i>Song Miao and Duanquan Lin</i>	155
Muscle Proteins <i>Mike Boland, Lovedeep Kaur, Feng Ming Chian, and Thierry Astruc</i>	164
Natural Antioxidants in Foods <i>Bingcan Chen and Minwei Xu</i>	180
Natural Sweeteners <i>Jean-Baptiste Chéron, Axel Marchal, and Sébastien Fiorucci</i>	189
Nitrates <i>Gayatri Suresh, Weihui Xiong, Tarek Rouissi, and Satinder Kaur Brar</i>	196
Oligosaccharides: Structure, Function and Application <i>Yan Wang, Qingbin Guo, H Douglas Goff, and Gisèle LaPointe</i>	202
Pectin in Foods <i>Randall G Cameron</i>	208
Phospholipids <i>Meizhen Xie</i>	214
Phosphates <i>Gary A Dykes, Ranil Coorey, Joshua T Ravensdale, and Amreeta Sarjit</i>	218
Phytosterols <i>Arjen Bot</i>	225
Plant Protein Ingredients <i>Andrea K Stone, Yun Wang, Mehmet Tulbek, and Michael T Nickerson</i>	229
Salts and Salt Replacers <i>Elena S Inguglia, Joseph P Kerry, Catherine M Burgess, and Brijesh K Tiwari</i>	235

Seaweed Polysaccharides (Agar, Alginate Carrageenan) <i>Katerina Alba and Vassilis Kontogiorgos</i>	240
Sequestrants as a Food Ingredient <i>Benjamin M Bohrer</i>	251
Starch <i>Iris J Joye</i>	256
Sugar Alcohols <i>Małgorzata Grembecka</i>	265
Surfactants <i>Natalie Ng and Michael A Rogers</i>	276
Artificial Antioxidants <i>João C M Barreira and Isabel C F R Ferreira</i>	283
Synthetic Food Colors <i>Maria G Corradini</i>	291
Encyclopedia of Food Chemistry: Water <i>Peter Chen and Michael A Rogers</i>	297
Water-Soluble Vitamins <i>Hannah Pinchen and Paul Finglas</i>	305
Waxes <i>Yaqi Lan</i>	312
Introduction to the Volume: Food Adulteration & Contamination <i>Richard H Stadler</i>	317
New Breeding Techniques: Detection and Identification of the Techniques and Derived Products <i>Yves Bertheau</i>	320
Biogenic Amines in Food: A Review of Factors Affecting Their Formation <i>G Tabanelli, C Montanari, and F Gardini</i>	337
Plant Alkaloids <i>Birgit Dusemund, Bernd Schaefer, and Alfonso Lampen</i>	344
Pyrrolizidine Alkaloids: Analytical Challenges <i>Oliver Keuth, Hans-Ulrich Humpf, and Peter Fürst</i>	348
Big Data Applications in Food Safety and Quality <i>Stephanie Pollard, Hossein Namazi, and Ramin Khaksar</i>	356
Omics Methods For the Detection of Foodborne Pathogens <i>David I Ellis, Howbeer Muhamadali, Malama Chisanga, and Royston Goodacre</i>	364
New Analytical Frontiers in Mycotoxin Research <i>Laura Righetti and Chiara Dall'Asta</i>	371
Next-Generation Sequencing <i>Martin Wiedmann and Laura M Carroll</i>	376
Dioxins and Dioxin-like PCBs in Feed and Food <i>Peter Fürst</i>	384

Modified Mycotoxins: A New Challenge? <i>H -U Humpf, Michael Rychlik, and Benedikt Cramer</i>	393
Mycotoxins in Food and Feed: An Overview <i>Joerg Stroka and Carlos Gonçalves</i>	401
Occurrence & Risk of OTA in Food and Feed <i>Vita Di Stefano</i>	420
Occurrence & Risk of Aflatoxins in Food and Feed <i>Martien C Spanjer</i>	424
Pesticide MRLs and Impact on Global Trade <i>Marina Rusch, Gordon Cameron, and Karsten Hohgardt</i>	428
Pesticides: An Update on Mass Spectrometry Approaches <i>Jon W Wong, Jian Wang, Kai Zhang, Douglas G Hayward, Paul Yang, and James B Wittenberg</i>	433
Pesticides: Evaluation Process in the EU <i>Claudia Heppner</i>	449
Polycyclic Aromatic Hydrocarbons in Food and Feed <i>Thomas Wenzl and Zuzana Zelinkova</i>	455
Veterinary Drugs: Progress in Multiresidue Technique <i>Patricia Regal, Alexandre Lamas, Carlos M. Franco, and Alberto Cepeda</i>	470
Endocrine Disrupters: A Review <i>Alberto Mantovani</i>	481
Acrylamide: US FDA Guidance to Industry <i>Lauren Posnick Robin and Eileen Abt</i>	487
Acrylamide: An Overview of the Chemistry and Occurrence in Foods <i>Aytül Hamzahoğlu, Burçe Ataç Mogol, and Vural Gökmen</i>	492
Dietary Acrylamide: An Update on the Chronic Risks <i>Janneke Hogervorst</i>	500
Advanced Glycation End Products (AGEs): Occurrence and Risk Assessment <i>Michael Hellwig and Thomas Henle</i>	525
Furan and Alkylfurans: Occurrence and Risk Assessment <i>Gabriele Scholz and Richard H Stadler</i>	532
Processing Contaminants: Furfuryl Alcohol <i>Alex O Okaru and Dirk W Lachenmeier</i>	543
Heterocyclic Aromatic Amines: An Update on the Science <i>Medjda Bellamri and Robert J Turesky</i>	550
Managing Acrylamide at the Agricultural Stage: Variety Selection, Crop Management, and the Prospects for Solving the Acrylamide Problem Through Plant Breeding and Biotechnology <i>Nigel G Halford</i>	559
MCPD Esters and Glycidyl Esters: A Review of Analytical Methods <i>Shaun MacMahon</i>	569
MCPDE and GE: An Update on Mitigation Measures <i>Zsolt Kemeny, Krish Bhagga, Falk Brüse, Adina Creanga, Rob Diks, Luisa Gambelli, Yves Le Bail-Collet, and Daniel Ribera</i>	578

Mineral Oils in Food: An Update <i>Koni Grob and Maurus Biedermann</i>	588
N-Nitroso Compounds in Foods <i>Michael Habermeyer and Gerhard Eisenbrand</i>	593
Migration From Food Contact Materials <i>Gregor McCombie and Maurus Biedermann</i>	603
Process Contaminants: A Review <i>Michael Murkovic, Franco Pedreschi, and Zuzana Ciesarová</i>	609
Food Allergens: A Regulatory/Labelling Overview Including the VITAL Approach <i>Carmen Diaz-Amigo and Bert Popping</i>	615
Food Allergens: An Update on Analytical Methods <i>Michael J Walker</i>	622
Food Allergens: Seafood, Tree Nuts, Peanuts <i>Marie-Claude Robert</i>	640
Food Counterfeiting: A Growing Concern <i>John Spink</i>	648
Food Defense <i>Andrew G Huff</i>	652
Food Fraud and Adulteration: Where We Stand Today <i>John Spink</i>	657
Food Fraud and Vulnerability Assessments <i>Saskia M van Ruth</i>	663
Food Fraud Vulnerabilities in the Supply Chain: An Industry Perspective <i>Christophe Cavin, Geoffrey Cottenet, Christophe Fuerer, Lien-Anh Tran, and Pascal Zbinden</i>	670
Food Chemistry and Analysis for the Purpose of Kosher and Halal <i>Joe M Regenstein</i>	679
Modern Concepts in Chemical Risk Assessment <i>Dieter Schrenk</i>	685
Emerging Food Safety Risks <i>Farai Maphosa</i>	690
Managing Chemical Hazards in HACCP <i>Jantra Daolert</i>	699
The Legislative Landscape in the EU: Challenges Faced by the Food Industry <i>Andrew Curtis</i>	709
Biocides: A Critical Review of Current and Proposed EU Legislation <i>Heiko Faubel</i>	715

## VOLUME 2

Antioxidant and Flavor in Spices Used in the Preparation of Chinese Dishes <i>Yan Ping Chen and Hau Yin Chung</i>	1
--	---

Anthocyanins in Food	10
<i>Xiaonan Sui, Yan Zhang, Lianzhou Jiang, and Weibiao Zhou</i>	
Caramelization in Foods: A Food Quality and Safety Perspective	18
<i>Tolgahan Kocadağlı and Vural Gökmen</i>	
Carbohydrate Active Enzymes Applied in the Production of Functional Oligosaccharides	30
<i>Fabiano Jares Contesini, Evandro A de Lima, Fernanda Mandelli, Gustavo P Borin, Rafael F Alves, and César Rafael F Terrasan</i>	
Chemically Reducing Properties of Maillard Reaction Intermediates	35
<i>George P Rizzi</i>	
Protein Oxidation	41
<i>Leticia Mora, Marta Gallego, M-Concepción Aristoy, and Fidel Toldrá</i>	
Coffee Flavor	48
<i>Adane Tilahun Getachew and Byung-Soo Chun</i>	
Configuring Phenolic Antioxidants for Frying Applications	54
<i>Felix Aladedunye and Eliza Gruczynska</i>	
Milk Protein Interactions	63
<i>Anant Chandrakant Dave and Harjinder Singh</i>	
Effect of Heat on Food Properties	70
<i>Rana Muhammad Aadil, Ume Roobab, Abid Aslam Maan, and Ghulam Muhammad Madni</i>	
Effect of Emerging Processing Technologies on Maillard Reactions	76
<i>Mohamed Koubaa, Shahin Roohinejad, Tanyaradzwa E Mungure, Bekhit Alaa El-Din, Ralf Greiner, and Kumar Mallikarjunan</i>	
Effect of Storage on Fruit Bioactives	83
<i>Rana Muhammad Aadil, Ume Roobab, Muhammad Kashif Iqbal Khan, and Ubaid Ur Rahman</i>	
Enzymatic Production of Antioxidants and Their Applications	92
<i>Taiwo O Akanbi and Colin J Barrow</i>	
Factors Influencing Red Wine Color From the Grape to the Glass	97
<i>Jacqui M McRae, Bo Teng, and Keren Bindon</i>	
Fermentation of Grains	107
<i>Isam A Mohamed Ahmed, Fahad Y Al-Juhaimi, and Alaa El-Din Ahmed Bekhit</i>	
Fruit Pigment Changes During Ripening	117
<i>Wee Sim Choo</i>	
$\alpha$ -Galactosidase and Its Applications in Food Processing	124
<i>Lu-Kwang Ju, Abdullah A Loman, and S M Mahfuzul Islam</i>	
Influence of Food Processing Operations on Vitamins	129
<i>Merve Tomas and Seid Mahdi Jafari</i>	
Microbial Xylanases in Bread Making	140
<i>Seema Dahiya and Bijender Singh</i>

## PREFACE

---

This is an exciting time for all who wish to understand the nature of food and how it changes during storage, processing, cooking and digestion. This is because science has turned its focus onto soft matter and food is very largely soft matter. Earlier scientific effort was preoccupied with simple molecules in solution and solids (preferably pure crystalline proteins). When you think about it, knowing the total protein, carbohydrate, lipid and vitamin contents of a food doesn't tell you much about the nature of the food and how it will provide nutrients for us. Now we are seeing a huge effort to understand soft matter, which is directly applicable to food. Meaning we are increasing our knowledge of how food components (both macromolecules such as proteins and polysaccharides as well as smaller molecules) interact chemically with each other; leading ultimately to understanding the complex chemical structure of foods (everything from apples and ice cream to vegetable protein meat-substitutes and food for a visit to Mars).

A golden age for food research has begun, with so many new techniques available such as CRISPR, isothermal calorimetry (ITC), analytical ultracentrifugation (AUC), small angle neutron and X-ray scattering (SANS, SAXS), surface plasmon resonance, electronic tweezers, and computer modelling (for example molecular dynamics simulations for understanding the interactions of proteins and polysaccharides, enzymes and substrates, bioactives and encapsulating agents). This is in addition to the tried and tested techniques of nuclear magnetic resonance (NMR), mass spectroscopy, electron and confocal microscopy, high performance liquid chromatography (HPLC), and gas chromatography. Biosensors publications are huge and nanotechnology is a hot topic for research.

The *Encyclopedia of Food Chemistry* is for people who have a basic knowledge of food chemistry and wish to expand their understanding of a topic based on information from a reliable source. No fake news here! We welcome you to enjoy the excitement captured here by experts from across the planet.

## Overview

Appearance, flavour, texture and nutritional value are the four main quality factors in foods. The first three are referred as 'sensory acceptability factors' because they are perceived directly by the senses. In fruit and vegetables, the latter defined as any edible part of plants consumed for food that is not a mature fruit or seed (e.g. leaves, roots, stems, bulbs, tubers ...) and mature fruit that are consumed as part of a main meal rather than dessert (e.g. tomato, pepper) (Radovich, 2011), texture has a significant contribution to the overall quality, and it is one of the main attribute for the acceptance in the market from the consumer's point of view (Contador et al., 2015). Texture also determines the acceptability of some part of fruit or vegetable and the way they are usually eaten, e.g. the skin of some fruit or vegetables is eaten with the fleshy portion when it is thin, as in the strawberry, but it is not eaten when it is thick, hard, hairy or fibrous, as in mango or peach. The definition of 'texture' is difficult since it includes a wide range of attributes which determine the feel of food within the mouth and the way these attributes can be measured. For this reason, it is better to talk about 'textural properties', a group of related properties, rather than 'texture', a single parameter. Bourne (2002) defined the textural properties of a food as '*that group of physical characteristics that arise from the structural elements of the food, are sensed primarily by the feeling of touch, are related to the deformation, disintegration, and flow of the food under a force, and are measured objectively by function of mass, time, and distance*'. Among the different textural properties that can be perceived or measured in a food, firmness and juiciness are the most important parameters in the case of fruit or vegetables (Toivonen and Brummell, 2008). Firmness and juiciness are complex traits depending upon physical anatomy of the tissue (cell shape and size), cell wall thickness and strength, the way in which cells bind to form the flesh tissue (extension and strength of adhesion areas between adjacent cells) and cell turgor. Fruit and vegetables are mainly comprised by parenchyma cells, thin-walled cells with metabolic activities such as photosynthesis of storage sites of starch or other compounds. The presence of non-parenchyma cells (epidermal cells, vascular elements, fibers and sclereids) influences texture since most of these cells contain thickened walls (Harker et al., 1997a; Toivonen and Brummell, 2008; Mercado et al., 2011). Vegetable tissues generally have a greater proportion of cells with thickened and lignified cell walls, being usually harder than ripe fruit. Also, fleshy fruit and vegetables with thick highly impermeable cuticle, reduced water loss and whole turgor could contribute significantly to fruit firmness (Gómez-Galindo et al., 2004; Saladié et al., 2007).

Fleshy fruit undergoes a ripening process that results in the modification of textural properties, acquiring firstly the desired texture for eating but later an undesirable texture that leads to economically important postharvest losses. Physiologically, fruit are classified as climacteric or non-climacteric, depending on the role of ethylene in the promotion of fruit ripening. From a textural point of view, fruit can be classified in those that soften greatly as they ripen (e.g. peach, apricot, melon, plum, tomato, strawberry), and those that soften moderately as they ripen (e.g. apple, quince, nashi pear, cranberry, watermelon) (Bourne, 1979). Fruit from the first category tend to have a short postharvest life, acquiring a melting texture as they ripen, and show a poor correlation between firmness at harvest and after storage. By contrast, fruit belonging to the second category generally have a long storage life, a crisp, fracturable texture, and show a close relationship between firmness at harvest and after storage. The climacteric or non-climacteric condition does not correlate with the textural properties, e.g. some climacteric fruit are soft and melting (peach) while others are crisp (apple); similarly, some non-climacteric fruit are soft (strawberry) while others display a crisp texture (watermelon). During ripening, cell walls are extensively modified, changing their mechanical properties, and inter cellular adhesion is reduced due to the dissolution of the middle lamella (Brummell, 2006; Mercado et al., 2011). These modifications in conjunction with the reduction of turgor pressure lead to fruit softening. Juiciness is determined by cellular turgor and the pattern of tissue breakage during biting and chewing. Juicy texture is associated with large cells which break open releasing intracellular content; fruit with a dry texture tend to have small cells that separate along the middle lamella with little cell rupture (Harker et al., 1997b). Ultimately, firmness and juiciness depend on cell wall strength and inter cellular adhesion. Thus, when intercellular adhesion areas are stronger than cell walls, cells break and liberate their content making crunchy and juicy textures, while when the cell walls are stronger than middle lamella, the weak intercellular adhesion produces soft-melting textures, attributing to the main mode of tissue failure, either cell breakage or cell separation, a central role on the perception of fruit and vegetable texture (Christiaens et al., 2016). The postharvest physiology of vegetables varies widely because of the broad range of tissue types. Vegetables not derived from fruits do not suffer a ripening process; the loss of textural quality in these vegetables is associated to cell wall modifications, that generally occur to a lesser extent than in fruit, senescence, specially in leafy vegetables, and reduced turgor due to transpirational water loss and leakage of osmotic solutes (Brummell and Toivonen, 2018; Gómez-Galindo et al., 2004; Goulao et al., 2010; Ranganathan et al., 2016).

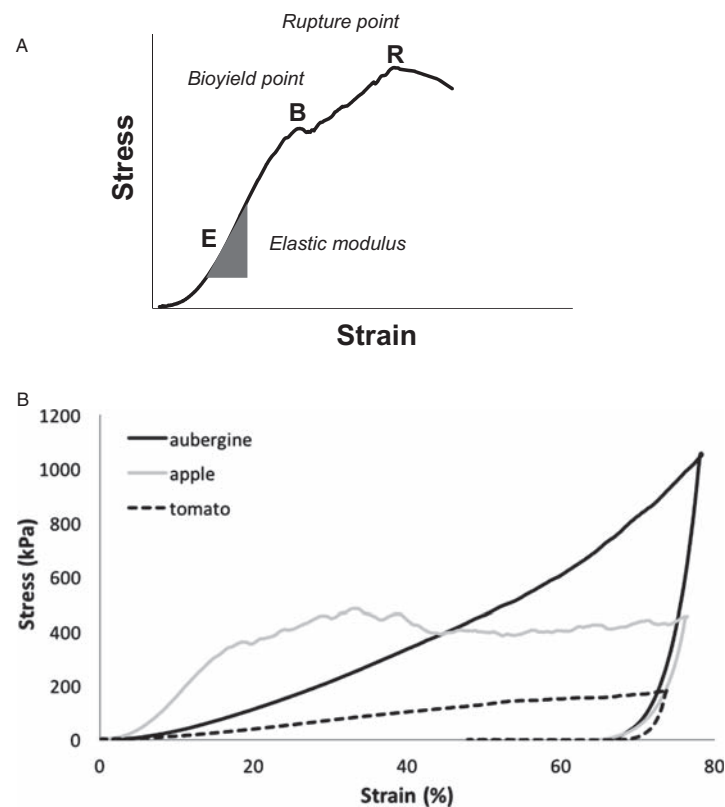

## Mechanical Assessment of Fruit and Vegetable Texture

Firmness has been mostly assessed by both, puncture testing machines or penetrometers, widely used in food industry, and universal testing machines (UTM) like Instron or Texture Analyser, preferred in food science (Abbott, 2004). Penetrometers offers a quick and handy assessment of firmness based on a unique output parameter defined by the maximum force to disrupt the tissue

(herein named as hardness). In contrast, UTM are time-consuming but provides an output of precise measurements of stress, strain, distance and time. Here, stress ( $\sigma$ ) is defined as force per unit area, and strain ( $\epsilon$ ) is dimensionless and defined by dividing the difference between the final and initial deformations by the initial deformation (Niklas, 1992). Thus, in the simplest and widely used uniaxial compression test (compared to a whole hand squeeze) a typical stress–strain curve (Fig. 1A) includes relevant texture parameters: elastic zone or linear limit at the initial phase, where the sample recovers its original shape once stress ceased; elastic modulus (E) defined by the slope of the curve in the elastic zone; bioyield point (B), shortly after the end of the elastic zone sometimes there is a first noticeable decrease in slope which indicates the start of cell disruption at local level; and rupture point (R), as the first prominent positive peak with a substantial decrease in force as deformation increases, that marks a major tissue failure beyond which the force can behave either increasing again, level off or decreasing (Abbott, 2004; Contador et al., 2015). Fig. 1B depicts several possible scenarios of different agronomic samples. Overall, the hardness obtained by hand penetrometers is a good enough approach for agronomical purposes in the field, but UTM are advisable when a deeper texture analysis is required or when several types of fruit textures are compared (Cornuault et al., 2018). Juiciness is often measured according to the amount of juice released from a cut tissue or during tissue homogenization (Harker et al., 1997b). Apart from the disruptive mechanical assessments described here, other texture analysis includes the sensory analysis by panelists as well as non-destructive approaches (eg. acoustic-based, NMR, spectroscopy-based) (Chen and Opara, 2013), which are considered emerging techniques for its potential in high throughput analysis of crop texture at industrial level.

### Cell Wall Composition and Structure

Primary cell walls are composed of polysaccharides, a small proportion of glycoproteins and, in some specialized cells, noncarbohydrate substances such as lignin, suberin or cutin. Primary cell wall comprises a load-bearing framework of cellulose together with other polysaccharides and glycoproteins embedded in a more soluble matrix of pectic polysaccharides (Carpita and Gibeault, 1993). Type I walls, those present in most plants contain about 30% each of cellulose, hemicelluloses and pectins, and 1%–10% of structural glycoproteins. The amount of pectins can be much higher in fleshy fruit, accounting up to 60% of cell wall mass (Redgwell et al., 1997a; Prasanna et al., 2007). Type II walls, characteristics of some monocots contain lower amount of pectins and structural proteins. Additionally, middle lamella is the first layer deposited after cell division, so it is located at the interface where the walls of

**Figure 1** (A) Typical stress–strain diagram from a uniaxial compression test. (B) Stress–strain curves from texture analysis by compression test at maximum strain of 70% in three fruit with contrasting texture. E: elastic modulus defined as the slope in the elastic zone; B: bioyield point; R: rupture point.

neighbouring cells come into contact. This thin layer, enriched in pectins, functions as a flexible adhesive layer between cells (Willats et al., 2001).

Cellulose is the main scaffolding of plant cell walls. It is composed by linear chains of  $\beta$ -(1–4) linked D-glucose (Glc) that associate together by hydrogen bonds to form microfibrils. Hemicelluloses are formed by (1–4)- $\beta$ -linked backbones of Glc, xylose (Xyl) or mannose (Man), decorated with neutral or slightly acid sugar side chains. Xyloglucan (XG), linear chains of (1–4)- $\beta$ -D-glucose with numerous Xyl units linked at regular sites to the O-6 position of Glc units, is the most abundant hemicellulosic component in Type I walls. Xyloglucans adhere to cellulose microfibrils by hydrogen bonds and are long enough to span the 20–40 nm distance between adjacent microfibrils, linking them together forming a network (Park and Cosgrove, 2012). Glucuronoarabinoxylans (GAXs) is the main cross-linking glycan in Type II walls.

Pectins are complex polymers largely composed of GalA (Yapo, 2011a). These carbohydrates are classified in three main domains: homogalacturonan (HG), rhamnogalacturonan I (RGI) and rhamnogalacturonan II (RGII). HG, the most abundant pectin domain, is formed by a linear backbone of  $\alpha$ -(1–4) GalA units. Xylogalacturonan (XGA) is a HG substituted with xylose residues which is also abundant in storage tissues of reproductive organs. RGI are highly ramified pectins formed by a backbone of the disaccharide (1–2)- $\alpha$ -L-rhamnose-(1–4)- $\alpha$ -D-galacturonic acid, with 20%–80% of rhamnose residues substituted with arabinan, galactan or arabinogalactan side chains (Yapo, 2011b). Finally, RGII is a branched polymer composed of a 9 GalA residues backbone substituted with four heteropolymeric side chains containing more than 20 uncommon sugar residues. The glycosyl sequence of RGII is highly conserved in all vascular plants (O'Neill et al., 2004). RGII in the cell wall are usually cross-linked by a borate diester (O'Neill et al., 2004). How the different pectin domains are interconnected is poorly understood. The classical model describes pectin as a HG linear backbone (smooth regions), interspersed with rhamnosyl residues and alternated with branched RGI regions (hairy regions) (Voragen et al., 2009). The analysis of pectins at nanoscale level by atomic force microscopy has revealed novel characteristics such as HG branches attached to HG backbone that challenge current model of pectin structural organization (Posé et al., 2018; Wang et al., 2018). HG chains can be cross-linked by calcium (Carpita and Gibeau, 1993). Pectins, XG and cellulose microfibrils can also be covalently linked (Zykwinska et al., 2008; Wang et al., 2015). As regard as the localization of these pectin domains, demethylated HG is concentrated in the tricellular junction zones between cells and in the middle lamella; RGI would be located in the cell wall, where they might contribute to interlink pectin and cellulose microfibrils; RGII seems to be widespread in the wall except in the middle lamella (Vincken et al., 2003; Posé et al., 2018; Wang et al., 2018).

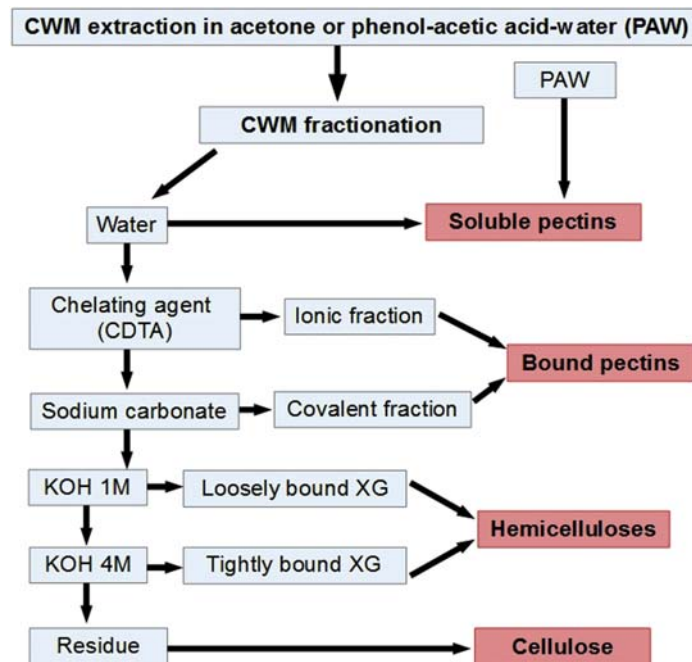

The most accepted hypothesis about the structure of primary walls shows it as a fundamental framework of cellulose-hemicellulose embedded in a pectin matrix (Doblin et al., 2010). XG might facilitate a close contact between cellulose microfibrils in certain regions, called “hot spots”. It has been suggested that pectins also play a key role in wall biomechanics (Park and Cosgrove, 2012). Supporting this role, functional analyses of genes encoding pectin degrading enzymes in fruit with contrasting texture, such as strawberry, tomato or apple, have found that the suppression of their expression increases fruit firmness and extends shelf life, as it will be discussed later.

## Cell Wall Analysis

A brief description of general procedures for cell wall extraction and analysis is necessary to understand the role of its different components in fruit texture. *In situ* studies of the cell wall can be performed by different analytical techniques, e.g. immunolocalization of cell wall components, solid state NMR and AFM (Vicente et al., 2007). However, most studies use a destructive procedure based in the isolation and purification of the different cell wall components by solubilisation using a series of extractants (Fig. 2). This approach involves the irreversible breakage of bonds among the different wall components and therefore important information about their *in situ* localization is lost. This could be important in ripening fruit since this process is not uniform over the whole fruit tissues. For cell wall extraction, different solvents, such as phenol based solutions, are used to inactivate cell wall hydrolases from plant homogenates (Huber, 1991; Fry, 2000). Then, the residue enriched in cell wall material (CWM) is treated with dimethylsulphoside or digested with amylase to remove starch. CWM is sequentially extracted by solutions to produce fractions enriched in a specific wall component (Fig. 2). Despite the limitations of this chemical extraction above commented, the cell wall fractions obtained reflect to some extent particular polymer moieties within the cell wall. First fractions (phenol and water) extract polysaccharides that are readily soluble or poorly bound to the matrix; chelating agents extract pectins rich in HG from middle lamella; sodium carbonate extracts pectins loosely bound to the wall and enriched in neutral sugars; finally, KOH solutions solubilise xyloglucans loosely and tightly bound to the wall. The insoluble residue mainly contains cellulose.

## Fruit and Vegetable Softening and Cell Wall Modifications

Textural changes in fruit during ripening and postharvest storage are mainly associated with the dissolution of the middle lamella and the disassembly of the primary cell wall (Brummell, 2006; Goulao and Oliveira, 2008; Mercado et al., 2011) (Fig. 3). Although the temporal sequence of cell wall disassembly events and the degree of these changes is fruit-specific and even cultivar-specific, some modifications are common to most species, such as the depolymerization of hemicelluloses, the solubilization and depolymerization of pectins and the loss of neutral sugars from pectin side chains (Brummell, 2006). These changes in cell wall are mediated by the action of a broad variety of cell wall degrading enzymes or proteins secreted from the symplast into the cell wall space,

**Figure 2** Schematic diagram of the general procedure for cell wall extraction and fractionation into the different cell wall components. CWM: cell wall material; PAW: phenol-acetic acid-water; XG: xyloglucans.

**Figure 3** Main processes taking place in the cell wall during fruit softening.

generally encoded by ripening-related genes (Goulao and Oliveira, 2008; Goulao et al., 2010; Mercado et al., 2011). Additionally, some evidence indicates that pectins can be degraded spontaneously by hydroxyl radicals generated as the fruit ripens (Airianah et al., 2016). In general, cellulose crystallinity is not affected during fruit softening (Newman and Redgwell, 2002).

XG depolymerization during ripening is common to many fruit (e.g. tomato, avocado, melon, kiwifruit, peach); however, others fruit soften without apparent changes in XG molecular weight (e.g. apple, raspberry) or show a cultivar dependent response (e.g. strawberry) (Brummell, 2006). Besides the reduction of hemicellulose size, the loss of the structural integrity of the cellulose-XG network has also been suggested as a primary cause of softening. Two different proteins participate in this process, expansins and xyloglucan endotransglycosylase/hydrolase (XTH). Expansins disrupt non-covalent interactions between hemicelluloses and cellulose microfibrils promoting cell wall loosening and extension (Cosgrove, 2000; Choi et al., 2006). The XTH genes encode proteins that can potentially have XG endo-transglycosidase activity, non-hydrolytic cleavage and ligation of XG chains, and endo-hydrolase activity, yielding irreversible chain degradation (Eklöf and Brumer, 2010). Expansins and XTH are encoded by large gene families including specific members involved either in the maintenance of the cell wall during fruit growth or in the cell wall disassembly during fruit ripening.

Pectins are the cell wall polysaccharides subjected to most dramatic changes during fruit ripening. These modifications involve an increase in their solubilization, depolymerization and degree of demethylesterification, and a loss of neutral sugars (Paniagua et al., 2014). The disentanglement of the pectin network may also facilitate the swelling of the cell wall due to the penetration of

water into enlarged intermicrofibrillar spaces (Redgwell et al., 1997a). This process would allow increased mobility of wall enzymes within cell wall matrix and increased accessibility of hydrolytic enzymes to their substrates. Pectin solubilization refers to an increase in the content of pectins loosely bound to the cell wall, those easily extracted with water, and reflects a modification of their extractability due to changes in their structure and/or chemical composition. Usually, the higher amount of soluble pectins is paralleled to lower contents of ionically and/or covalently bound pectins, suggesting that these bound fractions are the source of soluble pectins (Brummell, 2006). Pectin solubilization is directly related with the texture of ripe fruit, i.e. fruit with a soft and melting texture (e.g. avocado, kiwifruit, blackberry, tomato, persimmon, melon, peach or strawberry) show a high to moderate solubilization, while those with a crisp texture (e.g. apple, watermelon or nashi pear) display a low or undetectable solubilization (Mercado et al., 2011). In apple, it has been found that sensory evaluation of juiciness is positively correlated with the GalA content in water soluble pectins while sensory crunchiness and firmness correlate negatively with this component (Billy et al., 2008).

Several processes can contribute to the solubilization of pectins (Paniagua et al., 2014). A marked loss of neutral sugars, mainly Ara and Gal, from RGI side chains is an early event in the ripening of some fruit (Redgwell et al., 1997b). Side chains from RGI might anchor pectins to the wall by physical entanglement with other wall polymers or by binding to the cellulose-hemicellulose network (Zykwinska et al., 2008; Wang et al., 2015), and, consequently, their loss could weaken the pectin network. However, some fruit show extensive solubilization without significant loss of arabinose or galactose (e.g. plum), while others (apple and nashi pear) display an extensive loss of galactose but slight pectin solubilization (Redgwell et al., 1997b; Ng et al., 2015). A progressive demethylesterification of HG mediated by pectin methylesterase (PME) is common to the ripening of many fruit (Mercado et al., 2011). Demethylesterification facilitates the hydrolysis of HG by endo-polygalacturonase (PG) or pectate lyase (PEL) since these enzymes needs at least 4 demethylated GalA residues of the HG backbone to cleavage the glycosidic bonds (Chen and Mort, 1996). Additionally, demethylesterification might create large regions of negatively charged HG which would contribute to the loosening of pectins by electrostatic repulsion (Brummell, 2006). The methylesterification status of pectins seems to be more related to the middle lamella and tissue integrity rather than to fruit firmness. Transgenic suppression of PME activity in tomato reduced pectin methylesterification but did not affect fruit firmness; however, fruit shelf life was notably shortened due to the loss of tissue integrity as result of a reduced amount of bound  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  in the apoplast (Tieman and Handa, 1994).

Pectin depolymerization is not as general as pectin solubilization and in many fruit it takes place late in ripening (Mercado et al., 2011). Some species show a significant loss of high molecular weight pectins (e.g. avocado, tomato, peach, kiwifruit), while others display a low to moderate depolymerization (e.g. strawberry, blueberry, melon, apple). This process can be also cultivar-specific. Despite this diversity, functional analyses of genes encoding pectinases in fruit with contrasting textural properties have demonstrated that pectin depolymerization is a fundamental process in fruit softening. In strawberry, a soft fruit, transgenic suppression of PG or PEL genes increased fruit firmness and extended postharvest shelf life (Jiménez-Bermúdez et al., 2002; Quesada et al., 2009). These improvements were related to a lower depolymerization of bound pectins, a lower degree of pectin solubilization and a higher tissue integrity (Santiago-Doménech et al., 2008; Posé et al., 2013). The visualization of pectins from these transgenic fruit with an atomic force microscope revealed a positive correlation between the preservation of the nano-structural complexity of pectins (pectin length, branching and number and size of pectin aggregates) and fruit firmness (Posé et al., 2015). In tomato, transgenic suppression of PG did not affect fruit firmness but improved shelf life due to a higher middle lamella integrity (Smith et al., 1990; Kramer et al., 1992). Recently, it has been found that suppression of a PEL gene also reduces softening in this fruit (Uluisik et al., 2016). Down-regulation of an endo-PG in apple also results in firmer and juicier fruit (Atkinson et al., 2012).

Our knowledge about cell wall modifications in fresh vegetables is limited when compare with fruit mainly due to the less dramatic textural changes that suffer these products. By contrast, there are ample literature about the effect of processing on textural properties of vegetables (Van Buggenhout et al., 2009; Ranganathan et al., 2016). As previously described for fruit, pectin size, branching and solubility has been related to firmness in some root and storage organs such as potato or carrot (Gómez-Galindo et al., 2004; Ranganathan et al., 2016). The reduction of arabinan and galactan side chains in RGI makes potato tubers more brittle when subjected to compression (Scheller and Ulvskov, 2010), indicating a key role of the pectin matrix in textural properties. In stem and inflorescence vegetables like asparagus, broccoli and cauliflower, hardening may occur after harvest due to tissue lignification (Goulao et al., 2010). Textural changes in leafy vegetables are mainly associated with the loss of cell turgor. However, modifying cell wall properties can have a direct impact on texture and shelf life. The transgenic silencing of XTH genes in lettuce produces smaller and thicker leaves with an extended shelf life (Wagstaff et al., 2010).

## Conclusions

Firmness and juiciness are the most important textural properties in fruit and vegetables. Both parameters depend on the anatomy of the plant tissue, the strength of cell walls, the cohesiveness of the middle lamella and the cell turgor. Fruit undergo a ripening process that substantially modify their texture, leading to fruit softening. The rate of this process determines the postharvest shelf life of the product. Loss of cell turgor can be important in some fruit; however, cell wall disassembly during fruit ripening is considered the main factor causing softening. Among the different wall components, both hemicellulose and pectins are modified during fruit ripening, although the mechanisms involved in these processes are largely unknown. Genetic transformation studies with genes encoding pectin degrading enzymes, such as polygalacturonase or pectate lyase, suggest that the metabolism of pectins is a major event regulating fruit firmness and shelf life. During ripening, pectins are subjected to solubilization, depolymerization and elimination of neutral side chains, being the pectin

solubilization process the change that best correlate with softening. Vegetables generally are firmer and less susceptible to softening than fruit due to the presence of thicker cell walls. The physiological basis underlying textural changes in these vegetables are less known due to the broad range of tissues and organs that comprise this group of products. Some of them suffer cell wall alterations in the pectin matrix that correlate with textural properties. In others, textural changes are more related to senescence and loss of cell turgor.

## Glossary

**Artefact** something observed in a scientific investigation or experiment that is not naturally present but occurs as a result of the preparative or investigative procedure

**Fixation** procedure to preserve cell structures in their current state. Inactivates enzymes that might disrupt cell morphology and toughens cell structures to ensure they do not move or change during staining and observation. Common chemical fixatives include glutaraldehyde, formaldehyde and ethanol.

## Overview

Texture is critical for consumer acceptability of fresh fruits and vegetables. Apples for example should be crisp and firm, however when stored inappropriately, they can become mealy and soft. These and many other textural properties relevant to postharvest and processing behaviour are related to the microstructure of tissue. Tissue microstructure has conventionally been visualized using light microscopy coupled with chemical staining or immunolabelling, or by scanning electron microscopy (SEM) (for examples, see [Ng et al., 2013](#)). These techniques are informative, but often require extensive sample preparation, making them prone to artefacts. This review explores two microscopy imaging techniques and their applications in providing better understanding of fruit microstructure: atomic force microscopy (AFM), revealing the arrangement and changes of cell wall polymers during softening, and X-ray micro-computed tomography (micro-CT), allowing visualization of tissue structure largely in their native state.

## Atomic Force Microscopy (AFM)

### Principle

AFM forms images of surfaces using a physical probe that scans the specimen surface, most commonly either close enough for forces associated with atoms to be detected (non-contact; AC mode) or touching the surface continuously (contact; DC mode) or intermittently (tapping mode) ([Fig. 1](#)). A detailed description of the mechanics of an AFM can be found in [Torre et al. \(2011\)](#). AFM can operate both in air and in liquids. A detailed description of the various operating modes and principles are described in [Kirby et al. \(1996\)](#), [Kirby \(2011\)](#) and [Morris et al. \(2010\)](#). For a guide on AFM experimental design, refer to [Gavara \(2017\)](#).

### Applications

AFM has been used to investigate isolated cell walls, sub-fractions enriched for pectin, or cellulose. During fruit softening, biochemical analyses of cell walls suggested a decrease in frequency of pectin branching and chain length ([Ng et al., 2013](#)). Using AFM, these changes were confirmed on the atomic scale; pectin chains in ripe fruit were shorter and the molecular width decreased ([Paniagua et al., 2014](#)). However, molecular width assessments need to be interpreted carefully, as AFM can be susceptible to artefacts such as from 'probe broadening' effects ([Morris et al., 2010](#)). Other artefacts can be introduced from the way that the sample is prepared; e.g. to expose the cellulose microfibrils for imaging, pectin and hemicelluloses are removed by sequential extraction, resulting in induced aggregation and increased diameter of the observed underlying microfibrils ([Thimm et al., 2009](#)). Example AFM amplitude images (non-contact mode) of apple cell wall microfibrils revealed after pectin removal are shown in [Fig. 2](#). For example deflection images (contact mode), refer to [Thimm et al. \(2009\)](#). For technical issues, practical solutions and a description of common image artefacts, consult [Kirby \(2011\)](#). For in-depth reviews on the application of AFM in plant cell wall polysaccharide studies, refer to [Paniagua et al. \(2014\)](#) and [Wang and Nie \(2018\)](#).

**Table 1** summarizes observations of nanostructural changes in cell wall polysaccharide extracts during softening. **Table 2** summarizes studies using various preparation methods to image cellulose microfibrils in their closest to native form.

**Figure 1** Block diagram of an atomic force microscope. A tip is moved across the sample surface and changes in magnitude of the force between tip and sample are measured and used to produce a three-dimensional profile of the sample's surface. The tip is attached to a flexible cantilever allowing vertical movement. A laser beam is focused onto the back of the cantilever, which reflects onto a position-sensitive photodetector consisting of photodiodes. The difference in electrical potential between the photodiode signals indicates the position of the laser spot, the angular deflection of the cantilever and the respective displacement of the tip, generating a topographical image of the sample.

**Figure 2** AFM amplitude images of 'Scifresh' (also known as 'Jazz™') (ripe, firm) (A) and 'Royal Gala' (ripe, soft) (B) apple cell walls. Native cortex tissue was excised and rinsed with 50 mM CDTA buffer pH 6.5 to remove pectic matrix to reveal the underlying cell wall structures, hemicellulose and cellulose. Apples were harvested at optimum maturity and stored at 0.5 °C for 20 weeks prior analysis. Images were captured using an MFP-3D atomic force microscope (Asylum Research, Santa Barbara, CA, USA) operating on non-contact mode using silicon tip with nominal spring constant of 2.5 N m<sup>-1</sup>, NSG II (ND-MDT CSG II Moscow, Russia). The drive amplitude was set between 2.0 and 4.0 V, with drive frequency between 50 and 100 Hz. The scan size was 5 μm<sup>2</sup>, scan rate 1–5 Hz, and scan angle 0–45°. Images were captured and processed using MFP-3D software running parallel with IGOR Pro v4. The firmer apple 'Scifresh' showed higher frequency of larger diameter fibrils, with mean fibril width of 269 nm, while the softer apple 'Royal Gala' had mean fibril width of 248 nm. For further supporting biochemical analysis, the reader is referred to [Ng et al. \(2013\)](#).

## X-Ray Micro-Computed Tomography (Micro-CT)

### Principle

In Micro-CT, a series of X-ray images is captured as the sample rotates (180° or 360°) and these images are used to visualize the sample in 3D through back projection ([Fig. 3](#)). Micro-CT occurs without destructing samples, as they are scanned under normal

**Table 1** AFM nanostructural observations of cell wall extracts isolated from cell walls of softening fruit

<i>Fruit</i>	<i>Cell wall extract</i>	<i>Observation during postharvest softening</i>	<i>References</i>
Chinese cherry	SSP	SSP became narrower, shorter and less entangled during softening. Crisp cultivar had wider and shorter chains than soft cultivar.	Zhang et al. (2008)
	WSP	Molecular width of WSP and CSP chains decreased.	Lai et al. (2013)
	CSP		
	HC	Higher percentage of thicker HC chains in ripe crisp fruit than soft fruit. HC fibrils regular in ripe crisp fruit but irregular in ripe soft fruit.	Chen et al. (2009)
Tomato	CSP	CSP became narrower, shorter and more linear during softening.	Xin et al. (2010)
Peach	WSP	WSP and CSP chain lengths similar between crisp and soft fruit of two cultivars. Only crisp fruit showed CSP and SSP branching. SSP chains of crisp fruit were significantly longer than those of the soft fruit.	Yang et al. (2009)
	CSP		
	SSP	Controlled-atmosphere conditions inhibited the degradation of WSP and CSP as molecules had a greater width than fruit stored in air. Decrease in amount of branched SSP and reduction in size and number of aggregates observed over storage.	Yang et al. (2005); Yang, Lai, An & Li (2006a); Yang, Feng, An & Li (2006b)
		In unripe fruit, SSP occurred as large aggregates, whereas CSP occurred as single linear chains with less aggregates. SSP chain width decreased with cold-storage time and increasing storage temperatures.	Zhang et al. (2010, 2012)
Chinese jujube	WSP	CSP and SSP molecular width and length decreased with softening.	Wang et al. (2012)
	CSP		
	SSP		
Pear	WSP	Compared to ripe soft fruit, crisp fruit had larger WSP chains, thicker and more branched CSP molecules, a denser network of SSP molecules, and thinner but more homogeneous distribution of hemicellulose molecules that tended to tangle. Cellulose microfibrils were similar.	Zdunek et al. (2014)
	CSP		
	SSP		
	HC		
Carrot	WSP	During cold-storage, CSP and SSP chains decreased in length and width, WSP chains were short overall, and dense SSP network structure disappeared.	Cybulska et al. (2015)
	CSP		
	SSP		
Strawberry	WSP	Widths and lengths of pectin chains reduced during cold-storage. CaCl <sub>2</sub> treatment decreased the degradation of CSP and SSP.	Chen et al. (2011)
	CSP		
	SSP	CSP chains shortened and pectin branching decreased during softening.	Posé et al. (2012)
Apricot	CSP	CSP chain branching and length and HC chain width decreased during cold-storage. CaCl <sub>2</sub> reduced pectin degradation.	Liu et al. (2009); Liu et al. (2017)
	HC		
Chinese quince	HC	Entangled and branched HC chains in ripe fruit. Treating fruit hydrothermally degraded large chain polysaccharides to shorter ones and exposed branched chains.	Liu et al. (2018)

Abbreviations: SSP, ester-bound pectin; WSP, water-soluble pectin; CSP, calcium-bound pectin; HC, hemicelluloses.

ambient conditions without much preparation (Hertog et al., 2012). Coupled with synchrotron radiation, micro-CT is capable of visualizing cell walls (Karahara et al., 2015). Using Micro-CT, tissue porosity, void sizes, void count, shape factor and the degree of cell connectivity can be quantified rapidly and non-destructively, requiring no sample fixation, hence minimizing creation of artefacts. Prolonged scanning times, however, can cause drying out of samples, especially when small. To prevent this, the sample can be coated in a layer of wax, parafilm, or cling-film. For further information on underlying physics, technical background and manipulation and analysis of the data, refer to Landis and Keane (2010) and Karahara et al. (2015).

## Applications

Micro-CT is a powerful tool for non-destructively assessing fruit internal quality and to evaluate internal development of structural changes in a fruit and their relationship with texture. Micro-CT has for example been used to investigate physiological internal

**Table 2** AFM sample preparation techniques and observations of cellulose microfibrils in plant cell walls

<i>Plant material</i>	<i>Sample preparation method</i>	<i>AFM operating mode</i>	<i>Observation</i>	<i>References</i>
Apple Water chestnut Potato Carrot Celery	Tissue homogenized, filtered, re-suspended in sodium dodecyl sulfate and Na <sub>2</sub> SO <sub>5</sub> , ball-milled and frozen. Frozen suspension deposited on mica  (a) Freshly-cut epidermal peel imaged directly (b) Sample freeze-dried and mounted to a metal-disk  CWM isolated using HEPES-buffered phenol and ethanol. Pectin and hemicellulose removed by sequential extraction with chelator and alkali	Imaged in air; DC mode  Imaged in air, water or 50% ethanol; DC mode  Imaged in water; DC mode	No structural changes during freeze-thawing. Microfibrils appear as uniform structures in the order of 25 nm diameter.  Imaged under water, never-dried cellulose microfibrils had diameter of 6–25 nm. With decreasing water content, microfibril diameter increased. Freeze-dried material showed larger microfibril diameter than air-dried material.  Microfibril diameter increased after pectin and HC removal, with tendency to self-associate and form aggregates. Treatment with chelator increased the gaps between microfibrils, and severely disrupted structure and orientation of microfibrils. Treatment with strong alkali restored parallel microfibril orientation.	<a href="#">Kirby et al. (1996)</a>  <a href="#">Thimm et al. (2000)</a>  <a href="#">Thimm et al. (2009)</a>
Cucumber hypocotyls	Samples bisected longitudinally, fixed in paraformaldehyde. Dehydrated in 100% ethanol, critical point dried, and coated with platinum	Imaged in water, PBS buffer, air; DC mode	Cucumber hypocotyls could only be imaged partially-hydrated, with microfibrils around 50 nm in diameter.  Cell walls in the coated samples were similar to fresh, fixed, or partly dehydrated samples. Images showed undulated and meandered surfaces. Dehydration had negligible effect on microfibril organization.	<a href="#">Marga et al. (2005)</a>
Strawberry Peach Rambutan Apple	Tissue blended in acetone, then NaClO <sub>2</sub> + NaOH + acetic acid, freeze-dried. Sonication in water, spread onto freshly-cleaved mica and air-dried  CWM was prepared, and pectin and HC removed by sequential extraction with chelator and alkali. Samples were suspended in 50% ethanol and vacuum-dried onto glass slides	Imaged in air; DC mode  Imaged in air; tapping mode	Cellulose microfibrils were ultrathin and 1–2 nm in width, composed of approximately 10 glucan chains.  After removal of pectin and HC, a fine network of cellulose microfibrils was observed (random orientation for some cultivars, others more aligned). Thicker microfibrils correlated with crisper, harder and juicier texture; softer cultivars had thinner microfibrils.	<a href="#">Niimura et al. (2010)</a>  <a href="#">Cybulska et al. (2013)</a>

Abbreviations: CWM, cell wall material; DC, direct contact; HC, hemicellulose; PBS, phosphate-buffered-saline.

**Figure 3** Diagram of the principle of X-ray micro-computed tomography (micro-CT). Two-dimensional projection images of an object are obtained by using X-ray beams from multiple angles, due to rotation of the object. X-rays passing through the material are detected by a charge-coupled detector. The 2D projections are used to construct a 3D dataset using a set of algorithms, which effectively simulate the back projection of the whole image set to reconstruct the structure that would have given rise to it. Examples of virtual slice images of two different apple cultivars are shown in **Fig. 4**. For example image stacks and 3D reconstruction of ripe apple cortex tissue, the reader is referred to the **Online Supplementary Multimedia Material Movie 1 and 2**, respectively.

**Figure 4** Micro-CT single virtual slice image of 'Scifresh' (ripe, firm) (A) and 'Royal Gala' (ripe, soft) (B) apple cortex tissue. Apples were harvested at optimum maturity and stored at 0.5 °C for 20 weeks prior analysis. Sample preparation and micro-CT imaging as described in [Hall et al. \(2016\)](#). Micro-CT revealed that the firmer apple cultivar 'Scifresh' had greater cell-to-cell connectivity (grey) and lower frequency of intercellular air spaces (black), while the softer apple cultivar 'Royal Gala' showed presence of more intercellular air spaces, that had larger variation of sizes, and that were distributed more uniformly throughout the tissue scanned.

defects or storage-associated disorders in fruit, e.g. translucency in pineapples ([Haff et al., 2006](#)), core breakdown in pears ([Lamertyn et al., 2003](#)), watercore disorder of apples ([Herremans et al., 2014](#)), chilling injury in pomegranates ([Magwaza and Opara, 2014](#)) and bruise volume in apples ([Diels et al., 2017](#)). **Table 3** summarizes the use of micro-CT for investigating microstructural characteristics associated with fruit texture. For an in-depth review on the fundamentals and application of micro-CT in other food structure investigations, refer to [Schoeman et al. \(2016\)](#).

**Table 3** X-ray micro-CT applications on various fruits

Fruit	Sample preparation	Observations during postharvest storage	References
Apple	Excised cylindrical samples placed in plastic tube and wrapped with cling-film	Ripe 'Jazz' apples that were firmer were less porous with smaller intercellular air spaces than softer 'Golden Delicious'.	Ting et al. (2013)
	Excised cylindrical samples in plastic tube	Air spaces at random patterns and with complex distributions in apples after controlled-atmosphere storage. Multifractal Generalized Dimensional Analysis was used to characterise the heterogeneity of pore space structure.	Mendoza et al. (2010)
	Excised cylindrical samples	Development of statistical correlation functions to precisely quantify spatial distribution of cell versus void spaces in apple tissue is presented. Descriptors such as degree of cell connectivity, cell phase and clusters can be used to accurately quantify structure changes over cold-storage.	Derossi et al. (2017)
Apple Pear	As above	Describes an automated analysis of 3D structure to provide numerical microstructural parameters such as cell shape, size, volume, void elongation, void volume, which were used to correlate with effective diffusivity.	Herremans et al. (2015)
Pear	Excised cylindrical samples wrapped in parafilm	Mealy pear fruit were more porous with larger pores compared with non-mealy fruit. Mealy fruit had larger and more oval-shaped cells, while non-mealy fruit cells were more spherical.	Muziri et al. (2016)
Kiwifruit	As above	Fruit with different firmness, weight, soluble solids and dry matter content showed a high variability in porosity and pore size without apparent correlations.	Cantre, East, Verboven et al. (2014a)
Cucumber	As above	Percentage of long and continuous gas-filled intercellular spaces decreased with storage, as water blocked them due to senescing cells.	Kuroki et al. (2004)
Mango	As above + packed in polystyrene foam	Softening was associated with a decrease in pore size and an increase in pore fragmentation and pore specific surface area. Ripe and unripe fruit could be classified correctly using micro-CT, allowing for determining ripeness of fruit non-destructively.	Cantre, Herremans, Verboven, Ampofo-Asiama & Nicolai (2014b)

## Appendix A Supplementary Data

Supplementary data related to this article can be found online at <https://doi.org/10.1016/B978-0-12-814026-0.21680-6>.

## Acknowledgements

We thank Drs. Ian Hallett and Ross Atkinson (Plant and Food Research, New Zealand) for critically reviewing the manuscript, Prof. Richard Haverkamp (Massey University, Palmerston North, New Zealand) for AFM practical guidance, and Michael Loh (Fonterra Research and Development Centre, Palmerston North, New Zealand) for micro-CT assistance.

### Glossary

**Cytoplasm** A clear substance enclosed within the cell membrane, excluding the nucleus.

**Embryo** A rudimentary plant contained within a seed.

**Exalbuminous** Lacking of endosperm at the maturity stage. Most of the endosperm is absorbed by the developing embryo and nutrients are stored in the cotyledons.

**Gelatinisation** An irreversible process of disrupting the crystalline structure of starch granules and solvating the exposed hydroxyl groups of amylose and amylopectin by water molecules in the presence of heat and water.

**Glycemic index (GI)** A classification system for carbohydrate-containing foods based on the postprandial blood glucose response after ingestion of such foods.

**Integument** A protective cell layer surrounding the ovule that develops into the seed coat after fertilisation.

**Organelle** A small, specialised structure within a cell that performs a specific function.

**Ovule** A part of the female reproductive organ of seed plants that develops into the seed after fertilisation.

**Parenchyma** A ground tissue with thin primary cell walls, mainly found in the softer parts of the plant.

**Vascular bundle** A strand of vascular tissue that transports fluids and dissolved nutrients throughout the plant.

### Introduction

Legumes have been cultivated as foods for human consumption since ancient times. They are the edible seeds of leguminous plants in the *Leguminosae* family. Food legumes are classified into two groups of pulses and oilseeds. Pulses are the dried seeds of cultivated legumes, whereas oilseeds are mainly used for their oil content. Food legumes provide an important source of nutrients (i.e. carbohydrates, proteins, lipids, fiber, vitamins and minerals) for people in many parts of the world (Aykroyd and Doughty, 1982). They generally have a low glycemic index (GI) and only produce a moderate postprandial glycemic response following ingestion. Therefore, it is recommended to incorporate legumes as part of the diets for the glycemic management of diabetes (Rizkalla et al., 2002). The low GI characteristic is largely attributed to the cotyledon cell structure, which plays an important role in modulating digestion of starch in legumes (Berg et al., 2012). This article reviews the legume microstructure and its relationship to starch digestion.

### Seed Structure

The structure of a typical leguminous seed is shown in Fig. 1. Embryo constitutes the largest proportion of the mature seed. Seed coat (testa) forms a protective outer shell encapsulating the embryo. The principal structural features of the embryo include cotyledons, a hypocotyl (embryonic axis), and a radicle (embryonic root). Legumes are classified as dicotyledonous or dicots, since the embryo consists of two cotyledons that become a pair of embryonic leaves upon germination. Leguminous seeds are exalbuminous or nonendospermic in nature. Endosperms are present at the rudimentary stage of seed development, however they become vestigial upon maturity. The cotyledons contain the storage reserves of nutrients required for the early growth of the seedling. The external topography of the seed notably possesses two specialised markers residing on the seed coat: a hilum that is a funicular scar left where the seed is formerly attached to the maternal plant during development, and a micropyle that is a minute opening underneath one end of the hilum. Both are involved in controlling water entry to the seed (Stanley and Aguilara, 1985; Yousif et al., 2007).

### Seed Coat

According to Souza and Marcos-Filho (2001), the seed coat derives from the formation of inner and outer integuments surrounding the growing ovule. During seed development, the inner integument disappears while the outer one progresses into several distinct cell layers, forming the seed coat (testa) structure. Despite great variations in composition and microstructure among different legume species, the seed coat fundamentally comprises of four layers (Fig. 2):

---

**Figure 1** Structure of a leguminous seed. Reproduced with permission from: [https://commons.wikimedia.org/wiki/File:Dycotyledon\\_seed\\_diagram-en.svg](https://commons.wikimedia.org/wiki/File:Dycotyledon_seed_diagram-en.svg).

- *Cuticle*: an outermost layer of non-living, non-cellular membrane containing waxy depositions. The cuticle covers the seed, excluding the hilum, and is considered as the primary barrier to seed imbibition.
- *Epidermis*: a single layer of thick-walled and radially elongated macrosclereids or palisade cells. The appearance of a lucent region extending across the macrosclereid layer, also called light-line or *linea lucida*, might be observed due to the local variation in refractive indices of this region in some species.
- *Hypodermis*: a single layer of osteosclereids, also called pillar cells or hourglass cells depending on the pattern of cell thickness and shape. These cells are spaced widely apart and separated by air-filled intercellular spaces.
- *Interior parenchyma*: an innermost part of the seed coat, consisting of 5–12 layers of thin-walled and tangentially elongated parenchyma cells. Upon maturation of the seed coat, these cells lose the protoplast and the innermost layers are crushed, leaving behind disintegrated parenchyma fragments.

## Cotyledons

The cotyledons constitute a significant proportion of the seed weight and volume. These are highly organised structures with major components distributed within discrete cellular compartments (Fig. 3). The periphery of the cotyledons is overlaid with a single layer of epidermis cells. These thick-walled cells are filled with protein and devoid of starch granules. Vascular bundles, containing protein-filled, starch-free cells, are occasionally present in the cotyledons. The cotyledon tissue, for the most part, is made up of large parenchyma cells. The cell walls of two adjacent cells are joined to each other by the pectin-rich middle lamella. A cytoplasmic network fills up the space enclosed within the cell membrane of each parenchyma cell, and surround subcellular organelles including starch granules, protein bodies and oil bodies (Young and Schadel, 1990; Wood et al., 2011). The cotyledon cell microstructure of starch-rich legumes (e.g. beans, peas, chickpeas and lentils) differs greatly from that of oil-rich legumes (e.g. soybeans and peanuts).

## Starch-Rich Legumes

The inner parenchyma cell contains tightly-packed starch granules and small protein bodies that are embedded in a proteinaceous matrix, all encapsulated within a thick, mechanically robust cell wall (Fig. 4). The cell shape and size are highly variable. The cells are spherical, angular, or ellipsoid in shape, and normally range from 50 and 100 µm in size (Berg et al., 2012).

**Figure 2** Transversal section of seed coat structure (left) with a schematic drawing (right) showing four distinctive layers: the cuticle is an outermost layer covering the seed. Underneath the cuticle is the epidermis, which differentiates into macrosclereids (palisade cells). The centre of the seed coat is hypodermis, which differentiates into osteosclereids (hourglass cells). The innermost layer is the interior parenchyma, composed of disintegrated parenchyma layers. ### Oil-Rich Legumes

The cotyledons of oil-rich legumes such as soybeans possess distinctive structures (Fig. 5). At the subcellular level, two major constituents of proteins and lipids are assembled in specialised organelles, commonly called protein bodies (PBs) and oil bodies (OBs) respectively. The PBs are surrounded by numerous OBs, and together they are tightly packed and embedded in a cytoplasmic protein network of the cell (Campbell and Glatz, 2009). Soybean seeds generally contain 43%–48% protein and 18%–21% oil, with the protein content significantly higher than that of other plant-based foods. Starch granules accumulate in the parenchyma cells of the cotyledons during seed development, but rapidly decline to trace quantities with maturation (Stevenson et al., 2007).

### Starch Granules

Starch granules are the primary carbohydrate storage reserve, making up between 22% and 45% of the starch-rich leguminous seeds. The size, shape and surface morphology of native starch granules vary according to legume species and stages of seed maturity. The granule size ranges from 4 to 85  $\mu\text{m}$ . The granule shape is chiefly oval, though in some cases can be spherical, elliptic or irregular. The granule generally has a smooth surface with the absence of fissures (Hoover and Sosulski, 1991). However, the presence of deep fissures can sometimes be observed due to the compact packing of starch granules within the protein matrix (Hsieh et al., 1999). The molecular structure of legume starches is characterised by a mixture of linear amylose and highly branched amylopectin, with a high amylose content (24%–65%). Starch granules possess a semi-crystalline structure that contains both crystalline and amorphous regions. Legume starches typically display a C-type X-ray diffraction pattern (crystallinity), which is a mixture of A-type (cereal starches) and B-type (tuber starches) (Hoover and Sosulski, 1991).

## Protein Bodies

Protein bodies or aleurone grains are typically small, spherical organelles in the size range from 0.1 to 25  $\mu\text{m}$  in diameter. The PBs store up to 80% of the total protein in leguminous seeds, and supply a source of nutrients (i.e. carbon, nitrogen and sulfur) for the future needs of plant growth and development. The PB contains an amorphous protein matrix enclosed by a single lipoprotein membrane. The PB of some legume species contains structural inclusions of globoid crystals embedded in the proteinaceous matrix. The globoid is a phytic acid and cation storage compartment. The two major storage proteins, primarily located within the PBs, are vicilin-type (7S) and legumin-type (11S) globulins (Lott and Buttrese, 1978).

## Oil Bodies

Oil bodies or oleosomes are discreet, specialised organelles. They are usually spherical in shape and smaller than the PBs in size, ranging from 0.5 to 2.5  $\mu\text{m}$  in diameter. Triacylglycerol (TAG) is the predominant form of storage lipids. The structure of an OB consists of a central core of hydrophobic TAG molecules that are encapsulated and stabilised by a phospholipid (PL) monolayer embedded with integral proteins (mainly oleosins). The specific conformations of surface proteins and PL impart remarkable stability to the suspended OBs against destabilisation (coalescence and aggregation) in the aqueous environment of the cytoplasm (cytosol) (Tzen and Huang, 1992). The storage lipids in leguminous seeds are rich in fatty acids, including oleic, linoleic, linolenic acids and palmitic acids. Linoleic and linolenic acids are essential fatty acids that cannot be synthesised by the human body and must be obtained from dietary sources (Stanley and Aguilera, 1985).

## Cell Walls

According to Yousif et al. (2007), the cotyledon cell is enveloped by a thick, rigid, outer cell wall and an inner cell membrane. The cell membrane is a thin, semi-permeable, lipid bi-layer with embedded proteins. Its role is to protect the cellular interior from the outside environment by controlling the movement of ions and molecules in and out of the cell. The cell walls are divided into two classes based upon their mechanical properties and chemical composition: primary and secondary walls. In general, the cell wall comprises of three distinctive layers:

- *Primary wall*: a complex three-dimensional network composed of interacting structural components. The highly ordered, crystalline cellulose microfibrils (organised phase) are dispersed in a continuous noncellulosic matrix (amorphous phase). The matrix phase consists of pectins, hemicelluloses (mainly xyloglucan), and some minor structural proteins. The cellulose – xyloglucan framework acts as a major load-bearing structure, while the matrix of pectic polysaccharides functions as a plasticiser and controls wall porosity.
- *Secondary wall*: a significantly thicker, stiffer and stronger layer due to lignification process as compared to the non-lignified primary wall.
- *Middle lamella*: an intercellular layer, which is rich in pectic substances, cements the walls of adjacent cells together.

The composition of cell walls varies depending on legume species, cell type and developmental stage. In general, the primary wall consists of 9%–25% cellulose, 25%–50% hemicellulose, 10%–35% pectin, and ~10% protein, whereas the secondary wall consists of 41%–45% cellulose, 30% hemicellulose, and 22%–28% lignin (Yousif et al., 2007). The cotyledon cell wall of legumes is characterised to be predominantly composed of a mixture of polymers including arabinose-rich pectins, beta-glucans, galacturonans and xyloglucans (Shiga and Lajolo, 2006).

## Effects of Processing on Legume Microstructure

Food processing induces varying degrees of physical and chemical changes to the legume cotyledon structure, such as gradual plasticisation and solubilisation of pectic components in the middle lamella, leading to separation of intact cells (Tan et al., 2011). Other changes include rapid protein denaturation, partial starch gelatinisation, oil coalescence, disruption of cell wall integrity and release of intracellular substances (Campbell and Glatz, 2009; Berg et al., 2012). Traditional cooking of legumes by soaking, boiling or steaming is required for softening and textural tenderisation of the seeds prior to consumption. The common techniques employed in food legume processing and their effects on the cotyledon structure are summarised in Table 1.

## Effects of Legume Microstructure on Starch Digestion

Starch-rich legumes contain a significant proportion of a slowly digestible starch fraction, which can reduce the rate of starch digestion and lower the postprandial blood glucose response. A small fraction of indigestible starch in legumes, also referred to as physically inaccessible starch or resistant starch (RS), escapes the small intestine and arrives at the large intestine for fermentation by the colonic bacteria, generating beneficial physiological consequences (Tovar, 1996). The slow digestion properties of carbohydrates achieved upon the cooking and consumption of legumes can be attributed to various factors, including intrinsic properties of starch

**Table 1** Common processing techniques and their effects on legume cotyledon structure

Processing	Effects on legume cotyledon structure
Milling to flour	<ul style="list-style-type: none"> <li>• Disruption of cotyledon cells</li> <li>• Rupture of cell walls</li> <li>• Release of intracellular materials</li> <li>• Multi-cell flour particles containing disrupted cells close to the surface and intact cells in the interior</li> </ul>
Cooking in high-moisture environment (e.g. boiling and steaming, autoclaving)	<ul style="list-style-type: none"> <li>• Solubilisation of the pectin-rich middle lamella leading to separation of intact, swollen cotyledon cells</li> <li>• No to little disruption of cell walls</li> <li>• Leaching of soluble materials (e.g. amylose and soluble sugars) out of cells</li> <li>• Rapid denaturation of proteins</li> <li>• Partial gelatinisation of starch granules inside cells and distortion of the granule shape</li> </ul>
Oil extraction	<ul style="list-style-type: none"> <li>• Crushing and degradation of cotyledon cells and cell walls</li> <li>• Distortion of protein bodies and starch granules</li> <li>• Coalescence of oil droplets into larger drops of free oil</li> </ul>

Adapted from Berg, T., Singh, J., Hardacre, A., Boland, M.J., 2012. The role of cotyledon cell structure during *in vitro* digestion of starch in navy beans. *Carbohydr. Polym.* 87, 1678–1688; Campbell, K.A., Glatz, C.E., Johnson, L.A., et al., 2011. Advances in aqueous extraction processing of soybeans. *J. Am. Oil Chem. Soc.* 88, 449–465; and Young, C.T., Schadel, W.E., 1990. Microstructure of peanut seed: a review. *Food Struc.* 9, 317–328.

granules (e.g. amylose content and retrograded amylose), interactions between starch and fibers, and presence of amylase-inhibitors (Thorne et al., 1983). Yet, recent evidence has emerged indicating that rigidity and intactness of cotyledon cell structure is the predominant contributing factor to the and slow glycemic features of legumes (Berg et al., 2012; Brummer et al., 2015).

Previous studies have shown that, during cooking of cotyledon tissues (e.g. boiling and steaming), the cell walls and the protein matrix form physical barriers that impose restrictions on water availability, heat transfer and space, required for the swelling and gelatinisation of starch granules inside cells. Consequently, the progression in granular expansion and deformation is suppressed, and the starches in cooked tissues retain some of their ordered structures evidenced by the presence of residual birefringence under polarised light (Edwards et al., 2015; Hahn et al., 1977). In addition, cooking promotes solubilisation of pectic polymers involved in cell–cell adhesion, followed by separation of intact cotyledon cells rather than cell rupture. Since the strong cell walls cannot be disrupted by cooking and exhibit a high level of resistance towards enzymatic hydrolysis, they remain mostly intact throughout subsequent *in vitro* digestion. Moreover, the partially-gelatinised starch is of too high molecular mass to escape via the cell wall pores and remains encapsulated by the cell walls, its exposure to amylases is therefore reduced to a large extent during digestion. The combined effects of the restricted starch gelatinisation and the enzyme barrier properties of the cell walls cause a retardation in the *in vitro* rate and extent of starch digestion in legumes (Berg et al., 2012). Gelatinisation and digestion behaviours of starch inside individual cells isolated from cotyledon tissues have also been investigated. A single intact cell has been shown to have sufficient capacity to limit *in vitro* starch digestibility by providing an effective cell wall barrier against swelling and gelatinisation of intracellular starch granules as well as starch–amylase interactions (Dhital et al., 2016).

An *in vivo* study on the starch digestion in healthy humans after ingestion of cooked white beans provided further robust evidence. A significant proportion of RS was recovered in samples of ileal digesta (the effluent collected at the end of the small intestine). The ileal content, which was collected 3 hours after meals, contained part of the RS in a physically inaccessible form (trapped within intact cells). The formation of the RS was observed to be largely due to the partially degraded starch molecules that escaped small intestinal digestion due to the effect of plant cell wall encapsulation of starch (Noah et al., 1998).

Drastic food processing can be destructive to the cotyledon cells. Indeed, milling or high pressure treatment can disrupt the cell wall integrity and release the starch granules from the intracellular matrix. This makes the starch more accessible to amylolytic attack, resulting in a significant increase in the starch hydrolysis rate (Berg et al., 2012). Therefore, minimal processing for preservation of the intact cell structure is a crucial strategy for maintenance of the low and slow glycemic features of legumes and targeted delivery of RS to the large intestine.

## Conclusion

In short, food legumes are consumed as an important source of energy for humans. The majority of nutrients are assembled in the parenchyma cells of the cotyledons, and encapsulated within the thick, resilient cell walls. The cell walls serve as a physical barrier

that restricts the swelling and gelatinisation of intracellular starch granules, and impedes the access of amylolytic enzymes to the starch. This, in turn, results in the reduced rate and extent of starch digestion following the ingestion of cooked legumes. The study of legume microstructure can further our understanding of the important role it plays in regulating nutrient digestion, and can lead to better utilisation of food legumes.

# Meat Structure During Processing

Hanne Christine Bertram, Aarhus University, Årsløv, Denmark

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Comminuted meat products** Meat products that are manufactured from meat ingredients and that are reduced in size by means of grinding, chopping, flaking, or mincing. Commminuted meat products include products that have undergone a restructuring or reformulation.

**Differential scanning calorimetry (DSC)** DSC is a thermoanalytical technique, and the fundamental principle for this technique is that when a sample undergoes a physical transformation such as denaturation or phase transition, more or less energy (heat) is needed. For the measurements the difference in the amount of heat required to increase the temperature of a sample and a reference is monitored as a function of temperature. Whether less or more heat must flow to the sample depends on whether the process is exothermic or endothermic.

**Fourier transform infrared (FT-IR) spectroscopy** FT-IR is a technique used to obtain signals in the infrared spectral range. Infrared radiation is emitted or absorbed by molecules when they change their rotational–vibrational movements and thereby contain information about the structure of the molecule. The term Fourier transform infrared spectroscopy originates from the fact that a Fourier transform, which is a mathematical process, is carried out to convert the raw data into an actual spectrum.

**Meat curing** Curing is a processing method where salt or the combination of different salts (e.g., nitrite, nitrate, phosphate salts) is added to meat to reduce water activity and thereby obtain a preservation effect.

**Myofibrillar proteins** Constitute the structural protein skeleton of the muscle cell. Myofibrillar proteins consist mainly of myosin and actin, but other proteins such as titin are also present. The myofibrillar proteins are organized into thick and thin filaments that give rise to a striated appearance of the muscle fiber in a microscope.

**Proton NMR relaxometry** Spectroscopic technique where nuclei such as protons located in an external magnetic field are excited using a specific radiofrequency. The created signal is influenced by the local environment that the nuclei experience, and thereby information about biophysical/biochemical properties of the sample is provided.

## Nomenclature

NMR Nuclear magnetic resonance

SEM Scanning electron microscopy

T<sub>2</sub> relaxation Transverse or spin–spin relaxation

## Curing-Induced Structural Changes

Curing technologies is commonly applied in meat industry to either preserve or enhance meat products. During the process the curing agents (salts) will interact with constituents of the meat and thereby induce structural alterations at the molecular, microscopic, and macroscopic level. At the microscopic level [Offer and Trinick \(1983\)](#) visualized in pioneering work how the myofibrillar structures are modified by curing, which was ascribed to the binding of Cl<sup>−</sup> ions to the myofibrillar proteins with a resultant increased electrostatic repulsion. In their microscopic examinations, [Offer and Trinick \(1983\)](#) also noticed that curing-induced microstructural changes furthermore involve the solubilization of structural constraints in the organization of the myofibrils. This has been corroborated in nuclear magnetic resonance (NMR) T<sub>2</sub> relaxation studies of meat curing, which have confirmed a swelling of myofibrillar spaces caused by a salt-induced solubilization of the myofibrillar proteins ([Andersen](#)

et al., 2007). The analysis of intrinsic water populations in meat by NMR relaxation as a function of curing has also suggested that the separation of myofibrillar and extra-myofibrillar water that exist in fresh meat is disrupted during curing, resulting in the formation of a more “souplike” swollen protein matrix (Andersen et al., 2007).

At the molecular level, probing of protein secondary structures by Fourier transform infrared (FT-IR) microspectroscopy has also revealed that meat curing is associated with the formation of aggregated  $\beta$ -sheet structures in the myofibrillar proteins at the expense of  $\alpha$ -helical structures (Wu et al., 2006; Böcker et al., 2006).

In recent years, attempts have been made to relate curing-induced structural changes at the molecular, microscale, and macroscale level, respectively. Bertram et al. (2008) combined proton NMR relaxometry with confocal laser scanning microscopy (CLSM) and atomic force microscopy (AFM) to identify the associations between detailed structural changes and changes in water–protein interactions and water mobility and distribution. Different curing agents including  $\text{NaHCO}_3$ ,  $\text{Na}_4\text{O}_7\text{P}_2$ , and  $\text{NaCl}$  were examined, and from the CLSM examinations, it was evident that  $\text{NaHCO}_3$  resulted in a much more extensive swelling of the myofibrillar structures (Fig. 1). AFM analyses suggested that the different actions of  $\text{NaCl}$  and  $\text{NaHCO}_3$  could be attributed to less solubilization and more severe protein denaturation after  $\text{NaCl}$  curing. NMR relaxation analyses confirmed that the different curing agents influenced water–protein interactions differently, probably reflecting the differences in structure at the molecular level caused by variations in the effect of curing agent on protein conformations and protein denaturation (Bertram et al., 2008).

### Heat-Induced Structural Changes

Meat commonly undergoes heat-treatment as part of manufacturing or during cooking before consumption. Heat-treatment of meat is a multifaceted process involving several biophysical and chemical changes giving rise to structural changes. At the macroscopic level, an overall shrinkage of structures is seen during heat-treatment of whole meats. Bendall and Restall (1983) studied the physical changes during heat-treatment of myofiber bundles and individual muscle fibers up to 90 °C and found that up to about 63 °C the main physical change is a transverse shrinkage while above this temperature shortening of the muscle fibers also takes place. Later studies have reported similar results (Tornberg, 2005).

At the molecular level, heat will typically cause proteins to lose their native conformation (denature). Thus, the application of a heat-treatment (cooking, boiling, frying) to meat will cause a denaturation of the meat proteins, which is constituted of myofibrillar proteins (myosin, actin), connective tissue proteins (collagen), and sarcoplasmatic proteins. Differential scanning-calorimetry (DSC) has been used to examine heat-induced denaturation of meat proteins (Stabursvik et al., 1984; Bertola et al., 1994). DSC determines the endothermal or exothermal energy generated from a phase transition and can thereby provide information about the denaturation state of a protein. In the analysis of meat, up to four peaks corresponding to four different thermal transitions have been detected in the DSC thermogram (Zielbauer et al., 2016). Several studies have attempted to assign the detected DSC peaks to specific meat protein fractions. However, such an assignment is complicated because intermolecular interactions between the different meat proteins and the molecular environment (pH, ionic strength) will influence the transition temperature of the individual proteins. However, comparison of DSC measurements on isolated protein fractions and intact meat is to some extent plausible, and it is generally assumed that an endothermic peak in the temperature range 45–55 °C is reflecting the denaturation of myosin heads and that peaks in the temperature range 55–75 °C is reflecting the combined denaturation of myosin tails and sarcoplasmatic and collagen proteins, whereas actin denaturation is reflected by an endothermic peak around 72–75 °C (Macfarlane et al., 1981; Stabursvik et al., 1984; Pospiech et al., 2002; Zielbauer et al., 2016).

As the temperature increases, an unfolding of the meat proteins sets in with a resultant loss of their native conformation. When tertiary and secondary structures are severely disrupted, the proteins may aggregate. This phenomenon and other changes in protein secondary structures can be studied by using FT-IR microspectroscopy, which probes the molecular structure based on IR energy absorption of chemical bonds at specific frequencies related to molecular vibrations. FT-IR studies have revealed that heating of meat is accompanied by an increase in aggregated  $\beta$ -sheet structures at the expense of a decrease in  $\alpha$ -helical structures (Kirschner et al., 2004; Wu et al., 2007).

Meat is comprised by approximately 75% water, and the heat-induced structural changes in the meat proteins will concomitantly influence intrinsic protein–water interactions. Several studies have probed these heat-induced changes in protein–water interactions in meat by low-field proton NMR relaxometry (Fjellkner-Modig and Tornberg, 1986; Borisova and Oreshkin, 1992; Bertram et al., 2004; Christensen et al., 2011). Intriguingly, dynamic NMR relaxation measurements conducted during heating of meat have revealed that the water–protein interactions undergo substantial changes at 43 °C and 56 °C (Micklander et al., 2002; Bertram et al., 2005). These major shifts in water–protein interactions have been attributed to the onset of myosin denaturation and collagen denaturation, respectively, where the latter causes structural constraints and shrinkage (Bertram et al., 2005). A study combining DSC measurements and proton NMR relaxometry during meat cooking has confirmed a close relationship between meat protein denaturation and changes in protein–water interactions and intrinsic water mobility and distribution in the meat (Bertram et al., 2006).

## Structural Elucidation of Comminuted Meat Products

Comminuted meat products represent a major proportion of processed meat sold in retail. Typical product types include sausages manufactured by the addition of various ingredients to enhance and optimize functional attributes, texture, and taste. These comminuted meat products are traditionally based on raw materials with a relatively high fat content and/or addition of lard and typically contains 20%–30% fat and high water content as well. In the manufacturing of comminuted meat products, the addition of salt to the beef patties will solubilize the meat proteins, which will then act as a “glue” to stabilize the matrix. During a subsequent heat-treatment, the solubilized meat proteins will assist to form a continuous network with the fat particles and other coarse ingredients incorporated. The exact role of the proteins in the formation of a comminuted meat product has been subject for investigations, and different models have been proposed. Thus, it has been proposed that the structure of comminuted meat products can be considered and explained as a matrix exhibiting behavior as an emulsion with fat in a protein solution where the solubilized meat proteins act to stabilize the fat–water interface. The structure of comminuted meat products has also been explained based on a model of physical entrapment of fat particles and other coarse ingredients within a protein gel matrix formed during heat-treatment where an interfacial film made of meat proteins may surround the fat particles to stabilize these and hinder their coalescence (Gordon et al., 1992). A combination of CLSM and scanning electron microscopy (SEM) for examination of the structure of comminuted meat products coupled with detailed analyses of fat and water retention (determined gravimetrically) has revealed that although an interfacial film of protein forms at the surface of fat droplets, it is the intrinsic structure in terms of pore characteristics (pore size and distribution in the network) that is decisive for fat and water retention in a comminuted meat product (Liu et al., 2016).

Over the last decade, an increasing awareness of a strong link between dietary patterns and human health has emerged, and concern in relation to how intake of especially processed meat products affects our health has also arisen. Consequently, even though it is still a matter of dispute what role animal fat plays in relation to lifestyle diseases (Astrup et al., 2011; Lawrence, 2013), an interest in fat replacement or enrichment of comminuted meat products with health-promoting ingredients such as dietary fiber has emerged. Components that have been investigated as fat replacers in comminuted meat products include a variety of hydrocolloids, modified starches, and dietary fibers. A major challenge with fat reduction of meat products is to maintain the same textural attributes (Claus, 1991; Weiss et al., 2010). In this context, it is essential to understand how the intrinsic meat components as well as added ingredients influence matrix structure to be able to obtain a product that meets consumer satisfaction. Gibis et al. (2015) investigated how the use of carboxymethyl cellulose (CMC) and microcrystalline cellulose (MCC) as fat replacers influences the microstructure of fried beef patties. Using CLSM, Gibis et al. (2015) found that CMC and MCC exhibited very different effects on the microstructure of the beef patties. Even at a concentration of 1% (w/w) CMC, severe changes in the structure of the protein network were observed during frying. And at higher concentrations of CMC, a highly porous and uneven network was observed, revealing a low incorporation of CMC fibers into the protein-formed network. In contrast, MCC could be added in concentrations up to 3% (w/w) without negatively influencing the microstructure of the fried beef patties, and MCC displayed a much better capability for incorporation in the network formed by the meat proteins (Gibis et al., 2015). However, studies on other comminuted meat products have shown that the addition of CMC is very efficient in reducing moisture loss during heat-treatment (Barbut and Mittal, 1996; Han and Bertram, 2017). Dynamic NMR relaxation measurements during heat-treatment of a model meat system added a range of different fibers revealed that in the temperature range between 60–70 °C, the expulsion of water located in myofibrillar spaces was counteracted better by the addition of CMC than any other of the tested fibers (Han and Bertram, 2017). NMR relaxation measurements have also been used to indirectly probe the structural features at the molecular level in the study of addition of other components to comminuted meat products. A recent study investigated the addition of cassava starch to pork sausages, and proton NMR relaxometry could reveal that cassava starch addition increased the proportion of water located within the myofibrillar protein matrix (Zhang et al., 2014).

In addition to fat replacement with carbohydrate-based components, fat in comminuted meat products may also be substituted with alternative, healthier fat types. Thus, substitution of fat with olive oil (Ruiz-Capillas et al., 2012) and canola oil (Barbut et al., 2016) incorporated in a gel matrix has been investigated in Frankfurter-like sausage types. Structural features and interactions between protein and lipid constituents were investigated using Raman spectroscopy (Herrero et al., 2014). Raman spectroscopy showed that fat replacement with the olive oil bulking agent was associated with an increase in the amount of  $\beta$ -sheet structures (band at 1620–1720  $\text{cm}^{-1}$ ) in the proteins. This finding is likely reflecting the formation of aggregated intermolecular  $\beta$ -sheet structures, which has been found to be associated with network formation accompanied by a firm texture (Herrero et al., 2014). Specific Raman bands originating from lipid molecules also revealed differences in the structure of the lipids associated with fat replacement with the olive oil bulking agent that could indicate enhanced lipid–protein interactions in the reformulated product (Herrero et al., 2014).

## Concluding Remarks

The introduction of advanced spectroscopic and microscopic techniques in meat research has enhanced our understanding of meat structural characteristics at both the molecular and microscopic level. It is anticipated that these techniques will be advantageous in future where meat industry likely will be facing increasing demands for new, healthier product solutions. Such a demand will entail

product developments that require a comprehensive understanding of associations between raw material and ingredient properties, structural and functional attributes, and product texture and taste.

# The Structure and Properties of Eggs

Danaé S Larsen, Food Science Consultant, Zurich, Switzerland

© 2019 Elsevier Inc. All rights reserved.

## Structure of an Egg

The predominant function of an egg is a vessel for a developing embryo. At the centre of an egg is the yolk, surrounded by the egg white (albumen) and membranes within a hard calciferous shell. The yolk forms and develops in the ovary of the avian female and is released into the oviduct following ovulation, where it develops further, with first the albumen and then the shell membranes and shell deposited (Chambers et al., 2017). In a chicken egg, the albumen accounts for most of the mass at approximately 60%, followed by the yolk, 30% and the shell at 10% (Chambers et al., 2017).

The components inside the egg are organised by membranes. Two closely adhering membranes; the inner and outer shell membranes are composed of a network of various protein polysaccharide fibres (Belitz et al., 2009). These act as a barrier against bacteria, separate the albumen and shell, provide the scaffolding for shell formation in the oviduct and form a pocket of air between themselves, known as the air cell. The air cell is formed at the blunt end of the egg by the cooling and contracting of egg contents in the oviduct (Chambers et al., 2017). It is initially 5 mm in diameter, but this increases upon storage and provides a useful marker for estimating the age of an egg (Belitz et al., 2009).

The egg yolk is held in the centre of the egg by opaque twisted albumen 'ropes', which twist clockwise at the blunt end of the egg and counterclockwise at the tip. When an egg is cracked open, the chalazae separate from the albumen and remain with the yolk. On one side of the yolk, there is a latebra on which the blastoderm or germinal disc is found. The yolk is composed of plasma and granules (Guha et al., 2018) and is prevented from leaking into the albumen by the transparent vitelline membrane (Chambers et al., 2017) (Fig. 1).

## EggShell

The eggshell is essential for avian breeding and has three main functions; to protect the egg from the outside environment, to control water and gas flow during chick development and provide calcium for chick development after the yolk stores have been exhausted (Nys et al., 2004). It is a porous semi-permeable structure, which is, comprised mainly of calcium carbonate (94%) (Chambers et al., 2017). The shell can be divided into 4 parts; cuticle or bloom, spongy layer, mammillary layer and pores. The cuticle is the thinnest and outermost layer, approximately 10 µm and is composed of mucilaginous protein (Belitz et al., 2009). The spongy layer makes up the bulk of the shell thickness and is cemented to one side of the mammillary layer, with the other side of the mammillary layer adhered to the shell membrane (Belitz et al., 2009). Pores allow for the limited flow of gases in and out of the shell while the cuticle serves as a barrier against microorganisms, dust and debris (Chambers et al., 2017). The composition of the shell provides a protective environment for the developing embryo.

Eggshells vary in colour, generally due to the need for environmental camouflage dependent on the birds habitat. Domestic chicken shells are generally white or brown but some genotypes of hen produce blue and green eggs (Chambers et al., 2017). Duck eggs vary from white through blue and green, whereas many wild birds and game birds; quail, pheasant, guinea fowl for example lay spotted eggs. It has been observed that Japanese quail seek out substrates to lay their eggs based upon those that provide

**Figure 1** Schematic cross-sectional diagram of a chicken egg modified from (Belitz, Grosch, & Schieberle, 2009). 1 germinal disc (blastoderm), 2 yolk membrane, 3 latebra, 4 light colored yolk layer, 5 dark colored yolk layer, 6 chalaza, 7 egg white (albumen) thin gel, 8 albumen thick gel, 9 pore, 10 air cell, 11 shell membrane, 12 inner egg membrane, 13 shell surface cemented to the mammillary layer, 14 cuticle, 15 spongy calcareous layer.

the most camouflage. A study by Lovell et al. (2013) showed that the selection of laying substrate by the females was influenced by the degree of egg maculation (or spots on the eggshell), with females choosing laying substrate that matched the degree of maculation of their own eggs. This suggested that these quail inherently “understood” their own eggshell patterning and were able to choose substrate for optimal camouflage based upon their own phenotype. In the commercial sector, the colour of chicken eggs does drive regional consumer demand although there are no differences in the quality and sensory properties of the egg such as taste, based on its colour (Bell, 2002).

### Egg White (Albumen)

Accounting for the bulk of the volume of an egg, the albumen is an aqueous solution of various globular proteins, transparent with a yellow tint in colour. Albumen is 88% water, 11% protein, 1% carbohydrates and trace amounts of lipids (<1%) (Kovacs-Nolan et al., 2005). Both thin and thick albumen are present in the egg, with the latter differing in viscosity due to an increased presence of ovomucin protein. Albumen from a freshly laid egg has a pH of 7.6–7.9 and during storage increases to 9.7 because of solubilized CO<sub>2</sub> diffusing through the shell (Belitz et al., 2009). There are several important proteins present in albumen, these include the major proteins; ovalbumin, ovotransferrin, ovomucoid, lysozyme and ovomucin and the minor proteins; avidin, cystatin, ovomacroglobulin, ovoflavoprotein, ovoglycoprotein and ovomucoid. Of these proteins, the most abundant is ovalbumin, a phosphorylated glycoprotein, which accounts for 54% of the total protein in egg white (Kovacs-Nolan et al., 2005). Ovalbumin is denatured quite easily during whipping or vigorous shaking of its aqueous form (Belitz et al., 2009), a property of great use in the food industry when making whipped desserts, souffles, baking etc. The proteins in albumen exhibit biological activity, many of which are related to protecting the egg from spoilage microorganisms. They act as enzymes, for example, lysozyme, as enzyme inhibitors in the case of ovomucoid and ovomucoid, as well as complex-forming agents for coenzymes, for example, flavoprotein and avidin (Belitz et al., 2009).

### Egg Yolk

The egg yolk is a complex system containing a number of insoluble suspended particles, approximately 0.3–2 µm in size (granules) in a clear-yellow fluid (plasma) (Guilmineau and Kulozik, 2006). It is an oil-in-water emulsion composed of lipids (65%), proteins (31%), carbohydrates, vitamins and minerals (4%) by dry weight (Belitz et al., 2009). Yolk plasma accounts for 80% of the yolk fraction (Freschi et al., 2011) and is comprised of 85% low-density lipoproteins (LDLs) and 15% globular glycoproteins, predominantly α-, β- and γ-livetins (Laca et al., 2015). The granules on the other hand consist of High-density lipoproteins (HDLs) (70%), phosphatidylcholine (16%) and LDLs (12%) (Anton, 2013; Belitz et al., 2009).

## Functional Properties of Eggs

### Nutrition

Eggs from many different birds are a staple of the human diet and are consumed worldwide. The Food and Agriculture Organization of the United States (FAO), estimates that to 8.9 kg of eggs are consumed per capita, per year worldwide, amounting to approximately 167 eggs per person, per year. This corresponds to an increase of 41% since 1990 and global egg production is now in excess of  $6.5 \times 10^7$  ton per year (FAO, 2016).

Reasons behind the popularity of eggs is that they are often called a ‘complete food’ as they contain many essential nutrients (Table 1) and are versatile with numerous uses as a meal on their own or an ingredient in sweet and savory foods (Song and Kerver, 2000). They are inexpensive, accessible to most people and are an important source of high-quality protein (Chambers et al., 2017). The average chicken egg contains over 6 g protein and is a source of the 9 essential amino acids for human health (Lunven et al., 2007).

Eggs contain the fat soluble vitamins A, E, K and D as well as B vitamins and are a good source of B2 and B12 (Chambers et al., 2017). They contain many essential minerals and also antioxidants. Carotenoids, specifically xanthophylls, lutein and zeaxanthin to name a few, are absorbed from the hens feed and are responsible for the colour of the yolk, the feed can be manipulated in terms of the carotenoid type and content to intensify the yolk colour (Belitz et al., 2009).

The lipid profile of chicken eggs contains the essential long-chain polyunsaturated fatty acids (LCPUFA), docosahexaenoic acid (DHA), eicosapentaenoic acid (EPA) and also arachidonic acid. EPA and DHA have many proven health benefits, in areas such as cardiovascular, brain and eye health (Fraeye et al., 2012). The amount and type of LCPUFA in eggs can also be modulated through the feed.

Eggs do contain a high amount of cholesterol, approximately 200 mg and thus they have been vilified in the past and the subject of many health warnings (Brown and Schrader, 1990), however, cholesterol is essential for normal function of the human body and nowadays guidelines indicate that in moderation eggs are a good food choice as part of a balanced diet (HHS and USDA, 2015).

**Table 1** Nutrient composition of 1 whole fresh egg

Overall, the nutrient composition of the egg remains relatively consistent among its own species but differences in diet, age of the chicken and environment can alter the composition somewhat ([Rizzi and Marangon, 2012](#)).

### Physicochemical Properties

Eggs exhibit a range of properties that are of use in the food industry. Eggs can be used to impart colour in foods such as fresh egg pasta or to add a distinct aroma or flavor such as in egg liquors. However, their most important functions are; emulsifying, foaming (whipability) and heat or pH induced coagulation, which will be briefly discussed here.

### Emulsification

An emulsion of two immiscible liquids such as oil in water where oil droplets are dispersed throughout a water phase often requires an emulsifier for stability. Egg is used as an emulsifier in a range of products, most commonly in mayonnaise and salad dressings. Both the egg yolk and whole egg have good emulsifying properties, due to the high proportion of LDLs and proteins that are present ([Anton et al., 2001](#)) and are used in the food and pharmaceutical industries. For industrial applications the egg yolk in its entirety can be used as an emulsifying agent or separated into granules (the precipitate) and plasma (the supernatant) by way of a fractionation method of dilution and centrifugation. Plasma shows the better emulsification properties compared to granules ([Anton, 2013](#)), however, granules are thermally stable, with greater heat-resistance than plasma. Seeing as protein solubility is also related to emulsifying properties, the greater heat sensitivity of plasma causes protein solubility to decrease when the temperature reaches 69 °C and a concurrent increase in viscosity is observed ([Le Denmat, Anton and Gandemer, 1999](#)). This makes granules a good option as an emulsifier in products that undergo pasteurization ([Anton, 2013](#)). From a nutrition standpoint using separated granules instead of the whole yolk decreases the total cholesterol content ([Laca et al., 2010](#)).

### Coagulation or Gelation

The coagulation properties of eggs make them effective binding agents and have applications in a range of food products ([Belitz et al., 2009](#)). Egg protein coagulation is a heat and pH dependent process, which is key to a range of physical and sensory properties in a variety of products. The proteins in egg white start to coagulate first at approximately 62 °C and the egg yolk at 65 °C and if pH is modified the egg white can also form a gel at room temperature at approximately pH 11.9 ([Belitz et al., 2009](#)).

When heat is applied to egg, the proteins undergo a conformational change and become partially denatured followed by aggregation of the denatured proteins. This causes an exponential increase in viscosity and the development of a continuous gel network, which needs to occur slowly to ensure a well-organized network, not a random network, which is prone to syneresis ([Phillips et al., 1994](#)). Formation of the network is due to the creation of covalent linkages, modifications to the thiol group-disulfide linkages and hydrophobic interactions ([Phillips et al., 1994](#)).

## Foaming

A foam is a 2-phase liquid-air system in which the mechanical action of whipping entraps air in a dispersed phase, increasing surface area and denaturing proteins. These denatured proteins form a thin layer, the surface phase (Li et al., 2018). The foaming properties of whipped egg white makes it an excellent leavening agent and thus a key ingredient in various foods (Belitz et al., 2009) such as soufflés, meringues, and cakes. Foaming agents must have the ability to rapidly adsorb at the air–water interface, experience conformational change at the interface and through intermolecular interactions form a cohesive viscoelastic film (Du et al., 2002). The physiochemical properties of the foam and its resulting stability are dependent on a number of factors including; microenvironment, temperature and composition of the solution (Ahmed et al., 2003; Bovskova and Míková, 2011).

The foaming characteristics are different between the different albumin proteins and in terms of importance in foam formation and stability can be ranked as follows: ovalbumin, ovotransferrin, lysozyme, ovomucoid, and ovomucin (Du et al., 2002). The superior foaming properties of Ovalbumin in particular, are enhanced by mild heat treatments, where its native rigid conformational state changes to an intermediary molten globule (partially unfolded stable) state, which due to its greater surface hydrophobicity and flexibility exhibits greater foam stability (Relkin et al., 1999). However, if heating increases, the intermediary becomes unstable and reaches the point of coagulation, causing a decrease in foaming ability (Relkin et al., 1999). The whipability of egg white is measured by the volume of foam and its stability over time, if the eggs are not separated cleanly, significant reduction in foam formation occurs even with as little as 0.1% yolk present (Belitz et al., 2009).

However, the yolk itself also has the ability to form foams, albeit with different properties to egg white foams. A stable foam of 6-fold volume increase is possible in egg yolk at elevated temperatures, 72°C producing the best results (Belitz et al., 2009). Heat stable sauces frequently use egg yolk as a foaming agent. Protein coagulation (and thus foam volume reduction), which occurs if temperatures increase further can be inhibited by the addition of a pH lowering ingredient, often acetic acid (Belitz et al., 2009).

## The Egg Industry

### Eggshell Waste

The eggshell and membranes account for approximately 10.2% of the whole egg and is a major waste product of the food industry (King'ori, 2011). Concern is growing on how to curb eggshell waste as costs involved in safely disposing eggshells are high due to their classification as a hazardous waste product (Laca et al., 2017). The two components of the eggshell; the shell itself and the shell membrane have different properties that can be exploited as useful byproducts in a range of industries.

The eggshell is a good source of calcium which can be easily extracted and used as a powdered calcium supplement (Brun et al., 2013) for humans and in animal feed. It is also commonly used in fertilizers and as a soil stabilizer (Amu et al., 2005). Eggshells have a history of being used as an adsorbent for heavy metals and organic dyes (Guru and Dash, 2014). As well as being used as a calcium source for making bioceramics (Balázi et al., 2007), composite fillers (Toro et al., 2007) and as environmentally friendly catalysts in industrial processes such as biodiesel production (Shan et al., 2016) for example. More recently in the medical field, eggshells have been successfully used in the development of advanced materials such as hydroxyapatite for bone tissue repair (Ramesh et al., 2016). Other potential applications make use of the eggshells natural UV protection (Maurer et al., 2014), where a study by Fechey-Lippens et al. (2017) found that chicken eggshells help to protect polystyrene and nylon from UV damage.

Shell membranes mainly consist of type I, V and X collagen (Arias et al., 1992) and this can be extracted and used in a number of applications in the food, cosmetic, biochemical and pharmaceutical industries. Components of eggshell membrane have been used as biosensors (Zhang et al., 2007) and biotemplates (Liang et al., 2014) to name a few applications.

### Future Prospects of the Egg Industry

Eggs are a key part of the human diet and have a wide range of applications as a food ingredient and in other industries. Due to their popularity the increasing production of eggs to meet consumer demand has and will continue to lead to increased amounts of hazardous waste. However, the range of uses for eggshells mentioned here offers just a small insight into the endless possibilities of adding value to eggshell waste and in doing so increasing the sustainability of the egg industry. This would provide solutions for the estimated 8 million tonnes of eggshell waste that are currently produced each year (De Angelis, Medeghini, Conte and Mignardi, 2017).

### Introduction

The shellfish processing industry has seen significant expansion in the past few decades and each year production rates are several thousand tons. This industry generates a significant amount of biowaste, i.e., mainly heads and exoskeletons, that may represent around 50%–70% of the initial weight (Nguyen et al., 2017). Crustacean waste is mainly organic matter (60%) with the remaining waste being the discarded shells and carapaces of crabs, lobsters and prawns (Pfeiffer, 2003). Usually the edible part of crustaceans only represents 20%–25% which leads to the unavoidable generation of waste (Jayathilakan et al., 2012). Currently, they may be discarded at sea, burned, landfilled, or simple left out to spoil. Each of these techniques can create environmental hazards (Bellich et al., 2016). Unfortunately, this suggests that valuable compounds such as chitin, proteins, and carotenoids are lost in the absence of further processing (Jaswir et al., 2011; Gortari and Hours, 2013; Senevirathne and Kim, 2012; Lodhi et al., 2014).

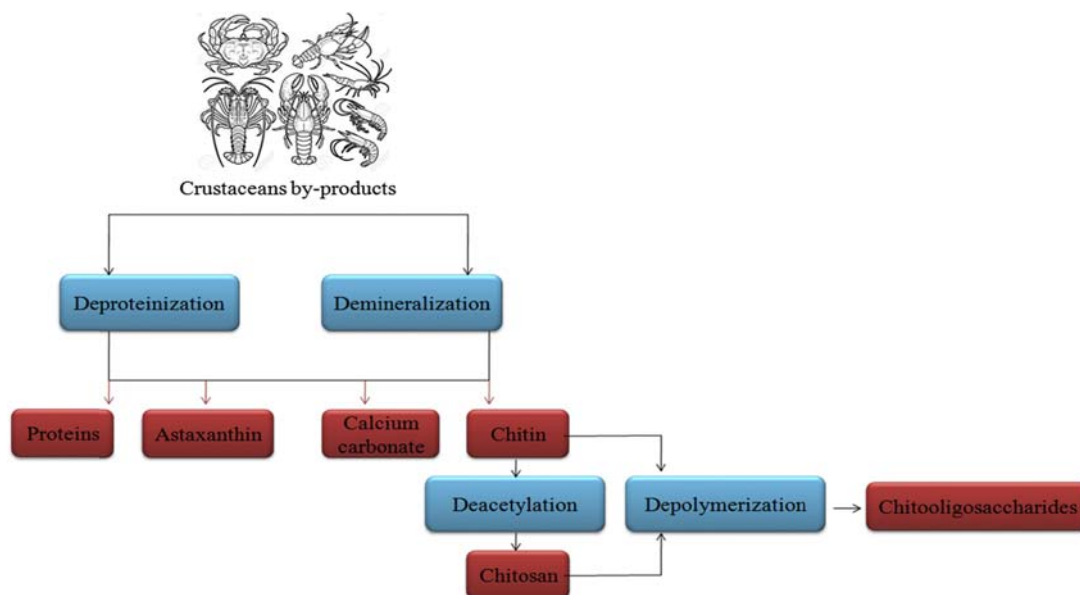

Chitin and its derivatives are non-toxic, biocompatible and biodegradable compounds that have many biological activities including antioxidant, anti-cancer, anti-microbial and anti-coagulant activities (Cheung et al., 2015; Azuma et al., 2015). In addition to the chitin, the waste stream is also rich in other compounds of high nutritional value and functionality including proteins, which can be up to 40% of the total waste weight, as well carotenoid pigments, mainly astaxanthin, which are responsible for the typical crustacean orange colour and are well known for their high antioxidant functions (Arancibia et al., 2014).

Underutilization of crustacean by-products not only leads to loss of potential profits but also requires paying disposal costs (Ospina Álvarez et al., 2014). Therefore, the industry has begun to develop technologies to make use of this waste and produce value-added compounds (Malaweera and Wijesundara, 2014).

This chapter identifies opportunities to develop value-added products from crustacean-processing by-products with different biological activity such as antioxidant, antibacterial and antifungal properties. Crustacean by-products such as chitosan are characterized by high antibacterial and fungicidal activities.

### Bioactive Compounds From Crustaceans and Their Biological Activities

From an economical point of view, it would be quite profitable to recover the by-products released from crustacean processing. The shell waste consists of the head, shell, and tail portions of crustaceans (Nguyen et al., 2017). Crustacean by-products include proteins, chitin, astaxanthin, and calcium carbonate (Fig. 1). Many studies have indicated that chitin, chitosan, and their derivatives

**Figure 1** Extraction of valuable compounds from crustacean by-products.

are biologically active polysaccharides. Potential uses in agriculture, water treatment, cosmetics, and the food and pharmaceutical industries are shown in [Table 1](#) ([Cheung et al., 2015](#); [Mao et al., 2017](#)).

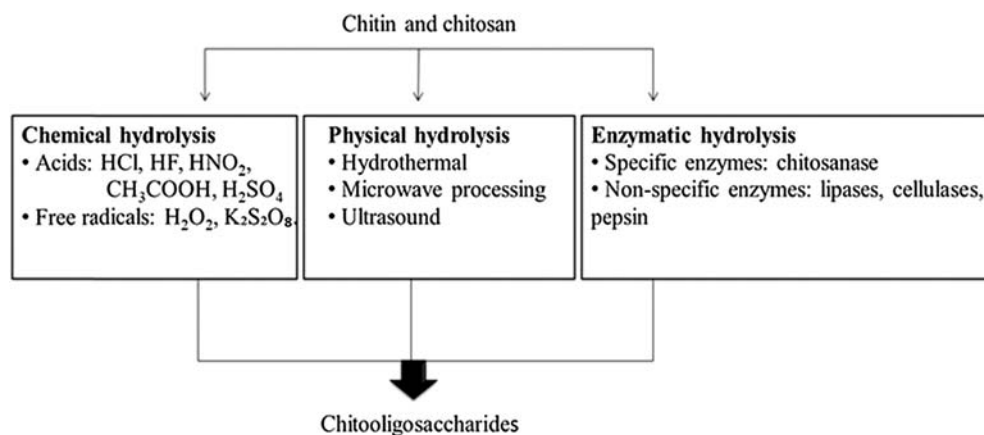

Chitin and chitosan are very abundant natural polymers with distinctive properties, such as bioactivity, biocompatibility and biodegradability ([Fenice, 2017](#)). The use of chitin and chitosan in food applications may involve the formation of biodegradable films and the preservation of food against microbial deterioration due to their antimicrobial activity. Chitosans have applications as coatings in meat and seafood products to prevent lipid oxidation, microbial growth and moisture loss. Chitosans also have pharmaceutical, medical, paper production, textile, wastewater treatment, biotechnology, cosmetics, and agriculture applications ([Bashar and Khan, 2013](#)). Currently, chitin and chitosan cannot be competitively produced using chemical synthesis or biotechnology and are, therefore, sourced from animals, usually from crustacean shells ([Vázquez et al., 2017](#)).

### Chitin and Its Derivatives (Chitosan and Chitooligosaccharides)

Chitin ( $C_8H_{13}O_5N$ )<sub>n</sub> is the second most abundant biopolymer on earth following cellulose. Chitin is a cellulose-like polysaccharide, which is a linear poly- $\beta$ -(1,4)-N-acetyl-D-glucosamine ([Anastopoulos et al., 2017](#)). It is a highly hydrophobic compound that is odourless and tasteless with a white or yellowish colour ([Kumar, 2000](#)). It can be solubilized in a few solvents such as fluorinated solvents (hexafluoroisopropanol, hexafluoroacetone), and chloroalcohols in conjunction with aqueous solutions of mineral acids, and dimethylacetamide containing 5% lithium chloride ([Sudha et al., 2017](#)). Chitin can be obtained from various sources including the exoskeletons of arthropods (insects, crustaceans, and arachnids) and molluscs (beaks and endoskeleton of cephalopods). Other organisms also produce chitin such as in the cell walls of fungi and yeasts, and the spines of diatoms ([Sharp, 2013](#); [Younes and Rinaudo, 2015](#)). The main natural sources of commercial chitin are crustacean shells including lobster, shrimp and crab shells ([Elieh-Ali-Komi and Hamblin, 2016](#)). Chitin occurs in nature in three polymorphic forms which are ordered crystalline microfibrils:  $\alpha$  chitin (anti-parallel strands),  $\beta$ -chitin (parallel chains), and  $\gamma$ -chitin (combination of  $\alpha$  and  $\beta$  structures) ([Khoushab and Yamabhai, 2010](#)).

Through partial chemical or enzymatic deacetylation, chitin can be converted to its most well-known derivative, chitosan. Chitosan is the N-deacetylated derivative of chitin. Chitosan contains copolymers of D-glucosamine (deacetylated units) and N-acetyl-D-glucosamine (acetylated units) linked by  $\beta$ (1,4)-glycosidic bonds. Therefore, the degree of deacetylation is generally defined by the glucosamine/N-acetyl glucosamine ratio. Chitosan is considered to be polycationic, nontoxic, biocompatible, and biodegradable.

Chitooligosaccharides (COS) are products of chitin and chitosan hydrolysis ([Fig. 2](#)). Depolymerisation to produce chitooligosaccharides can be achieved using different physical methods such as hydrothermal methods, microwave processing, ultrasound, chemical methods using acids, and enzymatic methods ([Montilla et al., 2013](#); [Jung and Park, 2014](#)). There is an increasing interest in COS because they are more suitable for some industrial applications because of their low molecular weights, low viscosity, and short chain lengths. Besides their water solubility properties, COS are also reported to have excellent biological properties: cholesterol lowering, antibacterial, antitumor, and immuno-enhancing effects ([Park and Kim, 2010](#)).

**Figure 2** Formation of chitooligosaccharides.

### Extraction of Chitin

The inedible parts of crustaceans (heads, shells, and tails) are considered excellent for chitin extraction (Younes and Rinaudo, 2015). Both chemical and biological methods are used to obtain chitin from crustacean waste (Pachapur et al., 2016). Crustacean by-products can be washed, dried, and size reduced (crushed or ground into a powder). The chemical method involves three steps to produce chitin (Pal et al., 2014):

- Demineralisation with an acidic treatment (generally HCl) to remove minerals (calcium carbonate and calcium phosphate), deproteinisation, and decolouration.
- Further deproteinisation with an alkali treatment (NaOH) to eliminate proteins from the demineralized shells.
- Further decolouration with acetone or organic solvent mixtures to remove the pigments including carotenoids to obtain colourless products.

The use of organic solvents can be a source of environmental concern and also damage other valuable compounds in the waste and limit the isolation of pigments and proteins (Paul et al., 2015). Therefore, enzymatic and biological treatments have been developed. The biological treatment consists of a fermentation of the crustacean biowaste using different bacteria (*Pseudomonas aeruginosa*, *Lactobacillus plantarum*, *Lactobacillus paracasei*, *Bacillus subtilis*, and *Serratia marcescens*) (Vázquez et al., 2013). For the demineralisation of crustacean shells, lactic acid-producing bacteria have been used while proteases from bacteria have been employed for the deproteinisation (Kandra et al., 2012).

### Carotenoids Components From Crustacean By-Products

Carotenoids are a group of natural pigments, coloured red, yellow or orange, that are widely distributed in nature. They are responsible for the different colours of fruits (e.g., tomato, cantaloupe, mango, and pumpkin), vegetables (e.g., carrots, broccoli, and spinach), and other plants (Raja et al., 2007). There are more than 600 known carotenoid structures described in the literature. Carotenoid pigments are potent antioxidants and they have the ability to act as pro-vitamin A, i.e., they can be converted into vitamin A in the human body. Carotenoids have other bioactivities with some evidence of being protective against cancer, aging, ulcers, cataracts and macular degeneration, heart attack, and coronary artery disease (Ibañez et al., 2011; Mezzomo and Ferreira, 2016). Carotenoids are also commonly used in food products as food-colouring.

Carotenoids are lipophilic compounds that include astaxanthin,  $\beta$ -carotene, lutein, lycopene, and zeaxanthin. Carotenoids have commercial value not only as food colourants or feed additives, but also as health promoting components, which are associated with their antioxidant properties.

Astaxanthin is a red fat-soluble pigment that was approved by the United States Food and Drug Administration and the European Commission as a food dye and food colourant in animal and fish feeds (Ambati et al., 2014). Astaxanthin (3,3'-dihydroxy- $\beta$ - $\beta'$ -carotene-4,4'-dione) is the main ketocarotenoid responsible for the red-orange colour in salmonids and crustacean. Astaxanthin is also naturally present in the microalgae *Haematococcus pluvialis* and in the yeast *Xanthophyllomyces dendrorhous*. Most of the astaxanthin found commercially is produced synthetically. Therefore, crustacean by-products, which are generally discarded, represent an important potential source of natural astaxanthin (Seabra and Pedrosa, 2010). In crustaceans, astaxanthins are found in a free form or complexed to proteins known as carotenoproteins. Astaxanthin content in crustaceans varies depending on species, season, and environmental grown conditions (Cahú et al., 2012; Nguyen et al., 2017).

Carotenoids are not synthesized *de novo* in animals. Thus, they are directly accumulated through the food chain or partly modified through metabolic reactions (oxidation, reduction, and translation of double bonds). Astaxanthin can be produced by crustaceans from other carotenoids especially their main precursor  $\beta$ -carotene (Caramujo et al., 2012). Carotenoids are beneficial for human and animal health due to their antioxidant properties that quench singlet oxygen and prevent lipid peroxidation.

Carotenoids may also improve reproduction and enhance immunity in marine animals. Photoprotection, camouflage, and signalling such as breeding colour are other uses of carotenoids by marine organisms (Maoka, 2011).

#### **Extraction of Astaxanthin From Crustacean By-Products**

Conventional methods for astaxanthin extraction from crustacean shell waste use different organic solvents such as dichloromethane, methanol, ethanol, petroleum ether, chloroform, hexane, and acetone (Dalei and Sahoo, 2015). However, solvent extraction could damage the astaxanthin structure. Besides, their use is considered expensive and may cause environmental pollution (López et al., 2004). Therefore, other techniques including supercritical fluid extraction (SFE) were developed as more efficient alternatives to traditional extraction. Supercritical fluids such as carbon dioxide (CO<sub>2</sub>) are inexpensive and regarded as GRAS solvents (Radzali et al., 2014). To increase carotenoid extraction, (carotenoprotein) proteolytic enzymes could be used since astaxanthin is present in crustaceans as a protein-pigment complex (Armenta-López et al., 2002).

#### **Proteins and Hydrolysates From Crustacean By-Products**

Crustaceans are a valuable source of proteins that contain high amounts of arginine, glutamic acid, glycine, and alanine and also provide essential amino acids for human and animal feed (Nguyen et al., 2017). The protein content in crustacean shell waste depends on the species and processing methods (Mao et al., 2017). Protein hydrolysates often are more functional than proteins with respect to emulsifying properties, solubility, and texturizing capability. After further hydrolysis free amino acids can be generated from peptides of various sizes (da Silva et al., 2017).

#### **Recovery of Proteins and Hydrolysates**

Proteins in crustacean biowaste are closely associated with chitin and minerals, and are obtained by deproteinization. Protein hydrolysis, can be done enzymatically or chemically (Vijaykrishnaraj and Prabhasankar, 2015). Chemical purification can be environmentally hazardous and may destroy some amino acids. To overcome the problems with chemical treatments, other processes have been suggested including microbiological fermentation using lactic acid bacteria and proteolytic enzymes (Gortari and Hours, 2013). Enzymatic methods are advantageous as they take place in milder controllable conditions and the generation of toxic compounds is minimized (Dieterich et al., 2014). For the hydrolysis of shellfish proteins, enzymes from microbial sources such as Alcalase, Neutrase, Protamex, and Flavourzyme could be used.

#### **Future Challenges and Trends for Comprehensive Use of Crustacean By-products**

At present, world crustacean waste materials are an underutilized resource. Most interest and attention both scientifically and industrially has been focused on chitin and chitosan. Chitin, chitosan, and their derivatives are valuable compounds due to their appealing properties of biodegradability, biocompatibility, and non-toxicity. Therefore, they can be used in a wide range of industrial applications in biomedicines, pharmaceuticals, agriculture, foods, cosmetics, textiles, and enzyme-immobilization. They also have many health benefits. Recently, it has become possible to industrially produce pure chitin crystals, called “chitin nanofibrils” (CN). Due to their specific chemical and physical characteristics, CN may have a range of industrial applications, from biomedical products and biomimetic cosmetics, to biotextiles and health foods (Morganti et al., 2011). In addition, a polymeric biocide film of CN-chitosan with high tensile strength has the advantage of being elastic, chemically stable and totally bio- and eco-degradable, compared with conventional antimicrobial films made of polyethylene. In view of the chemistry and biological properties of chitin and chitosan, along with their safe toxicity profile, chitin and chitosan have the potential to be used for the biomedical industry especially in tissue engineering, wound dressing and cancer diagnosis. The numerous uses of chitin and chitosan based materials even includes cancer targeting and drug delivery systems. Chitosan has potential applications in artificial kidney, bone, liver, tendon, blood vessel, blood anticoagulation, nerve, and burn treatments (Islam et al., 2017).

Astaxanthin has also been gaining popularity with humans as a dietary supplement due to its powerful antioxidant properties. Currently, astaxanthin products are available in the market as anticancer, anti-inflammatory and immunostimulants agents. It seems possible to use waste products obtained from the crustacean processing industry to produce healthy products, thus protecting the environment and beneficially contributing to the economy.

#### **Conclusion**

Shells, heads, and tails of crustaceans, represent around 50%–70% of crustaceans and are often discarded without further processing which poses a serious environmental hazard. The underutilized crustacean by-products have been identified as an important natural source of protein, chitin, and carotenoids (mainly astaxanthin). The extraction of valuable compounds could not only minimize the impact of waste on the environment but also provide value-added products that would also be socially beneficial.

# Microstructure of Dairy Fat Products

PR Ramel and AG Marangoni, Department of Food Science, University of Guelph, Guelph, ON, Canada

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Milk fat provides numerous benefits to food products. Besides nutritional value, flavor enhancement, and desirable mouthfeel, the crystal structure of milk fat also affects the mechanical properties of dairy fat products. The crystal structure of milk fat has been characterized at different length scales using a range of methods such as various microscopy methods, differential scanning calorimetry (DSC), pulsed nuclear magnetic resonance (pNMR), and X-ray scattering techniques (Acevedo, 2012; Acevedo et al., 2011; Marangoni et al., 2012; Peyronel and Campos, 2012). The effect of compositional changes and various environmental factors on the crystallization behavior and crystal structure of milk fat have also been extensively studied.

The thermal behavior of milk fat greatly depends on the arrangement and properties of triacylglycerols (TAGs) which constitute 98% of its composition. TAGs are composed of a glycerol backbone with three fatty acids (FAs) esterified on to it at stereospecific positions (Jensen et al., 1991; McGibbon and Taylor, 2006). The type of FAs present as well as their distribution on the glycerol backbone determine the properties of the TAG molecule (Jensen et al., 1991; Palmquist, 2009; Tzompa-Sosa et al., 2014). In milk fat, these FAs can be short, medium or long chain, and saturated or unsaturated. This diversity in TAG composition in combination with the presence of minor components such as mono- (MAGs) and diacylglycerols (DAGs) in milk fat further lead to the complex thermal behavior and broad melting range of milk fat from  $-40^{\circ}\text{C}$  to  $40^{\circ}\text{C}$  (Timms, 1980; Shi et al., 2001; Wright and Marangoni 2002, 2003; Mazzanti et al., 2004).

In this chapter, the crystal structure of milk fat at different length scales as affected by various internal and external factors will be reviewed. Furthermore, as the crystal structure of milk fat has great impacts on the microstructure and overall properties of dairy fat products, the crystal structure of milk fat within food products will also be discussed.

## Milk Fat Crystal Structure at Different Length Scales

### Molecular Level (Polymorphism)

During crystallization, milk fat melt becomes supersaturated with TAGs that have become supercooled due to high undercooling (*i.e.*, the crystallization temperature is sufficiently lower than the melting point of the particular TAGs) (Marangoni et al., 2012). The supersaturation of TAGs is very important as it determines the polymorphism of milk fat (Kloek et al., 2000; Sato, 2001; Dibildox-Alvarado et al., 2010; Marangoni et al., 2012).

Polymorphism is referred as the various conformations in which TAGs can pack and stack in a lamellar crystal forming various geometrical packing arrangements within the TAG unit cell (Marangoni et al., 2012; Sato, 2001). The more compact or dense the TAG packing, the more bonds or interactions they make and the more stable they are (D'Souza et al., 1990). In milk fat, three polymorphic forms have been identified namely  $\alpha$  ( $\alpha$ ) – hexagonal geometrical packing,  $\beta'$  ( $\beta'$ ) – orthorhombic perpendicular, and  $\beta$  ( $\beta$ ) – triclinic, in increasing order of stability (Woodrow and deMan, 1968; Sato, 2001; Lopez et al., 2001, 2005; Marangoni and Wesdorp, 2013a). Using wide-angle X-ray diffraction (WAXD), the polymorphs of milk fat have been characterized by Bragg's peaks corresponding to  $d$ -spacings of  $4.15\text{\AA}$  ( $\alpha$ ),  $3.8$  and  $4.2\text{\AA}$  ( $\beta'$ ), and  $4.6\text{\AA}$  ( $\beta$ ). Upon crystallization, the  $\alpha$  polymorph is usually formed first which eventually transforms into the  $\beta'$  or  $\beta$  form as the  $\alpha$  polymorph is thermodynamically unstable (Sato, 2001; Sato and Ueno, 2011). The order in which these polymorphs are formed can be explained using the concept of activation energies for nucleation (Marangoni et al., 2012). A lower activation energy is required for the formation of the  $\alpha$  polymorph as it is less ordered than the packing of the  $\beta'$  and  $\beta$  polymorphs. As a consequence, a faster nucleation into the  $\alpha$  polymorph is frequently observed (Grotenhuis et al., 1999; Marangoni et al., 2012; Marangoni and Wesdorp, 2013b; Martini et al., 2001; Sangwal and Sato, 2012).

At high undercooling conditions (fast cooling rate) the formation of the least stable  $\alpha$  crystals is further favored (Lopez et al., 2001, 2005). During fast cooling, TAGs do not have time to self-assemble into more compact, and stable forms, therefore they adapt a more accessible, less ordered polymorphic form -  $\alpha$  (Marangoni et al., 2012). On the other hand, at very slow cooling rates, the  $\beta'$  or  $\beta$  polymorphs of milk fat are formed because TAGs (usually uniform TAGs) have time to self-assemble into the more compact crystalline lattice (Martini et al., 2001). With the application of agitation, shear, and/or ultrasonication, a faster transition of the  $\alpha$  polymorph to more stable forms is observed due to enhanced movement of molecules or partial melting of crystals which provides a mobile phase for the recrystallization of TAGs into more stable polymorphic forms (Frydenberg et al., 2013; Mazzanti et al., 2003; Mazzanti et al., 2009).

In terms of composition, the presence of high amounts of saturated TAGs coupled with sufficient liquid milk fat result in the formation of the  $\beta$  polymorph (Tzompa-Sosa et al., 2016). Furthermore the dilution of milk fat with canola oil allows for the formation of  $\beta$  crystals, while the addition of rapeseed oil results in a faster transition of  $\alpha$  to  $\beta'$  form due to increased mobility of molecules (Kaufmann et al., 2013; Wright et al., 2005).

### Nanoscale (Crystalline Nanoplatelets)

After supersaturation of TAGs, nucleation then occurs wherein TAG molecules organize in a crystalline lattice to form TAG lamellae that further stack into crystalline domains (Marangoni et al., 2012; Marangoni and Wesdorp, 2013b; Sangwal and Sato, 2012). The stacking of several TAG lamellae, as held together by London-van der Waals forces, result in the formation of crystalline nanoplatelets (CNPs) (Acevedo and Marangoni, 2010, 2015; Ramel et al., 2016a).

The nanostructure of milk fat is greatly dependent on the properties and aggregations of CNPs. CNPs in milk fat have been visualized using cryogenic transmission electron microscopy (cryo-TEM) after extraction involving the application of controlled shear and removal of oil by washing with a cold solvent such as isobutanol (Ramel et al., 2016b). The dimensions (length, width and thickness) of CNPs have been measured and analyzed from the micrographs. The thicknesses of the CNPs, or the crystalline domain size have been confirmed through the Scherrer equation (crystalline domain size) based on lamellar thickness calculated from small-angle x-ray scattering (SAXS) data (Acevedo and Marangoni, 2015; Acevedo et al., 2011; Ramel et al., 2016b). Other properties such as surface properties and the types of aggregations of CNPs have been described through the fitting of ultra-small angle x-ray scattering (USAXS) patterns into the Unified Fit and Guinier-Porod models (Peyronel et al., 2014; Ramel et al., 2016b). The effect of various factors on the nanostructure of milk fat has not been studied.

### Mesoscale (Microstructure)

The continuous aggregation of CNPs then result in the formation of large polycrystalline aggregates that can be visualized using polarized light microscope (PLM) and scanning electron microscope (SEM). Milk fat crystal structure at the mesoscale (approximately 1–200  $\mu\text{m}$ ) have been described according to its crystal habits (size and shape) which include spherulites, needle-like crystals, platelets, disordered aggregates and fractal-like aggregates (Marangoni et al., 2012).

At fast cooling rates ( $>0.5$   $^{\circ}\text{C}/\text{min}$ ), smaller milk fat crystals are formed while at slow cooling rates ( $\leq 0.5$   $^{\circ}\text{C}/\text{min}$ ), larger crystals develop (Campos et al., 2002; Wiking et al., 2009). Furthermore, the application of controlled agitation, shear, and ultrasound during crystallization results in the formation of many small crystals. On the other hand, fewer and larger crystals are formed when milk fat is crystallized statically. Agitation and shear allows for uniform heat transfer and possible breaking of large crystals into smaller ones which allows for the formation of many nuclei that act as starting point for growing crystals (Frydenberg et al., 2013; Kaufmann et al., 2012; Martini et al., 2008; Wagh et al., 2016; Wiking et al., 2009).

In terms of composition, the microstructure formed by milk fat from the mixing of its fractions has been extensively studied. TAGs in milk fat can be categorized according to their melting points into high melting fraction (HMF), middle melting fraction (MMF), and low melting fraction (LMF) (Dimick et al., 1996; Timms, 1980; van Aken and Visser, 2000). In a recent work by Ramel and Marangoni (2016), it was found that high concentrations of HMF in binary and ternary mixtures of milk fat fractions result in the formation of many small rod or needle-like crystals (Fig. 1), while relatively higher concentrations of MMF and LMF result in the formation of large spherulites (Fig. 2). The presence of numerous saturated TAGs in HMF allows for the formation of many nuclei under high undercooling conditions. On the other hand, with high amounts of LMF, higher ratios of liquid fat are present which results in a delay in crystallization resulting in multidimensional growth (Ramel and Marangoni, 2016).

## Crystal Structure of Milk Fat Indairy Products

### Butter

Butter is an emulsion product made from cream wherein the continuous phase is fat (*i.e.*, milk fat crystals) and the dispersed phase is water. Two major processes that are important for determining the final microstructure of butter include churning and working (Wright et al., 2001). During churning at 15–20  $^{\circ}\text{C}$ , the continuous collision of fat globules results in damage of the fat globule membrane through piercing by milk fat crystals and the formation of large clumps of butter grains—partial coalescence. Working then follows to reduce moisture and water droplet size allowing increased contact between crystals which in turn strengthens the fat crystal network (Wright et al., 2001). Fig. 3 shows the resulting microstructure of butter.

Rapid cooling of cream for butter-making results in the formation of relatively small crystals that allow for the formation of a firm fat crystal network due to increase in crystalline interactions (Wright et al., 2001). Furthermore, in terms of polymorphism, the  $\alpha$  form is initially observed in cream which readily transforms into the  $\beta'$  polymorph upon churning (Buldo et al., 2013). Transformation of the  $\alpha$  form into  $\beta'$  and  $\beta$  polymorphs is also observed when cream for butter-making is matured (Ronholt et al., 2012). In margarines and shortenings, the  $\beta'$  polymorph is associated with a spreadable and elastic product, while the  $\alpha$  and  $\beta$  polymorphs have been related to a soft, and grainy or non-spreadable product, respectively (Danthine, 2012; deMan, 1992).

**Figure 1** Polarized light (PLM) micrographs of binary mixtures of high melting (HMF) and middle melting (MMF) fractions of milk fat, crystallized isothermally at 5 °C. Scale bar corresponds to 100  $\mu\text{m}$ . Reproduced from [Ramel and Marangoni \(2016\)](#) with permission from the Royal Society of Chemistry.

### Whipped Cream and Ice Cream

Products that are also dependent on stabilization by a continuous fat crystal network are whipped cream and ice cream. The crystal network created by milk fat globules that have partially coalesced traps air bubbles upon whipping of cream ([Fig. 4](#)). The stability of the network is affected by the amount of liquid fat and the size of milk fat crystals. Too much liquid fat in the system can cause the foam to collapse due to competitive displacement at the interface, and crystals that are too large can pierce through air bubbles. Very small globules (up to the Nano range) result in the reduction of percent overrun which is the amount of air bubbles that can be incorporated in the network ([Truong et al., 2014a,b](#)).

The microstructure of ice cream is also greatly affected by the properties of the milk fat crystal network. Homogenization is an important step in ice cream manufacture which results in small fat droplets coated with proteins becoming dispersed throughout the ice cream matrix. The addition of low molecular surfactants, or emulsifiers then displaces protein and aid in enhancing partial coalescence, *i.e.*, to increase interactions between crystals piercing through globules ([Goff, 2008](#)). The network formed by partially coalesced fat surrounded by emulsifiers or proteins then stabilize the air bubbles that are incorporated in ice cream during whipping or by vacuum or air injection under high pressure ([Goff and Hartel, 2013](#); [Goff, 1997](#)). This whipping process also introduces shear into the system which further enhances partial coalescence.

### Chocolate

In chocolate, milk fat is blended with cocoa butter for flavour and other desirable sensory qualities. When HMF is added to cocoa butter, larger crystals are formed which results in reduced crystalline interactions and a less compact network, therefore preventing extensive hardening of the product. Furthermore, addition of milk fat TAGs was found to help prevent bloom formation by delaying the transition of the  $\beta$ -V polymorph to  $\beta$ -VI polymorph which is responsible for the formation of white film on the surface of chocolate ([Sonwai and Rousseau, 2010](#)).

**Figure 2** Polarized light (PLM) micrographs of ternary mixtures of high melting (HMF), middle melting (MMF), and low melting (LMF) fractions of milk fat, showing increasing amounts of MMF, crystallized isothermally at 20 °C. Scale bar corresponds to 100 μm. Reproduced from [Ramel and Marangoni \(2016\)](#) with permission from the Royal Society of Chemistry.

### Cheese and Processed Cheese

Milk fat globules in cheese and processed cheese products appear as spheres embedded in the spaces or pockets within the protein gel matrix formed mainly by caseins ([Fig. 5](#)). Proper emulsification of fat within the protein matrix is important for the desirable viscoelastic and melting properties of cheese and processed cheese products. The thermal history and polymorphism of milk fat was found to affect the viscoelastic properties of processed cheese ([Gluguem et al., 2009, 2011](#)). In studies by [Ramel and Marangoni \(2016 and 2017a,b,c\)](#), it was found that the embedding of milk fat within a protein matrix as that in processed cheese products results in the formation of higher ratios of the  $\beta$  polymorph to the  $\beta'$  form, while milk fat in bulk is mostly in the  $\beta'$  form ([Ramel and Marangoni, 2017a](#)). The main mechanism for the formation of the most stable crystal polymorph of milk fat in processed cheese products was found to be due to the confinement of milk fat TAGs that forces them to arrange themselves in the most compact and dense form ([Ramel and Marangoni, 2017b](#)). The microstructure of processed cheese rather than the polymorphism of milk fat was found to be greatly correlated with its rheological properties.

### Conclusions

In this chapter, the importance of the crystal structure of milk fat in the formation and stability of the microstructure of various dairy fat products is described. By characterizing the structure of milk fat at different length scales and studying the effect of various internal and external factors on the structure of milk fat, we now have a better understanding of how the properties of the milk fat crystal network affects the rheological and other sensory properties of dairy fat products. With the development in the methods for studying the structure of milk fat, interactions between milk fat and the different ingredients in the food matrix can be better analyzed.

# The Structure and Properties of Ice Cream and Frozen Desserts

H Douglas Goff, Dept. of Food Science, University of Guelph, Guelph, ON, Canada

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Overrun** The amount of air whipped into a product during scraped-surface freezing, as a percent of the unwhipped product, based on the equation (Vol. of ice cream – Vol. of mix)/Vol. of mix × 100%.

## Introduction

Ice cream and frozen desserts are a food category that is characterized by normally being aerated and eaten while frozen. The legal definitions of ice cream and other frozen desserts vary widely. In the United States and Canada, for example, ice cream must contain a minimum of 10% by wt. of milkfat and contain no other non-dairy fat or protein source ([United States Food and Drug Administration, 2017](#)). In these markets, the term “frozen desserts” are used to characterize both products containing non-dairy fats and non-dairy products. However, in Europe, the Euroglaces Code for Edible Ices ([Euroglaces, 2013](#)) provides a much broader definition of ice cream, essentially being an aerated emulsion, hence containing fat, that is eaten while frozen and therefore comprising both dairy and non-dairy versions. They distinguish milkfat containing products as “Dairy Ice Cream”. Also within this broad category are a range of other products, for example frozen yogurt, sherbet and sorbet. Gelato is an Italian-style ice cream with its own compositional guidelines. With gelato, whipping is done with low shear and low overrun, so there is less colloidal structure formed. There are also numerous sub-categories of ice cream, including light and lowfat versions, no sugar added versions, high-fat premium versions, etc. [Table 1](#) provides an overview of typical compositional values for ice cream and frozen desserts that all fall within the category of food products defined as above. The main focus of this chapter is the structure of these products and the properties of the products that result from structure. Structure is certainly dependent on composition, but overall there are generally four phases: fat globules, air bubbles, ice crystals and a freeze-concentrated unfrozen solution of sugars, proteins, polysaccharides and other soluble ingredients. The balance of each, and the importance of each to physical properties and product performance, will depend largely on the source and quantity of fat, proteins, sugars, etc. The first section will introduce the composition and processing steps. Then structure and properties will be divided between the colloidal structure, that arise from the presence of fat and air, and the aqueous phase structure, that arise from the presence of ice crystals and freezing point depression from solutes in the unfrozen aqueous solution. The main properties arising from each phase are creamy texture, dryness on extrusion, shape retention, resistance to melting and shrinkage dependent on the colloidal phase, and smooth to coarse texture, shelf-life, and softness/scoopability dependent on the aqueous phase.

**Table 1** Approximate composition (%) of commercial frozen desserts by formulation category

Group	Milk fat	Milk solids-not-fat	Sweeteners <sup>a</sup>	Stabilizers <sup>b</sup>	Total solids
Non-fat ice cream	<0.5	12–14	18–22	1.0	28–32
Low-fat ice cream	2–5	12–14	18–21	0.8	28–32
Light ice cream	5–7	11–12	18–20	0.5	30–35
Economy ice cream	8–10	10–12	15–17	0.4	32–36
Standard ice cream	10–12	9–10	14–17	0.2–0.4	36–38
Premium ice cream	12–14	8–10	13–16	0.2–0.4	38–40
Super premium ice cream	14–18	5–8	14–17	0–0.2	40–42
Gelato-style ice cream	4–8	9–12	15–24	0.5	32–42
Frozen yogurt: regular	3–6	9–13	15–17	0.5	30–36
Frozen yogurt: non-fat	<0.5	9–14	15–17	0.6	28–32
Sherbet	1–2	1–3	22–28	0.4–0.5	28–34

<sup>a</sup>Includes sucrose, glucose, corn syrup solids, maltodextrins, polydextrose and other bulking agents, some of which contribute little sweetness.

<sup>b</sup>Includes ingredients such as locust bean gum, guar gum, cellulose gum and carrageenan, as stabilizers, and also mono- and di-glycerides, as emulsifiers.

## Formulations, Ingredients and Manufacturing

Most companies design recipes that are unique, however there are many similarities within each category of product, as shown in [Table 1](#). The formulation defines the quantity of each component present, e.g., fat, milk solids-not-fat (MSNF), sweeteners, stabilizers, emulsifiers and water, whereas the recipe defines the quantity of each ingredient present, many of which provide more than one component of the formulation, e.g., cream, milk, condensed milk, liquid sugars, dry ingredients, etc. Flavouring materials are added to the mix components after mix processing, and it is typical to produce many flavours from the same base mix. Formulations and recipes will depend on the type of product being developed, its segmentation within the market (e.g., low-cost vs. high-cost), any health or nutrition claims being associated with the product (e.g., low-fat or no-sugar-added), the availability of ingredients (e.g., fresh cream vs. frozen butter when fresh cream is not available), and other factors that help to differentiate one brand from another.

Most formulations start off by defining the fat level. The legal minimum for ice cream in several countries is 10% by wt., but it can vary from as low as 3%–4% in low-fat products to as high as 16% in super-premium products. Milkfat is usually provided by cream, butter or anhydrous milkfat, whereas the most common non-dairy fats are from coconut or palm kernel, since fat must be partly solid at whipping temperature (as described in detail below). Fat provides smooth, creamy texture from lubrication in the mouth and provides structure, resulting in dryness, shape retention and resistance to rapid structural collapse during melting, as will be further described below.

The MSNF category provides the milk proteins, which are responsible for emulsification of fat, stabilization of air and water holding capacity, and the lactose and milk salts, which contribute to freezing point depression. Typical usage levels are 9%–12%, to provide 3%–4% protein. Concentrated sources of MSNF include condensed skim or whole milk, skim milk powder and whey-based ingredients such as whey powder or whey protein concentrates. Milk protein concentrates can also be used. In non-dairy frozen desserts, the MSNF category is usually replaced with a source of plant protein such as pea, soy, rice or other, and bulking materials such as maltodextrins, starch or inulin.

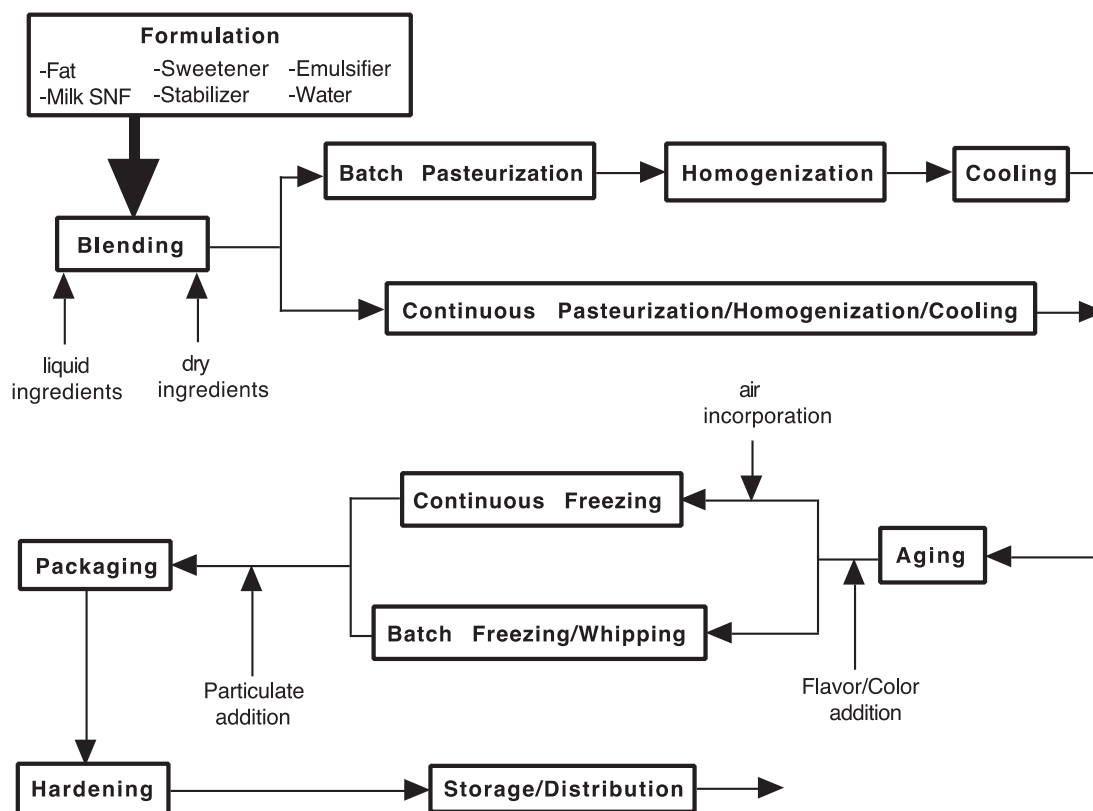

The sweetener category provides sweetness and freezing point depression. Sucrose is the most common source, and can be used alone at 14%–15%, but starch hydrolysate sweeteners (glucose solids), from corn, wheat tapioca or other starch sources, are also quite common and provide body and texture from the oligosaccharide and maltodextrin components, depending on the extent of hydrolysis (usually given as Dextrose Equivalent (DE) number). Typical recipes might replace 3%–4% of the sucrose with 4%–6% starch hydrolysates, depending on their sweetness. In No-Sugar-Added, low Glycemic Index formulations, the sugars are normally replaced by sugar alcohols, such as the disaccharide maltitol, which can replace sucrose at a 1:1 ratio for freezing point depression, or the small molecular weight polyol erythritol, which can replace sucrose at a 1:3 ratio for freezing point depression. In that case, other bulking agents may be required to provide total solids. Since the sugar alcohols are not as sweet as sucrose, a high-potency sweetener such as sucralose or the natural sweetener stevia may be used to enhance and balance the sweetness and flavour.

Stabilizers and emulsifiers are important food additives for their structural contributions, as will be discussed below. Stabilizers are normally soluble, indigestible polysaccharides such as guar gum, locust bean gum, and carboxymethyl cellulose, with a combined usage level of ~0.15%–0.25%. They interact with the water phase and can also interact with the proteins in the aqueous phase ([Cheng et al., 2015](#)). Carrageenan is often added at ~0.01% to inhibit phase separation between these polysaccharides and the casein micelles, the milk protein particle, which is incompatible in solution with these polysaccharides. The two common emulsifiers are mono-glycerides, typically at 0.15% depending on the fat content, and egg yolks at ~2%. These interact with the fat phase to provide fat structuring and air stability, as will be described in detail below.

The final category of ingredient is the source of water, to solubilize and disperse the ingredients and create the liquid mix. Total solids, the sum of the above, might range from 32%–40%, depending on formulation, which means that the water component would be 60%–68% (100-TS%). The source of water can be added water, milk or skim milk, and the contributions also coming from ingredients such as cream, condensed skim, liquid sugars, etc.

Ice cream and frozen desserts are manufactured in two main steps, mix making and freezing ([Fig. 1](#)). Mix making entails blending and solubilizing the ingredients with high shear blenders and recirculation through blending tanks, perhaps with pre-heating up to 30–40 °C depending on the choice of ingredients, pasteurizing the mix with either batch (~70 °C, 30 min) or continuous high temperature short time (HTST, ~80 °C, 30 s) pasteurizers, homogenizing the mix with a high-pressure valve homogenizer, typically two-stage at 18 MPa and 3.5 MPa, depending on the composition and fat content, cooling the mix to 4 °C or less, and ageing at this temperature for > 4 h in holding tanks.

After ageing is completed, the mix is typically sub-divided to smaller aliquots, flavoured with soluble flavours, and then either batch frozen (small-scale operations) or pumped through a continuous scraped-surface heat exchanger ("barrel" freezer), to a draw temperature of < -4 to -7 °C, depending on composition and freezer capacity. Within the freezing cylinder ("barrel"), the rapid removal of heat by the refrigerant causes the mix to freeze onto the inside surface of the barrel, where it is rapidly scraped off by the dasher and into the bulk flow ([Drewett and Hartel, 2007](#)). The minute ice crystals within this layer then mature and grow as the product freezes further to a final value of ~50% of the water frozen before exiting the barrel ([Russell et al., 1999](#); [Cook and Hartel, 2010](#)). Air is incorporated at the inlet to the barrel and the shear induced by rapid agitation from the dasher inside the barrel is responsible for the formation of small air bubbles as the mix freezes and progresses toward the exit. The air content of ice cream is defined by the overrun, the increase in volume of the mix as a result of the air incorporation ((air vol./mix vol.) × 100%). Typical overrun values vary from 25%–50% in high-quality premium products to 110%–120% in economy brands. The agitation and aeration within the barrel induce a destabilization or partial coalescence of the fat emulsion, causing some fat globules to adsorb to and

**Figure 1** Flow diagram of the processing steps in ice cream manufacture (SNF, solid-non-fat).

stabilize the air bubble interfaces and also causing some of the fat globules to develop a particle network of fat throughout the unfrozen phase of the ice cream.

Following scraped-surface freezing, any flavouring materials that will be discrete and visible within the product, such as fruits, nuts, ripple sauces etc., are stirred into the semi-frozen ice cream through an ingredient feeder and/or ripple pump and the ice cream is then packaged and moves immediately into a hardening freezer. This second freezing step is normally done in spiral freezers with low temperature ( $\sim -30$  to  $-35$  °C) and high velocity circulating air (high convective heat transfer coefficients), with a goal to reduce core temperatures of the packages to  $\sim -20$  °C within 4 h.

## Structure and Properties

The structure of the liquid ice cream mix can be described as an emulsion of fat globules, which are partly crystalline as a result of cold ageing, a dispersion of casein micelles, if present in the recipe, and a solution of sugars, soluble proteins, salts, stabilizers and other components (Fig. 2). The freezing processes convert this structure to one comprised of ice crystals, air bubbles, fat globules, some of which are adsorbed to the air bubbles and some of which are partially-coalesced into aggregates and potentially a continuous particle network, and an unfrozen continuous phase that is freeze-concentrated compared to the mix due to the removal of water as ice (Figs. 2 and 3). These structural elements will be sub-divided into the colloidal structure and the aqueous structure and will be discussed, along with the major physical properties and performance parameters arising, in detail within each section following.

### Colloidal Structure

The colloidal structure is comprised of the fat globules and the air bubbles (Fig. 4). Homogenization of the fat creates the original size distribution of fat globules. At intermediate fat content,  $\sim 7\%$ – $12\%$ , fat globule sizes are typically normally distributed around a median of  $0.5\ \mu\text{m}$ , with none larger than  $2.0\ \mu\text{m}$ . This is the result of homogenization pressures of  $\sim 18\ \text{MPa}$  after formation of a suitable pre-emulsion when solid fat sources are used, bearing in mind that cream is already an emulsion. At higher fat levels, less pressure is used so that fat globules do not become too numerous and more prone to churning in the barrel freezer, whereas at lower fat levels,  $4\%$ – $6\%$ , fat structure can be enhanced with high pressure homogenization to enlarge its surface area. If fat levels are too

**Figure 2** Highly schematic illustration of the structure of ice cream mix and ice cream. Ice cream mix contains partially crystalline fat globules and casein micelles as discrete particles in a solution of sugars (including lactose), salts, dispersed whey protein and stabilizers, etc. The surface of the fat globule demonstrates the competitive adsorption of casein micelles, other milk proteins and added emulsifiers. Ice cream contains ice crystals, air bubbles and partially-coalesced fat globules as discrete phases within an unfrozen serum containing the dissolved material (including lactose). The partially-coalesced fat agglomerates adsorb to the surface of the air bubbles, which are also surrounded by protein and emulsifier, and link the bubbles through the lamellae between them.

**Figure 3** Low-temperature scanning electron microscopy image of ice cream structure, showing all structural elements, the unfrozen phase (UFP), ice crystals (I), air bubbles (A) and fat globules adsorbed at the air interface (F). Bar = 20  $\mu\text{m}$ .

low, <3%–4%, very little fat structuring takes place and colloidal structure needs to be replaced with further aqueous structuring. Since milkfat, coconut oil and palm kernel oil are partially comprised of saturated fatty acids, the ageing step of <4 °C for >4 h will result in a semi-crystalline fat droplet.

The surface of the fat droplet immediately after homogenization will be stabilized by a mixture of surface-active proteins (casein micelles and whey proteins) and emulsifiers (monoglyceride or phospholipids from egg yolks). During the ageing period, the emulsifiers will continue to displace proteins from the fat surface, as they lower the interfacial tension and work towards a more thermodynamically-stable equilibrium (Goff et al., 1999). This is especially true for casein micelles, due to their bulky nature, but less displacement occurs with protein membranes comprised of whey proteins or caseinate. Non-dairy plant proteins need to be evaluated for their behaviour. The emulsifiers are much smaller in molecular weight compared to the proteins, for example

**Figure 4** The colloidal structure of ice cream mix and ice cream. (a), Fat globules (F) in mix with crystalline fat within the globule and adsorbed casein micelles (C), as viewed by thin section transmission electron microscopy. With emulsifier present, the level of casein adsorption is very low. (b), Close-up of an air bubble (A) with adsorbed fat, as viewed by low temperature scanning electron microscopy. (c), Air bubble (A) with adsorbed fat cluster (FC) that extends into the unfrozen phase, as viewed by thin section transmission electron microscopy with freeze substitution and low temperature embedding.

the polar head group of an alpha-monoglyceride is comprised only of the 2-carbon non-esterified portion of the glycerol molecule, such that their continued adsorption produces a much thinner membrane at the fat interface (Fig. 4a), and hence a fat droplet that is much more prone to shear-induced partial coalescence in the barrel freezer (Bolliger et al., 2000).

Within the barrel freezer, air is added and the dasher whips this air into progressively smaller air bubbles with progressively more surface area (Sofjan and Hartel, 2004; Xinyi et al., 2010). At the same time, the ice phase is forming, which is concentrating the fat and air and enhancing the induced shear. The combination of these actions causes the fat globules to undergo a destabilization process. The air bubble surfaces will be formed by protein from the aqueous phase (Zhang and Goff, 2004) but are rapidly stabilized by fat adsorbing at the surface (Zhang and Goff, 2005) (Fig. 4b). Concomitantly, fat droplet collisions in the shear field induce the process of partial coalescence, which is enhanced by the thin membrane induced by the emulsifiers (Bolliger et al., 2000). The solid fat crystals within the droplets are responsible for maintaining some of the spherical shape of the droplets, which allows them to form chains and clusters rather than to coalesce into larger droplets (Mendez-Velasco and Goff, 2012) (Fig. 4c). The latter happens when too much oil is present within the droplets. The liquid oil remaining in the mostly-solid droplets is responsible for helping to create fat-fat interactions through the formation of oil necks at the point of contact. If the droplet is almost completely solid, then there is less tendency for collisions to lead to aggregation (Sung and Goff, 2010). Likewise if too much protein is present at the fat interface, fat droplet collisions will not result in the same extent of fat adsorption to air bubbles or fat partial coalescence.

This structuring of fat leads to several important physical properties in the product. The first is dryness on extrusion. With optimal fat structuring, the product appears dry as it is removed from the barrel and is better able to hold flavouring inclusions. It is also able to hold its shape much better, resulting in a soft-frozen product that is able to be cut into a wide array of novel shapes, cakes, etc. Extensive fat structuring can lead to visible churning of butter particles whereas sub-optimal fat structuring leads to a wet-appearing product with little shape retention. This happens with insufficient or no emulsifier, or with fat sources that are either too solid or too liquid at whipping temperature, or with fats that have not been fully crystallized as a result of insufficient ageing or ageing too warm.

A second important manifestation of optimal fat structuring is the ability resist collapse and flow of the product during melting (Daw and Hartel, 2015). During “meltdown”, the ice crystals melt as a function of heat transfer from the ambient environment, but as the ice melts the structure can either resist collapse due to an extensive three-dimensional fat particle network or it will melt quickly if there is no underlying fat network to hold the air bubbles and aqueous phase in place (Muse and Hartel, 2004). Too much resistance leads to the “does not melt” defect in which melted ice cream resembles a stiff, dry whipped cream product, whereas too little resistance results in a product that is very prone to dripping and with a weak body and mouthfeel as the melted ice cream returns rapidly to its mix-like structure. This structural feature can also be felt as improved texture and mouthfeel due to the slower structural collapse in the mouth.

Another important manifestation of optimal colloidal structure is a stable air phase (Xinyi et al., 2010). The air bubbles need to be stabilized by adsorbed protein and fat so that they remain as distinct bubbles with an interface. Without appropriate air stability, the bubbles are prone to coalescence and channeling, and this often leads to shrinkage as some of the air escapes out of the product during storage and distribution (especially at somewhat elevated temperatures).

### Aqueous-phase Structure

The aqueous phase is comprised of the ice crystals and the freeze-concentrated unfrozen phase, which contains the solutes (sugars, lactose and salts) and the dispersed macromolecules (protein and stabilizers). Unlike the colloidal phase, which is created at the time of manufacturing and remains mostly stable thereafter, the balance between ice and unfrozen water within the aqueous phase is in thermodynamic equilibrium, defined by the solute concentration and the temperature. Thus it is continually changing post-manufacture with changes to product temperature. These changes in water:ice equilibrium can lead to rapid increases in ice crystal

size, and hence to loss of shelf life. Thus, discussion of the aqueous phase needs to focus on ice formation and ice crystal size distribution, solute concentration and freezing point depression, leading to appropriate softness and scoopability, and finally the detrimental effects of heat shock on quality and shelf-life.

The ice crystal size and size distribution is formed by rapid heat removal in the scraped surface freezer followed by rapid hardening, together with minimizing any potential for melting of ice crystals in the delicate temperature range between these two processes. Hence addition of flavouring materials and packaging of the product should also be done rapidly and with no exposure to warm temperatures. As was discussed in the Manufacturing section above, ice crystals form initially at the barrel wall and then are rapidly scraped off into the bulk where they mature and grow as further water molecules continue to deposit on existing crystals (Cook and Hartel, 2010). Hence the barrel freezer is primarily responsible for ice crystal formation whereas the goal of rapid hardening is to maintain as many of these small crystals as possible. There may be limited further nucleation during the hardening stage but it is overwhelmingly dominated by growth (Russell et al., 1999).

Ice crystals are pure solid water particles. During the process of crystal growth, solutes are continually excluded out of the crystalline lattice (Adapa et al., 2000). Thus, as ice crystal growth proceeds, the solutes and all other substances in the unfrozen phase become freeze-concentrated in an ever-decreasing volume with reductions in temperature. Freezing point depression is governed by Raoult's Law, which indicates that it is a molar concentration effect, hence influenced both by molecular weight and weight concentration of solutes. The principal solutes in ice cream formulations are the added sugars, lactose and milk salts. Additionally, post-pasteurization flavourings that are added also may have to be accounted for, particularly if they contain high sugar content that becomes incorporated into the bulk of the ice cream. For example, added cooked and sweetened strawberries would contribute to freezing point depression, whereas a distinct ripple sauce, even though also high in sugar, would not contribute to freezing point depression of the ice cream since it remains distinct, in that case the sugars within the ripple sauce simply keep the ripple softer than the ice cream, rather than influencing the ice cream *per se*. The combined effect of all solutes in the mix on freezing point depression can be calculated (Whelan et al., 2008) and is generally shown as a freezing curve (Fig. 5), which illustrates the initial freezing temperature (achieved within the barrel freezer) and then the amount of water frozen (ice formed) as a function of temperature for each formulation. Hence the sugars are dictating the ice phase volume at any specific subzero temperature. The freezing temperature of the unfrozen phase is equal to the ambient temperature of the product. If temperature rises or falls, the ice:unfrozen water will maintain an equilibrium balance, following this freezing curve.

If ice cream is being manufactured for scooping, it is critical that the freezing curve of all flavours overlaps in the temperature zone of the scooping cabinet freezer, otherwise some products will be much firmer than others, which makes scooping difficult and results in large product inconsistencies. Another important manifestation of the freezing curve is that ice crystals are more prone to growth and recrystallization when there is more water present in the product (Hagiwara and Hartel, 1996), i.e., on the elevated plateau portion of the freezing curve. This will be discussed further below.

If ice cream temperature is very cold and highly freeze-concentrated, the unfrozen phase can undergo a glass transition and itself become an amorphous solid. Below the glass transition temperature ( $T_g$ , usually a value of  $-28$  to  $-30$  °C is used), ice cream can be stored for many months with no change in structure. At temperatures above the  $T_g$ , mobility within the unfrozen phase is possible and recrystallization, the movement of water from one crystal to another to cause a net increase in median size, can occur (Fig. 6). At constant temperatures, this process, known as Ostwald ripening, is slow. However, with temperature fluctuations, melting and refreezing along the freezing curve occurs. Melting can cause the loss of the tiniest of the ice crystals, whereas refreezing typically

**Figure 5** Ice cream freezing curve, showing the relationship between temperature and frozen water for two mixes that vary in solute concentration. There is more water frozen at both draw temperature and retail cabinet temperature for the mix with lower concentration and/or higher molecular weight of solutes, compared to that with higher concentration and/or lower molecular weight of solutes. Heat shock occurs by melting and refreezing water, a result of raising and lowering temperature as seen by moving up and down the freezing curve.

**Figure 6** Ice crystals in ice cream as seen with low temperature scanning electron microscopy. Image on the left in freshly-frozen and hardened ice cream, image on the right in heat-shocked ice cream. Same magnification in both images, bar = 100  $\mu\text{m}$ .

causes the largest crystals to grow at a faster rate (in an effort for the system to minimize surface area and hence surface free energy; Adapa et al., 2000). Hence melt-refreeze recrystallization is much faster compared to isothermal Ostwald ripening (Regand and Goff, 2002). The rate of recrystallization is a function of the quantity of unfrozen water, hence again not just temperature but also the combined effects of the solutes (Hagiwara and Hartel, 1996). If a formulation produces a low freezing curve, it will be more prone to recrystallization at any given storage temperature compared to one with a higher freezing curve (Fig. 5). Also, at lower temperatures there is less melting and refreezing for a fixed temperature interval than for the same temperature interval at higher temperatures, due to the shape of the freezing curve (Fig. 5), hence ice cream is more prone to recrystallization at elevated temperatures than at temperatures closer to the  $T_g$ .

The size distribution of ice crystals in ice cream is directly related to its sensory quality. It has been shown that sensory perception of iciness and coarse textures correlate directly to ice crystal size (Russell et al., 1999). Usually a median size of 45  $\mu\text{m}$  is used as an upper limit. Once median size exceeds this sensory threshold, ice cream quality is noticeably affected (Fig. 6). Shelf life is mostly dictated by the development of coarse/icy textures, since there is very little enzymatic activity and no bacterial growth and there are very few, if any, chemical reactions occurring, maybe a bit of oxidation of fat, but slow, especially since mostly saturated fat is used. The polysaccharide stabilizers can help to control ice crystal growth during temperature fluctuations (Hagiwara and Hartel, 1996; Flores and Goff, 1999; Adapa et al., 2000). They do so by becoming freeze-concentrated in the unfrozen phase and, since they are large molecular weight biopolymers, exceeding their critical concentration and becoming highly viscous. Cryo-gelling can also occur in the case of locust bean gum, and protein polysaccharide interactions can also influence unfrozen phase biopolymer structure (Cheng et al., 2015). This exceedingly high viscosity or biopolymer structure in the unfrozen phase limits migration and thus tends to preserve ice crystal size distributions for longer periods (Regand and Goff, 2002). Hence maintenance of shelf life depends on freezing point depression/freezing curves, the presence of stabilizing gums and on maintenance of low and constant storage temperatures.

## Conclusions

The structure of ice cream and frozen desserts can be very complicated and prone to defects arising as a result of not optimizing structure for product performance. These products are emulsions and foams, have a temperature-dependent ice:unfrozen water equilibrium that is affected by dissolved solutes in solution, and also have dispersed macromolecules in the unfrozen phase. Physical properties arise from this complicated structure and these affect product performance. Attributes including dryness on extrusion, shape retention during melting, scoopability and texture all depend extensively on structure. Changes in structure with storage time, especially ice recrystallization, can dramatically reduce shelf life, from months to days, so a thorough understanding of the creation and control of structure is critical for successfully delivering high quality products to the consumer.

## Introduction

Milk is a highly complex fluid, composed of multiple elements that exist in different states, such as lactose and minerals in true solution, fats in an emulsion, and proteins in a colloidal state. This makes it highly versatile beyond being consumed fresh, and it is turned into a wide variety of products including cheese, butter, fresh fermented products, and a wide range of powders. Dairy powders offer the advantage of a longer shelf life and lower shipping costs due to reduced shipping volume, however, if they are to be used in liquid form they require reconstitution.

It is desirable for reconstitution to be quick and require minimal stirring, with the end product closely resembling the liquid state prior to concentration and drying. However, reconstitution is a complex process and depends on the powder structure and the reconstitution conditions, such as temperature, stirring speed and water composition (Syll et al., 2012).

Powder structure can be defined in many ways and is determined by the processing, transport and storage history of the powder. This work focuses on the particle level related structures, which include the key properties of particle size, shape, density, and both surface and bulk composition. However, structure at the molecular level is discussed where appropriate, such as where the denaturation and interaction of proteins contributes to the reconstitution behaviour of the powder.

## Rehydration Characteristics

Rehydration is a complex process and has to be defined for the structure-rehydration relationship to be understood. Rehydration of dairy powders is usually grouped into four key steps in order of occurrence: sinking, wetting, dispersing and final solubilizing (Pisecky, 2012).

Sinkability measures the time that it takes for particles to penetrate through the surface of the water, whilst wettability is a measure of how well the powder absorbs water. In practice “wettability” is often used for industrial measurement to represent both, as they are difficult to distinguish by measurement (Pisecky, 2012). Whilst there is an ISO method for wettability (ISO/TS 17758:2014), no such standardized method for sinkability exists. Wettability is measured by weighing out a specific quantity of powder and dropping it into a beaker with water in a controlled manner. Wettability is taken as the time that it takes for all of the powder to penetrate the surface of the water. The exact measurement conditions depend on the type of dairy powder being tested (Pisecky, 2012).

Alternate measurements of wettability have also been used where the standard methods have been found to be inappropriate due to extremely poor wetting, such as of non-agglomerated casein powders (Gaiani et al., 2007). These include contact angle measurement for monitoring milk protein concentrate (MPC) wettability (Crowley et al., 2015; Fitzpatrick et al., 2016) and the initial period of turbidity measurement (Gaiani et al., 2007).

The next step in the rehydration process is dispersibility, where the powder begins to break up into individual particles. Powder is stirred by hand into a specific quantity of water for 10 to 20 s. The resulting solution is passed through a fine mesh and either the total solids of the resulting solution or the residue remaining on the mesh are measured. Any material remaining on the mesh is considered undispersed, and the larger this is the poorer the dispersibility of the powder (Pisecky, 2012).

Meanwhile, solubility, is a measure of the final solution, and is well standardised for skim and whole milk powder. It is measured using an insolubility index (IDF Standard 129A:1988) and the test is conducted using a high speed mixer followed by centrifugation to determine un-dissolvable content.

Alternative methods have been proposed for measuring rehydration properties of different dairy powders, again especially for protein powders that exhibit widely different reconstitution characteristics from whole and skim milk powders. The definitions of dispersibility and solubility have become blurred as most studies do not relate alternative methods to the standard procedures, and thus the general terms of rehydration or reconstitution characteristics are used. The main three alternative methods applied are: measuring the change in turbidity during reconstitution (Gaiani et al., 2006; Gaiani et al., 2005; Gaiani 2009); monitoring the change in particle size using laser light scattering (Mimouni et al., 2009; Syll et al., 2012; Chen and Lloyd, 1994) or focused beam reflectance measurement (Fang et al., 2011). It should be noted that in these measurements the end-point of dispersion or solubility is inconsistent between papers, thus making results difficult to compare.

## Types of Dairy Powders

A survey of literature referenced in this work and the big dairy powder manufacturers such as Arla, Fonterra and Amul, demonstrates the range of dairy powders being produced. The large range of dairy powders available has been driven by increasing demand for different nutritional and functional protein products and advances in separation technology (Tavares and Malcata, 2016; Kelly, 2011). It is not possible to have a discussion of the structure and rehydration properties of dairy powders without first knowing

**Table 1** Different types of dairy powders and typical compositions

Main type	Sub-types	Composition notes
Whole milk powder (WMP)	regular (un-agglomerated) agglomerated (AWMP)	min 26% fat
Skim milk powder (SMP)	instant (IWMP) regular (un-agglomerated) instant/agglomerated (ISMP) ultra-heat treated (UHT)	min 26% fat, 0.15%–0.25% lecithin ~1% fat
Fat filled powders	varied, depends on milkfat substitute	
Whey protein	whey protein concentrate (WPC) whey protein isolate (WPI) cheese whey powder (sweet/acid) demineralised whey	30%–80% protein >90% protein
Milk protein concentrate (MPC)	MPC40–85 milk protein isolate (MPI)	40%–85% protein >90% protein
Casein powders	micellar casein (MC) sodium/calcium caseinate (SC/CC)	84%–92% protein
Cream powder		55%–72% fat
Buttermilk powders	sweet buttermilk powders acid buttermilk powders	
Lactose		pure

exactly what type of powder is under discussion, and also how it was manufactured. Some of the key powders are summarised in **Table 1**.

The powders produced in the largest quantity are whole and skim milk powders. These are manufactured by spray drying whole and skim milk respectively, with slight variations in the processing conditions to obtain instantised and UHT versions. Instant whole milk powder (IWMP) has a high fat content and a surfactant, lecithin, added to make the powder wettable. Fat filled powders are a subset of whole milk powders (WMP) where the butterfat has been substituted with animal or vegetable fat in order to make a more economical product (Pisecky, 2012).

Historically whey powder was originally manufactured from the liquid remaining after cheese manufacture, with sweet and acidic whey being by-products of rennet-coagulated and acid-coagulated cheeses respectively (Pisecky, 2012). However, with the development of different membrane filtration and separation technologies, the range of whey protein powders has expanded significantly. Skim milk can also be used as the raw starting material, for example in the production of whey protein concentrates (WPCs) and whey protein isolates (WPIs). In addition to the whey powders shown in **Table 1** other whey products include purified proteins from fractionation and hydrolysed products. Whey protein isolate is a term used to denote very high protein content whey powders.

MPCs have been described by Kelly (2011) as “protein-enriched forms of skim milk”, as the whey to casein protein ratio is the same (Nasser et al., 2017). The acronym is often followed by a number, which specifies the total protein content of the powder, and the wide range available caters to a variety of applications, such as cheese or yogurt making. MPCs can be formed through a number of routes, such as membrane filtration of skim milk followed by spray drying, with adjustment to the protein specification taking place through the addition of WPC, WPI, or caseinates, etc (Kelly, 2011). The exact route depends on the specific protein level desired. Similar to whey protein powders, the milk protein isolate form is used to designate very high protein content milk protein concentrate (MPC).

Micellar casein is produced by microfiltration of skim milk followed by diafiltration of the retentate (Gaiani et al., 2005). Caseinate products are made from the precipitation of casein from skim milk using acid or enzymatic coagulation, followed by milling, drying and grinding. The salt form of the caseinate are prepared through a reaction with alkali solution, such as sodium or calcium hydroxide (Sarode et al., 2016).

Cream and buttermilk powders have not received much attention in literature. Similarly, buttermilk powder is not a strongly marketable product, and therefore also has not been the focus of significant research such as protein powders (Pisecky, 2012). Lactose is widely used in applications such as infant formula and pharmaceuticals (Carpin et al., 2017), however as it is a sugar, its structure-rehydration relationship is less complex and will not be discussed.

## Structure-Rehydration Relationships

Structure encompasses a large spectrum of powder parameters, and includes not only the structure of the individual proteins, fat globules and particles, but also the structure of the bulk powder. The bulk composition is discussed as the dominating structural feature driving powder rehydration characteristics due to the overriding interaction between water, proteins, fat and lactose.

However, the bulk composition does not necessarily reflect the surface composition, and addition of surfactants, such as lecithin, has been used to modify the surface of WMP particles in order to make them wettable. In addition, within the same type of powder structural features such as the density, shape and size of the particles become important in driving both the dissolution rate and in determining the voidage between the particles that is available for water penetration.

### Effect of Bulk Composition

It could be said that the largest effect on rehydration originates from the bulk chemical composition of the powder. Whilst specific structural features may give powders variability within a specific type, the composition effect is dominant and not always easy to overcome with other structural modifications.

For example lactose and minerals have to be rehydrated into true solution, fat into an emulsion and the proteins into a colloidal state; lactose and minerals are highly soluble, fat is hydrophobic and proteins are generally hydrophilic, although the casein and whey protein fractions show different properties. The relative proportion of these compounds is very important, for example [Richard et al. \(2013\)](#) found that the addition of lactose to poorly soluble MC powder improved its rehydration time by 5.2 times.

Skim milk powders rehydrate easily, with wetting taking less than 30 s and a minimum dispersibility of 90% within 10 to 20 s ([Pisecky, 2012](#)). This is because of the low fat and high lactose content. Whilst regular WMP rehydrates poorly due to the high fat content, IWMP is especially designed and can have better rehydration characteristics than SMP with a wettability of approximately 15 s and minimum dispersibility of 95% ([Pisecky, 2012](#)). Although the actual wettability and dispersibility of the powders vary depending on the powder and operational parameters during manufacture, overall the rehydration times of SMP and IWMP are very quick.

The two main types of protein, whey and casein tend to have opposing rehydration characteristics, with whey protein powders having good reconstitution ability. [Table 2](#) shows that whey permeate and WPI powders take in the order of a few minutes to rehydrate.

Meanwhile powders with a high casein content, such as MPC, MPI, and casein itself, generally have poor rehydration characteristics, which worsen with increasing protein content ([Crowley et al., 2015](#)). This is the reason that the total rehydration behaviour of high protein powders is often measured by monitoring the change in particle size using static light scattering or focused beam reflectance measurement, as opposed to using the methods described previously ([Gaiani et al., 2005](#)). Different criteria are used for classifying the powder as reconstituted, such as when the median particle size reaches an asymptote ([Syll et al., 2012](#); [Fang et al., 2011](#)) or when it reduces to a pre-specified size ([Ji et al., 2015, 2016a,b](#)).

Another key difference is that the reconstitution process of protein powders usually employs high speed mixers, as opposed to SMP and IWMPs where manual agitation is sufficient. Hence, due to the differences in the measurement techniques, the exact type of powder and the end-point of rehydration, the reported times can vary appreciably. Some example rehydration times for high casein powders are shown in [Table 2](#), and they vary from 20 minutes to over 24 hours, with 'hours' being the typical timescale, with the exception of sodium caseinate.

Although the overall bulk composition is important, how the powder is processed is as well. For example MC and WPI mixed before spray drying or after spray drying significantly affects rehydration of proteins. [Gaiani et al. \(2007\)](#) found that mixing the two proteins before spray drying significantly improved the rehydration characteristics of the powder compared with dry mixing post manufacture, possibly due to steric hindrance of whey preventing the MC folding during drying.

Another example is that excessive heat treatment and shearing during manufacture denatures proteins, imposes a high protein load on fat globules, and encourages protein–protein interactions, which impedes good solubility characteristics ([GEA, 2010](#); [McKenna, 2000](#)). A further example is the addition and removal of calcium, such as used for fortification, which has profound effects on the powder properties such as heat stability during reconstitution ([Deeth and Lewis, 2015](#)). These examples illustrate how processing affects reconstitution through changes in the molecular structure.

**Table 2** Rehydration times for different protein powders

Powder	Rehydration time
MPCs	Highly dependent on protein content, but MPC80 was not fully rehydrated after 30 minutes in the work by <a href="#">Fang et al. (2011)</a> , some MPCs shown to not be fully rehydrated after 24 hrs ( <a href="#">Crowley et al., 2015</a> ) although most formed stable suspensions, >3.5 hrs for MPC85 ( <a href="#">Mimouni et al., 2009</a> )
MPI	40–60 minutes ( <a href="#">Ji et al., 2015</a> ; <a href="#">Ji et al., 2016a,b</a> ), only 44% solubilised after 60 minutes ( <a href="#">Fitzpatrick et al., 2016</a> )
MC	from 20 minutes ( <a href="#">Ji et al., 2016a,b</a> ), to 4–35 hours depending on storage ( <a href="#">Nasser et al., 2017</a> ), to 6–8 hrs depending on stirring speed ( <a href="#">Syll et al., 2012</a> ), 9–14 hrs reported by ( <a href="#">Gaiani et al., 2005, 2007, 2009</a> ), 3–5 hrs depending on stirring speed ( <a href="#">Richard et al., 2013</a> )
SC	4 minutes ( <a href="#">Ji et al., 2016a,b</a> )
CC	>90 minutes ( <a href="#">Ji et al., 2016a</a> ), ~6 hours for four commercial products ( <a href="#">Moughal et al., 2000</a> )
Whey permeate	95% solubilisation after 1 minute ( <a href="#">Fitzpatrick et al., 2016</a> )
WPI	within 6 minutes ( <a href="#">Ji et al., 2016a</a> ), 17 minutes ( <a href="#">Gaiani et al., 2007</a> ), 4 minutes ( <a href="#">Gaiani et al., 2009</a> )

### Effect of Surface Composition

During dissolution, the surface of the particles sees the water first, and therefore the surface composition, or surface chemistry, is a factor that can be altered to change the rehydration behaviour. The addition of lecithin is a simple example of how a surface coating of a surfactant makes a hydrophobic powder wettable and easy to reconstitute, as with its application for instantising regular whole milk powder.

Some whey powders are also lecithinated and agglomerated, similar to IWMP, however in this case it is used to delay water absorption, as the proteins are very hydrophilic and instant absorption of water can interfere with dispersion (GEA, 2010).

Storage has a profound effect on the structure of dairy powders, resulting in worsening rehydration properties over time. McKenna (2000) found that it caused a 'skin' to develop on the surface of high protein particles that reduces water penetration. Mimouni et al. (2010) investigated the effect of storage on MPCs and found that interactions between casein micelles increase, resulting in a structure that prevents dispersion of the micelles and other components dispersing into the water. Similar to McKenna, the formation of a compact 'skin' on the surface of the particles caused the slowing of dissolution with storage (Mimouni et al., 2010). Increased interactions between surface casein micelles and migration of fat to the surface during storage were similarly implicated by Nasser et al. (2017).

Additionally, it has been reported that fat tends to be over-represented on the particle surface in comparison with the bulk composition (Kim et al., 2002, 2009; Gaiani et al., 2010). This was similarly found by Gaiani et al. (2006) for spray dried casein powders, in addition to the surface being depleted of minerals and lactose. The wettability of the powders was found to be correlated with the surface lactose content, whilst the dispersion of the powders was more affected by the bulk composition.

### Effect of Particle Size

Agglomeration to increase the particle size has long been investigated as a means of improving the rehydration ability of powders. Neff and Morris (1968) showed that the agglomeration of SMP, up to a limit, improved the reconstitution behaviour of SMP in 1968. Part of the instantisation process of manufacturing IWMP is the recycling of fine particles back into the spray dryer to create larger agglomerates (Pisecky, 2012). However, agglomeration only works up to a certain particle size, and above that hinders reconstitution as very large particles take a long time to dissolve. The different powder types have different 'optimal' particle sizes for reconstitution.

It is well known that IWMP rehydrates best with less than 10% particles < 125 µm and less than 10% particles > 500 µm, as the fine and coarse particles affect both the wetting and dispersing behaviour (Pisecky, 2012; Boiarkina et al., 2017). Gaiani et al. (2011) found that the optimal size for dispersion increased with increasing fat fraction, with 160 µm, 180 µm and 220 µm being optimal for SMP, semi-SMP and WMP respectively.

The effect of agglomeration on proteins is similarly complex. For example, Gaiani et al. (2007) found that rehydration time was retarded when MC powder was agglomerated, but had only a small positive effect on WPI powder. For MC the dispersibility of larger particle sizes over 350 µm decreased to 0, supporting the negative correlation. The negative effect of agglomeration on rehydration of MC powder was similarly found by Richard et al. (2013). Calcium caseinate, similar to MC, was also found to dissolve poorly with or without agglomeration (Ji et al., 2016a). One notable exception of the casein powders is sodium caseinate, which rehydrated rapidly in the work of Ji et al. (2016a), even at the smaller particle size.

Akin to the work of Gaiani et al. (2007), the negligible effect of agglomeration on WPI was also found in (Ji et al., 2016a), and the dispersibility of WPI increased slightly with decreasing particle size down to 40 µm.

Overall, powders made with hygroscopic materials such as lactose and minerals, or WPI, tend to rehydrate faster, with a favourable effect of an increase in particle size, up to a limit. But in powders where the dissolution of the individual particles are slow, like MC, increasing the particle size has the opposite effect.

### Effect of Particle Density

Although this is a structural parameter that is not often investigated in research, the higher the density of the particles the better they are able to sink and penetrate the surface tension of water for better rehydration (Birchal et al., 2005). The Handbook of Milk Powder Manufacture (Pisecky, 2012) recommend that the particle density be at least 1.15 g/cm<sup>3</sup> for fat containing powders for good wettability. The effect of particle density on other types of powders has not been investigated, and it is not known whether the recommendation of Birchal et al. (2005), that occluded air in droplets should be avoided during atomisation to increase the particle density, should apply across all spray dried dairy powders. However, the premise is sensible, although minimum or optimal particle density requirements for different powders are not known.

### Effect of Particle Morphology

Particle morphology can be measured through a number of parameters, such as convexity, solidity, circularity and elongation (Gaiani et al., 2011; Boiarkina et al., 2016). However, until recently, with advances in computing power and image processing techniques, it was not possible to quantitatively measure the morphology of a powder. Pisecky (2012) described the ideal agglomerate

shape for skim and whole milk powder dissolution as being a 'loose grape', as 'onion' shapes tend to take a long time for the particles to fully dissolve. Thus, a lot of the discussion of the shape of particles is tightly linked with powder agglomeration (Williams, 2007; Williams et al., 2009).

There has been little work looking at the link between dairy powder morphology and powder rehydration characteristics in a quantitative way. Gaiani et al. (2011) looked at morphological descriptors for understanding rehydration properties of different dairy powders. The convexity, sphericity and size were included in a partial least squares model for predicting the solubility and dispersibility of the powder, and the model performed well. However, due to the nature of the model, it is not clear exactly how these shape parameters affect the rehydration behaviour, or indeed if they are just indicators of powder type.

Boiarkina et al. (2016) investigated the difference in morphology between different spray drying plants and found that particle convexity and solidity were higher for the plant producing IWMP with the best rehydration properties, however this was also the plant that produced particles with a larger average particle size. Therefore the authors concluded that morphology is likely to be an indicator of the agglomeration state, and the size is likely to swamp any direct shape effect on dissolution.

## Conclusions

The structure and rehydration properties of dairy powders are intimately interlinked, starting with the powder composition. Skim and instant whole milk powders have been long developed to rehydrate well, through particle size enlargement and lecithination for WMP. On the other hand, the structure-rehydration relationship of the wide array of protein powder available is not well understood. Casein powders tend to have long rehydration times, unlike whey protein powders. The surface structure and composition is important for rehydration, which changes with processing and storage conditions. Any processing or storage conditions that denature proteins, encourage protein-protein interactions or protein incorporation into fat globules retard powder rehydration ability. Particle size is important for some powders, such as SMP and IWMP, but not for others, such as casein powders, where an increase in particle size generally worsens the rehydration time. Powder rehydration is highly complex, and methods for modifying the structure, such as the surface composition, can be used to modify rehydration behaviour of different dairy powders. However, in order to do this, the structure-processing relationship needs to be understood.

Chocolate, or *Theobroma cacao*, brings a smile to faces everywhere. It has a deep history and can be traced back to the Mayan empire as the drink of the gods, but how exactly does the chocolate that we know come to be?

According to Merriam Webster, chocolate is a “food prepared from ground cacao beans” (Definition of Chocolate, 2018). The *T. cacao* tree produces pods containing cacao beans. “Cacao” is a botanical reference for the unfermented beans. Once harvested and fermented, these beans are now called “cocoa”, the major ingredient in chocolate products (Minifie, 1999).

Chocolate appears in the FDA’s Code of Federal Regulations (CFR) in 6 different categories – chocolate liquor, cocoa powder, breakfast or high fat cocoa, milk chocolate, sweet chocolate (semi-sweet or bittersweet), and white chocolate. Each type has a different “Standard of Identity” that must be met to legally be called chocolate. Chocolate can only contain cocoa butter and butter oil as fat sources and may only obtain chocolate flavor from the chocolate liquor. Additional flavors, such as dairy and those mimicking chocolate, may not be used (Food and Drug Administration, 21. C.F.R. 163.123, 2016). Table 1 lists the standards for sweet and milk chocolates. White chocolate must also only contain cocoa butter and butter oils added with dairy ingredients (21. C.F.R. 163.130, 2016), but it does not contain any cocoa particles (hence, the white color).

Chocolate processing begins on cacao plantations typically found within 15° of the equator. Cacao beans grow in pods on *T. cacao*. Once a tree reaches maturation, each pod harvested will typically have 30–40 cacao beans (Lima et al., 2011). The beans and pulp are removed from the pods and fermented for one to six days, depending on bean type (Afoakwa et al., 2008b). After fermentation, the beans are dried to a moisture content around 6%–8%, packed and shipped to bean processing centers as raw cocoa beans (Afoakwa et al., 2008b).

The fermented dried beans are cleaned and roasted before the winnowing process where the shells are separated from the nibs. The shells, about 10%–14% dry weight of the bean, are typically seen as a waste product (Afoakwa et al., 2008b). Once separated, the nibs may go through an alkalization step for additional color and flavor development or go straight to the grinding process, crushing the nib into small particles. The crushing step allows the cocoa butter to be released from the bean, creating chocolate liquor. Once ground, chocolate liquor can be pressed to separate the cocoa butter from the cocoa powder.

Chocolate liquor is the ground nib containing liquid cocoa butter with cocoa particles suspended throughout. Although some alcohol is produced during fermentation, it is quickly converted into other products, rendering chocolate liquor nonalcoholic. Liquor can either be pressed, separating cocoa butter from cocoa powder, or the liquor can go straight to chocolate production. To make chocolate, liquor is combined with additional cocoa butter, sugar, and other ingredients, such as milk products, creating a paste. This paste is then refined before conching.

Refining the chocolate paste reduces the particle size of the sugar and milk particles. Reduction of particle size impacts the texture, mouthfeel, and overall quality of the final product. Particle size in chocolate ranges from around 10–50 µm in the US and Europe (Jeffery, 1993). In production, a five-roll refiner is most common; the chocolate passes sequentially through the gaps between each roller. As the chocolate is processed, the gap thickness is reduced, creating smaller particles by attrition and breakage. Upon exiting the refiner, the cocoa mass has become solid, in the form of flakes, because of the high particle surface area. Once fully refined, the flakes are conched.

Conching is a process where shear and heat are applied to the refined mixture in two phases – dry and wet. Developed in 1879 by Rodolphe Lindt in Switzerland, conching is a key step in processing as the refined flakes become liquefied under shear. Liquefaction ensures the fat particles adequately coat sucrose, cocoa powder, and milk powder surfaces (The Lindt). During the initial “dry” conching phase, water and undesirable flavors are lost and flavor development continues. This is followed by a ‘wet’ conche, where additional cocoa butter and lecithin are added, ensuring all nonfat particles are coated with fat.

Overall, conching results in a product with desirable flavor development, and reduced water and low boiling point volatiles (Beckett, 2015). Lecithin, an emulsifier, is added to achieve desired yield stress and viscosity (Afoakwa et al., 2008a). Finally, the chocolate is ready to be tempered, formed by molding, depositing, or enrobing, and ultimately enjoyed.

**Table 1** “Standard of Identity” for sweet and milk chocolates

Chocolate type		Liquor		Milk fat		Milk components
		Minimum	Maximum	Minimum	Maximum	
Sweet	Sweet	15%	35%	–	12%	–
	Semi-Sweet	35%	–	–	12%	–
	Bittersweet					
Milk		10%	–	3%	–	12%

## Important Chocolate Processes

The processing of cocoa beans into bars requires several steps. Proper fermentation and drying is necessary for high quality chocolate. These processes allow valuable flavor precursors to develop within the bean.

### Fermentation and Drying

Fermentation of the beans is critical for flavor and aroma development. The beans and pulp are removed from the pod and placed in baskets, heaps, or boxes for fermentation, which lasts for one to six days depending on the bean type (Afoakwa et al., 2008b). Fermentation of the beans is still largely uncontrolled, occurring based on whatever microorganisms are present in the local environment. As the temperature during fermentation increases, the pulp drains from the beans (Schwan and Wheals, 2004). At about the third day, the beans reach between 45–50 °C and remain at this temperature until fermentation is complete.

The pulp composition surrounding the beans is about 85% water and 11% sugars (Minifie, 1999). The anaerobic conditions allow for microbial breakdown where yeast convert the sugars in the beans to ethanol. This ethanol is converted to acetic acid, carbon dioxide, and water by bacteria. During this time, the bean germinates and subsequently dies as the pulp drains off the beans (Hartel et al., 2018). Additionally, internal structural breakdown occurs, releasing enzymes and decreasing the pH from around 5.5–5.8 to 4.75–5.19 as acetic acid and lactic acid fermentation progress (Hartel et al., 2018; Lopez, 1979; Rohan and Stewart, 1967).

Numerous chemical changes take place during fermentation. Polyphenols are broken down into quinones and other compounds, while proteins and sugars are hydrolyzed into peptides and reducing sugars. These latter products serve as precursors for cocoa flavor and aroma development during roasting (Afoakwa et al., 2008b). Unfortunately, the highly nutritional polyphenols in chocolate, particularly catechin and epicatechin, are broken down during fermentation, reducing the nutritional status of the final chocolate.

Once fermentation is complete, the beans are dried. Drying the beans results in loss of moisture and, because of the warm temperatures, the start of flavor development. The desired moisture for shipping beans is around 6%–8%, which prevents the growth of molds. Drying techniques include air drying, shade drying, and sun drying, with sun dried beans having the most recognizable chocolate sensory properties (Hurst et al., 2011). Once dried, the beans are shipped to facilities to be processed and turned into chocolate products.

### Roasting

Dried cocoa beans are cleaned, sterilized and roasted upon arrival at the chocolate manufacturing plant. The beans are roasted at temperatures ranging from 120–150 °C for anywhere between 5 and 120 min, allowing further flavor development from fermentation precursors (Afoakwa et al., 2008b). Roasting also serves as an important safety step in chocolate processing. Fermented cocoa beans have high microbial counts and roasting sterilizes the beans, rendering them safe for consumption. Some chocolates on the market are 'raw', indicating that this kill step has not occurred. These products can still have high microbial contamination and be unsafe for consumption (Hartel et al., 2018).

Large scale roasting of beans is typically done in either a batch roaster or through continuous roasting. Batch roasting often occurs in a large drum with hot air blowing onto the beans to increase temperature. Several types of continuous roasting processes exist, including those that use radiation heating and heating tunnels. Overall, roasting parameters that need to be monitored are time and temperature because they drive moisture loss and govern flavor development reactions.

When roasting, it is important to ensure the beans are heated evenly but without burning the shell (Minifie, 1999). Roasting reduces the amount of moisture in the bean and allows for the shell to be loosened from the nib. This loose shell allows for easier separation from the nib during winnowing. The nib continues through production to be ground into chocolate liquor or pressed to expel the cocoa butter and cocoa powder.

## Important Chocolate Characteristics

The previously described processes develop the characteristic flavors and aromas associated with chocolate. These characteristics, along with the physical aspects of chocolate structure, will be discussed in further detail.

### Flavor and Aroma

It is important to understand how taste, flavor, and aroma differ and the roles each play when eating chocolate. Taste is comprised of the five basic attributes: sweet, salty, bitter, sour and umami. These tastes, in conjunction with trigeminal sensations, such as spicy, cooling, astringent, etc., and aroma make up the flavor of a substance. Flavor and aroma both play a key role in the quality of chocolate. Flavor is defined as "the sensation caused by and those properties of, any substance taken into the mouth which stimulates one or both of the senses of taste and smell, and/or also the pain, tactile and temperature receptors in the mouth" (American Society of Flavor Chemists). Aroma is the perception of flavor. There are over 10,000 aromas recognizable, including floral, spices, and dairy notes. Recognizing and characterizing these flavors and aromas helps to ensure chocolate quality over time.

The development of flavors and aromas from the fermentation, drying, roasting, and conching processes create the characteristic chocolatey notes. Bean origin impacts chocolate flavor and aroma; bean blending is common practice for a balanced profile although single origin chocolates are becoming increasingly popular. Other ingredients, such as milk products in milk chocolate, also contribute to the flavors and aromas of chocolates.

Alkalization is a technique commonly used to alter the flavor and color of cocoa, making it darker. Whole beans, nibs, liquor, and powder can all be alkalized using either potassium or sodium carbonate. This process results in a pH increase (hence the term alkalization) from around 5.2 to 6.8 and up (Hartel et al., 2018), which changes the pathways of the Maillard reaction and changes the volatile flavors generated. This technique can be beneficial; however, some argue that true chocolate flavors are lost.

Milk chocolates also develop flavor and aroma with the inclusion of dried milk powders, whether whole milk or nonfat milk powders. These powders are added to the liquor and sugar to form a chocolate paste that is refined. Milk powders are processed in a variety of ways, creating differences in how they affect chocolate. Particle shape, size, structure, and composition all impact chocolate processing conditions. In milk powders, the ability of milk fat to interact with cocoa butter and particles has the greatest impact, specifically on the crystallization of the cocoa butter (Liang and Hartel, 2004).

Some milk chocolates utilize the milk crumb process instead of or in addition to milk powders. Milk crumb is made by evaporating fresh milk, condensing it to about 90% total solids. During evaporation, the Maillard Reaction occurs between the milk protein and sugars, developing caramelized and creamy flavors (Minifie, 1999). The crumb is mixed with chocolate liquor and dried to a powder containing about 1% moisture for use in a similar manner as milk powders.

## Structure

The structure of chocolate is quite complex, yet these structures play an important role in chocolate quality. Various different aspects will be discussed: particle size and rheological properties, fat phase, tempering chocolate, and fat bloom.

### Particle Size and Rheology

One important differentiating factor between brand and quality of chocolate is smoothness. This attribute is governed by the size of the various particles that make up its dispersed phase. Chocolate is approximately 60%–70% dispersed particles (sucrose crystals, cocoa powders, and milk powders) contained within a fat phase, the cocoa butter. These particles have a large impact on chocolate mouthfeel (Afoakwa et al., 2009). Since humans can detect particle sizes ranging from 16–20  $\mu\text{m}$  depending on the matrix of the system (Hartel et al., 2018), the refining step, described previously, must reduce the particle size to less than this. High quality chocolates have small particles and impart a smooth, creamy mouthfeel. However, reducing particle size too much has undesirable consequences, related to how well the melted chocolate can flow.

Melted chocolate must have the proper flow properties for the intended application (Afoakwa et al., 2008a). The two parameters that govern these flow properties, or how easily the melted chocolate can be pumped or formed, are yield stress and viscosity. Yield stress is a term used to explain the “stand-up” properties of a material. Something with a high yield stress, like thick mashed potatoes, resists the force of gravity and does not flow unless some pressure is applied (as in a pump). Viscosity describes the thickness or consistency, with water having low viscosity and honey having much higher viscosity. Both yield stress and viscosity are critical to chocolate processing.

From pumping across plants, to depositing or coating, the flow properties of a chocolate are critical to efficient operation. They must also be balanced with the intended application (Hartel et al., 2018). Chocolates used for molding generally have a thinner consistency with little to no yield stress, so the fluid chocolate flows readily to fill all the nooks and crannies in the mold. Chocolates used in depositing, like the Hershey’s Kiss or chocolate chips, have a thicker consistency with a high yield stress. Such products are simply deposited onto conveyor belts and must retain their shape prior to cooling. The high yield stress of these chocolates provides the stand-up properties needed.

To control chocolate flow properties, manufacturers rely on composition factors. High fat content, for example, provides greater separation for the particles and reduces both yield stress and consistency. Lecithin, an emulsifier, is added at low levels (<0.5%) specifically to reduce viscosity. It acts by coating sugar crystals to prevent aggregation. Finally, particle size plays a key role in chocolate viscosity, with smaller particles giving higher viscosity than larger particles at a given fat content.

### Fat Phase

The main fat phase of chocolate comes from cocoa butter, although milk fat is often used in both milk and dark chocolates to moderate texture. Cocoa butter is a unique fat in nature; it is hard at room temperature yet completely melts in the mouth, with no waxy aftertaste. Rapid melting in the mouth results in rapid release of volatile aroma compounds, adding to the delightful flavor experience. But not all cocoa butters are the same. Cocoa butters from different geographical regions have varying chemical composition, giving them slightly different flavor profiles and melting characteristics (Hartel et al., 2018; Talbot, 2017).

In melted chocolate, the cocoa butter is liquid, but upon cooling, it solidifies into a crystalline form. However, cocoa butter crystallization is complex because it can take on multiple forms, depending on how it was crystallized. Cocoa butter has six known polymorphs or distinct crystalline forms, characterized by Form I–VI. Each form results in a varying degree of stability and each crystal has a distinct melting point (Wille and Lutton, 1966). Lower polymorphs, Forms I–IV, form looser crystalline structures and are quite unstable, wanting to transform into the more stable Forms V and VI (Afoakwa et al., 2009). Of these, the three main polymorphs of concern are often called  $\beta'$ ,  $\beta$ -V and  $\beta$ -VI, with their melting points shown in Table 2. The most desirable crystal form in chocolate is  $\beta$ -V based on its relatively long stability and its desirable melting point. Form  $\beta$ -VI, while technically the most

stable, is difficult to generate and has a melting point above mouth temperature. Proper tempering of chocolate is necessary to create  $\beta$ -V crystals.

### Tempering Chocolate

Tempering chocolate is a thermal treatment designed to create the proper crystalline form,  $\beta$ -V, allowing for chocolate to set properly and from a strong network (Windhab, 2017). Well-tempered chocolate results in a product with a glossy shine, an audible snap, good contraction from the mold, and resistance to bloom during storage. There are numerous methods to make tempered chocolate, although all are focused on creating the desirable  $\beta$ -V crystal (Hartel et al., 2018). The methods of tempering different chocolate types (sweet, milk, and white) are the same, with only the temperature points varying slightly.

If melted chocolate is simply allowed to cool without being tempered, the cocoa butter quickly forms unstable polymorphs. Rapid and uncontrolled transformation of these unstable crystals into more stable polymorphs leads to particle rearrangement and unsightly spots on the surface. These spots are called bloom, in this case caused by improper tempering. To accomplish good temper, melted chocolate is first cooled to rapidly promote formation of unstable polymorphs, primarily  $\beta'$ , and then heated slightly to promote transformation to the stable  $\beta$ -V polymorph. The end result of tempering is liquid chocolate with a few percent of  $\beta$ -V seeds; this liquid chocolate can then be used for molding or depositing. Upon cooling of tempered chocolate, the  $\beta$ -V seeds dominate solidification of the liquid cocoa butter, resulting in chocolates with desirable properties, including resistance to bloom during storage (Hartel et al., 2018).

### Chocolate Bloom

There are various types of bloom that can occur in chocolate. Sugar bloom occurs when moisture condenses on the surface of chocolate. A droplet of water on the surface draws sugar out of the matrix, which then recrystallizes as a white mound when the water evaporates. Sugar bloom is most common when unwrapped chocolate is removed from a freezer or refrigerator and exposed to humid air. If the surface temperature is lower than the dew point of the air, water condenses, eventually leading to sugar bloom.

Solidification of untempered chocolate also results in a form of bloom, distinguished by whitish spots surrounding a dark inner region. The whitish spots are thought to be depleted of fat and concentrated in particles (Lonchampt and Hartel, 2006).

Of most concern to the chocolate maker is long-term storage bloom. Even well-tempered chocolate is prone to gradual development of a whitish/gray surface tinge over time. Although this type of bloom looks like mold growth, it is merely the rearrangement of cocoa butter crystals at the surface that gives this appearance. Storage bloom is generally associated with appearance of the most thermodynamically stable cocoa butter polymorph,  $\beta$ -VI, although the polymorphic transition is not necessarily the cause of bloom (Bricknell and Hartel, 1998).

Chocolate makers have studied storage bloom for decades; however, the specific mechanisms that cause bloom are still unclear and the means for completely eliminating it remain elusive. It is generally accepted that storage bloom in chocolate occurs when a portion of the fat phase migrates to the surface, allowing recrystallization of cocoa butter over time, resulting in formation of a dull, whitish/gray surface (Hartel et al., 2018). Chocolate scientists continue to study bloom mechanisms in hopes of finding solutions to this centuries-old problem.

### Future of Chocolate

The future of chocolate will depend on a variety of factors, such as changes in the climate affecting the cacao growing regions of the world and developing solutions to better control and understand fermentation. Shifting temperatures and lack of humidity are already impacting cacao production. Potential solutions may include selective breeding or even genetically modified crops to help growers adapt to these continual changes (Climate and Chocolate). Controlling fermentation more carefully (rather than relying on the local microbiota) is also likely to help growers adapt to changes and lead to more controlled flavors/aromas of chocolate.

**Table 2** Melting points of cocoa butter polymorphs

<i>Polymorphic form</i>	<i>Melting point (C)</i>
$\beta'$	27–29
$\beta$ -V	34–35
$\beta$ -VI	36

# Traditional African Bread and the Physicochemical Properties of Unfermented Flatbreads

Geremew Bultosa, Botswana University of Agriculture and Natural Resources, Gaborone, Botswana

© 2019 Elsevier Inc. All rights reserved.

## Overview

Bread is a staple diet for communities across the globe. As humans progressed from hunter–gatherer communities to sedentary agriculture, they learned how to process bread from cereal grains grown in their area. Manual grain harvesting, threshing, grain cleaning, pounding with mortar and pestle for decortication, stone grinding to flour, mixing of flour with water to make dough, and baking on heated earthenware (clay baking griddle), on heated stone slabs, or in hot ashes were early technologies communities used in the production of their traditional/indigenous breads. In addition to wheat, barley, sorghum, maize, millets, and teff grains are widely used in the preparation of traditional breads in Africa. These cereal grains in the form of unfermented or fermented dough are baked and consumed as flat or semileavened bread. Those from wheat flour are used to process unfermented flat or fermented leavened bread. In many African countries, wheat grain production and supply are limited and because of this, composite flours from different cereal grains, legumes, and starchy food sources (tubers and roots) are also used. Common traditional breads consumed in different parts of Africa, their major ingredients, and their structural natures are described in **Table 1**. The list is by no means all inclusive for bread consumed throughout the African continent. Closely related breads or the same bread in terms of recipe and processing methods may also be called by different names in different communities. In the northern African regions, bread processed from wheat is popular, and to some degree breads processed from sorghum, millets, and maize are also consumed. In the eastern African regions, countries such as Ethiopia, Eritrea, Sudan, and parts of Somalia and Kenya, bread processed from the grains of teff, wheat, sorghum, and millets, particularly finger millet, are consumed. In the East African community countries Kenya, Uganda, Tanzania, Burundi, Rwanda, and South Sudan, breads processed from maize, sorghum, wheat, millets, and rice are consumed. In the southern African regions, bread processed from maize, wheat, sorghum, and pearl millet are consumed. In the western African regions, bread processed from sorghum, millets, fonio, cassava, wheat, rice, and maize are consumed. In the central African regions, bread processed from sorghum, millets, wheat, maize, and cassava are consumed. With the global nature of the wheat supply chain, different types of wheat breads are consumed in almost all African urban and semiurban areas.

## Bread Types Consumed in Africa

The traditional African breads may be classified based on the type of basic raw materials used and as unfermented, fermented aerated (leavened) (cross reference to article 2), flat (single layered or double layered), thin, or thick breads. The basic raw materials used are sources of carbohydrates (starches, fibers, and sugars), proteins, enzymes, minerals, lipids/fats, and bioactive/phytochemical compounds (**Figure 1**, **Table 2** (cross ref article 2) and **Table 4**). Because of differences in the chemical composition among wheat, maize, sorghum, teff, and millets, breads vary in terms of quality (nutrition, texture, and sensory properties) and cultural acceptance across regions. Furthermore, bread recipes; processing practices such as grain cleaning, soaking, decortication, pounding, milling, and dough making; fermentation conditions; the nature of fermenting microorganisms; and baking conditions can also influence the properties of the bread. In this article, the nutrient compositions of cereal grains (**Table 2**) and legumes/pulses, tubers, and roots (**Table 1** cross reference article 2) used in African traditional breads are included. The physicochemical properties inherent to bread making of cereal grains (**Table 4**) and legumes/pulses, tubers, and roots (**Table 2** cross reference article 2) are described along with the nutrient compositions of some baked breads (**Table 3**). Anatomical/histological structures of wheat (**Figure 1**), maize (**Figure 2**), and sorghum grains (**Figure 3**) are given as examples, because they are important to understand the processing of cereal grains. The methods of processing and properties of unfermented African flatbreads are described next.

## Unfermented Flatbreads

Unfermented flatbreads are probably the earliest type of processed food made by humans and predate the baking of fermented breads (Haaland, 2007). These types of bread are processed at large from wheat, maize, sorghum, teff, different species of millet, and rice grain flour. After grain cleaning, the processing of flatbread can vary depending on grain type, composition, and functionality **Table 2** (cross ref article 2) and **Table 4**. The properties of the bread can also vary, depending on flour particle size, whether the flour is refined or decorticated or whole grain flours are used, and if other ingredients (salt, oils/fats, and/or spices) are added. In addition, dough properties, dough relaxation, and baking methods all contribute. Often there are ceremonial/ritual attachments to certain breads, and in some communities bread is baked as a thanksgiving for the harvest, whereas others are attached to cultural and religious festivities.

**Table 1** Some traditional breads consumed in Africa and their common ingredients and structural features

<i>Bread name</i>	<i>Ingredients</i>	<i>Fermented/unfermented/flatbread/whole grain flour product</i>	<i>Country</i>
<i>Anise bread</i>	Wheat flour, yeast, salt, water, anise seed, maize	Leavened bread	Morocco
<i>Aish merahrah</i>	Maize flour with 5%–10% ground fenugreek seeds; maize dough fermented overnight with sourdough starter	Fermented; flattened into round disk-shaped pita-type bread	Egypt
<i>Baladi/balady</i>	Coarse wheat (about 82% extraction)/nearly whole wheat flour (85%–95%), yeast or starter from natural fermentation, water, salt, and olive oil; high water absorption, dough raises in oven and separates into two thin layers from steam generated, making top and bottom crust	Fermented pocket bread/sandwich bread, rough-textured bread	Egypt, Sudan
<i>Bazin</i>	Barley flour, water, salt, with soup from date syrup, olive oil, black pepper, tomato, onion, garlic, and mint	Unfermented bread (Neolithic dish made of dough and sauce)	Libya
Cassava–wheat bread	Bread wheat flour, cassava flour/cassava starch	Fermented composite bread	Nigeria
<i>Chapati/roti/chapati-like</i>	Wheat, maize, sorghum, or millet flours, water, salt. Optional ingredients (chopped onion, chili, coriander leaves and/or grated coconut)	Unfermented/unleavened flatbread	Uganda, Kenya, Tanzania
<i>Chà-chà-bsa/ché-ché-bsa</i> (pizza-like)	Wheat flour, salt, water	Unfermented flatbread; for consumption, baked bread is broken into pieces and mixed with spiced butter, false cardamom, red pepper	Ethiopia
<i>Chikwange/yikwanga/ntuka/bugali/ kmonmogo/chawada/bobolo/ myondo/mboung/mangbele</i>	Cassava pulp fermented, ground to flour-like, sieved to produce flavor, pounded, and then steamed/cooked as bread wrapped in banana leaf	Fermented cassava bread	Congo, Tanzania, Cameroon, Gabon, Congo Brazzaville, Central African Republic
<i>Cumboo</i>	Teff flour; sometimes sorghum and millet flours are mixed with teff; baked from fermented/early fermented dough	Thick fermented bread	Ethiopia
<i>Defo dabo (difo daabo)</i>	Wheat flour	Thick fermented bread	Ethiopia
<i>Hambasha/himbasha</i>	Wheat flour	Fermented semileavened flatbread; celebratory, slightly sweet, often served at special occasions; several varieties, most distinctive flavoring is ground cardamom seeds	Ethiopia and Eritrea
<i>Harcha</i>	Coarse semolina, high fat, salt, and water	Unleavened flatbread with high fat content, rough surface, and a long shelf life	Algeria
<i>Hibist</i>	Cereal grain flours intended to be used for all purposes of baking	Steamed bread	Ethiopia
<i>Injera/enjera/caabita/budeena</i>	Teff flour, sometimes sorghum and finger millet flours	Fermented, crepe-like, soft, spongy, sour, circular flatbread, whole grain flour product	Ethiopia and Eritrea
<i>Inya</i>	Cassava alone or mixed with either sorghum or millets	Fermented flat; when mixed with millet is a thick sweet bread	Uganda
<i>Kenkey</i>	Maize flour	Fermented maize dough dumpling-like bread	Ghana

(Continued)

**Table 1** Some traditional breads consumed in Africa and their common ingredients and structural features—cont'd

<i>Bread name</i>	<i>Ingredients</i>	<i>Fermented/unfermented/flatbread/whole grain flour product</i>	<i>Country</i>
<i>Kisra</i>	Sorghum flour, also sometimes from millet flour	Fermented, sour, pancake-like flatbread, relatively thin, with no holes, and no spongy, supple, soft, and moist in texture	Sudan, Ethiopia
<i>Kitta, bixxille, daguwalo</i>	Teff flour, sometimes sorghum and finger millet flours	Thicker than injera, unleavened or slightly leavened	Ethiopia
<i>Khubz</i>	Wheat flour	Rolled like pizza	Morocco
<i>Khobz eddar</i>	Fine durum semolina, water, fat, milk, yeast, egg, salt, and sesame	Leavened flatbread	Algeria
<i>Kwon kal</i>	Millet, cassava flours	Big round lump like	Uganda
<i>Laaffisso</i>	Sorghum flour	Fermented, semileavened flatbread	Ethiopia
<i>Lahoh/lohoh</i>	Sorghum flour, warm water, yeast, and a pinch of salt; self-rising flour	Leavened, spongy, pancake-like flatbread	Djibouti and Somalia
<i>Lahooh</i>	Sorghum flour along with wheat flour and/or corn flour	Flatbread, bulkier than <i>injera</i> and <i>kisra</i>	Somalia and Djibouti
<i>Maadjouna</i>	Fine durum semolina, water, salt	Unleavened flatbread, short shelf life, for immediate consumption after baking	Algeria
<i>Mathlouaa</i>	Fine durum semolina, dry yeast as leavening agent	Leavened flatbread, light and spongy, short shelf life, to be consumed on the day baked	Algeria
<i>Mehrahras</i>	Durum wheat flour	Leavened bread, fine uniform crumb structure and somewhat yellowish color; low loaf volume compared to bread wheat	Egypt
<i>Ngome</i>	Millet flour, water, and vegetable oil; home-ground and coarse millet flour	Flatbread	Mali
<i>Pita bread</i>	Wheat flour, salt, sugar, yeast, water, with optional ingredients (sugars, oils, or improving agents)	Low specific volume, pocket-like thin bread processed from lean dough, low in fat	Morocco, Egypt, Tunisia, Libya, Algeria
<i>Potbrood</i>	Wheat flour and sweet corn flour	Leavened bread	South Africa
<i>Owambo bread or Oshikwiila</i>	Pearl millet flour, water, seasoned with salt and/or sugar	Unleavened bread	Namibia
<i>Rakhsis</i>	Fine durum wheat semolina, fat, salt, water	Unfermented flatbread, thin, soft, homogeneous surface without blisters, firm crust, and a compact crumb; relatively long shelf life	Algeria
<i>Terablesi</i>	Wheat flour of low extraction rate (70%), salt, and yeast	Leavened bread	Tunisia
<i>Ujeqe dodogoyi, madombolo, umbhako, ledombolo, sigenza, ujeqe, monepola oa poone e ncha</i>	Maize, sorghum, or wheat flour	Steamed bread, round white-gray loaf, moist, soft, fine, firm with sticky crumb; nonwheat breads are crumbly, hard, and fibrous	South Africa
<i>Wheat bread</i>	Bread wheat flour, water, salt, yeast, fat/shortening, optional various bread improvers	Leavened bread	All countries

Céréales. 145, 3–7 and Brouns, F., Hemery, Y., Price, R., Anson, N.M., 2012. Wheat aleurone: separation, composition, health aspects, and potential food use. Crit. Rev. Food Sci. Nutr. 52, 553–568; color image available online.

### Maize Bread

Maize (*Zea mays* L.), also called corn, is a tropical cereal. The grain is hull-less (grains are loosely adhered to glumes, allowing easy removal during threshing), has the largest size among the cereal grains, and comes in many colors. The accumulation of different types of anthocyanins (cyanidins, pelargonidins, and peonidins) and other polyphenols in the pericarp, testa, and aleurone layer of the grain confers a blue, purple, or red color, whereas the orange color is due to the accumulation of carotenoids (lutein, zeaxanthin,  $\beta$ -cryptoxanthin, zeinoxanthin, antheraxanthin, and  $\beta$ -carotene) (Suri and Tanumihardjo, 2016). Widely cultivated varieties are flint, dent, floury, sweet, popcorn, high lysine (high protein quality), waxy, and amylomaize, and of these, flint, dent, and floury maize grains are widely milled into maize meals and flour (Nuss and Tanumihardjo, 2010).

Prior to processing, hand-cleaned maize grains are washed and soaked in potable water (about 3–12 h) (Greiner and Konietzny, 2006) and then gently scrubbed/polished with a mortar and pestle before soaking to remove the tip cap. Soaking facilitates bran (pericarp, tip cap, and germ) separation. After soaking, the grains are decorticated by pounding with a wooden mortar and pestle. The pericarp, tip cap, and germ are detached by the impact of pounding. The process also leads to different degrees of damage to the testa, germ, and aleurone layer. The pounded mass is spread, often on plates made from a variety of materials (plastic, stainless steel, jute bags, wood, or woven grass), and dried in the sun. The dried mass is sifted or winnowed (blowing air current through the mass) to separate light bran materials from the maize meal (samp). The process may not result in complete separation of clean endosperm; hence broken pericarp, germ, testa, and aleurone layer may remain, which can be nutritionally beneficial. On soaking and pounding, some micronutrients can also diffuse into the endosperm and some water-soluble nutrients and bioactive compounds can be lost by leaching. The maize meal is milled into fine flours (about <75–212  $\mu$ m) using stone mills or cottage mills (metal plates composed of stone attrition mills or hammer mills). Stone mills generate heat (Doblado-Maldonado et al., 2012) and result in damage to the starch granules, proteins, and unsaturated fatty acids compared with roller milling technology. In ancient milling, maize grains are hand milled by using a small, light top stone to rub the grains over a large, heavy, stationary stone. The same way of milling is also used for sorghum, wheat, barley, teff, and the millet grains. The flour produced is hand mixed with water and kneaded to make a consistent dough that can be easily spread. The dough is allowed to rest for some time (approximately 10–45 min) to allow uniform hydration of the flour particles and relax and stabilize disulfide bonds in the maize zein proteins, which assists in shaping of the dough. After shaping, the dough is flattened and spread onto a lightly greased baking griddle (clay or metal baking pan), covered with a lid, and steam baked. Various heat sources are used, including electricity, natural gas, and wood- and coal-burning fires. To bake variations of the bread, open pans can also be used (without steaming) and the bread is flipped to bake both surfaces evenly. Such flatbread is not fermented and thus is not aerated and presents with a dense structure. During baking, starch granules swell and gelatinize, proteins are denatured, and the bread is set. The color and flavor of flatbreads are influenced by the Maillard and caramelization reactions as well as by the type of maize grain used. Since fermentation is not involved, antinutrients such as phytic acid and condensed tannins (proanthocyanidins) can be present in the bread (Suri and Tanumihardjo, 2016). This is due to parts of the grain rich in these compounds (e.g., aleurone layer and germ) remaining in the flour

**Table 4** Bread-making physicochemical functionality features of cereal grains used in African traditional breads

Cereal grain	Physicochemical functionality	References
Bread wheat ( <i>Triticum aestivum</i> )	<p>Gluten forms continuous matrix around starch granules within matured cell of starchy endosperm; less hydrophobic than either kafirin of sorghum or zein of maize; forms viscoelasticity that favors strong dough gas holding suitable for processing of leavened aerated bread.</p> <p>Protein content 11%–14%, high in carbohydrates (74%–78%), low in fat (2%) and ash (1.5%–2.0%).</p> <p>Hard grains that are high in proteins and more vitreous are suitable for leavened bread making. Soft and medium-hard grains with 10%–12% proteins are suitable for processing of unfermented chapati-like flatbreads.</p> <p>White flours are used to process white bread, reconstituted brown bran for brown bread, whole grain flours for whole grain bread.</p> <p>Gluten proteins are allergens and cause celiac disease in some individuals.</p> <p>Starches are of large bimodal size (small spherical 1–10 <math>\mu\text{m}</math>, large lenticular 10–35 <math>\mu\text{m}</math>), but trimodal sizes are also reported.</p> <p>Amylose 23%–29%.</p> <p>Starch granule damage is influenced by milling degree (2%–4% starch granule damage is essential for bread processing). For unleavened flatbread processing a high level of starch granule damage (&gt;5%–15%) is essential.</p> <p>A-type starch granules with low starch gelatinization temperature of 58°C–64°C compared with tropical cereal grains, which can favor baking of thick dough.</p> <p>Endogenous wheat enzymes play a role in the modification of dough for bread baking.</p> <p>Leavened bread has distinct crust and crumb structures.</p> <p>Color and flavor are contributed to bread by Maillard and caramelization reactions.</p> <p>Whole grain breads can supply bioactive compounds (fiber from nonstarch carbohydrates, alkylresorcinols, benzoxazinoids, lignans, phenolic acids, C-glycosides of flavones, flavonols, flavanonols, proanthocyanidins, phytosterols, and tocols). Colored compounds are from colored wheat grains.</p>	Andersson et al. (2014); Taylor et al. (2016)
Durum wheat ( <i>Triticum durum</i> )	<p>White bread processed from refined wheat flours is limited in bioactive compounds.</p> <p>Gluten forms continuous matrix around starch granules within matured cell of starchy endosperm; less hydrophobic than either kafirin or zein; forms viscoelasticity but weak compared with bread wheat, less gas-holding ability, which leads to low bread loaf volume of distinct uniform fine crumb structures with relatively short shelf life compared with bread wheat.</p> <p>Protein content high (13%–14%), high in carbohydrates (71%–73%), low in fat (2%) and ash–minerals (1.8%–2.0%)</p> <p>Whole grain or semolina can be milled to flour.</p> <p>Durum wheat is high in grain hardness resulting in higher starch granule damage than bread wheat, yellowish flour.</p> <p>A-type starch granules; starches are of large bimodal size (small spherical 1–10 <math>\mu\text{m}</math>, large lenticular 10–35 <math>\mu\text{m}</math>), but trimodal sizes are also reported.</p> <p>Amylose 26%–28%. Low starch gelatinization temperature of 52°C–64°C compared with bread wheat, which can favor baking of thick dough compared with tropical cereal grains.</p> <p>Endogenous durum wheat enzymes can play roles in the modification of dough for bread baking.</p> <p>Maillard and caramelization reactions influence bread flavor and crust color.</p> <p>Can supply bioactive compounds (fiber from nonstarch carbohydrates, alkylresorcinols, benzoxazinoids, lignans, phenolic acids, C-glycosides of flavones, flavonols, flavanonols, proanthocyanidins, phytosterols, and tocols). Carotenoids (4–8 <math>\text{mg kg}^{-1}</math>) are accumulated in the endosperm of durum wheat grains. Semolina flours can be limited with bioactive compounds derived from pericarp, seed coat, aleurone layers, and germ, however can bear carotenoid compounds from endosperm.</p>	Shewry and Hey (2015); Taylor et al. (2016); Kezih et al. (2014)

Maize (*Zea mays*)

Free of the type of gluten proteins found in wheat grains. Zein is contained in isolated storage protein bodies and is a hydrophobic monomeric polypeptide, but less hydrophobic than kafirin, highly crosslinked due to high sulfur-containing amino acids but less so than in kafirin. It is much smaller in molecular size than the HMW-GSs of wheat, with a limited degree of viscoelastic properties because of limited protein body disruption upon dough making compared with wheat, but better than sorghum and millet proteins in making weak viscoelasticity.

Low in protein content (8%–10%) and quality, high in lipids/fats (4.0%–5.0%) if germ and aleurone layers are not removed, low in ash (1.2%–1.5%)

A-type starch granules, of size 5–30  $\mu\text{m}$ ; large sizes are polygonal and small are spherical.

Amylose 25%–28%. Amylomaize (50%–70%) and waxy maize (>99%) amylopectin varieties exist. Amylomaize contributes significant resistant starches.

Bran-removed maize meal flours contain large amounts of starches followed by proteins and endosperm cell wall nonstarch polysaccharides.

High starch gelatinization temperature of 62°C–72°C limits baking of wheat-type thick bread.

Arabinoxylans (pentosans) contribute to flatbread baking; lower  $\alpha$ -amylase and  $\beta$ -amylase activities with less amylolytic activity.

Can supply bioactive compounds (fiber from nonstarch carbohydrates, phenolic acids, flavonoid phenolic compounds, phytosterols, tocots) depending on degree of pericarp, testa, aleurone layer, and germ removal. Phenolic and carotenoid compounds are variable among differently colored maize grains. Purple/blue maize grains are sources of anthocyanins and nonanthocyanin flavonoids (rutin, hirsutrin, morin, kaempferol, quercetin, naringenin, hesperitin). Yellow maize grains are sources of carotenoids: zeaxanthin and lutein. Decortication and bran removal can reduce bioactive compounds. Soaking can reduce phytic acids and soluble bioactive compounds.

Nuss and Tanumihardjo (2010); Suri and Tanumihardjo (2016)

Sorghum (*Sorghum bicolor*)

Free of the type of gluten found in wheat grains. No dough viscoelastic properties, limited gas-holding and leavening capacity. Kafirin proteins found isolated in protein bodies. They are hydrophobic monomeric polypeptides, highly crosslinked due to high sulfur-containing amino acids, much smaller in molecular size than HMW-GSs of wheat, with insignificant protein body disruption upon dough making.

Protein content is 10.0%–12.0%, protein quality is poor and even poorer when cooked/baked; high in carbohydrates (70.0%–75.0%), nonstarch polysaccharides from endosperm are predominantly insoluble; high in fat (4.0%–4.5%), low in ash (1.6%), moderate in dietary fiber (6.3%).

Bran-removed sorghum meal flours contain large amounts of starches followed by proteins and endosperm cell wall nonstarch polysaccharides.

Amylose for common varieties is in the range 19%–33%. A-type starch granules, with a high starch gelatinization temperature of 68°C–78°C.

Small starch granules present in the pericarp limit clean endosperm separation on milling.

Arabinoxylans (pentosans) contribute to flatbread baking; lower  $\alpha$ -amylase and  $\beta$ -amylase activities with less amylolytic activity compared with wheat flour. Some varieties contain condensed tannins.

Can supply bioactive compounds (fiber from nonstarch carbohydrates; phenolic acids; flavonoid phenolic compounds, notably 3-deoxyanthocyanidins luteolinidin and apigeninidin; policosanols; phytosterols; tocots) depending on degree of pericarp, testa, aleurone layer, and germ removal.

Most sorghum varieties are recognized by their high phenolic compounds, low proteins, and starch digestibility. Black sorghums are high in anthocyanins. Decortication and bran removal can reduce bioactive compounds. Soaking can reduce phytic acids and soluble bioactive compounds.

**Table 4** Bread-making physicochemical functionality features of cereal grains used in African traditional breads—cont'd

Cereal grain	Physicochemical functionality	References
Teff ( <i>Eragrostis tef</i> )	<p>Free of the type of gluten found in wheat. Prolamins of teff are dimers with no dough viscoelastic properties and a single dominant sequence. Even though they have a high degree of homology with <math>\alpha</math>-prolamins of maize and sorghum, the prolamins (eragrostins) of teff are different. Limited gas-holding and leavening capacity, insignificant protein body disruption upon dough making. <math>\alpha</math>-Globulins in teff are implicated in playing a major role in the large size protein body aggregation observed in teff influencing dough properties.</p> <p>Protein content 9.4%–13.3%, high in carbohydrates (73.0%), low in fat (2.0%–3.1%), medium in ash content (2.7%–3.0%), medium in crude fiber content (2.0%–3.5%).</p> <p>A-type starch granules, compound type. Individual starch granules 2–6 <math>\mu\text{m}</math>, high starch gelatinization temperature of 68°C–80°C. Because of its small grain size (about 0.9–1.7 mm in length, 0.7–1.0 mm in diameter, individual grain mass <math>\leq 2</math> mg) always milled to whole grain flour; low fat, and rancidity development over duration of usage insignificant (milled whole teff grain flours are used from one to two months at household handling).</p> <p>Endogenous teff enzymes play a role in the modification of dough for bread baking.</p> <p>Can supply bioactive compounds (high fiber from nonstarch carbohydrates, high phenolic acids, and low flavonoids). Relatively high in mineral contents, notably calcium, magnesium, and iron.</p>	Hager et al. (2012); Bultosa (2016); Zhang et al. (2016); Marti et al. (2017); Shumoy et al. (2017)
Rice ( <i>Oryza sativa</i> )	<p>Free of the type of gluten found in wheat. No dough viscoelastic properties, no or insignificant gas-holding and leavening capacity, insignificant protein body disruption upon dough making.</p> <p>Protein content in white rice is very low (6.3%), high in carbohydrates (mostly starches) (80.1%), very low in fat (1.4%), very low in ash–minerals (0.4%) and fiber (2.4%). A-type starch granules, polygonal compound type, individual granules 2–7 <math>\mu\text{m}</math>. Amylose percentage variable, from very low (5%–12%) to low (12%–20%), intermediate (20%–25%), or high (25%–33%); intermediate amylose content is preferred in bread baking. High starch gelatinization temperature of 65°C–78°C.</p> <p>Major proteins are globulins and glutelins, similar to oat proteins, but different from other cereal grains, in which the major proteins are prolamins. Insignificant bioactive compounds from white rice flour (small amount of fiber from endosperm nonstarch carbohydrates).</p>	Han et al. (2012); Amagliani et al. (2016)
Pearl millet ( <i>Pennisetum glaucum</i> )	<p>Free of the type of gluten found in wheat. Pennisetin protein has no dough viscoelastic properties; similar to <math>\alpha</math>-zein, but slightly smaller; limited gas-holding and leavening capacity; insignificant protein body disruption upon dough making.</p> <p>High in protein content (11.6%–11.8%), high in carbohydrates (67.0%–67.5%), high in fat (4.8%–5.0%), high in ash (2.3%), high in dietary fiber (11.3%). Shelf life for whole grain flours is poor, and can get rancid because of its high fat content.</p> <p>Amylose 20.0%–32.5%, shape polygonal with some pores on the surface and a few spherical granules with size range 3.5–23.0 <math>\mu\text{m}</math>. A-type starch granules, gelatinization temperature range 60.9°C–86.3°C.</p> <p>Higher <math>\alpha</math>-amylase activities than wheat.</p> <p>Can supply bioactive compounds (fiber from nonstarch carbohydrates, phenolic acids) depending on degree of pericarp, testa, aleurone layer, and germ removal. Low in flavonoid phenolic compounds, but significant flavones present are glucosylvitexin, glycovitexin, and vitexin.</p> <p>Decortication and bran removal can reduce bioactive compounds. Soaking can reduce phytic acid and soluble bioactive compounds.</p>	Kajuna (2001); Saleh et al. (2013); Annor et al. (2014); Kaur et al. (2014)
Finger millet ( <i>Eleusine coracana</i> )	<p>Free of the type of gluten found in wheat. No dough viscoelastic properties, limited gas-holding and leavening capacity, insignificant protein body disruption upon dough making.</p> <p>Protein content variable (6%–13%), high in carbohydrates (about 72%), low in fat (1.5%), high in ash–minerals (2.7%), high in dietary fiber (11.5%).</p> <p>Finger millet's thin membranous pericarp is loosely attached to the seed coat (utricle grain structure), and on handling and slight abrasion becomes detached. Testa is unique among millets, having five layers and strongly adhered to the endosperm, often milled to nearly whole grain flours. High in mineral content, notably calcium, potassium, phosphorus, and magnesium.</p> <p>Amylose 14.4%–16.2%. Compound-type starch granules, shape polygonal with some indentation on the surface, a few spherical, with size range 2.5–24.0 <math>\mu\text{m}</math>. A-type starch granules, high gelatinization temperature of 64.5°C–75.0°C.</p> <p>Endogenous finger millet enzymes play a role in the modification of dough for bread baking.</p> <p>Can supply bioactive compounds (high fiber from nonstarch carbohydrates, high phenolic acids: ferulic, p-coumaric, and cinnamic acids, and flavonoids such as catechin, galocatechin, epicatechin, procyanidin dimer are high since testa layer is often milled with the endosperm).</p>	Kajuna (2001); Saleh et al. (2013); Annor et al. (2014); Chandra et al. (2016); Adebisi et al. (2017)

Foxtail millet ( <i>Setaria italica</i> )	<p>Free of the type of gluten found in wheat. No dough viscoelastic properties, limited gas-holding and leavening capacity, insignificant protein body disruption upon dough making.</p> <p>Protein content high (11.2%–12.3%), high in carbohydrates (60.9%–63.2%), high in fat (4.0%–4.3%), high in ash–minerals (3.3%), high in fiber (6.7%).</p> <p>A–type starch granules. Amylose 11.4%–32.0%, shape polygonal with a few spherical granules with size range 2.5–24.0 <math>\mu\text{m}</math>. Starch gelatinization temperature range 66.7°C–78.0°C.</p> <p>Utricle grain structure: pericarp and testa are loosely attached. Flour milled from unpolished grains can be high in fat unless immediately used and prone to rancidity.</p> <p>Can supply bioactive compounds (high fiber from nonstarch carbohydrates, high phenolic acids, intermediate flavonoids, and insignificant proanthocyanidins).</p>	Saleh et al. (2013); Annor et al. (2014); Kumari et al. (2017); Sharma and Niranjan (2017); Adebisi et al. (2017)
Proso, common, or white millet ( <i>Panicum miliaceum</i> )	<p>Free of the type of gluten found in wheat. No dough viscoelastic properties, limited gas-holding and leavening capacity, insignificant protein body disruption upon dough making.</p> <p>Protein content 12.5%, high in carbohydrates (70.4%), low in fat (1.1%–3.5%), medium ash (1.9%–3.1%), high in fiber (5.2%).</p> <p>A–type starch granules, amylose 17.2%–33.9%, shape polygonal with a few spherical granules with size range 2.5–24.0 <math>\mu\text{m}</math>. Starch gelatinization temperature range 62.0°C–84.4°C.</p> <p>Utricle grain structure: pericarp and testa are loosely attached.</p> <p>Can supply bioactive compounds (medium level fiber from nonstarch carbohydrates, high phenolic acids, low flavonoids, and insignificant proanthocyanidins).</p>	Kajuna (2001); Saleh et al. (2013); Annor et al. (2014); Adebisi et al. (2017)
Fonio, black or iburu ( <i>Digitaria iburua</i> Stapf)	<p>Free of the type of gluten found in wheat. No dough viscoelastic properties; prolamin proteins show some degree of hydrophobic character, but limited in gas-holding and leavening capacity; insignificant protein body disruption upon dough making.</p> <p>Protein content low (8.9%), but high in some amino acids (leucine 9.8%, methionine 5.6%, and valine 5.5%), high in carbohydrates (69.4%), medium in fat (3.0%), medium in ash (2.2%), medium in dietary fiber (8.5%).</p> <p>Amylose 19.3%–21.2%, polygonal, size range 2.0–13.5 <math>\mu\text{m}</math>. Gelatinization temperature range 62.0°C–84.4°C.</p> <p>Very small grain size (about 1.6–1.8 mm long and 0.8 mm wide, individual grain mass about 0.5–0.6 mg), often milled to whole grain flour. High viscous pentosan content limits glucose absorption.</p> <p>Can supply bioactive compounds associated with whole grains (high fiber, phenolic acids, waxes).</p>	Edema et al. (2013); Jideani and Jideani (2011).
Fonio, white or acha ( <i>Digitaria exilis</i> Stapf)	<p>Free of the type of gluten found in wheat. No dough viscoelastic properties; prolamin proteins show some degree of hydrophobic character, but limited in gas-holding and leavening capacity; insignificant protein body disruption upon dough making.</p> <p>Protein content low (7.1%), high in carbohydrates (69.3%), medium in fat (3.1%), medium ash–minerals (2.1%), medium in dietary fiber (7.4%).</p> <p>Amylose 22.6%–26.1%, polygonal, dented granules with size range 2.0–13.1 <math>\mu\text{m}</math>, high lipid in starch granules. Gelatinization temperature range 62.0°C–84.4°C. Proteins are rich in methionine and cysteine.</p> <p>Very small grain size (about 1.6–.8 mm long and 0.8 mm wide, individual grain mass about 0.5–0.6 mg), often milled to whole grain flour. High viscous pentosan content limits glucose absorption.</p> <p>Can supply bioactive compounds associated with whole grains (high fibers, phenolic acids, waxes).</p>	Jideani and Jideani (2011).

HMW-GS, high-molecular-weight glutenin subunit.

**Figure 3** Sorghum grain anatomical structure (Obilana, 2004).

after milling, although soaking and decortication can reduce levels somewhat. Phytic acid has a strong binding affinity for minerals such as calcium, magnesium, manganese, iron, potassium, copper, and zinc at physiological pH and therefore can reduce absorption in the intestine (Greiner and Konietzny, 2006). This is of most concern in countries where grains form a large proportion of the daily diet. Condensed tannins, even though they are antioxidants, can inhibit mineral bioavailability and digestive enzyme activities, but can also be reduced by the decortication and winnowing actions used.

Unfermented maize flatbreads are consumed fresh on a daily basis as they do not store well because of rapid staling. Maize bread is rich in carbohydrates but can be limited in protein and micronutrient content (Table 3).

### Sorghum Bread

Sorghum (*Sorghum bicolor* (L.) Moench) is a tropical cereal with hull-less grains of different colors: white, brown, red, yellow, lemon yellow, cream, and black. Some sorghum varieties are known to accumulate condensed tannins (proanthocyanidins) in their inner integument layer around the testa and are bitter in taste. Sorghum is often marketed as an antioxidant-rich health food because of its high polyphenol content, especially 3-deoxyanthocyanins (luteolinidin and apigeninidin) (Cardoso et al., 2017). In Africa, sorghum is an ingredient in bread, porridge, and fermented beverages. To process sorghum, the grains are hand cleaned, washed, soaked in water (about 15–30 min), and decorticated by hand pounding with a mortar and pestle (Yetneberk et al., 2005). Decortication separates the fibrous pericarp and leads to some damage to the aleurone layer and germ. The decorticated mass is spread and sun dried and then winnowed to separate the pericarp and germ from the meal. The meal (mainly endosperm) is milled as described for maize. For unfermented flatbread, fine flour (about <75–200  $\mu\text{m}$ ) is required instead of the coarser grist used to make porridge.

Sorghum dough properties are influenced by the level of starch granule damage, protein content, degree of crosslinking of kafirin proteins (the major storage proteins of sorghums), and amount of arabinoxylans (pentosans) present (Kulamarva et al., 2009). The dough is worked by hand and baked as described for unfermented maize flatbread. Sorghum flatbreads are dense and unaerated, with a distinct aroma, crispiness, and chewability. Bread color is influenced by the type of sorghum grain and the polyphenol compounds remaining in the flour from remnants of the seed coat and testa and by the Maillard reaction during baking. Steam generated throughout the dough during baking can lead to a minor degree of bread expansion, as sorghum kafirin proteins form networks with damaged starch granules and cell wall polysaccharides. The baking action gelatinizes starch and facilitates digestibility of the bread. Starch and protein digestibility of the bread can be limited because of inhibition of digestive enzymes

from specific phenolic compounds such as remnants of condensed tannins and the high degree of crosslinking of kafirin protein with disulfide bonds (Cardoso et al., 2017). However, unfermented sorghum flatbread has many health-promoting properties, it is a low glycemic bread and shows the presence of phenolic compounds, policosanols, and phytosterols.

### Teff Bread

Teff (*Eragrostis tef* (Zucc.) Trotter) is a tropical cereal originating in Ethiopia; its cultivation and usage as food are also largely confined to Ethiopia, and as a result so too is the consumption of unfermented teff flatbreads (*kitta/bixxille* and *maaxino caabita*).

Teff grains are hull-less, are very small in size (0.9–1.7 mm in length, 0.7–1.0 mm in diameter, mass  $\leq$  2 mg), and range in color from white to milky white, brown, and dark brown (Bultosa, 2016). Brown teff grain is often erroneously referred to as red teff. The popularity of teff is somewhat on the rise because of its superior nutritional properties in comparison with more common cereal grains (wheat, maize, sorghum, barley, and rice) and its usability as a whole grain, and because it is gluten free. Thus cultivation is expanding into South Africa and internationally into the Netherlands and grain-growing regions of the United States, namely Montana, South Dakota, and Idaho. Because of the small grain size, decortication is impractical; instead the grains are winnowed, sieved, and milled into whole grain flour (approximately 99% extraction) using a disk attrition mill. Therefore, the pericarp, testa, aleurone layer, germ, and endosperm are all part of teff flour with different degrees of particle size reduction. In general, a flour average particle of about 90.7–98.4  $\mu$ m in diameter is achieved, with starch granule damage of approximately 5.56%–5.85% reported (Abebe et al., 2015). This increased level of damaged starch granules in the flour leads to an increase in water absorption and hydrolysis of starches into fermentable sugars by the action of  $\alpha$ - and  $\beta$ -amylases and thus affects the rheology and nutrient profiles of the dough. Fine teff flour is preferred for making teff bread (unfermented *kitta* bread, *injera*, or *cumboo*) as opposed to coarse flour (grist). The dough is worked by hand and rested for up to 1 h (before commencement of fermentation), shaped, flattened, and baked on a red-hot clay baking griddle that has been greased with a fat or oil (in traditional practice often using rapeseed meal) to avoid sticking. Bread baked this way is thick, with limited eyes (holes on the surface) and a rusty iron color on its base compared with fermented *injera*, which is thin, semileavened, with multiple eyes and a light rusty iron color on the base. The eyes on the surface of unfermented teff bread are a result of steam expansion in the dough matrix. Teff prolamin proteins have lower hydrophobicity, contain more basic polypeptides, and are less polymerized than maize or sorghum proteins, and these properties were implicated to contribute to the superior flatbread baking properties observed (Adebowale et al., 2011). Bread baked from unfermented teff grain flour is high in dietary fiber, minerals, and phytochemicals (Marti et al., 2017) such as the phenolic compounds protocatechuic, vanillic, syringic, *p*-coumaric, sinapic, ferulic, and rosmarinic acids; catechin; and naringenin (Shumoy et al., 2017). As with other unfermented breads, phytic acid can still be a concern.

### Millet Bread

Millet is a tropical cereal that produces small hull-less grains. They comprise pearl millet (*Pennisetum glaucum*), finger millet (*Eleusine coracana*), kodo millet (*Paspalum setaceum*), proso millet (*Panicum miliaceum*), foxtail millet (*Setaria italica*), little millet (*Panicum sumatrense*), barnyard millet (*Echinochloa utilis*), guinea millet (*Brachiaria deflexa*), and brown top millet (*Brachiaria ramosa*). Teff and fonio (*Digitaria exilis* and *Digitaria iburua*) are also described as part of the millet. Of these, pearl, finger, and guinea millets and fonio are important grain-producing crops for millions of smallholder farmers in semiarid dry land in Africa, used predominantly for bread, porridge, and fermented beverages. In addition to their basic nutrients, most millet grains are noted for their high levels of phenolic compounds such as phenolic acids and anthocyanins (Saleh et al., 2013). In terms of mineral nutrients, finger millet is a good source of calcium, magnesium, and potassium (344, 137, and 408 mg/100 g, respectively) (Chandra et al., 2016). Traditional unfermented millet flatbreads are made from either decorticated or nearly whole grain flour (Kajuna, 2001; Saleh et al., 2013). For the production of whole flour, millet grains are cleaned, washed (without or with conditioning: the process of adding water to adjust the moisture content of grains for optimal flour extraction), and milled (plate milling/stone milling). The milled stock is separated into flour and bran by sieving. Flour variations include different types of millet, whether the grain/kernel structure is a caryopsis or utricle, and fat content (1.5%–5.2%) (Saleh et al., 2013). In the caryopsis-type structures (pearl millet, sorghum, maize, wheat, and barley), the pericarp is adhered to the seed coat and decortication can be undertaken to remove the pericarp layer. In utricle structures (finger, foxtail, and proso millet), however, the thin membranous pericarp is loosely attached to the seed coat, which in turn is intimately attached to the endosperm; hence the seed coat is often milled with the endosperm. In finger millet, the thin layered membranous pericarp is loosely attached to and covers the entire seed and can be easily detached via abrasion or during postharvest handling (Shobana and Malleshi, 2007). Thus, because the seed coat is so intimately attached to the fragile endosperm, it is incorporated into the milled whole grain flour. The seed coat and aleurone layer contribute a significant amount of phytic acid, polyphenols, and dietary fiber and impart a chewy texture, but also contribute a dark color and somewhat musty odor to the final bread.

Pearl millet has a larger germ and so is often decorticated. If pearl millet is milled into whole flour, because of its high fat content (about 5%), rancidity can occur from the lipase activity in the germ, aleurone layer, and pericarp; thus often it must be quickly processed into bread after milling (Saleh et al., 2013). The degree to which particles are reduced and starch granules are damaged during milling is dependent on millet grain type, drying conditions, and milling force. In traditional processing, decortication is conducted by gentle pounding with a wooden mortar and pestle. The decorticated mass is milled into flour by hand using stone mills. Because millet proteins do not have the gluten proteins that are found in wheat, which favor a viscoelastic dough,

significant starch granule damage is required during milling for the dough to become cohesive. To make bread, the flour is mixed with water, salt, and other optional ingredients (oils, spices, onions, dates, eggs, milk, nuts, sesame seeds, and/or black cumin [*Nigella sativa*]) and baked on a griddle or iron pan. Freshly baked millet bread is soft and flexible but quickly stales upon storage (within a day).

### Wheat Bread

Wheat is cultivated in many parts of the world, from the north (67° N in Scandinavia and Russia) to the south (45° S in Argentina), including pocket highlands of the tropics and subtropics (Peña-Bautista et al., 2017). The predominate cultivated wheat types are hexaploid (bread wheat/common wheat, *Triticum aestivum* L. subsp. *aestivum*), followed by tetraploid (macaroni/pasta wheat, *Triticum turgidum* L. subsp. *durum* (Desf.) and rivet/poulard wheat, *T. turgidum* L. ssp. *turgidum*). Wheat grains are hull-less, with color variations in bread wheat including red, white, purple, blue, black, and light yellow, as well as endosperm textures from soft to hard. The black, purple, and blue colors are due to the occurrence of anthocyanins, and the red color is from catechins and proanthocyanidins in the pericarp, testa, and aleurone layer of the grains (Lachman et al., 2017). Hard and soft bread wheat is used in the manufacture of bread and cookies (biscuits), respectively. Durum wheat is an amber-yellow color due to carotenoids (lutein, zeaxanthin, and  $\beta$ -carotene) in its endosperm, and the endosperm texture is harder than that of bread wheat, but the strength of its gluten proteins is weaker than that of bread wheat.

Unleavened wheat flatbreads are widely consumed throughout many African countries. Traditionally, cleaned wheat grains are washed and soaked in water for approximately 30 min to 1 h. The soaked grains are decorticated with a wooden mortar and pestle to detach the beeswing pericarp layers. The pounding action damages, to different degrees, the testa, aleurone layer, and germ, while removal of the outer layers of pericarp from the crease region is challenging and may be incomplete. The pounded grain mass is spread and dried in the sun. The dried mass is winnowed and milled to different particle sizes using a traditional stone mill, plate mill, or hammer mill (Bressiani et al., 2017). Often flour produced by traditional milling methods has better nutritional and bioactive compound profiles (high extraction rate) compared with roller milled and refined wheat flour, because remnants of the testa, aleurone layer, and germ are still present in the flour. However, shelf life can be short compared with roller milled flour. The dough rheology is significantly different from that of dough from nonwheat flour because of the viscoelastic nature of wheat gluten proteins (Taylor et al., 2016; Ortolan and Steel, 2017). Flour of 10%–13% protein content, with high gliadin/glutenin ratio, and with starch granule damage (>5%–17%) is known to produce quality unfermented wheat flatbreads (Parimala and Sudha, 2015).

To make the traditional *chà-chà-bsa* flatbread from Ethiopia, wheat flour and salt are mixed and worked by hand with gradual addition of water (Mesfin, 2006). The dough is kneaded, rested (15–30 min), kneaded again, shaped into a flat disk, and baked (and flipped) on a lightly greased pan to attain a crisp texture and a golden brown color. Using durum wheat to make flat unfermented bread means that, due to the greater grain hardness and subsequently greater amount of starch granule damage during milling, there is more water absorption, limiting water for gluten network development in the dough. During baking, the bread can puff up a little, and it exhibits a dense, softer texture because of its weak gluten network. The color of the bread is cream-yellow due to its high carotenoid content. The bread stales quickly; for example, *maadjouna*, a durum wheat flatbread from Algeria, is good if consumed during the day baked (Kezih et al., 2014). Other types of flatbreads (*harcha* and *rakhsis*) are also produced from durum wheat semolina in Algeria. Mineral micronutrients can be limited because of inhibition by some phytic acids (Buddrick et al., 2014). Nevertheless, in terms of dietary fiber, phenolic acids, some B vitamins, and vitamin E, flatbread processed from whole or semiwhole wheat grains (partially decorticated grains) are superior to refined white wheat bread. Durum wheat also provides provitamin A carotenoids, and additional ingredients such as fats, other grain flours, fruit, vegetables, and spices also have the potential to improve the nutrient and bioactive profile of the bread, which is of importance in areas where bread is a dietary staple. Wheat-based flatbreads are often baked twice per day and consumed fresh because of their fast staling nature.

### Trends and Future Prospects

Flatbread is a dietary staple in some regions of Africa; in other regions porridge made from maize, sorghum, and millet grains is more commonly consumed. Traditional processing methods are still practiced for flour milling, using stone, attrition, or hammer mills. In rural villages, processing activities, such as decortication, dough processing, and baking, are at large conducted by women, and the practices are time and energy consuming. For the retail market, roller milling technology is used to mill wheat flour. However, roller milling technology for the production of maize, sorghum, teff, millets, and fonio flours for bread baking is limited. Instead, maize and sorghum grains are mostly milled to grist for the production of porridge and snacks. Thus, there is inconsistency in the commercial supply of bread-grade maize and sorghum flour. Large-scale milling of teff, millet, and fonio flour is also limited in part because supply is confined to specific geographic locations in Africa and there is limited research into processing innovations. Because such large amounts of flatbreads are consumed on a daily basis in Africa, there is great potential for innovation and to respond to the increase in nutritional awareness. Flatbreads are starting to be made with blends of flours from other sources, for example, legumes, pulses, oil seeds, starchy tubers, and roots. And many flatbreads, such as those made from maize, sorghum, teff, millets, and fonio, are naturally gluten free and thus suitable for celiac patients (Taylor et al., 2016). More research into

improved processing technologies and ingredient selection is required, as is the continuation of research into crops biofortified for iron, zinc, and vitamin A, as in some places these deficiencies are on the rise (Bouis and Saltzman, 2017).

## Conclusions

Traditional African breads are diverse in their structures, depending on their formulation and method of production, and thus have different nutritional and sensory properties. Unfermented flatbreads have not changed a great deal, considering how long humans have been making them, and in Africa, traditional bread is largely processed in the home or in cottage industries. Although there are some unwanted but naturally occurring by-products in some unfermented flatbreads, the nutritional density of bread can easily be increased by utilizing the large range of cereal grains present in Africa. Improvements in processing, such as fortifying flour with vitamins and minerals, grain modification through pretreatment (soaking and sprouting/germination), and allowing dough to ferment, can be implemented. As the food supply chain becomes more globalized, efforts to automate bread manufacture in Africa can be investigated to make these traditional breads part of the mainstream bread sector.

## Overview

### Fermented Semileavened Flatbreads

Fermented breads of the semileavened variety are probably one of the most ancient forms of traditional biotechnology, learnt by humans through the mixing of cereal grain flour with water. This process involves the formation of sourdough by the action of microorganisms (lactic acid bacteria (LAB) and yeasts), which are naturally present in the raw materials, utensils used in processing, or the surrounding environment. Many different types of breads consumed in African households are made through the sourdough process often from sorghum, teff, millet, maize, and wheat (Table 1 cross ref article 1). The nutrient composition of these cereal grains and other bread components are summarized in Table 2 (cross ref article 1) and Table 1, respectively. The microorganisms responsible for fermentation are mixtures of LAB and/or yeasts that lead to the production of different organic acids, aromas, nutrient profiles, and the leavening action on the bread structure (Chavan and Chavan, 2014). Crumb and crust formation are influenced by many factors, including cereal grain type, particle size of the flour, protein and carbohydrate content, additional ingredients (bran, salt, oil/fat, dried fruit, spices), dough processing, activity of the fermenting microorganisms, and baking conditions. Sourdough is classified into three different types (Vuyst and Neysens, 2005). In Type I (traditional sourdoughs), a sourdough is restarted using portions of dough from previous fermentation (backslopping). Type II is an industrial accelerated sourdough, which uses adapted strains to start fermentation. This sourdough can be in liquid form, so it can be easily pumped through an industrial bakery. Type III sourdough (dried sourdough) is used by industrial bakeries, since the quality is constant with limited end-product variations, which may arise from the freshly produced sourdough starter. Using any one of these sourdough methods improves bread quality in various aspects, such as loaf volume, palatability, flavor generation (unique to a given sourdough), synthesis of prebiotic exopolysaccharides, reduced antinutrients, improved mineral nutrient bioavailability, decreased glycemic index, reduced bread staling, reduced ropy spoilage (bacterial spoilage caused by *Bacillus* spp. forms a sweet fruity odor of rotting pineapple or melons and a discolored, soft, sticky crumb), and extension of shelf life (Moroni et al., 2009). In Africa, *injera* and *kisra* are the best examples of Type I sourdough, semileavened flatbreads.

### Fermented Teff Bread: *Injera*

*Injera* (crepelike circular flatbread, sour, soft, and spongy) is a staple bread in Ethiopia and Eritrea (Fig. 1). *Injera* is largely processed from teff grain flour. Other cereal grains used are sorghum, finger millet, rice, barley, wheat, and maize alone or in combination with teff grain as composite flours. Of these, *injera* processed from 100% teff grain flour is superior in terms of quality and acceptance by the community that predominantly eats *injera*. Indigenous *injera* is made as follows: after cleaning the teff grain by sifting and sieving, the grain is milled into flour of fine particle size with significant levels of starch granule damage. Dough is made by combining flour with water (1:2 w/v) and worked by kneading to evenly hydrate all the flour particles. Teff has very small starch granules (2–6 µm in diameter), combined with their damage as a result of milling, and along with proteins and nonstarch polysaccharides from the pericarp and endosperm cell walls, teff flour absorbs more water compared to sorghum, maize, barley, and millet flour. The dough (or batter at this stage) is covered and left to ferment for between 24 and 48 h (Bultosa, 2016). The duration of fermentation is influenced by the environmental conditions such as ambient temperature and may take up to 72 h. Also the conditions for the fermenting microorganisms such as dough pH and degree of starch granule damage during milling will contribute to fermentation time. Teff *injera* manufacture involves two stages of fermentation, involving a complex group of microorganisms. A total of 107 LAB and 68 yeast strains have been observed in teff fermentation when making *injera* (Desiye and Abegaz, 2013). Initial fermentation lowers the pH of the batter to about 5.8 and then LAB, of which *Pediococcus pentosaceus*, *Pediococcus cerevisiae*, *Lactobacillus fermentum*, *Lactobacillus brevis*, *Lactobacillus plantarum*, *Lactococcus piscium*, *Leuconostoc mesenteroides*, and *Streptococcus faecalis* can be common, and it can take about 18 h to drop the pH further to approximately 3.8. At about 22–24 h, *Saccharomyces* and *Torulopsis* yeasts have been observed in the batter, and at the 48 h, yeasts belonging to the genera of *Candida* and *Pichia* were the dominant strains isolated from the batter. Initial fermentation is the spontaneous action of fermenting microorganisms that are present in the immediate environment. For subsequent (next batch) baking of *injera*, a small portion of fermented batter from the previous fermentation called *irsho/ersho/raacitii* (yellow liquid that accumulates on the surface of fermenting batter at the end of the first phase of fermentation and discarded) is used in a backslopping role as an inoculum. Also batter residue left at the end of second phase of fermentation is saved to serve as *irsho*. *Irsho* was reported to contain approximately 96.4% moisture and comprise of amino acids, glucose, maltose, minerals, vitamins (riboflavin and niacin), and of variable microbial flora involved in the fermentation of teff dough (Parker et al., 1989; Ashenafi, 1994). Grain amylase enzymes, together with some strains of LAB noted for the production of amylase enzymes (Lealem and Gashe, 2008), are involved in the conversion of some starch

Legumes/pulses/tubers/roots	Composition and functionality	References
Soybean ( <i>Glycine max</i> )	Free of wheat gluten, low in sulfur-containing amino acids, high-quality proteins with complete essential amino acids, no dough viscoelastic properties, no gas-holding and leavening capacity. High protein content (36.5%), low carbohydrate (30.2), high in fat (19.9%), including polyunsaturated fatty acids (linoleic and linolenic acids), high in dietary fiber 9.3%. Amylose 11.8%–16.2%, spherical- to polygonal-shaped starch granule, 0.7–4 µm in size, low gelatinization temperature 52.0–57.9 °C, C <sub>B</sub> -type starches (mixture of A- and B-type), starch granules more resistant to hydrolysis by alpha-amylase. Source of minerals (calcium, iron, phosphorus, magnesium) and vitamins (pro-vitamin A, thiamine, and riboflavin). Bioactive compounds in flour: fiber, phenolic acids, isoflavones, peptides, omega-3 fatty acids, leucoanthocyanins, tocopherols, phytosterols. Seed requires blanching or steam heat treatment to inactivate soybean lipoxygenase enzymes that leads to beany flavors (rancidity due to fatty acid oxidation). After seed coat removal, fat-free flours, full fat flours, and soybean protein isolates can be used for different bread character.	Garg et al. (2016); Shao et al. (2009); Liu (2004)
Cowpea ( <i>Vigna unguiculata</i> )	Antinutrients present (phytates, saponins, lectins and protease/trypsin inhibitors). Free of wheat gluten, low in sulfur-containing amino acids and high in lysine, no dough viscoelastic properties, limited gas-holding and leavening capacity. High protein content about 23.5%, medium in carbohydrate 60.0%, low in fat 1.3%, high in dietary fiber 10.6%. Amylose 25.8%–33.0%, oval- and kidney-shaped starch granules 5.0–37.5 µm in size, high gelatinization temperature 70.5–81.0 °C, C type starch granules. High starch retrogradation properties. Bioactive compounds in flour: fiber, flavonols (catechin and (epi)afzelechin), phenolic acids, anthocyanins, oligosaccharides, peptides. Depending on seed coat removal, in some varieties, there are proanthocyanidins (condensed tannins). Antinutrients present (phytates, saponins, tannins and protease inhibitors).	Ojwang et al. (2013); Hoover et al. (2010)

**Table 2** Bread-making functionality features of legumes/pulses, tubers, and roots used in composite breads—cont'd

Legumes/pulses/tubers/ roots	Composition and functionality	References
Faba (fava) bean ( <i>Vicia faba</i> )	Free of wheat gluten, low in sulfur-containing amino acids and high in lysine, no dough viscoelastic properties, limited gas-holding and leavening capacity. High protein content 26.1%, medium in carbohydrate 58.3%, low in fat 1.5%, high in dietary fiber 25.0%. Amylose 17.0%–42.0%, oval- and spherical-shaped starch granules 9.0–48.0 µm in size, high gelatinization temperature 64.3–75.3 °C, C type starch granules. Bioactive compounds in flour: high fiber, phenolic acids, oligosaccharides, peptides. Antinutrients present (phytates, tannins, saponins, lectins, protease inhibitors, vicin and convicine).	Multari et al. (2015)
Cassava ( <i>Manioc esculenta</i> )	Free of wheat gluten, no dough viscoelastic properties, no gas-holding and leavening capacity, very low protein content 1.9%, high in carbohydrate 78.8%, very low in fat 0.5%, low in dietary fiber 3.9%. Amylose 17.0%–33.0%, oval- and truncate-shaped starch granules 4.0–45.0 µm in size, medium gelatinization temperature 62.3–75.9 °C, A and C type starch granules. Bioactive compounds in flour: limited fiber and resistant starches. Treatment required (drying, fermentation) to reduce toxic cyanogen glycosides. Bland taste.	Awoyale et al. (2017); Ayele et al. (2017); Zhu (2015a)
Yam ( <i>Dioscorea</i> spp.)	Free of wheat gluten, no dough viscoelastic properties, no gas-holding and leavening capacity, low in protein content 3.4%, high carbohydrate 67.9%, very low in fat 0.4%, high in dietary fiber 11.6%. Amylose variable but for most species are 17.0%–33.0%, starch granule shape depending on species, some oval, ellipsoidal, round, triangular, or polygonal, size ranges from 7–10 µm to 28.0–49.5 µm, high gelatinization temperature 74.7–84.4 °C, C (a mixture of A and B) type starch granules. Bioactive compounds in flour: water-soluble proteins (diosgenin and dioscorine), water soluble fibers (allantoin, a steroid saponin dioscin, and resistant starches).	Amandikwa et al. (2015); Zhu (2015b)
Taro, Cocoyams ( <i>Colocasia esculenta</i> L.)	Free of wheat gluten, no dough viscoelastic properties, no gas-holding and leavening capacity, fresh corm is low in protein content 2.5%, carbohydrate 19.0%, very low in fat 0.2%, and fiber 0.4%. But on dry matter basis, taro flour can be high in carbohydrates (70%–80% starch), high in potassium. Amylose 14.0%–19.4%, starch granule shape, rounded, ellipsoidal-truncated, 0.5–5.0 µm in size, highly digestible A-type starch granules, high gelatinization temperature 81.0–85.0 °C. Good water absorption properties due to small starch granule surface area. Acridity (irritation, itching, and burning of skin) from corm oxalic acid (H <sub>2</sub> C <sub>2</sub> O <sub>4</sub> ), which binds calcium, potassium, sodium, and ammonium. Acridity removal demands peeling, grating, soaking, and fermentation. Bioactive compounds in flour: mucilage fiber, anthocyanins (cyanidin-3-glucoside, pelargonidin-3-glucoside, and cyanidin-3-chemnoside).	Kaushal et al. (2015); Odeku (2013)

into fermentable sugars. During fermentation (at a stage when the yellow liquid/*irsho* separates from the batter), to facilitate greater conversion of starch, a portion of about 10% of sediment batter is withdrawn and cooked to gelatinize the starch and make *absit* (a dough binder). After cooling to approximately 46 °C, *absit* is mixed back into the batter (initiating the second phase of fermentation, which lasts for approximately 20–30 mins) for further utilization by yeast and LAB. The fermented batter is then thinned with water to attain the desired batter consistency. Using a rotational pouring action of the batter from the peripheral to the center of baking griddle, a flat circular form is achieved (Fig. 1A). This is steam baked for approximately 2–3 mins. The gases produced during fermentation are loosely held within the batter system, and during baking, they escape leaving behind honeycomb structures on the surface of the bread called “eyes of injera” (Fig. 1B and D). The sourness of *injera*, in particular, is influenced by the duration of fermentation. *Injera* baked from shortly fermented batter is slightly sour and has a weak molasses aroma, but *injera* from batter that has been fermented for more than 24 h is markedly sour in taste. *Injera* color varies from cream white to brown and is influenced by the color of the teff grain and to some degree by the Maillard reaction that is particularly noticeable on the underside of the *injera*, which has a shiny, pale to light brown appearance. *Injera* has a spongy texture, and it can easily be rolled without fracturing (Fig. 1C). Texture can be influenced by swollen and gelatinized starch, as well as bran, embryo fragments, cell walls, protein bodies, and microorganisms that are present (Parker et al., 1989). During teff fermentation, a decrease in starch and insoluble fiber content and a limited amount of protein modification were reported (Marti et al., 2017). Starch was utilized to the extent of approximately 9% by the fermenting microorganisms (Umata and Faulks, 1988). The limited protein modification during fermentation is implicated as a contributor for protein network formation in fermented teff products. The fermentation action can reduce phytic acid content of *injera* by up to 91%–93%, due to activity of the phytase enzymes present in the fermenting batter (Umata et al.,

**Figure 1** Baked *injera* from white teff flour: (A) *injera* baking on griddle, (B) baked *injera* stacked, (C) rolled *injera* bottom side as outer surface of the roll, and (D) eyes of *injera* on the top side.

2005; Abebe et al., 2007). This reduction of phytic acid contributes toward the increased bioavailability of the minerals (iron, zinc, and calcium).

#### **Fermented Sorghum Bread: Kisra/Kissra**

*Kisra* is fermented sorghum flatbread (1.0–1.5 mm thick, 30–45 cm in diameter), similar to a thin pancake that is widely consumed in Sudan (AwadElkareem and Taylor, 2011). *Kisra* is also processed from millet grain (Mariod et al., 2017). A type of fermented flatbread, similar to *kisra*, called *laaffisso*, made from sorghum is also consumed in Ethiopia. To make *kisra*, cleaned sorghum grains are milled into whole grain flour using mechanical stone mills. For *laaffisso*, sorghum grains are washed, soaked, decorticated by hand with a wooden mortar and pestle, spread, sun-dried, and sifted/winnowed to remove the detached components (significant pericarp, germ, and seed coat). The dried processed grains are milled in a similar fashion to whole grain sorghum flour. The shelf life of these types of flour is not long because the damage to the germ leads to rancidity. Dough or batter is made by hand mixing sorghum flour with water (1:2 w/v) (Mahgoub et al., 1999). The initial fermentation is spontaneous. *Kisra* fermentation predominantly occurs through the action of LAB: *P. pentosaceus*, *Lactobacillus confusus*, *L. brevis*, *L. fermentum*, and *Lactobacillus amylovorus* (Rahman et al., 2010). *Enterobacteriaceae* has been observed initially in fermentation but becomes completely inhibited after 16 h of fermentation, due to the low pH of the batter as a consequence of LAB activity. The involvement of yeasts (*Candida intermedia*, *Candida krusei*, and *Debaryomyces hansenii*) and molds (*Aspergillus niger*, *Penicillium* sp., *Fusarium* sp., and *Rhizopus* sp.) were also reported, even though most molds were found to be inhibited after 8 h of fermentation (Rahman et al., 2010). The potential presence of *A. niger* is not of great concern as many strains of LAB inhibit mold and possible mycotoxin production (Perczak et al., 2018). Five percent of the batter is saved from the previous batch fermentation and mixed into the new batch as a starter. The batter is covered and allowed to ferment for 12–24 h to produce a fermented sorghum dough called *Aowasa* in Sudan. The thinned, fermented dough is spread in a thin layer on a heated clay hot plate and cooked for 20–40 s until the final moisture content is about 52%–53%. Baked *kisra* is described as having a nonspongy, supple, soft, and moist texture. The color, texture, and protein

digestibility of *kisra* were found to be influenced by the type of sorghum grain used (AwadElkareem and Taylor, 2011). The color can range from cream (from white sorghum grain) to dark brown (from sorghum varieties containing condensed tannins). *Kisra* from nontannin sorghum grains is flexible with an open structure of many regular gas cells, whereas bread with a more brittle, denser structure with fewer and smaller gas cells was observed in *kisra* processed from sorghum containing condensed tannins (AwadElkareem and Taylor, 2011). Variations in gas cell size and distribution are a product of the degree of fermentation. The *in vitro* protein digestibility (IVPD) was reported to be poor in *kisra* processed from sorghum that contained condensed tannins. Fermentation improved the IVPD, but cooking decreased IVPD further in *kisra* because of cross-linking among kafirin proteins (AwadElkareem and Taylor, 2011). During fermentation, many observations have been reported, including minor protein modification (proteolysis to amino acids and peptides), utilization of soluble sugars, an increase in organic acids (Osman et al., 2010), a decrease in thiamine, an increase in riboflavin (Mahgoub et al., 1999), and a reduction in tannins, phytic acid, and trypsin inhibitory activities (Rahman and Osman, 2011).

#### **Fermented Pearl Millet Bread**

Among millets, pearl millet is predominately cultivated in Africa and Asia (particularly India) where high temperature (about 30 °C) and limited rainfall (250 mm) prevails. Pearl millet grain is regarded as superior in some of its nutrient contents such as protein and fat (Taylor et al., 2010) compared to common cereal grains such as wheat, sorghum, and maize. The grain is an ovoid shape 2.0 to 3.4 mm in length and 2.5 mm in diameter and weighs 8 to 11 g (Hama et al., 2011). In Namibia, the traditional processing practice for pearl millet starts with cleaning the grains (winnowing, hand sorting, sifting), conditioning (soaking in water, 24–48 h), followed by decortication with a mortar and pestle to remove the bran (pericarp, germ, and testa layer) (Mallet and du Plessis, 2001; Taylor et al., 2010). The decorticated grains are again soaked in water for 1–2 days during which time lactic acid fermentation takes place. The fermented mass is partially sun-dried and milled with a mortar and pestle into a fine flour. Milling into a fine flour is necessary to damage the starch granules to some degree to facilitate water absorption, which leads to the production of a cohesive dough. Dough is molded into large flattened balls and is panfried or roasted or boiled in water. The processed pancakelike bread is consumed fresh or stored in plastic for a short shelf life.

#### **Fermented Maize Bread**

During traditional processing, maize grains are cleaned and soaked (3–12 h) and then decorticated with a wooden mortar and pestle. The decorticated mass is spread, dried, and sifted/winnowed to separate the bran and other lightweight materials from the maize meal. The maize meal is then milled into fine flour (<75–212 µm) with stone, disc attrition, or hammer mills. The flour is mixed with water, and dough is worked by hand. The dough is left to ferment, then thinned with water to the required consistency for baking thin or thick flatbreads. Thick bread is usually baked from early fermented dough. A portion of fermented dough is saved for sourdough processing in the next batch of bread. *Injera* can also be made from maize. When manufacturing maize *injera*, at the stage the yellowish liquid *irsho* is removed from the fermenting vat, a portion of batter (10%) is withdrawn from the sediment, cooked, cooled (about 46 °C), and then mixed back into the fermenting batter. After 20–30 mins more fermentation, the batter is thinned and baked on a baking griddle for 2–3 mins. Maize *injera* is sticky after baking compared to teff *injera*. After 1 day, maize *injera* becomes fragile and loses its rollable nature. The physicochemical properties of the dough are modified during the sourdough process by the fermentative action of LAB and yeast. Leavened wheat type bread (such as European style bread) cannot be produced from maize flour because maize zein proteins do not have the required viscoelastic properties that come from wheat gluten proteins. Because of this, wheat style bread made from maize has low loaf volumes and has a hard, dense crumb. However, sourdough technology along with selected strains of LAB was reported to improve the quality of wheat style maize bread primarily due to starch granule modification (Falade et al., 2014).

#### **Steamed Breads**

Steamed breads processed from wheat, maize, or sorghum grain flour are consumed in regions of Southern Africa (South Africa, Botswana, Lesotho). The basic ingredients for steamed bread are grain flour (wheat, maize, or sorghum), water, yeast, and salt (Manley and Nel, 1999). Other baking ingredients used are sugar, shortening, and ascorbic acid.

South African steamed bread from wheat is made from a basic dough and follows a typical bread-making methodology. Dough is left to rise (approximately 90 mins, 30 °C, 85% relative humidity), punched down, molded into the desired shape, and proved on a plate for a further 40–60 mins (30 °C, 85% relative humidity). The plate and dough is then placed on a stand inside a saucepan of shallow water and steamed for approximately 1 h. This produces a round white-gray loaf with a moist, sticky, and soft texture devoid of a crust. The crumb structure can vary from open to dense depending on the degree of leavening. The flavor of steamed bread is subtle and delicate. This type of bread has reduced lysine amino acid loss and will not lead to acrylamide formation (Ma et al., 2014). But because of its high moisture content, steamed bread is highly susceptible to spoilage and thus the shelf life is short.

#### **Ujeqe**

*Ujeqe* is a traditional steamed bread of Zulu (South Africa) origins made by boiling or steaming crushed green maize or sorghum. The green maize grains are wet milled by grinding on a stone to a thick paste. The ground mass is made from the whole grain

because the pericarp, germ, and endosperm fractions are all crushed together. Since the maize is harvested at an early maturity stage, the sugar level is higher than mature maize grains. Salt can be added during stone grinding, and then the dough is shaped and left to rise. The risen dough is wrapped with maize leaves or husks and steamed for approximately 1 h. Similar maize bread by the vernacular name of *monepola oa poone e ncha* or *malitsibana* or *mohlefe* (green mealie bread) is consumed in Lesotho (Nkhabutlane, 2014). Such breads are consumed until the harvest of the dry mature maize grain. The color of the bread is influenced by the maize grain color (white, yellow, or blue). The bread has an intense aroma with a dense and fibrous texture and is in itself satiating. Even though, no physicochemical data are available, such bread is likely to be high in fiber and bioactive compounds.

### Kenkey

*Kenkey* is a stiff, sour, steamed dumpling type maize bread consumed in Ghana. It is fermented with LAB and yeast. Traditional processing can take up to 4–6 days and is labor and time intensive (Oduro-Yeboah et al., 2016). There are two main types of *kenkey* (Ga *kenkey* and Fante *kenkey*) originating from the Ga and Fante ethnic groups, which also differ in some of their processing techniques. In *kenkey* manufacture, whole maize grains are cleaned and steeped in water for 1–2 days, which initiates fermentation and facilitates wet milling. The steeped grains are washed with water containing clay (implicated to contribute iron) and ground (stone grinding or disk attrition mill) into wet flour. The dough is kneaded by hand (dough 50% moisture), tightly packed into containers (wooden, aluminum, enamel, or plastic), and further fermented for 2–4 days. A portion of fermented dough (about half) is cooked to gelatinize the starch, called *aflata*. The *aflata* is mixed back into the uncooked dough in a ratio that varies from 2:3 to 2:1 for Fante *kenkey* and 1:1 for Ga *kenkey*, then shaped into round balls wrapped in plantain leaves (Fante *kenkey*) or maize husks (Ga *kenkey*) and cooked in boiling water for about 3 h for Ga *kenkey* and for 3–6 h for Fante *kenkey*. Another variant, called white *kenkey* (*Nsiho*), is made from branless maize and steamed for 1–2 h. The desired texture of *kenkey* is cohesive, coarse particle bread that is not too sticky or crumbly. In addition to the quality of the maize grain, the activities of proteases, amylases, cell wall hydrolases, and lipase enzymes during steeping and fermentation are reported to impact *kenkey* quality (Oduro-Yeboah et al., 2016). Even though a reduction in phytic acid content has been observed, mineral availability such as calcium is limited in *kenkey*. Soaking is reported to reduce dietary fiber content and improve *in vitro* protein digestibility and lysine availability (Nche et al., 1996).

### Wheat Leavened Breads

Bread wheat and durum wheat flour are widely used to bake traditional African breads particularly in the northern African region, eastern African highland regions, and southern African regions where wheat is intensively cultivated (Table 1, cross reference article 1). The bread baked from wheat can be thin and aerated (still somewhat of a flatbread) or thick with greater aeration and formed into different shapes depending on the mold or pan type used. Typical traditional wheat bread (thick) is shown in Fig. 2. In traditional processing, wheat grains are cleaned, washed and soaked, decorticated, or rubbed by gentle pounding using a wooden mortar and pestle to detach the beeswing bran layer. The pounding action also damages the germ and testa layer to different degrees depending on impact applied. The decorticated grains are spread, dried in the sun, sifted to remove the detached bran, and milled into a fine flour using stone attrition/plate or hammer mills (Doblado-Maldonado et al., 2012). The flour is mixed with water, yeast, and salt. The dough is worked by hand, with the gradual addition of water to develop the gluten network (gluten polymerization). Sometimes, edible oils are worked into the dough and other ingredients such as black cumin, flax, or fenugreek seeds are spread on the dough surface after shaping. The dough is left to rise. Wheat grain flour is required to have a significant amount of starch granule damage (3%–8%) to be available for amylase enzymes to release fermentable sugars from the starch, which is then utilized by yeast. After 2–3 h, the dough is punched down, to break up any clusters of yeast and to favor yeast to access un-utilized nutrients such as sugars in the dough (Struyf et al., 2017), shaped, and transferred to lightly greased baking pan for the second proving.

The metabolic activity of yeast is one factor that influences the final loaf in terms of loaf volume, nutrient content, taste, and aroma, which in turn depends on the nature of the dough matrix, yeast strain, and fermentation conditions (Struyf et al., 2017). For example, an ideal temperature for yeast dough fermentation is from 25 to 32 °C. During the first 10 mins of baking, the dough expands further because of heat-induced water vapor, gas, and ethanol expansion in the dough matrix. The activity of the yeast is halted, proteins are denatured, and starch is gelatinized, and the dough gradually sets into an aerated foam structure. Baking is complete when the crust becomes light to medium brown in color. The crumb is predominantly influenced by the viscoelastic nature of the gluten protein network along with other trapped components (starch, endosperm cell wall, nonstarch polysaccharides, and lipids) that favor the expansion and holding of the gas formed air cells in the matrix. Expansion is influenced by gluten quality (Ortolan and Steel, 2017) and yeast fermentation (Struyf et al., 2017). Because of the weak viscoelastic properties of the gluten protein in durum wheat compared to bread wheat gluteins, a fine uniform crumb with low loaf volume and short shelf life is formed (Kezih et al., 2014). The bread crust color and flavor are mainly influenced by the Maillard and caramelization reactions and the flavor compounds generated by the method of fermentation and any additional ingredients. The type of wheat and the fiber levels also have an impact on the crumb structure (Rosa-Sibakov et al., 2015). For example, durum wheat contains carotenoids, giving a noticeable yellow tint. Bread loaf volume, softness, moistness, flavor, color, and bread staling are also influenced if an edible oil or fat is added to the dough (Pareyt et al., 2011). Antinutrients such as phytic acids are reduced by the degree of aleurone and germ removal and by the degree of phytase enzymes activated during dough fermentation. Bioactive compounds such as phenolic acids imparted to bread are variable depending on the amount of bran and endosperm cell walls in the flour used.

### Composite Breads

With increasing urbanization on the African continent, bread consumption in many African communities has shifted toward leavened wheat bread (not that unlike European style wheat bread). Contemporary consensus on the definition of wheat bread is that it includes the basic ingredients: wheat flour, water, yeast, and salt. However, in many African regions, particularly in semiarid and arid climates, wheat cultivation and production are not possible. Wheat is a key global commodity, and for many African nations, the price and supply of foreign wheat are not viable or sustainable. Wheat grain flour is also limited in terms of protein quality (particularly lysine), provitamin A carotenoids, minerals (iron, zinc, and calcium), essential fatty acids, and some bioactive compounds. All these are the driving factors for composite bread to become a greater presence in African bread making. Among others, composite bread is produced from wheat and either cassava, cowpea, maize, sorghum, fava bean, millet, or fofo. A mixture of wheat with cassava and maize or soybean or just wheat and yam or wheat and taro flour is also common. When wheat bread is processed with composite flours, there are variable effects on the bread loaf volume, crumb and crust structure, sensory properties and acceptance, shelf life, and nutrients, due to the differences in the functionalities of the different types of flour used (Table 4, cross reference article 1 and Table 2). With composite flour, a decrease in bread loaf volume, an increase in the bread mass/density, a dense crumb structure, and cracked crusts have been observed in contrast to bread produced from 100% wheat flour. This is predominately due to influence on the viscoelastic properties of wheat gluten (Noorfarahzilah et al., 2014; Ayele et al., 2017). When bread wheat is blended with bland tasting flour such as cassava, the influence on the final bread flavor is negligible; however, others such as soybean flour can impart a beany flavor. Soybean flour is also higher in fat than other flours, and oxidation can occur unless the lipids are stabilized prior to processing (Shao et al., 2009; Olaoye and Ade-Omowaye, 2011). To overcome this, whole soybeans are blanched or steam treated to inhibit the soybean lipoxygenase enzyme, which can lead to the production of beany, grassy, and rancid flavors (from compounds: 1-octen-3-ol, 1-hexanol, hexanal, 1-pentanol, (E)-3-hexen-1-ol, 2-hepta-none, and 2-pentylfuran) in products.

Composite soybean flour bread (10%–17%) was found to be acceptable and improved the nutrient composition of the bread with respect to protein, amino acid, essential fatty acid, and mineral content, as well as soybean isoflavones, dietary fiber, and peptide bioactive compounds (Liu, 2004). When wheat flour is blended with starchy flours (cassava, yam, and taro), due to limited fat content, the loaf volume is decreased and moistness, flavor, color, and antistaling qualities are negatively influenced unless the fat content is supplemented during production. The addition of coarse grain flour (sorghum, maize, teff and millet) can increase bioactive compounds (dietary fiber, phenolic compounds, carotenoids, phytosterols, tocopherols, and tocotrienols) but decrease the bread loaf volume due to dilution of wheat gluten proteins. With mounting evidence that whole grain consumption can reduce the risk of some diseases such as diabetes, various cardiovascular diseases, and cancers (Benisi-Kohansal et al., 2016), bread processed from whole grains such as teff, fonio, finger millet, and sorghum are becoming increasingly appealing. However, there is some concern about the risk of surface contamination from pesticide residues, mycotoxins, and heavy metals when the outer layers of grains are not removed. Good agricultural practices, adequate grain drying, cleaning, and removal of a small portion of the outer layers can help to decrease the risk, but still preserve the health benefits associated with whole grains. Starch granule properties, including granule size, differences in gelatinization temperature, the extent of starch modification during milling, dough processing, and baking, are all factors that contribute to quality differences.

The gelatinization temperature of tropical cereal starches from maize, sorghum, rice, teff and millets are approximately 10 °C higher than wheat starch (Table 4, cross reference article 1). The gelatinization temperature of cassava, taro, yam, cowpea, and fava bean starch are also reportedly higher as well (Table 2). When composite bread is produced with the inclusion of coarse grains, there are some consumer acceptance issues. Typically, bread with greater than 30% non-wheat flour is deemed to be unsatisfactory in terms of texture and loaf volume. Bread with 5% to 20% non-wheat flour was found to be almost as acceptable as 100% wheat flour bread, even though it varies with the type of flour used. This acceptance is important for the composite bread industry to expand and deliver improved, healthful bread to the population.

### Trends and Future Prospects

Before wheat roller milling and the industrialization of baking on the African continent, bread was processed from cereal grains cultivated by communities. Bread-processing methods were also variable and uniquely adapted toward particular types of grain. However, with the spread of roller wheat milling technology throughout Africa, bread processed from refined wheat flour has also become part of many African diets. However, recent trends in promoting nutrition to prevent diet-related disease have caused a shift back to processing bread from brown (bran included), coarse grain and whole grain flour, and composite flour has become more popular. Research is ongoing globally to find ways to produce wheat-like bread from non-wheat flour through process modification, including milling variation, soaking, germination, enzyme treatments, moist heat treatments, changes in blending proportions and the inclusion of hydrocolloids.

### Conclusions

Semileavened and leavened or fermented African bread is processed from a variety of cereal grains. Those processed from teff, finger millets, and fonio benefit nutritionally from the use of the whole grain, and are also naturally free of wheat type gluten proteins. This holds great promise for the introduction of African bread into the international market, especially with the rise of gluten intolerances and coeliac disease around the world. Much of the fermented semileavened bread production still happens in the traditional style in the household or in cottage industry in Africa. Research efforts are focused on the standardization of processing methods, strain development of fermenting microorganisms, and automated technology, although there is still a way to go before these types of bread can become global commercial products.

## Introduction

Flatbreads are very popular type of bread, especially in those parts of the world where bread is consumed as a major source of dietary protein and calories (Mir et al., 2014). It is believed that people have been making flatbreads for more than 6000 years. The world's oldest baking oven was found in Babylon in 4000 BC and records of flatbread baked in the hot ashes or on heated stone slabs in the old kingdom of Egypt in 2500 BC (Kumar, 2016). Various ancient cooking methods that resemble modern day methods were used such as the tandoor, a simple wood-fired oven consisting of an earthen pot with a refractory brick wall. It originated in Persia (Iran), was brought to India by Arabs via Afghanistan in 3000 BC, and is still used today in India for the baking of tandoor bread. Small mud-plastered ovens similar to tandoors have been found in Harappa and Mohenjo Daro dating to 2500 BC in the ancient valley of India and Pakistan (Parimala and Sudha, 2015; Kumar, 2016).

Flatbreads are the most primitive type of bread prepared by humans because the ingredients were readily available and simple; flour, water, and sometimes salt were used and without any specialized tools, kneaded into pliable dough before being shaped by hand and baked. Flatbreads could be eaten at every meal, due to the ease of making them, and they also functioned as plates with other foods being served on top of them or the flatbreads could be ripped into pieces and used as an implement to facilitate eating other parts of the meal. Of great importance, among the people of India and the Middle East, forms of flatbreads are also found in Europe, Africa, Southeast Asia, and the Americas (Parimala and Sudha, 2015). The consumption of Indian flatbreads has also spread to Western countries where their popularity is increasing due to their versatility (Mir et al., 2014). In India, there are several forms of flatbreads such as *chapati*, *parotta*, *puri*, and *tandoori roti* (Fig. 1), which are consumed as part of the daily diet. Indian flatbread is made from wheat flour and water, with or without the addition of yeast or other leavening agents and ingredients such as salt. The variation comes from production and baking method (Prabhasankar et al., 2003; Kurhade et al., 2016). In contrast to European style leavened wheat bread, Indian flatbreads have little to no crumb (Fig. 2), and thus it is the crust that is of the most importance, in both functionality during the meal and sensory properties.

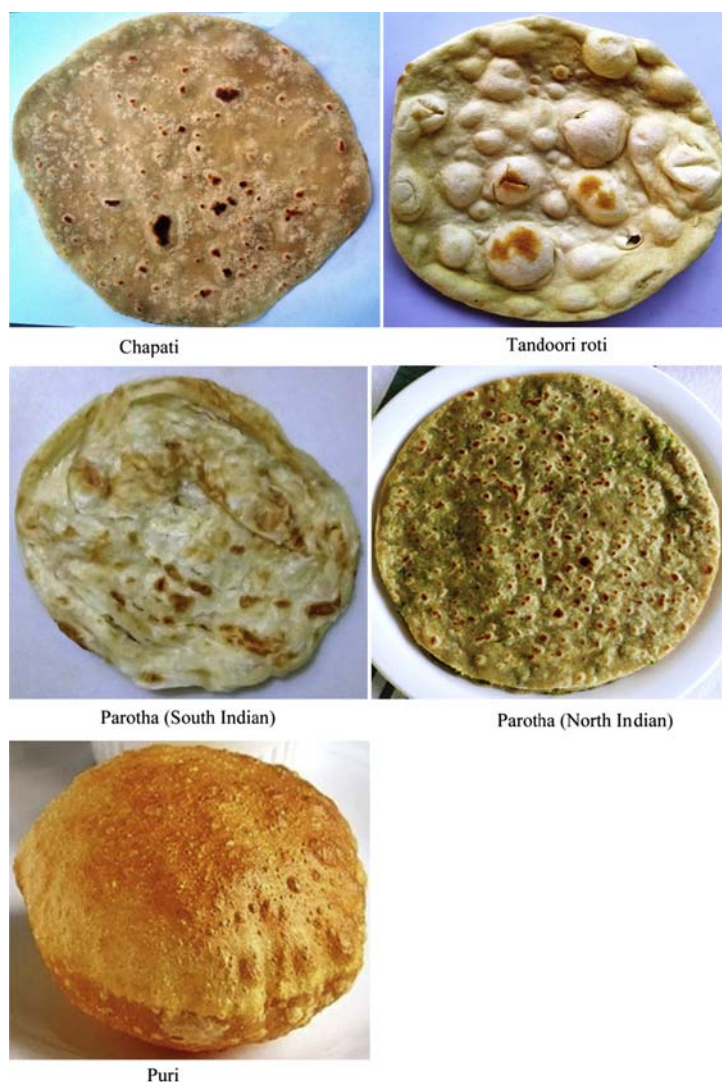

The structure of bread can be described as a multiphase colloidal system, including, but not limited to, polysaccharides, proteins, fats, salt, and water, all of which influence the final physical and sensory properties of the product. The microstructure of flatbreads is dominated by gelatinized starch granules wrapped up in a continuous matrix of denatured protein (Prabhasankar et al., 2003). Both gelatinization of starch granules and denaturation of the protein matrix occur due to the heat applied during the baking process. Porosity occurs in leavened breads, due to the production of carbon dioxide from leavening agents, such as yeast, which leads to air cavities and void structures. In contrast, in unleavened breads, gas cells are not formed in the microstructure as there are no leavening agents, and thus a closed structure is observed (Sidhu et al., 1990). Indian flatbreads are known for their special quality attributes, which have specific properties for their function as part of a meal. These properties are not only controlled by the chemical composition of the raw ingredients but also from ingredient interactions *in situ* and the processing technique. The microstructure of bread has a significant effect on its texture and sensory properties (Gao et al., 2015).

## Method of Production

In general, the flatbread-making process involves several basic steps (Fig. 3). The first step in the preparation of flatbreads is the selection of ingredients. The formulations of flatbreads vary from region to region, but the basic steps remain the same. Mixing is the important step in flatbread preparation and involves the uniform mixing and kneading of all the ingredients. During mixing, the wheat flour is hydrated and viscoelastic gluten protein network is formed. The way in which the dough is mixed and kneaded depends upon the type of method used (mechanical or by hand), water absorption, and type of bread desired (Saxena and Rao, 1996; Gocmen et al., 2009; Mir et al., 2014).

Leavened breads require fermentation as a basic requirement. The optimum temperature–time combination is necessary to produce a good quality end product with the correct aerated texture (Mir et al., 2014). The yeast or sourdough starter initiates fermentation, making the dough lighter and extensible. Normally dough is rested to allow complete flour particle hydration and the relaxation and development of the gluten network. The dough then becomes more coherent, and it achieves a point of maximum consistency. This is the point to which dough should be worked to produce a good quality bread. The dough changes from a viscous slurry into a viscoelastic mass, and the gluten forms a continuous film which enables easy sheeting with minimal stickiness (Qarooni, 1996; Parimala and Sudha, 2015). Molding is an important step in flatbread production whereby the dough is divided into 30–50 g pieces and then traditionally rounded between the palms of the hand (Kurhade et al., 2016). On a commercial level, the rounded dough is sheeted (rolled or flattened) into a circular shape. Each type of flatbread has a different shape, size, and thickness to produce variable products.

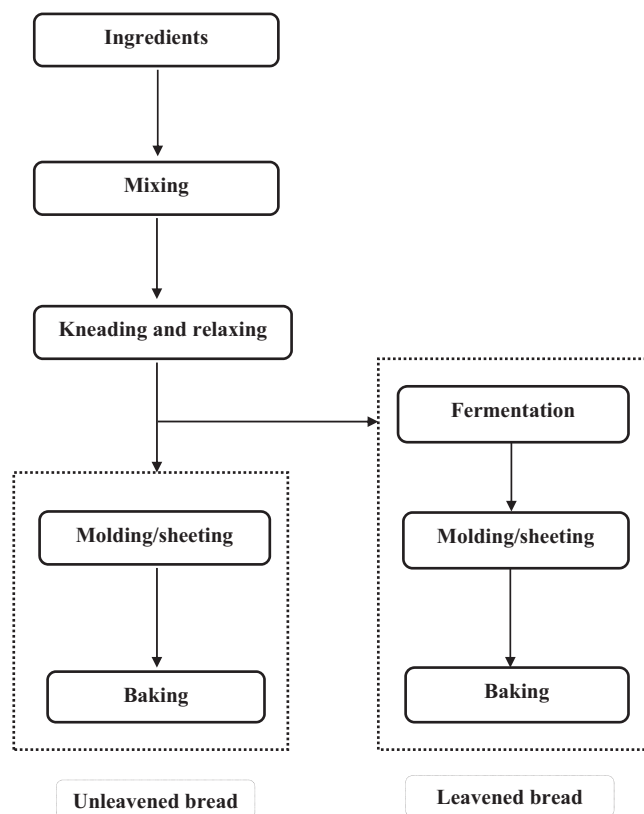

**Figure 1** Some common Indian flatbreads.

**Figure 2** Crust and crumb of flatbread (tandoori roti).

Baking is the last and the most important step in flatbread production. The flat dough is baked in various pans, in a tandoor, or an oven as per the type of bread desired. Various physical and chemical changes, including moisture loss, volume expansion, starch gelatinization, protein denaturation, crust formation, and browning, take place during baking. The extent of starch hydration, swelling, and reassociation is affected by the heating rate during baking (Sidhu et al., 1990; Mir et al., 2014). To achieve optimal baking, the common industrial practice is to bake bread in the controlled, constant temperature oven (Mondal and Datta, 2008).

**Figure 3** Typical flow sheet for the preparation of Indian flatbreads.

### Examples of Indian Flatbreads and Their Structure

In India, wheat is a dietary staple and is most commonly consumed in the form of different types of flatbreads, such as *chapati*, *parotta*, *puri*, *tandoori roti*, *phulka*, *papad*, and *nan* (Kumar, 2016). These are predominantly made from whole wheat, but refined or blended flours are also used. A number of modifications in formulations have been made to improve the quality and favorable sensory properties. These formulations vary from region to region, but the basic ingredients (wheat flour, water, and salt) are the same. Butter, vegetable shortening, or nonfat powdered milk may be added to improve the taste and aroma (Mir et al., 2014).

Variation is observed in the basic micro- and macrostructure of flatbreads. In unleavened breads, the dough is prepared from wheat flour and water without the use of yeast or leavening agent. The starch granules in the dough undergo almost no change during the short period of resting time. The steam generated during baking is responsible for the development of the matrix consisting of gelatinized starch on the inside of crust and in the crumb areas. Thus crumb of unleavened breads is much denser compared with leavened bread (Sidhu et al., 1990). The degree of deformation and folding of starch granules also varies between the crust and crumb of flatbreads. Starch granules maintain their integrity on the outside of the crust, but in the crumb, all the starch granules lost their identity and only a continuous matrix of gelatinized starch is observed. These differences also seem to be related to the water availability in the crust and crumb (Sidhu et al., 1990). On the other hand, the formation of gas cells with diverse volumes and shapes during the baking process is the major factor that determines the texture of leavened breads (Mir et al., 2014).

#### Chapati

*Chapati* is an unleavened flatbread and is the principal flatbread consumed on the Indian subcontinent. The ingredients such as flour, water, and salt are kneaded into pliable dough before being shaped and baked. The desired quality characteristics of *chapatis* are pliability, soft texture, light cream-brown color, with a slight chewiness and baked wheat aroma (Hemalatha et al., 2014). Almost 90% of the wheat produced in India is used in the production of *chapati* (Kurhade et al., 2016). The other 10% of wheat is used for making other breads, biscuits, and cake (Parimala and Sudha, 2012).

Microscopy studies have shown that the microstructure of *chapati* has gelatinized starch granules scattered throughout the crumb that lead to the formation of a continuous starch network (Fig. 4). The protein matrices are wind together to form aggregates (Hemalatha et al., 2010, 2014), and the protein matrices and starch granules overlap one another to also form aggregates (Kurhade et al., 2016). Sidhu et al. (1990) reported that the starch granules are distorted on the inner part (facing toward crumb) of the *chapati* crust. In comparison, the starch granules mostly lose their integrity in the *chapati* crumb, and only a continuous matrix is visible.

### Tandoori Roti

*Tandoori roti* is a popular flatbread on the Indian subcontinent. As the name suggests, it is baked in a tandoor. The *tandoori roti* is similar to a *chapati* with respect to ingredient composition but varies in size and thickness. *Tandoori roti* is somewhat thicker and larger than *chapati*; on average it is 15–20 cm in diameter and 5–8 mm thick. The crumb-to-crust ratio in *tandoori roti* is greater than that of a *chapati*. A *tandoori roti* is less pliable than a *chapati*, with a rough surface and several large blisters (Saxena et al., 2000). A literature search finds no information about the microstructure of *tandoori roti*, but one can assume some similarities with *chapati*. Generally, *tandoori roti* made from whole wheat flour has a better texture and flavor as compared to those made from refined flour (Saxena and Rao, 1995). Moisture condensation on the sheeted dough gives rise to the formation of blisters during baking. The desirable characteristics of *tandoori roti* are a typical baked aroma and slightly brittle and chewy texture (Rao and Manohar, 2003).

### Parotta

*Parotta* is another type of Indian flatbread prepared from wheat flour, water, refined oil, and salt. The optional ingredients are sugar and egg. Two different types of *parotta* are prepared in India: *South Indian parotta* and *North Indian parotta*. *South Indian parotta* containing several distinct layers is baked on a hotplate, or on a shallow iron plate heated by gas or wood. *North Indian parotta* is made by pan-frying sheeted dough on a hotplate and may be stuffed with different vegetables (Indrani et al., 2011; Sudha et al., 2015).

*Parotta* consists of several distinct layers and is slightly thicker than *chapati*. There is a slight difference between the microstructure of the outer and middle layers (Prabhasankar et al., 2003). The middle layers of *parotta* have less starch granule distortion compared to the outer layers. The microstructure of the outer layers shows a change in shape of both types of starch granules (large and small) due to gelatinization. Protein and starch molecules were observed to adhere closely (Fig. 5). However, in the middle layers, these molecules were much closer and their deformation was reduced (Prabhasankar et al., 2003; Indrani et al., 2011).

In comparison to *chapati*, the starch granules present in the crust of *parotta* are much more deformed and have a shriveled appearance but maintain a weak visible outline in the crumb under magnification. The application of fat to the outside of *parotta* during baking likely serves as an oil bath between the crust and baking pan, thus facilitating better heat transfer. The fat present between the *parotta* layers (smeared between individual layers during sheeting) may also maintain starch granule integrity during the baking process. Both of these phenomena may lead to the differences observed between the crust and crumb of *chapati* and *parotta* (Sidhu et al., 1990).

### Puri

*Puri* is an unleavened deep-fried flatbread prepared in many South Asian countries including India, Pakistan, and Bangladesh. It is consumed for breakfast, or as a snack or light meal. It is prepared from either whole or refined wheat dough containing a small amount of salt (Shaikh et al., 2007; Kumar, 2016). The dough pieces are made into round balls, rolled into circles, and deep fat fried in vegetable oil. The dough is prepared without using any leavening agent. The steam generated during frying results into puffing, thus separating the crust from the crumb. This steam is also responsible for the development of gelatinized starch matrix on the inside of crust and in the crumb areas. The crumb of *puri* appears to be very dense in comparison to bread prepared with the yeast (Sidhu et al., 1990).

In *puri*, the starch granules are partially gelatinized but retain their integrity possibly due to less water absorption, which restricts the swelling of the starch granules during frying (Fig. 6). The gelatinized starch granules were found to be wrapped up in a continuous protein matrix. The *puri* crust showed eruptions and the development of a protein matrix during deep frying. Crust eruptions are formed due to the explosion of starch granules during frying operation (Sidhu et al., 1990). The starch granules were more deformed and folded on the inside of the crust (Parimala and Sudha, 2012).

### Influence of Bread Structure on Properties

The structure of any given food product is essentially a template of the properties of that food system, representing its material behavior, physical stability, appearance, sensory performance, and other attributes related to the overall quality of that particular food (Day and Golding, 2016). Bread structure is the organization of food ingredients and their interactions during the baking

**Figure 6** Microstructure of *puri*. Parimala, K.R., Sudha, M.L., 2012. Effect of hydrocolloids on the rheological, microscopic, mass transfer characteristics during frying and quality characteristics of *puri*. *Food Hydrocoll.* 27, 191–200.

process, forming different types of structures in the end product (Heertje, 2014). The structural properties of flatbreads are controlled not only by chemical composition of the raw material but also by their interaction at the molecular level (Nishinari, 2004).

Various subjective and objective assessment systems have been used to evaluate flatbreads including physical and sensory characteristics. These include volume, crust color, presence of blisters, and uniformity of shape, as well as texture, crumb color, and flavor. Pliability, shear value, and tearing resistance are typical features used as criteria to evaluate flatbreads of Indian origin. Moreover, instrumental techniques such as texture analyzer, colorimeter, and scanning electronic microscopy are also exploited to evaluate their quality (Parimala and Sudha, 2015; Sudha et al., 2015).

Indian flatbreads are usually prepared from wheat flour, which is good source of starch and gluten. The gelatinization of starch granules and denaturation of the protein matrix are a consequence of heat to which these components are subjected during baking. Water loss and mixing of structural components that take place during baking may be responsible for the resultant chewiness, which is a typical quality attribute of flatbreads (Prabhasankar et al., 2003; Sidhu et al., 1990). Insights into how the structure of food changes during processing and during consumption are essential for producing a high-quality end product. The breakdown of food material during mastication affects the overall sensorial experience, and the breakdown during gastrointestinal transit is increasingly being used to demonstrate the role of food structure in the digestion and uptake of micro- and macronutrients (Nishinari, 2004). These microstructural properties can be used to identify processing parameters that affect the overall quality of product (Cafarelli et al., 2014).

## Conclusion

Understanding the microstructure of foods is important as it has a direct effect on the quality of the product. Many factors such as ingredients, preparation methodology, and baking procedure affect the quality of bread structure. These variables and their interactions affect the bread microstructure, which in turn influences the sensory, textural, and physical properties of the bread.

## Introduction

Soy products have been consumed increasingly nowadays because of its high protein content and other beneficial components. Soy products are widely distributed, such as tempeh, natto, douchi, soy milk, tofu, dried bean curd, and others. Tempeh, natto, and douchi are the same type of fermented products from soybean seeds in different countries. Soy milk is a typical colloid food consisting of water, protein, lipid, and other trace constituents. Tofu and dried bean curd are typical protein-based foods, which can be used to produce many types of other soy products. Moreover, tofu and its derived products are considered to have the similar structure. Therefore, the structure and its effect on the physicochemical properties of tofu are the main focus in this chapter.

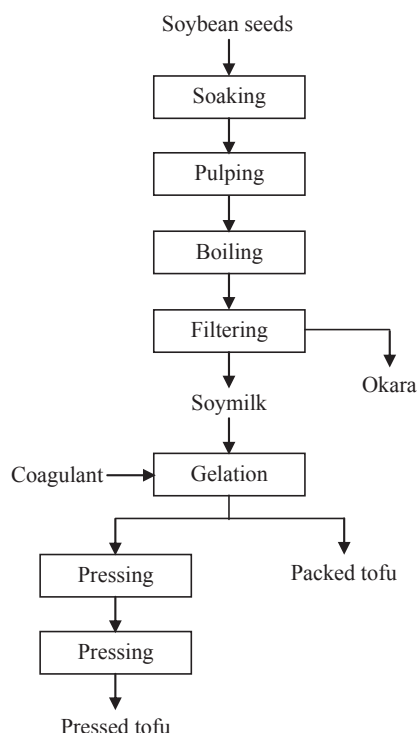

The flow diagram of tofu processing is shown in Fig. 1. As a typical gel food, the formation of tofu is mainly attributed to the gelation property of soybean proteins. Simply, thermally denatured soybean proteins aggregate to form protein aggregates because of the increased hydrophobic groups around the protein molecular surface induced by heating. When a coagulant is added, the aggregated proteins further interact with each other to form the polymerized proteins with a stable three-dimensional network structure. Other nonprotein components, such as water, polysaccharides, lipid, and other trace components, are entrapped in this network to influence the structure of tofu. The structure of tofu determines the physicochemical properties of tofu product. However, the structure formation of tofu is influenced by various factors, involving the quality of soybean seeds and processing technology, resulting in various types of tofu for satisfying different consumers (Table 1).

## Structure Formation of Tofu

The structure formation of tofu is influenced by several factors, which include the composition of soybean proteins, other nonprotein components, thermal treatment methods of soy milk, the types of coagulant, and its usage conditions. Therefore, different types of tofu structure can be obtained, resulting in different yields and edible qualities of tofu.

## Protein Composition of Soybean Seed

The composition of soybean proteins directly determines the tofu quality. Among the soybean proteins, 11S and 7S proteins, also known as the major components of glycinin and  $\beta$ -conglycinin, respectively, are most important two storage proteins that influence the structure and finally the texture of tofu. As shown in Fig. 2A, glycinin is a hexamer and each monomeric unit has an acidic polypeptide chain and a basic polypeptide chain via a disulfide bond (Malaki Nik et al., 2009). The acidic and basic subunits associate into two hexagonal rings via electrostatic interaction and hydrogen bonding (Nishinari et al., 2014). Glycinin composes of five types of subunits, which can be divided into three groups, namely group I ( $A_{1a}B_{1b}$ ,  $A_{1b}B_2$ ,  $A_2B_{1a}$ ), group IIa ( $A_5A_4B_3$ ), and group IIb ( $A_3B_4$ ) (Adachi et al., 2003). Sulfur amino acids, such as methionine and cystine, are contained in high quantity in glycinin to contribute to form the necessary disulfide bonds.  $\beta$ -Conglycinin is a mixture of heterotrimeric and homotrimeric glycoprotein, which consists of three *N*-glycosylated subunits, including  $\alpha'$ ,  $\alpha$ , and  $\beta$ , through the hydrophobic interaction and hydrogen binding

**Figure 1** The flow diagram of tofu processing.

**Table 1** The commonly consumed types of tofu and their characteristics

	Types	General characterization	Physicochemical properties	Shelf life	Syneresis	Appearance
Pressed tofu	Hard/firm tofu or momen tofu	Coagulated by many coagulants: nigari, acidic tofu whey, and GDL Pressed after tofu whey removal and stored under refrigeration No pasteurization	~80% Water content Compact internal structure; high hardness, firmness, and toughness Relatively rough taste and strong beany flavor	Several days in bulk (2–4 days)	High	
	Soft tofu	Coagulated by gypsum Processed by pressing unbroken bean curd Less removal of tofu whey No pasteurization	~90% Water content Medium firm or hard Tender, elasticity, and fine texture Light beany flavor	Several months in a pouch pack	Low	
Packed tofu	Silken tofu or kinugoshi tofu	Coagulated by GDL or dilute CaSO <sub>4</sub> solution Gelation in a pouch pack and molding without pressing No removal of tofu whey and less loss of nutrients Pasteurized after packaging	~90% water content Bland taste and fine texture Soft cheeselike texture but firm enough to retain shape after slicing Fine and smooth texture Light beany flavor	Several months in a pouch pack	Low	

GDL, glucono- $\delta$ -lactone.

(Fig. 2B) (Maruyama et al., 1998). Comparatively,  $\beta$ -conglycinin has less content of sulfur amino acids. Therefore, no effective disulfide bonds are formed to stabilize the structure of  $\beta$ -conglycinin. As reported by Bairy et al. (2010), the isolated glycinin formed a coarse gel network with a pore size of 2–3  $\mu\text{m}$  stabilized by the disulfide cross-links and noncovalent interactions. The heat-induced gels of isolated  $\beta$ -conglycinin showed a fine dispersed network with a pore size of 0.5–0.6  $\mu\text{m}$  formed from the randomly

**Figure 2** Possible schematic diagrams of glycinin (A) and  $\beta$ -conglycinin (B) molecules. Modified from Nishinari, K., Fang, Y., Guo, S.T., Phillips, G.O., 2014. Soy proteins: a review on composition, aggregation and emulsification. *Food Hydrocoll.* 39, 301–318.

aggregated assembly of clusters. However, the formation of a three-dimensional network of tofu gel is contributed to the interactions among the subunits of these two storage proteins via different types of chemical bonds (Yamauchi et al., 1991). For example, during heating, the basic subunits of glycinin react with the  $\beta$  subunit of  $\beta$ -conglycinin via a secondary bond; the acidic and  $\alpha$ ,  $\alpha'$  subunits tended to interact with each other through disulfide bonding.

As a result of discrepancies in amino acid composition and subunit composition of glycinin and  $\beta$ -conglycinin, different gelling properties can be obtained. Moreover, the special microstructures of glycinin and  $\beta$ -conglycinin determine the different types of structure transformation under various conditions, such as temperature, pH, ion type, and its strength and others.

### Thermal Treatment of Soy Milk

After the soaking and pulping processes, soy milk can be obtained by filtering the okara either before or after the heating treatment. Generally, firm tofu with higher gel strength and water holding capacity (WHC) can be obtained from the heat-treated soy milk compared with the unheated soy milk (Tang, 2007). Soy milk is stabilized by the electrostatic repulsion among the solid portions consisted of soybean protein particles and oil bodies consisting of triacylglycerols (TAGs), phospholipids, and oleosins at the ambient temperature. When raw soy milk is heated, protein particles, mainly the glycinin and  $\beta$ -conglycinin, are gradually prone to denature to expose the hydrophobic groups. The structure of oil bodies also simultaneously changes to impact on the denaturation of proteins. Consequently, significant changes are founded in the particle composition of soy milk, which is closely influenced by the heat temperature and time. The specific introduction of the changes in particle formation and gelation of soy milk induced by heat can be found in the previous review (Peng et al., 2016).

It is worth noting that the thermal denaturation temperature regions of glycinin and  $\beta$ -conglycinin are different: 65–75 °C for  $\beta$ -conglycinin and 85–95 °C for glycinin (German et al., 1997). Consequently, changes in structure of many of the protein subunits take place to form the complicated aggregates of soybean proteins using one-step heating. However, when stepwise heating of soy milk was performed to selectively denature glycinin and  $\beta$ -conglycinin, significantly increased gel strength and textural qualities of the coagulant induced tofu were obtained (Liu et al., 2004; Shin et al., 2015). Controlled heating results in effective denaturation of glycinin and  $\beta$ -conglycinin to form the protein aggregates with optimum state for the subsequent coagulation.

### Coagulation

The formation of tofu is completed by adding appropriate coagulant in appropriate concentration to the heated soy milk after heating. The aggregated soybean proteins can spontaneously assemble each other to generate polymerized proteins. However, these molecular weight-increased macromolecules are not enough for the formation of network structure needed by tofu products.

The network structure of tofu can be further modified to be coarse or fine due to the different coagulation mechanisms when different coagulants and concentrations are used. The specific coagulation mechanisms for the formation of tofu can be found in the previous review (Peng et al., 2016; Zhang et al., 2016). Based on the different coagulation mechanisms, different microstructures of tofu could be obtained, resulting in different textural properties and sensory quality. As shown in Fig. 3A, small pores

distributed uniformly in a dense and well-connected network were found in the  $\text{Ca}^{2+}$ -induced tofu; by contrast, the tofu induced by microbial transglutaminase (MTGase) showed larger pores and flakelike network structure with discontinuous and loose state (Yasir et al., 2007). As shown in Fig. 3B, for the concentration of a coagulant, the term of optimal coagulant concentration (OCC) was used to describe the most appropriate amount used for obtaining the best satisfying microstructure of tofu under the set processing conditions (Onodera et al., 2009).

### Other Components in Soybean Seeds

Apart from soybean proteins, water, lipids (i.e., TAGs and phospholipids), carbohydrates (i.e., sucrose, stachyose, rhamnose), phytic acid, and others are contained in the filtrated soy milk. Along with the formation of three-dimensional network these nonprotein components interacted with each other or with the aggregated proteins to be as part of the composition of tofu. Consequently, the nonprotein components are able to influence the denaturation of soybean proteins and coagulation of aggregated proteins and thereby positively and adversely influence the texture of tofu.

As mentioned above, soybean lipid is present in soy milk in the form of oil bodies. Most of these oil bodies release from the dissolved state maintained by the interactions among TAGs, phospholipids, and oleosins and finally float on the surface of soy milk accompanying with the denaturation of soybean proteins (Peng et al., 2017). However, lipids are also involved in participating in the coagulation of tofu to become a component of tofu. Similarly, water and the water-soluble carbohydrates are entrapped in the pores during the formation of three-dimensional network of tofu (Shen and Kuo, 2017). Thus, the hardness and firmness of  $\text{CaSO}_4$ - and Glucono- $\delta$ -lactone (GDL)-induced tofu were negatively related to the contents of lipids, sucrose, free sugar, and starch; however, these textural properties were positively related to the stachyose content (Poysa and Woodrow, 2002; Song et al., 2013).

As a type of metal chelator, phytic acid can bind both soybean proteins and metal ions to interfere with the coagulation by reducing the bridging action between metal ions and aggregated proteins, which is essential to the network structure of tofu (Lim et al., 1990). As a result, reduced breaking stress, hardness, and springiness of tofu made from soybean seed with high content of phytic acid were observed. However, the influence of phytic acid on the textural properties of tofu can be modified by selecting a nonsalt coagulant or increasing the OCC of the selected salt coagulant.

### Physicochemical Properties

Excellent edible acceptability and texture are important characteristics, resulting in the increasing consumption of tofu. These characteristics are always determined by the physicochemical properties of tofu. In general, WHC, texture, sensory, syneresis, and

**Figure 3** The microstructures of tofu induced by  $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$  and MTGase under the same processing conditions (A) and tofu induced by GDL in different concentrations under the same processing conditions (B). *GDL*, glucono- $\delta$ -lactone; *MTGase*, microbial transglutaminase. Res.* 15, 265–274 and Yasir, S., Sutton, K., Newberry, M., Andrews, N., Gerrard, J., 2007. The impact of transglutaminase on soy proteins and tofu texture. *Food Chem.* 104, 1491–1501.

nutritional value are the most used quality attributes for evaluating the quality of tofu. The stability maintaining these physicochemical characteristics of tofu during production processes and product development is vital for keeping the market competitiveness of tofu industry. Thus, to figure out the relationship and how to relate between the network structure of tofu and its physicochemical characteristics is very important.

### Water Holding Capacity

Water plays an important role in the physicochemical properties of tofu. By using low-field nuclear magnetic resonance, three types of water are present in the tofu matrix (Li et al., 2014). Water distributed in the interspaces of network structure (such as the pores and gaps among the continuous phase) is considered the free water. Water closed to the polymerized proteins and distributed in the small meshes of tofu microstructure is regarded as the physically binding water. The third-type water is known as the chemical binding water and an integral part of the cross-linked proteins, which are distributed in the protein molecules. Based on these proposed distributions of water, the content of water retained in tofu matrix is usually evaluated by WHC influenced mainly by the free water and physically bound water. In addition, pores and meshes with different sizes exist in the three-dimensional network of different types of tofu so that WHC is usefully measured as a quality attribute for reflecting the yield, texture, color, and taste of tofu. Therefore, measurement of WHC of tofu is of practical benefit to tofu manufacturers (Cai et al., 1997).

A strong and negative correlation between water loss, indicated by WHC, and the hardness of tofu is commonly considered. When more water is bound and trapped in the network-containing proteins and other constituents, a stronger gel is formed. It is being noted that this bound water in the network structure of tofu should not be confused with the unbound water that was regarded as having a negative influence on the tofu hardness (Min et al., 2005; Yang and James, 2013). Furthermore, from the visual examination, tofu with high WHC appears smooth, whereas tofu with low WHC has a coarse texture, which is affected by the type of coagulant and its concentration. The GDL- or MTGase-induced tofu, for instance, has the relatively high WHC compared with that of the salt-induced tofu (Zhang et al., 2016).

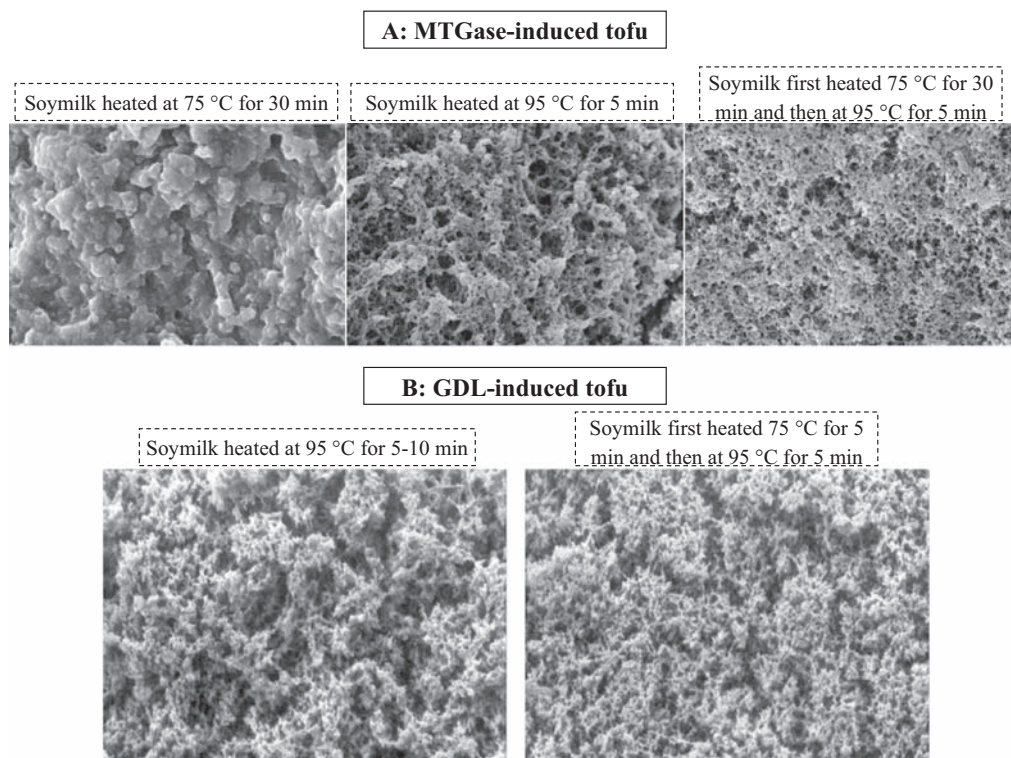

### Textural Properties

Tofu can be sliced to small pieces and shaped for foods with various forms, which is a benefit of its characteristic texture. The textural properties of tofu are the most important quality attributes used for evaluating the acceptability of tofu. For example, firm tofu often possesses greater hardness and cohesiveness so that more power is needed to break down its structure. Higher elasticity and greater chewiness are usually observed in tofu with high springiness, causing it more difficult to eat. Therefore, the factors that determine the formation of three-dimensional network structure of tofu could closely relate to the textural characteristics of tofu.

As mentioned earlier, the contents of glycinin (11S) and  $\beta$ -conglycinin (7S), content ratio (11S/7S), and their subunit profiles directly impact the formation of network structure of tofu and consequently the textural properties of tofu. In general, 11S proteins enhance the textural properties of tofu; however, 7S proteins have the opposite effect. Thus, gels made from 11S proteins have finer network structure, resulting in higher hardness, gel strength, and breaking stress than gels made from 7S proteins (Poysa et al., 2006; Renkema et al., 2001). In particular, the hardness, elasticity, cohesiveness, and chewiness of tofu have a significantly positive relationship with the 11S/7S ratio.

The hardness of gels made from the subunits of 11S proteins decreased in the order of group IIa, IIb, and I (Tezuka et al., 2000). However, regardless of the types of coagulant used, the group IIb subunit was reported to play a major role in contributing to the firmness of tofu, while the group IIa subunit showed a negative effect on the hardness and firmness of tofu (Poysa et al., 2006). Therefore, silken tofu made from soybean seeds without the group IIa subunit showed firmer structure than that made from the group IIa subunit-containing soybean variety (James and Yang, 2014). Moreover, when  $MgCl_2$  was used as a coagulant, the group I subunit was observed to have the greatest effect on the firmness of tofu than other subunits (Tezuka et al., 2004). For example, the breaking stress value of tofu made from soybean seeds with the group I subunit was twice as high as that of tofu made from soybean seeds without the group I subunit (Tezuka et al., 2000). The hardness values of gels made from  $\alpha'$ -lacking 7S proteins, 7S proteins with all three subunits ( $\alpha$ ,  $\alpha'$ , and  $\beta$ ), and  $\alpha$ -lacking 7S proteins under the same processing conditions were observed in a decreasing order (Mohamad Ramlan et al., 2004). The content of 7S $\alpha'$  subunit is known to be significantly negatively related to the hardness, elasticity, cohesiveness, and resilience of tofu. Therefore, soybean genotypes lacking both the 7S $\alpha'$  and the 11S group IIa subunits and with higher contents of 11S group I and IIb subunits can produce firmer tofu.

Denaturation of soybean proteins by heating of soy milk is the prerequisite for the formation of tofu network structure. For  $CaSO_4$ -induced tofu, the hardness, cohesiveness, and chewiness are negatively related to the heating time. For MTGase-induced tofu, more continuous and homogenous coral-like structure and higher hardness were observed in the tofu made by heating soy milk at moderate temperature and proper time, such as 75 °C for 30 min (Tang, 2007). However, this moderate temperature does not denature the glycinin completely so as to make the MTGase-induced tofu with loose or uncompact structure (shown in Fig. 4A). Therefore, as shown in Fig. 4B, it has been confirmed that a denser, finer, and more homogenous network structure was observed in GDL-induced tofu with increased apparent Young's modulus when soy milk was heated first at 75 °C for 5 min and then at 95 °C for 5 min (Liu et al., 2004). In addition, effective denaturation of both glycinin and  $\beta$ -conglycinin benefits the formation of compact and fine network structure of tofu to increase its hardness and breaking stress in spite of the type of coagulant.
