Exposure estimates performed around the year 2000 indicated that the exposure of a considerable part of the European population exceeds the established HBGVs. This triggered numerous measures, including *inter alia* intensified identification and reduction of source emissions, installation of filters in incinerators, and also setting of legal limits for feed and food in order to withdraw commodities with the highest contamination from the market.

## Legal Limits for Dioxins and PCBs in Feed and Food

### Feed

Maximum levels (termed maximum content) for dioxins, the sum of dioxins and DL-PCBs, and the sum of the six NDL-PCBs 28 + 52 + 101 + 138 + 153 + 180 are laid down in Annex I, Section V of Directive 2002/32/EC (EC, 2002/32) on undesirable substances in animal feed. All levels are expressed relative to a feed with a moisture content of 12% (88% dry matter, DM). The current legal limits for dioxins and the sum of dioxins and DL-PCBs are based on WHO<sub>2005</sub>-TEFs. While the legal limits for dioxins range between 0.75 and 5 ng WHO<sub>2005</sub>-TEQ/kg with the highest level for fish oil, the maximum contents for the sum of dioxins and DL-PCBs are between 1 and 20 ng WHO<sub>2005</sub>-TEQ/kg, both relative to a moisture content of 12%. The maximum content for NDL-PCBs is based on the sum of the six indicator-PCBs and ranges between 10 µg/kg and 175 µg/kg with the highest limit for fish oil, each relative to a moisture content of 12%. Maximum contents in feed are neither based on toxicological considerations nor deduced from feeding habits, but are derived from the frequency distribution of dioxins and PCBs in the respective feed commodity following the principle “strict but feasible”. In general, the maximum contents were set around the 90th percentile of the respective frequency distribution. Feed products have to comply with all three legal levels.

As a peculiarity, all legal limits for dioxins and PCBs are set as upper bound concentrations (UB). These are calculated on the assumption that all values of the different congeners below the limit of quantification (LOQ) are equal to the numerical value of the LOQ.

According to Article 5 of Directive 2002/32/EC, Member States shall prescribe that products intended for animal feed containing levels of an undesirable substance that exceed the maximum level fixed in Annex I may not be mixed for dilution purposes with the same, or other, products intended for animal feed.

In addition to maximum contents, also action thresholds are set separately for dioxins and DL-PCBs, respectively in Annex II of Directive 2002/32/EC. The action thresholds also refer to products relative to a moisture content of 12%. Action thresholds are meant as an early warning tool. They are set at around 2/3 of the corresponding maximum content. If a sample exceeds the action threshold but is still below the maximum content, the product can be marketed. Nevertheless, an exceedance of action thresholds is an indication of an increased contamination level substantially above background. Consequently, the competent authorities of the Member States, in cooperation with economic operators shall carry out investigations to identify the sources of the contaminants in order to reduce and eliminate the emissions.

## Food

Maximum levels (MLs) for dioxins, the sum of dioxins and DL-PCBs, and the sum of the six NDL-PCBs are laid down in Commission Regulation (EC) No 1881/2006 ([EC, 1881/2006](#)), as amended. The MLs for dioxins and the sum of dioxins and DL-PCBs are both based on the application of the WHO<sub>2005</sub>-TEFs, and are given as pg WHO<sub>2005</sub>-TEQ/g. MLs for the NDL-PCBs are set as the sum of the concentrations of the six indicator-PCBs. The derivation of the MLs based on frequency distributions follows the same approach as for feed. All MLs for food represent upperbound values. Except for certain fish and fish products, liver of fish and terrestrial animals, and foods for infants and young children, all other MLs for dioxins, the sum of dioxins and DL-PCBs, and NDL-PCBs are given on a fat basis. The MLs for dioxins and the sum of dioxins and DL-PCBs expressed on a fat weight basis are not applicable for foods containing < 2% fat. These have to be calculated on a product basis, assuming a fat content of 2%. Depending on the foodstuff, the MLs for dioxins range between 1 and 2.5 pg WHO<sub>2005</sub>-TEQ/g fat, and 0.1 to 3.5 pg WHO<sub>2005</sub>-TEQ/g wet weight, respectively. The MLs for the sum of dioxins and DL-PCBs are between 1.25 and 6 pg WHO<sub>2005</sub>-TEQ/g fat, and 0.20–20 pg WHO<sub>2005</sub>-TEQ/g wet weight, respectively. For the sum of the six NDL-PCBs, the MLs are set between 1 and 300 ng/g wet weight and at 40 ng/g fat for all commodities which are based on fat weight.

According to Article 3 of Regulation (EC) No 1881/2006, foodstuffs not complying with the MLs shall not be used as food ingredients, and foodstuffs complying with the MLs shall not be mixed with foodstuffs which exceed the MLs. Article 7 of the Regulation stipulates that by way of derogation, Finland, Sweden and Latvia may authorize the placing on their market of specific fish species originating in the Baltic region and intended for consumption in their territory with levels of dioxins and/or DL-PCB higher than those set out in the Regulation. These derogations apply only provided that a system is in place to ensure that consumers are fully informed of the dietary recommendations with regard to the restrictions on the consumption of the respective fish species by identified vulnerable sections of the population in order to avoid potential health risks.

As for feed, the legislation for food also includes an early warning tool which is termed “action levels (ALs)”. The separate setting of ALs for dioxins and DL-PCBs as well as their enforcement in case of exceedance follows the same approach as described for the action thresholds in the feed legislation. The most recent amendment of ALs for dioxins and DL-PCBs in food was stipulated by Commission Recommendation 2014/663/EU ([EU, 2014/663](#)).

## Sampling and Analysis

Because of the low levels of dioxins and DL-PCBs which are mostly in the fg/g or pg/g range, powerful analytical methods are required to not only separate the toxic congeners from the non-toxic ones but also to unequivocally quantify the concentrations at the legal limits.

Unlike in the US, in the European Union there are no fixed standard methods for the determination of dioxins and PCBs in feed and food. Instead, the EU follows the “criteria approach”. Strict analytical performance criteria are set by the EU Commission. As long as these criteria are fulfilled which has to be demonstrated in a traceable manner, the analysts can use their method of choice. In addition, the fitness of purpose of the analytical methods have to be substantiated by successful participation in proficiency tests which is controlled by the accreditation bodies.

Detailed requirements for methods of sampling and analysis for the control of levels of dioxins and PCBs in foodstuffs and feed are laid down in Commission Regulation (EU) No 2017/644 ([EU, 2017/644](#)) and in Commission Regulation (EU) No 2017/771 ([EU, 2017/771](#)), respectively. Besides provisions concerning methods of sampling depending on the size of the lot, packaging, transport, storage, and handling of the samples in the laboratory, the two Regulations also stipulate the analytical performance criteria, such as precision, addition of isotope-labelled standards, gas chromatographic separation, and maximum tolerances for retention times, as well as provisions for the interpretation of results and requirements for assessing the compliance of a lot or sub-lot with the legislation.

The analysis of dioxins and PCBs in feed and food is either performed by bioassays or by mass spectrometric based methods. While bioassays can be considered as semi-quantitative screening methods allowing a high sample throughput, gas chromatography coupled to high resolution mass spectrometry (GC-HRMS) and GC coupled to tandem mass spectrometry (GC-MS/MS) are assigned as confirmatory methods.

The Chemical Activated Luciferase gene eXpression assay (CALUX) is the most commonly used bioassay in dioxin and DL-PCB analysis. It mimics the mode of action of dioxins and DL-PCBs in mammals. Rat and mouse hepatoma cells are genetically modified by embedding a DNA fragment from the firefly encoding for luciferase in the “dioxin responsive elements” (DREs) in the DNA ([Sanderson et al., 1996](#)). After exposure of the cells with the sample extract and addition of luciferin, the resulting concentration dependent light reaction can be measured by a luminometer. As the CALUX is sensitive to all compounds that act through the Ah receptor, it requires some efforts to remove potential disturbing co-extracts. This can best be done by including a sulphuric acid containing step in the clean-up process which destroys labile compounds but does not affect dioxins and DL-PCBs. As NDL-PCBs do not bind to the Ah receptor they cannot be measured by CALUX.

Another bioassay that is occasionally used is the EROD assay ([Kennedy et al., 1993](#)). It finally measures the deethylation of ethoxyresorufin to resorufin following exposure of mammalian cell lines to dioxin and DL-PCB containing extracts.

Bioassay results are given as “Bioanalytical Equivalents (BEQs)”. As there are some differences between the relative response of dioxins and DL-PCBs in the bioassays and the WHO-TEFs, non-compliant and suspect results that are above a certain cut-off-level

have to be confirmed by GC-HRMS or GC-MS/MS. The advantage of the latter methods is the ability of a congener-specific analysis which does not only give a “yes/no” result, but also valuable hints of the potential source of the contamination derived from the analysed congener profile. Moreover,  $^{13}\text{C}_{12}$ -labelled standards can be added at the very beginning of the analysis giving information on the losses of the analytes in question. Nowadays, it is good practice in confirmatory feed and food analysis to add all seventeen  $^{13}\text{C}_{12}$ -labelled dioxin congeners with 2,3,7,8-chlorine substitution and all twelve  $^{13}\text{C}_{12}$ -labelled DL-PCBs as internal standards, i.e. each congener of interest is quantified on its corresponding internal standard. At the last step before the chromatographic separation a further  $^{13}\text{C}_{12}$ -labelled standard is added, which is used to calculate the recovery of the various congeners.

## Levels in Feed and Food

### Feed

Feed materials of plant origin and compound feed of plant origin are generally low contaminated with dioxins and PCBs. The levels are in most cases near the ubiquitous background contamination. Somewhat higher concentrations can be found in roughages and grass samples because of their long growing period and the expression of their contaminant levels relative to a moisture content of 12%. If the feedingstuffs contain feed material of animal origin, especially derived from fish, the dioxin and PCB levels are generally higher than in feed commodities of plant origin.

In their 2012 report where EFSA evaluated the occurrence data in feed submitted by 26 European countries, they reported that the feed group with the highest average level of dioxins and DL-PCBs was “fish oil”, followed by “feed for fur animals, pets and fish” and “fish and other aquatic animals, their product”. Some high levels could also be observed in a few samples of “other feed additives” and “vegetable oils and their by-products”.

Due to natural formation under high pressure and temperature, dioxins can also be formed and determined in some clay materials (Holmstrand et al., 2006). Some of these contaminated clays, such as Mississippi ball clay (Hayward et al., 1999) and kaolinite clay (Jobst and Aldag, 2000) caused incidents because of their use in animal feed. Hoogenboom et al. (2010) investigated the use of kaolinite to help to remove poor quality potatoes which led to an incident with milk from dairy cows and meat from ruminants fed the contaminated potato peel. Dioxins have also been detected in other minerals used in animal feed, such as zinc oxide (Kim et al., 2011) and feed supplements containing copper sulphate (Ferrario et al., 2003).

The contamination of feed with dioxins and/or PCBs was often the initial incident that resulted in deterioration of food of animal origin. Prominent examples are *inter alia* pentachlorophenol (PCP) contaminated saw dust as carrier in pre-mixed choline chloride in 2000, use of waste wood for drying of bakery leftovers in 2003 and introduction of fatty acids from biodiesel production intended for industrial uses into feed for food producing animals. Malisch and Kotz (2014) summarize these incidents and illustrate the consequences for the contamination of food of animal origin.

### Food

Performing a pathway analysis, Fürst et al. (1992) concluded that diet represents the main route of exposure to dioxins. While more than 90% of the total daily intake was estimated to be derived from food, exposure via air and soil was considered to contribute less than 10%. Because of the lipophilic properties, persistence and accumulation in the food chain, food samples of animal origin are of special importance. Those food commodities, especially from mammals, generally only contain 2,3,7,8-chlorinated congeners at measurable level, unless they are affected by an extraordinary contamination. Other non-toxic congeners are to the greatest possible extent metabolized. This is illustrated by a typical analysis of a cow's milk sample (Fig. 3). It shows the GC-HRMS determination of 2,3,7,8-TCDD at a concentration of 0.25 pg/g fat.

While the upper two chromatograms show the ion traces for the native analyte with retention time, area and ratio of the two measured fragments characteristic for TCDDs, the two lower chromatograms display the fragments measured for the  $^{13}\text{C}_{12}$ -labelled internal standards. Although there exist 22 different TCDD isomers, solely 2,3,7,8-TCDD, the only TCDD congener with 2,3,7,8-chlorine substitution can be determined and quantified against its isotope labelled standard.  $^{13}\text{C}_{12}$ -labelled 1,2,3,4-TCDD was added at the end of the clean-up just before injection into the GC to calculate the recovery of the various congeners.

A different situation can be seen for food samples of plant origin. These samples are generally affected by airborne contamination and in contrast to animals and humans, plants lack the possibility of metabolising the contaminants. As a result, plant samples do not only contain the toxic 2,3,7,8-chlorinated congeners but also a number of non-toxic congeners. This is demonstrated in Fig. 4 which shows the GC-HRMS analysis of tetrachloro-dibenzofurans (TCDFs) in a kale sample.

While the upper two chromatograms show the ion traces of the native tetrachloro-dibenzofuran analytes, the two lower chromatograms present the fragments of the isotope labelled 2,3,7,8-tetrachloro-dibenzofuran (2,3,7,8-TCDF). The upper two chromatograms illustrate that in addition to the toxic 2,3,7,8-TCDF a number of other non-toxic TCDFs are present in the sample. A total of 38 different TCDF isomers are theoretically possible. This fact demands thorough skills from the analyst as the toxic congeners have to be separated from the non-toxic ones in order to avoid false positive results which may have severe consequences for the food business operators.

Plants are generally not able to uptake considerable amounts of dioxins from the soil. Exceptions are zucchini and pumpkin. Hülster et al. (1994) studied the uptake of dioxins by zucchini and related plant species from two contaminated soils. The

**Figure 3** Determination of 2,3,7,8-TCDD in cow's milk by GC-HRMS.

experimental design allowed the discrimination of several uptake pathways and an evaluation of their contribution to the total dioxin contamination of the plants. For zucchini and pumpkin, both belonging to the genus *Cucurbita*, root uptake of dioxins and subsequent translocation to the shoots and into the fruits was found to be the main contamination pathway. In contrast, cucumber plants (*Cucumis sativus* L.) are mainly contaminated by deposition of airborne dioxins and thus show much lower dioxin concentrations. In fruits of zucchini, the dioxin levels were approximately two orders of magnitude higher than in other fruits and vegetables analysed.

The surveys on the contamination of food with dioxins and PCBs revealed some food commodities that generally contain elevated contamination levels. Bruns-Weller et al. (2010) analysed sheep liver and reported that around 90% of the samples exceeded the European maximum levels. In the corresponding meat of the sheep only low concentrations of dioxins and DL-PCBs were determined, all below the MLs in force. The results did not show any significant differences in contamination between female or male sheep. Moreover, no correlation was found between the age of the animals and the dioxin and DL-PCB levels in their liver. EFSA (2011) assessed the risk to public health related to the presence of high levels of dioxins and DL-PCBs in liver from sheep and deer and identified a lower activity of CYP1A enzymes in sheep compared to cattle and other ruminants as a possible reason for higher dioxin and DL-PCB levels in sheep liver. Furthermore, EFSA concluded that on individual occasions, consumption of sheep liver could result in high intakes exceeding the TWI, and that the frequent consumption of sheep liver, particularly by women of child-bearing age and children, may be a potential health concern.

Another product that is generally highly contaminated with dioxins and PCBs is fish liver. This is especially true for fish liver originating from the Baltic proper. Also certain fish species from this area are often contaminated, especially with dioxins. One possible reason is the release of effluents from the pulp and paper mills in the past. As some of the concerned countries could demonstrate that the benefits of fish consumption is superior to the possible impairment caused by dioxins and PCBs, they got exceptions from the EU Commission under specific pre-conditions to place certain fish species originating in the Baltic region that exceed MLs on the market in their territory.

Eggs from laying hens kept on ground or outdoors often contain higher dioxin and PCB levels than conventionally produced chicken eggs. This was shown especially for organic eggs where numerous samples exceeded the existing MLs. DeVries et al. (2006) reviewed the possible factors which influence the elevated levels. Ingestion of soil, uncontrolled intake of excrements and usage of litter produced from pentachlorophenol (PCP) treated wood may be possible sources. PCP which is generally contaminated with substantial amounts of dioxins from the synthesis, was a widely used wood preservative but its application is meanwhile banned.

EFSA periodically evaluates occurrence data on dioxins, PCBs and other contaminants submitted by European countries. The aim is not only to generate a data base on occurrence of contaminants but also to combine these data with consumption surveys to perform exposure estimates for the European population, and to monitor a potential decline of the contaminants in food and feed. The latest evaluations were performed in 2010 and 2012 (EFSA, 2010, 2012). In summarizing the occurrence data submitted

**Figure 4** Determination of tetrachloro-dibenzofurans in a kale sample by GC-HRMS.

from 26 European countries, EFSA concluded that “meat from eels” and “fish liver and derived products” contained the highest average contamination levels for both dioxins and PCBs. The non-ortho PCBs were the main contributor to total WHO<sub>2005</sub>-TEQs, making up between 21.0% and 74.5%, followed by PCDDs and PCDFs which together represented between 12.4% and 73.2% of the total TEQ level. Moreover, a decrease in the contamination levels of dioxins and PCBs was observed over the years in the three food groups taken into consideration for the time trend analysis: “raw milk and dairy products”, “hen eggs and egg products” and “muscle meat from fishes other than eels”. However, EFSA stated that it cannot be excluded that the heterogeneity in the foods constituting the groups, in the countries of origin covered and targeting strategies between the years, has influenced the observed trends.

More meaningful is an analysis of the contamination trend over time if the food products are collected from the same area and are analysed with the same analytical equipment. Fürst studied the dioxin and PCB contamination of dairy products from all dairies in North Rhine-Westphalia/Germany with own milk delivery every four years between 1990 and 2014. In order to investigate whether seasonal trends exist, each dairy was sampled four times per year. Meanwhile, more than 600 individual samples were analysed. Fig. 5 shows the frequencies of the dioxin levels determined in the samples analysed between 1990 and 2014. In order to allow a comparison with the data generated prior to 1998, all results are expressed as I-TEQ values calculated with the international TEFs proposed by NATO/CCMS in 1988, and not with the WHO-TEFs which were only published in 1998 for the first time. The concentrations calculated as I-TEQs only differ marginally from the results calculated with the WHO<sub>2005</sub>-TEFs.

The Figure clearly illustrates that with each survey the dioxin levels tend to lower values and the range of contamination becomes smaller. This demonstrates that the measures to reduce dioxin emissions and to close known sources show positive and beneficial effects. However, the last two surveys conducted in 2010 and 2014 revealed similar results. This may be an indication that the reduction is levelling off. In any case, the mean dioxin concentration in the analysed dairy products has decreased by 75% since 1990. A similar decrease of 70% was estimated for DL-PCBs since 1998 when they were included in these surveys for the first time.

The EFSA (2012) report on the “update of the monitoring of levels of dioxins and PCBs in food and feed” also estimated the dietary exposure for the European population based on the occurrence levels submitted by 26 European countries and the different dietary surveys collated in the EFSA Comprehensive European Food Consumption Database, representing seven age classes (infant, toddler, other children, adolescent, adult, elderly and very elderly). As a result, EFSA stated: “Chronic dietary exposure to the sum of dioxins and DL-PCBs was estimated to be on average between 0.57 and 2.54 pg WHO<sub>2005</sub>-TEQ/kg b.w. per day and at the 95th percentile between 1.2 and 9.9 pg WHO<sub>2005</sub>-TEQ/kg/kg b.w. per day depending on the population group. Between 1.0 and 52.9% of individuals were estimated to exceed the TWI of 14 pg TEQ/kg b.w. The major contributor to total exposure was milk and dairy products for almost all infant and toddler groups, whereas it was fish and seafood products for most of the adolescents, adults, elderly and very elderly groups. Meat and meat products also contributed significantly to total exposure. A general decrease in exposure to the sum of dioxins and DL-PCBs was observed between 2002–04 and 2008–10, estimated to be between 16.6% and 79.3% according to the different population groups.”

**Figure 5** Dioxins in dairy products from North Rhine-Westphalia 1990–2014.

Surveys performed in the past decades have indicated that due to numerous measures the emissions of dioxins and PCBs are reduced, their occurrence in the environment and thus the exposure of the European population has substantially decreased. However, due to criminal or grossly negligent actions of individuals, a number of incidents occurred in the past two decades causing massive feed contamination and subsequent food adulteration which foiled the successful measures to reduce human exposure with dioxins and PCBs. Prominent examples are the Brazilian citrus pulp pellet case 1997, the Belgian PCB incident 1999, the Irish pork and beef incident 2008, the German biodiesel case 2011, and others. Pentachlorophenol related incidents causing considerable dioxin contamination, such as the Dutch wood-shaving litter case 2004, the Indian guar gum pollution 2008, and continuously non compliances of chicken eggs from small holdings are further examples. [Malisch and Kotz \(2014\)](#) give a comprehensive overview on these incidents and the consequences for human exposure. As these incidents do not only have severe financial consequences but most notably spoil the numerous efforts to minimize human exposure, vigilance remains necessary also in the future to identify hitherto unknown sources and consider dioxins and PCBs in food and feed as a continuous matter of concern.

### Glossary

**Mycotoxins** Secondary metabolites of filamentous fungi.

**Modified mycotoxins** This term summarized all modified forms of mycotoxins that differ in their chemical structure from the parent toxin.

**Masked mycotoxins** This term is used in older literature for plant metabolites of mycotoxins and should no longer be used.

### Nomenclature

AcDON acetyl-deoxynivalenol  
AFB<sub>1</sub> aflatoxin B<sub>1</sub>  
AFM<sub>1</sub> aflatoxin M<sub>1</sub>  
AME alternariol monomethyl ether  
AOH alternariol AOH  
DOM deepoxy-deoxynivalenol  
DON deoxynivalenol  
DON3Glc deoxynivalenol-3-O- $\beta$ -glucoside  
DONS deoxynivalenol-sulfonate  
FB<sub>1</sub> fumonisin B<sub>1</sub>  
HFB<sub>1</sub> hydrolyzed fumonisin B<sub>1</sub>  
HFB<sub>2</sub> hydrolyzed fumonisin B<sub>2</sub>  
HT2 HT-2 toxin  
NCM-FB<sub>1</sub> N-(carboxymethyl)-fumonisin B<sub>1</sub>  
NDF-FB<sub>1</sub> N-(1-deoxy-D-fructos-1-yl)-fumonisin B<sub>1</sub>  
NIV nivalenol  
norDON thermal degradation products of DON  
norNIV thermal degradation products of NIV  
OTA ochratoxin A  
Sa sphinganine  
So sphingosine  
T2 T-2 toxin  
ZEN zearalenone  
ZEN14Glc zearalenone-14-O- $\beta$ -glucoside  
ZEN14Sulf zearalenone-14-sulfate  
 $\alpha$ -/ $\beta$ -ZEL  $\alpha$ -/ $\beta$ -zearalenol  
 $\alpha$ -/ $\beta$ -ZEL14Glc  $\alpha$ -/ $\beta$ -zearalenol-14-O- $\beta$ -glucoside

### Introduction

Mycotoxins are toxic secondary metabolites of filamentous fungi, which are produced under suitable temperature and humidity conditions. Mycotoxins are well known as contaminants of food and feed and due to their toxic potential they may pose a potential health risk for humans and animals. Mycotoxins are in most cases low molecular weight compounds and they have no biochemical significance in fungal growth and development.

Numerous mycotoxins have been characterized to date, the most relevant are aflatoxins such as aflatoxin B<sub>1</sub> (AFB<sub>1</sub>) besides deoxynivalenol (DON), fumonisins e.g. fumonisin B<sub>1</sub> (FB<sub>1</sub>), zearalenone (ZEN), ochratoxin A (OTA), T-2 Toxin (T2), alternariol (AOH), citrinin and patulin (Fig. 1). These toxic fungal secondary metabolites, also named “parent” mycotoxins, can occur as “free” compounds in infested food and feed, but can also be converted in various ways into products with altered chemical structures

**Figure 1** Structures of relevant mycotoxins.

with different physico-chemical, chemical and biological properties. Such modified forms of the “free” parent mycotoxins can be formed in fungi, or in plants and animals used for food and feed production, as well as during food and feed processing. As such “modified” forms are more and more detected in food and feed they should be taken into account for risk assessment, as they may substantially contribute to the overall toxicity of mycotoxins.

### Examples and Structures of Modified Mycotoxins

As several different terms such as “bound”, “hidden” or “masked” mycotoxins have been used in the past, Rychlik et al. (2014) proposed a new definition of modified mycotoxins, which is summarized in Fig. 2 with representative examples. According to this definition mycotoxins can be classified on the first level in “free”, “modified” and “matrix-associated” mycotoxins.

#### “Free” Mycotoxins

The term “free” includes all “unmodified” or parent mycotoxins such as ochratoxin A, aflatoxin B<sub>1</sub>, deoxynivalenol or fumonisins as shown in Fig. 1, which are produced as secondary metabolites of various fungi. Based on this definition intermediates in the biosynthetic pathway such as 3- and 15-acetyl-deoxynivalenol (AcDON) also belong to “free” mycotoxins. However these compounds can also be classified as modified mycotoxins when they are formed in plants.

#### “Matrix-Associated” Mycotoxins

“Matrix-associated” mycotoxins include mycotoxins which are covalently or non-covalently bound to matrix compounds such as proteins or starch. Non-covalent interactions, also described as “physical entrapment”, are mediated by hydrogen, ionic or any other kind of non-covalent binding. Such physical entrapment is especially described for fumonisins and is regarded as analytical issue as it leads to low recovery rates and an underestimation of fumonisin levels. One possibility to overcome this unspecific entrapment is a chemical hydrolysis of fumonisins and the quantification of hydrolysed fumonisins as described in a recent review by Dall’Asta and Battilani (2016).

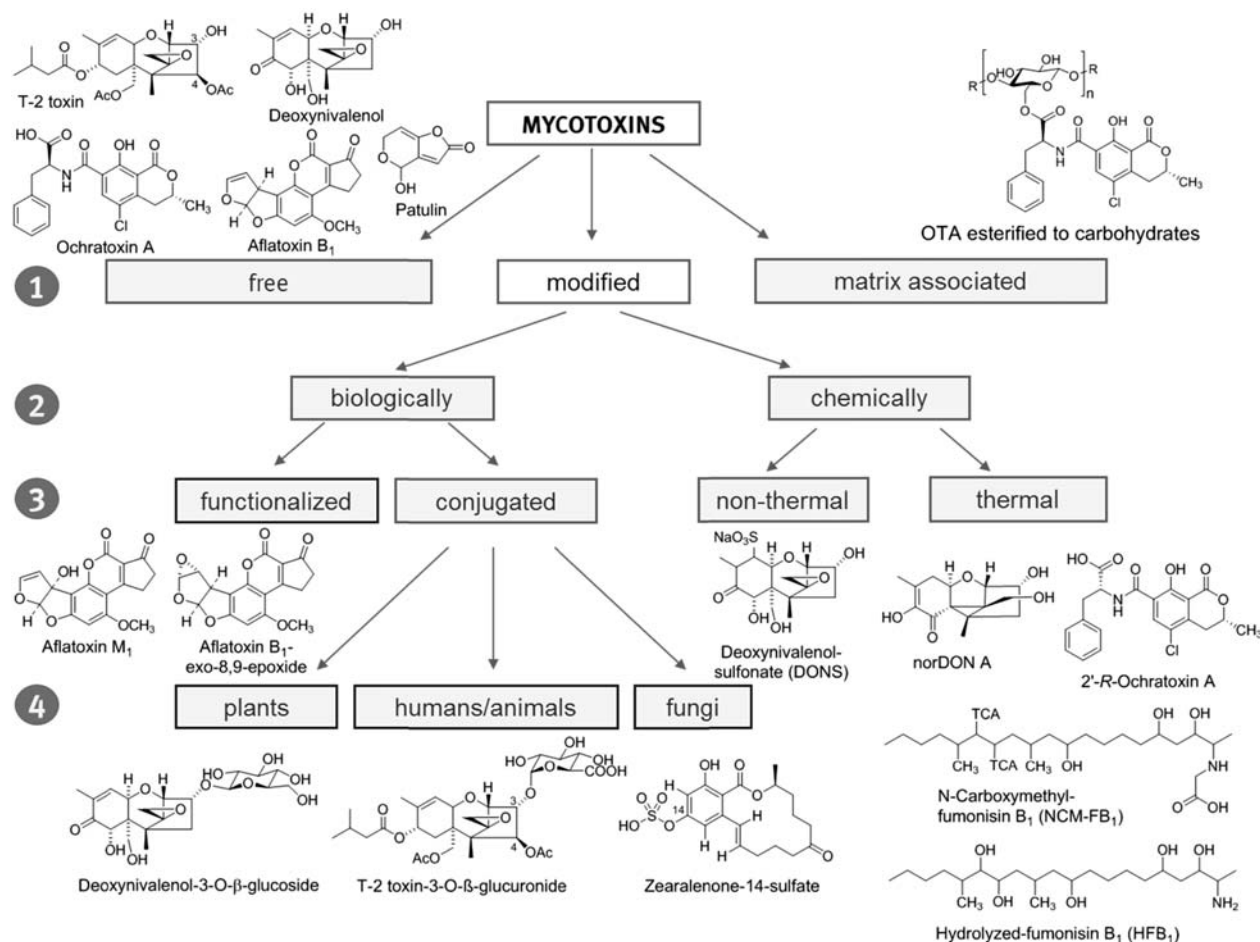

Covalently bound forms of mycotoxins have been proposed for the first time by Shier (2000) based on experiments with radio-labelled fumonisins and later confirmed by Seefelder et al. (2003) in model experiments. During food processing the tricarballic acid side chains of fumonisins can react with polysaccharides and proteins leading to covalently bound forms of fumonisins (Seefelder et al., 2003). Such covalently bound forms of fumonisins can be quantified with the above mentioned chemical hydrolysis method leading to hydrolysed fumonisins. Other covalent binding reactions of mycotoxins with polysaccharides have been described for OTA by Bittner et al. (2013) and for DON by Zachariasova et al. (2012). Ochratoxin A esterified to carbohydrates such as cellulose (see Fig. 2) could be identified in model heating experiments by high resolution mass spectrometry (Bittner et al., 2013).

### Modified Mycotoxins

On the next level (level 2, Fig. 2) modified mycotoxins can be subclassified as “biologically” or “chemically” modified forms.

#### Chemically Modified Mycotoxins

Chemically modified mycotoxins can be further divided in level 3 into forms generated by “thermal” and “non thermal” reactions. Thermal degradation reactions have been described for several mycotoxins and are of relevance as thermal processing methods

**Figure 2** Definition and examples of “free”, “matrix bound” and “modified” mycotoxins. The different hierarchic levels are indicated by numbers 1–4 (definition according to Rychlik et al., 2014).

including baking, roasting, frying and extruding belong to the main food processing technologies. Examples are *N*-(1-deoxy-D-fructos-1-yl)-fumonisins B<sub>1</sub> (NDF-FB<sub>1</sub>) and *N*-(carboxymethyl)-fumonisins B<sub>1</sub> (NCM-FB<sub>1</sub>) which are formed in a Maillard-type reaction between fumonisins and reducing sugars (Humpf and Voss, 2004). During this reaction NDF-FB<sub>1</sub> is formed in the first step as unstable intermediate, which is further converted to NCM-FB<sub>1</sub> (Fig. 2). The latter is detectable in processed corn samples in the µg/kg range (Seefelder et al., 2001). Other examples are norDON A-F (Fig. 2) and norNIV A-C as thermal degradation products of DON and NIV (Bretz et al., 2005, 2006a). As example of a non thermal chemically modified mycotoxin DON-sulfonate is shown in Fig. 2. This reaction product is formed when animal feed is treated with sodium bisulfite to reduce the DON levels in contaminated feed. The structure was described by Young et al. (1986) and later confirmed by Beyer et al. (2010) and Schwarz et al. (2013). In the latter study further DON sulfonates have been identified in model experiments.

However it should be mentioned that some modified mycotoxins, e.g. hydrolysed fumonisins B<sub>1</sub> (HFB<sub>1</sub>) (Fig. 2), can be classified in different categories. HFB<sub>1</sub> is “chemically modified” as it is formed during nixtamalization, which is a traditional alkaline cooking process of corn to produce masa and tortilla chips (Humpf and Voss, 2004). However HFB<sub>1</sub> can also be classified as “biologically modified” as it was identified together with partially hydrolysed FB<sub>1</sub> as intestinal metabolite of FB<sub>1</sub> in piglets (Fodor et al., 2008).

### Biologically Modified Mycotoxins

According to Fig. 2 biologically modified mycotoxins can be further divided in level 3 into “functionalized” and “conjugated” forms. One example of the first group is the highly reactive aflatoxin B<sub>1</sub> metabolite aflatoxin B<sub>1</sub>-exo-8,9-epoxide, which is functionalized in the liver of humans and animals by cytochrome P450 and is responsible for the formation of DNA adducts (Guengerich, 2005). Another prominent example is aflatoxin M<sub>1</sub> (AFM<sub>1</sub>), the hydroxylation product of aflatoxin B<sub>1</sub>, which is detectable in milk of animals and humans exposed to aflatoxin B<sub>1</sub> (Masri et al., 1967). The conjugated biologically modified mycotoxins can be further subclassified in level 4 into plant, fungal and human/animal conjugates (Fig. 2).

## Plant Conjugates

Examples for plant conjugates are phase II metabolites such as deoxynivalenol-3-O- $\beta$ -glucoside (DON3Glc) (Fig. 2), zearalenone-14-O- $\beta$ -glucoside (ZEN14Glc) or T2/HT2-3-O-glucoside (Sewald et al., 1992; Engelhardt et al., 1988; Busmann et al., 2011). For a detailed literature overview of plant modified mycotoxins see recent review articles (Freire and Sant'Ana, 2018; Rychlik et al., 2014; Berthiller et al., 2013). Concerning the sugar configuration of naturally occurring T2 and HT2-glucosides contradictory results have been published as summarized in Schmidt et al. (2018). Such glucosides as well as other plant metabolites have been termed in the past "masked mycotoxins" as they are not detectable with routine analytical methods due to structural changes (Gareis et al., 1990; Berthiller et al., 2013). However as several structures of plant conjugates of mycotoxins have been elucidated and analytical methods are also available the term "masked mycotoxins" should be not longer used as proposed by Rychlik et al. (2014). Other modified forms such as (Malonyl)-glucosides of *Alternaria* mycotoxin alternariol (AOH) have recently been described in tobacco plant cells (Hildebrand et al., 2015). Besides glucosides other phase II metabolites such as DON-3/15-sulfate have been identified in wheat artificially contaminated with *Fusarium graminearum* (Warth et al., 2015).

## Fungal Conjugates

Fungi are also able to modify the chemical structure of mycotoxins produced by other fungal species. Typical fungal conjugates are zearalenone-14-sulfate or *N*-*O*-acyl fumonisins, which are produced by *Fusarium* spp (Plasencia and Mirocha, 1991; Bartok et al., 2013).

## Human/Animal Conjugates

Conjugation reactions by humans and animals are phase II reactions such as the glucuronidation of mycotoxins. Examples are the formation of HT2-3/4-glucuronides (Fig. 2) or DON-3/15-glucuronides (Welsch and Humpf, 2012; Uhlig et al., 2013). Specific glucuronidases are responsible for the formation of these conjugates, resulting in species dependent differences in the mycotoxin glucuronide pattern. As an example, for HT-2 toxin, glucuronidations at the 3- and 4-hydroxy-group are possible. Incubation studies with microsomes from different species showed that pig liver microsomes can indeed form HT2-3- and HT2-4-glucuronide whereas in all other tested species (rat mouse, human) only HT2-3-glucuronide was detectable (Welsch and Humpf, 2012).

## Analysis of Modified Mycotoxins

The first evidence that mycotoxin analysis needs considering modified forms was reported by Gareis et al. (1990), who quantitated zearalenone-14-O- $\beta$ -glucoside (ZEN14Glc) in wheat by an indirect enzymatic approach. The latter authors released "masked" ZEN after treatment with  $\beta$ -glucosidase and measured ZEN by HPLC-FLD in comparison with untreated samples. Among indirect methods enzymatic treatments are one approach besides chemically releasing the free toxin by acidic or alkaline hydrolysis. These indirect methods are still in use, but restricted, on the one hand, to glucoside or sulfate conjugates as only these can be cleaved by easily available enzymes. On the other hand, chemical treatment as the other approach may lead to degradation of the free toxin thus rendering the method inaccurate. Indirect variants are the method of choice when the modified toxin is not available as analytical standard. However, as the indirect methods principally do not guarantee a complete cleavage, direct methods are generally considered more accurate. For a review of analytical methods, one has to differentiate between approaches to detect modified mycotoxins and validated methods for quantitation. In this chapter, only the latter ones will be covered (Table 1), as only these are a solid basis for calculating occurrence data and allow a subsequent risk assessment.

Most of the methods are targeted at modified DONs such as DON-3-glucoside (DON3Glc), acetylated DONs and thermally formed norDON modifications. For ZEN, LC-MS/MS methods are applied for simultaneous quantitation of ZEN, ZEN14Glc, ZEN-14-sulfate (ZEN14Sulf),  $\alpha$ -zearalenol ( $\alpha$ -ZEL),  $\beta$ -zearalenol ( $\beta$ -ZEL), and their respective phase II metabolites. In case of fumonisins, as already mentioned above, the "hidden" forms can be hydrolysed by alkaline treatment to the hydrolysed fumonisins HFB<sub>1</sub> and HFB<sub>2</sub>, the latter of which are also generated from FB<sub>1</sub> and FB<sub>2</sub> during this treatment. HFB<sub>1</sub> and HFB<sub>2</sub> are also formed by nixtamalization as a traditional processing of corn and may occur also in these products. Therefore, these two toxins have also to be considered as modified forms along with NCM-FB<sub>1</sub> mentioned before. A direct LC-MS/MS-method for FB<sub>1</sub>, HFB<sub>1</sub>, and NCM-FB<sub>1</sub> with [<sup>2</sup>H<sub>6</sub>]-FB<sub>1</sub> as internal standard has been developed by Seefelder et al. (2001) and an indirect method for "free, hidden and total" fumonisins by Oliveira et al. (2015). However, the term "hidden" is likewise ambiguous as the term "masked" and should be replaced by "matrix-associated". For the thermally generated modifications of OTA, namely 2'-OTA and 2'-decarboxyOTA, Cramer et al. (2008) developed a stable isotope dilution assay by using deuterated internal standards. Recently, Walravens et al. published LC-MS/MS methods for modified *Alternaria* toxins by using the labelled free toxin [<sup>2</sup>H<sub>4</sub>]-AME as internal standard for tomato products (Walravens et al., 2016) and cereal products (Walravens et al., 2014). For the first described modified mycotoxin, aflatoxin M<sub>1</sub>, a lot of methods already exist mainly due to its early discovery and due to existing regulatory maximum limits in many countries.

**Table 1** Compilation of validated methods for quantitation of modified mycotoxins

Compound	Method	Matrix	LOD	Reference
DON3Glc, AcDON	direct LC-TOFMS	malt, beer	1 µg/kg	Kostelanska et al. (2011)
DON3Glc	direct LC-MS/MS with [ <sup>13</sup> C <sub>6</sub> ]-DON3Glc as internal standard	beer	3 µg/L	Habler et al. (2016)
"Total DON"	indirect ELISA after hydrolysis with trifluoromethanesulfonic acid	corn	100 µg/kg	Tran et al. (2012)
norDON A, B, C	direct LC-MS/MS with ZAN as Internal standard	cereal products	1–2.5 µg/kg	Bretz et al. (2006a)
DON3Glc, AcDON, ZEN14Glc, ZEN14Sulf, α-ZEL, β-ZEL, α-ZEL14Glc, β-ZEL14Glc, HFB <sub>1</sub> , Aflatoxin M <sub>1</sub>	Direct LC-MS/MS	nuts	5–110 µg/kg	Varga et al. (2013)
DON3Glc, AcDON, ZEN14Glc, ZEN14Sulf, α-ZEL, β-ZEL, α-ZEL14Glc, β-ZEL14Glc	Direct LC-MS/MS with DOM and ZAN as internal standards	cereal products	5–13 µg/kg	De Boevre et al. (2012)
ZEN14Glc	indirect ELISA after hydrolysis with glucosidase from <i>A. niger</i>	wheat, corn, breakfast cereals, feed	3.0 µg/kg	Beloglazova et al. (2013)
HFB <sub>1</sub> , NCM-FB <sub>1</sub>	direct LC-MS/MS with [ <sup>2</sup> H <sub>6</sub> ]-FB <sub>1</sub> as Internal standard	tortilla chips, nacho chips, corn flakes	10 µg/kg	Seefelder et al. (2001)
Hydrolysed and "hidden" fumonisins	indirect LC-MS/MS after hydrolysis with aqueous KOH	corn	10–40 µg/kg	Oliveira et al. (2015)
2'-R-OTA, 2'-decarboxyOTA	direct LC-MS/MS with deuterated internal standards	coffee	0.3 ng/kg	Cramer et al. (2008)
AOH-3-sulfate, AOH-3-glucoside, AME-3-glucoside; AME-3-sulfate	direct LC-MS/MS with [ <sup>2</sup> H <sub>4</sub> ]-AME as Internal standard	tomato products	0.3–1.0 µg/kg	Walravens et al. (2016)
Aflatoxin M <sub>1</sub>	direct LC-MS/MS	milk	0.6 ng/kg	Campone et al. (2013)

Although many new modified mycotoxins are currently being discovered, the development of validated methods is still restricted by the limited availability of analytical standards and certified reference materials. Commercially available up to now are only DON3Glc, AcDON and aflatoxin M<sub>1</sub>. For the other modified forms to be used in quantitation, chemical syntheses have been reported for norDONs (Bretz et al., 2006a), for modified forms of ZEN, α-ZEL and β-ZEL (Grabley et al., 1992; Mikula et al., 2013a, 2013b, 2014, Michlmayr et al., 2017), for NCM-FB<sub>1</sub> (Seefelder et al., 2001), for 2'-R-ochratoxin A and 2'-decarboxy ochratoxin A (Cramer et al., 2008) and for modified forms of AOH and AME (Walravens et al., 2014). Biotechnological syntheses of modified ZEN were performed by plant cell cultures (Engelhardt et al., 1988), by yeasts (Poppenberger et al., 2006) or by *F. graminearum* (Plasencia and Mirocha, 1991).

Another obstacle for developing accurate methods is the lack of stable isotope labelled internal standards, which are the state of the art for the regulated "free" mycotoxins due to ideal compensation for matrix effects and ionization interferences in LC-MS. The only reported labelled modified mycotoxins up to date are U-[<sup>13</sup>C<sub>17</sub>]-aflatoxin M<sub>1</sub>, [<sup>13</sup>C<sub>6</sub>]-DON3Glc (Habler et al., 2016), [<sup>2</sup>H<sub>3</sub>]-3-AcDON (Bretz et al., 2006b), [<sup>13</sup>C<sub>2</sub>]-3-AcDON, [<sup>13</sup>C<sub>2</sub>]-15-AcDON (Asam and Rychlik, 2007), [<sup>2</sup>H<sub>5</sub>]-2'-R-OTA, [<sup>2</sup>H<sub>5</sub>]-2'-decarboxyOTA (Cramer et al., 2008) as well as dihydrocitrinone, a human metabolite of citrinin (Bergmann et al., 2018).

## Occurrence of Modified Mycotoxins

A view at occurrence data of modified mycotoxins reveals that a representative basis only exists for aflatoxin M<sub>1</sub> and to a lesser extend for DON3Glc.

For aflatoxin M<sub>1</sub> the most recent review on its occurrence has been published by Womack et al. (2016). Contents in milk marketed in the EU are mostly below the EU maximum limit of 0.05 µg/kg, whereas milks from Serbia, India, Mexico and Sudan were reported to contain up to 1.2, 3.8, 7.6 and 6.9 µg/kg respectively.

For DON3Glc, naturally contaminated wheat was found to contain high contents sometimes exceeding 1000 µg/kg (Berthiller et al., 2009). For risk assessment the ratio between DON3Glc and its free form is important as many monitoring data still miss the information on the modified form. The molar ratios were found to be quite variable within ranges depending on the type of cereal and product. In a recent opinion from the EFSA Panel on Contaminants in the Food Chain (Knutsen et al., 2017a) the DON3Glc to DON ratio for grain-based food products (except for beers) was 10% in mean and for malt and beers around 100% in mean. Surveys

from the UK (Vendl et al., 2010), the Czech Republic (Malachova et al., 2011), China (Li et al., 2012) and Canada (Tran et al., 2012) revealed that cereals are contaminated with DON3Glc globally.

In case of norDON modifications, norDON A is reported to be the most abundant form in many cereal products with a maximum of 36 µg/kg in wholemeal crackers, which accounted for 27% of the DON content (Bretz et al., 2006a).

For ZEN and its modifications in cereals and cereal-based foods only few data are available from De Boevre et al. (2012, 2013, 2014) and Vendl et al. (2010). In corn, for the sum of  $\alpha$ -ZEL and  $\beta$ -ZEL a maximum of 7970 µg/kg was found and for the sum of ZEN14Glc, ZEN14Sulf,  $\alpha$ -ZEL14Glc and  $\beta$ -ZEL14Glc a maximum of 9750 µg/kg (De Boevre et al., 2014). For some staple foods like bread and breakfast cereals the sum of the amount of modified forms of ZEN even exceeded the EU maximum limits for ZEN of 50 and 75 µg/kg, respectively.

Among modified fumonisins, HFB<sub>1</sub> and HFB<sub>2</sub> are found in processed corn products after nixtamalization and may exceed the amount of FB<sub>1</sub> as has been reported for tortilla chips, corn flakes and nacho chips. In some of the latter samples, NCM-FB<sub>1</sub> was also detected and in one case of corn flakes also exceeded the amount of FB<sub>1</sub> (Seefelder et al., 2001). Steeping and washing steps in the process usually lead to reductions of up to 80%, e.g. in tortillas as reviewed by Humpf and Voss (2004).

The already mentioned "hidden" fumonisins in corn in several studies have been reported to exceed the free forms by up to 145% (Oliveira et al., 2015) or even by 263% (Falavigna et al., 2012).

For OTA, the thermally formed diastereomer 2'R-ochratoxin A was found in a maximum of 0.63 µg/kg in roasted coffee, which was equivalent to 26% of the content of the natural OTA isomer. In contrast to this, only very low amounts of 2'-decarboxy ochratoxin A were detected (Cramer et al., 2008).

Alternaria toxins are considered to be "emerging" mycotoxins and even for the free toxins only few validated methods are available. Therefore, the methods for modified forms are even more scarce. The only group to report occurrence data on modified *Alternaria* toxins was that of Walravens et al. (2016), who quantified sulfates of AOH and alternariol monomethyl ether (AME) in tomato products. Whereas glucuronides were not detectable, AOH-3-sulfate was found up to maximum contents of 8.7 µg/kg and AME-3-sulfate to 9.9 µg/kg in tomato concentrates, which referred to 43% of AOH and 116% of AME, respectively.

## Toxicity of Modified Mycotoxins

As several forms of modified mycotoxins have been described in the past (Fig. 2) and their occurrence in food samples confirmed, informations concerning toxicity and metabolism are needed. Key question is especially in the case of mycotoxin conjugates or matrix-associated forms of mycotoxins whether they can be converted into the parent mycotoxin during digestion in humans and animals or during food processing, potentially leading to adverse health effects. In the case of chemically modified mycotoxins several in vivo and in vitro studies have been performed. Only a few examples will be described here. Further detailed information concerning the toxicity of modified mycotoxins can be found in the literature (European Food Safety Authority, 2014; Freire and Sant'Ana, 2018; Rychlik et al., 2014).

Howard et al. (2002) evaluated the effect of NCM-FB<sub>1</sub> in a dose-response feeding study in mice for 28 days. NCM-FB<sub>1</sub> in doses up to approximately 140 µM/kg diet had no effect on characteristic parameters (Sa/So ratio, ceramide levels, serum analytes, organ weights, hepatic structure), which were affected by FB<sub>1</sub> (Howard et al., 2002). Other thermally modified mycotoxins mentioned above showed no or much lower cytotoxicity in cell culture experiments. NorDON A showed no cytotoxicity in concentrations up to 100 mM in IHKE cells and 2'R-ochratoxin A was by a factor of ten less cytotoxic compared to OTA (Bretz et al., 2006a; Cramer et al., 2008).

The above described DON sulfonates, which are formed upon treatment of DON-contaminated feed material with sodium bisulfite, are much less cytotoxic compared to DON as was shown in animal and cell culture studies (reviewed in Daenicke et al., 2012).

In the case of phase II metabolites such as sulfates or glucosides several studies have shown that these conjugates are stable in the upper gastrointestinal (GI) tract but effectively cleaved during digestion by the intestinal microbiota (reviewed in Freire and Sant'Ana, 2018). McCormick et al. (2015) showed that 70% of T2-3-O- $\alpha$ -glucoside and T2-3-O- $\beta$ -glucoside are hydrolysed within 24 h of incubation by bacteria found in human feces. T2 and HT2 as well as so far unknown metabolites were detectable in amounts of up to 58% of the initial glucoside concentration. In another recent study the hydrolysis of several mycotoxin glucosides was confirmed. DON3Glc and nivalenol-3-O- $\beta$ -glucoside were hydrolysed within 24 h liberating the parent mycotoxins. T2-3-O- $\alpha$ -glucoside was also hydrolysed (ca. 70% within 24 h) and T2 was further deacetylated to HT2. ZEN14Glc as well as glucosides of  $\alpha$ -/ $\beta$ -ZEL are rapidly hydrolysed (ca. 97% within 4 h), however besides the parent toxins 40%–70% of unknown metabolites were formed (Gratz et al., 2017). Matrix-associated mycotoxins such as OTA-saccharide esters or starch/protein-bound forms of fumonisins (Seefelder et al., 2003; Bittner et al., 2013) might also be cleaved by the gut microbiota or by digestive enzymes. However, in the case of matrix-associated mycotoxins the available data concerning toxicity are rather limited.

These examples clearly show that in the case of mycotoxin conjugates and matrix-associated mycotoxins the parent compounds are released during digestion and contribute to the overall mycotoxin level and potentially increase the toxic effects, assuming that the liberated mycotoxins are effectively absorbed after hydrolysis in the GI tract. For this reason modified mycotoxins should be considered during risk assessment, which has been also highlighted by the European Food Safety Authority assigning group tolerable daily intake values or relative potency factors for modified mycotoxins of DON (Knutsen et al., 2017a), ZEN (EFSA, 2016) as well as T2 and HT2 toxins (Knutsen et al., 2017b).

## Future Perspectives

Modified mycotoxins can be formed in various chemical and/or biochemical reactions and pose a potential health risk for humans and animals. As there are currently many open questions concerning the occurrence, analysis, formation and toxicity of modified mycotoxins research activities have to be intensified in the near future.

Furthermore toxicity data of modified mycotoxins are scarce and limited in many cases to *in vitro* data. Thus until sufficient data are available for risk assessment, modified mycotoxins should be considered as similarly toxic as the parent mycotoxin in order to avoid any adverse effects in humans and animals.

In the case of modified mycotoxins formed during food and feed processing, uncertainties concerning the potential risk for humans and animals can be overcome by setting legislative maximum levels of mycotoxins for raw materials and not only for the end products.

### Glossary

**Aptamer** short single DNA or RNA oligonucleotides, whose 3-D structure can bind specific to other molecules.

***Aspergillus* fungi** filamentous fungi, whose spores are arranged similar to water trickles running out of an aspergil or ewer.

**Endocrine disruptor** substance that interferes with the hormonal system.

**Immunoaffinity** procedure using antibodies raised against a molecular structure with the aim to specifically enrich and/or purify the target molecule.

**Molecular imprinted polymer** synthetic polymers used for molecular recognition

**Mycotoxin** toxin produced by filamentous fungi.

**p53 tumor suppressor gene** important regulatory gene in the initiation of cell apoptosis preventing a cell turning malignant.

***Penicillium* fungi** filamentous fungi, whose spore arrangement is remindful to strands of a brush.

**St. Antoniusfire** Synonym for the disease ergotism, resulting in gangrene, burning sensations, hallucinations and ultimately loss of limbs and death.

**Turkey "X" disease** disease in poultry that marked the research in mycotoxins and led to the discovery of aflatoxins in the 1960s.

### General

Mycotoxins are a chemically diverse group of substances produced by filamentous fungi. The molecular weight of the mycotoxins relevant for food and feed safety ranges approximately from 100 g/mol, such as moniliformin (Fig. 1) or nitropropionic acid (Fig. 2) to about 700 g/mol such as fumonisin B1 (Fig. 3) or beauvericin (Fig. 4). A classification of a substance as mycotoxin is purely done by the fact that it is a secondary metabolite of a filamentous fungus and toxic to humans or animals, while other properties, such pharmaceutical usability as antibiotic (Pal et al., 2017) might be present as well.

The occurrence of mycotoxins is however not limited to agricultural products, as fungi can spoil almost any sufficiently humid organic material. As a result, fungal growth on building materials (Nielsen et al., 1998) may result in the production of similar mycotoxins than those found in food, such as sterigmatocystin or alternaria toxins (Nielsen, 2003; Ren et al., 1998). However not all fungal spoilage results in the production of mycotoxins.

More than a thousand fungal metabolites have been spectroscopically described (Cole and Schweikert, 2003), including the mycotoxins identified as a public health concern.

The reason why fungi produce mycotoxins is not fully understood in all cases. However the biosynthesis has been extensively studied and the typical metabolic pathways were identified. These pathways (also in combination) lead to numerous secondary metabolites, including mycotoxins (Bu'Lock, 1980). In a few cases like the trichothecene deoxynivalenol (DON) its production by the fungi has an evolutionary advantage as DON is a key element in the pathogenicity, allowing the fungi to weaken the plant and causing fusarium head blight (FHB) in wheat (Gunupuru et al., 2017).

The toxic effects of the mycotoxins differ as widely as they differ in their chemical structure. Aflatoxin B1 is carcinogenic to humans (Group 1 classification by the International Agency for Research on Cancer) and hepatotoxic (International Agency for Research on Cancer, 2012). The action of zearalenone (ZON) and its metabolites is not targeting a specific organ but systemic to humans and animals as they are endocrine disruptors (EFSA Scientific Committee, 2016a). Trichothecenes like DON and T-2 toxin interfere with protein synthesis and consequently result in numerous effects ranging from immune dysfunction to vomiting, which brought DON also the synonym "vomitoxin". Fumonisin show different carcinogenic and pathologic effects depending on the animal species affected (Marasas, 2001), while ergot alkaloids are neurotoxic. As a result health risks of mycotoxins have to be evaluated individually based on their mode of action, their occurrence in food and feed as well as the metabolic pathways for detoxification within an animal species.

### Historical and Regulatory Background

Mycotoxin intoxications are known since centuries in Europe and outbreaks occurred in irregular intervals. The historically most relevant outbreaks are related to *Claviceps purpurea* resulting in ergotism (also called St. Antoniusfire) (van Dongen and de Groot, 1995). Cereals infested with sclerotia of *C. purpurea* contain the toxic ergot alkaloids. Symptoms of the disease inspired the painter

**Figure 1** Moniliformin.

**Figure 2** Nitropropionic acid.

**Figure 3** Fumonisin B<sub>1</sub>.

**Figure 4** Beauvericin.

Pieter Bruegel (the Elder) in his 1568 painting "The beggars". It is remarkable that the outfit of the depicted beggars reflects different societal classes indicating that ergotism was of general public concern (Barker, 1927) already by that time.

Other major mycotoxicosis outbreaks were described in the past, such as "cardiac beriberi" in Asia, which is caused by consumption of *Penicillium citreonigrum* infested rice and the "alimentary toxic aleukia" in the 1940s in former Russia caused by fusarium

toxins in cereals that were left in the field over winter (as result of war time) and affected humans and animals (Pitt and Miller, 2017).

In 1960 more than 100.000 turkeys died in the United Kingdom, after being fed with aflatoxin contaminated peanut meal (Latham, 1964). This incidence, which was the beginning of the awareness for mycotoxins at global scale, was called the turkey "X" disease. Rapidly the causing factor "X" was identified as aflatoxin B1 (and G1) (Wannop, 1961). Initially research focused on the safety of peanuts for animal feed (Latham, 1964), while the global extent of the aflatoxin impact is nowadays addressed (Wild and Gong, 2009; Ostry et al., 2017; Gong et al., 2002; Richard, 2008; Wild et al., 2015). Still nowadays several decades after the turkey "X" disease mycotoxicosis outbreaks occur occasionally like aflatoxicosis in African regions (Azziz-Baumgartner et al., 2005) or cardiac beriberi in Brazil (Rosa et al., 2010).

This finding paved the way to the development of a number of analytical methods based on chromatography for aflatoxins and many other mycotoxins (Betina, 1993a). In the aftermath of the turkey "X" disease the probable involvement of cyclopiazonic acid was discussed (Cole, 1986) while potentially overlooked at that time due to the easier detectable and highly toxic aflatoxins. In the course of instrumental and analytical development a number of mycotoxins were discussed as potential food and feed contaminants (Directorate-General, 1994), however only a fraction has been identified to potentially impose a general public health risk. These are regulated in many parts of the world (van Egmond and Jonker, 2004; van Egmond et al., 2007), with the European Union having the most extensive regulation on mycotoxins in food (European Commission, 2006a) and feed (European Commission, 2002) (European Commission, 2013).

Currently efforts are made by the European Food Safety Authority (EFSA) to evaluate "emerging" mycotoxins and their potential for public and animal health concern. The resulting EFSA scientific opinions address the scientific questions needed by legislators and risk managers and a number of mycotoxins have been addressed in the past like the ergot alkaloids, alternaria toxins, beauvericin and others (EFSA website on Opinions). This is been fostered by recent advances in coupling liquid chromatography with mass spectroscopy, allowing the screening of hundreds of fungal metabolites (Vishwanath et al., 2009; Malachová et al., 2014) with a single method. This technology is currently the most useful tool for generating occurrence data, which is a key challenge for any risk assessors like the EFSA or the U.S. Food and Drug Administration.

The worldwide list of regulations on mycotoxins (van Egmond and Jonker, 2004) demonstrates that almost 100 countries have implemented regulations for mycotoxins in 2003 covering 87% of the world population and the levels for aflatoxins put into national legislation correspond in the majority of cases with those set by the Codex Alimentarius (CODEX excerpt). An overview of the rather extended list of mycotoxins regulated in the European Union given in Table 1.

## Social and Economic Impact of Mycotoxins

The setting of maximum permitted levels by risk managers is linked to the consumption pattern, local availability and production of the produce as well as international trade while respecting the conclusions of the health risk assessment. As a result risk managers may conclude differently how to manage a mycotoxin risk. Such a difference was subject of the 2001 World Bank report (Otsuki et al., 2001) regarding new EU legislation for aflatoxins in food which was thought to have a negative influence on African countries exporting to the European market. This conclusion was updated in 2005 (World Bank, 2005), correcting the estimates on financial losses as highlighted in 2001. These losses did not verify an in contrary a number of exporting countries benefited from the new legislation.

Studies on the economic impact of produce loss due to mycotoxin contamination have improved and are used to help all stakeholders involved on the food/feed production chain estimating the impact due to mycotoxin contamination (Wu, 2015). Especially

**Table 1** Summary of mycotoxin limits in the EU in 2017 (European Commission, 2002, 2006a, 2006b, 2013)

Mycotoxin	Food products (µg/kg) <sup>a</sup>		Products for animal feed (µg/kg) <sup>a</sup>	
	Lowest level	Highest level	Lowest level	Highest level
Aflatoxin B1 (Σ of aflatoxins)	0.1 (–)	5 (10)	5	20
Aflatoxin M1	0.05	0.025	–	–
Deoxynivalenol	50	750	900 <sup>b</sup>	12000 <sup>b</sup>
Fumonisin B1+B2	200	1000	5000 <sup>b</sup>	60000 <sup>b</sup>
Ochratoxin A	0.5	10	10 <sup>b</sup>	250 <sup>b</sup>
Zearalenone	20	200	100 <sup>b</sup>	3000 <sup>b</sup>
T-2 & HT-2 toxin	15 <sup>b</sup>	200 <sup>b</sup>	50 <sup>b</sup>	2000 <sup>b</sup>
Patulin	10	50	–	–
Citrinin	2000	2000	–	–
Ergot sclerotia	500 000 (0.5 g)	500 000 (0.5 g)	1 000 000 (1 g)	1 000 000 (1 g)

<sup>a</sup>Lowest and highest level depends on the food type.

<sup>b</sup>Levels marked with an asterisk are indicative/recommended (maximum) levels.

in the European Union the economic impact on trade becomes apparent by the number of notifications in the European Union Rapid Alert System for Food and Feed. In 2016 mycotoxins accounted for more than 1/3rd of all food/feed border rejections at European ports of entry. These rejections exceeded those resulting by the presence of pathogens, and exceeding limits for heavy metals and pesticides (European Union, 2017).

## The Different Mycotoxin Groups

### The Aflatoxins

Aflatoxins is the first group of mycotoxins studied extensively after the turkey “X” disease outbreak. In food of plant origin aflatoxins B<sub>1</sub>, B<sub>2</sub>, G<sub>1</sub> and G<sub>2</sub> (Figs. 5–8) occur with different pattern, depending on the fungal species (e.g. *Aspergillus flavus* or *Aspergillus parasiticus*) and the fungal growth conditions. The name aflatoxin is derived from (*A*)spergillus (*fla*)vus, however a number of other *Aspergilli* have been identified to produce aflatoxins, too (Ito et al., 2001). The typification B or G is linked to their appearance under ultra violet light (366 nm), namely blue or green, depending on the presence of a cyclic ketone or a lactone in the molecular structure. The classification number refers to a double bond (indexed as 1) or saturated bond (indexed as 2) at the position 8, 9 of the molecule. Due to their native fluorescence they are relatively easy to detect with chromatography, an asset for their discovery in the turkey “X” disease investigation.

**Figure 6** Aflatoxin B<sub>2</sub>.

**Figure 7** Aflatoxin G<sub>1</sub>.

**Figure 8** Aflatoxin G<sub>2</sub>.

Aflatoxin B<sub>1</sub> (AFB<sub>1</sub>) is the predominant aflatoxin found and in addition the most potent natural carcinogen known to man. Its toxicity depends on the animal species (Patterson and Allcroft, 1970), resulting in rainbow trout being extremely sensitive, while within an animal species toxicity is generally age dependent.

The mode of action leading to its carcinogenicity has been studied in great detail and is result of the formation of a highly reactive epoxide along the 8, 9 position. The enzyme involved is mainly found in the liver. In a following step the epoxide can react with either DNA/RNA or proteins, forming a covalent adduct (Oesch et al., 1999). If such adduct leads to the dysfunction of the tumor suppressor gene p53 it can lead to a malignant cell cycle (Hsia et al., 1992; Bressac et al., 1991). Despite its high carcinogenicity the number of actual cases of primary liver cancer is low in industrialised countries, while in other parts of the world, where chronic hepatitis is prevalent, an increased aflatoxin exposure significantly increases cancer rates (Henry et al., 2002; Kew, 2003). The exposure to aflatoxins in the African continent can be relatively high and occasional aflatoxin outbreaks occurred in recent times in Kenya, resulting in acute toxicities, eventually leading to human casualties (Azziz-Baumgartner et al., 2005).

Aflatoxins are also metabolized to a number of other metabolites of which aflatoxin M<sub>1</sub> (hydroxylated AFB<sub>1</sub>) is the most known. This can be found in milk when AFB<sub>1</sub> is taken up by mammals. The conversion rate is approx. 5% of the AFB<sub>1</sub> ingested (Britzi et al., 2013) and gave reason for setting maximum levels for AFB<sub>1</sub> in animal feed (European Commission, 2002). As a result of this transformation of AFB<sub>1</sub>, aflatoxin M<sub>1</sub> is considered a modified mycotoxin (Rychlik et al., 2014).

Closely related to the aflatoxins is sterigmatocystin (Fig. 9), a metabolic precursor leading to production of the aflatoxins in the fungal cells. It is produced by *Aspergillus versicolor* and *Aspergillus nidulans* who cannot further metabolise sterigmatocystin to aflatoxins as they lack the needed enzymes (FAO and WHO, 2017a). The occurrence in food and feed is considered low compared to that of aflatoxins according to some studies (Scott, 2004), while it has been observed that about 20% of all analysed sorghum samples contain sterigmatocystin in some regions of the world (FAO and WHO, 2017a). However its genotoxic effect with *in vitro* experiments of human cell lines has shown to be greater than that of AFB<sub>1</sub> (Theumer et al., 2018), while a review of studies come to a slight different conclusion interpreting *in vivo* experiments (FAO and WHO, 2017a).

### The Trichothecenes

Trichothecenes are produced by a number of different fungi (Wannenmacher and Wiener, 1997) and they have the same core structure, being 12,13-epoxytrichothec-9-ene (FAO and WHO, 2017b). The most known and studied mycotoxin of the trichothecen family for food and feed safety concerns is deoxynivalenol (DON) (Fig. 10). It occurs as result of cereal infestation with *Fusarium graminearum* and *Fusarium culmorum* in the field and can be found in corn, wheat and other cereals grown in temperate climates. Next to DON, some fusarium fungi produce also acetylated forms of DON, namely 3-acetyl and 15-acetyl DON.

**Figure 9** Sterigmatocystin.

**Figure 10** Deoxynivalenol.

**Figure 11** HT-2 toxin.

Several dozen trichothecenes have been described and are produced by a number of *Fusarium* species, like *Fusarium sporotrichioides*, *Fusarium langsethiae*, however only DON, T-2 and HT-2 toxin (**Fig. 11**) have drawn attention for public health so far. Trichothecenes are classified into different groups as result of structural differences. The type-A trichothecens (T-2 and HT-2 toxins, diacetylscipenol) have a functional group other than a ketone at carbon position 8. They occur less frequently but are more toxic than the type-B trichothecens such as DON and nivalenol, who possess the keto-function ([Directorate-General, 1994](#)). While DON has been reported in a large number of different cereals, T-2 and HT-2 toxin are often associated with oat ([Pettersson et al., 2011](#)). However, their presence, like DON, is found across cereal species and environmental climatic zones ([Morcia et al., 2016](#)).

While trichothecenes show gastrointestinal, dermatological and immunotoxic effects, they vary from toxin to toxin and the affected species. This manifests to poultry being comparably tolerant to DON, while T-2 and HT-2 toxins are extremely toxic to cats ([EFSA Scientific Committee, 2017a](#)). The animal susceptibility is also reflected in the levels stipulated for feed in Europe ([European Commission, 2006b](#)).

### The Ergot Alkaloids

The ergot alkaloids (EA) are a rather large group of roughly 80 closely related compounds sharing a common backbone structure, which is ergoline (**Fig. 12**) of which ergotamine (**Fig. 13**) is the most known one. Sclerotia containing EA were used for medical purposes since centuries. The EA exhibit a number of neurological effects and are used as pharmaceuticals ([Eadie, 2001](#)). Intoxications result mainly in neurological disorders such as numbness of the limbs, convulsions and hallucinations, gangrene and ultimately death.

**Figure 12** Ergoline.

**Figure 13** Ergotamine.

**Figure 14** Lysergic acid diethylamide (LSD-25).

Different from the other mycotoxin producing fungi, the sclerotia of *C. purpurea* can largely be removed mechanically from cereals like rye or wheat. However, for this the sclerotia must sufficiently differ from the cereal kernels with respect to size, density or color (Scott, 2009). Currently ergot is regulated in the European Union by visual/microscopic identification of the sclerotia as “foreign” particles (European Commission, 2006a, 2006b). Taking note that ergot alkaloids vary significantly in sclerotia and that analytical methods are availability for these alkaloids the current strategy focuses on setting limits for individual ergot alkaloids. Relevant for the chemical analytical monitoring of ergot alkaloids is that the different alkaloids act partially synergistically or antagonistically. This aspect makes a food/feed safety evaluation complex (EFSA Scientific Committee, 2012).

The most known ergot alkaloid derivative is the highly neurologically active lysergic acid diethylamid (LSD) which became a known drug leading to psychotic effects even if taken only at fractions of a milligram. The synthesis of LSD (Fig. 14) was triggered by the success in which nicotinic acid was modified before, leading to the stimulant nikethamid (Coramine). This synthesis approach to modify pharmacologically active substances was known that time by Albert Hofmann who first synthesized LSD in 1943.

### Zearalenone

Zearalenone (ZON) (Fig. 15) is a metabolite of *Fusarium graminearum* and *F. culmorum* infesting mainly corn, wheat and barley but also other cereals. ZON acts as an endocrine disruptor and its toxicity is animal species dependent. Concerning the metabolism of ZON in animals, it is important to note that the toxicity of ZON is linked to the way an animal metabolises this mycotoxin. In particular the pathway leading to the modified form  $\alpha$ -zearalenol (Fig. 16), with the keto function reduced to a hydroxyl group, plays a key role for the toxicity as the EFSA concluded a much higher estrogenic potency factor for this metabolite. Other metabolites like  $\alpha$ -zearalanol (also known as zeranol) (Fig. 17) with a saturated bond, are marketed as anabolic agents and growth promoters. As a result, the EFSA addressed the co-occurrence of different metabolites of ZON by publishing a “health based guidance value for ZON and its modified forms” in food and feed (EFSA Scientific Committee, 2016a; 2017b).

**Figure 15** Zearalenone.

**Figure 16**  $\beta$ -Zearalenol.

**Figure 17**  $\alpha$ -Zearalenol.

### The Fumonisin and Moniliformin

The fumonisins, in particular fumonisin B1 (Fig. 4) and fumonisin B2 were the last group of mycotoxins identified that impose great public health concerns. Their discovery in 1988 in South Africa as the chemical agents responsible for equine leukoencephalomalacia (ELEM) in horses and pulmonary edema (PE) in pigs (Marasas, 2001) involved a decade of international research collaboration. Fumonisin are produced mainly by *Fusarium verticillioides* (*Fusarium moniliforme*) infesting mainly corn and relate to different toxicological observations dependent on the animal species. Next to the specific effects known for horses and pigs, rats develop primarily liver cancer and for humans a strong indication exist that fumonisins cause esophageal cancer (Gelderblom et al., 1988; Somdyala et al., 2003).

Fumonisin interfere with the sphingosine metabolism. This is used as a biomarker for exposure (Shephard et al., 2013; Qiu et al., 2001; van der Westhuizen et al., 2010). Next to corn other agricultural produce like asparagus or garlic can be contaminated as well (Seefelder et al., 2002). However, recent data shows that fumonisin contamination in commercial dry garlic is comparably low (Tonti et al., 2017). Besides the initial assumption that only *Fusarium* fungi can synthesize the fumonisins, it was shown that some *Aspergilli* are as well producers of this mycotoxin group (Perrone and Gallo, 2017; Munkvold et al., 2018).

Moniliformin (Fig. 1) is produced by *F. moniliforme* and can co-occur with fumonisins. It is made of a cyclic 4 carbon ring and is considered an “emerging mycotoxin”, reported in Norwegian cereals (Uhlig et al., 2004) as well as in other regions of the world (Jestoi, 2008). Current data showed that the levels found in retail samples of central Europe during 2016–7 were less contaminated than those reported in previous years (Herrera et al., 2017).

## The Alternaria Toxins

The group of *Alternaria* fungi are capable to synthesize a number different of secondary metabolites, however only a few have been identified as toxicologically relevant for public food safety (EFSA Scientific Committee, 2016b). These are tenuazonic acid (Fig. 18), alternariol (Fig. 19), alternariol monomethyl ether (Fig. 20), altenuene and tentoxin (Fig. 21). Alternaria toxins can be found in cereals, oil seeds, like sunflower or canola as well as a number of vegetables (in particular tomatoes and carrots) and fruits. Tenuazonic acid is the most abundant alternaria toxin and can reach levels of several mg/kg in vegetables or fruits with sufficient high water content. Since *Alternaria* fungi grow also at temperatures near the freezing point, even chilled products can become contaminated. Black spots, (next to other types of spoilage) are an indicator for alternaria infestation.

Sunflower seeds are frequently contaminated and levels can differ for shelled and peeled seeds. As a result the way of consumption (habit of dehulling salted seeds in the mouth in some countries) is important when drawing conclusions for the exposure to alternaria toxins from sunflower seeds.

## Ochratoxin A

Ochratoxin A (OTA) (Fig. 22) is known as potential contaminant in a number of food stuffs and has been monitored in the last 2 decades due to the fact that it occurs in products of high market value, such as spices, coffee, cocoa, wine or licorice but also in grapes and cereals, in particular barley. It is produced by some *Penicillium* as well as *Aspergillus* fungi. A mycotoxin often associated with OTA is citrinin, which gained attention in the EU due to the levels occasionally found in “fermented” red yeast rice, a product taken as natural medicine against high cholesterol levels. Both mycotoxins are potent nephrotoxins and are regulated in the European Union. OTA has been associated with Balkan endemic nephropathy, while there is doubt whether other factors, such as the plant toxin aristolochic acid, play a key role. In the body OTA binds tightly to serum albumin (Riley and Voss, 2011). This allows the

Figure 18 Tenuazonic acid.

Figure 19 Alternariol.

Figure 20 Alternariol monomethyl ether.

**Figure 21** Tentoxin.

**Figure 22** Ochratoxin A.

monitoring of long term OTA exposure with ease compared to most other mycotoxins that are either rapidly excreted or metabolized. Due to consumption pattern and the occurrence of OTA it is a frequently found biomarker in humans. Remarkable is that OTA can be used to monitor the consumption of coffee since a specific heat induced degradation product of OTA is only formed during coffee roasting and has been exclusively identified in the blood of coffee drinkers (Cramer et al., 2015).

### Patulin

Patulin (Fig. 23), chemical name (2,4-Dihydroxy-2H-pyran-3-(6H)ylidene)acetic acid, 3,4-lactone or 4-Hydroxy-4H-furo(3,2-c)pyran-2(6H)-on, [CAS: 149-29-1] is one of the mycotoxins with the largest number of synonyms associated with it, namely: clairformin, clavacin, clavatin, claviformin, expansin(e), gigantint, leucopin, mycoin, mycoin C, mycoin C3, patulin(e), penicidin, penantint and terinin.

It is produced by a number of fungi such as *Penicillium*, *Aspergillus* and *Byssoschlamys* and is primarily found in apples and products such as puree or juice thereof. As a result it enters the food chain almost exclusively via rotten fruits.

Modern production technology allows effective elimination of patulin by identifying rotten apples and/or excavating potentially rotten parts with water jet streams leading to apple products of high quality and little concern with respect to patulin. Another effort to reduce patulin is the application of good manufacturing practice (GMP) (Food and Agricultural Organisation, 2003; State of Michigan, 2016).

**Figure 23** Patulin.

Patulin was extensively tested as an antibiotic agent after the discovery of penicillin in mid last century (Stuart-Harris et al., 1943). It has been shown in various tests to be a mutagen and genotoxic. However no conclusion exists to categorize it as carcinogen and therefore it is classified by the IARC in group 3. It has been shown in a self-experiment with isotope labelled patulin, that human metabolism appears to be effective in dealing with moderate levels of patulin (Rychlik, 2003).

Nonetheless as apple products are frequently consumed by infants and young children (Raiola et al., 2015) patulin reduction management is important since *Penicillium expansum* can produce concentrations up to 1 g per liter in apple juice if it is grown to fully cover juice in Petri dishes and in 1995 an outbreak of diarrhea in Denmark was associated with patulin found in blueberries (Berg et al., 1995).

### Beauvericin and the Enniatins

Beauvericin (Fig. 3) and enniatins A, A1, B and B1 are often mentioned in the context of “emerging mycotoxins”. Enniatins (incl. Beauvericin) are cyclic peptides similar to some macrolid-antibiotics like valinomycin. Even though Beauvericin has been described as an antibiotic mycotoxin in 1969, the attention as food contaminant just grew in the last decade of the last century in Scandinavia when weather conditions favored the fungi that produced beauvericin (Logrieco et al., 2002; Uhlig et al., 2007). Beauvericin is produced by a number of *Fusarium* fungi, while it was first discovered as metabolite of *Beaveria bassiana*, a fungus that attacks insects, which led also to studies for its insecticidal use (Wang and Xu, 2012).

In 2013 a multi-screening on 83 samples of food and feed raw materials revealed that beauvericin and enniatins are found more frequently than deoxynivalenol in about 98% of all analyzed samples. However the maximum observed levels were less than 1/10th of that of deoxynivalenol (Streit et al., 2013).

The limited availability of fit-for-purpose reference substances (purified and characterized mycotoxin portions) are one of the reasons for a delayed monitoring of emerging mycotoxins by larger groups of laboratories (Goncalves et al., 2017) and this makes exposure estimation difficult for risk assessors.

### Gliotoxin and Mycotoxins With Lesser Frequency

Gliotoxin (Fig. 24) is not an explicitly regulated mycotoxin in any country. However it is produced by a number of fungi, including *Aspergillus fumigatus*, whose spores are ubiquitous in the global environment (Weidenbömer, 2001). It is further produced by *Byssosclamyces nivea* and *Paecilomyces variotti*, which are patulin producer and the acid-tolerant *Penicillium roqueforti*, the producer of roquefortin C. Gliotoxin is often associated with fungal in-door pollution while it has also been reported in cereals, and dried fruits. It is considered an “important mycotoxin with fewer occurrences” in the same way as citreoviridin, griseofulvin, mycophenolic acid,  $\beta$ -nitropropionic acid, kojic acid, penitrems, penicillic acid, viomellein, vioxantin and xanthomegnin and walleminols (Marroquín-Cardona et al., 2014).

*A. fumigatus* and gliotoxin exposure to animals was studied in recent years in South America (Monge et al., 2012, 2013; Pena et al., 2015) indicating the presence of the fungi but no exposure to the toxin. These results must however be evaluated with care, as the obtained limits of detection reported were relatively high (44  $\mu\text{g/kg}$ ) compared to those of routinely analyzed mycotoxins such as aflatoxin B1 (1.6  $\mu\text{g/kg}$ ), fumonisin B1 (2.4  $\mu\text{g/kg}$ ), resulting in a large fraction of left censored data (=below the limit of detection) (Monge et al., 2012).

*A. fumigatus* commonly grows on decaying organic material (including food or feed waste) and is identified as a frequent fungi in silage (Pettersson et al., 2004). Monitoring silage for gliotoxin, showed that levels up to 20 mg/kg or more can be reached (Keller et al., 2012). This is an important aspect in current ambitions aiming at reducing food waste or re-directing materials that are classified as unfit for human consumption as insect feed (Van Huis et al., 2013). Therefore such new streams in the food and feed chain may require the monitoring of some metabolites like gliotoxin.

Figure 24 Gliotoxin.

## Spoiled and Cured Food

The growth of mycotoxin producing fungi on food items in the household is a common phenomenon. The main targets for fungal spoilage are fresh fruits like strawberries, vegetables like carrots or semi-dry food like bread or preserves like marmalade/jam. The fungal strains involved can range from *Botrytis cinera* or *Rhizopus stolonifera* on strawberries to *Cladosporium butyris* on fatty products like butter. When products are visibly spoiled they are classified as unfit for consumption. Therefore they are not considered a public health concern and should be properly disposed.

On the other hand a number of fungi are used for curing food like cheese, sausages or other meat like Swiss Luma<sup>®</sup> beef. In Europe *Penicillium* fungi are primarily used and a few of them have shown to be able to produce mycotoxins (ochratoxin A and citrinin) depending on the growth conditions. However others have also shown to be cytotoxic in cell tests. Therefore fungi used for curing should be tested prior selection to conclude on their safe use (Gareis et al., 1999).

## Modified Mycotoxins

More and more chemically changed mycotoxins, that are the result of different modes of metabolism or chemical reaction have been identified in the last decade. These biological or chemical modification are mainly result of the plant defense mechanism or thermal processes. Both terms, “masked mycotoxins” as well as “modified mycotoxins”, exist in literature and a proper classification to address the differences has been proposed (Rychlik et al., 2014). The biological modification aims at neutralizing or excreting mycotoxins by the organism. Trichothecenes like DON are plant (cereal) pathogens (McCormick et al., 2011) and the metabolism to DON-3-glycoside (Fig. 25) allows the plant cell to expel the compound from the cytosol into the vacuole (Berthiller et al., 2016) reducing the toxicity to the plant. This defence also reduces the overall amount of all DON related compounds in those plants that make efficient use of this principle (Lemmens et al., 2016). As a result cereal varieties that are efficient in this, are more resistant to fusarium head blight.

In general two major pathways are known for the biological modification of mycotoxins, namely the phase-I-metabolism and phase-II- metabolism. Phase-I metabolites are characterized by oxidation, reduction or equivalent alteration of the mycotoxin leading to substances like de-epoxy-nivalenol (Fig. 26) or  $\alpha$ -zearealenol (Fig. 16). Phase-II metabolites are the result of a conjugation reaction such as glucosylation, leading to DON-3-glycoside or ZON-sulphate (Fig. 27).

In recent years a number of modified mycotoxins have been identified, either as plant or animal metabolites. Due to their toxicological potential, metabolites of DON and ZON as well as a number of fumonisin derivatives have been described (Berthiller et al., 2012) and it was concluded that their presence can generally contribute to the overall exposure to mycotoxins. One reason is that the toxic potential can be partially regained when the modified forms are “re-metabolized” to the parent mycotoxin, like it has been shown for DON in pigs (Nagl et al., 2014).

**Figure 25** Deoxynivalenol-3-glycoside.

**Figure 26** Deepoxy deoxynivalenol.

**Figure 27** Zearalenone-4-sulphate.

The possible metabolism of ZON to  $\alpha$ -zearalenol and other metabolites as described in the paragraph on ZON is interesting for the safety evaluation of feed and novel-foods when insects are subject to consumption as proposed and authorized (European Union, 2015; Makkar et al., 2014). In 1991 it was shown that  $\alpha$ -zearalenol is the main metabolite in mealworms and is excreted with the feces with a conversion rate of approx. 30% and thought to be a detoxification process prior any public discussion on endocrine disruptors (de Rijk et al., 2015 Hornung, 1991).

Taking into account the estrogenic effect that has been estimated by the EFSA (60-fold compared to ZON) (EFSA Scientific Committee, 2016a) insects fed with ZON levels at currently tolerated limits for animals (European Commission, 2006b) might have the potential to amplify the estrogenic potential compared to that in the feed they grew on themselves if fed further to animals or are eaten by humans without precaution like proper elimination of the metabolites of ZON.

## Analytical Techniques

Prior discussions on analytical methods for mycotoxins, their often inhomogeneous distribution in agricultural products must be addressed (Whitaker, 2010). Especially aflatoxins are heterogeneously distributed (de Rijk et al., 2015), while others like deoxynivalenol are more homogeneously distributed within consignments (Biselli et al., 2008). The reason for a more homogeneous distribution is the usually area-wide fungal infestation of the cereals prior harvest. Aflatoxins on the other hand occur often in “hot-spots” (Fig. 28) and contaminate individual agricultural items such as single peanut/pistachio kernels, or single dried figs at minor frequency but high concentration (Schatzki and Haddon, 2002; Toyofuku et al., 2009; da Gloria, 2011). A tool that tackles this problem and generates sampling schemes with a defined seller and buyer risk has been developed by the FAO (Mycotoxin Sampling Tool). The challenges in preparing a laboratory sample for chemical analysis (at gram size) from an aggregate sample (at kg size) has been investigated and a watery slurry mixing procedure is proposed as reliable solution to reduce the sample size representatively (Spanjer et al., 2006).

Classical analytical techniques for mycotoxins used thin-layer chromatography (TLC) combined with liquid–liquid or column chromatography clean up (Betina, 1993b) and either instrumental (optical) or visual detection. Modern routinely used – confirmatory – methods for mycotoxin monitoring or control make use of liquid chromatography (LC) coupled to mass-spectroscopy (MS) (De Girolamo et al., 2017; Meneely et al., 2011). The introduction of LC-MS technology allows furthermore the simultaneous determination of numerous mycotoxins and fungal metabolites (Vishwanath et al., 2009). The key challenges when quantifying

**Figure 28** Workers removing a fungal “hot spot” in a corn shipment at the port of Dar es Salaam in 1993. Courtesy of Henry Njapau, National Institute for Scientific and Industrial Research, Lusaka, Zambia.

mycotoxins with MS are matrix effects that in the majority of cases suppress the signal in the detector compared to the signal from pure reference materials. Such suppression effects are dependent on the sample analyzed and often require either standard addition or matrix matched calibration if no stable-isotope labelled reference materials are available (Rychlik and Asam, 2008).

Despite instrumental progress with MS technology, TLC is still widely used in many regions of the world. Reason is that local conditions favor methods that are technically easy to control. In addition, despite a considerable shift to mass selective detectors in industrialized countries; fluorescence detection is still one of the most reliable and easy to implement methodologies for those mycotoxins that exhibit a natural fluorescence like the aflatoxins, zearalenone or ochratoxin A. As aflatoxins B1 and G1 undergo fluorescence quenching derivatization is frequently used and different types exist. Only post column derivatization techniques (Papadopoulou-Bouraoui et al., 2002) offer real benefits as pre-column derivatization (usually with trifluoro acetic acid) results in rather polar products that elute usually with matrix peaks. In combination with an immunoaffinity clean-up limits of quantification in the range of 20 ng/kg or lower can be achieved for aflatoxin B1. These reasons often favor the use of fluorescence detection for aflatoxins.

Methods using solely UV absorbance are considered not any more state of the art and are disfavored since the desired selectivity of the signal is questionable (European Commission, 2016). This challenge was demonstrated by the interpretation of chromatograms during a survey on the occurrence of patulin in a number of apple products and during method validation studies (Yurdun et al., 2001).

Parallel to chromatographic methods, the development of antibodies specific to smaller molecules like mycotoxins (Fremy and Usleber, 2003) as well as molecular imprinted polymers (MIPS) led to the development of mycotoxin specific sensor systems (Peltonmaa et al., 2018) and to powerful sample cleanup procedures (Lucci et al., 2017; de Smet et al., 2009). In recent years the advances in the development of aptamers for molecular recognition (Ruscito et al., 2016) open similar aspects similar like antibodies or MIPS.

In particular enzyme-linked immune sorbent assays (Goryacheva et al., 2007) and lateral flow devices (Zheng et al., 2006) are widely applied for mycotoxin screening, while sensor based applications are described either as prototypes or as instruments for end users (Maragos and Busman, 2010; Chauhan et al., 2016; Vidal et al., 2013). A few screening methods have been tested for eligibility in official food control in the EU and the USA (Lattanzio et al., 2016; United States Department of Agriculture, 2018) as their use for official control is regulated in both, in the EU (European Commission, 2014) and in the USA (United States Department of Agriculture, 2015, 2017).

Detection methods for mycotoxin contamination by non-destructive approaches have been proposed using different technologies. Vibrational spectroscopic methods (e.g. infra-red) focus not directly on the presence of the mycotoxin itself, but on co-occurring changes within the fungal infested material (Sieger et al., 2017; Lee et al., 2015; Fox and Manley, 2014). Also sound waves are used to identify specific changes in the kernel structure indicating mycotoxin presence after fungal infestation (Juodeikiene et al., 2014). An important application of spectroscopic instrumentation is its use in machine sorting, which is widely used in cereal and dried fruit (nuts) industry (Stasiewicz et al., 2017).

A comparably simple visual screening method is the so called bright greenish yellow fluorescence (BGYF) induced under ultra-violet light by a mercury lamp with 366 nm wavelength. The observed fluorescence associated with the presence of other fungal metabolites like kojic acid produced from *A. flavus* or *A. parasiticus* indicates the likelihood of aflatoxin presence (da Gloria, 2011; Hrsuka et al., 2017; Shotwell and Hesselstine, 1981).

The development of analytical methods for mycotoxins is annually followed up since more than a decade in a series of reviews critically evaluating new methodologies with respect to their use in the analytical laboratory analyzing food and feed for mycotoxins in routine control and research (Berthiller et al., 2017).

In order to derive sound conclusions from analytical methods for risk assessment as well as legal enforcement of regulatory limits the availability of standardized methods with validated performance characteristics for precision and trueness is a principal requirement.

Standardized methods with such validated performance characteristics are provided by various standardization bodies like the European Committee for Standardization (CEN), the International Standardization Organisation (ISO) and AOAC International and the inventory of methods covers all mycotoxins of public health concern.

Furthermore tools to monitor the implementation of analytical methods within testing laboratories are important (called proficiency tests). They allow to prove the proper implementation of analytical methods and are a cornerstone in the accreditation of testing laboratories according to ISO 17025.

Proficiency test schemes for the determination of mycotoxins in food and feed are provided by a number of organisations focusing on national and international test laboratories and are usually open to all interested testing laboratories.

## **Mycotoxin Prevention/Detoxification**

The main strategy to combat the presence of mycotoxins in food and feed is prevention. Numerous approaches ranging from improved agricultural practices to traditional breeding for resistant plant varieties and genetic engineering (= novel breeding technologies) have been applied with success. Monitoring weather conditions that favor fungal growth were realized by meteorological

data maps, predicting the occurrence of mycotoxin and consequently allowing punctual combat strategies (Schaafsma and Hooker, 2007). The field application of non-toxic competitive fungi is another strategy (Accinelli et al., 2018).

Mycotoxins are fairly stable along the food production chain. However there are processing techniques that can lead to a significant degradation resulting in a lower toxic potential (Estiarte et al., 2018), while not all degradation products are non-toxic *per se*. Fumonisin and aflatoxins undergo massive degradation during nixtamalization, a traditional treatment of corn with lime or ash. It is originated from Latin America and initially applied to improve the processing and sensory properties of corn flour (Voss et al., 2017).

Aflatoxins in feed can be largely reduced at industrial scale with ammonia, while this treatment is however not totally benign as it also lowers the nutritional value of the feed (Hoogenboom et al., 2001; Bailey et al., 1994). In recent years a number of feed additives have been tested for their ability to lower the toxic effect of mycotoxins in feed. Such products target different approaches, like binding mycotoxins such as the aflatoxins and making them unavailable for digestion (Wang et al., 2017) or detoxifying mycotoxins like fumonisins during digestion by enzymatic degradation (Schwartz-Zimmermann et al., 2018). As European legislation requires an authorization for such products several have been authorized in the European Union (European Union, 2013, 2014) and are marketed under tradenames like FumEnzyme® or MycoFix®.

In literature such additives are often referred to as “mycotoxin binders” (Kolossova and Stroka, 2001). An alternative attempt to reduce the toxicity of aflatoxins is chemoprevention, which targets the *in vivo* production of aflatoxin B1 epoxide (Bolton et al., 1993).

# Occurrence & Risk of OTA in Food and Feed

Vita Di Stefano, University of Palermo, Palermo, Italy

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Ochratoxin A (OTA) is a ubiquitous mycotoxin produced mainly by fungal species of the genera *Aspergillus* and *Penicillium*, detected worldwide in various food and feed sources and represents a potential human health hazard. OTA is nephrotoxic and is suspected of being the main etiological agent responsible for human Balkan endemic nephropathy (BEN) and associated urinary tract tumours. International Agency for Research on Cancer (IARC) has classified OTA as a possible human carcinogen (group 2B). The mycotoxin ochratoxin A (OTA) is the most important and most common member among several structurally related ochratoxins. It is a secondary metabolite produced mainly by the following three fungal species *Aspergillus alutaceus* (formerly known as *A. ochraceus*), *A. carbonarius*, and *Penicillium verrucosum* (EFSA, 2006).

Cereals and cereal by-products constitute a major part of the daily diet of the human and animal populations. The total annual yields of cereals globally add up to more than 2000 million tons. Because they are easy to package and transport, they are used for producing a large variety of highly desirable foods, beverages and feed.

However, an investigation on a worldwide scale showed that 25% to 40% of cereals are contaminated by mycotoxins (El Khoury and Atoui, 2010).

Due to high stability, mycotoxins represent an important problem not only during cereal grain production in field, but also in storage, transport, processing and post-processing steps. This contamination can occur in several times, in the field and/or during storage.

It is especially in the countries with hot and wet climatic conditions (in particular African countries, South Asia and South America) that the growth of toxigenic filamentous fungi is most favoured. Thus, rice, corn, and millet, the basic foods of the populations of these countries, are often contaminated by ochratoxins (Nguyen et al., 2007).

## Occurrence in Food

The main OTA sources included cereals, spices, coffee, tea, cocoa, wine and beer. Thus, worldwide, cereals are considered as being the major source of OTA contamination, where 50% of human daily intake of this mycotoxin is due to the consumption of different cereals derived products including rye-wheat bread, multigrain bread, cereal porridge, fine bakery wares, breakfast cereals, sweet biscuits and muesli. Due several toxicological effects, the analysis of OTA content in foodstuffs is need. The control at all stages of product processing need accurate and sensitive analytical methods (Table 1).

In the recent Spanish study, the OTA occurrence was 0.72 ng/g in corn-based breakfast cereals, 0.29 ng/g in wheat-based breakfast cereals and 0.28 ng/g in loaf bread (Coronel et al., 2012). A Lebanese report show that the food products exhibiting the highest concentration of OTA were cereal-based products, in particularly, "biscuits and croissants" (mean OTA concentration 2.8 ng/g) (Raad et al., 2014). OTA was detected in samples of breakfast cereals collected in France, with OTA in the range of 0.2–8.8 ng/g. The highest concentration was determined in a sample containing dry fruit and bran (Moliné et al., 2005). Regarding contamination of bread, Duarte et al. (2010) compiled the data on the occurrence of OTA in different types of bread worldwide. The mean values of positive samples of wheat bread ranged from 0.07 ng/g in Switzerland to 13 ng/g in Morocco, although they are mostly below 0.50 ng/g (Legarda and Burdaspal, 2001; Zinedine et al., 2007).

Wine, together with cereals, represents the second largest source of OTA human intake (4.7%–29.7%) and several surveys were conducted to assess the relevance of the presence of this mycotoxin in wine and grape products (Silva de Abreu et al., 2016). The presence of OTA in the grape can be shifted from grain grapes to wine during its brewing. Zimmerli first detected OTA in wines (1996), since then, the presence of OTA in wines has been reported from a number of European and other countries wines,

**Table 1** Occurrence in different food and maximum levels of OTA

Cereal and cereal products		≤ 0.01–13 ng/g
Beer		≤ 0.01–0.50 ng/mL
Wine	Dessert wine	≤ 0.01–15.25 ng/mL
	Red wine	≤ 0.01–7.63 ng/mL
Cocoa and cocoa products		0.25–7.8 ng/g
Milk		5–8 ng/L
Spices		≤ 0.01–98.2 ng/g
Coffee (roast and ground)		0–10 ng/g
Herbal teas (licorice root)		1.4–252.8 ng/g

with an apparent increase in levels in wines originating from southern areas of Europe (Remiro et al., 2013; Bellver Soto et al., 2014; Di Stefano et al., 2015a,b).

OTA levels in wine depend on different factors such as vineyard location (latitude), weather (rain, temperature, relative humidity in the vineyards), period of harvest, pesticide treatments and the wine brewing technique employed. Currently, EU legislation permits a maximum of 2 ng/g of OTA in wine and grape juice (EC n°1881/2006); this limit does not apply to liquor or dessert wines with more than 15% alcohol content.

Many recent works highlight the presence of considerable levels of OTA in wines, musts and grape juices (up to 7 ng/mL).

OTA levels usually are higher in red than in rose wines, following by the whites, mostly due to the must maceration with the skin of the grain grape, which could enhance OTA extraction. In sweet or special wine, wine making practices and the temperatures reached promote growth of OTA mould producers.

It is difficult to compare OTA levels in wines from different countries due to the great variety of wines analysed and the differences between the limits of detection used in each analytical method.

However, red and sweet wines seem to be the most contaminated; in particular wine samples from southern regions presented higher incidences and concentrations of OTA, as consequence of the warm temperatures and humid weather conditions, which favour fungus growth and mycotoxin's production. In any case, due to their toxicity, a low but continued dietary exposure to OTA could contribute to a risk to consumers, so its level in wine should be as low as reasonably achievable (Di Stefano et al., 2015a,b).

OTA has also been detected in other beverages such as beer. The origin of OTA mycotoxin in beer comes from contamination of prime material used for its processing as barley, malt, or cereal derivatives. Contaminated barley grains contain ochratoxigenic strains, which are transferred to beer. Currently EU Commission has not yet fixed the maximum admitted level of OTA concentration in beer. Recent monitoring about OTA content in beers was performed and analysed samples showed concentration levels below 0.2 ng/mL (Mateo et al., 2007).

OTA contamination occurs also in cocoa and chocolate-based products. There are only a few publications concerning the analysis of OTA in cocoa and in cocoa products; in one of these studies levels of ochratoxin A in cocoa and cocoa products available in Canada showed an incidence of 100%, with concentrations ranging from 0.25 to 7.8 ng/g (Turcotte and Scott, 2001). Another study of ochratoxin A occurrence was carried out by Serra Bonvehí (2004), where 138 samples of cocoa by-products (cake, mass, shell, nibs, butter and powder) from some cocoa producing countries (Indonesia, Ivory Coast, Ghana, Malaysia, Nigeria, Ecuador, Honduras and Peru) were analyzed. 120 (87%) samples had OTA above the detection limit (0.1 ng/g). The highest contamination was found in shell (11 ng/g, followed by cake (2.6 ng/g) and powder (2.41 ng/g). At the present time, there are no EU limits for cocoa and cocoa products, although these are presently under consideration (EC n°1881/2006). Recently, the European Commission stated that '*on the basis of the information available, it does not appear necessary for the protection of public health to set a maximum level of OTA in ... cocoa and cocoa products ...*' (Commission Regulation No. 105/2010). It is concluded that cocoa does not represent a major source of ochratoxin A in the diet. However, one concern is the fact that chocolate-containing products are widely consumed by children who are more sensitive to the effects of mycotoxins. Thus, it is important that constant monitoring should be carried out of their occurrence and also to find ways to prevent the contamination in the cocoa production chain.

OTA may also occur in milk. However, there is a paucity of information on the rate of transfer of this toxin into milk for dairy cows. In dairy sheep, the carryover is less than 1%. In a survey conducted in the northwest of France in 2003, Boudra et al. (2007) evaluated the presence of OTA in bulk milk from farms based on corn silage and cereal grains. OTA was detected in three milk samples at low levels, 5–8 ng/L, that do not appear to pose any particular risk to milk consumers.

## Risk Assessment

The Joint FAO/WHO Expert Committee on Food Additives (JECFA) established a Provisional Tolerable Weekly Intake (PTWI) of 100 ng/kg bw/week (equivalent to 14.3 ng/kg bw/day), derived from a lowest-observed-adverse-effect level (LOAEL) of 8 µg/kg bw/day that caused minimal kidney changes in pigs (JECFA, 2001, 2008).

The European Food Safety Authority (EFSA) established a Tolerable Weekly Intake (TWI) of 120 ng/kg bw/week (equivalent to 17 ng/kg bw/day), derived from the same pig LOAEL but applying a slightly different uncertainty factor (EFSA, 2006). It reconfirmed this in 2010 (EFSA, 2010).

Health Canada has established a TDI of 3 ng/kg bw/day based on a benchmark response of 10% above background from the same pig study.

EFSA (2006) estimated total dietary exposures of 2–3 ng/kg bw/day (ca. 15–20 ng/kg bw/week) and 6–8 ng/kg bw/day (ca. 40–60 ng/kg bw/week) for average and high adult consumers (97.5th percentile) respectively. It was noted that exposure could be higher amongst children and certain consumer groups with preferences for particular foods.

RIVM (2009) estimated that >20% of 2- to 6-year-olds in the Netherlands exceed EFSA's tolerable daily intake (TDI) of 17.1 ng/kg bw/day (as derived from the TWI). This was the case in about 40% of 2-year-olds and 11% of children aged 4 and above. At worst the TDI was exceeded by up to four times.

## Regulations (EU)

Within the EU, maximum levels for OTA are defined for several raw materials. For example, in the spices and licorice categories a limit of 20 ng/g for licorice root has been set ([Commission Regulation No. 105/2010](#)); 15 ng/g for white and black pepper, ginger, nutmeg, and turmeric ([Commission Regulation No. 2015/1137](#)); 20 ng/g for dried chilies, chili powder, cayenne, and paprika; and 15 ng/g for mixtures containing one or more of the aforementioned spices.

The Scientific Commission of the European Community have regulated the maximum levels of OTA for unprocessed cereals (5 ng/g), products derived from cereals (3 ng/g) and processed cereal-based foods and baby foods for infant and young children (0.5 ng/g) ([EC n°1881/2006](#)).

## Occurrence in Animal Feed

The feed supply chain is a crucial element for all livestock production systems. Cereals and cereal byproducts constitute a major part of the daily diet of animals and are important ingredients in animal compound feed. Mycotoxins represent a significant risk to animal health and are a significant issue for a safe feed supply chain.

In animal feeding, the contribution of forages to total mycotoxin intake could be significant. Recent studies reported not only that preserved forages, like silage, can be an important source of mycotoxins in ruminant diet, but also that fresh forage and/or pasture can be a route of exposure to these contaminants.

A high incidence of multi-mycotoxin contamination has been reported in feed. Co-occurring mycotoxins may exhibit additive or synergetic toxic effects well documented by many studies and represents an extremely common problem in feed industry world that should be routinely monitored ([Smith et al., 2016](#)).

Moreover, globalized feed grain trade may distribute mycotoxins outside of their natural occurrence geographical areas, complicating the prediction of mycotoxin contamination in compound feed. OTA maximum levels and guidance values in animal feed have been set in Commission Directive 2003/100/EC and Commission Recommendation 2006/576/EC.

In a study carried out in Spain with a large number of ingredients sampled from the same feed mill, were found levels of OTA above the levels recommended by the EU legislation (<50 µg/kg) in a reduced number of samples of maize (up to 225 µg/kg) and barley (up to 90 µg/kg) ([Espada, 2008](#)).

In Brazil, [Rosa et al. \(2009\)](#) described the OTA occurrence in corn, brewers grain and finished swine feed samples collected from different factories. Corn samples (44%) were contaminated with 42–224 µg/kg of OTA. The animal feed (31%) and samples of brewers grain (13%) were contaminated with 36–120 µg/kg and 28–139 µg/kg of OTA, respectively.

Ochratoxin-contaminated feed has its major economic impact on the poultry industry. Chickens, turkeys, and ducklings are susceptible to this toxin. Clinical signs of avian ochratoxicosis generally involve reduction in weight gains, poor feed conversion, reduced egg production, and poor egg shell quality. Economic losses also occur in swine farms, linked to nephropathy and costs for the disposal of carcasses. Toxicity does not seem to constitute a problem in cattle, because OTA is rapidly detoxified by rumen protozoa and bacterial enzymes into less toxic metabolites.

OTA amount in animal feed varies from country to country. The highest amounts have been reported in Northern Europe and North America. Specifically, the highest frequencies were described in Denmark (57.6%), Canada (56.3%) and Yugoslavia (25.7%), showing isolated samples with values of OTA contamination above 5000 ng/g ([WHO, 2002](#)).

The impact of mycotoxins entering the feed supply chain could increase in the future. Most predictions indicate that climate change scenarios, with global warming, could affect agriculture and increase and change the threat of fungal invasion of crops.

## Conclusion

Currently, data on the natural occurrence of Ochratoxin A in various food products and animal feed in different regions of the world are still scarce and make a final risk assessment impossible.

Emerging evidence, however, suggests an effect of climate and, thus, climate change including increases in temperature and other related variables (e.g., humidity/moisture) to the occurrence of mycotoxins in agricultural products.

The scientific community has done a lot in the last years, to identify and quantify the mycotoxins in food, clarify their destination in the plant, during processing or through the metabolism of microorganisms and animals, as well as possible health effects.

More generally, however, the current study reinforces the need for regular surveillance of OTA in agricultural products, as well as investigation of factors which drive OTA contamination.

Data on the possible interactions between different mycotoxins are still limited or non-existent, especially through high consumption food products, and is expected to result in greater human health problems. The need a regular monitoring of highly consumed foodstuff, is suggested.

## Occurrence & Risk of Aflatoxins in Food and Feed

Martien C Spanjer, NVWA – Netherlands Food and Consumer Product Safety Authority, Utrecht, The Netherlands

### Introduction

Aflatoxins were discovered after the sudden death of turkeys in England in spring 1960. As the cause of the disease was a mystery for some time, it was called "Turkey X-disease". As the number of casualties raised quickly over 100,000 and the mortality rate was almost 100%, thorough investigations were started promptly. The affected turkeys looked to be in good condition, just until right before their sudden death, when they showed nervous behaviour before falling into coma and collapsed. After autopsy some necrotic tissue was discovered in the liver, clearly indicating exposure to poison. Looking for the possible intake of aflatoxin the feed chain was traced back from the affected farms, revealing peanut meal being imported from Brasil to be the most likely source, as it glowed up when exposed to UV light, suggesting contamination by molds.

Detailed investigations lead to the conclusion the peanut meal was contaminated with fungi from the genus *Aspergillus*, specifically the species *Aspergillus flavus* and *Aspergillus parasiticus*. Further investigations revealed the chemical compounds which were responsible for the death of the turkeys. These toxins were named aflatoxins, after the mold *A. flavus*, which was responsible for the most toxic one: aflatoxin B<sub>1</sub> (AFB<sub>1</sub>). Its chemical structure is given in Fig. 1. Related aflatoxins are aflatoxin G<sub>1</sub>, aflatoxin G<sub>2</sub> and aflatoxin M<sub>1</sub>. Aflatoxins B are named after the blue color when seen in fluorescent light, whereas aflatoxins of the G type show greenish-yellow light in similar conditions. Aflatoxin M<sub>1</sub> is a metabolite which is produced in humans and animals. Exposure by aflatoxin B<sub>1</sub> due to consumption of contaminated food or feed leads to formation of the metabolic version aflatoxin M<sub>1</sub>, which is excreted in urine. In the female sex it can be transferred via the placenta to the foetus, thus exposing the unborn generation already with aflatoxin during pregnancy of the mother and thereafter by mother's milk as well.

### Contamination

Aflatoxins are regularly measured in nuts, dried fruits, spices, oil seeds, cereals, corn, rice and milk. Worldwide, aflatoxins are most frequently found in peanuts, pistachios, hazelnuts, Brazil nuts, figs, nutmeg and corn. Contamination can occur before harvest, during the time between harvesting and drying, and in storage. Contamination of milk by aflatoxin M<sub>1</sub> occurs when cows are fed with feed which is contaminated with AFB<sub>1</sub>, for example contaminated corn or peanut cake of poor quality. All contamination of a commodity starts with favorable conditions for mold growth. The crucial factors which primarily cause mold growth are moisture, temperature and pests. Molds can grow over a wide range of temperatures, so as well under field conditions as well during storage. In general, the rate of mold growth will decrease with decreasing temperature and lower

Figure 1 Chemical structures of aflatoxins ([www.chemspider.com](http://www.chemspider.com)).

moisture content of food or feed. In this respect water content in the commodities is specified by the water vapour in between the food kernels (i.e. grains or nuts). This differs from the moisture content of the kernels, as moisture content is water which is bound/included in the kernels itself. Molds grow by utilising intergranular water vapour, the concentration of water which is in equilibrium between free water within the kernels and the water vapour in the actual environment of the kernels. This water concentration is described either in terms of the relative humidity (%) or water activity ( $a_w$ ) at a certain temperature. The latter describes the ratio of the vapour pressure of water in the kernel to that of pure water at the same temperature. The relative humidity is equivalent to the water activity expressed as a percentage, calculated by  $a_w \times 100\%$ . For a given moisture content, different commodities vary by water activity and thus can express different mold type and growth rate. Water activities which are necessary for mold growth range from 0.77 to 0.90, with a tendency for mold growth increasing with temperature. The water activity for growth of *A. flavus* mold ranges from 0.78 to 0.84. Aflatoxin production starts above  $a_w = 0.84$ . The higher the water activity the larger the production of aflatoxins. *A. flavus* grows in the temperature range of 10–43 °C. The optimal growth rate occurs around 30 °C. Aflatoxins are produced at the temperature range 15–37 °C. Aflatoxin production between 20–30 °C is greater than at higher or lower temperatures. The effect of water activity and temperature on mold growth of *A. parasiticus* is similar to that of *A. flavus*. Mold growth of *A. parasiticus* requires an  $a_w$  of 0.84, whereas aflatoxin production starts at an  $a_w$  of 0.87. The effect of temperature on the growth of *A. parasiticus* and the production of aflatoxins is optimal at approximately 28–30 °C.

Aflatoxin contamination can occur pre-harvest when the crop plant is growing or post-harvest during processing, packaging, distribution and storage of commodities. Generally, all crops and cereals that are improperly stored under favourable temperature and humidity conditions for a prolonged time can be subject to mold growth and aflatoxin contamination. Maize is considered to be the crop relatively susceptible to aflatoxins contamination, while rice is the least. In practice this means, for example, that corn can be safely stored for 1 year at a moisture level of 15% and a temperature of 15 °C. However, when stored at 30 °C, the same corn will be significantly affected by molds within 3 months. The presence of molds does not guarantee that harmful aflatoxin levels are present, but indicates a significant risk of contamination by aflatoxins. Corn can also be affected by *A. flavus* in the field, when conidia from soil-inhabiting organisms are carried by air into the silks of the corn plant, where under suitable environmental conditions infections of corn ears can occur. Other commodities, like peanuts, are prone to infection at high temperatures and low-moisture levels, commonly known as drought stress. Irrigation supplies water and lowers soil temperature as well, which allows for normal plant development and greatly reduces aflatoxin risk. Water is also the best insect control available in that it makes the peanut plant much less susceptible to pests such as cornstalk borer, burrower bugs, corn earworm and spider mites. In pistachios another phenomenon favours aflatoxin contamination, as the hulls can split prior to maturity of the nuts, creating an open portal of entry for fungi and also may involve damage by insect larvae.

## Adverse Health Effects

Aflatoxins have carcinogenic, teratogenic, hepatotoxic, mutagenic and immunosuppressive effects, with the liver being the target organ. Aflatoxins are associated with both acute toxicity as well as chronic carcinogenicity in humans and animals. The International Agency of Research on Cancer (IARC, 2012) classified aflatoxin B<sub>1</sub> as a Group 1 carcinogen, with high risks for hepatocellular carcinoma in individuals exposed to aflatoxins. Acute toxicosis, usually rare in developed countries, can occur in developing countries, whereas chronic carcinogenicity is a global problem. The LD<sub>50</sub> values range between 0.5 and 10 mg/kg body weight in different animal species. In humans, acute aflatoxicosis is characterized by vomiting, abdominal pain, pulmonary and cerebral edema, coma, convulsions and even death. In animals, symptoms of gastrointestinal dysfunction, reduced reproduction, reduced feed conversion and efficiency, lowered milk and egg production and anemia have been reported. The toxic effects of AFB<sub>1</sub> are principally due to the binding of bioactivated AFB<sub>1</sub>-8,9-epoxide to cellular macromolecules, particularly mitochondrial and nuclear nucleic acids and nucleoproteins, resulting in cytotoxic effects. The double bond in the furan ring of AFB<sub>1</sub> and AFG<sub>1</sub> can be oxidised and form a reactive 8,9-exoepoxide that readily reacts with DNA and other nucleophiles. In DNA, the AFB<sub>1</sub>-N7-guanine is formed, which may subsequently lead to transversion mutations. Co-exposure to hepatitis viruses, in particular hepatitis B has a strong impact on the carcinogenic risk to aflatoxins. In epidemiological studies, there is interaction with hepatitis B infection, and subjects positive for hepatitis B surface antigen (HBsAg) show at least a multiplicative risk when present together with aflatoxin exposure (FAO/WHO, 2017). After entering the body, aflatoxins are metabolized by the liver to a reactive epoxide intermediate or hydroxylated to become the less harmful aflatoxin M<sub>1</sub>, which will be excreted in the urine. Aflatoxin M<sub>1</sub> as such is less harmful when compared to aflatoxin B<sub>1</sub>. Therefore IARC classified it in Group 2B, possibly carcinogenic to humans. Human exposure to aflatoxin M<sub>1</sub> occurs primarily via consumption of milk and milk products from animals that have consumed contaminated feed (Anonymous, 2004). It has also been found in human breast milk.

Outbreaks of aflatoxicosis directly affecting humans are rare. The first one, reported in India, led to the death of 100 people in 1974. In April 2004, one of the largest aflatoxicosis outbreaks occurred in rural Kenya, resulting in 317 casualties and 125 deaths (Lewis et al., 2005). Aflatoxin-contaminated homegrown maize was the source of the outbreak. The extent of market maize contamination revealed that 55% of maize products had aflatoxin levels greater than the Kenyan regulatory limit of 20 µg/kg, 35% had levels above 100 µg/kg and 7% had levels higher than 1000 µg/kg. Another incident occurred in Serbia, after the country had been affected by severe drought during 2012, causing an increased prevalence and high levels of aflatoxin contamination in maize for feed, reported to have a mean contamination level of 36.6 µg/kg, with 53.5% of the samples above 10 µg kg<sup>-1</sup> (Torović, 2015).

Due to this contamination, in 2013 and 2014 aflatoxin M<sub>1</sub> was determined in 80 samples of milk and 21 samples of infant formulae on the Serbian market. All milk samples collected in 2013 showed AFM<sub>1</sub> contamination in the range 0.02–0.32 µg/kg, with a mean level of 0.13 µg/kg, 75% of the samples exceeding the EU maximum limit for AFM<sub>1</sub> in milk of 0.05 µg/L. In 2014, AFM<sub>1</sub> was found in 83%, 70%, 80% and 58% of the samples collected in April, July, September and December, respectively, where only 5% of the samples taken in July exceeded the limit.

## Legislation

Due to the hazardous effects of aflatoxins almost every national and international public health and governmental authorities such as the US Food and Drug Administration (FDA), World Health Organization (WHO), Food Agriculture Organization (FAO) and the European Food Safety Authority (EFSA CONTAM Panel et al., 2018), have compiled risk assessment documents regarding contamination in food and feed. To achieve as harmonized limits as possible in the world, since 1956 the Joint FAO/WHO Expert Committee on Food Additives (JECFA), an international expert scientific committee that is administered jointly by the Food and Agriculture Organization of the United Nations (FAO) and the World Health Organization (WHO) was initiated. They publish risk assessments which are applied by the Codex Committee on Contaminants in Food (CCCF) to set maximum limits. The Codex maximum limit (ML) for a contaminant in a food or feed commodity is the maximum concentration of that substance recommended by the Codex Alimentarius Commission to be legally permitted in that commodity. As many contaminants occur naturally it would be impossible to impose a zero limit on these substances. To protect human health Codex works to keep these levels as low as possible based on sound scientific evidence. In case of contaminants which are considered to be genotoxic carcinogens or in cases where current exposure of the population or of vulnerable groups in the population is close to or exceeds the tolerable intake, maximum limits should be set at a level which is as low as reasonably achievable (ALARA). Such approaches ensure that food business operators apply measures to prevent and reduce the contamination as far as possible in order to protect human and animal health. It is furthermore appropriate for the protection of infants and young children, a vulnerable group, to establish the lowest possible maximum limits, which are achievable through a strict selection of raw materials used for manufacturing of baby food. These considerations resulted in adopting strict regulatory maximum limits for aflatoxin B<sub>1</sub> in most countries in the world on the presence of aflatoxins in food and feed from as low as 0.1 µg/kg in baby food to 8 µg/kg for almonds, pistachios and apricot kernels, intended for direct human consumption or use as an ingredient in foodstuffs. For total aflatoxins, the limits for the sum of aflatoxin B<sub>1</sub>, aflatoxin B<sub>2</sub>, aflatoxin G<sub>1</sub> and aflatoxin G<sub>2</sub> range from 4 to 20 µg/kg. For feed the limits depend on the target animal and vary between 5 and 20 µg/kg for aflatoxin B<sub>1</sub> in feed with a moisture content of 12%. The lowest value, for lactating animals, will result in milk which fulfills the EU limit of 0.050 µg/kg for aflatoxin M<sub>1</sub>, as the metabolism in the cow has a conversion factor of 100. Codex set the limit for aflatoxin M<sub>1</sub> at 0.50 µg/kg, so 10 times higher.

## Sampling

The most crucial step in the analysis of aflatoxins in food is the sampling procedure, which greatly contributes to the reliability of the results and the final decision on compliance or non-compliance for an entire lot or batch. This is due to the fact that mold growth originates only from just those spots in a field or storage where the moisture and temperature are optimal for aflatoxin production. Therefore the contamination is very heterogeneous. Except for liquid commodities such as milk or processed food, i.e. peanut butter, sampling methods which are applied for residue analysis or for checks on nutritional composition of food are not suitable for aflatoxin analyses, as contamination is not homogeneously distributed in grains, nuts, spices or dried fruits. Basic sampling procedures are described in detail in European Commission Regulation (EC) No. 401/2006 and in the standard ISO 24333: 2009 of the International Standardization Organisation. A typical sampling schedule for a 25 tonnes truck load of cereal grains requires taking 100 incremental samples of 100 g according to the EC sampling plan and 20 incremental samples of 500 g according to the ISO schedule, in both cases revealing an aggregate sample of 10 kg to be delivered in the laboratory. In both cases a laboratory sample has to be taken from the homogenized 10 kg. In case of dispute an arbitrary subsample best be taken of the homogenized laboratory sample, which is another challenge, as the subsample for analysis has to be representative for the laboratory sample. Any procedure which does not take the heterogeneity of the contamination into account will lead towards a questionable outcome of the analysis.

## Analysis

Chromatography is the most commonly used technique for aflatoxin analysis in food and feed. The earliest chromatographic method is thin layer chromatography (TLC), which is a rapid screening method for aflatoxins by visual assessment or instrumental densitometry. However, current trends in aflatoxin analysis in food are focused on application of robust, fast, easy to use and cheap technologies that are able to detect and quantify aflatoxins with a high sensitivity and selectivity in a single test. To meet those needs, many chromatographic methods such as HPLC coupled with fluorescence (FLD) or mass spectrometry (MS) detectors have been developed. Rapid tests are more commonly applied when quick screening is required in the field or in industrial processing procedures.

Enzyme-linked immunosorbent assay (ELISA) provides easy testing, with many validated kits commercially available for detection and quantification of aflatoxins. If necessary positive ELISA results could be confirmed by a suitable chromatographic method, especially when used in a matrix not specified by the manufacturer of the assay. For any test has to be kept in mind how representative is the single drop of the obtained extract, as applied in the test, for taking a decision on a complete field, silo, truck or ship load.

## Prevention

Aflatoxins are chemically and thermally stable during food processing, including cooking, boiling, baking, frying, roasting and pasteurization. Once these compounds are present in food or feed it is very difficult to eliminate them. Several efforts have been made to find a chemical decontamination process, without very much success. Only for feed the use of ammonia has gained some industrial application in Brazil, Mexico and some States in the USA (i.e. in Texas). Another option is to inactivate aflatoxins by means of binding the compounds to adsorbing agents, which are excreted by the animal. The critical issue there is whether the bound aflatoxin is not released by the binding agent, for example in the acidic stomach content. After a long period of scientific investigations about inactivation agents (binders) the European Commission concluded that bentonite has the ability to reduce Aflatoxin B<sub>1</sub> contamination in pig, poultry and ruminant feed (EC No 1060/2013). Chemical decontamination of food is forbidden anywhere in the world. For food only sorting out infected kernels is a safe option to reduce aflatoxins. Optical sorting technology is available to reject discoloured, diseased and damaged seeds, nuts, grains, rice, pulses, fruits and spices ([www.buhlergroup.com/optical-sorting](http://www.buhlergroup.com/optical-sorting)).

All together the best way to avoid contamination is prevention. Therefore a number of control strategies for aflatoxin contamination in crops are investigated: controlling preharvest drought stress, breeding programs for heat and pest resistant varieties and assessing potential biocontrol agents. Due to the uncontrollable weather conditions, cultivation of a crop usually encounters a period of drought and stress during growing, flowering and kernel development. The weather conditions are the major factors for increased aflatoxin contamination. Irrigation will reduce drought stress and lower the soil temperature as well. Other factors that have to be taken care of by farmers are plant nutrition (fertilisers), manage plant diseases (fungicides), pest control (pesticides), weed reduction (herbicides) and avoid excessive plant density to achieve better ventilation in the field. An additional option is to apply crop rotation. Growing sugar beet after harvesting peanut will reduce the amount of *Aspergillus species* in the soil, thus giving a better starting point for the next peanut crop. Involving corn in this circulation process is not an option, as corn is easily affected by mold, which will affect any next crop, even after extensive tillage. The Codex Alimentarius Website (<http://www.fao.org/fao-who-codexalimentarius/codex-texts/codes-of-practice/en/>) gives codes of practice for prevention and reduction of aflatoxin contamination in peanuts (CAC/RCP 55-2004), in tree nuts (CAC/RCP 59-2005), dried figs (CAC/RCP 65-2008) and for reduction of aflatoxin B<sub>1</sub> in raw materials and supplemental feeding stuffs for milk producing animals (CAC/RCP 45-1997).

### Glossary

**Acceptable Daily Intake (ADI)** The ADI of a chemical is the daily intake which, during an entire lifetime, appears to be without appreciable risk to the health of the consumer on the basis of all the known facts at the time of the evaluation. It is expressed in milligrams of the chemical per kilogram of body weight.

**Acute Reference Dose (ARfD)** The ARfD of a chemical is an estimate of the amount of a substance in food and/or drinking-water, normally expressed on a body-weight basis, which can be ingested in a period of 24 hours or less without appreciable health risk to the consumer on the basis of all known facts at the time of the evaluation.

**Maximum Residue Level (MRL)** The MRL means the upper legal level of a concentration for a pesticide residue in or on food or feed set in accordance with the Regulation (EC) No 396/2005, based on good agricultural practice and the lowest consumer exposure necessary to protect vulnerable consumers (Article 3(2)(d) of Regulation (EC) No 396/2005). The terms 'maximum residue level' and 'maximum residue limit' are often used interchangeably.

**Codex MRLs (CXL)** The CXL means an MRL set by the Codex Alimentarius Commission (Article 3(2)(e) of Regulation (EC) No 396/2005).

**No Observable Adverse Effect Level (NOAEL)** The highest exposure level at which no adverse effects can be identified in tests.

**Pesticide** Pesticide means any substance intended for preventing, destroying, attracting, repelling, or controlling any pest including unwanted species of plants or animals during the production, storage, transport, distribution and processing of food, agricultural commodities or animal feeds, or which may be administered to animals for the control of ectoparasites. The term includes substances intended for use as a plant-growth regulator, defoliant, desiccant, fruit thinning agent, or sprouting inhibitor and substances applied to crops either before or after harvest to protect the commodity from deterioration during storage and transport. The term normally excludes fertilizers, plant and animal nutrients, food additives and animal drugs.

**Note:** Within the European Union the term 'pesticide' is solely used for substances used in PPPs.

### Introduction

Plant protection products (PPPs) are formulations containing one or more active substances and in most cases co-formulants in a solid, liquid or gaseous stage to protect plants or plant products. The application of PPPs on crops in agriculture, horticulture or on plant products during storage can result in measurable levels of pesticide residues in or on harvested products, but also in products of animal origin and processed products. These pesticide residues must not entail any risks for human and animal health and the environment.

The protection of consumers and the trade of the products were from the beginning the two main aspects in MRL setting. MRL setting started about 50 years ago on national level (in Germany: in 1966 for products of plant origin, in 1973 for products of animal origin) and international level (in the European Union (EU): in 1976 for fruits and vegetables with Council Directive 76/895/EEC, followed by 86/362/EEC, 86/363/EEC and 90/642/EEC). Since EU directives needed to be transposed at that time into national legislation, each Member State devised its own laws causing deviations that may hinder free trade within the EU.

As a result of numerous serious food safety incidents during the 1990s (BSE, residues and contaminants (dioxin), etc.), the European Commission launched a White Paper on Food Safety on 12th January 2000 (EC, 2000). In order to achieve the highest standards of food safety in the EU, the White Paper on Food Safety served as a start for a new legal basis for appropriate food and animal feed production and food safety control. It sets out a number of measures which "will enable food safety to be organized in a more coordinated and integrated manner"; these include:

- the establishment of an independent European Food Authority with responsibility for "independent scientific advice on all aspects relating to food safety, operation of rapid alert systems, communication and dialogue with consumers on food safety and health issues as well as networking with national agencies and scientific bodies"
- a new legal framework covering all sectors of the food production and distribution chain, including animal feed production, primary production, food processing, storage, transport and retail sale (integrated approach "from farm to table", also referred to as "from farm to fork", "from stable to table")
- a harmonization of national control systems
- a dialogue with consumers and information of emerging food safety concerns and risks

Therefore, in 2002, the European Parliament and the Council adopted [Regulation \(EC\) No 178/2002](#) laying down the general principles and requirements of food law and setting up the European Food Safety Authority (EFSA) as an independent agency responsible for scientific advice and support. In 2009, the [Regulation \(EC\) No 1107/2009](#) concerning the placing of plant protection products on the market was adopted. Concerning MRLs in or on food and feed of plant and animal origin, the [Regulation \(EC\) No 396/2005](#) was already implemented in 2005. This Regulation “directly concerns public health and is relevant to the functioning of the internal market” (recital 2 to [Regulation \(EC\) No 396/2005](#)).

## Regulation and Control of Pesticides in the European Union

A PPP cannot be placed on the market without prior authorization. In the EU, the placing of the PPPs on the market is based on a two-step procedure. The first step consists of the approval of the active substance, while in the second step the authorization of the PPP containing the approved active substance may be granted. Both procedures are principally regulated by the framework [Regulation \(EC\) No 1107/2009](#). The approval of active substances takes place at EU level, where EFSA prepares the final risk assessment of active substances and Member States vote on the approval. Only after the active substance is approved, the use of PPPs can be evaluated and authorized at Member States level. The period of authorization of a PPP is based on the period of approval of the active substances contained therein as it is limited (max. 10 years for first approval according to Article 5 of [Regulation \(EC\) No 1107/2009](#)). Three years before expiry of the approval, a producer of the active substance may submit an application for renewal of approval (Article 15 of [Regulation \(EC\) No 1107/2009](#)). Similarly, if an authorization holder wishes to continue to place its PPP on the market after the expiry date of its authorization, an application for renewal is required.

[Regulation \(EC\) No 1107/2009](#) describes requirements and procedures for approval of active substance and for the authorization of PPPs with involvement of applicant, Member States, EFSA, European Parliament and Council. As required by [Regulation \(EC\) No 1107/2009](#) (Article 4), an active substance can only be approved for use in PPPs when it has been found to be both effective for pest control and safe for human, animals and the environment. The data requirements for active substances and for PPPs are defined by Regulation (EC) No 283/2013 and by Regulation (EC) No 284/2013, respectively. In addition, further Guidelines and Guidance Documents provided by the European Commission, the EFSA and the Organization for Economic Co-operation and Development (OECD) may apply. The OECD Guidelines for the testing of chemicals provide about 150 of the most relevant internationally agreed testing methods to identify and characterize potential hazards of chemicals ([OECD, n.d. a](#)). Additional OECD Guidance Documents may help in interpretation. Guidelines and Guidance Documents used to fulfill data requirements are described in two Commission Communications attached to Regulations (EC) No 283/2013 and No 284/2013 (Commission Communication, 2013/C 95/01 and 2013/C 95/02). For harmonization of MRL calculations, the OECD has developed an OECD MRL calculator which has been adopted at international level and, therefore, on which MRL proposals should be based ([OECD, n.d. b](#)).

With the application for approval of active substance for placing PPPs on EU market, a complete list of tests and studies in accordance with Article 8 of [Regulation \(EC\) No 1107/2009](#) should be submitted by the applicant. The Member State (i.e. Rapporteur Member State (RMS)) submits a draft assessment report to the EFSA for risk assessment and expert consultation after which EFSA issues a conclusion. Based on EFSA’s independent risk assessments, the European Commission and Member States through the Standing Committee on Plants, Animals, Food and Feed (SCoPAFF) approve pesticides. Approved active substances are included into Regulation (EU) No 540/2011, the “positive” list of active substances approved for use in PPPs. Member States may authorize the use of PPPs containing active substances from this list. However, a PPP cannot be authorized without a fixed MRL. The establishment of a MRL at a level compliant with the envisaged use is one of the main requirements laid down in Article 29(1)(i) of [Regulation \(EC\) No 1107/2009](#).

A MRL for pesticides residue is a legally established maximum concentration of a particular active substance expected to be found in or on a particular food and/or feed commodity after use of the PPP in accordance with the label instructions (Good Agricultural Practice (GAP)). MRLs are set according to the principle “as low as reasonably achievable” (ALARA), following the main principle of using pesticides as much as necessary and as little as possible.

Since 1 September 2008, setting or amending of MRLs is regulated in the EU by [Regulation \(EC\) No 396/2005](#) replacing four Council Directives on MRLs which had to be transposed into national legislation before (Directives 76/895/EEC, 86/362/EEC, 86/363/EEC and 90/642/EEC). The main purpose of [Regulation \(EC\) No 396/2005](#) is to ensure a high level of consumer protection and to establish harmonized provisions relating to maximum levels of pesticide residues in or on food and feed of plant and animal origin. Additional provisions on import tolerances and Codex MRLs (CXLs) are necessary to facilitate international trade. As defined in Annex I to [Regulation \(EC\) No 396/2005](#), MRLs are set for raw agricultural commodities. To all active substances not mentioned in Annexes II, III, IV or V to the Regulation (and thus not approved in the EU), a default MRL of 0.01 mg/kg applies. This value represents a limit of quantification (LOQ) as residues have to be set as close to zero as possible.

[Regulation \(EC\) No 396/2005](#) lays down the rules and the procedure for setting MRLs with clear roles of the Member States, the EFSA and the European Commission. For setting appropriate MRLs, data in accordance with [Regulation \(EC\) No 396/2005](#) shall be submitted (toxicological studies, residue trials, and analytical methods), i. e. the same data requirements apply as set out in Regulations (EC) No 283/2013 and 284/2013 including the accompanying guidelines and guidance documents (s. above). The objective of residue trials, which have to be conducted in accordance with the proposed GAP, is to determine the maximum amount of pesticide residues in food and feed commodities at the time of consumption by humans and animals. Toxicological evaluation is

carried out on the basis of animal testing in order to obtain inter alia toxicological limits. The acceptable daily intake (ADI) and acute reference dose (ARfD) are calculated by dividing the no observed adverse effect level (NOAEL) - the highest dose without harmful effects - by an uncertainty factor of at least 100 to compensate for potential differences between animals and humans and for differences between individuals. The potential chronic (long-term) and acute (short-term) dietary exposure of consumers to pesticide residues are estimated using a calculation model of EFSA, the Pesticide Residue Intake Model (PRiMo). This model implements internationally agreed risk assessment methodologies published by the WHO (WHO, 1997) and contains national food consumption data provided by Member States and in addition WHO cluster diets (EFSA, 2018a). For establishment of MRLs, level of residues determined in trials, data on toxicology and food consumption are to be taken into account. Only if the amount of residues is acceptable in regard to health, i. e. if the estimated long-term and short-term exposure of consumers to residues remains below the ADI and the ARfD thresholds, and the residues can be determined by commonly available methods, a MRL can be set and afterwards an authorization for use of a PPP can be issued. The RMS evaluates the data submitted by the applicant and prepares an evaluation report concerning the necessary MRL. The EFSA prepares the final risk assessment and issues a reasoned opinion regarding the consumer safety of the proposed MRL. Provided that EFSA's risk assessment does not identify any unacceptable risks to consumers, the European Commission, through the SCoPAFF, finalizes the procedure by setting an EU-harmonized MRL and publishing a regulation on MRLs setting, amending the Regulation (EC) No 396/2005. After that, the PPP can be authorized at national level.

It is important to emphasize that MRLs are trading standards and not necessarily toxicological safety levels as they are usually set much lower than the levels that would pose a risk to consumers. Therefore, exceeding the MRL does not necessarily imply an adverse effect on human health. However, products/commodities with residues above the respective MRL must not be placed on the market as they do not comply with legal requirements. Exceedings of MRLs can occur for different reasons such as incorrect use of a PPP, use of authorized PPPs on unauthorized crops or contamination during storage and transport. Competent authorities in the Member States are responsible to enforce the safe use of PPPs.

In accordance with Regulation (EC) No 396/2005 (Article 26ff. to be changed in future by Regulation (EU) 2017/625 (Article 155)), official controls have to be carried out in each Member State, to ensure that food placed on the market is in compliance with afore-mentioned regulations. In each Member State, two control programs are in place for residues: an EU-coordinated control program with a number of samples analyzed each year by each Member States being proportional to their populations, and a national control program. The EU-coordinated control programs represent randomized controls and define pesticides and food products to be monitored by all Member States. In contrast, the national control programs are mainly risk-based as Member States define certain products which are expected to contain pesticide residues in concentrations exceeding MRLs, or products that may pose risks for consumer safety. The monitoring results of both control programs have to be submitted to the EFSA and the European Commission. The EFSA has to prepare an annual report on pesticide residues, analyzing the data in view of the MRL compliance of food products available on the EU market and the exposure of consumers to pesticide residues. The main purpose of the data analysis is to give the European Commission, acting as risk manager, the necessary information to decide on risk management policy issues.

Official Controls according to Article 68 of Regulation (EC) No 1107/2009 are aimed to monitor production, packaging, labeling, storage, transport, marketing, formulation, parallel trade and use of plant protection products. Member States have to report the results to the EU.

A potential risk to consumer health from food or feed is given when the exceeding of the MRL results in an exhaustion of the ARfD. In this case, the affected Member State circulates the information via the EU Rapid Alert System for Food and Feed (RASFF) – an online database designed to ensure the swift exchange of information between its members (28 EU Member States, EFSA, Commission, Norway, Liechtenstein, Iceland and Switzerland). Created in 1979, RASFF database provides a round-the-clock service to ensure that urgent notifications are shared quickly and allows the members to check whether they are affected and if a need for action is necessary. Food safety risks may be averted by taking the required measures such as giving information to the public and withdrawing the products from the market (EFSA, 2018b).

## Regulation and Control of Pesticides in International Trade

At the global level, MRLs are established by the Codex Alimentarius Commission (CAC). The CAC was founded by the Food and Agriculture Organization of the United Nations (FAO) and the World Health Organization (WHO). The statutes of the CAC, as stated in Article 1 (a) "protecting the health of the consumers and ensuring fair practices in the food trade" (CAC, 2016), were adopted in 1961 by the 11th Session of the FAO Conference and in 1963 by the 16th Session of the World Health Assembly. The Codex Alimentarius (Latin, meaning Food Code) is a collection of standards, codes of practice, guidelines, and other recommendations relating to foods, food production, and food safety. The CAC is responsible for providing safe and healthy food by setting internationally valid food standards. The founding of the World Trade Organization (WTO) and especially the implementation of the WTO "Agreement on the Application of Sanitary and Phytosanitary Measures" (SPS Agreement), increased the importance of the CAC organization's standards (FAO/WHO, 2018a).

The CAC is supported by an Executive Committee and several subsidiary bodies, referred to as Codex Committees, which prepare draft standards for submission to the Commission. Four different types of Committees exist, horizontal or General Subject Committees (10 Committees), vertical or Commodity Committees (6 Committees), ad hoc Intergovernmental Task Forces (one

Task Force) and Coordinating Committees (6 Committees), through which regions or groups of countries coordinate food standards activities in the region, including the development of regional standards (FAO/WHO, 2018b). The Codex Committee on Pesticide Residues (CCPR) is one of the general Committees. The work is always organized stepwise starting with a proposal and ending up with the adoption of the standard by the CAC. A few general Committees are supported by scientific bodies preparing evaluations. One of scientific bodies is the FAO Panel of Experts on Pesticide Residues in Food and the Environment and the WHO Core Assessment Group on Pesticide Residues (JMPR) giving advice to the CCPR (FAO, 2018).

### SPS-Agreement

The WTO was established in 1995 after nearly 10 years of trade negotiations (Uruguay Round). The WTO agreements cover goods, services and intellectual properties. One of these agreements is the General Agreement on Tariffs and Trade (GATT) (for goods): The agreement incorporates several Annexes. One of these Annexes covers health regulations for farm products (SPS Agreement). The SPS Agreement by itself does not set standards for food safety, animal and plant health, it mentions bodies responsible for setting these standards. The CAC is one of these standard setting bodies. The standards provided by these bodies are implemented as international standards. Through the SPS Agreement, harmonization is induced by encouraging members to introduce measures meeting these standards. Possible requirements may be the inspection of products that products must come from disease free areas or need to undergo certain processing steps or treatments before reaching the consumer. The use of certain additives or the setting of MRLs are further possible measures. The sovereignty of Member States is not supposed to be reduced by these measures and established measures cannot disadvantage other members. The international standards provide an indispensable level of protection from which deviations are only possible under special conditions. National modifications to the standards need to be scientifically justified by an adequate risk assessment. Additionally, these changes need to be notified to the other members in order to assess compliance with the standards, possible effects on trade and as general information to the other members for acknowledgement. The adoption of sanitary and phytosanitary measures has increased over the past years. This increase is not necessarily positive. Some countries use these measures to establish trade barriers to protect their own producers of agricultural products from foreign competition (WTO, 2018a).

The enforcement of standards is overseen by the responsible national authorities of each individual country (FAO, 2003). Diverse approaches and interpretations can lead to different conclusions resulting in negotiations and a final ruling by the WTO (WTO, 2018b).

### Influence of MRLs on Trade

According to the SPS Agreement, MRLs are a valid standard to globally provide safe and agricultural products. International MRLs (also referred to as CXL) are adopted by the CAC being agreed upon in the CCPR. CXLs are annually aligned, unless concerns are raised. Concerns can be discussed in council meetings prior, at CCPR meetings, shortly before or in between the CAC meetings. They may be addressed as observations documented in the protocol of the CAC meeting or in concern forms as described in the CCPR manual. Usually, the discussions result in a common position presented at the CAC meeting by the EU acting as sole legally entitled force.

A standardized procedure to set MRLs is only available in some countries and regions. The calculation models to determine MRLs still vary in different countries. The EU is one of the members establishing robust MRLs. Setting of MRLs is regulated by Regulation (EC) No 396/2005 which is valid in all Member States and therefore, MRLs are harmonized throughout the EU (Farnsworth, 2018). Countries without the possibility to set a MRL for a specific pesticide-commodity combination can adopt an existing CXL to facilitate trade. More important for those countries is the possibility to produce food of plant and animal origin that can be exported to other countries (Foletti and Shingal, 2014).

The removal of national requirements and differences through harmonization of the MRLs has simplified the exchange of agricultural goods within the EU. For the same reasons, market access for importers from outside the EU has become easier than before. Homogeneity has positively affected agri-trade within the EU but also with non-EU states (BMEL, 2016). Recent figures support the assumption that in general, a harmonization of standards has increased agri-trade. Intra-EU trade has grown by 72% from 2005 to 2016 to reach a value of 350 billion EUR. Trade with Non-EU Members has relatively increased even more. The total trade value has grown from 57.6 billion EUR in 2005 to 129.1 billion in 2015 - a total increase of 124%. Globally the value of trade in food exceeded the mark of 1.12 trillion US\$ in 2017 (EU, 2017).

Nevertheless, fair trade is still an illusion. Not all countries adopt CXLs. Different interpretations of study results may lead to different toxicological endpoints and/or different residue definitions that may hinder acceptance of a CXL.

### **Pesticide Identification by Chromatography-Mass Spectrometry**

Since the 1940s, synthetic organic pesticides have been used to control a variety of pests to protect crops and agricultural commodities. Government agencies such as the U.S. Environmental Protection Agency and the Pest Management Regulatory Agency of Health Canada are involved in the regulation of pesticides by establishing pesticide tolerances in foods. The [U.S. Food and Drug Administration \(2012\)](#), the [European Food Safety Authority \(2017\)](#), and the organizations that provide guidance on international food standards, such as [CODEX Alimentarius \(2017\)](#), have adopted identification criteria for pesticides based on chromatography-mass spectrometry procedures. Guidance criteria using mass spectrometry require retention times based on a chromatographic separation technique, the presence of the precursor and/or diagnostic ions based on the fragmentation of the precursor, and ratios between prominent characteristic ions ([Lehotay et al., 2008](#)). These diagnostic fragment or product ions are generated by in-source fragmentation when using selected ion monitoring (SIM) on a single quadrupole mass analyzer, or by collision induced dissociation when using selected or multiple reaction monitoring (SRM, MRM) on a tandem (i.e., triple quadrupole or quadrupole-ion trap) mass analyzer. GC-MS or LC-MS equipped with a triple quadrupole mass analyzer operating in SRM or MRM mode (GC-QqQ-MS/MS or LC-QqQ-MS/MS) is the preferred platform for pesticide analysis because of its capability to quantitate as well as identify pesticides based on retention time of the precursor mass and the selective mass fragmentation of the precursor into product ions. Identification of the pesticide is crucial for regulatory, compliance, and enforcement purposes to ensure that a pesticide is unambiguously present in the complex food matrix above a level of concern.

Before mass spectrometry became the dominant detector, confirmation of pesticides using non-selective detectors based on element selection (presence of heteroatoms such as halogens, nitrogen, and phosphorus) or spectrophotometric detection (e.g., UV, fluorescence) was achieved by chromatographic retention time from different capillary chromatography columns, analysis performed on different detector systems, or use of another orthogonal method. Identification by chromatography-MS eliminates the need for confirmatory or secondary analysis since one injection provides retention time, precursor and product ion masses, and ion ratios provide unequivocal evidence that the pesticide is present in the food sample. The retention time and the resulting unique fragmentation pattern from a mass spectrum can be used to differentiate a pesticide (or any other analyte) from other molecular components in the food extract.

### **The Influence of Mass Spectrometry on Sample Preparation for Pesticide Analysis**

Mass spectrometry has made an important impact for the multiresidue pesticide methods that are currently being used for analysis. Prior to the use of mass spectrometry, pesticide methods used large sample sizes, large amounts of organic solvents, and usually required expensive clean-up to minimize the influence of co-eluting matrix components that may interfere in the detection of the pesticide by a less selective detection system ([Anastassiades et al., 2003](#)). One of the first multiresidue pesticide procedures was developed by [Jones and Riddick \(1952\)](#) when they extracted organochlorine pesticides from animal and plant

tissue and dairy products using acetonitrile as an organic extraction solvent and detected the pesticides from the extracts by colorimetry. Paul Mills at the U.S. Food and Drug Administration (FDA) applied the procedure to extract and isolate pesticides from fruits and vegetables and detected the pesticides by thin-layer chromatography (Mills, 1959) and later, gas chromatography-microcoulometric detection (Mills et al., 1963). Typically, these procedures involve extracting the food sample with acetonitrile, partitioning with petroleum ether and a sodium chloride saturated solution, cleaning up on a florisil column with an eluting solvent, and removing the excess solvent using steam and a Kundera-Danish concentrator. Over the years, pesticide sample preparation methods were modified as new pesticides, such as organophosphorus pesticides, pesticides containing heteroatoms such as nitrogen, sulfur, and oxygen, and pesticides with different chemical and physical properties, were added to the multiresidue procedures. Acetone, ethyl acetate, and methanol have been used instead of acetonitrile as alternative extraction solvents. In the 1970s, FDA replaced acetonitrile with acetone as the extraction solvent, followed by a dichloromethane/petroleum ether partitioning and various extract cleanup strategies using adsorption column chromatography (florisil) or solid-phase extraction cartridges (using modified silica and later polymer-based particles crosslinked with octadecyl C18-linked ligands) allowing pesticide detection using gas chromatography equipped with element selective (nitrogen-phosphorus, flame photometric, electron capture, electroconductivity) (Luke et al., 1975, 1981). Ethyl acetate was another extraction solvent which was popularly used for gel permeation chromatography clean-up procedures to remove lipids and high molecular weight matrix components from the food extracts. These different procedures were modified over the years as GC-MS and LC-MS replaced GC and HPLC.

Anastassiades et al. (2003) evaluated the pros and cons of current sample preparation procedures for pesticides. They optimized certain steps which formed the basis of the Quick, Easy, Cheap, Effective, Rugged, and Safe (QuEChERS) procedure. This procedure streamlined acetonitrile-based extraction processes by using smaller sample sizes (i.e., from 50–100 g to 10–15 g), less solvent (50–100 mL to 10–15 mL), and simplified the extraction and cleanup steps so that each step is performed manually with 50 mL tubes and a centrifuge. Extraction and partition of pesticides from food into acetonitrile are enhanced by the addition of salts, initially anhydrous magnesium sulfate and sodium chloride. The preparation is simplified by using a clean-up step transferring the acetonitrile extract into a second centrifuge tube containing either one or more sorbents such as primary-secondary amine- (PSA) and octadecyl (C18)-linked silica or graphitized carbon that can remove matrix interfering components. The QuEChERS procedure is flexible and modular as many steps of the procedure can be modified, such as sample size, solvent volume, solvent choice, sorbent choice, and adopted for either GC-MS or LC-MS analysis. No longer are laboratories required to use large sample sizes or solvent volumes except for very unusual circumstances. This trend is being accelerated by the increasing sensitivity, simplicity and flexibility of GC-MS and LC-MS.

Many analytical and laboratory-based companies sell QuEChERS consumable products commercially that offer different variations of QuEChERS to allow the tailoring of the sample procedure to target specific pesticides and different food matrices. New sorbents such as carbon nanotubes (Abdulrauf and Tan, 2016; Qin et al., 2015), zirconia (Rajski et al., 2013), and polymers (Han et al., 2016) have been created to remove pigments, fats, lipids, and other matrix components that may interfere in the analysis of pesticides (López-Blanco et al., 2016; Parrilla Vázquez et al., 2016). As acetonitrile extraction procedures became optimized with QuEChERS, acetone- and ethyl acetate-based extraction procedures also underwent their own simplification and modification. Laboratories using acetone or ethyl acetate-based extraction procedures have shown that these methods demonstrate equivalency with QuEChERS over a large number of pesticides and range of food matrices, as well as with sample preparation time and consumable use (Lehotay et al., 2005; Pihlström et al., 2007; Uclés et al., 2014, 2017a,b; Lozano et al., 2016). The introduction of QuEChERS and other efficient sample preparation products and procedures have improved the preparation and analysis of pesticides and other non-polar analytes of importance in food and environmental analyses. Currently, QuEChERS and generic “dilute-and-shoot” procedures are the preferred approaches to analyze a wide variety of pesticides, chemical residues, and chemical contaminants in food for analysis by GC-MS and LC-MS (Romero-González et al., 2016). Table 1 lists some sample preparation procedures for pesticide analysis they have been simplified and amenable to both GC-MS and LC-MS analysis using QuEChERS or modified or simplified versions of previously developed methods using the commonly used extraction solvents acetonitrile, acetone, and ethyl acetate.

### From GC to GC-FS-MS to GC-MS/SIM to GC-QqQ-MS/MS

During the 1980s, GC-MS was used to compliment established gas chromatography instruments equipped with element selective detection such as electron capture (ECD), nitrogen-phosphorus (NPD), flame photometric in phosphorus and sulfur mode (FPD-P, FPD-S), electrolytic conductivity (ELCD), and halogen selective (XSD) detectors that were selective for specific heteroatoms present in pesticides such as chlorine, bromine, nitrogen, phosphorus, and sulfur. As the technology matured and improved, costs became affordable. Eventually GC-MS transitioned into the sole and dominant instrument for analyzing pesticide residues. During the same time, the replacement of packed glass columns with capillary columns became commercially available in the 1970s and 1980s offering improved separations and chromatographic resolution. Improvements in chromatography and mass spectrometry, as well as instrument availability and cost, accelerated its use in pesticide analysis.

The commercialization of the quadrupole mass spectrometer in the 1970s led to the use of mass spectrometry as the major detector for pesticide analysis used today. The quadrupole mass filter (QMF) was relatively simple and inexpensive to manufacture over other mass spectrometers, such as sector and time-of-flight instruments (Sparkman et al., 2011). The quadrupole mass

**Table 1** LC-MS/MS and GC-MS/MS procedures using a single multiresidue pesticide procedure for fresh produce

Sample preparation procedure				LC-MS/MS				GC-MS/MS				Reference
Procedure	Extraction solvent	Partition solvent	Clean-up	LC column (cm × mm × μm)	Mobile phase	LC run time	No of pesticides by LC-MS/MS	GC column (m × mm × μm)	Injection mode	GC run time	No of pesticides by GC-MS/MS	
Mini-Luke	Acetone	Petroleum ether/ Dichloromethane	None	C18 (10 × 2.1 × 1.7)	MeOH/H <sub>2</sub> O/AF	10 min	109	VF-5MS (30 × 0.25 × 0.25)	PTV/LVI	21.34	71	Dutch mini-Luke method ( <a href="#">EURL-FV, 2014-M12</a> )

spectrometer consists of four parallel rods aligned to form a circular or hyperbolic cross section. It is a scanning mass analyzer that uses the stability of ion trajectories in oscillating electric fields to select and separate ions according to their mass-to-charge ratios ( $m/z$ ). A positive and negative direct current (DC) potential and an alternating radiofrequency (RF) potential is superimposed on each rod pair. This RF voltage causes the ions to spiral as they traverse through the quadrupole toward the detector. The DC and RF potentials are adjusted to allow ions of a given  $m/z$  ratio to remain stable within the rods and pass through to the detector, while others are ejected. To acquire a mass spectrum, the DC and RF potentials must be ramped in a constant ratio across a specified range (Mellon, 2003; Niessen and Correa, 2017).

Quadrupole mass spectrometers typically operate in either full scan (FS) or selected ion monitoring (SIM) modes. In GC-full scan-MS mode (GC-FS-MS), charged ions are monitored over a large  $m/z$  range giving a complete spectrum of electron impact (EI) mass fragments formed in the source. In SIM mode (GC-MS/SIM), a finite number of specific ions are selected and measured. The advantage of operating in full scan mode is that identification of the pesticide of interest can be determined by comparing the mass spectrum obtained from the sample to a reference mass spectrum of the pesticide. Full scan analysis includes comprehensive MS libraries of many chemical compounds and software algorithms to match spectra and deconvolute spectra by removing interfering peaks and subtracting the background (Ueno et al., 2008; Ragnar Norli et al., 2010). There are full scan MS databases available that contain thousands of reference compounds such as the one developed by the National Institute of Standards and Technology (NIST). Used in conjunction with software tools and algorithms, experimental MS spectra for an unknown can be rapidly screened and matched to an MS spectrum for a reference compound. One of the first demonstrations of GC-MS for pesticide analysis was performed by Stan (1989, 2000), whose work demonstrated that identification of pesticides using GC-FS-MS and GC-MS/SIM could be achieved by probability-based matching using the NIST database. Major disadvantages of the GC-FS-MS approach are that full scan screening procedures lack the higher sensitivity of SIM due to scanning over a full  $m/z$  range in the presence of the sample matrix and matching criteria between experimental and reference spectra could be complicated limiting confident identification. Additionally, GC-FS-MS is not effective to detect pesticides at the default tolerances, with limits of quantitation greater than the 0.01 ppm level.

A more popular approach is to use GC-MS/SIM for the analysis of pesticides because of the increased sensitivity to measure at the parts-per-billion (ppb) level. The current identification criteria for GC-MS/SIM is better defined due to the limited mass information collected. In SIM, a focused scan range permits only the ions that are characteristic of the pesticide to be selected, increasing the dwell time and thereby the sensitivity of the targeted analyte. Identification using GC-MS/SIM is achieved by providing typically three or four characteristic ions of the pesticide analyte with ion ratios in an acceptable range, typically  $\pm 30\%$  relative or  $\pm 10\%$  absolute. These criteria ranges have been established by governing agencies such as European Food Safety Agency (2017) and the U.S. Food and Drug Administration (2012). One of the first comprehensive works that included a validated sample preparation method and utilized GC-MS/SIM for instrumental analysis of pesticides was performed by Fillion et al. (1995) of Health Canada. The sample preparation procedure involved an acetonitrile salt-out extraction with sodium chloride of the pesticides from the food matrix, followed by clean-up of the acetonitrile extracts using solid-phase extraction using tandem primary-secondary amine-linked silica (PSA) and graphitized carbon black sorbents column cartridges. The analysis was performed using GC-MS/SIM using two injections to cover 199 pesticides, each run requiring approximately 65 mins. Identification was achieved by the presence of quantitation and qualification ions at defined retention times and ion ratio tolerances. This work represented one of the first multiresidue methods for pesticide analysis solely utilizing mass spectrometry detection for both quantitation and identification. The method developed by Fillion et al. (1995, 2000) is the basis for procedures used by other organizations and laboratories (Japan Department of Food Safety Ministry of Health, Labour and Welfare; Pang et al., 2006, 2015). Other stand-alone GC-MS/SIM procedures soon followed based on varying extraction solvents and clean-up procedures (Mercer and Hurlbut, 2004; Ueno et al., 2004; Mercer, 2005). Many of these procedures are still being used today.

The quadrupole ion trap (QIT) mass analyzer was commercially available in the 1980s and evaluated for pesticide analysis. In a three-dimensional (3D) ion trap, RF and DC potentials are applied to oscillate ions at a secular frequency and selectively eject ions into the detector (Lacorte et al., 2015; Niessen and Correa, 2017). This analyzer employs the same principles as the quadrupole analyzer mentioned above, as it uses a RF only electric field for the storage and scanning of ions by  $m/z$  ratios. One of the benefits of the ion trap is its capability of performing tandem (MS/MS) and MS<sup>n</sup> experiments. One of the earlier applications of the ion trap was performed by Cairns et al. (1993) who analyzed fresh produce extracts prepared by the Luke Method in both FS and SIM mode for over 245 pesticides. Schachterle et al. (1994) demonstrated collision-induced dissociation steps by GC-QIT-MS/MS to study malathion in an orange extract. Hirahara et al. (2006) evaluated 200 pesticides in various crops at 0.01 mg/kg, determined recoveries in the range 50%–150% for 194 pesticides, and found that identification could be better achieved by GC-MS/MS rather than GC-MS/SIM.

The use of gas chromatography-tandem mass spectrometry (GC-MS/MS) has shown to improve the selectivity to the analytes, reduce the background, and increase the sensitivity. Multiresidue pesticide analysis by ion trap MS/MS tends to be slower than triple quadrupoles for selected reaction monitoring (SRM) acquisition, requiring more time to complete a SRM event per scan cycle due to the necessity of ion storage. GC-QqQ-MS/MS using a triple quadrupole platform operating in SRM or MRM mode proved to be much more efficient for multi-residue methods. As the name suggests, the original triple quadrupole mass analyzer consisted of “three” quadrupoles arranged in series after the source, the first of which selects the precursor ion, a second which functions as a collision cell using an energetic, inert gas such as nitrogen or argon, and a third quadrupole to filter selected fragment or product ions for detection (Yost and Enke, 1979). Modern triple quadrupole instruments consist of a dedicated collision cell instead of a second quadrupole to provide better collision efficiencies, improved electronics to increase scanning speeds, and faster computers

that can process data acquisition. GC-QqQ-MS/MS provides improved selectivity and sensitivity for target pesticides by selecting specific precursor-to-product ion transitions that reduce contributions from matrix background and other co-eluting and isobaric analytes.

GC-QqQ-MS/MS has replaced GC-MS/SIM due to compound selectivity resulting in less interference of co-eluting chemical components from a complex food matrix and superior signal-to-noise allowing for lower limits of detection and quantitation. Garrido-Frenich et al. (2005) demonstrated the use of GC-QqQ-MS/MS for the screening, identification, and quantitative analysis of 130 pesticides. Samples were prepared using a simple method procedure by extracting/homogenizing the food sample with ethyl acetate, filtering through anhydrous sodium sulfate, and solvent exchanging to cyclohexane. A 11.6 min GC temperature program using one MS/MS transition was used for screening step. Any presumptive pesticide positive would require a second GC-MS/MS analysis consisting of two or three MS/MS transitions for confirmation and quantitation. Current GC-QqQ-MS procedures can achieve screening, identification, and quantification in one determinative step. A review on the role of GC-QqQ-MS/MS in pesticide residue analysis in food and environment matrices by Hernández et al. (2013) provides several examples and references that reveal improvements in methods performance in comparison to traditional GC and GC-MS approaches. GC-QqQ-MS/MS has been used to analyze a large number of pesticides in fresh produce (Okiihashi et al., 2007; Pihlström et al., 2007; Wong et al., 2010; Hakme et al., 2018; Lozano et al., 2016; Lee et al., 2017; Khan et al., 2018), dried botanical supplements (Hayward et al., 2013), spices (Ahammed Shabeer et al., 2018), and tea (Hayward et al., 2015; Pang et al., 2015; Chang et al., 2016).

Studies by Portolés et al. (2010, 2012a,b) and Cherta et al. (2013) evaluated the use of chemical ionization (APCI) instead of the traditional electron impact ionization (EI) to generate intact molecular ions in GC-QqQ-MS/MS. EI (70 eV) tends to be excessive which may result in extensive fragmentation of the pesticides that will compromise selectivity, sensitivity, and identification (Portolés et al., 2012a,b). Existing chemical ionization (CI) methods in both positive and negative (PCI, NCI) modes for GC-MS analysis involve introducing an energetic gas such as ammonia, methane or isobutane to induce fragmentation have been previously investigated for pesticides (Biros et al., 1972; Dougherty et al., 1972). However, CI is not frequently used in multi-residue pesticide procedures because it is not as universal as EI and requires different modes (positive and negative CI) and multiple injections to cover a wide range of pesticides (Alder et al., 2006). APCI, a softer form of ionization used in LC-MS, was coupled a GC-QqQ-MS instrument to evaluate a wide range of pesticides in food samples and compared to results generated by GC-EI-QqQ-MS/MS (Portolés et al., 2012a,b). Of the pesticides studied, the molecular ion could not be generated using EI but the APCI source generated  $M^+$  and/or  $[M+H]^+$  ions. The use of GC-API-QqQ-MS/MS allowed for more selective and sensitive transitions in SRM mode using  $[M+H]^+$  as a precursor ion and could further expand the use of GC-MS applications to pesticide analysis.

### Liquid Chromatography-Triple Quadrupole Tandem Mass Chromatography (LC-QqQ-MS/MS)

Liquid chromatography (LC) was primarily used for the analysis of carbamate insecticides that involved liquid chromatographic separation, followed by post-column derivatization, and the fluorogenic derivatives were analyzed by fluorescence detection (Moye and Scherer, 1977). The pesticides that are used today have replaced their more toxic predecessors and are designed to be more species specific, less persistent, and are designed to degrade to less toxic by-products in the environment. Most of these pesticides also tend to be thermally-labile and not amenable to the elevated temperature conditions used in GC and GC-MS analysis. Additionally, many current target pesticides do not possess significantly unique chromophores that can be spectrophotometrically detected. While the majority of pesticide laboratories transitioned directly to LC-QqQ-MS/MS, single quadrupole and ion trap mass analyzers were also explored. Single quadrupole mass analyzers were limited in identification of pesticides in complex matrices. The major disadvantage of the early LC-QIT-MS/MS systems was that quantitation could be challenging due to the limited dynamic range especially in the presence of sample matrix (Soler et al., 2005). Despite limited selectivity, one advantage of LC-MS applications was that the intact molecular adduct in the form of  $[M+H]^+$ ,  $[M+NH_4]^+$ ,  $[M-H]^-$ , could be detected unlike in GC-MS with electron impact (EI) ionization. LC-MS typically uses electrospray ionization (ESI) in both positive and negative modes to generate the formation of precursor ions  $[M+H]^+$ ,  $[M+NH_4]^+$ , and  $[M-H]^-$ , based on the atomic composition and properties of the pesticide. However, other related ionization sources such as atmospheric pressure chemical ionization (APCI) and atmospheric pressure photoionization (APPI) have been used in limited studies (Takino et al., 2004; Yoshioka et al., 2004).

The work of Klein and Alder (2003) was one of the first to successfully demonstrate the use of LC-QqQ-MS/MS for the determination of 108 pesticide analytes, of which 98 and 10 pesticides were analyzed by positive and negative electrospray ionization mode, respectively. The sample procedure utilized a methanol extraction, clean-up of the aqueous methanol extract using a diatomaceous earth (ChemElut) column, elution of the pesticides from the column with dichloromethane, and evaporation and filtration of the extract into a vial for LC-QqQ-MS/MS analysis. Recoveries at the 10 µg/kg (ppb) level in a variety of produce matrices were in the 70%–120% range with a relative standard deviation  $\leq 25\%$ . This seminal paper also provides criteria to optimize the triple quadrupole analyzer by establishing the optimal collision energies to generate the most intense precursor-to-product transition ions, assessing the magnitude of matrix effects, and demonstrating the applicability of LC-MS/MS for multiclass pesticide analysis. In a 2006 review, Alder et al. (2006) evaluated the selection of pesticides or classes of pesticides that would optimally be determined either by GC-MS (or GC-MS/MS) or LC-MS/MS. Although the authors realized no one technique is capable of analyzing the more than 860 active substances used in pesticide formulations, an evaluation of approximately 500 pesticides (e.g., organophosphorus, carbamate, organochlorine, sulfonylurea, triazole, triazine, urea, pyrethroid, aryloxyphenoxy propionate, aryloxy alkanolic acids, and other non-classified pesticides) revealed 135 and 47 of those that could not be detected by GC-MS and LC-MS,

respectively. However, 33 of the 47 pesticides that were not detected by LC-MS/MS were organochlorine pesticides, many of which are legacy compounds and are no longer being registered for use as pesticides. Many of the pesticides that are not amenable to GC-MS analysis tend to be thermally unstable and are at risk of decomposing due to the heated conditions of the GC inlet and column oven. For all compounds that are analyzed by both GC-MS and LC-MS, better performance of LC-MS/MS was typically observed and attributed to larger injection volumes and sample capacity in LC-MS instruments.

Since the work of Klein and Alder (2003), LC-QqQ-MS/MS or hybrid quadrupole-ion trap (LC-QqIT-MS/MS) tandem mass spectrometry has been the primary procedure used by many laboratories to perform multiresidue analysis for pesticides in a variety of food matrices. Due to the declined use of chlorinated pesticides and the increased use of thermally-labile pesticides, LC-MS has overtaken GC-MS as the primary instrument for pesticide analysis. Although QuEChERS is probably the most popular method used to prepare the food matrices for extracts, other procedures that had origins from GC and GC-MS procedures have been modified for LC-MS analysis (EURL-FV(2010-M1), EURL-FV (2010-M4), EURL-FV (2014-M12), Pang et al., 2006, Payá et al., 2007).

### Future Status of MS: High Resolution MS (GC-HRMS, LC-HRMS)

Although tandem mass spectrometry in GC-QqQ-MS/MS and LC-QqQ-MS/MS provides nearly unambiguous identification of pesticides in foods, its shortcomings did not go unrecognized as laboratories began to evaluate high resolution mass spectrometry with applications for full scanning analysis as possible complements or replacements to triple quadrupole platforms. Chromatography coupled to tandem mass spectrometry is a targeted and optimized procedure for quantitation and identification in multiresidue pesticide analysis but it requires *a priori* knowledge of the pesticide such as retention time, collision energies, and product ions. Chromatography-HRMS shows potential as a screening procedure and/or an alternative quantitative procedure to LC-QqQ-MS/MS with comparative sensitive to quadrupole mass analyzers. Full scan HRMS workflows do not require retention time and compound-specific MS parameters, except in data processing, allowing data to be re-evaluated for retrospective analysis. The high resolving power that allows accurate mass assignments is a main advantage of these mass analyzers. The IUPAC definition of resolution is defined as  $m/\Delta m$ , where  $m$  is the mass of an individual ion of interest and  $\Delta m$  is the width of the individual peak (Niessen and Falck, 2015). Resolution allows for increased confidence of identification of the pesticide analytes by improving the quantitative mass accuracy, and therefore, assists in providing structural assignments and fragmentation of product ions. Another important term associated with HRMS is resolving power, which determines the separation required between two Gaussian peaks at their apices,  $m_1$  and  $m_2$ , expressed as the peak width in mass units (Niessen and Falck, 2015). Mass resolving power is defined as  $m_1/(m_1 - m_2)$  in relation to mass,  $m_1$ . High resolution mass spectrometry can distinguish ions with the same nominal mass but with different elemental compositions (isobaric ions), measure the exact monoisotopic mass and the isotopic mass distribution (due to the isotopic contributions of the atoms, i.e.,  $^{12}\text{C}$ ,  $^{13}\text{C}$ , and  $^{14}\text{C}$ ), determine elemental composition, and provide structural elucidation of the chemical of interest.

HRMS mass analyzers provide mass accuracy as co-eluting compounds can be discriminated and measured to the 0.0001 amu and can therefore provide more definitive information for structure assignments of precursor and product ions. Early research on TOF and QTOF mass analyzers and the commercial availability of the benchtop Orbitrap in the last decade accelerated interest in the use of HRMS as a complement to LC-QqQ-MS/MS or as a standalone platform to screen for less frequent pesticides, pesticide metabolites, degradation products, and other co-residues and contaminants in the same food matrix. Development of qualitative screening methods can streamline the laboratory approaches to identify unwanted and undesirable chemicals in food products by minimizing the quality control measurements that are associated for quantitative analysis (Mainero Rocca et al., 2017). The design between the two mass analyzers, time-of-flight and orbitrap, are based on two entirely different physical principles. Further detailed descriptions are provided by Radionova et al. (2016), Boesl (2017) for the TOF, and Perry et al. (2008), Zubarev and Makarov (2013) for the Orbitrap, respectively, and the review by Kaufmann and Teale (2017) provides a detailed description of the advantages and disadvantages of both high resolution mass analyzers. Both GC- and LC-HRMS procedures for multiresidue pesticides procedures for fresh produce using TOF and Orbitrap platforms, have been thoroughly investigated and evaluated as indicated in Table 2. Most of the sample preparation procedures used were based on QuEChERS and the number of pesticides increased when a hybrid instrument (Q-TOF, QOrbitrap) was used for the analysis.

### GC-TOF-MS and GC-Q-TOF-MS Pesticide Analysis

Time-of-flight (TOF) mass analyzers determine the  $m/z$  of ions based on the time ions travel and separate from each other in a field-free region (flight or drift tube) under the influence of an electric field as they reach the detector (Lacorte et al., 2015). TOF instruments are commonly manufactured with a reflectron, which is an ion optical devices that “reflects” or changes the direction of the ions which increases their path length and brings differing ion kinetic energies into phase before the ions enter the detector, allowing for increased separation and increasing resolution. The advantages of the TOF mass analyzer are its high scan and data acquisition rates which can acquire spectra at a faster rate (10–50 spectra/s) than other mass analyzers and generate high resolution spectra containing accurate mass measurements. Unit-resolution TOF also trades resolution for high acquisition rates (500 spectra/s) and gives linearity of four orders of magnitude (Hernández et al., 2011). The high acquisition rate is advantageous for characterizing narrow and sharp peak widths that are generated in capillary, high-speed, and comprehensive two-dimensional GC (GC×GC). A

TOF mass spectrometer provides sufficient acquisition rates capable of producing sufficient data points to define chromatographic peak shapes. GC×GC-TOF MS has been used for pesticide analysis in produce (Zrostlíková et al., 2003; Banerjee et al., 2008; Lehotay et al., 2011).

Early work on high resolution GC-TOF was evaluated for its sensitivity in full scan acquisition mode, resolving power, and accurate mass measurements (Leandro et al., 2007; Hernández et al., 2011). While these features are desirable, early TOF analyzers had limited dynamic range and resolution (~7000 full width at half mass, FWHM). Cajka and Hajšlova (2004), Cajka et al. (2008) were one of the first groups to analyze pesticides using GC-TOF-MS and found that most of the pesticides could be detected below 10 µg/kg and demonstrating performance characteristics, such as mass accuracy and pesticide detectability, exceeding those performed by other conventional mass analyzers. Cervera et al. (2012) evaluated a GC-TOF-MS for 55 pesticides for targeted and non-targeted analysis of pesticides in fruits and vegetables. QuEChERS extracts of various food matrices were analyzed in full scan mode and the most abundant ion was used as the quantitation ion while the other diagnostic ions were used for confirmation. The recoveries were between 70%–120% and precision < 20% but only half the pesticides could be validated at the 0.01 µg/kg level. Hayward and Wong (2009) compared the performances of GC-TOF-MS (resolving power of ~6000 at  $m/z$  200 and mass accuracy of 5 ppm) and GC-MS-SIM methods of 170 pesticides in ginseng root extracts and found that there were no significant differences in the concentrations or geometric limits of detection (LODs) measured for pesticides in commercial ginseng roots using either of the two techniques.

Increased resolution and the addition of a quadrupole improved the instrument performance for GC-QTOF-MS analysis. Portolés et al. (2010) and Zhang et al. (2014) developed methods to screen and identify more than 100 pesticide residues in fresh produce using GC-QTOF-MS/MS. Portolés et al. (2010) expanded their work from QqQ to QTOF using an atmospheric pressure ionization (API) source rather than the highly fragmented EI ionization source to generate molecular ions while in the Zhang et al. (2014) study, a screening workflow for screening and analyzing pesticides was developed that included a retention time index, accurate mass full scan MS database, and MS/MS identification. A database or library is a collection of reference retention times and exact masses of ions from MS and MS/MS scans for each pesticide that can be used to search, retrieve, and match the experimental data. This workflow involved full scan screening to search for 165 pesticides by chemical formula match and MS/MS identification of the product ion using accurate mass measurement. Over 80% of pesticides at 5 ng/mL or lower concentrations could be confirmed in each matrix using at least two representative ions with their response ratios from the MS spectra. In Portolés et al. (2010), a list of 100 GC-amenable pesticides including organochlorine, organophosphorus and organonitrogen compounds, were evaluated using the API source. The addition of water as a modifier was tested to promote the generation of protonated molecules and revealed that screening could be easily performed with this source by investigating the presence of the protonated molecule ion  $[M+H]^+$ . The developed procedure was applied to pesticide screening in different food samples and has allowed the presence of several pesticides to be confirmed such as chlorpyrifos ethyl, deltamethrin and endosulfan sulfate. The results shown by both research groups revealed the promising use and application of GC-API-QTOF-MS, high resolution MS/MS experiments, and mass spectra libraries/database to better and rapidly identify detected pesticide residues in complicated food matrices.

### GC-Orbitrap MS and GC-QOrbitrap-MS for Pesticide Analysis

Recently, GC-EI-QOrbitrap MS and GC-EI-Orbitrap MS became commercially available a decade after the deployment of LC-Orbitrap systems (Peterson et al., 2010, 2014). Mol et al. (2016) first evaluated the GC-EI-QOrbitrap MS for pesticide residue analysis in fruits and vegetables prepared by QuEChERS. The instrument performed in full scan mode with a resolving power of 60,000 and achieved a mass accuracy within  $\pm 2$  ppm over a wide concentration range. Sufficient LOD/Qs  $\leq 0.5$  pg in produce matrices, a wide concentration range (up to 5 orders of magnitude), acceptable recoveries 70%–120% and repeatability (RSD  $\leq 10\%$ ), and good matching against NIST reference library were observed. Tienstra and Mol (2018) further extended the study to effectively analyze pesticides and polychlorinated biphenyls in cereals and feed ingredients. Lozano et al. (2018) evaluated the GC-EI-QOrbitrap for the identification and quantitation in multiresidue pesticide analysis of baby foods in full scan mode. Their results were similar to those produced by Mol et al. (2016) and identification was determined by retention time and the presence of two diagnostic product ions with a mass accuracy  $\leq 5$  ppm and signal-to-noise ratio of the peaks  $\geq 3$ . GC-EI Orbitrap MS was determined to be suitable for GC-MS applications and an alternative to GC-QQQ-MS/MS. However, since EI is the only ionization source available for the QOrbitrap, the excessive fragmentation from EI limits its potential and MS/MS capabilities.

### LC-TOF-MS and LC-QTOF-MS

One of the first LC-HRMS procedures for pesticide analysis was performed by Ferrer and Thurman (Ferrer et al., 2005, 2006; Thurman et al., 2006) who developed a multiresidue method utilizing LC-TOF-MS for the analysis of several classes of pesticides in water and vegetable samples. In-source fragmentation was used to generate one and two fragment ions for 96 and 49, respectively, of the 101 pesticides studied. Quantitation of water and produce samples was determined using matrix-matched calibration curves with correlation coefficients  $\geq 0.99$  or higher and the average instrument limits of detection (LODs) in the presence of the matrix was  $\sim 3$  µg/kg. Pesticides with higher LODs tend to be halogenated consisting of Br, Cl, and F (e.g., bromoxynil, captan,

chlorpyrifos-methyl, fluoroacetamide, fluoroxypry, spiromefesin, teflubenzuron, and trifluralin). The strength of the study pertains to the determination of high mass accuracies of the product ions which can be used to deduce the structure of the fragment ions, and how this information can be useful for identification. The approach by Ferrer et al. was also used by other groups to screen pesticides in fruit and vegetable commodities as listed in [Table 2](#).

As in the case of GC-MS, the addition of a quadrupole in a hybrid QTOF mass analyzer can significantly improve screening applications. An example of a screening and identification procedure using LC-QTOF-MS was developed by [Pang et al. \(2018\)](#) to evaluate 485 pesticides in fruits and vegetables. An accurate mass database based on retention times and accurate masses of the precursor using LC-TOF-MS in full scan mode and an MS/MS spectral library based on the product ions using reference standards was developed by LC-QTOF-MS/MS. The screening process was established and mass deviation, retention time assignments, and ionization was optimized improving the accuracy of the screening procedure and reducing the rates of false-positive and false-negative results. The screening procedures were applied to over 12,500 samples of fruit and vegetable samples throughout the country over a four-year survey.

### LC-Orbitrap-MS and LC-QOrbitrap-MS

The Orbitrap is composed of a spindle-shaped central electrode and a barrel-shaped outer electrode ([Perry et al., 2008](#); [Eliuk and Makarov, 2015](#)). From the ion source, ions traverse through a series of optical lens and stages of differential pumping to achieve a low vacuum environment and are transferred into a curved RF-only trapping quadrupole known as the C-trap ([Bateman et al., 2009](#)). Ions are injected from the C-trap through additional stages of differential pumping into the Orbitrap, where a mass spectrum is acquired by image current detection. The injected ions orbit the central electrode and oscillate along the horizontal axis at frequencies related inversely to the square root of  $m/z$ . A Fourier transformation (FT) translates this frequency into  $m/z$  values and their amplitudes into intensities. The longer the transient signal is recorded, the higher is the resolution of the mass spectrum obtained. The FT of a transient signal yields results in a highly-resolved, accurate-mass Orbitrap mass spectrum. The QOrbitrap consists of a quadrupole mass filter followed by a high-energy collision dissociation (HCD) cell used to induce fragmentation of selected precursor ions prior to mass analysis by the Orbitrap.

When the LC-Orbitrap MS became commercially available approximately 10 years ago, several groups began its evaluation of its feasibility for pesticide analysis ([Alder et al., 2011](#); [Hayward et al., 2011](#); [Mol et al., 2012](#); [Rajski et al., 2014](#)). [Alder et al. \(2011\)](#) assessed the sensitivity to be sufficient to screen for pesticides prepared from a QuEChERS procedure in full scan mode. [Mol et al. \(2012\)](#) investigated the use of the LC-full scan HRMS and all-ion fragmentation (AIF) for qualitative screening for a test set of 130 pesticides spiked in commodities at 10, 50 and 200  $\mu\text{g/kg}$ , prepared using QuEChERS without cleanup, using a database of 556 pesticides in 21 fruit and vegetable commodities. Detection was based on the extraction of the exact mass at  $\pm 5$  ppm and  $\pm 30$  s of the major precursor and diagnostic ions. [Rajski et al. \(2017\)](#) confirmed the work of [Mol et al. \(2012\)](#) by evaluating QuEChERS extracts of plant foods and determined that a resolution of 35,000 and 70,000 was sufficient for the analysis of pesticides in fruits and vegetables.

Although the hybrid ion trap-orbitrap mass spectrometer had been available for some time, the commercialization of the QOrbitrap mass analyzer was of tremendous interest for pesticide analysis and was studied by several groups ([Jia et al., 2014](#); [Wang et al., 2014](#)). One of the first comprehensive studies utilizing LC-QOrbitrap MS was performed by [Wang et al. \(2014\)](#). Pesticides were extracted from samples using the QuEChERS procedure. LC-ESI-Q-Orbitrap MS in full MS scan mode, and LC-ESI QOrbitrap Full MS/dd-MS/MS (i.e., data-dependent scan mode) obtained product ion spectra for identification. LC-ESI-QOrbitrap MS quantification was achieved using matrix-matched standard calibration curves along with the use of isotopically-labeled standards or chemical analogues as internal standards to achieve optimal method accuracy. The method performance characteristics include overall recovery, intermediate precision, and measurement uncertainty evaluated according to a nested experimental design. For the 10 matrices studied, 94% of the pesticides in fruits and 91% in vegetables had recoveries between 81%–110%, 99% of the pesticides in fruits and 99% of the pesticides in vegetables had an intermediate precision of  $\leq 20\%$ , and 97.8% of the pesticides in fruits and 96% of the pesticides in vegetables demonstrated measurement uncertainty of  $\leq 50\%$ . Overall, the LC-ESI-QOrbitrap MS demonstrated acceptable performance for the quantification of pesticide residues in fruits and vegetables. The LC-ESI-QOrbitrap Full MS/dd-MS/MS along with library matching shows great potential for identification and is being investigated further for routine practice.

### Pesticide Screening Using LC-HRMS

Much of the early work on pesticides using LC-HRMS tends to focus on single stage mass analyzers, consisting of either a TOF or Orbitrap. Although the single stage Orbitrap system consists of a multipole collision cell adjacent to the Orbitrap, known as an HCD cell to induce fragmentation, the system was limited to all-ion fragmentation (AIF) experiments. It was the introduction of hybrid instruments, particularly a QTOF or QOrbitrap mass analyzer that provided opportunities to perform targeted and non-targeted MS/MS data acquisition experiments such as data-dependent acquisition (DDA), and data-independent acquisition (DIA) ([Zhu et al., 2014](#); [Wang et al., 2016](#); [Renaud et al., 2017](#); [Rajski et al., 2017](#); [Rauniyar et al., 2017](#)). DDA (or dd-MS/MS discussed in the preceding section) involves an inclusion list of retention times and precursor ions and a narrow quadrupole isolation window of 1–4 Da. An MS/MS scan is triggered when a targeted precursor is detected above a defined intensity threshold. The result is a very selective MS/MS spectrum of the analyte with minimal interference from the matrix co-extractives ([Wang et al., 2016](#); [Rajski et al.,](#)

**Table 2** LC and GC methods coupled to high resolution mass spectrometry (HRMS)

GC-HRMS											
Commodity	Sample preparation	MS analyzer	Acquisition	Resolution	Pesticides	Column type Ionization (m × mm × μm)		Injection	Run time	Sensitivity	Reference
Fresh produce	ASE (EtOAc)/GPC clean-up	Quad-TOF	Full Scan and MS/MS	8500 (FWHM)	100	APCI	HP-5MS (15 × 0.25 × 0.25)	Splitless	45	> 10 μg/kg	Portolés et al. (2010)

2017). For a non-targeted procedure, DIA is often used where the entire mass range is divided into  $m/z$  isolation segments by the quadrupole. The quadrupole isolation window is opened to larger mass segments i.e., 25–100 Da and each mass window is subjected to fragmentation one segment at a time. AIF is the least selective mode of fragmentation because there is no quadrupole pre-selection involved as all ions undergo fragmentation, while DDA is the most selective and specific. DIA lies in between the other two modes, where the degree of selectivity is based on the width of the mass isolation windows.

The first demonstration of DIA was performed by Zomer and Mol (2015) using a non-targeted approach of data acquisition with fragmentation. Their non-targeted approach used a combination of a full-scan acquisition event followed with variable DIA (vDIA) MS/MS for screening applications. vDIA involves smaller isolation windows of 100  $m/z$  width for the mass range 100–500  $m/z$  and larger isolation windows of 500  $m/z$  for the range of 500–1000  $m/z$ .

Other laboratories (Rajski et al., 2017; Goon et al., 2018; Wang et al., 2017) have also used vDIA acquisition for pesticide screening. Wang et al. (2017) developed a target screening of 448 pesticide residues in fruits and vegetables using ultrahigh-performance liquid chromatography coupled with electrospray ionization quadrupole-Orbitrap high-resolution mass spectrometry (UHPLC-ESI-QOrbitrap) and a compound database (CDB). Their work, for the first time, described a procedure for the development of a CDB and its applications for target screening using LC/ESI QOrbitrap Full MS/dd-MS/MS and Full MS/DIA. They optimized screening applications by addressing in-spectrum mass correction, retention time alignment, and response threshold adjustment when building the CDB, which are critical parameters to minimize false negative/positive rates for routine screening. The validated target screening method is capable of screening at least 94% and 99% of 448 pesticides at 10 and 100  $\mu\text{g/kg}$ , respectively, in fruits and vegetables without having to evaluate every compound manually during data processing, significantly reducing the workload in routine practice. The advantage of DIA analysis is that the instrumental setup is very simple, no specific retention times and masses are required *a priori*, and the only scans required are mass ranges provided in the mass isolations windows. This makes DIA very manageable compared to DDA and provides better specificity than AIF.

## Conclusions

Current instruments are more sensitive and improved than their predecessors but there are existing problems regarding matrix effects with GC-MS and LC-MS. Ion suppression is a problem for LC-MS because matrix components tend to compete with the pesticide for charge in the ion source. Matrix enhancement in GC-MS is a common observation because the enhanced analyte signal is a result of the co-extractives in the matrix (as opposed to a calibration standard prepared in solvent) protecting the analytes of interest in the heated regions (i.e., liner) of the gas chromatograph. These matrix effects on GC-MS and LC-MS systems require the use of matrix-matched calibration standards or the method of standard addition for quantitation. In addition to the instrument itself, improvements in sample preparation has also evolved and this will continue.

GC-MS was the primary instrument for the analysis of pesticides, but because many of the pesticides that were compatible for GC and GC-MS analysis are no longer in use and are being replaced by less toxic and persistent pesticides that also tend to be thermally-labile, they are more suited for LC-MS analysis. Although there are advances in GC-MS instruments, such as APCI interfaces for providing less fragmentation compared to electron impact ionization and other mass analyzer platforms such as high speed TOF for multidimensional gas chromatography (GC $\times$ GC-TOF MS), high resolution TOF, QTOF, Orbitrap, and QOrbitrap mass analyzers, the number of pesticides primarily used for GC-MS analyzers is becoming smaller compared to the increasing number of pesticides analyzed by LC-MS procedures.

The use of GC-QqQ-MS/MS and LC-QqQ-MS/MS tend to be the current standard of analyzing pesticides because both identification and quantitation can be achieved in a single injection. These techniques are sensitive enough to detect most of the pesticides at the default tolerances or assigned limit of quantitation. Criteria for the identification of pesticides have been well studied and established and are based on MS/MS results. Sample preparation procedures for multipesticide analysis have evolved and have become streamlined and less complexed due to the introduction and continual use of mass spectrometry. Recent interest in chromatographic methods coupled to HRMS platforms forecasts a future where these instruments may play an important role in screening. Screening tends to require less validation than quantitative methods but requires the use of robust software tools, compound databases, and mass spectral libraries that can search for more pesticides as well as other residues and chemical contaminants, toxins, and important chemical analytes. The use of compound databases and/or libraries can reduce the need to have available pesticide standards that are needed for targeted GC-MS/SIM, GC-MS/MS or LC-MS/MS methods.

### Glossary

The Glossary below is mainly taken from Regulation EC (No) 1107/2009 and from the European Commissions' webpage ([https://ec.europa.eu/food/plant/pesticides\\_en](https://ec.europa.eu/food/plant/pesticides_en))

**Authorisation of a plant protection product** An administrative act by which the competent authority of a Member State authorises the placing on the market of a plant protection product in its territory.

**Competent authority** Any authority or authorities of a Member State responsible for carrying out the tasks established under this Regulation.

**Environment** Waters (including ground, surface, transitional, coastal and marine), sediment, soil, air, land, wild species of fauna and flora, and any interrelationship between them, and any relationship with other living organisms.

**Good Agricultural Practise (GAP)** The nationally recommended, authorised or registered safe use of plant protection products under actual conditions at any stage of production, storage, transport, distribution and processing of food and feed.

**Harmful organisms** Any species, strain or biotype belonging to the animal kingdom or plant kingdom or pathogenic agent injurious to plants or plant products.

**Maximum residue level (MRL)** Highest level of a pesticide residue that is legally tolerated in or on food or feed when pesticides are applied correctly (Good Agricultural Practice).

**Metabolite** Any metabolite or a degradation product of an active substance, safener or synergist, formed either in organisms or in the environment. A metabolite is deemed relevant if there is a reason to assume that it has intrinsic properties comparable to the parent substance in terms of its biological target activity, or that it poses a higher or comparable risk to organisms than the parent substance or that it has certain toxicological properties that are considered unacceptable. Such a metabolite is relevant for the overall approval decision or for the definition of risk mitigation measures.

**Micro-organisms** Any microbiological entity, including lower fungi and viruses, cellular or non-cellular, capable of replication or of transferring genetic material.

**Pesticide** Something that prevents, destroys, or controls a harmful organism ("pest") or disease, or protects plants or plant products during production, storage and transport. The term includes, amongst others: herbicides, fungicides, insecticides, acaricides, nematocides, molluscicides, rodenticides, growth regulators, repellents, rodenticides and biocides. They are primarily used in the agricultural sector but also in forestry, horticulture, amenity areas and in home gardens.

**Plants** Live plants and live parts of plants, including fresh fruit, vegetables and seeds.

**Plant products** Products of plant origin in an unprocessed state or having undergone only simple preparation, such as milling, drying or pressing, but excluding plants.

**Plant protection products** "Pesticides" that protect crops or desirable or useful plants.

**Producer** A person who manufactures plant protection products, active substances, safeners, synergists, co-formulants or adjuvants on his own, or who contracts this manufacturing to another party, or a person designated by the manufacturer.

**Residues** One or more substances present in or on plants or plant products, edible animal products, drinking water or elsewhere in the environment and resulting from the use of a plant protection product, including their metabolites, breakdown or reaction products.

**Substances** Chemical elements and their compounds, as they occur naturally or by manufacture, including any impurity inevitably resulting from the manufacturing process.

**Tests and studies** Investigations or experiments whose purpose is to determine the properties and behaviour of an active substance or of plant protection products, predict exposure to active substances and/or their relevant metabolites, determine safe levels of exposure and establish conditions for the safe use of plant protection products.

**Vulnerable groups** Persons needing specific consideration when assessing the acute and chronic health effects of plant protection products. These include pregnant and nursing women, the unborn, infants and children, the elderly and workers and residents subject to high pesticide exposure over the long term.

**Zone** A group of Member States as defined in Annex I Regulation (EC) No 1107/2009; Zone A – North (Denmark, Estonia, Latvia, Lithuania, Finland, Sweden); Zone B – Centre (Belgium, Czech Republic, Germany, Ireland, Luxembourg, Hungary, Netherlands, Austria, Poland, Romania, Slovenia, Slovakia, United Kingdom); Zone C- South (Bulgaria, Greece, Spain, France, Italy, Cyprus, Malta, Portugal).

## Legal Basis of the Evaluation of Active Substances of Plant Protection Products in the EU

The term “pesticides” is commonly used broader than “plant protection products” (PPP) and covers also products such as biocides. In this article the terms “pesticides” and “PPP” are used as synonyms, and do not refer to biocides.

In the EU the evaluation of a new active substance, amendment or renewal of approval of an active substance, that can be used in plant protection products follows a comprehensive process with different responsibilities for risk assessors in the European Union Member States (MS) and the European Food Safety Authority (EFSA), and risk managers in the European Commission (EC) and EU MS. The respective legislative process and procedure is outlined in the “General Food Law”, Regulation EC (No) 178/2002 (EU, 2002) and specific pesticide Regulations such as Regulation (EC) No 1107/2009 (EU, 2009) related to new active substances, and in the Commission Implementing Regulation EU 844/2012 (EU, 2012a) for the renewal of approval of active substances. Regulation EU 686/2012 (EU, 2012b) provides information on the evaluation of active substances whose approval will expire between 1 January 2013 and 31 December 2018. Commission Implementing Decision 2016/C 357/05 (EU, 2016a) and Regulation EU 2016/183 (EU, 2016b) allocates MS for the evaluation of active substances which approval will expire between 1 January 2019 and 31 December 2021.

Special provisions for approval apply for basic substances, which are, generally speaking “*active substances, not predominantly used as plant protection products such as beer, fructose or sodium chloride, but which may be of value for plant protection and for which the economic interest of applying for approval may be limited*” as outlined in Art. 23 of Regulations (EC) No 1107/2009 (EU, 2009).

## The Process of the Evaluation

The process starts with a data package provided by an applicant such as a producer who wishes to receive authorisation for a new active substance or renewal of approval of an active substance, with the submission of an application to a MS, called the rapporteur MS (RMS). The RMS carries out an admissibility check of the application. If the application is admissible, the RMS notifies the applicant, the other MS, the EC and EFSA. The RMS prepares a draft assessment report (DAR) for new active substances, or - for renewal of approval - a renewal assessment report (RAR). During this process, the RMS can request additional studies or information to the applicant. The DAR/RAR provides an assessment if the active substance can be expected to meet the approval criteria. This report is submitted to the EC and EFSA. It should be noted that there is a common structure of the DAR agreed by the EU. For basic substances the dossier is sent directly to the EC, which sends a mandate to EFSA. EFSA carries out an independent scientific review to ensure consistency in the evaluation. This process is also called “peer review process” and comprises the following steps:

1. Commenting: EFSA makes the summary dossier and the DAR/RAR available to the public, all MS, EC, ECHA, and the applicant, and invites all to submit comments on the DAR/RAR during a 60 day period. EFSA also comments on the DAR/RAR. The RMS collates the comments in a table.
2. Consideration of the comments: EFSA invites the RMS to address the comments and the applicant has the possibility to react. In addition, EFSA can ask the applicant to submit additional information to MS, EC, and EFSA during a maximum period of 90 days. The need for additional information is identified between EFSA, EC and RMS.
3. Expert meeting: If needed, EFSA organises expert consultation meetings in the different disciplines, e.g. toxicology, residues, ecotoxicology with MS experts, including the RMS. The outcome of the meeting is summarized in a report.
4. Drafting of the EFSA conclusions: EFSA has to adopt within 120 days - or 150 days if there is an expert consultation meeting - after the commenting period a conclusion whether the active substance can be expected to meet the approval criteria. The MS receive the final draft conclusion for written consultation before the adoption by EFSA. The EFSA conclusion is the conclusions of the peer-reviewed assessment, identifies data gaps, issues which could not be finalised and critical areas of concern. It may include options for risk mitigation measures.

To ensure the same level of protection for humans, animals and the environment, the approval or non-approval is done at EU level. On the basis of the EFSA conclusion the EC prepares a proposal for approval or non-approval of an active substance. A committee comprising MS representatives, called the Standing Committee on Plants, Animals, Food and Feed (PAFF), votes on the EC proposal. The final legislative decision whether or not to approve the active substance is published in the EU Official Journal. This information is also available in the EU pesticide database of active substances. This database is kept regularly updated and contains also information on EU pesticides maximum residue levels (MRLs) (link provided under Chapter “relevant websites”). A new active substance is usually approved for 10 years, while an application for renewal of approval can be granted for up to 15 years. The whole process can vary greatly, depending on the complexity of the dossier, and may take between 2.5 and 3.5 years.

## The Application

The application consists of a summary and a dossier, and provides information on i) the intended use of the active substance, which must be representative, this means used on a widely grown crop, in each geographical area (zone), ii) the amount to be applied to protect the crop, as well as iii) the pesticide residue level remaining on the crop after such application (EU, 2009). In addition, the dossier contains the respective scientific information and the results of tests and studies, in line with the regulatory data requirements (see Chapter 1.3). In addition, the dossier must contain scientific peer-reviewed open literature related to the active substance

and its relevant metabolites providing information on possible side-effects on human and animal health, the environment and non-target species.

A similar procedure needs to be followed when the authorisation of a PPP is asked by an applicant to a MS (EU, 2009). Under EU law, MS are responsible for the evaluation and authorisation of the use of an active substance-based formulation only if the pesticide active substance is on the EU list, although MS have the possibility for exceptional authorisations of products containing non-approved substances. Applications are assessed and approved by the national authority where they are submitted. For pesticide authorisation, the EU is split into three zones: North, South and Centre where countries with similar agricultural, plant health and environmental conditions are grouped together. When a pesticide is authorised for use in one MS, its use could be also allowed in other MS of the same zone. This process is called mutual recognition.

### Data Requirements for Active Substances

For new or renewal of approvals of active substances which expired on 1 January 2016 or later, the data requirements are outlined in Commission Regulation (EU) No 283/2013 (EC, 2013a), commonly referred to as “new data requirements”. A high-level overview of the data requirements, meaning what type of information needs to be provided in the dossier by the applicant is outlined below, according to the Annex to Commission Regulation (EU) No 283/2013.

- Identity of the active substance
- Physical and chemical properties of the active substance
- Further information on the active substance (e.g. use, function, mode of action)
- Analytical methods
- Toxicological and metabolism studies
- Residues in or on treated products, food and feed
- Fate and behaviour in the environment
- Ecotoxicological studies
- Literature data
- Classification and labelling

Furthermore, specific guidance documents and test methods based on international or European standards for the areas mentioned above are available to assist applicants and risk assessors. They are summarized in the EU notice (EC, 2013c), or - if developed after 2013 - available on the Website of the Directorate General SANTE (link provided under Chapter “relevant websites”). Guidance documents can be developed by EFSA, are published on the Authority’s Website, and may be adopted by MS representatives in PAFF, e.g. the EC guidance on the assessment of exposure of operators, workers, residents and bystanders in risk assessment for plant protection products (EFSA, 2014; EC, 2017). As long as an EFSA guidance document is not adopted by PAFF, e.g. guidance on risk assessment on bees (EFSA, 2013), or guidance on the establishment of the residue definition for dietary risk assessment (EFSA, 2016), it is not formally applicable.

For the data requirements for active substances which approval expired before 1 January 2016, transitional measures apply as stated under Article 3 (active substances) and 4 (plant protection products) of Commission Regulation (EU) No 283/2013 (EC, 2013a). Within this context, reference to Commission Regulation (EU) No 544/2011 (EU, 2011a) for active substances and Commission Regulation (EU) No 545/2011 (EU, 2011c) for plant protection products, the so called “old data requirements” is made. The EC guidance document on the interpretation of transitional measures for the data requirement for active substances and plant protection products according to Regulation (EC) No 283/2013 and Regulation (EC) No 284/2013 provides further details (EC, 2015).

The above is relevant for active substances, however it should be noted that the “new” data requirements for plant protection products are available in Regulation (EU) No 284/2013 (EU, 2013b) and the specific guidance documents and test methods are summarized in an EU notice (EC, 2013d). The “old data requirements” for plant protection products are outlined in Commission Regulation (EU) No 545/2011 and in the EC guidance document on the interpretation of transitional measures for the data requirements for active substances and plant protection products according to Regulation (EC) No 283/2013 and Regulation (EC) No 284/2013 (EC, 2015). In addition, MS have to perform the assessment in line with the “Uniform Principles for the Evaluation and the Authorisation of Plant Protection Products” adopted by Commission Regulation (EU) No 546/2011 (EU, 2011b).

### Risk Assessment of Active Substances

The objective of the risk assessment of an active substance is to evaluate the safety of an active substance and its residues, this means assessing if the active substance has any harmful effect on human and animal health, including those on vulnerable groups or any unacceptable effects on the environment. This is done by concluding whether the active substance can be expected to meet the approval criteria, which are outlined in Article 4 of Regulation (EC) No 1107/2009 (EU, 2009). This is a stepwise approach by first establishing if the active substance or renewal of approval of an active substance fulfils first the approval criteria related to genotoxicity, carcinogenicity, reproductive toxicity and fate and behaviour as outlined under 3.6.2 to 3.6.4 and 3.7 of Annex II of Regulation (EC) No 1107/2009 (EU, 2009). If these criteria are satisfied the assessment shall continue to establish whether the other approval criteria set out in points 2 and 3 of Annex II are satisfied. Point 3.6.5 outlines the criteria related to endocrine disrupting properties. It

should be noted that on 12 December 2017 the measures concerning specific scientific criteria for the determination of endocrine disrupting properties proposed by the EC were agreed with a qualified majority by PAFF, and subsequently adopted by the EC. These measures will be published in the EU Official Journal in 2018.

The EFSA conclusion is the conclusion on the peer-reviewed assessment (EFSA, 2016).

Appendix A of the EFSA conclusion contains a “list of end points” for an active substance and the representative formulation, listing the agreed end points of studies submitted in support of the application.

## **Legal Basis of Pesticides Residues in Food and Feed**

Pesticides or plant protection products - when applied to plants or plant products - might leave traces, which are called pesticides residues. However, as outlined in Article 4, 2a, and 2b of Regulation (EC) No 1107/2009 (EU, 2009), residues of plant protection products “shall not have any harmful effects on human health, including that on vulnerable groups, or animal health, taking into account known cumulative and synergistic effects where the scientific methods accepted by the Authority [EFSA] to assess such effects are available, or on groundwater” and “they shall not have any unacceptable effect on the environment”.

Regulation (EC) No 396/2005 establishes the rules governing the setting and the review of pesticide maximum residue levels (MRLs) at European level (EU, 2005). In the EU the highest legally permitted amount of pesticides on food or feed when applied correctly, meaning according to the “Good Agricultural Practice”, is called the maximum residue level (MRL). The amounts of residues in food must be as low as possible, in view to protect consumers and vulnerable groups such as children and the unborn. If there is no specific MRL set, a default value of 0.01 mg/kg is applicable. In the EU, MRLs apply to products of plant and animal origin and parts thereof and listed in Annex I of Regulation (EC) No 396/2005 to be used as fresh, processed and/or composite food or feed in or on which pesticide residues may be present. Annex I comprises MRLs on around 315 fresh and processed products of different pesticides (app. 1100) which are used in the EU and Third countries, and which are recorded in the database of pesticides EU MRLs, published on the Website of the Directorate General SANTE (link provided under Chapter “relevant websites”) in the EU pesticides database, and are regularly updated. EU MRLs are also applicable to food imported into the EU.

## **The Process of Setting MRLs**

The MRL setting is a comprehensive process with different responsibilities for risk assessors in the European Union Member States (MS) and the European Food Safety Authority (EFSA), and for risk managers in the European Commission (EC) and the MS. The respective legislative process is outlined in specific Regulations, such as Regulation (EC) No 1107/2009 and in particular in Regulation (EC) No 396/2005 (EU, 2005). If the intended use of the pesticide requires an amendment of the existing MRL set out in Regulation EC 396/2005, the details are outlined under Article 6 to 11 of Regulation (EC) No 396/2005. The process to modify the MRL starts with an application which needs to be submitted by the applicant to a MS, called evaluating MS (EMS). The EMS prepares an initial risk assessment and an “evaluation report (ER)”. This report is reviewed by EFSA. EFSA issues the outcome in a “reasoned opinion”. MS and EC decide whether to accept the proposed MRL, and if so, the MRL is listed in Annex II (new MRL) or Annex III (modified MRL) of Regulation (EC) No 396/2005. Following this, the MS can authorise the pesticide. A MRL application may also be submitted by importers in case the legal limits need to be revised for food produced in third countries that is intended for the EU market.

In addition, EFSA is asked to carry out a review of all existing MRLs 12 months after the inclusion or non-inclusion of an active substance in Annex I to Directive 91/414/EEC. Under Directive 91/414/EEC, only a few representative uses were evaluated, whereas MRLs set out in Regulation (EC) No 396/2005 (EU, 2005) have to accommodate all uses authorised within the EU, and uses authorised in third countries that have a significant impact on international trade. EFSA developed the Pesticide Residues Overview File (PROFile) which is an inventory of all pesticide residue data relevant to the risk assessment and MRL setting for a given active substance. The PROFile provides data on the nature and magnitude of residues in primary crops; processed commodities; rotational crops; livestock commodities; and the analytical methods for enforcement of the proposed MRLs. The process is slightly different to the one outlined above on modification of MRLs. The RMS submits to EFSA the PROFile and the ER, and during a completeness check period, MS can submit additional information. Based on this overall information, EFSA prepares a draft reasoned opinion, circulates the reasoned opinion for written comments to MS. EFSA considers these comments during the finalisation of the reasoned opinion. In 2016, the EC published a guidance document on the MRL setting procedure aiming to providing clarity on the various steps involved in the procedure, on the timelines and on specific circumstances related to the MRL setting process (EU, 2016c). Since spring 2017 this procedure was slightly revised to gain efficiency. The first review using this new procedure is related to the review of existing MRLs for glyphosate, which will be published by EFSA beginning 2018.

## **Data Requirements for Pesticide Residues**

The date of submission of the application to the EMS determines which data requirements and guidance documents are applicable. This could be either the “new data requirements” outlined in Commission Regulation (EU) No 283/2013 (EU, 2013a) or the “old data requirements” outlined in Commission Regulation (EU) No 544/2011 (EU, 2011a) (see also Chapter 1.3). The data requirements which are applicable in the transitional period of “new” and “old” data requirement are provided in the EC guidance document on

the interpretation of transitional measures for the data requirements for active substances and plant protection products according to Regulation (EC) No 283/2013 and Regulation (EC) No 284/2013 (EC, 2015), respectively. In addition, the assessment is performed in accordance with the legal provisions of the Uniform Principles for the Evaluation and the Authorisation of Plant Protection Products (EU, 2011b).

To assist applicants and risk assessors, specific technical guidelines are available and are outlined under Chapter 1.3 related to the “new” data requirements. The guidance documents related to “old data requirements” established in Regulation (EU) No 544/2011 (EC, 2011a) are published on the Website of the Directorate General SANTE (link is provided under “relevant websites”) and refer for example to metabolism and distribution in plants (EU, 1997a), general recommendations for the design, preparation and realisation of residue trials (EU, 1997b), testing of plant protection products in rotational crops (EU, 1997c), processing studies (EU, 1997d), metabolism and distribution in animals (EU, 1997e), storage stability studies (EU, 1997f), and MRL plant calculator EU-OECD (OECD, 2011).

### The Risk Assessment of Pesticide Residues

EFSA carries out a risk assessment based on the toxicological reference values (acute reference dose and/or acceptable daily intake) for the active substance, and the expected exposure of consumer groups including e.g. children and vegetarians, based on the residues expected in food. EFSA uses the Pesticide Residue Intake Model, called PRIMo, which includes national food consumption data and unit weights provided by MS, to estimate the chronic (long-term) and acute (short-term) dietary consumer exposure to pesticide residues. A new version (rev.3) of PRIMo was released at the beginning of 2018. The risk assessment, including the MRL proposals, is presented in “reasoned opinions” and may be approved by the EC and MS. The reasoned opinions need to provide information whether the analytical method for routine monitoring is appropriate, the anticipated LOD for the pesticide/crop combination, and an assessment of the risk for exceeding the acceptable daily intake or acute reference dose in light of the modification of the MRL, the contribution of the residues in the product for which the MRL was requested to the overall intake. The most critical information is provided in a list of end points annexed to the reasoned opinion. It provides information on the studies assessed by EFSA in the framework of the EU pesticides peer review, including the end points of studies submitted in support of the current MRL application.

### Monitoring of Plant Protection Products

Inspection services in MS verify if the residues in the food comply with the legal limits, i.e. the EU harmonised MRLs as laid down in Regulation (EC) 396/2005. According to Article 31 of Regulation (EC) No 396/2005, MS are requested to share the results of the official controls and other relevant information with the EC, EFSA and the other MS. Specialised laboratories test more than 700 pesticides in around 370 food products/food groups and more than 20 million individual data are reported to EFSA. This data is summarized on an annual basis in the EU pesticide monitoring report, as laid down in Article 32 of Regulation (EC) No 396/2005. EFSA also carries out a dietary exposure assessment. EU risk managers, the EC and MS use this data to e.g. carry out a review of existing MRLs, or enhance future monitoring programmes. The latest results from the 2015 EU report on pesticide residues in food demonstrated that 97% of 84,000 samples were compliant with the legal limits, the respective MRLs (EFSA, 2017).

### Urgent Scientific Advice

Under specific circumstances, the EC can also ask urgent scientific advice to EFSA in case there are questions related to the potential health risk due to the presence of e.g. elevated levels of an active substance in food. For example, this was the case in 2009 where the presence of nicotine in wild mushrooms of up to 0.5 mg/kg was identified. EFSA carried out a risk assessment by estimating the short and long-term dietary exposure to nicotine compared to the derived health based guidance values, the acute reference dose, and the acceptable daily intake. Based on the scientific advice by EFSA, risk managers were able to take measures to allow the placing on the markets of dried mushrooms from the 2008 season, provided that they are safe for EU consumers (EFSA, 2009).

# Polycyclic Aromatic Hydrocarbons in Food and Feed

Thomas Wenzl and Zuzana Zelinkova, European Commission, Joint Research Centre, Geel, Belgium

© 2019 Elsevier Inc. All rights reserved.

## General

Depending of the area of work and the closely-linked number of markers used to estimate the polycyclic aromatic hydrocarbons (PAHs) content in different matrices, many people tend to limit their thoughts to one to 16 compounds. In fact, PAHs constitute a whole class of substances of fused aromatic rings, which are composed of carbon and hydrogen atoms only. PAHs are ubiquitous, semi-volatile substances. They originate from natural and anthropogenic sources. Natural sources for PAH emissions could be forest, bush-, and prairie fires, or volcano eruptions (Manzetti, 2013). Anthropogenic sources comprise domestic and industrial combustion processes, aluminium and coke production, crude oil spills, as well as exhausts of all kinds of combustion engines (Achten and Hofmann, 2009; Djinojic-Stojanovic et al., 2013; Mastral and Callen, 2000). High molecular weight PAHs may be formed during catalytic hydrocracking of petroleum or may be found amongst others in coal tar pitches, carbon black, or Diesel particulate matter (Fetzer, 2007; Alegbeleye et al., 2017). Rubber debris of wheels of cars and trucks containing carbon black are another source for the release of PAHs into the environment. The European Environment Agency (EEA) reported for the period of 1990 to 2011 a decrease of PAH emissions in EU by 58%. The total release of PAHs in 27 EU Member States was in 2011 still almost 1100 t, which however is an underestimation due to the limitations in the number of PAHs covered and gaps in reporting (Schindlbacher et al., 2013).

The formation reactions of PAHs depend on the type of fuel and reaction conditions (Richter and Howard, 2000). Mechanisms governing the formation of aromatic compounds in differently fuelled flames were reviewed elsewhere (Richter and Howard, 2000). The pattern of PAHs and derived indices are often used to conclude on their origin (Stogiannidis and Laane, 2015).

The higher the molecular mass of PAHs becomes, the lower is their water solubility and the higher their octanol/water partition coefficient, indicating increasing unpolarity. The simplest PAH is naphthalene, containing two fused aromatic rings. The International Union for Pure and Applied Chemistry (IUPAC) developed a harmonised system for denominating PAHs (International Union, 1998; Ehrenhauser, 2015). However, it did not find full acceptance, which is reflected in scientific literature by the preferred use of common names for denoting PAHs rather than employing IUPAC terminology. An overview of IUPAC and alternative names was presented by the US National Institute of Standards and Technology (NIST), which compiled the structures, names, CAS numbers and some physical data of 660 PAHs (Sander and Wise, 1997). This report evolved to a free accessible online database (NIST PAH Database, 2015).

Large PAHs are of less importance in the food area. The largest compounds that were monitored so far in a wider range of food are dibenzopyrenes, which consist of six fused benzene rings. However, their content in food is usually very low. More abundant are in food PAHs with lower molecular weight.

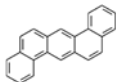

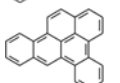

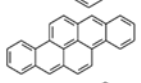

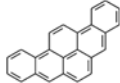

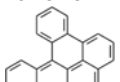

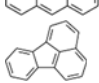

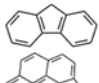

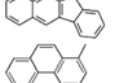

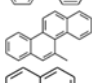

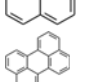

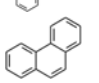

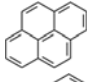

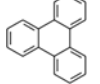

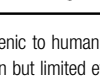

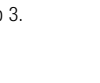

In addition to the terrestrial research on PAHs, it shall be mentioned that PAHs are common and abundant compounds in space (Boersma et al., 2013).

## Toxicology of PAHs

Despite not knowing the compounds, first observations of the carcinogenicity of PAHs were made end of the 18th century by Sir Percival Pott, who linked scrotal cancer of young chimney sweepers to the exposure to soot (Earl, 1819). Later it was proven by experiment that PAHs contained in soot were responsible for the cancer. The acute toxicity of PAHs is low. However, metabolic activation to form di-epoxides, radical cations, or o-quinones may lead to the formation of stable DNA adducts, which might initiate both mutations and cancer (Xue and Warshawsky, 2005; Ewa and Danuta, 2017). The metabolism and toxicology of PAHs, and their risk to human health were assessed and reviewed by several authors and international organizations, such as the Scientific Committee on Food (SCF), the FAO/WHO Joint Experts Panel on Food Additives (JECFA), the International Agency for Research on Cancer (IARC), and the European Food Safety Authority (EFSA) (European Community, 2002; Xue and Warshawsky, 2005; International Agency, 2010, 2012; Joint FAO/WHO Expert Committee, 2006; Culp et al., 1998; Rota et al., 2014; Koganti et al., 2001; European Food Safety Authority, 2008). The IARC assessed the carcinogenicity of 60 PAHs and several occupations involving coal derived PAHs. It concluded that different occupational exposures, such as during coal gasification, are carcinogenic to humans (International Agency, 2010). Additionally it identified benzo[a]pyrene as Group 1 carcinogen (carcinogenic to humans), and some other 16 PAHs as Group 2A (3 substances) respectively Group 2B (13 substances) carcinogens, which indicate probably, and respectively, possibly carcinogenic to humans (International Agency, 2010). The majority of evaluated PAHs were not classifiable as to their carcinogenicity to humans, which was frequently caused by the lack of adequate data. Details on composition of sets of PAHs assessed by the different expert panels and the outcome of the assessment are provided in Table 1.

**Table 1** Assessment of PAHs by different expert panels and composition of different priority lists

IARC classification: group 1 = carcinogenic to humans, group 2A = probably carcinogenic to human, group 2B = possibly carcinogenic to humans, group 3 = not classifiable as to carcinogenicity to humans.

G: genotoxic, nG: not genotoxic; GC: genotoxic and carcinogenic; i: included in evaluation but limited evidence or not conclusive data; na: not assessed; nr: included in evaluation, but not rated; x: included in list; = : identical with common name.

<sup>a</sup>IARC evaluation comprised additional, not listed PAHs, which were classified into group 3.

## Exposure to PAHs

For humans, different routes of exposure to PAHs were identified and extensively studied. They comprise inhalation, ingestion and skin contact. More than 500 native, alkylated, and partially hydrated PAHs were described in main stream cigarette smoke (Rodgman and Perfetti, 2006). Inhalation of combustion products and uptake via food are the primary routes of exposures to PAHs for non-smokers. The relative contribution of one or the other route cannot be generalized, as the exposure depends both of the place of residence and of eating habits. Environmental exposure to PAHs is higher in large cities and highly industrialized areas than in rural areas (Zhang and Chen, 2017; Cachada et al., 2016; Lambert et al., 2012). Also the uptake of PAHs by migration from plastic and rubber materials of consumer products through skin contact cannot be neglected (Bokkers et al., 2016). The potential leaching of PAHs from toys into the saliva of infants led to the setting of restrictive measures (European Union, 2013).

However, both JECFA and EFSA concluded that the major route of exposure of humans to PAHs is food (Joint FAO/WHO Expert Committee, 2006; European Food Safety Authority, 2008). EFSA calculated a median dietary exposure to BaP and the 4 EU marker PAHs (PAH4, see Table 1) for the mean European dietary consumer of 3.9 ng/kg body weight per day (bw/d) and 19.5 ng/kg bw/d respectively, resulting in margins of exposure (MOEs) of 17900 and 17500 respectively (European Food Safety Authority, 2008). As both MOEs were significantly above the threshold value of 10000, EFSA concluded a low concern for consumer health. The MOEs for high dietary consumers were close or even below the MOE threshold, raising potential concern for consumer health. Australia concluded for the local population that the exposure to PAHs from food is of low health concern (MOEs > 10000) and does not justify legal action. Similar was the outcome of the second French total diet study, which revealed for French consumers a low health risk from the dietary exposure to PAHs (Santonicola et al., 2017a). However, this study was performed after the EU implemented stringent maximum levels (Yu et al., 2011). Scientific literature contains besides these favourable findings also reports on the average dietary exposure of large populations to BaP amounting to about twice the median European level (Cai et al., 2012).

Exposure to PAHs, respectively to their metabolites, occurs already prenatal and continues postnatal via intake from the air and human breast milk (Perera et al., 2005; Urbancova et al., 2017; Pulkrabova et al., 2016; Santonicola et al., 2017a; Yu et al., 2011; Loutfy et al., 2017).

PAHs are not equally distributed in the diet. Certain food products bear higher risk of contamination than others. Details on the potential PAH content of food commodities such as edible oils, meat and fish, vegetables, spices and herbs, food supplements, and other relevant food products are presented further down.

## Monitoring and Maximum Levels

The interpretation of data on the PAH content of different matrices such as soil, water, air, and food is complicated by the disagreement of the composition of the sets of PAHs studied in the different areas (Wenzl et al., 2006). One has to understand that each combination of PAHs was established with a certain aim, and none of them can be used to fully picture the exposure to PAHs. However, the kind and number of monitored PAHs is in some areas more of historical relevance than founded on current requirements (Keith, 2015; Andersson and Achten, 2015). The continued monitoring of the so called 16 EPA PAHs in food, a set of 16 PAHs that was prioritized end of the 1970s by the US Environmental Protection Agency (EPA) may be mentioned in this context, as only part of them were identified as of major concern for human health (Joint FAO/WHO Expert Committee, 2006; Keith, 2015). Toxicological evaluations by JECFA and the SCF led in the EU to the establishment of a list of 16 priority PAHs, which were classified carcinogens (European Union, 2005; European Community, 2002; Joint FAO/WHO Expert Committee, 2006). For reasons of distinction from the 16 EPA PAHs, they are frequently denominated as 15+1 EU priority PAHs. An overview of the composition of the priority lists is given in Table 1.

Differences exist also in the evaluation and interpretation of analytical data. Some countries, such as EU member states favour evaluation of exposure based on individual substances, or combinations thereof (European Union, 2011). Among these countries, differences exist in the number of marker substances used to represent the overall exposure to PAHs, which is indicated by differences in the number of regulated PAHs (Table 2). Studies revealed that BaP alone is not a good indicator for exposure to PAHs as it was absent in many samples containing other PAHs. A set of four PAHs, consisting of BaP, BaA, BbFA, and CHR, was found more representative for the overall PAH content of food (European Food Safety Authority, 2008). Consequently, maximum levels (MLs) were set in the EU for the sum of these four PAHs in addition to the MLs for BaP alone (Table 2) (European Union, 2011, 2015a, 2015b).

Other countries such as Australia, Canada and the USA use toxic equivalency factors (TEFs) to estimate the potential threat brought by PAHs contained in certain food product to human health (Food Standards, 2004). The latter system works in analogy to the one established for chlorinated dibenzo-p-dioxines and dibenzofurans. However, expert panels contested the suitability of TEFs in the area of PAHs in food due to the lack of oral toxicity data of individual PAHs, and differences in the mode of action (Joint FAO/WHO Expert Committee, 2006; European Food Safety Authority, 2008). Canada is the only of the three before mentioned countries that set maximum levels based on toxic equivalents (TEQ), particularly for olive pomace oil. Toxic equivalents represent the concentration of a certain PAH in a food product corrected with the corresponding TEF.

**Table 2** Maximum levels for PAHs in food in EU and other jurisdictions

			Maximum levels [ $\mu\text{g/kg}$ ]	
Foodstuffs			BaP	Sum of BaP, BaA, BbFA and CHR
European Union	6.1.1	Oils and fats (excluding cocoa butter and coconut oil) intended for direct human consumption or use as an ingredient in food	2.0	10.0
	6.1.2	Cocoa beans and derived products	5.0 $\mu\text{g/kg}$ fat	30.0 $\mu\text{g/kg}$ fat as from 1.4.2015
	6.1.3	Coconut oil intended for direct human consumption or use as an ingredient in food	2.0	20.0
	6.1.4	Smoked meat and smoked meat products	2.0 as from 1.9.2014	12.0 as from 1.9.2014
	6.1.5	Muscle meat of smoked fish and smoked fishery products, excluding fishery products listed in points 6.1.6 and 6.1.7. The maximum level for smoked crustaceans applies to muscle meat from appendages and abdomen. In case of smoked crabs and crab-like crustaceans it applies to muscle meat from appendages.	2.0 as from 1.9.2014	12.0 as from 1.9.2014
	6.1.6	Smoked sprats and canned smoked sprats (25) (47) ( <i>Sprattus sprattus</i> ); Smoked Baltic herring $\leq 14$ cm length and canned smoked Baltic herring $\leq 14$ cm length (25) (47) ( <i>Clupea harengus membras</i> ); Katsuobushi (dried bonito, <i>Katsuwonus pelamis</i> ); bivalve molluscs (fresh, chilled or frozen) (26); heat treated meat and heat treated meat products (46) sold to the final consumer	5.0	30.0
	6.1.7	Bivalve molluscs (smoked)	6.0	35.0
	6.1.8	Processed cereal-based foods and baby foods for infants and young children	1.0	1.0
	6.1.9	Infant formulae and follow-on formulae, including infant milk and follow-on milk	1.0	1.0
	6.1.10	Dietary foods for special medical purposes intended specifically for infants	1.0	1.0
	6.1.11	Cocoa fibre and products derived from cocoa fibre, intended for use as an ingredient in food	3.0	15.0
	6.1.12	Banana chips	2.0	20.0
	6.1.13	Food supplements containing botanicals and their preparations	10.0	50.0
		Food supplements containing propolis, royal jelly, spirulina or their preparations		
	6.1.14	Dried herbs	10.0	50.0
	6.1.15	Dried spices with the exception of cardamom and smoked <i>Capsicum</i> spp.	10.0	50.0
Peoples Republic of China		Paddy, wheat	5.0	
		Smoked or baked meats	5.0	
		Smoked or baked aquatic products	5.0	
		Fats and oils, and fat emulsions	10.0	
Russian Federation		Vegetable oils – all types, vegetable oil fractions	2	
South Korea		Edible oil	2.0	
		Sukjihwang & gunjihwang	5.0	
Canada		Olive pomace oil	3 $\mu\text{g/kg}$ TEQ <sup>a</sup>	
Hong Kong		Edible oils [also applies to edible fats]	10 $\mu\text{g/kg}$ <sup>b</sup>	
Brazil		Olive oil	2.0 $\mu\text{g/kg}$

### Analytical Methods to Determine PAHs in Food and Feed

Analytical methods for the determination of PAHs were developed already long before the publication of the US EPA's priority list. However, their number increased rapidly after this milestone was set, focusing further mainly on the 16 prioritised PAHs. The number of published analytical methods is enormous. A search in Scopus(R), using the terms "PAH" and "analytical method"

resulted in more than 570 hits. A detailed discussion of these publications would go far beyond the length and scope of this manuscript. Therefore, only the overall concepts of analytical methods for the determination of PAHs in food are presented, omitting a systematic discussion of their pros and cons. The latter information can be found in several review papers, which focus on different matrices and analytical techniques (Moret and Conte, 2000; Plaza-Bolaños et al., 2010; Purcaro et al., 2013; Wise et al., 2015; Bansal et al., 2017; Buczyńska et al., 2013; Wenzl et al., 2006).

The development of analytical methods for the determination of PAHs in food has to respect the particular properties of the targeted analytes and of the matrix. Robustness of the method and potential for automatization are as well important aspects.

It is necessary to separate PAHs from the food matrix prior to measurement by either gas chromatography or liquid chromatography. A difference in performance of one or the other with regard to accuracy of results was not observed (Sykes et al., 2013). Both separation techniques may be combined for PAH analysis with different detection systems. Single quadrupole gas chromatography mass spectrometry (GC-MS) and high performance liquid chromatography with fluorescence detection (HPLC-FD) were for decades the methods of choice. Few laboratories applied gas chromatography high resolution magnetic sector mass spectrometry for the determination of PAHs in food (Simon et al., 2008; Ziegenhals et al., 2008a). The advancement of mass spectrometry combined with increased affordability of instruments led in the last decade to the broad application of tandem mass spectrometers combined with both gas chromatography (GC-MS/MS) and ultra-performance liquid chromatography (UPLC-MS/MS) (Veyrand et al., 2007). Gas chromatography time of flight mass spectrometry (GC-TOF) and GC-quadrupole TOF (GC-QTOF) mass spectrometers are employed for PAH analysis only in special cases, as the detection systems of TOF mass spectrometers are not yet as sensitive as those of (tandem-) quadrupole mass spectrometers (Drabova et al., 2012). However, modern GC-MS instruments are sufficiently sensitive for the implementation of current legislation on PAHs contents of food. A further improvement of the detectability of PAHs is therefore considered of rather low priority.

Measurements by GC electron ionisation mass spectrometry suffer from the high stability of the condensed aromatic ring systems, resulting in poor analyte fragmentation. The low informative value of EI mass spectra requires good chromatographic separation of isobaric species, as co-elution could lead to wrong peak assignment and consequently wrong conclusions. Despite improvements in GC column technology, it is not yet possible to baseline separate all critical pairs, such as TRI and CHR, within one run (Gómez-Ruiz and Wenzl, 2009; Bordajandi et al., 2008).

Whereas EI is the preferred ionisation method for all gas chromatographic mass spectrometric measurements, dopant assisted atmospheric pressure photo ionisation (APPI) is applied in place of electro spray ionisation (ESI) in the measurement of PAHs by LC-MS/MS (Itoh et al., 2006; Hollosi and Wenzl, 2011). However, at present PAHs are rarely analysed by LC-MS/MS in routine, which is probably due to the need of higher investment in instrumentation, limited applicability of the APPI source, and risk for quick deterioration of instrument performance due to matrix deposition on the lamp. Experiences from 12 proficiency tests on the determination of the 15+1 EU priority PAHs, respectively the 4 EU marker PAHs, in various food showed that HPLC-FLD is suitable for the determination of almost all PAHs in most of the studied matrices. CPP cannot be detected by FD due to the absence of fluorescence. Also complex matrices such as cocoa products and black pepper posed problems to laboratories applying HPLC-FD.

As in all chemical analyses, sample preparation and measurement must be dovetailed and optimised for obtaining high quality results. In PAH analysis, the lipophilicity and volatility of PAHs are directly affecting the design of analytical methods. The high volatility of two- and three ring PAHs might lead to losses during sample preparation, whereas the low volatility of six-ring and larger PAHs challenges the measurement by gas chromatography. Consequently, internal standardisation with, ideally, carbon 13 labelled PAH analogues is a prerequisite for achieving a high level of accuracy. Many food products containing potentially PAHs are rich in fat content. Thus for the analysis of these products it is necessary to separate PAHs from the fat fraction, as the latter interferes usually with chromatographic analysis. The initial separation from the matrix occurs in an extraction, respectively partitioning step. Solid food is extracted with an unpolar to mid-polar organic solvent or solvent mixture such as petrol ether, *n*-hexane, or a mix of *n*-hexane and acetone. The extraction step alone is usually not selective enough to provide extracts that can be injected into the measurement instrument. One or more clean-up steps are commonly integrated in the analytical procedure. Open column normal phase chromatography on silica, gel permeation chromatography, and/or solid phase extraction are traditionally applied clean-up techniques (Ziegenhals et al., 2008a; Veyrand et al., 2007). The downside of these techniques is the consumption of sometimes large amounts of organic solvents. Thus, more environmentally friendly methods were developed, which however might have a narrow scope, or whose method performance characteristics were sometimes inferior to those of traditional methods (Purcaro et al., 2007; Bansal et al., 2017).

Miniaturization was seen as a possibility of reducing the consumption of organic solvents, which however might put the representativeness of the analysed sample at stake. Attempts were also made to adapt the QuEChERS method, which is widely used for the determination of pesticides in fruits and vegetables, for PAH analysis (Anastassiades et al., 2003). The developed methods were applied for different fatty and non-fatty food items (Portolés et al., 2017; Urban and Lesueur, 2017).

Standardized analytical methods are available from different sources (Table 3). They are based on either HPLC-FD or GC-MS analysis and are applicable starting from edible oils up to a broad range of food. In addition to the international standards, analytical methods were validated by collaborative trial for the determination of PAH in certain food commodities (Simon et al., 2010; Mastovska et al., 2015).

Scientific literature did not yet report on non-chromatographic rapid analysis methods for the determination of PAHs in food in routine.

**Table 3** Standardised analytical methods for the determination of PAHs in food

	<i>Title</i>	<i>Analytical technique</i>	<i>Scope</i>	<i>PAHs covered</i>	<i>Working range</i>
ISO 15753:2016 <sup>a</sup>	Animal and vegetable fats and oils — Determination of polycyclic aromatic hydrocarbons	HPLC-FD	Animal and vegetable fats and oils Excluded: palm oil, olive pomace oil, and fat from milk and milk products	NA, AC, ACL, FL, AN, PHE, FL, CHR, BaA, PY, BaP, BbFA, BkFA, BghiP, DBahA, ICP	0.2–1.0 µg/kg
ISO 22959:2009	Animal and vegetable fats and oils – Determination of polycyclic aromatic hydrocarbons by on-line donor–acceptor complex chromatography and HPLC with fluorescence detection	HPLC-FD	Determination of polycyclic aromatic hydrocarbons (PAHs) in edible fats and oils. ## Occurrence of PAHs in Food

### Fats and Oils

Environmental contamination as well as production processes such as drying, grilling, roasting, and smoking can affect the contents of PAHs in food significantly. The lipophilicity of PAHs makes especial fatty food matrices prone to PAH contamination. No wonder that edible fats and oils belong to the most relevant food matrices in this respect and that maximum levels were set in different jurisdictions primarily for this food category. Environmental contamination is considered the main source for contamination with PAHs of virgin edible oils, presuming state of the art harvest and production processes are used (Rodríguez-Acuña et al., 2008). Failing to meet current standards, by e.g. exposing olives during harvest to exhausts of harvesting machines, or ventilating storage tanks with unfiltered ambient air might result in substantial increase of PAH contents. Application of special clays during the refining of crude fats and oils serve to reduce PAH content levels of highly contaminated batches (Hua et al., 2016). The collection of PAH occurrence data by EFSA revealed that 90% of the about 2000 fats and oil samples complied with the at that time applicable maximum level for BaP of 2.0 µg/kg (Fig. 1) (European Food Safety Authority, 2007). However, the compilation of notifications entered from January 2010 until March 2018 into the EU Rapid

**Figure 1** PAH contents compiled by EFSA for different food categories (European Food Safety Authority, 2007). n: indicates the number of samples used for the calculation of statistical descriptors.

**Figure 2** Levels of PAH contents of notification to the Rapid Alert System for Food and Feed over the period 2010 to 2018 (European Union RASFF). ◇: indicates BaP; △: indicates the sum of contents of BaA, BaP, BbFA, and CHR. Number within brackets indicates the number of notifications entered in RASFF for the particular food category, independent of the number/kind of PAHs concerned.

Alert System for Food and Feed (RASFF) reveals that elevated PAH levels can still be found in products intended for the market (Fig. 2) (European Union RASFF). The situation on other markets is similar to that in EU (Molle et al., 2017; Shi et al., 2016a; Tfouni et al., 2014; Jiang et al., 2015).

Contact of cocoa beans with exhausts of drying installations during artificial drying might cause increased PAH levels in cocoa products, such as cocoa butter and consequently in chocolate, and cocoa powder (Misnawi, 2012; Raters and Matissek, 2014; Ziegenhals et al., 2009).

### Meat, Fish, and Products Thereof, and Seafood

Smoking of meat and fish is one of the oldest methods used for conserving these otherwise fast deteriorating foods. However, smoked meat and smoked fish, as well as products thereof can contain high levels of PAHs. EFSA reported mean levels for BaP in smoked fish and smoked meat in the 1 µg/kg range, whereas maximum levels were two orders of magnitude higher, and consistent with maximum levels reported to the RASFF for smoked fish. High PAH contents of smoked food are usually linked to poor smoking practices such as direct contact of food items to hot smoke from glow, to the intensity of smoking, and to unfavourable surface to volume ratios of the smoked food (Pöhlmann et al., 2013; Ledesma et al., 2015; Zachara et al., 2017). The latter applies to smoked sprats and small smoked herring, of which several consignments produced within the EU were withdrawn in recent years from the EU market, as they exceeded the applicable maximum levels for PAHs for this type of food. There are reports on high PAH contamination levels of intensely smoked small fish also from other regions of the world (Essumang et al., 2012). However, elevated PAH contents of smoked meat and smoked fish are not the general rule as observed for commercial smoked meat products analysed in Germany (Jira, 2009; Zachara et al., 2017). Codex Alimentarius acknowledged the shortcomings in manufacturing practices, and potential lack of awareness of contamination of food with PAHs during smoking and issued a code of practice for reducing the contamination of food with PAHs during smoking and direct drying processes (Codex Alimentarius, 2009).

The levels of PAHs in non-smoked fish are much lower than in smoked fish (Drabova et al., 2013).

Pollution of the sea by e.g. environmental deposition of PAHs, by leakages in petroleum production, and after ship accidents may cause contamination of seafood with PAHs. EFSA reported for bivalve molluscs a mean BaP content of about 2 µg/kg, whereas the mean contents of BaA, BbFA, and CHR were higher. Bivalve molluscs are of special concern in this respect, as they bioaccumulate PAHs (Hellou et al., 2005). For this reason they are used for biomonitoring of the PAH contamination of the sea. Accidents such as on the Deepwater Horizon rig in the Gulf of Mexico, or the sinking of the Prestige oil tanker close to the Spanish coast caused consequently the temporary ban of harvesting of bivalve molluscs such as oysters and other seafood. However, studies showed that the initially increased PAH contents of mussels went quickly back to background levels (Óscar et al., 2006; Gohlke et al., 2011).

Smoked products are usually prepared on industrial scale, whereas barbecued meat, another source for exposure to PAHs is mainly prepared at household level, and therefore much more difficult to control. Depending on eating habits, barbecued meat might significantly contribute to the overall exposure to PAHs (Duedahl-Olesen et al., 2015). In this respect parameters such as

the type of barbecue (charcoal, gas, electrical), distance between heat source and meat, type of meat product cooked, the use of barbecuing pans, and exposure time influence the PAH content of the prepared food (Rose et al., 2015; Lee et al., 2016; Viegas et al., 2012; Gorji et al., 2016). EFSA reported a maximum value of 19.9 µg/kg BaP in heat-treated meat, which does not necessarily refer to barbecued meat (Fig. 1). However, a Danish study on different types of commercially barbecued meat revealed for e.g. 26 tested beef burgers an average BaP content of 3.0 µg/kg and for PAH4 7.7 µg/kg, with maximum values of 17.5 µg/kg and 48.0 µg/kg (Duedahl-Olesen et al., 2015).

### Beverages

A number of studies focused on the PAH content of beverages, especially in tea (*Camellia sinensis*) and coffee. PAHs are formed in coffee during roasting of the beans, whereas they are deposited on the tea leaves mainly during drying (Tfouni et al., 2013; Guatemala-Morales et al., 2016). Both food items might contain significant amounts of PAHs in the dry product (Drabova et al., 2012; Tfouni et al., 2013; Shi et al., 2016b; Kayali-Sayadi et al., 1999; Orecchio et al., 2009; Badolato et al., 2006; Houessou et al., 2005; Pincemaille et al., 2014; Guatemala-Morales et al., 2016; Garcia Londoño et al., 2015; Ziegenhals et al., 2008b; Lin et al., 2006). However, the concentrations in the ready-to-drink beverages are low due to the small amount of powder used per serving (Pincemaille et al., 2014; Orecchio et al., 2009; Lin et al., 2006). Herbal teas can also contain high levels of PAHs in the powder, but as for tea and coffee low amounts in the prepared infusion (Ziegenhals et al., 2008b; Thea et al., 2016).

### Herbs Spices and Food Supplements

The contamination of herbs and spices with PAHs is known since long. However, growing attention was put in recent years on the contamination of these food items with PAHs. This led in the EU to the setting of maximum levels for herbs and spices (see Table 2) (European Union, 2015a). PAHs might be deposited on herbal plants from the air, taken up from the soil, or enter the product during processing such as drying. The levels of PAHs in herbs and spices vary a lot. Contents for the sum of four EU marker PAHs were reported from “not detected” up to a few tenths of microgram per kilogram product (Ziegenhals et al., 2007; Rozentale et al., 2018). This agrees very well with levels observed in medicinal herbs (Tripathy et al., 2015; Ishizaki et al., 2011). A recent survey covering 150 samples from the market, comprising six types of dried herbs and spices, did not reveal any exceedance of the EU maximum levels (Rozentale et al., 2018).

Special cases constitute cardamom and smoked herbs and spices, such as smoked *Capsicum* species, smoke pepper, or smoked salt. These food items might contain hundreds of microgram per kilogram PAHs (Ziegenhals et al., 2007). The smoked spices are used to provide a smoky taste to food, without the need to apply smoke flavours. However, cardamom and smoked *Capsicum* species are exempted from the EU legislation, due to the on the one hand low consumption volumes of these commodities, and on the other hand otherwise severe consequences for the supply with them.

Food supplements constitute a large group of different products ranging from minerals to vitamins. PAHs were primarily found in food supplements containing edible oils, in propolis products and herbal food supplements such as spirulina, St. John's wort, or *Ginkgo biloba* products (Zelinkova and Wenzl, 2015; Martena et al., 2011; Danyi et al., 2009; Moret et al., 2010). Some of these products contained BaP at levels of tenths of µg/kg (Moret et al., 2010; Zelinkova and Wenzl, 2015). Also the PAH levels described before for dry powdered tea have to be seen in a different light, if tea powder is used as a food supplement, instead of a hot beverage. The contribution to the daily exposure to PAHs depends of course on the consumed amount of product. Despite the intake of food supplements is usually low, their contribution to the overall exposure could in exceptional cases be relevant (Zelinkova and Wenzl, 2015; Danyi et al., 2009; Moret et al., 2010).

### Cereal Products, Milk, and Infant Food

EFSA concluded in 2008 that cereal products are the major contributor to the exposure of Europeans to PAHs (European Food Safety Authority, 2008). This is not at all caused by a high PAH content of cereal products, which are usually, from the analytical point of view, even at challenging levels, but by the high consumption volumes of cereal products (Ciecierska and Obiedziński, 2013; Rozentale et al., 2017; Kacmaz et al., 2016).

Similarly, to human breast milk, PAHs can also be found in milk of ruminants. Studies on milk and milk powders revealed low levels of PAHs (Girelli et al., 2014; Naccari et al., 2011). Milk powder and vegetable fats are important ingredients of infant formulae. To protect infants from high exposure to PAHs, restrictive maximum levels were set in EU for infant food (see Table 2). Several studies, conducted in different geographical regions, demonstrated that the tested commercial infant formulae would largely comply with EU maximum levels (Petrarca and Godoy, 2018; Iwegbue et al., 2014; Cho and Shin, 2012; Ciecierska and Obiedziński, 2010; Rey-Salgueiro et al., 2009). However, some exceedances were reported for ready-to-eat baby food containing various ingredients such as meat or fish (Santonicola et al., 2017b).

### Vegetables

Vegetables might be contaminated with PAHs via atmospheric deposition or by uptake from the soil (Amato-Lourenco et al., 2017; Tuteja et al., 2011). However, the former is more likely as PAHs with high molecular weights (four rings and above) adsorb strongly

to particulate matter and the organic fraction of soil, and get therefore less likely in contact with roots or tubers. Low molecular weight PAHs (2-ring and 3-ring PAHs) are transported via the air and get easier in contact with leafs and fruits (Amato-Lourenco et al., 2017; Tuteja et al., 2011). The levels of PAHs in fresh fruits and vegetables are normally low, but can in exceptional cases, which might include the cultivation of the plant in a heavy polluted area and favoured uptake of PAHs by the plant/fruit due to e.g. a waxy surface, reach levels in the low microgram per kilogram range (Paris et al., 2018).

## Feed

Due to their ubiquity, animals are exposed to PAHs via inhalation and uptake with the feed (Takagi et al., 2005; González-Gómez et al., 2018). Few studies dealt with PAH contents in feed and the resulting exposure of animals (Ciganek et al., 2002; Ciganek and Neca, 2006; Beauchamp et al., 2002; Berntssen et al., 2010; Easton et al., 2002). For example, the daily intake of the sum of 16 EPA PAHs by lactating cows fed a combination of hay and compound feed, and of pigs fed a feed mixture was estimated to 14160 µg and 164 µg respectively (Ciganek et al., 2002). The high exposure levels of the ruminants were caused by the large ingestion of hay. Concerns regarding the transfer of PAHs from feed to animal products, particularly milk proved to be unsubstantiated (Grova et al., 2000, 2006; Kan et al., 2003). This finding is supported by experiments with radio-labelled PAHs, in which three <sup>14</sup>C-labelled PAHs supplied to a lactating goat were excreted without entering milk in substantial amounts (Grova et al., 2002).

Among 25 popular feed ingredients, Alfalfa and calcium phosphate were identified as potentially significant contributors to the PAH levels of animal feed (Fernández-González et al., 2012). The fibre component was recognised already earlier as a major source of PAHs in feed (Yebra-Pimentel et al., 2012).

The recycling of food waste into aquafeed pellets raised questions regarding the potential contamination of feed with PAHs stemming from processed food. However, the recycled food did not significantly contribute to the PAH content of the pellets.

Salmon from aquaculture contained higher levels of PAHs than wild-caught salmon, which was reasoned by the exposure of farmed salmon to PAHs contained in commercial aquafeed (Easton et al., 2002). The input of PAHs via aquafeed was reflected in the PAH contents of sediments in the direct vicinity of aquaculture cages (Tsapakis et al., 2010). The level of PAHs in fish depends on the composition of the aquafeed. The replacement of fish meal and fish oil in aquafeed to a large extent with vegetable based ingredients, aiming at reducing the levels of persistent organic pollutants (POPs, such as dioxins (PCDD) and polychlorinated biphenyls (PCBs)), caused an increase of PAH levels in farmed salmon (Berntssen et al., 2010). This increase was the consequence of a higher PAH content of the vegetable-based ingredients compared to the fish based ingredients. However, using vegetable ingredients with a low PAH content for the preparation of aquafeed might achieve the desired reduction of POP levels by simultaneously keeping the PAH levels in finished fish low (Nácher-Mestre et al., 2010).

Little is known about the content of PAHs in pet food. One study aimed to identify patterns of bioaccumulation, of amongst others PAHs in cats and dogs, presented also PAH content data of 16 commercial pet foods (Ruiz-Suárez et al., 2015). They contained two to four ring PAHs, but hardly any larger PAHs.

## Veterinary Drugs: Progress in Multiresidue Technique

Patricia Regal, Alexandre Lamas, Carlos M. Franco, and Alberto Cepeda, Universidade de Santiago de Compostela, Lugo, Spain

© 2019 Elsevier Inc. All rights reserved.

### Veterinary Drugs: A Whole World of Residue Possibilities Out There

Veterinary drugs are pharmacologically active substances that may be administered to animals in order to maintain and/or to restore an optimal health status. In this sense, veterinary formulations are widely used in animal husbandry as therapeutics to treat diseases and infections, in the control of parasitic diseases, and also to help alleviate pain and inflammation in sick or injured animals. In addition to their therapeutic and prophylactic uses, veterinary drugs can also be intended for zootechnical purposes, in the form of products applied to healthy animals for non-pathologic objectives (i.e. non therapeutic claims), for instance estrus synchronization or fertility improvement. These chemicals can also be administered to domestic or wild animals to ease management, including tranquilizers, sedatives and anesthetics. Lastly, certain veterinary drugs have the ability to enhance animal production through various metabolic mechanisms (anabolic hormonal compounds, antimicrobials,  $\beta$ -agonists, thyreostatics, corticosteroids) and as such they have been used extensively as growth promoters in livestock farming for many years. However, this latter use has been banned in most European countries as a measure to protect consumers (EC, 1996a; EC, 2003a,b; EC, 2008), meaning that alternative products must be used.

In Europe, the classification of medicinal products for veterinary use is governed by Directive 2001/82/EC, as amended by Directive 2004/28/EC (EC, 2004). In accordance with Article 1 of Directive 2001/82/EC, as amended, the definition of veterinary medicinal product includes any substance or combination of substances presented as having properties for treating or preventing disease in animals; or any substance or combination of substances which may be used in or administered to animals with a view either to restoring, correcting or modifying physiological functions by exerting a pharmacological, immunological or metabolic action, or to making a medical diagnosis. In parallel, medicated feedstuffs are mixtures of veterinary medicinal products and feeds which are ready prepared for marketing and intended to be fed to animals without further processing, because of its curative or preventive properties or other properties. In accordance with Article 67 of Directive 2001/82/EC, as amended, veterinary medicinal products require a veterinary prescription and the prescription is also required for food-producing animals unless an exemption has been granted.

The rational use of veterinary drugs in animal husbandry, along with improvements in management and animal feeding, have greatly contributed to achieving the high rates of productivity that most farms worldwide are showing nowadays. Strictly, veterinary drugs can also be used to treat wild, companion and/or sports animals, but their administration to non-food-producing animals is not important from the point of view of food safety, at least not directly. The use of veterinary drugs in food-producing animals has the potential to generate residues in animal-derived edible products (meat, milk, eggs and honey), and in this sense their irrational administration may pose a health hazard to the consumer (EU, 2010). Many factors can influence the occurrence of residues in animal products, including pharmacokinetic characteristics of the drug, animal metabolism, dose, withdrawal period, etc. To prevent risk, it is necessary to use these drugs rationally, only when they are really indicated, at the right dose and moment, and respecting withdrawal periods established for each edible product. Ideally, all veterinary drugs should only be used in consultation and under the direction of veterinarians as their particular knowledge and training have remarkable significance in preventing unnecessary residues and consequent public health hazards.

In Europe, national monitoring plans should sample feed and animals with the aim of detecting illegal treatments or controlling compliance of the permitted ones with the maximum residue limits (MRLs) for veterinary medicinal products set out in the Annex to Commission Regulation (EC) 37/2010, the maximum levels for pesticides set out in Regulation (EC) 396/2005, or the maximum levels laid down in relevant legislation on contaminants (EC, 2005; EU, 2010). The EU requires that foodstuffs (meat, milk, eggs) obtained from animals treated with veterinary medicines or exposed to chemicals used in animal husbandry must not contain any residue at a level that might represent a hazard to the health of consumers. An evaluation of the residues and the subsequent establishment of MRL are only considered for active substances for which consumer exposure represents a particular concern. Before a veterinary preparation can be authorized in Europe, the active drug must be included as an allowed substance in the first table of the Annex to Commission Regulation (EC) 37/2010. The second table of the same Annex includes a list of substances that must not be used in veterinary medicines for use in food producing animals or in biocidal products for use in animal husbandry. Similar examples take place in other regions and countries, for instance in the USA, where US Food and Drug Administration regulates veterinary drugs through the FDA's Center for Veterinary Medicine (CVM) (<https://www.fda.gov/>). Before a new animal drug may receive FDA approval, the sponsor must establish that the new animal drug is safe (for the animal, persons administering it or otherwise associated to the animal and in terms of environmental impact) and effective. Canada, Japan, China, Argentina, Brazil or Australia follow similar trends, but important differences exist in the authorized substances among countries (Masía et al., 2016).

Roughly, veterinary drugs can be classified according to not only their therapeutic objective, mode of action, chemical properties and/or structure, but also to the existence (or not) of authorization for their administration in food-producing animals in different regions of the world. Based upon the foregoing, and undertaking a food-residue perspective, the following classification has been preferred in this work as presented in Table 1: permitted, banned and borderline drugs in the European Union (EU).

**Table 1** Veterinary drugs classified according to the existence of authorization for using them in food-producing animals in the European Union

Permitted	Antimicrobials (antibiotics, antibacterials, coccidiostats, histomonostats) Corticoids/Glucocorticoids Antiparasitic agents, including carbamates, pyrethroids and other pesticides (against endo and ecto-parasites) Sedatives, tranquilizers, anesthetics $\beta$ -Agonists: clenbuterol Non-steroidal anti-inflammatory drugs (NSAIDs)
Banned	Antimicrobials (as growth promoters) Corticoids/Glucocorticoids (as growth promoters) $\beta$ -Agonists Steroids (androgens, estrogens, gestagens) Stilbenes, stilbene derivatives, and their salts and esters Antithyroid agents Resorcylic acid lactones Recombinant bovine somatotropin Chloramphenicol, chloroform, chlorpromazine, colchicine, dapsone, dimetridazole, metronidazole, nitrofurans (including furazolidone) and ronidazole Synthetic dyes (malachite green)
Borderline	Natural hormones and mycotoxins (zearalenone, $\alpha/\beta$ -zearalenol) Prohormones SARMs SERMs Cascade prescription

### Permitted Drugs

Antimicrobials are, by far, the largest and most varied of all the existing groups of veterinary drugs. These compounds are also the most commonly used in animal husbandry worldwide, mainly due to the constantly shifting production practices, from extensive farming systems to large-scale intensive farming operations that routinely require antimicrobials. Recent research has projected a rise of 67% in antimicrobial consumption by 2030, in comparison to 2010, and nearly double in Brazil, Russia, India, China, and South Africa (Van Boeckel et al., 2015). In the previous article, authors stated that chicken and pigs appear as the most frequent target species, mainly because of the relatively lower use of antimicrobials per animal unit and the lower animal densities characteristic of cattle farms.

Antimicrobials means substances produced either synthetically or naturally, used to act against (kill or inhibit) micro-organisms, including bacteria, viruses or fungi, or of parasites, in particular protozoa (EC, 2003b). The term antimicrobial includes antibiotics, but not vice versa. Antibiotic means antimicrobials/antibacterials produced by (or derived from) a microorganism, but does not include substances that are synthetic or semisynthetic, or those obtained from plants or animals. Coccidiostats and histomonostats are antimicrobials too, in this case intended to kill or inhibit protozoa infections. Notice that residues of antibacterials, being the largest and most widely known and studied class of antimicrobials, are amongst the most important in food analytical chemistry. Antibacterial drugs are administered to animals to treat a disease or infection, and may therefore result in residues in food of animal origin. They can also be used to promote growth as feed additives. In this sense, their use was banned in the EU more than a decade ago (EC, 2003b).

Shortly after antimicrobial drugs were discovered and introduced into human medicine, they were used in veterinary medicine. There are hundreds of antimicrobial drugs, most of which belong to a few major classes ( $\beta$ -lactams, aminoglycosides, quinolones and fluoroquinolones, sulphonamides, tetracyclines, lincosamides, phenicols, nitrofurans, nitroimidazoles, ionophores ...) (Reeves, 2012). However, only some of these drugs are approved for their use in food-producing species, and the presence of their residue in food is therefore also regulated, as in the particular case of Europe (EU, 2010). Yet besides the already mentioned residue concerns, the influence of animal treatments with antibiotics on the phenomenon of antimicrobial resistances is of particular importance. Already in 1945, the doctor who revolutionized medicine with his discovery of penicillin, Sir Alexander Fleming, warned of the potential for these resistances to become a public health problem: "then there is the danger that the ignorant man may easily under-dose himself and by exposing his microbes to non-lethal quantities of the drug make them resistant" (Hudson et al., 2017). Because of the emergence of microbes resistant to antibiotics that are used to treat human and animal infections, the European Commission decided to phase out the marketing and use of antibiotics as growth promoters in animal feed (EC, 2003b). In this context, the WHO list of critically important antimicrobials for human medicine provides a ranking of medically important antimicrobials for risk management of antimicrobial resistance due to non-human use. The current revision (fifth) took place at the seventh meeting of the Advisory Group on Integrated Surveillance of Antimicrobial Resistance (AGISAR) held in Raleigh, United States of America in 2016 (Aidara-Kane et al., 2018).

Apart from the well-known antimicrobials, many other veterinary drugs have been authorized for administration in animal production. Those include antiparasitic agents, drugs acting on the nervous system (sedatives, tranquilizers,  $\beta$ -agonists –not for growth promotion), corticoids or glucocorticoids (methylprednisolone, dexamethasone, betamethasone, prednisolone –not for growth promotion) and non-steroidal anti-inflammatory drugs (NSAIDs) (EU, 2010). It is obvious that antibacterial drugs have attracted much attention in the field of analytical chemistry, but the monitoring of residues from other veterinary medicines in food should not be neglected. In this sense, multi-residue and multi-class techniques offer a very attractive opportunity from an analytical point of view as the analyst may perform determinations of several groups of drugs in a single analysis.

### Banned Drugs

Some substances are considered to represent a clear hazard to the safety of the consumer when present at any level in food, and they must not be used in veterinary practice in stockfarming. Council Directive 96/23/EC classified all these drugs together in a single group called group A, comprising banned substances according to Directive 96/22/EC, i.e. growth promoters and drugs abused in animal fattening, and compounds with no MRL (EC, 1996b). The group of growth promoters includes substances having a hormonal action (steroid hormones, stilbenes, resorcylic acid lactones), antithyroid agents or thyreostats (thiouracils and mercaptoimidazole analogues) and  $\beta$ -agonists, all capable of enhancing growth rate (EC, 2003a). These compounds are banned in the EU and other countries, but authorized in others like the US. Strictly speaking, thyreostats cannot be considered growth promoters since their effect is not anabolic. In turn, corticosteroids are steroid hormones used in human and veterinary medicine as antipyretic, anti-inflammatory and anti-allergy drugs. They are authorized for therapeutic treatments in food producing animals with their corresponding withdrawing times between treatment and slaughtering. Accordingly, maximum residue limits (MRLs) have been established for authorized corticosteroids in milk, muscle, liver, kidney and fat (EU, 2010). Even though formally they are permitted drugs, they can be also used illegally as growth promoting agents, synergistically combined with other molecules such as  $\beta$ -agonists or anabolic agents. Estrogenic, gestagenic and androgenic compounds (EGAs), as well as thyreostatic, corticosteroids and  $\beta$ -agonists, may be used alone or combined in growth promoting cocktails with low concentrations of several drugs, making even more difficult their detection. In this context, multiresidue approaches should be preferred for monitoring purposes.

The administration of exogenous somatotropin to cattle is considered a hormonal tool to increase profit. Recombinant bovine somatotropin (rbST) can be used to enhance milk production in cows and in other dairy ruminants, and its potential as growth promoter has been also demonstrated. The administration of rbST is permitted in several countries including the United States, Brazil, and Mexico, among others, while it has been banned in others, for instance Canada, Australia, and New Zealand. In 1999, the European Union decided to definitively ban possible use of rbST (EC, 1999). Due to the particular characteristics of this veterinary drug (polypeptide hormone), no multiresidue methods have been developed so far to determine somatotropin and its recombinant variants in food (Regal et al., 2017).

Veterinary drugs with no MRL because a safe residue limit could not be established are chloramphenicol, chloroform, chlorpromazine, colchicine, dapsone, dimetridazole, metronidazole, nitrofurans (including furazolidone) and ronidazole. The identification of these banned substances is important in a large number of matrices and at trace levels because there is a zero-tolerance policy on their presence in food. Lastly, synthetic dyes as malachite green have been used as therapeutic multi-usage drugs to reduce parasitic, microbial, and fungal diseases aquaculture. Dyes with pharmacological activity can be categorized into triarylmethanes, phenothiazines, xanthenes, acridines, and azo compounds. Their use in the EU is not permitted, but they can be still utilised illegally because of relatively low cost, availability and high efficacy.

### Borderline Residues

Borderline drugs can often be some of the most challenging. For example, a coccidiostat for use in pigs or poultry in the EU should be assessed as a feed additive, whereas the same product for use in cattle has to be assessed as a veterinary medicinal product. Also, certain natural compounds such as zearalenone may be found in animal feed due to cereal contamination with fungi. Despite belonging to the group of prohibited compounds (resorcylic acid lactones), its presence can be considered natural and unavoidable. In this particular example, the *in vivo* metabolites of zearalenone are the key to distinguish illegal use of zeranol from consumption of food contaminated with *Fusarium* spp. toxins. Likewise, natural hormones have arisen as a real weak point of residue monitoring plans due to their natural origin. The existence of high variability through animals in terms of natural hormonal levels has been reported. This latest fact makes almost impossible to establish legal thresholds to control any exogenous administration of natural hormones to animals. Innovative *in vivo* methods that are useful include targeted and untargeted profiling methods, metabolic pathways analyses, the omics technologies, and gas chromatography coupled to combustion/isotope ratio mass spectrometry (GC-C/IRMS).

Selective androgen receptor modulators (SARMs) constitute a novel class of androgen-receptor ligands with anabolic properties (~steroids) but with less androgenic side-effects. They have been already banned by World Anti-Doping Agency (WADA) but their potential misuse in animals cannot be discarded (Cesbron et al., 2017). Similarly, the group of anti-estrogenic substances includes selective estrogen receptor modulators (SERMs), but also aromatase inhibitors and anti-estrogens. They are prohibited in human sports doping but they also pose a risk of illegal use in animal husbandry for fattening purposes (Meijer et al., 2017).

An additional and interesting example of borderline situations is the so-called 'Cascade' prescription. The 'Cascade' is an exceptional EU mechanism designed to deal with situations where there is no suitable authorized product for the treatment of an animal. In order to avoid unacceptable suffering in an animal, a veterinary practitioner is enabled to prescribe medicines off-label, within very strict limitations. If a medical product is used outside its authorized uses, the veterinarian must specify an appropriate withdrawal period for the slaughter of treated animals or for the production of milk, eggs or honey. Cascade shall apply provided that pharmacologically active substances included in the medicinal product have a MRL established by Commission Regulation (EU) 37/2010, but not necessarily in the species for which it is intended to be used. Also, the veterinarian responsible for prescribing the medicine must specify an appropriate withdrawal period of not less than 7 days for eggs and milk, and 28 days for meat from poultry and mammals including fat and offal (EC, 2004). A good example is lidocaine hydrochloride (2%), approved in the US for use in cattle as a local anaesthetic but licensed only for horses in the European Union. Nevertheless, LIDO may be used in other species under the provision of the cascade.

## Residue Analysis: Past, Present and Future

Two international conferences, in particular, the EuroResidue (ER) series and the Ghent series (the International Symposium on Hormone and Veterinary Drug Residue Analysis – VDRA), give a recognized platform to discuss all aspects of residues of veterinary drugs in the food production chain (van Ginkel and Bergwerff, 2008). The renowned organizing committees of EuroResidue conferences and Ghent symposia established an agreement to deliberately alternate dates, offering food chemist, veterinarians, analyst and other food experts a great opportunity to meet on a regular basis, reflecting the worldwide trends in residue analysis (<http://www.euroresidue.nl/> and <http://www.vdra.be/>). Thus, an international meeting of experts on veterinary drug residues takes place every two years from 1994 on, alternatively in Egmond aan Zee (ER, The Netherlands) and in Ghent (VDRA, Belgium). In this context, one could consider that the specific matters discussed at each edition of these conferences have covered the state-of-the art and future trends in residue science, technologies and policies, at that time. Therefore, a journey through the posters, oral communications, lectures, special issues, books of abstracts ... resulting from ER and VDRA meetings, since their very beginnings, will clearly depict the history and development of veterinary residue analysis, for those interested in exploring the past, present and future of this analytical field.

It was in the ER of 2008 (van Ginkel and Bergwerff, 2008) that the so-called omic techniques (transcriptomics, proteomics, metabolomics) emerged as feasible and applicable alternatives for food residue analysis, especially in the field of hormonal growth promoters. Also, the stunning capabilities of high resolution mass spectrometers (time-of-flight, Orbitrap, FTICR ...) received great attention and these instruments were suggested as representative options of modern instrumental residue analysis. As highlighted during VDRA 2010, the use of ultra-high performance liquid chromatography (UHPLC) hyphenated with accurate mass spectrometry became much more common, along with omic approaches (De Brabander et al., 2010). In ER 2016, these approaches consolidated their position in the development of modern multiresidue methods, and the interest for methods detecting (multiple) antibiotics (simultaneously) exploded (Bergwerff, 2016). In Table 2, a summary of the multiresidue methods published in the corresponding special issues of EuroResidue VI and VIII is presented.

In this context, conventional residue analysis dealing with classic immunoassays, growth inhibition assays, thin layer chromatography, liquid and gas chromatography, UV detectors, triple quadrupole mass spectrometers ..., are still present, and such classic techniques play an important role in routine residue control programs and should coexist with more innovative techniques, since residue analysis must be affordable for everyone.

## Method Validation

Clear rules on how laboratory analysis had to be carried out and results interpreted were provided in Commission Decision 2002/657/EC, implementing Council Directive 96/23/EC, which established criteria and procedures for the validation of analytical methods to ensure the quality and comparability of analytical results generated by official laboratories (EC, 2002). Moreover, the Decision introduced a procedure to establish minimum required performance limits (MRPL) for analytical methods employed to detect substances for which no permitted limit (MRL) had been established. For the first time, the concepts of decision limit ( $CC\alpha$ ) and detection capability ( $CC\beta$ ) were introduced, as quality parameters that must be established during the validation of an analytical method. Currently, the evolution in analytical equipment and progress in scientific research, accompanied by recent European regulatory changes, seems to demand an update or revision of the 2002/657/EC. The current validation method described in European Commission Decision 2002/657/EC is designed for quantitative methods. As for qualitative screening methods, the approach provided in the Guideline for the validation of screening methods for residues of veterinary medicines (initial validation and transfer) by Community Reference Laboratory in 2010, is better adapted and detailed.

## Trends in Sample Size and New Matrices

Current trends in residue analysis include the use of small sample amounts, and innovative non-invasive matrices such as saliva, hair and feathers. On the other hand, more classic options such as urine and blood samples, are still of importance for

**Table 2** Summary of the multiresidue methods published in the corresponding Special Issues of EuroResidue VI (2009, *Analytica Chimica Acta*, vol. 637, issues 1–2) and VIII (2017, *Food Additives and Contaminants: Part A*, vol. 34, Issue 4, pages 451–652). Purely methodological, comparative, or pharmacokinetic studies have been excluded

Dispersive SPE (d-SPE); Immuno-affinity chromatography (IAC); Metal-Chelate Affinity Chromatography (MCAC); turbulent flow chromatography (TFC).

their simplicity and representativeness (Bergwerff, 2016; van Ginkel and Bergwerff, 2008). The determination of residues in edible products cannot be replaced for many reasons, such as the accumulation of residues, and on this basis matrices as liver, muscle, kidney, eggs and milk remain among the most popular options in veterinary drug analysis. Even chicken claw can be used for human consumption and it has been recently used as target sample to determine antimicrobials residues (Cornejo et al., 2017).

Insects are not traditional consumed by the European population, but they are very popular in countries as Mexico, Colombia, Thailand, Indonesia or South Africa. Lately, edible insects have been suggested as novel food alternatives by EU, and already various insect species have been authorized for human consumption. In this context, a new area of action is opening up for multi-residue methods (Poma et al., 2017).

## Multiresidue Techniques

To measure the low concentrations of veterinary drugs that are usually found as residues in food and animal matrices, highly selective, sensitive and accurate analytical methods are needed. Due to the large number of drugs existing on the veterinary market, the use of multi-residue methods capable of analyzing large numbers of analytes and metabolites in one single run has become the most common and most efficient approach for residue monitoring. The term multiresidue was born in the field of pesticide pollutants (insecticides, herbicides, fungicides, rodenticide, molluscicides, nematocides, plant growth regulators and others), possibly due to the great number of compounds included in some groups, such as organochlorines, and their broad distribution in the environment. Because of the cost-effective and time-effective nature of this analytical approach, multiresidue methods rapidly invade other fields.

Traditional methods for single-class/single-residue analysis still exist, but modern multi-class/multiresidue methods, mainly using LC-MS instruments, are now dominant because they are more cost-effective and time-effective, they are selective towards individual drugs and their metabolites, highly sensible (very low LODs and LOQs), and also accurate for identification and confirmation (Frenich et al., 2014; Mainero Rocca et al., 2017; Masiá et al., 2016; Stolker et al., 2007; Toldrá and Reig, 2006). A graphical overview of the most frequent multiresidue analytical workflow nowadays is presented in Fig. 1.

### Multi-residue and Multi-class?

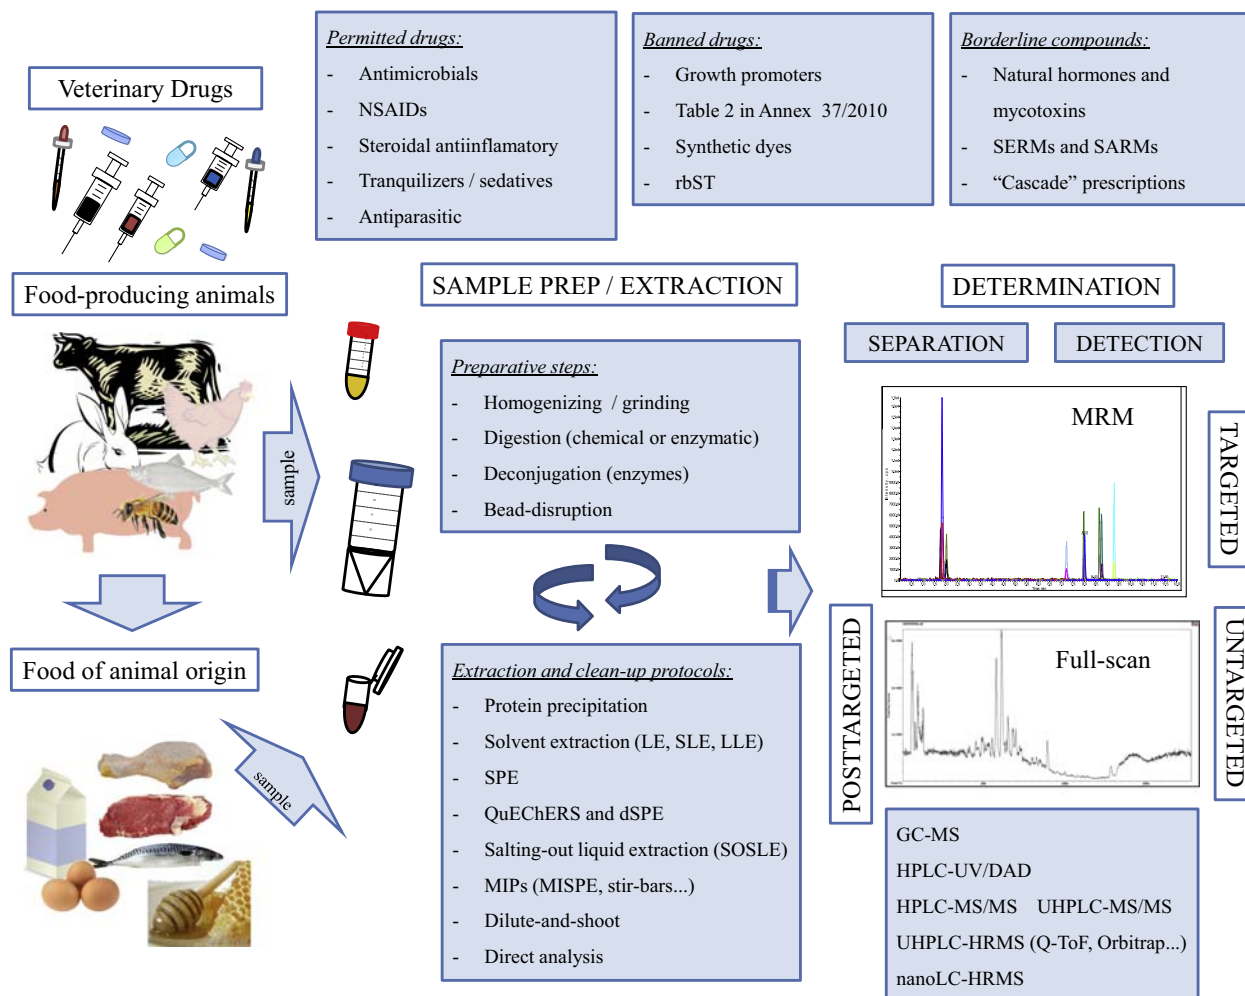

Multi-residue methods include large numbers of compounds, in order to determine the presence of residues of multiple veterinary drugs in a single run, saving sample, solvents, time and analytical costs. In some cases, the specific purpose is covering frequent synergistic/additive combinations of veterinary drugs, such as corticosteroids and beta-agonists, or antimicrobial combinations, amongst others. It is a fact that the terms multi-residue and multi-class are often used interchangeably, but they are not and should not be considered synonyms. Multi-class methods are analytical solutions capable of detecting drugs belonging to different chemical groups or drug categories/classes. Interesting and illustrative examples of a real multiclass, multiresidue (and even multi-matrix) methods have been recently presented, including also food-packaging contaminants, pesticides, mycotoxins and others (Anumol et al., 2017; Ortellì et al., 2009; Piatkowska et al., 2016; Pérez-Ortega et al., 2017; Rizzetti et al., 2018; Zhao et al., 2017). Other frequent term is multi-analyte, referred to a method that may include both multiple residues and natural compounds (or exogenous natural compounds?), from the same veterinary class or from different groups (van Tricht et al., 2018).

## Multiresidue Extraction and Sample Preparation

The selective, accurate and reproducible detection of multiple analytes in different matrices and at low concentrations requires a careful optimization of the analytical method. As some matrix components co-elute with the target compounds and/or interfere with the detector, it is difficult to get a successful multiresidue method without applying an efficient extraction procedure to the sample. Currently, sample preparation is still the most laborious step of the analytical process, especially in the case of multi-analyte analysis. Some of the most common techniques available nowadays for sample clean-up and extraction of veterinary drugs are nicely summarized in a recent review by Mainero Rocca et al. (2017). The commonest reported techniques are solvent extractions (in its various forms), solid-phase extraction (SPE) and the Quick, Easy, Cheap, Effective, Rugged, and Safe (QuEChERS) approach.

Solvent extractions are still very popular for sample preparation in residue analysis, as they have demonstrated to be both straightforward and effective tools in the laboratory. In many occasions, the solvent effectiveness is enhanced with ultrasound assistance, automatic shaking or mechanical disruption such as bead-disruption. Different variants of solvent extraction are liquid extractions and solid-liquid extractions (LE, SLE) as well as liquid-liquid partitioning (LLE). In the first two options, a solvent (buffers, acetonitrile, methanol, acidic water ...) is added to a liquid or a solid sample, respectively, for different purposes, and the solvent is then recovered mixed with the sample matrix. Liquid-liquid extractions are based on the ability of an analyte to distribute itself between an aqueous solution and an immiscible organic solvent. In this variant, only one phase is recovered from the mixture. Organic phase will retain the lipophilic (hydrophobic) compounds, and aqueous phase will concentrate the lipophobic (hydrophilic) residues. In this context, acetonitrile have been one of the most popular deproteinization solvents and

**Figure 1** Workflow of the most frequent and up-to-date multiresidue analytical strategies used nowadays for confirmatory and screening determinations of veterinary drug residues.

*n*-hexane frequently combined as the degreasing solvent. In LLE, *tert*-butyl methyl ether (TBME), dichloromethane and ethyl acetate are amongst the best options in terms of recovery. These very simple preparative solutions have widely demonstrated to be effective for the simultaneous determination of hundreds of compounds, also in part thanks to their coupling with modern LC and MS instruments (Cao et al., 2018; Ortellì et al., 2009; Wittenberg et al., 2017). In other cases, sample has been simply diluted and shot, a procedure that involves limited sample treatment. Dilute-and-shoot procedures present a high sample throughput, but some important limitations are occurrence of abundant matrix effects, which compromise detection limits, quantitative aspects, method selectivity and instrument maintenance frequency (Mainero Rocca et al., 2017; Masiá et al., 2016).

Salting-out supported liquid extraction (SOSLE) is a rather novel extraction and clean-up technique, based on high salt concentration in the aqueous donor phase, enabling a supported liquid-liquid extraction with a relative polar organic acceptor phase such as acetonitrile. The concept of salting-out in combination with the technique of supported liquid-liquid extraction was proposed by Kaufmann et al. (2014). The proposed technique resulted in milk extracts of equal or superior cleanliness and with higher average recoveries than those obtained with QuEChERS or SPE. Recent research has reaffirmed its soundness in multi-residue analysis for other matrices such as muscle and eggs (Alcántara-Durán et al., 2018). The Quick, Easy, Cheap, Effective, Rugged and Safe (QuEChERS) methodology was originally developed for pesticides, but it was rapidly proposed for the analysis of veterinary drugs in a variety of different matrices. QuEChERS are now a referent to extract simultaneously multiple pesticides and veterinary drugs in food (Mainero Rocca et al., 2017; Masiá et al., 2016). It has also demonstrated to be effective as additional step for removing the fat phase in fatty samples after liquid extractions (Giaccone et al., 2018). It is important to note that QuEChERS is a variant of dispersive solid phase extraction (dSPE) (Socas-Rodríguez et al., 2017). As an example of its great capabilities, d-SPE with in-vial filtration was successfully applied to the high-throughput analytical determination of >100 veterinary drug residues, representing at least 13 different classes, in bovine muscle (Schneider et al., 2015). The novel Enhanced Matrix Removal-Lipid (EMR-Lipid) technology, from Agilent, is a unique sorbent released in 2015 that selectively removes lipids in

complex matrices, using a convenient dispersive solid phase extraction (dSPE) format. The EMR-Lipid sorbent integrates very well with QuEChERS or protein precipitation extracts, collecting the lipids present in aqueous extracts. Various multiresidue methods have implemented this technology, with very little interferences and enhanced time-saving, for hundreds of residues in different animal tissues (Anumol et al., 2017; Rizzetti et al., 2018).

Even now, classical solid phase extraction (SPE) is a frequently used, low-cost and easily automated method to pretreat food samples and it can be coupled to both liquid and gas chromatography. A wide variety of SPE cartridges exist that improve the extraction of analytes from complex matrices. In this sense, new formats have been created, for instance SPE columns for automated protein precipitation and removal of phospholipids (Rejtharová et al., 2017). In addition to this, the 96-well SPE plate formats save the analyst a great deal of time, introducing high-throughput capabilities into SPE field (Blokland et al., 2017; van Tricht et al., 2018). Molecularly imprinted polymers (MIPs) emerged with force a decade ago as promising SPE sorbents, the so-called MISPE cartridges. However, the use of MIPs for SPE is a rather new and scantily explored research domain, particularly for the analysis of certain groups of veterinary drugs. The superiority of MIPs as selective SPE sorbents (MISPE) for the analysis of residues in food has been extensively demonstrated during the last decade; several studies have compared classical SPE sorbents and MISPE sorbents (Regal et al., 2012). Also, novel formats have emerged for multianalyte extraction in food, including for example molecularly imprinted stir-bars, monoliths and/or on-line clean-up columns, suggesting a clear tendency towards miniaturization in MIP technology (Lv et al., 2013; Xu et al., 2011; Zhang et al., 2014).

Last but not least, any sample preparation protocol is usually started with homogenization or grinding of a considerable amount of sample. Hereafter, an aliquot of sample is taken for analysis, in most occasions transferring the desired analyte into a homogenous liquid medium or solvent. Often, the drug is bound to matrix components (protein, keratin, glucuronic acid, sulfate ...) and must be freed by mechanical, chemical (alkaline, acidic) or enzymatic treatments. For example, the metabolism of many veterinary drugs after administration to the animal ( $\beta$ -agonists, NSAIDs, steroids and anabolics, antibacterial ...) includes formation of sulfate and/or glucuronide conjugates that must be hydrolyzed before (or after) further extraction of the target compound (Socas-Rodríguez et al., 2017). The use of  $\beta$ -glucuronidase/arylsulfatase from *Helix pomatia*, for example, is suitable for enzymatic digestion of urine, retina, serum, liver, muscle, kidney and milk samples. Obviously, this deconjugation is occasionally necessary in matrices collected from the animal, but that's never the case in feed or drinking water samples. For hair or similar samples, basic digestions with sodium hydroxide or mechanical pulverization to free the compound from this tight matrix are both acceptable and successful alternatives (Leporati et al., 2014; Stolker et al., 2009). In some situations as determination of steroid esters in hair, chemical digestion of hair at high temperature can easily hydrolyze the analyte, and hence the use of reducing agents such as dithiothreitol and tris(2-carboxyethyl)phosphine hydrochloride or the application of alternative techniques as cryogenic grinding are required (Gratacos-Cubarsi et al., 2006; Regal et al., 2008).

### Multiresidue Separation and Detection

A huge number of multiresidue methods have been developed so far in food chemistry. Classically, the most common strategy is to couple a separation technique (liquid/gas chromatography, LC/GC) with a simple detector such as ultraviolet (UV) or diode array (DAD) detectors, or to a more complicated mass-spectrometer. Actually (ultra-)high performance liquid chromatography (HPLC and UHPLC) with triple-quadrupole tandem mass spectrometry (MS/MS) is the most frequent and effective technique for confirmatory analysis, with proper prior pre-treatment and extraction (Frenich et al., 2014; Masiá et al., 2016; Toldrá and Reig, 2006).

Classic analytical techniques used for multiresidue analysis of veterinary drugs and growth promoters are moving from target methods, mainly liquid chromatography coupled to triple quadrupole mass spectrometers (HPLC-MS/MS platforms), towards untargeted full scan mass spectrometry utilizing accurate high resolution mass spectrometers (HRMS instruments) and ultra-high performance liquid chromatographers (UHPLC systems) (Ferrer and Thurman, 2009). Published methods show that time-of-flight (ToF-MS) and Orbitrap technologies are both very powerful high-resolution options for screening and confirmatory multi-residue analysis of veterinary drugs in food (Jia et al., 2017; Ortelletti et al., 2009; Pérez-Ortega et al., 2017; Stolker et al., 2008). These approaches may be used not only in targeted analysis but also in non-target determinations and retrospective screenings (post-target) of hundreds of compounds, or even in the identification of unknowns (Jia et al., 2017; León et al., 2016; Masiá et al., 2016). Also, nanoflow liquid chromatography (nanoLC) enables the use of high dilution factors (1:100) due to its high sensitivity. This relatively innovative LC system has been coupled to HRMS for the multiresidue determination of almost 100 veterinary drug residues in honey, veal muscle, egg and milk, achieving a complete removal of matrix-effects (Alcántara-Durán et al., 2018). Interestingly, this latter approach would make the use of matrix-matched calibration or standard addition methods no longer necessary.

Still, HPLC-MS/MS analytical platforms are more affordable than UHPLC-HRMS systems, and also provide higher selectivity and sensitivity than LC coupled to conventional detectors. Furthermore, LC-MS/MS alternatives fulfill the requirements demanded by the Commission Decision 2002/657/EC by combining analyte separation and structural information, providing unequivocal detection and confirmation of a substance (EC, 2002). In this context, HPLC-MS/MS methods have been frequently used for determination of various classes of veterinary drugs in different matrices (Piatkowska et al., 2016; Pontes et al., 2017; Rejtharová et al., 2017; Wittenberg et al., 2017). Nevertheless, many UHPLC-MS/MS multiresidue multi-class methods have also been successfully validated and implemented so far (Zhao et al., 2017). Some authors have suggested that, instead of using expensive UHPLC

systems, core-shell columns permit a smooth and easy adaptation of UHPLC protocols into more affordable HPLC instruments (Schneider et al., 2015).

# Endocrine Disrupters: A Review

Alberto Mantovani, Istituto Superiore di Sanità, Roma, Italy

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Bioaccumulation** The accumulation of a substance in the tissues of an organism. It is more frequent for fat-soluble (lipophilic) substances.

**Endocrine disrupter/disruptor** A natural and/or man-made chemical that triggers adverse health effects by altering the hormone system.

**Exposure** The qualitative (which way) and/or quantitative (how much) evaluation of the likely intake of a hazard.

**Hazard** Any agent with the potential to cause an adverse health effect.

**Isoflavones** A type of compounds naturally occurring in plants of the bean family: many isoflavones are biologically active, having estrogen-like properties.

**Pesticide** Any substance or mixture of substances intended for preventing, destroying, or controlling any pest that may harm humans, animals, plants or agricultural products.

**Risk assessment** A science-based process to evaluate the severity and probability of a health effect consequential to exposure to a hazard.

## Introduction

Endocrine disrupters (or disruptors: ED) are natural and/or anthropogenic chemicals that trigger adverse health effects by altering the endogenous hormone system (Solecki et al., 2017). Diet is a major exposure route to most ED; four broad categories may be considered from the viewpoint of food chains contamination:

- i. ED that can bioaccumulate in organisms (e.g., polychlorinated biphenyls –PCBs-, polybrominated flame retardants, like PBDE), thereby affecting components of the food chain that are most susceptible to environmental pollution (European Food Safety Authority, 2005a; European Food Safety Authority, 2011a). Perfluoroalkyl substances, like PFOS and PFOA, are emerging persistent ED that contrary to PCB and PBDE are not lipophilic (Wu et al., 2015);
- ii. ED employed in the production of food, such as pesticides (Mantovani et al., 2008), substances used in feeds (Mantovani et al., 2009) and their metabolites. Examples are ethylene bisdithiocarbamates (thyroid inhibiting) and triazoles (impairing the synthesis of steroid hormones). The enactment of up-to-date regulations, as well as the enforcement of appropriate farming practices are critical to control potential risks for consumers. An issue of concern is the presence of multiple pesticide residues in a significant fraction (20% and more in Europe) of fruits and vegetables (European Food Safety Authority, 2013a). The European Food Safety Authority (EFSA) has tackled this issue in 2013: based on the available knowledge, the most robust and conservative approach is the assumption of effect additivity and the formation of “cumulative assessment groups”. Compounds that have the same effect in the same target organ, such as hypothyroidism, are assumed to act in an additive way, even though their chemical structures and molecular mechanisms are different (European Food Safety Authority, 2013a; European Food Safety Authority, 2013b);
- iii. ED released into food from contact materials, processing aids, etc. A well-known example is the plasticizer bisphenol A, an EDC showing mainly estrogen agonism, present in polycarbonate plastics and epoxy resins. In European Union bisphenol A has been forbidden in baby bottles in 2011; due to widespread use, an aggregate exposure of the general population still occurs through migration from food contact materials as well as from non-food sources, e.g. thermal papers (European Food Safety Authority, 2015a). Another main example are several phthalates, used in manufacturing of PVC (Petersen and Jensen, 2010);
- iv. the fourth group of ED includes a variety of bioactive compounds naturally present in food. In such cases, the effects may be beneficial or detrimental, depending on the dose, chemical form and endocrine status of the organism (e.g., age, gender). For instance, the ability of certain phytochemicals (e.g., quercetin, largely present in fruits) to interfere with androgen-related pathways has been shown to depend also from their specific intracellular distribution (Smeriglio et al., 2014). In the case of certain essential nutrients, “endocrine disruption” may be caused by a deficiency, as well as by an excess. Iodine-deficient hypothyroidism is a major endocrine disorder worldwide, but iodine excess may also alter thyroid function; high-dose supplementation of feeds with iodine may increase the risk of iodine excess in consumers through the active carry-over of the element in milk and eggs (European Food Safety Authority, 2005b).

The ensuing paragraphs deal with two main issues: the impact of ED on food safety for developmental lifestages and the influence of dietary styles and food constituents.

## ED and Developmental Lifestages

The exposure to ED in newborns and small infants presents specific features: an early body burden may be derived from in utero exposure: small infants consume a very limited variety of food, only breast milk in many cases, so that contamination of a single item may determine the safety of their entire diet. Furthermore, internal defences of neonates against contaminants are limited by the immaturity of both hepatic detoxification and the blood–brain barrier (Neal-Kluever et al., 2014). Breastfeeding may transfer a mixture of lipophilic compounds (PCBs, brominated flame retardants, dioxins) from the maternal body burden to the newborn: in the 90's it was estimated that approximately 10% of the body burden of dioxin-like substances at 25 years of age may be attributable to breastfeeding during the first six months of life (Patandin et al., 1999), while breast-fed infants are still among the population groups with higher PBDE intake (European Food Safety Authority, 2011a). The possible presence of contaminants in human milk must be balanced against the in disputed benefits of breastfeeding for the child health, that include providing the neonatal intake of iodine which is essential to optimal thyroid function, hence, to the functional development of the brain (Azizi and Smyth, 2009). Because of these enormous benefits, it is not recommendable to reduce exposure to ED by restricting breastfeeding, except in circumstances associated with very high levels of contamination, e.g., contamination by dioxins from e-waste pollution in developing countries (Frazzoli et al., 2010). In most situations, the best way to reduce infant exposure to lipophilic ED is to act at preconceptional and gestational stages, by reducing the exposure and body burden of women at fertile age. For instance, a recent Italian investigation found significant levels of PBDE in Italian girls, especially in those with precocious thelarche: however, no obvious correlations were found with diet or lifestyles of girls, hinting to, yet unrecognized, maternal exposure determinants (Deodati et al., 2016).

Patterns of food consumption are also different in children and adolescents compared to adults; for instance, milk may be a particularly important source of exposure for children to dioxins and PCBs (Fattore et al., 2008) and PBDE (European Food Safety Authority, 2011a). Specific commodities popular among children and adolescents might be an important source of some ED: in California children (2–8 years) the consumptions of hotdogs, chicken nuggets, French fries and chips, and microwave popcorn were significantly associated with serum concentrations of perfluoroalkyl substances, like PFOA (Wu et al., 2015). It is not just a matter of exposure. The period from infancy through to puberty encompasses dynamic processes of growth and development; it may represent a window of specific susceptibility to the effects of ED on the development of reproductive, cognitive, immune and metabolic functions and also on the susceptibility to cancer later in life. Consequently, several papers are calling for a greater attention toward post-natal development in toxicological testing and risk assessment (Mantovani and Fucic, 2014; Narciso et al., 2017).

According to consistent scientific evidence, the prenatal development is the phase most susceptible to ED effects on all body systems and functions regulated by the endocrine networks, such as the reproductive and nervous systems (Latini et al., 2010) as well as body metabolism and composition; indeed, prenatal ED exposure is implicated in the risk of obesity and/or type II diabetes (Heindel et al., 2017). Typically, ED elicit “delayed developmental effects”: interferences with the programming of normal endocrine-signalling pathways during prenatal life lead to adverse consequences later in life on reproductive tissues, thyroid, liver metabolism, etc., as indicated by a wealth of experimental studies (Maranghi et al., 2007, 2010, 2013a ; Kay et al., 2014).

A comprehensive characterization of effects upon intrauterine exposure is pivotal for ED risk assessment; in the meanwhile, some issues deserve close attention. First, attention should be given to the possible differences in toxicokinetics between human and rodents, including those related to the physiology and structure of the placental filter; indeed, when assessing the toxicological studies on BPA, EFSA has translated the dose levels used in rodent developmental toxicity studies into oral human equivalent doses (European Food Safety Authority, 2015a). Second, in general the delayed developmental effects are quite specific and related to the ED mechanisms; moreover, they may appear as subtle changes, however adverse in the long run. New conceptual approaches, such as Adverse Outcome Pathways, will be useful to predict clinically-relevant adverse effects from molecular and cellular biomarkers (Leist et al., 2017).

## ED, Dietary Habits and Food Constituents

Dietary habits are influenced by socioeconomic, cultural and religious factors and individual choices (e.g. vegetarianism/veganism), which may exert a considerable impact on the intake of nutrients, bioactive substances, residues and contaminants. For instance, the extensive consumption of fatty foods of animal origin does increase the intake of lipophilic ED (European Food Safety Authority, 2005a; European Food Safety Authority, 2011a; Fattore et al., 2008). The contributions of individual food commodities to the overall intake of an ED or a group of ED depend on background contamination, as well as on patterns of food preparation, storage and consumption. For instance, management of cereals and nuts before, during and after harvest is critical to the level of contamination by zearalenone, a potent estrogenic mycotoxin (European Food Safety Authority, 2011b). More in general, the preparation and vending of street foods (an important food security component for developing countries) might lead to significant toxicological risks (Proietti et al., 2014).

Main foods, and their production chains, are vulnerable to the contamination by specific ED. Cereals, major food staples worldwide, are vulnerable to contamination by the potent estrogenic ED zearalenone, in particular corn (European Food Safety Authority, 2011b). Cereals may also accumulate from soil and water the toxic heavy metal cadmium which may have estrogen-like effects and specifically impair the production of the erythropoietin hormone within the renal proximal tubular cells, a rather

unique ED effect (European Food Safety Authority, 2009). Cadmium presents specific uptake mechanisms in other edible seeds, such as flaxseeds, which may be added to bread; the presence of antioxidant, and potentially endocrine-active, substances such as lignans in flax seeds appears to counteract the pro-oxidant action of cadmium (Dragone et al., 2016).

The production of fruits and vegetables needs to be closely watched as these commodities are widely recognized as a source of nutrients, fibre and antioxidants, but are also the major source of pesticide residues. Whereas in the European Union the exposure to pesticide residues is well controlled, with just a minor fraction of residues not complying with the legal limits, the presence of a substantial percentage of vegetables with multiple residues still remains a problem (European Food Safety Authority, 2013a; European Food Safety Authority, 2013b). The possibility that certain pesticide metabolites, present as residues, have specific toxicological characteristics must not be overlooked: one example is ethylenethiourea, a metabolite of ethylene bisdithiocarbamate fungicides, and a potent thyrostatic agent (Maranghi et al., 2013a).

In general foods of vegetable origin are not an important source of lipophilic ED, with some exceptions: in Italy vegetable oils accounted for 11%–16% of the dietary intake of PCB, a finding potentially relevant to the protection of the Mediterranean diet (Fattore et al., 2008).

Foods of vegetable origin are also a source of natural endocrine-active substances. For instance, soy is a rich source of isoflavones, such as genistein, daidzein, etc.; they are chemically related to  $17\beta$ -oestradiol and possess oestrogenic properties, as well as interact with the synthesis of thyroid hormone. In Europe the isoflavone intake is highest in consumers of soy-based supplements, vegans/vegetarians and other groups with frequent soy consumption (European Food Safety Authority, 2015b). Soy isoflavones bind to both oestrogen receptors, ER $\alpha$  and ER $\beta$ , their estrogenic activity depending on the distribution of receptors in different tissues, according also to gender and lifestage. When assessing the safety of soy-based supplements in pre- and post-menopausal women, the EFSA considered that a health-based guidance value could not be established and that several rodent studies suggest the capacity to increase proliferation of breast epithelium and endothelium. On the other hand a wealth of human studies did not support that the usual intake of soy isoflavones through supplements (up to 150 mg/day) is associated with increases of uterine or mammary cancer in the general, healthy population (European Food Safety Authority, 2015b). Besides oestrogenic action, isoflavones may inhibit thyroid peroxidase and/or other steps of thyroid hormones iodination (Divi and Doerge, 1996); when iodine status is suboptimal, a high intake may adversely affect thyroid function in children (Milerová et al., 2006).

Since endocrine-active plant compounds and xenobiotics with ED features may be concomitantly present in the diet, some studies investigated whether and how they might interact. Some evidence suggest that isoflavones like daidzein, genistein or quercetin can partially antagonize ED that bind to estrogen receptors (e.g., bisphenol A) by competing for common biological targets (Han et al., 2002; Dolinoy et al., 2007). The available, limited, in vivo studies investigating the co-exposure to isoflavones and xenobiotic ED show dishomogeneous results; for instance, genistein counteracts the antiestrogenic action of persistent organochlorines in testis and liver (Penza et al., 2007), it has a less than additive effect on hypospadias induction with the antiandrogenic fungicide vinclozolin (Vilela et al., 2007), while it has an additive effect with the insecticide methoxychlor, an estrogen agonist (Guo et al., 2002). In addition, even though the actual exposure levels to estrogen-active xenobiotics might be too low to elicit an effect *per se*, they might add up to the estrogenic activity of the dietary isoflavones (van Meeuwen et al., 2007). Possible additivity or interactions, thus, may depend on mechanisms of xenobiotic ED as well as on tissue susceptibility (e.g., distribution and density of receptors). The available data indicate that further research is worthwhile, because the issue may be relevant for consumer's safety.

Other endocrine-active compounds are present in vegetables. Several cyanogenic compounds are recognized goitrogens, such as thiocyanates and isothiocyanates derived from glucosinolates ingested in, among other items, Brassicaceae (turnips, cabbages, etc) (European Food Safety Authority, 2008). Furanocoumarins, present in grapefruit and other citrus fruits, are powerful inhibitors of sulfotransferase enzymes involved in the removal and detoxification of xenobiotics and essential to the metabolism of steroid and thyroid hormones (Harris and Waring, 2008). The risk from the presence of these substances is very low for healthy subjects consuming a balance and varied diet. However, high thiocyanate intake is associated with markers of hypothyroidism in populations with low iodine status (Steinmaus et al., 2013); also, the effects of certain therapeutic drugs could be altered by inhibitors of sulfotransferases (van Ede et al., 2008).

Without direct hormone actions, a diet rich in fruits and vegetables may afford some protection toward environmental ED. Dietary fibre is important in modulating the bioavailability of estrogens and their intestinal metabolism by microbiome (Aubertin-Leheudre et al., 2008). The intake of specific plants may reduce the reproductive effects of ED in rodents, due to their antioxidant properties; indeed, oxidative stress is an event featuring in ED-induced adverse outcomes (Rachid et al., 2016).

As already pointed out, foods of animal origin are the main source for ED able to concentrate in food chains.

Milk and dairy products are vulnerable to the prolonged contamination of pastures by persistent lipophilic ED, especially in contamination hotspots due to long-term disposal of persistent chemicals (Battisti et al., 2013). For the exposure of the general population, the role of milk and dairy products depends also on their lipid content; the habitual consumption of partially skimmed milk in infancy was shown to reduce exposure to dioxin-like compounds and the resulting body burden by 10%–20% (Yaktine et al., 2006).

The ecological and metabolic characteristics of food-producing animal species are important determinants of the contamination of foods. For instance, markedly higher levels of dioxins and dioxin-like PCBs are found in liver from sheep compared to cattle exposed to similar environmental levels. Dioxins from airborne emissions are deposited on soil. Sheep nip herbage close to ground surface, hence the involuntary intake of pasture soil is higher since than in cattle, which normally nip vegetation 5–10 cm above the ground surface. Moreover, compared to cattle sheep may have a lower CYP1A1 activity, which is the key enzyme to metabolize dioxin-like compounds to hydroxy-derivatives (European Food Safety Authority, 2011c).

Seafood, with its variety of species, classes and even phyla, is the paradigm to show the role of the characteristics of the edible organisms. In general, large fatty fishes are more liable to contamination by lipophilic pollutants like PCBs or PBDE; the persistent, but not lipophilic perfluoroalkyl substances are more prevalent in large predatory fishes (like tuna) and in molluscs and crustaceans, which might suggest, respectively, biomagnification in food webs and uptake from sediments (Mantovani et al., 2015). Farmed fish presented background levels of persistent pollutants comparable to caught fish: conventional aquaculture feeds are made with proteins and fats derived from marine organisms, thus reproducing the marine food web in the aquaculture farm (European Food Safety Authority, 2005c). Accordingly, the use of feed ingredients less vulnerable to pollution would facilitate the exploitation of fish as an important source of nutrients such as iodine and polyunsaturated fatty acids (Mantovani et al., 2015).

An interesting aspect of seafood is the concurrent presence of contaminants and nutrients that act on the same pathways, e.g., ED targeting thyroid and iodine. Infants with high dietary intake through fish of PCBs and hexachlorobenzene (another bioaccumulating ED that may alter the metabolism of thyroid hormones) showed only modest changes in thyroid parameters, possibly due to a protective effect of the concomitant iodine intake (Dallaire et al., 2008). However, juvenile female mice exposed to low levels of persistent polyhalogenated ED through a salmon-based rodent diet showed several, however subtle, adverse effects, including on thyroid and steroid hormone balance (Maranghi et al., 2013b). Therefore, a protective effect of fish dietary matrix should not be assumed to occur in all scenarios.

## Conclusions

Diet is recognized as a major route of exposure to ED. The ED issue in food safety can be divided in two broad fields:

- i. regulated substances with ED properties (pesticides, food contact materials, feed additives, etc.), where the testing framework required for authorization should be up-to-date in order to identify and characterize ED effects. The main option to protect consumers is to set and enforce regulations on the use of such substances
- ii. environmental contaminants and natural substances: risk assessment depends on available knowledge and weighing of uncertainties. Protection of consumers could make avail an array of options, including the reduction of environmental emissions, targets control programmes and risk communication.

Whereas the above considerations may apply to all chemicals in foods, ED features such as the potential exposure to multiple chemicals, the high vulnerability of the next generation and the many knowledge gaps call for policy measures which integrate science and precaution. Areas which require increased scientific knowledge include: the mechanisms underlying combined effects, the full characterization of long-term effects upon developmental exposures, the factors modulating dietary exposures, from the ecology of edible organisms through to dietary styles. Last but not least, the interactions between contaminants and natural food components can support the risk-benefit assessment of foods that are rich sources of both ED and nutrients, such as fish. Empowerment about good practices of farmers, food enterprises and consumers can reduce the exposure to, e.g., pesticides residues and food contact materials. Overall, ED call for science supporting the risk assessment, as well as for risk assessment providing clear and fit-for-purpose messages for protecting consumers health.

# Acrylamide: US FDA Guidance to Industry

**Lauren Posnick Robin and Eileen Abt**, Office of Food Safety, Center for Food Safety and Applied Nutrition, Food and Drug Administration, College Park, MD, United States

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Acrylamide is a substance that forms in foods from a chemical reaction between asparagine, an amino acid, and reducing sugars such as glucose and fructose. This reaction is part of the Maillard reaction, which leads to color, flavor, and aroma changes in cooked foods (Motttram et al., 2002; Stadler et al., 2002, 2003). Although many of the Maillard reaction products impart favorable characteristics to food, the formation of acrylamide in food is undesirable, because acrylamide is an animal carcinogen and has the potential to cause cancer in humans (National Toxicology Program (NTP), 2011).

Acrylamide formation occurs primarily in plant-based foods, notably potato products such as french fries and potato chips; cereal-grain-based foods such as cookies, crackers, breakfast cereals, and toasted bread; and coffee. Acrylamide formation usually occurs at elevated temperatures used when frying or baking (above 120 °C (248 °F)) and under low moisture conditions, although acrylamide has also been identified in some fruit and vegetable products heated at lower temperatures or higher moisture conditions (Amrein et al., 2007; Roach et al., 2003; FDA, 2006a,b).

Although it would be difficult to remove acrylamide from food completely, reducing acrylamide levels in foods may mitigate human health risks from exposure to acrylamide. For this reason, international efforts have focused on identifying techniques that can reduce acrylamide in foods and disseminating that information in the form of codes of practice, toolboxes, and guidance documents (e.g., FoodDrinkEurope, 2013; Codex Alimentarius, 2009), including the United States Food and Drug Administration (FDA) *Guidance for Industry: Acrylamide in Foods* (FDA acrylamide guidance) (FDA, 2016a).

## FDA Laws, Regulations, and Guidance Documents

To understand the acrylamide guidance, it is helpful to know more about what a guidance document is and what it is not. The Federal Food, Drug, and Cosmetic Act (FD&C Act) and other federal laws establish the legal framework within which FDA operates. FDA can develop regulations based on these laws, typically through a process known as “notice and comment rulemaking,” which allows for public input on a proposed regulation before FDA issues a final regulation. FDA regulations, which are found in Title 21 of the Code of Federal Regulations (CFR), have the force of laws, but they are not part of the FD&C Act.

FDA guidance documents, such as the FDA acrylamide guidance, are neither laws nor regulations and are not intended to be binding on industry or the public. FDA guidance documents describe the agency's current thinking, interpretation of, or policy on a regulatory issue. When issuing guidance, FDA follows procedures required by the FDA Good Guidance Practices regulation (21 CFR 10.115) for developing, issuing, and using guidance documents. Guidance documents do not include mandatory language such as “shall,” “must,” “required,” or “requirement,” unless FDA is using these words to describe a statutory or regulatory requirement.

FDA field investigators are expected to review guidance documents that apply to their work prior to inspections of food facilities, and inspection instructions may reference guidance documents. Investigators may ask about awareness of issues raised in guidance documents and have general discussions about information in guidance with firm management. However, because guidance is not a requirement for firms to follow, any observations investigators make during an inspection must be based on regulations or law, not guidance.

## Acrylamide Guidance Development

The FDA *Guidance for Industry: Acrylamide in Foods* provides information to help growers, manufacturers, and food service operators reduce acrylamide levels in certain foods. This guidance draws on the scientific literature; guidance materials prepared by industry, other governments, and international organizations; and public comments from manufacturers to present approaches to reduce acrylamide in foods at various stages from farm to table.

This guidance is intended to suggest a range of possible approaches to reducing acrylamide levels and not to identify specific recommended approaches. This guidance also does not identify any specific maximum recommended level or action level for acrylamide. Instead growers, manufacturers, and food service operators are encouraged to evaluate approaches that may be relevant to their particular processes and to consider adopting approaches that reduce acrylamide levels in their products. Because acrylamide reduction is an active area of research, the guidance also discusses mitigation methods that were still in the experimental stage when the guidance was developed, in addition to mitigation methods currently in use.

FDA began development of its draft guidance in 2009 with a *Federal Register* (FR) notice (74 FR 43134) that requested scientific data and information on methods for reducing acrylamide levels in food (e.g., changes in ingredients, cooking parameters, and mitigation methods for small manufacturers) and on reductions that manufacturers had achieved in acrylamide levels (e.g., levels

of reduction and factors affecting reductions, including variables affecting the ability to consistently achieve certain levels of acrylamide). Comments received by FDA addressed the many factors contributing to variability in acrylamide levels and the challenges in controlling this variability for the purpose of establishing maximum or recommended acrylamide levels. These comments addressed such factors as seasonal changes in the composition of raw materials, variations in individual product formulation, differences in processing equipment and parameters (e.g., type of cooking apparatus and temperature control), and consumer cooking behavior. Based on these comments and other factors, FDA concluded that it would be appropriate to develop guidance that would include information on reducing acrylamide, rather than developing specific maximum recommended levels for acrylamide in foods.

In 2013, FDA published a draft version of the *Guidance for Industry: Acrylamide in Foods* (78 FR 68852). After considering the public comments received on the draft guidance document, the final guidance was released in 2016 (FDA, 2016a). The guidance is available on the FDA website, along with other information on acrylamide.

Other governments and international organizations have taken similar approaches to providing guidance on mitigation. Examples include the Codex Alimentarius “Code of Practice for Reduction of Acrylamide in Foods” (Codex Alimentarius, 2009), the “Acrylamide Toolbox” produced by FoodDrinkEurope (FoodDrinkEurope, 2013), FoodDrinkEurope Toolbox brochures on selected foods for small- and medium-sized businesses (FoodDrinkEurope, 2014a–e), and “Guidelines to Authorities and Consumer Organisations on Home Cooking and Consumption” (HEATOX Project, 2006a) and “Manual on Strategies to Food Industries [and Restaurants] to Minimize Acrylamide Formation” (HEATOX Project, 2006b) produced by the Heat-Generated Food Toxicants: Identification, Characterization and Risk Minimisation (HEATOX) Project. The European Union Commission Regulation 2017/2158 (EC, 2017) setting benchmark levels for acrylamide in selected foods also establishes mitigation measures. The FDA acrylamide guidance document encourages manufacturers to review all available resources when considering approaches to reducing acrylamide levels in their products.

## Guidance Content

The current version of the FDA acrylamide guidance is organized into six major sections (A through F). The introduction (Section A) includes introductory comments on acrylamide monitoring and analysis, specifically, recommending that manufacturers be aware of acrylamide levels in their products to determine the effectiveness of acrylamide reduction techniques; noting that because acrylamide can vary significantly between identically prepared products, extensive sampling may be required to detect the effects of process changes; and that one approach to reducing analytical testing (e.g., by standard methods such as liquid chromatography/tandem mass spectrometry or gas chromatography/mass spectrometry) is to identify a characteristic that can be monitored as a proxy for acrylamide, such as color or moisture, and to calibrate variation in this characteristic to analytically determined acrylamide levels. To be effective, such analysis may have to be performed on a product-by-product basis.

The technical sections of the guidance cover the following topic areas. Section B covers potato-based foods, including information on raw materials, processing and ingredients, and product-specific information on french fries, sliced potato chips (crisps), and fabricated potato chips and other fabricated potato snacks. Section C covers cereal-based foods, including information on raw materials, processing and ingredients. Additional sections (Sections D through F) cover other foods; preparation and cooking instructions on packaged frozen french fries; and information for food service operations.

Section B,i, “Potato-based foods, raw materials,” focuses on growing and handling conditions that affect reducing sugar levels in potatoes. As stated in the guidance, in potatoes, reducing sugars are present in excess compared with asparagine, and reducing sugar levels are an important factor driving acrylamide formation. Careful control of reducing sugar levels can reduce acrylamide formation in finished potato products such as french fries and potato chips. Among the factors that affect reducing sugar levels are potato variety, growing and harvesting practices, maturity, handling, and storage conditions (including temperature and control of sprouting). This section includes the following recommendations that may reduce acrylamide (FDA, 2016a):

- Selecting potato varieties that are low in acrylamide precursors, keeping in mind seasonal variation.
- Optimizing potato maturity by controlling planting time, harvest time, and input management, and by removing immature tubers before processing.
- Avoiding handling potatoes with excessive roughness, avoiding bruising potatoes, and sorting out or carefully trimming potatoes with defects.
- Avoiding cold temperatures during harvest, transport, delivery, and storage.
- Managing storage conditions to control sprouting and provide ventilation.
- Monitoring reconditioning results and avoiding reconditioning potatoes stored for prolonged periods.
- Assessing reducing sugar levels in incoming potatoes, identifying target levels for incoming potatoes, or using treatments to reduce sugar levels.

Section B,ii, “Potato-based foods, processing and ingredients,” reviews the processing of french fries, sliced potato chips, fabricated potato chips, and other fabricated potato snacks. For french fries, the guidance focuses on production of frozen, par-fried french fries that are cooked to completion in a food-service establishment or in consumer homes. Levels of acrylamide are low in the par-fried fries, but increase significantly in the final cooked product. The guidance focuses on changes in processing by frozen french fry

manufacturers that can affect acrylamide levels in the final products. Specifically, the guidance includes the following processing recommendations that may reduce acrylamide ([FDA, 2016a](#)):

- Cutting fries in shapes with lower surface area to volume ratio and screening out small fragments.
- Changing blanching practices (although such changes may affect product quality).
- Using sugar dips to reduce variability (but using reducing sugars such as fructose in dips may increase acrylamide).
- Using alternative coloration methods to discourage over-baking.
- Using sodium acid pyrophosphate (SAPP), and evaluating other dip or batter ingredients to determine if they contribute to acrylamide formation during frying.

For sliced potato chips, a typical production process consists of peeling, washing (and/or blanching), slicing, frying, sorting, seasoning, and packaging chips. The guidance includes the following processing recommendations that may help reduce acrylamide in sliced potato chips ([FDA, 2016a](#)):

- Increasing peel removal.
- Washing or soaking potato chips before frying (but this may cause unacceptable changes to the chips).
- Cutting thinner potato chip slices.
- Decreasing frying temperatures to 175 °C (347 °F) or below and targeting higher moisture endpoints (but it is important to determine if moisture endpoints provide acceptable product quality).
- Using lower temperatures during final cooking stages and using techniques like flash frying, vacuum frying, or batch frying.
- Sorting by color, by providing a useful indicator of acrylamide levels, especially if correlated with measured levels of acrylamide in specific products.

For fabricated potato chips and other fabricated potato snacks, a typical production process consists of preparation of a dehydrated potato product such as potato flakes or granules, mixing with water and other ingredients to form dough, sheeting the dough, cutting, cooking (frying or baking), sorting, seasoning, and packaging. For extruded potato-based snacks, an extrusion step, with cutting and forming operations, follows dough formation. Some considerations for sliced potato chips also apply to fabricated potato chips or other potato-based snacks. Because of the use of doughs and potato-flake ingredients, other techniques (such as the use of asparaginase to decrease asparagine levels or substitution of potato flakes with other ingredients) may also be useful. Specifically, the guidance includes the following processing recommendations that may help reduce acrylamide in fabricated potato chips and other fabricated potato snacks ([FDA, 2016a](#)):

- Selecting potato flakes with lower levels of reducing sugars, e.g., by specifying maximum sugar levels, buying early in the processing season, or by mixing flakes from different sources. Flakes treated with acidulants, calcium, or asparaginase during flake production may also produce flake-based products with lower acrylamide.
- Partially substituting potato flakes with other ingredients.
- Adding calcium salts to potato doughs.
- Adding acidulants to potato doughs.
- For some products, adding asparaginase to potato doughs.
- In fabricated potato chips, decreasing cooking temperatures, using lower final temperatures in multistage processes, and using higher moisture endpoints.

Section C,i, “Cereal-based foods, raw materials,” reviews information on raw materials and processing approaches that may reduce acrylamide in cereal-based foods. In cereal grains such as wheat, asparagine is present in excess compared with reducing sugars. Therefore, the concentration of asparagine, not reducing sugars, is the important factor driving acrylamide formation. Cereal grain type, grain variety, and growing conditions are some of the factors that affect asparagine levels. For cereal-based foods, the guidance includes the following processing recommendations that may help reduce acrylamide ([FDA, 2016a](#)).

- Using wheat varieties that are lower in asparagine and using wheat grown with adequate soil sulfate and without excessive nitrogen fertilization.
- Partially substituting low-asparagine cereal grains for high-asparagine cereal grains.

Section C,ii, “Cereal-based foods, processing and ingredients,” reviews information on raw materials and processing approaches that may reduce acrylamide in cereal-based foods. For dough-based cereal products, the ability to use asparaginase and substitute ingredients provides additional options for acrylamide mitigation compared with intact potato products. The guidance includes the following specific recommendations for ingredients and processing that may help reduce acrylamide in cereal-based foods ([FDA, 2016a](#)).

- Replacing ammonium bicarbonate in cookies and crackers with alternative leavening agents, while avoiding overall increases in sodium levels.
- Replacing reducing sugars with nonreducing sugars, using reducing sugars with lower fructose content, and only adding sugar coatings to breakfast cereals after toasting.
- Using asparaginase treatment may reduce acrylamide, but asparaginase dose, contact time, dough water content, pH, and water chlorination are important considerations.

- Using calcium supplementation in non-calcium-fortified breads or breakfast cereals (but the addition of calcium propionate may increase acrylamide levels).
- Using yeast fermentation and changing fermentation conditions.
- Lowering thermal input through modifying baking times and temperatures and considering alternative baking technologies.
- Monitoring production by using color as an indicator of acrylamide, but the correlation between color and acrylamide may have to be determined on a product-by-product basis.
- Setting a higher moisture endpoint and monitoring moisture levels in finished products may be useful as an indirect indicator of acrylamide levels (FDA, 2016a).

Section D, “Other foods,” notes that coffee is a significant source of acrylamide exposure for adults, but that only limited information is available on factors known to affect acrylamide concentrations in coffee (FDA, 2016a).

Section E, “Preparation and cooking instructions on packaged frozen french fries,” and Section F, “Information for food service operations,” reflect the fact that final cooking conditions can be the major factor in determining final acrylamide levels in cooked fries prepared from packaged frozen french fries, as well as in other foods prepared in food service operations, such as baked goods. The guidance includes the following recommendations that may help reduce acrylamide in such foods (FDA, 2016a).

- Providing appropriate cooking instructions on frozen french fry packages to guide final preparation by consumers and food service operators.
- Educating food service workers to follow proper frying techniques for french fries.
- Selecting potato varieties that are low in reducing sugars for frying or roasting, properly handling and storing potatoes, and using certain cooking practices for foods made from potatoes.
- Baking and toasting breads and other baked goods to a light brown, not a dark brown color; and avoiding overly dry or crusty cereal-based products.

The final acrylamide guidance is available at [www.fda.gov](http://www.fda.gov). As guidances can be updated, it is good practice to check the FDA website for changes in the future.

## **Food Safety Modernization Act and Acrylamide**

In 2011, the FDA Food Safety Modernization Act (FSMA) (FSMA, 2011) was signed into law. This broad-reaching act gave FDA a legislative mandate to develop comprehensive preventive controls for food and feed facilities and new tools, such as mandatory recall, expanded records access, expanded administrative detention, suspension of facility registration, enhanced product tracing, and third party laboratory testing. To implement the law, FDA has issued regulations on produce safety, accredited third-party certification, mitigation strategies against intentional adulteration, sanitary transportation of human and animal food, foreign supplier verification programs, and preventive controls for human and animal food. Most relevant to acrylamide is the cornerstone prevention rule entitled “Current Good Manufacturing Practice, Hazard Analysis, and Risk-Based Preventive Controls for Human Food” (FDA, 2015). This rule, which became final in September 2015, requires food facilities to have a food safety plan in place that includes an analysis of hazards and implementation of risk-based preventive controls to significantly minimize or prevent identified hazards.

As part of FSMA’s implementation, FDA also has issued multiple guidance documents for industry, including the draft guidance entitled “Hazard Analysis and Risk-Based Preventive Controls for Human Food: Draft Guidance for Industry” (hazard analysis guidance). Chapters 1–5 and several appendices were published in August 2016 for public comment (FDA, 2016b). Chapters 6 and 15 have also been published for comment. The guidance is intended to help manufacturers consider the biological, chemical, and physical hazards that are commonly of concern in food plants and that should be addressed in a hazard analysis. It addresses ingredient-related hazards, process-related hazards, and hazards that may be introduced from the food-production environment (facility-related hazards). The guidance states that is important for manufacturers to understand the potential hazards that may be associated with products using the raw materials and other ingredients, processes, and equipment specific for those products, as well as the environment of their specific facility.

As required under FSMA, if manufacturers identify hazards requiring a preventive control, they have to determine what preventive controls are needed to reduce food safety risks and ensure the safety of their products for human consumption. As examples of chemical hazards requiring a preventive control, the guidance includes pesticides, heavy metals, drug residues, industrial chemicals, environmental contaminants, mycotoxins, allergens, unapproved colors and additives, substances associated with a food intolerance or food disorder, and radionuclides. Some process-related chemical hazards are included, such as hazards related to product formulation (e.g., sulfites that are a hazard for those consumers who are sensitive to them); and hazards that may be unintentionally introduced into food, such as industrial chemicals that are used in a facility for purposes other than food production.

Despite being considered a processing contaminant, acrylamide is not included as a hazard requiring a preventive control in the current draft hazard analysis guidance. As stated in Chapter 3 of the hazard analysis guidance, FDA has “not included such contaminants [i.e., acrylamide] in [a list of Common Sources of Chemical Hazards] as potential process-related chemical hazards that may require a preventive control as part of a food safety plan under part 117 because we believe that more information is

needed regarding appropriate levels and effective controls.” However, the hazard analysis guidance also reiterates the recommendation in the FDA acrylamide guidance that manufacturers evaluate approaches to acrylamide reduction that may be relevant to their particular processes and consider adopting approaches, if feasible, that reduce acrylamide levels in their products. Questions about FSMA and preventive controls, including how preventive controls relate to acrylamide, can be addressed to FDA’s FSMA Technical Assistance Network (TAN).

## Glossary

**Schiff base** Imine compound, formed from the reaction between an aliphatic or aromatic amine and a carbonyl compound by nucleophilic addition forming a hemiaminal, followed by dehydration.

**5-Hydroxymethyl-2-furfural (HMF)** An organic compound formed by the dehydration of certain sugars or by the Maillard reaction.

**$\alpha$ -Hydroxycarbonyl compound** A class of organic compounds possessing the secondary  $\alpha$ -hydroxy ketone functional group.

**Azomethine ylide** An iminium ion that occurs via decarboxylation of Schiff base during Maillard reaction.

**Amadori compound** Aminodeoxysugar derivatives formed in foods through the Maillard reactions.

**3-Aminopropionamide (3-APA)** An intermediate product in the acrylamide formation during thermal degradation of asparagine.

**Strecker aldehyde** An aldehyde compound formed by the Strecker degradation from an  $\alpha$ -amino acid.

**Electrophile** A compound or functional group accepts electrons.

**Nucleophilic group** Functional group donates electrons.

## Nomenclature

**IARC** International Agency for Research on Cancer

**HMF** 5-hydroxymethyl-2-furfural

**3-APA** 3-aminopropionamide

**EFSA** European Food Safety Authority

**WHO** World Health Organization

## Introduction

Acrylamide (or acrylic amide, prop-2-enamide) is an  $\alpha$ ,  $\beta$ -unsaturated carbonyl with a chemical formula  $C_3H_5NO$  (Fig. 1).

Acrylamide had been used as an industrial chemical in paper industry, water treatment, dam, tunnel and sewer construction for different purposes for years, but it was firstly discovered in thermally treated foods in 2002. Acrylamide had been intensively used to repair the water leaks and in October 1997, it was realized that it accidentally leaked to water systems from a railway tunnel in Sweden. It caused to death of the fish living in the river and paralysis of cows drinking from the river. After this incident, researchers in Stockholm University started to study the effects of acrylamide-contaminated water. During their research, they tried to confirm the presence of acrylamide-hemoglobin adducts in exposed animals and they interestingly discovered that acrylamide-hemoglobin adducts was not only found in cows and fish exposed to leak but also in unexposed humans living outside the contaminated area (Mills et al., 2009). Within this information, researchers considered that acrylamide might be a food contaminant. In a conducting study, it was reported that higher amounts of acrylamide-hemoglobin adduct was observed in rats fed with fried feed (Tareke et al., 2000). Eventually in 2002, Swedish National Food Administration (NFA) published that acrylamide was found in different thermally treated foods including potato chips, French fries and bakery products.

**Figure 1** Chemical structure of acrylamide.

## Formation Mechanism

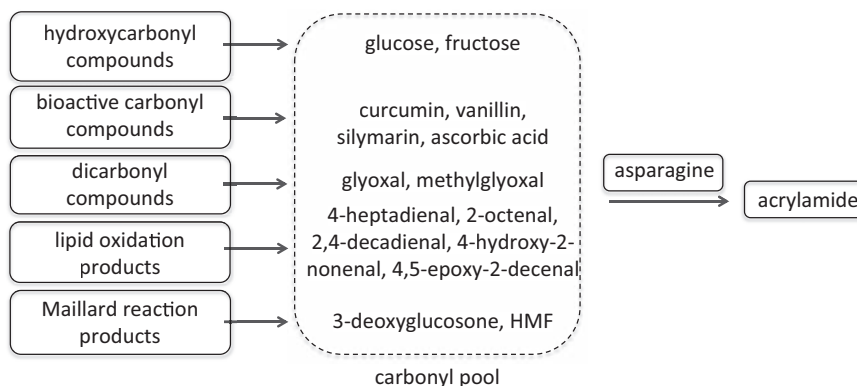

Since acrylamide is classified as a 'probable human carcinogen' by the International Agency for Research on Cancer (IARC), so much effort to evaluate its formation mechanism has been done so far (WHO, 1994; Eriksson, 2005; Manson et al., 2005). It has been found out that the Maillard reaction, the reaction between amino acids and reducing sugars as a result of heating food, was found to be the key responsible mechanism for the formation of acrylamide in certain starch-based foods, such as potato chips, French fries, bread and cereal products (Mottram et al., 2002b; Stadler et al., 2002; Tareke et al., 2002).

Experiments conducted by Zyzak et al. (2003) using labeled asparagine and glucose revealed that both carbon atoms and the nitrogen of acrylamide were derived from asparagine. As asparagine forms the backbone of acrylamide, it was confirmed that asparagine was the responsible amino acid for the formation of acrylamide. However, it was stated that formation rate of acrylamide is faster when asparagine is heated with carbonyl compounds such as reducing sugars (Yaylayan et al., 2003). Even asparagine itself is converted to acrylamide; studies carried out with different carbonyl compounds showed that carbonyl compounds react rapidly with asparagine yielding acrylamide (Stadler et al., 2002; Stadler and Scholz, 2004; Schieberle et al., 2005; Hamzalioglu and Gokmen, 2012). In this manner, reaction yield depends on carbonyl source and its ability to decarboxylate Schiff base (Blank, 2005).

In addition to significant contribution of mostly known  $\alpha$ -hydroxycarbonyl compounds such as fructose and glucose to acrylamide formation (Yaylayan and Stadler, 2005), glyoxal, methylglyoxal, 5-hydroxymethyl-2-furfural (HMF) and other sugar degradation products bearing carbonyl groups have also been reported to trigger acrylamide formation during heating (Gokmen et al., 2012; Amrein et al., 2004; Amrein et al., 2006). Studies carried out with galactose, lactose, and even non-reducing sugar sucrose resulted in comparable amounts of acrylamide when heated with asparagine at 180 °C (Stadler et al., 2003). Sucrose is assumed to lead to acrylamide formation through its hydrolysis to reducing sugars, glucose and fructose, during thermal treatment. Besides these carbonyl compounds, it was shown by Hamzalioglu and Gokmen (2012) that bioactive carbonyl compounds also participate in Maillard reaction yielding to acrylamide formation. Among the bioactive carbonyl compounds, it was revealed that curcumin, ascorbic acid, dehydroascorbic acid, silymarin and vanillin react with asparagine for the formation of acrylamide. Additionally, some carbonyl compounds of virgin olive oil phenolic extracts and pyridoxal also act like precursor of acrylamide (Kotsiou et al., 2010; Zeng et al., 2009). Moreover, carbonyl compounds produced during processing of foods might contribute to acrylamide formation. Zamora and Hidalgo (2008) showed that several carbonyl compounds formed as a result of lipid oxidation contributed to the conversion of asparagine into acrylamide. Other researchers also investigated that oil oxidation level affected carbonyl formation and positively influenced the formation of acrylamide in dry fat-rich model systems (Capuano et al., 2010). All these carbonyl compounds, present in the food or formed during processing, create a carbonyl pool and involve in acrylamide formation as summarized in Fig. 2.

Formation of acrylamide is given in Fig. 3. Firstly,  $\alpha$ -amino group of asparagine reacts with the carbonyl group of carbonyl source yielding N-glycosyl-asparagine (carbinolamine), which then forms Schiff base through the removal of one molecule of water as a result of heating under dry conditions at temperatures above 120 °C. The moisture content of system determines the direction of the reaction. When the reaction condition is high-moisture, Schiff base may rearrange to form Amadori compounds. Since these stable compounds cannot decarboxylate, rearrangement of Schiff base is not prerequisite for the formation of acrylamide in this mechanism. Lately they decompose for the formation of color and flavor compounds (Stadler et al., 2004; Yaylayan et al., 2003; Ledl and Schleicher, 1990).

Decarboxylation of Schiff base, yielding an azomethine ylide (decarboxylated Schiff base) that may form imine I and II, is the second step of acrylamide formation. It may also proceed through Schiff base betaine or oxazolidin-5-one (Zyzak et al., 2003; Yaylayan et al., 2003). Hydrolyses of imine I leads to the Strecker aldehyde (3-oxopropanamide) formation, which does not release

**Figure 2** A reactive carbonyl pool converting asparagine into acrylamide. Modified from Kocadağlı, T., Göncüoğlu, N., Hamzalioglu, A., Gökmen, V., 2012. Chapter 17 Relationship between antioxidants and acrylamide formation. In: Gökmen, V. (Ed.), *Acrylamide in Food*, 2016, Academic Press, pp. 325–353

**Figure 3** Formation pathway of acrylamide. Adapted from Stadler, R.H., Robert, F., Riediker, S., Varga, N., Davidek, T., Devaud, S., Goldmann, T., Hau, J. and Blank, I., 2004. In-depth mechanistic study on the formation of acrylamide and other vinylogous compounds by the Maillard reaction. *J. Agric. Food Chem.* 52, 5550–5558.

high amounts of acrylamide (Stadler et al., 2004; Blank et al., 2005). Imine II could form acrylamide directly through 1,2-elimination. It also could form acrylamide through  $\beta$ -elimination of decarboxylated Amadori compound (Wedzicha et al., 2005).

Additionally, formation of 3-aminopropionamide, which then deaminates to form acrylamide, as a result of hydrolysis of imine II is also possible (Zyzak et al., 2003). On the other hand, it is believed that Strecker aldehyde, which is formed through hydrolysis of imine I, is one of the direct precursors of acrylamide (Mottram et al., 2002a).

Even Maillard reaction was proposed as the major route for acrylamide formation, there are also some minor routes. Alternatively to acrylamide formation from asparagine through Maillard reaction, it was shown that asparagine might be converted to acrylamide in the absence of any carbonyl compound (Fig. 4). This is a non-Maillard pathway and 3-aminopropionamide (3-APA) is the major precursor in this route, which is generated directly from asparagine (Granvogl and Schieberle, 2007; Granvogl et al., 2004).

**Figure 4** Formation of acrylamide through 3-APA. Modified from Granvogl, M., Jezussek, M., Koehler, P., Schieberle, P., 2004. Quantitation of 3-Aminopropionamide in Potatoes: A Minor but Potent Precursor in Acrylamide Formation. *J. Agric. Food Chem.* 52, 4751–4757.

**Figure 5** Formation of acrylamide from acrolein. Adapted from Stadler, R.H., Studer, A., Chapter 1 Acrylamide formation mechanisms, In: Gökmen, V. (Ed.), *Acrylamide in Food*, 2016, Academic Press, pp. 1–17.

Formation of acrylamide through 3-APA proceeds in a lower extent. However, 3-APA might also be generated in foods under enzymatic action on asparagine, and rapidly converted to acrylamide even under aqueous conditions and at relatively low temperatures (Becalski et al., 2011).

Acrolein is also one of the precursors in acrylamide formation and could be formed through oxidative lipid degradation, carbohydrate degradation and Maillard reaction (Stadler and Studer, 2016). As shown in Fig. 5, acrolein is oxidized to acrylic acid and then reacts with ammonia (produced from  $\alpha$ -amino acids via Strecker degradation in the presence of carbonyl compounds) yielding acrylamide (Yasuhara et al., 2003). However, since acrolein is highly reactive, it prefers reacting with food components than oxidation to acrylic acid. Acrylic acid could also be formed from thermal decomposition of aspartic acid, carnosine and  $\beta$ -alanine (Stadler et al., 2003; Yaylayan et al., 2004; Yaylayan and Stadler, 2005).

### Further Reactions of Acrylamide With Other Food Components

As stated before, acrylamide is an  $\alpha,\beta$ -unsaturated carbonyl and these structural properties make it electrophile. Due to its highly electrophilic nature, it readily reacts with nucleophilic groups such as amino and thiol groups in foods through Michael type addition. Hidalgo and others carried out the studies investigating the Michael type reactions of both thiol and amino compounds with acrylamide (Hidalgo et al., 2010; Hidalgo et al., 2011; Zamora et al., 2010). They reported that thiol compounds are easily added to carbon–carbon double bond of acrylamide. Similarly, they showed that acrylamide could react with amino compounds as well. However, reaction yield with thiol compounds were 100–300 times higher than with amino compounds. In addition, formation of Michael adducts of acrylamide with thiol compounds takes place even at low temperatures in a very high extent. Also, reactions of acrylamide with thiol compounds are encouraged in the presence of amino compounds (Hidalgo et al., 2010; Zamora et al., 2010; Hidalgo et al., 2011).

### Factors Affecting Acrylamide Formation

Extensive studies carried out on the formation kinetics of acrylamide formation since its discovery in heated foods provided the important factors affecting its formation in detail (Martins and Van Boekel, 2005; Claeys et al., 2005a,b; Granda and Moreira, 2005). As stated before, asparagine is the main responsible amino acid from acrylamide formation and reducing sugars highly affect its conversion rate to acrylamide. Physical state of precursors in food has also been found to be important for the reaction rate (Van der Fels-Klerx et al., 2014). Asparagine is abundantly found in potatoes and concentration of reducing sugar limits the conversion of asparagine into acrylamide in potato products. Contrary to reducing sugars, asparagine concentration is limited in cereals thus it determines the acrylamide formation in cereal products. Accordingly, reduction in precursors results in limiting acrylamide content in heated potato and cereal products. For this, use of low-asparagine and/or low carbonyl crop varieties or controlling growth and storage conditions of crops were found to be effective (Haase et al., 2004; Haase and Weber, 2003; De Wilde et al., 2006; Muttucumaru et al., 2013). Selection of low-asparagine varieties was not only recommended for potatoes and cereals but also for chicory, which is the raw material of coffee substitutes and leads to acrylamide formation during roasting (Loaec et al., 2014). However, this could not be recommended for coffee beans since they already contains low levels of asparagine ( $0.3\text{--}0.9\text{ g kg}^{-1}$ ) (Stadler and Scholz, 2004). Asparaginase enzyme was found to greatly affect acrylamide formation. Asparaginase catalyzes the conversion reaction of asparagine into ammonia and aspartic acid, which makes asparagine unable to react to form acrylamide. Using this enzyme in different foods as ingredients, e.g. mashed potato, bakery products, or as dipping solution, e.g. for French fry, effectively decreased the final acrylamide content of these foods.

Presence or incorporation of compounds such as amino acids, bioactive carbonyl compounds that might compete with the precursors affects the reaction rate (Rydberg et al., 2003; Hamzalioglu and Gokmen, 2012). Incorporation of inorganic salts to the recipe was found as effective in controlling acrylamide content in foods by blocking the formation of some intermediates or accelerating the polymerization of acrylamide (Simko et al., 2009; Gokmen and Senyuva, 2007; Sadd et al., 2008; Amrein et al., 2004; Kolek et al., 2007). As stated before, formation of Schiff base between the carbonyl and asparagine is the first step in acrylamide formation and it was proposed that presence of  $\text{Ca}^{2+}$  prevented the formation of Schiff base and thus of acrylamide (Gokmen and Senyuva, 2007). In addition, it was confirmed by Kolek et al. (2007) that acrylamide polymerization was strongly accelerated by the presence of NaCl yielding polyacrylamide, which is biologically inactive. Several carbonyl compounds formed through the lipid oxidation contribute to the formation of acrylamide (Zamora and Hidalgo, 2008). Therefore, acrylamide formation might be affected by the addition of antioxidants, which avoid lipid oxidation and consequently formation of carbonyl compounds. On the other hand, Ou et al. (2010) proposed that antioxidants could attack acrylamide when they are in oxidized form. They found that acrylamide content decreased due to radical-induced elimination in the presence of antioxidant compounds both in the acrylamide and in the asparagine-glucose model systems. Oxidized antioxidant addition could cause significant reduction in acrylamide content of both asparagine-glucose and acrylamide model system.

Apart from the precursors, process conditions have strong influence on acrylamide formation. Formation of acrylamide is directly related to the amount of heat (temperature–time) applied and final moisture of the food (Claeys et al., 2005b; Hedegaard et al., 2007; Knol et al., 2005). Kinetic studies in model systems showed that the increase in acrylamide was relatively moderate in the case of temperature applied ranging between 150 and 170 °C (Gertz and Klostermann, 2002). However, in French fries, it was reported that acrylamide linearly increased by increasing frying temperature (especially higher than 175 °C) (Matthaus et al., 2004; Taeymans et al., 2004). For this reason, FoodDrinkEurope recommended a maximum frying temperature as 175 °C in the Acrylamide Toolbox (FoodDrinkEurope, 2013). Furthermore, the amount of acrylamide in these French fries also increased when the frying time was extended at the same temperature. From the moisture point of view, the suitable regions for acrylamide formation were discovered as the surface and a thin layer just below the surface. Since these regions were exposed to higher temperatures, acrylamide was mostly concentrated in these regions (Acar and Gokmen, 2009). Accordingly, Gokmen et al. (2006) indicated that acrylamide was mostly found in the outer parts of French fries.

## Occurrence in Foods

After the discovery of presence of acrylamide in heated foods, European Commission started to have data about acrylamide concentrations in foods. Within the acquired data, basically, foods rich in carbohydrate and asparagine, processed at high temperature, and containing low moisture have the highest potential to form acrylamide. Boiling doesn't lead to acrylamide formation, whereas baking, deep-fat frying, roasting cause to form acrylamide in certain foods (Tornqvist, 2005). In June 2015, the European Food Safety Authority (EFSA) published a report including the acrylamide levels in monitored foods. As indicated in this report, acrylamide is formed in baked or fried carbohydrate-rich foods mostly in French fries, potato chips, breads, biscuits and coffee. **Table 1** gives the summary of the recent results published by EFSA (EFSA, 2015). Indicative values for some foods determined by European Commission were also given in **Table 1**. Indicative values are not legal limits but further investigation is recommended if an indicative value is exceeded. Additionally, in 2017, EU Commission prepared a recent regulation proposal in which benchmark acrylamide levels were specified (**Table 1**) (EU, 2017). It was stated that benchmark levels could be used to test the performance of mitigation measures that will be used by the industry. The Council of European Parliament will review draft of regulation and after its approval, European food operators will likely be enforced by the mandatory limits on acrylamide in food and this will lead them to review their food operations.

According to these data, French fries, potato crisps, coffee and coffee substitutes were found to be containing the highest amounts of acrylamide. However, all these acrylamide content of foods should be considered together with the consumption amount in order to evaluate the total risk and exposure to acrylamide.

Acrylamide amounts in foods greatly varied depending on both process conditions and precursor concentrations. Accordingly, considering the bakery products, no acrylamide was detected in bread crumbs (Ahrne et al., 2007) whereas acrylamide concentration was more than 2000  $\mu\text{g kg}^{-1}$  in crackers (EFSA, 2015) due to the differences in moisture contents. Since potato is rich in asparagine, fried potato products, including French fries, potato crisps and snacks, have also been reported to contain high levels of acrylamide with mean values of 332–580  $\mu\text{g kg}^{-1}$ .

As reported by EFSA, mean acrylamide concentration was found to be as 578  $\text{ng g}^{-1}$  in roasted coffee (EFSA, 2015). Differences in species of roasted coffee were found to strongly affect acrylamide formation. Acrylamide content of roasted Robusta coffee beans was analyzed to be 45%–55% higher than that of Arabica coffee beans under the same roasting conditions (Summa et al., 2007). Higher acrylamide levels were detected in instant coffee and cereal based coffee substitutes but, chicory-based coffee substitutes showed the highest levels of indicative value of 4000  $\mu\text{g g}^{-1}$ .

Roasted nuts, such as almond, have been reported to contain acrylamide. Acrylamide concentration given in literature was 260  $\text{ng g}^{-1}$  for roasted almonds and 2147  $\text{ng g}^{-1}$  in dark roasted almonds (Amrein et al., 2005a). On the contrary, very little acrylamide was detected in both roasted hazelnuts (16–56  $\text{ng g}^{-1}$ ) and chestnuts (90  $\text{ng g}^{-1}$ ) since they contain relatively low amounts of asparagine in raw (Zilic, 2016; Amrein et al., 2005b).

**Table 1** Levels, indicative values and benchmark levels ( $\mu\text{g kg}^{-1}$ ) of acrylamide in foods (EFSA, 2015; EU, 2017)

	<i>n</i>	<i>Median</i> ( $\mu\text{g kg}^{-1}$ )	<i>Mean</i> ( $\mu\text{g kg}^{-1}$ )	<i>P95</i> ( $\mu\text{g kg}^{-1}$ )	<i>Indicative value</i> ( $\mu\text{g kg}^{-1}$ )	<i>Benchmark level</i> ( $\mu\text{g kg}^{-1}$ )
French fries	1378	196	332	1115	600	500

Black olives in brine	3	313	454	–	–	–

Mean, median, P95: mean, median and 95th percentile contamination level presented as the middle bound (MB) estimate.

As stated above, formation of acrylamide is strongly dependent to excessive thermal treatment at high temperatures. Even though such conditions are not generally applied to table olives, acrylamide content of canned black ripe olives was found around  $2000 \mu\text{g kg}^{-1}$ . Recent studies have also confirmed that acrylamide has been only detected in California-style black ripe and California-style green ripe olives, not detected in Spanish-style and Greek-style olives. Sterilization was proposed to be responsible step from the formation of acrylamide in canned black ripe olives. Acrylamide was not detected in olives without thermal treatment (Casado and Montano, 2008). Additionally, acrylamide content of Californian style green ripe olives were comparably lower than black ripe olives. This was due to formation of acrylamide precursors during darkening, which then will be converted to acrylamide in the course of sterilization (Charoenprasert and Mitchell, 2014).

Apart from the thermally treated foods, acrylamide was reported to be present in drinking water due to the contamination during the water treatment process. During this process, acrylamide is released from the residual monomer of polyacrylamide. The World Health Organization (WHO) announced a value of  $0.5 \mu\text{g L}^{-1}$  for residual acrylamide concentration in drinking waters, whereas this limit value was specified as  $0.1 \mu\text{g L}^{-1}$  by European Union. However, acrylamide levels in potable waters coming from the rivers treated with polyacrylamides were analyzed as lower than  $5 \mu\text{g L}^{-1}$ . Similarly, drinking waters analyzed from different countries all contained acrylamide in lower amounts (Chu and Metcalfe, 2007; Brown and Rhead, 1979). Consequently, acrylamide content of common foods are greatly higher than the maximum residual acrylamide concentrations in water.

## Summary

Acrylamide, a classified probable carcinogen to humans, is primarily formed through the Maillard reaction and mostly found in carbohydrate-rich foods. Asparagine is the main responsible precursor for its formation, and several carbonyl compounds contribute to its higher conversion to acrylamide. Acrylamide is dense in foods exposed to excessive heat treatment and having high amounts of asparagine together with reducing sugars. Potato chips, French fries, pan-fried potato products, biscuits, crisp bread, coffee and coffee substitutes are some of the examples of these foods.

# Dietary Acrylamide: An Update on the Chronic Risks

Janneke Hogervorst<sup>a</sup>, Hasselt University, Diepenbeek, Belgium

© 2019 Elsevier Inc. All rights reserved.

## Nomenclature

AA acrylamide  
APC adenomatous polyposis coli  
BMDL10 bench mark dose lower limit 10  
BMI body mass index  
CI confidence interval  
CONTAM panel contaminants in the Food Chain panel  
CYP2E1 cytochrome P4502E1  
DNA deoxyribonucleic acid  
EFSA European Food Safety Authority  
FFQ food frequency questionnaire  
FSH follicle-stimulating hormone  
GA glycidamide  
KRAS Kirsten rat sarcoma viral oncogene homolog  
µg/kg bodyweight microgram per kilogram bodyweight  
MoBa study Norwegian Mother and Child Cohort Study  
MOE margin of exposure  
NHANES National Health and Nutrition Examination Survey  
NOAEL no observed adverse effect level  
OR odds ratio  
RR relative risk  
SGA small for gestational age  
SH-group sulfhydryl group

## Introduction

Due to its presence in many every-day foods, virtually every person is exposed to acrylamide on a daily basis. When ingested, acrylamide is well absorbed from the stomach and gastrointestinal tract and is distributed with the blood to all organs and tissues (EFSA, 2015). Thus, it has the potential to cause adverse effects throughout the whole body.

Acrylamide is a soft electrophile which means that it can bind with soft nucleophiles such as cysteine residues in proteins (EFSA, 2015). Proteins with a diversity of functions, such as antibodies, receptors, hormones, and enzymes, often contain cysteine residues. Cysteine residues consist of intra- and inter-molecular disulfide bonds, important for protein folding and stability, or of free thiols (SH-groups). Free thiols are often part of the catalytic activity site in enzymes. Thus, by binding to these cysteine residues, acrylamide can potentially affect many proteins with a diversity of functions. Interference with the function of proteins can lead to the disturbance of various physiological processes.

Acrylamide itself has low reactivity towards hard nucleophiles such as DNA (EFSA, 2015). In contrast, the epoxide metabolite of acrylamide, glycidamide, has the potential to alkylate DNA due to its epoxide moiety (EFSA, 2015). Through this alkylation, glycidamide can lead to DNA point mutations, which can initiate tumors by changing the DNA sequence, potentially activating oncogenes or inactivating tumor suppressor genes. In addition, glycidamide is a clastogen, which means that it can cause breakages in DNA that can also lead to cancer (EFSA, 2015).

Acrylamide has been proven to cause cancer, neurotoxicity, reproductive toxicity and developmental toxicity in experimental animal studies (EFSA, 2015). No experimental studies have been performed on humans because they are deemed unethical. The available epidemiological evidence comes from observational studies.

In humans, occupational exposure to acrylamide has not clearly been shown to be associated with an increased risk of cancer, even though the exposure in occupational settings was higher than exposure through diet (EFSA, 2015). However, it has to be kept in mind that exposure routes in occupational settings are mostly inhalation and dermal absorption whereas dietary exposure is through ingestion. In addition, the historical occupational cohorts were mainly made up of men, lacked thorough data to adjust for potentially important other risk factors for cancer and estimated individual acrylamide exposure rather crudely. Epidemiological data on neurotoxic health effects of acrylamide stem from case studies and occupational exposure studies, in which effects on both

the peripheral and central nervous system were observed, at doses considerably higher than the doses to which we are exposed through diet.

There is scarce data, both from animal and epidemiological studies, on possible effects of acrylamide on the immune, metabolic and cardiovascular system.

In 2015, the European Food Safety Authority (EFSA) performed a full risk assessment for dietary acrylamide intake. It concluded that the thus far available epidemiological studies did not yield sufficient evidence to be able to be used in risk characterization and it thus based its risk assessment on experimental animal data only. The outcome of the risk assessment was that there is a high level of concern with regard to dietary intake for neoplastic (carcinogenic) effects but a low level of concern for non-neoplastic effects (neurotoxicity, and developmental and reproductive toxicity) (EFSA, 2015).

In the following sections, the different chronic health risks of dietary acrylamide are discussed based on results from experimental animal studies and epidemiological studies, with a focus on the latter.

## Carcinogenicity

In 2-year experimental studies with rats, acrylamide repeatedly proved to cause tumors in the thyroid and mammary gland (latter in females) and the scrotal mesothelioma in male rats. In mice, acrylamide causes cancer in among other the lungs, skin and Harderian gland (EFSA, 2015). It can thus be concluded that acrylamide is a multispecies, multisite carcinogen. The results of these studies are summarized in **Tables 1** and **2**. It has been argued that acrylamide behaves in human bodies the same way it does in animals in terms of uptake, metabolism and genotoxicity, and therefore it was classified as a probable human carcinogen by the International Agency for Research on Cancer in 1994 (IARC, 1994).

Initially, all attention with regard to the carcinogenic mechanism of acrylamide was focused on the genotoxicity of acrylamide's metabolite glycidamide. In recent years, alternative mechanisms for carcinogenesis are considered: increasing oxidative stress, interference with cell division by forming adducts on meiotic/mitotic spindle kinesin proteins causing aneuploidy, and interfering with sex hormone systems (Besaratnia and Pfeifer, 2007). Alternative mechanisms were put forward for several reasons. In rodent studies, DNA adduct formation and DNA damage alone could not account for the observed organ specificity for tumor induction in the rodents (Segeberback et al., 1995). In addition, because of the difference in the efficiency to metabolize acrylamide to glycidamide in mice and rats, it is unlikely that all tumors resulting from acrylamide exposure in rats and mice occur by the same mechanism. Furthermore, some of the tumors observed in rodents upon acrylamide exposure are known or hypothesized to be caused by non-genotoxic mechanisms, such as sex hormone-induced tissue proliferation (Haber et al., 2009; Maier et al., 2012).

For its 2015 acrylamide risk assessment, EFSA based its estimation of the risk of cancer related to dietary acrylamide exposure on the animal studies. They calculated the bench mark dose lower limit 10 (BMDL10), which is the lower limit of the confidence interval around the modeled estimated dose that increased the incidence of the most sensitive cancer (occurring at the lowest dose) outcome (Harderian gland adenomas and adenocarcinomas in male B6C3F1 mice) by 10% over the incidence in controls. In this way, they arrived at a reference point value of 0.17 mg/kg bodyweight per day. This reference value is then divided by the estimated dietary exposure of humans and the so-called margin of exposure (MOE) is calculated. For genotoxic carcinogenic effects, it is determined that the MOE has to be 10000 or more. Because the MOE for cancer ranged from only 50 to 425 in different age groups, EFSA arrived at the conclusion that there is important cause for concern with regard to the carcinogenic risks of dietary acrylamide intake (EFSA, 2015).

For humans, the body of evidence for dietary acrylamide intake and cancer is less clear than for experimental animals, as might be expected because the doses in humans are lower and harder to assess, and observational studies cannot be controlled for interfering or confounding factors to the extent that experimental studies can be.

The association between dietary acrylamide intake and the risk of several cancers has been studied in several epidemiological studies, both retrospective (case-control studies) and prospective (prospective cohort studies) in nature, and using both food frequency questionnaire-derived acrylamide intake and acrylamide biomarkers. The studies with their characteristics and results are summarized in **Table 3**.

For some cancers, an association between increased acrylamide intake and increased risk was observed in some studies but not in other studies on the same cancers. This is not unusual for epidemiological research. In situations where there is no agreement between studies, such as is the case here with studies showing an association while other studies do not, a meta-analysis that statistically pools all the available evidence is useful. In 2015, a meta-analysis was performed (Pelucchi et al., 2015). A relative risk (RR) of borderline statistical significance for renal cancer (RR = 1.20; 95% confidence interval (CI), 1.00–1.45) comparing the highest category of acrylamide intake to the lowest was calculated. Among never-smokers, comparing the highest category of acrylamide intake to the lowest, borderline statistically significant associations were observed for endometrial (RR = 1.23; 95% CI, 1.00–1.51) and ovarian (RR = 1.39; 95% CI, 0.97–2.00) cancers. The authors of the meta-analysis concluded that dietary acrylamide is not related to the risk of most common cancers but a modest association for kidney cancer, and for endometrial and ovarian cancers in never smokers only, cannot be excluded (Pelucchi et al., 2015).

With regard to breast cancer, the picture emerging from the epidemiological studies is heterogeneous with some studies showing indications for an increased risk of estrogen receptor-positive breast cancer (Olesen et al., 2008; Pedersen et al., 2010) or for premenopausal women (Burley et al., 2010) while other studies show no associations or indications for an inverse association (**Table 3**).

**Table 1** Tumor incidence derived from the 2-year NTP carcinogenicity assays with acrylamide in B6C3F1 mice (NTP, 2012)

EFSA Journal 2015; 13(6):4104, 321 pp. <https://doi.org/10.2903/j.efsa.2015.4104>. Number of mice per dose group: 42–48

For esophageal cancer, 2 studies suggest that there may be an increased risk in overweight persons (Hogervorst et al., 2008a,b; Lin et al., 2010).

In addition, positive associations with acrylamide intake were observed for some cancers but only 1 study so far has been performed for those cancers: colorectal cancer with KRAS mutations in men (Hogervorst et al., 2014), lung cancer in smoking men (Hirvonen et al., 2010), oral cavity cancer in women (Schouten et al., 2009), lymphatic malignancies in men (Bongers et al., 2012), and melanoma in men (Lipunova et al., 2017). For these cancers, more epidemiological studies are needed.

Several studies have been performed for prostate, pancreatic, stomach, bladder and laryngeal cancer but no clear increased risks were observed in relation to acrylamide intake (Table 3).

In addition, for lung cancer in women (Hogervorst et al., 2009a,b) and colorectal with a truncating APC mutation in women (Hogervorst et al., 2014), inverse associations were observed but these cancers were only once so far. Also for these cancers, more epidemiological studies are needed.

If it is true that acrylamide exerts both a risk-increasing and protective effect with regard to cancer, then studies on total cancer incidence and mortality are important to judge the net effect of acrylamide. There recently was 1 study on cancer mortality in Chinese men and women that showed increased risks of cancer mortality (total, respiratory system, and digestive tract cancer) in Chinese elderly (Liu et al., 2017b). However, the main dietary sources of acrylamide exposure in this study (stir-fried vegetables) were very different from those in Western countries (e.g., fried potatoes, coffee) and it would be interesting to know whether associations are also observed in Western populations.

Adapted from EFSA CONTAM Panel (EFSA Panel on Contaminants in the Food Chain), 2015. Scientific Opinion on acrylamide in food. EFSA Journal 2015;13(6):4104, 321 pp. doi:10.2903/j.efsa.2015.4104.

Based on the experimental animal data, it was calculated that the relative risk for cancer in humans would only range between approximately 1.015 and 1.05 when comparing the part of the population with extremely high acrylamide intake to the part of the population with a mean intake (Hagmar and Tornqvist, 2003). Detecting risks that low would require hundreds of thousands of cases in an epidemiological study, which is practically unfeasible. However, the fact that statistically significant risks and higher risks than calculated from animal studies were observed for some cancers in epidemiological studies may indicate that humans are more susceptible to the carcinogenic effect of acrylamide than rodents (Hogervorst et al., 2010).

Two epidemiological studies on ovarian cancer (Obon-Santacana et al., 2016b; Xie et al., 2013) and 1 for endometrial cancer (Obon-Santacana et al., 2014) have investigated the association with acrylamide and glycidamide to hemoglobin adducts (medium to chronic term biomarkers (approximately 4 months) of internal exposure to acrylamide), but observed no associations. Some would argue that this renders strong evidence against a causal association between dietary acrylamide intake and these cancers but it is important to keep in mind that this biomarker also has drawbacks when it comes to representing long-term dietary acrylamide intake, which has to be assessed accurately in order to be able to link it to diseases that take a long time to develop, such as cancer (Hogervorst et al., 2010). For example, the biomarkers acrylamide and glycidamide to hemoglobin adducts still only represent a relatively short exposure period and may be susceptible to seasonal influences. In addition, it is not specific for dietary acrylamide intake and also represents acrylamide exposure through active or passive smoking. Furthermore, this biomarker is expressed per gram of hemoglobin in the blood sample and there are many factors that influence hemoglobin levels. Finally, the biomarker does not allow discrimination between long-term low, with incidentally high intake levels of acrylamide, and long-term moderate intake levels, while the latter is expected to be more relevant for carcinogenesis.

From the epidemiological work described above, it can be concluded that there may be a positive association between acrylamide intake and renal, endometrial and ovarian cancers.

In light of the still thin evidence there is that acrylamide at current dietary levels causes renal, endometrial and ovarian cancer, we need a way to better understand the causality of this link. Although experimental studies on acrylamide and cancer in humans are off-limits, it should be possible, in the era of molecular epidemiology using omic techniques, to investigate the biological plausibility for acrylamide at current dietary levels to cause cancer.

One example of such research is to study whether genetic variability in genes involved in acrylamide metabolism modifies the association between acrylamide and cancer. In recent analyses from a Dutch prospective cohort study, there were indications that genetic variants in cytochrome P4502E1 (CYP2E1: the enzyme responsible for the metabolism of acrylamide to glycidamide) modified the association between acrylamide intake and endometrial and ovarian cancer risk, which supports the idea that these associations are causal (Hogervorst et al., 2016, 2017).

In future studies, it seems justified to analyze associations separately for men and women because some tumors were only associated to acrylamide intake in one of the sexes, which may be due to the potential effect of acrylamide on sex hormone systems.

To conclude, due to the potential carcinogenic risks associated with dietary acrylamide intake, be it the risks estimated from animal studies or the risks shown from the epidemiological studies, there is every reason to try and reduce the intake of acrylamide through food.

## Neurotoxicity

Experimental animals exposed to acrylamide exhibited both peripheral and central nervous system toxicity, such as hind-limb paralysis, reduction in rotorod performance and histopathological changes in peripheral nerves and central nervous system structures (EFSA, 2015). As the most sensitive neurotoxic effect, the Contaminants in the Food Chain (CONTAM) panel of EFSA that performed the 2015 acrylamide risk assessment selected peripheral nerve (sciatic) axonal degeneration in male F344 rats exposed to AA in drinking water for two years. For this endpoint, they calculated the so-called bench mark dose lower limit 10 (BMDL10) which is the lower limit of the confidence interval around the modeled estimated dose that increased the incidence of the health outcome (peripheral nerve (sciatic) axonal degeneration in this case) by 10% over the incidence in controls. For this endpoint, they calculated the so-called they arrived at a reference point value of 0.43 mg/kg bodyweight per day. This reference value was divided by the estimated dietary exposure of humans to calculate the MOE for neurotoxicity. Taking into account differences between rodents and humans and differences between humans, it is determined that the MOE for non-neoplastic effects has to be 100 or more. Because the MOE for neurotoxicity ranged from 126–1075 in different age groups, EFSA arrived at the conclusion that no neurotoxicity is expected to follow from dietary acrylamide exposure (EFSA, 2015).

However, some experts have concerns that low levels of exposure may be cumulative in nature and just take a longer time to sort effects (Erkekoglu and Baydar, 2014). Since rats only live two years and humans around 80 years, it is not inconceivable that low level acrylamide exposure has effects on the nervous system later on in life.

So far, there has only been one epidemiological study on the association between dietary acrylamide intake and neurotoxicity. In a prospective cohort study of elderly Chinese, increased acrylamide intake was associated with mild cognitive decline and with an increased risk of poor cognitive function after 4 years of follow-up in men but not in women (Liu et al., 2017a). However, the main dietary sources of acrylamide exposure in this study (stir-fried vegetables) were very different from those in Western countries.

In addition, because of the exquisite sensitivity of fetal and neonatal brain development to toxicological insults, research on the possible association between gestational and neonatal acrylamide exposure and neurotoxicity in the developing child seems warranted.

## Reproductive Toxicity

In rodents, acrylamide has effects on various endocrine and reproductive functions, especially on male reproduction. Acrylamide causes among other perturbed sperm functionality and sperm reservoirs in the epididymis, genotoxicity in several types of testicular cells, Leydig cell toxicity, and changes in sex hormones such as testosterone and prolactin (EFSA, 2015). These effects may be caused by acrylamide-induced damage of proteins and/or by damage of nucleic acids and proteins by acrylamide's metabolite glycidamide. The most sensitive reproductive effects selected by EFSA were reduced sperm counts and effects on sperm and testis morphology with a no observed adverse effect level (NOAEL), the dose at and below which no adverse effects are seen anymore, of approximately 2 mg/kg bodyweight per day. This dose is higher than the reference dose determined for neurotoxicity and therefore EFSA concluded that no reproductive effects of dietary acrylamide intake are to be expected either (EFSA, 2015).

There are no epidemiological studies on the reproductive toxicity of acrylamide apart from 3 studies that investigated the association between acrylamide exposure and blood or urinary sex hormone levels in different study populations.

In a cross-sectional study from the United States that used a food frequency questionnaire (FFQ) to assess acrylamide intake, there were some statistically significant associations between acrylamide intake and plasma sex hormone levels in both pre and postmenopausal women (Hogervorst et al., 2013). Plasma luteal estradiol and free estradiol levels were statistically significantly increased in normal weight premenopausal women with higher acrylamide intake. In postmenopausal women, statistically significant inverse associations were observed between AA intake and plasma estrone, free estradiol and prolactin levels in normal weight women. In overweight postmenopausal women, statistically significant positive associations were observed between AA intake and plasma testosterone and androstenedione levels. In a cross-sectional Japanese study in premenopausal women, also using an FFQ to estimate acrylamide intake, a higher acrylamide intake was associated with lower plasma total and free estrogen levels and a higher follicle-stimulating hormone (FSH) level. The association with total and free estrogen levels was only present in women with a body mass index (BMI) higher than 20.5 kg/m<sup>2</sup> (Nagata et al., 2015).

In another Japanese cross-sectional study by the same authors but this time in preschool children (aged 3–6 years), acrylamide intake was significantly positively associated with testosterone and androstenediol levels in urine in boys (Nagata et al., 2018). There were no statistically significant associations with sex hormones in girls. The authors concluded that acrylamide exposure of preschool-age boys may alter their androgen metabolism.

In all 3 studies, there were some statistically significant associations between acrylamide intake and sex hormones. However, the results come from very diverse populations, using different bodily fluids, and with widely varying dietary acrylamide sources, which makes it hard to draw conclusions at this time. In addition, the results on adult women from the American and Japanese study seem to partly contradict each other. More epidemiological studies in this area, also studies using acrylamide biomarkers, are needed. It would also be of interest to have epidemiological studies on the association between dietary acrylamide and fertility.

## Developmental Toxicity

In experimental studies, rats and mice exposed prenatally and/or neonatally to acrylamide showed signs of developmental toxicity, such as skeletal variations, impaired body weight gain, histological central nervous system changes, and neurobehavioral effects (EFSA, 2015). Some effects did not occur without maternal toxicity also taking place. The lowest NOAEL reported for developmental toxicity was 1.0 mg/kg bodyweight per day for neurodevelopmental toxicity (reduced learning task performance) from studies in rats exposed gestationally and neonatally. This NOAEL is higher than the reference dose that was calculated for neurotoxicity and therefore EFSA, in their latest acrylamide risk assessment (2015), arrived at the conclusion that no adverse developmental effects of acrylamide are expected to occur at dietary intake levels (EFSA, 2015).

However, 3 recent epidemiological birth cohort studies have consistently shown an association between increased maternal acrylamide exposure during pregnancy and a reduced fetal growth (Duarte-Salles et al., 2013; Kadawathagedara et al., 2016; Pedersen et al., 2012). These epidemiological studies on acrylamide exposure and birth outcomes are summarized in Table 4 and 5. Every one of these studies used an FFQ to estimate acrylamide intake and 1 study additionally measured acrylamide and glycidamide to hemoglobin adduct levels in umbilical cord blood.

All 3 studies observed a statistically significant association with an increased risk of the newborn being small for-gestational age (SGA), both in the whole study population and in the subpopulation of neonates from non-smoking mothers. These associations are in line with experimental animal studies in which increased acrylamide exposure led to a reduced birth weight of the animals. However, the dose levels at which this occurred in animals were so high that they also caused toxicity to the mother (EFSA, 2015). Thus, it is questionable whether the same mechanism of action operates in humans at dietary levels (if it is a causal effect) and animals at massively high dose levels. EFSA did not give the epidemiological findings (of 2 studies published at the time) any weight in their risk assessment, mainly because of lack of a known mechanism for these associations in humans. As mentioned above, based on the animal data, they ruled developmental effects at dietary doses to be unlikely (EFSA, 2015).

Although it is known that reduced fetal growth predisposes for adverse health outcomes later in life, such as cardiovascular disease, diabetes and overweight (Eriksson, 2016), it remains to be studied further whether gestational acrylamide exposure is associated with those health outcomes through effects on fetal growth.

In one of the cohorts (the Norwegian Mother and Child Cohort Study (MoBa)) in which an inverse association with fetal growth was seen, the association between prenatal dietary acrylamide exposure and postnatal growth was investigated (Kadawathagedara et al., 2018). Increased acrylamide intake was statistically significantly associated with a higher risk of overweight/obese status at 3, 5

**Table 4** Characteristics of the epidemiological studies on the association between dietary acrylamide intake and birth outcomes

References	Name of cohort	Country	Method for acrylamide intake assessment	Study size	Range of intake

and 8 years of age. In contrast, an increase in the level of the exposure biomarker acrylamide to hemoglobin adducts was associated with reduced BMI and body fat in a cross-sectional analysis among adults from the National Health and Nutrition Examination Survey (NHANES) (Chu et al., 2017). However, the association was only observed in persons who actively smoked themselves and in persons who were exposed to environmental tobacco smoke, so confounding by tobacco smoke cannot be excluded.

The epidemiological findings summarized above and in Tables 4 and 5 indicate the urgent need to gather further data on the potential important effects of acrylamide on human prenatal and postnatal development. More studies along the line of the presented studies should be performed and it would also be helpful to try and interrogate the causality of the observed inverse association by investigating the biological plausibility (mechanism of action) using biomarkers.

### Other Possible Chronic Health Effects of Dietary Acrylamide Intake

Whereas it might be expected that acrylamide, due to its potential adverse on fetal growth, may lead to increased risks of metabolic disease such as diabetes in later life, an opposite association was seen in the NHANES study (Lin et al., 2009). Adults with a higher level of acrylamide to hemoglobin adducts had lower serum levels of insulin and insulin resistance. However, this association was only statistically significant among smokers, which again raises concern for confounding by smoking. Obviously, more epidemiological research on this topic is needed.

Immunotoxicity has so far hardly been studied as a possible health outcome of acrylamide exposure in animals and is therefore not a part of the risk assessments that have been performed for acrylamide.

In a study on mice (oral dose range: 12.5–50 mg/kg body weight per day), acrylamide caused immunotoxicity as shown by a reduction in immune blood cells, pathological changes in the spleen, and reduced body and organ weights, potentially by inducing apoptosis or oxidative stress (Zamani et al., 2017). Again in mice, orally exposed to acrylamide for 30 days, spleen and thymus weights and lymphocyte counts were decreased, and pathological changes were observed in spleen, lymph glands and thymus upon acrylamide exposure (Fang et al., 2014).

In rats exposed to acrylamide through gavage (dose range: 0–60 mg/kg bodyweight per day) for 5 days or to 0–175 mg/kg by a single oral dose, a dose-dependent decrease was observed in peripheral blood lymphocytes and the gut-associated lymphoid tissue, which is a part of the immune system that protects the body from invasion through the gut (Yener et al., 2013). In another study on rats, acrylamide caused a decrease in spleen, thymus and mesenteric lymph nodes weights. In addition, a decrease in cellularity of the spleen, thymus, bone marrow and the population of circulating blood lymphocytes population was observed (Zaidi et al., 1994).

A recent cross-sectional analysis from the epidemiological NHANES study showed increased risks of eczema and itchy rash associated with increased hemoglobin adducts levels of acrylamide and glycidamide (Guo et al., 2017). So far, this is the only epidemiological study related to immunotoxic effects of acrylamide. Clearly, more research is needed on the potential immunotoxic effects of acrylamide.

### Conclusions

With regard to the carcinogenic effects of acrylamide, experimental rodent studies unequivocally show that acrylamide causes cancer in different species and in different tissues. Epidemiological studies so far have resulted in a less strong body of evidence but there are indications for increased risks of some cancers (renal, endometrial and ovarian). Should those risks be true, then they are considerably higher than the risks based on extrapolation from the experimental animal studies. Thus, there clearly is every reason to be concerned about current dietary exposure levels with regard to cancer.

For other health effects than cancer, the indications that dietary acrylamide intake is a reason for concern are fewer. However, several epidemiological studies have consistently shown inverse associations between gestational acrylamide exposure and fetal

**Table 5** Associations between dietary acrylamide intake and birth outcomes

Gestational age, parity, sex of the child, age of the mother, maternal BMI, maternal gestational weight gain, and smoking during pregnancy

Model for birth weight, length and head circumference: study centre, maternal age at delivery, parity, height, maternal education level, tobacco consumption during pregnancy, gestational age at delivery, sex  
 Model for SGA: study centre, maternal age at delivery, maternal education level, tobacco consumption during pregnancy, maternal weight gain during pregnancy

growth, which can have important repercussions on children's development and future health. The fact that developmental effects in humans were not expected based on extrapolation from animal studies should not be a reason to classify those epidemiological findings as less credible. Humans are not rodents and human data, if of high quality, are preferable over animal data. Therefore, more epidemiological research on the possible effects of dietary acrylamide exposure on fetal growth and neonatal development (and on mechanisms of action) is urgently needed.

In the mean time, every possible effort should be taken by the food industry to lower acrylamide levels. In addition, more advice for the general public on dietary acrylamide intake reduction is warranted, especially during sensitive time windows, such as pregnancy and childhood.

Furthermore, more epidemiological research is needed on possible effects of acrylamide on the nervous system, both in elderly and childhood populations. Lastly, I encourage epidemiological studies on reproductive effects of acrylamide, considering that associations between acrylamide intake and sex hormone levels have been observed in various populations, on immunotoxic and cardiotoxic effects, and on the incidence of metabolic disease. For all these latter health effects, the evidence for their occurrence at dietary level exposure is still flimsy. In the era of omics research possibilities, it would be helpful to conduct those studies with collection of omics data in order to try to elucidate the biological plausibility of observed associations.

# Advanced Glycation End Products (AGEs): Occurrence and Risk Assessment

Michael Hellwig and Thomas Henle, Chair of Food Chemistry, Technische Universität Dresden, Dresden, Germany

## Overview

The research on chemical reactions between carbohydrates and amino compounds was established by Louis-Camille Maillard over one century ago (Maillard, 1912). The complexity of the reaction has been the subject of countless works and the chemistry, physiology and technology of the Maillard reaction have been reviewed frequently (see for instance Ledl and Schleicher, 1990; Hellwig and Henle, 2014; Lund and Ray, 2017).

According to the fundamental Hodge scheme (Hodge, 1953), which is still valid today, the Maillard reaction is subdivided into three stages (Fig. 1): In the first stage, Amadori rearrangement products (ARPs) are formed from reducing sugars and amino groups of free amino acids, peptides, and proteins. The ARPs are the first stable intermediates of the Maillard reaction. In the second stage, ARPs are degraded via enolization and elimination reactions to 1,2-dicarbonyl compounds, which may react again with free amino groups or with the guanidino group of arginine. The complex spectrum of Maillard reaction products (MRPs) can thus be subdivided into various classes of compounds, namely (i) Schiff bases and Amadori rearrangement products (ARPs), (ii) dicarbonyl compounds and their N-free reaction products, and (iii) glycated amino acids and polymerized brown pigments. Examples of glycated amino acids are shown in Fig. 2. Resulting from lysine, main representatives are carboxyalkylated derivatives such as N- $\epsilon$ -carboxymethyllysine (CML) and N- $\epsilon$ -carboxyethyllysine (CEL), and pyrrole derivatives incorporating the  $\epsilon$ -amino group of lysine such as pyrroline and formyllysine (Hellwig and Henle, 2014). Further important products are pyrrolinones such as pronyllysine and amides such as lactoyllysine. At arginine residues, hydroimidazolones such as G-H1, MG-H1 and 3-DG-H are the main reaction products. Pentosidine and glucosepane were described as the most important crosslinking structures in glycation reactions beneath the imidazolium salts GOLD, MOLD, and DOLD.

## “AGE” – Still a Reasonable Expression?

The fact that Maillard reactions also occur *in vivo* was first demonstrated by Rahbar (1968) and Bunn et al. (1975) with the characterization of HbA<sub>1c</sub>, a hemoglobin variant containing an N-terminal fructosylvaline moiety at the  $\beta$ -chain. In order to differentiate between such non-enzymatically formed sugar adducts to proteins and the well-known enzymatic glycosylation of proteins, the expression “glycation” was proposed by the IUPAC in 1984 (IUPAC, 1984) and is now synonymously used with the term “Maillard reaction”. The expression “advanced glycosylation end products”, later termed “advanced glycation end products” (AGEs), was introduced into biomedical glycation research by Brownlee et al. (1984). This term was needed in order to distinguish reversibly bound glycation adducts on proteins (Schiff bases, Amadori products) from irreversibly covalently modified protein structures (“brown fluorescent pigments which crosslink proteins”; Brownlee et al., 1984). As a first structural example for a possible AGE, the crosslinking structure 2-(2-furoyl)-4(5)-(2-furanyl)-1H-imidazole (FFI) was isolated and characterized (Brownlee et al.,

Figure 1 General scheme of the Maillard reaction (CML, N- $\epsilon$ -carboxymethyllysine).

**Figure 2** Glycated amino acids (“advanced glycation end products”). Nle, norleucyl residue; Nva, norvalyl residue.

1984), but later turned out to be an artifact of acid hydrolysis (Gerhardinger et al., 1990). In the following decades, the expression “AGE” became generally applied to stable products formed during the late stage of the Maillard reaction independently on the molecular weight.

From the term “advanced glycation end products”, it becomes apparent that the reaction products must be linked to the attachment of sugars or their degradation products to proteins such as those compiled in Fig. 2. These structures comprise a huge structural diversity. Glycation can modify the polarity of the side-chains of the parent amino acids lysine and arginine to more polarity (Amadori products) or less polarity (pyrrole derivatives). Positive charges of lysine and arginine side-chains can not only be masked by glycation but even inverted by carboxyalkylation. The overall accessibility of side-chains can be reduced by crosslinking. All these chemical modifications together change the physico-chemical properties of proteins, for example the solubility and the isoelectric point.

Despite this structural diversity, several sum methods for the determination of the “AGE concentrations” of foods and the “AGE status” in physiological samples have been established and were applied widely in the literature. These methods are based on the measurement either of “AGE fluorescence” or immunoreactivity of AGEs (Meerwaldt et al., 2004; Uribarri et al., 2010; Fernandez-Gomez et al., 2015; Takeuchi et al., 2015). From a chemical point of view, however, it must be noted that statements about an “AGE concentration” resulting from such methods are scientifically incorrect. A specific “AGE fluorescence” has been postulated based on the fluorescence of the above mentioned compound FFI (excitation wavelength, 370 nm; emission wavelength, 440 nm). It is obvious, since many fluorescent MRPs are known, that this “AGE fluorescence” does not represent one defined structure, but is always the sum of different individual structures with varying spectroscopic properties, whose composition may change depending on the composition of the matrix. Furthermore, as not all AGEs are fluorescent, calculation of an “AGE content” based on fluorescence measurements must lead to a false estimation of the modification of proteins by the Maillard reaction. Nevertheless, the measurement of skin autofluorescence, which was attributed to glycation, has been proposed as a diagnostic tool in the monitoring of diabetic complications (Meerwaldt et al., 2004). The same problems arise for immunological methods used for quantification of AGEs. Such methods make use of antibodies that have been raised against glycated proteins, with the glycation being induced for example by glucose or 3-DG (Papanastasiou et al., 1994; Takeuchi et al., 2001). The proteins used for antibody production are often poorly characterized in terms of the formation of individual MRPs, whereas experience of the Maillard reaction teaches that the preparations must contain a broad spectrum of individual amino acid derivatives. Poor specificity and comparability as well as crossreactivity between antibodies are, therefore, inevitable (Morioka et al., 2017). Data collections, reporting on the “AGE content” of foods, therefore, must be handled with care, as the concentration values based on immunological techniques (mostly reported in “AGE units per kg protein” or similar) are generally not validated by alternative techniques and very often are merely impossible (see below). Today, it must be state of the art to use specific and more reliable methods for the quantification of MRPs, primarily HPLC-MS/MS, to overcome the shortcomings of the sum methods based on fluorescence and immunobiology (Teerlink et al., 2004;

Assar et al., 2009; Scheijen et al., 2016). The use of such methods is called for by the scientific community (Calder et al., 2011; Tessier and Birlouez-Aragon, 2012; Kellow and McCoughlan, 2015; DeChristopher, 2017).

The uncritical use of effect-based analytical tools mainly in studies dealing with physiological aspects has led to much confusion in glycation research in the last decades, raising the question as to whether the use of the expression “AGE” continues to make sense. In the opinion of the authors, structure-based analytical means must be applied to approach the actual concentrations of individual glycation-derived structures in food products and physiological media. This becomes clear when concentrations of individual glycated amino acids and “AGE concentrations” are compared.

## Formation and Occurrence of Individual MRPs in Food

Only few individual MRPs have been reliably quantified in foods up to now. Consistently, the most important MRPs in foods are the Amadori products, accounting for >90% of the total amount of MRPs. While ARPs have been quantified mostly after conversion to furosine by acid hydrolysis (Fig. 1), recent works based on HPLC-MS/MS methods reveal differences in the patterns of individual ARPs in individual foodstuffs: Fructosyllysine is the most relevant ARP in the honey proteome, whereas maltosyllysine predominates in the beer proteome (Hellwig et al., 2016, 2017). Food systems containing reducing sugars and free amino groups react very sensitively even to comparatively mild heat treatments such as the UHT process in dairy processing. The concentrations of ARPs in UHT-treated milk can be 10 times as high as those in pasteurized or raw milk (Henle et al., 1995). Particularly high concentrations of Amadori products can be found in more strongly heat-treated foods such as bread, breakfast cereals and processed meat products (Table 1). However, a comparison of ARP concentrations in bread crust, bread crumb, and pasta products, which differ strongly in their heating conditions, reveals that these differences are no longer mirrored in the ARP concentrations. This is due to the progress of the Maillard reaction which entails the degradation of the thermodynamically unstable ARPs. The patterns of glycated amino acids formed in the final stage of the Maillard reaction strongly depend on the heating conditions (temperature/time) and often also on the water activity. Moreover, oxidation reactions may play a role as is known from the conversion of fructosyllysine to CML. The water activity is decisive for the formation of pyrrole compounds such as pyrroline and formylpyrroline. Correspondingly, food products that have undergone strong heat treatment always contain higher amounts of late-stage MRPs than mildly treated products (cf. milk and evaporated milk). This is also valid for different heat impact regions in the same food product (cf. whole bread and bread crust).

Due to the pathways of formation of MRPs described in the preceding sections, it is not intriguing that protein- and carbohydrate rich foods will contain the highest amounts of these substances (Table 1). Counterintuitively, databases compiling “AGE concentrations” based on an ELISA method have reported high AGE concentrations especially in fat-rich foods such as processed meat and fish products and butter, whereas the concentrations in protein-rich food such as eggs, bread, and pasta products were low (Goldberg et al., 2004; Uribarri et al., 2010). It has been argued that it is very difficult to bring in line the data obtained with the unvalidated ELISA methods with the chemistry of the Maillard reaction (Calder et al., 2011), and that the semi-quantitative data need to be interpreted with caution (Scheijen et al., 2016). Moreover, these data stand in contrast to the outcome of several structure-based works on MRPs of different groups (Assar et al., 2009; Scheijen et al., 2016; Hellwig et al., 2016, 2017) and do not withstand a closer examination by superior validated analytical techniques such as HPLC-MS/MS.

## Physiological Relevance of Dietary AGEs

Glycation reactions are a common side-reaction in biological systems and occur in the human body throughout the lifespan. It is indisputable that protein modifications brought about by glycation reactions may alter the functionality of proteins and other

[m] Scheijen et al., 2016. n.d., not detectable. –, no data available.

biomolecules. On a molecular level, modification of particular arginine residues was shown to negatively influence collagen functionality (Dobler et al., 2006), and crosslinking reactions due to *in vivo* glycation may deteriorate the biomechanical properties of cartilage (Bank et al., 1998).

Lots of studies have been conducted in order to estimate to what extent dietary MRPs contribute to the *in vivo* concentrations, and if diets rich in MRPs lead to physiologically negative effects such as inflammatory processes, oxidative stress, insulin resistance, or endothelial dysfunction (for reviews, see Kellow and Savage, 2013; Van Puyvelde et al., 2014; Kellow and McCoughlan, 2015; Clarke et al., 2016). Several studies agree that (i) dietary AGEs are taken up into circulation after ingestion and contribute to the “AGE pool” of the body, (ii) these AGEs may accumulate in the body thereby prolonging their negative impact (“glycotoxins”, Koschinsky et al., 1997), (iii) AGEs exert negative effects on human health through interaction with a special “receptor for advanced glycation end products (RAGE)”. This has led to a widely accepted narrative in glycation research (“AGEs are a risk for human health”) that may have led to publication bias precluding researchers from submitting data not confirming this hypothesis (Kellow and Savage, 2013).

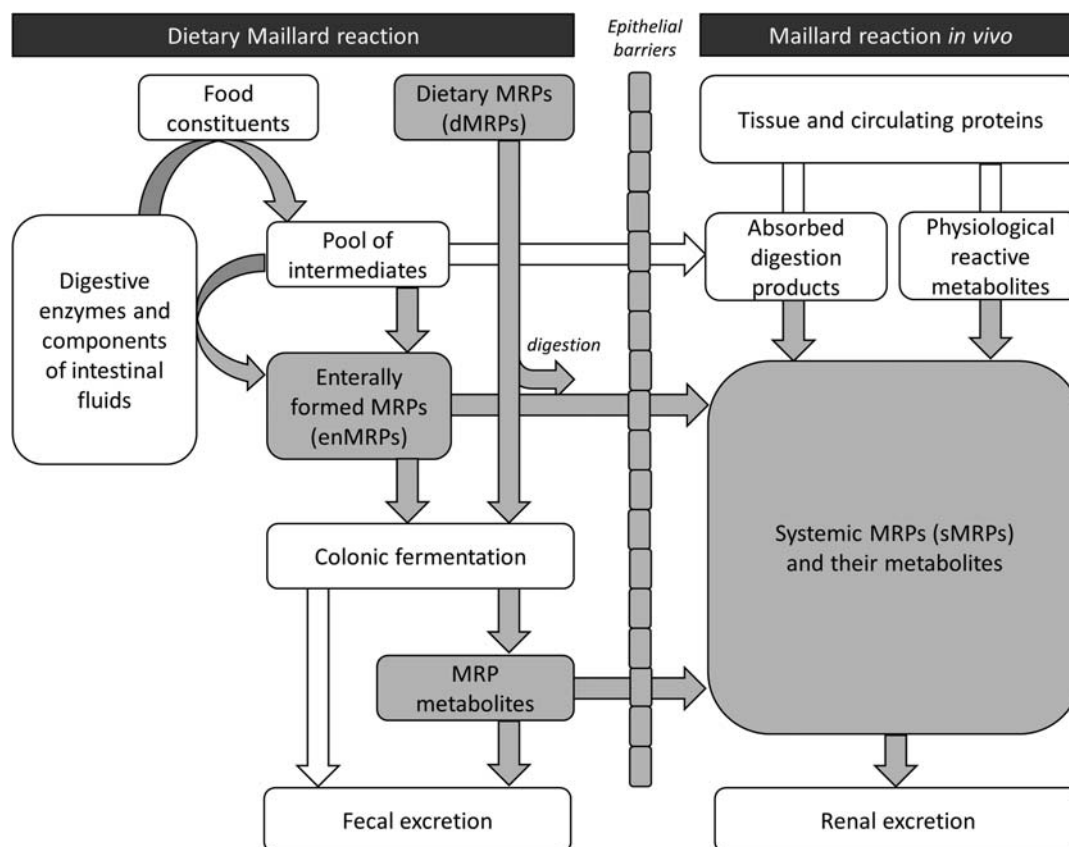

All three points have been challenged in the last years, and it becomes clear that general conclusions on the biological effect of AGEs cannot be made due to their strong structural diversity. The absorption of AGEs is precluded by digestion and transport processes. MRPs in food are mostly protein-bound and need to be released from proteins during digestion. Amino acids with a basic or unpolar side-chain such as fructosyllysine or pyrraline are more easily released from proteins than amino acids with an acidic side-chain such as CML (Hellwig et al., 2014). Transport via the small intestinal epithelial membrane is only possible for free amino acids, di- and tripeptides. Free glycated amino acids cannot pass this barrier due to the narrow substrate specificity of amino acid transporters. Some glycated dipeptides, however, were shown to be transported into cells expressing the peptide transporter PEPT1. After intracellular cleavage, free glycated amino acids may pass into the systemic circulation, but they are rapidly excreted via the urine, because they are no substrates of renal amino acid transporters (Bergmann et al., 2001; Förster et al., 2005; Hellwig et al., 2011). Therefore, dietary glycated amino acids cannot accumulate in the body.

Moreover, the design of the studies was critically reviewed: “AGEs” in the experimental diets are often generated by extreme heating methods, and it cannot be excluded that essential micronutrients, for example thiamine, decompose simultaneously (Buetler and Henle, 2009). From a mechanistic point of view, it must be argued as to whether the same MRPs are formed under preparation conditions such as roasting and deep-frying as compared to boiling, implying that strong qualitative differences may be existent behind a different quantitative “AGE concentration” as measured by ELISA or fluorescence spectrometry. Nevertheless, differences observed in studies comparing “AGE-rich” and control diets are often traced back to a single MRP, very often CML. However, owing to the commonly practiced use of the databases of Goldberg et al. (2004) and Uribarri et al. (2010), it is largely uncertain which individual MRPs have been taken up in which concentrations.

### **Risk Assessment of Dietary AGEs – Is This Even Possible?**

Regarding the study design discussed above, it must be concluded that up to now—to the best of our knowledge—only one study is available that links a single glycated amino acid to an adverse effect. In this preliminary study, 5-hydroxymethylfurfural (HMF) and pyrraline (Fig. 2) were identified as mutagenic substances in the Ames test (Omura et al., 1983). Nevertheless, the exposure to HMF from food was shown not to be of toxicological relevance (Janowski et al., 2000). On the other hand, positive effects of glycated proteins and “maillardized” food items such as malt and bread crust were identified in animal studies as judged from an increase in the activity of renal and hepatic chemoprotective enzymes (glutathione-S-transferase, UDP-glucuronyl transferase). These chemopreventive effects were partly traced back to the defined substances *N*-methylpyridinium and pronyllysine (Fig. 2, Lindenmeier et al., 2002; Somoza et al., 2003). As defined in Article 1 (9) of regulation (EC) No 178/2002 of the European Parliament and of the Council, laying down, *inter alia*, procedures in matters of food safety, ‘risk’ means a function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard. At present, neither adverse health effects nor any negative effect resulting from, e.g., cell or animal studies can be unequivocally linked to the dietary uptake of glycated amino acids. Therefore, for reasons of semantics as well as due to basic considerations with respect to risk theory, it is not possible to calculate a “risk” for dietary AGEs. This, of course, must not prevent food scientists to study possible adverse as well as positive effects of process-induced protein modifications.

With respect to MRPs, research may not solely regard the concentrations of individual compounds in the diet, but must take into account the individual bioavailability of compounds, their reactivity during intestinal digestion and their metabolism by the colonic microbiota. Research in food chemistry has brought forward our understanding of these issues in recent years, starting from the question as to how dietary MRPs or dietary constituents can influence the “pool” of MRPs in the circulation or in tissues. In the opinion of the authors, there are at least three types of MRPs that are of relevance when the physiological role of the Maillard reaction is discussed (Fig. 3). The first type of MRPs are those that form in foods and that can be quantified by chemical analysis of foods, the “dietary MRPs” (dMRPs). The second type are the MRPs that form under physiological conditions in tissues and on circulating proteins, collectively termed “systemic MRPs” (sMRPs). Dietary glycated amino acids cannot simply cross the epithelial barrier, as they are mostly protein-bound. However, some of them may appear in free or peptide-bound form during intestinal proteolysis. Glycated dipeptides may then be transported into enterocytes and further pass into circulation thereby contributing to the pool of sMRPs (Hellwig et al., 2011, 2014). However, the chemistry during digestion may be even more complex, because the pool of digestion intermediates that is present postprandially and the different pH and ionic environment may enable new

**Figure 3** Proposed pathways for the metabolic fate of MRPs.

chemical reactions. 1,2-Dicarbonyl compounds such as methylglyoxal and 3-deoxyglucosone are not stable during simulated intestinal digestion (Degen et al., 2013, 2014). It must be supposed that these compounds react with digestive enzymes, unabsorbed dietary protein fragments or other components of intestinal fluids, thereby generating a third class of MRPs, namely enterally formed MRPs (enMRPs). These products may be structurally identical to the dMRPs known up to now, but may just as well represent novel structures. In this context, the consumption of high amounts of fructose may be of particular relevance with respect to the formation of enMRPs (DeChristopher, 2017). A recent animal study has shown that long-term feeding of mice with excessive glucose caused an increase in methylglyoxal-derived MRPs, whereas excessive fructose consumption caused an increase in glyoxal-derived MRPs such as CML in liver tissue (Mastrocola et al., 2013). We conclude that the intestinal tract is a reaction space whose significance has been overlooked up to now. Research on the occurrence of dietary MRPs must further consider the potential of enMRP formation after ingestion.

MRPs are subject to colonic fermentation (Hellwig et al., 2015), but apart from reported changes in the composition of the microbial consortium (Tuohy et al., 2006), the formation of novel MRP metabolites is completely underexplored. Metabolites may be formed both from dMRPs and enMRPs. As such metabolites may theoretically be taken up into circulation and show bioactivity, research in this area is urgently needed.

# Furan and Alkylfurans: Occurrence and Risk Assessment

Gabriele Scholz and Richard H Stadler, Nestlé Research Center Lausanne, Lausanne, Switzerland

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**BMD, benchmark dose** The BMD is the minimum dose of a substance that produces a clear, low level health risk, usually in the range of a 1%–10% change in a specific toxic effect such as cancer induction.

**BMDL10, benchmark dose lower confidence limit** The lower confidence level of the dose that results in an increase of cancer incidence by 10% above background.

**Exposure assessment** One of the key steps in risk assessment, consisting of a thorough evaluation of exposure to a hazard and a quantification of the amounts involved.

**Deterministic exposure assessment** Exposure assessments using point values of occurrence and intakes to produce a point estimate of individual or population exposure.

**HBGV, health-based guidance value** Guidance on safe consumption of substances that takes into account current safety data, uncertainties in these data, and the likely duration of consumption.

**MOE, margin of exposure** In toxicology, the MOE of a substance is the ratio of its PoD (BMDL<sub>10</sub> or similar) to its estimated dose of human intake. It is used in risk assessment to explore safety concerns arising from the presence of potentially toxic substances in food.

**PoD, point of departure** In toxicology the PoD is defined as the point on a toxicological dose-response curve established from experimental data generally corresponding to an estimated low effect level or no effect level. It is used to derive a safe level of exposure.

**LoD, limit of detection** The LoD is the lowest concentration of a substance that can be detected using standard tests but which is too small to be measured with certainty.

**LoQ, limit of quantification** the LoQ is the lowest concentration of a substance that can be measured with certainty using standard tests.

**LB, lower bound estimate** An estimate of the minimum exposure to a potentially harmful substance, normally zero, which takes into account normal consumption of food which contains negligible amounts of the substance.

**UB, upper bound estimate** A way of estimating exposure to a particular compound from analytical data by assigning the lowest value which can be detected (or quantitated) to all samples with levels below this value. For a toxic chemical this gives the most pessimistic estimate of exposure (i.e. the real level of exposure will always be below the upper bound estimate).

**Risk assessment** A specialised field of applied science that involves reviewing scientific data and studies in order to evaluate risks associated with certain hazards. It involves four steps: hazard identification, hazard characterisation, exposure assessment and risk characterisation.

## Introduction

Furan and a number of furan derivatives such as 2- and 3-methylfuran are known to be present in certain heat processed foods where they contribute to flavor and aroma. First described in coffee (Maga, 1979), food analytical data on furan were published in 2004 when its presence was described in a variety of foods including canned and jarred foods and coffee (FDA, 2004; EFSA, 2004). Furan is a volatile heterocyclic organic compound used as a chemical intermediate in the chemicals industry. It can also be generated and released by human activities (combustion, fires, exhausts) and is present in cigarette smoke. Human exposure, however, occurs mainly via food. Furan is a potent liver toxin, induces liver cancer in rodents and is classified as ‘reasonably anticipated to be a human carcinogen’ (NTP, 2016) and as ‘possibly carcinogenic to humans’ (group 2B; IARC, 1995). Evidence is accumulating that furan induced carcinogenicity involves mainly non-genotoxic mechanisms of action. The current thinking is that methylfurans

(MeF) share toxic and mechanistic properties with furan suggesting dose additivity. Exposure to furan(s) via the diet, particularly in high intake consumers including infants receiving baby foods in jars may represent a health concern.

## Analytical Methods

Several analytical methods to quantify furan in different foodstuffs have been described in the literature over the past decade, mostly based on headspace (HS)-GC-MS, due to the volatility of the analyte, with a boiling point at 32 °C (FDA, 2004; Nyman et al., 2006, 2008). Furan needs to be volatilised from the food or beverage matrix, requiring certain conditions (e.g. sample fluidity, equilibrium temperature and time, addition of inorganic salts such as ammonium sulfate) that promote release of the analyte. The initial HS-GC-MS method published by the FDA in 2004 required certain improvements, particularly related to headspace oven temperature and risk of furan forming adventitiously during analysis at temperatures at 80 °C (Morehouse et al., 2008; Nyman et al., 2008). Today, most methods apply equilibration temperatures in the range of 40–50 °C, which provides comparable results as judged from different literature surveys on furan in food. The contribution of the food matrix and food components to the generation of furan during analysis may, therefore, be significant, and together with other parameters impact the partition coefficient of furan (Senyuva and Gokmen, 2005; Huang and Barringer, 2016).

Many of the analytical methods published to date apply an SPME (solid phase microextraction) GC-MS, with the advantage that SPME in general enables superior sensitivity by concentrating the analyte on the fiber (Table 1). In fact, many different surveys on furan in foods are based on methods utilizing SPME, covering several different fiber types that have been assessed and used for analysis, e.g. carboxen/polydimethylsiloxane (CAR/PDMS), divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS), polydimethylsiloxane/divinylbenzene (PDMS/DVB), polyacrylate, and carbowax/divinylbenzene (CW/DVB) (Goldmann et al., 2005; Altaki et al., 2017). However, care must be taken to avoid *in situ* formation of furan during thermal desorption, that takes place at temperatures ranging from 200–300 °C (Adams et al., 2012).

Mass spectrometry with the addition of isotope labelled internal standards is the best choice for the reliable quantification of furan (and MeF) in foods, using characteristic ions (e.g. furan molecular ion at  $m/z = 68$  as quantifier,  $m/z = 39$  and  $m/z = 69$  as qualifiers;  $d_4$ -furan at  $m/z = 72$ ) in the selective ion monitoring (SIM) mode. For the analysis of MeF, Becalski et al. (2010, 2016) utilized  $d_4$ -furan, 2-methylfuran- $d_3$  (methyl- $d_3$ ) and 3-methylfuran (methyl- $d_4$ ) as internal standards for a wide range of jarred and canned foodstuffs, including coffee (roast and ground coffee, instant coffee). Several investigations have, however, quantified MeF based on the response of  $d_4$ -furan (Chaichi et al., 2015; Fromberg et al., 2014), noting that the boiling points are somewhat higher for MeF (63–65 °C).

Recently, a GC-FID (flame ionization detection) based method was developed and applied to determine furan, 2-MeF and pentylfuran in fruit juices. The method achieves a comparable LoQ to mass spectrometry based approaches (Hu et al., 2016). However, FID is non-specific, and thus the identification of the analytes is dependent on retention time, requiring clean chromatograms with no interference in the regions where the analytes elute. The applicability of FID is therefore most probably limited to only a few 'cleaner' food matrices.

In 2015, the European Standard EN 16620 was published that describes a HS-GC-MS method to determine furan in coffee and coffee products (CEN (European Committee for Standardization), 2015). However, one major gap today from the analytical perspective is the lack of an official or agreed standard method encompassing furan as well as the alkylfurans for the concerned foodstuffs, which is important in case that risk management measures for certain foods are proposed or implemented. Certified reference materials would be a major advantage, to ensure appropriate laboratory performance.

**Table 1** Selected single and multimethod for the determination of furan and MeF in different foodstuffs

Foodstuff	Analytes	Principle of the method	LoQ (ng/g)	References
Coffee	Furan, 2-MeF, 3-MeF	HS-GC-MS; isotope labelled standards for all analytes	3 (roast and ground coffee)	Becalski et al. (2016)
Fruit juices	Furan, 2-MeF, 2-pentylfuran	HS-SPME-GC-FID	0.18 (furan); 0.14 (2-MeF)	Hu et al. (2016)
All foodstuffs	Furan, 2-MeF, 3-MeF	HS-GC-MS; isotope labelled standards for all analytes	>1 (all foodstuffs)	Becalski et al. (2010)
Baby foods	Furan	HS-SPME-GC-MS; isotope labelled standard	0.04–0.11 (depending on foodstuff)	Altaki et al. (2017)
All foodstuffs	Furan, 2-MeF, 2,5-diMeF, 2-ethylfuran, 2-pentylfuran	HS-GC-MS; isotope labelled furan	2.4 (all foods except crisps) 2.9 (crisps)	Fromberg et al. (2014)
Bread (crust)	Furan	Automatic HS-trap GC-MS; isotope labelled standard	0.1	Huault et al. (2016)

## Occurrence

### Formation

Research over the past decade has revealed several pathways to the formation of furan, mainly via thermal reactions (e.g. sugar decomposition, Maillard reaction) and oxidative processes. Much of the earlier work was done in model systems, revealing the importance of substances such as ascorbic acid, selected amino acids (e.g. serine, cysteine), carbohydrates (pentoses, hexoses), polyunsaturated fatty acids (PUFAs) and carotenoids as precursors to furan formation (Yaylayan, 2006; Vranova and Ciesarova, 2009).

The oxidative pathway involving PUFAs leads to a key intermediate, namely the secondary lipid oxidation product 4-hydroxy-2-butenal, that can cyclise to 2,5-dihydro-2-furfural and subsequently release  $\text{H}_2\text{O}$  to afford furan. The carbohydrate pathways can be driven via the well known Maillard reaction, involving also amino acids. Sugar breakdown without amino acid assistance furnishes smaller fragments (e.g. acetaldehyde) or aldotetrose derivatives, such as 3,4-dihydroxybutanal. Cyclisation affords the tetrahydro-2,4-furandiol, that through loss of water yields furan. Alternatively, dehydration of 3,4-dihydroxybutanal gives rise to 4-hydroxy-2-butenal, that reacts further as described above for the PUFAs. An alternative pathway to furan is furoic acid, that could be formed by a Cannizzaro reaction of 2-furfural. Decarboxylation under thermal conditions is probably rapid, and may be an alternative pathway in certain products (Varelis and Hucker, 2011).

Fewer studies have been conducted on the formation of alkylfurans. Becalski et al. (2010) demonstrated the formation of both 2-MeF and 3-MeF from  $\beta$ -carotene and other isoprenoids. This pathway may be predominant in foods that harbour corn or tomato constituents. Carbonyl- or hydroxycarbonyl degradation products of amino acids (e.g. threonine, alanine) can rearrange and furnish alkylfurans, a pathway of relevance in meat products. Alternatively, lipid oxidation may lead to 4-hydroxyalk-2-enals that can rapidly cyclise under release of  $\text{H}_2\text{O}$  to afford the corresponding alkylfuran (Fig. 1).

### Levels in Foods

#### Furan

Occurrence data for furan are available for thermally processed foods, such as coffee, canned and jarred foods, including baby foods, soups and sauces. Besides the occurrence data from the published literature, national and international health authorities such as the US FDA and the European Food Safety Authority (EFSA) are collecting analytical data made available publicly (US FDA, 2008; EFSA, 2011, 2017). The EFSA (2017) has summarised close to 18,000 analytical data from European member states, non-European governments, from food industry associations and the published literature. Occurrence data from different sources were shown to be generally in agreement. Highest levels of furan were identified in coffee (including beans, roast and ground coffees, instant coffees and brews) followed by certain alcoholic beverages, composite foods, herbs, spices and condiments, and foods for infants and small children (Table 2). In baby foods highest furan levels were found in meat and vegetable-based products, while lower levels were reported in fruit and cereal based baby food products (EFSA, 2011). A large proportion of the analytical data available have been generated on products as taken from the shelf, and not as prepared for consumption.

Losses of furan due to evaporation during final preparation have been investigated in a couple of studies with very variable results (Roberts et al., 2008; Kim et al., 2009). Based on limited information and a several assumptions such losses were quantified for coffee and baby foods in jars (EFSA, 2017), and were taken into account in the exposure assessment (see below). Although practices used in home cooking in theory may similarly lead to furan generation, a few studies indicate that home cooking of freshly prepared foods is not a significant source of furan exposure, neither through inhalation nor through consumption (Crews,

**Figure 1** Simplified reaction pathways from PUFAs and amino acids to alkylfurans.

**Table 2** Furan levels in foods

Food group	Mean MB range ( $\mu\text{g/kg}$ )
All coffee beverages (powder)	126.5–1990.9
All coffee beverages (liquid)	2.3–146.7
Alcoholic beverages	1.1–57.4
Composite food (including frozen products)	11–33.5
Herbs, spices and condiments	3.4–31.6
Food for infants and small children	2.6–31
Grains and grain-based products	7.8–28.7
Snacks, desserts, and other foods	11.1–15.3
Fish and other seafood (including amphibians, reptiles, snails and insects)	14
Starchy roots and tubers (potatoes and potato products)	12.7
Cocoa beans and cocoa products	10.9
Meat and meat products (including edible offal)	8.6
Sugar and confectionary	8
Milk and dairy products	0.8–7.7
Legumes, nuts and oilseeds	6.1
Vegetables and vegetable products (excl. solids for beverage preparation)	6
Fruit and fruit products	3.7–5.5
Fruit and vegetable juices	3.5
Tea and herbs for infusions (solid)	1.5
Animal and vegetable fats and oils	0.8
Tea (infusion, liquid)	0.8

Levels represent the range of mean middle bound (MB) values across the sub-categories. Different sub-categories were combined to present the powder and liquid categories of coffee (across coffee, instant coffees and coffee substitutes). Modified from EFSA (2017).

2009; Fromberg et al., 2014; Roberts et al., 2008), including baby foods freshly cooked at home (Bianchi et al., 2006; Lachenmeier et al., 2009). Home cooking using pressure-cooking devices did not generate measurable amounts of furan (Arisseto et al., 2013).

### Alkylated Furans

Due to their structural similarity with furan, possibly similar formation pathways and indications for co-occurrence, the alkylated furans 2- and 3-MeF and 2,5-dimethylfuran (2,5-diMeF) have been addressed concomitantly with furan (Becalski et al., 2010; Fromberg et al., 2014; Habibi et al., 2013; Palmers et al., 2015). Apart from a few specific examples, furan seems to be the predominant form in various canned and jarred foods. Most notably, concentrations of 2-MeF in coffee were consistently 4 to 5 times higher than those of furan. 2-MeF was detectable in most canned and jarred foods, including baby foods in jars, at levels lower than furan (Becalski et al., 2010; Palmers et al., 2015; Palmers et al., 2016); except for some canned tomato products, and canned meat and seafood products that contained significantly higher 2-MeF levels compared to furan. Specifically canned corn and tomato products seemed to contain higher levels of 3-MeF, otherwise levels of 3-MeF were rather low. In agreement with Becalski et al. (2010), Fromberg et al. (2014) reported 2-MeF levels lower than furan, but about 3 times higher levels of 2,5-diMeF in canned foods (no details available). Habibi et al. (2013) determined high levels of 2-MeF and 2,5-diMeF in infant cereals (low sample number) with levels of 2,5-DiMeF exceeding 2-MeF and furan. Overall, there is a lack of analytical data on alkylated furans, that preclude statistical analysis and a solid exposure assessment in humans.

### Exposure

Dietary furan exposure assessments are available from national surveys on dietary consumption, using deterministic methodology, as reported by international authorities (JECFA, 2011; EFSA, 2017). Exposure ranges determined in these surveys are summarised in Tables 3 and 4.

Infants are exposed to highest levels of furan, with mean exposures of  $0.99 \mu\text{g (kg bw)}^{-1} \text{ day}^{-1}$  (at the upper bound scenario) and high exposures (95th percentile) of  $1.82 \mu\text{g (kg bw)}^{-1} \text{ day}^{-1}$ . The next highest exposure populations are elderly and very elderly people with mean and 95th percentile exposures of  $0.75$  and  $1.27 \mu\text{g (kg bw)}^{-1} \text{ day}^{-1}$ , respectively.

Overall, mean adult exposures are generally below  $1 \mu\text{g (kg bw)}^{-1} \text{ day}^{-1}$ . Estimates from the US are slightly lower, because they were based on quantified analytical results generated on foods as consumed (JECFA, 2011). The 95th percentile exposure ranges generally remain below  $2 \mu\text{g (kg bw)}^{-1} \text{ day}^{-1}$ , including exposures in infants and children. The mean and high exposures determined by international and national authorities are overall very consistent and differences are likely attributed to different survey methodologies applied.

**Table 3** Mean and 95th percentile exposures in non-European countries by age groups

Country	Age group	Mean exposure [ $\mu\text{g (kg bw)}^{-1} \text{ day}^{-1}$ ]	p95 exposure [ $\mu\text{g (kg bw)}^{-1} \text{ day}^{-1}$ ]	References
USA (furan levels 2004)	2+ years	0.25		JECFA (2011)
	2–5 years	0.23		
	15–45 years	0.24		
USA (furan levels 2007)	2+ years	0.26	0.61	JECFA (2011)
	0–1 years	0.41	0.99	
Brazil	6–11 months	0.46–0.82	1.34–2.40 (p99)	Arisseto et al. (2010)
Chile	9 months	0.25		Mariotti et al. (2013)
	10–13 years	0.50–0.51		
	64 years	0.09–0.11		
China	Adults	0.093	1.767 (p90)	Sijia et al. (2014)
	6 months	0.333		
Korea	6 months	0.017		Kim et al. (2009)
Taiwan	6 months	0.470		Liu and Tsai (2010)

**Table 4** Mean and p95 upper bound (UB) exposures across European surveys by age groups (EFSA, 2017)

Age group	Mean exposure in $\mu\text{g (kg bw)}^{-1} \text{ day}^{-1}$ (range)	p95 exposure in $\mu\text{g (kg bw)}^{-1} \text{ day}^{-1}$ (range)
Infants	0.54 (0.21–0.99)	1.14 (0.42–1.82)
Toddlers	0.45 (0.31–0.65)	0.76 (0.46–1.08)
Other children	0.37 (0.27–0.52)	0.61 (0.40–0.86)
Adolescents	0.22 (0.14–0.31)	0.39 (0.28–0.58)
Adults	0.33 (0.14–0.54)	0.69 (0.25–1.22)
Elderly	0.36 (0.15–0.61)	0.70 (0.28–1.27)
Very elderly	0.34 (0.16–0.75)	0.60 (0.32–0.96)

According to EFSA (2017), the biggest contributor to dietary exposure in adults is coffee (40%–80%), other foods contribute less to exposure (above 5%, but less than 20%): cereal products, vegetable products, meat products and dairy. In older children (aged 4–6 years) the biggest contributors were breakfast cereals (40%), and in small children (>6 months) jarred baby foods were the most important contributor to dietary furan exposure.

The assessment of exposure to alkylated furans is currently based on limited data published in the literature. The inclusion of 2- and 3-MeF strongly affected total furan exposure, in particular in adults, elderly and very elderly, via coffee. Total furan exposure can more than triplicate compared to furan alone, depending on the survey. Infants and small children are much less affected due to the low level of coffee consumption.

Exposure assessment of furan (and alkylated furans) is hampered by a number of uncertainties, that will lead to either over- or underestimation of exposure:

- Most of occurrence data are generated on products as purchased from the shelf and not as prepared for consumption. Only for coffee the losses due to the extraction of powder to brew was taken into account (EFSA, 2017), but not for the possible losses of furan during standing of coffee after brewing and before consumption. The same accounts for the preparation of baby foods in jars (heating in open or closed jar, with or without stirring, etc.). These factors are strongly depending on consumer behaviour, are highly variable and, therefore, not quantifiable.
- Information on the consumption of fresh produce vs commercially processed (including canned and jarred) foods is not usually available in dietary consumption surveys. Assuming that, for instance, all vegetables are consumed from canned sources will lead to exposure overestimation (EFSA, 2017).
- Furan formation during cooking in the home may represent an additional source of exposure, such as toasting of bread at home, or cooking using home pressure cooking devices (Crews, 2009; Arisseto et al., 2013). This would potentially lead to underestimation. However, a few quantitative assessments led to the conclusion that this has a minor impact on furan exposure (EFSA, 2017).

## Toxicological Aspects

The primordial target organ of short and long term oral furan exposure conducted in numerous studies in rats and mice is the liver.

## Absorption, Distribution, Metabolism and Elimination

Furan is efficiently absorbed and metabolized after oral administration in rodents. Important routes of elimination are expired air (as unchanged furan or  $\text{CO}_2$ ) and the excretion of polar metabolites in urine, bile and faeces. Excretion is mostly complete after 24

hours. After oral administration of radiolabelled furan, highest concentrations are found in the liver, the organ of extensive metabolism of furan (Burka et al., 1991). Macromolecular binding, mainly to protein, is found in the liver (Burka et al., 1991). A physiologically based pharmacokinetic model was developed from in vitro and inhalation studies that adequately modelled distribution and excretion in rats, including from oral exposure (Kedderis et al., 1993), and was extended to build species specific models for mice and humans (Kedderis and Held, 1996). These models demonstrated that the rate of furan metabolism was shown to be limited by hepatic blood flow, and not by its enzymatic bioactivation. Furan metabolism involves ring opening to the reactive intermediate *cis*-2-butene-1,4-dial (BDA), catalyzed by cytochrome P450 CYP2E1 in the liver (reviewed in Peterson, 2013; Moro et al., 2012). BDA can covalently react with macromolecules like tissue protein and DNA. BDA is metabolized further via glutathione (GSH) conjugation. Multiple GSH conjugates and their degradation products were described in urine, as well as protein and amino acid adducts possibly derived from degraded protein adducts and reaction products with cellular (poly)amines (Peterson et al., 2011; Hamberger et al., 2010).

Trapping experiments in vivo and in vitro, experiments with modulators of liver GSH conjugation and microsomal protein binding studies suggest that 2- and 3-MeF (Ravindranath et al., 1984, 1986; Ravindranath and Boyd, 1985) and 2,5-diMeF (Li et al., 2015; Wang et al., 2014 & 2015) follow similar bioactivation pathways as furan via ring-opened reactive intermediates. The resulting intermediates are shown in Fig. 2.

### Carcinogenicity

In chronic oral studies (2 year cancer bioassays), neoplastic lesions (hepatocellular adenoma and carcinoma) in both male and female mice increased in a dose dependent way, along with a number of non-neoplastic liver lesions including lesions of the biliary tract (NTP, 1993; Moser et al., 2009). Hepatocellular adenoma and carcinoma were similarly increased in rats dosed for 2 years orally with furan (NTP, 1993; Maronpot et al., 1991). In addition, dose related increases of neoplasms of the biliary tract and mononuclear cell leukemia were observed in this species. Markedly, incidences of cholangioadenoma and -carcinoma were very high at the lowest dose levels tested ( $2 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$ ), in both male and female rats. In stop-exposure studies, in which rats were treated orally with furan at  $30 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$  for limited time periods (6 weeks to 13 weeks), and then left for up to 2 years without further treatment, high incidences of cholangiocarcinoma or hepatic tumors were observed as well (Maronpot et al., 1991; Elmore and Sirica, 1993). Because of the high incidences of cholangiocarcinoma observed at the lowest dose of furan ( $2 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$ ) in the NTP cancer bioassay (NTP, 1993), another study was recently completed extending to much lower doses (0, 0.02, 0.044, 0.092, 0.2, 0.44, 0.92 and  $2 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$ ) (Von Tungeln et al., 2017), in order to resolve the dose response at low doses and to be able to perform dose response modeling (see below). Importantly, rats did not develop cholangiocarcinoma at any dose up to the highest dose of  $2 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$ . Liver tumors were not detected (found at higher doses in the previous study, and in mice). Importantly, the classification of hepatobiliary effects was done according to a new and standardized classification scheme for laboratory rodents (Thoolen et al., 2010). Following this scheme, biliary lesions identified were classified as cholangiofibrosis (at  $0.2 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$  and higher), exhibiting a non-linear dose response. Importantly, cholangiofibrosis and cholangioadenoma are considered non-neoplastic lesions (non-cancer, meaning a threshold effect), while only cholangiocarcinoma is defined as a neoplastic effect. In addition, re-classification of samples from the 1993 NTP study confirmed that cholangiocarcinoma was only observed at the highest dose ( $8 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$ ). At the lower doses, cholangiocarcinoma were re-classified as fibrosis or adenoma.

Methylfurans have not been tested in chronic oral studies in rodents. 2-MeF was tested in a 28 day study in rats, exhibiting liver toxicity and increased serum cholesterol and increased levels of thyroid hormones T3 (triiodothyronine) and T4 (thyroxine) at the dose of  $1.5 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$ . A NOAEL of  $0.4 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$  was identified (Gill et al., 2014). In a similar study with 3-MeF, liver toxicity was observed with significant histological changes of the liver at  $1.5 \text{ mg (kg$

**Figure 2** Furan, methylfurans and their ring-opened reactive intermediates. Modified from EFSA (2017).

$\text{bw}^{-1} \text{ day}^{-1}$  and a NOAEL of  $0.3 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$ . Increases in serum T3 and T4 were observed as well (Gill et al., 2015). In a 90 day study with gavage administration of 3-MeF (Gill et al., 2018), increased levels of serum markers of liver injury and histopathological changes in the liver were observed at  $0.25 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$ , a NOAEL was determined at  $0.075 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$ . At higher doses, other organs were affected (kidney, spleen). Benchmark dose modelling resulted in a BMDL<sub>10</sub> (the lower confidence level of the dose that results in an increase of cancer incidence by 10% above background) of  $0.08 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$  in male rats and  $0.05\text{--}0.17 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$  in female rats for increased incidence of liver lesions (Gill et al., 2018). Compared to an earlier, similar study on the parent compound furan (Gill et al., 2010), 3-MeF was more toxic at lower doses and to more organs. Overall, 2- and 3-MeF and furan show similar toxicities to the liver and to the kidney at higher doses after oral dosing, and to the lung (after i.p. dosing). These data also indicate that their toxic potencies are in the same order of magnitude (Gill et al., 2018).

### Genotoxicity and Mutagenicity

Furan was negative in most bacterial mutagenicity tests (Ames mutagenicity test in *Salmonella typhimurium*). Weakly positive results were obtained in strain TA100 on one instance and in TA98 in another instance in the presence of metabolic activation only (reviewed in EFSA, 2017). In most in vitro mammalian test systems furan tested positive, such as for mutagenicity in mouse lymphoma cells, chromosomal aberrations and sister chromatid exchanges in CHO (Chinese hamster ovary) and other cell lines (reviewed in EFSA, 2017). Negative results were obtained in the micronucleus test in lymphocytes. Negative results in bacterial and mammalian in vitro test systems were ascribed to the general deficiency of cell systems in CYP2E1 incapable for metabolic activation of furan to BDA, which is in agreement with positive results obtained directly with the metabolite BDA in bacterial mutation assays (Peterson et al., 2000) and mutations, single strand breaks and crosslinks in mammalian cells (Kellert et al., 2008; Marinari et al., 1984). Similar to furan, 2-MeF and 2,5-diMeF tested mostly negative in bacterial mutation assays, while in mammalian cells positive results were obtained for chromosomal aberrations, in vitro micronucleus and the comet assay (reviewed in EFSA, 2017).

In vivo genotoxicity tests in rats and mice treated short term by gavage gave mixed results. High doses were generally required to obtain genotoxic effects including chromosomal aberrations (oxidative) DNA damage, strand breaks and crosslinks, micronuclei, mutations and adducts (reviewed in EFSA, 2017; Ding et al., 2012; McDaniel et al., 2012).

In vivo test results are unavailable for 2- and 3-MeF. 2,5-diMeF was tested recently for genotoxicity in normal and transgenic mice expressing sulfotransferase. No convincing evidence for genotoxicity in the in vivo SCGE assay was found after single oral doses of 75, 150, or 300  $\text{mg (kg bw)}^{-1}$  (Hoie et al., 2015).

### DNA Adducts

Furan was found to covalently bind to proteins in vitro in liver microsomal extracts, and to tissue proteins in vivo after intragastric administration (Burka et al., 1991; Parmar and Burka, 1993). No DNA binding in vivo was observed in those earlier studies. BDA was found in cell-free systems to react with amino acids, proteins, DNA and individual 2-deoxynucleosides, being able to form crosslinks between amino acids (Peterson, 2006). The formation of crosslinks between amino acids in proteins, between protein and DNA and within DNA double strands was proposed as a mechanism of toxicity of furan (Byrns et al., 2004). Results from in vitro cellular mammalian tests (e.g. the alkaline comet assay in mammalian cells) did not unambiguously demonstrate the formation of DNA crosslinks from BDA (JECFA, 2011).

A more recent study (Neuwirth et al., 2012) examined incorporation of  $^{14}\text{C}$ -isotopically labeled furan into the DNA of liver and kidney of male F344 rats treated orally for 28 days with a low but carcinogenic dose ( $2 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$ ), and a sub-carcinogenic dose ( $0.1 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$ ). DNA isolated from kidney and liver was analyzed. Based on the  $^{14}\text{C}$  incorporation rate into liver DNA, average adduct levels of 1.7 and 33 adducts in  $10^8$  nucleotides were determined, respectively, using sensitive Accelerator Mass Spectrometry.  $^{14}\text{C}$  incorporation into the non-target tissue kidney was about 3 fold lower. Comparing the peak profile of digested liver DNA with reference DNA adducts generated by incubating single 2-deoxyribonucleosides with BDA, however, did not reveal any correspondence. The structures of the peak(s) containing radiolabeled DNA could not be identified. None of the adducts formed after incubation of BDA with individual deoxynucleosides dA, dG, dC or with salmon sperm DNA were identified in liver tissue after treatment of rats with either a single dose of  $0.92$  to  $9.2 \text{ mg (kg bw)}^{-1}$  or after repeated doses of  $4.4 \text{ mg (kg bw)}^{-1} \text{ day}^{-1}$  for 45 to 360 days (Churchwell et al., 2015). In none of the treatment groups levels of liver adducts exceeded the background levels (from vehicle treated animals) of about 1.2–2.4 adducts per  $10^8$  nucleotides, irrespective of dose and treatment duration. The authors concluded this as being consistent with general evidence for the absence of in vivo genotoxicity of furan. Still, uncertainty remains about the possible structurally unidentified adduct (Neuwirth et al., 2012) that might derive from a DNA–DNA or DNA–protein crosslink, which was also suggested from alkaline comet assay results in mouse liver and from results in fetal turkey liver (Cordelli et al., 2010; Jeffery et al., 2012).

### Epigenetic Changes

Apart from the controversial debate on genotoxicity, recent evidence points to persisting epigenetic changes induced by furan, recently reviewed by de Conti et al. (2017). These consist in global DNA demethylation, decreases in acetylation and methylation

of chromatin modifying genes and histones (Conti et al., 2014; de Conti et al., 2015; Tryndyak et al., 2017) and altered expression of microRNAs (Chen et al., 2012; de Conti et al., 2016; Dong et al., 2016) in liver of rats in response to furan treatment, compared to unaffected tissue or tissue from control rats. Recently, histone adducts were also identified with a glutathione-BDA conjugate at a pre-carcinogenic stage after low dose oral furan treatment (Nunes et al., 2016). Although the mechanistic interpretation of the causal implications of specific epigenetic changes is difficult, particularly with respect to the experimental settings of dose and duration of treatment, collectively such changes are thought to support the concept of a non-genotoxic mechanism of action (de Conti et al., 2017).

### Mode of Action

The liver is the primary target organ of furan toxicity. In rodents, furan induces hepatocellular adenoma and carcinoma, and cholangiofibrosis at low doses. Sufficient evidence indicates that the toxicity of furan is mediated through a reactive di-aldehyde intermediate, *cis*-2-butene-1,4-dial (BDA), generated via metabolic activation by the cytochrome P450 CYP 2E1 (Peterson, 2006). BDA is capable to covalently bind to tissue macromolecules (proteins, DNA) (Byrns et al., 2006), and is able to form multiple conjugates with glutathione (GSH) and cellular polyamines (Peterson et al., 2011). The major metabolites and degradation products found in urine (and partially in bile) are derived from GSH-conjugation and degradation of adducted proteins (Kellert et al., 2008; Lu et al., 2009; Lu and Peterson, 2010; Hamberger et al., 2010).

The present thinking is that oxidative stress with associated production of oxidative DNA damage (8-oxodeoxyguanosine) in liver and blood, gene expression alterations and epigenetic changes are likely involved in the mode of action along with an inflammatory and cell proliferative response (EFSA, 2017). In addition, epigenetic effects induced by furan, affecting global DNA methylation and methylation and acetylation of histones for instance, indicate indirect mechanisms of DNA damage and genotoxicity and are considered threshold effects.

### Dose Response Modelling

Based on the rodent toxicities detailed above, food safety authorities considered hepatocellular adenoma and carcinoma, and cholangiofibrosis as the pivotal and most sensitive endpoints for neoplastic and non-neoplastic effects, respectively. Dose response data from several 2-year cancer studies were found suitable for benchmark dose (BMD) modelling. Table 5 summarises the results of the BMD modelling studies, including references to the source data, the mathematical models applied and the resulting BMDL<sub>10</sub> values. These were further used as so-called 'points of departure' (PoD) by food safety authorities to assess the risk using the Margin of Exposure approach (ref to 'Risk Assessment' section).

### Risk Assessment

Since furan carcinogenicity was suspected to involve a genotoxic mechanism of action, and even in the most recent opinion such a mechanism could not finally be ruled out, no safe levels of exposure were derived and the Margin of Exposure (MOE) approach is applied. The MOE consists in calculating the ratio between actual estimated total human exposure and the point of departure (PoD), i.e. the reference dose for the pivotal toxicity endpoint derived from an animal study, usually expressed as the BMDL<sub>10</sub>. In the risk assessment of genotoxic carcinogens, a MOE of 10,000 or higher with the neoplastic endpoint would be considered of low priority for risk management. MOEs for furan with the BMDL<sub>10</sub> for liver cancer were found to be about 10'000 or below depending on the age group and dietary intake surveys. MOEs were below 10,000 in infants fed with baby foods in jars and in the elderly population mainly via intake of coffee. Taking into account additional exposure to methylfurans, the MOEs significantly decreased further in elderly populations. For non-genotoxic compounds, MOEs of more than 100 are usually considered of low health concern, and correspond to the uncertainty factors applied to derive safe exposure levels (Health Based Guidance Levels),

**Table 5** Results of benchmark dose modelling studies

Toxicity endpoint	Species & sex	Cancer bioassay	BMDL <sub>10</sub> [mg (kg bw) <sup>-1</sup> day <sup>-1</sup> ]	Model	References
<b>Neoplastic</b>					
Hepatocellular adenoma & carcinoma	Male rats	NTP (1993)	1.28	average	Carthew et al. (2010)
Hepatocellular adenoma & carcinoma	Female mice	Moser et al. (2009)	0.96	multistage	JECFA (2011)
Hepatocellular adenoma & carcinoma	Female mice	combined from NTP (1993) and Moser et al. (2009)	1.31	average	EFSA (2017)
<b>Non-neoplastic</b>					
Cholangiofibrosiss	Male rats	Von Tungeln et al. (2017)	0.11–0.12	different models	Von Tungeln et al. (2017)
Cholangiofibrosis	Male rats	Von Tungeln et al. (2017)	0.064	average	EFSA (2017)

entailing a factor of 10 for interspecies- and 10 for interindividual variability. Using the relevant non-neoplastic endpoint, cholangiofibrosis, results in MOEs around 100. Addition of methylfurans further decreased the MOEs to below 100, particularly in infants and elderly. Thus, no matter if addressing furan from the angle of genotoxicity or not, including combined exposure with methylfurans or not, margins of exposure are close to or below those considered of low concern in several population groups, including small infants and elderly people. Thus, food safety authorities have come to the conclusion that furan exposure in humans via food may present a health concern (JECFA, 2011; EFSA, 2017), and introduction of mitigation efforts in food are indicated.

## Summary

Furan is a volatile compound formed in food during heating processes including roasting and sterilisation. Human exposure to furan and its methylated derivatives occurs mainly via food, major contributors being canned and jarred foods and roasted foods such as coffee.

Furan and similarly its methylated derivatives are thought to be toxic and carcinogenic via reactive intermediates formed by the metabolism in the liver. The metabolites react with cellular molecules such as proteins, and glutathione, leading to oxidative stress and cell and tissue damage, mainly in the liver. At present the involvement of epigenetic effects is gaining attention. Inflammation and compensatory proliferation are thought to lead to fibrosis, and ultimately to hepatocarcinoma. At present, current evidence strongly points to a non-genotoxic mechanism of action in the carcinogenicity of furan. Cholangiofibrosis is a very sensitive endpoint in rats with a low BMDL<sub>10</sub>, resulting in low margins of exposure for dietary intake in humans. In conclusion, no matter if the human risk is interpreted from the perspective of a genotoxic effect, or if the non-cancer endpoint of cholangiofibrosis is considered, margins of exposure with estimated human dietary intakes are considered low. Authorities have concluded this as an indication for a health concern and mitigation strategies are advised and under development.

### Glossary

**Exposure** Exposure for food risk assessment is typically assessed as daily intake or population-based intake for average and worst-case scenarios.

**Risk** Likelihood or probability that a specific hazardous exposure or dose will produce a toxic effect.

**Risk assessment** The process by which the potential adverse effects arising from exposure are characterized.

### Nomenclature

ADI Acceptable daily intake

EC European Commission

EPA US Environmental Protection Agency

### Overview

Furfuryl alcohol (C<sub>5</sub>H<sub>6</sub>O<sub>2</sub>) (CAS# 98-00-0), also known as 2-furanmethanol, 2-furylcarbinol, 2-furancarbinol,  $\alpha$ -furylcarbinol, furfuralcohol and 2-hydroxymethylfuran, is a colorless to slightly yellowish liquid with a characteristic fainting odor. Selected physical and chemical properties of furfuryl alcohol are described in Ullmann's Encyclopedia of Industrial Chemistry (Hoydonckx et al., 2007). Furfuryl alcohol is a high production-volume chemical with industrial applications, including production of furan resins and wetting agents, and as a solvent (Grosse et al., 2017).

Mechanistically, furfuryl alcohol is a reduction product of furfural, a product obtained from the pentoses of corncobs, roasted coffee meal and sugarcane bagasse (Gandini, 2010). Furfural can be converted to furfuryl alcohol via a number of microbial and chemical pathways. Microbiologically, it is produced following the action of yeast species such as *Saccharomyces cerevisiae*, *Pichia stipitis* (Diaz De Villegas et al., 1992) and *Neospora tetrasperma* (Eilers and Sussman, 1970) on furfural. Fig. 1 illustrates this natural generation of furfuryl alcohol from maltose and 2-deoxyribose while Fig. 2 shows the thermal degradation of quinic acid to furfuryl alcohol. Industrially, the hydrogenation of furfural using catalysts such as palladium (Gandini, 2010), nickel, CuCrO (Jacobson et al., 1958; Taylor et al., 2017) and other metal alloys produces furfuryl alcohol (Huang et al., 2007). Also on a laboratory scale, furfuryl alcohol can be synthesized from furfural via the Cannizzaro reaction, which involves disproportionation of an aldehyde to an alcohol in basic conditions (Swain et al., 1979).

### Uses

Furfuryl alcohol is an important industrial chemical for the polymer industry that is used to produce synthetic fibres, rubbers, resins, e.g., dark thermostatic resins resistant to acids, bases and resins used for strengthening ceramics and wood (Gandini, 2010; Huang et al., 2007). The compound may serve as a solvent for furan resin, pigment, varnish, as rocket fuel and fuel additive (Vorotnikov et al., 2012). Furfuryl alcohol may be also used as a food additive and a mechanical reinforcement for highly porous polymeric matrices (Cui et al., 2016; Gandini, 2010). Furfuryl alcohol is used industrially as a wetting agent, a gel retarder, a liquid propellant,

**Figure 1** Degradation of reducing sugars to generate furfuryl alcohol. Reprinted with permission from Vanderhaegen et al. (2004b). Copyright 2004 American Chemical Society.

**Figure 2** Heat degradation of quinic acid to yield furfuryl alcohol in coffee. Adapted with permission from Moon and Shibamoto (2010). Copyright 2010 American Chemical Society.

a flavouring agent and in foundry cores (Cui et al., 2016). The EU regulation (EC) No 872/2012 lists furfuryl alcohol as a flavouring substance with no limit or restrictions on its use (European Commission (EC), 2012).

## Occurrence and Exposure

Furfuryl alcohol occurs as a natural constituent in a wide variety of foods and food components in varying concentrations and also widely as a food additive. According to a recent review (Okaru and Lachenmeier, 2017), furfuryl alcohol was found in various foods and beverages including coffee beans (>100 mg kg<sup>-1</sup>), fish products (≈ 10 mg kg<sup>-1</sup>), wines (1–10 mg L<sup>-1</sup>) and pineapple juice (8 mg L<sup>-1</sup>) (Okaru and Lachenmeier, 2017). Table 1 summarizes the occurrence of furfuryl alcohol in some foods and beverages.

**Table 1** Furfuryl alcohol content in various foods and beverages

Category [reference]	N	Furfuryl alcohol concentration							Units <sup>a</sup>

<sup>a</sup>The ambiguous unit ppm was interpreted as mg L<sup>-1</sup> for liquids/beverages and as mg kg<sup>-1</sup> for solid foods.

<sup>b</sup>All samples evaluated (spirits types whiskey, rum, brandy as well as various wines and breads) were below the limit of detection (LOD; 3.2 mg L<sup>-1</sup>).

<sup>c</sup>Studies from the same research group with probably overlapping data.

<sup>d</sup>Number of samples not provided. The data are suggested as being “usual concentrations” found in these food/beverage types.

Preprinted from (Okaru and Lachenmeier, 2017). Copyright 2017 by the authors. Licensee MDPI, Basel, Switzerland; distributed under the terms and conditions of the Creative Commons Attribution (CC BY) license (<http://creativecommons.org/licenses/by/4.0/>).

Furfuryl alcohol has been reported to occur naturally in coffee, roasted almonds, cooked apples, apple juice, canned beef, in cognac oil and also it is used to flavour butter, butterscotch, caramel, fruits, bread and brandy among other foods (Burdock, 2004). It has also been found in beverages (19 ppm), ice cream (88 ppm), candy (59 ppm), baked goods (110 ppm) and in spirits (10 ppm) (National Research Council (US), 1965; Okaru and Lachenmeier, 2017). Furfuryl alcohol also contributes to the flavour of foods and beverages such as odor of French fries (Wagner and Grosch, 1998), other deep-fried products such as breaded fish products (IARC, in press) and roasted beef (Cerny and Grosch, 1992).

The occurrence of furfuryl alcohol has also been reported in rice cakes as an odor component (Buttery et al., 1999), non-dry fat milk (Karagül-Yüceer et al., 2002) and also in wines aged in barrels (De Simón et al., 2003) and also in *Boletopsis lucomelas*, a mushroom (Nosaka and Miyazawa, 2014) and also in cooked pine mushrooms and is thought to be formed from the various thermal reactions during cooking and hence could be used as marker for grading cooked pine mushrooms (Cho et al., 2006). Furfuryl alcohol has also been identified as one of the major volatile compounds in the kiwifruit (*Actinidia eriantha*) at concentration of up to 162 µg kg<sup>-1</sup> (García et al., 2012). Lactic acid bacterium affects the production of furfuryl alcohol in soy sauce (Harada et al., 2016). Furfuryl alcohol along with other furanic compounds occurs in smoked-cured bacon (Yu et al., 2008) and paste fish (Gili et al., 2010).

Furfuryl alcohol may also be used as one of the marker compounds to differentiate between *arabica* and *robusta* coffee (Hron et al., 2009). Similarly, the occurrence of furfuryl alcohol in wines is an indicator of microbial guided reduction of furfural during storage in barrels. However, degradation of furfural to furfuryl alcohol may also occur in the absence of bioflora (Pérez-Prieto et al., 2003). Furfuryl ethyl ether, an ageing staling flavor compound in beer is an indicator of the presence of furfuryl alcohol (Vanderhaegen et al., 2004a) which is thought to originate from the Maillard reaction that occurs during wort boiling, malt kilning or as a result of yeast reduction of furfural. However furfural has been shown to inhibit yeast metabolism (Vanderhaegen et al., 2004b).

Apart from diet, exposure to furfuryl alcohol can also be from occupational sources (Ribeiro and Filho, 2006). Furfuryl alcohol in combination with other chemicals such as formaldehyde has been shown to affect lung function in workers handling furan resins

(Ahman et al., 1991). Also it has been detected in gas formed from furan binding resins at a mean concentration of 4.8 ppm with 22% of the determinations exceeding the 5 ppm threshold limit value (TLV) (Virtamo et al., 1976). For review on occupational exposure, see (IARC, in press).

### Analytical Methods

Furfuryl alcohol has been analyzed in various matrices using gas chromatography with flame ionization detection (GC-FID) including in workspaces following active trapping onto suitable adsorbent material and subsequent thermal desorption (International Standard Organization (ISO), 2000; Tschickardt, 2002) and in kiwifruit (Garcia et al., 2012). Also gas chromatography-UV spectrometry (GC-UV), has been used for the determination of volatile organic compounds in settles dust in homes (Nilsson et al., 2005). Gas chromatography-mass spectrometry (GC-MS) has been used to determine furfuryl alcohol in mushrooms (Nosaka and Miyazawa, 2014) and environmental water (Kawata et al., 2001). A headspace solid phase microextraction coupled to gas chromatography-mass spectrometry method for the furanic compounds including furfuryl alcohol was developed and validated for the analysis of deep-fried fish products (Pérez-Palacios et al., 2013, 2012) while high performance liquid chromatography (HPLC) has been used to separate furfuryl alcohol together with other furanic derivatives in transformer/rectifier oil (Lin et al., 2016). Aroma compounds including furfuryl alcohol in Shanxi aged vinegar have been characterized and quantitated using authentic standards by GC-MS/MS operated on selected reaction monitoring mode (Liang et al., 2016). Furfuryl alcohol in coffee and other matrices can also be analyzed using nuclear magnetic resonance (NMR) spectroscopy (Okaru and Lachenmeier, 2017).

### Toxicology

Furfuryl alcohol is well absorbed across biological membranes in humans and animals (Grosse et al., 2017). Furoic acid is the main phase I metabolite of furfuryl alcohol. Furfuryl alcohol is first metabolized by oxidation to furfural before being converted to furoic acid, which is then decarboxylated to CO<sub>2</sub>. The acid may be excreted unchanged or conjugated with glycine (major metabolite) and/or condensed with acetic acid (Nomeir et al., 1992).

Despite the contribution of furfuryl alcohol to the aroma of foods and beverages, some studies have revealed the potential toxicity in animals and humans (Sujatha, 2008; Arts et al., 2004; Goldsworthy et al., 2001; Wilson et al., 1992). The main reported adverse effects of furfuryl alcohol are mainly on the epithelium of the olfactory and respiratory systems. However, pure furfuryl alcohol is harmful when inhaled, if swallowed, and in contact with skin. Currently, furfuryl alcohol does not appear to have genotoxic potential (*in vivo*) with evidence of carcinogenic activity of furfuryl alcohol in rats being thresholded at low doses. In a 2-year inhalation studies, male mice exposed to the highest tested concentration had a significantly increased incidence of renal tubular degeneration and a significantly increased combined incidence of renal tubular adenomas and carcinomas. In a single study on F344 rats and B6C3F1 mice exposed to furfuryl alcohol vapor for 6 hours per day, 5 days per week for 14 days (0, 16, 31, 63, 125, 250 ppm) or 13 weeks (0, 2, 4, 8, 16, 32 ppm) inflammation and/or metaplasia of respiratory epithelium was observed for the 14 day study (Irwin et al., 1997).

The postulated mechanism of carcinogenicity of furfuryl alcohol using reverse mutation assays with *Salmonella typhimurium* TA100-derived strains is by the formation of a 2-sulfo-oxymethylfuran, an electrophile reacting with DNA to form nucleoside adducts of 2'-deoxyadenosine and 2'-deoxyguanosine. Another study indicated that furfuryl alcohol may induce sister chromatid exchange in human lymphocytes *in vitro* and *in vivo* (World Health Organization (WHO), 2001).

According to WHO IARC, the evidence that furfuryl alcohol is metabolically activated via sulphate conjugation to electrophilic 2-sulphoxymethylfuran is judged as "strong". Furfuryl alcohol-specific DNA adducts were found in non-tumour tissue of patients with lung cancer, in mice, and in bacteria expressing human sulfotransferase (Grosse et al., 2017). Based on "sufficient evidence of carcinogenicity in experimental animals" and no data in human beings, the WHO IARC has classified furfuryl alcohol as "possibly carcinogenic to humans" (Group 2B) (Grosse et al., 2017; IARC, in press).

### Risk Assessment and Mitigation

The FEMA reported the typical use levels of furfuryl alcohol (ppm) as a flavouring substance in the following foods/beverages as follows: non-alcoholic beverages (19 ppm), ice cream, ices (88 ppm), candy (59 ppm), baked goods (110 ppm) and alcoholic beverages (10 ppm) (Adams et al., 2011). JECFA sets an acceptable daily intake (ADI) of 0–5 mg kg<sup>-1</sup> body weight and considers it to be of no safety concern when used within the levels permissible for use as a food flavor (Burdock, 2004). According to WHO IARC (IARC, in press), the human intake estimates are well below 0.15 mg kg bw<sup>-1</sup> day from food additives. Consuming one cup of espresso coffee may lead to an intake of 0.03 mg kg bw<sup>-1</sup>. While more detailed exposure assessments are lacking, the current evidence suggests furfuryl alcohol as being a low risk if any.

Nevertheless, since the cooking and handling conditions have a great influence on the residual levels of furanic compounds in heated foods, efforts should be made reduce furanic compounds without affecting the content of volatile compounds that contribute to the aroma and flavor of fried foods (Pérez-Palacios et al., 2013). For instance the addition of sulfite in beers (Vanderhaegen et al., 2004b) and dimethyldicarbonate (Spillman et al., 1998) may inhibit Maillard browning by nucleophilic

reaction with the double bond of Maillard intermediates, such as 3,4-dideoxyhexosulos-3-ene (3-DDH) (Vanderhaegen et al., 2004b).

## Glossary

**Biomarkers** are used for exposure assessment. Some examples of biomarkers are chemicals or their metabolites in urine, plasma, or reactive intermediates covalently bound to DNA- and protein as adducts. These endpoints represent biomarkers of exposure.

**DNA adduct** is a chemical covalently bound to DNA that can lead to a mutation during cell division and initiate the cell to a cancerous state.

**Epigenetics** is the study of biological mechanisms that switch genes on and off. One common mechanism is through the methylation of cytosine to form 5-methylcytosine, resulting in changes in gene expression. In mammals, DNA methylation occurs almost exclusively in CpG dinucleotides. In diseases, such as cancer, CpG islands in the gene promoter regions undergo aberrant hypermethylation, resulting in transcriptional gene silencing.

**Genetic polymorphisms** in carcinogen-metabolizing enzymes are variants in genes encoding for phase I enzymes, such as cytochrome P450 oxidases, or phase II conjugation enzymes, such as glutathione S-transferases. The genetic alterations include single-nucleotide polymorphisms, the insertion or deletions of nucleotides, or changes in gene copy numbers, which can cause an increase, decrease, or abolish the pathways of metabolism and impact the biological effects of carcinogens.

**Signal transduction** is a process by which a chemical or physical signal is transmitted through a cell as a series of molecular events, often by protein phosphorylation catalyzed by protein kinases, which results in a cellular response, such as downstream changes in protein expression and activity.

**The Maillard reaction** is named after the French chemist Louis-Camille Maillard, who initially described the reaction between amino acids and sugars in 1912. The reaction represents a collection of a complex group of chemical processes that can occur between amino acids and reducing sugars that give cooked meats and other browned foods their distinctive flavor and aroma.

**Tumor promotion** is the multistage process of cancer development providing the conditions for a single initiated cell to survive and multiply, and undergo clonal growth.

## Nomenclature

### Heterocyclic aromatic amines

**IQx** 2-amino-3-methylimidazo[4,5-*f*]quinoxaline  
**MeIQx** 2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline  
**4,8-DiMeIQx** 2-amino-3,4,8-trimethylimidazo[4,5-*f*]quinoxaline  
**7,8-DiMeIQx** 2-amino-3,7,8-trimethylimidazo[4,5-*f*]quinoxaline  
**Trp-P-1** 2-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole  
**Trp-P-2** 2-amino-1-methyl-5*H*-pyrido[4,3-*b*]indole  
**Glu-P-2** 2-aminodiprido[1,2-*a*:3',2'-*d*]imidazole  
**Glu-P-1** 2-amino-6-methyldiprido[1,2-*a*:3',2'-*d*]imidazole  
**MeIQ** 2-amino-3,4-dimethylimidazo[4,5-*f*]quinoline  
**IQ** 2-amino-3-methylimidazo[4,5-*f*]quinoline  
**PhIP** 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine  
**MeAαC** 2-amino-3-methyl-9*H*-pyrido[2,3-*b*]indole  
**AαC** 2-amino-9*H*-pyrido[2,3-*b*]indole  
**dA** 2'-deoxyadenosine  
**dG** 2'-deoxyguanosine

### DNA Adducts

**dG-C8-MeIQx** *N*-(2'-deoxyguanosin-8-yl)-MeIQx  
**dG-N<sup>2</sup>-MeIQx** 5-(2'-deoxyguanosin-N<sup>2</sup>-yl)-MeIQx  
**dA-N<sup>6</sup>-MeIQx** 5-(2'-deoxyadenosin-N<sup>6</sup>-yl)-MeIQx  
**dG-C8-4,8-DiMeIQx** *N*-(2'-deoxyguanosin-8-yl)-4,8-DiMeIQx  
**dG-C8-IQ** *N*-(2'-deoxyguanosin-8-yl)-IQ  
**dG-C8-MeIQ** *N*-(2'-deoxyguanosin-8-yl)-MeIQ  
**dG-N<sup>2</sup>-IQ** 5-(2'-deoxyguanosin-N<sup>2</sup>-yl)-IQ

dA-*N*<sup>6</sup>-IQ 5-(2'-deoxyadenosin-*N*<sup>6</sup>-yl)-IQ  
 dG-C8-A $\alpha$ C *N*-(2'-deoxyguanosin-8-yl)-A $\alpha$ C  
 dG-C8-MeA $\alpha$ C *N*-(2'-deoxyguanosin-8-yl)-MeA $\alpha$ C  
 dG-C8-PhIP *N*-(2'-deoxyguanosin-8-yl)-PhIP

#### Other Abbreviations

HAA heterocyclic aromatic amines  
 NAT N-acetyltransferase  
 ppb parts per billion  
 SULT sulfotransferase  
 UGT uridine 5'-diphospho-glucuronosyltransferase  
 ER- $\alpha$  estrogen receptor alpha  
 PR progesterone receptor  
 AR androgen receptor  
 MAPK mitogen-activated protein kinase  
 ERK extracellular signal regulated kinase  
 EGFR epidermal growth factor receptor

## Overview

Heterocyclic aromatic amines (HAAs) are formed in well-done grilled meats, poultry, and fish, and several HAAs arise during the combustion of tobacco smoke or emitted in diesel exhaust (Sugimura et al., 2004; Felton et al., 2000). The concentrations of HAAs generally occur in the parts per billion level (ppb) in cooked meats but in some instances the levels can vary by over a 100-fold range. 2-Amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline (MeIQx) and 2-amino-1-methylimidazo[4,5-*b*]pyridine (PhIP) are two of the most abundant HAAs formed in grilled ground beef and poultry prepared under common household cooking practices, while 2-amino-9*H*-pyrido[2,3-*b*]indole (A $\alpha$ C) is the most abundant HAA present in tobacco smoke (Manabe et al., 1991; Zhang et al., 2011). The chemical structures of several prevalent HAAs are presented in Fig. 1.

The Maillard reaction is involved in the formation of the amino-imidazo-containing HAAs, where the precursors of HAA formation originate from creatine, amino acids, and hexoses present in the meat (Jagerstad et al., 1991; Murkovic, 2004). The formation of amino-imidazoquinolines and amino-imidazoquinoxalines occurs by reaction of 2-methyl-pyridine or 2,5-dimethyl-pyrazine with acetaldehyde and creatinine (Milic et al., 1993). Other HAAs arise by the high-temperature (>300 °C) heating of amino acids, such as glutamic acid, tryptophan, phenylalanine, or proteins (Matsumoto et al., 1981; Murkovic, 2004).

HAAs are mainly metabolized by hepatic P450 1A2 in rodents and humans, and by P450s 1A1 and 1B1 in extrahepatic tissues (Turesky and Le Marchand, 2011). Cytochrome P450 (P450) enzymes oxidize the heteroaromatic rings of HAAs to form

**Figure 1** Chemical structures of representative HAAs formed in cooked meats and tobacco smoke condensate. The top row depicts amino-imidazopyridine, amino-imidazoquinolines and amino-imidazoquinoxalines, and the bottom row represents several HAAs derived from the pyrolysis of amino acids.

**Figure 2** Major pathways of metabolism of several prototypical HAAs by P450s and phase II conjugation enzymes.

detoxicated metabolites, whereas N-oxidation of the exocyclic amine group produces the genotoxic N-hydroxylated-HAA metabolites (Fig. 2) (Turesky and Le Marchand, 2011). These metabolites can undergo conjugation reactions by phase II enzymes such as N-acetyltransferases (NATs) or sulfotransferases (SULTs) (Hein, 2000; Chevereau et al., 2017), to form unstable intermediates that react with DNA to form adducts; some of these adducts may induce mutations during cell division (Fig. 3). The principal HAA-DNA adducts arise from reaction between the C-8 atom of deoxyguanosine (dG) and the electrophilic N-oxidized exocyclic amino groups of the HAAs, to produce dG-C8-HAA adducts. The reactive intermediates of IQ and MeIQx also form adducts between the  $N^2$  group of dG and the C-5 atom of IQ and MeIQx, and minor adduct formation occurs at the  $N^6$  atom of deoxyadenosine (dA) and the C-5 atom of IQ and MeIQx (Fig. 3) (Jamin et al., 2007; Bessette et al., 2009). These adducts are believed to be responsible for the mutagenic effects of HAAs. There are notable interspecies differences in catalytic activity and regioselectivity of the oxidation of HAAs by P450s; such differences can influence the DNA-binding potential and toxicological properties of these genotoxins (Turesky et al., 1999, 2001). Moreover, components in the diet can act as chemopreventive agents and alter the metabolism of HAAs, and thus diminish their biological effects (Higdon et al., 2007).

Some risk assessment studies suggest that HAAs may not pose an important health risk because daily exposure levels to HAAs are 100,000 to  $1 \times 10^6$  of the daily dose required to induce tumors in rodent models (Layton et al., 1995; Lutz and Schlatter, 1992; Gaylor and Kadlubar, 1991). However, humans are exposed to more than 20 HAAs, and interspecies differences in metabolism

**Figure 3** DNA adducts of representative HAAs formed with dG and dA. dR: deoxyribose

and bioactivation of HAAs, and tumor promoting factors may increase the carcinogenic potential of HAAs (Sugimura, 1992; Sugimura et al., 2004; Turesky and Le Marchand, 2011). Some epidemiological studies have observed an association between frequent consumption of cooked red meats containing HAAs and other carcinogens and an increased risk for the development of colorectal cancer (Norat et al., 2005). The working group of the International Agency of Research on Cancer recently concluded that red meat is 'probably carcinogenic to humans' (Group 2A carcinogen) and a risk factor for colorectal cancer (Bouvard et al., 2015). The frequent consumption of red meat was also positively associated with pancreatic and with prostate cancer. PhIP, in particular, has been the focus of much research because it is the most mass-abundant carcinogenic HAA formed in well-done cooked meats and poultry (Sugimura et al., 2004; Felton et al., 2000), and the only HAA reported to induce tumors in the colorectum, pancreas, and prostate of rodents (Shirai et al., 2002; Sugimura et al., 2004). Recent studies have shown that PhIP also exerts epigenetic effects *in vitro* and changes in cellular events that impact cellular growth and tumor promoting properties at dose concentrations approaching human exposures (Laubert et al., 2004; Chen et al., 2017). Thus, further research is required to understand the role of HAAs in the etiology of dietary associated cancers.

### Biological Activity: Genotoxicity and Cancer

The genotoxicity of HAAs varies by over a >1000-fold in bacterial mutagenicity assays (Sugimura et al., 2004); however, these large differences in ranges of potency are generally not observed in mammalian cell assays or in long-term carcinogen bioassays (Sugimura et al., 2004; Glatt, 2006). These discrepancies in biological effects are attributed to differing metabolic enzyme activation systems, differing DNA adduct repair capacities, differing gene locus endpoints for mutagenicity, and different base sequence contexts and neighboring base effects on the HAA-DNA lesions, all of which affect mutation frequencies (Turesky, 2002). HAAs induce tumors in rodents at multiple organs that include: the oral cavity, liver, stomach, lung, colorectum, pancreas, prostate and mammary glands, during long-term feeding studies (Sugimura et al., 2004). Despite the large differences in genotoxic potencies of HAAs in different cell assays, the carcinogenic potency of many HAAs in experimental animals is within approximately 10-fold, depending upon the species or organs affected. 2-Amino-3-methylimidazo[4,5-f]quinoline (IQ) is also a powerful liver carcinogen in non-human primates, and one of the most powerful carcinogens assayed in cynomolgous monkeys (Adamson et al., 1990). Recent studies have reported a rapid induction of colon and prostate-induced carcinogenesis in P450 1A-humanized mice compared to wild-type mice following treatment with PhIP (Cheung et al., 2011; Li et al., 2012), reinforcing the notion that human P450 enzymes more efficiently bioactivate HAAs to reactive intermediates than the rodent counterparts (Turesky et al., 1999; Turesky and Le Marchand, 2011).

### HAA and Genomic and Non-genomic Regulation

In addition to their DNA-damaging and mutagenic properties, certain HAAs, such as PhIP, are capable of inducing changes in gene expression by different mechanisms (Fig. 4). In human breast cancer cells, PhIP is a potent estrogen and binds to receptor alpha (ER- $\alpha$ ) (Laubert et al., 2004). ER- $\alpha$  is a transcription factor that regulates the expression of targeted genes upon the binding of its ligand, the estrogens. Estrogen signaling through ER- $\alpha$  in breast cancer cells results in cell proliferation and survival signals but also the suppression of anti-proliferative and apoptotic signals (Frasor et al., 2003). In MCF-7 cells, a breast cancer cell line that expresses ER- $\alpha$ , PhIP induces transcriptional activities of ER- $\alpha$  at concentrations ranging between  $10^{-10}$  to  $10^{-6}$  M; the lower concentrations approach the levels of dietary exposure to PhIP in humans (Laubert et al., 2004). Compared to other environmental chemicals, the estrogenic potency of PhIP is strong. For example, butylated hydroxyanisole, a widely used dietary antioxidant and a known stimulator of ER- $\alpha$ , induces the transcriptional activity of ER- $\alpha$  *in vitro* at concentrations starting from  $10^{-5}$  M (Jobling et al., 1995). The activation of ER- $\alpha$  by PhIP leads to the proliferation of MCF-7 cells and an up-regulation of the expression of the proto-oncogene *c-Myc* (Laubert et al., 2004). *c-Myc* is a key factor for cell cycle regulation and progression. Under normal quiescent cell conditions, the expression of *c-Myc* is under tight transcriptional control and its level of expression ranges between undetectable to very low. However, under cellular proliferation conditions, the expression of *c-Myc* is up-regulated (Gabay et al., 2014).

Another genomic mechanism by which PhIP can induce proliferation in breast cancer cells is through the progesterone receptor (PR). Following exposure to PhIP, there is an increase in the expression of PR as a marker of ER- $\alpha$  activation (Laubert et al., 2004). Like the estrogens, progesterone is believed to be major player in breast cancer development. In breast cancer cells, the PR is activated by the binding of its ligands, which include naturally occurring ovarian steroid hormones, progesterone, or synthetic ligands such as progestins. The activation of PR leads to the transcriptional up-regulation of its targeted genes, including epidermal growth factor receptor (EGFR), *c-fos*, *p21*, and *cyclin D1*. Many of these genes are associated with tumor proliferation, resistance to chemotherapies, and tumor aggressiveness (Lange and Yee, 2008).

PhIP also binds to the androgen receptor (AR), leading to downstream AR events in human prostate cancer cells (Glass-Holmes et al., 2015). Like ER- $\alpha$  and PR, AR is a nuclear factor which is activated by interaction with androgenic hormones, such as testosterone and dihydrotestosterone, to express multiple genes involved in normal growth, homeostasis of the prostate. Under pathological conditions, AR and its downstream events are critical factors in prostate carcinogenesis (Lonergan and Tindall, 2011).

PhIP can also modulate the proliferation and the survival of breast cancer cells through cell signaling pathways. For example, the treatment of MCF-7 cells with PhIP leads to the activation of the mitogen-activated protein kinase (MAPK) extracellular signal regulated kinase (ERK) pathway (Laubert et al., 2004; Creton et al., 2007). The ERK pathway is activated

**Figure 4** Mechanisms of gene expression modulation of PhIP, by binding to ER- $\alpha$  (Genomic pathway) and through cell signaling (non-genomic, ERK phosphorylation), in breast cancer cells. The mechanism(s) by which PhIP impacts ERK pathway activation is unknown.

by the phosphorylation of ERK-1 and/or ERK-2, which lead to the modulation of transcription of genes that are involved in the regulation of proliferation, differentiation, and survival of breast cancer cells (Maemura et al., 1999). ERK pathway is activated by PhIP independently from the activation of ER- $\alpha$  since the activation of ERK pathway is also observed in MCF-10A cells, a breast cancer cell line that does not express ER- $\alpha$  (Venugopal et al., 1999). However, the mechanism by which PhIP leads to the activation of the ERK pathway remains unknown (Fig. 4). The activation of ERK pathway by PhIP is associated with an inhibition of apoptosis in MCF-10A under serum and growth factor deprivation conditions. Indeed, under these conditions, PhIP lead to the phosphorylation of ERK-2 with a concomitant increase in the expression of the two anti-apoptotic factors Bcl-2 and Bcl-xl (Venugopal et al., 1999).

## Human Biomonitoring

### Urinary Metabolites

Urine is a useful biological fluid for the measurement of exposure to various classes of carcinogens, since large quantities can be obtained noninvasively. The analysis of HAAs or their metabolites in urine do not shed light on DNA damage; however, such measurements can assess the capacity of an individual to bioactivate or detoxicate HAAs, and assess the impact of genetic polymorphisms in carcinogen metabolism enzymes on health risk (Hecht, 2002). HAAs are rapidly absorbed from the gastrointestinal tract and are eliminated in urine as multiple metabolites, with up to several percent of the dose present as the parent compounds within 24 hours of consuming grilled meats (Boobis et al., 1994; Turesky and Le Marchand, 2011). The percent of the dose of MeIQx and PhIP excreted in urine as genotoxic *N*-oxidized metabolites greatly exceeds that reported in the rodent, showing that human P450 1A2 *in vivo* biotransforms a larger portion of the HAA dose into genotoxic intermediates than rodents (Turesky et al., 1998; Walters et al., 2004; Kulp et al., 2004). Major pathways of detoxication of MeIQx occur by conjugation enzymes

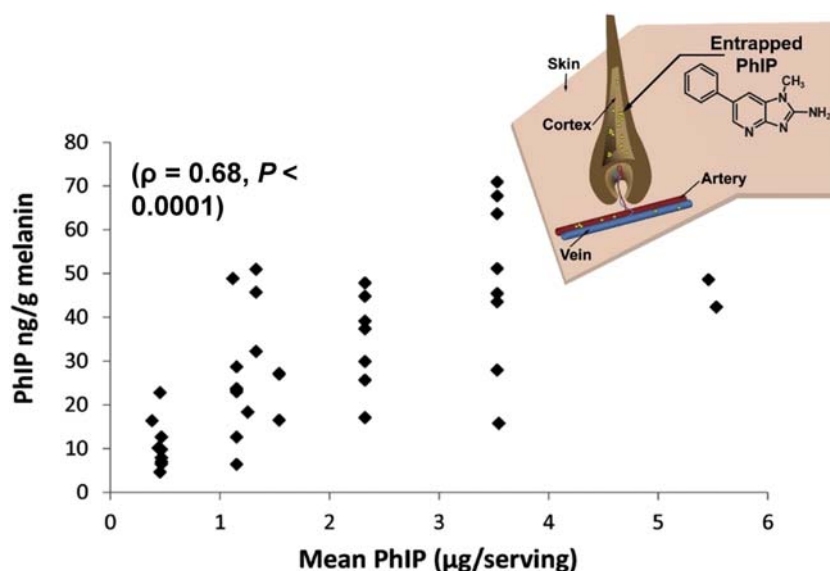

including SULT and uridine 5'-diphospho-glucuronosyltransferases (UGTs), to produce, respectively, the sulfamate and  $N^2$ -glucuronide conjugates of MeIQx (Fig. 2) (Turesky et al., 1998; Gu et al., 2011). UGT isoforms 1A1 and 1A9 strongly contribute to the metabolism of PhIP, and  $N$ - and  $O$ -linked conjugates of the genotoxic metabolite 2-hydroxyamino-1-methyl-6-phenylimidazo[4,5- $b$ ]pyridine (HONH-PhIP) have been identified as the major metabolites of PhIP in urine of carnivores (Walters et al., 2004; Kulp et al., 2004; Turesky et al., 2015; Cai et al., 2016). A $\alpha$ C undergoes P450-mediated ring oxidation at the 3- and 6-positions of the heteroaromatic rings as major pathways of metabolism and detoxication, by human liver microsomes, human hepatocytes, and in vivo in humans (Fig. 2) (Bellamri et al., 2017; Konorev et al., 2015).

### Hair Biomarker

Urinary biomarkers of HAAs may be at undetectable levels for individuals who chronically but intermittently consume cooked meats, and these individuals can be misclassified. There is a need to establish stable, long-term biomarkers of HAAs. Human hair has served as a matrix to biomonitor various drugs and contaminants, such as nicotine, narcotics, and hormones (Alexander et al., 2002; Appenzeller and Tsatsakis, 2012). PhIP strongly binds to pigments in hair, and the levels of PhIP accrued in hair in a dose-dependent manner (Fig. 5). However, the binding of other HAAs to hair is considerably less. The levels of PhIP accrued in hair may be superior to inferring estimates of dietary intake of PhIP through food frequency questionnaires (Le Marchand et al., 2016; Turesky et al., 2013). However, long-term, non-invasive biomarkers of the biologically effective internal dose of HAA, such as DNA or protein adducts are still sought for molecular epidemiology studies.

### DNA Adduct Formation

Early reports on HAA-DNA adducts formation in rodents was done by  $^{32}$ P-postlabeling techniques (Schut and Snyderwine, 1999). The level of adduct formation in tissues does not necessarily correlate with tumorigenesis, indicating that tumor promoting factors, such as cell proliferation, are important in the tumorigenesis process (Sugimura, 1992). HAA-DNA adducts of  $^{14}$ C-radiolabeled-MeIQx and  $^{14}$ C-PhIP measured by accelerator mass spectrometry were reported to form at higher levels in human than formed in colon of rats given the same size proportional dose of chemical (Dingley et al., 1998).  $^{14}$ C-PhIP-DNA adduct formation in white blood cells of human subjects given an oral dose of PhIP (70  $\mu$ g/person) reached levels of modification up to 1.5 total adducts/ $10^9$  DNA bases 4–6 h post-treatment, but rapidly declined at 24 h post-treatment (Dingley et al., 1999). A gas chromatography/mass spectrometry method, based upon alkaline hydrolysis of DNA, revealed the presence of PhIP in colorectal mucosa of several individuals at levels of up to several adducts per  $10^8$  DNA bases (Friesen et al., 1994). Another study detected a labile adduct of PhIP at levels of several adducts per  $10^8$  DNA bases in long-lived lymphocytes in about 30% colorectal cancer subjects (Magagnotti et al., 2003). The levels of adduct varied 10-fold between the lowest and highest levels, suggesting differences in the intake of PhIP or interindividual variation in PhIP metabolism and bioactivation. The PhIP-DNA adduct (dG-C8-PhIP) was detected in exfoliated epithelial cells from milk of lactating mothers in 30 of the 64 samples analyzed, with a mean value of 4.7 adducts/ $10^7$  nucleotides, by the  $^{32}$ P-postlabeling method (Gorlewska-Roberts et al., 2002). In the other study, PhIP adducts, presumably dG-C8-PhIP, were detected in human breast tissues at levels of  $\sim 1$  adduct per  $10^7$  bases, by means of an immunohistochemistry method, in 82% and 71% of the normal breast tissue sections from the cancer and control patients respectively (Zhu et al.,

**Figure 5** The accrual of PhIP in newly grown hair in volunteers on a four week semi-controlled feeding study of well-done cooked meat (Le Marchand et al., 2016).

2003). Other studies employing immunohistochemistry reported frequent detection of dG-C8-PhIP in the DNA of pancreas and prostate of cancer patients (Zhu et al., 2006; Tang et al., 2007). The MeIQx-DNA adduct (dG-C8-MeIQx) adduct was detected by the  $^{32}\text{P}$ -postlabeling assay in colon and kidney DNA of several individuals at levels estimated at several adducts per  $10^9$  DNA bases (Totsuka et al., 1996). A recent pilot study employing liquid chromatography with high resolution accurate tandem mass spectrometry identified dG-C8-PhIP, but not DNA adducts of other HAAs, in prostate DNA from about 25% of the prostate cancer patients (Xiao et al., 2016). Adduct levels ranged from 2–120 adducts per  $10^9$  DNA bases. Collectively, these findings reveal that HAA-DNA adduct formation occurs in human tissues, even though the concentrations of HAAs in the diet are generally at low ppb levels. However, the biological significance of HAA-DNA adducts at these low levels of DNA modification remains to be elucidated (Nagao et al., 1996).

## Future Trends

The major pathways of metabolism of HAAs reveal interspecies similarities as well as important differences in the enzymology of metabolism which can influence the toxicological properties of HAAs. Recent advances in mass spectrometry instrumentation, particularly high resolution accurate mass spectrometers and improved sensitivity permit the detection of multiple DNA adducts at extremely low levels, or permit the use of less DNA for measurements of DNA adducts (Xiao et al., 2016; Balbo et al., 2014; Guo et al., 2017). With the identification of such biomarkers, the interactive effects of genetic polymorphisms of enzymes involved in metabolism (both activation and detoxication) and DNA repair enzymes may be correlated to the levels of DNA adduction products of HAAs and clarify the role of these chemicals in dietary associated cancers.

## Acknowledgment

A portion of the work conducted in the Turesky laboratory was supported by NIH Grants R01CA122320, R01CA134700, and R01CA134700-S1 of the Family Smoking Prevention and Tobacco Control Act.

## Glossary

**Margins of exposure (MOE)** A term used in toxicology, the MOE is defined as the ratio of the level at which a small but measurable effect is observed to the estimated exposure dose; it is also sometimes defined as the ratio of the maximum no-adverse-effect-level to the estimated exposure dose.

**Maillard reaction** This reaction, which was named after the French chemist, Louis Camille Maillard, who first described it in 1912, comprises a series of non-enzymatic reactions between reducing sugars and amino groups, principally those of amino acids. The Maillard reaction is promoted by high temperature and low moisture content and, therefore, occurs mainly in cooked foods prepared by frying, baking and roasting.

**Reducing sugar** A reducing sugar is one that is capable of acting as a reducing agent because it has a reactive double bond in a free aldehyde group (e.g. glucose and maltose) or a free ketone group (e.g. fructose).

**RNA interference (RNAi)** A genetic modification technique that results in gene silencing.

**Genome editing** A term given to several techniques that use specially-designed oligonucleotides or targeted nucleases to generate mutations in specific target genes within an organism's genome.

**TALENs** Transcription activator-like effector nucleases, used in genome editing.

**CRISPR-Cas** Clustered, regularly-interspaced, short palindromic repeats (CRISPR) and the Cas9 nuclease, used in genome editing.

## Introduction

Processing contaminants may be defined as substances that are produced in a food when it is cooked or processed, are not present or are present at much lower concentrations in the raw, unprocessed food, and are undesirable either because they have an adverse effect on product quality or because they are potentially harmful (Curtis et al., 2014b). A processing contaminant that is proving particularly difficult for the food industry is acrylamide ( $\text{CH}_2=\text{CH}-\text{CONH}_2$ ). Acrylamide is classed as a probable (Group 2a) human carcinogen by the International Agency for Research on Cancer (1994) based on its action in rodents, and also has reproductive and neurotoxicological effects at high doses (Friedman, 2003). It forms in food as a result of the Maillard reaction; a series of non-enzymic reactions between free (soluble, non-protein) amino acids and reducing sugars, such as glucose, fructose and maltose, that occurs during high-temperature ( $>120^\circ\text{C}$ ) cooking and processing. Acrylamide is produced when the free amino acid that participates in the later stages of the reaction is asparagine (Mottram et al., 2002; Stadler et al., 2002). Fried, baked and roasted potato, cereal and coffee products are the major sources of dietary intake. The issue is not easy to solve because acrylamide forms from naturally-occurring precursors (free asparagine and reducing sugars), and because the Maillard reaction also gives rise to the colors, flavors and aromas that consumers expect of fried, baked and roasted foods, and that define food types and brands. Indeed, acrylamide formation correlates closely with color formation in products such as potato chips and color can be used as a quality control measure. This was the basis of the UK Food Standards Agency's 'Go for Gold' campaign of 2017, which encouraged consumers to cook foods to a light brown color (Food Standards Agency, 2017).

Acrylamide is present in food at levels typically ranging from tens of parts per billion (ppb) ( $\mu\text{g kg}^{-1}$ ) in soft bread to several hundred ppb in biscuits, French fries and potato chips (UK crisps). The concentrations used in rodent toxicology studies may be two to three orders of magnitude higher than that, and the risk posed by dietary exposure is therefore difficult to gauge, requiring extrapolation from the effects of high doses for relatively short periods of time in rodents to lower doses for much longer periods of time in humans. Nevertheless, the European Food Safety Authority (EFSA) Expert Panel on Contaminants in the Food Chain (CONTAM) stated in its 2015 report that the margins of exposure for acrylamide indicate a concern for neoplastic (tumour-inducing) effects (EFSA CONTAM Panel, 2015). This forced the hand of the European Commission with respect to reviewing its regulations on the presence of acrylamide in food. The Commission had already issued 'Indicative Values' for the presence of acrylamide in food in 2011 and revised them downwards for many products in 2013 (European Commission, 2013). These values were not meant to be maximum limits or safety thresholds; rather they were set at levels that the Commission believed should be achievable, based on the results of its monitoring programme (EFSA CONTAM Panel, 2015). If a product is found to exceed the Indicative Value the relevant food safety authority should take action to ensure that the manufacturer addresses the problem. As a result of the CONTAM report, the Commission has drawn up strengthened risk management measures including compulsory Codes of Practice and

**Table 1** Indicative values and benchmark levels for acrylamide in food, set by the European Commission (2013, 2017)

<i>Food</i>	<i>Indicative value 2013 (<math>\mu\text{g kg}^{-1}</math>) (ppb)</i>	<i>Benchmark level 2017 (<math>\mu\text{g kg}^{-1}</math>) (ppb)</i>
French fries	600	500
Potato chips (UK crisps)	1000	750
Soft bread (wheat)	80	50
Soft bread (other)	150	100
Breakfast cereals	400	300
Biscuits	500	350
Crackers	500	400
Crispbread	450	350
Gingerbread	1000	800
Cereal-based baby foods	50	40
Roast coffee	450	400
Instant coffee	900	850

the renaming of Indicative Values as Benchmark Levels, with reduced Benchmark Levels for most products (European Commission, 2017) (Table 1). These regulations could be in force by mid-2018. The proposals also state that the setting of Maximum Levels with regulatory enforcement for acrylamide in certain foods should be considered as soon as the new framework is in place.

### The Need for Agricultural and Crop Management Solutions to the Acrylamide Problem

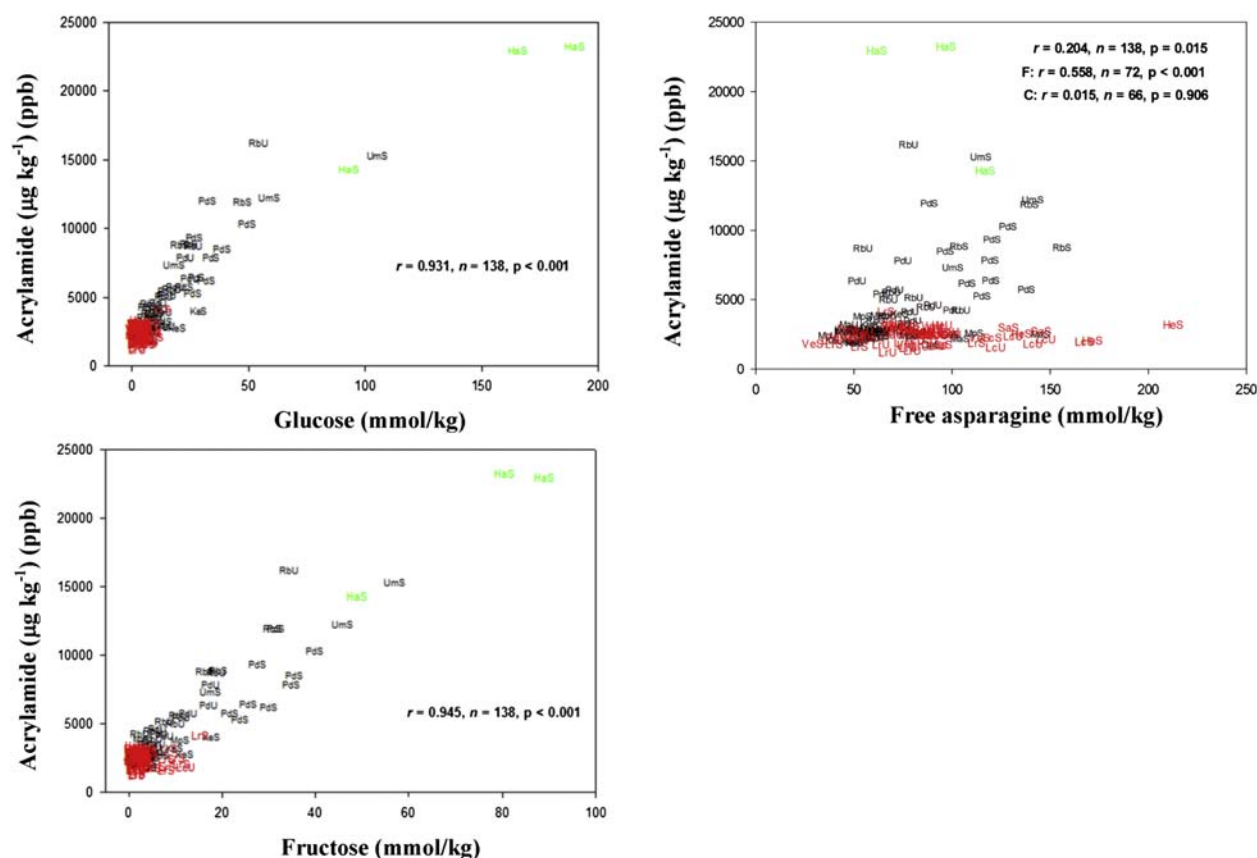

Acrylamide was first discovered in food in 2002 (Tareke et al., 2002). Since then, the food industry has worked hard to reduce the levels of acrylamide in its products, and the methods that have been developed have been compiled in a 'Toolbox' produced by FoodDrinkEurope, the latest update of which was published in 2014 (Food Drink Europe, 2014). The measures that have been implemented for potato chips, for example, include improved control of cooking temperature and duration, monitoring of moisture levels in the finished product, post-frying quality control based on color, switching to very low-sugar potato (*Solanum tuberosum*) varieties, used only within their optimum storage window, and the careful control of storage temperature and conditions. In potato products, the concentration of reducing sugars has more impact on acrylamide formation than free asparagine, although free asparagine concentration does contribute to the variance in some datasets, particularly for French fry as opposed to chipping varieties, due to the generally higher concentrations of reducing sugars in the former (Fig. 1). Manufacturers have therefore also introduced checks on potato reducing sugar concentration at time of harvest, during storage and at the factory gate. Potato tubers contain very little maltose, so glucose and fructose are the predominant reducing sugars.

Analyses of European manufacturers' data on acrylamide in potato chips showed a 53% reduction in mean acrylamide levels from 763 ppb in 2002 to 358 ppb in 2011 (Powers et al., 2013). However, analysis of data up to 2016 showed that since 2011 there has been a levelling off, with the mean level for 2016 being 412 ppb; still a 46% reduction from 2002 but higher than the 2011 figure (Powers et al., 2017). This suggests that the most effective acrylamide reduction measures had been devised and implemented by 2011. Acrylamide levels also showed marked seasonal variability, being highest in the first half of the year when potatoes were being used from storage, and lowest from July to September when potatoes were being harvested (Fig. 2). This was consistent with the results of several studies showing an effect of storage on the concentration of reducing sugars and potential for acrylamide formation in potato (De Wilde et al., 2005; Elmore et al., 2015; Halford et al., 2012b; Muttucumaru et al., 2014). These studies led to advice being issued that potatoes should only be used for chipping, frying and roasting within their recommended storage window (Halford et al., 2012a), and highlighted the challenge faced by the food industry in processing such a variable raw material to give a level of acrylamide in the end-product that consistently complies with Indicative Values or Benchmark Levels. Even with additional processing measures, further substantial reductions may not be achievable without a step change in the acrylamide-forming potential of the raw material.

The study by Powers et al. (2017) also showed a marked geographical variation in acrylamide levels in chips, with the levels in chips produced in the north of Europe (Denmark, Finland, Lithuania, Latvia, Norway and Sweden) considerably higher than the rest of Europe. This, coupled with the seasonality of acrylamide levels, means that if the new European Benchmark level is confirmed at 750 ppb, the 'failure' rate in this region is likely to be > 30% during the first half of the year (Fig. 3). Even in the other regions of Europe, the 'failure' rate will exceed 10% in some months.

Given these findings, and the fact that the potato supply and processing chain must be prepared for medium- and long-term changes in the regulatory framework on acrylamide, there is an urgent need for the breeding of potatoes with much less potential for acrylamide formation than are available now. In other words, potato varieties with much lower concentrations of reducing sugars and/or free asparagine, together with improved stability of sugar concentrations during storage.

**Figure 1** Graphs showing correlations between glucose, fructose and free asparagine concentration and acrylamide formation in potato flour heated to 160 °C for 20 min. Points on the graphs from French fry varieties are denoted by F in black, while those for crisping varieties are denoted by C in red and the boiling variety, Harmony, in green. The results for correlation ( $r$ ) are given for all three types overall and in the case of free asparagine also for French fry and crisping types separately. The points are codes for the varieties Maris Piper (Mp), Pentland Dell (Pd), King Edward (Ke), Daisy (D), Markies (Ma), Russet Burbank (Rb), Umatilla Russet (Ur), (Lady Claire (Lc), Lady Rosetta (Lr), Saturna (Sa), Hermes (He), Verdi (Ve) and Harmony (Ha), followed by un-stored (U) or stored (S). Reproduced from Muttucumaru, N., Powers, S.J., Bridson, A., Elmore, J.S., Mottram, D.S., Halford, N.G., 2014. Evidence for the complex relationship between the concentrations of free amino acids, sugars and acrylamide-forming potential in potato. *Ann. Appl. Biol.* 164, 286–300.

Similar data is not available for cereal products, but there is no reason to believe that the situation is any different, with the need for low acrylamide-forming potential varieties just as urgent. Cereal grains generally have lower concentrations of free asparagine than potato tubers, and higher concentrations of reducing sugars, with maltose being a major reducing sugar in addition to glucose and fructose. The different ratio of free asparagine to reducing sugars means that it is free asparagine rather than reducing sugar concentration that determines acrylamide-forming potential (reviewed by Curtis et al., 2014b) (Fig. 4).

### Genetic and Agronomic Approaches to Reducing the Acrylamide-Forming Potential of Potato

Most potato chip manufacturers favor a light brown chip color, with any intrinsic flavor incidental compared with the strong, artificial flavors that are added to the product. This means that low reducing sugar concentration has been a target for breeders developing potato varieties for that market since long before the acrylamide issue arose. Varieties used for French fry production and home cooking tend to have higher reducing sugar concentrations because consumers expect French fries to have color, and fresh potatoes to develop color and flavor as they fry and roast them. Indeed, most consumers will use color development as an indicator that the potatoes are cooked. However, there is considerable variation between varieties even within the different types, both in their composition at harvest and the stability of their sugar concentrations during storage (Elmore et al., 2015; Halford et al., 2012b; Muttucumaru et al., 2014, 2017). Fig. 5 contrasts the acrylamide levels in chips made from two UK chipping varieties, Lady Claire and Lady Rosetta, and two French fry varieties, Pentland Dell and Markies, through nine months of cold storage after their harvest in October 2011 (Halford et al., 2012b). The first striking aspect of this graph is the range in acrylamide levels, from approximately 100 ppb for lady Claire throughout the storage period to over 2500 ppb for Pentland Dell by the end of the storage period. The varieties also show contrasting responses to storage, with Lady Rosetta comparable with Lady Claire during early storage but already

**Figure 5** Acrylamide formation ( $\mu\text{g kg}^{-1}$ ) (ppb) in chips made from four contrasting potato varieties through nine months of storage at 8.5–9.5 °C. Plotted from data provided by Halford, N.G., Muttucumaru, N., Powers, S.J., Gillatt, P.N., Hartley, L., Elmore, J.S., Mottram, D.S., 2012. Concentrations of free amino acids and sugars in nine potato varieties: effects of storage and relationship with acrylamide formation. *J. Agric. Food Chem.* 60, 12044–12055.

coming out of its optimal storage window by January. Markies on the other hand showed the highly unusual characteristic of decreasing levels of acrylamide formation during late storage.

This and other studies (Amrein et al., 2003, 2004; Becalski et al., 2004; De Wilde et al., 2005; Elmore et al., 2015; Muttucumaru et al., 2014, 2017) showed that the use of appropriate varieties for specific end uses, for example switching to very low-sugar varieties for chip production, was an important strategy for reducing acrylamide formation in potato products. It also led to the advice that potatoes should be stored under carefully-controlled temperature (typically 8.5–9.5 °C) and conditions, and used only within their optimum storage window, which differs between varieties (Halford et al., 2012a). The increases in acrylamide formation in chips made from potatoes that have been stored for a long time arise from increases in reducing sugar concentration, which in turn are caused by cold and senescent sweetening. Cold sweetening occurs at storage temperatures around and just above 4 °C, while senescent sweetening occurs as potato tubers break dormancy. The onset of senescent sweetening defines the end of the optimum storage window for a particular variety. The storage temperature of 8.5–9.5 °C is a compromise because colder temperatures would promote cold sweetening while warmer temperatures would allow the potatoes to sprout. Both cold and senescent

sweetening are associated with vacuolar invertase activity, which converts sucrose to glucose and fructose (Clasen et al., 2016; Zhu et al., 2014; Wiberley-Bradford and Bethke, 2018).

As well as identifying potato varieties with low acrylamide-forming potential, attempts have been made to define optimum crop management regimes. Nitrogen application, for example, can increase acrylamide-forming potential of potatoes but the effect is type-dependent, with French fry varieties showing an increase in response to nitrogen that is not apparent in chipping varieties (Muttucumaru et al., 2013). Even within type, different varieties exhibit different responses, making the situation even more complicated. Sulfur application has no significant effect on its own, although application at 15 kg per hectare does mitigate the effect of high nitrogen application on the acrylamide-forming potential of some varieties.

The effect of water supply has also been investigated, and even mild drought stress (e.g. lack of irrigation in the field in the UK) has been shown to cause significant changes in tuber composition (Muttucumaru et al., 2015). However, these differ from those caused by more extreme drought stress, with free proline accumulating in some varieties under mild drought stress and free asparagine in some varieties under severe drought stress. Notably, in that study, potatoes grown commercially in the UK with irrigation had more acrylamide-forming potential than potatoes grown without irrigation (Muttucumaru et al., 2015), but different genotypes responded differently to the same treatment, indicating that there is no single, unifying potato tuber drought stress response.

The complexity and inconsistency between varieties of these findings mean that no advice has been given on crop management of potato for acrylamide mitigation, except to fertilise with nitrogen and irrigate sufficiently only to ensure the health and yield of the crop, and no more. Given the lack of a crop management strategy, reductions in the acrylamide-forming potential of potatoes will require breeding of new, improved varieties. A key question for breeders is what targets should they aim for: low reducing sugar concentration and sugar stability during storage, or reduced free asparagine concentration, or both. Decreasing the concentration of reducing sugars may seem the obvious target, but chipping varieties in particular have been bred for low sugar concentrations for many years, and the lowest may already be close to the minimum to be 'fryable' to give an acceptable color and texture, as well as flavor and aroma for those products with subtle or no added flavoring. The concentration of reducing sugars affects all products of the Maillard reaction, whereas free asparagine concentration specifically affects acrylamide formation, making the latter arguably the better target. Extensive genetic resources are now available for breeders to enable them to reduce the free asparagine concentration of potatoes. The trait has been shown to segregate in a breeding population and quantitative trait loci have been identified (Shepherd et al., 2010, 2013), while potato genome data is now available (Potato Genome Sequencing Consortium, 2011) and genes encoding asparagine synthetases and other important enzymes can be mapped.

The problem of reducing the acrylamide-forming potential of potatoes also lends itself to biotechnological approaches. Indeed, genetically modified (GM) potato varieties with greatly decreased concentrations of free asparagine and/or reducing sugars, together with improved stability of sugar concentrations during cold storage, have already been developed and marketed in the USA by the Simplot Company of Boise, Idaho. The varieties are called Innate<sup>®</sup> and Innate<sup>®</sup> Generation 2. Both have reduced expression in the tuber of asparagine synthetase gene, *ASN1*, as well as reduced expression of two genes encoding enzymes of starch breakdown (phosphorylase L (*PhL*) and starch-associated R1 (*R1*)), and a gene (*PPO5*) encoding polyphenol oxidase, an enzyme involved in bruising, all as a result of RNA interference (RNAi). Innate<sup>®</sup> Generation 2 also has reduced expression of vacuolar invertase (*VInv*), and increased resistance to late blight through incorporation of a resistance gene from *Solanum venturii*. The low concentration of free asparagine and reducing sugars in the tubers of Innate<sup>®</sup> Generation 2 is claimed to reduce acrylamide-forming potential by 90% compared with conventional potatoes, effectively solving the problem. There is currently no prospect of these or any other genetically modified varieties being grown in Europe, highlighting how far behind crop biotechnology is in the UK and Europe compared with the USA, and how this is beginning to compromise efforts to improve food safety. Nevertheless, the new biotechnological techniques of genome editing are also applicable to acrylamide mitigation and being essentially mutagenesis techniques may escape the restrictive regulations covering GM crops in Europe. Indeed, the *VInv* gene has already been targeted using transcription activator-like effector nucleases (TALENs) (Clasen et al., 2016). Lines with full *VInv* knockouts were produced, and the tubers from these plants had extremely low levels of reducing sugars and were used to make chips with much lower levels of acrylamide than chips produced from control tubers.

## Genetic and Agronomic Approaches to Reducing the Acrylamide-Forming Potential of Cereal Grains

Free asparagine concentration determines the acrylamide-forming potential of cereal grain, and both wheat (*Triticum aestivum*) and rye (*Secale cereale*) show large differences between varieties (Curtis et al., 2009, 2018, 2010; Postles et al., 2013). Fig. 6, for example, shows the free asparagine concentration in the grain of commercial wheat varieties grown in a field trial in the UK in 2012–2013. Free asparagine concentration in wheat grain can vary from location to location and year to year (Curtis et al., 2009), but eight varieties, Claire, Cocoon, Croft, Delphi, Monterey, Horatio, Myriad and Cordiale, have been shown to be consistently low in free asparagine concentration, relative to other varieties, across multiple field trials (Curtis et al., 2018). Of these, Claire, Cocoon, Croft, Delphi and Monterey are all soft, biscuit types (classified as Group 3 in the UK), while Horatio and Myriad are soft Group 4 (used mainly for animal feed and bioethanol production). Only Cordiale is a hard (Group 2) wheat considered appropriate for breadmaking.

**Figure 6** Free asparagine concentration in grain of winter wheat varieties grown in a field trial in the UK in 2012–2013. Reproduced with modification from Curtis, T.Y., Powers, S.J., Wang, R., Halford, N.G., 2018. Effects of variety, year of cultivation and sulphur supply on the accumulation of free asparagine in the grain of commercial wheat varieties. *Food Chem.* 239, 304–313.

Most of the 'low' varieties are therefore soft wheats, but selecting varieties for low free asparagine simply on the basis that they are soft would be simplistic and potentially counter-productive because some soft varieties are high in free asparagine. Note also that the list of 'low' varieties may not be exhaustive because there is insufficient data available for some varieties to make an assessment.

As robust data on free asparagine concentrations becomes available it would be appropriate to include it in variety descriptions. Currently there may still be too much uncertainty for end users to trust variety rankings, partly because free asparagine concentration is very sensitive to environmental and crop management factors. However, excluding varieties in the 'high' group could be a sensible course of action in the short term. Another problem that food producers face is that the turnover in varieties in the UK is so rapid that by the time enough is known about asparagine concentrations the variety may no longer be available. The only solution to this is for testing to be carried out by breeders during variety development, and this is currently not done. Food producers may also find that the availability of low free asparagine, soft wheat varieties is limited: soft, biscuit wheat cultivation in the UK has declined dramatically in recent years, partly because Claire, a stalwart of that market, is susceptible to new strains of rust. Nevertheless, wheat users in the UK are relatively well off compared with producers who are reliant on other grains, or any cereal grain produced outside the UK: while there is some data available on free asparagine concentration in commercial rye varieties grown in the UK (Postles et al., 2013), data for wheat or rye grain in other countries is very limited, and there is no data that I am aware of for other cereals, at least in the public domain.

The fact that lower free asparagine concentrations would reduce the acrylamide-forming potential of cereal grains has reinvigorated interest in the genetic control of asparagine accumulation. Asparagine is of interest anyway, because it is an important nitrogen storage and transport molecule in many plant species, due to its relatively high nitrogen to carbon ratio (2:4, compared with 2:5 for glutamine, 1:5 for glutamic acid and 1:4 for aspartic acid, for example) and its relative chemical inertia (Lea et al., 2007). It accumulates to high concentrations during processes such as seed germination and in response to a range of abiotic and biotic stresses (Lea et al., 2007; Lea and Azevedo, 2007; Halford et al., 2015), including poor disease control (Curtis et al., 2016) (Fig. 7). Indeed, it can become the predominant free amino acid in cereal grains under some stress conditions, an example of how stress can have profound effects on crop composition (Halford et al., 2015).

Free asparagine concentration also correlates positively with nitrogen availability in the grain of barley (*Hordeum vulgare*) (Winkler and Schön, 1980), wheat (Martinek et al., 2009) and rye (Postles et al., 2013, 2016), while deficiencies in other minerals become important when there is a plentiful supply of nitrogen (reviewed by Lea et al., 2007). Sulfur deficiency in particular can cause a massive (up to 30-fold) increase in the accumulation of free asparagine in wheat, barley and maize (*Zea mays*) (Baudet et al., 1986; Curtis et al., 2009, 2014a; Granvogl et al., 2007; Muttucumaru et al., 2006; Shewry et al., 1983) (Fig. 7). Rye responds in similar fashion in response to severe sulfur deficiency in pot experiments (Postles et al., 2016) but is less responsive under field conditions (Postles et al., 2013) (Fig. 7). Consistent with this, asparagine synthetase gene expression in wheat and rye has been shown to increase under sulfur-limited growth conditions (Byrne et al., 2012; Gao et al., 2016; Postles et al., 2016), a response that appears to involve the protein kinase, TaGCN2 (Byrne et al., 2012).

The responses of wheat shown in Fig. 7 mean that the practice of ensuring sulfur sufficiency (an application rate of 20 kg sulfur per hectare is recommended; Curtis et al., 2014a) and effective disease control should be adopted to mitigate the problem of acrylamide formation in wheat products. In addition, late application of nitrogen should be avoided. In particular, if nitrogen is applied when sulfur is limiting it will accumulate as free asparagine, increasing acrylamide risk without achieving the desired result of improving protein quality. These crop management practices have been included in the draft Codes of Practice published by the European Commission (European Commission, 2017). It would also be helpful for regulatory authorities to take the consequences for acrylamide-forming potential into account when considering the risks and benefits of mineral fertiliser and fungicide usage.

A key enzyme in asparagine synthesis is asparagine synthetase, which catalyses the ATP-dependent transfer of the amino group of glutamine to a molecule of aspartate to generate glutamate and asparagine. Wheat has four asparagine synthetase genes, called *TaASN1-4* (Gao et al., 2016). *TaASN4* has not been characterised in any detail. Of the others, the expression of *TaASN2* in the embryo (wholegrain fraction) and endosperm (white flour fraction) during mid to late grain development is the highest of any of the genes in any tissue (Fig. 8). This makes *TaASN2* a logical target for genetic interventions, including genome editing.

**Figure 8** Differential expression of asparagine synthetase genes in different tissues of wheat. Reproduced from Gao, R., Curtis, T.Y., Powers, S.J., Xu, H., Huang, J., Halford, N.G., 2016. Food safety: structure and expression of the asparagine synthetase gene family of wheat. *J. Cereal Sci.* 68, 122–131.

## Concluding Remarks

Genetic and agronomic approaches to solving the acrylamide problem could eventually lead to massive savings for the food industry, dwarfing the cost of the research involved. Step reductions in the acrylamide-forming potential of potatoes have already been achieved using GM techniques, and may also be possible in all the affected crops using other modern breeding methods, such as mutagenesis and genome editing, effectively solving the problem. Success in this area will ensure that consumers continue to enjoy the variety and health benefits of potato and cereal products while food safety is improved. It could also ensure the continued use of grains that are known for their health benefits but which currently have a relatively high acrylamide-forming potential, such as wheat, barley and rye. These are also the major grains produced in northern and western Europe and other temperate regions.

## Introduction

Fatty acid esters of 3-monochloropropanediol (3-MCPD), 2-monochloropropanediol (2-MCPD), and glycidol are toxicologically relevant contaminants produced during the deodorization of edible oils. They are not found in virgin, unrefined oils, and are generated during the high temperatures (>200 °C) applied during deodorization (Svejkovska et al., 2006; Destailats et al., 2012a, 2012b; Shimizu et al., 2012; Freudenstein et al., 2013; Ermacora and Hrnčířík, 2014a). While there are still questions regarding their specific mechanism of formation, there is evidence that 3-MCPD esters are formed from organochlorines naturally present in palm oil prior to processing (Nagy et al., 2011). In addition, while they do form in all edible oils during deodorization, they tend to form at the highest concentrations in palm oil (Kuhlmann, 2011; MacMahon et al., 2013c).

Fatty acid esters of glycidol, 3-MCPD, and 2-MCPD all pose potential food safety concerns. The risk is not from the fatty acid esters themselves, but from the free forms of glycidol, 3-MCPD, and 2-MCPD, which are produced when the esters are hydrolysed during digestion. Glycidol is classified by the IARC as a "likely human carcinogen" and some authors have suggested it should be kept at concentrations as low as is reasonably achievable in food (WHO, 2000; EFSA, 2016). Free 3-MCPD has been shown to be carcinogenic in rats, and the Joint Food and Agriculture Organization/World Health Organization Expert Committee on Food Additives recommended a maximum tolerable daily intake for 3-MCPD from its esters of 4 µg/kg body weight per day (FAO, 2016). While 2-MCPD is not nearly as well studied from a toxicological perspective, it has been shown to have heart and muscle affects (Schilter et al., 2011; Andres et al., 2013). While these risks are associated with the free versions of these compounds, animal studies have shown that free 3-MCPD is produced from 3-MCPD esters during digestion with 86% efficiency (Abraham et al., 2013), with the digestion efficiency of glycidyl esters even higher (Appel et al., 2013). As the risk from these contaminants is from the free compounds, and not the intact esters, results are often reported as "bound MCPD" and "bound glycidol." This refers to the total concentration of MCPD or glycidol that would be released if all the fatty acid esters present in a sample were quantitatively hydrolysed.

While the potential toxicological risk is from the free compounds produced during digestion, the fact that the compounds exist in oils as fatty acid esters significantly complicates their analysis. Vegetable oils consist primarily of 5 fatty acids, palmitic acid, linolenic acid, linoleic acid, oleic acid, and stearic acid. Palm kernel and coconut oil also contain significant quantities of lauric acid and myristic acid. Those 7 fatty acids occurring in combination in an edible oil produce a possibility of 7 different glycidyl esters. The situation is far more complicated in MCPD esters, as they have 2 –OH groups that can form fatty acid esters. There are 7 possible 2-MCPD mono-esters and 14 possible 3-MCPD mono-esters (because in 3-MCPD esters, the two –OH groups are not equivalent). In addition, there are 28 possible di-esters for 2-MCPD and 3-MCPD (Dubois et al., 2012). As a result, analytical methods cannot simply target 3 contaminants, but theoretically must target 84 different compounds to ensure the detection of all possible fatty acid combinations.

To address the complexity of detecting so many target compounds, some researchers employ so-called “indirect” methodology. Instead of targeting the intact fatty acid esters, the methods use a hydrolysis step to release free 3-MCPD, 2-MCPD and glycidol. In general, this is followed by a derivatization step and analysis by gas chromatography-mass spectrometry (GC–MS). Early methods developed to target these contaminants exclusively utilized this approach, and were critical in bringing attention to the presence of MCPD and glycidyl esters in oils (Weißhaar, 2008). However, the most widely used method at the time was later shown to produce inaccurate results (Haines et al., 2011; Hrnčič et al., 2011; Kaze et al., 2011). Partially in response to this issue, direct methods were developed that were capable of detecting the intact fatty acid esters without the need for hydrolysis.

The accuracy of indirect methodology has improved, and now there are several which have been collaboratively studied (AOCS official method Cd 29a-13, 2017; AOCS official method Cd 29b-13, 2017; AOCS official method Cd 29c-13, 2017). Indirect approaches present many advantages. The methods release and target the free compounds, which are the source of risk from a food safety perspective. Because only the 3 compounds are targeted, only 3 analytical standards (potentially along with 3 internal standards) are required. The indirect methods utilize GC–MS, which are generally readily available and easy to operate, where direct methods require liquid chromatography-mass spectrometry (LC-MS). However, unlike direct methods which do not involve any conversion of the target analytes, indirect methods present the possibility of the formation of artefacts. In addition, information about the esters as they occur in oils and foods is lost. As some studies have indicated potential differences in the toxicology of MCPD mono- and di-esters, that information could be useful in assessing potential risk (Buhrke et al., 2011). In addition, measuring the fatty acid esters directly can be useful in determining the impact of industrial efforts to mitigate the formation of these esters during deodorization, as it may be more straightforward to reduce the formation of glycidyl and MCPD mono-esters relative to MCPD di-esters (MacMahon et al., 2013c). In addition, as these methods are extended to complex foods, which incorporate an extraction component, the direct methods are able to demonstrate extraction performance across all the fatty acid esters, which significantly differ from one another in polarity.

This chapter will review the various indirect and direct methods that have been published for the detection of MCPD and glycidyl esters in oils and foods. Their relative strengths and weaknesses will also be discussed, as appropriate. The methods will be presented chronologically, with an emphasis on methods that represented major advances in the field and are still widely used.

## Discussion

Analytical methods that were first proposed for the detection of MCPD and glycidyl esters used an indirect approach (see Fig. 1). By hydrolysing the wide variety of fatty acid esters, releasing free 2-MCPD, 3-MCPD, and glycidol, the analysis is greatly simplified, essentially only requiring 3 standards. While the methods first proposed were critical for bringing attention to this issue, one of the most widely used early methods (Weißhaar, 2008) was later shown to provide inaccurate results (Hrnčič et al., 2011; Kaze et al., 2011). The sodium chloride used in the procedure reacts with non-MCPD compounds in the oil to produce MCPD, leading to artificially high detected concentrations (Haines et al., 2011).

It was a direct method developed by researchers at Archer Daniels Midland (ADM) (Haines et al., 2011) that provided perhaps the most compelling evidence of the issues with early indirect methodology. The ADM method requires no sample clean-up; a droplet of oil is weighed, combined with internal standard, and analysed by high-performance liquid chromatography with time of flight mass spectrometry (LC-TOF-MS). The method uses low concentrations of sodium acetate in the mobile phase and employs electrospray ionization (ESI) to monitor the sodium adducts of the MCPD mono- and di-esters of palmitic, linolenic, linoleic, oleic and stearic acids. Interferences are minimized by taking advantage of the high resolution of the TOF-MS system. The method also detects glycidyl esters of palmitic, linolenic, linoleic, oleic, and stearic acids (see Fig. 2).

Comparisons between the ADM approach and the indirect methods of the time helped lead to the development of accurate indirect methods for the detection of MCPD and glycidyl esters. However, the use of non-volatile salts requires extensive cleaning of the TOF-MS system and replacement of the ESI needle on a weekly basis. In addition, the chromatographic conditions do not

separate 3-MCPD esters from isomeric 2-MCPD esters. As they both have identical precursor ion masses, it is impossible to accurately quantify 2-MCPD esters and 3-MCPD esters without separating them chromatographically.

As mentioned previously, the ADM method did help lead to the development of greatly improved indirect approaches. One such approach, the SGS 3-in-1 method (Kuhlmann, 2011), utilizes a low temperature (below  $-22^{\circ}\text{C}$ ) base-catalyzed hydrolysis to indirectly detect fatty acid esters of 3-MCPD, 2-MCPD and glycidol (See Fig. 1). These conditions avoid the undesirable conversions resulting from previous indirect methodologies. The hydrolysis is followed by reaction with a derivatizing agent, phenyl boronic acid (PBA), to produce an analyte volatile enough for analysis by GC-MS. PBA reacts with both 2-MCPD and 3-MCPD, producing derivatives that can be separated by GC and analysed independently. The analysis of glycidol is accomplished by its conversion to 3-monobromopropanediol (3-MBPD), and the application of a matrix dependent correction factor to account for the partial formation of 2- and 3-MCPD from glycidol during the alkaline transesterification.

This method produces accurate results, has been collaboratively studied, and is an official method of the American Oil Chemists' Society (AOCS Cd 29-13b) and the German Center for Fat Analysis (DGF). The ability to detect 2-MCPD, 3-MCPD and glycidyl esters in a single analysis is a major advantage, although a second injection of the oil sample is needed to determine the matrix dependent correction factor for glycidol. One challenge is the maintenance of the low temperatures applied during hydrolysis

( $-22^{\circ}\text{C}$ ), which are critical for minimizing undesirable side reactions. In addition, the hydrolysis requires 16 hours, so the analysis cannot be completed in a single day.

Researchers at Unilever proposed an acid-catalyzed transesterification which produced no degradation of either 3-MCPD (Hrnčirík et al., 2011) or 2-MCPD (Ermacora and Hrnčirík, 2012), allowing for simultaneous analysis of both isomers (see Fig. 1). While acid catalysis does create the possibility of side reactions with chlorides, the authors eliminated this possibility by including a liquid-liquid extraction step (Ermacora and Hrnčirík, 2012) to remove chloride ions. The acid hydrolysis process does lead to the conversion of glycidol to a glycerol ether (Hrnčirík et al., 2011). While this ensures glycidol will not interfere with the analysis of MCPD esters, it would seem to eliminate the possibility of a method which can simultaneously detect 2-MCPD, 3-MCPD and glycidyl esters, as glycerol ethers are also produced from the hydrolysis of triglycerides. To allow for the analysis of glycidyl esters, prior to acid hydrolysis, the sample is reacted with sodium bromide under mildly acidic conditions. This converts the glycidyl esters to 3-monobromopropanediol (3-MBPD) mono-esters. As 3-MBPD esters are chemically similar to MCPD esters, they can all be transesterified, derivatized, and analysed by GC-MS simultaneously. The formation of 3-MBPD from glycidol was employed by Kuhlmann, as well, but by reacting glycidol with sodium bromide after the alkaline hydrolysis step was complete.

Beyond the use of a small number of standards and relatively simple analytical equipment, characteristics of all indirect methods, the Unilever approach offers a number of unique advantages. By producing 3-MBPD mono-esters from glycidyl esters prior to hydrolysis, the sensitivity of the method to detect bound glycidol is increased. The approach also allows for the analysis of 2-MCPD, 3-MCPD, and glycidyl esters in a single quantitative analysis. Most other indirect approaches require two separate analyses, either to account for conversions that take place during alkaline hydrolysis or to determine the concentrations of glycidyl esters via the difference between two assays. And while the method employs a 16 hour hydrolysis, it is conducted at  $40^{\circ}\text{C}$ , an easier temperature to maintain than the  $-22^{\circ}\text{C}$  required by the SGS 3-in-1 method. The method has also been successfully collaboratively studied and is an official method of the American Oil Chemists' Society (AOCS Official Method Cd 29a-13, 2017).

Due to the lengthy hydrolysis times required in indirect methods, combined with the resulting loss of structural information of the esters as they occur in oils, there have been continued efforts in the development of direct methods. The Nestlé Research Center has extensively researched MCPD and glycidyl esters, including formation mechanisms, mitigation strategies, analytical methods, and toxicology. One major contribution was the demonstration that only 10 3-MCPD di-ester analytical standards (shown in bold in Fig. 2) are required to target more than 90% of the bound 3-MCPD in the di-ester form in most commonly consumed vegetable oils (the only exceptions are palm kernel and coconut) (Dubois et al., 2012).

Nestlé's approach for the direct analysis of MCPD and glycidyl esters incorporates a solid-phase extraction (SPE) clean-up to remove more polar material from the oil matrix prior to analysis using ESI LC-TOF-MS (Dubois et al., 2012). While this greatly improved ruggedness compared to the ADM approach, the researchers also acknowledged that the method's inability to separate isomeric 2-MCPD and 3-MCPD esters impacts the accuracy of the quantitation, with the method only capable of roughly estimating the combined concentrations of the two analytes. As the two compounds have different toxicological properties, they need to be accurately quantified separately for risk assessment purposes. In addition, Nestlé researchers demonstrated that they have vastly different ionization efficiencies using ESI, so even accurately estimating the combined concentrations of the analytes in a single chromatographic peak is impossible. The method also targets glycidyl esters, but does so with recoveries ranging from 44%–87%. Accurate analysis of glycidyl esters required the use of a gel permeation chromatography (GPC) extraction procedure, followed by additional clean-up by SPE and LC-MS analysis (Dubois et al., 2012). While this did increase the effort required to analyze an individual oil sample, this approach improved recoveries for glycidyl esters to 68%–111%.

Researchers at the U.S. Food and Drug Administration published the most extensive direct method, using a two-step SPE clean-up and liquid chromatography-tandem mass spectrometry (LC-MS/MS) using ESI to target the 2-MCPD, 3-MCPD, and glycidyl esters containing lauric, myristic, palmitic, linolenic, linoleic, oleic and stearic acid (see Fig. 3) (MacMahon et al., 2013a, 2013b, 2014). This method was the first direct method to chromatographically separate isomeric MCPD mono- and di-esters, allowing it to provide accurate quantitation for both sets of analytes. As they constitute 90+% of vegetable oil matrices, removal of triglycerides is critical for accurate and reproducible LC-MS method performance. As triglycerides fall between glycidyl esters/MCPD mono-esters and MCPD di-esters in polarity, two separate SPE clean-ups to purify those two groups of target analytes were required.

This approach offers a number of advantages. At the time of publication, all other direct methods analysed isomeric 2-MCPD and 3-MCPD esters as a single chromatographic peak, making accurate quantitation impossible. The two-step SPE clean-ups ensure reliable instrument performance even after hundreds of injections. While the clean-up does take several hours to complete, it is much faster than the hydrolysis step required for indirect methods, and allows the complete analysis of oil samples within a single working day. The method employs several isotopically-labelled internal standards, avoiding the need for time consuming and laborious standard addition quantitation. It was used in a survey of 116 vegetable oil samples purchased in the United States (MacMahon et al., 2013c). However, compared to indirect methods, the requirement of a high-end LC-MS/MS system is costly in terms of purchasing the equipment and requires a high level of expertise to operate. The cost for the large number of standards required is also significant. The method also requires two separate two-step SPE clean-ups, as well as two injections, for the analysis of all MCPD and glycidyl esters in a given sample. In addition, while they have identical ionization efficiencies using ESI, the method cannot chromatographically separate isomeric sn-2 3-MCPD esters from 2-MCPD mono-esters; only the sum of the two can be accurately quantified.

Figure 3 (continued).

Expanding methods to target MCPD and glycidyl esters in foods presents a new challenge. The analysis of oils involves dissolving the entire sample in a non-polar solvent prior to analysis; there is no need for an extraction step. This is not the case with complex foods, where the contaminants are found in a matrix environment made up not only of fat, but polar elements such as proteins, sugars, water, and other natural components of a given food. An extraction procedure must be used that is stringent enough to quantitatively extract all of the MCPD and glycidyl esters, but is still mild enough to ensure that no structural conversions take place. Many traditional methods of fat extraction from foods involve harsh procedures, such as the use of hydrochloric acid or ammonia, which would be likely to cause conversion or destruction of the target analytes. Complex foods also may contain interferences not found in oils, potentially requiring adjustments to established clean-up or quantitation procedures.

Another critical point relates to the demonstration of accuracy for detecting these contaminants in a complex food. In oils, spiking MCPD and glycidyl esters represents a reasonable approach to demonstrate method accuracy, as the analytes will readily disperse homogeneously throughout the sample. For complex foods, this is not the case, and it is nearly certain that a MCPD/glycidyl ester spike applied to the surface of a food matrix will be more easily extracted than if the esters were contained in the vegetable oil ingredient and brought through the entire production process. The current lack of available food reference materials with known concentrations of MCPD and glycidyl esters further complicates matters, as method authors must find another approach beyond simple spiking to properly demonstrate the method's accuracy.

Unilever researchers published the first validated approach for the detection of MCPD and glycidyl esters in oil-based food products, specifically targeting fat-based spreads, creams, margarine, and mayonnaise (Ermacor and Hrnčirik, 2014b). While these products contain a high percentage of fat, extending the analytical methodology to these matrices proved quite challenging. A number of different solvent systems were compared, with the addition of water and 1:2 heptane: methyl *tert*-butyl ether providing the highest extraction yields. Extraction solvent volumes also required extensive optimization, with a 2:3 (v/v) ratio of organic to aqueous extraction solvent producing 30%–40% higher yields than a 2:1 (v/v) ratio. A number of temperatures were also examined, with 60 °C sufficient to enhance the break-up of emulsions without leading to the formation or decomposition of target analytes.

As discussed previously, the lack of available reference materials or existing reference methods makes conducting a proper validation challenging. The authors took advantage of an industrial production facility by producing pilot scale (100 kg batch per production) samples incurred with known amounts of MCPD and glycidyl esters. The authors produced 13 formulations with different levels of fats, compositions, and ester concentration.

The method represents the first thoroughly validated method for the detection of MCPD and glycidyl esters in complex food products. The use of pilot scale production of reference materials ensured the extraction was applicable to actual samples. And the method targets highly consumed, high fat products that have the potential to be significant sources of exposure to MCPD and glycidyl esters. It was successfully collaboratively studied, and is an official method of the American Oil Chemists' Society (AOCS Official Method Cd 30-15). That said, it does target a fairly narrow group of foods, as all these products are oil-in-water

or water-in-oil emulsions. While it's possible the method would be applicable to other food matrices, the extraction yields were lower in products containing milk proteins, with recoveries improved by the addition of a small amount of isopropanol to the aqueous extraction solvent. The authors specifically state that methods to target MCPD and glycidyl esters in food products should be dedicated and validated for specific food types.

U.S. Food and Drug Administration research focused on the development of a direct method to detect MCPD and glycidyl esters in infant formula (Leigh and MacMahon, 2016). Due to infants' low body weights and formula commonly being used as the sole source of infant nutrition, there is a need for methodology to detect MCPD and glycidyl esters in formula to determine infant exposure and to assess risk. Extraction methods for infant formula pose a particular challenge given the complexity of the matrix, consisting of dried, thoroughly homogenized fats, carbohydrates and proteins.

Attempts to use the extraction system developed by Unilever to extract oil-based products were unsuccessful, as emulsions formed with the formula samples that led to very low extraction yields. A number of extraction solvent systems were employed, and while nearly all worked for soy-based formula, very few provided high fat extraction yields in milk-based formula. More polar organic solvents proved more effective at extracting the fat from milk-based formula samples. This is likely due to the relatively hydrophobic character of milk proteins, with the more polar solvent minimizing the interactions between the extraction solvent and the proteins, allowing for a more distinct separation between aqueous and organic layers. While 1-butanol produced the highest extraction yields of all the solvents tested, it is not very volatile and took hours to evaporate. Therefore, ethyl acetate was selected as the optimal practical extraction system. The incorporation of a high-speed centrifugation (14,500 g) and the addition of sodium sulfate led to acceptable fat recoveries (>90%) and reproducibilities.

While the extraction was effective at removing the fat from all types of infant formula, it was critical to confirm that the ethyl acetate was also effective at recovering the entire range of MCPD and glycidyl esters. As their polarities vary, with MCPD di-esters less polar than triglycerides and MCPD mono-esters and glycidyl esters significantly more polar, it's conceivable that the extraction system could be biased towards extracting one group or the other. As discussed previously, spiking is not suitable to demonstrate extraction efficiencies in complex foods, so the authors produced an in-house infant formula reference material using ingredients typically found in formula. A combination of oils with known concentrations of MCPD and glycidyl esters were used to produce a liquid infant formula, which was then freeze dried. The final product was visually indistinguishable from commercial formula and, since it was milk-based, would present a challenging matrix to measure extraction yields. Recoveries ranged from 82%–109% for the entire range of 3-MCPD and glycidyl esters that occur in vegetable oils, helping confirm the method was effective for the analysis of infant formula.

The FDA method involves a simple, liquid–liquid extraction procedure that did not involve the use of complex instrumentation or expensive equipment. In addition, method performance was confirmed beyond simple spiked samples by analyzing the recoveries of the intact esters in a homemade reference material. Based on ester recovery data from this reference material, as well as validation data obtained from a variety of spiked commercial infant formula samples, the performance of the extraction procedure is rugged and reliable, yielding highly reproducible results. Using the previously published LC-MS/MS methodology for detection and quantitation, this procedure is suitable for producing MCPD and glycidyl ester occurrence data in all varieties of commercially available infant formulas, and was used in the most extensive survey of infant formula to date (Leigh and MacMahon, 2017). In addition, it's the only extraction method in food that has demonstrated accurate recoveries across all the individual 3-MCPD and glycidyl esters that commonly occur in vegetable oils. The method has since been extended to a wide range of complex foods (Leigh et al., 2017).

Researchers at the Joint Research Center also have published a method for the analysis of bakery and potato products, smoked/fried fish and meat, and cereal products (Zelinkova et al., 2017). The authors employed a pressurized extraction with methyl *tert*-butyl ether as the solvent. The fat extract was then analysed using the Unilever method (AOCS standard Cd29-13a). The authors took care to ensure that this indirect method was applicable to the fat extracts from complex foods. However, while method performance was highly reproducible, there were no reference materials included in the study to ensure the method's accuracy. The method is also not applicable to infant formula (Wenzl et al., 2015), a significant drawback given the importance of monitoring MCPD and glycidyl ester concentrations in formula to determine infant exposure and to assess potential risk. This is consistent with observations from FDA researchers who identified infant formula as the most analytically challenging food matrix they encountered.

While great progress has been made on the analysis of MCPD and glycidyl esters in oils over the past few years, with a number of methods producing comparable and accurate results, the analysis of complex foods is still developing. The challenges of extracting the wide variety of fat-containing foods combined with the lack of commercial reference materials slows the progress of development. However, there are a number of published methods which have recently been validated in complex foods. Moving forward, comparing their performance to one another and to standard reference materials is necessary to ensure accurate data is being produced for exposure and risk assessment purposes.

MAG monoacylglycerols  
NH<sub>4</sub>Cl Ammonium Chloride  
PMTDI provisional maximum tolerable daily intake  
T25 dose dose at which is observed a 25% increase in incidence of a tumour above background incidence in the lifespan of the species  
TAG triacylglycerols  
TDI tolerable daily intake  
TRV toxicological reference value  
NTP United States National Toxicology Program

## Background

3-monochloropropane-1,2-diol and glycidol and their esters (so called 3-MCPD(E) and G(E) in the text) are processing -induced contaminants primarily found in refined fats and oils, and foods containing fats and oils.

These compounds have been previously evaluated by JECFA (1993, 2002, 2007, 2017) and EFSA (2013, 2016, 2018).

For free 3-MCPD, the European Commission Regulation (EC) No 1881/2006 has set maximum levels of 3-MCPD of 0.02 mg/kg for hydrolysed vegetable protein and soy sauce (European Commission, 2006). Provisions for methods of sampling and analysis for the official control of 3-MCPD were laid down in Commission Regulation (EC) No 333/2007 (European Commission, 2007). Recently, the European Commission has set limits of GE in vegetable oils and fats, in vegetable oils and fats intended for baby foods and process cereals intended for infants and young children, infant formula, follow-on formula and foods for special medical purposes intended for infants and young children (European Commission, 2018).

## Safety Assessment of 3-MCPD(E) and G(E)

Both 3-MCPD(E) and G(E) are efficiently absorbed following ingestion, the esters being efficiently hydrolyzed into 3-MCPD and glycidol in the digestive tract. Their metabolism has been reviewed in depth by EFSA and JECFA (as cited above).

GE was shown to be genotoxic. Toxicity studies on glycidol showed a low acute toxicity, renal toxicity, temporary/reversible infertility, immunotoxicity and neurotoxicity. In oral long-term studies in mice and rats, glycidol induced tumours in various tissues in both sexes. The Lowest Adverse effect Level was set at 17.9 and 26.8 mg/kg b.w. per day for mice and rats, respectively.

The United States National Toxicology Program (NTP, 1990, 2007) concluded that there was “clear evidence for carcinogenic activity”. The International Agency for Research on Cancer (IARC, 2000) classified glycidol as probably carcinogenic to humans (Group 2A).

Both JECFA and EFSA considered the carcinogenesis as the pivotal effect for risk assessment. JECFA calculated as toxicological reference value (VTR), a benchmark dose for a 10% response (BMDL10) of 2.4 mg/kg bw per day.

EFSA considered that a BMDL10 cannot be derived because of inadequacy of the data for modelling, and set a T25 dose (25% increase in incidence of a specific tumour above background incidence in the lifespan of the species) of 10.2 mg/kg b.w. per day.

3-MCPD(E) was found positive for genotoxicity *in vitro* but not *in vivo*. Short term studies on 3-MCPD showed lethal effects due to acute kidney failure. Two-year long oral toxicity studies at non-lethal doses demonstrated dose-related effects on kidney in rats (Sunahara et al., 1993; Cho et al., 2008a) but not in mice (Jeong et al., 2010; Cho et al., 2008b). Effects occurring at the highest dose were shown on hematology, urine analyses, liver functions, male infertility and neurotoxicity.

Both EFSA and JECFA concluded that the main target organs in rodents are kidneys and male reproductive organs, renal tubular hyperplasia being the most sensitive effect that might also lead to cancer by a non-genotoxic mode of action. JECFA derived a PMTDI of 4 µg/kg bw per day and EFSA set a TDI of 2.0 µg/kg bw per day.

Using different dataset and food consumption surveys, EFSA and JECFA found comparable dietary intakes for 3-MCPD(E) and G(E). For all class of age except infants, G(E) intakes ranged from 0.1 to 2.1 µg/kg bw per day and 3-MCPD(E) dietary intakes were comprised between 0.2 and 3.8 µg/kg bw per day.

Results on infants exclusively consuming infant formula showed similar estimates for glycidol (up to 4.9 µg/kg bw per day). But on 3-MCPD some discrepancies appear: JECFA found dietary intakes up to 25 µg/kg bw per day when the maximum level for EFSA was only 3.2 µg/kg bw per day.

Risks were characterized using the Margin of Exposure (MoE) approach by both JECFA and EFSA. MoEs were calculated by dividing toxicological reference values by exposure levels.

Even considering different toxicological reference values and different ways of dietary intake estimation, both committees reached similar conclusions for G(E). MoEs were too little mainly for high consumers and particularly for infants receiving formula only. EFSA and JECFA then concluded on a health concern linked to G(E) dietary exposures.

Concerning 3-MCPD(E), both EFSA and JECFA concluded on the absence of safety concern for most classes of age including high consumers. However, they expressed some concerns on infants, with some emphasis on infants fed only on formulas, as the PMTDI is exceeded in some countries (JECFA, 2017) and as a slight exceedance of the TDI was observed by the EFSA (2018).

EFSA and JECFA agreed that the dataset of levels of G(E) and 3-MCPD(E) in foods have to be completed to refine the dietary exposure calculations, since food categories such as ice-cream and chocolate were not included in the previous exposure assessment due to limited amount of data. They also pointed out that recent analyses have to be considered because of analytical method improvements and because of current industrial efforts to mitigate these compounds. These analytical efforts need to quantify separately free and esters chemical forms.

Concurrently, additional toxicological testing is also requested to complete the hazard profile (i.e. reprotoxicity on 3-MCPD(E); metabolism and carcinogenicity of G(E)).

Both EFSA and JECFA also evaluated available information on 2-monochloropropane-1,2-diol and its esters (2-MCPD(E)). But, even exposure were estimated by the EFSA, the limited toxicological information available did not allow to undertake a risk characterization (EFSA, 2016; JECFA, 2017). However, mitigation of 3-MCPD(E) as described in the following chapters will have similar effects on 2-MCPD(E) and other chloropropanols.

## Strategies to Mitigate Monochloropropane-1,2-Diol and Glycidyl Esters in Refined Edible Fats and Oils

### Introduction

Following a decade of research, it has become clear that the formation of monochloropropane-1,2-diol and glycidyl esters (MCPDE and GE) during edible oil refining is strongly dependent on the quality of the oil at each point in the supply chain. This implies that reduction of these process contaminants can be achieved in several ways at various steps in the supply chain. The applied measures can enhance each other when implemented properly. Focus could be on the removal of the reaction precursors, adapting the reaction conditions and the removal of the reaction products. These strategies are more or less aligned with the oil supply chain, differentiating between crude oil production, refining process, and post-treatment steps.

During the last decade, industry has been actively working on mitigation tools, the results of which have been summarized before in guidance documents (FEDIOL, 2015; BLL, 2016). Also the Codex Alimentarius initiated efforts to develop a Code of Practice (Codex Alimentarius, 2018).

### Proposed Mechanism of 3-MCPDE and GE Formation

Since their discovery, the potential mechanism of 3-MCPDE and GE formation has been studied and reviewed in the literature (Hamlet et al., 2011; Rahn and Yaylayan, 2011; Cheng et al., 2017).

As shown in Fig. 1, formation of 3-MCPDE involves predominantly triacylglycerols (TAG) and a chlorine donor. Destailats et al. (2012a) proposed two formation pathways of MCPD diesters in palm oil. In general, organochlorines in crude and semi refined oils react via thermal decomposition at deodorization temperature, resulting in the release of hydrogen-chloride (HCl). This HCl initiates reaction with acylglycerols, resulting in generation of MCPD diesters and elimination of free fatty acids. The first pathway to

**Figure 1** Proposed mechanisms for the formation of 3-MCPDE at high temperatures ( $T > 200\text{ }^{\circ}\text{C}$ ) in the presence of HCl evolved from the thermal decomposition of trace amounts of organochlorines (Destailats et al., 2012a).

form 3MCPDE involves the formation of a reactive cyclic acyloxonium ion intermediate. The other route is a direct nucleophilic substitution reaction of a chloride ion on the open acyloxonium ion.

As shown in Fig. 2, the precursors of GE formation were identified as diacylglycerols (DAG) (Destailats et al., 2012b). Also monoacylglycerols (MAG) have been proposed as potential precursors for the GE formation (Cheng et al., 2017). The mechanisms described, include intramolecular rearrangement through charge migration and differ from each other in the nature of intermediate (acyloxonium ion or oxonium ion) and the leaving group (free fatty acid or water).

**Figure 2** Proposed mechanisms for the formation of glycidyl ester (GE) from diacylglycerol at high temperatures (Destailats et al., 2012b).

## Refining Principles

Refining is done to obtain stable, clear oils with neutral taste, neutral odor and to improve the shelf-life. It is also imperative that potential contaminants, if present in the crude oil, are efficiently removed. Although - concerning the refining process - 3-MCPDE and GE are formed only during deodorization, the prior steps greatly influence the formation capacity. Various process versions are available to choose for different oil types and qualities. In general, two basic processes are applied, in which the main difference is the way the free fatty acids are removed from the oil (Fig. 3).

In chemical refining, free fatty acids (FFA) are removed by saponification with sodium hydroxide in the neutralization step. In contrast, in physical refining process (Kővári et al., 2000; Stage, 1985) free fatty acids (FFA) are evaporated in the deodorization stage, together with other volatile substances.

In chemical refining the basic process stages are neutralization, washing, bleaching and deodorization (Anderson, 2005; van Duijn and den Dekker, 2013; Gupta, 2017). As process variants, degumming can be applied prior to neutralization, while dry washing (absorption on silica or cellulose) can replace the water washing step. For wax containing oils like sunflower, dewaxing or winterization steps are included in the refining process.

The main steps of physical refining are degumming, bleaching and the so-called deodorization, or the stripping of free fatty acids (Hamm, 2013; van Duijn and den Dekker, 2013). Different degumming and washing techniques as well as dewaxing or winterization can be added to the total process.

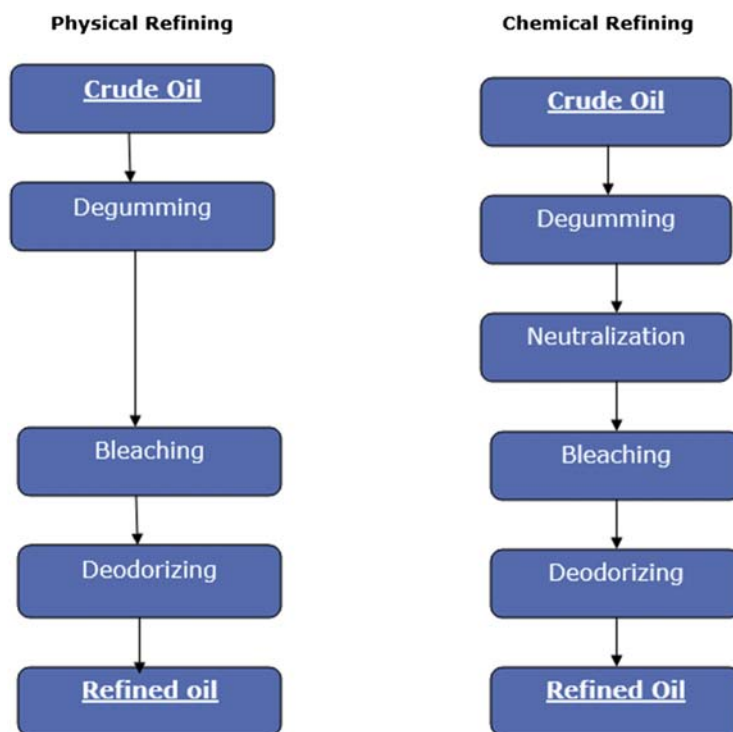

Crude oil with a phosphor content 10–20 mg/kg (like palm oil) can be degummed by the so-called dry-degumming process. Acids (e.g. phosphoric acid) are applied to facilitate hydration of the phosphatides and removal in the bleaching step. The phosphatides are actually removed together with the spent bleaching earth during filtration (Hamm, 2013; Gupta, 2017).

Crude oils with high phosphor content (200–800 mg/kg, like seed oils) require a wet degumming step, which includes again hydration of phosphatides, followed by separation of the formed gums by centrifugation. The wet processes can comprise simple water degumming or acid degumming (enhanced phosphor removal assisted by citric- or phosphoric acid) or enzymatic degumming.

## Reduction of Precursors in Crude Oils

Since the formation of MCPDE and GE depends on the various precursors to form this compounds, effective measures would target the removal of this precursors.

It has been shown that the precursors for MCPDE formation can be derived from a wide range of organochlorine components or inorganic chloride compounds, present in the oil. The chlorine seems to originate from fertilizers, e.g. KCl and NH<sub>4</sub>Cl, and chloride-containing pesticides used in palm oil cultivation or FeCl<sub>3</sub> used as flocculant in waste water treatment (Destailats et al., 2012a; Craft

**Figure 3** Simplified scheme of a vegetable oil refining processes (FEDIOL, 2015).

et al., 2012a). Upon heating the oil during the final processing step of deodorization, the chlorine is released through decomposition yielding Cl<sup>-</sup> ion. This in turn will react with the oil itself, i.e. the tri-, diglycerides to form 2- and 3-MCPDE (Destailats et al., 2012a). Monoglyceride levels in oil are generally very low, typically 0.3% (Goh and Timms, 1985), hence their contribution to MCPDE formation is very low (Destailats et al., 2012b). As the type and amount of pesticides and fertilizer applied will vary for each crop, it can be well conceived that there will be differences in the MCPDE forming potential between different oils, even though the underlying chemistry is the same.

The knowledge on the behavior of organochlorine precursors, even though they have only partially been identified, has led to potentially important approach for MCPDE mitigation. It has been shown that removal of the chlorine precursors by washing can improve the quality of the crude oil, in terms of a lower tendency to form MCPDE as well as GE (Matthäus, 2015; Ramli et al., 2011; Zulkurnain et al., 2013). Moreover, it has been shown that the earlier mitigation is done in the supply chain, the better and the more efficient it works (Craft et al., 2012b; Nagy et al., 2011). Nowadays, water washing of palm oil, generally with 1–5 % w/w of water, is increasingly being tested and implemented at full scale in palm oil mills (Zulkurnain et al., 2013; Ramli et al., 2011).

The other reactant, important for the formation of MCPDE and GE, are obviously the acylglycerols that make the oil themselves. Vegetable oils generally consist of TAGs (86%–96%), DAGs (4%–12%) and MAGs (~0.3%) and free fatty acids (1%–5%) (Goh and Timms, 1985). The partial acylglycerols DAG and MAG are to the larger extent the result of enzymatic hydrolysis, activated during seed or fruit processing. Palm oil processed in the regular way can contain free fatty acid (FFA) levels up to 5% with concomitant diglyceride levels as high as 10% (average around 6.5%) (Goh and Timms, 1985). In seed oils FFA levels are generally 0.5%–1.5% with DAG levels < 2.5% (Gupta, 2017).

In the case of MCPDE, it has been shown that the mechanism of formation is mostly through TAGs reacting with the HCl with consequent release of free fatty acids. However, also DAGs can react in this way albeit that they are less reactive (Destailats et al., 2012b).

The formation of GE was found to be correlated to diglyceride levels (Matthäus, 2011) as most important precursor, but can be formed also from monoglycerides (Destailats et al., 2012a). Contribution of monoglycerides in the formation of GE is small as compared to the role of diglycerides (Goh and Timms, 1985). This relation to DAG is one of the reasons why palm oil and likely other high FFA-oils (e.g. lampante olive oil), contain significantly higher levels of GE as compared to seed oils (EFSA, 2016).

Reducing the level of partial glycerides therefore is another important mitigation tool, especially to mitigate GE. As palm oil is a fruit oil, active enzymes will start to hydrolyze the oil within the fruits itself, the moment the bunch is cut from the tree. Thus minimizing the time delay between harvesting and milling can significantly enhance the oil quality regarding the FFA content. Premium quality palm oil, processed as quickly as possible after harvesting, can contain less than 2% free fatty acid (Craft et al., 2012a).

## Individual Steps in Oil Refining

### Degumming, Neutralization and Washing

Degumming, neutralization and washing are the refining steps, which are common in using water and centrifugal separators (except dry degumming), that have significant impact on MCPDE and GE formation during deodorization. In general, application of water helps removing chlorine containing precursors (Pudel et al., 2011). Changing the acidity of the oil environment can play a crucial role in the MCPDE- and GE forming-potential of an oil. It has been shown that acidic conditions promote the formation of MCPDE (Destailats et al., 2012a), whereas GE is in fact broken down under such conditions (Smidrkal et al., 2011). Conversely MCPDE are rapidly decomposed under alkaline conditions (Smidrkal et al., 2011; Velišek et al., 2002; Hamlet et al., 2003). Even an equilibrium has been suggested between the formation of MCPDE and GE, depending on the reaction conditions (Freudenstein et al., 2013), especially hydrochloric acid level (Destailats et al., 2012a).

Wet degumming processes are specifically used for seed oils because of their high phosphatide content as discussed in Refining Principles section. Apart from water, citric acid or phosphoric acid can also be used to facilitate non-hydratable phospholipid removal. The percentage of hydration water typically equals with the percentage of phosphatides in the crude oil. Under these conditions chlorine and chlorinated compounds may also be removed to the gum phase, which was observed with reduction of 3-MCPDE formation capacity (Ramli et al., 2011; Matthäus, 2011; Craft et al., 2012a).

Oils can also be degummed using phospholipase A or C enzymes.

For palm oil, often dry degumming is applied, in which concentrated acid is added to the oil, removing the phosphatides in the subsequent bleaching process. It means that the added acid is not removed by centrifuging, but in the bleaching step. Applying acid in dry degumming is a significant factor of MCPDE formation as the acid can increase formation of 3-MCPDE (Schurz, 2010). The impact depends on the acid dosage and the amount of bleaching earth added for decolorization and removing the acid (Ramli et al., 2011).

In the neutralization process, first phosphoric acid is added to the oil to help removing the non-hydratable phosphatides and then this acid and the free fatty acids are neutralized with caustic solution. The caustic can optionally be applied in excess. Turning to basic conditions in neutralization contributes to lower MCPDE in the refined oil. This has also been suggested by Papastergiadis et al. (2016) and Pudel et al. (2011), describing that alkaline washing is more effective than regular water washing. The effect was described to be more pronounced on fresh crude oil. This is in agreement with the consequence from the need to reduce and remove the acidity in the oil prior to high temperature heating, i.e. the final deodorization step and a potentially more efficient chlorine-precursor removal.

Washing with water is routinely applied for seed oils after neutralization or post-degumming. Concerning washing of crude palm oil, [Matthäus \(2015\)](#) demonstrated the positive impact of increasing temperature (60–100 °C) and washing water amounts (5%–20%).

### Bleaching

Bleaching has important influence on MCPDE through the type and amount of bleaching earth. It is important to realize, that the bleaching step actually shows two effect, being on one hand the precursor removal by adsorption and on the other hand a potential addition of acidity towards the deodorization step. As shown, the higher the pH of the clay, the lower the MCPDE content of the refined oil is ([Ramli et al., 2011](#); [Ibrahim et al., 2016](#)). Because there are actually different effects taking place in bleaching, the overall effect on 3-MCPDE and GE of bleaching clay dosage on MCPDE and GE is not obvious. [Pudel et al. \(2011\)](#) did not find significant influence of increasing clay use (0.7% to 1.5%), [Matthäus et al. \(2011b\)](#) showed positive impact of excess dosing (3% versus 1%) and [Brüse \(2015\)](#) showed various relations depending BC type and refining steps applied (chemical vs. physical refining). Concerning hydrochloric acid activated bleaching earth, [Ibrahim et al. \(2016\)](#) and [De Greyt \(2014\)](#) concluded that with increasing chlorine content in the clay, increasing levels of MCPDE were found in the oil after deodorization. Whereas mostly hydrochloric acid-activated clays have been used in the past, today there is a clear shift towards phosphoric acid-activated, or physically activated (non-acid treated) bleaching clays, reducing the acidity of the oil as well as the chlorine input into the process. The effect of reduced acidity is discussed in more depth in the following chapter.

A more extreme example of adsorption was shown in ([Ermacora and Hrnčirik, 2014](#)). Isolation of polar compounds with silica treatment impacted significantly the MCPDE and GE formation. Similar adsorption but far less effective was also observed earlier by ([Strijowski et al., 2011](#)). However, both methods make use of high amounts of adsorbents lowering the oil processing yield and cost and further post-refining would be required to achieve normal quality oil.

### Acidity Control Towards Deodorization Step

Changing the acidity of the oil environment can play a crucial role in the MCPDE- and GE forming-potential. It has been shown that acidic conditions promote the formation of MCPDE ([Destailats et al., 2012a](#)). Conversely MCPDE are rapidly decomposed under alkaline conditions ([Smidrkal et al., 2011](#); [Velišek et al., 2002](#); [Hamlet et al., 2003](#)) and even an equilibrium has been suggested between the formation of MCPDE on the one hand, and GE on the other, depending on the reaction conditions ([Freudenstein et al., 2013](#)), especially the hydrochloric acid level ([Destailats et al., 2012a](#)). This pH character of the oil is especially important in the deodorization step.

All process steps can actually influence the pH of the oil before the deodorization step. Obviously, a dosing alkaline component directly to the deodorization can be more efficient than an alkali treatment like neutralization which is followed by a bleaching step with acid activated bleaching clay. For this reason and further reasons on practicality and economics, various means have been studied to neutralize acidity towards deodorization. Good results have been shown in below examples mostly in small scale experiments, now requiring transfer and implementation to full factory scale.

Sodium carbonate and sodium bicarbonate were shown to lead to low levels of MCPDE when added to oil prior to heating or deodorization ([Smidrkal et al., 2011](#)). Also common bases like sodium hydroxide, potassium hydroxide have been proposed for neutralizing the oil and thereby avoiding high MCPDE levels in the refined oil. Whether this is the result of the complete inhibition of the formation reaction or the degradation of MCPDE formed is unclear at this point.

Next to the bases mentioned before, bases commonly used as interesterification catalyst have shown to lead to low MCPDE levels when added to the oil before high temperature treatment. The use of sodium methoxylate and ethoxylate is claimed to reduce MCPDE level, independent on the question whether the interesterification process takes place or not ([Brüse and Kruidenberg, 2012](#); [Hed et al., 2014](#); [Bhaggan and Werleman, 2012](#)).

Finally, the addition of small traces of soap for this purpose has been described ([Ronglone and Heydinger-Galante, 2012](#)). This option is actually not so surprising if one considers the fact that adding bases will always lead to lowering acidity but also to soap formation. As this is an equilibrium reaction, adding soap will also lead to a lower acidity. After above processes soap still need to be removed by any adequate post treatment step.

Interestingly, it is known since long that soaps can also induce interesterification during high temperature deodorization ([Willems and Padley, 1985](#)). As both interesterification and MCPDE- and GE-formation follow similar mechanisms, both revolving around the formation and removal of a cyclic acyloxonium ion pathway, this may explain why soaps are involved in both processes ([Rozendaal and Macrae, 1997](#); [Destailats et al., 2012a,b](#)).

### Deodorisation

This process step is where the actual formation of MCPDE and GE formation takes place. Oils that are refined chemically, are generally deodorized at 220–240 °C depending on the oil quality and presence of volatile contaminants. In the physical refining process, where FFA is removed, higher temperatures in the range of 235–250 °C, are applied for seed oils, whereas in the case of palm oil 250–270 °C is used to remove the free fatty acid and to achieve the low color targets for the refined oil as well.

Based on experiments in a gastight system it was observed that the reaction formation of MCPDE is practically complete within half hour after heating ([Shimizu et al., 2012](#)). Other experiments also indicate that the deodorization temperature and time have a limited influence on the MCPDE content ([De Greyt, 2014](#); [Matthäus, 2015](#)).

GE formation during deodorization particularly depends on the DAG level (Craft et al., 2012a) and the temperature. Its formation will start at temperatures  $>200^{\circ}\text{C}$  (Destailats et al., 2012a). In heating and deodorization experiments at  $235^{\circ}\text{C}$  temperature, and threshold DAG content of 4% (corresponding to 1.9%–2.5% FFA in the crude oil) was observed, above which GE content increased exponentially. The lower free fatty acid content in crude oil and lower deodorization temperature could explain the lower sensitivity of seed oils to GE formation, compared to palm oil. Obviously, time and temperature are always of the essence as in any chemical reaction. This is clearly illustrated - next to positive effect of lower pressure - by the results from experiments comparing deodorization of corn oil at 235 and  $250^{\circ}\text{C}$  (Papastergiadis et al., 2016).

Reduced GE formation and the same time efficient FFA removal can be obtained applying dual temperature deodorization. This includes short time stripping of volatile compounds at  $240\text{--}260^{\circ}\text{C}$  followed by deodorization at low temperature, 200 or  $220\text{--}230^{\circ}\text{C}$  (Papastergiadis et al., 2016).

In palm oil, a high temperature during deodorization is required not only to remove free fatty acids but to induce 'heat bleaching', i.e. degradation of carotenoids as well, GE will form under these conditions. Therefore such processing requires a second treatment to remove GE through bleaching to meet the low GE levels required nowadays ( $<1$  ppm in the EU), followed by a second low-temperature deodorization step in a 'two-stage' refining process (Brüse and Kruidenberg, 2012). This will be explained further in Removal of Contaminants From Refined Oil section.

Next to temperature and time, also other conditions like pressure and steam will impact the 3-MCPDE and especially GE results. This is for a significant part due to removal of the GE and will therefore be explained further in the next chapter. However, enhancing the GE stripping and reducing formation through high vacuum short path distillation was shown to yield oils with no detectable levels of MCPDE and  $\text{GE} < 0.7$  ppm at a deodorization temperature of  $150\text{--}210^{\circ}\text{C}$  (Pudel et al., 2011). Conventional deodorization of the same oil sample at  $260^{\circ}\text{C}$  resulted in much higher levels of GE (6.4 ppm) and 3MCPDE (3.0 ppm). In the same study poor sensory quality of the refined oil samples was observed, while high color was obtained due to lack of heat bleaching. The insufficient sensory quality was restored applying an additional post-deodorization at a significantly lower temperature ( $180^{\circ}\text{C}$ ) (Pudel et al., 2016). Similar results were also obtained in a dual temperature deodorization process where heat bleaching was obtained at  $250\text{--}270^{\circ}\text{C}$  with a short-residence time, followed by a longer second deodorization step at  $200^{\circ}\text{C}$  to reduce off-flavors without formation of GE (Pudel et al., 2011, 2016).

### Removal of Contaminants From Refined Oil

Glycidyl esters have a molecular weight low enough to be stripped off during regular deodorization conditions, similar to monoglycerides (Goh and Timms, 1985). The stripping of GE was indeed shown to occur, comparing levels obtained in oil after heat treatment in closed ampoules at lab-scale, and samples from regular open-steam stripping. In closed system significantly higher levels of GE were observed (Craft et al., 2012a). Like for other volatiles, the efficiency of removal is dependent on the temperature and stripping steam rate applied (Özdikicierler et al., 2016). This means that during deodorization formation and removal happens simultaneously and GE content of the deodorized oil is determined by the rate difference.

Similar principles can also be applied on finished products. One example is the stripping of GE in packed bed column under low vacuum ( $<1$  mbar) as described by (Hogan, 2017). The high surface area, combined with an enhanced steam stripping efficiency at the low vacuum would result in a refined oil with good quality and low GE.

Another example is the polishing or post-refining of fully refined oils after long distance transport. Such oils and fats show some off-flavors and to get such oils back into the accepted specifications for application in food, they are often re-deodorized upon arrival. This refreshment usually does not impact the 3-MCPDE content, because their formation already took place in the deodorization step applied in the first refining process. However, the glycidyl ester content may be influenced in this deodorization step. The new "equilibrium" depends on GE precursor (DAG) levels and the conditions in the deodorization (temperature, pressure, and steam). This means, that post-refining of oils and fats, if done at mild conditions and on oils containing significant amount of GE, will reduce the GE level. However, if the oil to be re-processed already has a low level of GE, the polishing step itself could contribute to a further increase in the level of GE.

Alternative to polishing by post-deodorisation is a full post-refining step including bleaching and deodorization. This process is applied if metal (e.g. Fe) content is increased, or if lower color is desired, or on purpose to reduce glycidyl ester (GE) levels. During the bleaching step the glycidyl esters are reacted to monoglycerides. The efficiency of this step depends on temperature, bleaching clay type, the amount and the moisture content. Because the reduction of GE is a catalytic process, acid activated clays are more efficient than neutral clays, but both types are capable in removing the glycidyl esters. Because bleaching has negative impact on flavor and taste, after bleaching a post-deodorization step is required. If this deodorization is done at low temperatures ( $130\text{--}190^{\circ}\text{C}$ ) with retention time, steam and pressure at standard conditions, glycidyl ester (GE) levels can be kept at very low levels (Brüse and Kruidenberg, 2012).

A large range of materials was investigated on the removal capacities for 3-MCPDE and GE mainly based on silica, e.g. zeolites, alumina-, magnesium and calcium silicates (Strijowski et al., 2011). Only some of these materials were shown to lead to up to 40% reduced levels of GE. Also cellulose, Kieselguhr, and activated carbon were tested and especially acid-washed active carbon was found to reduce GE levels in palm oil by some 95% (Cheng et al., 2017).

Using higher volatility of 3-MCPDE and also GE compared to Triglycerides (3-MCPDE have similar volatility like Diglycerides) short path evaporation at elevated temperatures of  $200\text{--}280^{\circ}\text{C}$  can be applied (Brüse, 2014, 2015; Mellerup, 2014). Significant 3-MCPDE reduction will only be possible with high yield losses.

## Impact of Oil and Fat Modification Techniques

Next to the standard refining, there are also oil modification steps applied to oils and fats, depending on the required properties and end application. For most of these modification techniques fully refined oils and fats are applied and these processes are common part of oil refineries. The most important technologies in this field fractionation, interesterification and hydrogenation. The following sections will describe the impact of these modification steps on the levels of 3MCPDE and GE.

### Fractionation

The most common way of fractionating fats is the so-called 'dry fractionation' technique, especially used to fractionate palm oil. During fractionation crystals are formed upon cooling the oil. The oil is then separated into a liquid fraction (olein) and a more solid fraction (stearin) by filtration. The 3-MCPDE and GE in this process concentrate in the liquid fraction like also other minor compounds (e.g. colour compounds or DAG). For the stearin fraction, this means that reduction of 3-MCPDE and GE up to 40% can be observed, while for the olein fraction an increase of about 10% can be found. Further fractionation of the olein can lead to an increase in 3-MCPDE and GE in the superolein of about 30%.

### Hydrogenation

The hydrogenation of fats and oils is a metal (normally Nickel) catalyzed process adding hydrogen to the double bonds in unsaturated fatty acids in the oil. The hydrogenation process is applied to increase the melting point by turning these unsaturated fatty acids in less-unsaturated-, and fully saturated ones. This broadens the options for application of these hydrogenated oils and fats. Until now little research was done on the impact of hydrogenation on the levels of 3-MCPDE and GE. However, observations at full factory scale revealed, that there is only limited impact on the levels of 3-MCPDE, while glycidyl esters are normally removed completely. When to be used in food applications, after hydrogenation the oil needs to be re-bleached to guarantee sufficiently low nickel levels. Finally, the oil will undergo another deodorization step during which again GE can be formed.

### Interesterification

Interesterification is a process of rearranging the fatty acids on the glycerol backbone. This rearrangement of the fatty acids results in a new triglyceride composition and therewith new crystallization- and melting properties, which is required for application in many final products.

Two different interesterification processes are applied in the oil and fat industry, chemical interesterification and enzymatic interesterification. Chemical process usually applies an alkaline catalyst such as sodium methoxide, while in enzymatic interesterification a lipase is applied (usually immobilized on a carrier). The enzymatic interesterification is a process under normal conditions and does not show an effect on 3-MCPDE or GE. However, because the process can include a post bleaching step, and will also include deodorization there can again be an overall impact on final glycidyl ester levels depending on the execution of those two steps.

The chemical interesterification process can significantly impact the 3-MCPDE and also the GE level. The interesterification process can be split into the following process steps: 1) contacting the oil or fat blend with the catalyst, 2) neutralization of the catalyst to stop the reaction, 3) post-bleaching, and 4) post-deodorisation. During the first step 3-MCPDE is reduced. At the same time, glycidyl ester levels increase during this step. After the subsequent neutralization of the catalyst and the bleaching, these glycidyl esters are removed. Again some GE could be formed in the final deodorization step required after the interesterification bleaching.

## Conclusions

Science showed health concerns of 3MCPDE and GE, process contaminants formed during the refining of oils and fats. Since about a decade, research and development work did improve understanding on toxicology and bioavailability of these compounds, did improve analytical methods, did lead to better understanding of the formation of these compounds, and helped to develop mitigation measures that could partly be implemented. The developed mitigation methods are dealing with avoidance of precursors in the supply chain, reduction of precursors during refining, suppression of formation during the deodorization step and removal of 3-MCPDE and especially GE from the finished products. Because the formation mechanism of both compounds is different, and because single mitigation methods are often not sufficient, in many cases combinations of mitigation methods are required. The selection of methods to be implemented need also to take into account the type of oil involved, its quality, the available technologies in a plant, and possible environmental barriers.

Mitigation methods needed to be scaled up from small lab scale to industrial scale, which first was done focusing on special products and now is also applied more for bulk products. During implementation of mitigation measures no compromises can be made on food-safety or quality aspects, which in many cases will require extra steps or even double refining.

# Mineral Oils in Food: An Update

Koni Grob and Maurus Biedermann, Kantonales Labor Zürich, Zürich, Switzerland

© 2019 Elsevier Inc. All rights reserved.

## Glossary

GCxGC comprehensive two-dimensional gas chromatography

MOSH mineral oil saturated hydrocarbons

MOAH mineral oil aromatic hydrocarbons

POSH polymer oligomeric saturated hydrocarbons

White mineral oil mineral oil product low in MOAH

## Definition of Mineral Oil

What is referred to as “mineral oil” in foods are products predominantly derived from crude mineral oil through various raffination procedures. However, analytically they cannot be distinguished from Fischer-Tropsch oils made of natural gas or even from methane obtained from wastes. For toxicological reasons, the main components were separated into mineral oil saturated hydrocarbons (MOSH) and mineral oil aromatic hydrocarbons (MOAH) (Biedermann et al., 2009). Rather crude products may also include heterocyclic components, such as thiophenes (sometimes used as markers).

Mineral oil products vary widely, primarily according to the raffination process. They differ according to molecular mass range (distillation), MOAH content (extraction of MOAH, hydrogenation) and viscosity (ranging from low viscosity oils to waxes; dewaxing).

## Mineral Oil in Food: A Historical View

Most of the early findings are from the Kantonales Labor Zürich, Switzerland, a small official food control authority, which meant that, whenever possible, measures were taken to stop the contamination. Much of the history was determined by the difficulty to analyze mineral oils as contaminants. In the 1980s, the Kantonales Labor Zürich developed on-line coupled HPLC-GC, i.e. the pre-separation of the sample or extract by normal phase HPLC and the automated transfer of the complete HPLC fraction containing the components of interest into GC. This was the technique of choice, but few other laboratories dealt with the subject up to probably 2008, since on-line HPLC-GC was considered too complicated. This caused progress to be slow. The method used up to 2008 only determined the MOSH; the MOAH content was estimated considering the detected mineral oil product.

In 1986, during the analysis of the fatty acid composition, more than 1% MOSH were detected in a biscuit, which was from spraying the baking mold with a white mineral oil used as release agent. In 1989, it was incidentally noted that the hazelnuts on the market (but not those from the own garden) contained typically 20–50 mg kg<sup>-1</sup> MOSH. It turned out that the hazelnuts (from Turkey, some from Italy) were imported in jute bags of around 50 kg. These bags, most manufactured in Bangladesh, were made of fibers batched with around 7% of a mineral oil to render them suitable for spinning. Already the next harvest largely arrived in jute bags batched with vegetable oils. In 1991, a first article was published on hazelnuts, coffee, cocoa beans/chocolate and rice contaminated from jute and sisal bags at up to many 100 mg kg<sup>-1</sup> of mineral oil (Grob et al., 1991a).

The analysis of the MOAH in a batching oil revealed polyaromatic hydrocarbons up to the benzopyrenes, but largely alkylated, i.e. different from the polycyclic aromatic hydrocarbons (PAH) formed at high temperatures (Grob et al., 1991b). Only after it had also been shown that such MOAH were present in food (Moret et al., 1997), industry took measures to switch to bags free of mineral batching oil for imports to Europe, but the bags used outside Europe are still mostly the conventional ones.

Subsequently many more sources of food contamination with mineral oil hydrocarbons were identified. White oils were used to get rice shiny after raffination (typically 1000–3000 mg kg<sup>-1</sup> rice), as release agents (in bakery products typically 600–2000 mg kg<sup>-1</sup>), lubricating oils, hydraulic oils, cleaning agents used in food manufacturing (e.g. vegetable oils), defoamers, additives in plastics, binders for fines in animal feeds or dust binders for wheat and rice. Waxes were used in paper for cheese and processed meat or to improve water-resistance of paperboard, but also as coatings and glazing agents for confectionery. At public collection sites, used motor oils and similar wastes ended up in used edible oils and in this way entered feeds for hens and pigs. Finally, diesel oil and lubricants from harvesting machinery, as well as aerosols from environmental pollution, mainly from diesel oil, lubricants and debris from tires and road bitumen, were shown to contaminate foods. A summary was given in the opinion of the European Food Safety Authority (EFSA) from 2012 (EFSA CONTAM Panel, 2012) and a review by Purcaro et al. (2016), but the list of sources is probably still incomplete. Many of these sources of contamination were reduced or stopped, largely without legal measures or enforcement outside Switzerland.

In 2008, mineral oil was detected in Ukrainian sunflower oil, which drew the attention to this type of contamination and triggered numerous laboratories to analyse mineral hydrocarbons. EFSA evaluated the related health risk for crude and refined sunflower oils with up to 7300 and 2000 mg kg<sup>-1</sup> mineral oil, respectively, and concluded that “although being undesirable for human consumption, [it] would not be of public health concerns” (EFSA, 2008). However, it was neglected that the mineral oil contained 17%–37% MOAH (Biedermann and Grob, 2009). This prompted the further development of the analytical method to enable the determination of the MOAH fraction (Biedermann et al., 2009).

Since the year 2000, recycling of polyethylene terephthalate (PET) for food contact materials (FCMs) became widely discussed, and EU Regulation 282/2008 provided strict rules on the materials acceptable for recycling and the cleaning process. This created a striking contrast to recycling of paper and board, since most recycled fiber material is not made for food contact and usually no cleaning is applied. As mineral oils were a timely subject, they seemed suited to bring not only the recycling of paper and board to the attention of authorities, but also the use of mineral oil solvents in off-set printing inks used for FCMs (Biedermann and Grob, 2010), in particular to the German Federal Institute for Risk Assessment (BfR), widely recognized as the leading reference for paper and board in food contact. This initiative triggered an avalanche of activities.

Printers rapidly switched to mineral-oil-free inks. After a statement of the BfR in December 2009 (German Federal Institute, 2009), the German Federal Ministry of Food, Agriculture and Consumer Protection (BMELV) presented a first draft of a regulation on the migration of MOSH and MOAH from recycled paper and board. It struggled with numerous difficulties and, for a number of reasons, was still not implemented in 2017: lacking assessment to derive risk-based legal limits, the contamination not being limited to migration from recycled paper and board (a more general regulation would be preferable), mineral oil hydrocarbons just being an example of a far wider range of contaminants (Biedermann and Grob, 2013) and the subject not limited to Germany (an EU regulation would be more adequate). This placed the German authorities under pressure, primarily by NGOs (which seemed unfair, as the German authorities took the initiative).

In early 2017, the European Commission initiated a project on a broad monitoring of mineral oil hydrocarbons in foods (Commission Recommendation (EU), 2017/84), intended as a database for an evaluation by EFSA and possible measures.

## Chemical Analysis

MOSH and MOAH are complex and widely varying mixtures; their determination as contaminants is demanding. Flame ionization detection (FID) is the method of choice for quantitation, since all hydrocarbons give virtually the same response per mass. Gas chromatography is best suited, not only because of FID, but also for the separation from other hydrocarbons. However, MOSH and MOAH mainly form broad humps of unresolved chemical species, which presupposes their isolation from all other constituents in the extracts and causes sensitivity to be relatively low.

Pre-separation can be achieved by liquid chromatography on small columns packed with silica gel modified with a small amount of silver nitrate (e.g. Fiselier et al., 2013), but most routine laboratories use HPLC on silica gel on-line and in automated manner coupled to GC-FID. Coupling to GC requires a technique enabling to transfer whole HPLC fractions, usually comprising 300–500 µL of eluent. In the case of mineral oil analysis, this is done by eluent evaporation in a 7–10 m × 0.53 mm i.d. uncoated precolumn partially concurrently with the transfer, exploiting solvent trapping and the retention gap technique. The solvent vapors are largely discharged through a vapor exit installed at the exit of the precolumn (Biedermann and Grob, 2012a).

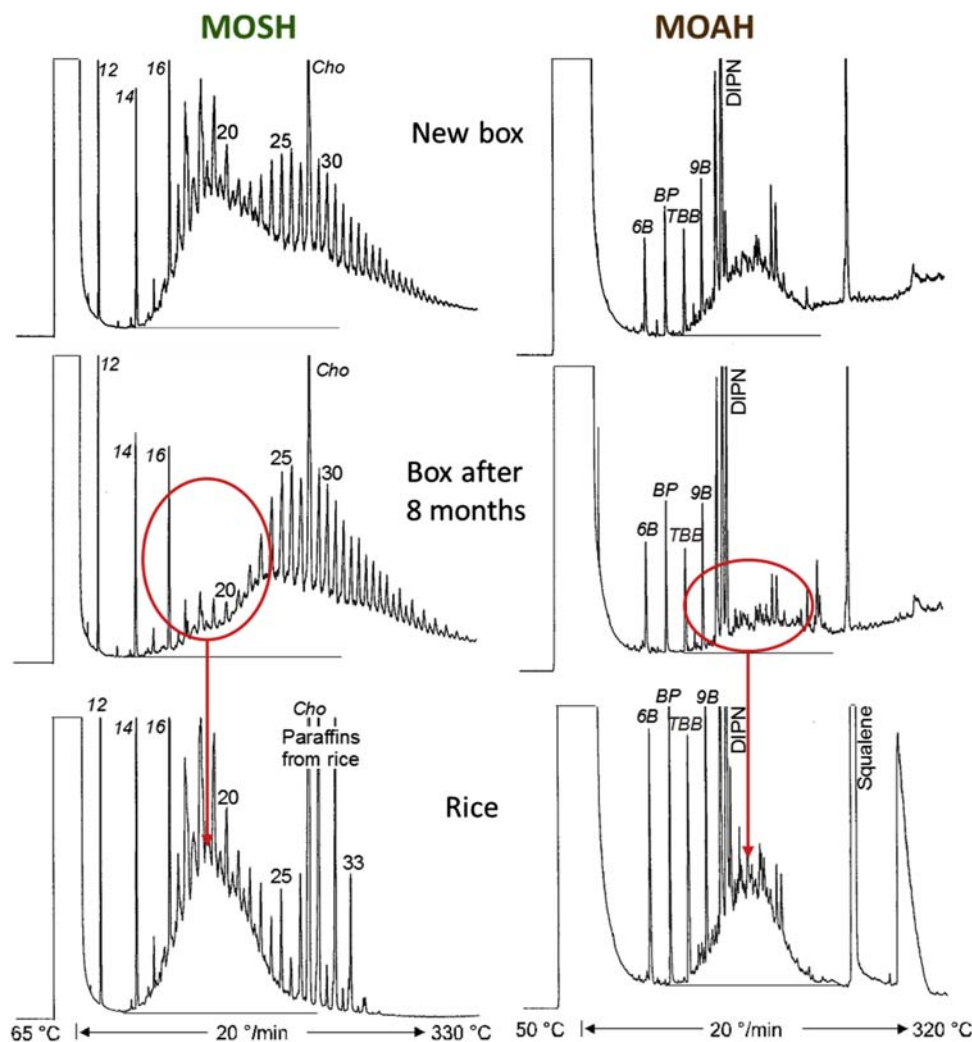

The most critical step is the interpretation of the chromatograms, particularly drawing the baseline above which the hump is integrated and the recognition of interfering hydrocarbons of other origins, such as *n*-alkanes of plant waxes, squalene and other terpenes as well as synthetic hydrocarbons (such as POSH or oligomers of polyolefins used in paperboard coatings). This presupposes experience on how such interferences are presenting themselves in chromatograms (Biedermann and Grob, 2012b), but often also auxiliary techniques, either to remove the interferences, e.g. of long chain *n*-alkanes by activated aluminum oxide or epoxidation of olefins (Biedermann and Grob, 2012a). A more detailed analysis, e.g. better distinguishing between MOSH and POSH or characterizing the composition of the MOAH, can be obtained by comprehensive two-dimensional gas chromatography (GCxGC) (Biedermann and Grob, 2015).

Fig. 1 shows HPLC-GC-FID chromatograms of MOSH and MOAH related to a sample of rice packed in a box of recycled board (Biedermann and Grob, 2010). The top chromatograms (MOSH and MOAH) are from an extract of the new box. The MOSH formed a hump ranging from *n*-C<sub>14</sub> to about *n*-C<sub>50</sub>, with some *n*-alkanes on top. The major part (from *n*-C<sub>14</sub> to about *n*-C<sub>25</sub>) was from printing inks used in the recycled material, primarily newspapers. The later eluted *n*-alkanes are from waxes, probably used to improve the water resistance of some recycled paper and board. They are located on a part of the hump that could have originated from defoaming agents used in pulping.

After eight months of storage, most of the early eluted MOSH were transferred to the rice (see circle and arrow; 19 mg kg<sup>-1</sup> rice). Since transfer was through the gas phase (evaporation and recondensation), the migration was limited to hydrocarbons up to about *n*-C<sub>24</sub>.

The MOAH formed a hump, in terms of volatility or GC retention times corresponding to the early eluted MOSH (probably part of the ink solvent). This hump was topped by diisopropyl naphthalene (DIPN) from recycled carbonless copy paper (the most specific marker for mineral hydrocarbons from recycled paper and board) and a later eluted pair of peaks probably from the coating (butylene styrene). Again, the more volatile compounds largely migrated into the rice (5 mg kg<sup>-1</sup> rice).

**Figure 1** HPLC-GC-FID chromatograms of extracts from a new box of recycled paperboard, the box after storing rice in it during eight months and of the rice into which the volatile hydrocarbons had migrated. DIPN, diisopropyl naphthalene; numbers, n-alkanes of given carbon number. 12, 14, 16, Cho (cholestane), 5B (n-pentyl benzene), BP (biphenyl), TBB (tri-tert. butyl benzene) and 9B (n-nonyl benzene), internal standards. ## Toxicity

The earlier risk assessments were mostly limited to MOSH, i.e. “white” (largely MOAH-free) products. In the 1990s, a number of subchronic 90-days studies with rats were reported using a range of mineral oil products characterized by viscosity and range of molecular mass. The focal end point was granuloma formation in liver, spleen and mesenteric lymph nodes. Mainly based on the results of Smith et al. (1996), the Joint FAO/WHO Expert Committee on Food Additives (JECFA) established a classification in 2002 that is widely respected up to today. High acceptable daily intakes (ADIs) were allocated to microcrystalline waxes (0–20 mg kg<sup>−1</sup> body weight; bw; specified by an average relative molecular mass ≥500 Da and a carbon number at the 5% distillation point ≥25), to high viscosity mineral oils P100 (0–20 mg kg<sup>−1</sup> bw; average mass ≥500 Da and a carbon number at the 5% distillation point ≥28), and to medium and low viscosity class I oils P70 (0–10 mg kg<sup>−1</sup> bw; average mass ≥480 Da and a carbon number at the 5% distillation point ≥25). To waxes or oils of lower mass range, no ADI or a temporary ADI of 0.01 mg kg<sup>−1</sup> bw were allocated, respectively, the low ADI being withdrawn in 2012 owing to insufficient data. Hence, products of a relatively high molecular mass were strongly privileged and considered acceptable up to very high intake.

This evaluation did not take into account that before 1990 numerous papers reported frequent occurrence of granulomas in human tissues that had been associated to mineral oil (e.g. Boitnott and Margolis, 1970; Dincsoy et al., 1982; Cruickshank, 1984).

Early doubts about the JECFA classification were cast by Scotter et al. (2003), showing that the strongest MOSH accumulation in Fischer 344 rats fell into the range of the oils considered of least concern. Also in human adipose tissue (obtained from Caesarean sections), much of the strongly accumulated MOSH was in this range (Concin et al., 2008).

In 2012, EFSA published an opinion on mineral hydrocarbons in food (EFSA, 2012). No health-based guidance values were derived for MOSH because of insufficient data, particularly with regard to accumulation, for MOAH because of potential presence of genotoxic constituents. Dietary exposure to MOSH in the European population, estimated as 0.03–0.3 mg kg<sup>-1</sup> bw/day, was considered of “potential concern”. MOAH with three or more rings were also considered of “potential concern”, as they may include mutagenic and carcinogenic species.

In 2014, human tissues were analyzed for mineral hydrocarbons. No MOAH were detectable. The mean MOSH concentration in the mesenteric lymph nodes (MLN) was 223 mg kg<sup>-1</sup>, in liver 131 mg kg<sup>-1</sup>, in adipose tissue 130 mg kg<sup>-1</sup>, in spleen 93 mg kg<sup>-1</sup> and in lung 12 mg kg<sup>-1</sup>. The maxima, found in MLN and spleen, were 1390 and 1400 mg kg<sup>-1</sup>, respectively. For a quarter of the subjects, the calculated total amount of MOSH in the body exceeded 5 g (Barp et al., 2014). The MOSH accumulated in liver and spleen clearly differed from those in adipose tissue in terms of mass distribution and types of structures (Biedermann et al., 2015).

In a project initiated by EFSA, MOSH accumulation in terms of mass distribution and composition was investigated in Fischer 344 rats (Biedermann et al., 2015; Barp et al., 2017). The main findings were that the concentrations in human tissues were far higher than it would be extrapolated from animal experiments and estimated human exposure, presumably due to long-term accumulation and a higher absorption at lower concentrations in food. At the highest concentrations measured in human spleen, a significantly increased organ weight in the rats was noted. Maximum accumulation in rat liver and spleen was around C<sub>29</sub>, i.e. in the range of the class I oils so far considered of low concern. It was concluded that the ADI for class I oils is far too high (300–3000 times above the present exposure estimated by EFSA and already considered of “potential concern”) and that the classification should be reconsidered.

In Fischer 344 rats, granuloma formation was linked to wax components, primarily *n*-alkanes and *n*-alkyl monocyclic MOSH; a dewaxed oil of similar molecular mass distribution did not trigger granuloma formation. However, it had previously been reported that the strong accumulation of *n*-alkanes in Fischer 344 rats is not observed in other animals, particularly Sprague Dawley rats (e.g. Griffis et al., 2010). Since *n*-alkanes from natural sources (such as surface waxes of, e.g., apples) are little accumulated in human tissues, it was questioned whether Fischer 344 rats are adequate models for granuloma formation in humans. However, this would imply that the granulomas observed in human tissues would have to be formed by another mechanism, possibly not observed in Fischer 344 rats.

The genotoxicity of the MOAH fraction depends on its composition. Crude mineral oils contain genotoxic constituents (IARC, 1984); in fact, an oil used for batching jute fibers has been shown to be a tumor promoter on mouse skin (Mehrotra et al., 1987). For technical products, however, oils are refined to render them negative in the mouse skin test or the extraction test IP 346 (Mackereer et al., 2003; Gray et al., 2013). Raffination involves extraction and partial hydrogenation, which preferentially remove the less alkylated polyaromatic MOAH. At a given point, in some oils at MOAH concentrations above 15%, merely monoaromatic MOAH are left, including polycyclic hydrocarbons of which only one ring (or two isolated rings) are aromatic. There are neither indications that mono- or diaromatic MOAH include genotoxic species, nor is there generally recognized evidence of absence or data to estimate the potency of genotoxicity, which hinders the specification of a health-based guidance value.

## Conclusion

Up to a few years ago, “food grade” mineral oils were considered quasi edible. For instance, near Zürich, every week a truckload of mineral oil was delivered to an industrial bakery and used in the production of the bakery wares. This rather “loose” attitude was not supported by solid risk assessment – the concentrations in human tissues were assumed far lower than they really were. Fortunately this has changed and the large entries into food have ceased.

However, there is urgent need for better clarification of toxicity in order to implement improvement where necessary, but also to stop exaggerated alerts. Questions concern the genotoxic potency of MOAH in mineral oil products of given grades. For the MOSH, better safety assessment is needed for the concentrations occurring in human tissues. As high values are close to or even above those in animal experiments at the highest dose, no adequate safety margin can be derived. More toxicological end points should be taken into consideration, including increased organ weights.

### Introduction

Knowledge about N-nitroso compounds (NOC) has been accumulated in studies dating back to the early fifties of the 20th century up to the present time. The strong carcinogenic potential of N-Nitroso-dimethylamine (NDMA) has already been described in 1956 by Barnes and Magee (Barnes and Magee, 1954). In the following decennia, more than 300 compounds were investigated chemically and biologically. Carcinogenicity and other biological effects were found to depend on structural features, and the overwhelming part was found to be mutagenic and carcinogenic in-vitro and in-vivo (Preussmann, 1990; Reed, 1996).

In 1964 (Ender et al., 1964), the occurrence of a hepatotoxic factor was reported in herring meal produced from sodium nitrite-preserved herring used as feed for sheep. Although appropriate analytical methods were not available yet at that time, NDMA was identified as the most probable causative agent, apparently being present at rather high concentrations in that specific feed. NDMA was suspected to have arisen from the treatment of the fishmeal with nitrite. These early findings triggered a large series of analytical studies to uncover the presence of N-nitroso compounds in nitrite/nitrate treated food. The then challenging and difficult analytical detection of N-nitroso compounds greatly benefitted from the advent of highly specific and sensitive detection methods, such as the thermal energy analyzer (TEA) (Fine and Rounbehler, 1975) and later coupled gas chromatography (GC) or liquid chromatography (LC)/triple mass spectrometry (LC-MS/MS/MS) methodology that allowed specific measurements at low parts per billion (ppb) levels in foods and other biological materials. N-nitroso compounds were subsequently detected in many areas of the human environment, including foods, feeds, cosmetics, consumer goods, pesticides, drugs and at working places involved in production and handling of such items, mostly (but not always) in rather low concentrations.

### Chemistry and Formation

There are two main categories of NOC: N-nitrosamines and N-nitrosamides (Fig. 1).

Whereas N-nitrosamines are chemically rather stable, N-nitrosamides (encompassing N-nitrosourea, -carbamate and -guanidine derivatives) are less stable, directly generating electrophilic alkylating or arylating species, depending on their structure and the respective (physico-) chemical conditions.

In practically all situations where nitrosating agents encounter N-nitrosatable amino compounds, NOC may be formed. In aqueous acidic environments, amines (classically secondary ones) react with nitrous acid. Under proton catalysis, nitrite and nitrous acid generate the actual nitrosating species, either dinitrogen trioxide ( $N_2O_3$ ) or tetroxide ( $N_2O_4$ ) or nitrous acidium (Nitrosonium) ion  $NO^+ \cdot H_2O$ . The mechanism of nitrosation is exemplified for a secondary amine in Fig. 2.

Since only the unprotonated amine nitrogen undergoes nitrosation, the  $pK_a$  value of a given amine governs the nitrosation rate. Strongly basic dialkylamines ( $pK_a > 9.5$ ) have their maximal nitrosation rate at around pH 3.5, close to the  $pK_a$  value of  $HNO_2$  (Mirvish, 1975). In general, weakly basic amines, such as morpholine ( $pK_a = 8.7$ ) are much more rapidly nitrosated than strongly

**Figure 1** Structures of NOCs.

**Figure 2** Exemplified nitrosation reaction mechanism.

basic ones. In the presence of aldehydes, especially formaldehyde, nitrosation is strongly catalyzed and proceeds even at neutral or basic pH values. This reaction has been found relevant for certain environmental conditions (including specific working places) where there is co-occurrence of amines, aldehydes and nitrosating agents (Keefer and Roller, 1973).

Early on, acid-catalyzed nitrosation has been suspected to occur in the stomach (Druckrey et al., 1961) as a possible way of in-vivo formation of N-nitroso compounds. This in-vivo formation has been found relevant especially for weakly basic amines.

Tertiary amines may also generate nitrosamines by dealkylating nitrosation, however in general at much lower reaction rates as compared to nitrosamine formation from secondary amines (Smith and Loeppky, 1967). Nitrosation of primary amines in aqueous solution results in unstable diazonium intermediates that react with water to alcohols.

The nitrosation reaction can be inhibited by NOx scavengers, such as ascorbic acid,  $\alpha$ -tocopherol, primary amines, tannins or other phenolic compounds (Loeppky et al., 1994). Total human exposure to NOC results from exogenous exposure to preformed NOC but also from endogenous exposure. The latter can result from in-vivo nitrosation by intake or in-vivo formation of precursor compounds. The relative proportion of exogenous versus endogenous NOC exposure and their respective human health relevance is still not fully elucidated.

The total “exogenous” exposure to NOC may encompass exposure related to “life style factors” (such as tobacco, food and cosmetics, drugs, household products, air) but also to specific working place conditions (e.g. in the rubber, leather, metal, chemical or related industry). The endogenous exposure, based on in-vivo formation, depends on the uptake of precursor agents (nitrate, nitrite, NOx and N-nitrosatable amino compounds) and on NOC formation kinetics predominantly in the gastro-intestinal tract.

## Occurrence in Food

### Formation

Contamination of food with nitrosamines is primarily connected to various processes during manufacture, storage and/or cooking or to migration from packaging materials. The NOC formation requires the presence of N-nitrosatable amines and of nitrosating agents (Sen, 1988; Bartsch and Spiegelhalter, 1996; Pfundstein et al., 1991). Nitrogen oxides (NOx) primarily may result from addition of nitrate and/or nitrite which are interconvertible by microbial activity, for instance during the curing process of meat products. Additionally, a variety of technical processes, handling and storage conditions to which food or food constituents are exposed, such as direct drying or kilning and smoking have been found to favour NOC formation from food constituents by contact with NOx. Nitrosamines most frequently found in foods are NDMA, N-nitrosopyrrolidine (NPYR), N-nitrosopiperidine (NPIP) and N-nitrosothiazolidine (NTHZ). Certain N-nitrosated amino acids are also found, including the N-nitroso products of sarcosine (NSAR), 3-hydroxyproline and proline (NPRO), thiazolidine-4-carboxylic acid (NTCA), oxazolidine-4-carboxylic acid (NOCA) and N-nitroso-2-methyl-thiazolidine-4-carboxylic acid (NMTCA) as well as its oxazolidine analog N-nitroso-2-methyl-oxazolidine-4-carboxylic acid (NMOCA) (Fig. 3) (Tricker and Kubacki, 1992). NPRO and NTCA are most frequently found in foods. Of note, with the exception of NSAR, which is a relatively weak carcinogen, N-nitrosated amino acids are not considered mutagenic or carcinogenic.

### Meat and Meat Products

The formation of N-nitrosamines in meat and meat products can occur as a result of various processing techniques such as smoking, salting and/or curing. Curing involves the development of a curing microflora that is responsible for the generation of NO from nitrite and nitrate. Curing is an ancient technique of food preservation bringing about extended shelf life, but also heat stable colour and flavour development of cured products. The characteristic red colour of cured meats results from the formation of a NO-myoglobin complex. Curing meat with nitrite/nitrate is still a common practice. In 2017 the European Food Safety Authority (EFSA) has re-evaluated the safety of nitrate and nitrite added to food. An acceptable daily intake for nitrate of 3.7 mg/kg bw/day was derived, while for nitrite an ADI of 0.07 mg/kg bw/day was calculated, based on increased methaemoglobin as benchmark response (BMR) (EFSA et al., 2017a, 2017b). However, EFSA concluded that it was not possible to discern the amount of NOC formed by addition of nitrite at the authorized levels from those produced already in the food matrix where nitrite has not been added.

**Figure 3** Structure of NOCs found in food.

In the early eighties volatile N-nitrosamines were found in about one-third of almost 400 meat and sausage samples from the German and also from the US market (Spiegelhalder et al., 1980a, 1980b; Sen et al., 1976). Reduction of nitrite content in curing salt, decreased addition of nitrate and regular use of nitrosation inhibitors, such as ascorbic acid and/or tocopherols, brought about a significant reduction in contents of volatile N-nitrosamines in meat products as shown in studies from the late eighties where levels up to 5 µg/kg (Italy), 8 µg/kg (Sweden) or 14 µg/kg (China) were found while in Germany levels were only up to 2.5 µg/kg. Mainly NDMA, NPYR, NPIP, NDBA and NDEA were found.

Studies in model systems showed that the content of NPYR in cured meat products can increase as a consequence of thermal treatment or processing (Janzowski et al., 1978). Thermal decarboxylation of nitrosated amino acids generates the respective volatile N-nitrosamines (NPRO → NPYR; NSAR → NDMA). NPYR can be formed by heat-induced decarboxylation of nitrosoproline as well as by direct nitrosation of pyrrolidine which is reported to be present in meat products at levels up to 20 mg/kg (Pfundstein et al., 1991). Thermal decarboxylation of NPRO may also occur from N-terminal NPRO containing peptides (Janzowski et al., 1978; Tricker et al., 1984, 1985). Relative high amounts of peptide bound NPRO can be released by enzymatic degradation or chemical hydrolysis (Dunn and Stich, 1984). Non volatile NOC have been found in nitrite treated or smoked meat products in substantial concentrations, for example in cured meat up to 360 µg/kg NPRO (Janzowski et al., 1978; Tricker et al., 1984, 1985b). N-nitrosothiazolidine (NTHZ), has been found in smoke-treated products in concentrations up to 10 µg/kg (Helgason et al., 1984; Lijinsky et al., 1988; Ellen et al., 1986) and up to 1010 µg/kg in fried bacon (Massey et al., 1991). N-Nitroso-oxazolidine (NOCA) was identified in smoked mutton (40–70 µg/kg) together with its 5-methyl derivative (MeNOCA) in concentrations of 30–120 µg/kg (Tricker and Kubacki, 1992).

Formation of NOCA and NTCA in food may occur by reaction of formaldehyde generated during the smoking process with serine, threonine or cysteine present in the processed food to yield oxazolidine, 5-methyl-oxazolidine- or thiazolidine-4-carboxylic acid (OCA, MeOCA or TCA), which can subsequently be nitrosated to the corresponding NOC (Tricker and Kubacki, 1992; Sen et al., 1986). NTCA was found in different smoke treated meat products in amounts up to 1 mg/kg (Helgason et al., 1984; Sen et al., 1986), in uncooked bacon up to 1.4 mg/kg (Pensabene and Fiddler, 1985), and up to 13.7 mg/kg in fried bacon (Sen et al., 1986). Recently analysis by the Bavarian Food Surveillance Office from 2014 showed that in 40 samples of smoked bacon only 15 samples contained no NOC above the limit of detection while in 25 samples NOCs were detected. From these 25 samples, 18 contained NDBA (0.37–3.9 µg/kg), 5 samples NDMA (0.44–0.5 µg/kg), 2 samples NDPA (0.43–3.0 µg/kg) and 18 samples NPIP (0.31–7.7 µg/kg) (Bavarian Office, 2015).

### Fish and Fish Products

In fish and fish products, NDMA is the most commonly reported volatile N-nitrosamine, detected in a variety of fish products (cooked or smoked fish samples and conserved fish) in concentrations from 0.5–8.0 µg/kg (Tricker et al., 1991). Contents appear to depend on the way of preparation. Fish heated over an open gas flame (high NO<sub>x</sub>-content) showed a 30-fold increase of NDMA, whereas cooking with an electric hot plate showed no such effect (Maki et al., 1991). The apparently higher NDMA concentration reported for Asian fish products compared to western diets may be a consequence of the different preparation or conservation methods (curing, smoking) (Bartsch and Spiegelhalder, 1996). In a study from Finland on smoked fish, NDMA (up to 28.5 µg/kg) was found (Penttilä et al., 1990).

To summarise, in EU countries means of 0.2–3.0 µg/kg NDMA were observed for fish products. Data from Japan and China reported sporadically higher values (mean up to 5.9 µg/kg in certain Japanese) with even up to >130 µg/kg in certain Chinese fish products (Habermeyer et al., 2009).

### Beer and Other Alcoholic Beverages

Contamination of beer with N-nitrosamines was found to primarily result from thermal treatment of the malt (kilning). In 70% of 158 different beer samples tested, NDMA was identified at a mean concentration of 2.7 µg/kg with the highest concentration found

of 68 µg/kg. Other N-nitrosamines like NDEA and NPYR were only found very rarely (Spiegelhalder et al., 1979, 1980a). Precursors of NDMA in malt are hordenin, gramine and dimethylamine, the latter in concentrations of 5.5–12 mg/kg (Pfundstein et al., 1991). Hordenin and gramine are naturally occurring alkaloids with a tertiary amine structure and are produced in barley during the malt germination process. Gramine is nitrosated more rapidly than hordenin, however hordenin concentrations are higher (Mangino and Scanlan, 1985). It has been found that the heating technique is of major importance. Heating the air in the kilning process by direct firing resulted in substantially higher amounts of NDMA in the malt (up to 1080 µg/kg) compared to indirect heating using heat exchanger technology (Spiegelhalder and Preussmann, 1983). In particular gas burner flames operating at high temperatures (>1400 °C) generate substantial amounts of NOx that can react with amines in the malt resulting in increased NDMA formation in the kiln. Reduced NOx generation and resulting lower NDMA formation was achieved by modifications in the firing technique using indirect heating and lower operating temperatures (Tricker and Kubacki, 1992; Tricker et al., 1991). This is reflected by the observed NDMA levels in beer samples from the German market which were at a mean level of 2.7 µg/kg (<0.5–68 µg/kg) in 1977/78 (Spiegelhalder et al., 1979). The levels subsequently decreased to 0.28 µg/kg (<0.5–9.2 µg/kg) and 0.44 µg/kg (<0.5–7 µg/kg) in 1980 and 1981 (Spiegelhalder and Preussmann, 1983; Frommberger, 1985) and further down to about 0.1–0.15 µg/kg (<0.5–1.7 µg/kg) in the late eighties (Ministerium, 1983; Tricker et al., 1991). In the years 2000–2, about 15% of the beer and malt samples showed NDMA levels above the technical guidance value for Germany of 0.5 µg/kg for beer and 2.5 µg/kg for malt. Studies from this decade on beer from the German market showed the majority of the samples having NDMA levels either below the limit of detection (<0.1 µg/kg) or <0.5 µg/kg (see Table 1) (Bayrisches).

Only up to 2.2% of the samples showed NDMA above the technical guidance value of 0.5 µg/kg for beer. Similar results were observed for NDMA in the brewing malt. The reduction of NDMA concentrations in beer was observed also in other countries showing similarly reduced NDMA levels down to 0.074 µg/kg in USA/Canada 1991 (Scanlan et al., 1991), to 0.1 µg/kg in Sweden 1994 (Österdahl et al., 1994) or to 0.11 µg/kg in Spain 1996 (Izquierdo-Pulido et al., 1996).

Accordingly, for the US and Canada, a reduction of NDMA contaminations down to 1%–5% of previous levels has been reported by Scanlan and Barbour (Scanlan et al., 1991). Since NDMA levels in beer have continued to be reduced, it appears worthwhile to reconsider today's relative contribution of beer consumption to the total dietary exposure to N-nitrosamines. Approximately 30% of dietary NDMA exposure have been estimated earlier to result from beer consumption in Germany, with an estimated contribution of about 0.1 µg NDMA per person and day (Österdahl, 1988; Habermeyer et al., 2009). The daily uptake of NDMA resulting from the consumption of beer in France and Spain was estimated to be 0.02–0.03 µg per person (Mavelle et al., 1991; Izquierdo-Pulido et al., 1996). Other alcoholic beverages were also studied for contamination with volatile N-nitrosamines. Goff and Fine (Goff and Fine, 1979) examined wine, sherry, liqueur, gin, brandy, vodka, rum, and whiskey. Only the latter sporadically showed some NDMA contamination with concentrations between 0.3–3 µg/kg.

### Milk Products and Cheese

In general, only rather low concentrations of NDMA were found in cheese and milk powder. In two of eight cheese samples, NDMA was detected at concentrations of 0.8–1.1 µg/kg (Tricker et al., 1991). This confirmed results from an earlier study with 200 cheese samples where a rather low contamination was reported (Spiegelhalder et al., 1980a). Studies by Sen and Seaman (Sen and Seaman, 1981) reported a mean NDMA concentration of 0.4 µg/kg in Canadian samples, whereas in two studies in Europe, even smaller trace amounts of NDMA were found in milk powder (mean: 0.07 µg/kg NDMA) (Österdahl, 1988; Tricker et al., 1991). In the US, mean NDMA concentrations of 0.7–1.05 µg/kg were reported for milk powder products (Scanlan et al., 1994).

### Other Foods

Low amounts of N-nitrosamines (<1 µg/kg, primarily NDMA) have been reported for instant coffee, infant formula, cocoa, powdered egg, and instant soup (Österdahl, 1988; Tricker et al., 1991; Sen and Seaman, 1981). Spices showed contaminations with NDMA (mean: 0.3 µg/kg, max: 1.4 µg/kg), NPYR (mean: 1.75 µg/kg, max: 29 µg/kg) and NPIP (mean: 1.8 µg/kg, max:

**Table 1** NDMA in beer from the German market

Year/Sample	Number of samples analysed	NDMA < LOD	NDMA below technical guidance value (<0.5 µg/kg)	NDMA > 0.5 µg/kg
2011	132	124 (93.9%)	6 (4.6%)	2 (1.5%)
2012	182	180 (98.9%)	2 (1.1%)	–
2013	197	193 (98.0%)	4 (2.0%)	–
2014	314	202 (64.3%)	105 (33.4%)	7 (2.2%) <sup>a</sup>
2016 - craft beer	88	22 (25.0%)	66 (75.0%)	–
2016 - normal beer	156	31 (19.9%)	123 (78.8%)	2 (1.3%)

LOD, Limit of detection: 0.1 µg/kg.

<sup>a</sup>3 samples using a smoked malt.

23 µg/kg) (Tricker et al., 1991). Peak contaminations with NPIP and NPYR were found in ground pepper, also containing high amounts of respective precursor amines like piperidine (535–642 mg/kg) and pyrrolidine (41–91 mg/kg) (Pfundstein et al., 1991). NDMA (max: 16 µg/kg) and NPYR (max: 6.1 µg/kg) were also found in dried chillies and in dried chilli powder (Tricker et al., 1988).

In fermented vegetables (Chinese cabbage and radish) NDMA (up to 13 µg/kg), NPIP (up to 14 µg/kg), and NPYR (up to 96 µg/kg) have been reported to sporadically occur (Poirier et al., 1987a). In *Brassica oleracea* from India, NDMA (15–16 µg/kg), NPYR (19–25 µg/kg), NPRO (2.1–3.5 µg/kg), and NTCA (0.7 µg/kg) were found (Kumar et al., 1990).

### Human Dietary Exposure to N-Nitrosamines

Table 2 summarizes daily exposure to volatile N-nitrosamines from food in different countries (Habermeyer et al., 2009). NDMA is the most common N-nitrosamine found in food and thus contributes primarily to the total human exposure. As a result of the mitigation measures applied since the eighties, e. g. reduction of nitrite content in curing salt or addition of nitrosation inhibitors such as ascorbic acid or tocopherols as well as the improved kilning processes for barley malt production (Tricker and Kubacki, 1992), the mean exposure to NOC could be reduced from 1.1 µg/person/day (Germany 1980) to about 0.2–0.3 µg/kg in 1990.

Importantly, humans are not only exposed to NOC via dietary uptake, but may also be exposed at specific working places (Federal Institute for Occupational Safety and Health, 552; Federal Institute for Occupational Safety and Health, 611). This is not discussed here but may need consideration in individual risk assessments.

For most industrialized countries, the dietary intake of volatile N-nitrosamines can be estimated to reach approximately < 0.1–0.6 µg/person, respectively < 1.7–27 ng/kg body weight (Bartsch and Spiegelhalter, 1996; Osterdahl, 1988; van Maanen et al., 1996). Beer, processed meat products and fish are considered the main sources of exposure.

By contrast, based on N–NO-group specific analysis to detect the “apparent total N-nitroso compounds” (ATNC), the daily exposure to non volatile N-nitroso compounds was estimated to reach much higher levels, approximately 10–100 µg/person (Tricker and Kubacki, 1992; van Maanen et al., 1996; Challis, 1996). A substantial contribution to this exposure is attributed to beer and bacon consumption (Challis, 1996; MAFF, 1992). Of note, although many non volatile N-nitroso compounds identified in food, such as most N-nitroso amino acids are not considered to be biologically active, the whole spectrum of non volatile NOC to be expected in that group still awaits chemical identification and biological characterisation. It is assumed that the fraction of characterized non volatile N-nitroso compounds is approximately just 10% of the total ATNC content (Tricker and Kubacki, 1992).

Another important exposure pathway is the endogenous formation of NOC. Most nitrosated amino acids are not carcinogenic or mutagenic and practically quantitatively excreted in the urine. They can therefore be utilized as biomarkers for endogenous nitrosation. There have been many attempts to assess endogenous formation of NOC, predominantly by NPRO measurement in urine, stool and other biological media. Although it has been clearly demonstrated that carcinogenic NOC might easily be formed when the appropriate precursors are being taken up, endogenous formation of carcinogenic NOC has not been evaluated adequately yet with respect to their human health relevance and especially concerning human cancer risk. It is well known, that there is endogenous formation of nitrosating agents and that certain disorders, such as inflammatory diseases, bacterial, viral or parasite infections and the like can substantially increase endogenous formation of nitrosating agents and thus enhance the risk of forming carcinogenic NOC in vivo. It is still not clearly established yet, whether NPRO is a valid biomarker for endogenous formation of NOC other than those arising from nitrosation of amino acids or peptides (Habermeyer et al., 2015). It thus remains a mandatory research need to develop in the future biomarkers with better predictivity to reliably assess the overall risk of endogenous NOC formation in humans, including potentially carcinogenic NOC.

### Toxicology, Toxicokinetics

After oral intake, N-nitrosamines are well absorbed from the gastrointestinal tract. Further uptake routes encompass inhalative or dermal exposure, leading to uptake rates similar to the oral route. N-nitrosamines are distributed with the blood stream and are

rapidly metabolised, predominantly in the liver particularly at low concentrations (Mirvish, 1995). However other tissues are competent as well to metabolize nitrosamines. Most N-nitrosamines are precarcinogens, requiring metabolic activation. With few exceptions the elimination of intact parent compounds is minor to negligible, due to the generally fast and effective biotransformation of N-nitrosamines.

The first step in the metabolic activation consists of hydroxylation at the  $\alpha$ -C position, mediated by cytochrome P450 dependent monooxygenases (CYP450). This results in the formation of an  $\alpha$ -hydroxy-N-nitrosamine, a proximal carcinogen. The  $\alpha$ -hydroxy-N-nitrosamine is unstable, releases an aldehyde to form an even more unstable monoalkylnitrosamine. The latter rearranges into the corresponding diazonium intermediate that reacts as an electrophile with biomolecules such as DNA, RNA, proteins or glutathione, forming covalent adducts with appropriate nucleophilic centers (Fig. 4) (Shu and Hollenberg, 1997).

The metabolic activation of NOC by CYP450 depends on their structure, and also varies for different CYP450 isoenzymes. Of major importance for metabolic activation of N-nitrosamines in humans are CYP450 2E1, 2A3, 2A6, and 3A4 (Shu and Hollenberg, 1996; Yang et al., 1994). Due to the varying expression of CYP450 isoenzymes in different organs, N-nitroso compounds can also undergo biotransformation in extrahepatic tissues, e.g. lung, gastrointestinal tract or other organs.

N-nitrosamines with longer side chains may also be hydroxylated at positions other than the  $\alpha$ -C atom. The resulting hydroxylated metabolites might be directly excreted or further oxidized to the respective acids or carbonyl compounds or may undergo conjugation reactions by phase II enzymes, the resulting conjugates undergoing excretion via bile or urine.

Metabolically generated reactive electrophilic compounds lead to alkylation of DNA bases, mainly at N-7, O6, N-3 of guanine (see Fig. 4), N-1, N-3, N-7 of adenine the O2- and O4-position of thymine and of phosphate diester groups of the nucleic acid backbone. Although N-7 alkylguanine in general is a major DNA base adduct resulting from N-nitrosamines, this lesion is considered of rather low promutagenic potential, in contrast to alkyltransfer to the oxygen atoms of nucleobases. Especially alkylation of O6-alkylguanine, O4- and O2-alkylthymidine entail mutations that result in DNA mismatches and miscoding and represent mutagenic lesions that may result in malignant transformation.

### Further Aspects of Exposure and Risk Assessment

As a consequence of the previously described mitigation measures for foods and also for cosmetic products (not discussed here), a consistent reduction of contamination with N-nitrosamines, and thus of human exposure, down to about  $<0.1$ – $0.6$   $\mu\text{g}/\text{person}/\text{day}$  for NDMA (see Table 2), respectively  $<1.7$ – $10.0$  ng NDMA/kg body weight/day (based on a body weight of 60 kg) has been achieved. Based on these data, a margin of exposure (MOE) may be calculated. The MOE describes the ratio between human exposure and a benchmark dose (BMD) associated with a certain benchmark response (BMR) from long term animal experiments. As BMD, the T25 may be chosen, reflecting the dose rate in mg/kg/d which in a long term carcinogenicity experiment will give 25% extra tumor risk over background tumor incidence. EFSA prefers another point of departure for risk assessment: the BMDL, which is the lower one-sided confidence bound of the BMD, derived by modelling dose response data to arrive at the 95% confidence interval of a BMD, set by default at 10% extra risk over background tumor incidence (BMDL10) (EFSA, 2005; O'Brien et al.,

**Figure 4** Reaction mechanism of dialkyl nitrosamines and DNA adduct formation.

2006; EFSA Scientific Committee et al., 2017). The T25 and BMDL10 values for various carcinogenic NOC have been published in two opinions concerning risk assessment of nitrosamine contamination in cosmetics and consumer products by SCCS in 2012 (Table 3), based on available rodent carcinogenicity studies (SCCS, 2011).

According to EFSA, a MOE of 10.000 or higher would be considered of low concern with respect to human health and may confer a low priority for risk management actions (Yurchenko and Mölder, 2007). An MOE estimate for N-nitrosamines occurring in food is given in Table 4.

On the basis of the above “historical” occurrence data, the MOE can be estimated to range between 2700 and 15 900. Results of more recent research published in the following years contributes to better understand parameters governing the process-related formation of nitrosamines, for instance in meat products and thus to support mitigation.

Thanks to tremendous progress in analytical methodology this research has also provided more recent data on nitrosamine occurrence in European foods, to allow for updated estimates of human exposure (Yurchenko and Mölder, 2007; Campillo et al., 2011; Drabik-Markiewicz et al., 2009, 2010, 2011; Herrmann et al., 2015). NDMA was most often found, together with varying spectra of other nitrosamines, such as NDEA, NPYR, NPIP and, in rare cases, even NMEA and NDBA. In more than 100 samples of dry fermented sausages of the European market quantifiable levels of nitrosamines were reportedly found only in rare cases. With one exception (about 12 µg/kg NPIP in a pepper salami) total nitrosamine levels remained below 5.5 µg/kg. Also, no connection was found between contents of biogenic amines and of nitrosamines (De Mey et al., 2014). Sporadically, NMOR was found in traces below the LOQ and was hypothesized to originate possibly by migration of morpholin from packaging or anticorrosion material.

Data on nitrosamine exposure from processed meat products in Denmark informed about mean total contents (all samples) of < 1 µg/kg, corresponding to dietary exposure levels of 1.1 ng/kg bw/d in children (4–6 years) and 0.34 ng/kg bw/d in adults, based on consumption data from the Danish National Survey of Diet and Physical Activity (Herrmann et al., 2015).

With reference to the BMDL10 value of 27 µg/kg bw/d for NDMA derived by SCCS, MOE values of 24 500 and 79 000 are to be derived for volatile nitrosamine exposure (Herrmann et al., 2015).

In a recent study encompassing more than 380 foods from the Korean market (7 largest cities) sampled over 3 years, about similar contents of volatile nitrosamines were found in meat products (Park et al., 2015). NDMA was again detected most frequently, others appeared at lower concentrations. Negative to very low contents were reported for milk products and cheese.

In contrast, remarkably high individual findings (up to 15 µg/kg) were noted for fresh vegetables and mushrooms, seasoning and vegetable oil. Salted fish was reported with some exceptionally high levels (up to more than 300 µg/kg). Unfortunately no discussion was addressed to the potential causes and consequences of these findings, nor was a systematic dietary exposure assessment included, based on consumption figures, to allow for an MOE calculation. Especially the findings in salted fish may deserve further scrutiny, since salted (and dried) fish has been associated earlier with relatively high NDMA contamination. Regular consumption of salted fish was found associated with enhanced occurrence of nasopharyngeal tumors in Southeast Asia (Poirier et al., 1987b). Contamination with NDMA of salted fish has recently also been studied in China. Fifty-four samples of Chinese salted fish obtained from five provinces were analyzed. The results indicated concentrations of NDMA in 57.4% of the samples

**Table 3** Dose descriptors T25, BMDL10 and TD50 for selected carcinogenic nitrosamines

NOC	T25-method <sup>a</sup> (mg/kg bw/d)	BMDL10 <sup>b</sup> (mg/kg bw/d)
NDMA (N-Nitrosodimethylamine)	0.058	0.027
NDEA (N-nitrosodiethylamine)	0.085	0.018
NPYR (N-nitrosopyrrolidine)	0.57	0.16

<sup>a</sup>dose in animal experiment with 25% tumour incidence.

<sup>b</sup>Benchmark Dosis Lower confidence Limit for 10% enhanced tumour incidence.

Table compiled by authors from data given in Ref. SCCS (2011).

**Table 4** Margin of exposure calculation for NDMA

Carcinogen	BMDL10 [mg/kg bw/d]	Estimated human exposure [ng/kg bw/d]	MOE
NDMA	0.027	< 1.7 – 10.0	<2700–15 900

exceeding the limit (acceptable China national standard value of 4 µg/kg), with a median of 5.8 and a range of 0.2–89.4 µg/kg (Qiu et al., 2017).

## Conclusions

The majority of the estimated exposure relates to food intake. As mentioned, NOC are present in the human environment not only in foods, but may also be present in cosmetics and other non food products, giving rise to an aggregate systemic human exposure. Based on average consumption figures, sustained development and application of mitigation measures have brought about substantial reduction of food contamination levels. However if dietary exposure situations are identified that are characterized by a low margin of exposure this may create health concerns and requires targeted mitigation measures.

Of note, an important source of NOC exposure that in general outweighs dietary exposure discussed here relates to tobacco smoking and/or consumption of non smoked tobacco products (chewing tobacco, snuff etc). Tobacco related exposure results in intake especially of tobacco-specific nitrosamines, highly potent carcinogens. Tobacco smoke-related exposure occurs not only by active smoking but also by passive exposure to indoor tobacco smoke (Hecht, 1998).

# Migration From Food Contact Materials

Gregor McCombie and Maurus Biedermann, Official Food Control Authority of the Canton of Zurich, Zurich, Switzerland

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**FCM** Food contact material; any material or article intended to come into contact with food

**Migration** The transfer of substances from an FCM to food

**NIAS** Non-intentionally added substances; substances that are not starting materials in the manufacture of FCMs i.e. oligomers, impurities and reaction products

**IAS** Intentionally added substances; starting materials in the manufacture of FCMs (e.g. monomers or additives)

**GC** Gas chromatography

**MS** Mass spectrometry

**FID** Flame ionisation detection

**GCxGC** Comprehensive two-dimensional gas chromatography

## Introduction

A food contact material (FCM) may be any article or material which is in contact with food. This contact can be during food processing (e.g. conveyor belts), food preparation and consumption (e.g. pans, plates, forks) or food storage (e.g. packaging). When FCM are in contact with food they may transfer some of their components to the food, a process which, in food science, is commonly referred to as migration. As a source of food contamination packaging in particular is generally high risk, as food is often stored for significant amounts of time in its packaging and/or hot during the filling process. The type of materials which are used as FCM cover a very wide range of chemistry and include plastics, elastomers, resin coatings, metals, adhesives, printing inks and paper/board.

Despite the modest attention FCMs receive in food safety, migration from packaging is by far the biggest source of organic contamination in food (Grob et al., 2006). There have, however, been several examples, where problems from migration from FCM have been identified and in some cases addressed. At times, this led to significant damages to food business operators and large investments from the public sector.

It is beyond the scope of a single article on migration from FCMs to be comprehensive. Therefore, examples shall be presented and possible strategies to find substances migrating from FCMs that may be of concern to consumers. Alternative sources for information on FCM can be found at the European Reference Laboratory on food contact materials (EURL-FCM) or the charity Food Packaging Forum.

## Examples

Typically, in migration a distinction between intentionally added substances (IAS) and non-intentionally added substances (NIAS) is made. To the authors' knowledge, the biggest database on IAS contains more than 10,000 entries (Van Hoeckel et al., 2017). They are substances used in the manufacture of a wide range of FCMs and were compiled from European and national legislation and the Council of Europe's Resolutions. The database is accessible through <https://fcm.wiv-isp.be/About.aspx>. A few examples shall illustrate where there have been problems with IAS in the past.

In 1991 contamination of nuts, rice and cocoa products with up to 500 mg/kg **mineral oil** were reported from jute bags used for transport (Grob et al., 1991). The bags had been treated with high-boiling mineral oil components, so called batching oil, to render the fibers flexible. This practice has been banned for food destined for the European market.

An age old and well known contamination of food by **lead and cadmium** from ceramics is even believed to have been a problem in the Roman Empire. The US food and drug agency took action against lead contamination from ceramics in 1971 after a family of six were poisoned by such articles in 1970 (Gilmore et al., 2013). This also led to a European Regulation for lead and cadmium in 1984 (84/500/EEC). Though the issue seems less severe nowadays, the release of heavy metals from ceramics remains an active area of food safety considerations to this day (Beldi et al., 2016).

A substance which caused a relatively large scale scandal in Europe was **2-Isopropylthioxanthone (ITX)**. It is a so called photo initiator which is used in UV-curing printing inks (Sagrati et al., 2006). The issue arose due to an alert of the Italian authorities in 2005 to the **European Rapid Alert for Food and Feed** system, and has led to many since. In a survey ITX was found in amounts up to

357 µg/kg food from the German market in 2007 (Rothenbacher et al., 2007). Since the issue was identified, it has been largely solved by the advent of low migration inks for food packaging (Lago et al., 2015).

When **Bisphenol-A-diglycidyl ether** (BADGE), a starting material in the manufacture of epoxy based can coatings, was first discovered to migrate into food, there were no available data on genotoxicity, despite the reactive epoxide groups (Fig. 1). (Biedermann et al., 1996) This was in stark contrast to the detected levels in food of up to 57 mg/kg. Since then it was established that BADGE is not genotoxic and there is now a European Regulation (EC No 1895/2005) setting levels of safe migration of BADGE and some other related substances.

More recently, **formaldehyde** migration from melamine plastic was rediscovered in 2005 (Bradley et al., 2005). A total of 10% of the tested articles were found not to comply with regulation on the migration of formaldehyde, which seems surprising considering the topic had been reported much earlier (Ishiwata et al., 1986; Martin et al., 1992). This may to some extent reflect the lack of attention FCM have received in the area of food safety. These findings resulted in EU-wide legislation to tackle the issue in 2011 (Commission Regulation (EU) No 284/2011).

**Plasticisers** in polyvinyl chloride plastic (PVC) regularly attract media attention. Initially, this was focussed on the group of the phthalic acid esters of which the most prominent substance is di-2-ethylhexyl phthalate (DEHP). Plasticisers are lipophilic and therefore are prone to migrate into fatty food. PVC is mainly used for FCM in cling film and sealing gaskets of glass jars. For the latter type of food contact material a pan European campaign with over 400 samples in 2011 showed that a quarter of all roughly 300 relevant samples (oily content) were non-compliant with respect to plasticiser migration (McCombie et al., 2012). The most incidences of exceedances was due to sum of plasticisers, the highest migration for the sum of plasticisers was 1314 mg/kg food. Unfortunately, the situation had not improved in a follow up campaign in 2013 (McCombie et al., 2015). To this date, there are still many sealing gaskets made from plasticised PVC on the market. The migration issue seems to be moving forward, only by the development of alternative plastics for the gaskets for food containing oil (e.g. [www.pano.de/](http://www.pano.de/)).

Finally, Bisphenol A (BPA) deserves a mention as an IAS, because it receives a very large amount of attention from the scientific community and the press. One of the main sources of BPA in food was from polycarbonate (most prominently baby bottles, which are banned now), for which it is a starting material. The safety assessment of this substance has been reviewed and refined many times. One of the main issues is a debate on non-linear low dose effects which are not well covered by current regulatory toxicology (EFSA, 2015).

The number of potentially migrating substances is estimated to be around ten times higher than the list of IAS mentioned earlier (Grob et al., 2006). These substances are reaction products such as oligomers and degradation products as well as impurities. These substances are usually referred to as NIAS. Many of these substances are unknown, let alone risk assessed and arguably pose the biggest risk for food safety. There have been several examples such substances being detected in food of which a selection shall be mentioned here.

At around the same time as the aforementioned formaldehyde, high levels of migrating **primary aromatic amines** (PAA) were discovered to migrate into food. These are impurities or degradation products from dyes used in colored plastic FCM, such as black nylon kitchen utensils (Mortensen et al., 2005). This problem was tackled in legislation together with formaldehyde (Commission Regulation (EU) No 284/2011).

**Mineral oil** became of major interest as a group of migrating substances a second time, many years after the batching oil problem had been solved for Europe. One of the main sources for the contamination was recycled paper and board, which is produced from newspapers, where mineral oil based printing inks are commonly used (Biedermann and Grob, 2010). Recycled paper and board, however, has been analysed in more detail, and 330 substances were detected that could be of concern (Chemisches et al., 2012). The estimation of potential concern was based on basic assumptions on the ratio of packaging to food weight and used standard cutoffs for substances used, based on EFSA guidelines. Interestingly, only two thirds of the substances could be identified by the authors. In fact for recycled paper and board it has been stated that a comprehensive safety assessment of all potentially migrating substances is not feasible (Biedermann and Grob, 2013). The most promising solution to this problem to date, seems to be the protection of food by applying a functional barrier. For packaging systems with an internal bag inside a box of recycled paper a method for testing and specifying the desired barrier properties has been proposed (Fiselier and Grob, 2012; Biedermann-Brem and Grob, 2014; Richter et al., 2014).

**Oligomers** of various plastics have also been seen to migrate into food. The short chain oligomers and low molecular weight cyclic oligomers may have toxicological properties that differ significantly from the monomers and are, therefore, not necessarily covered by restrictions on the monomers. For styrene this led to an **opinion** of the German Federal Institute for Risk Assessment (Bundesinstitut für Risikoforschung, BfR) stating health risks are unlikely. Oligomers of polyethylene terephthalate (PET) on the

**Figure 1** Bisphenol-A-diglycidyl ether (BADGE).

other hand are still poorly investigated with migration properties only recently becoming available for a wider range of oligomers (Hoppe et al., 2017). Polyolefin oligomers (polyolefin hydrocarbons, POH) constitute the highest amount of material migrating from such plastics (Biedermann-Brem et al., 2012). They are structurally similar to mineral oils and they may contain also cyclic and unsaturated substances (McCombie et al., 2016). A thorough risk assessment on these structures is not available at the time of writing, despite very high use of polyolefins as FCM. Finally, a cyclic oligomer from epoxy-based resins – the cyclic product of BPA and BADGE (cyclo-di-BADGE) – has been reported to be found to migrate up to a level of 1980 µg/kg. Though genotoxicity had been ruled out the level of migration requires more toxicological data (Biedermann et al., 2013).

The last example of an identified NIAS which may migrate into food is di-ethylhexyl maleate (DEHM). This substance is an impurity of di-ethylhexyl sulfosuccinate – an emulsifier in the varnish applied to cardboard boxes. The maximum level detected in food was 1.5 mg/kg and there was no data available on toxicology for these levels of resulting exposure (Fiselier et al., 2010).

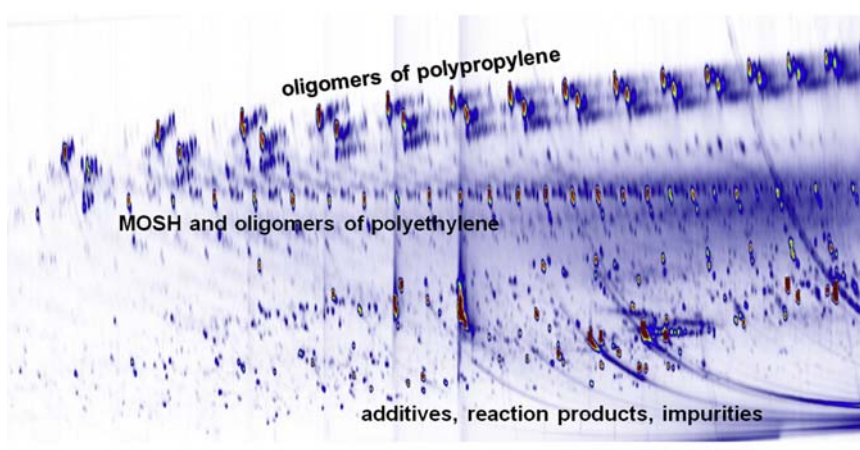

## Strategies for Finding Migrating Substances Including NIAS

Despite the aforementioned issues that were found for specifically regulated IAS, much of the focus in food science with respect to FCM deals with NIAS. These are regulated as a whole, by the requirement that they may not migrate into food at levels which could endanger human health (EU 1935/2004). The identification of NIAS that could lead to a contamination of food above a critical level presents a considerable challenge as was stated by a working group from the International Life Science Institute (ILSI) along with some ideas as to how to approach the issue (ILSI Packaging Materials Task Force, 2015). A review on strategies from 2013 may also give further insights to readers (Nerin et al., 2013; Humston-Fulmer and Binkley, 2017). Even with a focus on a subset of NIAS, such as oligomers, the challenge remains significant (Hoppe et al., 2016).

As the relevance of NIAS depends strongly on the quantity that may migrate into food, quantification is a central aspect to NIAS investigations. Commonly used detection techniques, such as electrospray mass spectrometry, are inherently difficult, as the detector response is substance dependent, ultimately making quantification of unknowns impossible (Pieke et al., 2017).

We believe the best solution to date is the use of the unsurpassed resolving power of comprehensive two dimensional gas chromatograph (GCxGC), which has been described before in the context of FCM (McCombie et al., 2016; Biedermann et al., 2014). The technology can be used with mass spectrometric detection (for identification, clues to substance structure) or with flame ionisation detection (FID). The later is unsurpassed for quantification of unknowns as the response is as close to substance independent, as is achievable. Fig. 2 shows the GCxGC chromatogram of an extract from a recycled polyolefin granulate, where each spot is a peak representing a substance. The resolving power and the richness of the data is immediately apparent. As a side effect, the exceptionally sharp peaks in GCxGC results in a sensitivity gain, compared to one dimensional GC. For the analysis of FCM we believe a column set with a polar column (50% phenyl and 50% methyl polysiloxane) in the first dimension and an apolar column (100% methyl polysiloxane) on the second dimension is particularly useful, as it permits group type separation of hydrocarbons, as marked in Fig. 2. Furthermore, the polar substances in the bottom section of the chromatogram elute with excellent peak shapes. As GCxGC is an untargeted approach IAS are also included in the analysis.

The assessment of risk associated with a given NIAS depends on the exposure and the toxicity of the substance. There are neither available data on the toxicity nor on the substance identity, for a given peak, for most NIAS. There are, however, scientifically recognised maximal exposure levels for substances with limited data, which are describe in a concept of Threshold of Toxicological Concern (EFSA Scientific Committee, 2012). The tolerable exposure threshold for genotoxic substances is at 0.0025 µg/kg b.w./day, which is 600 times lower than that of the so called Cramer III substances at 0.3 µg/kg b.w./day. In the absence of a structure it must be assumed that a NIAS is genotoxic, as its genotoxic potential cannot be assessed.

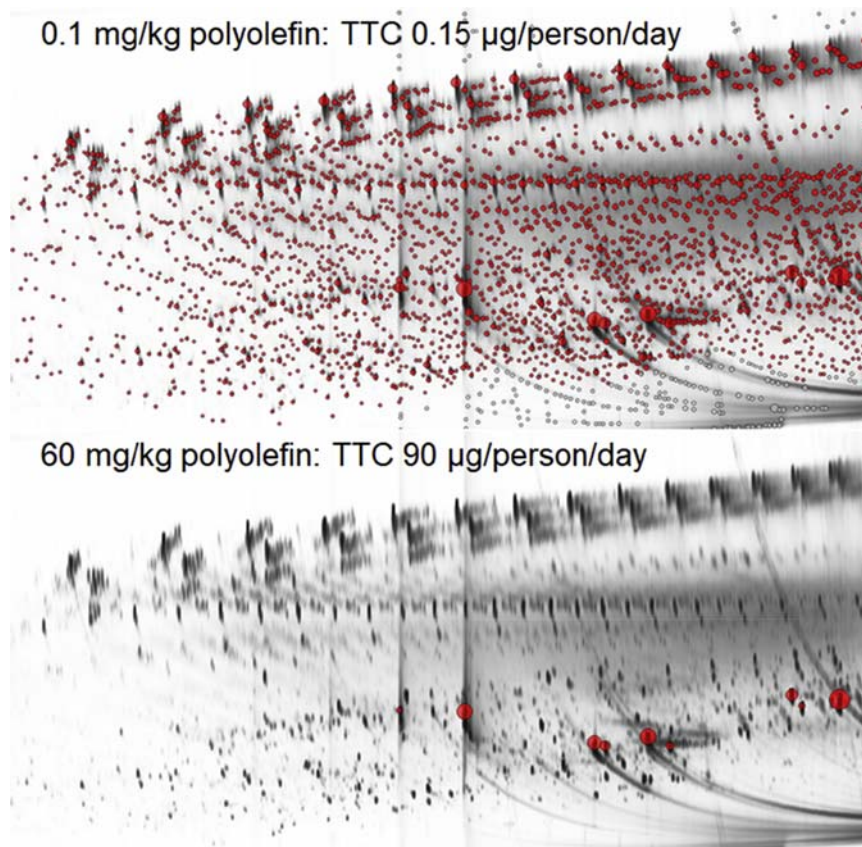

**Figure 2** GCxGC chromatogram of an extract from a recycled polyolefin.

Making some basic assumptions on the quantity of consumed food packed in the FCM of interest (150 g/day) and the amount of food in contact with the FCM (1 kg food in contact with 10 g plastic), a body weight of 60 kg and a transfer of 100% allows the picking of peaks of interest in an extract, such as the one presented in Fig. 2. The threshold can be set by adding appropriate amounts of internal standard. The results of the picking of the peaks of interest is given in Fig. 3; in the top panel the threshold has been set for genotoxic (or potentially genotoxic) substances, while it was set for Cramer III substances in the bottom panel. Note that such an estimate of peaks of interest is only valid, if the detector response shows minimal differences between analytes, as is the case for FID. In order for an in-depth risk assessment to be able to focus on the abundant substances (peaks highlighted in red in the bottom panel), genotoxicity must be ruled out for all of the peaks marked in red in the top panel. To achieve this, the minimal work would be to identify the low intensity peaks (highlighted in red in the top panel) and to perform an in-silico analysis to determine genotoxic potential. In some cases it might also be appropriate to sum up the signals from a group of substances, which are expected to act similarly on an organism such as the oligomers. Please note that the assessment of relevant peaks was performed on an extract. This has the disadvantage of one having to make certain assumptions such as 100% transfer or a the weight ratio packaging/food. However, it also has advantages such as increased sensitivity (more reliable threshold) and circumvention of polar food simulants, which are unsuitable for GC analysis. Although the assessment aspect of migrating substances is not covered by this review it should be mentioned that the strategy outlined above does not cover the full assessment currently discussed by EFSA for the approval of new IAS (EFSA, 2016).

A drawback of GCxGC is the limited range of molecular mass and polarity, which GC analysis can cover. Though the latter may be addressed by derivatisation such as acetylation or silylation. Nevertheless, complementary analytical techniques such as LC-MS are still needed for a full coverage of NIAS. The extent of the coverage of an extract can be estimated by size exclusion chromatography and evaporative light-scattering detection. The coverage of components < 1000 da (considered toxicologically relevant) in GCxGC may vary depending on the material under investigation.

In the future, it may also be possible to determine the genotoxicity of an entire mixture using a bioassay (Koster et al., 2012). There are however to date some issues with using in-vitro genotoxicity tests for mixtures and how they relate to accepted OECD tests for single substances. In particular, there are open questions on the sensitivity of such tests.

**Figure 3** The chromatogram from Fig. 2 with peaks highlighted in red which are relevant for potential migration. In one case genotoxicity is assumed for all substances (top) in the other for none (bottom).

## Conclusions

As it is not feasible to comprehensively cover the issue of migration from food packaging, this chapter is intended to highlight the underestimated issue and give the reader an idea of the scope and challenges of the field. There are thousands of unidentified or toxicologically uncharacterised, chemicals which may migrate into food from food contact materials. The levels of migration often exceed those which would required investigation according to modern scientific cutoff criteria. The examples in this review demonstrate that there have been various issues, which may very well only be the tip of the iceberg.

There is a need for more research in the area. A combination of analytical tools is required to investigate migration. To date one of the most powerful techniques is GCxGC with a resolving power to separate thousands of substances in a single run and can be combined with a variety of detectors including FID, which has a nearly substance independent detector response.

### Glossary

**BMDL10 (BenchMark Dose Level)** Study endpoint that is associated with a 10% extra risk of an adverse effect in exposed test animals, as compared to the background levels of risk.

**EPA PAHs** The United States Environmental Protection Agency has classified 16 of the PAHs as priority-pollutants based on toxicity, potential for human exposure, frequency of occurrence at hazardous waste sites, and the extent of information available. Of these PAHs US EPA considers seven (benzo(a)anthracene, chrysene, benzo(a)pyrene, benzo(b)fluoranthene, benzo(k)fluoranthene, dibenz(a,h)anthracene, and indeno(1,2,3-cd)pyrene) as probable human carcinogens.

**JECFA** The Joint FAO/WHO Expert Committee on Food Additives (JECFA) is an international scientific expert committee that is administered jointly by the Food and Agriculture Organization of the United Nations and the World Health Organization. It has been meeting since 1956, initially to evaluate the safety of food additives. Its work now also includes the evaluation of contaminants, naturally occurring toxicants and residues of veterinary drugs in food.

**Maillard reaction** Heat induced reaction of reducing sugars with amino acids. Complex reaction from which aroma active substances and melanoidins originate.

**MOE (Margin Of Exposure)** The MOE is a ratio of two factors which assesses for a given population: the dose at which a small but measurable adverse effect is first observed and the level of exposure to the substance considered.

**Solid Phase Extraction (SPE)** Sample preparation method by which compounds that are dissolved in a liquid are separated from other compounds according to their physical and chemical properties. This is used to concentrate and purify samples for analysis. It can be used to remove the matrix from the samples (e.g. blood, urine, foods, soil) to eliminate interferences during chromatographic analysis.

**TAMDI (Theoretical Maximum Daily Intake)** Predicted maximum daily intake of a residue (mg per person per day), assuming that it is present at the maximum residue level and that average daily consumption of foods per person is represented by assessed regional diets.

### Nomenclature

List of nomenclature used including all definitions and units.

**AαC** 2-Amino-9H-dipyrido[2,3-b]indole

**Glu-P-1** 2-Amino-6-methyl-dipyrido[1,2-a:3',2'-d]imidazole

**Glu-P-2** 2-Amino-dipyrido[1,2-a:3',2'-d]imidazole

**IQ** 2-Amino-3-methylimidazo[4,5-f]quinoline

**MeAαC** 2-Amino-3-methyl-9H-dipyrido[2,3-b]indole

**MeIQ** 2-Amino-3,4-dimethylimidazo[4,5-f]quinoline

**MeIQx** 2-Amino-3,8-dimethylimidazo[4,5-f]quinoxaline

**PhIP** 2-Amino-1-methyl-6-phenylimidazo[4,5-b]pyridine

**Trp-P-1** 3-Amino-1,4-dimethyl-5H-pyrido[4,3-b]indole

**Trp-P-2** 3-Amino-1-methyl-5H-pyrido[4,3-b]indole

**TDI** Tolerable Daily Intake (mass kg<sup>-1</sup> bw day<sup>-1</sup>)

### Introduction

Heat treatment of foods is a key operation in the industry resulting in the development of a large range of flavors and tastes through the Maillard Reaction (MR). Besides reducing or even eliminating biological contamination the heat treatment results in modifications for improving the texture and aroma. The major concern arising from heating processes comes from the formation of compounds that are not naturally present in foods but may develop during heating or preservation processes and may reveal harmful effects such as mutagenic, carcinogenic and cytotoxic effects (Neo Formed Contaminants, NFC). In parallel to the aroma formation harmful substances can be formed. Some selected groups are discussed in this chapter; namely, the heterocyclic

aromatic amines, furan derivatives, acrylamide, polycyclic aromatic hydrocarbons (PAHs), monochloropropanediols (MCPD). The concentrations in the foods are normally low and even conditions favoring the formation of these compounds do not lead to acute toxicity but prolonged exposure could increase the risk of cancer of different organs. (Fig. 1)

In the following paragraphs we will give a brief discussion about those compounds considering important issues such as their occurrence, mechanisms of formation and techniques of mitigation, toxicology and exposure.

## Heterocyclic Amines

This group of compounds was first identified by the group of Sugimura at the National Cancer Center Research Institute in Japan in the 1970's. They are formed during intensive heating of protein rich foods as pyrolysates from amino acids or as part of the Maillard reaction from carbohydrates, amino acids, and creatine. Of the currently 30 compounds described up to date only 10 are known to be carcinogenic in rodents.

## Quantification in Foods

The current analytical method of choice is liquid chromatography with mass selective detection. Although it is possible to use UV detection the sensitivity is low and the selectivity very limited to obtain accurate results. The sensitivity and selectivity of triple quadrupole MS is sufficient for good accuracy. Some of the less polar substances (PhIP, A $\alpha$ C, MeA $\alpha$ C, Trp-P-1, Trp-P-2, Glu-P-1, Glu-P-2) can be determined by its fluorescence which is sufficiently sensitive. In any case the clean-up using a liquid extraction with ethyl acetate and subsequent solid phase extraction (SPE) with cation exchange materials is necessary. The complex matrix of intensively heated meat and the extremely low concentrations are a challenge for the analytical chemist. A very specific SPE material – copper phthalocyanin – was used for selective enrichment of the HCAs in a series of matrices (e.g. meat, air, river water) – but was not commercially available.

## Occurrence in Foods

The concentrations found in heated meat or fish are in the low ppb range (0–10 ng g<sup>-1</sup>). Intensive heat treatment results in significantly higher concentrations. Normally, PhIP is the compound occurring at higher concentrations with values of up to 480 ng g<sup>-1</sup> in e.g. barbecued chicken breast.

## Chloropropanediols, Glycidol and Esters

3-MCPD was first identified by the group of Velisek in Prague/CZ who showed that it is formed during manufacturing of acid-hydrolyzed vegetable protein. This hydrolysate can be used for production of soy sauce. 3-MCPD has been reported to be nephrotoxic as well as toxic to reproduction. In addition, there are some reports on its potential carcinogenicity. Inconsistent toxicological data are published with a clear genotoxic potential *in vitro* shown in experiments using *Salmonella typhimurium* TA100 (with and without T9 mix, indicating base-pair substitution) and no genotoxicity in TA98 (indicating frameshift mutations) using similar conditions; no genotoxicity was determined *in vivo*.

**Figure 1** Structures and commonly used abbreviations of the carcinogenic heterocyclic amines.

The IARC classified 3-MCPD as potentially carcinogenic to humans (group 2B). The TDI of this non-genotoxic carcinogen was set to  $2 \mu\text{g kg}^{-1} \text{ bw}$ . The fatty acid esters of 3-MCPD and glycidol have the same toxicity as the non-conjugated glycerol derivatives since they are hydrolyzed completely during digestion.

### Analytical Considerations

3-MCPD is commonly analyzed after derivatization with phenylboronic acid forming dioxoboranes by GC-MS. Other derivatization agents (e.g. acetone, heptafluorobutyl imidazole) are also possible resulting in a better column life but with lower sensitivity. For the determination of esters direct or indirect (i.e. after release from the esters) methods have been applied. For the direct analysis LC-MS methods were developed which show the heterogeneity of the reaction products.

### Formation and Occurrence in Foods

The formation of chloropropanols from lipids involves a nucleophilic attack by a chloride ion on the least sterically hindered carbon of the glycerol moiety. As the free alcohol in e.g. diacylglycerols is not a good leaving group for this nucleophilic attack the most probable mechanism might be via an intermediary formed epoxide or a cyclic acyloxonium ion with which the chloride is reacting. A direct nucleophilic substitution of the ester is also possible.

Glycidyl esters are formed during refining of vegetable oils containing high amounts of diacylglycerols or monoacylglycerols. The formation of the glycidylesters is independent from the formation of the MCPD esters.

The mean daily exposure for the younger age groups was for 3-MCPD  $0.5\text{--}1.5 \mu\text{g kg}^{-1} \text{ bw}$ , for 2-MCPD  $0.2\text{--}0.7 \mu\text{g kg}^{-1} \text{ bw}$  and for glycidol  $0.3\text{--}0.9 \mu\text{g kg}^{-1} \text{ bw}$ . The daily exposure for the adult and older population ranged from  $0.2\text{--}0.7 \mu\text{g kg}^{-1} \text{ bw}$  (3-MCPD),  $0.1\text{--}0.3 \mu\text{g kg}^{-1} \text{ bw}$  (2-MCPD), and  $0.1\text{--}0.5 \mu\text{g kg}^{-1} \text{ bw}$  (glycidol).

A survey of the data shows that the highest concentrations including the esters were found in palm oil with a mean of  $2900 \mu\text{g kg}^{-1}$  for 3-MCPD,  $1600 \mu\text{g kg}^{-1}$  for 2-MCPD and  $4000 \mu\text{g kg}^{-1}$  for glycidol. Other oils than palm oil contains significantly lower amounts. Margarine contains  $670 \mu\text{g kg}^{-1}$  3-MCPD,  $240 \mu\text{g kg}^{-1}$  2-MCPD and  $580 \mu\text{g kg}^{-1}$  glycidol. Other food groups that are highly contaminated are potato crisps, hot surface cooked pastries, cookies and short crusts.

3-MCPD is formed from lipids and chloride ions during heat processing of foods. The highest concentrations are found in systems containing lecithin. The main occurrence of 3-MCPD in foods is in soy sauce produced by acid hydrolysis. For this, defatted soy beans and other proteins from cereals are treated with 4–9 M hydrochloric acid at  $103\text{--}110^\circ\text{C}$  for 20–35 h.

### Furan

Furan ( $\text{C}_4\text{H}_4\text{O}$ ) is a small organic compound with high volatility (boiling point:  $31^\circ\text{C}$ ) and lipophilicity. The presence of furan in a broad range of heat processed foods ( $0\text{--}6000 \text{ mg kg}^{-1}$ ) has received considerable since it is considered as a “possible carcinogenic compound to humans”. Multiple pathways are involved in furan formation in foods. The thermal degradation and rearrangement of sugars and amino acids, as well as the thermo-oxidation of polyunsaturated fatty acids and ascorbic acid, have been proposed as the mechanisms responsible for its generation in foods. Despite its high volatility, furan has also been found in low-moisture foods processed in open containers, such as potato chips, crackers, crisp breads, and toasted breads. A better understanding about the effect of processing conditions over furan generation in heat processed foods is necessary to develop effective mitigation technologies. Since high levels of furan were detected in tomato sauces, fruit juices, and baby foods, most research has been focused to improve the understanding about its formation in these types of food matrixes. Furan levels in food are reported to range from a few  $\mu\text{g kg}^{-1}$  to  $7000 \mu\text{g kg}^{-1}$ . The highest furan concentrations were found in roasted and instant coffee, followed by baby foods and soups which showed maximum concentrations slightly higher than  $200 \mu\text{g kg}^{-1}$ . Foods less subjected to heat processing conditions, such as milk or fruit juice, are the less contaminated items. In this sense it was reported that furan was present in a number of foods, with the highest levels being found in coffee. Just recently, the US Food and Drug Administration (US FDA) published a report on the occurrence of furan in a number of foods that undergo thermal treatment, especially canned and jarred foods. Furan levels of over  $100 \text{ mg kg}^{-1}$  were found principally in three categories of major foods; coffee, baby food, and sauces and soups; all of them sold in hermetically sealed packages that do not allow the evaporation of furan. Baby food was of particular interest as a high proportion of samples sold in jars and cans contained furan and such foods may form the sole diet of many babies. The estimated intake based on consumption of baby food from glass jars was  $< 0.2$  to  $26 \text{ mg furan per day}$  or  $< 0.03$  to  $3.5 \text{ mg kg}^{-1} \text{ bw per day}$  for a 6 month old baby weighing 7.5 kg. The daily intake for adults from canned or jarred vegetables was estimated to be 1.1 to 23 mg, and from beer was 1.3 to 50 mg. The daily intake from coffee based was 2.4 to 120 mg, making coffee the major dietary source for adults.

Furan has been considered as a possible carcinogen to humans (2B) by the International Agency for Research on Cancer (IARC). The liver is the main target organ of furan-induced toxicity in rats and mice with a clear dose-dependency and probably acting by a genotoxic mechanism. Studies performed by the JECFA have revealed the comparatively small margin of exposure (MOEs of 960 and 480 for average ( $0.001 \text{ mg kg}^{-1} \text{ bw per day}$ ) and high ( $0.002 \text{ mg kg}^{-1} \text{ bw per day}$ ) dietary furan exposures) between human exposure and the furan doses which induce liver tumor in experimental animals. Since a genotoxic mode of action could be associated with furan-induced tumor formation, current human exposure levels to this contaminant may indicate a risk to human

health and the necessity for its mitigation. Previous information clearly shows that furan exposure could represent a critical public health risk, specifically in infants since furan is a carcinogenic compound that might act via a DNA-reactive genotoxic metabolite. Moreover, the mechanism of furan induced carcinogenicity in rodents as well as the levels and effect of furan on humans has not yet been clarified. Furan was found to induce hepatocellular adenomas and carcinomas in rats and mice, and high incidence of cholangiocarcinomas in rats at doses higher than of  $2 \text{ mg kg}^{-1} \text{ bw}$ . Due to limited relevant experience with regard to toxic effects associated with neither human exposure nor epidemiology a final conclusion concerning genotoxic or mutagenic activity of this molecule has not been drawn yet.

### Furfuryl Alcohol

The identification of a new mechanism of activation of vinyllogous alcohols by sulphotransferases has raised concerns about the presence of compounds like furfuryl alcohol (FA) in foods. FA occurs in high amounts in a limited number of foods and even if the mutagenic/carcinogenic activity is low, there might be a risk due to the high exposure. FA is formed by heating of carbohydrate rich foods; the concentrations of FA can reach several hundred  $\text{mg g}^{-1}$ . Although FA can polymerize in acid media the concentration of the monomer is still high in heated foods; especially in roasted coffee. FA gives a burnt, cooked sugar and rubber like odor; when FA interacts with dihydroxy benzene or trihydroxy benzene as it is occurring during roasting of coffee it will produce a bitter taste. However, FA is used as a flavoring agent with an acceptable daily intake of up to  $0.5 \text{ mg kg}^{-1} \text{ bw}$ .

FA can be formatted from degradation of reducing sugars. In this sense, glucose or fructose can undergo isomerization reactions at high temperatures. The key intermediate in this isomerization reaction, 1,2-enediol, is also considered as the starting intermediate in the degradation reactions by  $\beta$ -elimination producing an unstable compound 3-deoxyaldoketose which then undergoes a cleavage reaction producing formic acid and a  $\text{C}_5$ -compound. The  $\text{C}_5$ -compound (2-deoxypentose) will react further by cyclization and aromatization forming FA. FA as a furan derivative is occurs mainly in roasted coffee. Though the polymerization and evaporation proceeds during the roasting of coffee the concentration of the monomeric FA is still high in the finished products. The concentration of FA is  $267 \text{ mg g}^{-1}$  in instant coffee and in  $564 \text{ mg g}^{-1}$  coffee roasted at  $210^\circ\text{C}$  for 3 min. Additionally, FA is also found in rice cakes ( $2\text{--}2.3 \text{ mg g}^{-1}$ ), bread  $190 \text{ mg g}^{-1}$ , honey  $1.6 \text{ mg g}^{-1}$ , toasted almonds ( $6.0 \text{ mg g}^{-1}$ ), non-fat dried milk stored for 3 months at room temperature  $15 \text{ mg g}^{-1}$ , popcorn ( $0.038\text{--}0.082 \text{ mg g}^{-1}$ ), corn tortilla chips ( $0.54 \text{ mg g}^{-1}$ ), roasted cocoa powder ( $0.021 \text{ mg g}^{-1}$ ), among others.

The estimated daily FA intake is  $130 \text{ mg kg}^{-1} \text{ bw}$  with a margin of safety of  $462 \text{ mg kg}^{-1}$ . FA is mutagenic to *S. typhimurium* strain TA 100 engineered for the expression of human SULT1A1. The mutagenicity of FA is dose dependent and increases its mutagenicity when the amount of FA increases. In mice which received FA with the drinking water the DNA samples of liver, kidney and lung contain DNA adducts. In rodents which were exposed to FA tumors that contained the 2-methylfurfuryl adduct were formed but at lower concentration exposure ( $0.06 \text{ mg kg}^{-1} \text{ bw}$  and day) no tumors were formed. Although the acute toxicity of FA is not relevant in the foods they could be activated with sulphotransferases to highly reactive compounds which are then mutagenic/carcinogenic whose detailed risk is not yet known and additional work is pending.

### Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) are a group of diverse organic compounds chemically recognized with two or more aromatic rings in their structure. PAHs generally occur in complex mixtures, which may consist of hundreds of compounds. For most of the PAHs their carcinogenic and genotoxic potential constitute the critical factor for the hazard and risk characterizations.

#### Human Exposure

The major exposure for non-smokers is from foods; for smokers the contribution from smoking can be significant. Food can be contaminated from environmental sources (air, soil, water), industrial food processing, and some domestic cooking practices.

#### The PAHs List of Interest

In 1970, a set of 16 PAHs which are frequently found in environmental samples has been proposed by the U.S. Environmental Protection Agency (EPA) to be monitored. There were acenaphthene, acenaphthylene, anthracene, fluoranthene, fluorene, naphthalene, phenanthrene, pyrene, benz[a]anthracene, benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[ghi]perylene, benzo[a]pyrene, chrysene, dibenz[a,h]anthracene, and indeno[1,2,3-cd]pyrene. In the EU, the Scientific Committee on Food (SCF) assessed the toxicity of PAHs in 2002. The SCF prioritized compounds based on the health risk rather than on occurrence in food and recommended the monitoring of 15 PAHs, including 8 high molecular weight PAHs that are also part of the U.S. EPA list. As the most suitable indicators of occurrence of PAHs in food, eight compounds (PAHs8), namely benz[a]anthracene, benzo[b]fluoranthene, benzo[k]fluoranthene, benzo[ghi]perylene, benzo[a]pyrene, chrysene, dibenz[a,h]anthracene, and indeno[1,2,3-cd]pyrene were selected. Benzo[a]pyrene was suggested as a marker of occurrence of carcinogenic PAHs in food.

The IARC has identified 12 PAHs of the EU list as carcinogenic to humans (group 1), and probable (group 2A) or possible (group 2B) human carcinogens. Other PAHs not defined as carcinogens may act as synergists.

### Legislation on PAHs in Food

The most comprehensive regulations are given in the European Union for different food categories in which higher levels of PAHs could be expected. Maximum limits are set for a group of four PAHs including benzo[a]pyrene by the Regulation (EU) No 835/2011.

### Determination of PAHs

In the literature a number of in-house validated methods are reported, although there is still a lack of standardized methods for the analysis of PAHs. Because the concentrations of PAHs in food are very low, generally in the range of ppb units, the methods usually consist of several extraction and sample purification steps to reach the low detection limits. The two main instrumental analysis techniques for determination of PAHs in food are an HPLC with selective and sensitive fluorescence detection and a gas chromatography with single quadrupole (MS), tandem mass spectrometry (MS/MS), and high resolution mass spectrometry, respectively.

### Occurrence of PAHs in Food

Data from surveys indicate that the most frequently present PAHs in foodstuffs are the low molecular weight PAHs from the EPA list (particularly those of two or three benzene rings). These PAHs are less relevant from the toxicological point of view and do not contribute to the genotoxic and carcinogenic potential of PAHs. Food can be contaminated by PAHs that are present in air, soil, or water, or during food processing and cooking. The levels of PAHs found in unprocessed foods in rural areas reflect the background contamination that could originate from long distance airborne transportation of contaminated particles.

Processed foods are contaminated by PAHs during drying (seeds and kernels producing oils), smoking (meat, fish and dairy products) and cooking of food at high temperatures (grilling, frying, roasting, baking), and certain preservation techniques (milk).

With respect to food groups, the highest levels of total PAHs were detected in meat and meat products ( $26 \mu\text{g kg}^{-1}$ ), oils and fats ( $23 \mu\text{g kg}^{-1}$ ) and cereals ( $20 \mu\text{g kg}^{-1}$ ). The highest individual PAHs levels corresponded to phenanthrene ( $27 \mu\text{g kg}^{-1}$ ), naphthalene ( $26 \mu\text{g kg}^{-1}$ ), and fluoranthene ( $14 \mu\text{g kg}^{-1}$ ), while the lowest levels were reported for benzo[a]pyrene ( $1.3 \mu\text{g kg}^{-1}$ ) and benzo[k]fluoranthene ( $1.3 \mu\text{g kg}^{-1}$ ). Based on available data, food consumption was shown to be the main source of PAHs intake and thus highlighted the importance of research on PAHs in food and the development of mitigation strategies to reduce their contents in food.

### Acrylamide

Acrylamide (AA) is a hazardous contaminant classified as 'probably carcinogenic' for humans and recognized as a genotoxic carcinogen in laboratory animals. Evidence from animal studies shows that acrylamide and its metabolite glycidamide are genotoxic and carcinogenic. In 2015, the European Food Safety Authority (EFSA) confirmed that acrylamide in food potentially increases the risk of developing cancer for consumers in all age groups.

### Analytical Considerations

In complex matrices it can be determined after extraction procedures to water or other polar organic solvents by analytical methods using GC/MS after bromination. If derivatization is not used, the extract clean-up is more demanding. LC/MS analysis has the advantage that the LC technique in reversed-phase mode is directly compatible with an aqueous solvent that is best suited for extraction of acrylamide from foods. For this reason, most survey data for acrylamide have been obtained using LC-MS/MS analysis.

### Occurrence of Acrylamide in Food

The presence of acrylamide in foods is supposed not to be from external sources (environment, packaging materials), but as a consequence of natural processes via the Maillard reaction during heat treatment. It is predominantly formed from asparagine in the presence of reducing sugars in certain foods when exposed to temperatures higher than  $120^\circ\text{C}$  at low moisture conditions (baking, frying, grilling, roasting, toasting). Raw materials which contain the abovementioned precursors in significant levels are cereals, potatoes, green coffee and various kinds of vegetables and fruits. Foodstuffs prepared from these raw materials by thermal processing are suspicious of high acrylamide content, independent on commercial or home preparation.

According to the data collected and published by the EFSA in 2015, acrylamide was detected in following food categories in average content: coffee ( $520 \mu\text{g kg}^{-1}$ ) and coffee substitutes ( $1500 \mu\text{g kg}^{-1}$ ), potato crisps and snacks ( $390 \mu\text{g kg}^{-1}$ ) and potato fried products ( $310 \mu\text{g kg}^{-1}$ ), biscuits, crackers and crisp bread ( $270 \mu\text{g kg}^{-1}$ ), breakfast cereals ( $160 \mu\text{g kg}^{-1}$ ), other products based on potatoes, cereals and cocoa ( $97 \mu\text{g kg}^{-1}$ ), cereal baby foods ( $73 \mu\text{g kg}^{-1}$ ), soft bread ( $42 \mu\text{g kg}^{-1}$ ), baby foods other than cereal

(24  $\mu\text{g kg}^{-1}$ ). Among other products the extraordinary high are vegetable crisps (1900  $\mu\text{g kg}^{-1}$ ). The distribution of acrylamide levels in particular food categories is summarized in the scientific opinion of the EFSA.

### Mitigation Efforts and Tools

The effort to minimize acrylamide content in frequently consumed foods has been transformed into the recently approved Commission Regulation 2017/2158 establishing mitigation measures and benchmark levels for the reduction of the presence of acrylamide in food which shall apply from 11 April 2018. When the benchmark levels set to the particular food category are exceeded, a food business operator (FBO) is obliged to review the mitigation measures applied and adjust processes and controls with the aim to achieve levels of acrylamide as low as reasonably achievable below the benchmark levels. Industry guidance has been developed by various food sectors at national and EU levels, e.g. The Acrylamide Toolbox by Food Drink Europe and the Guidance for Industry by the Food and Drug Administration (US FDA). Among proposed most relevant intervention steps are storage and selection of raw material with low level of precursors, adjustment of heat transfer, application of additives preventing acrylamide formation, enzymatic treatment with asparaginase in order to eliminate asparagine.

### Exposure Level and Risk

The estimates of daily acrylamide intake range from 0.4 to 1.9  $\mu\text{g kg}^{-1}$  bw for the mean exposure, and from 0.6 to 3.4  $\mu\text{g kg}^{-1}$  bw for 95th percentile exposure across surveys and age groups. Children are the most exposed age group on a body weight basis. Acrylamide is metabolized in the body to glycidamide. Both are conjugated with urinary mercapturic acid, forming adducts with hemoglobin as well as DNA. They can be used as biomarkers for measuring the exposure to acrylamide. In epidemiological studies AA intake was not associated with an increased risk of most common cancers, but the evidence is limited and inconsistent.

### Conclusions

Food processing results in chemical changes that are not always favorable. A change of the texture and the formation of aroma, the elimination of harmful or spoiling bacteria are accompanied by the formation of possibly harmful compounds. The concentrations found in foods are normally low and with limited relevance. However, when specific foods are consumed to excess or the heat treatment is too intensive the cancer risk can increase. Some of the compounds discussed in this chapter are known to be extremely carcinogenic. Careful cooking and limited uptake of potentially contaminated foods reduce the risk significantly.

## Introduction

### What Is an Allergy

Our immune system has the essential function to protect us from “invaders” like bacteria or viruses. This is done by ingesting the invader by a mast cell and presenting parts of it on its surface, which triggers the formation of antibodies that specifically recognize the invader. If, at a later time, the same bacterium or virus invades again, antibodies are already there to participate in the elimination of the foreign agent. In some cases, the immune system, by a mechanism not well understood, mistakes certain proteins, including those from food, as “invaders” and triggers an immune response. These events are known as food allergic reactions. An allergic episode can involve one or several body systems, i.e., respiratory, cutaneous, circulatory and digestive. Sensitivity to food proteins and the characteristics of the reactions vary among allergic individuals, and also between episodes. The exposure to food allergens can trigger symptoms ranging from mild to severe, and even fatal.

### Who Is Affected

While the total number of food-allergic individuals globally are estimated to range between 1%–10% (Chafen et al., 2010), the number of indirectly affected persons is significantly higher. This can be easily demonstrated with the following example:

- Thomas is a 10-year-old boy and suffers from an allergy to milk. Who is affected?
- Thomas parents need to ensure that he does not consume milk-containing products.
- Thomas grandparents, uncles and aunts also need to ensure that when Thomas is around, no food containing milk proteins is served to him.
- Thomas goes to school with lunch-time catering. Therefore, the caterers need to be aware not to serve milk-containing products to him. This includes products where milk is not an obvious ingredient. Example is a potato mash, which can be made with milk or cream for smoothness.
- Thomas also plays soccer and the team goes to lunch and celebrations following their matches. The trainer needs to ensure that Thomas does not consume milk proteins in those places.
- When Thomas is invited to birthday parties, the friends’ parents also need to ensure that Thomas does not consume milk-containing products during the party.

This example demonstrates that while the number of directly affected people with food allergies may seem small, the number of indirectly affected people is significantly larger.

### What Is the Difference Between an Allergy and Gluten Intolerance

Food allergies and intolerance to gluten (celiac disease) are often mixed and used interchangeably, even sometimes by experts. This is not very surprising since gluten-containing cereals can trigger both, allergies and intolerances. Celiac disease is estimated to be around 1% in developed countries, although this figure is thought to be significantly higher due to the fact that only a fraction of affected individuals is diagnosed (Catassi and Fasano, 2008). Although there are many unknowns about the mechanisms of food allergies and celiac disease, it is known that food allergy is a hypersensitivity mediated by IgE (humoral component) while celiac disease has a more cellular basis, and it is not only limited to the digestive system.

### Allergenic Foods: Food Ingredients and Food Contaminants

Foods, that cause allergic reactions in a small percentage of the population, are healthy for the majority. The main risk for allergic individuals happens when they are inadvertently exposed to the allergenic source. For example, if allergens are not listed as ingredient on a product label (due to omission) or because the food allergen is present in the final product due to cross-contamination. If allergenic foods can be food contaminants, what is the difference between them and contaminant-only compounds like pesticides and mycotoxins? The primary difference is the acute effect of food allergens after consumption by sensitive individuals. While a dose of pesticide residues or mycotoxins which slightly exceeds the legal limit is unlikely to cause substantial, short term health effects for those consuming it, this is significantly different for food allergens. In many cases, small amounts of food allergens can trigger severe and sometimes life-threatening effects in question of seconds. The onset of the reaction usually occurs within 30 minutes after exposure to the offending food. The most sensitive allergic individuals may suffer anaphylactic shock, that may lead to death, if not treated immediately (for instance, with an epi-pen as first aid). Many examples are not described only in the scientific literature, but they also make headlines in the press. A recent example is the case of an allergic person dying from consumption of a dish in an Indian restaurant containing peanuts (Withnall, 2017). Another issue specific to food allergens is the adventitious contamination and carry-over during production. This happens for example when different foods are produced on the same production

line, and the first one contains food allergens as part of the recipe, while the second, produced on the same line and after cleaning, does not. Remains in pipes, mixers or conveyer belts from the first production can inadvertently contaminate the second product where no food allergen is part of the recipe and therefore is not labelled. Other examples are the carry-over of particles in a factory through air-flow from one production lines containing allergens as part of the recipe to another which does not. The possibility of carry-over and adventitious contamination has led to a proliferation of the so-called “precautionary allergen labeling” (PAL, also known as “May contain” labelling). This is discussed in more detail at a later point.

## Regulations

This section describes the different existing regulation of selected countries and regions. It is not to be considered as exhaustive list since many countries follow [Codex Stan 1-1985](#) (REV 2010) and it can reasonably be assumed that more countries will follow. As it can be seen by Europe and Canada, some countries add additional allergens to the list of those required to be labelled on pre-packaged foods. All the rules require the labeling of certain food allergens when used as food ingredients.

### Europe

Europe has one the most extensive lists of food allergens requiring labelling, if one excludes the voluntary items on the Japanese food allergen labelling list below. How did Europe get to this list and what were the regulatory developments from when food allergens initially entered the regulatory arena? Europe is the region which has most likely seen the largest number of changes to allergen labelling between its first introduction and the current regulations, forcing food industry and consumers to constantly catch up with the changes ([Popping and Diaz-Amigo, 2018](#)).

Let’s take a step back to when the first attempts of harmonizing food labelling were made back in 1979: The [79/112/EEC](#) was a general directive on how food sold to the final consumer had to be labelled. Neither allergens nor gluten were mentioned in this directive. This directive experienced a major overhaul in 2000 by the enactment of the [Directive 2000/13/EC](#), and still, there was no mention of food allergens or gluten. Two years later, the so-called Food Safety Regulation was introduced. The [178/2002/EC](#) was a regulatory milestone, and article 14 stated clearly:

#### Article 14

Food safety requirements

1. Food shall not be placed on the market if it is unsafe.
2. Food shall be deemed to be unsafe if it is considered to be:
  - (a) injurious to health;
  - (b) unfit for human consumption.

While one may think that this automatically triggers labelling of food allergens, this was not the case. Regulators had the average, healthy, European consumer in mind and tried to protect from food fraud or tainted foods.

A year later, European manufacturers and consumers woke up to the first allergen labelling requirement: the European Commission published an amendment to the general food labeling [Directive \(2000/13/EC\)](#): the [Directive 2003/89/EC](#) became the “Allergen Labeling Directive”. The European Commission explained in the “whereas” to this Directive that the objective was aimed to “achieve a high level of health protection for consumers and to guarantee their right to information”. In annex IIIa, allergens and substances of intolerance that now required labeling were listed. It is important to notice here that this Directive applies to food ingredients. This 12-strong group contained:

- Cereals containing gluten (i.e., wheat, rye, barley, oats, spelt, kamut, or their hybridized strains) and products thereof;
- Crustaceans and products thereof;
- Eggs and products thereof;
- Fish and products thereof;
- Peanuts and products thereof;
- Soybeans and products thereof;
- Milk and products thereof (including lactose);
- Nuts, i.e., almond (*Amygdalus communis* L.), hazelnut (*Corylus avellana*), walnut (*Juglans regia*), cashew (*Anacardium occidentale*), pecan nut [*Carya illinoensis* (Wangenh.) K. Koch], Brazil nut (*Bertholletia excelsa*), pistachio nut (*Pistacia vera*), and macadamia nut and Queensland nut (*Macadamia ternifolia*), and products thereof;
- Celery and products thereof;
- Mustard and products thereof;
- Sesame seeds and products thereof; and
- Sulfur dioxide and sulfites at concentrations of more than 10 mg/kg or 10 mg/L expressed as SO<sub>2</sub>.

While there are twelve groups listed for labelling, from the analytical perspective, these were significantly more as each of the cereals, each of the fish species, the different mustards (yellow, brown, black) and each of the nuts need to be detected.

Another remarkable issue was that this Directive did not list any exemptions, but rather included all “products thereof”. This means that under this Directive, even highly refined oils and even pure vitamins derived from these plants require labeling, although the allergen triggering proteins are no longer present.

The suppliers of raw materials and food ingredients launched an initiative to remedy this situation. They argued that the labeling of highly refined products would be unnecessary and detrimental to the quality of life of allergy sufferers as it further limits their already small list of safe products to select from.

The European Commission followed their argumentation and issued a temporary exemption list through yet another amendment of the [Directive 2000/13/EC](#) (and indirectly also to the [Directive, 2003/89/EC](#)). The exemptions in the [Commission Directive 2005/26/EC](#) were the following:

### **Cereals Containing Gluten**

- Wheat-based glucose syrups, including dextrose;
- Wheat-based maltodextrins;
- Glucose syrups based on barley; and
- Cereals used in distillates for spirits

### **Eggs**

- Lysozyme (produced from egg) used in wine; and
- Albumin (produced from egg) used as fining agent in wine and cider

### **Fish**

- Fish gelatin used as a carrier for vitamins and flavors; and
- Fish gelatin or isinglass used as fining agents in beer, cider, and wine.

### **Soybean**

- Fully refined soybean oil and fat;
- Natural mixed tocopherols (E306), natural D- $\alpha$ -tocopherol, natural D- $\alpha$ -tocopherol acetate, and natural D- $\alpha$ -tocopherol succinate from soybean sources;
- Vegetable oil-derived phytosterols and phytosterol esters from soybean sources; and
- Plant stanol ester produced from vegetable oil sterols from soybean sources.

### **Milk**

- Whey used in distillates for spirits;
- Lactitol; and
- Milk (casein) products used as fining agents in cider and wine.

### **Nuts**

- Nuts used in distillates for spirits; and
- Nuts (almonds and walnuts) used (as flavor) in spirits.

### **Celery**

- Celery leaf and seed oil; and
- Celery seed oleoresin.

### **Mustard**

- Mustard oil;
- Mustard seed oil; and
- Mustard seed oleoresin.

It is important to remember that this amendment was a temporary one.

In the meantime, European Commission seemed to have identified two additional products that can trigger allergic reactions in susceptible individuals: lupins and mollusks. This triggered another amendment, the [Commission Directive 2006/142/EC](#), to the already amendment-rich [Directive 2000/13/EC](#) (before its repeal in 2011, the 2000/13 EC counted more than 40 amendments and three corrections).

In 2007, the time for the temporary exemptions had run out and the 2000/13/EC experienced a major overhaul regarding its requirement for allergen labelling. All previously mentioned amendments were consolidated in the [Commission Directive 2007/68/EC](#), which again, amended the Directive 2000/13/EC. With that, European regulators had arrived at a now 14-strong group of food allergy- and intolerance triggering substances that had a number of exemptions:

1. **Cereals containing gluten** (i.e., wheat, rye, barley, oats, spelt, kamut, or their hybridized strains) and products thereof, *except* wheat-based glucose syrups, including dextrose; wheat-based maltodextrins; glucose syrups based on barley; and cereals used for making distillates or ethyl alcohol of agricultural origin for spirit drinks and other alcoholic beverages.
2. **Crustaceans** and products thereof.
3. **Eggs** and products thereof.
4. **Fish** and products thereof, *except* fish gelatin used as carrier for vitamin or carotenoid preparations; and fish gelatin or isinglass used as fining agents in beer and wine.
5. **Peanuts** and products thereof.
6. **Soybeans** and products thereof, *except*: fully refined soybean oil and fat; natural mixed tocopherols (E306), natural D- $\alpha$  tocopherol, natural D- $\alpha$  tocopherol acetate, and natural D- $\alpha$  tocopherol succinate from soybean sources; vegetable oil-derived phytosterols and phytosterol esters from soybean sources; and plant stanol ester produced from vegetable oil sterols from soybean sources.
7. **Milk** and products thereof (including lactose), *except* whey used for making distillates or ethyl alcohol of agricultural origin for spirit drinks and other alcoholic beverages; and lactitol.
8. **Nuts**, i.e., almonds (*A. communis* L.), hazelnuts (*C. avellana*), walnuts (*J. regia*), cashews (*A. occidentale*), pecan nuts [*C. illinoensis* (Wangenh.) K. Koch], Brazil nuts (*B. excelsa*), pistachio nuts (*P. vera*), macadamia nuts and Queensland nuts (*M. ternifolia*), and products thereof, *except* nuts used for making distillates or ethyl alcohol of agricultural origin for spirit drinks and other alcoholic beverages.
9. Celery and products thereof.
10. Mustard and products thereof.
11. Sesame seeds and products thereof.
12. Sulfur dioxide and sulfites at concentrations of more than 10 mg/kg or 10 mg/L expressed as SO<sub>2</sub>.
13. Lupin and products thereof.
14. Mollusks and products thereof

It is very noticeable that lysozyme and albumin from egg, and mustard oils and oleoresins are no longer on the list of derivatives exempt from labelling.

Another major milestone, not only for food allergen labelling, but for food labelling in general, was the so-called Consumer Information [Regulation 1169/2011](#), published in 2011. A major difference is that while the 2000/13/EC was a Directive, allowing “national” flavors of implementing local legislation, the 1169/2011 is a Regulation, which must be adopted by all European member states immediately and without change.

The [Regulation 1169/2011](#) maintained the list of groups listed in the [Directive 2007/68/EC](#) requiring labeling while still expanding the scope by including not only packaged but also non-prepackaged products (e.g., in bakeries). It also requires catering outlets to provide allergen information to customers. This applies to restaurants and canteens alike. European Commission also made clear, that the [Regulation 1169/2011](#) is also prone to changes as new evidence comes to light. It reads in Article 21, Section 2: “In order to ensure better information for consumers and to take account of the most recent scientific progress and technical knowledge, the Commission shall systematically reexamine and, where necessary, update the list in Annex II by means of delegated acts, in accordance with Article 51.” But like all previously mentioned Directives, this Regulation also only addresses the labelling requirements for ingredients and does not consider adventitious contamination with allergens through carry-over, leaving a significant regulatory gap causing insecurity with food manufacturers and consumers alike. Instead, in July, the European Commission explained to food manufacturer and consumers, what “milk” and “egg” and “nuts” mean in the [EC/1169/2011](#). [Commission notice C \(2017\) 4864](#) states:

“Egg” in Annex II, point 3 refers to eggs from all farmed birds.

“Milk” in Annex II, point 7 refers to milk from the mammary gland of farmed animals.

“Nuts” as listed in Annex II, point 8 are to be understood as an exhaustive list.

Even though it is acknowledged that ostrich eggs are unlikely to be used as ingredients in most products, it means that analytically, there is still a need to have detection systems available. Equally, minks, being farmed mammals, are not known to produce significant amounts of milk that is used as ingredient. Still, there is at least theoretically a need to develop analytical tools to prove absence.

While this clarification may not contribute significantly to clarify the situation for food manufacturers and affected consumers, it certainly leaves one of the major issues, the precautionary allergen labelling (PAL), unresolved.

At this point it should be noticed that the DG JRC and DG SANCO met in 2016 to discuss the issue. One of the key statements is that any PAL needs to be risk assessment based, closing the door to ingredient manufacturers which like to be covered for any eventualities without necessarily evaluating their risk of having contaminated products appropriately ([O’connor et al., 2017](#)). The report from this meeting was published in November 2017.

Also, it is worth noting that Germany already introduced in 2014 *de facto* action levels for food allergen labelling through its enforcement bodies ALTS committee (Waiblinger and Schulze, 2018).

Gluten-free labelling had previously been regulated in the Regulation EC/41/2009 but it made perfect sense to integrate this also into the Consumer Information Regulation EC/1169/2011. To do this, several legal acts were necessary: Regulation (EC) No. 609/2013 repealed several regulations dealing with food intended for infants and young children, food for special medical purposes, and total diet replacement for weight control. It included repealing gluten-free labeling Regulation (EC) No. 41/2009, effective July 20, 2016. Approximately 6 weeks later, on August 21, 2013, the Commission issued a Commission-delegated Regulation (EC) No. 1155/2013 amending Regulation No. 1169/2011. The third regulation (EC) No. 828/2014 then stated the “requirements for the provision of information to consumers on the absence or reduced presence of gluten in food.”

## USA

In the US the applicable regulation is the Food Allergen Labeling And Consumer Protection Act of 2004, or short FALCPA. Like Europe, the basis for allergen labelling in the United States is the Codex Standard CODEX STAN 1-1985 Framework. FALCPA adopted the Codex “big eight” groups of major food allergens with some modifications, i.e., it only includes wheat from the list of cereals containing gluten:

- milk
- eggs
- fish (e.g., bass, flounder, cod)
- crustacean shellfish (e.g., crab, lobster, shrimp)
- tree nuts (e.g., almonds, walnuts, pecans)
- peanuts
- wheat
- soybeans.

Because FALCPA only included examples for fish, crustacean shellfish and tree nut, instead of an exhaustive list of major allergic foods in these groups, in 2006, the US FDA made a list of what was consider a “tree nut”. This list includes: Almond (*Prunus dulcis* (Rosaceae)), beech nut (*Fagus* spp. (Fagaceae)), Brazil nut (*Bertholletia excelsa* (Lecythidaceae)), butternut (*Juglans cinerea* (Juglandaceae)), cashew (*Anacardium occidentale* (Anacardiaceae)), chestnut (Chinese, American, European, Seguin) (*Castanea* spp. (Fagaceae)), Chinquapin (*Castanea pumila* (Fagaceae)), coconut (*Cocos nucifera* L. (Arecaceae alt. Palmae)), filbert/hazelnut (*Corylus* spp. (Betulaceae)), ginkgo nut (*Ginkgo biloba* L. (Ginkgoaceae)), hickory nut (*Carya* spp. (Juglandaceae)), lichee nut (*Litchi chinensis* Sonn. Sapindaceae), macadamia nut/bush nut (*Macadamia* spp. (Proteaceae)), pecan (*Carya illinoensis* (Juglandaceae)), pine nut/pinon nut (*Pinus* spp. (Pinaceae)), pili nut (*Canarium ovatum* Engl. in ADC. (Burseraceae)), pistachio (*P. vera* L. (Anacardiaceae)), shea nut (*Vitellaria paradoxa* C.F. Gaertn. (Sapotaceae)), walnut (English, Persian, black, Japanese, California), heartnut, butternut (*Juglans* spp. (Juglandaceae)). Similarly, the US FDA further clarified that fish and crustacean shellfish include those species listed in [The Seafood List](#).

## Canada

At the time of preparing this article the latest amendment to the Canadian Food and Drug Regulations “1220 — Enhanced Labelling for Food Allergen and Gluten Sources and Added Sulphites” was done in December 2016. Looking at the allergens which require labelling, Canada list is similar to the European but does not require labelling of celery and lupine.

## AUS/NZ

The Food Safety Australia and New Zealand (FSANZ) also requires the labeling of an extended “big eight” list of priority food allergens: peanuts, tree nuts, milk, eggs, sesame seeds, fish, shellfish, soy, lupin and wheat, according to the [Australia New Zealand Food Standards Code](#) – Standard 1.2.3 (Information requirements – warning statements, advisory statements and declarations). Like in the European labelling regulation, FSANZ also exempt certain derived products from labelling. These include:

- glucose syrups made from wheat starch (subject to low limits)
- fully refined soy oil
- soy derivatives (tocopherols and phytosterols)
- fish isinglass
- distilled alcohol from wheat or whey.

## Japan

The currently active labeling act for food allergens is Food Labeling Act No. 70 (Shoji et al., 2018). Japan has one of the more dynamic labelling regulations. The regulatory authorities revise the list of regulated allergens based on the result of food allergy prevalence surveys, which are conducted periodically (2001–02; 2011–12). Japan has in fact two different lists:

- List of food allergens subjected to “mandatory” labeling: Egg, milk, wheat, buckwheat, peanut, shrimp, and crab.
- List of “recommended” allergens for labeling: Abalone, squid, salmon roe, orange, cashew nuts, kiwi fruit, beef, walnut, sesame, salmon, mackerel, soybean, chicken, banana, pork, matsutake, peach, yam, apple, and gelatin.

Japan, as one of the few countries setting labelling threshold for allergens, requires products with more than 10 mg/kg of the target allergen (soluble protein) in the finished product to be labelled. The determination of these quantities can only be performed by Japanese Official methods, which have been validated in the course of a national ring trials (Shoji et al., 2018).

## China

China is also following Codex. As it states in the National Food Safety Standards GB 7718-2011 on pre-packed food labels, section 4.4.3.1, regulators require “the use of easily identifiable names in the list of ingredients” on the package if any of the following are present:

- Gluten-containing cereals and their products (such as wheat, rye, barley, oats, spelt or their hybrids);
- crustaceans and their products (such as shrimp, lobster, crabs, etc.);
- fish and their products;
- eggs and their products;
- peanuts and their products;
- Soybeans and products thereof;
- milk and dairy products (including lactose);
- nuts and nuts products.

## VITAL

When it comes to labeling thresholds, Japan with its 10 mg/kg (Shoji et al., 2018) and Germany with its action level ALTS list (Waiblinger and Schulze, 2018) are exemptions. Most countries do not provide threshold guidance for those levels at which labeling for allergens should occur.

This gap was identified by the Allergen Bureau. It developed in 2007 an allergen management strategy called Voluntary Incidental Trace Allergen Labelling (VITAL), which is based on risk analysis. A group of experts analyzed existing literature, especially clinical trials for eliciting doses, and determine eliciting doses for triggering food allergens in 1% or 5% of the allergenic population. In 2014, these levels were updated to the following values described in Table 1 (Taylor et al., 2018).

For other allergens, insufficient data or data of insufficient quality had been available to make a recommendation. To determine how much ingested food would trigger an allergic reaction based on the values of Table 1, they need to be multiplied with the amounts individuals are likely to consume in a single serving. For this, the Allergen Bureau has developed a toolset that is available from their Website as subscription service. These recommendations for labeling thresholds are currently used as reference by the food manufacturing industry.

**Table 1** Amount of allergenic protein recommended by the VITAL Scientific Expert Panel (Taylor et al., 2018)

Allergen	Protein level in mg
Peanut	0,2
Milk	0,1
Egg	0,03
Hazelnut	0,1
Soy	1,0
Wheat	1,0
Cashew	2,0 (provisional)
Mustard	0,05
Lupin	4,0
Sesame	0,2
Shrimp	10

And to take this full circle, the German ALTS action levels mentioned earlier (Waiblinger and Schulze, 2018), are actually based in their majority on the VITAL-recommended values. Unfortunately, at this point, the European Food Safety Authority (EFSA) has not provided a Europe-wide recommendation as to such levels and is unlikely to do so before 2021.

Additional Information on food allergen regulations, food allergen management, survey and detection methods can be found in the open access Special Section of the Journal of AOAC International (2018, 101(1)) on Food Allergens (Diaz-Amigo and Popping, 2018).

## Food Allergens: An Update on Analytical Methods

Michael J Walker, Michael Walker Consulting Ltd, Newtownabbey, Northern Ireland

© 2019 Elsevier Inc. All rights reserved.

### Glossary

**Coeliac disease** an autoimmune condition caused by ingestion of gluten

**Digital PCR** A PCR carried out with massive partitioning of the initial DNA in microwells or droplets such that a binary result (present or absent) is achieved from each microwell or droplet. From this if the molecule population follows the Poisson distribution the distribution of target molecule within the sample can be accurately approximated allowing for a quantification of the target

**DTT** dithiothreitol, a reducing agent used to reduce the disulfide bonds in proteins

**ELISA** enzyme-linked immunosorbent assay, a technique using antibodies to detect and quantify allergens;

**iFAAM** Integrated Approaches to Food Allergen and Allergy Risk Management – a 4 year (2013 to 2017) €9 million EU-funded project, built on an earlier €14.3 million research (EuroPrevall). IFAAM was led by the University of Manchester (UK) and involved 38 partners. <http://research.bmh.manchester.ac.uk/iFAAM>

**In silico** performed on computer or via computer simulation by analogy with *in vivo*, and *in vitro*, commonly used to refer to experiments done in living organisms, and in laboratory settings respectively.

**Intercalating dye** compound which binds with DNA and thus enables detection of amplified PCR product, generally by fluorescence, examples are SYBR Green and EvaGreen,

**LC-MS/MS** liquid chromatography mass spectrometry/mass spectrometry, a technique that uses liquid chromatography to separate analytes of interest followed by their detection and characterisation by fragmentation pattern and charge to mass ratio in tandem mass spectrometers;

**LFD** lateral flow device - low cost rapid simple point of use assays based on ELISA.

**LOD** limit of detection, the lowest quantity of a substance in a sample that can be distinguished from a sample in which the substance is absent, usually within a stated confidence interval;

**LOQ** limit of quantitation, the lowest concentration at which the analyte can not only be reliably quantified with an acceptable level of uncertainty;

**MRM** Multiple reaction monitoring

**PCR** polymerase chain reaction, a process in which thermal cycling separates double stranded DNA, and with the introduction of short single strands of nucleic acid allows the synthesis of a new set of double stranded DNA, repetition of the cycle amplifies the DNA amount to levels at which it can be reliably detected and characterised

**Post translational modification** covalent and generally enzymatic modification of proteins following protein biosynthesis, includes phosphorylation, glycosylation, nitrosylation, methylation, acetylation, lipidation and proteolysis and influences almost all aspects of normal cell biology

**RM** reference material, a material, sufficiently homogeneous and stable with reference to specified properties, which has been established to be fit for its intended use in measurement

**Shotgun proteomics** Also known as "Bottom-up" proteomics and refers to the characterization of proteins by analysis by LC-MS/MS of peptides released through proteolytic digestion of intact proteins.

### Introduction

What is food allergy? Food allergy is an increasing public health problem, particularly in developed nations. It is a subset of conditions collectively known as food hypersensitivity. Some adverse reactions to food are predictable, for example any individual might succumb to food poisoning. But there are reactions to food which affect only some people; moreover these are unpredictable, that is to say, they affect the susceptible person unexpectedly. When those reactions subsequently occur every time the person eats a given amount of the trigger food the reactions are 'reproducible' and termed 'food hypersensitivity'. Thus food hypersensitivity is: '*objectively reproducible symptoms or signs initiated by a defined stimulus at a dose tolerated by 'normal' subjects*' (Johansson et al., 2001). Food hypersensitivity can take many forms but if mediated by the immune system is food allergy, especially if an immune protein, immunoglobulin E, IgE (Schroeder and Cavacini, 2010) is involved. There are other forms of food allergy called 'non-IgE-mediated gastrointestinal food-induced allergic disorders', for further discussion of these and food allergy itself (see Walker and Gowland, 2017).

Food hypersensitivity also includes coeliac disease, an autoimmune adverse reaction to ingested gluten in which the small intestine becomes inflamed and unable to absorb nutrients. It can cause a range of symptoms including diarrhoea, abdominal pain and bloating. Gluten is a protein found in wheat, barley and rye (McIntosh et al., 2011). There are also a range of food intolerance

conditions, for example lactose intolerance (Walker and Gowland, 2017). Sensitivity to sulphites, a widely used set of food additives, can cause severe, even life threatening asthmatic reactions in sensitive subjects (Vally and Misso, 2012; EFSA, 2014).

### Sensitisation and Elicitation

Two processes are involved in IgE mediated food allergy – sensitisation and elicitation. Susceptible individuals undergo sensitisation, which can occur at any age, when an immunologically driven reaction develops to specific food proteins. Thereafter ingestion of those food proteins elicits, within a short time, release of inflammatory mediators such as histamine causing symptoms of, in increasing seriousness, mild lip tingling, pruritus (itch), urticaria (hives, a raised, itchy rash), diarrhoea, vomiting, asthma, and angioedema (swelling caused by a build-up of fluid). The most severe allergic reaction is anaphylaxis (Burks et al., 2012), an often rapid onset clinical emergency in which a multi-organ systemic allergic reaction precipitates life threatening airway, breathing or circulatory problems. Although fatal food anaphylaxis is rare there are well-documented detriments to the quality of life for allergic consumers and their families and carers (Ventner et al., 2015). There are burdens on health care, on businesses (food recalls, for example) and on regulators (Madsen et al., 2012). In less developed countries where, owing to poor labelling and awareness, significant challenges may exist. Currently, those with food allergies must adhere to lifelong avoidance of the eliciting food(s).

### Food Allergens

Jurisdictions that manage food allergy risks by labelling legislation include sulphites in such law however all other legislated allergens are large molecule proteins (Gendel, 2012).

### Protein Families

Proteins are made up of amino acids linked by amino-carboxylate condensation ('peptide bonds') into polyamides, also more frequently called polypeptides, and serve many functions in living organisms. Protein structure includes the sequence of the constituent amino acids, and the way in which amino acid side chains covalently link the polypeptide chains making up the primary structure of the protein. The most important of the side chain links is the disulfide bond between two cysteine residues. The amino acid chains are coiled and folded in an ordered way largely maximising their hydrogen bonding (secondary and tertiary structure). If more than one polypeptide chain is present these are packed in an ordered manner known as the quaternary structure. Common structures include the  $\alpha$ -helix,  $\beta$ -pleated sheet and the irregular globular proteins (Simmonds, 1992; Aalberse, 2000). Food allergens belong to a somewhat limited group of protein families of plant or animal origin. Important plant protein families that frequently include allergenic proteins include the cereal seed storage prolamins, cupins and the profilin and Betv1 families. Significant animal food allergens are present in milk, egg, and seafood. Mammalian milk allergens are found in three protein families,  $\alpha$ -lactalbumin,  $\beta$ -lactoglobulin, and caseins. In hens' eggs the protein ovomucoid is important and in seafood there are two major groups of allergenic proteins, the tropomyosins of crustaceans and molluscs and the parvalbumins in fish and amphibians. Allergenicity is often associated with protein thermal stability and resistance to proteolysis, the ability to form oligomers, and the tendency to aggregate (Breiteneder and Mills, 2005).

### Allergen Nomenclature

Systematic allergen nomenclature was initiated by Marsh, Løwenstein and Platts-Mills in 1980 (Breiteneder and Chapman, 2014). Each allergen name is now derived from the first three letters of the genus and the first letter of the species followed by a numeral to indicate the allergen in the chronological order of purification. Thus as peanut belongs to the genus *Arachis* and the species *Arachis hypogaea*, the allergens are Ara h 1, Ara h 2 and so on. Ara h 2 is member of the prolamin protein superfamily. An allergen nomenclature subcommittee exists under the auspices of the World Health Organization (WHO), and the International Union of Immunological Societies (IUIS), with criteria for including allergens in the systematic nomenclature (the Website is <http://www.allergen.org/index.php>). Other examples include milk from the cow, *Bos domesticus*, for example Bos d 8, the caseins, and chicken, *Gallus domesticus* hence hens' egg contains Gal d 2, ovalbumin. The AllFam database is a resource for classifying allergens into protein families (<http://www.meduniwien.ac.at/allfam/>).

### Risk Assessment and Risk Management

Official risk management of food allergy depends mainly on food labelling. Food ingredients that may trigger food allergy (priority major allergens) or hypersensitivity reactions (gluten and sulfites) are specified in law (Gendel, 2012). If included in a foodstuff the designated ingredients must be disclosed in the list of ingredients of the food. In the European Union, EU, these ingredients must be highlighted, for example in **bold print** in the list of ingredients (European Parliament and Council, 2011). The global standard for food allergen labelling is that of the Codex Alimentarius (Codex Alimentarius, 2010) which lists eight allergens, although individual jurisdictions such as the EU legislate for more, Table 1. A review of other jurisdictions is provided by Gendel (2012). However,

**Table 1** Allergens legislated for in the European Union, Regulation 1169/2011, Annex II

<i>Annex II entry</i>	<i>Examples</i>
Cereals containing gluten and products thereof	Wheat Rye Barley Oats
Crustaceans and products thereof	Shrimp/prawn Crab Lobster Crayfish
Eggs and products thereof	
Fish and products thereof	
Peanuts and products thereof	
Soybeans and products thereof	
Milk and products thereof	Skimmed milk powder Cheese
Nuts, and nut products namely	Almond Hazelnut Walnut Cashew Pecan Brazil Pistachio Macadamia
Celery and products thereof	
Mustard and products thereof	
Sesame seed and products thereof	
Sulfur dioxide/sulfites	
Lupin and products thereof	
Molluscs and products thereof	Mussels Scallops Cockles Oyster Clam

There are limited exceptions cited in Annex II of ingredients that do not contain sufficient allergenic protein to elicit a reaction.

unintended allergens, which might cross contaminate the supply chain during harvest, transport, storage or processing, are treated differently. Food business operators must implement a risk assessment in order to establish whether a hazard is likely to occur, and seek to either eliminate this risk, or reduce the risk of contamination to acceptable levels below which only the most sensitive allergic subject might react. Advisory (“may contain ...”) labelling is often used but should only be applied when there is a demonstrable and significant risk of allergen contamination (European Parliament and Council, 2002; Monks et al., 2010). Walker et al. (2017a,b) have reviewed the management of food allergens in the UK Retail Supply Chain.

Risk assessment approaches have been developed by the Allergen Bureau Voluntary Incidental Trace Allergen Labelling, VITAL and the Integrated Approaches to Food Allergen and Allergy Management (iFAAM) consortium to manage food allergen risk. These apply milligram per kilogram allergen protein ‘action levels’ derived from the estimated eliciting dose extrapolated from dose-distribution relationships for the allergen and the food serving size. The eliciting dose is the predicted amount of allergenic food, that may provoke an allergic reaction in a given percent of the population. Table 2 shows estimated reference doses and the related action levels calculated for a specific food serving size (Taylor et al., 2014).

Thus analysis for food allergens may be required from percentage down to milligram per kilogram (parts per million) concentrations, with the emphasis on the latter.

## Food Allergen Analysis

### Why Is Food Allergen Analysis Needed?

Food allergen analysis is a key component in protecting people with allergy from harm and ensuring businesses are able to provide food that is safe for them. Regulatory risk management of food allergens hinges on labelling disclosure to facilitate avoidance. Thus surveillance and enforcement of allergen labelling frequently turns on analysis to support and protect consumers and responsible businesses.

**Table 2** Reference doses and typical concentrations

Food	Reference dose (EAACI food allergy & anaphylaxis guidelines)	Typical <sup>b</sup> action levels mg kg <sup>-1</sup>
Peanut ED 1%	0.2 mg peanut protein	2
Cow's milk ED 1%	0.1 mg milk protein	1
Egg ED 1%	0.03 mg egg protein	0.3
Hazelnut ED 1%	0.1 mg hazelnut protein	1
Soya ED 5%	1.0 mg soya protein	10
Wheat ED 5%	1.0 mg wheat protein	10
Cashew ED 5%	2.0 mg cashew protein	20
Mustard ED 5%	0.05 mg mustard protein	0.5
Lupin ED 5%	4.0 mg lupin protein	40
Sesame seed ED 5%	0.2 mg sesame protein	2
Shrimp ED 5%	10 mg shrimp protein	100
Fish ED 5%	0.1 mg fish protein <sup>a</sup>	1

ED  $x$  %, Eliciting Dose for  $x$  % of the allergic population.

<sup>a</sup>provisional.

<sup>b</sup>assuming a portion size of 100 g.

Irresponsible replacement of almond powder with peanut powder has caused death thus with increasing need to demonstrate traceability and integrity in the supply chain analysis is needed to check that food is what it is claimed to be, and encourage systems to reduce exposure to fraud.

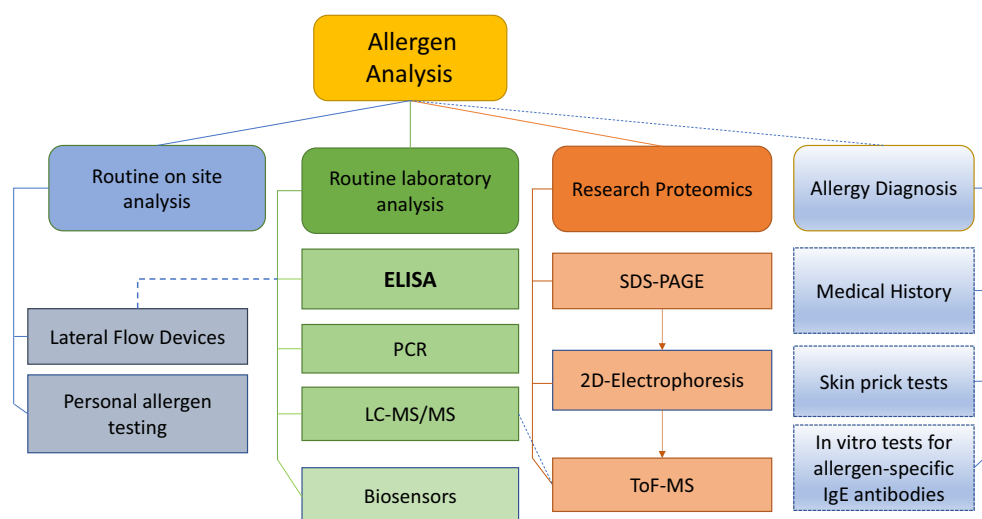

Validation and verification of factory cleaning requires allergen analysis.

If something does go wrong investigation of recalls and incidents may require allergen analysis. Allergen analysis has provided key evidence in criminal or civil action in the courts. Investigation of adverse reactions may require analysis to find out what caused the reaction, and therefore enable the individual to avoid it in the future. Investigation of fatalities may require analysis for example of food seized at the incident, stomach contents or other forensic exhibits (Gowland and Walker, 2014).

It should be remembered that food allergy can develop to any consumed food, not just those foods included in labelling legislation.

### How Is Food Allergen Analysis Carried out?

Fig. 1 shows an over view of analytical approaches applied to food allergens in different disciplines. A distinction must be made between research tools, routine industrial or enforcement laboratory analysis, on-site and personal allergen testing and testing for allergy diagnosis. Many techniques have been applied, Table 3 illustrates most of the commonly applied approaches (Walker et al., 2008).

**Figure 1** An over view of analytical approaches applied to food allergens.

**Table 3** Main and subsidiary techniques for allergen detection

<b>Routine techniques</b>	
ELISA	Routinely used, capable of standardisation, quantified results, good precision but results can be kit dependent. Targets proteins (in some, but not all, cases allergens) therefore of direct relevance to allergic consumers. Relatively inexpensive if operated batch wise.
Lateral Flow Devices, LFD	LFD are based on ELISA and offer low cost rapid simple point of use assays capable of use by non-technical staff. Exhibiting similar specificity and limits of detection to ELISAs they are semiquantitative with subjective quantitation and reproducibility can be less than with ELISA.
Real time PCR	Detects DNA rather than protein therefore not probative of the presence of an allergen but sensitive. DNA more stable than proteins under harsher extraction conditions. Quantitative results can be obtained.
LC-MS/MS	Mass spectrometry platforms are becoming the gold standard technologies for protein characterisation and quantification. Shotgun and targeted protein identification and quantification by mass spectrometry have been successfully applied to the analysis of allergens in processed food matrices. Mass spectrometry allows harsher extraction conditions than can be used with ELISA. The basis of routine liquid chromatography -mass spectrometry (LC-MS or LC-MS/MS) approaches are that the extracted protein is broken down into its constituent peptides using enzymatic digestion. The peptides can then be chromatographed and detected as with small molecule MS. Expensive to set up and run but multiplexing automated runs are the norm and metrological traceability is achievable.
<b>Less routine or research techniques</b>	
PCR	See above - not quantitative.
PCR-ELISA	PCR but with ELISA endpoint. As for PCR but can be laborious owing to the extra steps introduced by the ELISA.
Biosensors	Trade examples are Biacore, (surface plasmon resonance) Bioveris, Luminex, and can be used to detect protein or DNA. Some applications – hazelnut, egg and milk noted. Expensive set-up costs but rapid real time throughput achievable.
SDS-PAGE	Used to characterise allergens. Elaborate and time consuming, use human sera but antibodies can be raised in animals after allergen characterised.
Immunoblotting	Has been used but not widely owing to elaborate procedures necessary. In an antibody-containing gel standard or sample allergen proteins migrate according to their electrophoretic mobility forming rocket-shaped precipitates. The height of the 'rockets' is proportional to the amount of allergen protein.
Rocket Immuno-electrophoresis (RIE)	Simple and inexpensive screening of food samples, semi quantitative. Standards and sample extracts are spotted onto membrane strips. Detection is by incubation with enzyme-labelled antibodies which bind to the target antigens. The spots are visualized by addition of a substrate which is transformed by an enzymic reaction into a coloured product. The intensity of the spots is proportional to the amount of antigen
Dot immunoblotting	
RAST, EAST	Radioallergosorbent and Enzyme allergosorbent - <i>in-vitro</i> diagnostic tests which have been applied to food analysis (historic interest only).

## Research Proteomics

Gel electrophoresis, commonly used for protein separation, depends on the differential mobility of proteins in a gel under an applied electric field and as a function of their size, shape and net charge. The gel is usually a polyacrylamide, hence Polyacrylamide Gel Electrophoresis, PAGE. If the extracted proteins are dissolved in an anionic detergent, e.g. sodium dodecyl sulphate (SDS), SDS-PAGE can be performed to separate proteins largely on the basis of their molecular weight. This arises because almost all non-covalent interactions in the native proteins are disrupted by SDS, each anionic moiety of which binds to a low number of amino acids yielding a highly negatively charged protein-SDS complex of generally spherical shape. Mercaptoethanol or dithiothreitol, DTT, can also be added to reduce disulphide bonds (which otherwise stabilize folded protein conformations substantially, Creighton, 1988). Reduction of disulfide bonds folded within the protein structure can also be achieved by more harsh conditions such as high temperature, or by 6 M guanidine chloride or 8 M urea, in effect denaturing the protein (Monera et al., 1994).

Visualisation of the separated proteins is by staining, with reagents such as silver, fluorescent dyes, coomassie brilliant blue, or less frequently now, radio-labelling. SDS-PAGE yields information on the extracted proteins, such as if they are aggregated or modified. However more information can be obtained by enzymatic digestion of each protein 'spot' in the gel and liquid chromatography – tandem mass spectrometry, LC-MS/MS (see below) which has largely replaced Edman degradation. The latter uses sequential reaction of the N-terminal amino acid with phenyl isothiocyanate for cleavage and subsequent identification (Edman, 1950; Mann, 2016).

Extracted proteins can be analysed by 2D-electrophoresis which allows the resolution of complex mixtures of proteins, and qualitative and semi quantitative protein profiles. Protein extracts can also be characterized by 1D-Polyacrylamide Gel Electrophoresis, PAGE, in combination with immunoblotting using allergen specific animal antibodies where available. Mass spectrometry has a significant role to play in allergen characterisation, profiling post translational-modifications such as glycosylation or phosphorylation which occur naturally and or may be induced thermally or chemically during food processing (Monaci and Visconti, 2009).

## Routine Allergen Analysis

### Immunological Approaches

Immunological approaches make use of the ability of certain proteins, called antibodies, to bind with high selectivity to targets, called antigens. Antibodies are generally raised in animal hosts making use of the animal's immune system which, necessarily, recognises only large molecules. Small molecules (haptens) must be covalently bound to carrier proteins to elicit recognition and antibody production in the host animal. In the clinical format, radioimmunoassay, RIA, developed in 1960 by Berson and Yalow in New York, and Ekins in London, detection and quantity estimation depended on counting emissions from radioactive labelled antibodies or antigens. Resource requirements were demanding, special laboratory facilities to handle radioactivity, expensive counting instrumentation, and safety and waste disposal considerations. A less demanding label was needed. Although it had been thought that attaching a bulky enzyme would sterically hinder the immunochemical reaction between antigen and antibody, enzyme labels were proposed independently by Perlmann and Engvall in Stockholm (Engvall and Perlmann, 1971) and Schuurs and van Weemen in the Netherlands (van Weemen and Schuurs, 1971). The former developed enzyme linked immunosorbent assay, ELISA, and the latter enzyme immune assay, EIA, both building on foundational work by many research groups. Clinical applications in the form of both commercial kits and in-house set-ups burgeoned with an exponential rise in the number of clinical papers published between 1976 and 1990 (Lequin, 2005). The first commercially produced immunoassay kits for food analysis appeared in the mid 1980's (Allen, 1986), with applications to analytes such as aflatoxins, and antibiotic and other veterinary residues (Franek and Hruska, 2005). Early environmental applications were for the triazine herbicides which the author well recalls using in a court case on soil contamination in the 1990s.

Antibodies recognise sequences of amino acids in the target protein called epitopes. Such sequences may be linear or conformational (Fig. 2). Disruption of the higher order protein structure may cause conformational epitopes to become unrecognisable to the targeting antibodies (Fig. 3).

Antibodies may be either polyclonal or monoclonal. Polyclonal antibodies are purified from the serum of a suitable mammal (for example, rabbit, goat or sheep), that has been injected with the antigen. The immune response in the animal produces a mixed population of antibodies that bind to numerous different recognition sites (or epitopes) on the protein. This is an advantage in constructing assays since a knowledge of the precise orientation of an analyte is not a prerequisite for success. However the finite stock of antibodies from an animal is easily consumed, and batch-to-batch variability is an issue. Monoclonal antibodies are derived from a single hybridoma cell line tailored to recognise a single epitope with high immunogenicity. Typically the antigen is introduced into a mouse and the cells that produce antibodies (B lymphocytes) are extracted from the spleen of the mouse and added to a culture of cancer (myeloma) cells. The fusion of the B cell and myeloma cell is termed a hybridoma. The antibodies from each hybridoma line will recognise a single epitope which gives monoclonal antibodies a selectivity advantage over polyclonal antibodies albeit monoclonal antibodies are more expensive given their laborious method of production (Pang, 2010a).

### Enzyme Linked Immunosorbent Assay, ELISA

ELISA first made it routinely possible to detect food allergens. Since the technology resides in the antibodies rather than the apparatus (Allen, 1986) ELISA is relatively easy to use, largely specific to the target allergenic foods, reasonably rapid, not expensive if applied batch-wise and exhibits suitable limits of detection for many allergens. Thus, currently, routine food allergen analysis is

**Figure 2** Linear and conformational amino acid sequences.

**Figure 3** Disruption of higher order protein structure causes conformational epitopes to become unrecognisable to the targeting antibodies.

**Figure 4** Basic principle of a 'direct sandwich' ELISA.

dominated by ELISA which, although there are limitations, yields quantification which, with certain caveats, is relevant and largely accepted by the food industry.

It is possible to construct an ELISA if the antibodies to the analyte of interest can be commercially sourced and many research groups do this routinely. The complexity of food as a matrix, the problems of allergen analysis and the expertise and experience of commercial ELISA kit manufacturers renders buying a kit and validating it in-house the optimum course of action for most routine purposes. The processes of construction an ELISA are well described in trade publications (for example [Bio-Rad, 2017](#)).

**Fig. 4** illustrates the basic principle of a 'direct sandwich' ELISA. Firstly, capture antibodies are bound to the well of a microtitre plate, secondly, a solution containing either calibrant allergen or an extract of the food under test is incubated in the well. Allergen, if present, becomes bound to the capture antibody. A washing step to dispose of unbound components is followed by introduction of further antibodies which bind to the captured allergen forming a 'sandwich'; a linked enzyme after further washing catalyses a colour change in an introduced chemical substrate which is detected spectrophotometrically. It is usual to include an acidic 'stop' reagent which also alters the colour and hence the detection wavelength ([Pang, 2010b](#)). A calibration curve is constructed from calibration solutions commonly supplied with the commercial kit; a typical curve is illustrated in **Fig. 5**.

There are other ELISA formats (see for example [Bio-Rad, 2017](#)) but the main alternative to the sandwich ELISA is the competitive format, essential when there is only one binding epitope on the target, for example hydrolysed products containing protein fragments or peptides. In the competitive format any assayed allergen in a sample extract or calibration solution is allowed to compete with the same allergen pre-bound to a microtiter plate well or enzyme. An inverse relationship between the analytical signal and the concentration of assayed allergen is produced.

The well-bound format works like this. A fixed amount of the allergen intended to be targeted is bound to each well, the sample extract or calibration solution is introduced followed by a standard amount of enzyme linked antibody and incubated. If there is no target allergen in the solution added to the well all the well-bound allergen will be conjugated to the introduced enzyme linked

**Figure 5** Typical direct ELISA calibration curve.

antibody. On adding the enzyme substrate the maximum amount of coloured reaction product ('signal') will be produced. An increasing amount of target allergen in the added solution competes with the well-bound allergen for the enzyme linked antibody resulting in decreasing enzyme remaining in the well after washing. Thus when the signal substrate is added decreasing amounts of coloured reaction product will be produced, hence the inverse relationship between the analytical signal and the concentration of assayed allergen.

## Practical Considerations

### Extraction

Extraction of the sample matrix to yield a solution for presentation to the ELISA is a complex issue. There are often structural changes in the target allergen molecules by modification, aggregation and interactions with other food components (e.g., lipids, starches, polyphenols) in complex processed food matrices that hinder simple extraction and inhibit subsequent antibody binding. High temperature processing and extremes of pH pose the same difficulties (Mills et al., 2009). Chocolate is recognized as a difficult matrix from which to recover allergen proteins for the above reasons. The addition of non-target protein to the test sample is used to reduce polyphenol-binding of the target allergen proteins to enhance extraction efficiency, skimmed milk powder or fish gelatin are used for this purpose. The surfactant sodium lauryl sulfate (SDS), is used for protein solubilization, and the reducing agent 2-mercaptoethanol is useful for protein dissociation by disulfide bond cleavage and both have been employed to enhance target allergen extraction (see also the section on 'Research Proteomics' above). Owing to its malodour and hazard categorization 2-mercaptoethanol has been successfully replaced by sodium sulfite in some instances (Ito et al., 2016).

The extraction of gluten is a problem that has received particular attention. The most commonly used solvent in gluten extraction is aqueous alcohol (60% ethanol or 50% propanol). However, to deal with disulphide bonds formed in processed foods reducing agents such as 2-mercaptoethanol or tris(2-carboxyethyl)-phosphine (TCEP) and disaggregating agents such as guanidine or sodium dodecyl sulphate (SDS) are used in combination with aqueous alcohols. Depending on the food matrix, defatting with n-hexane may be required for products with more than 10% fat. In general the compatibility of the extraction solvent with the subsequent analytical procedure obviously needs to be verified for each procedure (McIntosh et al., 2011; Scherf and Poms, 2016).

### Validation and Familiarisation With the Assay

Validation of the ELISA in the laboratory using it is essential. It is also important for staff using any commercial ELISA to become thoroughly familiar with the assay before attempting to produce data for reporting to clients. This can take place during validation of the ELISA in-house. Guidance on validation of allergen ELISAs is available (Abbott et al., 2010) and, in brief, should include the usual parameters (Table 4) with special focus on cross reactivity, intermediate precision and matrix interference.

### Pipetting

Pipetting accuracy in ELISA has been aided by multichannel micropipettes. However all micropipettes must be used and stored with care, and must be serviced and calibrated regularly (Blues et al., 2004), and see also micropipette manufacturers' guides (for example Gilson (undated)). Care must be taken as regards placement at the microtiter plate and avoidance of aerosol splashing.

### Plate Washing

Washing the microtiter plate is an essential step in any ELISA and must be undertaken thoroughly and with care according to the kit instructions.

**Table 4** Validation

(j) measurement uncertainty;

---

**Follow the Procedure**

ELISA manufacturers work hard to perfect the procedure for each kit and although there are shortcomings in presentation and editing for some kits the kit procedure must be followed exactly. Since antibody–antigen reactions may not come fully to equilibrium in the timescale of an assay particular attention must be paid to timings. Similarly incubation and ambient temperatures are crucial for enzyme reactions and must be adhered to. It is usual to apply multiple replicates on the microtitre plate (duplicate or triplicate aliquots). Calibration curves must be constructed for each microtitre plate used on the day of assay and should follow the kit instructions – some kit manufacturers provide access to a spreadsheet for this purpose.

For particularly important results it is advisable to repeat the quantification of an allergen by a different ELISA platform.

**Laboratory Environment**

It is important to ensure the laboratory environment does not cross contaminate the sample. For example, blenders used for homogenization of the sample can be difficult to clean thoroughly, and atmospheric aerosols or dust can contaminate the sample with other foods, or pollen that might be homologous with an assayed allergen can enter via open windows.

For assays for which there are significant consequences, such as legal action, it may even be important to carry out the work of evidence recovery and analysis in a dedicated restricted-access containment suite. Such a facility is designed to guard against any possibility of laboratory cross-contamination. When working in the containment suite analysts must gown-up in disposable (colour-coded) forensic coveralls. Positive-pressure air-handling should be considered and environmental swabbing to ensure the area remains free of allergens must be carried out. Maximum use should be made of disposable equipment, extending to the recycling of blenders to non-sensitive areas of other work if they have been used with a positive sample or control. Separate safety cabinets should be used for different aspects of the work. The analysts must take care over their own diet to ensure that a major food allergen has not been recently consumed when working in the containment suite (Walker, 2012).

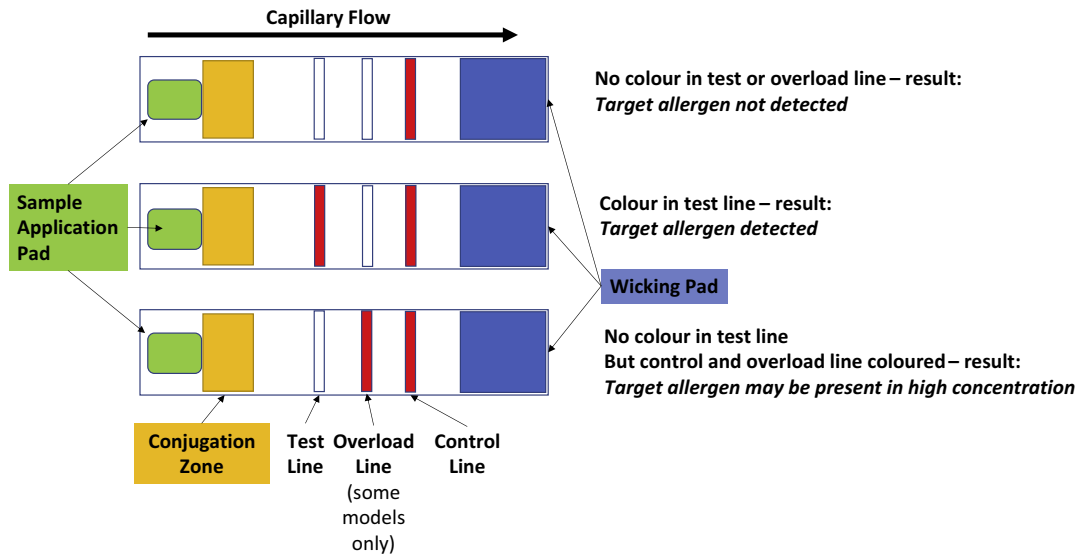

**Reporting**

A report should state the method of analysis and be in the format [X] mg/kg (or mg kg<sup>−1</sup>) as Y, where [X] is the best estimate of the concentration of allergen found in the analysis of the sample received after in-laboratory homogenisation, extraction and analysis by a validated method, and Y is either the allergen protein or the name of the food. But if the whole food is the reporting basis the conversion factor from allergen protein to whole food must be given. Conversion factors should be reported with literature references to the typical protein contents of the allergen. As a matter of routine the basis of data as allergen or (preferably) allergen protein should be specified every time a datum is given in a method or report.

**Lateral Flow Devices**

Lateral flow devices, LFD, probably most familiar as pregnancy test kits, are based on ELISA. LFD offer low cost rapid simple point of use assays capable of use by non-technical staff. Exhibiting similar specificity and limits of detection to ELISAs as a form of immunochromatography they offer some tolerance of interferences. They are, however, semiquantitative with subjective quantitation and reproducibility can be less than with ELISA.

LFDs consist of a strip of material such as nitrocellulose, nylon or other materials that support capillary flow with different compartments from a sample application zone at one end to a wicking zone at the other end which pulls along and captures the applied liquid sample extract and reagents. LFDs can be used to check incoming ingredients for target allergens, to assess

**Figure 6** Basic principle of a lateral flow device.

production line cleaning regimes by swabbing or testing rinse water or for any of the uses ELISA is normally put to. Validation is required before use and manufacturers should be consulted about sample extraction.

Fig. 6 shows typical LFD format. The sample liquid is applied to the sample application pad where it flows to a conjugation zone containing allergen-specific antibody coupled to a label to enable visualization of results. The label can be coloured latex beads, colloidal metals such as gold, increasingly in nanoform, or a fluorescent compound. Any allergen protein present in the sample binds to the labelled allergen-specific antibody which flows onto a test line. The test line contains immobilized allergen-specific antibody which captures the allergen protein with its attached labelled antibody. The accumulated label shows up as a colour or fluorescence in the test line which is proportional to the amount of allergen in the sample. Unbound labelled allergen-specific antibody continues to travel along the strip to a control line containing immobilized antibody raised against the species used to produce the allergen-specific antibody. If the test has worked (i.e. capillary flow has occurred unimpeded by sample matrix or malfunction) the species-antibody captures the labelled allergen-specific antibody and colour accumulates in the control line. A positive result therefore consists of a coloured test line and a coloured control line. A negative result consists of an uncoloured test line and a coloured control line.

However if the target allergen protein is present at a very high concentration the labelled allergen-specific antibody may be saturated with allergen protein leaving no sites at which the immobilized allergen-specific antibody in the test line can bind. Allergen protein may also travel ahead of the allergen-bound-labelled allergen-specific antibody to saturate the capture antibody in the test line. Either way, this is known as the 'hook effect' and would result in a blank test line and a coloured control line – i.e. a false negative. If this is suspected 100 to 1000 times serial dilutions of the sample extract should be tested. Some LFDs include an 'overload line' where an additional allergen-specific antibody present in the conjugate zone can be detected. Absence of colour in both the overload and test lines could signal a high allergen concentration which should be investigated by serial dilution and retest (Baumert and Tran, 2015).

The first LFD for an allergen appears to have been developed by Mills et al. (1997). The LFD employed a simple one-step extraction method and was able to detect as little as 0.01% (w/w) of peanut in marzipan and 0.1% (w/w) of peanut in chocolate. Roasted nuts were also detected, down to a concentration of 0.1% (w/w) in both foods. Polyclonal antibodies were raised to conarachin, the 7S globulin of peanut, and used as both the capture and detector elements of the assay. No significant cross-reaction with proteins from a range of nuts and legumes was seen. The final steps utilized an avidin-biotin detection system and tetramethylbenzidine as the substrate.

## Reference Materials

The importance of reference materials, RM, for allergen analysis has been emphasized by many. Commercially available ELISA kits exhibit variable and manufacturer specific sensitivities and cross-reactivity. In proficiency testing multimodal datasets for allergen ELISAs are common and different assigned values have to be generated for the different kits used. PCR and LC-MS/MS assays require appropriate calibrators for quantification and reference materials for method validation (Walker et al., 2016).

Taylor et al., 2009 were the first to describe with examples the preparation of naturally incurred standards as allergenic food residues incorporated into various representative food matrices and then processed in a manner similar to 'real-world' food processing and this approach has stood the test of time in this and other contexts.

Reference materials produced by National Measurement Institutes exhibit the highest standards. However there are few RMs produced solely with allergen analysis in mind. The Joint Research Centre (JRC), the European Commission's science and knowledge service, is a major producer of reference materials (JRC, 2017). The JRC produced a material for peanut analysis including 6 vials containing peanuts prepared at different roasting temperatures and times (IRMM – 481). Several milk powder and dried whole egg reference materials are available from JRC (BCR – 685) and the U.S. National Institute of Standards and Technology (NIST, 2017) (NIST – SRM 1549a) (NIST – SRM 8445). NIST produced a peanut butter standard reference material certified for the content of proteins (NIST – SRM 2387). LGC (LGC, 2017) has made available a mechanically defatted light roasted peanut flour in 5 g vials under Argon (LGCQC1020) which is from the same source and batch of peanut flour used for recent protein detection studies. Values are provided for nitrogen and water content and the material will prove useful for allergen protein measurement (Lee et al., 2018a, 2018b). LGC also have available a quality control set based on a chocolate dessert mix used as the vehicle for oral food allergen challenges in clinical studies (Johnson et al., 2014). Each set contains a blank unit and a unit with 10 mg kg<sup>-1</sup> gravimetrically incurred peanut protein (LGCQC101-KT). Within the iFAAM project, the material was used as a ring test sample for ELISA and Mass spectrometry analysis. A consortium of LGC, University of Manchester and Romer Laboratories commenced work in 2018 on a multi-allergen reference material on contract to the UK Food Standards Agency.

The MoniQa Association (MoniQa) have produced the first validated reference material for food allergen analysis. They manufactured milk powder biscuits (cookies) at two agreed concentrations, 3.5 mg of milk protein per kg of cookie (LOW-MQA 102016) and 35 mg of milk protein per kg of cookie (HIGH-MQA 082016). The materials are sold alongside the dry skimmed milk powder (SMP-MQA 092014) and a blank cookie (BLANK-MQA 082015). In the near future, the production of egg and soy-based reference materials is expected.

The FAPAS (Food Analysis Performance Assessment Scheme) produced a cake mix reference material containing gluten, egg, and milk (FCAL7-PRO10RM). Differently from the MoniQa material, egg and milk were added as a known amount of total ingredient to a commercial cake mix manufactured to be gluten-free, egg-free and milk-free. The material is currently not available. FAPAS produces two quality control materials: cooked biscuits containing hazelnut and peanut (T27171QC) and chocolate containing hazelnut (FCAL8-CON2QC). For the products described, the protein concentration assignment was done by consensus assessment based on ELISA analysis.

Work undertaken by the JRC (Rzychon et al., 2017) has assessed the variation in results between ELISA measurements of gluten and its likely impact on the enforcement of the EU gluten-free legislation. The study systematically examined the feasibility of harmonizing gluten ELISA assays by the introduction of (a) a common extraction procedure, (b) a common calibrator, such as a pure gluten extract and (c) an incurred matrix reference material. The comparability of measurements was limited by a weak correlation between kit results caused by differences in the selectivity of the methods. This lack of correlation produced bias that was not corrected by using a reference material alone. The use of a common calibrator reduced the between-assay variability to some extent, but variation due to differences in selectivity of the assays was unaffected. The authors advocate consensus on robust markers and their conversion to “gluten content”.

## DNA Based Methods - PCR

DNA, deoxyribonucleic acid, is the hereditary material in almost all organisms, where nearly every cell has the same DNA. DNA is located in the cell nucleus (nuclear DNA). Smaller amounts of DNA can also be found in the mitochondria (mitochondrial DNA or mtDNA). While each cell has one nucleus which aids quantification, mitochondria are more abundant per cell hence mtDNA is more attractive with regard to sensitivity. The information in DNA is stored as a code made up of four chemical bases: adenine (A), guanine (G), cytosine (C), and thymine (T). The sequence of these bases determines the information available for expressing proteins essential to the organism. DNA bases pair with each other, A with T and C with G, to form base pairs. Each base is also attached to a sugar molecule and a phosphate molecule. Together a base, sugar, and phosphate are called a nucleotide. Nucleotides are arranged in the now familiar double helix. An important property of DNA is that it can replicate, or make copies of itself. Each strand of DNA in the double helix can serve as a pattern for duplicating the sequence of bases (U.S. National Library of Medicine, 2017a).

DNA PCR analysis can be thought of as a series of procedural steps: sampling, sample preparation, DNA extraction, DNA quantitation, PCR setup, equipment operation, software analysis, manual analysis, and user interpretation. The collection of samples, their handling and continuity of evidential material, as well as the spatiotemporal separation of the laboratory into pre- and post-PCR areas are all important to successful results especially when working to a forensic standard (Valdivia and Burns, 2010; Goodwin et al., 2011).

DNA extraction kits are commercially available. A cetyltrimethylammoniumbromide (CTAB) protocol is a common starting point for DNA extraction and Valdivia and Burns (2010) have described in an approachable manner the effective sample preparation of nuts, to maximise the quantity and quality of DNA extracted. Quantitation of the extracted DNA in order to facilitate appropriate aliquoting for amplification and subsequent quantification of the assayed species is required, for example by surface tension systems enabling the analysis of microlitre sample volumes (e.g. the NanoDrop spectrophotometer). UV spectrometry or fluorometric approaches (e.g. PicoGreen) may also be used. As with ELISAs, polyphenols (e.g. in cocoa products) may inhibit extraction. Extracted DNA to which amplification is applied has been purified however inhibition of amplification by carried over lipids, polysaccharides and certain mineral salts, as well as extraction chemicals themselves, must be guarded against.

The Polymerase chain reaction (PCR), developed by Kary Mullis in the 1980s amplifies nucleic acid sequences with high specificity thus enabling the identification of plant and animal species. Amplification occurs enzymatically via repeated cycles of.

- DNA denaturation (double strand separation into single strands by heat denaturation),
- oligonucleotides or 'primers' selective for the species are added and anneal to each single strand and
- DNA polymerase promotes extension.

The DNA polymerase enzyme can add extra nucleotides to the primer by using the genomic DNA as a template. Subsequent heat denaturation and annealing of the second primer to the newly synthesized single-strand DNA allows synthesis of a complementary DNA strand (U.S. National Library of Medicine, 2017b). After sufficient cycles (up to 30–40) the amplified product can be visualised in several ways. For example an end-point PCR with capillary electrophoresis (CE) detection of soya, maize, cotton, sugar beet and lupin is described by Busby and Burns (2014) illustrating method development including the sourcing of primers or their *in silico* design using 'primer BLAST' based on sequence data deposited in GenBank. Basic Local Alignment Search Tool, BLAST, finds regions of similarity between biological sequences (NIH, 2017).

The most common approach is now real-time PCR (quantitative real-time PCR, qPCR). This is based on the measurement of a fluorescent signal that increases during the amplification of PCR products, for example by 'TaqMan' chemistry. In this approach a target-specific oligonucleotide probe has a fluorescent 'reporter' dye and a 'quencher' attached. The proximity of the quencher to the dye prevents the detection of fluorescence. When the probe binds to the amplified target DNA the quencher is separated from the reporter dye allowing measurement of the fluorescence which is proportional to the amount of amplified PCR product (Navarro et al., 2015). A sigmoid curve is obtained when the fluorescence level is plotted against the number of amplification cycles ( $C_q$ , previously  $C_t$ ). This can be used to quantify the target DNA present in the sample before the reaction by the threshold PCR cycle at which the fluorescence signal can be distinguished from the background noise. The more DNA originally present the fewer cycles required for the fluorescence to exceed the threshold.

Design of primers and probes is one of the most crucial factors affecting the success and quality of qPCR analyses and should meet specific criteria. The formation of primer-dimers and other non-specific products should be avoided or reduced. Multiple primers and probes software programs and websites are available many of them free. These tools often consider the default requirements for primers and probes, although new research advances in primer and probe design should be progressively added to different algorithm programs. After a proper design, a precise validation of the primers and probes is necessary (Rodríguez et al., 2015).

Melt curve techniques applying intercalating dyes play an important role in screening for allergen species. The melting point (dissociation of double stranded DNA) of PCR product is a function of its constituent nucleotides and can be instrumentally exhibited as an inflection in the fluorescence–temperature curve. The first derivative thereof generates 'peaks' at the melting temperature which are diagnostic for the species of interest. See also 'Complementary Techniques' below.

For some allergen targets DNA PCR is the only routine approach currently available. A well-known example is celery for which a specific ELISA is not possible owing to cross reactivity within the Apiaceae (or, Umbelliferae) family particularly to carrot and parsley (Daems et al., 2017). DNA-based techniques often have advantages in terms of better sensitivity and greater specificity. In addition, as an analyte DNA is generally more stable than proteins although DNA degradation does occur by extremes of, for example, temperature and pH (Gryson, 2010). Primers and probes of base pair sequence length too long to anneal to degraded DNA are best avoided, base pair sequence lengths of 150–200 are generally optimum. A PCR assay is more rapid to develop than an ELISA when novel antibodies need to be generated and PCR opens the possibility of multiplex analysis. While amplification of the base pair sequence that codes for the allergenic protein is the ideal many PCR assays amplify a gene specific only for the species and while this is strong evidence for the presence of the allergenic protein PCR has been criticised as it does not detect the actual protein(s). It should also be remembered that small primer sequences may be found in genomes other than the intended target and that sequence databases are incomplete and some entries may be misattributed. Thus method validation, including exploration of potential cross reactivities is mandatory. For two allergens, egg and milk, DNA methods are not applicable since DNA from (a) hens' eggs and chicken meat and (b) cows' milk and beef are indistinguishable. See also 'Complementary Techniques' below.

See Holzhauser and Röder (2015) for further discussion of PCR including a list of the major published methods for individual allergens.

In summary, real-time PCR methods allow the detection of allergenic ingredients in food products at levels of 10 mg kg<sup>-1</sup> or lower. Although they do not directly measure the hazard (protein), they are especially valuable for foods for which no ELISA based test is available (e.g. celery) or where ELISA results are ambiguous (Prunus species). PCR assays are probative of the source species DNA (which may not be present e.g. egg white) rather than the allergen protein and are essentially qualitative at present. Quantification based on copy number can be derived from cycle thresholds but requires reference materials to construct a calibration curve although digital PCR may circumvent this difficulty (Burns et al., 2010).

## Mass Spectrometry

The principles and applications of mass spectrometry, MS, and hyphenated techniques coupling chromatographic techniques to MS (LC-MS and LC-MS/MS) are dealt with elsewhere in this encyclopedia.

The basis of routine liquid chromatography-mass spectrometry (LC-MS or LC-MS/MS) approaches are that the extracted protein is broken down into its constituent peptides using enzymatic digestion.

**Figure 7** Basic principle liquid chromatography-mass spectrometry (LC-MS/MS).

Mass spectrometry, MS, the gold standard technology for small molecule identification and quantification, is increasingly applied to protein characterisation and quantification. Given the challenges faced by other allergen quantification approaches there is a need for methods that confirm molecular identity and are capable of validated quantification. MS methods, e.g. multiple reaction monitoring of peptides arising from enzymatic digestion of proteins, offer such advantages along with the possibility of multiplexed high throughput analysis. Shotgun and targeted protein identification and quantification by MS have been successfully applied to the analysis of allergens in processed food matrices. Shotgun proteomics, also known as “bottom-up” proteomics refers to the characterization of proteins by analysis of peptides released (or ‘cleaved’) through proteolytic digestion of intact proteins. In a typical shotgun proteomics experiment, the peptide mixture is then fractionated and subjected to LC-MS/MS analysis with the use of isotopically labelled internal standards, [Fig. 7](#). Peptide identification is achieved by comparing the tandem mass spectra derived from peptide fragmentation with theoretical tandem mass spectra generated from *in silico* studies making use of protein databases. [Zhang et al., 2013](#) describe in detail protein extraction, proteolytic digestion, and MS peptide ionization, separation, and fractionation methods and the identification of post translational modifications. Quantification is also addressed by Zang et al. Proteolysis is typically carried out by trypsin but at least 10 other enzymes with differing cleavage specificities have been applied.

Shotgun proteomics provides information on protein/peptide structure and on chemical/thermal modifications occurring during food processing. MS offers a number of advantages for the detection of protein allergens in food matrices. Firstly, it offers the stringent specificity required for confirmation of the presence of the analytes of interest by monitoring specific peptides as markers of allergenic proteins, especially when employing selected reaction monitoring (SRM) experiments on triple quadrupole instruments. Secondly, it offers a wide dynamic range and high sensitivity can be achieved if the correct sample preparation techniques are implemented. Thirdly, the sample preparation and method can be designed to target the particular class of molecule of interest. In the application of mass spectrometry for the detection of allergens, ideally, the target analyte would be the specific molecule giving rise to the allergenic response and the detection of peptides for the detection of allergens in foods has been reported ([Sealey-Voyksner et al., 2016](#)). The targeted SRM approach is capable of multiplex analysis. However, the technique requires a high level of expertise and costly equipment. More importantly, the complexity of most food matrices represents a significant challenge in the development of MS methods where matrix homogeneity, protein content, protein stability and solubility and process induced modifications of the proteins are generally less well understood. The effects of the tertiary and quaternary structure of the allergen proteins need also to be considered. Extraction efficiency is often overestimated with difficulties stemming from thermal and processing induced protein insolubility and protein reaction with matrix compounds such as tannins and polyphenols although MS allows harsher extraction conditions than can be used with ELISA. There is difficulty in determining recovery owing to lack of reference methods and reference materials. There is lack of metrological traceability to secure standardisation and harmonisation of results.

Guidelines have been published ([Johnson et al., 2011](#)) dealing with criteria for the selection of target protein analytes, peptides, MS transitions, optimization of protease digestion, quantification (e.g. through standard addition or isotopically labelled peptide standards), and effective validation of methods and harmonization of results through the use of naturally-incurred reference materials spanning several types of food matrix.

MS approaches are the only means of obtaining metrologically traceable absolute quantification of allergen proteins. This is the property of an analytical result which allows measurements made under different conditions (e.g. at different times, by different people, in different locations, using different procedures) to be compared in a meaningful way. It is achieved through a series of unbroken ‘calibration chains’ for each parameter in the measurement process which influences the final result, and its associated measurement uncertainty, within an international infrastructure, the International System of Units (the SI) ([BIPB, 2006](#); [Barwick and Wood 2010](#)). SI traceable assignment of the concentrations of allergenic proteins in food matrices has been achieved ([Cryar et al., 2012, 2013](#); [Groves et al., 2017](#)) but further work of this nature would greatly facilitate the standardisation of current analytical techniques for food allergens.

Non-exhaustively the literature contains useful papers on MS approaches to allergen analysis. The following studies illustrate the approaches being developed and the problems being tackled. [Popping and Godefroy \(2011\)](#), introduced a set of papers in the Journal of AOAC International flagging allergen detection by mass spectrometry as ‘the new way forward’. The edition included a study from [Monaci et al. \(2011\)](#) on the detection of milk allergens based on the identification of unique peptides in the tryptic digests of cookie and wine extracts using an RP-HPLC separation coupled to an Exactive nonhybrid mass spectrometer using

Orbitrap technology. The high mass accuracy and resolution provided by the Orbitrap analyzer allowed a fast preliminary identification of four previously proposed peptide markers of caseins using only accurate values of the  $m/z$  of their ions. No interference was observed, despite the complexity of the analyzed matrixes. Moreover, the availability of a high-energy, collisionally activated dissociation cell integrated in the mass spectrometer enabled acquisition of peptide MS/MS-like spectra through post-source fragmentation. Confirmation of peptide marker identity could then be achieved by a comparison between experimental and predicted product ions. See also Monaci et al. (2011b). Lutter et al. (2011) contributed studies on the development and validation of a method for the quantification of milk proteins in food products based on LC-MS.

Heick et al. (2011a) reported the first screening method for the simultaneous detection of seven allergens by LC-MS/MS. The method was based on extraction of the allergenic proteins from a food matrix, followed by enzymatic digestion with trypsin. The chosen marker peptides were implemented into one method that is capable of the simultaneous detection of milk, egg, soy, hazelnut, peanut, walnut and almond. The method was used to detect all seven allergenic commodities from incurred bread material, baked according to a standard recipe from the baking industry. Detected concentrations ranged from 10 to 1000 mg kg<sup>-1</sup>. Heick et al. (2011b), went on to compare the LC-MS/MS method with commercially available ELISA test kits. Carrera et al. (2012) described the rapid (less than 2 h) direct detection of the major fish allergen, parvalbumin, by selected MS/MS ion monitoring mass spectrometry. Trypsin digestion under an ultrasonic field provided by High-Intensity Focused Ultrasound (HIFU) was used with monitoring of nineteen parvalbumin peptide biomarkers in a linear ion trap mass spectrometer.

By contrast, Cucu et al. (2012) developed a MALDI-based identification of stable protein derived tryptic marker peptides for hazelnut which can be often present as a cross-contaminant. The authors suggest the identified peptides could be further used as analytical targets for the development of more robust quantitative MS methods for hazelnut detection in processed foods.

Di Stefano et al. (2012) published a mini-review of applications of LC-MS/MS for food analysis including for allergens. Abdel Rahman et al. (2013) described the proteomics of characterizing and quantifying allergenic proteins from shrimp as a means of controlling occupational asthma in the seafood industry. The proteins were extracted from shrimp tissue and profiled by gel electrophoresis. Allergenic proteins were identified based on their reactivity to patient sera and were structurally identified using tandem mass spectrometry. Tropomyosin, arginine kinase, and sarcoplasmic calcium-binding protein were found to be the most significant allergens. Multiple proteolytic enzymes enabled 100% coverage of the sequence of shrimp tropomyosin by tandem MS. Monaci et al. (2013) studied multi-allergen quantification of fining-related egg and milk proteins in white wines by high-resolution MS. Selected tryptic peptides were used as quantitative markers for milk (casein) and egg-white (lysozyme and ovalbumin) proteins, added to commercial white wines at sub-ppm levels. An evaluation of protein digestion yields was also performed by implementing the <sup>15</sup>N-valine-labelled analogues of the best peptide markers identified for  $\alpha_{S1}$ -casein and ovalbumin. The tryptic digests of the dialyzed wine extracts were run on liquid chromatography/high resolution mass spectrometry (LC/HRMS) with peptides providing the most intense electrospray ionization (ESI)-MS response chosen as quantitative markers of the proteins under investigation. Six-point calibrations were performed by adding caseinate and egg-white powder in the concentration range between 0.25 and 10  $\mu$ g mL<sup>-1</sup>, to an allergen-free white wine. The following three peptide markers, LIEWTSSNVMEER, GGLPINFQTAADQAR and ELINSWVESQTNGIIR, were highlighted as best markers for ovalbumin, while GTDVQAWIR and NTDGSTDYGLILQINSR for lysozyme and YLGYLEQLLR, GPFPPIV and FFVAPFPEVFGK for caseinate. Limits of detection (LODs) ranged from 0.4 to 1.1  $\mu$ g mL<sup>-1</sup>.

Uvackova et al. (2013) studied an independent quantitative mass spectrometry (MS<sup>E</sup>) approach in quantifying important allergenic proteins and detected relevant peptides carrying known epitopes in wheat grain extracts. These authors looked at 76 wheat allergenic sequences downloaded from the AllergenOnline database ([www.allergenonline.org](http://www.allergenonline.org)) as a starting point. Alcohol soluble extracts of gliadin and glutenin proteins were analyzed. This resulted in identification and quantification of 15 allergenic protein isoforms that belong to amylase/trypsin inhibitors,  $\gamma$ -gliadins, and high or low molecular weight glutenins. Additionally, several peptides carrying four previously discovered epitopes of  $\gamma$ -gliadin B precursor were detected. These data were validated against the UniProt database, which contained 11764 *Triticeae* protein sequences. The identified allergens are discussed in relation to Baker's asthma, food allergy, wheat dependent exercise induced anaphylaxis, atopic dermatitis, and celiac disease (i.e., gluten-sensitive enteropathy). Posada-Ayala et al. (2015) looked at a novel LC-MS method for the sensitive determination of the mustard allergen Sin a 1 in food. Mustard allergen Sin a 1 was purified from yellow mustard seeds and was detected with a total of five peptides showing a linear response (lowest LOD was 5 ng). Sin a 1 was detected in mustard sauces and salty biscuit ( $19 \pm 3$  mg kg<sup>-1</sup>) where mustard content was not specified.

Popping and Diaz-Amigo guest edited a further special edition of J AOAC International in 2017 on 'a global reflection on food allergen regulations, management, and analysis'. the present author's research group contributed three papers on (a) the science behind the ground breaking analysis for allergens by ELISA, molecular biology, and protein mass spectrometry during the investigation of the almond and mahaleb incidents in 2015 (see below), (b) managing food allergens in the UK retail supply chain and Groves et al. (2017) on recovery of food allergens from solid processed matrices applying SI (International System of Units) traceably quantified milk protein solutions and a novel extraction method. There were contributions to the J AOAC Int special edition from five continents on topics as diverse as food allergen labelling and regulation, quantitative ELISA, targeted and novel mass spectrometry approaches to allergen analysis and analytical devices for use by consumers. The edition is open access and available on the J AOAC International Website.

## Clinical Testing

The diagnosis of food allergy is still based primarily on a detailed medical history and comprehensive physical examination. Clinical or laboratory tests only serve as an add-on tool to confirm the diagnosis. The standard techniques include skin prick testing and *in-vitro* testing for specific IgE-antibodies, and oral food challenges. Properly done, oral food challenges continue to be the gold standard in the diagnostic workup. Recently, unconventional diagnostic methods are increasingly used. These include food specific IgG, antigen leucocyte antibody and sublingual/intradermal provocation tests, as well as cytotoxic food and applied kinesiology and electrodermal testings. These, however, lack scientific rationale, standardisation and reproducibility (Gerez et al., 2010).

## Complementary Methods

It is now well known that an incident investigated in the UK in 2015 of cumin alleged to be contaminated with almond, a risk for people with almond allergy, was caused by the *Prunus* species, *Prunus mahaleb*. It turned out that the initial findings of almond were based on almond-ELISAs that cross reacted with an almond-related species *P. mahaleb*. The author's investigation of the analytical aspects of the incident provides an illustration of the need for complementary, or 'orthogonal' approaches to the resolution of some problems of allergen analysis where one technique alone is insufficient to provide a definitive answer. The utility of ELISA solely as a screening tool for the *Prunus* family and extent of cross reactivity were confirmed. Two novel PCR assays were developed, one specific for *P. mahaleb* (Burns et al., 2016) and the other a screening method capable of identifying common *Prunus* DNA (Nixon et al., 2016). Peptides unique to almond and mahaleb were identified along with the conditions required for their extraction, tryptic digestion, chromatography and mass spectrometry and criteria for peptide identification to forensic standards (Inman et al., 2018).

The publication of an overview of the *Prunus* investigation (Walker et al., 2017a,b) enables a staged approach to be taken to any future incident thought to involve *Prunus* species and provides a template for the investigation of similar incidents. Successful resolution of the incidents described was aided by access to a multidisciplinary team of forensically aware analytical chemists, molecular biologists, protein mass spectrometrists, statisticians and food law specialists. A similar investigation of peanut and almond contamination of cumin in North America bears out the complex nature of the spice supply chain and the need for orthogonal confirmation of ELISA screening results (Garber et al., 2016). Work by Faeste et al. (2010) on celery prefigured the need for orthogonal methods for allergens although at the time no methods for the specific detection of celery protein in foods had been published. Faeste et al. (2010) developed a sandwich celery ELISA using polyclonal anticelery antibodies with an LOD of 0.5 mg kg<sup>-1</sup> in buffer; however, it was applicable only for the screening of food products because of extensive cross-reactivity with potato and carrot proteins. Using nanoLCion-trap MS/MS, a number of proteins in the three vegetable species were identified as candidates for causing cross-reactions due to amino acid sequence homologies. Among others, a novel patatin (Sola t 1)-like protein was detected in celery and a flavin adenine dinucleotide binding domain-containing protein (Api g 5)-like protein was identified in carrot. The utility of triple-quadrupole MS/MS for specific and quantitative analysis of celery, potato, and carrot allergens was evaluated using whole protein extracts. Several unique precursor ion-to-product ion transitions were determined for each species, suggesting the feasibility of developing an MS-based screening method to specifically detect celery allergens in foods.

# Food Allergens: Seafood, Tree Nuts, Peanuts

Marie-Claude Robert, Institute of Food Safety and Analytical Science, Lausanne, Switzerland

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Although firm prevalence data are lacking, there is a strong impression that food allergies have increased in prevalence in the last 2–3 decades, and appear to disproportionately affect people in industrialized/westernized regions. Food allergies are more common in children compared to adults, and a rather short list of foods account for the more serious disease burden, namely peanut, tree nuts, fish, shellfish, egg, milk, wheat, soy, and seeds (Sicherer and Sampson, 2017).

To help consumers with food allergen avoidance, most developed countries mandate labelling of the most common allergenic foods such as peanuts, tree nuts, milk, eggs, fish, crustacea/shellfish, soy and wheat or cereals containing gluten, as well as ingredients derived from those foods in accordance with the 1999 Codex Alimentarius Commission (Allen et al., 2014).

Although prevalence is said to increase, some food allergies have a high rate of resolution in childhood: milk, egg, wheat and soy with continued resolution into adolescence. Nonetheless other food allergies typically have low rates of childhood resolution and persist in adulthood: peanut and tree nuts allergy. Allergy to seeds, fish and shellfish are also considered persistent, but studies are lacking to define clearly their natural course (Savage et al., 2016).

The most common food allergy among adults is shellfish, affecting an estimated 3.6% of US adults according to a self-report survey. This marks a 44 percent increase from the 2.5% prevalence rate published in Sicherer et al. (2004). Similarly, these data suggest that adult tree nut allergy prevalence has risen to 1.9% from 2008 estimate of 0.5%, an increase of 260%. Today, peanut allergy prevalence is estimated at 2.4% amongst adults (Gupta et al., 2017) while it was reported at 1.2% in 2002 (Sicherer et al., 2004).

We compiled in this review the latest scientific knowledge progress on persistent food allergies: the seafood, tree nut and peanut allergies, in particular.

## Seafood

Seafood plays an important role in human nutrition and health, as it contains excellent source of highly assimilated proteins, vitamins and polyunsaturated fatty acids. The consumption of fish and shellfish is continuously increasing worldwide, but can provoke serious IgE antibody-mediated adverse reactions in sensitive individuals. The seafood allergy and anaphylaxis epidemic is particularly serious. Seafood allergy, including shellfish (crustacean and molluscs) and fish, is typically life-long affecting up to 5% of all children and 2% of all adults (Sharp and Lopata, 2014).

Attention should be paid to the ingestion of seafood infested with *Anisakis* larvae, as it can cause a disease called anisakiasis with symptoms similar to true seafood allergy. Other adverse reactions to seafood, including histamine fish poisoning and intolerance to histamine can also trigger clinical symptoms which, although non IgE-mediated, are similar to true seafood allergy (Prester, 2016).

While shellfish and fish allergy are often discussed concurrently, the allergens causing allergic sensitization are entirely different: parvalbumins for fish and tropomyosins for crustaceans and molluscs.

## Fish Allergy

If fish consumption has been shown to increase worldwide each year, rising above 20 kg a year in 2016 for the first time (FAO, 2016), fish intake varies considerably between different regions. Traditionally, consumption is highest in coastal areas, but this pattern may become less pronounced.

Unlike other food allergies, which are typically observed in babies and young children, an allergy to fish may not become apparent until adulthood; as many as 40% of people reporting a fish allergy had no problems with fish until they were adults (Sicherer et al., 2004).

Prevalence rate of self-reported fish allergy range from 0.2% to 2.29% in the general population, but can reach up to 8% among fish processing workers. Where the gold standard challenge criteria has been used, the worldwide prevalence rate for fish allergy ranges between 0% and 0.3% (Moonesinghe et al., 2016). Fish allergy seems to vary with geographical eating habits, type of fish processing, and fish species exposure.

Fish allergy is typically known to be life-long, in contrast to clinical allergies to milk, egg, wheat and soy which are typically outgrown despite frequently persistent skin prick test (EFSA, 2014). However, fish allergy may sometimes resolve, as reported for 3.5% of fish-allergic patients in one American study (Sicherer et al., 2004). Recently tolerance induction to different types of fish through desensitization has been shown to be successful (Casimir et al., 1997; Nakajima et al., 2005; D'Amelio et al., 2017) providing hope to these sensitive patients. But unless a specific fish species was shown safe to eat by provocative challenge, patients should avoid all fish species as cross-reactivity among various species of fish may exist (Helbling et al., 1999).

Fish-allergic symptoms are the same than other IgE-mediated food allergies and can range from mild (e.g. runny nose, headache, skin rashes) to moderate (e.g. nausea, vomiting, and diarrhea) to a potential fatal reaction: anaphylaxis. Fish meat is one of the foods most commonly provoking severe anaphylaxis (Lopata and Lehrer, 2009).

The major fish allergen characterized is parvalbumin in addition to several less well-known allergens (see Table 1). Parvalbumins have been reported to be the major and only fish allergen for 95% of patients suffering from IgE-mediated fish allergy (Swoboda et al., 2002). Parvalbumins are heat resistant and were shown to keep their IgE-binding capacity after heating at 100 °C for 10 min, and after digestion with proteolytic enzymes or denaturation with chemicals (EFSA, 2014).

Latest data estimated the dose eliciting reactions in 10% of the allergic population (ED<sub>10</sub>) at 27.3 mg of fish proteins (Ballmer-Weber et al., 2015).

### Shellfish Allergy

Similarly to the consumption of fish, which has increased steadily in the past four decades, shellfish (crustacean and mollusk) consumption has increased more than threefold. This is mainly due to the increased production from aquaculture and the constant decrease in their price (FAO, 2016).

The prevalence of seafood allergy varies considerably between regions and between children and adults. Generally, shellfish allergy is more frequent worldwide than fish allergy. In decreasing frequency, shrimp, crab, lobster, clam, oyster, and mussel are the most common shellfish allergens reported (Prester, 2016). Based on self-reporting or questionnaire based methods, prevalence may reach 10% of the general population, but based on challenge studies, the reported prevalence decreases to a maximum of 0.9% in the general population (Moonesinghe et al., 2016).

Crustacea causes most shellfish reactions, and these tend to be severe. Shellfish allergy will generally develop within minutes to an hour of eating shellfish. The symptoms may be mild but shellfish allergy may also trigger anaphylaxis. It is reported to be amongst the four major causes of food anaphylaxis, with peanuts, tree nuts, and fish (Sampson, 2000).

According to Ballmer-Weber et al. (2015), the ED<sub>10</sub> for shrimp, which is the best studied crustacean allergen and the one showing highest allergy frequency for crustaceans, is 2500 mg shrimp proteins. This eliciting dose does surprisingly not follow the dose distribution of other known major allergens and is not in full agreement with Taylor et al. (2014), who set the ED<sub>05</sub> for shrimp at 10 mg shrimp proteins.

So far, tropomyosins have been considered major allergens in shellfish allergy, but some crustacean allergic individuals only show IgE-binding to non-tropomyosin allergens (Abramovitch et al., 2013). Several allergenic shellfish proteins have been identified in shrimp, crab, lobster, abalone, mussel, or oyster, these are listed in Tables 2 and 3. In a crustacean-allergic individual, the probability of reacting to another crustacean species has been estimated to be 75%, but cross-reactivity between tropomyosin from crustacean and tropomyosin from mollusks seems to be more limited as the sequence homology is markedly lower than within crustaceans (EFSA, 2014). As clinical data is lacking, no eliciting dose for mollusks has been established so far. Nonetheless, there

is one report describing improvement of shrimp allergy following immunotherapy for dust mite (Cortellini et al., 2011), showing that treatment of this allergy is possible.

## Tree Nuts

Tree nuts is the collective term used to describe nuts that grow on trees. Tree nuts are defined in Europe as almonds (*Amygdalus communis* L.), hazelnuts (*Corylus avellana*), walnuts (*Juglans regia*), cashews (*Anacardium occidentale*), pecan nuts (*Carya illinoensis* (Wangenh.) K. Koch), Brazil nuts (*Bertholletia excelsa*), pistachio nuts (*Pistacia vera*), macadamia or Queensland nuts (*Macadamia ternifolia*). In the USA, tree nuts requiring mandatory ingredient labeling include additionally beech nut, butternut, chestnut, chinquapin, coconut, ginko nut, hickory nut, lichee nut, pine nut or pinon nut, pili nut, and sheanut.

Tree nuts are one of the most common foods causing acute allergic reactions and nearly all tree nuts have been associated with fatal allergic reactions. Prevalence of individual tree nut allergies varied significantly by region with hazelnut known as the most common tree nut allergy in Europe, walnut and cashew for the USA and Brazil nut, almond and walnut most commonly reported in the UK (McWilliam et al., 2015). Similar to peanut allergy, tree nut allergy tends to persist into adulthood. Resolution rates for tree nut allergy might be lower than those for peanut allergy, with 9% resolution rate only (Couch et al., 2017).

Allergic reactions to tree nuts can result from primary IgE-mediated mechanisms or, alternatively, via secondary cross-reactivity mechanisms to birch pollen, in a form of food allergy known as oral allergy syndrome or pollen food syndrome. In individuals with birch pollen sensitization, birch pollen-specific IgE can cross-react with similar proteins found in a range of fresh fruits, vegetables and nuts (apple, apricot, carrot, celery, hazelnut, peach, peanut, pear, potato and plum) resulting in oral pharyngeal symptoms (McWilliam et al., 2015).

Allergic reactions occur typically within minutes after ingestion of small amount of the offending nut with symptoms including hives, angioedema, or vomiting. Reactions may become life-threatening and involve anaphylaxis. Tree nuts and peanut together account for 70%–90% of reported food-induced anaphylaxis fatalities, with tree nuts alone accounting for around 18%–40% (McWilliam et al., 2015).

With few exceptions (notably limited peanut cross-reactivity with pistachio and walnut), peanut antigens do not serologically cross-react with tree nuts. Walnut, pecan, and hazelnut form a group of strongly cross-reactive tree nuts. Hazelnut, cashew, Brazil nut, pistachio, and almond form a group of moderately cross-reactive tree nuts. Cross-reactivities between these groups are less pronounced (notably limited cross-reactivity of walnut and pecan with Brazil nut). The strongest cross-reactivities among tree nuts follow botanical family associations: (1) walnut and pecan in the family Juglandaceae and (2) cashew and pistachio in the family Anacardiaceae (Goetz et al., 2005). Considering the potential severity of the allergy and issues with accurate identification of particular nuts in prepared foods, caution would seem prudent, and total elimination of the nut family (perhaps with the exception of previously tolerated nuts eaten in isolation) is suggested (Sicherer, 2001).

The majority of nut allergens are seed storage proteins, such as vicilins, legumins and 2S albumins. Other nut allergens are PR proteins (chitinases, Bet v 1 homologues and LTPs) and structural proteins (profilins and oleosins). Profilins are panallergens (present in pollens, nuts, seeds, fresh fruit and other vegetables). Additional proteins have recently emerged as allergens in tree nuts, including manganese superoxide dismutase (MnSOD), 60S acidic ribosomal protein P2, and cytosolic small heat shock protein. Full details about allergenic proteins from different tree nuts are available in Table 4.

If tree nuts have often been implicated as responsible for allergic reactions, two studies confirm significant increase in tolerance to the offending tree nuts following immunotherapy: Enrique et al. (2005) demonstrates successful tolerance to hazelnut after sublingual immunotherapy, as assessed by double-blind placebo controlled food challenge. The mean hazelnut quantity provoking objective symptoms increased from 2.29 to 11.56 g. In Scurlock et al. (2016), walnut oral immunotherapy induced clinical desensitization to both walnut and a test tree nut (pecan, cashews, hazelnut, pistachio) after 38 weeks on therapy.

With 202 data points, sufficient low-dose clinical challenge data was made available for hazelnut so that it is today the only tree nut allergen for which an eliciting dose was derived. The ED<sub>01</sub> (Taylor et al., 2014) is set at 0.1 mg hazelnut proteins (Taylor et al., 2014) while the ED<sub>10</sub> is according to Ballmer-Weber et al. (2015) set at 8.5 mg hazelnut proteins.

## Peanut

Peanut is commonly believed to belong to the nut family, it is in fact a groundnut and classified as a legume. Legumes represent 27% of the primary crop production worldwide. Legumes are excellent sources of proteins, however they can also elicit dangerous allergic reactions. Peanut is here a typical example.

The prevalence of peanut allergy has risen significantly across the developed world over the past few decades, with a recent estimate of around 2% among UK children. Severe reactions to peanut are rare, but peanut allergy remains a leading cause of fatal food-related anaphylaxis. While there have been important advances in peanut desensitization, primary prevention remains the most attractive strategy for addressing this rise (Foong et al., 2017).

Peanut is reported as the most common food causing severe IgE mediated reactions in children and adolescents in the USA and Europe. It is estimated that 0.8% children in the USA and 1.5% children in the UK suffer from peanut allergy (Venter et al., 2010). Peanut allergy prevalence is reported to decline with increasing age to an estimate of 0.26% (Ben-Shoshan et al., 2010) to 0.48%

**Table 4** Tree nut allergens

Common name (Scientific name)	Allergen	Biochemical name	Superfamily/family	Molecular weight <sup>a</sup>
Almond ( <i>Prunus dulcis</i> )	Pru du 3	ns-LTP 1	Prolamin	9
	Pru du 4	Profilin	Profilin	14
	Pru du 5	60s Acidic ribosomal prot. P2		10
	Pru du 6	Amandin, 11S globulin (legumin-like protein)	Cupin	360
Brazil nut	Ber e 1	2S Albumin (sulfur-rich)	Prolamin	9
	Ber e 2	11S Globulin	Cupin	29
Cashew nut ( <i>Anacardium occidentale</i> )	Ana o 1	Vicilin-like protein	Cupin	50
	Ana o 2	Legumin-like protein	Cupin	55
	Ana o 3	2S Albumin	Prolamin	14
Chestnut ( <i>Castanea sativa</i> )	Cas s 1	PR-10	Bet v 1	22
	Cas s 5	Chitinase		
	Cas s 8	ns-LTP 1	Prolamin	12–13
	Cas s 9	Cytosolic class I small heat-shock protein	Hsp17.5	17
Hazelnut ( <i>Corylus avellana</i> )	Cor a 1	PR-10	Bet v 1	17
	Cor a 2	Profilin	Profilin	14
	Cor a 6	Isoflavone reductase homologue	Bet v 5	35
	Cor a 8	ns-LTP 1	Prolamin	9
	Cor a 9	11S Globulin (legumin-like)	Cupin	40
	Cor a 10	Luminal binding protein	Hsp70	70
	Cor a 11	7S Globulin (vicilin-like)	Cupin	48
	Cor a 12	Oleolin	Oleolin	17 <sup>b</sup>
	Cor a 13	Oleolin	Oleolin	14–16 <sup>b</sup>
	Cor a 14	2S Albumin	Prolamin	15–16 <sup>b</sup>
Pecan ( <i>Carya illinoensis</i> )	Car i 1	2S Albumin	Prolamin	16
	Car i 2	Vicilin-like protein	Cupin	55
	Car i 4	11S Globulin (legumin-like)	Cupin	55.4 <sup>c</sup>
Pistachio ( <i>Pistacia vera</i> )	Pis v 1	2S Albumin	Prolamin	7
	Pis v 2	11S Globulin subunit	Cupin	32
	Pis v 3	7S Globulin (vicilin-like)	Cupin	55
	Pis v 4	Manganese superoxide dismutase	Superoxide dismutase	25.7
	Pis v 5	11S Globulin subunit	Cupin	36
Walnut - Black walnut ( <i>Juglans nigra</i> )	Jug n 1	2S Albumin	Prolamin	15
	Jug n 2	Vicilin	Cupin	56
	Jug n 4	11S Globulin (legumin-like)	Cupin	33, 22
Walnut – English walnut ( <i>Juglans regia</i> )	Jug r 1	2S Albumin	Prolamin	15–16
	Jug r 2	Vicilin	Cupin	44
	Jug r 3	ns-LTP 1	Prolamin	9
	Jug r 4	11S Globulin	Cupin	58
	Jug r 5	PR-10	Bet v 1	20
	Jug r 6	Vicilin-like protein	Cupin	47

Extracted from EFSA NDA Panel (EFSA Panel on Dietetic Products, Nutrition and Allergies) (2014) and WHO/IUIS Allergen Nomenclature (1984).

(Emmet et al., 1999) proven by challenge in adults. Peanut allergy does in some cases resolve with age, with a 20% rate of resolution among young patients at age 4 (Sicherer and Sampson, 2017).

The clinical expression of peanut allergy is fairly predictable, and it has the tendency to be severe, although the severity may vary with different episodes of ingestion (Al-Muhsen et al., 2003). Reported symptoms include typical Ig-E mediated allergy symptoms such as facial swelling, rash, itch, wheeze, vomiting, breathing difficulty, abdominal pain and cramps, cyanosis and collapse but may also lead to fatality. Severe symptoms were reported to be more common in adults (Hourihane et al., 1997).

According to Allen et al. (2014), the ED<sub>01</sub>, which is the dose eliciting reactions in 1% of the peanut allergic population, is 0.2 mg peanut proteins. This figure is based on data from 750 subjects. The reference dose for peanut is 25 times lower than the lowest dose that Wainstein et al. (2010) reported as leading to anaphylaxis. Recently, Ballmer-Weber et al. (2015) confirmed the ED<sub>01</sub> published by Allen et al. (2014) providing a peanut ED<sub>10</sub> value at 2.8 mg peanut proteins.

Peanut is the best characterized legume in regard to its allergenic content, with 16 allergens registered by the World Health Organisation/International Union of Immunological Societies (WHO/IUIS) Allergen Nomenclature Subcommittee (Table 5).

**Table 5** Peanut (*Arachis hypogea*) allergens

Allergen	Biochemical name	Superfamily/family	Molecular weight <sup>a</sup>
Ara h 1	7S Globulin (vicilin-type)	Cupin	64
Ara h 2	Conglutin (2S albumin)	Prolamin	17
Ara h 3	11S Globulin (legumin)	Cupin	60.34 (fragment)
Ara h 5	Profilin	Profilin	15
Ara h 6	Conglutin (2S albumin)	Prolamin	15
Ara h 7	Conglutin (2S albumin)	Prolamin	15
Ara h 8	PR-10	Bet v 1	17

<sup>a</sup>Molecular weight (SDS-PAGE).<sup>b</sup>kDa.

Extracted from EFSA NDA Panel (EFSA Panel on Dietetic Products, Nutrition and Allergies) (2014).

Clinically relevant cross-reactivity between peanut and at least one other legume was found to be low to moderate, with 10%–15% of children allergic to peanuts also allergic to soybean and 28% of peanut allergic patients in a French study cross-reacting with lupine (Cabanillas et al., 2017).

Peanuts are consumed boiled in certain countries, such as China, and in some southern US states such as Florida, Georgia, and Alabama, while this kind of treatment is quite uncommon for peanut processing in other areas of the world. However, boiling has been extensively studied in peanut due to the increased evidence that this treatment can alter peanut allergenicity. On the contrary, it has been largely demonstrated that roasting has the capacity to increase the IgE-binding properties of peanut allergens up to a 90 fold (Cabanillas et al., 2017).

There is today no cure for peanut allergy, but oral desensitization therapy as well as proactive early introduction of peanuts in the baby's food are promising routes for decreasing its prevalence. The Learning Early About Peanut (LEAP) study, a randomized, open-label, controlled trial of which 640 high-risk (defined as having severe eczema and/or egg allergy) infants from 4 to 11 months were randomized to either consume peanut regularly or avoid it until 5 years of age, provided robust evidence that early introduction of peanuts significantly decreased the frequency of the development of peanut allergy among children at high risk for this allergy. This study has overall changed worldwide recommendations related to early foods (including allergenic foods) introduction (Du Toit et al., 2015). As an example, the latest US pediatrician guidelines recommends the introduction of peanut into the diet of children at around 6 months of age as long as they do not have egg allergy or severe eczema (Foong et al., 2017).

## Concluding Remarks

Although prevalence of seafood, tree nut and peanut allergies is said to have been increasing in the past decades, there is today hope that immunotherapy treatment will help induce desensitization.

In the meanwhile, the unique way of preventing allergic reactions in sensitized patients remains avoidance of the offending food and accurate food labelling plays an essential role in the safeguard of allergic patients' health. In 2007, the Voluntary Incidental Trace Allergen Labelling (VITAL) risk assessment system (Allergen Bureau, 2007) was launched. This system ensures uniform precautionary labelling at a defined level of risk based upon scientific principles. In this view, the need of determining the compliance of food labels has prompted the development and improvement of analytical methods for the detection and quantification of food allergens. Up to know, the main limiting factors of method validation were the lack of reference methods and reference materials, but early 2017, the MoniQA Association (2011) has successfully started to sell validated reference material for the analysis of milk allergen. According to MoniQA Association (2011), further reference materials are in preparation; still seafood, peanut and tree nuts reference materials need to be developed. Once available, the harmonization of suitable methodologies for the detection of these allergens could be started.

## Food Counterfeiting: A Growing Concern

John Spink, Food Fraud Initiative, Michigan State University, East Lansing, Michigan, USA

© 2019 Elsevier Inc. All rights reserved.

### Counterfeiting and Intellectual Property Rights

When dealing with laws and regulations, the term “counterfeiting” has a very specific application to intellectual property rights (IPR). *Intellectual property rights* (IPRs) are “rights given to persons over the creations of their minds (They usually give the creator an exclusive right over the use of his/her creation for a certain period)” (WTO, 1994). IPRs are comprised of four categories: trademark, patent, copyright, trademark, and trade secret. Summarizing the definitions:

- **Trademark:** “a symbol, word, or words legally registered or established by use as representing a company or product” (Merriam-Webster, 2004).
  - **Geographical Indication:** This is a type of trademark that identifies the location of origins such as a country, region, or territory.
- **Patent:** “a right or title for a set period, especially the sole right to exclude others from making, using, or selling an invention” (Merriam-Webster, 2004).
  - **Trade Dress:** a combination of trademark and patent that protections of the use of where a shape, image, or decoration that represents the company or product.
- **Copyright:** “the exclusive legal right, given to an originator or an assignee to print, publish, perform, film, or record literary, artistic, or musical material, and to authorize others to do the same” (Merriam-Webster, 2004).
- **Trade Secret (Protection of Undisclosed Information):** “a secret device or technique used by a company in manufacturing its products” (Merriam-Webster, 2004).

As defined by the International Standards Organization (ISO), a *counterfeit* is a “material good imitating or copying an *authentic material good*” where *material good* is “manufactured, grown product or one secured from nature” (ISO, 2018). Also, *authentic material good* is “material good produced under the control of the legitimate manufacturer, the originator of the goods or rights holder” (ISO, 2018). Then *rights holder* is the “legal entity either holding or authorised to use one or more intellectual property rights” (ISO, 2018). The counterfeiting concept is usually associated with trademarks or the logos of material goods. A related term is *piracy* that is usually applied to a copyright or patent violation for a published work such as a book, song, or movie.

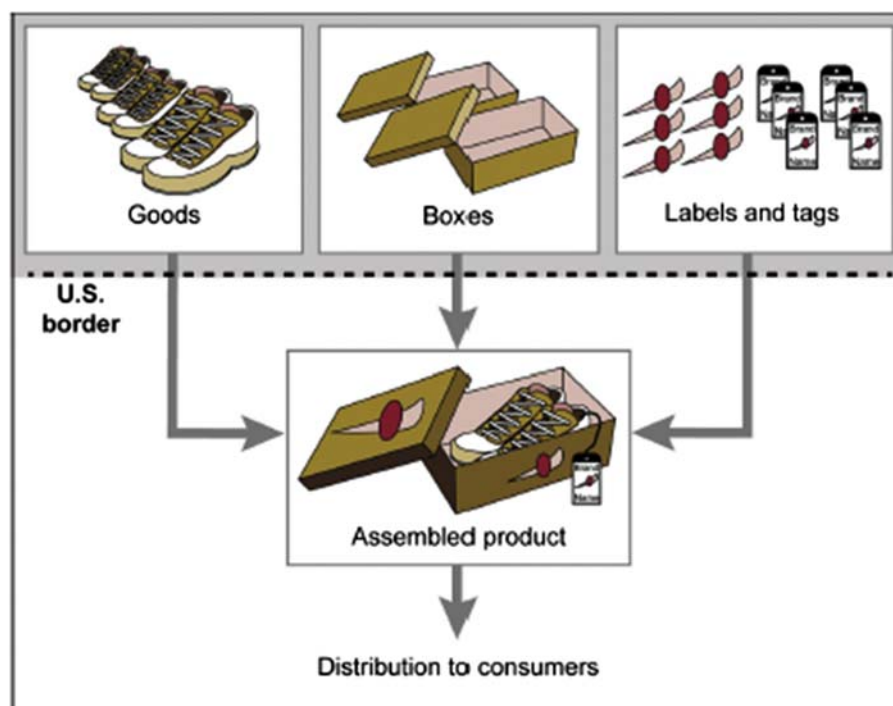

To consider the full challenges for securing legal IPR protection it is important to further review concepts such as the IPR being “validly registered,” if there is a law against manufacturing IPR violating product or it may be just illegal to export, and then also considering the laws and law enforcement priority for the importing country. Definitions are included with emphasis added since each point is critical in the legal protection (WTO, 1994):

- **Counterfeit trademark goods:** “shall mean any goods, including packaging, bearing without authorization a *trademark* which is identical to the trademark *validly registered* in respect of such goods, or which cannot be distinguished in its essential aspects from such a trademark, and which thereby infringes the rights of the owner of the trademark in question under the law of the *country of importation*.”
- **Pirated copyright goods:** “shall mean any goods which are *copies* made without the consent of the right holder or person duly authorized by the right holder *in the country of production* and which are made directly or indirectly from an article where the making of that copy would have constituted an infringement of a copyright or a related right *under the law of the country of importation*.”

In some cases, it may NOT be illegal to produce the product in one country, and the production is only illegal upon importation by another country. If the product is never exported or imported, then there may be no legal IPR violation. In other instances, what is illegal in one country may not be illegal in another. To avoid a customs agency seizure of the most expensive part of the cost of goods, the counterfeiters may import “genuine, generic” materials or finished goods and then send a small package of the counterfeit trademark components such as labels and tags. The components can be assembled inside a country to avoid customs investigations and reduce the amount of product that would be seized in a raid (Fig. 1).

Considering another challenge, the trade secret protection is important, but much more difficult to control. In some cases, a rights-holder may try to protect the IPR through confidentiality and non-disclosure agreements rather than register a patent or copyright to avoid the required public disclosure which would place the sensitive information in the public domain – a counterfeiter would be able to find detailed instructions to counterfeit the product. Also, the term “fake” and “knockoff” are sometimes used but should be avoided because they do not have a formal definition and so can cause confusion.

At this point in the chapter, it is important to establish that criminal or public health incidents related to food are handled under two separate types of laws: *food* or *material goods*. A “food law” typically focuses on the safe and secure production, manufacturing, and distribution with a priority based on minimizing the public health threat. A violation can be a strict liability so guilt even without knowledge or intent. On the other hand, the “material goods” laws focus on other aspects of the product, such as trademark counterfeit violation, where the intent is often necessary for guilt or prosecution.

**Figure 1** Domestic Assembly of Foreign Manufactured Counterfeit Goods. From GAO (2017).

The regulatory or criminal law enforcement response is activated from the food/public health perspective and most likely results in an immediate recall. This recall is important for reducing the public health threat but now leads the criminal investigation to be very challenging since the criminal is altered and the evidence (the fraudulent product) is recalled or destroyed by the criminal. The government and law enforcement priority – high to lower – is public safety (drugs, guns, violence), public health, large-scale economic crimes that disrupt markets or governments, then declining economic crimes, and then violations that are only technical. A counterfeit food that has a public health threat would be in the “public health” category and thus take precedence before the economic crime.

Regarding applying the IPR laws, the prosecution of cases is usually challenging and complex because often “two states of mind” need to be proven which include “intentional trafficking in counterfeits” AND “knowing use of a counterfeited mark” (Hilliard et al., 2007). If the plaintiff can establish that they did not know the product was counterfeit – such as parallel trade or diversion – “this eliminates the application of the counterfeit laws” (Hilliard et al., 2007).

An example of a typical food fraud investigation is the INTERPOL-Europol Operations OPSON. The seventh annual operation includes over 50 countries and over 20 companies. The scope balances the maximum economic impact while the priority is on the most severe public health threats. The focus on public health is evidenced in that some countries such as Austria included an inter-agency team enforcement agencies (police - law enforcement, customs -import controls, and Food Administration Vienna -food agency) while other countries such as Denmark and the US only include food agencies (Veterinary and Food Administration - food agency and Food and Drug Administration - food agency, respectively). The priority and assigned participants was reflected in the efforts and results of seizures: Deceiving consumer (26%, e.g., falsely labeled extra virgin olive oil), Food safety (22%, e.g., infringement related to storage conditions of the goods), Fiscal infringement (19%, e.g., Alcohol duties), and then finally Intellectual Property Rights - Counterfeiting (1%, e.g., all IPR, including appellations of origins).

Counterfeiting (IPR) is one type of food fraud in the hierarchy of adulterant-substances (dilution, substitution, concealment, unapproved enhancements), mislabeling/misbranding, grey market production/theft/diversion, and counterfeiting (IPR) (Spink and Moyer, 2011). The overall food fraud vulnerability assessment can consider counterfeiting and coordinate countermeasures and control systems in the food fraud prevention strategy. While the challenges of defining and prosecuting counterfeiting have been presented, the review emphasizes the efficiency of applying crime prevention concepts not to try to “catch bad product” but to try to “prevent food fraud from occurring in the first place.”

## Food IPR Counterfeiting

The magnitude of the economic impact of counterfeiting and piracy is very challenging to estimate to the point that it is probably impractical even to try to create a statistically significant estimate. While there are no very accurate or precise estimates, it is generally believed that for all products counterfeiting to be in the hundreds of billions of dollars. Overall there is an estimate that a broad

definition of counterfeits equates to “5%–7%” of world trade, with some pharmaceutical estimates above 10% worldwide, and other individual markets well above 50%.

A study of the economic impact of counterfeiting and piracy found that quantitative estimates were based on three core reference documents including the International Chamber of Commerce, the OECD report, and a press release from the U.S. Federal Bureau of Investigation (Spink and Fejes, 2012). Each of these documents was based on qualitative estimates such as “5%–7% of world trade” and repeated so often that the estimates reached a “mythological stature even among scholars” (Spink and Fejes, 2012). There was an assumption that since the estimate was repeated so many times that it must have been based on a sound statistical methodology and data collection. While this may be the belief, the core references were clear in their statements. For example, in the OECD report, it stated: “The overall degree to which products are being counterfeited and pirated is unknown, and there do not appear to be any methodologies which could be employed to develop an acceptable overall estimate” (OECD, 2008).

The U.S. Government Accountability Office (GAO) published “Observations on Efforts to Quantify the Economic Effects of Counterfeit and Pirated Goods” which was originally specified to establish an economic impact estimate (GAO, 2010). The GAO report reviewed global estimates and concluded that the data for the previous estimates had not been systematically evaluated or collected and did “rely excessively on fragmentary and anecdotal information; where data are lacking, unsubstantiated opinions are often treated as facts” (GAO, 2010). GAO stated that quantifying counterfeiting as a whole “is difficult, if not impossible” (GAO, 2010). They also stated, “One expert characterized the attempt to quantify the overall economic impact of counterfeiting as ‘fruitless,’ while another stated that any estimate is highly suspect since this is covert trade and the numbers are all ‘guesstimates’” (GAO, 2010).

Thus, for food counterfeiting – and for the overall food fraud – establishing methodologically sound, accurate and precise economic impact estimates is probably impossible. But, considering the general focus on vulnerabilities, the lack of a hard estimate is not a critical problem and actually is not even a hindrance. A focus on the vulnerability and “fraud opportunity” does not require a lot of data but does require deeper insight on the type of fraud, type of fraudsters, and actual incidents. These first need a review of the types of market and products that are being counterfeited.

The industry-led food fraud prevention initiatives focus on vulnerability – in both assessing the problem and also for selecting risk treatments – so this lack of an economic impact is not an insurmountable challenge. When addressing this question for food products, the OECD report stated “Unfortunately, the survey has shed very little light on the actual magnitude and scope of counterfeiting in the food and drink sector. Part of the reason for this is that there seems to be genuine and widespread misunderstanding in this sector of what is actually covered by counterfeiting [such as IPR versus all fraud]” (OECD, 2008).

The confusion on classification includes when there is a mention of “counterfeit food.” For example a report of “seizures of counterfeit (trademark infringing) fresh strawberries, cinnamon and coconut oil” defined the violation as the trademark of the brand and not the product, itself (OECD, 2016). The counterfeit strawberries, cinnamon, and coconut oil were actually strawberries, cinnamon, and coconut oil but the brand name was used without authorization.

Counterfeit material goods can be split into deceptive and non-deceptive categories.

- **Deceptive counterfeits** “are intended to deceive the consumer into believing they are purchasing a genuine product” (Spink et al., 2013).
- **Non-deceptive counterfeits** “are not intended to deceive consumers – in many instances products are promoted as ‘fakes,’ ‘knock-offs,’ or ‘counterfeits’” (Spink et al., 2013).

Next, the counterfeit product threat is present in two basic market extremes with many variations in between primary market and secondary markets. On one end, the **primary market** is through authorized resellers which are for “Consumers who demand goods of genuine, non-infringing origin establish a market that is referred to in this report as the primary market.” Then, “The only way that counterfeiters and pirates can penetrate this market is to deceive consumers into believing that their products are authentic (deceptive counterfeits).” At the other end is the **secondary market** or black market that were “Under certain conditions, consumers are often willing to purchase products they know are not legitimate.” Then, in this case, the customers are seeking counterfeit product (non-deceptive counterfeits). There are other markets in between such as products not sold through authorized resellers, legal diverted product, or other types of “gray markets.”

A **black market** is “An illegal market for goods that are controlled or prohibited by the government, such as the underground market for prescription drugs” (Black’s Law Dictionary, 2015). A **gray market** is “A market in which the seller uses legal but sometimes unethical methods to avoid a manufacturer’s distribution chain and thereby sell goods (especially imported goods) at prices [usually] lower than those envisioned by the manufacturer” (Black’s Law Dictionary, 2015). To note, the parallel **trade** or **diversion** is “Goods bearing valid trademarks that are manufactured abroad and imported into another country to compete with domestically manufactured goods bearing the same valid trademarks” (Black’s Law Dictionary, 2015).

For food products, consumers may be seeking a good deal, but they are – regardless of the market type – almost universally seeking genuine products.

To address all types of counterfeiting and for all products, to a “The Economic Impact of Counterfeiting and Piracy” was published by the Organization for Economic Co-Operation and Development (OECD) (OECD, 2008). Their survey of industry included several insights that pertain to the food industry:

- “The incidence of infringement is considerably lower when physical counterfeiting is necessary to misrepresent the product (as opposed to simply copying the packaging, labeling, trademark and the general appearance of items being substituted)”

- The physical counterfeiting of a deceptive product that has high consumer detection is more challenging because “as this requires a considerably more sophisticated enterprise to successfully carry out the substitution and convince retailers and the buying public that they are original items.”
- “For example, the counterfeiting of frozen or canned food is much more difficult [than counterfeiting other product such as luxury goods or apparel] as this would require specialized equipment to produce the substitute items, as well as to store and transport them, and this severely reduces the potential incentive for counterfeiting.”
- “In the experience of the industry, products most subject to counterfeit action are those that are the simplest to replace with passable substitutes, and whose substitutes would not be readily detected by the consumer (and sometimes the wholesalers and retailers). Tea, rice and vodka were examples of such items provided by respondents to the OECD survey.”
- “Several respondents noted that counterfeiting and infringement of trademarks in food are relatively low compared to other products, due to generally low-profit margins and the significant logistical challenges associated with the production, handling, transport, and distribution of food products.”
- “[The challenges of the food manufacturing characteristics would be further magnified for perishable products, which require even more sophisticated handling and distribution chains capable of handling these products efficiently.”

So a “*professional*” type of counterfeiter (who only focuses on counterfeiting as a their profession) would find the IPR counterfeiting of food to be more challenging than for other products because of the lower margins, perishable product, high quality needed to deceive consumers that the counterfeit is a genuine product, the challenge of inserting the counterfeit product in the legitimate supply chain, the challenge of procuring so much of the raw materials, and the specialized manufacturing equipment. That said, an “*occupational*” type of counterfeiter (who is in the food industry as a profession and supplements their income conducting fraud) would not face most of those challenges and could leverage the criminology concept of Routine Activities Theory to be aware of new, emerging, or nuanced fraud opportunities. This insight is valuable when considering the “fraud opportunity,” food fraud vulnerability assessment, and the food fraud prevention strategy. This insight would help identify the vulnerable nodes in the supply chain as well as where and how the fraudulent product would try to enter the supply chain.

## Conclusion

The intellectual property rights counterfeited food products are a significant threat with a very challenging prevention strategy. Fortunately, the industry-led food fraud vulnerability assessment and food fraud prevention strategy efforts include IPR counterfeiting as a “type of fraud” and integrate countermeasures and control systems across a company. When the entire food risk continuum is considered there can benefit from other efforts – such as random quality control checks in a marketplace – that help reduce the fraud opportunity for counterfeit foods. This food fraud prevention strategy focus already includes criminology theory such as situational crime prevention that already considers the counterfeit product threat. The anti-counterfeiting efforts are most efficiently implemented when considered in the hierarchy of all fraud and all products.

# Food Defense

Andrew G Huff, Michigan State University, East Lansing, MI, United States

## Introduction

Ongoing terrorist activity has reinforced the need to enhance the security of the United States across all critical infrastructures including the food and agriculture system. After September 11, 2001, the United States' Congress responded by passing the Public Health Security and Bioterrorism Preparedness and Response Act in 2002 which was signed into law by President Bush later that year. Per the USDA, Food defense is the protection of food products from contamination or adulteration intended to cause public health harm or economic disruption (USDA, <https://www.fsis.usda.gov/wps/portal/fsis/topics/food-defense-defense-and-emergency-response>). However, the definition provided by the USDA and more broadly the US government does not adequately address all the concerns of food producers and consumers. This chapter's definition of food defense is the protection of food, plants and animals from intentional contamination with the intent to cause harm.

The Bioterrorism Preparedness and Response Act required that the Food and Drug Administration (FDA) implement several regulations applicable to the food defense: (1) Administrative Detention of Imported Food; (2) Establishment and Maintenance of Records; (3) Food Facility Registration; and, (4) Prior Notice of Imported Food. Food Defense requirements were further expanded when the Food Safety Modernization Act (FSMA) was signed into law by President Obama in 2011. FSMA aims to further enhance the safety of the United States food supply by shifting FDA's focus from responding to contamination incidents after they occur, to ensuring that private industry food companies mitigate food defense risks and prevent food defense events from occurring.

FSMA also provided FDA with new enforcement authorities designed to achieve higher rates of compliance with food defense risk identification and mitigation as defined by the FDA at qualifying food facilities. FSMA also gave the FDA to regulate imported foods similarly to domestic foods. FSMA Section 103 requires facilities registered with the FDA to:

- analyses to identify and evaluate known or reasonably foreseeable hazards that may be associated with the facility, including hazards that may be introduced intentionally; and,
- develop and implement comprehensive, science-based preventive controls to provide assurances that the identified hazards will be significantly minimized or prevented and addressed, and that food and feed manufactured, processed, packed or stored by such facilities will not be adulterated or misbranded.

Importantly, FSMA includes the requirement that FDA develop regulations concerning how food facilities are to assess whether they are required to conduct vulnerability assessments, develop and implement mitigation strategies to address intentional contamination events. Additionally, food-defense provisions of FSMA Section 106 state that such regulations shall apply only to food and feed for which there is a high risk of intentional contamination, as determined by the FDA, in consultation with the Secretary of Homeland Security, that could cause serious adverse health consequences or death to humans or animals. Foods subject to the requirements include those foods for which the Agency has identified clear vulnerabilities (i.e., a food product with a short shelf-life, vulnerability to intentional contamination at critical control points, and foods produced in bulk or batch form). Under FSMA, FDA is directed to issue regulations to protect against the intentional adulteration of food and animal feed, including the establishment of science-based mitigation strategies to prepare and protect the food supply chain at specific vulnerable points. The goals of food defense are to prevent foodborne contamination, force increased corporate responsibility, identify food system vulnerabilities, analyze the risks in food production systems and processes, and implement effective mitigation strategies. Lastly, food defense aims to improve immediate response systems and improve crisis communication to the public.

## Attacker Motivation

Food Defense is protection against intentional contamination of food products. While identifying who may want to attack a food system can aid specific food defense mitigation strategies, knowing the specific motivations of attacker's is not necessary to implement effective food defense mitigation strategies. To properly develop effective preventative controls to mitigate food defense risks it is not necessary to know who wants to attack the system or why since the food defense vulnerabilities and risks in the food system do not vary based on the attacker's motivations. Vulnerabilities and risks in food production system remain constant unless the food production system is altered in some way or unless there is some change that alters human behavior in the food production environment. However, understanding the attacker's motivation can help those involved with assessing and mitigating risks identify vulnerabilities in the food production system.

Attacker motivations can vary greatly. In terrorism, intentional contamination is motivated by drawing attention to the terrorist act itself. In the case of economically motivated adulteration (e.g., counterfeiting, ingredient substitution) the criminal typically does not want the act to be noticed, since the longer it is undetected the longer the adulterator avoids punishment and receives economic benefits. There are almost an infinite number of motivations to intentionally contaminate food; however, the most frequently identified motivations are: (1) Terrorism aim to kill or harm as many people as possible publicly; (2) Economically Motivated Adulteration (EMA) aims to increase the profitability of a product; (3) Eco-Terrorism an interest group economically damages

an industry or company without killing people; (4) Extortion aims to obtain financial gain. To develop an effective food defense system, understanding the security issues associated with humans is necessary to better understand how to identify vulnerabilities in the food production system, mitigate food defense risks, and investigate and respond to intentional contamination events when they occur.

## Food Defense Plans

The food defense plan (FDP) is a document that is used to operationalize food defense strategy. Typically, the FDP is operationalized via trained personnel carrying out the standard operating procedures (SOPs) described in the company's plan. The FDP can be assembled collaboratively by a team within the company that takes the results of the facility's vulnerability assessment, ranks the issues per their importance to food defense, and develops mitigating preventive controls that will likely guard against intentional contamination events. The FDA has software to assist in the vulnerability assessment, programs to aid in the development of the FDP, and has laboratory and database resources that can assist with analysis of suspects or known harmful agents.

A properly executed FDP helps a food company identify effective food defense mitigation strategies. A FDP may increase food defense preparedness and it can be particularly helpful in responding to intentional contamination events. The FDP should be reviewed and updated bi-annually to remain relevant. This includes properly supervising and mentoring managers responsible for overseeing food defense and verifying that the plan is effectively mitigating food defense risks by measuring and evaluating the outcomes of Red Team Assessments. A Red Team Assessment is an independent group within the organization that challenges an organization to improve its effectiveness by assuming an adversarial role or point of view. Often, the Red Team Assessment occurs during normal food production conditions and the employees within the organization are unaware that the Red Team Assessment is occurring. Benefits of the assessment include challenges to preconceived notions and clarifying the problem state that planners are attempting to mitigate. More accurate understanding can be developed of exploitable vulnerabilities and identify instances of bias among employees responsible for food defense. Identifying and documenting known vulnerabilities, keeping records of mitigation activities, and striving for continuous improvement and employee training as the facility personnel and processes change over time increases the likelihood the food defense plan will be effective at mitigating food defense risks.

The food defense management team is responsible for developing, monitoring, and maintaining the FDP. In many instances, obtaining assistance from consultants and other outside experts is necessary to ensure the proper analysis of food defense vulnerabilities and risks, and to develop and implement effective food defense risk mitigation techniques and strategies.

When conducting a vulnerability assessment, or developing or modifying an FDP, it is imperative to select mitigation procedures and technologies that are effective and practical to the characteristics and day-to-day operation of the food production facility, as well as the food facility's physical environmental characteristics. There is not a single solution to food defense. Rather, each food defense mitigation technology or strategy can be viewed as a layer of Swiss cheese, and as layers of Swiss cheese are stacked on top of each other its more difficult for an object to pass through the combined layers of cheese. The more layers of food defense mitigation, the more resilient the food defense system or facility will be to intentional contamination events. Every food facility should have its own unique food defense plans (even those operated by the same company) based upon the types of processes, products, conditions, and different employees present. Finally, it is extremely important to select food defense mitigation strategies and technologies that effectively mitigate intentional contamination likelihood through qualitative and quantitative vulnerability and risk analyses.

## Assessing Food Defense Vulnerabilities

FSMA directs the FDA to require preventive controls against intentional adulteration at vulnerable points in the food system and inside food facilities. Each registered facility is required to have preventive controls in place that guard against the possibility of intentional contamination (a.k.a. intentional adulteration). The necessary controls and mitigation strategies needed to comply with regulations will vary considerably based on the product or commodity produced and the types of processes used in production. The vulnerabilities of each facility and production process need to be assessed to build a preventive control strategy that reduces the ease and probability of intentional contamination. Vulnerability assessments are like the hazard analysis required by the FDA for food safety; however, vulnerability assessments are different since they focus on acts of intentional contamination. Vulnerability assessments also focus on the characteristics of facilities, and the underlying manufacturing processes and systems, rather than the potential for food safety hazards. In the context of food defense, vulnerability is defined as a weakness in the design, implementation, or operation of an asset or system that can be exploited by an adversary. Vulnerability assessment is a process used to identify specific points in food facilities and processes where intentional contamination has the greatest potential to instill fear in consumers, and harm the government, industry, economy, or the public's health. It is a systematic process of identifying and prioritizing the weaknesses (i.e., vulnerabilities) in a food production system or individual food facility. Vulnerability assessments require brainstorming and thinking critically from an adversarial perspective to effectively identify exploitable weaknesses, and to then place effective and cost effective controls or mitigation strategies within the FDP.

FSMA requires privately owned companies and organizations to implement measures to protect against the intentional adulteration of food by bad actors. FSMA requires companies to implement practical food defense measures at specific points in the food

supply chain where intentional contamination has the greatest potential to cause serious harm. The specific points where controls need to be placed can be determined using vulnerability assessment tools like the FDA's CARVER + Shock, Food Defense Plan Builder, red team analysis, systems analysis, physical security assessment, and cyber security assessments. Strategies to prevent intentional adulteration best apply to foods in bulk or batch form that have not been packaged. Foods that are widely distributed in large quantities are potentially the most valuable target to adversaries. Contaminated foods that many people consume in a short time span (e.g., fluid milk), and contain multiple servings, are potentially of highest value to the adversary because of the likelihood of wide spread serious adverse health consequences and death from intentional contamination. The use of industry best practices along with guidance from FDA, United States Department of Agriculture Food Inspection Service (FSIS), and the Department of Homeland Security (DHS) form the basis for vulnerability assessments, which must be incorporated in the Food Defense Plan to be practical and effective. Food companies may use other approaches or modify the approaches that are referenced to suit their organization's needs and available resources.

To begin the process of a vulnerability assessment, the food defense team must identify and record all the food facility's production processes and characteristics. Each of the identified operations, processes, and critical control points must be evaluated to measure and quantify the vulnerabilities, and to create mitigation strategies and implement food defense technologies to reduce the likelihood of intentional contamination. Keep in mind that up until this point that food defense threat has not been discussed. The food defense threat directly comes from people that attempt to intentionally contaminate food products, or indirectly from people that inadvertently provide access to vulnerabilities in food production systems and facilities.

There are many types and examples of vulnerabilities that all derive from people. For example, Employees working at companies with relatively low employee morale, work values, security knowledge, security awareness, and poor attitudes are more vulnerable to attack. Companies where employees are not aware of security and intentional contamination, or are not focused on protecting their employer, the outcomes of their work, or the quality and safety of their products are less likely to engage protective behaviors and are more vulnerable to intentional contamination. Having employees with high employee morale, strong values, security knowledge, security awareness, and positive attitudes greatly reduces the likelihood that an intentional contamination event will be successful. Fostering a security aware environment, and creating incentives to maximize security within the company, may be the best protective measures against intentional contamination.

The insider threat is a difficult problem facing all food production companies. To mitigate the threat and vulnerability, using staff screening at all organizational levels may prevent persons with prior criminal histories from having access to the food system. Employee screening will not eliminate vulnerability to intentional contamination, but may reduce the likelihood of people with a history of poor judgment from having access to the system. Often, terrorists have no criminal background and are well educated, and employee screening typically will not prevent these people from working or gaining access to your facility. Some employees may exhibit suspect behaviors. Caution must be taken of employees that want late night, cleanup, multi-shift, less desirable work schedules, or assignments where they are overqualified. Employees with suspect behaviors should be reassigned to other equal tasks, be closely supervised, and monitored with various security technologies.

## Quantifying Food Defense Risk and Management

The goal for any approach, procedure, or tool used to analyze food defense risk is to facilitate the identification and quantification of food defense vulnerabilities within the facility and determine the risk that the food defense vulnerabilities pose. This is somewhat like the hazard analysis step used in food safety risk analysis and hazard identification, and additional vulnerabilities may be discovered or explored during the assessment. Regardless of similarities, or differences between, different methods of vulnerability and risk assessment, there are multiple valid ways to assess risk in an organization. The method of assessment is not overly important as most assessments have similar outcomes. However, engaging the Food Defense Team in the adversarial mindset, and forcing the team to use critical thinking to mitigate identified food defense risks may be the most beneficial component of the food defense process.

Operational Risk Management (ORM) is a good example of one approach to assessing risk. ORM enhances traditional risk management through a specific six-step process, utilizing analytical tools to optimize risks and mission outcomes. The United States military regulation defines ORM as the systematic the process of identifying hazards, assessing risk, analyzing risk control options and measures, making control decisions, implementing control decisions, accepting residual risks, and supervising/reviewing the activity for effectiveness.

To better understand how to assess the risks associated with intentional contamination, the ORM Step 2 (assess the risk) is outlined below to specifically determine how risks are assessed and ranked for identifying the appropriate mitigation steps.

Step 2 requires the food defense team to assess the risks and hazards, and to analyze the probability of occurrence versus the severity of exposure. This step requires the food defense team to question the impacts to people, materials, facilities, operations, distribution, and the environment. The food defense team may choose from the available impacts' severity categories (catastrophic, critical, moderate, or negligible). The combined analysis of probability and severity is commonly performed in the Risk Assessment Matrix.

			PROBABILITY				
			Frequent	Likely	Occasional	Seldom	Unlikely
			A	B	C	D	E
SEVERITY	Catastrophic	I	1	2	6	8	12
	Critical	II	3	4	7	11	15
	Moderate	III	5	9	10	14	16
	Negligible	IV	13	17	18	19	20
			Risk Levels				

The severity and probability of occurrence are important to fully assess the risks presented by intentional contamination. The severity is generally a more objective measurement whereas the estimation of the probability of occurrence is more subjective. The following gives examples of both severity and probability of occurrence ([http://www.uscert.gov/control\\_systems/satool.html](http://www.uscert.gov/control_systems/satool.html)):

### Severity

- Catastrophic - Death(s) and/or complete business disruption
- Critical - Severe injury and illness and/or major business disruption
- Moderate - Minor injury or illness and/or minor business disruption
- Negligible - Less than minor injury or illness and/or less than minor business disruption

### Probability of Occurrence

- Frequent - Occurs often and population is continuously exposed
- Likely - Occurs several times and population are exposed regularly
- Occasional - Will occur sporadically within a population
- Seldom - Rarely occurs in a population
- Unlikely - So unlikely you can assume it will not occur or rarely occurs in a population

The matrix can be used to review each of the potential vulnerabilities, and can be used to make more informed decisions about severity and frequency. Numbers or values can be assigned to aid in setting priorities for the food defense plan. Lower numbers or values (in the red zone of the matrix) are especially important and are likely at the highest risk.

Other factors can have an influence on the level of risk assigned during the vulnerability assessment. These subjective factors are based on the ability of a specific food or operation to be easily targeted by criminals or terrorists.

For example, intelligence concerning a threat to a food may increase its probability of occurrence. Also, certain characteristics of foods may make them higher risk. These can include: foods made in large batches may reflect a large population of consumers; foods that require or have a uniform mixing process can contaminate all servings in a single batch; short shelf life foods have minimal time to identify problems and intervene, and are rapidly consumed by people; and, ease of access to targets increases their attractiveness.

As part of the vulnerability assessment, the facility must be critically reviewed either by a food defense team walk-through or by an outside consultant. The first step is to develop a facilities diagram illustrating secure and insecure areas. The assessment process can be completed face-to-face or can be assisted via computer software. It should be noted that the Department of Homeland Security can aid with Critical Infrastructure Vulnerability Assessments. DHS's assessment team, site operators, and local law enforcement can examine a facility upon request and complete a physical security vulnerability assessment at any facility. The Department's Protective Security Coordination Division conducts specialized field assessments to identify vulnerabilities, interdependencies, and cascading effects of nationally significant critical infrastructure and key resources (CIKR). These vulnerability assessments are the foundation of the National Infrastructure Protection Plan's risk-based implementation of protective programs designed to prevent, deter, and mitigate the risk of a terrorist attack while enabling timely, efficient response, and restoration in an all-hazards post-event situation. DHS has a team of Protective Security Advisors (PSA). They are highly experienced and well trained to conduct critical infrastructure protection and vulnerability assessments. Because most US critical infrastructure is privately owned, the effectiveness of vulnerability assessments depends upon the voluntary collaboration of private sector owners and operators. DHS facilitates information sharing between the government and individual sites and industry sectors, as well as between facilities and sectors by offering comparative assessment data that supports national-level, cross-sector risk analysis of nationally significant

CIKR. For the DHS's federal, state, and local partners, special reports are available (e.g., Characteristics and Common Vulnerabilities, Potential Indicators of Terrorist Activity, and Protective Measures). These reports identify common critical infrastructure vulnerabilities, sector-specific background information, and the types of terrorist activities that might be successful in exploiting these vulnerabilities.

## Vulnerability and Food Defense Plans

The food defense team is a key element in the strategy and approach to development of a food defense system. One of the primary functions of the team is to develop a functional food defense plan. Typically, persons knowledgeable in food defense and security measures will be the primary developers of the food defense plan. In practice, the format of food defense plan varies per the characteristics of the process and product or based on the needs of the specific industry. A typical Food Defense Plan is organized in four sections: (1) Outside security measures; (2) Inside security measures; (3) Personnel security measures; and, (4) Incident response security measures. The results of the vulnerability assessment will identify the areas of concern and help determine where points of control are needed within the food defense plan. Like with a food safety hazard analysis, the vulnerability assessment should be a written or electronic document that identifies the areas discussed, documents the discussion, and provides a rationale as to the level of risk (including the severity and occurrence). If the identified vulnerabilities or risks need to be mitigated, then this information needs to be included in the food defense plan. Records of the vulnerability assessment and the outcomes need to be part of the facilities overall food defense program and may be subject to review by regulators.

## Summary

Food defense is not a new or even recent problem. Intentional contamination of food and water supplies has existed throughout human history. The only thing that has changed is how society approaches the problem of intentional contamination. Food defense vulnerabilities originate in the design, implementation, or operation of a food production process, critical control point, or system that can be exploited by an adversary. Food defense vulnerability identification is a systematic process used to identify specific points in the food system where intentional contamination has the greatest potential to cause economic or public health harm. The process of identifying and prioritizing the vulnerabilities in a food system can be completed in person, by using specialized computer software to assist in the task, or by outside experts (consultants or others). Vulnerability assessments require brainstorming and critical thinking from an adversarial perspective to effectively conduct the assessment, and to then place the proper controls or mitigation strategies within the food system. The assessment results are used to form the basis for the food defense plan by identifying the points of control where mitigation is appropriate. The Food Defense Team's assessment rationale and results should be documented and be a part of the food defense program records. Due to the complexity and diversity among processing facilities, not all vulnerability assessments will be the same, even those that may be designed for the same food product. Regardless, what matters most is that the team and the organization routinely and systematically engages in the food defense risk analysis and mitigation process.

# Food Fraud and Adulteration: Where We Stand Today

John Spink, Food Fraud Initiative, Michigan State University, East Lansing, Michigan, USA

© 2019 Elsevier Inc. All rights reserved.

## Introduction to Food Fraud

**Food fraud** – including the sub-category of the U.S. FDA defined *economically motivated adulteration* or EMA – is generally defined as illegal deception for economic gain using food (ISO, 2011; Spink and Moyer, 2011; GFSI, 2012; SSAFE, 2012; CRS, 2014; DEFRA, 2014; CFSA, 2015a,b; CODEX, 2017; GFSI, 2017). This has become a separate food industry focus along a continuum that starts with food quality and food safety and now also includes a separate focus on food defense. Addressing food fraud prevention requires a fundamentally different approach since the fraudsters are intelligent adversaries who are clandestine, stealthy, and actively seek to avoid detection.

While the food fraud term has been used for many years, the research on the definition was first published in a 2011 peer-review, refereed journal article “Introducing the Public Health Threat of Food Fraud” (Spink and Moyer, 2011). While there is a continuing evolution of the details and application – such as by the International Standards Organization (ISO), Codex Alimentarius (CODEX), and European Committee for Standardization (CEN), the UK Elliott Review, and others – the basic definition has remained. A key consideration is how food fraud fits into the hierarchy of all other food risks.

The scope of food fraud is beyond food ingredients and adulterant-substances that can cause public health harm to all types of fraud and for all products. The key point is that all types of fraud can create a vulnerability that could become a root-cause of a health hazard. The types of food fraud include: adulterant-substances (dilution, substitution, concealment, unapproved enhancements), mislabeling/misbranding, grey market production/theft/diversion, and counterfeiting (intellectual property rights) (Table 1).

The basic food risks are *food quality* (unintentional act with no public health or economic harm), *food safety* (unintentional act with public health harm), *food defense* (intentional act with intent for public health or economic harm), and food fraud (Spink, 2011). To effectively manage all food risks then all food risks should be assigned to a specific cell, and every incident should be assigned to a specific food risk type. For effective management, there should be a formal incident assignment system that includes

**Table 1** Food fraud types, definitions, and examples

GFSI (1) type of food fraud	Definition from SSAFE (2)	Examples from GFSI FFTT (3)	General type of food fraud
Dilution	The process of mixing a liquid ingredient with high value with a liquid of lower value.	<ul style="list-style-type: none"><li>Watered down products using non-potable/unsafe water</li><li>Olive oil diluted with potentially toxic tea tree oil</li></ul>	Adulterant-substance (Adulterant)
Substitution	The process of replacing an ingredient or part of the product of high value with another ingredient or part of the product of lower value.	<ul style="list-style-type: none"><li>Sunflower oil partially substituted with mineral oil</li><li>Hydrolyzed leather protein in milk</li></ul>	Adulterant-substance or Tampering
Concealment	The process of hiding the low quality of a food ingredients or product.	<ul style="list-style-type: none"><li>Poultry injected with hormones to conceal disease</li><li>Harmful food colouring applied to fresh fruit to cover defects</li></ul>	Adulterant-substance or Tampering
Unapproved enhancements	The process of adding unknown and undeclared materials to food products in order to enhance their quality attributes.	<ul style="list-style-type: none"><li>Melamine added to enhance protein value</li><li>Use of unauthorized additives (Sudan dyes in spices)</li></ul>	Adulterant-substance or Tampering
Mislabelling/Misbranding	The process of placing false claims on packaging for economic gain.	<ul style="list-style-type: none"><li>Expiry, provenance (unsafe origin)</li><li>Toxic Japanese star anise labeled as Chinese star anise</li></ul>	Tampering
Grey market production/theft/diversion	Outside scope of SSAFE tool.	<ul style="list-style-type: none"><li>Mislabeled recycled cooking oil</li><li>Sale of excess unreported product,</li><li>Product allocated for the US market appearing in Korea</li></ul>	Over-run, Theft, or Diversion (4)
Counterfeiting (IPR)	The process of copying the brand name, packaging concept, recipe, processing method, etc. of food products for economic gain.	<ul style="list-style-type: none"><li>Copies of popular foods not produced with acceptable safety assurances</li><li>Counterfeit chocolate bars</li></ul>	Counterfeiting (IPR)

Notes: (1) GFSI – Global Food Safety Initiative; (2) SSAFE – Safe Secure and Affordable Food For Everyone; (3) GFSI FFTT – Global Food Safety Initiative: Food Fraud Think Tank; (4) Gray Market – a market employing irregular but not illegal methods; Theft – something stolen; Diversion/Parallel Trade – the act or an instance of diverting straying from a course, activity, or use.

Adapted from Spink and Moyer (2011), Spink (2013), SSAFE Organization (2015), PWC (2016), GFSI (2017), and Spink et al. (2017).

		<b>Motivation</b>
Food Quality	Food Fraud (1)	Gain : Economic
Food Safety	Food Defense	Harm: Public Health, Economic, or Terror
Unintentional	Intentional	
<b>Action</b>		

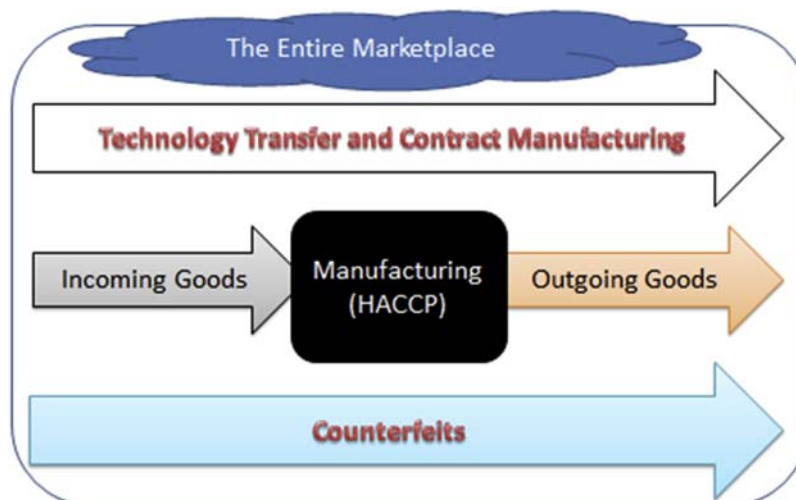

(1) Includes the subcategory of economically motivated adulteration and food counterfeiting

**Figure 1** Food Risk Matrix (Spink, 2011).

clear identification of who is “accountable” for managing the incident. The Food Risk Matrix is an efficient way to present the relationship between the risks (Fig. 1) (Spink, 2011).

The Food Risk Matrix is an efficient way to review all types of food risks and to make sure that everything is covered under the broader concept of “food integrity.” *Food Integrity* has an evolving definition but is generally “ensuring that food which is offered for sale or sold is not only safe and of the nature, substance, and quality expected by the purchaser but also captures other aspects of food production, such as the way it has been sourced, procured and distributed and being honest about those elements to consumers” (DEFRA, 2014). Another related term is *food authenticity* which is generally regarded as the process and confirmation “ensuring that food offered for sale or sold is of the nature, substance, and quality expected by the purchaser” (DEFRA, 2014). In addition, the focus on crimes on food products has led to the use of the term *food crime* which “has two common definitions of (1) incidents involving food that is a violation of a criminal statute and (2) Food Fraud incidents that are conducted on a larger scale” (MSU-FFI, 2018).

Another consideration is the scope of food fraud is where the vulnerabilities occur. The Food Supply Chain Vulnerabilities for the “Entire Marketplace” including the company supply chain of “Incoming Goods” and “Manufacturing.” The manufacturing process is managed by HACCP. The proprietary supply chain focus usually ends when “Outgoing Goods” leave the manufacturing plant. An area that is often not considered is risks in “Technology Transfer and Contract Manufacturing” where someone had legal and authorized access to your products, recipes, patents, trademark, and genuine packaging. Finally, “Counterfeits (IPR)” is often not a focus because the product is completely outside the proprietary supply chain and maybe never even enters the legal and legitimate supply chain. The focus must be on the entire supply chain because a problem at in any vulnerability could lead to a health hazard, economic impact, and a recall (Fig. 2).

**Figure 2** The Food Supply Chain Vulnerabilities (Spink, 2011).

## Food Fraud History and Shift to Prevention

While food fraud has been ongoing since the very beginning of commerce, it has been recorded as far back as 400 BCE. A series of more impactful incidents – combined with increased impact based on improved detection and traceability capabilities – has led to more of a research focus which has led to the refinement of an interdisciplinary approach focused on prevention. A series of escalating food fraud incidents created and had maintained a focus on the topic.

- 2004 – Sudan Red carcinogen colorant in paprika and other spices (adulterant-substance)
- 2007 – Melamine in infant formula and pet food (adulterant-substances)
- 2012 – Horsemeat in beef (adulterant-substance)
- Future – and an ongoing stream of incidents identified as “food fraud”

The increasing public health and economic harms led to specific research that defined food fraud and then the need for a more holistic, all-encompassing focus on the root-cause or a shift from response to prevention. In crime prevention and criminology, once a crime is specifically defined, it can be identified and categorized. For example, the system of Food and Feed Safety Alerts - European Commission (RASFF) now has a category for “fraud and adulteration.” Incidents now can be categorized in this specific category. For example, before this category was established, the melamine incident the assigned “hazard category” would have probably been “chemical contamination” and the horsemeat incident assigned to “Labelling absent/incomplete/incorrect” or “industrial contaminants.” These two incidents now can be assigned to “fraud and adulteration” which can lead to a coordinated focus to detect, deter, and prevent.

A natural evolution in the research on an emerging threat is a shift from intervention and response back to prevention (Fig. 1) (Spink, 2011). While prevention is the logical starting point, the cycle usually begins when a problem or incident is identified. The concern leads to a focus first on intervention such as identifying melamine as the toxin and then determining detection methods. Next, once melamine is identified as the problem and the detection test is defined, there is a focus on finding and removing the melamine-contaminated products from the marketplace. Finally, once the crisis has been managed, there should be a review of how to prevent this incident – or like problems – from occurring again. This shift to prevention is most efficient when leveraging Criminology theories that focus on reducing the opportunity or vulnerability.

When beginning to focus on prevention, there should be a focus on the root-cause of the problem which, in this case, is not *E. coli* but a human criminal adversary. “If the biological organism in question were a microbe so, we would naturally leverage the discipline of microbiology; for food fraud, the biological organism in question is a human, so it is natural to leverage Social Science and Criminology.” While the field of Criminology is firmly developed the ideas are novel to microbiologists and food scientists. Specifically, the crime prevention focus has been studied since the mid-1970s in Situational Crime Prevention which focused on the physical characteristic that allows a crime to occur. Researching the physical space of crime is “Environmental Criminology” whereas studying the criminal is “Traditional Criminology.” Situational Crime Prevention is based on more basic theories of Rational Choice Theory (criminals believe they will not get caught) and Routine Activities Theory (criminals become aware of opportunities in their daily life). Considering that a company is trying to protect a specific product and a country is trying to defend a border or consumer, for food fraud prevention, the focus on Situational Crime Prevention is immediately actionable and very resource efficient.

These theories are presented in the “Crime Triangle” which has been adapted to the food fraud with elements that include: victim, fraudster, and guardian or hurdle gaps (Fig. 3) (Spink, 2011).

At this point, it is important to review the types of fraudsters and to specifically address the threat of violence or retaliation against a food inspector, purchasing agent, or a manufacturing plant receiving dock worker. The types of *fraudster* include recreational (action for entertainment to amusement), occasional (infrequent, opportunistic), occupational (incidents at their place of employment either as an individual actor in collaboration with the company), or professional (crime fully finances their lifestyle Spink et al., 2013b). It is then crucial to understand the *type of offender organization* including individual/small group, general criminal enterprise, Organized Crime (formal structure and extensive threat not just “crime that is organized”), terrorist organizations (supporters or direct members), foreign government offenders (state-sponsored crime), and others (Spink, 2011).

For example, a “food inspection” becomes a “criminal investigation” when there is a collection of evidence that could criminally convict an individual or group. Many times a food safety inspector unknowingly shifts from a traditional audit (“let’s check the lot codes to see if they match the manifest?”) to a criminal investigation (“how come you said you used 50 pallets of the product but only have invoices for two?”). Considering the threat of violence against that food inspector, the most dangerous situation is against

**Figure 3** Food Protection Plan Progression (Spink, 2011).

a novice criminal who might get anxious and immediately, violently retaliate. A hardened criminal who is well versed in the investigation and prosecution system would not resist and would be non-threatening.

Often the corporate liability insurance for a food safety inspector does not cover criminal investigations. If an inspector is sent into a situation where fraud occurs any harm may not be covered by insurance and – if there is knowledge of actual fraud – the supervisor or company managers may be criminally liable for creating this danger.

### The Role of the Public–Private Partnership and the Role of Food Science and Technology

Considering the optimal role of the public-private partnership—the interaction of government, industry, and others such as academics and associations – is especially important when dealing with a complex, inter-disciplinary, inter-agency, and international issue such as food fraud prevention. Among others, entities such as INTERPOL and Europol have led collaborations such as through Operation Opson, the European Commission funded the Food Integrity Project, the World Health Organization (WHO) and Food and Agricultural Organization of the United Nations (FAO) has begun work within Codex Alimentarius (CODEX), and the industry collaboration of the Global Food Safety Initiative (GFSI) has created a harmonized and standardized overall food safety management system.

A key efficiency is that there is currently coordination and communication in the public-private partnership. While the requirements are evolving and formalizing, an efficient and holistic system is developing (Fig. 2). Government agencies are starting to formally recognize the value of “accredited third-party certification” as a valuable and resource-saving system. For example, in the “Third-Party Audits and FSMA” report, the U.S. Food and Drug Administration (U.S. FDA) stated, “FDA contemplates leveraging third-party audits as part of its overall compliance strategy” (FDA, 2017). The formal leveraging of third-party audits has been discussed publicly by a wide-range of international governments. While not a substitute for a formal government inspection the third-party audits are becoming more and more relied upon when governments have increasing confidence in the system and when under pressure of reduced human and financial resources.

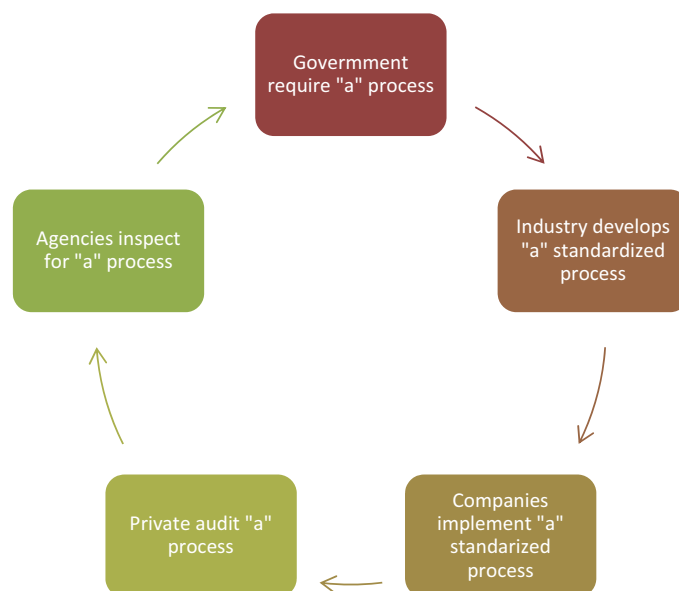

An efficient system is for the government to require “a” process to assess and manage all hazards including those that are economically motivated. This is a specific quoted requirement in laws such as the U.S. Food Safety Modernization Act section on “hazard analysis.” By requiring “a” process – but not specific details – the government makes this a priority but also allows for industry innovation, coordination, and harmonization. The government requirement increases the industry focus on developing and managing systems, companies to fully develop prevention strategies, the private third-party audits to be strong, and then agencies may be confident in relying upon the audits, which end up further protecting the food supply chain which is the ultimate goal of the government food laws (Fig. 4).

Finally, the concepts of defining the term, exploring the scope of the problem, considering crime prevention about the public-private partnership, lead to an efficient and effective consideration of how to address the problem. Addressing the problem includes identifying vulnerabilities, conducting an assessment, and then considering the optimal role of food science and technology.

Think about a sick person visiting a medical doctor. Overall there is a process for “diagnosis,” then consider a series of possible “treatments,” and each treatment considers a “prognosis” (Fig. 5). The diagnosis is similar to considering vulnerabilities. The treatments are the countermeasures or control systems which do include “do nothing.” Finally, each diagnosis-treatment option should

**Figure 4** The Crime Triangle applied to Food Fraud (Spink, 2011#1418). Adapted from Felson, M., 1998. Crime and Everyday Life. Pine Forge Press, Thousand Oaks, California.

**Figure 5** Public-Private Partnership Cycle Reinforcing “a” Process.

**Figure 6** Continuum of Diagnosis, Treatment, Prognosis, and the Decision.

consider a prognosis or result of the effort. For example, if fraud is occurring at 1% to 5% of the finished good, then there is no need for a treatment that reduces the sensitivity from 1 part per thousand to 1 part per million (Fig. 6).

**Vulnerabilities:** The vulnerabilities need to be identified from the perspective of the “fraud opportunity” and not just previous adulterant-substance incidents or the application of detection methods. For example, the fraud may not involve an adulterant-substance. For example, they may reduce the amount of a valuable ingredient and replace with a filler ingredient. Also, a fraudster may research the current test methods and figure a way to circumvent or fool the current tests. For example, switching from horse-meat to stolen or lower quality beef.

**Assessment:** The risk assessment should cover all types of fraud and for all products. If the identification of vulnerabilities is not full and the assessment is only focused on specific areas, then the entire company is not protected. A human criminal adversary may perceive the threat and shift their type of crime. This follows the logic from Rational Choice Theory and the Crime Displacement.

**Optimal Role of Science and Technology:** Food science and technology provides the critical role of detection. If the fraud cannot be detected, then the intervention step never starts, and the prevention process is not activated. Detection is the most complex of the countermeasures or control systems but cannot be efficient or optimized without the previous criminology and quality management identification of vulnerabilities and risk assessments. Once the root-cause has been investigated and identified, then a very precise and defined “specification” can be provided for selection or development of countermeasures or control systems (Spink et al., 2013a; IUFoST, 2016). In many cases “more” testing is not needed but just a re-focus of resources or refined communication of information.

In an article co-authored by Professor Elliott from Queen’s University Belfast and Kevin Swoffer who was the former subject matter expert for the Global Food Safety Initiative (GFSI), “Whilst better means of detecting Food Fraud are required, “success” must be measured in terms of how the activities support prevention” (Spink et al., 2013a).

## Conclusion

Food fraud is becoming a unique and specific research area for government, industry, and academics. The focus has expanded to an extremely interdisciplinary task starting with social science and criminology, applying risk management and decision sciences, to include information technology and data analytics science, leveraging supply chain management, before the resource-allocation

decision-making such as from Enterprise Risk Management and COSO managerial accounting practices, before providing food science and technology researchers with a very clear scope and specification of detection requirements. It is important and critical to realize that Social Science and Criminology are – naturally – key “science & technology” parts of the food fraud response.

## Food Fraud and Vulnerability Assessments

Saskia M van Ruth, Wageningen University and Research, Wageningen, The Netherlands

© 2019 Elsevier Inc. All rights reserved.

### Glossary

**Counterfeiting** The process of copying the brand name, packaging concept, recipe, processing method etc. of food products for economic gain.

**Dilution** The process of mixing a liquid ingredient with high value with a liquid of lower value.

**Food fraud mitigation measures** Hard and soft actions that are taken to combat against identified food fraud vulnerabilities.

**Food fraud vulnerability assessment** The process of collection and evaluation of information on potential food fraud risk factors as well as mitigation measures which, when combined, determine the actual fraud vulnerability.

**Food fraud vulnerability** Susceptibility or exposure to a gap or deficiency that could place consumer health at risk and/or have an economic or reputational impact on a food company's operations if not addressed.

**Food fraud** A collective term encompassing the deliberate and intentional substitution, addition, tampering, or misrepresentation of food, food ingredients or food packaging, labelling, product information, or false/misleading statements made about a product for economic gain.

**Food adulteration** The process in which the quality of food is lowered secretly and intentionally either by the addition of inferior quality material or by extraction of valuable ingredients/constituents in order to mislead customers for own economic gain.

**Mislabeled** The process of placing false claims on packaging for economic gain.

**Substitution** The process of replacing an ingredient or part of the product of high value with another ingredient or part of the product of lower value.

**Unapproved enhancement** The process of adding unknown and undeclared materials to food products in order to enhance their quality attributes and conceal fraud.

### Introduction to Food Fraud

Food fraud is the intentional, deceptive misrepresentation of foods for financial gain (Spink et al., 2017). Fraud is a form of criminal behaviour in any definition of crime: whether we consider the legal (acts forbidden by law) or the non-legal definition. The two share two crucial elements: criminal behaviour is harmful and morally reprehensible (Passas, 2005). Food fraud qualifies for both. Food fraud always involves at some stage deliberate dishonesty to obtain an advantage from or cause losses to or harms against individuals (e.g. consumers), groups (e.g. companies, market actors and investors) or the state (e.g. tax and revenue). In this sense, we can distinguish these intentional acts from a range of behaviours and regulatory violations that are often referred to as 'non-compliance' issues, such as carrying out inadequate due diligence on suppliers, or 'lawful but awful' practices (Lord et al., 2017).

Food fraud involves all forms of misrepresentation, i.e. full (counterfeiting/mislabeled) or partial replacement (adulteration) of the original product. Some products may be fully replaced because of their added value due to their brand/type of product (expensive wines, premium brand dairy products) or due to special attributes related to production origin (organic) or geographical origin. Adulteration concerns the removal of ingredients or constituents or their substitution by lower value counterparts. Examples are dilution of high value extra virgin olive oil with refined olive oil, bulking out spices with inferior material, or inflating meat with water. In some cases, it may also concern the apparent enhancement of constituents determining the product's value, such as the protein content of milk. Furthermore, it may concern also concealment which is required to cover up the adulteration practices. Examples are the addition of colourants to spices, or Manuka pollen to diluted Manuka honey to disguise the fraudulent product and deceive the customer and the laboratory checking the product.

Awareness of food fraud and its consequences has raised in the past decade. Cases, such as melamine in infant formula in China in 2008 (Rovina and Siddiquee, 2015) and the substitution of beef by horsemeat in the EU in 2013, set the alarm bells ringing. Food fraud has often been considered an economic issue, but recent cases have highlighted that these practises are detrimental to businesses and economies, but also ruin consumer confidence. After the various incidents in the past decade, both industry and authorities recognized that a single incident can have global market consequences, with broad implications for company brands, industry performance, people's lives, and countries' reputations.

## Impact of Food Fraud

Food fraud impacts seriously on businesses involved, their customers, others in the chain or tier who are painted with the same brush, as well as the consumers. Losses may include social losses and punishments, third party losses (e.g. extra testing), confidence losses, sales losses and over payment, as well as recall losses. The kinds of impact of various fraud cases has been studied by Bindt (2016). Across the board, social losses and punishments are most frequently reported. Sale drops ranged between 13%–80% for the cases studied, stock prices declined by 37%–75%, and confidence/trust in industries was reduced by 7%–64%.

Let's take the melamine incident as an example to list the various kinds of losses. The social losses of the melamine case were enormous: 240,000 infants got ill, 60,000 were hospitalized, and six children died (Dani and Deep, 2010). The Chinese court involved imposed death penalties, imprisonment and fines on the offenders (Cucchiella and Gastaldi, 2006). The scandal resulted in the bankruptcy of the Sanlu Group co, Ltd in 2008, a company that sold the melamine tainted infant formula, leaving a debt of \$160 million. Financial losses reached far beyond the Sanlu Group though. Ten days after disclosure, the sales of the Chinese companies Mengniu and Yili dropped by 80%, and overall sales of the dairy sector in China dropped by 30%–40% (Dani and Deep, 2010; Lu and Tao, 2009). Stock prices of companies dropped between 37%–60% at that time (Evershed and Temple, 2016). Purchase volume of milk decreased to ~20% of normal sales on 22 September 2008 (Qian et al., 2011). The estimated recall costs for the Chinese dairy industry amount \$3 billion, whereas worldwide recall expenses are estimated on \$18 billion (based on 30 affected brands in more than 60 countries) (Xiu and Klein, 2010; Evershed and Temple, 2016). Chinese dairy products were boycotted by 30 EU countries and confidence in the Chinese dairy industry plummeted. When interviewed in that period, 45%–64% of the Chinese consumers perceived at least one of the Chinese dairy products (milk (powder), yoghurt, ice cream) as unsafe (Qiao et al., 2010). The Chinese dairy industry is still recovering from this incident today, nearly a decade later.

## Fraud Vulnerable Food Product Groups

When people try to manage food fraud risks, one of the first questions asked is which products are more at risk than others? In fact, we do not know because there is no global fraud case report system. However, there are some databases with specific data sources that may shed some light. Some products or chains appear more frequently in these databases than others. This phenomenon was explored by carrying out an inventory of the most frequently reported food product groups in three public databases (Weesepeol and van Ruth, 2015). The Foodfraud.org database (USP, 2017) comprises primarily scientific reports on food fraud. Out of the 615 reports on eight major product groups in the 2008–13 period, the five predominant food product groups are in decreasing order: (1) herbs and spices, (2) olive oils, (3) vegetable oils (not including olive oils), (4) milk and milk products, and (5) honey and royal jelly (Fig. 1, upper graph). The Rapid Alert System for Food and Feed of the European Commission comprises a section on food fraud reports (RASFF, 2017). This section included 201 reports for these eight groups in the 2008–13 period. The five prime food product groups in this database are (1) fish and fish products, (2) meat and edible offal, (3) nut, nut products and seeds, (4) milk and milk products, and (5) honey and royal jelly (Fig. 1, lower graph). In this RASFF database, cases are reported by authorities, but only if there is a safety risk and a concern that other EU member states may be affected as well. The differences in ranking of product groups from the two databases are caused by their very different data sources. Although the ranking differs, generally the same food products appear in the list, except for the oil categories (olive oils and vegetable oils). Although there are numerous food fraud reports on oils, in this period obviously very few were associated with safety risks in the EU.

## Tempted Offenders

But what about the offenders? What drives them, and how do they interact with their environment? There is some popular belief that food fraud is mostly an external threat caused by organized crime groups seeking to permeate the food supply chain. Although politically convenient, it seems more often a problem within the food system itself and committed by legitimate food supply chain actors. Lord et al. (2017) argued that food fraud is better understood as an 'endogenous' phenomenon within the food system where legitimate occupational actors and organizations are in some way necessarily involved rather than being an 'exogenous' phenomenon perpetrated by externally organized (transnational) 'criminal enterprise'. The melamine case is a good example of fraud that was committed by legitimate dairy chain actors.

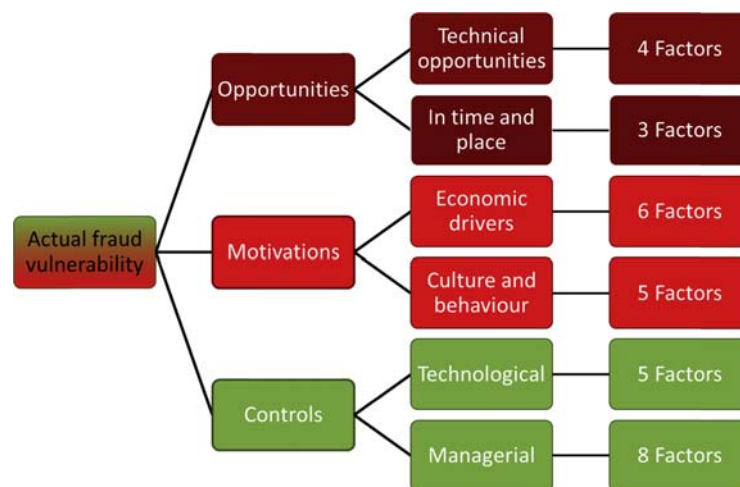

Food fraud is the interplay between the motivated actors, and their (social/criminal) networks, to make the most of fraudulent opportunities that arise (Lord et al., 2017). These opportunities are presented by victims and by those entrusted with controlling risks (Levi, 2012). For example, this may occur within businesses where certain malpractices may be 'acceptable' and within facilitative market and industry structures and cultures. The goal of fraudsters may indeed be to maximize profit but in other cases this may be a secondary outcome as actors in the supply or production chain seek to maintain their business. Some will act out of greed, but many also out of need. If it has become a certain culture to commit fraud in a supply chain network, law-abiding businesses in the same chain are affected as well. In some cases, these businesses are affected to the extent that they must choose between 'being driven out of business' or 'swim with the tide' to survive the severe and unfair competition (Baucus and Near, 1991). Frauds may be of pre-planned, but may be more often a response to a situation, or be more of a slippery-slope nature (Lord et al., 2017).

**Figure 1** Division of the major food product groups of the reports in the [Foodfraud.org](https://www.foodfraud.org) database (upper graph) and the Rapid Alert System for Food and Feed (RASFF) database (lower graph) in the EU in the period 2008–13.

### Fraud Vulnerability

To get insights into the ‘what’ and the ‘who’, but also especially the ‘why’ of food fraud, the criminological routine activity theory (Cohen and Felson, 1979) is quite suitable to describe the various facets of food fraud. Applying the theory, food fraud can be conceptualized as the outcome of the convergence in time and place of 1) motivated offenders and 2) suitable targets (opportunities) in 3) the absence of capable guardians (van Ruth et al., 2017). The vulnerability to fraud results from openings for undesirable events resulting from weaknesses or flaws related to the system (Spink et al., 2017). It can be framed by enablers and drivers existing in the system, as well as counteracting control measures. The actual fraud vulnerability of a company is determined by the key elements opportunities, motivations and control measures. The three key elements can again be subdivided into six sub categories. These categories comprise (1) technical opportunities, (2) opportunities in time and place; (3) economic drivers, (4) culture and behaviour, (5) technical control measures and (6) managerial control measures (visualized in Fig. 2). Each sub category comprises

**Figure 2** Schematic presentation of the food fraud vulnerability concept based on the routine activity theory: the three key elements opportunities, motivations and controls, their sub categories, and number of fraud factors.

of several factors. They are detailed in [Table 1](#). The selection of these fraud factors and its scientific justification has been published previously ([van Ruth et al., 2017](#)). Food fraud vulnerability results from threats from both the external and the internal environment of a business. Therefore, some of the factors need to be considered for the own company as well as for external environmental layers, such as the direct suppliers and customers, the wider chain/industry network, and the (inter)national environment.

## Fraud Vulnerability Assessments

The surfacing fraud cases have increased the need to strengthen companies' ability to combat fraud within their organizations and across their supply chains ([Manning and Soon, 2014](#)). Because of the raised awareness in industry food fraud needs nowadays to be considered in food quality/safety management plans. The Global Food Safety Initiative published a white paper ([GFSI, 2014](#)), in which was announced that two food fraud mitigation steps in the form of two new key elements in the GFSI Guidance Document would be added. These elements required a company (1) to perform a food fraud vulnerability assessment and (2) to have a control plan in place ([GFSI, 2014](#)). Since food fraud vulnerability assessments did not exist yet, several initiatives started to develop protocols. For example, the U.S. Pharmacopeia Convention (USP) developed the USP tool to guide companies to identify the most vulnerable ingredients within their supply chains and to choose valid situation-specific mitigation measures ([USP, 2014](#)). Furthermore, organizations such as the Grocery Manufacturers Association in the US ([GMA, 2016](#)), the British Retail Consortium ([BRC, 2015](#)), the European Spices Association ([ESA, 2017](#)), and the feed industry ([GMP+, 2017](#)) among others developed questionnaires and guidelines to identify fraud vulnerabilities. At the same time, also in response to the GFSI white paper, a large interactive and iterative process with representatives from the global food industry, retail, authorities and the scientific community commenced, which was initiated and coordinated by SSAFE. SSAFE is a non-profit collaboration of various multinational companies. The aim was to develop a practical, but science-based food fraud vulnerability self-assessment tool, a tool which would be based on the theoretical concept described in the section 'Fraud Vulnerability' of this chapter. Through a very extensive process the self-assessment was developed and validated. The self-assessment tool can be downloaded as spreadsheet for free in various languages ([SSAFE, 2017](#)), but has also been made available as a free downloadable app by PwC/SSAFE ([PwC, 2017](#)). The assessment comprises 50 questions and associated answering grids based on the fraud factors, and was tested globally. Nine questions relate to opportunities, 20 to motivations and 21 to control measures. The answering grids present descriptions of low, medium and high vulnerability situations for each question and link to a score system. The scores (1,2,3) can be visualized in spider web diagrams for a first impression of the company's vulnerability. An example for a meat processor is presented in [Fig. 3](#). They show moderate vulnerability in view of opportunities and motivations (some red areas), and partly implementation of control measures but with room for improvement (some green area).

## Fraud Vulnerability in Various Chains

We have seen in the previous sections that the number of fraud reports varies with product groups, but also with data sources. Fraud vulnerability assessments are designed to assess a company's vulnerability to fraud. However, they may also provide insights in the vulnerability in supply chains as well as across supply chains when applied to groups of actors. In a current study various tiers in the fish, meat, milk, olive oil, organic bananas, and spice supply chains were assessed for their fraud vulnerabilities with the SSAFE food

**Table 1** List of food fraud key elements, sub categories and individual fraud factors

<i>Fraud key elements</i>	<i>Sub categories</i>	<i>Fraud factors</i>
Opportunities	Technical opportunities	<ul style="list-style-type: none"> <li>• Simplicity/complexity of adulteration</li> <li>• Simplicity/complexity counterfeiting</li> <li>• Availability of technology and knowledge to adulterate</li> <li>• Availability of detection technology</li> </ul>
	Opportunities in time and place	<ul style="list-style-type: none"> <li>• Accessibility to materials in production/processing</li> <li>• Transparency supply chain network</li> <li>• Historical evidence</li> </ul>
Motivations	Economic drivers	<ul style="list-style-type: none"> <li>• Supply and pricing of materials</li> <li>• Special product attributes or value determining components of materials</li> <li>• Price differences in countries</li> <li>• Economic health business</li> <li>• Level of competition</li> </ul>
	Culture and behaviour	<ul style="list-style-type: none"> <li>• Financial strains imposed on suppliers</li> <li>• Business strategy</li> <li>• Ethical business culture</li> <li>• Previous criminal offences</li> <li>• (Inter)national corruption level</li> <li>• Victimization</li> </ul>
Controls	Technological controls	<ul style="list-style-type: none"> <li>• Specificity and accuracy of fraud monitoring system</li> <li>• Systematics and autonomy of verification of fraud monitoring system</li> <li>• Accuracy information system for mass balance control</li> <li>• Extensiveness tracking and tracing system</li> <li>• Fraud contingency plan</li> </ul>
	Managerial controls	<ul style="list-style-type: none"> <li>• Strictness ethical code of conduct</li> <li>• Application integrity screening</li> <li>• Support whistle blowing system</li> <li>• Contractual requirements suppliers</li> <li>• Social control and transparency across supply chain</li> <li>• Established guidance for fraud prevention across supply chain</li> <li>• Specificity national food policy</li> <li>• Strictness enforcement for fraud prevention regulation/law</li> </ul>

**Figure 3** Spider web diagrams of the fraud vulnerability assessment of a meat processor: opportunities, motivations and control measures. Numbers refer to questions 1–50 in the SSAFE food fraud vulnerability self-assessment tool (van Ruth et al., 2018).

fraud vulnerability assessment tool (van Ruth et al., 2018). Thirteen fraud factors related to opportunities and motivations scored high across all supply chains indicating their importance as general fraud drivers and enablers. They included: availability technology and knowledge to adulterate raw materials/final products; fraud detectability in raw materials/final products; historical evidence of fraud in raw materials/final products/branch of industry; supply and pricing of raw materials; valuable components or attributes of raw materials; corruption level in the country of the supplier; economic conditions of the branch of industry; the level of competition in the branch of industry; and price asymmetries. Use of control measures varied across supply chains and tiers, but technical controls were generally more implemented than managerial controls. Comparing the various chains significant differences in vulnerability for about half of all the fraud factors was observed. Thus, considerable differences between chains existed and could be explained by approximately 50% of the fraud factors. Different tiers (e.g. processor, trader, retailer), only showed significant differences for one out of seven of the fraud factors results. Consequently, the chain seems to be more important for perceived fraud vulnerability than the position (tier) in the chain. When ranking the various chains, it appeared that fraud vulnerability was highest

in the spices chain, which was followed by the olive oil, meat, fish, milk and organic banana chains. Regarding tiers, the wholesale/traders group appeared most vulnerable, and they were followed by retailers and processors. When comparing these results with the [foodfraud.org](http://foodfraud.org) databank results in the previous section, it appears that there is certainly overlap in product groups/chains. Spices and olive oil were reported most frequently in the 2008–2013 period, and scored also high in terms of fraud vulnerability by the actors in the chain. Milk, fish and meat scored lower, both regarding reports in the databank and in terms of fraud vulnerability by the actors in the chain. There is considerably discrepancy with the RASFF databank though, which is probably because fraud cases with a safety impact and with a risk for other EU member states are reported only. On the contrary the fraud vulnerability assessment does not discriminate between vulnerabilities with or without potential safety impact.

## Concluding Remarks

To manage food fraud risks in the food industry, it is pivotal to map fraud vulnerabilities. Various factors need to be considered: those that make products suitable targets as well as those that drive and influence the potential offender. When these vulnerabilities have been mapped and vulnerability appears high, there are two options. The first option is to avoid the situation, which will often mean cease activities. Often that is not acceptable or not even feasible. Alternatively, one may try to mitigate the risk by implementing control measures. Depending on the control measures the fraud vulnerability may be reduced to an acceptable level. Fraud vulnerability assessments allow authorities to discover weak points in the system, which they can use for risk-based, dedicated enforcement of legislation. Finally, these assessments may be used in science to improve the understanding of food fraud occurrence by elucidation of the interaction of fraud drivers, enablers and controls.

## Background: Food Fraud and Economically Motivated Adulteration (EMA)

Food fraud is a generic term encompassing a wide range of deliberate fraudulent activities such as counterfeiting (fraudulently passing off inferior goods as established and reputable brands), product tampering, product diversion (sale or distribution of products outside the intended markets), theft, smuggling and others malpractices (Spink et al., 2016a; Global Food Safety Initiative, 2014; US Pharmacopeia appendix XVII, 2015). This generic term needs to be distinguished from the economically motivated adulteration (EMA or economic food adulteration) which is the result of intentional addition, substitution, dilution, unapproved enhancement or concealment performed in food raw materials or finished products using foreign compounds (adulterants) to increase revenue. Economic food adulteration corresponds to the scope that we are going to cover in this chapter (in line with the definition of food fraud in the European Union, see EU, 2014). Moreover, it is worth differentiating food fraud from food defense, where intentional adulteration is ideologically motivated to cause public health harm, economic harm or terror.

## Food Adulteration Is a Criminal Act of Potential Safety Concern

Economically motivated adulteration (EMA) is of increasing concern for society. It deprives the consumer of the quality products they intend to purchase, decreasing consumer trust and leading potentially to significant consequences on human health (Spink and Moyer, 2011; Everstine et al., 2013). To maintain consumer trust, food companies must remain alert to potential adulteration and work actively with their suppliers to identify and mitigate the associated risks (Stadler et al., 2017). This requires industries to implement an effective *food adulteration management system*.

## Food Adulteration Management System

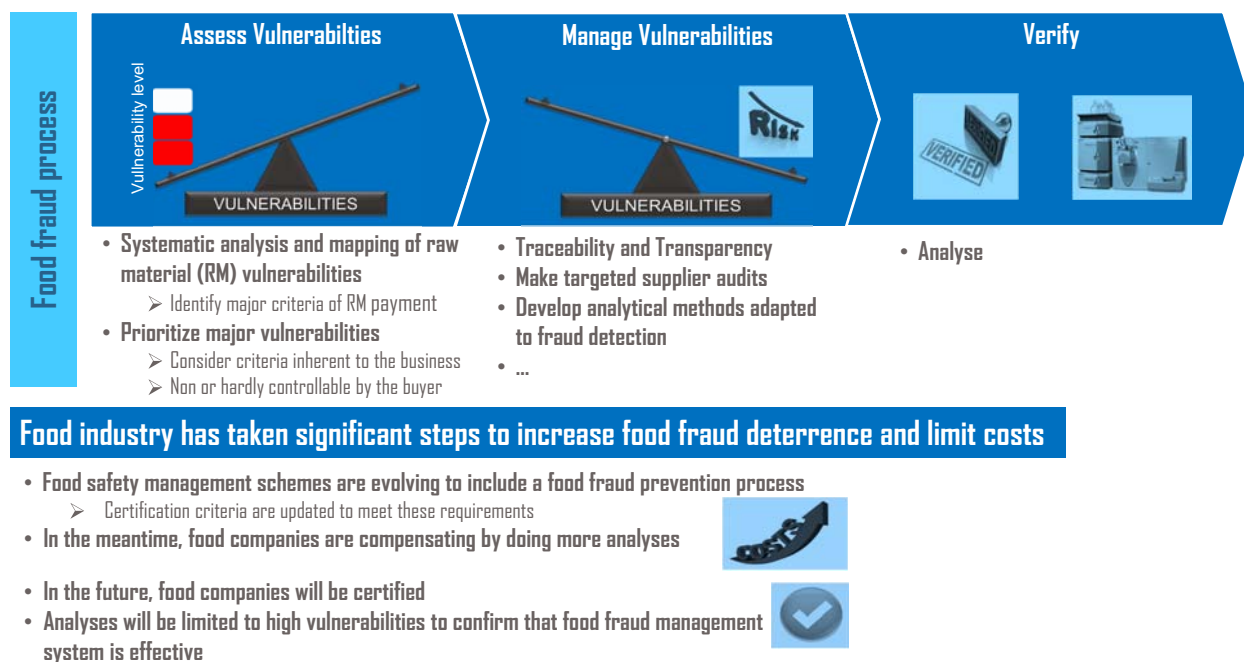

Management of food safety risks often focuses on hazards that occur naturally in foods or come from the environment (e.g. heavy metals) or the food production chain (e.g. food processing, storage and handling). Those hazards are adequately identified and managed. In contrast, in the case of food adulteration, industries are facing unknown adulterants where the traditional risk-based preventive control systems cannot be applied (Stadler et al., 2017; Spink et al., 2017).

The food industry has recently taken significant steps to prevent the risk of food adulteration in the food value chain. The Global Food Safety Initiative (GFSI) is an industry-led initiative within the Consumer Goods Forum (CGF) aiming at mitigating food safety risks across the value chain. GFSI has introduced additional requirements for food safety schemes (e.g. British Retail Consortium (BRC), FSSC 22000) to address the risk of food adulteration. Consequently, the food safety schemes recognized by the food industry at large (e.g. food producers, manufacturers, distributors) have updated their certification criteria to meet the requirements defined by GFSI for food fraud prevention (GFSI, 2014; BRC food issue 7, 2014). These requirements ensure that adequate food safety management schemes include a food fraud prevention process. Such process begins with an evaluation step to identify and characterize vulnerabilities in the food supply chain (vulnerability assessment) and is followed by the design, validation and implementation of mitigation measures (Fig. 1).

## Vulnerability Assessment

It is important to know what drives the fraudsters to better understand vulnerabilities in food adulteration (Van Ruth et al., 2017; Cavin et al., 2016). The term vulnerability is normally applied for economic food adulteration addressing both public health and economic consequences rather than the term risk used in food safety (USP appendix XVII, 2015; Spink et al., 2016b).

Guidance document and self-assessment tools have been developed by a number of organizations (e.g. USP appendix XVII, 2015; SSAFE, 2017; FDF, 2014) to help food companies undertake their own vulnerability assessment and implement appropriate control plans. In general, a higher level of processing will induce a higher vulnerability since it is easier to adulterate a raw material that has been transformed into liquids or powders (e.g. oils or milk powders). Weight is the most common payment criterion but other criteria are often used (protein or fat content, color etc.), giving additional adulteration opportunities and thus, increasing the number of substances that can be used by fraudsters. Materials paid on the basis of multiple payment criteria are often highly vulnerable. Fresh milk, which is paid based on the volume, protein content, fat content and bacteriological quality, is a good example. It is one of the most adulterated raw material worldwide. Many milk adulterants have been identified and can be grouped by classes of adulteration related to the different milk payment criteria (Cavin et al., 2016; Poonia et al., 2017).

**Figure 1** Food fraud management process to assess and manage vulnerabilities and verify that the process is effective. By application of this process and introduction of new requirements for food safety schemes (certification criteria for food fraud prevention), the food industry has taken important initiatives to increase food fraud deterrence and limit the costs of analyses.

Food companies are often facing adulteration vulnerabilities on many raw materials in various food categories, highlighting the need for prioritization. Such prioritization can take into account additional vulnerability criteria inherent to the business such as the raw material volume purchased, average prices, and prices fluctuations that are often hardly controllable by the buyer (e.g. a particularly low market price may indicate a lack of food control/or regulatory enforcement framework in the country of origin or country of transit).

Large-scale economic food adulteration cases are reported in the scientific literature but smaller local incidents are usually identified by web scouting of media sources worldwide. Therefore, the vulnerability assessment is a live process, which needs regular updates for effectiveness (see food fraud mitigation guidance [USP appendix XVII, 2015](#)). Commercially available webscouting tools (e.g. Digimind, Radian6) or online regularly updated databases (e.g. Horizon scan, USP food fraud database) are available. These tools help food industries in their continuous identification of new emerging food vulnerabilities. However, and this is inherent to the nature of economic adulteration, current tools will hardly predict pro-actively new food vulnerabilities potentially associated with economic, regulatory, geopolitic or other rapid changes occurring worldwide. In this context, some industries and internationally funded research projects (e.g. [EU Food Integrity project](#)) are working on automated Early Warning digital approaches for food adulteration. They are looking for abnormalities in characteristic attributes or key drivers of food adulteration and further process them using statistical models to help identifying alerts predicting new vulnerabilities within the supply chain.

### Identification of Adulterants of Safety Concern Based on Past Incidents

While economic food adulteration is not in principle intended to harm consumers, dramatic consequences on human health occurred in the past, often by ignorance of the adulterant toxicity. Therefore, the vulnerability assessment is also aimed at identifying adulterants of major safety concern for which analytical methods are required rapidly (if not available yet). Previous cases help extrapolating the risk to other food raw materials. For example, Sudan dyes and lead oxide addition in spices led to the identification of many illegal dyes and inorganic pigments of significant health concern for humans ([Ramesh et al., 2005](#); [EFSA, 2005](#)). Similarly, the identification of ground peanut shells and almonds proteins in cumin and paprika highlighted the risk of allergenicity associated with spent materials that can easily be added as bulking agents in raw material powders ([FDA consumer advice, 2017](#)). It also helped to identify other practices linked to allergens such as the addition of cow milk in coconut milk. Moreover, toxic plant varieties such as the Japanese star anise containing high level of anisatin versus the traditional Chinese plant led to further research of toxic adulterants which could be used by substitution with other plant varieties from the same family ([Moore et al., 2012](#)). As a result, several toxic compounds have been identified in spices, herbs, oils and even indirectly in fish following substitution of tuna by bonito (*Sarda sarda*) from tropical area contaminated with toxic algae (ciguatera). In addition, past adulteration cases

demonstrated that fraudsters are mainly opportunists and may not care of potential health issues. The use of protein hydrolysates extracted from leather residues that have been previously treated and colored with chemicals is a good example. Those residues contain dangerous substances including possible residual levels of Chromium (VI), a highly toxic element for humans (Chaudhary and Pati, 2016). Another example is refined cooking oils collected from restaurants or even gutters (Ng et al., 2015). In addition to residual toxic contaminants such as acrolein, gutter oils could be of allergenicity concern if used previously for cooking seafoods (shrimps, calamari) or other food allergens (fish) and partially refined.

### Strength and Limitation of the Vulnerability Assessment

The initial assessment step is also required to identify common types of vulnerabilities between different food categories, such as sugar addition (e.g. sucrose, inulin, invert sugars from various plants such as beet, cane or corn, high fructose syrups from maltose, isomaltose) in fruit juices and honey, where a similar analytical strategy can be applied. Vulnerabilities common to different raw materials and categories is considered in the prioritization of the development and implementation of new mitigation measures. The substitution of species origin, the addition of bulking agents in powders, the enhancement of protein content in raw materials rich in protein and the concealment of raw materials using preservatives, bleaching agents or dyes are examples of major classes of vulnerabilities that will impact many raw materials and food categories and can be used to prioritize new developments.

The example of cardboard found recently in beef in the meat substitution crisis in Brazil or the addition of paper pulp in milk before drying demonstrated the limitation of the vulnerability assessment in the identification of unexpected adulterants. Therefore, it is important that new analytical methods for the detection of food adulteration take this unpredictability into account. This essential aspect will be further discussed later in the analytical evolution for food fraud detection. However, a special focus will be made initially on the analytical requirements for two main classes of vulnerabilities that have been the subject of recent food crises: A) Substitution of species origin and B) Enhancement or substitution of protein.

Beside the European horsemeat scandal in 2013, cases of meat substitution (minced or specialties such as sausages) have been identified for a very long time and are still identified regularly worldwide. In addition, mislabeling of fish and seafood has been the subject of different surveys from retail outlets and supermarkets showing that 25% (but up to 70% according to fish species) were regularly substituted (Warner et al., 2013). Two recent surveys testing oregano authenticity also identified a high percentage of adulterated samples (24% in UK and 60% in Australia) being substituted with up to 70% of foreign leaves (e.g. myrtle, olive, sumac or cistus) (Black et al., 2016a,b; Choice Australia, 2017). These are just some examples showing the need for rapid detection of species origin across food categories.

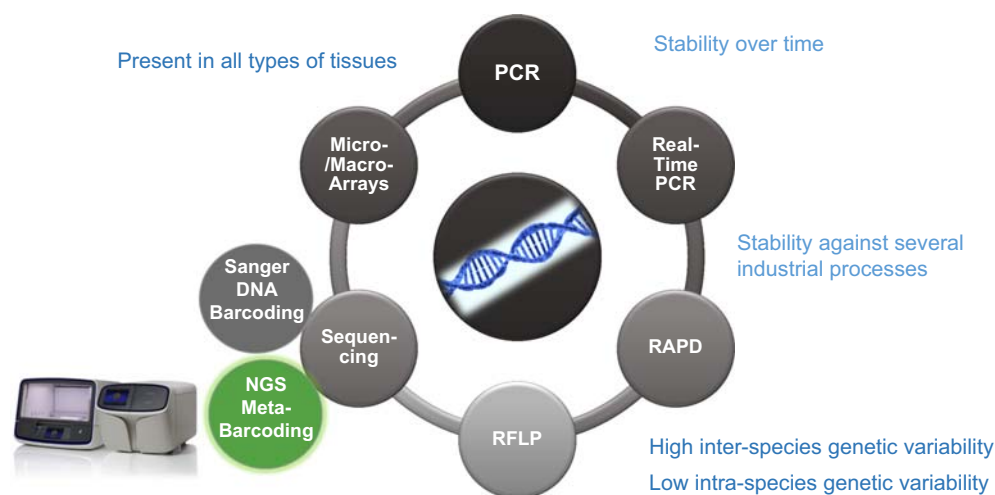

Protein content is a key payment criterion for raw materials under the form of powders (flours, concentrates, isolates) across many food categories (e.g. fish, meat, dairy, soya, leguminous seed, cereals and others). Therefore, the risk of substitution by cheap proteins from plant, animal or insect origin or by hydrolyzed protein produced from animal residues (leather, feather, horn) is significant. In addition, the impressive list of nitrogen-rich compounds (N-rich) calls for new analytical methods or potentially even other solutions that will be mentioned below. This category is critical because of the potential dramatic health consequences as those seen during the melamine crisis (Ingelfinger, 2008; Xin and Stone, 2008), where melamine was added artificially to increase the protein content in pet food and infant formula.

### Evolution of DNA-Based Approaches for Identification of Species Substitution

DNA-based methods are considered as the reference approach for species identification, and have been extensively applied during the EU horsemeat scandal. Compared to proteins, DNA is known to be more stable over time, more resistant to heat and industrial treatments, and present in all tissue types. Several DNA-based methods have been described to identify species from meat, fish and plants, generally all based on Polymerase Chain Reaction (PCR) (Kumar et al., 2015). Classical PCR and real-time PCR methods have been extensively published and are very specific to their targets. They are regularly applied by official control laboratories and service laboratories. Restriction Fragment Length Polymorphism (RFLP) and Random Amplification of Polymorphic DNA (RAPD) have been described as more flexible approaches than targeted PCR (Fajardo et al., 2010), but could lead to ambiguous results on closely related species. These approaches are unfortunately very targeted and often detect only the most common species, whereas more exotic species can be used for substitution; therefore detection methods must cover a broader range of species (Fig. 2).

Recently, the improvement of hybridization and (nano-)fluidic systems has allowed the development of macro- and micro-arrays. For species identification, they are usually based on PCR followed by hybridization of amplicons on arrays spotted with (many) different species-specific probes. A simple macro-array has recently been developed, allowing the detection of 32 meat species, including exotic species such as camel, kudu, cat, dog, fox and rat (Cottenet et al., 2016). The method allowed to detect these species down to 1% (w/w) which complies with the European requirement for meat adulteration. This macro-array is well adapted to meat species identification, but its application to fish reaches its limit knowing that salmon, tuna and white fish largely exceed 32 species. Similarly, this approach can not be applied on plant species identification with more than 300,000 plant species described by botanists.

While all these approaches are targeting a limited number of species, untargeted methods are more and more being developed and used. For DNA-based methods, DNA sequencing is the untargeted approach. Classical Sanger DNA sequencing has been shown to be highly reliable in identifying species. This technology is the basis of the International Barcode of Life initiative (iBOL) which

**Figure 2** Overview of the main DNA-based methods for species identification. With DNA molecule being well-conserved, stable over time, and present in all tissue types, various technologies have been developed over the past years, with NGS being the newest one and expected to be the next reference approach.

developed an identification system for eukaryotic organisms using DNA sequence variability (DNA barcodes). DNA barcoding is now frequently used to detect species substitution in fish and meat, and showed cases of substitution in United States close to 30% and 20% of fish and meat samples, respectively (Staffen et al., 2017; Quinto et al., 2016). In addition to meat and fish, DNA barcoding is also used for plant species identification. However, this technology is applicable to pure/single pieces and not to processed samples (e.g. ground or powder) susceptible to contain several species. If several species are present in the sample, the sequencing spectra from each species overlap and the final chromatogram is unreadable. In addition DNA barcoding usually targets long DNA fragments close to 600 base pairs (bp) preventing its application to processed samples where DNA could be degraded in shorter fragments of 100–200 bp. Mini-barcoding methods have been described to amplify shorter DNA fragments and detect degraded DNA, but they are not considered as the reference approach yet.

Evolution of Sanger DNA sequencing to Next Generation Sequencing (NGS) and meta-barcoding has allowed to reliably identifying species not only in pure/single species but also on mixtures. NGS is a DNA sequencing technology in which all DNA fragments are individually sequenced and recorded. Like classical DNA barcoding, meta-barcoding also starts with a PCR step to amplify consensus DNA fragments from meat, fish or plant. All individual PCR amplicons are then sequenced by NGS. Since all amplicons are sequenced and numerated, identification of species in a mixture is not only possible, but quantification could also be considered. DNA meta-barcoding is usually based on mini-barcodes and is thus more applicable to processed samples than DNA barcoding. In addition NGS presents the possibility to pool the tested samples altogether which can drastically reduce the analytical costs and lead to an affordable technology.

NGS DNA meta-barcoding has already been described on meat species identification and showed reliable species identification not only on classical species but also on more exotic ones (Staats et al., 2016). Some of them have been spiked down to 1% (w/w) and were successfully detected. Application on fish species identification also showed satisfactory results. Similarly, meta-barcoding allowed reliable species identification, even on very close-related species like the various tuna species, or the wide Salmonidae family (Pacific salmon species, Atlantic salmon species, Trouts etc.). NGS has also been shown to reliably identify plant species in spices, herbs and botanical supplements which are well known to be vulnerable to species substitution (Staats et al., 2016). With more than 300,000 plant species, identification of closely related species can be less precise and can be limited to the genus or family level in some cases, and depending on the developed method.

With its ability to identify thousands of species, and its applicability to mixtures and processed samples, NGS is expected to be the reference species identification tool in the coming years. It can be applied for meat, fish, and plant species identification. In addition, application to insects has already been described (Shokralla et al., 2015), knowing that insect can be considered as a hygienic issue in the food supply chain, but also as a protein-rich food ingredient, certainly prone to some adulteration once more commercialized.

### Analytical Detection of Protein Enhancement

Protein content in foods is commonly measured by determining the amount of nitrogen (N) and converting it into protein using a specific nitrogen-to-protein conversion factor (Nitrogen Conversion Factor or NCF). Nitrogen is measured by digestion (Kjeldahl) or combustion (Dumas). Those two methods are widely accepted for protein quantification although the accuracy of the conversion factors is regularly questioned. While those methods are able to quantify nitrogen in an extensive variety of matrices, they can be deceived by addition of N-rich compounds and are unable to detect protein substitution (Moore et al., 2010).

### Adulteration by Nitrogen-Rich Compounds

Targeted analyses such as high-performance liquid chromatography - ultraviolet detection (HPLC-UV) or liquid chromatography - tandem mass spectrometry (LC-MS/MS) remain limited because of their targeted nature; they require a knowledge of the potential adulterants and are, by definition, blind to novel substances. In contrast, untargeted analytical methods such as near-infrared (NIR) and Principal Component Analysis (PCA) can be used to detect deviations from reference models (e.g. detection of adulterants in milk) (Balabin and Smirnov, 2011; Santos et al., 2013). This approach requires a sufficient level of homogeneity within the target food category to allow the creation of a pertinent model. Reference models have to be developed for each raw material at risk and need to be maintained on a continuous basis to monitor and correct for natural deviations.

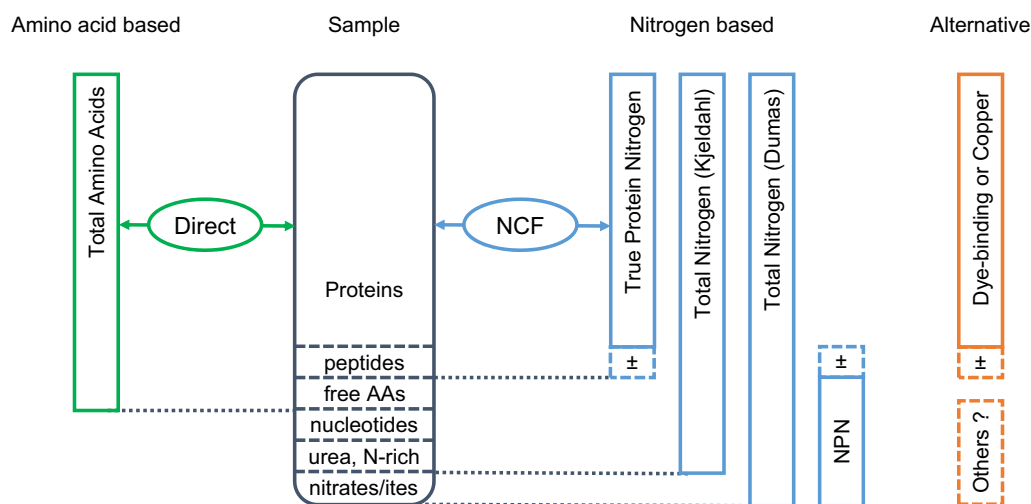

Another way to tackle adulteration by N-rich compounds is to assess protein content in a more specific manner (true protein content). In milk, proteins can be precipitated to measure (true) protein nitrogen, a value not impacted by adulterants such as melamine. Comparison of true and total protein nitrogen can reveal N-rich compounds addition (USP FCC, 2016). However, this approach is currently only validated in milk and cannot be applied to foods with a high variability of non-protein nitrogen content or to adulterants that precipitate under similar conditions.

In the long term, a payment scheme based on true protein content would remove the incentive for adulteration by N-rich compounds altogether. Amino acid profiling is the only method able to directly measure true protein content but is more complex than nitrogen-based methods; it requires two distinct sample hydrolyses and a comprehensive quantification of all amino acids that is prone to cumulative errors (which has however to be weighed against the vagueness of the NCFs used in nitrogen-based methods). Amino acid profiling methods are likely to further improve in the near future and could be used to establish reference values for a large variety of raw materials. Of note, amino acid profiling also measures free amino acids and small peptides, and the definition of true protein content will require an alignment between all the stakeholders to re-define globally accepted payment schemes.

Rapid copper-based (biuret, Lowry or BCA) or dye-binding (anionic dyes or Bradford) methods have also been assessed for their ability to measure true protein content. While those methods are not strictly specific for proteins and can be deceived by chemical substances, they could be calibrated against a reference value such as that obtained by amino acid profiling (Fig. 3).

### Adulteration by Protein Substitution or Addition

Apart from addition of N-rich compounds, protein adulteration can also be achieved by substitution with cheaper protein sources or dilution with bulking agent and addition of cheaper protein sources. There, most methods described above cannot be applied because the adulterants share many properties with the food matrices to which they are added. Amino acid profiling might be used to detect foreign protein addition provided the profile of the adulterant is radically different from that of the target food matrix, and provided the amino acid profile of the food product is well established. Infrared spectroscopy has been shown to be able to detect addition of soymilk into bovine milk (Jaiswal et al., 2015).

**Figure 3** Schematic measures of protein quantification. Sample nitrogen is distributed between various compartments (proteins, peptides, urea, nitrates, etc.). Different protein quantification methods based on nitrogen (blue) differ in their selectivity: combustion (Dumas) measures all nitrogen and Kjeldahl measures all organic nitrogen plus ammonia. To measure true protein nitrogen, proteins are precipitated before establishing their nitrogen content by Kjeldahl or Dumas. Non-protein nitrogen (NPN) can either be directly measured from the non-precipitated material or obtained by difference between total and true protein nitrogen. Peptides are found in both protein and non-protein nitrogen fractions (±) because the cutoff between peptides and proteins is blurry. To convert nitrogen into protein content, nitrogen-based methods rely on Nitrogen Conversion Factors (NCFs) whose accuracies are regularly questioned. In absence of separation, amino acid quantification (green) directly measures the sum of proteins, peptides and free amino acids (AAs) without the need for conversion factors. Alternative methods should be calibrated against a reference method and could be influenced by other compounds that are not related to nitrogen.

In principle, powder protein samples (concentrates, isolates ...) contain enough DNA to be detected by NGS (see previous section on DNA-based approaches for species identification). Therefore, NGS could in principle also be used as a screening tool to detect the presence of added protein. Of note, NGS cannot be used when the adulterant comes from a different part of the same organism (i.e. offals in meat), or when the adulterant is derived from the target food matrix (i.e. whey in milk ...). In those cases, specific methods and/or appropriate surrogate markers have to be developed for each particular vulnerability.

By-products such as protein hydrolysates (leather, feather ...) possess particular characteristics that differ from standard protein samples, notably with respect to polypeptide size distribution and number of free C- and N-termini. Those characteristics can be used to detect added hydrolyzed products either by methods that are sensitive to polypeptide length (i.e. non-protein nitrogen, Bradford) or that react with particular chemical groups (i.e. free amino groups). The nature, heterogeneity, and degree of hydrolysis of the adulterant will profoundly impact the efficacy of those methods for the detection of added hydrolysates.

When the source of adulteration cannot be identified by NGS, or when a direct identification of the foreign protein source is needed, peptides generated by proteolytic digestion of the samples can be analysed by LC-MS/MS to identify the corresponding proteins. Hydrolyzed samples can be analysed similarly without need for prior proteolysis.

## Analytical Evolution for Food Adulteration Detection

A number of technologies have already been applied successfully to verify the authenticity of raw materials with regard to their composition, processing or origin. They include molecular methods (DNA-based approach), rapid spectroscopic methods (e.g. near- and mid-infrared spectroscopy, Fourier transform Raman (FT-Raman) or nuclear magnetic resonance) or spectrometric methods (e.g. LC-MS/MS, MALDI-MS and others).

Application of analytical platforms other than genomic (DNA-based methodologies described above for species substitution) have been shown to provide good complementary solutions. Publications and applications related to food adulteration detection using spectroscopy is increasing very fast. Near- or mid-infrared spectroscopy and, more recently, Raman technology propose several advantages in terms of ease of use, speed (high sample throughput), and minimal sample preparation (Ewing and Kazarian, 2017). Applications of these spectroscopic technologies combined with chemometric analyses have been shown as powerful tools (Qu et al., 2015; Zhang et al., 2011; Cozzolino, 2012). Moreover, significant technical advancements in miniaturization have been achieved using new technologies for generating optical mechanical functions in the near- or mid-infrared spectroscopy but also with regard to high resolution spectrometers. These various degree of sophistication (from handheld to benchtop spectrometer) make them valuable for raw materials inspection by industries e.g. in the field or milk collection centers, at raw material reception areas or in specific laboratories requiring more sophisticated facilities. These techniques have a wide range of applications from solid, semi-solid and liquid samples and thus have been applied to many food matrices for food adulteration detection. They are highly efficient to discriminate species origin, geographical origin in parallel to qualitative and quantitative analysis of specific ingredients and physical properties (e.g. proximates and freezing point in raw milk, phenols, alpha-farnesene in apples) (Huck et al., 2016; Wang et al., 2017; Wang and Yu, 2015). Moreover, NIR and MIR spectroscopic technologies are widely used in the dairy industry to analyse proximates such as protein, fat, at the same time as performing a rapid untargeted screening of potential adulterants (Coitinho et al., 2017; Botelho et al., 2015; Poonia et al., 2017). Miniaturization is still ongoing with the apparition of handheld infrared spectroscopic devices which are promising (e.g. for fish, milk, meat) (Grassi et al., 2018; Nieuwoudt et al., 2016; Schmutzler et al., 2015). When combined with immunoassay and sensors these new technologies will become more and more critical for rapid adulteration detection.

Food adulteration detection also often requires more specialised laboratory analyses (such as spectrometric technologies and more sophisticated spectroscopy technologies such as nuclear magnetic resonance (NMR). The SNIF-NMR technique (site specific natural isotope fractionation-NMR) along with chemometric data treatment has been widely applied for classification of wine origin and identification of substitution with cheaper ones (Charlton et al., 2010). This technique has been successfully extended to fruit juices and honey adulteration with sugar (e.g. beet sucrose or modified sugars). Specific companies have further developed screening applications for over 3000 fruit juices. Detection of foreign sugar addition in fruits juices and honey has been complemented by the analysis of stable isotope in food (isotope ratio mass spectrometry, IRMS). This technology is also widely applied to determine the geographical origin of many raw materials and the identification of synthetic molecules in ethanol, vinegar or flavorings as well as for the differentiation of organic versus conventional farming methods (Rossier et al., 2016; Manning and Soon, 2014).

As described by Ellis et al. (2016), recent metabolomics studies appear to encompass a diverse range of applications for adulteration detection. For example, nuclear magnetic resonance (NMR) metabolite fingerprinting has been used for the determination of the country of origin of coffee, detection of saffron dilution from cheaper plants, and fully automated analysis of wine authenticity (Spraul et al., 2015). Others have used metabolomics (gas chromatography mass spectrometry (GC-MS) based multimarker profiling) to elucidate discriminant markers for the authentication of expensive raw material (e.g. the expensive coffee Kopi Luwak). In some cases, a combination of methodologies using metabolic approaches is necessary. It is the case for example for the detection and quantification of oregano adulteration with foreign leaves where FT-IR and LC-MS-based metabolic profiling has been used (Black et al., 2016a,b).

For speed and simplicity, efforts have recently been made towards the development of ambient mass spectrometry (AMS) technologies. Their new ionization technique allows samples to be analysed directly with no (or limited) sample preparation with

a high resulting sample throughput (Black et al., 2016a,b). The rapid growth with over 30 different techniques available have shown interesting applications for food fraud detection. Interestingly, a number of them (e.g. direct analysis in real time (DART), easy ambient sonic spray ionization (EASI), liquid extraction surface analysis (LESA), rapid evaporative ionization (REIMS)) have demonstrated not only qualitative but also quantitative applications. Detection of hazelnut oil in extra virgin oil down to 6% and adulteration of soft cheese with vegetable oils at 1% (w/w) were shown using DART technology (Vaclavik et al., 2009; Hrbek et al., 2014). Surface extraction and direct ambient MS analysis of cooked meat species showed detection of 5% (w/w) chicken in beef samples using LESA (Montowska et al., 2014). The use of REIMS for rapid characterization of meat products showed possible detection of meat mixtures at a limit of 5% (w/w) (Balog et al., 2016). These new technologies are producing fast and accurate results comparable to those obtained from conventional techniques such as LC-MS or NMR. Identification of white fish species using REIMS showed nearly 99% correct classification with species identification obtained within a few seconds unlike any other form of food fraud analysis (Black et al., 2017).

## Conclusions

Food adulteration deterrence is complex because of its unpredictable nature. Significant efforts have been made recently in many aspects by food companies, authorities and academics. Beside finding new analytical approaches, food manufacturers are also improving the knowledge of their supply chain in term of length (number of tiers), complexity and vulnerability. Food chain transparency and full raw material traceability is primordial for an effective food fraud prevention system. A consortium regrouping different organizations has been created to work on new platforms designed to be compatible between all partners, such as food manufacturers, raw material suppliers, and even authorities. Ideally, the system should provide supply chain transparency in real-time, with end-to-end product traceability. New emerging technologies such as the blockchain should further help to reach this goal, increasing accountability and thus providing to suppliers, regulators and consumers higher trust on food integrity. Recent alliances have been formed with a computer organization to create a standard-based method of collecting data about the origin, safety and authenticity of food. Initial application showed that the blockchain technology could reduce the time to trace a package of specific raw materials (e.g. fruits) from the farm to the store from days to few seconds.

Mapping supply chain vulnerabilities is leading to the identification of the most vulnerable chains where confidence to suppliers may be lower (e.g. raw materials are purchased through traders that may have multiple vendors and procure through auctions). Enhanced attention (e.g. regular vendor audits, addition of new parameters to prevent food adulteration in supplier purchasing specifications) are being performed on the most vulnerable raw materials in order to increase confidence to suppliers, in addition to regular monitoring. Analytical technologies and methodologies are evolving to be better adapted to food adulteration detection. Untargeted analytical methodologies, which are often required for rapid detection of raw material abnormalities, are easier to implement today and can be used to detect unknown adulterants. Instrument suppliers are more and more integrating specific software in their hardware to help building and running chemometric models. DNA-based approaches are also much more performant such as NGS with the possibilities to detect not only single species but mixtures via sequencing and associated databases. Miniaturization of instruments is an additional significant technical advancement for direct verification of raw materials early in the chain at low cost. More sophisticated methods are also evolving rapidly to get simpler with the development of ambient technologies requiring minimum sample preparation. This results in diverse applications in food fraud detection with a decrease of cost related to raw material surveillance. As shown in this document, food manufacturers are implementing many preventive actions all along the supply chain to increase significantly the food adulteration deterrence.

# Food Chemistry and Analysis for the Purpose of Kosher and Halal

Joe M Regenstein, Department of Food Science, Cornell University, Ithaca, NY, United States

© 2019 Elsevier Inc. All rights reserved.

## Introduction

The objective of this chapter is to introduce the kosher and halal laws and as this is done, the author will try to indicate where food chemistry, particularly food analysis, might be challenged to provide analyses that will aid in insuring the integrity of the process. In some cases these can be quite challenging. It should be noted that on-site inspection by religious personnel remains the main way to insure the integrity of the system and laboratory testing is a way to back-up the inspectors as most food manufacturing facilities do not have continuous inspection.

## The Kosher and Halal Laws

Before looking into the laws, it may be helpful to understand the religious significance of these dietary laws for Jews and Muslims. The kosher (kashrus) dietary laws determine which foods are “fit or proper” for consumption by Jewish consumers who observe these laws. The halal dietary laws determine which foods are “lawful” or permitted for Muslims. For both religions, the food laws are a small part of a comprehensive system of religious laws cover many aspects of daily life. How an individual Jew or Muslim will live their life is a personal matter often influenced by the standards of the local community. Although these variations may at times be frustrating making products for these markets. But it is also a great strength internally to be able to respect within group diversity.

Why do Jews and Muslims follow dietary laws? The explanation by Rabbi I. Grunfeld provides an explanation that really speaks on behalf of both religions although it is clearly of Jewish origin ([Grunfeld, 1972](#)).

And ye shall be men of a holy calling unto Me, and ye shall not eat any meat that is torn in the field

Exodus XXII:30.

Holiness or self-sanctification is a moral term; it is identical with ... moral freedom or moral autonomy. Its aim is the complete self-mastery of man.

To the superficial observer it seems that men who do not obey the law are freer than law-abiding men, because they can follow their own inclinations. In reality, however, such men are subject to the most cruel bondage; they are slaves of their own instincts, impulses and desires. The first step towards emancipation from the tyranny of animal inclinations in man is, therefore, a voluntary submission to the moral law. The constraint of law is the beginning of human freedom ....

The three strongest natural instincts in man are the impulses of food, sex, and acquisition. Judaism does not aim at the destruction of these impulses, but at their control and indeed their sanctification. It is the law which spiritualizes these instincts and transfigures them into legitimate joys of life.

## The Kosher and Halal Market

Both kosher and halal are important specialty markets. Briefly, the deliberate consumers of kosher food, i.e., those people who specifically look for the kosher mark, are estimated to be over 12 million Americans (of which 2/3 are not Jewish) and they are purchasing almost 15 billion dollars of kosher products ([Lubicom Marketing Consulting, 2012](#)). Others include consumers who may find kosher products helpful in meeting their own dietary needs such as Muslims, Seventh Day Adventists, vegetarians, vegans, people with various types of allergies – particularly to dairy, grains, and legumes – and general consumers who for one reason or another prefer kosher products. By undertaking kosher certification, companies incrementally expand their market, i.e., increased incremental sales.

On a global scale, the halal market is a significant component of trade in foods. The number of Muslims is estimated to be between 1.3 and 1.8 billion people (i.e., 20% to 25% of the world's population!) and inter-country trade in halal products continues to grow. In many countries halal certifications acceptable to the national government have become necessary for products to be allowed to be imported.

### The Kosher Dietary Laws With Reference to Halal Dietary Laws

The laws predominantly deal with three issues, all focused on the animal kingdom with a fourth set of laws dealing with the holiday of Passover that are added to the regular laws but focus more on the plant kingdom.

There are also many additional laws dealing with special issues such as grape juice, wine, and alcohol derived from grape products; Jewish supervision of milk; Jewish cooking, cheese making, and baking; equipment kosherization; purchasing new equipment from non-Jews; and old and new flour. Those with potentially challenging analytical needs will be discussed.

#### Allowed Animals

Ruminants with split hoofs that chew their cud (ruminants), the traditional domestic birds (e.g., chicken, turkey, duck and geese), and fish with fins and removable scales (i.e., visible and they do not tear the skin; cycloid and ctenoid, all fish with scales have fins) are generally permitted.

Pigs (which have often become the symbol of both kosher and halal observance) and camels (a ruminant without a split hoof) are not permitted although the latter is halal.

Among commercially available birds, the ostrich family is prohibited for kosher but is accepted as halal. Animals that spend their entire life in the water are permitted by some in the halal community although there is a great deal of divergence with respect to the acceptability of marine life.

Most insects are not kosher. A few types of grasshoppers/locust are kosher and halal. Modern IPM (integrated pest management) programs that increase the level of insect infestation in fruits and vegetables can cause problems for the kosher consumer, who must inspect produce suspected of having insects and then remove any insects found. The red pigments carmine and cochineal are not permitted by most rabbinical supervisors, although a few do permit it because it comes from the inedible shell. The Muslim community also debates this topic although many of the Muslim schools of thought prohibit it. However, bee's honey and shellac (lac resin), an insect exudate are permitted by most kosher and halal authorities.

#### Analytical Challenges

Can one detect the presence of any material from a non-kosher animal? If the adulterant still contains DNA, the testing protocols are being developed. However, this is more difficult for certain animal-based derivatives without DNA such as fats and oils and its derivatives (e.g., mono- and di-glycerides). Can one use the fatty acid profile to determine relatively small amounts of contamination? Another important animal ingredient, gelatin (and collagen) can be obtained from a number of different fish and animals. As the use of insects for food increases, new analytical challenges will need to be addressed. The challenge in many cases is not only to determine their presence when one suspects a particular adulterant might be present, but to do so without knowing which adulterant one might be looking for, which is often the greatest challenge for analytical chemists. And some of these issues are also of concern to the broader community because of the issue of mislabeling.

#### Prohibition of Blood

Ruminants and fowl must be slaughtered according to Jewish law by a specially trained religious slaughterman (shochet) using a special knife designed for the purpose (chalef). The knife must be razor sharp and totally free of nicks. It must have a very straight blade that is at least twice the diameter of the neck of the animal to be slaughtered. This knife is checked after each slaughter. The cut is done horizontally across the neck in a specifically designated region. Both carotid arteries and both jugular veins along with the windpipe and esophagus are cut. When done right on calm animals, this leads to strong bleeding which leads to rapid unconsciousness of the animal in a calm fashion. The Muslim community uses a similar slaughter along with a blessing. They highlight not sharpening the knife in front of the animal, not allowing another animal see the slaughter, and having the animal facing Mecca. Some Muslim scholars permit pre-slaughter stunning of an animal and some rabbis permit post-slaughter stunning.

#### Analytical Challenges

The importance of blood removal is central to the process for both Muslims and Jews. The use of blood derived ingredients is prohibited. Can one determine if such compounds were used as opposed to the natural post-bleed-out blood found in the animal? Can one tell after the fact if an intervention was used in addition to the traditional slaughter?

Slaughtered animals for kosher are subsequently inspected for visible internal organ defects by rabbinically-trained inspectors, with a special emphasis on the lungs. Meat and poultry must be further prepared by properly removing certain veins, arteries, prohibited fats, blood, and the sciatic nerve. To further remove the prohibited blood, red meat and poultry must then be soaked, salted and rinsed within 72 h of slaughter. Livers and hearts will be handled separately. If this is not possible, then according to some Rabbis meat may be specially washed (begissing, a real wash and not just a light spray) and this wash procedure may be repeated for up to two more times, each time within 72 h of the previous washing. This is done to make sure the blood and meat surfaces remain moist.

The soaking is done for half an hour in cool water (not cold), thereafter, the salting is done for 1 h with all surfaces, including cut surfaces and the inside the cavity of a chicken or turkey. After the hour of salting, the meat is then rinsed three times. The salted meat must be able to drain throughout and all the blood being removed must flow away freely. The special crystal size used for this process is called kosher salt (crystals large enough to not dissolve in an hour, but small enough to adhere and totally cover surfaces).

### Analytical Challenges

Some fraudulent operators have soaked the meat in brine to obtain more easily “salt” the meat. Can one use changes in the muscle or the blood of the meat to determine whether proper salting with salt crystals has been done?

Some concern has been raised about the salt level in kosher meat. Note that only the surfaces are salted, generally using primal cuts (i.e., 20–40 pound pieces of meat), and that the penetration of the salt is less than a half centimeter in red meat (NY Department of Agriculture and Markets, personal communication). Many pieces of meat, as consumed, have therefore not been directly subjected to the salt treatment. If salt content in a diet is a very important consideration, then one should cut off all surfaces and not use any of the drippings that come out during cooking as much of the salt that goes into the meat at the surface is cooked out with the drippings.

Any ingredients or materials that might be derived from animal sources are generally available in a kosher and/or halal form derived from plant oils. A possible exception might be normative mainstream gelatin, which is now being produced from kosher beef hides or fish. Also some kosher rennet, the cheese-coagulating enzyme, is obtained from the dried fourth stomach of a kosher-slaughtered milk-fed calf although most commercial cheese today is made using microbial enzymes that come either from genetically modified bacteria or other microbes whose coagulating enzyme(s) can be successfully used. Microorganisms must be produced in kosher or halal systems (i.e., all ingredients and the equipment are kosher or halal).

### Prohibition of Mixing of Milk and Meat

Thou shalt not seeth the kid in its mother's milk.

Exodus XXIII:19, Exodus XXXIV:26, Deuteronomy XIV:21

This passage appears three times in the Torah (the first five books of the Hebrew Scripture) and is therefore considered a very serious admonition. As a result, the law cannot be violated even for non-food uses of such mixtures such as pet food. Neither can one derive benefit from such a mixture. The meat side of the equation has been rabbinically extended to include poultry (but not fish) as both meat and poultry need to be inspected, deveined, salted, and soaked. The dairy side includes all milk derivatives.

Keeping meat and milk separate in accordance with kosher law requires that the processing and handling of all materials and products fall into one of three categories:

1. A meat product
2. A dairy product
3. A neutral product called “pareve”.

### Analytical Challenges

How does one detect a dairy product in small amounts, recognizing that modern dairy products include materials like caseinates, whey, lactose, dairy protein hydrolysates, and derivatives of whey including whey alcohol and citric acid (which if derived from whey would according to most authorities remain dairy).

The pareve category includes all non-meat or non-dairy products and includes all plant products along with eggs, fish, honey, and lac resin (shellac). To assure the complete separation of milk and meat, all equipment, utensils, pipes, steam, etc. must be kept in the properly designated category.

Pareve ingredient or product must be produced on equipment that has undergone equipment kosherization (see Section on **Equipment Kosherization**).

### Other Kosher Issues

#### Grape Products

To be kosher, all grape juice-based products can only be handled by observant Jews from grape-pressing to final processing. If the juice is heated to at least 140 °F (or 60 °C), then it can be handled by any worker, as an ordinary kosher ingredient. Some rabbis require a higher temperature.

### Analytical Challenge

Can one after the fact determine the approximate temperature of heating?

#### Jewish Cheese (*gevinas yisrael*)

Most normative mainstream kosher supervision organizations require that a Sabbath-observing Jew add the coagulating agent, i.e., the agent such as chymosin that causes curd formation. Any ripened cheese that does not meet this requirement is unacceptable. This rule does not apply to fresh cheeses.

Kosher whey can be created more easily than kosher cheese. If all the ingredients and equipment used during cheese making are kosher, the whey will be kosher as long as the curds and whey have not been heated together above 120 °F (49 °C) before the whey is drained off. This is true even if a rabbi has not added the coagulant.

**Analytical Challenge**

Can one determine the maximum temperature received by the whey?

**Cholev Yisroel**

Some kosher-observant Jews are concerned about possible adulteration of milk with the milk of non-kosher animals, such as mare's milk or camel's milk, and therefore require that the milk be watched from the time of milking (i.e., on the farm). "Cholev yisroel" milk is required by some of the stricter kosher supervision agencies for all dairy ingredients. Rabbis who accept non-"cholev yisroel" milk in the United States do so for two reasons. First, they believe that the laws in the United States and many other developed countries are strong enough to assure that adulteration does not occur. Second, the non-kosher milks are worth more money than kosher milks, so there is no incentive to add the non-kosher milk.

**Analytical Challenge**

Can one detect the presence of a non-kosher milk or milk ingredients?

**Passover**

The Passover holiday occurs in spring and requires observant Jews to avoid eating the usual products made from the five Biblically prohibited grains: wheat, rye, oats, barley, and spelt (Hebrew: chometz). One can only eat the special unleavened holiday bread from wheat (Hebrew: matzos). Some matzos are made to a stricter standard with rabbinical inspection beginning in the field. For others supervision does not start until flour milling. Matzo made from oats and spelt are now available for consumers with wheat allergies.

In the middle ages, the rabbis of Europe also made products derived from corn, rice, legumes, mustard seed, buckwheat, and some other plants (Hebrew: kitnyos) prohibited for Passover that they believed could be made into flour and might be mistaken for chometz. In addition to the actual "flours" of these materials, many contemporary rabbis also prohibit derivatives such as corn syrup, corn starch, and corn starch derivatives such as citric acid. A small number of rabbis permit the oil from kitnyos materials, or liquid kitnyos products and their derivatives such as corn syrup. The major source of sweeteners and starches used for production of "sweet" Passover items are either real sugar or potato or cassava (tapioca) starches.

**Analytical Challenge**

Can one determine if any prohibited materials have been used?

**Kosher: Other Processing Issues****Equipment Kosherization**

There are three ways to make equipment kosher or to change its status back to pareve. Rabbis generally frown on regularly going from meat to dairy or vice-versa. Most conversions are from dairy to pareve or from treife to one of the categories of kosher. There is a range of processing procedures to be considered, depending on the equipment's prior production history.

After a plant, or a processing line, has been used to produce kosher pareve products, it can be switched to either kosher dairy or kosher meat without a special equipment kosherization step. It can also subsequently be used for halal production (from pareve or dairy lines, not always from meat lines), and then, finally, for non-kosher products. In many cases, a mashgiach (the rabbinically approved kosher supervisor), is needed on site for equipment kosherization, so it normally is beneficial to minimize the number of changeovers from one status to another. Muslims also have a procedure for changing equipment that generally involves a supervised washing.

The simplest equipment kosherization occurs with equipment that has only been used for cold products. This requires a good liquid caustic/soap cleaning – i.e., the type of cleaning done normally in most food plants. Some plants do not normally do a wet clean up between runs (e.g., a dry powder packing plant or a chocolate line), and these would need to seek specific rabbinical guidance for the change-over if permitted. Materials such as ceramics, rubber, earthenware, and porcelain cannot be koshered.

Most food processing equipment is operated at cooking temperatures, generally above 120 °F (49 °C), the temperature that is usually rabbinically defined as "cooking." However, the exact temperature for "cooking" depends on the individual rabbi and may also be product specific (range 110–140 °F (~43–60 °C)) with 120 °F (49 °C) being agreed upon in the US for dairy products. Such equipment must be thoroughly cleaned with liquid caustic/soap. The equipment must then be left idle for 24 h, after which it is "flooded" with boiling water in the presence of a kosher supervisor. The details depend on the equipment being kosherized. In some cases, particularly foodservice establishments, a "pogem" (bittering agent, oftentimes ammonia) is used in the boiling water in lieu of the 24 h wait. The absolutely clean equipment (e.g., silverware) is put into the pogem containing boiling water followed by a second boiling with clean water.

In the case of ovens or other equipment that uses "fire," or dry heat, kosherization involves heating the metal until it glows. Again, the supervising rabbi is generally present while this process is taking place. Sometimes the same oven can be used sequentially for pareve and dairy baking. The details are beyond the scope of this chapter and require a sophisticated rabbinical analysis. If kosherization of an oven is needed, this often requires the use of a blow torch to heat surfaces to "red hot."

## Kosher and Allergies

Many consumers use the kosher markings as a guideline to determine whether food products might meet their special needs including allergies. There are, however, limitations that the particularly sensitive allergic consumer needs to keep in mind. The kosherization procedure may not yield 100% removal of previous materials run on the equipment.

In a few instances where pareve products contain small amounts of fish (such as anchovies in Worcestershire sauce), this ingredient may (but not always) be marked as part of the kosher supervision symbol as fish cannot be used directly with meat. Many certifications do not specifically mark this if the fish in the initial material is less than 1/60 (a special amount used by the rabbis to determine if a process of nullification can be used after the fact). Someone who is allergic should always carefully read the ingredient label including the allergy warning. Kosher should be used only for a first screening of products.

## Additional Information About the Halal Dietary Laws

### Halal Dietary Laws

The halal dietary laws define food products as halal (permitted), haram (prohibited) and put a few items go into the category of makrooh (questionable to detestable), which is often the most controversial. The law deals with the following five issues; all but the last are in the animal kingdom.

### Prohibited and Permitted Animals

As previously mentioned, pork is prohibited, as are the carnivorous animals and birds of prey. Again the ruminants, including the camel is permitted, but also the rabbit. However, most Muslims consider horsemeat to be makrooh. Birds are specifically those that do not use their claws to hold down food.

The animals fed unclean or filthy feed (e.g., formulated with biosolids (sewage) or protein from tankage), must be quarantined and placed on clean feed for a period varying from three to forty days before slaughter to cleanse their systems.

### Analytical Challenge

Besides previous questions, can one determine what an animal ate just before slaughter? With the internal organs available and more challenging without them.

Food from the sea, namely, fish and seafood, are the most controversial among the various denominations of Muslims. Certain groups, particularly Shiia, only accept the kosher fish, while others consider as halal everything that lives in the water all the time. But others may consider some of these makrooh and avoid them. Animals that live both in water and on land (amphibians) are not consumed by the majority of observant Muslims.

The status of insects is uncertain except that locust is specifically mentioned as halal. However, from legal discussions, it seems that both helpful insects like bees, ants, and spiders, and harmful or dirty creatures like lice, flies, and mosquitoes are all haram.

Eggs and milk from permitted animals are also permitted for Muslim consumption. Unlike kosher, there is no restriction on mixing meat and milk.

### Prohibition of Blood

According to the Quranic verses, blood that pours forth is prohibited for consumption. There is general agreement among Muslim scholars that anything made from blood is unacceptable.

### Analytical Challenge

Can one determine the presence of blood or blood derivatives such as fibrin/fibrinogen in foods?

### Proper Slaughtering of Permitted Animals

In addition to those discussed earlier, there is the rule that only after the blood is allowed to drain completely from the animal and the animal has become lifeless can the dismemberment begin.

### Prohibition of Alcohol and Intoxicants

Consumption of alcoholic drinks and other intoxicants is prohibited.

Although there is no allowance for added alcohol in any beverage like soft drinks, small amounts of alcohol contributed naturally from food ingredients may be considered an impurity and hence ignored. Synthetic or grain alcohol may be used in food processing for extraction, precipitation, dissolving and other reasons, as long as the amount of alcohol remaining in the final product is very small, generally below 0.1%. Each importing country may have its own guidelines.

### Analytical Challenge

Can the source of the alcohol be determined, i.e., beverage alcohol or industrial alcohol? Also for kosher can the source of the alcohol (or vinegar) be determined in terms of both grape based alcohol and grain/kitnyos alcohol?

## Both Kosher and Halal

### Biotechnology

Rabbis and Islamic scholars currently accept products made by simple genetic engineering; e.g., chymosin (rennin) was accepted by the rabbis about a half a year before it was accepted by the US FDA. The basis for this decision involves the idea that the gene isolated from a non-kosher source was not “visible.” Subsequently, it is copied many times *in vitro* and then eventually injected into a host where it is then reproduced many times. Thus, the original source of the “gene” is essentially totally lost by the time the food product appears. The production conditions in the fermenters must still be kosher or halal, i.e., the ingredients and the fermenter, and any subsequent processing must use kosher or halal equipment and ingredients. A product produced in a dairy medium would be kosher dairy. Mainstream rabbis may approve porcine lipase made through biotechnology when it becomes available, if all the other conditions are kosher. Islamic scholars are still considering the issue of products with a porcine gene; although a final ruling has not been established, the leaning seems to be towards rejecting such materials.

If the gene for a porcine product were synthesized (i.e., it did not come directly from the pig), Islamic scholars still need to determine if they will accept it. Again the leaning seems to be negative. Because the religious leaders of both communities have not yet determined the status of more complex genetic manipulations; such a discussion is premature.

**MoA** Mode of Action  
**MOE** Margin of Exposure  
**NOAEL** No Observed Adverse Effect Level  
**POD** Point of Departure  
**TFI** Tolerable Daily Intake

## Introduction

The presence of contaminants in food is non-intended in most cases, being due to certain events or steps during the process of production of the food product including all raw materials or ingredients. They can be detected in the final food product intended for consumer use (Schrenk and Cartus, 2017). Thus, contaminants differ from additives, ingredients etc. which were added on purpose, e.g. for technological or other reasons. Furthermore, compounds that did not enter the food process from outside but were generated during the process (e.g. thermal treatment) such as acrylamide or furan are also considered as contaminants, sometimes also specified as ‘process contaminants’. As an example, Table 1 shows a list of contaminants assessed by the CONTAM-Panel of the European Food Safety Authority (EFSA) since January 2014.

Furthermore, it is evident that sometimes contaminants may also originate from illegal or criminal addition of chemicals during the food production process.

In contrast to contaminants, residues are ‘left-overs’ from the intended use of plant protection chemicals (in food of plant origin) or veterinary drugs (in food of animal origin) in agricultural production processes. In cases where such chemicals were factually not used but nevertheless found in the product, contamination e.g. via drift of pesticides from crop fields in the vicinity etc. may have occurred, however, i.e., such findings could also be classified as contaminants.

Food of animal origin, coffee or cereal products are examples of foods that were under discussion in recent years because of the detection of chemical contaminants.

**Table 1** Selected Scientific Opinions published by the European Food Safety Authority (EFSA), CONTAM Panel, 2014–2017 ([www.efsa.europa.eu](http://www.efsa.europa.eu))

Contaminant(s)	References (EFSA Journal)
Chromium in food and drinking water	12(3), 3595

## Data Selection and Use in Toxicological Risk Assessment

The toxicological risk assessment of chemical compounds starts by describing the structural and physico-chemical features of the compound as detailed as possible. Furthermore, the pathways of generation or synthesis and methods of quantitative analysis of the compound should be known and be discussed. Another cornerstone in risk assessment is the analysis of levels (contents) in various categories and types of food. At this stage, it is often required to take into account other sources or levels, e.g. in the environment, at the workplace etc.

On the basis of occurrence data of this type, the assessment of human exposure follows. It considers databases for regional, national or international consumption of certain food categories and types. Since marked variations in consumption occur, e.g. between nations, probabilistic methods are applied which make use of the distribution of consumption data e.g. for fish, cereals, meat and meat products etc. Multiplying these data with levels of the contaminant in the respective food category for average or high (95th percentile) consumers of this category yields estimates for exposure. The data then can be refined for various cohorts, age groups etc. taking into account average body weights in these groups.

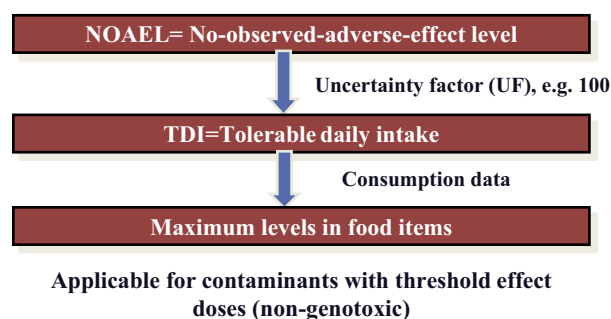

In the next step, facts on the fate and effects of the compound of interest in relevant biological systems are gathered. Such relevant systems comprise animal (mammalian) models such as experimental animals, isolated organs, cells, subcellular fractions or purified enzymes. Usually, human studies are not available for ethical reasons with the exception of certain test data on mild skin irritation or similar. Nevertheless, studies in human cells, subcellular organelles (e.g. mitochondria), enzymes, receptors etc. are possible. It has to be noted, however, that data from human permanent cells, which are quite popular among scientists, are of limited value in quantitative risk assessment. In vivo and in vitro studies try to provide reliable estimates on absorption e.g. in the gastrointestinal tract, metabolism, distribution and elimination from the body. Since the extrapolation of such in vitro data to the in vivo situation has become more and more reliable in the last years, a reduction of animal testing in toxicological risk assessment appears feasible in the future.

The next step in risk assessment is the selection and analysis of data about the toxic (adverse) effects of the compound. Also in this case most data are usually derived from experimental animals, since they reflect the complexity of an intact mammalian organism. These comprise particularly data from acute, subacute or chronic feeding or gavage studies, i.e., the test compound was mixed in to the feed or given intra-gastrically. A special requirement for quantitative risk analysis is the use of different dose levels, some of them showing pronounced effects, others no effects. The latter are used for the derivation of a non-toxic dose level (NOAEL = No-observed-adverse-effect level) as shown in Fig. 1. In this scenario, a sufficient number of animals and a thorough documentation of effects including a critical review of any findings also in untreated (negative control) animals are needed. Finally, the critical toxic effect, the so-called 'toxic endpoint', should be a clearly defined easy to measure effect with obvious adversity. The effect should become worse with increasing dose levels. It should be biologically plausible and statistically relevant (different from negative controls).

Ideally, mechanistic findings are available which allow an understanding of the compound's Mode of Action (MoA). Under these conditions, the confidence in the risk assessment process is strongly improved, in particular if similar MoAs were reported for structurally related compounds.

An appropriate understanding of the MoA is crucial in several respects. First, the extrapolation of findings from animal experiments to humans can be evaluated much more effectively, if the MoA is known. In many cases an identical MoA is considered to be operative or at least feasible in humans. While the physiology of rodents can differ considerably from that in primates, certain MoAs are known not to occur in humans thus making the respective findings in an animal (e.g. rodent) species irrelevant for human risk assessment.

Frequently, chemicals can affect the body's functions attacking more than one target. Thus they elicit a spectrum of different symptoms that not necessarily originate from the same MoA. Cadmium is a good example since it can affect both kidney function and bone growth both effects not sharing the same MoA. In such cases, the more sensitive endpoint is usually chosen since protective risk management measures protecting the most sensitive target will also protect other targets. The situation becomes more complicated if carcinogenicity (tumor formation) is one of the critical endpoints. Here, the characterization of the MoA as genotoxic vs. non-genotoxic plays a decisive role.

**Figure 1** Derivation of a Tolerable Daily Intake (TDI) and of maximum levels in food from a No-observed-adverse-effect level (NOAEL).

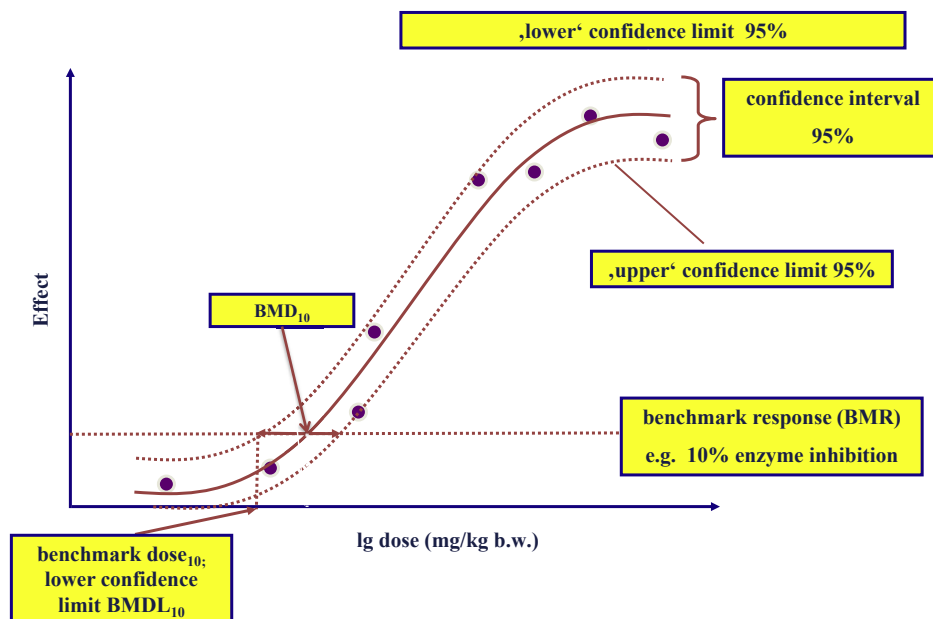

## Characterization of the MoA as Genotoxic/Carcinogenic Using In Vivo and In Vitro Methods

Investigations using in vitro models can be of great value in order to characterize the MoA. They often have been initiated by findings from in vivo experiments and are aimed at elucidating the molecular MoA in more detail. A widely used method is the use of primary cells, i.e., cells freshly isolated from animal or human tissue. It is a major advantage of these cells that they reflect the response of normal cells in the body in a highly authentic manner. Unfortunately, after prolonged culture the cells lose many of their specific properties, making their further use less valuable. For these reasons, the isolation of such cells usually requires the sacrifice of animals or the availability of specimens from humans. Permanent cell lines sometimes are a good alternative, although they differ substantially in many aspects from their original counterparts in the body. In most instances, permanent cell lines were originally isolated from tumors making them even less indicative for effects in normal cells. In general the value of such in vitro models for the prediction of a broad pattern of adverse effects in animals and humans is overestimated. They can be important sources of information, however, if clearly defined mechanistic issues shall be addressed. For this purpose it has to be established that the model responds in a way similar to normal cells in the intact organism. Examples are the activation or blockage of receptors, the triggering of apoptosis, cell division etc.

A particularly successful application of in vitro cell culture models is the issue of genotoxicity of chemicals. Here, a variety of in vitro tests in bacteria (Ames test) or mammalian cells is used. A positive outcome indicates a (direct or indirect) effect of the test compound or its metabolite(s) on the DNA, e.g. via direct chemical interaction or by effects on DNA processing factors in the cell. As a result a permanent alteration in the base sequence and/or the chromatin structure may occur even leading to a complete loss of parts of the genome. Such effects could be correlated with an increase in tumor incidence (carcinogenicity) although such in vitro findings do not allow an absolutely reliable prognosis on the carcinogenic potential of the compound in vivo. In a typical case, the compound would then be tested in a chronic animal study. If it turns out to be carcinogenic, the evaluation of in vitro data can be very helpful in understanding the MoA. In a few cases, however, the in vitro models are inadequate to predict in vivo genotoxicity. The opposite case is more frequent, i.e., an in vitro positive finding of genotoxicity cannot be confirmed by animal testing.

## Risk Characterization and Recommendations for a Health-Based Guidance Value

If the data on toxicity are considered sufficient, a selection is made among the various non-neoplastic endpoints including neuro-, immuno- and reproductive toxicity. The data are then used for the derivation of quantitative dose-response relationships. These are usually established by applying mathematical models (best fit models). The modeled function usually has statistical confidence bands reflecting the variability of the data/the estimate. Since the critical effect height has been defined prior to the experiment (e.g. 10% inhibition of thyroid hormone production), the dose causing this effect can be derived. The lower limit of its 95%-confidence interval is termed BMDL<sub>10</sub> (Benchmark Dose 10%, lower confidence limit; Fig. 2). Alternatively, a NOAEL can be derived (see above). Both BMDL and NOAEL are called 'Point of Departure' (POD), i.e., a starting point which may allow the calculation of

**Figure 2** Benchmark-dose-modeling and derivation of a BMD<sub>10</sub>- and a BMDL<sub>10</sub>-value.

a health-based guidance value by applying a safety (or uncertainty) factor (usually 100). A typically guidance value is a 'Tolerable Daily Intake' (TDI), i.e., a daily exposure level per kg body weight which is considered safe (without adverse effects) for humans. For chemicals accumulating in the body due to a long elimination half-life (such as cadmium or dioxins) the tolerable dose for a period longer than one day is usually derived.

The situation is fundamentally different when it comes to genotoxic carcinogens. It is a current paradigm in toxicology that for (directly acting) genotoxic carcinogens no ineffective (safe) threshold exists. This assumption is based on the idea that a single base modification in the DNA could lead to a critical mutation eventually becoming the precursor of a cancer cell. In fact this assumption appears highly unlikely since the genome undergoes multiple damage events on a daily basis without transformation into cancer. Such factors include sunlight, other ionizing irradiation or genotoxic natural compounds (e.g. in food). Since many chemicals under scrutiny by toxicologists are 'man-made' they appear to be avoidable which may also nourish the idea of a 'zero tolerance'. In reality, food contaminants of this type, as all environmental carcinogens, cannot be avoided completely. Likewise the presence of polycyclic aromatic hydrocarbons has been documented in ancient samples dating many thousand years back (Isosaari et al., 2002). The presence of acrylamide in food cannot be avoided if food is heated which will remain the fundamental procedure in our type of food preparation.

These considerations illustrate a severe communication problem. In the past dose-response data of carcinogenicity in animals were extrapolated to the (usually much lower) exposure levels in human cohorts. Linear extrapolation thus allowed the calculation of 'hypothetical cancer victims'. Sometimes such calculations resulted in dramatic numbers. There was a 'general agreement' that a hypothetical (extra) risk of one in a million is acceptable, leading to the result that the associated dose is called 'virtually safe' (Vainio and Hemminki, 1989). Therefore, it is also called the 'acceptable risk model'. The concept is hampered, however, by several drawbacks, one being the high uncertainty resulting from a linear extrapolation over several orders of magnitude. The extrapolation is unavoidable since lower doses, relevant for human exposure, would not result in additional tumor-bearing animals because of the low efficacy of low doses. The only way to address the low efficacy would be an enormous increase in the number of test animals per group, a completely unrealistic scenario for several reasons.

Furthermore, the predicted cancer cases in the 'acceptable risk model' cannot be verified since the risk is calculated for a uniform exposure level identical for all members of the cohort. Thus the incidence of cancer is considered as a stochastic event not related to a particularly high individual exposure. For these reasons this model is no longer in use.

It has been replaced by the Margin-of-Exposure (MoE) model (EFSA Scientific Committee) which is particularly used for substances which are genotoxic and carcinogenic. It starts from a POD for carcinogenic effects, usually a BMDL<sub>10</sub> from animal experiments and compares it to an average or high exposure in a given human cohort (e.g. consumers in the EU) taking into account various age groups (Benford et al., 2010). If this comparison reveals a difference of 10,000-fold or higher, the situation is classified as 'of low concern' while in case of a lower MoE it is considered as of concern (Table 2). Likewise, the average exposure towards acrylamide in all age groups (European consumers) or the exposure with pyrrolizidine alkaloids in high-end consumers among toddlers were classified by EFSA as 'of concern' (EFSA BIOCONTAM Panel, 2015, 2011). The classification is thought to provide a basis for management decisions by authorities, in parliaments etc. It can be used to give recommendations or to set maximum values in food items etc. An example for maximum values for genotoxic carcinogens are aflatoxins (European Commission, 2006). Their maximum values were set, however, based on the ALARA principle (*As Low As Reasonably Achievable*) which is based on an expert agreement taking into account feasible measures to reduce the level of contamination. Since this principle is not based on pure scientific toxicological considerations, there have been suspicions that it might reflect a 'half-hearted deal' with industry. The future must show if the practical implication of the MoE concept can provide a better protection of the consumer than the ALARA principle.

Furthermore, it should be noted that the value of animal data for risk assessment of contaminants is more or more under discussion. Since in vitro experiments in most cases do not provide quantitative data useful for risk assessment, epidemiological studies (in humans) are envisaged as a better solution. According to most risk assessment experts, however, such data are useful in a few special cases only. Reliable correlations are typically found under 'strong' influences such as smoking, alcohol or drug abuse, malnutrition etc. For food contaminants, the relatively low level of exposure in consumers and the presence of many variable factors such as individual diet etc. make the data very heterogenous. In contrast to studies at the workplace where in 'simple' cases a single chemical prevails in causing adverse effects, or where a certain type of chemical mixture is consumed at a relatively high dosage on

**Table 2** Classification of Margin-of-Exposure values for genotoxic and carcinogenic contaminants by the European Food Safety Authority (Isosaari et al., 2002)

<i>Margin of exposure (MoE)</i>	<i>Classification</i>
<10,000	of concern
10,000–1,000,000	of low concern
>1,000,000	of no concern

a regular basis over a long period of time, a focused study on symptoms and diseases at common exposure to widespread contaminants appears extremely cumbersome if not useless.

## Summary

Chemical contaminants can enter the food chain at all levels, i.e., during production, harvest, manufacturing including packaging and storage. Their sources are manifold including infections by toxin-generating organisms, environmental contamination, process-related contaminants and migration from packaging materials etc. The toxicological risk assessment of these compounds comprises a series of steps starting from a thorough description of the chemical including its generation and reliable analysis, its sources and levels in the environment and in food, exposure assessment, and characterization of its toxicity. The latter includes dossiers on the toxicokinetics, the mode of action, the adverse effects in animals and humans and the final assessment of the consumer's risk. For this purpose, various tools have been developed which start from a classification of the contaminant as genotoxic or non-genotoxic. While for non-genotoxic compounds, maximum 'thresholded' exposure levels can be considered as safe, a Margin-of-Exposure approach describes the 'distance of safety' between overt carcinogenic doses in experimental animals and the actual exposure levels in humans.

Producers are confronted with the challenge to understand and possibly apply the principles of toxicological risk assessment. Therefore, it is mandatory that all food manufacturers, traders etc. as well as regulatory agencies have a solid knowledge on the principles mentioned above. A general defensive strategy against 'more stringent regulations' is not timely and will not address consumers' concerns in an adequate way.

## Emerging Food Safety Risks

Farai Maphosa, Danone Early Life Nutrition, Schiphol, The Netherlands

© 2019 Elsevier Inc. All rights reserved.

### Glossary

**Emerging risk** A risk to human, animal or plant health resulting from a new source or increased susceptibility or exposure to an existing source.

**Hazard** A substance or activity which has the potential to cause adverse effects to living organisms or environments.

**Risk assessment** A specialised field of applied science that involves reviewing scientific data and studies in order to evaluate risks associated with certain hazards. It involves four steps hazard identification, hazard characterisation, exposure assessment and risk characterisation.

**Risk management** The management of risks which have been identified by risk assessment. It includes the planning, implementation and evaluation of any resulting actions taken to protect consumers, animals and the environment.

**Risk-benefit analysis** A method for weighing up the likely risks (in terms of the incidence and severity) associated with exposure to a substance versus the likely benefits.

**HACCP** A hazard analysis and critical control point (HACCP) is a system that identifies, evaluates and controls hazards to food safety. It is implemented by food businesses to ensure safe production, storage and transport of food.

**Food contact material** Any material, typically packaging or kitchen equipment, designed to come into contact with foodstuffs.

### Nomenclature

List of nomenclature used including all definitions and units.

#### Abbreviation

MRLs	Maximum Residue Levels
WHO	World Health Organisation
FAO	Joint Food and Agriculture Organisation of the United Nations
JECFA	Expert Committee on Food Additives
TDI	Tolerable Daily Intake
ADI	Acceptable Daily Intake
BfR	German Federal Institute for Risk Assessment
ANSES	French Agency for Food, Environmental and Occupational Health & Safety
EFSA	European Food Safety Agency
FSA	Food Standard Agency
HACCP	Hazard Analysis Critical Control Points
TACCP	Threat Analysis Critical Control Points

## What are Emerging Food Safety Risks

If history repeats itself, and the unexpected always happen how incapable must man be of learning from experience

Goerge Bernard Shaw (1856–1950)

The term emerging food safety risks refers to issues, that present a risk to human health, arising from either unknown hazards or known hazards that are subject to new influences. The hazards maybe microbial, chemical residues, environmental contaminants, physical hazards and infestation, all of which can be detrimental to human health. Simply put, an emerging food safety risk is a new and unexpected hazard or threat. A re-emerging risk is a known hazard or threat which is increasing in frequency of occurrence or severity. Hazards maybe subjected to new influences such as new scientific insights on a hazard or new routes of human exposure from changing consumer habits, leading to the re-emergence of food safety issue.

For example, chlorate a known biocidal molecule that has been in use for decades for purification of drinking water and sanitation became an emerging food safety issue in 2014 following development of analytical methods in food matrixes at low limits of

quantification (CVUA, 2014). The detection of chlorate in foods prompted toxicological exposure assessments raising concerns beyond what had been known, challenging decades old sanitation practices. Alkaloids in food have emerged due to changing dietary habits for consumption of natural or organic foods and new trends for vegetarian foods. More alkaloids and their derivatives are now being identified as having food safety concerns (EFSA, 2013; EFSA, 2017a). Other notable emerging contaminants are methyl mercury, halogenated flame retardants, musks and UV filters in seafood resulting from both new scientific influences, changes in dietary habits and globalisation (Marques et al., 2017).

The identification of emerging food safety risks is paramount for protecting public health and maintaining consumer confidence in the food chain. Additionally emerging food safety issues can have huge negative impacts on the agri-food industry therefore is important to identify and prevent these impacts. The emergence of the link between BSE and the fatal human disease in 1995 resulted in suspension of all export markets for British beef impacting an estimated \$1.7b industry (Craven and Johnson 1999). Beyond human health, the impact of such a food safety risks has economic consequences not only on industry and its brands but also at national and regional levels. This chapter focusses on how food safety risks emerge and gives a framework for anticipation and identification in order manage them.

## Drivers of Emerging Risks

Emerging food safety risks arise due to various influences both scientific and socio-economic factors. These factors are like drivers bringing change into how hazards are perceived and therefore managed. Some of these drivers are shown in Table 1 with examples of food safety risks. Globalisation has brought about interconnectedness and complexity to the food chain making it increasingly difficult to ascertain and isolate causal factors which give rise to emerging food safety issues (SAFE-FOOD, 2013).

### New Science: the More We Know the More We Have Solve

Science is a key driver of emerging food safety issues. The application of scientific and technological advances to food production, measures of analysis and control is a major source of detecting and identifying emerging food safety issues.

New scientific information enables the assessment and establishment of toxicological end points and the setting of thresholds of concern. The main safety factors defining acceptable levels of exposure have been determined for many chemicals. These are the Acceptable Daily Intake (ADI) which pertains to residues of chemicals deliberately used in food production such as additives, pesticides and veterinary medicines, and the Tolerable Daily Intake (TDI) which pertains to chemical contamination of food from the environment. These safety factors are an indication of the amount of a chemical in food or drinking water that is not considered harmful if ingested every day over a lifetime (WHO). More recently the margin of exposure (MOE) is a tool used in risk assessment to explore safety concerns arising from the presence of a potentially toxic substance in food or animal feed. Also in use is the threshold of toxicological concern (TTC), a screening tool that provides conservative exposure limits in the absence of sufficient chemical-specific toxicological data. TTC is a science-based approach for prioritising chemicals with low-level exposures that require more data over those that can be presumed to present no appreciable human health risk (EFSA Glossary). In most cases the new knowledge generated leads to lowering of these safety factors and subsequently re-emergence food safety concern.

**Table 1** Drivers of emerging food safety risks

<i>Driver</i>	<i>Example of emerging food safety risk</i>
New Science and research	Acrylamide Monochloropropane-1,2-diol and Glycidyl Esters
Improved Analytical capabilities	Chlorate
Environment	Mycotoxins Heavy metals
Globalization	Marine biotoxins Biological hazards
Fraud	Melanie Horsemeat Scandal
Regulatory Loopholes	Dioxins Differing risk assessments positions for plant protection products
Novel foods and Technologies	Genetically Modified Organisms Nanoparticles
Consumer trends	Tropane alkaloids in organic Food Isoflavones in Soy based products

The increasing body of science linking the toxic effects of acrylamide, a process contaminant that has been in existence since man began cooking food, to cancer is a good example of how new science is a driver for emerging food safety issues. Animal studies had led to the classification of acrylamide as neurotoxic, genotoxic and as a probable human carcinogen (World Health Organization, April 1999), the key study in 2002, from the Swedish National Food Administration and researchers from Stockholm University reported significant levels of acrylamide in carbohydrate-rich foods that had been prepared/cooked by frying, grilling, baking or toasting brought acrylamide into the spotlight as an emerging food safety risk (Tareke et al., 2002). Risk and exposure assessments by both JECFA and EFSA have concluded that dietary exposure levels of acrylamide are indeed a concern for human health and advised continued efforts to reduce acrylamide in food (World Health Organization, 2005, EFSA, 2015a,b). Food industry has as a result invested in finding ways to reduce this process contaminant and have developed a Toolbox for reduction of acrylamide in food (Food Drink Europe: Acrylamide Toolbox, 2013).

Whereas industry has in the last century worked on ensuring food is adequately heated and cooked for prevention of microbial hazards and spoilage, today new scientific insights show that heating regimes need to also take into account prevention of heat process contaminants. Linked to acrylamide is furan and its methyl derivatives with possible human health impacts (Seok et al., 2015; EFSA, 2017b). Other heat process contaminants gradually becoming a concern are carboxy methyl Lysine (Nguyen et al., 2014), hydroxymethylfurfural (Morales, 2008; Abraham et al., 2011) and advanced glycation endproducts (Poulsen et al., 2013).

Another science driven food safety issue generating continuous debate is genetically modified technology (GMO). Contradicting scientific reports and risk assessments continue to fuel the GMO debate leading to a lack of consumer trust in the technology (Gaskell et al., 2005; World Health Organisation, 2014; EFSA, 2017c). As such consumer pressure groups press for GMO labelling of food products adding to the complexities for food industry, who have to manage global food supply chains.

Food safety concerns of nanoparticles have emerged with nanotechnology, the engineering of functional systems using very small particles that are less than 100 nm in size (He and Hwang, 2016). Nanotechnology is fast advancing in its use for example as nanosensors built into food packaging or nanocomposites in food containers to minimise carbon dioxide leakage out of carbonated beverages, or prevent oxygen inflow, moisture outflow, or the growth of bacteria to extend product shelf-life and sensory attributes (Jain et al., 2018). Health concerns arise on how nanoparticles behave in human systems, how the needle like structures may interact with human cells and potential to disrupt DNA structures. These nanotoxic attributes are linked to the small size and large surface area of nanomaterials, which enable easy dispersion and invasion of anatomical barriers in human body (He and Hwang, 2016) and also how nanoparticles may illicit allergy (Syed et al., 2013). Reports have started to emerge following new analytical capabilities to detect nanoparticles in foods putting focus on traditionally trusted and natural food additives such as tricalcium phosphate and calcium carbonate (Schoepf et al., 2017). In the next few years it can be anticipated that various nanoparticles beyond the ones commonly used and known today will be major food safety concern (Food and Beverage, 2017; Schoepf et al., 2017).

Studies on packaging and food contact materials have highlighted food safety concerns with mineral oil hydrocarbons, Bis phenols and phthalates. The toxicological impacts to human health continue to raise concerns in spite of the numerous attempts to prove their safety. Furthermore, there are increasing concerns with regards to the presence of non-intentionally added substances (NIASs) inherent to the food contact materials and end-up in food. NIAS substances are often difficult and in some cases not possible to identify and measure making it difficult to evaluate their safety upon exposure (Leeman and Lisette Krul, 2015). Ongoing efforts are underway to develop pragmatic, scientifically valid safety assessment evaluation of NIAS substances.

Endocrine disruption as a toxicological endpoint is an emerging topic that is more and more affecting many compounds: pesticides, biocides, veterinary drugs, and many food contact materials alike (Kabir et al., 2015).

### Improvements in Analytical Capability

Advances in analytical science have seen a lowering of the detection and quantitation limits for a multitude of chemical compounds in food, as well as the development of screening techniques which can simultaneously test for multiple chemical compounds. Enhanced analytical capability has highlighted the presence of hazards at low levels of concern, presence of chemical derivatives or breakdown substances. The simultaneous detection of the presence of multiple hazards has prompted questions on potential synergistic effects. New analytical tools have permitted the assessment of existing known hazards or threats bringing new insights but also show shortcomings in analytical capability.

Following improved analytical capacity and subsequent expansion of the toxicological database, ethyl carbamate known since the 1980s as probable genotoxic carcinogenic, became a food safety risk to human health prompting stricter regulations for food and drink (Dennis et al., 1989; Zimmerli and Schlatter, 1991). Chlorates have now been detected in all food products where chlorinated drinking water is used as a result of an improvement in the analytical method to quantify chlorate and perchlorate at levels as low as 0.005 mg/kg and 0.002 mg/kg respectively for these breakdown compounds of chlorine based agents (CVUA, 2014; EFSA, 2015a,b; Kettlitz et al., 2016). Food safety concerns from heat reaction products (acrylamide, furan, and other Maillard reaction products) are all arising today due to our ability to i) detect these compounds at low levels and, ii) ability to analyse and quantify their effects even at very low concentrations and diverse food matrices.

Sensitive and rapid screening methods for both targeted and non targeted chemical contaminants of concern; microorganisms using metagenomic sequencing techniques, screening for antibiotics (such as chloramphenicol and sulphonamides) and marine toxins (azaspiracids and tetrodotoxin), plant alkaloids and toxins (tropane alkaloids, pyrrolizidine alkaloids) will give rise to an

increase of food safety issues in the coming years. As rapid methods become affordable for screening large numbers of samples by different endusers, such as food safety and environmental agencies, research and monitoring laboratories, and consumer organisations, the food industry needs to be prepared to deal with the flood of emerging food safety issues (Marques et al., 2017; ANSES, 2017).

### Emerging Microbial Food Safety Risks

The Centers for Disease Control and Prevention (CDC) estimates there are 76 million cases of foodborne illness each year, resulting in 325,000 hospitalizations and 5000 deaths (IFT). There are more than 200 known diseases caused by food related pathogens, their toxins, or other substances. However a cause has not been identified for more than half of all recognized foodborne disease outbreaks, indicating that the real number of disease-causing agents is likely to be much larger than 200. The key microbiological agents of foodborne illness include viruses, bacteria, parasites, and toxins produced by algae and fungi (IFT). *Campylobacter*, *Salmonella*, verocytotoxigenic *Escherichia coli* (VTEC) and *Listeria* remain the main causal bacterial species of foodborne disease.

Whole genome sequencing of bacterial strains and environmental samples begins to take center stage in linking infections to food and food production facilities. As such, recent cases of *Salmonella agona* infections in France have been linked to infections in Spain and Sweden. Whole genome sequencing of historical samples has also given insights into this pathogens survival and potential re-emergence in food production facilities (EFSA and ECDC, 2018). Beyond whole genome sequencing it can be anticipated that the whole suite of genomic applications (metagenomics, transcriptomics, metabolomics) will become available to generating new knowledge that will impact the food industry and how we manage known and the many unknown microbiological hazards that will be identified and reported via these methods.

Emerging microbiological hazards are a results of new microorganisms or new virulence of know microorganisms, as new methods become available to identify and link a pathogen to food and illness. In this regard bacterial gene transfer has huge consequences for food safety, the *E. coli* O104:H4 outbreak in 2011 is an example of such a transfer of pathogenic or hyper virulent variants (EFSA and ECDC, 2011).

Antimicrobial resistance resulting from the extensive use of antibiotics in food production. Food-related bacteria and pathogens become resistant to antibiotics by mutations in their DNA or acquisition of antibiotic-resistant genes from their environment. The last decade has observed an emergence of antibiotic resistant zoonotic bacteria transmitted to humans via the food chain, and increased incidence of treatment failure and severity of disease, with negative impacts on public health (ECDC). Antimicrobial resistance has been observed in food related pathogenic *Salmonella typhi*, *Typhimurium* and *Enteritidis*, having resistance to ciprofloxacin, nalidixic acid and resistance to third and fourth generation cephalosporins. Meat and poultry are now know as key route for human exposure to fluoroquinolone and cephalosporin resistance. It is these food production systems that require particular attention to prevent the spread of resistance from these sources (EFSA, 2008). Risk assessments of antimicrobial resistance for specific food-bacterium combinations that are being undertaken will shed light on what food supply chains, and stakeholders, have to focus on to reduce and prevent public exposure.

Food borne viruses are transmitted by contaminated food and water. Viral food borne infections by hepatitis A, Norwalk virus and poliomyelitis virus remain the most common foodborne pathogens, causing over 60% of food-related illnesses in the Western world compared to about 10%–14% from bacterial infections of *Salmonella* and *Campylobacter* (Mead et al., 1999; Gould et al., 2013; CDC, 2018). There is a growing need to have systematic inspection and virological control criteria for the presence of viruses in the food. This can be aided today by exploiting the growing knowledge on viruses and their transmission coming from next generation sequencing tools enabling surveillance and detection of foodborne viruses outbreaks at an early stage.

### Impacts of Climate Change

Climate change cannot be ignored with regards to its impact on food safety. Several issues have been identified by Miraglia et al. (2009) such as:

- i) increase in mycotoxins formed on plant products in fields or during storage;
- ii) residues of pesticides in plant products affected by increases in pest infestations;
- iii) trace elements and/or heavy metals in plant products depending on changes in their abundance and availability in soils and due to shifting rainfall patterns (for example lead and arsenic);
- iv) polycyclic aromatic hydrocarbons in foods resulting from changes in long-range atmospheric transport and deposition in the environment;
- v) marine biotoxins in seafood from production of phycotoxins by harmful algal blooms;
- vi) and the presence of pathogenic bacteria in foods following more frequent extreme weather conditions, such as flooding and heat waves.

Mycotoxins for example are associated with different disease states in humans. The importance of proactively identifying the potential health and economic impacts of mycotoxins influenced by climate change has been emphasised including the need to monitor these toxic compounds as an emerging risk (Paterson and Lima, 2011; Baranyi et al., 2015). Similarly marine biotoxins have been observed as a significant and expanding food hazard throughout the world and have been associated with mass killings of marine life and illness and mortality in humans (FAO, 2004). Biotoxin poisoning events from Ciguatera fish were once confined

in tropical regions but have now been observed in other regions. Marine phycotoxins are now an emerging issue impacting the European shellfish and pelagic fish industries (SAFEFOOD, 2013).

### Emerging Consumer Trends Come With New Food Safety Risks

Firstly the challenge is for industry to ensure that food safety is not compromised in meeting consumer demands for minimally processed foods or more natural food products. Secondly the introduction of novel foods, novel food processing technologies and ready to eat convenient foods are watchout areas for emerging food safety risks (Kelsey et al., 2017). Thirdly the demand for organic foods and plant based alternatives of animal proteins come with emerging issues and food safety concerns that have to be mitigated.

The increased demand for organic crops and less modified crop varieties like sorghum, millet and buckwheat has lead to increased exposure to plant toxins like tropane alkaloids (EFSA, 2013; Adamse et al., 2014; Mulder et al., 2015), leading to regulations being put in place in 2016 to protect human health. Consequently ongoing research to understand plant toxins and their derivatives can be expected to shed light on more food safety risks. Pyrrolizidine alkaloids in tea and honey products are an example (EFSA, 2017a). Deoxynivalenol and its derivatives will likely re-emerge as a key concern once studies shed light on the modes of action and their interactions (EFSA, 2017d).

Use of novel ingredients with for example nanoparticles to give free flow functionalities (titanium dioxide and silicon dioxide) or as active agents to prevent spoilage have raised food safety concerns (Nanogenotox, 2013; Rapport d'étude, 2016; Wyser et al., 2016). As consumers seek alternatives for animal protein, it is important to note that there are food safety concerns that cannot be ignored. Recently the French food safety authorities pointed out concerns linked to isoflavone exposure from increased soya-based product consumption (ANSES, 2017). Concerns are also identified for insect proteins with regards to allergies, possible spread of microbiological and parasitic hazards and also potential exposure to pesticide and chemical contaminants used to control insects (Belluco et al., 2013).

### Economically Driven Emerging Food Safety Risk

Opportunities for economic gain via fraudulent practice in the food chain have lead to various food safety risks with grave consequences. Notable is the melamine scandal in infant milk formula which resulted in deaths and illness of children (WHO, 2009; Guan et al., 2009). Economically motivated food safety risks may come from adulteration of food to enhance quality properties (use of sudan red in herbs and spices Petrakis et al., 2017), substitution of a product or ingredient by an inferior alternative (horsemeat scandal Premanandh, 2013), and extension of product shelf life which may expose consumers to microbiological risks.

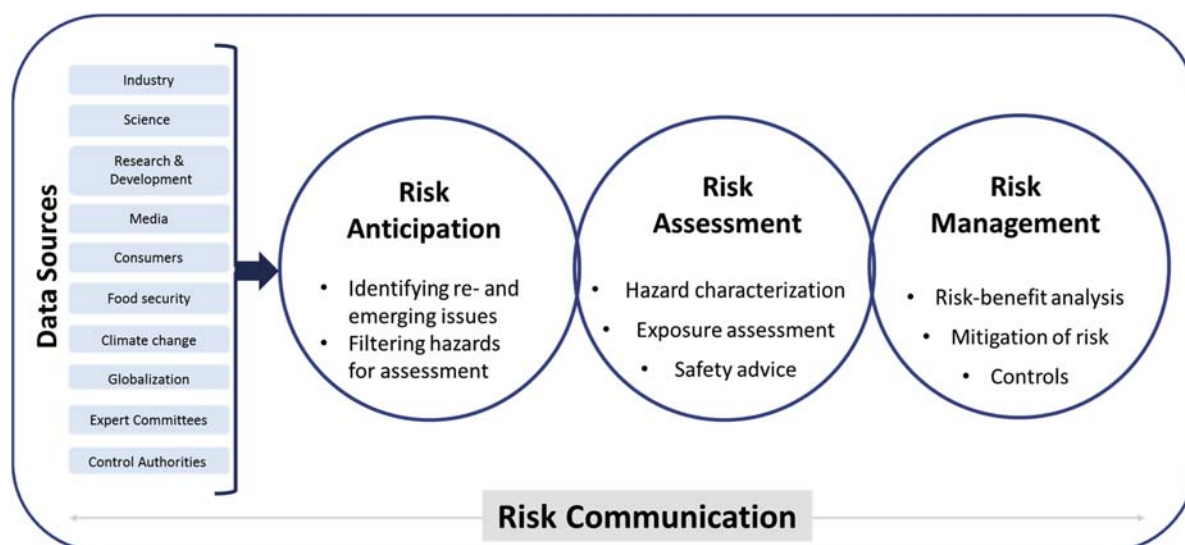

It is important to note here that high value products are more susceptible and also that malpractices are transferrable between industries. Counterfeiting is another route by which food safety risks are introduced in the food chain, often due to use of inferior materials, to maximize the gain. In this regard in order to anticipate potential economically driven emerging food safety issues, threat analysis critical control points (TACCPs) approach is used (Wei-En, 2016). TACCP like Hazard Analysis Critical Control Points (HACCPs) systems encourages systematic assessment of threats, evaluation of processes to identify points of vulnerability, and implementation of preventive actions to improve resilience against malicious attacks. Food fraud and food defense management systems are being implemented by food industry to anticipate on these food safety risks.

### Other Factors Driving Emerging Food Safety

SAFEFOOD (2013) and EFSA emerging risk exchange network. have summarised other influencing factors as being as social, economic, political, legislative, and food security. Indeed changes in legislative regulatory context can lead to an emergence of food safety issues. For example the lack of clarity or harmony in the European legislation on pesticides and biocides has lead to food safety concerns especially for substances with multiple uses. For example there are conflicts in the application of a default pesticide maximum residue levels to substances which are used within Good Manufacturing Practice to assure food safety and good microbiological quality. This is the case for commonly used biocides such as quaternary ammonium compounds. Risk assessment indicate that higher levels can be tolerated from the biocidal use of these substances, however concerns have arisen because that quaternary ammonium compounds have had also pesticide applications for which precautionary default maximum residue limits are enforced in EU (EFSA, 2014; Food Standard Agency, 2016). Thereby such compounds that are otherwise globally accepted worldwide as safe for sanitisation of food processing facilities have become a perceived emerging food safety issue.

### Detection of Emerging in Risk Analysis

Successful detection of emerging risks requires three key components: reliable data sources and skilled human intervention and an intelligence strategy that can be executed in the risk analysis cycle (Fig. 1). Detecting emerging risks is fundamentally a deliberate extension of risk assessment aimed at risk anticipation from the many sources and drivers of emerging food safety risks.

**Figure 1** Framework for anticipation and managing emerging risks.

### Reliable Data Analysis and Trending

Sources of data include: National Food Safety agencies (Bfr, ANSES, ANZ), International scientific committees (JEFCA, EFSA, US FDA), Scientific research, Trade and market data (Table 2). Equally important is media data and information on consumer patterns. The ability to bring together food supply chain stakeholder data including information from industry, primary production, non-governmental organisations and consumers is of utmost importance for early detection of emerging risks. The enormous volume of data requires powerful computing algorithms to analyse and visualize trends in the data to show baselines of typical hazard behaviours, detect peaks of abnormal or unusual events, and identify completely new issues. Meta analysis of data can help to link the abnormal or emerging issues to specific events that lead to their occurrence.

### Skilled Human Intervention

Data interpretation requires vigilance of human expertise and judgement. Several networks exist including Scientific and Governmental Panels and Units, Emerging risks networks, stakeholders consultations involving the whole end to end food supply chain.

**Table 2** Sources of data for detecting emerging risks

Source	Type of data	Impact for food safety
Research	<ul style="list-style-type: none"> <li>- Scientific knowledge on hazards, food safety threats, consumer patterns</li> <li>- Analytical methods</li> <li>- Meta-analysis of data</li> </ul>	<ul style="list-style-type: none"> <li>- New insights on known issues</li> <li>- Identification of emerging issues</li> </ul>
Food Safety Agencies FAO, JEFCA, EFSA, FDA (– US, China ANZ etc) (National and international)	<ul style="list-style-type: none"> <li>- Risk assessment</li> <li>- Exposure assessment</li> <li>- Evaluation of existing data</li> </ul>	<ul style="list-style-type: none"> <li>- Safety factors (TDI, ADI, MOE etc)</li> <li>- Advice for risk management</li> <li>- Facilitation of Information exchange</li> </ul>
Governments and Control Authorities	<ul style="list-style-type: none"> <li>- Alerts RASFF</li> <li>- Surveillance and monitoring data</li> <li>- Trends from controls</li> <li>- Trade and economic data</li> </ul>	<ul style="list-style-type: none"> <li>- Food safety policy and controls</li> <li>- Consumer education</li> </ul>
Industry and food supply chain	<ul style="list-style-type: none"> <li>- Scientific knowledge from research and development and innovation</li> <li>- Risk analysis in food safety management</li> <li>- Data on food ingredients, packaging materials, processing and production environments</li> </ul>	<ul style="list-style-type: none"> <li>- New insights on known issues</li> <li>- Identification of emerging issues</li> <li>- Management of food safety risks</li> <li>- Raising consumer awareness</li> </ul>
Media and Consumer	<ul style="list-style-type: none"> <li>- Food safety conversations on social media</li> <li>- Consumer insights on food preferences</li> <li>- Changing dietary habits</li> <li>- Global food trends</li> </ul>	<ul style="list-style-type: none"> <li>- Perception of food safety</li> <li>- Prevention of consumer panic</li> <li>- Awareness to enable informed choice</li> </ul>

Expertise is required for data analysis, signal detection and filtering and exchange of information for decision making from the many signals that are picked up in risk anticipation and management.

### An Intelligence Strategy

The steps in risk anticipation strategy include:

- i. Profiling and filtering potential risks that need further risk assessment. Analytics such as heatmaps and trend scorecards can be used to prioritise
- ii. Generating further data needed complete risk assessments. This often means that analytical methods have to be improved or developed for investigating hazards across different food matrixes and at multiple stages of production chain.
- iii. Reviewing new results and information taking into account the global food supply chain, not only isolated cases, to capture patterns and indicators that emerge in order to quantify the risks.
- iv. Making recommendations on how to control or change processes to reduce the likelihood of an emerging food safety risk impacting human health.
- v. Communicating and educating stakeholders, consumers and public to assure food is safe.

Emerging food safety issues, and their potential for evolving into real risks is complex and impacts beyond specific geographic, societal and organisational boundaries (Beck, 2007; Smith and Fischbacher, 2009). Therefore, strategies at identifying, and subsequently managing, emerging food safety issues must take into account the globalisation and interconnectedness of modern food chains and rapid transfer of information.

### Perspective

It is a fact that many foods are generally accepted as safe based on their history of safe consumption. However, emerging food safety risk have arisen as a result of new science and technology, new ways for bulk production to feed growing urban populations with changing consumer awareness and perceptions to food safety. Food safety management has improved over the years developing systems that ensure care is taken during development, primary production, processing, storage, distribution, handling and preparation of food. Emerging food safety risks need to be subjected to the risk analysis process to assess potential impacts and, if necessary, to develop approaches to manage the risks (WHO). Risk analysis involves: risk assessment, risk management, risk communication and risk-benefit analysis to guide the decision-making concerning food safety.

Systems such as HACCP and TACCP have been developed ensure comprehensive and systematic approaches for risk analysis in food industry (Wei-En, 2016). Whereas HACCP looks to find key points and implement management measures to prevent known hazards at those points in food production TACCP looks at points of threats or weakness in food supply chain that might lead to potential food safety issues. These two approaches of risk analysis for the whole food supply chain are crucial for anticipation and detection of re- and emerging risks and need to be incorporated in food safety management systems.

Food industry, control authorities, risk assessors and research need to setup processes to anticipate and prepare for emerging food safety issues. Additionally the risk analysis process should ensure that consumers are appropriately and adequately informed to avoid panic, detrimental changes to dietary habits and also unnecessary disruption to trade when food safety risks emerge.

### Glossary

**Accidental food (product) contact material.** It is a material that is not in direct contact but not separated from the food (product) by barrier.

**Control measure** Any action or activity that can be used to prevent or to eliminate food safety hazards, or to reduce them to an acceptable level ([International Standard, 2005](#)).

**Declaration of compliance (DOC)** A document issued by a competent authority of the supplier to certify that the delivered good or service meets the required specifications set by customer. It focuses on declaration of legal compliance and disclosure of chemical list required by law. It is also called certificate of compliance, certificate of conformance, or certificate of conformity.

**Design Qualification (DQ)** It aims to determine whether the design of machine & equipment is according to the URS.

**Direct food (product) contact material.** It is a material that is contacting, touching or in very close proximity to the food (product).

**Food safety hazard** Biological, chemical, or physical agent in food, or condition of food, with the potential to cause an adverse health effect ([International Standard, 2005](#)).

**Hygienic design and engineering** Design and engineering of equipment and premises assuring the food is safe and suitable for human consumption ([EHEDG, 2013](#)).

**Indirect food (product) contact material.** It is a material that is in direct contact due to separation by barrier.

**Installation Qualification (IQ)** It aims to determine whether the installation of machine & equipment were delivered correctly in an environment suitable for required operation based on the URS.

**Operational Qualification (OQ)** It aims to determine whether the machine & equipment performs as expected throughout its entire operating range based on the URS.

**Performance Qualification (PQ)** It aims to determine whether the machine & equipment performs as expected during routine operational range and worst case conditions based on the URS.

**Prerequisite Programs (PRPs)** Basic conditions and activities that are necessary to maintain a hygienic environment throughout the food chain suitable for the production, handling, and provision of safe end product and safe food for human consumption ([International Standard, 2005](#)).

**Product contact surface** A surface which is exposed intentionally or unintentionally to the product and surface from which splashed product, condensate, liquids or material may drain, drop, diffuse or be draw into the product or onto product contact surfaces or surfaces that come into contact with product surfaces of packaging materials ([EHEDG, 2013](#)).

**Qualification** Documented verification that determines whether all necessary requirements are met.

**Risk** A function of the probability of an adverse health effect and the severity of that effect when exposed to a specified hazards ([International Standard, 2005](#)).

**User Requirements Specification (URS)** A list detailing all essential requirements related to design, installation, operation, and performance of the unit to deliver expected performance.

### Introduction

The Hazard Analysis Critical Control Point (HACCP) system was pioneered by The Pillsbury Company with the National Aeronautics and Space Administration (NASA) and the US army laboratories to ensure the safety of foods consumed during spatial missions. It is a preventative system based on the Failure, Mode and Effect Analysis (FMEA). It is a systematic and science-based approach to identify specific hazards, assess risk and define control of food safety hazards. HACCP is a tool that focuses on prevention rather than relying on the end-product testing ([Mortimore and Wallace, 1998](#)). HACCP has been widely recognized and accepted as an effective tool to manage food safety by international organizations e.g. CODEX, ISO and WTO. It was initially used to ensure an absence of microbiological hazards in food. Later its application has been broaden to include physical and chemical hazards. This article describes how to manage chemical hazards in food following the HACCP principles. It emphasizes implementation of PRPs that support the chemical hazards analysis, how to identify potential chemical hazards, how to conduct a hazard analysis, and how to determine the control measures to control the chemical hazards in food manufacturing.

## Hazards Analysis

Hazards analysis aims to determine if the hazards are significant to food safety and identify the control measures for the significant hazards. The significant hazards are concluded based on the likelihood of occurrence (probability) and severity of adverse health effect. The hazards analysis involves identifying list of potential hazards in the materials and processing steps, defining severity of adverse health effects and likelihood of the identified hazards in order to conclude the significance.

The challenge in chemical hazards analysis is the fact that all substances can be poisonous if it is consumed in a high dose. Exposure to substances above an official agreed safe level e.g. ADI, PTWI, etc. according to intended food use can pose potential health concerns, which takes into account not only the amount in an individual product, but also the amount totally consumed by complete diet. Questions posted to individual food producer when perform hazards analysis is how to estimate the true level of contamination and how to define the total diet pattern of their consumer. Availability of following information is very important to perform chemical hazards analysis.

- Chemical hazards characteristic and/or scientific literature from reliable sources e.g. US FDA, EFSA, JECFA, Codex Alimentarius etc.
- Defined criteria for evaluation of significant hazard.
- How (and where) the ingredients and packaging materials are produced, controlled and transported to factory.
- Regulatory requirements related to ingredients, packaging materials, and finished product of the selling countries.
- Food safety incidents related to chemical hazards e.g. US FDA Recalls & Alerts, RASFF Food and feed safety alerts etc.
- History of non-conformities e.g. finished product out of specification and consumer complaints, etc.
- Information concerning PRPs implemented at suppliers and in own facilities including the verification results.
- Availability and capability of analytical methods.

Prerequisite programs (PRPs) are foundation of HACCP system and it must be implemented in all food manufacturing. Many people might interpret PRPs relate with hygiene and cleaning practices which primarily aim to prevent microbiological contamination. In fact majority of the hazards can be managed by well established PRPs, while the HACCP procedure focuses on the remaining hazards which will be managed in the critical processing steps in the production. In this article, PRPs cover conditions and activities that are necessary for producing safe product. PRPs are designed based on nature of the food, segment of the production, and type of hazards to be controlled. In some simple processes with low-risk operation e.g. refilling or repacking of dry beverages drinks, all hazards may be controlled by PRPs. More complicated production with higher-risk e.g. milk powder, UHT, and aseptic products, may require implementation of PRPs and HACCP plan to manage all hazards.

## Chemical Hazards

Food safety hazard is a biological, chemical, or physical agent in, or condition of, food with the potential to cause an adverse health effects, either by causing illness or injuries. The hazard is often confused with the term risk, which is a function of the probability of an adverse health effect and the severity of that effect, consequential to a hazards (s) in food (CODEX, 2003).

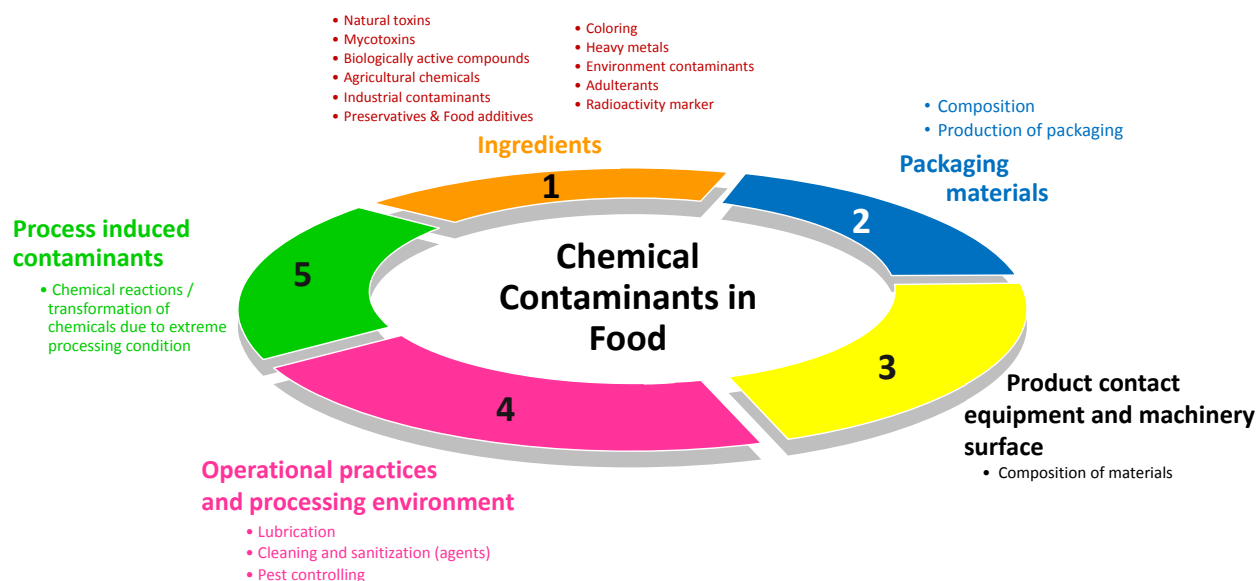

The chemical hazard is any chemical agent in food that has potential to produce adverse health effects or having inherent properties to cause harm. According to CODEX and ISO22000:2005, the chemical hazards broadly cover chemical contaminants and other chemicals that might be present in, or contaminate into ingredients and packaging materials, chemicals intentionally used or unintentionally used in the production and environment in manufacturing facilities, agents in food such as proteins and peptides that cause allergic reaction or hypersensitivity to minority group of consumer, under dose and overdose of nutrients resulting in nutritional deficiency and bacterial toxins (mycotoxins) produced by some groups of bacteria such as Aflatoxin, Ochratoxin A, fumonisins etc. The discussion in this article limits to chemical hazards excluding allergens and nutrition, which require different methodology to perform hazard analysis and define control measures.

Chemical hazards may include (i) chemical substance, a combination of various chemical compounds that can be present or contaminated in the product with high amount, sometimes visible e.g. lubricant, cleaning agents etc. and (ii) chemical contaminant, a single compound that can be present or contaminated in the product with a trace amount quantified through analysis e.g. Cadmium, Aflatoxin M1 etc.

Chemical hazards may come from various sources and may be introduced into food at different points of food chain from farm to fork. They may be broadly categorized according to how they are introduced in food production as following:

- Ingredients
- Packaging materials
- Product contact equipment and machine surface
- Operational practices and processing environment
- Process induced contaminants

Fig. 1 below illustrates origins of the chemical hazards. The hazards analysis and control measures of each type are discussed in later Sections.

**Figure 1** Chemical contaminants in food production.

### Severity of Adverse Health Effects

It is health effects that can be caused by the hazards if consumer consumes hazardous agent exceeding acceptable limits. Severity of the adverse health effect is hazard-specific. Biological and physical hazards usually pose short term health consequences, where chemical hazards potentially found in food may pose both short term and long term health problems depending on its toxicity and dose. It is highly substance-specific. This article classifies severity of adverse health effects for chemical hazards into two sets according to medical terminologies as follows:

- An acute condition is severe and rapid onset and/or a short course. It typically starts suddenly and is short lived. Some acute illnesses can be treated in a short time, while some can be cured by more sophisticated treatment. This condition may be caused by high quantity of chemical substance or chemical contaminant reached level of immediate health effect e.g. consuming 250 g of NaCl, 700 g of Ethanol or 2 g of Vitamin A etc. in one serve.
- A chronic condition is symptom that develops gradually and worsens over an extended period of time. It is persistent or otherwise long-lasting in its effects. The term chronic is usually applied when the course of the disease lasts for more than three months. This condition mostly refers to consumption of food contaminated with low amount of chemical contaminants over a long period of time and eventually results in illness.

The severity of adverse health effects can be ranked from mild to very severe effects e.g. fatality. **Table 1** below demonstrate examples of acute and chronic health effects.

**Table 1** Severity of adverse health effects

<i>Acute health effects</i>		<i>Chronic health effects<sup>a</sup></i>	
<i>Severity</i>	<i>Definition</i>	<i>Severity</i>	<i>Definition</i>
A	Can cause fatality	Alfa ( $\alpha$ )	proven to be mutagenic (no threshold effect) to humans
B	Can lead to serious illness	Beta ( $\beta$ )	proven to have a permanent effect on a vital organ to humans
C	Can cause illness	Gama ( $\gamma$ )	proven to have a mild transient physiological effect to humans
D	Can cause inconvenience	Delta ( $\delta$ )	Might have a mild transient physiological effect to humans
E	Almost of no significance		

<sup>a</sup>T. Stroheker et al. (2017)

## Likelihood of Hazards Occurring

The probability of hazard is qualitative and/or quantitative evaluation or estimation of frequency that hazard is potentially presented or contaminated in the specific ingredient, material or processing step. This becomes a challenge for chemical hazard analysis to properly evaluate the probability corresponding to type of chemical hazards and its health effects. This article describes 2 types of likelihood used in hazard analysis depending on type of chemical hazards. Following description and Table 2 are examples of the likelihood and its ranking:

- **Likelihood of occurrence:** It is a rough estimation of frequency that the chemical could possibly be present or contaminated in the ingredients or in the processing steps. The likelihood of occurrence is used mostly for presence of chemical substances which contaminates in the product in high amount. Evaluation or estimation of the likelihood of occurrence may be obtained through statistical information such as historical analysis or verification data. Following are examples of the likelihood of occurrence ranking:
  - Very unlikely or unlikely ( $<12.5\%$  probability of presence).
  - Rare ( $12.5 < X < 37.5\%$  probability of presence).
  - Could occur ( $37.5 < X < 62.5\%$  probability of presence).
  - Likely ( $62.5 < X < 87.5\%$  probability of presence).
  - Frequent ( $87.5 < X < 100\%$  probability of presence).
- **Likelihood to cause harm:** This likelihood does not only consider the likelihood of presence of the chemical hazards but also considers the impact of overall exposure to the consumer. The likelihood to cause harm is used for chemical contaminants which pose chronic health risk. The evaluation or estimation of the likelihood to cause harm is complicated taking into account the dose and exposure level. Example, the likelihood to cause harm may be categorized into 4 categories referring to 'A new global scientific tool for the assessment and prioritization of chemical hazards in food raw materials' (Stroheker et al., 2017); Negligible, Low, Medium, and High.

Two level of information are usually considered to quantify the likelihood of hazards in ingredients and packaging materials.

- In case there is insufficient information on how the ingredients and packaging materials is made. It is limited resources to collect own data, HACCP team may use information collected by externally recognized organization or historical incidents reported by authorities to estimate the likelihood of hazards. This '**intrinsic information**' does not relate to any specific source or origin of materials.
- Another level of information relates to specific source or origin of materials such as detail preventive programs and historical testing data obtained from various batches supplied by specific supplier. This '**local information**' reflects effectiveness of controls established at specific supplier.

For example generally the intrinsic likelihood of presence of antibiotics in raw milk is high, however in New Zealand the local likelihood is lower due to strong regulatory enforcement and Good Agricultural Practices (GAPs) at farm level. The specific supplier tests representative antibiotics of every incoming lot of raw milk to ensure that no contamination of antibiotic in the received milk.

One may use available data published by externally recognized organization to estimate the intrinsic likelihood while building up local data. Once the local data is sufficient, the local likelihood can be evaluated and used for further decision making.

## Hazards Assessment

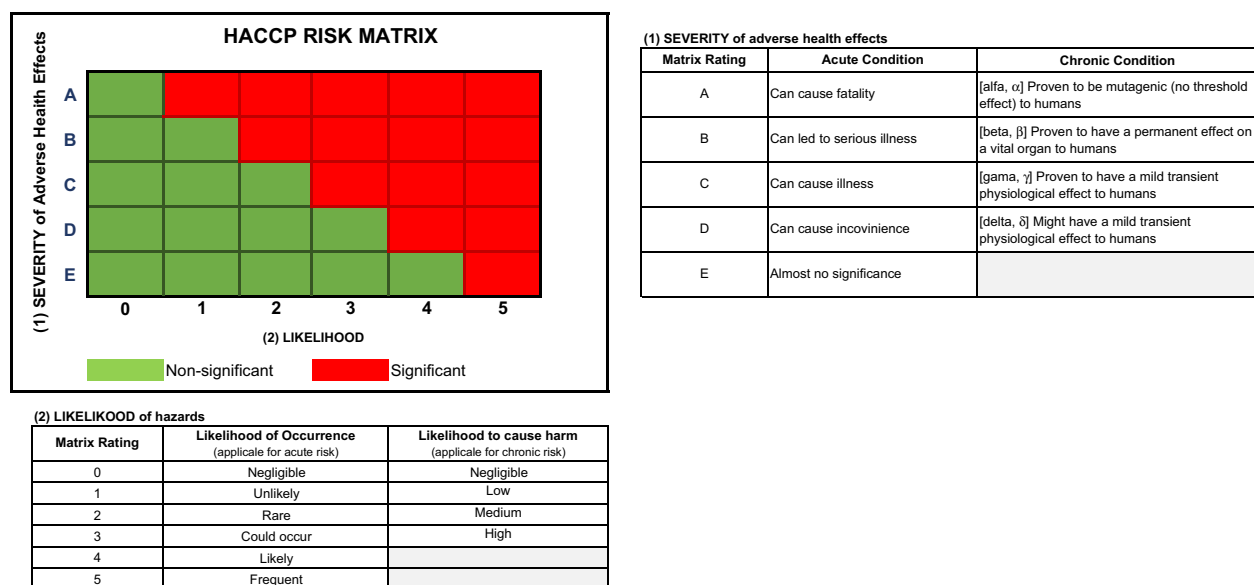

A hazard assessment is conducted to determine whether its control is required additionally from the established PRPs. Following two parameters should be taken into consideration when conducting hazards assessment:

- Severity of adverse health effect
- Probability of occurrence of hazards

The HACCP team may use hazard assessment table to relate severity of adverse health effects, likelihood of hazards, classify and prioritize the significant hazards from non-significant hazards. Fig. 2 below is example of the hazards assessment table.

**Table 2** Examples of ratings used for likelihood of occurrence and likelihood to cause harm

<i>Matrix rating</i>	<i>Likelihood of occurrence (applicable for acute risk)</i>	<i>Likelihood to cause harm (applicable for chronic risk)</i>
0	Negligible	Negligible
1	Unlikely	Low
2	Rare	Medium
3	Could occur	High
4	Likely	
5	Frequent	

**Figure 2** Example of hazards assessment table.

Once the potential chemical hazards are identified, severity of health effect (chronic or acute) and likelihood of hazards (likelihood of occurrence or likelihood to cause harm) are assessed, the significant hazards can be concluded. The non-significant hazards are controlled by existing PRPs. The significant hazard has to be managed through specific control measure which will be further categorized as CCPs or OPRPs. In some cases when the identified control measures are incapable to manage the significant hazards, modification is required which includes modification of materials source or origin, adjusting product recipe or formulation, improving existing control measures or establishing additional control measures.

## Chemical Hazards Analysis of Ingredients

### Prerequisite Programs for Managing Chemical Hazards in Ingredients

When the materials are contaminated with chemical hazards from upstream supply chain e.g. from supplier and during transportation to factory, there is no possibility to eliminate or reduce the contamination in downstream process. Following PRPs are important to ensure good quality of ingredients.

- Establishing material sourcing and approval program including food safety assessment process to ensure that supplier implements necessary control measures for chemical hazards e.g. Good Manufacturing Practices (GMPs), Good Agricultural Practices (GAPs), Good Warehouse Practices (GWPs) etc.
- Material purchasing specification to include food safety and regulatory requirements especially chemical contaminants.
- Establishing a material incoming check procedure prior to utilization of material in the production. Review of testing results stated in certificate of analysis (COA) may be acceptable as an incoming check, provided that sampling plan and analytical method used by the supplier is reliable.
- Establishing risk-based verification (analytical testing) program to verify the controls at supplier

### Potential and Likelihood of Chemical Hazards in Ingredients

Most of the chemical hazards present in food are chemical contaminants derived from ingredients, either they are naturally present in ingredient itself such as natural toxin like lectins, or generated during processing of the ingredient such as acrylamide in starch compounds that had been cooked in high temperature, or contaminated into the ingredients from manufacturing equipment and environment such as dioxins (Edwards, 2010). Following Table 3 are typical types of chemical hazards that may potentially be found in food ingredients.

In terms of likelihood of hazards, it is unlikely that ingredients are free from all undesirable chemical contaminants. But it does not mean that all chemical contaminants present in the ingredients will result in immediate adverse health effects to the consumer. The 'likelihood to cause harm' principle is used to estimate the contribution of contamination in the ingredients to total diet of the consumer and categorize chemical contaminants risk of the ingredients.

**Table 3** Types of chemical hazards and examples in food ingredients

<i>Types</i>	<i>Examples</i>
1. Natural toxins	Lectins, glucosinolates, hydrogen cyanide
2. Mycotoxins	Aflatoxins, Ochratoxin (OTA), Patulin, Trichothecenes (DON), Fumonisin, Zearalenone
3. Biologically active compounds	Agaric acid, aloin, berberine
4. Agricultural chemicals	Pesticides, veterinary drugs (antibiotics, growth promoters, hormones)
5. Industrial & environmental contaminants	Lubricants, sanitizers, oils, paints, dioxins, polychlorinated biphenyls (PCBs), Polycyclic aromatic hydrocarbons (PAHs), Benzo(a)pyrene, Nitrates
6. Processed induced compounds	Acrylamide, 3-MCPD, Ethyl carbamate, Heterocyclic amines
7. Preservatives, Food additives and coloring	Benzoic acid, Sulphur dioxide, Illegal colors e.g. Sudan dye,
8. Heavy metals	Cadmium, arsenic, lead, copper, mercury, aluminium
9. Food adulterants	Melamine, cyanuric acid, urea, food colors
10. Radioactivity marker	Trace of radiation

### Control Measures for Significant Chemical Hazards Originated From Ingredients

In principle, food manufacturer establishes PRPs and relies on control measures upstream at supplier to manage chemical contaminants in ingredients. An expected outcome from hazards analysis (especially with local information) of ingredients is all chemical contaminants are not significant. Thus the PRPs is maintained as part of routine. In some rare cases chemical contaminants in ingredients may be significant due to ineffective upstream controls. This is indicated in supplier audit report and verification testing results. In that situation, it is necessary to review and strengthen the PRPs at supplier. Alternatively, it might be necessary to change origin of ingredients or modify product recipe. Provided that analytical facility is available, contamination is homogeneous, and sampling plan is achievable, screening of incoming materials by chemical analysis before use in production might be an option while improving PRPs upstream. The chemical testing for release of materials could eventually become a CCP or an OPRP.

## Chemical Hazards Analysis of Packaging Materials

### Prerequisite Programs for Chemical Hazards Originated From Packaging Materials

Chemical hazards of concern in packaging materials are mostly chemical contaminants. The PRPs for packaging materials are comparable with the PRPs set for ingredients with additional of followings:

- Obtaining a declaration of compliance (DOC) from supplier to assure they supply material complying with defined specification.
- Establishing a risk-based packaging material development process to ensure that harmful or non-compliance substances are not used in production of packaging materials and that regulatory limits are respected for chemicals allowed to be used with restrictions.

### Potential and Likelihood of Chemical Hazards in Packaging Materials

The concerns in packaging materials are mainly chemical contaminants derived from materials coming into contact with food. It includes auxiliary items which could potentially constitute chemical hazards and transfer it in to food. Sources of chemical hazards are material compositions and processing aids used during packaging material production.

Typical examples of chemical hazards could potentially be found in packaging materials are:

- Toxic metals e.g. lead, cadmium, mercury and hexavalent chromium
- Bisphenol A (BPA) can be found in phenolic-epoxy can coating.
- Plasticisers e.g. *ortho*-phthalates (commonly referred to as phthalates), ESBO etc.
- Acrylonitrile in plastic, adhesives and synthetic rubber.
- Styrene (monomer) in polystyrene plastics and resins.

### Control Measures for Significant Chemical Hazards Originated From Packaging Materials

The risk-based packaging material development process ensures harmful substances including chemical contaminants are not used in packaging material production and that regulatory limits are respected for chemicals allowed to be used with restrictions. Therefore the chemical contaminants do not become significant hazards in packaging materials. In case the significant chemical contaminants hazards is addressed, it is necessary to review and/or modify the packaging material design and compositions, specification, and DOC.

### Chemical Hazards Analysis of Product Contact Equipment and Machine Surface

#### Prerequisite Programs for Chemical Hazards Originated from Product Contact Equipment and Machine Surface

The chemical hazards concerned in product contact equipment and machine surface are chemical contaminants. The PRPs set for product contact equipment and machine surface aims to minimize chemical contaminants migration from product contact surfaces to product. Hygienic engineering design, proper qualification, and acquiring the machine and equipment from reliable supplier are key to prevent chemical contamination to the product. Following PRPs are commonly suggesting to minimize chemical migration in food manufacturing.

- Establishing valid User Requirement Specification (URS) when purchasing new machine and equipment. The requirements include: (i) internal and regulatory requirements related to chemical contaminants, (ii) material component, and (iii) hygienic engineering requirements. There are several hygienic design and construction standards which widely recognized and it can be used as reference to create the URS such as: European Hygienic Design Group (EHEDG), National Sanitation Foundation (NSF) International, 3A Sanitary Standards Inc etc.
- Purchasing of machine and equipment from credible supplier e.g. supplier certified under recognized food safety schemes or Standards.
- Establishing prospective or retrospective qualification consists of Design Qualification (DQ), Installation Qualification (IQ), Operational Qualification (OQ), and Performance Qualification (PQ).
- Obtaining a declaration of compliance (DOC) from supplier declared that machine and equipment complying with recognized regulatory requirements or Standards related to product contact and accidental product contact parts.

#### Potential and Likelihood of Chemical Hazards in Product Contact Equipment and Machine Surface

Metals, alloys, plastics, silicones and rubbers are widely applied as food contact materials or accidental product contact materials in processing equipment in food industry. Therefore they are potential sources of chemical contamination to food, both from main components and unforeseen impurities (Karamfilova, 2016). The concerns related to chemical hazards in machine and equipment are mostly chemical contaminants similarly to packaging materials. Additional concerns are heavy metals include cadmium, inorganic tin, lead and mercury, hexavalent chromium, antimony and nickel (Cederberg et al., 2015; Edwards, 2010) which could be constituted in metals and alloys used in food contact materials in processing equipment.

As a general rule, migration of substances from food contact materials including processing equipment to food must not occur in amounts that endanger human health. Some food safety organization e.g. the Council of Europe has suggested specific release limits (SRLs) for most metals potentially used for processing equipment in contact with product (Cederberg et al., 2015).

#### Control Measures for Significant Chemical Hazards Originated From Product Contact Equipment and Machine Surface

Chemical contaminants might be identified as potential hazards in product contact equipment and machine surface, but it should not be significant supposing the PRPs are well implemented. The product contact surface specification is clearly defined and agreed by supplier, and later confirmed through the qualification process. The supplier complies with international recognized manufacturing standard and able to provide evidences of compliance. The challenge often relates to verification whether testing of certain chemical contaminants is necessary. It is mostly depends on product type and its specific regulatory requirements. In some case it requires a testing report of exact constructing material of the product contact surface such as in pharmaceutical requirements but it does not require any testing in other regulations. Similarly with the packaging materials, in case the significant chemical contaminants is addressed, the machine and equipment is no longer suitable to use in contact with food and it certainly requires modification or replacement.

### Chemical Hazards Analysis of Operational Practices and Processing Environment

#### Prerequisite Programs for Chemical Hazards Originated from Operational Practices and Processing Environment

Implementation of Good Manufacturing Practices (GMPs), sourcing and controlling of chemical utilization ensure minimizing risk of chemical hazards contamination due to inappropriate operational practices and inadequate processing environment.

- Generally the chemical which is intentionally or unintentionally used or applied onto food contact surfaces must be food-grade or compliant with well-recognized regulations or local regulation e.g. US FDA 21 CFR, Food Chemicals Codex (FCC). It means the chemical is acceptable to be used in product contact surface. This is managed through clear specification, supplier selection, review of certificate of analysis (COA) at chemical reception.
- Lubrication could cause chemical contamination to the product if it is not managed well. It is important to establish a lubrication procedure, define right frequency, use of food grade lubricant (e.g. NSF H1 grade) for accidental product contact surfaces, and establish storage control and traceability system of lubricants. This is to prevent excessive dosing and misuse of non-food grade lubricants.
- Cleaning and sanitization of production line and/or packaging materials: pay attention to selection of the chemicals used for cleaning and sanitizing to ensure the chemicals do not contain toxic or legally banned substances. Application of the chemicals must follow the recommended procedure defined by supplier especially the dosage and post treatment such as rinsing with water or drying with hot air etc.
- Pest management involves understanding of the nature of pests, prevent of entry, minimizing of their food source in the production which related to effective cleaning. In the case of infestation, it might require utilization of pesticides and fumigations. In such case, the treatment must be carefully planned and strictly controlled especially fumigation, it must only be done by licensed and trained individuals in full accordance with manufacturer instructions and subject to all local legal provisions.

### Potential and Likelihood of Chemical Hazards Related to Operational Practices and Processing Environment

The concerns related to operational practices and processing environment are mainly chemical substances which may occur in the production due to inappropriate operation practices and inadequate processing environment. It is mainly related to lubrication of moving parts, cleaning, sanitization of line and packaging materials, water treatment, and pest management. [Table 4](#) below presents examples of potential chemical hazards caused by inappropriate operation practices and inadequate processing environment.

Likelihood of occurrence (described in section [Likelihood of Hazards Occurring](#)) is used to estimate the likelihood of hazards related to operational practices and processing environment. Due the nature of operational related data, the rating criteria can be redescribed to suite its application as follow:

Rating 1 - Unlikely (there is no possibility of contamination to product or the contamination is not detectable).

Rating 2 - Rare (contamination is under controlled by PRPs and it might be detectable but below the regulatory or internal requirements)

Rating 3 - Could occur (contamination is being controlled by PRPs, however there is deviation observed in the verification program exiting the regulatory or internal requirements).

Rating 4 - Likely (contamination level is not technically being controlled under current PRPs.)

Rating 5 - Frequent (contamination is happening and able to detect by visual inspection).

### Control Measures for Significant Chemical Hazards Related to Operational Practices and Processing Environment

The chemical contaminants should not be of concern providing that all chemicals used or applied onto food contact surfaces must be food-grade or compliant with well-recognized regulations or local regulations. The chemical substances might be identified as potential hazards. However in principle, it should not be significant because there is no possible control measure to eliminate and reduce the contamination in the product. In case there is a significant chemical substance, it requires thorough review of material specification, supplier selection program, revisit the COA review procedure, chemical application procedure, cleaning procedure and pest management program.

## Chemical Hazards Analysis of Process Induced Contaminants

### Prerequisite Programs for Chemical Hazards Originated from Processing Condition

Managing the process induced contaminants starts in the product development stage where the processing condition is designed and optimized to prevent formation of undesirable chemical hazards.

### Potential and Likelihood of Chemical Hazards Generated From Processing Condition

The formation of undesirable chemicals during production of food has been confirmed through several scientific studies in past decade. Thermal heat treatment such as frying, baking, roasting, fermentation, drying, or extraction are known that can result in the formation of some chemical hazards in some food. Some examples of known contaminants:

- Acrylamide is formed from the reaction between asparagine and reducing sugars under heat treatment (high temperature) such as baking, frying, and roasting.
- Chloropropanols is a group of chemical contaminants, 3-Monochloropropane-1, 2-diol (3-MCPD) is the most notable of the group. It is formed in a reaction between hydrochloric acid and lipids in foods processed at high temperature

**Table 4** Potential chemical hazards and sources related to operational practices and processing environment

<i>Activity</i>	<i>Chemical use</i>	<i>Potential chemical hazards</i>	<i>Origin/source</i>	<i>Type of chemical hazards</i>
Lubrication (food contact and indirect contact)	Grease, oil	<ul style="list-style-type: none"> <li>• Lubricants e.g. grease or oil</li> <li>• PAHs</li> <li>• Prohibited (banned) chemicals.</li> <li>• Heavy metals (Cd, As, Pb, Hg, Ni)</li> </ul>	Excessive lubrication Presence in the chemical use for lubrication	Chemical substance Chemical contaminants
Cleaning and sanitization	CIP solutions (Sodium hydroxide, nitric acid and CIP aids).	<ul style="list-style-type: none"> <li>• Cleaning solution e.g. NaOH, Nitric acid.</li> <li>• Sanitizers</li> <li>• Chlorophenol.</li> <li>• Prohibited (banned) chemicals.</li> <li>• Perchlorate.</li> <li>• Heavy metals (Cd, As, Pb, Hg, Ni)</li> </ul>	Insufficient rinsing with water after cleaning with chemicals. Presence in the chemical use for CIP	Chemical substance Chemical contaminants
	Aseptic filling line - packaging and filling machine sanitization	<ul style="list-style-type: none"> <li>• Cleaning solution e.g. peracetic acid, hydrogen peroxide, sodium hypochlorite</li> <li>• Heavy metals (Cd, As, Pb, Hg, Ni)</li> </ul>	Remaining residue or insufficient rinsing with water after cleaning with chemicals.	Chemical substance
Steam making	Corrosion inhibitor/deposit control agent	<ul style="list-style-type: none"> <li>• Sodium bisulphite</li> <li>• Sodium sulfite</li> <li>• Sodium hydroxide etc.</li> <li>• Prohibited (banned) chemicals.</li> <li>• Heavy metals (Cd, As, Pb, Hg, Ni)</li> </ul>	Presence in the chemical use for sanitization Remaining residue of the used chemicals	Chemical contaminants Chemical substance
Water treatment	Chlorination	<ul style="list-style-type: none"> <li>• Chlorine (to form trihalomethanes – THMs)<sup>a</sup></li> <li>• Heavy metals (Cd, As, Pb, Hg, Ni)</li> </ul>	Remaining residue from chlorination Presence in the chemical use for chlorination	Chemical substance Chemical contaminants
Cooling water	Corrosion inhibitor/deposit control agent	<ul style="list-style-type: none"> <li>• Sodium hydroxide</li> <li>• Ethylenediamine tetraacetic acid</li> <li>• Tetrasodium salt</li> <li>• Sodium molybdate</li> <li>• Sodium bisulphite etc.</li> </ul>	Remaining residue from water treatment	Chemical substance
	Microbial growth inhibitors	<ul style="list-style-type: none"> <li>• Biocides e.g. alkyl polyglycoside, ammonium chloride</li> <li>• Chlorophenol.</li> <li>• Banned chemicals.</li> <li>• Perchlorate.</li> <li>• Heavy metals (Cd, As, Pb, Hg, Ni)</li> </ul>	Presence in the chemical use for cooling water	Chemical contaminants Chemical substance
Pest management	Infestation treatment by chemical e.g. pesticides or insecticides etc.	<ul style="list-style-type: none"> <li>• Methyl bromide</li> <li>• Phosphine</li> <li>• Chloropicrin</li> <li>• Ethyl formate</li> <li>• Sulfuryl Fluoride etc.</li> </ul>	Pesticides and fumigants have not been executed properly and inadequately ventilated.	Chemical substance

<sup>a</sup>Dorworth E.L. (1998)

- Furan can be formed through multiple pathways such as thermal degradation/Maillard reaction of reducing sugars alone or in the presence of amino acids, thermal degradation of amino acids, and thermal oxidation of ascorbic acid, poly-unsaturated fatty acids, and carotenoids.
- Heterocyclic aromatic amines are formed during the heat processing of protein-rich mixtures.

Most undesired chemicals are chemical contaminants. Likelihood of hazards should be assessed during new product development stage considering product composition, possibility of chemical reactions or by-product formation and confirmed hypothesis through product technical trial etc. It requires sufficient product knowledge, technical competence, and in some case might involve statistical calculation.

### Control Measures for Significant Chemical Hazards Related to Process Induced Contaminants

At the product development stage, if significant formation of undesirable chemical contaminants is expected, the most sustainable solution is reformulating the recipe or modifying processing condition to prevent the unwanted chemical reaction. As a result, the concerned contaminants are no longer an issue. However in some cases, it might not be possible to absolutely prevent formation but possible to minimize the contamination level. In such cases, optimum processing condition must be defined, validated, controlled, and monitored during production. Controlling of specific processing condition such as frying of noodle, baking of wafer etc., could eventually become a CCP or an OPRP.

### Conclusion

HACCP is a tool to assist in identifying hazards, prioritizing and determining how best to minimize the identified hazards. It will not result in elimination of all hazards (Van Schothorst, 2004). Therefore quality of the HACCP system depends mostly on competence of the HACCP team to utilize the tool and available information to establish practical and effective control measures. Chemical hazards analysis requires in-depth scientific knowledge about hazards characteristic, origins, health implication and probability of occurrence. Prerequisite programs is essential element of HACCP implementation especially for chemical hazards management where there is no downstream mitigation steps. Food manufacturer needs to allocate sufficient resources to ensure establishing of appropriate prerequisite programs upstream at supplier and in own manufacturing line to prevent contamination of chemical hazards.

## Glossary

‘competent authorities’ means the member state organisation(s) that have the legally delegated authority to enforce food safety legislation within the EU.

‘HACCP’ is an acronym for Hazard Analysis and Critical Control Point, a management system which identifies, evaluates, and controls hazards which are significant for food safety;

‘member state’ refers to a country which is member of the European Union (EU), a political and economic union of 28 European countries;

‘risk’ means a function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard;

‘risk assessment’ means a scientifically based process consisting of four steps: hazard identification, hazard characterization, exposure assessment and risk characterization;

‘risk management’ means the process, distinct from risk assessment, of weighing policy alternatives in consultation with interested parties, considering risk assessment and other legitimate factors, and, if need be, selecting appropriate prevention and control options.

## EU Regulatory Framework

The European Regulation which sets out Community procedures for contaminants in food ([Council Regulation \(EEC\) No 315/93, 1993](#)) defines a contaminant as any substance not intentionally added to food which is present in such food because of the production (including operations carried out in crop husbandry, animal husbandry and veterinary medicine), manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food, or as a result of environmental contamination (NB: The text specifically excludes extraneous matter such as insect fragments, animal hair, etc.).

The regulation also states the general principle that food containing a contaminant in an amount which is unacceptable from the public health viewpoint, and in particular at a toxicological level, shall not be placed on the market. According to the regulation contaminant levels shall be kept as low as can reasonably be achieved by following good practices at all the stages of production, and where necessary, maximum levels for specific contaminants shall be established.

Absolute responsibility for food safety is placed upon food businesses by [Regulation \(EC\) No 178/2002](#) (commonly known as ‘The General Food Law’). This states that food businesses are directly responsible for ensuring that no food is placed upon the market if it is unsafe i.e. if it is considered to be ‘injurious to health’, or else unfit for human consumption.

The regulation states that in considering whether any food is injurious to health, regard shall be had:

- (a) not only to the probable immediate and/or short-term and/or long-term effects of that food on the health of a person consuming it, but also on subsequent generations;
- (b) to the probable cumulative toxic effects;
- (c) to the particular health sensitivities of a specific category of consumers where the food is intended for that category of consumers ([Regulation \(EC\) No 178/2002](#)).

Additionally, under- the Food Hygiene Regulation ([Regulation \(EC\) No 853/2004](#)), most EU food businesses have a legal obligation to put in place, implement and maintain a permanent procedure or procedures based on the HACCP principles. These principles include identifying any hazards related to the food and its production, and ensuring that these are either prevented, eliminated or reduced to acceptable levels within the finished product and for its intended shelf life ([Regulation \(EC\) No 853/2004, 2004](#)). In this sense hazard means a biological, chemical or physical agent in, or condition of, food or feed with the potential to cause an adverse health effect.

The General Food Law and the Food Hygiene Regulation, therefore act as umbrella regulations, under which there are a series of Europe-wide provisions covering specific aspects of food safety and contamination. Most of these regulations align with the principle set out in Council Regulation (EEC) No 315/93 and they set specific legal limits for contaminants on the basis of risk assessment and taking into account good practice.

Such regulations include microbiological criteria ([Commission Regulation \(EC\) No 2073/2005, 2005](#)) for bacteria and viruses, specific and overall migration limits for food contact materials ([Regulation \(EC\) No 1935/2004, 2004](#)), and maximum residue limits for plant protection products ([Regulation \(EC\) No 1107/2009, 2009](#)) and for veterinary medicinal products ([Commission Regulation \(EU\) No 37/2010, 2009](#)). Comprehensive and complimentary legislation also exist which regulates and limits the use of certain food additives, flavourings, enzymes, and extraction solvents used in the production of food ([Regulation \(EC\) No 1333/2008, 2008](#)), including on a food safety basis (e.g. setting maximum usage levels and criteria for impurities/contaminants within

individual additives), and which regulates the placing on the market of novel foods ([Regulation \(EC\) No 258/97, 1997](#)) or foods which are derived from non-authorised genetic modification ([Regulation \(EC\) No 1829/2003, 2003](#)), and also irradiated food ([Directive, 1999/2/EC, 1999](#)).

For those chemical contaminants which are not covered under these specific legislative requirements, and which are the focus of this chapter, the EU has again followed the principle established under Council Regulation (EEC) No 315/93 and in many cases, has established maximum levels for specific foodstuffs. Many of these are currently listed within [Regulation \(EC\) No 1881/2006 \(2006\)](#) (as amended). Alternative approaches to managing chemical contaminants do exist, most notably with contaminants which may form during processing. There has been some tentative exploration of legislation in this area, most recently with the Commission's regulation on establishing mitigation measures and benchmark levels for the reduction of the presence of acrylamide in food ([Regulation \(EU\) No 2017/2158](#)).

Food business should also be aware that although the food safety legislation is seemingly segmented into these convenient categories, on occasion the regulations do crossover each other and when this happens resolution is not always clear cut. For example, maximum levels may exist for a specific contaminant in food and should therefore, theoretically, be managed via [Regulation \(EC\) No 1881/2006](#), however the same contaminant may also have a specific or overall migration limit for use in food contact materials and might feasibly therefore be managed by [Regulation \(EC\) No 1935/2004](#), or the contaminant may even be authorised as a plant protection product by [Regulation \(EC\) No 1107/2009](#) and may have a specific maximum residue limit. The question for the regulator is what is the source of the contamination? Is the contaminant derived from illegal use of a plant protection product or is the contamination adventitious? Where these conflicts do occur, they can create significant considerable problems as businesses strive to provide evidence of the safety of their food and full compliance with the legislation.

Lastly it is also worth noting that despite the existence of specific provisions and legal limits, and the legal obligations placed on food businesses to ensure that unsafe food is not placed upon the market, competent authorities in EU member states still retain the ability to impose restrictions and the ability to force a withdrawal from the market ([Regulation \(EC\) No 178/2002](#)) where they themselves believe a food to be unsafe.

## **Regulatory Enforcement of Maximum Levels for Chemical Contaminants, Monitoring and Reporting**

Whilst food businesses have a legal responsibility to ensure that the food they place on the market is safe, member states themselves have a legal responsibility to monitor for chemical contaminants and to enforce legislation.

At the time of writing, major revisions to the EU legislation on official controls have been agreed and have been published within the Official Journal of the European Union. The requirements will be gradually phased in and some of the new requirements will not apply until December 14, 2019 ([Regulation \(EU\) No 2017/625, 2017](#)). In the meantime, many similar requirements for enforcement and monitoring are actually set out within [Regulation \(EC\) No 882/2004](#) (as amended).

These requirements specify that member states shall ensure that official controls are carried out regularly, on a risk basis and with appropriate frequency, and shall be carried without prior warning (including on an ad hoc basis) at any of the stages of production, processing and distribution of feed or food and of animals and animal products. The regulation specifies that methods of sampling and analysis shall be established, and if no such rules exist, member states should use internationally recognized rules or protocols (e.g. standards published by the European Committee for Standardisation ([CEN](#))).

The regulation also requires member states to designate official (national) reference laboratories, and identifies a list of current EU reference laboratories for specified chemical contaminants. The reference laboratories have a legal role in co-ordinating comparative trials between laboratories across Europe and providing scientific and technical assistance to the Commission. In turn the Commission has a legal responsibility, which it carries out through its 'Health and Food Audits and Analysis Directorate' ([Europa EU](#)), to inspect the application of food safety legislation in individual member states and in non-EU countries exporting to the EU.

To this end legal provisions for the sampling and analysis for the official control of the maximum levels for chemical contaminants have been laid down in several associated regulations. For example, [Regulation \(EC\) No 401/2006](#) sets out sampling and analysis requirements for mycotoxins, whilst Commission [Regulation \(EC\) No 333/2007](#) covers lead, cadmium, mercury, inorganic tin, 3-MCPD and benzo(a)pyrene, and [Regulation \(EU\) No 2017/644](#) covers dioxins, dioxin-like PCBs and non-dioxin-like PCBs. Further guidance, in particular to assist the competent authorities in application of the sampling and analysis requirements, are available via the Commission's website ([EC Europa EU](#)).

Many of the EU's regulations and directives on chemical contaminants specify that the analytical data which is obtained as part of their monitoring programmes are submitted direct to the European Food Safety Authority (EFSA) for use in subsequent risk assessments.

The Commission has also published several 'Commission Recommendations' regarding monitoring of certain foods and certain contaminants. These are principally aimed at member states (although third parties can also submit relevant data) and are intended to gather occurrence data to support future risk assessment or risk management options. Whilst such recommendations are not legally binding, they do suggest target foodstuffs and contaminants to be monitored, and in some cases the conditions under which they are to be sampled and analysed.

Lastly the European Commission has established legislation for monitoring and control of foods imported into Europe. For example, [Regulation \(EC\) No 669/2009](#) (as amended), sets an increased level of official monitoring controls on imports, at point

of entry into the EU, of certain feed and food of non-animal origin from specific third countries on the basis of ongoing or emerging food safety concerns.

Where analysed foods fail to meet the current EU maximum levels for a specified chemical contaminant, the competent authority or authorities in the relevant member state(s) may request the withdrawal or recall of affected products from the market, or in the case of products entering the EU, may refuse entry at the border. Actions taken are reported via the European Union Rapid Alert System for Food and Feed (RASFF), an online communication tool principally for use by competent authorities to share information on unsafe products which may have crossed EU borders.

## EU Risk Assessment for Chemical Contaminants in Food

Where maximum levels or other legal interventions have been established these are normally based upon EU risk assessments delivered by the EFSA (in a limited number of cases by the EFSA's predecessor, the Scientific Committee on Food ([EU Scientific Committee, 1997](#))).

The EFSA was established by [Regulation \(EC\) No 178/2002](#) as an independent risk assessment body. Its role is to assess the available evidence on a specific food safety related issue, and to provide risk assessments for use by the relevant EU risk management and legislative bodies (i.e. the European Commission, European Council and European Parliament). Whilst the EFSA is able to assign work to itself, most if its workload stems from existing legislative requirements, with priorities agreed with the European Commission and other partners, taking into account available resources.

The Commission, member states or the European Parliament may request the EFSA to deliver a food safety risk assessment (typically in the form of a 'scientific opinion') based upon the available evidence. The EFSA will in turn confirm or reject the request, and as appropriate agree a deadline for delivery. Once a request is accepted it becomes a formal mandate and the EFSA maintains a public register of all questions and mandates on its website.

For chemical food contaminants, risk assessments are provided by the EFSA Panel on Contaminants in the Food Chain. The panel is composed of independent scientific experts with a three-year mandate, and external experts may be invited to contribute on a regular or ad hoc basis. The EFSA staff may also produce some scientific outputs, such as responses to urgent requests for advice, and monitoring and analysis information, and data on chemical contaminants, food consumption and emerging risks.

The EFSA scientific opinions on chemical contaminants take into account relevant scientific colloquia and conferences, data collected and submitted by member states or received from open calls, studies which are shared with the EFSA by stakeholders, peer reviewed literature research, own-initiative studies, and where required expert elicitation to address data gaps ([EU-ANSA](#)). In some cases, a draft scientific opinion is issued for a period of public consultation prior to formal adoption. Adoption is via consensus within relevant panel and possible minority opinions are recorded. The text is published within the EFSA's Official Journal as an open access document and a copy is sent to the originator of the request.

The EFSA scientific opinions follow a standard risk assessment template, and include hazard identification and characterisation, exposure assessment and finally risk characterisation, from which probability of an adverse effect to sub-sets of the population are calculated. It should also be noted that several members states maintain separate food risk assessment agencies. On occasion these agencies may arrive at different risk assessment conclusions from the EFSA, and whilst they will typically defer to the EFSA scientific opinion there are rare occasions when this does not occur, and individual member states may then choose to set their own risk management measures, independent of the Commission, and on the basis of protecting their national population.

## Risk Management Measures

With the publication of an EFSA scientific opinion there is often sufficient evidence for the Commission and member states to start discussions on appropriate risk management measures or else to agree that no further action is required.

The Commission may propose draft legal measures based upon discussions within the relevant EU member state expert group, and taking into consideration any additional evidence that is of relevance, for example the practicalities associated with setting a specific maximum level for a specific commodity and reported occurrence levels in specific foodstuffs.

In some cases, such as ergot ([Recommendation, 2012/154/EU, 2012](#)), the EFSA scientific opinion may indicate that the available data do not indicate a concern, but that the occurrence data (and as a result the calculated dietary exposure) on which this opinion is based is limited. A risk management decision may be taken to collect further data or seek further external scientific advice and reconsider the issue at a later stage.

Regulatory texts can take some time to be agreed amongst all 28 EU member states, they may require consultation with relevant stakeholders and may be subject to a considerable number of revisions before they are finalised. Under the current Commission's 'better regulation' agenda, a draft measure such as new or amended maximum levels for chemical contaminants will also be subject to a four-week long public consultation prior to vote within the appropriate EU Standing Committee.

For chemical contaminants in food, the relevant committee is the Standing Committee on Plants, Animals, Food and Feed. The Standing Committee is composed of representatives from all member states and is presided over by a Commission representative. Records of all agenda's and minutes of the Standing Committees are maintained on the Commission's website under the 'commitology register'.

Voted text are submitted to both the European Parliament and the Council for a final 3-month scrutiny period before publication in the Official Journal of the European Union, and the measure may specify an additional transitional period before it applies.

### **Challenges for Food Businesses Posed by New and Emerging Contaminants**

One of the biggest challenges for any food business is how to ensure information on new and emerging contaminant issues are tracked, and to understand how these issues might potentially impact upon the ingredients and processes that the business employs, and ultimately on their finished products.

Due to resource, it can be difficult for a food business to identify relevant scientific research on all potential chemicals of concern. There are a vast number of papers and journals of varying quality to be tracked, and an infinite combination of ingredients and potential hazards. Whilst monitoring of research does take place, food business may find their priorities are determined more by monitoring the legislation process, and through discussions within legislative for a and professional associations.

In terms of legislation tracking there is already, thankfully, a large amount of transparency embedded within the decision-making process of the Commission's Directorate-General Health and Food Safety. As mentioned previously, the EFSA maintains a register of questions on contaminants, and materials such as Standing Committee agendas, minutes and voted regulatory texts are generally available from the Commission's website. The Commission does communicate on most of the work that it is proposing to carry out, via presentations at conferences and symposiums and through communications such as work programmes on its website. Similarly, authorities in individual EU members states will often communicate to stakeholder on proposed work.

However, there are also occasions when critical regulatory decisions on specific contaminants are made rapidly or else at a very early stage, and the materials and data related to those decisions may not always be made publicly available, or publicly consulted in a timely manner e.g. agendas, minutes and early regulatory drafts from member state expert group meetings are often unavailable to stakeholders without submission of specific requests.

Furthermore, whilst a decision to initiate a risk assessment activity on a potential food contaminant should be based upon the best available scientific research on hazard identification and hazard characterisation, and on accurate occurrence and consumption data, regulators may feel themselves under political pressure from external sources (e.g. MEPs, individual governments or lobby groups) to act quickly, particularly when new or potentially acute hazards are identified.

In such circumstances there may be limited knowledge of the full range of factors which are relevant to the finished foodstuffs as it is placed on the market e.g. differing production methods, processing factors, recipe design, supply chains, size of market and consumption patterns.

Failure of food businesses, authorities and the scientific community to communicate to one another at an early stage when any potential hazard is being reviewed can lead to emphasis being incorrectly placed on one aspect of a contaminant and requiring corrections to made to legislation later down the line. For example [Regulation \(EU\) No 594/2012](#), amending Regulation (EC) 1881/2006, set maximum levels for ochratoxin A in spices and mixtures of spices containing one or more of several named spices at 15 µg/kg. For paprika (*Capsicum* spp.) specifically this level would have been applicable from January 2015, but at a late stage industry was able to demonstrate that even with application of good agricultural and manufacturing practice this level was not technically achievable. As a result, the lower level did not come into force and a higher maximum level of 30 µg/kg was retained. However, the uncertainty that the legislation introduced did cause major problems for suppliers and for food businesses who wished to purchase compliant materials. Manufacturers would have had to make contingency plans to accommodate the potential shortage of materials and the spike in prices which would have occurred had the lower level been introduced.

Regulation (EC) 1881/2006 also poses another problem for manufacturers in that in some instances it sets maximum levels for a raw material, and then a separate maximum level for a finished product. Again, using ochratoxin A as an example, raw cereals have a maximum level of 5.0 µg/kg, whereas all products derived from unprocessed cereals, including processed cereal products and cereals intended for direct human consumption have a maximum level of 3.0 µg/kg. In practical terms this means that manufacturers need to ensure that, via processing, they are able to further reduce levels. Whilst this might pose only a limited issue for products with lower cereal content, for some minimally processed cereal products it considerably limits the raw materials that can be used, and may mean that farmers are contracted to provide raw materials that meet the lower processed maximum level.

Lastly in some instances, decisions of relevance for food businesses may also be taken in other non-food for a, for example regulatory discussions on standards for fertilisers which are managed under-European Commission's Directorate-General for Internal Markets, Industry and Entrepreneurship and SMEs, and the EU Water Framework Directive which is managed under the European Commission's Directorate-General for the Environment.

### **Quality and Comparability of Monitoring Data**

All EFSA risk assessments include an estimation of exposure for various subpopulations, which is based upon national food consumption surveys (compiled as the EFSA Comprehensive European Food Consumption Database ([EFSA](#))) and occurrence levels reported within individual foodstuffs. As the exposure assessment is a key determinant in determining appropriate risk measures, it is critically important that the national food consumption surveys are updated on a regular basis, that they cover all parts of the

population, and that they correctly categorise foodstuffs. This is an area that is largely out of control of food businesses, but it is a genuine concern in instances where countries do not have accurate consumption data as this may result in risk assessors overestimating or underestimating exposure for a particular market, based on non-representative data from other member states.

It is also important that analytical methods that are being used to determine levels in product are as accurate as possible, that descriptions of the products that are sampled are accurate (including where possible the method of production), and that the product is sampled in the most appropriate location.

It can sometimes be difficult to establish accurate analytical methods, especially at an early stage in the research, and this may lead to an overestimate or underestimate of levels in foodstuffs, and issue compounded by differences in limits of quantification, measurement uncertainty and other intra-laboratory differences. An example is furan, which is a volatile chemical and possible carcinogen that is formed in some heat processed foods (EFSA J). Şenyuva and Gökmen (2007), reported that during sample preparation for headspace GC–MS analysis, furan was formed during headspace equilibration leading to an overestimation of reported levels in foodstuffs. This was correctly picked upon in Commission Recommendation, 2007/196/EC, where it states that sample preparation before analysis should be carried out with the necessary care to ensure that the furan content of the sample is not altered. Nevertheless, there are currently no official standard methods available for the analysis of furan and neither are there any certified reference materials available.

In the case of Commission Recommendation (EU) 2017/84 of 16 January 2017 on the monitoring of mineral oil hydrocarbons in food and in materials and articles intended to come into contact with food, there is also no agreement amongst researchers and member states as to a suitable test method and at the time of writing (almost a year after the coming into force of the recommendation) guidance from the JRC is still awaited. It remains to be seen how the EFSA and the Commission will assess the results of the monitoring given the lack of standard method. In the case of both furan and mineral oil hydrocarbons should maximum levels be set in the future then for enforcement it would be imperative that a standardised analytical method was agreed.

A number of other factors also have the potential to indirectly bias data sets which then go to inform EU-wide risk assessments, for example, in 2012 the Commission published a recommendation on the monitoring of the presence of ergot alkaloids in feed and food (Recommendation (EU) 2017/84, 2017). This recommendation suggests that member states should perform monitoring on the presence of six ergot alkaloids and corresponding epimers in unground cereals and in cereal products and compound feed and food. However, ergot alkaloids are psychotropic substances, and therefore in some EU member states a laboratory wishing to purchase the standards would be required to apply for specific controlled substance licences, thus making laboratory testing for ergot alkaloids relatively expensive and thereby indirectly influencing the data collection activity by limiting the number of analytical results in some countries on the basis of cost.

In other instances, a data set may be subject to bias because a member state goes significantly beyond the voluntary monitoring recommendation. In its recent scientific report on furan (Recommendation, 2012/154/EU, 2012) the EFSA noted that ~80% of samples submitted came from only five member states (and ~60% originating from one single Member State). The EFSA highlighted the uncertainty on whether possible country-based differences in the levels of furan in diverse food commodities are well represented.

Lastly there may even be issues with the quality of the laboratories that are being used to undertake monitoring. In the EFSA furan report ~30% of the governmental data lacked information on the analytical method that was used to analyse some food samples. In its report on acrylamide in 2012 (EFSA, 2012), the EFSA reported that approximately 5% of the analytical results for the period 2007–09 did not include an indication of the analytical method used, and that data on the percentage of accredited laboratories responsible for the submitted data was often missing, for example in 2007 only 2% of the data reported by member states included information on the laboratories accreditation status (this increased to 6% in 2008, 83% in 2009 and 94% in 2010).

## Summary

On paper the EU legislative process for chemical contaminants in food appears to be relatively simple and the basis for setting controls is reasonably transparent. However, as this chapter hopefully highlighted, it can also be incredibly challenging for food businesses to keep a track of all current requirements and proposals, and all emerging hazards or risks.

Food safety is a major responsibility for a food business of any size, and it requires not only awareness of products and processes, but also awareness regarding the interplay between existing legislation, and an understanding of that way in which risk measures are developed.

There are numerous factors at play which can indirectly influence the direction of the data gathering activities, the risk assessment and ultimately risk management measures, and food businesses need to recognise that scientific knowledge is continually evolving, that new emerging hazards and risks are constantly being identified and characterised, and that they need to be in a position to react to accordingly.

# Biocides: A Critical Review of Current and Proposed EU Legislation

**Heiko Faubel**, German Industrial Association for Hygiene and Surface Protection for Industrial and Institutional Applications (IHO)

© 2019 Elsevier Inc. All rights reserved.

## Introduction

The Biocidal Products Regulation EU/528/2012 (BPR) is applicable since 1 September 2013 and has already been revised since its entry into force. Prior to the BPR system, disinfectants had to be registered with the competent authorities in the respective Member States. By contrast, the biocides legislation provides for a two-stage procedure for the authorisation of biocidal products: First, the active substance must be included in Annex I; next, the products formulated with this active substance must be approved separately in each Member State.

The status of the BPR as a regulation means that it applies equally in all Member States and should make a significant contribution to the harmonisation of the European internal market. However, in most respects the Biocidal Products Regulation is only a rough framework; almost all detailed rules and implementing provisions are not yet clearly defined and put into practice in the Member States. Work is currently underway at European level on implementing acts to bring the regulation in a more precise form. This is intended to clarify most of the open issues.

The complexity and “rigidity” of the rules and the cost-driving detailed provisions are mainly caused by the competent authorities of the Member States within the European coordination process. Industry representatives have gained the impression that the national competent authorities cannot agree on a common denominator. As a result, each authority can bring in its own priority which then emerges in the implementation regime.

This can be illustrated by the example of the mixture toxicity issue where, quite often, mixture toxicity is brought forward by one Member State but assessed to be less relevant by the other Member States. Germany's priorities are another example: They increasingly focus on environmentally sound uses. Instead of developing a common position, it is preferred to integrate both special topics into the regulation. However, this approach does not take into account the benefits of disinfectants for increasing the level of hygiene. The emphasis of the rules is clearly on occupational health and safety and environmental protection, based on the experiences with pesticides. But it is worth noting that disinfectants are drastically different from pesticides because of their chemistry and application. Disinfectants are intended to act quickly (almost immediately) and do not need to be chemically very stable and long-lasting. The output is diametrically different too. Disinfectants are almost always used in controlled conditions in objects with disposal via the waste water systems. Unlike in other biocide and pesticide applications, there is no uncontrolled release into the environment.

But it is not only the regulation as such that is proving problematic in terms of individual national interpretations. Moreover, within the approval procedures under the BPR it is increasingly found that the assessment authorities in the Member States have different interpretations of the law and of the guidelines so that they do not make uniform requirements regarding the data to be submitted and the resulting approval conditions. Also in the application of the BPR in other legal areas and concerning national recommendations on the selection and use of disinfectants, the competent authorities and technical societies are extremely persistent in adhering to older, partly outdated scientific principles.

## International Evaluation Methods and Proof of Efficacy

The biocides legislation integrates not only the chemical and physical characterisations of products, their environmental behaviour and various risk assessments but also efficacy tests to ensure adequate disinfection. At the end of 2017, a legal opinion was published on the legal significance of national assessment methods and listing systems for the microbial efficacy of disinfectants in the scope of the Biocidal Products Regulation. This opinion notes that the BPR clearly gives priority to international methods. National methods are only accepted if no international method is available for special applications (e.g. in case of epidemics). Harmonised European standards are the first choice for such internationally recognised methods. This is viewed similarly by scientists and even by federal law courts. The state of the art in science and technology explicitly requires that methods be internationally recognised. Conversely, this means that national methods can never represent the state of the art in science and technology.

Additionally to questions of standardisation and methods, the BPR also regulates the application of any products. Thus, the concentration or exposure times specified in the approval conditions of the assessing authorities must be observed by the users. Furthermore, manufacturers or other third parties (for example, professional societies or associations) may not recommend any other conditions. This means that existing recommendations, e.g. from manufacturers and industry associations or other national associations under private law, may no longer deviate from the authorisation conditions for authorised biocidal products. The consequence: Specialist tests of laboratory results and any risk premiums in listing processes would be rendered obsolete.

The legal basis suggests that the current situation regarding the proof of efficacy is facing a fundamental change in the EU Member States. National methods for testing the efficacy of disinfectants and disinfection measures, which have been dominant for several decades, will increasingly lose in importance and slowly disappear. The focus of possible listing systems will shift significantly, up to checking the reliability of expert opinions and their results. In addition, the high priority given at EU level to the free movement of goods means that restrictions and exemptions are considered near-impossible. In the future, recommendations by experts, professional associations or national authorities will have to comply with the methods and application instructions as described in the approval processes.

### **Costs of the Authorisation Process**

The authorisation of disinfectants according to the Biocidal Products Regulation is a bureaucratic, complex and time and cost-intensive procedure, similar to that for pharmaceuticals and pesticides. This increases the costs per product from a few 10,000 euros to up to 500,000 euros, with this cost estimate referring only to external regulatory costs. Approximately 50 percent each of the costs fall to the share of additional investigations and fees charged by the authorities for the procedure, respectively. Internal costs, e.g. for development, quality assurance and staff, are additionally incurred by the companies.

The enormous increases in fees by the European Chemicals Agency (ECHA) and the national authorities are deemed particularly critical for small and medium-sized enterprises (SMEs). For a standard biocidal product authorisation in several countries, initial experience shows that the amounts in fees to be expected are comparable to the amounts that had to be invested previously in the preparation of the required dossiers. In more detail, within the approval process of a disinfectant, thus roughly 200,000 euros (simple product) to 500,000 euros (complex product) of basic costs arise (for example, for dossier preparation) plus costs for the Letter of Access (for the use of the raw material), approval costs per country and any annual fees.

Within the framework of a study, the EU Commission had the financial burden on disinfectant manufacturers due to compliance with legal requirements in Europe investigated (cf.: <http://bit.ly/2gQNArY>). The results of the study give cause for concern: Due to the impending loss of raw materials and the existing cost burden, negative effects on product development and hygiene levels must be feared. Moreover, these regulatory restrictions and the resulting burdens are a “development brake” for new active ingredients. In Germany alone, the regulatory and administrative expenses doubled between 2015 and 2017 by more than one percentage point (in relation to total sales). In the same period, the industry’s research and development spending in Germany fell by around 0.8 percentage points (research ratio in relation to total sales). This shows that the registration and approval fees will have an enormous impact on the availability of products: The product range might be reduced dramatically.

For the authorisation of biocidal products in the health care sector, manufacturers of disinfectants in Germany invest roughly between 40 and 60 million euros with a total market volume of around 250 million euros. In view of the financial dimensions, a company must consider very carefully whether special products can continue to be offered in the portfolio. The same applies to new product developments: After the administration process, their formulations cannot be changed in the light of customer feedback or practical experience without further horrendous costs. Thus, it is questionable whether the development of application-specific, specialized and individualized solutions will remain possible in the current scope in the future. For facilities that depend on precisely this, there is the threat of special products being no longer available and of price increases.

### **Summary**

The requirements for authorisation are increasing enormously. The Biocidal Products Regulation contributes to this, especially for disinfectant products. The manufacturers fully support the objective of making the handling and use of such products safer and of minimizing risks. However, the new legislation goes far beyond the goal in terms of effort and costs for product authorisation. These are disproportionate to the sales that can be achieved and put pressure on an industry which is characterized by medium-sized enterprises.

This in two respects: firstly, with regard to the enormous costs and, secondly, regarding staff capacities. Preparing the necessary dossiers requires qualified, mostly technically experienced personnel who must be withdrawn from research and development and application technology in order to carry out this work. This leads to bottlenecks and thus to reduced innovation and, in some cases, less customer service. It is expected that large, multinational corporations, raw material manufacturers or large contract manufacturers will be able to implement this requirement more easily. By contrast, most medium-sized enterprises can no longer afford own products in the described situation. Especially in Germany, there are large numbers of medium-sized enterprises that are also technology leaders in Europe. A reduction of available raw materials and disinfectants is foreseeable. To date, around two-thirds of all active ingredients have been taken from the market as a result of the high costs connected with European legislation.

The problem is that the use of disinfectants is also essential as prophylaxis to prevent the spread of dangerous germs such as EHEC or multi-resistant hospital germs (MRSA). However, this is not taken into account, for example, in the European Biocidal Products Regulation. Rather, the regulation gives more focus on environmental impacts or other potential risks. But in the near future, an end to production is threatening even for products for extreme conditions, such as epidemics in the veterinary sector.

This triggers a process where there are only losers in the end: Very special but highly important active ingredients could disappear from the product range, smaller manufacturers are giving up business fields, and competition is increasingly concentrating on a few

products with the same active ingredients. In addition, a significant decline in innovation activities in the industry is driven forward and a reduction in personnel and services for customer support is provoked. There is reason to fear a drop in the level of hygiene and an increase in the risk of the spread of germs.

The changes will become apparent to users by 2020: In the event of an epidemic, important products could no longer be made available in a timely manner, with the outlined risks for prevention and hygiene. The one-sided criteria laid down in legislation for the assessment of active disinfectant substances urgently need to be rethought and restructured, with a much higher priority to health protection aspects. A further reduction or restriction of disinfectants cannot be justified.

What alternative solutions are conceivable? One proposal from the industry is a different basis for the assessment of disinfectants. It could be well-targeted and meaningful to carry out the risk assessment for occupational health and safety and environmental protection according to the REACH criteria without demanding a second risk assessment under the biocides legislation – in order to contribute to a genuine reduction of the costs for the market availability of disinfectants and products. The authorisation of biocidal products within the framework of European legislation should always focus on the efficacy of disinfectants. This approach wants to enable users to fulfil their hygiene tasks, thus ensuring the protection of patients, personnel and health as well as comprehensive food safety.

## EDITOR BIOGRAPHIES

---

### EDITORS IN CHIEF

**Laurence Melton**

Professor Laurence Melton was the Inaugural Professor of Food Chemistry at the University of Auckland, New Zealand, where he set up degrees in Food Science and Wine Science. He has been a Principal Investigator for the Riddet Centre of Research Excellence for Food Research. Formerly he was Professor of Food Science at the University of Otago, at Dunedin, N.Z. and earlier a scientist at Unilever's Colworth House in Bedfordshire, UK. His major research interest is how food macromolecules interact to give foods their structure (e.g. the complex mixture of polysaccharides that comprise plant cell walls (dietary fibres) and the interaction of proteins and polysaccharides such  $\beta$ -lactoglobulin and pectins). He has published over 300 scientific papers and reports. Currently he is an Editor for Food Chemistry and Emeritus Professor at the University of Auckland. He wrote "As a teenager I was training to be an electrician but I thought it would be more exciting to be a chemist because there could be fires and explosions. And there were some. However, what kept me motivated over 50 years was the excitement of discovering stuff by doing research."

**Fereidoon Shahidi**

Professor Fereidoon Shahidi is a University Research Professor at the Memorial University of Newfoundland, Canada. He is highly respected for his research in such areas as marine products and functional foods.

**Peter Varelis**

Dr Peter Varelis is an applications chemist with Shimadzu Scientific Australia where he manages a team of chemists. Prior to joining Shimadzu he was a principal scientist and team leader at Food Standards Australia New Zealand. He trained as an organic chemist and has more than 20 years of research experience in both government and industry. His research interest is the application of mass spectrometry to the analysis of organic compounds that have implications for human health and nutrition. Peter obtained his PhD from the University of Western Australia. He was research professor at the Illinois Institute of Technology and principal research scientist with the Commonwealth Scientific and Industrial Research Organization in Australia. From 2007 through to 2011, Peter was a theme leader with the National Centre for Food Protection and Defense.

## SECTION EDITORS

**Rotimi Aluko**

Dr Rotimi Aluko, a Certified Food Scientist is a Professor in the Department of Food and Human Nutritional Sciences at the University of Manitoba, Winnipeg, Canada. He also serves as the Assistant Director of the Richardson Centre for Functional Foods and Nutraceuticals, Winnipeg. He obtained a PhD (Food Science) degree in 1996 from the University of Guelph, Ontario, Canada. His work focuses on the structure-function properties of bioactive proteins and peptides with special focus on oilseeds and pulses. In addition to over 170 journal article publications, Dr Aluko holds two patents on the antihypertensive properties of plant seed protein-derived peptides. Dr Aluko has trained over 70 people in various areas of food chemistry and human nutrition. He is a 2017 "Highly Cited Researcher" in the Agricultural Sciences category, which is recognition given to researchers with peer-reviewed journal citations in the top 1% in the world. Dr Aluko is a Fellow of the Canadian Institute of Food Science & Technology, the Institute of Food Technologists and the American Oil Chemists' Society. He currently serves as the Editor-in-Chief for the *Journal of Food Biochemistry* and an Associate Editor for *Current Topics in Nutraceutical Research*.

**John Birch**

John teaches Food Science undergraduate and postgraduate courses specializing in food chemistry, food processing and food quality management and safety.

His research area is on physicochemical composition and properties of food components, increasing value of secondary food processing products and their contribution to consumer health and wellness. Students research on value-added oilseed products, transesterification of oils with phenolic acids (to produce antioxidants), bioactive peptides, alternative protein sources to traditional farming practices, fish oil composition, stabilization and analysis of oxidative products, biofuel production from primary wastes, nanoencapsulation of bioactives, frying oil stability and lipid derived flavour in meat. Analytical instruments: HPLC, GC, GCO, PTRMS, GC-MS, NMR, DSC, TGA and access to specialized University instruments.

**Danae Larsen**

Danae Larsen, PhD, is a Food Science Consultant in Zurich, Switzerland. She has worked in various sectors of the food industry and academia, having held research positions in the School of Chemical Sciences and the Department of Chemical and Materials Engineering at the University of Auckland, New Zealand and at the Centre for Organismal Studies, Heidelberg University, Germany. Her research interests include, food structure, oral processing pathways, molecular biology, sensory perception, product development and the role of textural complexity in satiation and satiety.

**Michael Rogers**

Dr Rogers operates one of only three TIM-1 simulated GI tracks in Canada and the only one where physical properties of foods can be measured directly in the system. His research area focuses on lipid digestion kinetics of processed foods, with particular interest in developing infant formula that have similar digestion kinetics to human breast milk. Dr Rogers' joined the University of Guelph after holding faculty positions at Rutgers University and University of Saskatchewan, he was also the Director of the Gastrointestinal physiology laboratory at the New Jersey of Food, Nutrition & Health. He currently holds a Tier II Canadian Research Chair in Food Nanotechnology studying how to make high fat foods healthier. For his work on lipid structure and food nanostructures he has recently been awarded The Young Scientist Research Award from the American Oil Chemists' Society and has been appointed as a Fellow of the Early Career Scientists' Section of the International Academy of Food Science and Technology. He holds two patents, 70 peer reviewed manuscripts and more than 40 technical presentations.

**Richard Stadler**

Richard Stadler is Head of the Nestlé Institute for Food Safety and Analytical Sciences, based in Lausanne, Switzerland. His current research interests include food process contaminants, new analytical approaches in food safety, exploring digital solutions to identify and mitigate food chain risks. He is a member of several editorial boards of scientific journals, as well as Editor of the Journal "Food Additives & Contaminants". He is chairman of two expert groups in FoodDrinkEurope, and permanent guest in the "Senate Commission on Food Safety" of the German Research Foundation (DFG). He has published more than 120 scientific papers/book chapters in international journals, and is lecturer at the ETH Zürich.

**Dongxiao Sun-Waterhouse**

Dr Dongxiao Sun-Waterhouse is a Fellow of the New Zealand Institute of Food Science & Technology, a Chief Expert of the Guangdong Institute of Food Science and Technology, and Chair of the “Functional/Wellness Foods & Nutrition Working Group” of the International Commission of Agricultural and Biosystems Engineering. She also holds Chair Professorships at the South China University of Technology and Shandong Agricultural University. She has a wealth of experience working in the food industry, academia, research institutes and a food safety authority. Her R&D expertise encompasses food chemistry and biomaterials, food processing/manufacturing and food safety, industrial biotechnology, functional foods and nutrition. Her particular research strength is the smart use of food component interactions in food systems, as well as formulation and processing synergies, for wellness/functional food development and bioactive delivery. She has been actively involved in applied research and industrial consulting nationally and internationally to improve commercialisation outcomes. Dongxiao is a Section Editor of Elsevier's *Encyclopedia of Food Chemistry* and an Editorial Board member of the journal *Food Chemistry*. She has also acted as a conference convenor, conference chair, scientific advisory board member or organizing committee member for a number of international conferences.

## CONTENTS OF VOLUME 2

---

<i>Contributors to Volume 2</i>	<i>xv</i>
<i>Contents of all Volumes</i>	<i>xxiii</i>
<i>Preface</i>	<i>xxxvii</i>
Antioxidant and Flavor in Spices Used in the Preparation of Chinese Dishes <i>Yan Ping Chen and Hau Yin Chung</i>	1
Anthocyanins in Food <i>Xiaonan Sui, Yan Zhang, Lianzhou Jiang, and Weibiao Zhou</i>	10
Caramelization in Foods: A Food Quality and Safety Perspective <i>Tolgahan Kocadağlıoğlu and Vural Gökmen</i>	18
Carbohydrate Active Enzymes Applied in the Production of Functional Oligosaccharides <i>Fabiano Jares Contesini, Evandro A de Lima, Fernanda Mandelli, Gustavo P Borin, Rafael F Alves, and César Rafael F Terrasan</i>	30
Chemically Reducing Properties of Maillard Reaction Intermediates <i>George P Rizzi</i>	35
Protein Oxidation <i>Leticia Mora, Marta Gallego, M-Concepción Aristoy, and Fidel Toldrá</i>	41
Coffee Flavor <i>Adane Tilahun Getachew and Byung-Soo Chun</i>	48
Configuring Phenolic Antioxidants for Frying Applications <i>Felix Aladedunye and Eliza Gruczyńska</i>	54
Milk Protein Interactions <i>Anant Chandrakant Dave and Harjinder Singh</i>	63
Effect of Heat on Food Properties <i>Rana Muhammad Aadil, Ume Roobab, Abid Aslam Maan, and Ghulam Muhammad Madni</i>	70
Effect of Emerging Processing Technologies on Maillard Reactions <i>Mohamed Koubaa, Shahin Roohinejad, Tanyaradzwa E Mungure, Bekhit Alaa El-Din, Ralf Greiner, and Kumar Mallikarjunan</i>	76
Effect of Storage on Fruit Bioactives <i>Rana Muhammad Aadil, Ume Roobab, Muhammad Kashif Iqbal Khan, and Ubaid Ur Rahman</i>	83

Enzymatic Production of Antioxidants and Their Applications <i>Taiwo O Akanbi and Colin J Barrow</i>	92
Factors Influencing Red Wine Color From the Grape to the Glass <i>Jacqui M McRae, Bo Teng, and Keren Bindon</i>	97
Fermentation of Grains <i>Isam A Mohamed Ahmed, Fahad Y Al-Juhaimi, and Alaa El-Din Ahmed Bekhit</i>	107
Fruit Pigment Changes During Ripening <i>Wee Sim Choo</i>	117
$\alpha$ -Galactosidase and Its Applications in Food Processing <i>Lu-Kwang Ju, Abdullah A Loman, and S M Mahfuzul Islam</i>	124
Influence of Food Processing Operations on Vitamins <i>Merve Tomas and Seid Mahdi Jafari</i>	129
Microbial Xylanases in Bread Making <i>Seema Dahiya and Bijender Singh</i>	140
Lipases for Biofuel Production <i>Oseweuba Valentine Okoro, Zhifa Sun, and John Birch</i>	150
Lipase/Esterase: Properties and Industrial Applications <i>Oi-Ming Lai, Yee-Ying Lee, Eng-Tong Phuah, and Casimir C Akoh</i>	158
Holistic Control of Fats and Oils by NMR Spectroscopy <i>Elina Zailer</i>	168
Lipid-Derived Flavours and Off-Flavours in Food <i>Fereidoon Shahidi and Abreham Abad</i>	182
Lipophilized Antioxidants <i>Maria Cruz Figueroa-Espinoza, Claire Bourlieu, Erwann Durand, Jérôme Lecomte, and Pierre Villeneuve</i>	193
Meat Color: Factors Affecting Color Stability <i>Alaa El-Din Ahmed Bekhit, James D Morton, Zuhaib Fayaz Bhat, and Lingming Kong</i>	202
Meat Colour: Chemistry and Measurement Systems <i>Alaa El-Din Ahmed Bekhit, James David Morton, Zuhaib Fayaz Bhat, and Xu Zequan</i>	211
Homeostasis of Plasmalogens in Mammals <i>Masanori Honsho and Yukio Fujiki</i>	218
Biochemical Reactions During Fresh Meat Storage <i>José A Beltrán, Pedro Roncalés, and Marc Bellés</i>	224
Nonenzymatic Browning Reactions: Overview <i>Yuliya Hrynets, Abhishek Bhattacharjee, and Mirko Betti</i>	233
Pulsed Electric Fields Processing of Plant-Based Foods: An Overview <i>Sze Ying Leong and Indrawati Oey</i>	245
Oleogels in Food <i>Kristin D Mattice and Alejandro G Marangoni</i>	255
Oxidative Rancidity <i>Charlotte Jacobsen</i>	261

Pectic Enzymes <i>Jin-lan Xia and Pei-jun Li</i>	270
Phospholipases <i>Angeliki Bourtsala and Dia Galanopoulou</i>	277
Polyphenoloxidase in Fruit and Vegetables: Inactivation by Thermal and Non-thermal Processes <i>Filipa Vinagre Marques Silva and Alifdalino Sulaiman</i>	287
Processing Effects on Meat Flavor <i>Siripong Kanokruangrong, John Birch, and Alaa El-Din Ahmed Bekhit</i>	302
Proteases and Meat Tenderization <i>James David Morton, Zuhaib Fayaz Bhat, and Alaa El-Din Ahmed Bekhit</i>	309
Proteases as Digestive Aids <i>Utpal Bose, Crispin A Howitt, and Michelle L Colgrave</i>	314
Protection of Enzymes Against Thermal Degradation <i>Rosalía García-Torres, José I Reyes-De-Corcuera, and Daoyuan Yang</i>	322
Stabilization of Carotenoids in Foods <i>Amna Sahar, Ubaid Ur Rahman, Rana Muhammad Aadil, and Anum Ishaq</i>	330
The Role of Bioinformatics in the Discovery of Bioactive Peptides <i>Dominic Agyei, Erandi Bambarandage, and Chibuike C Udenigwe</i>	337
Thermal Analysis for Lipid Decomposition by DSC and TGA <i>Tengku Mohamad Tengku-Rozaina and Edward John Birch</i>	345
Pyrazines in Thermally Treated Foods <i>Javier García-Lomillo and Maria L González-SanJosé</i>	353
Formation of Selected Heterocyclic Flavor Chemicals in Beverages <i>Takayuki Shibamoto</i>	363
Xanthine Oxidase in Dairy Foods <i>Ali Rashidinejad and John Birch</i>	374
Bioactive Peptides <i>Leticia Mora, M-Concepción Aristoy, and Fidel Toldrá</i>	381
Resistant Starch Preparation Methods <i>Amir Amini Khoozani, John Birch, and Alaa El-Din Ahmed Bekhit</i>	390
Interactions of Milk Proteins With Minerals <i>Keegan Burrow, Wayne Young, Alan Carne, Michelle McConnell, and Alaa El-Din Bekhit</i>	395
Protein-Stabilised Emulsions <i>Chia Chun Loi, Graham T Eyres, and E John Birch</i>	404
Application of HPLC in characterisation of Triacylglycerols and Detection of Adulteration in Cold Pressed Seed Oils <i>Tanyaradzwa E Mungure, Alaa El-Din Bekhit, Alan Carne, Shahin Roohinejad, Kumar Mallikarjunan, and John Birch</i>	410
Enzyme Immobilization for Oligosaccharide Production <i>César R F Terrasan, Wilson G de Moraes Junior, and Fabiano J Contesini</i>	415
Interactions of Macromolecules: $\beta$ -Lactoglobulin Interaction With Pectins <i>Laurence D Melton, Amy Y Xu, Martin A K Williams, and Duncan J McGillivray</i>	424

Milk Protein–Polysaccharide Interactions in Food Systems <i>Natasha Nayak and Harjinder Singh</i>	431
Interaction Between the Polysaccharides and Proteins in Semisolid Food Systems <i>Min Zhang, Chanchan Sun, and Qian Li</i>	439
Protein–Starch Interactions in Cereal Grains and Pulses <i>Jitendra Paliwal, Sandeep Thakur, and Chyngyz Erkinbaev</i>	446
The Use of Spin-Label ESR Spectroscopy to Study Protein–Lipid Interactions <i>Musti J Swamy</i>	453
Lipoprotein Lipase and Its Interactions With Phospholipids <i>Yonghua Wang and Dongxiao Sun-Waterhouse</i>	462
Reactivity of Lipid Oxidation Products in Foods – Is Malondialdehyde a Reliable Marker? <i>Angelique Vandemoortele and Bruno De Meulenaer</i>	468
Protein–Lipid Interactions and the Formation of Edible Films and Coatings <i>Victor N Enujiughu and Ajibola M Oyinloye</i>	478
Protein Ingredients in Low- and Intermediate-Moisture Systems <i>Thom Huppertz</i>	483
Interactions Between Starch, Proteins and Lipids and the Formation of Ternary Complexes With Distinct Properties <i>Shujun Wang, Mengge Zheng, and Chen Chao</i>	487
O/W Emulsions Stabilized by Interactions Between Proteins and Polysaccharides <i>Vânia Regina Nicoletti Telis</i>	494
Changes in the Interactions Between Proteins and Other Macromolecules Induced by HPP <i>Bian-Sheng Li and Biao-Shi Wang</i>	499
Different Catalytic Activities of Microbial L-Glutaminases Against Bitter Amino Acid Phenylalanine in the Production of Kokumi $\gamma$ -Glutamyl Peptides <i>Juan Yang, Dongxiao-Sun Waterhouse, and Chun Cui</i>	505
Effect of the Structure of Tannins on Their Binding Site on a Human Salivary Proline-Rich Protein <i>Francis Canon</i>	510
Interactions Between Polyphenols and Macromolecules: Effect of Tannin Structure <i>Carine Le Bourvellec and Catherine M G C Renard</i>	515
A Molecular Thermodynamics Approach to Capture Non-specific Flavour–Macromolecule Interactions <i>Seishi Shimizu, Steven Abbott, and Nobuyuki Matubayasi</i>	522
Flavor Enhancement Induced by Taste–Odor Interactions <i>Guowan Su, Dongxiao Sun-Waterhouse, Yaqi Zhao, Weiwei He, and Mouming Zhao</i>	528
Encyclopedia of Food Chemistry: Protein–Phenol Interactions <i>Fereidoon Shahidi and Ruchira Senadheera</i>	532
Analysis of Flavonoid-Protein Interactions by Advanced Techniques <i>JuDong Yeo and Fereidoon Shahidi</i>	539
Covalent Interactions Between Proteins and Phenolic Compounds <i>Sascha Rohn</i>	544

Interactions Between Proteins and Polyphenols in Beer <i>Haifeng Zhao and Dongxiao Sun-Waterhouse</i>	550
Interactions Between Milk Proteins and Polyphenols in Model Systems or Complex Dairy Matrices <i>Seda Yildirim-Elikoglu</i>	554
Interactions of $\beta$ -Lactoglobulin With Small Molecules <i>Lei-Wen Xiang, Laurence D Melton, and Ivanhoe K H Leung</i>	560
Polyphenol-Protein Interactions and Changes in Functional Properties and Digestibility <i>Tugba Ozdal, İpek Ekin Yalcinkaya, Gamze Toydemir, and Esra Capanoglu</i>	566
The Potential Role of Polyphenol–Enzyme Interactions on Human Health <i>Gordon J McDougall</i>	578
Thermal Stability of Carotenoids– $\alpha$ -Lactalbumin Complex <i>Iuliana Aprodu, Loredana Dumitraşcu, and Nicoleta Stănciuc</i>	583
Component Segregation During Spray Drying of Milk Powder <i>M Foerster, M W Woo, and C Selomulya</i>	589
Impact of Antioxidants on Oxidized Proteins and Lipids in Processed Meat <i>M Estévez and J M Lorenzo</i>	600
Plant Antioxidant Extracts: Effect on Lipid or Protein Oxidation in Seafood Products <i>K H Sabeena Farvin and A Surendraraj</i>	609
Protein–Lipid–Phenolic Interactions During Soybean and Flaxseed Protein Isolation <i>Muhammad H Alu'datt, Taha Rababah, Mohammad N Alhamad, Majdi A Al-Mahasneh, Sana Gammoh, Mohammed Al-Duais, Carole C Tranchant, Stan Kubow, and Intez Alli</i>	621
Interactions Between Dietary Antioxidants and Plant Cell Walls <i>Catherine M G C Renard</i>	633
Interactions of Some Common Flavonoid Antioxidants <i>Dapeng Li, Dongxiao Sun-Waterhouse, Yongli Wang, Xuguang Qiao, Yilun Chen, and Feng Li</i>	644
Polyphenol Interactions and Food Organoleptic Properties <i>Susana Soares, Nuno Mateus, and Victor de Freitas</i>	650
Effects of Interactions Between Antioxidant Phytochemicals and Coexisting Food Components on Their Digestibility <i>Sukanya Thuengtung and Yukiharu Ogawa</i>	656
Bioactive Delivery Systems Based on Stimuli-Sensitive Biopolymer Stacks: Chitosan-Alginate Systems <i>Geoffrey I N Waterhouse and Dongxiao Sun-Waterhouse</i>	661
Interactions Between Food Ingredients and Nanocomponents Used for Composite Packaging <i>Adam Ekielski</i>	669
Use of Pectin to Formulate Antimicrobial Packaging <i>M M Gutierrez-Pacheco, L A Ortega-Ramirez, and J F Ayala-Zavala</i>	675
Effect of Three-Component Interactions Among Starch, Lipids and Proteins on the Glycemic Response <i>Javier Parada and Jose L Santos</i>	681
Encapsulation Systems Containing Multi-Nutrients/Bioactives: From Molecular Scale to Industrial Scale <i>Geoffrey I N Waterhouse and Dongxiao Sun-Waterhouse</i>	687

Nanoparticle-Based Encapsulation of Green Tea Polyphenols: An Approach to Enhance Their Bioavailability and Therapeutic Efficacy	695
<i>Feng Li, Yongli Wang, Dapeng Li, Dongxiao Sun-Waterhouse, Yilun Chen, and Xuguang Qiao</i>	
Food Soft Nano-Dispersions for Bioactive Delivery: General Concepts and Applications	701
<i>Maria D Chatzidaki and Aristotelis Xenakis</i>	
New Insights on Bio-Based Micro- and Nanosystems in Food	708
<i>Daniel A Madalena, Ricardo N Pereira, António A Vicente, and Óscar L Ramos</i>	
Oleogelation for Food Structuring Based on Synergistic Interactions Among Food Components	715
<i>Ashok R Patel</i>	
Protein-Based Nanodelivery Systems for Food Applications	719
<i>Ogadimma D Okagu, Bo Wang, Caleb Acquah, and Chibuike C Udenigwe</i>	
Edible Delivery Systems Based on Favorable Interactions for Encapsulation of Phytochemicals	727
<i>Jie Xiao, Wenbo Wang, Qingrong Huang, and Yunqi Li</i>	
Fabrication of Electrospun and Electrosprayed Carriers for the Delivery of Bioactive Food Ingredients	733
<i>Alex López-Córdoba, Jose Maria Lagarón, and Silvia Goyanes</i>	

## CONTRIBUTORS TO VOLUME 2

---

Rana Muhammad Aadil

*National Institute of Food Science and Technology,  
University of Agriculture, Faisalabad, Pakistan*

Abreham Abad

*Department of Biochemistry, Memorial University of  
Newfoundland, St. John's, NL, Canada*

Steven Abbott

*University of Leeds, Leeds, United Kingdom; and Steven  
Abbott TNC Ltd, Ipswich, United Kingdom*

Caleb Acquah

*Department of Chemical Engineering, Curtin  
University, Miri, Sarawak, Malaysia; and School of  
Nutrition Sciences, University of Ottawa, Ottawa,  
Ontario, Canada*

Dominic Agyei

*University of Otago, Dunedin, New Zealand*

Taiwo O Akanbi

*Deakin University, Geelong, VIC, Australia*

Casimir C Akoh

*University of Georgia, Athens, GA, United States*

Mohammed Al-Duais

*McGill Institute for Global Food Security, McGill  
University, Montreal, QC, Canada*

Fahad Y Al-Juhaimi

*King Saud University, Riyadh, Saudi Arabia*

Majdi A Al-Mahasneh

*Jordan University of Science and Technology, Irbid,  
Jordan*

Bekhit Alaa El-Din

*University of Otago, Dunedin, New Zealand*

Felix Aladedunye

*Feal Stability Consultants, Lethbridge, Canada*

Mohammad N Alhamad

*Jordan University of Science and Technology, Irbid,  
Jordan*

Inteaz Alli

*Department of Food Science and Agricultural Chemistry,  
McGill University, Ste-Anne-De-Bellevue, QC, Canada*

Muhammad H Alu'datt

*Department of Food Science and Agricultural Chemistry,  
McGill University, Ste-Anne-De-Bellevue, QC, Canada;  
School of Human Nutrition, McGill University, Ste-  
Anne-De-Bellevue, QC, Canada; and Jordan University  
of Science and Technology, Irbid, Jordan*

Rafael F Alves

*University of Campinas – (Unicamp), Campinas,  
Brazil*

# CONTENTS OF ALL VOLUMES

---

## VOLUME 1

Acids and Bases in Food <i>Iris J Joye</i>	1
Anthocyanins <i>Celestino Santos-Buelga and Ana M González-Paramás</i>	10
Aromas <i>Keith R Cadwallader</i>	22
Artificial Sweeteners <i>Runu Chakraborty and Arpita Das</i>	30
Betalains <i>Delia B Rodriguez-Amaya</i>	35
Carotenoids <i>Luxsika Ngamwonglumlert and Sakamon Devahastin</i>	40
Clarifying Agents <i>Harsh P Sharma, Aditya Madan, and D C Joshi</i>	53
Dietary Fiber (Psyllium, $\beta$ -Glucan) <i>Lilian E Figueroa and Marina Dello Staffolo</i>	61
Diglycerides <i>Reed A Nicholson and Alejandro G Marangoni</i>	70
Egg Proteins <i>Snigdha Guha, Kaustav Majumder, and Yoshinori Mine</i>	74
Enzyme Applications in Food Processing: Traditional Uses to New Developments <i>Takuji Tanaka</i>	85
Encyclopedia of Food Chemistry: Fat replacers <i>Michael A Rogers</i>	96
Flavor Enhancers and Modifiers <i>Nicole J Gaudette</i>	101

Flavors (Bittering Agents, Astringent Flavors, Pungency, Menthol) <i>Paul Hughes</i>	104
Galactomannans (Guar, Locust Bean, Fenugreek, Tara) <i>Vassilis Kontogiorgos</i>	109
Gases and Vapors Used in Food <i>Loong-Tak Lim</i>	114
Gelatin <i>Soottawat Benjakul and Phanat Kittiphattanabawon</i>	121
Hardstock Triglycerides <i>Dongming Tang</i>	128
Medium Chain Triacylglycerides <i>Fernanda Peyronel</i>	132
Milk Proteins <i>Ryan Hazlett, Christiane Schmidmeier, and James A O'Mahony</i>	138
Bioavailability of Minerals (Ca, Mg, Zn, K, Mn, Se) in Food Products <i>Mitra Nosratpour and Seid Mahdi Jafari</i>	148
Monoglycerides: Categories, Structures, Properties, Preparations, and Applications in the Food Industry <i>Song Miao and Duanquan Lin</i>	155
Muscle Proteins <i>Mike Boland, Lovedeep Kaur, Feng Ming Chian, and Thierry Astruc</i>	164
Natural Antioxidants in Foods <i>Bingcan Chen and Minwei Xu</i>	180
Natural Sweeteners <i>Jean-Baptiste Chéron, Axel Marchal, and Sébastien Fiorucci</i>	189
Nitrates <i>Gayatri Suresh, Weihui Xiong, Tarek Rouissi, and Satinder Kaur Brar</i>	196
Oligosaccharides: Structure, Function and Application <i>Yan Wang, Qingbin Guo, H Douglas Goff, and Gisèle LaPointe</i>	202
Pectin in Foods <i>Randall G Cameron</i>	208
Phospholipids <i>Meizhen Xie</i>	214
Phosphates <i>Gary A Dykes, Ranil Coorey, Joshua T Ravensdale, and Amreeta Sarjit</i>	218
Phytosterols <i>Arjen Bot</i>	225
Plant Protein Ingredients <i>Andrea K Stone, Yun Wang, Mehmet Tulbek, and Michael T Nickerson</i>	229
Salts and Salt Replacers <i>Elena S Inguglia, Joseph P Kerry, Catherine M Burgess, and Brijesh K Tiwari</i>	235

Seaweed Polysaccharides (Agar, Alginate Carrageenan) <i>Katerina Alba and Vassilis Kontogiorgos</i>	240
Sequestrants as a Food Ingredient <i>Benjamin M Bohrer</i>	251
Starch <i>Iris J Joye</i>	256
Sugar Alcohols <i>Małgorzata Grembecka</i>	265
Surfactants <i>Natalie Ng and Michael A Rogers</i>	276
Artificial Antioxidants <i>João C M Barreira and Isabel C F R Ferreira</i>	283
Synthetic Food Colors <i>Maria G Corradini</i>	291
Encyclopedia of Food Chemistry: Water <i>Peter Chen and Michael A Rogers</i>	297
Water-Soluble Vitamins <i>Hannah Pinchen and Paul Finglas</i>	305
Waxes <i>Yaqi Lan</i>	312
Introduction to the Volume: Food Adulteration & Contamination <i>Richard H Stadler</i>	317
New Breeding Techniques: Detection and Identification of the Techniques and Derived Products <i>Yves Bertheau</i>	320
Biogenic Amines in Food: A Review of Factors Affecting Their Formation <i>G Tabanelli, C Montanari, and F Gardini</i>	337
Plant Alkaloids <i>Birgit Dusemund, Bernd Schaefer, and Alfonso Lampen</i>	344
Pyrrolizidine Alkaloids: Analytical Challenges <i>Oliver Keuth, Hans-Ulrich Humpf, and Peter Fürst</i>	348
Big Data Applications in Food Safety and Quality <i>Stephanie Pollard, Hossein Namazi, and Ramin Khaksar</i>	356
Omics Methods For the Detection of Foodborne Pathogens <i>David I Ellis, Howbeer Muhamadali, Malama Chisanga, and Royston Goodacre</i>	364
New Analytical Frontiers in Mycotoxin Research <i>Laura Righetti and Chiara Dall'Asta</i>	371
Next-Generation Sequencing <i>Martin Wiedmann and Laura M Carroll</i>	376
Dioxins and Dioxin-like PCBs in Feed and Food <i>Peter Fürst</i>	384

Modified Mycotoxins: A New Challenge? <i>H -U Humpf, Michael Rychlik, and Benedikt Cramer</i>	393
Mycotoxins in Food and Feed: An Overview <i>Joerg Stroka and Carlos Gonçalves</i>	401
Occurrence & Risk of OTA in Food and Feed <i>Vita Di Stefano</i>	420
Occurrence & Risk of Aflatoxins in Food and Feed <i>Martien C Spanjer</i>	424
Pesticide MRLs and Impact on Global Trade <i>Marina Rusch, Gordon Cameron, and Karsten Hohgardt</i>	428
Pesticides: An Update on Mass Spectrometry Approaches <i>Jon W Wong, Jian Wang, Kai Zhang, Douglas G Hayward, Paul Yang, and James B Wittenberg</i>	433
Pesticides: Evaluation Process in the EU <i>Claudia Heppner</i>	449
Polycyclic Aromatic Hydrocarbons in Food and Feed <i>Thomas Wenzl and Zuzana Zelinkova</i>	455
Veterinary Drugs: Progress in Multiresidue Technique <i>Patricia Regal, Alexandre Lamas, Carlos M. Franco, and Alberto Cepeda</i>	470
Endocrine Disrupters: A Review <i>Alberto Mantovani</i>	481
Acrylamide: US FDA Guidance to Industry <i>Lauren Posnick Robin and Eileen Abt</i>	487
Acrylamide: An Overview of the Chemistry and Occurrence in Foods <i>Aytül Hamzahoğlu, Burçe Ataç Mogol, and Vural Gökmen</i>	492
Dietary Acrylamide: An Update on the Chronic Risks <i>Janneke Hogervorst</i>	500
Advanced Glycation End Products (AGEs): Occurrence and Risk Assessment <i>Michael Hellwig and Thomas Henle</i>	525
Furan and Alkylfurans: Occurrence and Risk Assessment <i>Gabriele Scholz and Richard H Stadler</i>	532
Processing Contaminants: Furfuryl Alcohol <i>Alex O Okaru and Dirk W Lachenmeier</i>	543
Heterocyclic Aromatic Amines: An Update on the Science <i>Medjda Bellamri and Robert J Turesky</i>	550
Managing Acrylamide at the Agricultural Stage: Variety Selection, Crop Management, and the Prospects for Solving the Acrylamide Problem Through Plant Breeding and Biotechnology <i>Nigel G Halford</i>	559
MCPD Esters and Glycidyl Esters: A Review of Analytical Methods <i>Shaun MacMahon</i>	569
MCPDE and GE: An Update on Mitigation Measures <i>Zsolt Kemeny, Krish Bhaggan, Falk Brüse, Adina Creanga, Rob Diks, Luisa Gambelli, Yves Le Bail-Collet, and Daniel Ribera</i>	578

Mineral Oils in Food: An Update <i>Koni Grob and Maurus Biedermann</i>	588
N-Nitroso Compounds in Foods <i>Michael Habermeyer and Gerhard Eisenbrand</i>	593
Migration From Food Contact Materials <i>Gregor McCombie and Maurus Biedermann</i>	603
Process Contaminants: A Review <i>Michael Murkovic, Franco Pedreschi, and Zuzana Ciesarová</i>	609
Food Allergens: A Regulatory/Labelling Overview Including the VITAL Approach <i>Carmen Diaz-Amigo and Bert Popping</i>	615
Food Allergens: An Update on Analytical Methods <i>Michael J Walker</i>	622
Food Allergens: Seafood, Tree Nuts, Peanuts <i>Marie-Claude Robert</i>	640
Food Counterfeiting: A Growing Concern <i>John Spink</i>	648
Food Defense <i>Andrew G Huff</i>	652
Food Fraud and Adulteration: Where We Stand Today <i>John Spink</i>	657
Food Fraud and Vulnerability Assessments <i>Saskia M van Ruth</i>	663
Food Fraud Vulnerabilities in the Supply Chain: An Industry Perspective <i>Christophe Cavin, Geoffrey Cottenet, Christophe Fuerer, Lien-Anh Tran, and Pascal Zbinden</i>	670
Food Chemistry and Analysis for the Purpose of Kosher and Halal <i>Joe M Regenstein</i>	679
Modern Concepts in Chemical Risk Assessment <i>Dieter Schrenk</i>	685
Emerging Food Safety Risks <i>Farai Maphosa</i>	690
Managing Chemical Hazards in HACCP <i>Jantra Daolert</i>	699
The Legislative Landscape in the EU: Challenges Faced by the Food Industry <i>Andrew Curtis</i>	709
Biocides: A Critical Review of Current and Proposed EU Legislation <i>Heiko Faubel</i>	715

## VOLUME 2

Antioxidant and Flavor in Spices Used in the Preparation of Chinese Dishes <i>Yan Ping Chen and Hau Yin Chung</i>	1
--	---

Anthocyanins in Food	10
<i>Xiaonan Sui, Yan Zhang, Lianzhou Jiang, and Weibiao Zhou</i>	
Caramelization in Foods: A Food Quality and Safety Perspective	18
<i>Tolgahan Kocadağlı and Vural Gökmen</i>	
Carbohydrate Active Enzymes Applied in the Production of Functional Oligosaccharides	30
<i>Fabiano Jares Contesini, Evandro A de Lima, Fernanda Mandelli, Gustavo P Borin, Rafael F Alves, and César Rafael F Terrasan</i>	
Chemically Reducing Properties of Maillard Reaction Intermediates	35
<i>George P Rizzi</i>	
Protein Oxidation	41
<i>Leticia Mora, Marta Gallego, M-Concepción Aristoy, and Fidel Toldrá</i>	
Coffee Flavor	48
<i>Adane Tilahun Getachew and Byung-Soo Chun</i>	
Configuring Phenolic Antioxidants for Frying Applications	54
<i>Felix Aladedunye and Eliza Gruczynska</i>	
Milk Protein Interactions	63
<i>Anant Chandrakant Dave and Harjinder Singh</i>	
Effect of Heat on Food Properties	70
<i>Rana Muhammad Aadil, Ume Roobab, Abid Aslam Maan, and Ghulam Muhammad Madni</i>	
Effect of Emerging Processing Technologies on Maillard Reactions	76
<i>Mohamed Koubaa, Shahin Roohinejad, Tanyaradzwa E Mungure, Bekhit Alaa El-Din, Ralf Greiner, and Kumar Mallikarjunan</i>	
Effect of Storage on Fruit Bioactives	83
<i>Rana Muhammad Aadil, Ume Roobab, Muhammad Kashif Iqbal Khan, and Ubaid Ur Rahman</i>	
Enzymatic Production of Antioxidants and Their Applications	92
<i>Taiwo O Akanbi and Colin J Barrow</i>	
Factors Influencing Red Wine Color From the Grape to the Glass	97
<i>Jacqui M McRae, Bo Teng, and Keren Bindon</i>	
Fermentation of Grains	107
<i>Isam A Mohamed Ahmed, Fahad Y Al-Juhaimi, and Alaa El-Din Ahmed Bekhit</i>	
Fruit Pigment Changes During Ripening	117
<i>Wee Sim Choo</i>	
$\alpha$ -Galactosidase and Its Applications in Food Processing	124
<i>Lu-Kwang Ju, Abdullah A Loman, and S M Mahfuzul Islam</i>	
Influence of Food Processing Operations on Vitamins	129
<i>Merve Tomas and Seid Mahdi Jafari</i>	
Microbial Xylanases in Bread Making	140
<i>Seema Dahiya and Bijender Singh</i>	
Lipases for Biofuel Production	150
<i>Oseweuba Valentine Okoro, Zhifa Sun, and John Birch</i>	
Lipase/Esterase: Properties and Industrial Applications	158
<i>Oi-Ming Lai, Yee-Ying Lee, Eng-Tong Phuah, and Casimir C Akoh</i>	

Holistic Control of Fats and Oils by NMR Spectroscopy <i>Elina Zailer</i>	168
Lipid-Derived Flavours and Off-Flavours in Food <i>Fereidoon Shahidi and Abreham Abad</i>	182
Lipophilized Antioxidants <i>Maria Cruz Figueroa-Espinoza, Claire Bourlieu, Erwann Durand, Jérôme Lecomte, and Pierre Villeneuve</i>	193
Meat Color: Factors Affecting Color Stability <i>Alaa El-Din Ahmed Bekhit, James D Morton, Zuhaib Fayaz Bhat, and Lingming Kong</i>	202
Meat Colour: Chemistry and Measurement Systems <i>Alaa El-Din Ahmed Bekhit, James David Morton, Zuhaib Fayaz Bhat, and Xu Zequan</i>	211
Homeostasis of Plasmalogens in Mammals <i>Masanori Honsho and Yukio Fujiki</i>	218
Biochemical Reactions During Fresh Meat Storage <i>José A Beltrán, Pedro Roncalés, and Marc Bellés</i>	224
Nonenzymatic Browning Reactions: Overview <i>Yuliya Hrynets, Abhishek Bhattacharjee, and Mirko Betti</i>	233
Pulsed Electric Fields Processing of Plant-Based Foods: An Overview <i>Sze Ying Leong and Indrawati Oey</i>	245
Oleogels in Food <i>Kristin D Mattice and Alejandro G Marangoni</i>	255
Oxidative Rancidity <i>Charlotte Jacobsen</i>	261
Pectic Enzymes <i>Jin-lan Xia and Pei-jun Li</i>	270
Phospholipases <i>Angeliki Bourtsala and Dia Galanopoulou</i>	277
Polyphenoloxidase in Fruit and Vegetables: Inactivation by Thermal and Non-thermal Processes <i>Filipa Vinagre Marques Silva and Alifdalino Sulaiman</i>	287
Processing Effects on Meat Flavor <i>Siripong Kanokruangrong, John Birch, and Alaa El-Din Ahmed Bekhit</i>	302
Proteases and Meat Tenderization <i>James David Morton, Zuhaib Fayaz Bhat, and Alaa El-Din Ahmed Bekhit</i>	309
Proteases as Digestive Aids <i>Utpal Bose, Crispin A Howitt, and Michelle L Colgrave</i>	314
Protection of Enzymes Against Thermal Degradation <i>Rosalía García-Torres, José I Reyes-De-Corcuera, and Daoyuan Yang</i>	322
Stabilization of Carotenoids in Foods <i>Amna Sahar, Ubaid Ur Rahman, Rana Muhammad Aadil, and Anum Ishaq</i>	330
The Role of Bioinformatics in the Discovery of Bioactive Peptides <i>Dominic Agyei, Erandi Bambarandage, and Chibuike C Udenigwe</i>	337

Thermal Analysis for Lipid Decomposition by DSC and TGA <i>Tengku Mohamad Tengku-Rozaina and Edward John Birch</i>	345
Pyrazines in Thermally Treated Foods <i>Javier García-Lomillo and Maria L González-SanJosé</i>	353
Formation of Selected Heterocyclic Flavor Chemicals in Beverages <i>Takayuki Shibamoto</i>	363
Xanthine Oxidase in Dairy Foods <i>Ali Rashidinejad and John Birch</i>	374
Bioactive Peptides <i>Leticia Mora, M-Concepción Aristoy, and Fidel Toldrá</i>	381
Resistant Starch Preparation Methods <i>Amir Amini Khoozani, John Birch, and Alaa El-Din Ahmed Bekhit</i>	390
Interactions of Milk Proteins With Minerals <i>Keegan Burrow, Wayne Young, Alan Carne, Michelle McConnell, and Alaa El-Din Bekhit</i>	395
Protein-Stabilised Emulsions <i>Chia Chun Loi, Graham T Eyres, and E John Birch</i>	404
Application of HPLC in characterisation of Triacylglycerols and Detection of Adulteration in Cold Pressed Seed Oils <i>Tanyaradzwa E Mungure, Alaa El-Din Bekhit, Alan Carne, Shahin Roohinejad, Kumar Mallikarjunan, and John Birch</i>	410
Enzyme Immobilization for Oligosaccharide Production <i>César R F Terrasan, Wilson G de Moraes Junior, and Fabiano J Contesini</i>	415
Interactions of Macromolecules: $\beta$ -Lactoglobulin Interaction With Pectins <i>Laurence D Melton, Amy Y Xu, Martin A K Williams, and Duncan J McGillivray</i>	424
Milk Protein–Polysaccharide Interactions in Food Systems <i>Natasha Nayak and Harjinder Singh</i>	431
Interaction Between the Polysaccharides and Proteins in Semisolid Food Systems <i>Min Zhang, Chanchan Sun, and Qian Li</i>	439
Protein-Starch Interactions in Cereal Grains and Pulses <i>Jitendra Paliwal, Sandeep Thakur, and Chyngyz Erkinbaev</i>	446
The Use of Spin-Label ESR Spectroscopy to Study Protein-Lipid Interactions <i>Musti J Swamy</i>	453
Lipoprotein Lipase and Its Interactions With Phospholipids <i>Yonghua Wang and Dongxiao Sun-Waterhouse</i>	462
Reactivity of Lipid Oxidation Products in Foods – Is Malondialdehyde a Reliable Marker? <i>Angelique Vandemoortele and Bruno De Meulenaer</i>	468
Protein-Lipid Interactions and the Formation of Edible Films and Coatings <i>Victor N Enujiugha and Ajibola M Oyinloye</i>	478
Protein Ingredients in Low- and Intermediate-Moisture Systems <i>Thom Huppertz</i>	483

Interactions Between Starch, Proteins and Lipids and the Formation of Ternary Complexes With Distinct Properties	487
<i>Shujun Wang, Mengge Zheng, and Chen Chao</i>	
O/W Emulsions Stabilized by Interactions Between Proteins and Polysaccharides	494
<i>Vânia Regina Nicoletti Telis</i>	
Changes in the Interactions Between Proteins and Other Macromolecules Induced by HPP	499
<i>Bian-Sheng Li and Biao-Shi Wang</i>	
Different Catalytic Activities of Microbial L-Glutaminases Against Bitter Amino Acid Phenylalanine in the Production of Kokumi $\gamma$ -Glutamyl Peptides	505
<i>Juan Yang, Dongxiao-Sun Waterhouse, and Chun Cui</i>	
Effect of the Structure of Tannins on Their Binding Site on a Human Salivary Proline-Rich Protein	510
<i>Francis Canon</i>	
Interactions Between Polyphenols and Macromolecules: Effect of Tannin Structure	515
<i>Carine Le Bourvellec and Catherine M G C Renard</i>	
A Molecular Thermodynamics Approach to Capture Non-specific Flavour–Macromolecule Interactions	522
<i>Seishi Shimizu, Steven Abbott, and Nobuyuki Matubayasi</i>	
Flavor Enhancement Induced by Taste–Odor Interactions	528
<i>Guowan Su, Dongxiao Sun-Waterhouse, Yaqi Zhao, Weiwei He, and Mouming Zhao</i>	
Encyclopedia of Food Chemistry: Protein–Phenol Interactions	532
<i>Fereidoon Shahidi and Ruchira Senadheera</i>	
Analysis of Flavonoid-Protein Interactions by Advanced Techniques	539
<i>JuDong Yeo and Fereidoon Shahidi</i>	
Covalent Interactions Between Proteins and Phenolic Compounds	544
<i>Sascha Rohn</i>	
Interactions Between Proteins and Polyphenols in Beer	550
<i>Haifeng Zhao and Dongxiao Sun-Waterhouse</i>	
Interactions Between Milk Proteins and Polyphenols in Model Systems or Complex Dairy Matrices	554
<i>Seda Yildirim-Elikoglu</i>	
Interactions of $\beta$ -Lactoglobulin With Small Molecules	560
<i>Lei-Wen Xiang, Laurence D Melton, and Ivanhoe K H Leung</i>	
Polyphenol-Protein Interactions and Changes in Functional Properties and Digestibility	566
<i>Tugba Ozdal, İpek Ekin Yalcinkaya, Gamze Toydemir, and Esra Capanoglu</i>	
The Potential Role of Polyphenol–Enzyme Interactions on Human Health	578
<i>Gordon J McDougall</i>	
Thermal Stability of Carotenoids– $\alpha$ -Lactalbumin Complex	583
<i>Iuliana Aprodu, Loredana Dumitraşcu, and Nicoleta Stănciuc</i>	
Component Segregation During Spray Drying of Milk Powder	589
<i>M Foerster, M W Woo, and C Selomulya</i>	
Impact of Antioxidants on Oxidized Proteins and Lipids in Processed Meat	600
<i>M Estévez and J M Lorenzo</i>	

Plant Antioxidant Extracts: Effect on Lipid or Protein Oxidation in Seafood Products <i>K H Sabeena Farvin and A Surendraraj</i>	609
Protein–Lipid–Phenolic Interactions During Soybean and Flaxseed Protein Isolation <i>Muhammad H Alu'datt, Taha Rababah, Mohammad N Alhamad, Majdi A Al-Mahasneh, Sana Gammoh, Mohammed Al-Duais, Carole C Tranchant, Stan Kubow, and Inteaz Alli</i>	621
Interactions Between Dietary Antioxidants and Plant Cell Walls <i>Catherine M G C Renard</i>	633
Interactions of Some Common Flavonoid Antioxidants <i>Dapeng Li, Dongxiao Sun-Waterhouse, Yongli Wang, Xuguang Qiao, Yilun Chen, and Feng Li</i>	644
Polyphenol Interactions and Food Organoleptic Properties <i>Susana Soares, Nuno Mateus, and Victor de Freitas</i>	650
Effects of Interactions Between Antioxidant Phytochemicals and Coexisting Food Components on Their Digestibility <i>Sukanya Thuengtung and Yukiharu Ogawa</i>	656
Bioactive Delivery Systems Based on Stimuli-Sensitive Biopolymer Stacks: Chitosan-Alginate Systems <i>Geoffrey I N Waterhouse and Dongxiao Sun-Waterhouse</i>	661
Interactions Between Food Ingredients and Nanocomponents Used for Composite Packaging <i>Adam Ekielski</i>	669
Use of Pectin to Formulate Antimicrobial Packaging <i>M M Gutierrez-Pacheco, L A Ortega-Ramirez, and J F Ayala-Zavala</i>	675
Effect of Three-Component Interactions Among Starch, Lipids and Proteins on the Glycemic Response <i>Javier Parada and Jose L Santos</i>	681
Encapsulation Systems Containing Multi-Nutrients/Bioactives: From Molecular Scale to Industrial Scale <i>Geoffrey I N Waterhouse and Dongxiao Sun-Waterhouse</i>	687
Nanoparticle-Based Encapsulation of Green Tea Polyphenols: An Approach to Enhance Their Bioavailability and Therapeutic Efficacy <i>Feng Li, Yongli Wang, Dapeng Li, Dongxiao Sun-Waterhouse, Yilun Chen, and Xuguang Qiao</i>	695
Food Soft Nano-Dispersions for Bioactive Delivery: General Concepts and Applications <i>Maria D Chatzidaki and Aristotelis Xenakis</i>	701
New Insights on Bio-Based Micro- and Nanosystems in Food <i>Daniel A Madalena, Ricardo N Pereira, António A Vicente, and Óscar L Ramos</i>	708
Oleogelation for Food Structuring Based on Synergistic Interactions Among Food Components <i>Ashok R Patel</i>	715
Protein-Based Nanodelivery Systems for Food Applications <i>Ogadimma D Okagu, Bo Wang, Caleb Acquah, and Chibuike C Udenigwe</i>	719
Edible Delivery Systems Based on Favorable Interactions for Encapsulation of Phytochemicals <i>Jie Xiao, Wenbo Wang, Qingrong Huang, and Yunqi Li</i>	727
Fabrication of Electrospun and Electrosprayed Carriers for the Delivery of Bioactive Food Ingredients <i>Alex López-Córdoba, Jose Maria Lagarón, and Silvia Goyanes</i>	733

**VOLUME 3**

Fruit and Vegetable Texture: Role of Their Cell Walls <i>José A Mercado, Antonio J Matas, and Sara Posé</i>	1
Atomic Force Microscopy (AFM) and X-Ray Micro-Computed Tomography (Micro-CT): Applications in Cell Wall Imaging of Softening Fruit <i>Jovyn K T Frost and Roswitha Schröder</i>	8
Legume Microstructure <i>Duc Toan Do and Jaspreet Singh</i>	15
Meat Structure During Processing <i>Hanne Christine Bertram</i>	22
The Structure and Properties of Eggs <i>Danaé S Larsen</i>	27
Crustacean By-products <i>Fatih Özogul, Imen Hamed, Yesim Özogul, and Joe M Regenstein</i>	33
Microstructure of Dairy Fat Products <i>P R Ramel and A G Marangoni</i>	39
The Structure and Properties of Ice Cream and Frozen Desserts <i>H Douglas Goff</i>	47
The Structure and Rehydration Properties of Dairy Powders <i>Irina Boiarkina and Brent Young</i>	55
Structure and Properties of Chocolate <i>Monica H Caparosa and Richard W Hartel</i>	61
Traditional African Bread and the Physicochemical Properties of Unfermented Flatbreads <i>Geremew Bultosa</i>	66
Traditional African Bread: Physicochemical and Sensory Properties of Fermented Breads <i>Geremew Bultosa</i>	81
Indian Flatbreads: How Structure Influences Properties <i>Shabir Ahmad Mir and Manzoor Ahmad Shah</i>	90
Tofu and Soy Products: The Effect of Structure on Their Physicochemical Properties <i>Qing Zhang and Wen Qin</i>	96

## PREFACE

---

This is an exciting time for all who wish to understand the nature of food and how it changes during storage, processing, cooking and digestion. This is because science has turned its focus onto soft matter and food is very largely soft matter. Earlier scientific effort was preoccupied with simple molecules in solution and solids (preferably pure crystalline proteins). When you think about it, knowing the total protein, carbohydrate, lipid and vitamin contents of a food doesn't tell you much about the nature of the food and how it will provide nutrients for us. Now we are seeing a huge effort to understand soft matter, which is directly applicable to food. Meaning we are increasing our knowledge of how food components (both macromolecules such as proteins and polysaccharides as well as smaller molecules) interact chemically with each other; leading ultimately to understanding the complex chemical structure of foods (everything from apples and ice cream to vegetable protein meat-substitutes and food for a visit to Mars).

A golden age for food research has begun, with so many new techniques available such as CRISPR, isothermal calorimetry (ITC), analytical ultracentrifugation (AUC), small angle neutron and X-ray scattering (SANS, SAXS), surface plasmon resonance, electronic tweezers, and computer modelling (for example molecular dynamics simulations for understanding the interactions of proteins and polysaccharides, enzymes and substrates, bioactives and encapsulating agents). This is in addition to the tried and tested techniques of nuclear magnetic resonance (NMR), mass spectroscopy, electron and confocal microscopy, high performance liquid chromatography (HPLC), and gas chromatography. Biosensors publications are huge and nanotechnology is a hot topic for research.

The *Encyclopedia of Food Chemistry* is for people who have a basic knowledge of food chemistry and wish to expand their understanding of a topic based on information from a reliable source. No fake news here! We welcome you to enjoy the excitement captured here by experts from across the planet.

# Antioxidant and Flavor in Spices Used in the Preparation of Chinese Dishes

Yan Ping Chen and Hau Yin Chung, Food and Nutritional Sciences Programme, School of Life Sciences, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong SAR, China

## Introduction

China has a long history of using spices to prepare dishes. Due to their strong and distinctive flavor and aroma in the fresh or dried state, they are used to mask or minimize the undesirable flavor, such as the bloody or raw flavor in the chicken, beef or other meats in the traditional Chinese cuisine (Lu et al., 2011). Some spices are native to China, such as the Sichuan Green pricklyash (Yang, 2008), while others are originally grown in the southern Asian countries such as India, Indonesia, Thailand, etc., but are now cultivated in China, such as the black pepper and cinnamon (Chomchalow, 2001).

Lipid is a major constituent in many commodities, such as in the meat of cattle, sea foods, and bakery products. Lipid oxidation has always been a major concern in the long-term preservation in the food industry. Oxidation of lipids will result in the production of undesirable volatile compounds. Such compounds may induce cancer or other diseases (Niki, 2016), and affect consumers' preference towards a food (Font-i-Furnols and Guerrero, 2014). Antioxidants are substances, when are present in the food at very low concentrations, could delay, control or prevent oxidative processes leading to the deterioration in food quality (Barden and Decker, 2016). Many researchers have reported the anti-oxidative property in spices. In fact, some spices have been used in the food industry as natural additives to maintain the food quality, and to provide stable sensory profiles (Radha krishnan et al., 2014). In this manuscript, we summarized some spices with focuses on their anti-oxidative property, their flavor descriptors and their applications in the food industry.

## Anti-oxidative Properties of Spices

### Mechanism of the Anti-oxidative Property in Spices

Antioxidants are broadly classified as primary and secondary ones. The primary antioxidants act as hydrogen donors or free radical acceptors, and generate more stable radicals (Nanditha and Prabhasankar, 2008). Spices as primary antioxidants (AH) could scavenge the peroxy and oxy radicals ( $RO_2\cdot$  and  $RO\cdot$ ) formed in the lipid propagation step to produce less active radicals ( $A\cdot$ ). These radicals ( $A\cdot$ ) will further react with each other or other radicals until they form stable molecules (ROOA and RA). In contrast to the peroxy and oxy radicals ( $RO_2\cdot$  and  $RO\cdot$ ), the less active radicals ( $A\cdot$ ) are not able to attract an H-atom from the unsaturated fatty acids (ROOH), thus, cannot initiate lipid peroxidation (Nanditha and Prabhasankar, 2008). Secondary antioxidants prevent or retard oxidation by suppressing the oxidation promoters, including metal ions, singlet oxygen, pro-oxidative enzymes and other oxidants (Barden and Decker, 2016). As secondary antioxidants, many spices act as chelating agents, binding to metal ions which act as catalysts for lipid oxidation.

### Chemical Assays for the Antioxidant Activity in Spices

The most commonly used assays to determine antioxidant activity in the food industry are chemical tests. Antioxidant activity can be monitored by a variety of assays which are grouped into four different methodologies as follows: 1) radical/ROS scavenging methods, such as ABTS/TEAC (Trolox equivalent antioxidant capacity) assay, and DPPH (2,2-diphenyl-1-picrylhydrazyl) assay; 2) non-radical redox potential-based methods, such as FRAP (ferric reducing antioxidant power) assay; 3) metal chelation capacity; and 4) total phenolic content (TPC) (Shahidi and Zhong, 2015). However, each type of assays has their limitations. For example, the results of ABTS/TEAC could be affected by their incubation times (Roginsky and Lissi, 2005), and the DPPH assay is only suitable for certain foods (Plank et al., 2012). Both TEAC and DPPH assays have been challenged for their lack in the biological relevance due to the use of artificial radical cation which is not found in food nor biological systems (Shahidi and Zhong, 2015). FRAP results might vary depending on the analysis time observed for the reaction between antioxidants and  $Fe^{3+}$  (Pulido et al., 2000). The total phenolic content assay is sensitive to changes in pH, temperature and reaction time, and the results could be overestimated by the non-phenolic reducing agents in the reaction system (Blasco et al., 2005). In Table 1, the anti-oxidative strengths of 19 commonly consumed spices in China were compared using ABTS, DPPH, FRAP, and total phenolic content assays. The results were similar to that of Risch and Ho's (1997) report in which spices are generally rich sources of antioxidants.

In Table 1, the anti-oxidant abilities determined by ABTS and FRAP ranged from 12.42 to 593.90  $\mu\text{mol TE g}^{-1}\text{ DW}$  and 37.80 to 771.00  $\mu\text{mol TE g}^{-1}\text{ DW}$ , respectively. The total phenolic content ranged from 3.53 to 58.25 mg GAE  $\text{g}^{-1}\text{ DW}$  among the spices (Table 1). The total phenolic content evaluates the anti-oxidant ability of phenolic content only, while ABTS and FRAP detect the ability of phenolic compounds in addition to other compounds such as flavonoids (Shahidi and Zhong, 2015). As a result, the anti-oxidant abilities of spices are different when different chemical assays are used, e.g. galangal and dried ginger using ABTS, DPPH, FRAP, and total phenolic content assays. Based on the results of ABTS, FRAP and total phenolic content assays, galangal had the highest strength among the 19 spices been tested (Table 1). However, its DPPH value was only 88.30%, much lower than

**Table 1** Comparison of anti-oxidant abilities among the 19 commonly consumed spices in China<sup>A, B</sup>

A, Values were expressed as means  $\pm$  standard deviation.

B, Values marked by the same low-case superscript letters (from 'a' to 'o') within a column denote statistically significant differences ( $P < 0.05$ ).

C, Data were expressed as  $\mu\text{mol}$  Trolox equivalent (TE) per 1 g dry weight (DW).

D, Data were expressed as mg gallic acid equivalent (GAE) per 1 g dry weight (DW).

Reproduced from Lu, M., Yuan, B., Zeng, M., Chen, J., 2011. Antioxidant capacity and major phenolic compounds of spices commonly consumed in China. Food Res. Int. 44, 530–536, with the permission from Elsevier.

that of Green prickleyash and Sichuan pepper which were 94.12% and 93.41%, respectively (Table 1). In Table 2, selected spices with their antioxidants commonly consumed in China were listed. Phenolic compounds and flavonoids are important antioxidants in spices, such as green prickleyash, Sichuan pepper, bay leaf, cinnamon, etc (Table 2). Most of the functional compounds could be found in the essential oils, such as in the clove and the cinnamon, which also contribute to the unique odor of the spices (Wei and Shibamoto, 2010).

The antioxidant abilities of different spices are affected by the differences in the chemical structures of the active components. For example, chemical structures of the pure ginger components (6-gingerol (6GE), 8-gingerol (8GE), 10-gingerol (10GE), and 6-shogaol (6SGE)) contain one hydroxyl group in their aromatic ring that contributes to their antioxidant properties (Fig. 1) (Pietta, 2000). The long hydrocarbon side chains present in the four compounds make them very soluble in oil, which in turn increases their ability to act as hydrophobic antioxidants (Fig. 1). However, their anti-oxidation abilities are not the same, which may be due to their differences in the hydrocarbon chain length (Fig. 2). In Figure 1, 6SGE contains a C=C double bond which is able to donate electrons easily and be oxidized. The side chain of 6GE contains a more polar hydroxyl group (–OH) which reduces its hydrophobicity as antioxidant in oil. Owing to the decrease in hydrophobicity, 6SGE has a higher anti-oxidant ability at 60 °C than that of 6GE in low fat foods (Fig. 2). The hydrophobicity increases with increasing length of the carbon side chain (Fig. 1), making 10GE more soluble in oil, and thus also a reasonably better hydrophobic antioxidant than that of 6GE (Fig. 2) (Si et al., 2018).

## Sensory Descriptors of Selected Spices Consumed in China

Sensory evaluation has been defined as a scientific method used to evoke, measure, analyze, and interpret those responses to products as perceived through the senses of sight, smell, touch, taste, and hearing (Stone and Sidel, 2004). Descriptors are a lexical language used in a sensory analysis to present sensation verbally by a subject when consuming food. When spices are served to panelists, different descriptors could be generated to profile them. Table 3 is an example of the sensory descriptors generated and used for the evaluation of the Chinese-style marinated chicken. To perform this evaluation, 25 consumers (ages between 20 and 30) were asked to rate the sensory properties of the products using six descriptors on color, texture, and flavor (Table 3) on the 10-cm line scales with increasing strength from left to right (Yusop et al., 2010).

In the Chinese cuisine, spices are often added to foods to mask the bloody or fishy flavor when preparing meat or fish dishes. Table 4 lists the odor descriptors in selected spices consumed in China. Ginger is a popular spice to increase the warm, spicy, and

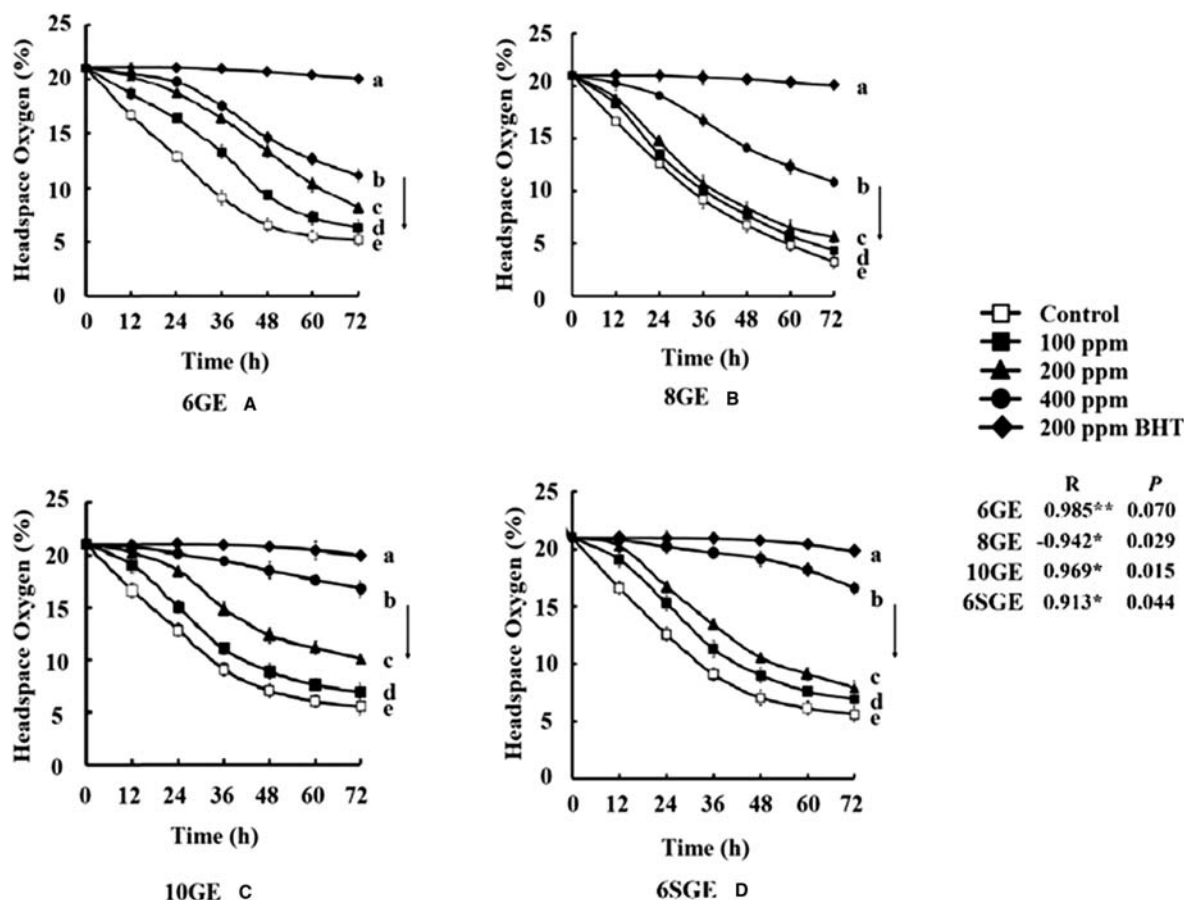

**Table 2** Antioxidant compounds in selected spices consumed in China

No.	Names	Anti-oxidant compounds
1	Galangal	Galangal (Lu et al., 2011)
2	Dried ginger	Gingerols, shogaols, zingerone (Embuscado, 2015)
3	Villous amomum fruit	Catechin and other flavonoids (Lu et al., 2011)
4	Tsaoko amomum fruit	Protocatechuic acid, and other phenolic acids; flavonoids (Lu et al., 2011)
5	Green prickleyash	Phenolic volatile oils (estragole, xanthoxylin), chlorogenic acid and other phenolic acids; quercetin, rutin and other flavonoids (Lu et al., 2011; Shan et al., 2005)
6	Sichuan pepper	Chlorogenic acid and other phenolic acids; rutin and other flavonoids (Lu et al., 2011)
7	Dried tangerine peel	Chlorogenic acid and other phenolic acids; rutin, naringin and other flavonoids (Lu et al., 2011)
8	Bay leaf	Phenolic acids; rutin, naringin and other flavonoids (Lu et al., 2011)
9	Cinnamon	Phenolic acids, phenolic volatile oil (2-hydroxycinnamaldehyde, cinnamyl aldehyde derivatives), flavan-3-ols (Shan et al., 2005)
10	Fennel	<i>trans</i> -Anethole, fenchone, estragole, limonene, camphene, $\alpha$ -pinene, fenchyl alcohol, anisaldehyde, myristicin, dillapiol (Lu et al., 2011; Hossain et al., 2008; Parthasarathy et al., 2008)
11	Cumin	Chlorogenic acid, ferulic acid and other phenolic acids; apigenin, luteolin, and other flavonoids (Lu et al., 2011)
12	Angelica dahurica root	Chlorogenic acid, caffeic acid, ferulic acid and other phenolic acids (Lu et al., 2011)
13	Nutmeg	Phenolic volatile oils, phenolic acid (caffeic acid, protocatechuic acid), rutin and other flavonoids, flavanols (Lu et al., 2011; Shan et al., 2005)
14	Star anise	Phenolic acids (protocatechuic acid), phenolic volatile oils (anethole), flavonoids (Shan et al., 2005)
15	Dried red chili pepper	Capsaicin, capsaicinol (Embuscado, 2015)
16	Mustard	Phenolic acids (Lu et al., 2011)
17	Black pepper	Volatile oils, phenolic amides, kaempferol, rhamnetin, quercetin (Embuscado, 2015; Shan et al., 2005)
18	White pepper	Volatile oils, phenolic amides (Shan et al., 2005)
19	Cloves	Phenolic acids (gallic acid), flavonol glucosides, phenolic volatile oils (eugenol, acetyl eugenol, isoeugenol), tannins (Embuscado, 2015; Shan et al., 2005)

**Figure 1** Structures of four constituents isolated from ginger: 6-gingerol (6GE), 8-gingerol (8GE), 10-gingerol (10GE), and 6-shogaol (6SGE). Reproduced from Si, W., Chen, Y.P., Zhang, J., Chen, Z.-Y., Chung, H.Y., 2018. Antioxidant activities of ginger extract and its constituents toward lipids. *Food Chem.* 239, 1117–1125, with the permission from Elsevier.

sweet flavors to food (Table 4), contributed by components such as  $\beta$ -sesquiphellandrene and (-)- $\alpha$ -curcumene,  $\alpha$ -Terpineol, citral  $\alpha$  and citral  $\beta$  and nerolidol  $\beta$  (Bednarczyk and Kramer, 1975). Huajiao is a very important ingredient in the preparation of the Chinese Sichuan cuisine. The most consumed species are the red huajiao (*bungeanum*) and the green huajiao (*schinifolium*) (Yang, 2008). Consumers could perceive the fresh, spicy, floral, cooling and green aroma in huajiao which contains a high content of essential oil (11%) in their raw state. In addition, most of them contribute distinctive tingling taste sensation (Table 4) (Yang,

**Figure 2** Percentage of headspace oxygen depletion determined for samples of canola oil containing 0, 100, 200, and 400 ppm of (A) 6-geringol (6GE), (B) 8-geringol (8GE), (C) 10-geringol (10GE), and (D) 6-shagaol (6SGE) and heated at 60 °C. **Table 3** Sensory terms used in the consumer evaluation of Chinese-style marinated chicken

Attribute	Description	
Color	Dark pink	0 = Light pink, 10 = dark pink
	Penetration	0 = No penetration, 10 = extreme penetration
Texture	Toughness	0 = Extremely tender, 10 = extremely tough
	Juiciness	0 = Extremely dry, 10 = extremely juicy
Flavor	Sourness	0 = Not sour, 10 = extremely sour
	Sweetness	0 = Not sweet, 10 = extremely sweet

Modified from Yusop, S.M., O'Sullivan, M.G., Kerry, J.F., Kerry, J.P., 2010. Effect of marinating time and low pH on marinade performance and sensory acceptability of poultry meat. *Meat Sci.* 85, 657–663, with the permission from Elsevier.

2008). Red chili pepper is another important ingredient in the Chinese Sichuan cuisine. Capsaicin (*trans*-8-methyl-N-vanillyl-6-nonenamide) is a major pungent ingredient in the chili pepper (Govindarajan and Salzer, 1986). The other sensorial feeling of chili pepper is contributed by flavor components such as 2,3-butanedione (caramel), 1-penten-3-one (pungent, spicy) and hexanal (grassy, herbal).

## Application in Food Industry

“Off-flavor” note in the rancid foods is perceived at very low threshold value which is contributed by the secondary oxidation products from lipid, including alcohols, aldehydes, ketones, hydrocarbons, volatile organic acids and epoxy compounds (Frankel, 1996; Kolakowska, 2003). Since concerns over the safety of the food additives have arisen in recent years, consumer demand for the use of

**Table 4** Odor descriptors in selected spices consumed in China

No.	Name	Odor descriptor
1	Galangal	Resembling ginger but with a distinct soapy overtone (Gautschi et al., 1999)
2	Dried ginger	Warm, spicy bite, a little bit sweet, not as strongly flavored as fresh ginger <sup>a</sup>
3	Villous amomum fruit	Pungent, warm <sup>b</sup>
4	Tsaoko amomum fruit	Specially fragrant, pungent, slight bitter <sup>c</sup>
5	Sichuan Huajiao	fresh, spicy, floral, cooling, and green aroma notes, distinctive tingling taste (Yang, 2008)
6	Dried tangerine peel	Sweet, fruity, incense, mellow
7	Bay leaf	Fresh green, eucalyptus, flowery, clove, black pepper (Kilic et al., 2004)
8	Cinnamon	Bark oil: A delicate aroma along with a sweet, pungent taste (Barceloux, 2009) Leaf oil: a warm, spicy and somewhat harsh odor that lacks the smooth consistency of bark oil (Barceloux, 2009)
9	Fennel	Metallic, anise-like, eucalyptus-like, almond-like, fir tree-like, moldy, geranium-like, citrus-like, vanilla-like, seasoning-like (Zeller and Rychlik, 2006)
10	Cumin	Seed oil: cumin, fatty, sweaty, pepper <sup>d</sup>
11	Angelica dahurica root	Acrid, warm, and with ascending and dispersing aroma in nature <sup>e</sup>
12	Nutmeg	Oil: sweet, woody, nutmeg, spicy with a slight terpy nuance <sup>d</sup>
13	Dried Red Chili Pepper	Caramel, pungent, spicy, grassy, herbal, fruity, sweet, almond (Junior et al., 2012)
14	Black pepper	Pine-like, warm-pepper (woody), pine-like(woody), warm-resinous, camphoraceous, then citrusy, floral-woody(citrusy), lilac-like (floral), spicy (clove-like), floral, woody-spicy, resinous, woody, floral, woody-floral (Pino et al., 1990)
15	White pepper	Fecal, swine-manure, horse-like, phenolic, cheese-like (Jagella and Grosch, 1999)
16	Cloves	Bud oil: sweet, woody, eugenol, spicy, medicinal, fresh and slightly balsamic with a nice bite <sup>d</sup>
17	Sesame seeds	Oil: popcorn-like, pungent, sweet, oily, solvent, peanut-like, burnt, aldehydic, spicy, anise-like, green (Shimoda et al., 1996)

natural products as alternative preservatives in particularly fatty foods has increased (Govarís et al., 2010). Spices have been reported to contribute significantly to the stabilization of food color, aroma, and texture (Jinap et al., 2015; Yusop et al., 2010). In the presence of spices, oxidation of fats/oils and lipid-containing foods is prevented by excluding the initiator and promoter elements which promoted the lipid oxidation during processing and refrigerated storage (Barden and Decker, 2016). The application of spices in the meat industry could be very desirable. In fact, one of the common practices is to marinate meat with spices to extend its shelf life (Radha krishnan et al., 2014). Meat marinating with spices is not only popular in Asian countries, such as Malaysia and Singapore (Jinap et al., 2015), but also in Europe (Leatherhead Food International, 2007). China was the world's largest producer of meat in 2009 (28% of the world's total production), its meat products including both Chinese style (45%) and western style (55%) ones, but the value-added and enhanced products had a low market share (Zhou et al., 2012). Marination is a traditional Chinese meat-processing method with a long history (Li et al., 2016). In order to offer healthier and more flavored products, the combination of modern meat industrial technologies and spices is needed (Li et al., 2016).

Owing to the large variety and the amount of components in the essential oil of spices, components such as phenolic acids can not only inhibit lipid oxidation but control foodborne pathogens at the same time (Risch and Ho, 1997). Spices could slow down rancidity and provide flavor (Dwivedi et al., 2006), leading to the retardation of spoilage and the extension of shelf-life, thus, maintaining the desirable quality and safety of food (Devatkal and Naveena, 2010). For example, Chinese 5-Spices often used in the preparation of ground beef can be used to extend the shelf-life of meat-based products for both shopkeepers and consumers (Dwivedi et al., 2006). The rancid odor and flavor from the spices-treated cooked ground beef were found to be significantly lower after 15-day storage at 2 °C when compared to that of the control (Dwivedi et al., 2006). The addition of spice extracts (*Syzygium aromaticum*, *Cinnamomum cassia*, *Origanum vulgare*, *Brassica nigra*, and their mixtures) effectively maintained or improved sensory attributes and extended the shelf-life of raw chicken meat during refrigerated storage (Table 5) (Radha krishnan et al., 2014). Sensory evaluation from experienced judges concluded that no significant differences in the sensory scores on the attributes between the chicken meats treated with and without spice extracts in the first 3 days of storage (Table 5). But the sensory scores of the control samples (positive control with 0.02% BHT; and negative control with no extract) started to decline after 3 days of storage, but not for the spice extract-treated samples (Table 5). The poor sensory scores in the control samples were due to the off-odor generated from lipid oxidation and protein degradation (Radha krishnan et al., 2014).

Both marination time and pH affect sensory properties of spices marinated meat (Yusop et al., 2010). In Table 6, Chinese-style marinated chicken was subjected to different marination times (30, 60, 120 and 180 min) and acidity (pH 3.0, 3.2, 3.4, 3.6, 3.8, 4.0 and 4.2), the sensory attributes (dark pink, color penetration, toughness, sourness, sweetness and juiciness) of the cooked products were evaluated. Results showed that all attributes were significantly ( $P < 0.05$ ) affected by marination time (Table 6). Dark pink color increased when marination time was extended. Samples marinated for 120 min received a consistently higher score in every

a-d With different letters in columns are significantly different ( $P < 0.05$ ).Modified from Yusop, S.M., O'Sullivan, M.G., Kerry, J.F., Kerry, J.P., 2010. Effect of marinating time and low pH on marinade performance and sensory acceptability of poultry meat. *Meat Sci.* 85, 657–663, with the permission from Elsevier.

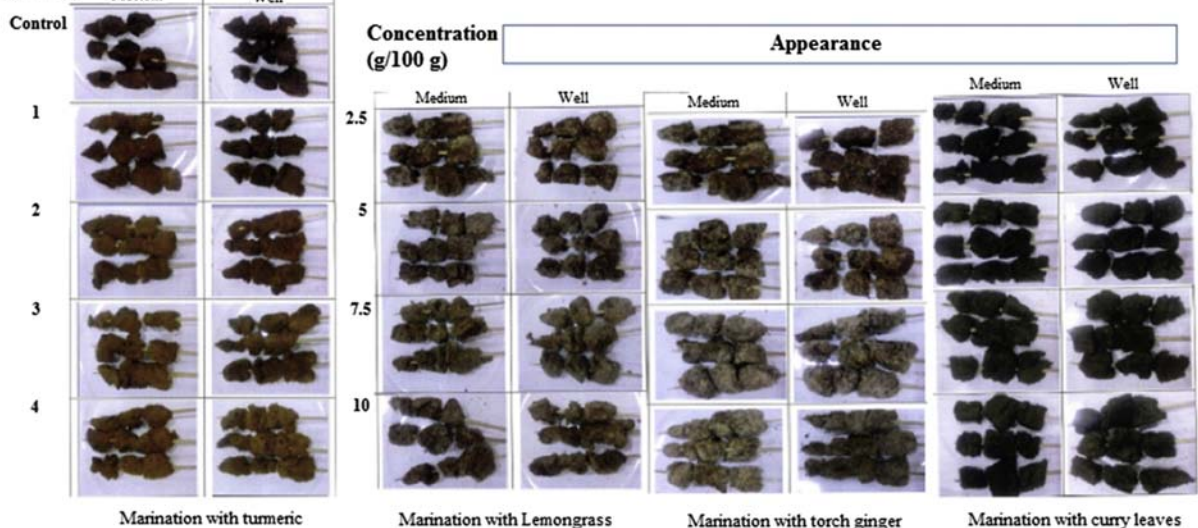

sensory attribute measured than other samples (Table 6). Sourness and sweetness were not found to be significantly affected by the marinade pHs. But the intensity of juiciness decreased significantly when marinade pH increased from 3.0 to 4.2 (Table 6).

Heterocyclic aromatic amines (HAs) are important mutagens/carcinogens generated during the cooking of meat at high temperature (Jägerstad and Skog, 2005), which also increase the risk of cancer (Zheng and Lee, 2009). However, they could be reduced by marinating the meat with spices (Jinap et al., 2015; Viegas et al., 2012). For example, Viegas et al. (2012) reported the inhibitory effect of antioxidant-rich meat flavoring (garlic, ginger, thyme, rosemary, and red chili pepper) reduced 90% HAs formed in the pan-fried beef. After 4-h marination, all beef samples had good overall quality even though only the surface was treated (Viegas et al., 2012). Fig. 3 shows the observed results on the color intensity of grilled meat previously marinated with selected spices (turmeric) at the concentrations of 1, 2, 3, and 4 g/100 g and curry leaves, torch ginger, and Lemongrass at the concentrations of 2.5, 5, 7.5, and 10 g/100 g. Browning of cooked meat suggested the formation of chemical complexes from the Maillard reaction (Jinap et al.,

#### A Concentration (g/100 g) Appearance

#### B Concentration (g/100 g) Appearance

**Figure 3** (A): The effect of different concentrations of selected spices i.e. turmeric, curry leaves, torch ginger and lemon grass on meat. (B): The effect of different concentrations of selected spices i.e. turmeric, lemon grass, torch ginger and curry leaves on satay. Reproduced from Jinap, S., Iqbal, S.Z., Selvam, R.M., 2015. Effect of selected local spices marinades on the reduction of heterocyclic amines in grilled beef (satay). LWT Food Sci. Technol. 63, 919–926 with the permission from Elsevier.

2015). All medium-heat cooked meats (controls), as well as the lemongrass- and torch ginger-treated ones showed less browning than that of the well-cooked meats (Fig. 3). Apparently, marinating meats with spices reduced their browning while samples without marination had more browning (Smith et al., 2008).

## Conclusions

Spices used in the preparation of Chinese dishes are rich sources of antioxidant and flavor making them good alternative source of food preservative and flavoring. Chemical assays are often used to determine the strength of antioxidants in spices. The antioxidant abilities of different spices are affected by the content of their phenolic, flavonoids and other compounds, as well as by the different chemical structures of the active components. Since spices possess both antioxidant and unique flavor, their application, particularly in the meat products, is more desirable.

### Chemical Structure of Anthocyanins

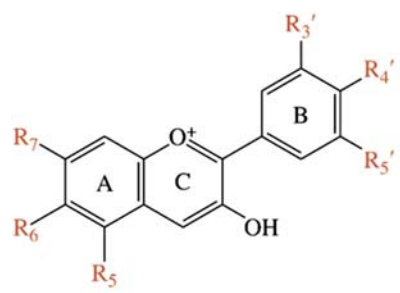

Being known for centuries as “coloured cell sap”, anthocyanins were named for the first time in 1835 by German botanist Ludwig Marquart from the Greek words of *anthos* (means flower) and *kyanos* (means blue) (Boldt et al., 2014). Anthocyanins are among the most important part of substances known as flavonoids, which are bioactive water-soluble plant pigments. They are widely extracted from flowers (e.g. peony, morning glory and geranium), vegetables (e.g. radish, curly kale, eggplant), and fruits (e.g. grapes, blueberries, cherries) where they are responsible for bright colours including red, blue, purple, and many more (Chung et al., 2015; Fernandes et al., 2013; Wiczowski et al., 2014).

Anthocyanins exist in plants in the form of glycosides predominantly, and the basic structure of anthocyanins contains an anthocyanidin core that is attached with sundry sugars and organic acids in the case of acylated anthocyanins. Anthocyanin core, also called anthocyanidin, consists of two benzoyl rings (A ring and B ring) and a heterocyclic ring (C ring), presenting a C6—C3—C6 basic skeleton with a total of 15 carbons (Fig. 1). To date, over seven-hundred anthocyanins have been identified from various plants; however, there are about twenty-three anthocyanidins (Andersen and Jordheim, 2014). According to the different numbers and positions of hydroxyl and methoxyl groups in the A and B rings, there are some selected anthocyanidins that are distinguished and valued by specialists (Fig. 1) (Cavalcanti et al., 2011; Chung et al., 2015; Tsuda, 2012).

An anthocyanidin can yield different types of anthocyanins through glycosylating or acylating different sugar moieties and phenolic or aliphatic acids (Bueno et al., 2012b). The most common glycoside derivatives found in nature are 3-monosides, 3-bisides, 3,5-, and 3,7-diglucosides (Kong et al., 2003). Cyanidin glycoside is the most predominant anthocyanin discovered in many fruits and vegetables (Boldt et al., 2014). The distribution of anthocyanins in some fruits is shown in Table 1 (Patras et al., 2010). Some common types of glucosides with different molecular weight (MW) for anthocyanins are pentoside moiety (MW: 132 Da), rhamnoside moiety (146 Da), glucoside moiety (162 Da), rutinoid moiety (rhamnose + glucose, 308 Da), neohesperidoside moiety (308 Da), sophoroside moiety (324 Da), glucosylrutinoside moiety (rhamnose + glucose + glucose, 470 Da), acetylglucoside moiety (204 Da), acetylrutinoside moiety (350 Da), and coumaroylglucoside moiety (308 Da).

### Function of Anthocyanins

Anthocyanins are known as natural antioxidants due to their ability to donate protons to highly reactive free radicals (Sadilova et al., 2007). In plants, anthocyanins are considered to act as photoprotectants preventing plants from the free radicals that are formed during photosynthesis (Hiemori et al., 2009). The antioxidant activity of anthocyanins is conferred by their chemical structure: the number and organisation of phenyl groups, the availability of electron-donating and electron-withdrawing groups in the ring structure, the degree of structural conjugation and the positive charge of anthocyanins (Castañeda-Ovando et al., 2009). Anthocyanins are reported to prevent further radical generation and protect cells from oxidative damage which is often associated with aging and various diseases caused by oxidative stress (Bueno et al., 2012a). Recently, anthocyanins were found to possess anti-inflammatory ability through modulating the NF-κB signaling pathways, thereby inhibiting the expression of proinflammatory cytokines (such as TNF-α, IL-6, and IL-10), the production of the inducible nitric oxide synthase (iNOS) and cyclooxygenase 2 (COX-2), and the utterance of adhesion molecules (ICAMs and VCAM-1) (Vendrame and Klimis-Zacas, 2015).

Anthocyanidin	R <sub>5</sub>	R <sub>6</sub>	R <sub>7</sub>	R <sub>3</sub> '	R <sub>4</sub> '	R <sub>5</sub> '
Aurantidin	OH	OH	OH	H	OH	H
Capensinidin	OCH <sub>3</sub>	H	OH	OCH <sub>3</sub>	OH	OCH <sub>3</sub>
Cyanidin	OH	H	OH	OH	OH	H
Delphinidin	OH	H	OH	OH	OH	OH
Europinidin	OCH <sub>3</sub>	H	OH	OCH <sub>3</sub>	OH	OH

Rosinidin	OH	H	OCH <sub>3</sub>	OCH <sub>3</sub>	OH	H

Figure 1 Chemical structure of selected anthocyanidins.

**Table 1** Occurrence of anthocyanins in some fruits

Sources	Major anthocyanin	Minor anthocyanins
Strawberry	cyanidin-3-glucoside	cyanidin-3-glucoside, pelargonidin-3-rutinoside
Blackberry	cyanidin-3-glucoside	cyanidin-3-rutinoside, malvidin-3-glucoside
Raspberry	cyanidin-3-glucoside	pelargonidin-3-glucoside, pelargonidin-3-rutinoside
Sweet cherry	cyanidin-3-rutinoside	cyanidin-3-glucoside, peonidin-3-rutinoside
Blackcurrant	cyanidin-3-rutinoside	cyanidin-3-glucoside, delphinidin-3-glucoside
Bilberry	delphinidin-3-galactoside	pelargonidin-3-glucoside, pelargonidin-3-galactoside

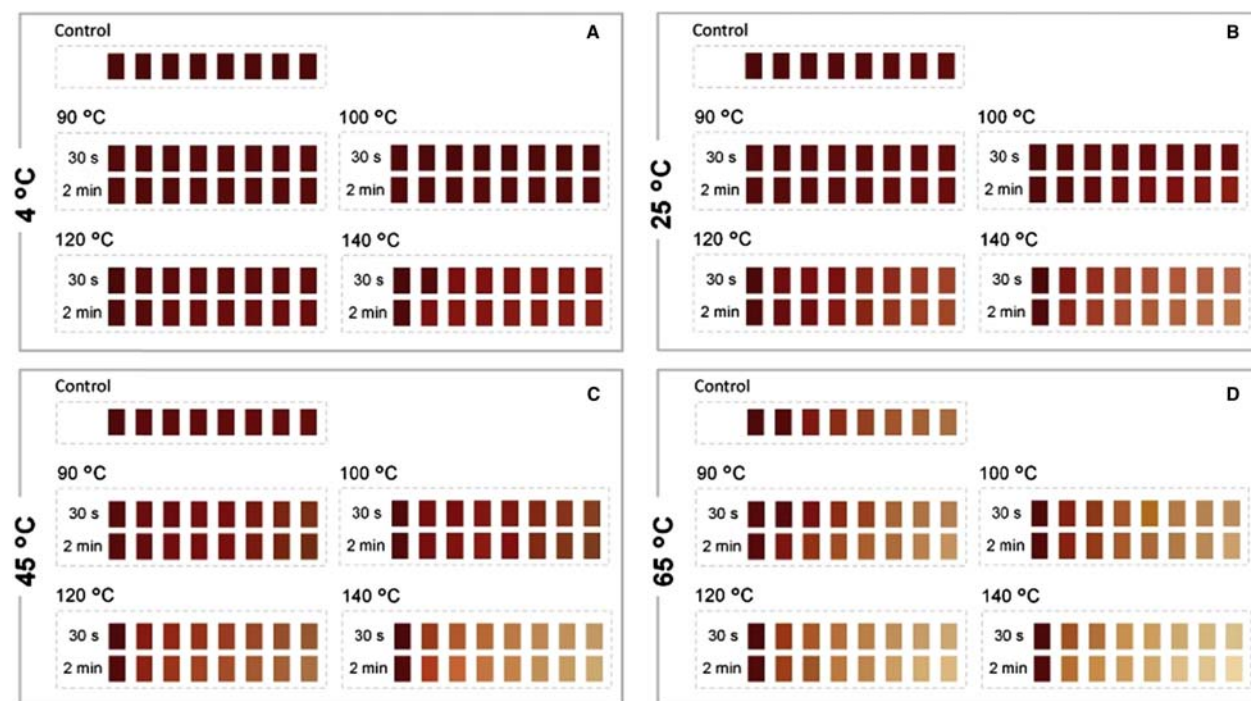

The intake of anthocyanins in the US diet was previously estimated to be between 180 and 215 mg per day, whereas the intake of other dietary flavonoids, such as genistein, quercetin and apigenin, was only between 20 and 25 mg per day (Hertog et al., 1993). However, the National Health and Nutrition Examination Survey (NHANES) 2001–2 highlighted the inaccurate anthocyanins intake data in the previous study, and pointed out that the average intake of anthocyanins in the US was much lower and at about 12.5 mg per day. Of the different aglycones, cyanidin, delphinidin, and malvidin were estimated to contribute 45, 21, and 15%, respectively, to the total intake of anthocyanins per day. Besides, nonacylated anthocyanins predominantly contributed 77% to the total intake of anthocyanins per day (Wu et al., 2006).

### Colour of Anthocyanins

Anthocyanins give plants their colours, which is important for their survival as they attract pollinators (Glover and Martin, 2012). Their range of brilliant colours has led to industrial use of anthocyanins as natural colourants in foods as substitutes to synthetic food colourants, and they have been recognised as one of the nine European Union selected natural colour classes. The resonance structure of anthocyanidin, comprising the flavylium cation (also known as 2-phenylbenzopyrylium) enables anthocyanins to act as colourants (Castañeda-Ovando et al., 2009). Within the same class of anthocyanins, there is a variation in colour, e.g. the increase of hydroxylation in the B-ring results in a bathochromatic shift from red to violet (pelargonidin → cyanidin → delphinidin) (Mateus and de Freitas, 2009). It has been found that the colour of anthocyanins varies significantly with pH (Fernandes et al., 2014). The pH dependent structural changes of anthocyanidin and resulting colour are illustrated in Fig. 2 (Yoshida et al.,

**Figure 2** pH dependent structural changes in the anthocyanidin chromophore and the resulting colour changes in aqueous solution. From Yoshida, K., Mori, M., Kondo, T., 2009. Blue flower color development by anthocyanins: from chemical structure to cell physiology. Nat. Product. Rep. 26 (7), 884–915, with permission.

**Figure 3** Colour swatches for anthocyanin in aqueous solution during storage. From Sui, X., Bary, S., Zhou, W., 2016. Changes in the color, chemical stability and antioxidant capacity of thermally treated anthocyanin aqueous solution over storage. *Food Chem.* 192, 516–524, with permission.

2009). Furthermore, the differences among various colours contributed by anthocyanins are found to be determined, to a great degree, by two groups of factor: internal factors and external ones. The internal factors are the structure of anthocyanins; with an increase of hydroxylation and the presence of methoxyl groups in the B ring, the hue of anthocyanins becomes lighter. The external factors, such as temperature, pH, and the type of solvent, also have a profound impact on the colour of anthocyanins (Mazza, 2007; Tsuda, 2012). For example, our previous work reported that anthocyanin aqueous solutions with or without a heat treatment showed excellent colour at the storage temperature of 4 °C; however, the anthocyanin aqueous solutions thermally treated at higher temperatures lost colour more easily than those heated at lower temperatures throughout storage (Fig. 3) (Sui et al., 2016a).

### Stability of Anthocyanins

The stability of anthocyanin compounds in a food matrix is dependent on several factors, such as their chemical structure, temperature, pH, light intensity, oxygen availability, and solid content of the matrix (He et al., 2016). In particular, temperature is reported as one of the major factors that impact the stability of anthocyanins. Moreover, anthocyanins show a greater stability in acidic media than in alkaline media (Cavalcanti et al., 2011). Meanwhile, isolated anthocyanins are unstable and highly susceptible to degradation (Giusti and Wrolstad, 2003).

### Chemical Structure Influence

The stability of anthocyanins is influenced by their chemical structure, i.e. substitutes in the B ring and the presence of additional hydroxyl (–OH) or methoxyl (–OCH<sub>3</sub>) groups (Fleschhut et al., 2006). Anthocyanins with complex structures of glycosylation and acylation exhibit remarkable stability to pH changes, thermal treatment, light exposure, etc (Dangles et al., 1993). Acylated anthocyanins are found to be more stable than their corresponding non-acylated forms. An example of an acylated anthocyanin is shown in Fig. 4. The acylation reaction is believed to enhance the stability of anthocyanins through protecting them from hydration (Brouillard, 1981; Goto, 1987). Acylated anthocyanins appear to prolong their half-life and slow down their decaying process under mild thermal treatment (Sadilova et al., 2006). However, high heat can easily break the chemical structure of acylated anthocyanins. The degradation of acylated anthocyanins starts from the degradation of their glycosylated and acylated groups, followed by hydrolyzing the sugar, leaving an anthocyanidin structure solely (Prasain et al., 2004).

**Figure 4** Chemical structure of an acylated anthocyanin, malvidin-3-(6''-acetyl)glucoside (monoisotopic mass = 535.14517 amu). From Barnes, J.S., Nguyen, H.P., Shen, S., Schug, K.A., 2009. General method for extraction of blueberry anthocyanins and identification using high performance liquid chromatography-electrospray ionization-ion trap-time of flight-mass spectrometry. *J. Chromatogr. A*. 1216 (23), 4728–4735, with permission.

### Co-pigmentation Influence

Co-pigmentation is a phenomenon during which the pigments and other colourless organic compounds or metallic ions form molecular or complex associations (Boulton, 2001). The stabilization of anthocyanins could be improved through intramolecular and intermolecular co-pigmentations, self-association, and metal complexing (Fig. 5) (Malien-Aubert et al., 2001). Thus, co-pigmentation of anthocyanins is the major mechanism for the stabilization of anthocyanins and their colour in plants (Davies and Mazza, 1993). Dyrby et al. (2001) reported that the co-pigmentation of anthocyanins in red cabbage offered the anthocyanins with greater stability than the isolated anthocyanins from blackcurrant, grape skin and elderberry in a soft drink model system.

### Temperature Influence

Temperature has been reported as one of the major factors in determining the stability of anthocyanins. The stability of anthocyanins was fast decreased as temperature rises (Maccarone et al., 1985). Total monomeric anthocyanins extracted from Bordo grape skin showed a loss of 95.1% at 55 °C and 90% R.H. for 35 days (Kuck et al., 2017). Castagnini et al. (2015) observed that increasing

**Figure 5** Anthocyanins co-pigmentation (A) self-association (B) intramolecular co-pigmentation (C) metal complexation, and (D) intermolecular co-pigmentation. From Castañeda-Ovando, A., Pacheco-Hernández, M.d.L., Páez-Hernández, M.E., Rodríguez, J.A., Galán-Vidal, C.A., 2009. Chemical studies of anthocyanins: a review. *Food Chem.* 113 (4), 859–871, with permission.

the temperature from 30 to 50 °C caused the loss of total anthocyanins in impregnated apple increased from 70% to 75%. Similarly, a decrease of 68% of total anthocyanins in mortino fruits was found during the drying at 60 °C for 10 h (López-Vidaña *et al.*, 2016). Even at lower temperatures, the degradation of anthocyanins is still a concern. Hellström *et al.* (2013) reported that the half-life ( $t_{1/2}$ ) of anthocyanins in both laboratory-prepared and commercial berry juices was much shorter at room temperature than at 4 °C and 9 °C. In our laboratory, we observed that in an aqueous solution the content of anthocyanins extracted from black rice was relatively constant at low temperatures (4 and 25 °C); however it significantly decreased at 120 and 140 °C (Sui *et al.*, 2016a).

### pH Influence

Anthocyanins are found in different chemical forms depending on the pH of the environment (Costa *et al.*, 1998; Fleschhut *et al.*, 2006). Typically, anthocyanins are more stable in acidic media of low pH than alkaline ones of high pH (Castañeda-Ovando *et al.*, 2009). At the pH of 1, flavylium cation is a dominant species with purple and red colours. At the pH between 2 and 4, quinoidal form is predominant with blue colour. At the pH between 5 and 6, two colourless species can be observed, which are carbinol pseudobase and chalcone. When the pH is greater than 7, the degradation of anthocyanins occurs, which depends on their substituents (Castañeda-Ovando *et al.*, 2009).

### Oxygen Influence

The presence of oxygen accelerates the degradation process of anthocyanins (Cavalcanti *et al.*, 2011). Specifically, this influence of oxygen can take place through a direct oxidative mechanism or through the action of oxidising enzymes, such as polyphenol oxidase (PPO). PPO catalyses the oxidation of anthocyanins to form brown condensation products (Patras *et al.*, 2010). It was reported that oxygen-restricted atmospheres retained the initial antioxidant capacity and anthocyanin content of fresh-cut strawberries over a storage period of 25 days (Odrizola-Serrano *et al.*, 2009). Under modified atmosphere storage conditions, the oxygen content of 60%–100% was found to increase the content of anthocyanins of freshly harvested blueberries in the initial period (0–7 days) of cold storage, however the content of anthocyanins was decreased with prolonging the storage (Zheng *et al.*, 2003).

### Solid Content and Water Activity Influence

Anthocyanins showed faster degradation in more concentrated liquid systems. Garzón and Wrolstad (2001) reported that the degradation of anthocyanins was greater in concentrates compared to juices in their study evaluating the stability of anthocyanins in strawberry juices and concentrates. Similar trends have been reported for anthocyanins in sour cherry juice (Cemeroglu *et al.*, 1994). This could be due to the closeness of reacting molecules in juices of higher soluble solid content (Patras *et al.*, 2010).

In solid/semi-solid systems, water activity is another factor influencing the stability of anthocyanins. Anthocyanins exhibited remarkable stability when stored in dry crystalline form (Markaris *et al.*, 1957). The degradation of anthocyanins in freeze-dried strawberry puree increased when being stored at increasing relative humidity conditions among 11%, 32%, 57%, 75% and 100% (Erlandson and Wrolstad, 1972). It was also reported that reducing water activity from 1.0 to 0.44 enhanced the stability of anthocyanins in model systems that were prepared using glycerol and pH 3.4 citrate buffer (Garzón and Wrolstad, 2001).

### Degradation of Anthocyanins

Knowledge about degradation mechanisms of anthocyanins is relatively little (Patras *et al.*, 2010; Sadilova *et al.*, 2006). It was believed that anthocyanins were decomposed via two possible pathways to end up with either chalcone and coumaric acid glycosides or aldehyde and benzoic acid derivatives (Patras *et al.*, 2010). Anthocyanins would decompose upon heating into a chalcone structure, the latter being further transformed into a coumarin glucoside derivative with the loss of the B-ring (Hrazdina, 1971). Sadilova *et al.* (2007) reported successive deglycosylation reactions in the initial steps of anthocyanin degradation at the pH of 1, yielding the respective aglycones. The sugar-free anthocyanidin aglycones latter were cleaved into a phenolic acid and a phenolic aldehyde. The aglycone-sugar bond is found to be more labile than other glycoside bonds at the pH of 2 to 4. However, at the pH of 1 all glycosidic bonds are accessible to hydrolysis; e.g. heating cyanidin-3-rutinoside at the pH of 1 results in the formation of rhamnose and glucose, but only traces of rutinose (Adams, 1973). In the case of acylated anthocyanins, the degradation of the anthocyanins was slowed down because the intermediate compounds formed during degradation were coloured flavylium cation before further degradation proceeds the same way as for their glycoside derivatives (Sadilova *et al.*, 2006). Through kinetic and Monte Carlo modeling, the degradation of cyanidin-3-glucoside and cyanidin-3-rutinoside can be modeled as first-order reactions in both aqueous solutions and semi-solid foods such as bread (Sui and Zhou, 2014; Sui *et al.*, 2014, 2015).

### Interactions of Anthocyanins With Proteins

The interactions between phenolic compounds and proteins are known to affect the structure of proteins, content of free polyphenols, antioxidant capacity and bioavailability of phenolic compounds in foods (Ozdal *et al.*, 2013). Specifically, both covalent and

non-covalent interactions between proteins and phenolic compounds frequently occur in food systems (Jakobek, 2015), which were reported to change the structural, functional, and nutritional properties of proteins (Ozdal et al., 2013). The non-covalent interactions between proteins and polyphenols are via hydrogen bonding and hydrophobic bonding and are reversible, i.e. van der Waals forces are involved (Arroyo-Maya et al., 2016; Ghorbani Gorji et al., 2015; Wang and Wang, 2015). In the case of covalent interactions, polyphenols are oxidized to quinones under alkaline conditions and incorporated into the side chains of proteins (Ozdal et al., 2013). They can irreversibly interact with the sulfhydryl and amino groups of proteins to form covalent C–N or C–S bonds with the phenolic rings. It was shown that anthocyanins were more likely to form covalent interactions with soy protein isolates (SPI) instead of non-covalent interactions (Sui et al., 2018). The addition of anthocyanins in SPI sodium phosphate buffer at the concentration of 0.05, 0.1%, and 0.2% (w/v) changed the secondary structure of SPI with a decreased amount of  $\beta$ -sheets and an increased amount of  $\beta$ -turns and random coils. The emulsifying and foaming properties of SPI were improved after its complexation with anthocyanins (Sui et al., 2018). Moreover, the complexation of SPI with anthocyanins was found to improve the digestibility of both native SPI and thermally denaturized SPI (Zhang et al., 2018). This observation suggested that anthocyanins may have an ability to alter the thermally-induced negative influence on the digestibility of SPI.

## Fortification of Anthocyanins in Foods

Potential use of natural “green” plant-extracted anthocyanins could offer the food processing industry an alternative solution to synthetic chemical antioxidants. Therefore, considering also the beneficial effect of these compounds on health, their incorporation in food products is of important value (Cevallos-Casals and Cisneros-Zevallos, 2004). Kazemi et al. (2017) fortified salted and yellow alkaline noodles with an anthocyanin extract from pomegranate peel, at 0.75% and 1.50% of the total weight of prepared noodles, to improve their antioxidant capacity. For bread fortified with anthocyanin-rich black rice extract powder at a relatively low level of 0.2% (i.e. 0.04% anthocyanins, flour based), the antioxidant capacity of its crumb decreased while that of the crust showed an increase (Sui et al., 2015). Bread fortified with various levels of anthocyanin-rich black rice extract powder (up to 4%, flour based) was further studied for its digestibility, and the rate of digestibility was found to be retarded by the anthocyanins in a dose-dependent manner (Sui et al., 2016b). Fortification of anthocyanins in foods may provide new opportunities to produce functional food products by improving their existing functionalities as well as creating new functionalities, thereby providing extra health benefits to consumers.

## Summary

Like many other polyphenols, stability and functionality are the two major issues about anthocyanins. Due to the varieties in their chemical structure, anthocyanins possess different stability. The environment factors, such as pH, temperature, and food components, are known to affect the stability of anthocyanins to certain extent. The antioxidant capacity of anthocyanins has been intensively studied over the years. However, variations in the antioxidant capacity of anthocyanins in food matrices and during metabolism are still unclear and debatable. Since the attention of today's consumers has been drawn to choose healthier foods, the application of anthocyanins in foods is expected to increase in the near future. Although the studies of anthocyanins have reached some milestones, clearly more research is still needed to well understand and confidently apply anthocyanins in foods in order to utilise, as well as further extend, their beneficial functionalities.

# Caramelization in Foods: A Food Quality and Safety Perspective

Tolgahan Kocadağlı and Vural Gökmen, Hacettepe University, Beytepe Campus, Ankara, Turkey

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Caramelization is a nonenzymatic browning reaction of sugars providing a caramel-like flavor during high temperature treatment of foods. Degradation of sugars is catalyzed by amino acids during the Maillard reaction, which is characterized by nitrogen containing low and high molecular weight compounds. At elevated temperatures, both reactions proceed together in a way that one affects the other.

The Maillard reaction may take place under milder conditions, but sugars are caramelized at temperatures above 120°C. Food products reach these elevated temperatures during processes like roasting (180–240°C) and baking (160–240°C). After drying of the outer layers of bakery products during heating, the surface can reach temperatures above 100°C where the browning and flavor development begin (Mogol and Gökmen, 2014a,b). Caramelization reactions are also observed in jams, canned fruit products, fruit juices and concentrates, soft drinks, honey, and sugar syrups during thermal treatment or storage. At milder temperatures, pH below three and above nine are often required to observe reactions in moderately higher rates (Kroh, 1994).

Food caramels are commercially available as caramel color, burnt sugars, aromatic caramel, and caramelized sugar syrups. Burnt sugars, aromatic caramel, and caramelized sugar syrups are produced without using additives, while additives are used for caramel color production. Caramel color is used as a colorant in food and beverages, and it is not usually a flavoring.

## Caramelization Reactions

The main reactions of sugar degradation are schematized in Fig. 1. The acyclic forms of sugars are very reactive, and more acyclic forms are found by increasing temperature. Isomerization, epimerization, dehydration, and oxidation reactions of the cyclic reducing sugar are initiated by ring opening followed by enolization (Speck, 1958). Aldose and ketose sugars isomerize via their common intermediate, 1,2-enediol. This isomerization also involves epimerization, that is, the change of the configuration of C-2 in aldoses and C-3 in ketoses. Glucose, fructose, and mannose are found in equilibrium in alkaline solutions (Fig. 2). Similarly, galactose, tagatose, and talose may interconvert each other. These aldose–ketose isomerization and epimerization reactions are known as the Lobry de Bruyn–Alberda van Ekenstein transformation (rearrangement) (LdB-AvE) (Angyal, 2001). Within these reactions, aldose–ketose interconversion predominates, and to a lesser extent epimerization is observed. Although the LdB-AvE rearrangement is observed faster in alkaline media, it can also occur limitedly in acidic media (Zhao et al., 2007). In addition to the alkaline conditions required for the isomerization, a considerable amount of glucose–fructose interconversion is observed during the heating of sugar-rich low-moisture foods and dry heating of sugars at elevated temperatures (Kocadağlı and Gökmen, 2016a,b).

**Figure 1** Main reactions of sugar degradation.

**Figure 2** Lobry de Bruyn-Alberda van Ekenstein transformation.

Aldose–ketose isomerization is substantially catalyzed in the presence of alkali and alkaline earth metal cations ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{+2}$ ) by increasing the rate of chain opening (Speck, 1958).

Aldose–ketose isomerization (LdB-AvE) is also observed in the reducing end of the oligosaccharides, such as maltose (4-*O*- $\alpha$ -D-glucopyranosyl-D-glucose) to maltulose (4-*O*- $\alpha$ -D-glucopyranosyl-D-fructose) and lactose (4-*O*- $\beta$ -D-galactopyranosyl-D-glucose) to lactulose (4-*O*- $\beta$ -D-galactopyranosyl-D-fructose). Maltose/maltulose ratio can be used as a marker of thermal input in certain cereal products such as cookies, crackers, breakfast cereals (García-Baños et al., 2004a), pasta (García-Baños et al., 2004b), and infant formula (Morales et al., 2004). Lactulose is an indigestible disaccharide with laxative and prebiotic properties. It can be formed during heating infant formula, milk, and milk products and can also be used as an ingredient. Isomerization reaction of lactose to lactulose during thermal treatment of milk is quantitatively more important than the Maillard reaction for the degradation of lactose (Berg, 1993).

In an acidic medium, enolization and subsequent  $\beta$ -elimination of 1–3 water molecules (dehydration) predominates. In an alkaline medium, enolization is followed by fragmentation reactions (including fragmentation after dehydrations and isomerizations) via splitting of carbon bonds, and subsequently recombination is observed via aldol addition. Enediols are oxidized via transition metal catalysis, such as  $\text{Cu}^{2+}$ , and also in the presence of oxygen.

During heating or drying of fruit products, heating of sugar with or without additives, and baking of sourdough, many dehydration products of sugars may form because of the acidic conditions of the products and high temperature. Enediols are also the key intermediates for the dehydration of sugars under acidic conditions. Dehydration refers to the removal of a water molecule by  $\beta$ -elimination mechanism from the carbon skeleton of a carbohydrate. Heating accelerates the dehydration especially under low moisture conditions and even in milder pH conditions because of an increment in acyclic forms. The dehydration may also occur under alkaline condition during heating, followed by extensive fragmentation. Dehydration of sugars produces several reactive deoxyosones, and more stable furan and pyran derivatives, which are important for the formation of caramel color and flavor.

3-Deoxyosone, having an  $\alpha$ -dicarbonyl structure, is formed by the removal of a water molecule from the third carbon of an aldohexose or a ketohexose (Fig. 3). When hexoses are glucose and fructose, 3-deoxyglucosone (3-deoxy-D-*erythro*-hexos-2-ulose) is formed. Similarly, galactose yields 3-deoxygalactosone (3-deoxy-D-*threo*-hexos-2-ulose) (Hellwig et al., 2010). Dehydration from C-4 of 3-deoxyglucosone produces 3,4-dideoxyglucosone-3-ene (3,4-dideoxy-D-*glycero*-hex-2-enos-2-ulose). Dehydration from a hemiacetal structure of 3,4-dideoxyglucosone-3-ene results in 5-hydroxymethyl-2-furfural (HMF, 5-hydroxymethylfuran-2-carbaldehyde). HMF is a rather stable product, and it is often used as an indicator of the thermal load applied to foods (Gökmen and Senyuva, 2006; Gökmen et al., 2007, 2008; Göncüoğlu and Gökmen, 2013). However, HMF might also behave as a reactive intermediate, especially at elevated temperatures, because of its carbonyl group (Nikolov and Yaylayan, 2011a,b; Gökmen et al., 2012).

**Figure 3** Dehydration of glucose and fructose.

Fructose gives rise to the formation of a wide variety of products because of its ability to be involved in both 1,2- and 2,3-enolization. Dehydration of fructose from C-1 through 2,3-enediol yields 1-deoxyglucosone (1-Deoxy-D-*erythro*-hexo-2,3-diulose) (Fig. 3). 1-Deoxyglucosone is the key reactive intermediate in the formation of many other reactive intermediates and important aroma compounds (Hirsch et al., 1995; Voigt and Glomb, 2009). Isomerization of 1-deoxyglucosone along the carbon chain is an important aspect in the formation of a wide range of products that are important for color and flavor development (Belitz et al., 2009).

Glucose and fructose oxidation produces glucosone (D-*arabino*-hexos-2-ulose) by removal of two protons, especially by transition metal catalysis and in the presence of oxygen. Nonoxidative degradation of glucosone yields C-5 intermediates, which are pentosone, 3-deoxypentosone, and 1-deoxypentosone (Gobert and Glomb, 2009).

Shorter chain  $\alpha$ -dicarbonyl compounds,  $\alpha$ -hydroxyaldehydes, and  $\alpha$ -hydroxyketones are formed by the cleavage of the carbon skeleton, especially through deoxyosones. Alkaline conditions accelerate the formation of fragments. These shorter chain carbonyl compounds are of importance because they substantially contribute to browning, and involve in the formation of flavor compounds (Hollnagel and Kroh, 1998).

Typical products of the fragmentation with one carbon is formaldehyde; with two carbons are glyoxal, 2-hydroxyacetaldehyde (glycolaldehyde), and acetaldehyde; with three carbons are 2,3-dihydroxypropanal (glyceraldehyde), 1,3-dihydroxyacetone, hydroxyacetone (acetol), methylglyoxal (pyruvaldehyde), 2-hydroxypropanal (lactaldehyde), hydroxymethylglyoxal; with four carbons are 2,3-butanedione (diacetyl), 1-hydroxybutan-2,3-dione, and with five carbons is 2,3-pentanedione (Fig. 4) (Smuda and Glomb, 2013). These can be formed by direct degradation of the carbon chain (after isomerization and/or dehydration) and also by condensation of the fragments. The mechanisms largely depend on the reaction conditions, and the source of carbon may come from different regions of the carbon skeleton. Some of these  $\alpha$ -dicarbonyl compounds may also form as secondary lipid oxidation products and in ascorbic acid degradation (Fujioka and Shibamoto, 2004; Schulz et al., 2007).

In addition to the formation of short-chain carbonyl compounds, carboxylic acids are also formed. Formic acid and acetic acid are formed from 3-deoxyglucosone and 1-deoxyglucosone, respectively. The main mechanism is hydrolytic  $\beta$ -dicarbonyl cleavage (Davidek et al., 2005; Smuda and Glomb, 2013), and to a lesser extent oxidative cleavage (Davidek et al., 2006).

Glycosidic bonds of oligosaccharides are cleaved by acid catalysis. Hydrolysis of the glycosidic bond is affected especially by pH and temperature, and also depends on the structure. Reducing oligosaccharides, such as maltose and lactose, may participate in browning reactions by producing various reactive intermediates (Hollnagel and Kroh, 1998). Degradation of polysaccharides might also be important at very high temperatures as in the case of coffee roasting.

Hydrolysis and decomposition of sucrose in sweet bakery products are of importance as inversion products glucose and fructose participate in nonenzymatic browning reactions. Moreover, cleavage of a glycosidic bond of sucrose releases glucose and fructofuranosyl cation (Fig. 5) (Perez Locas and Yaylayan, 2008). At elevated temperatures and under dry heating conditions, the fructofuranosyl cation produces HMF via elimination of a proton and dehydration (Perez Locas and Yaylayan, 2008). HMF formation with this pathway is more efficient than dehydration of 3-deoxyglucosone to HMF through acyclic intermediates (Perez Locas and Yaylayan, 2008). Another possible pathway for HMF formation is dehydration of fructose over cyclic intermediates (Antal et al., 1990; Mayes et al., 2014; Kocadağı and Gökmen, 2016a,b).

**Figure 4** Fragments with carbonyl moieties formed in caramelization.

Reactions of sugars are not only limited to the decomposition reactions but inter- and intramolecular glycoside bond formations are also observed. Oligomers with up to six carbohydrate units may form during caramelization of glucose, fructose, and sucrose via glycosidic bonding (Golun and Kuhnert, 2012; Golun and Kuhnert, 2013). These oligomers are also found in their dehydrated (up to eight  $\text{H}_2\text{O}$  loss) and hydrated forms.

Anhydrosugars (sugar anhydrides) are formed from aldohexoses by intramolecular condensation of the hemiacetal and other hydroxyl groups. Levoglucosan (1,6-anhydro- $\beta$ -D-glucopyranose or  $\beta$ -glucosan) is abundantly formed during heating of glucose, starch, and cellulose at high temperatures (Fig. 6). To a limited extent, its furanose form (1,6-anhydro- $\beta$ -D-glucofuranose) may also form (Velisek, 2014).

Intramolecular glycosidic bond formation is not observed in fructose, but difructose dianhydrides (Fig. 6) and their glycosylated derivatives are formed via fructofuranosyl cation (Audemar et al., 2017). Glycosidic bond formation between fructofuranosyl cation and fructose produces fructodisaccharides (fructobioses), which then form a tricyclic structure via intramolecular glycosidic bonding. Isomerization in the molecule gives various diastereomers and further glycosylation may give glycosylated derivatives. These difructose dianhydrides and their glycosylated derivatives are prebiotic compounds found in caramel (Mellet and Garcia Fernandez, 2010). Isomers of difructose dianhydrides are also important as they can be used for the authenticity of caramel and for the detection of addition of caramel in foods (Ratsimba et al., 1999).

## Flavor Development

Major flavor compounds formed during caramelization of sugars are oxygen-containing heterocyclic compounds, furanones and pyranones, and also carbocyclic compounds, cyclopentenolones. In these groups of molecules, caramel aroma appears if a planar vicinal enol-oxo configuration is found (Fig. 7) (Belitz et al., 2009). A volatile fraction of caramel constitutes low molecular weight compounds derived from degradation of sugars. These compounds may also play a role in the aroma of baked and roasted foods via caramelization reactions; however, many characteristic aroma compounds with relatively low odor thresholds are formed via involvement of amino acids in the Maillard reaction. Increment in fragmentation reactions during the Maillard reaction may also provide short-chain carbonyl compounds for aldol reactions required for the formation of compounds with a caramel flavor.

One of the important compounds is furaneol (4-hydroxy-2,5-dimethyl-2H-furan-3-one) (Fig. 8) with an intensive caramel flavor and a relatively low odor threshold (Zabetakis et al., 1999). It is found in caramel, biscuits, coffee, and dark beer. It can be formed via aldol condensation of hydroxyacetone and methylglyoxal followed by cyclization and dehydration (Velisek, 2014). It is mainly formed from L-rhamnose (6-deoxy-L-mannose) (Haleva-Toledo et al., 1997; Illmann et al., 2009). Another furanone with a higher odor threshold, norfuraneol (4-hydroxy-5-methyl-2H-furan-3-one), can be formed from the furanose form of 1-deoxyglucosone upon dehydration and splitting of formaldehyde (Velisek, 2014).

Sotolon (caramel furanone, 3-hydroxy-4,5-dimethyl-5H-furan-2-one) and abhexon (maple furanone, 5-ethyl-3-hydroxy-4-methyl-5H-furan-2-one) are powerful aroma compounds with relatively low odor thresholds (Maarse, 1991). Sotolon can be

**Figure 5** Degradation of sucrose and fructose to HMF. Adapted from Antal Jr., M.J., Mok, W.S., Richards, G.N., 1990. Mechanism of formation of 5-(hydroxymethyl)-2-furaldehyde from d-fructose and sucrose. *Carbohydr. Res.* 199, 91–109 and Locas, C.P., Yaylayan, V.A., 2008. Isotope labeling studies on the formation of 5-(hydroxymethyl)-2-furaldehyde (HMF) from sucrose by pyrolysis-GC/MS. *J. Agric. Food Chem.* 56, 6717–6723.

**Figure 6** Levoglucosan and difructose dianhydride

**Figure 7** Enol-oxo configuration found in compounds with caramel aroma.

produced from glycolaldehyde with 2,3-butanedione, and abhexon from glycolaldehyde and 2,3-pentanedione via aldol condensation (Belitz et al., 2009). Sotolon has caramel, maple syrup, and a burnt sugar odor at low concentrations, and fenugreek or curry odor at high concentrations (Tokitomo et al., 1980; Girardon et al., 1986). Abhexon has an intense maple syrup and typical protein hydrolyzate aroma. Both sotolon and abhexon can be formed from different precursors in different food products (Velisek, 2014).

Acetylformoin (2,4-dihydroxy-2,5-dimethyl-2H-furan-3-one) is another important furanone with a caramel flavor (Cutzach et al., 1999). It is formed from the dehydration of hexoses through 1-deoxyglucosone (Hofmann, 1998). Acetylformoin is found in many tautomeric forms in its acyclic structure (Goto et al., 1963). It is very reactive and unstable because of its reductone structure

**Figure 8** Compounds with distinct caramel flavor.

in the acyclic form. Acetylformoin is also an intermediate in furaneol formation (Hofmann and Schieberle, 2000). It can be found in aromatic caramel and burnt sugar (Paravisini et al., 2012).

Maltol is found in biscuits, roasted coffee, chocolate, caramel, malt, and beer. It has a high odor threshold and may not always contribute to the aroma of food (Belitz et al., 2009). It is one of the important odorants in burnt sugar caramels (Paravisini et al., 2012). Maltol is formed when glucose has a 4-*O* glycoside linkage, like in disaccharides maltose and lactose, and its formation from monosaccharides is negligible (Yaylayan and Mandeville, 1994). Isomaltol (2-acetyl-3-hydroxyfuran) also has a caramel-like flavor, and it is formed from hexoses, and especially from 4-*O*-substituted glucoses at higher concentrations.

Cyclopentenolones are alicyclic compounds formed from fragments of sugar degradation and have a distinct caramel flavor. Cyclotene (2-hydroxy-3-methyl-2-cyclopenten-1-one) has an intense burnt sugar and caramel flavor, and it can be formed from hydroxyacetone and 2-hydroxypropanal (Velisek, 2014).

The volatile fraction of sugar degradation contains many more compounds with different aroma properties and odor thresholds. Among others, diacetyl, 2,3-pentanedione, acetoin, furan, 2-methylfuran, 3-methylfuran, furfural, 2-acetylfuran, and 2-hydroxyacetylfuran are the constituents of the volatile fraction in thermally treated foods. Although they can be directly formed from sugar backbone during caramelization, carbon atoms from amino acid fragmentation may also be involved, and the quantitative distribution largely depends on the conditions and food product composition (Kerler et al., 2010).

## Browning Development

The nature of the pigment molecules responsible for the color development during heating sugars is largely unknown, similar to melanoidins formed in the Maillard reaction. During heating and storage of several food products, the Maillard reaction is responsible for nonenzymatic browning via catalysis of sugar dehydration and fragmentation by involvement of amino acids and incorporation of nitrogen to the polymers. At low pH values, amino compounds get protonated, making them less susceptible to participate in carbonyl-amine condensation, which is the first step of the Maillard reaction, because of the decrement in the nucleophilic strength of the amino group (Martins et al., 2000; Martins and Van Boekel, 2005). Browning in dessert wine, where these conditions are observed, is favored via caramelization reactions (Kroh, 1994). Removal of amino acids from citrus juices is known to decrease undesired nonenzymatic browning during thermal treatment and storage (Bharate and Bharate, 2014). However, browning still progresses to a limited extent via caramelization reactions and ascorbic acid degradation. Caramelization reactions of fructose might account for 10%–36% of the browning observed during heating fructose–lysine aqueous mixture (Ajandouz and Puigserver, 1999; Ajandouz et al., 2001). However, it is generally hard to make a conclusion to distinguish between caramelization and the Maillard reactions, especially at very high temperatures, for the contribution to browning.

During dry heating of solid sugars, reactivity is observed after melting or glass transition temperatures because transition from solid to liquid brings mobility to the molecules, which is required to observe any reaction at a considerable rate (Roos et al., 2013). Therefore the caramelization and browning in sugar solids requires higher temperatures. Melting temperatures of fructose, glucose, and sucrose are 127, 158, and 190°C, respectively (Roos and Drusch, 2016). Increasing temperature increases the kinetic energy of the molecules and thus caramelization reactions get faster. In parallel with that, more acyclic sugar molecules are found at higher temperatures, and thus fragmentation reactions provide an intensive dark color development. The increments in short-chain  $\alpha$ -dicarbonyl compounds,  $\alpha$ -hydroxycarbonyl compounds, and furan derivatives are associated with an increment in browning intensity (Hollnagel and Kroh, 1998; Kroh et al., 2008).

The presence of alkali metal cations (like NaCl, KCl, CaCl<sub>2</sub>) enhances the browning during caramelization of sugars. Color intensity increases with higher concentrations of NaCl and KCl in cereal model systems and breakfast cereals (Moreau et al., 2009b, 2011). Browning provided by NaCl is linked neither to the hygroscopic behavior of NaCl nor to the physical state of the cereal

**Table 1** Classification of caramel colors

Name	Plain	Caustic sulfite	Ammonia	Ammonium sulfite
Class	Class I, E150a	Class II, E150b	Class III, E150c	Class IV, E150d
Additive (promoter)	NaOH, KOH, Ca(OH) <sub>2</sub> , Na <sub>2</sub> CO <sub>3</sub> , K <sub>2</sub> CO <sub>3</sub> , H <sub>2</sub> SO <sub>4</sub> , acetic acid, citric acid	H <sub>2</sub> SO <sub>4</sub> , Na <sub>2</sub> SO <sub>3</sub> , K <sub>2</sub> SO <sub>3</sub> , NaOH, KOH, Ca(OH) <sub>2</sub>	NH <sub>4</sub> OH, (NH <sub>4</sub> ) <sub>2</sub> CO <sub>3</sub> , NH <sub>4</sub> HCO <sub>3</sub> , ammonium phosphate, Na <sub>2</sub> CO <sub>3</sub> , NaOH, KOH, Ca(OH) <sub>2</sub>	NH <sub>4</sub> OH, (NH <sub>4</sub> ) <sub>2</sub> CO <sub>3</sub> , NH <sub>4</sub> HCO <sub>3</sub> , ammonium phosphate, (NH <sub>4</sub> ) <sub>2</sub> SO <sub>3</sub> , NH <sub>4</sub> HSO <sub>3</sub> , Na <sub>2</sub> CO <sub>3</sub> , NaOH, KOH, Ca(OH) <sub>2</sub> , H <sub>2</sub> SO <sub>4</sub> , Na <sub>2</sub> SO <sub>3</sub> , NaHCO <sub>3</sub> , K <sub>2</sub> SO <sub>3</sub> , KHCO <sub>3</sub>
Color	golden-yellow	reddish-brown	brown-yellow	dark brown-grey
Colloidal charge	weak	negative	positive	negative
Uses	alcoholic beverages, coffee extract, bakery products, confectionary	spirits, vermouth, brandies, bakery products, confectionary	beer, vinegar, acidic foods, sauces, bakery products, confectionary	soft drinks, bakery products, confectionary

model systems (Moreau et al., 2009a). In cookies, the presence of NaCl, KCl, and CaCl<sub>2</sub> increases 2-furfural and 5-hydroxymethyl-2-furfural in parallel with browning (Kocadağlı and Gökmen, 2016c). Contribution of fructose to browning development is generally higher than glucose. Heating glucose with alkali metal cations increases the rate of isomerization of glucose to fructose; therefore more furan derivatives are formed from fructose, which might be associated with the colored pigment formation (Hollnagel and Kroh, 1998; Mayes et al., 2015; Kocadağlı and Gökmen, 2016a).

Alkaline pH is also necessary to increase browning intensity during heating of sugars and sugar-rich foods. Higher pH values also increase the rate of browning by increasing enolization, as temperature does. Enhancement of browning at alkaline conditions is related to the increasing rate of fragmentation reactions.

Caramel colors are produced by controlled heating of sugars at temperatures above 120°C, and pressure can also be applied. Sucrose, glucose, fructose, sugar syrups, and starch are the main sources of raw material. Caramel colors are classified into four categories depending on the additives used (FAO, JECFA) (Table 1). The additives are used as catalysts to promote browning and to achieve desired properties (such as colloidal charge) for specific food products. Ammonia-sulfite caramel is the darkest colored caramel, and it is commonly used in soft drinks. Nitrogen-containing heterocyclic compounds pyrroles, pyridines, pyrazines, and imidazoles are formed in the case of using ammonium salts, which are characteristic to the Maillard reaction.

## Potential Toxicants Formed During Caramelization

### Imidazoles

4(5)-Methylimidazole (4-MI) and 2-methylimidazole (2-MI) are found in class III and IV caramel colors, and 2-acetyl-4-tetrahydroxybutylimidazole (THI) is found only in class III caramel color (EFSA, 2011). 4-MI and 2-MI are classified as “possibly carcinogenic to humans (Group 2B)” by the International Agency for Research on Cancer (IARC, 2013). This classification is based on the sufficient evidence in experimental animals for the carcinogenicity of both compounds (IARC, 2013). THI is a potent immunosuppressant, which means it reduces the strength of the body’s immune system (EFSA, 2011). Maximum residue limits have been set for 4-MI as 200 mg kg<sup>-1</sup> in class III and 250 mg kg<sup>-1</sup> in class IV, and for THI as 10 mg kg<sup>-1</sup> on equivalent color basis by the European Union. 4-MI can be present in caramel colors up to 1000 mg kg<sup>-1</sup>, being higher in class IV, and varies largely (Henggel and Shibamoto, 2013). Concentration of THI can be up to 50 mg kg<sup>-1</sup> (Elsinghorst et al., 2013). 2-MI is generally found in lower amounts.

The imidazole ring is formed via reactions of reactive carbonyl compounds and ammonia that is found in class III and IV caramel colors. 4-MI has been proposed to be formed from methylglyoxal in the presence of ammonia (Fig. 9) (Moon and Shibamoto, 2011). THI is formed via iminofructosamine, which is formed in the reaction of hexoses with ammonia (Fig. 10) (Kroeplien et al., 1985). Although their presence is commonly of concern in caramel colors, they may also form in thermally processed foods during the Maillard reaction (Mottier et al., 2017). The source of nitrogen or ammonia in this case is the Strecker degradation of amino acids (Yaylayan and Haffenden, 2003).

Divalent cations Ca<sup>2+</sup> and Mg<sup>2+</sup> have been shown to decrease the formation of 4-MI (Wu et al., 2016). The levels of sulfide play an important role for the formation of 4-MI during class IV caramel color production, and addition of appropriate levels of sulfide decreases 4-MI formation (Lee et al., 2013). Due to the wide usage of caramel colors in several food products, controlling the exposure to imidazoles and other toxicants is of importance from the point of view of food safety.

**Figure 10** Formation of 2-acetyl-4-tetrahydroxybutylimidazole. Adapted from Kroeplien, U., Rosdorfer, J., Van Der Greef, J., Long, R.C., Goldstein, J.H., 1985. 2-acetyl-4(5)-(1,2,3,4-tetrahydroxybutyl)imidazole: detection in commercial caramel color III and preparation by a model browning reaction. *J. Org. Chem.* 50, 1131–1133.

### Furan and Derivatives

IARC has classified furan as “possibly carcinogenic to humans (Group 2B)” (IARC, 1995). The precursors of furan are sugars, amino acids, polyunsaturated fatty acids, carotenoids, and ascorbic acid in foods (Fig. 11) (Yaylayan, 2006). The reactivity of sugars for furan formation is in the order of erythrose > ribose > sucrose > glucose = fructose (Perez Locas and Yaylayan, 2004). It is a very volatile compound, and its presence in foods highly depends on the characteristics of foods. In caramel colors, its concentration can be ranged from 52 to 177  $\mu\text{g kg}^{-1}$  (EFSA, 2011).

**Figure 11** Furan formation pathways. Adapted from Perez Locas, C., Yaylayan, V.A., 2004. Origin and mechanistic pathways of formation of the parent furan: a food toxicant. *J. Agric. Food Chem.* 52, 6830–6836.

The main furan compound formed during heating of hexoses is HMF, and various other furan compounds are also formed to a lesser extent as mentioned above. HMF can reach extremely high concentrations up to  $30 \text{ g kg}^{-1}$  in caramel products (EFSA, 2011), and its levels might exceed  $1 \text{ g kg}^{-1}$  in dried fruits, roasted coffee, malt, vinegar, and various thermally treated sugar-rich foods (Morales, 2008). Its metabolite 5-sulfoxymethyl-2-furfural is of serious concern because of its genotoxicity (Capuano and Fogliano, 2011). Formation of furan derivatives highly depends on the thermal load applied, and therefore limiting thermal input is one of the main strategies that could be applied. Formulation changes, such as choice of sugar, is also important to mitigate furan derivatives (Şenyuva and Gökmen, 2007; Gökmen et al., 2008; Kocadağlı et al., 2012; Van der Fels-Klerx et al., 2014; Taş and Gökmen, 2016).

### $\alpha$ -Dicarbonyl Compounds

$\alpha$ -Dicarbonyl compounds are highly reactive compounds, and therefore their presence might be a concern both in foods and in vivo. In addition to their cytotoxic effects, they may also react with free or bound lysine and arginine, yielding advanced glycation end products, which are related to various health consequences (Henle, 2007; Hellwig and Henle, 2014).  $\alpha$ -Dicarbonyl compounds found in foods may cause dicarbonyl stress mainly in the gastrointestinal lumen (Degen et al., 2013; Degen et al., 2014; Rabbani and Thornalley, 2015). It has been shown that dietary exposure to glyoxal has tumor growth-promoting properties in the small intestine in mice (Svendsen et al., 2016). Moreover,  $\alpha$ -dicarbonyl compounds play a role in the formation of other toxicogenic compounds during food processing, such as acrylamide, furan, heterocyclic aromatic amines, and 4(5)-methylimidazole.

The major  $\alpha$ -dicarbonyl compound found in foods is 3-deoxyglucosone, among others (Degen et al., 2012; Gensberger et al., 2012, 2013; Kocadağlı and Gökmen, 2014). The concentration of 3-deoxyglucosone is generally quite higher than HMF. Thermal input, sugar composition, and pH are critical factors for the formation of  $\alpha$ -dicarbonyl compounds. Phenolic compounds are known to trap  $\alpha$ -dicarbonyl compounds in foods and in physiological conditions in vitro (Totlani and Peterson, 2005; Lo et al.,

**Figure 12** Reaction of methylglyoxal with (–)-epicatechin via electrophilic aromatic substitution.

2006).  $\alpha$ -Dicarbonyl compounds react with certain positions on the phenol ring via electrophilic aromatic substitution as shown for (–)-epicatechin in Fig. 12.

## Introduction

The seek for foods that possess physiological benefits apart from nutritional properties has increased in the last decades. These natural healthy products are called functional foods and are directly related to health promotion, reduction of disease risks and health care costs (Shahidi, 2009). Biologically-active food products comprehend a broad variety of molecules, such as polyunsaturated fatty acids, polyphenols and bioactive peptides, among others.

Prebiotics are non-digestible short-chain carbohydrates and have received extensive attention as functional foods because of their selective stimulation of the growth and/or activity of different benefic bacteria (Gibson and Roberfroid, 1995). These compounds are composed of sugars with different degree of polymerization (DP) and possess different molecular structures (Table 1).

Prebiotic oligosaccharides are naturally found in different vegetables such as chicory, onions, asparagus and garlic (Van Loo et al., 1995). However, the growing demand for industrial use requires more efficient processes. In this context, microbial enzymes can be applied to efficiently produce bioactive prebiotics. These biocatalysts are highly selective for the substrate allowing the obtainment of a large variety of functional oligosaccharides (Manas et al., 2017).

The most used enzymes are hydrolases that often catalyze transglycosylation reactions. Several glycoside hydrolases can form oligosaccharides with a great variety in nature. In addition, protein engineering strategies are a great alternative to modulate hydrolysis and transglycosylation activities, resulting in tailor-made oligosaccharides (Manas et al., 2017).

This review chapter focuses on the application of different enzymes in the production of biological oligosaccharides. Functional aspects of the prebiotics and enzyme characteristics are also reported.

## Oligosaccharides as Functional Foods

After a meeting organized by the Food and Agriculture Organization of the United Nations (FAO), prebiotic was defined as “a nonviable food component that confers a health benefit on the host associated with modulation of the microbiota” (Pineiro et al., 2008). This broader concept was thought to encompass many prebiotics that had not been considered. However, three criteria must be fulfilled in order to a candidate be a prebiotic: i) non-digestible by hydrolytic enzymes of gut microbiota and resistant to gastrointestinal absorption; ii) fermented selectively by specific bacteria present at intestinal microflora; iii) to be able to stimulate the growth and/or the activity of bacteria related to benefits to the host (Gibson et al., 2004).

Until 2024, it is expected that the prebiotic market size of food and beverage exceeds USD 7 billion (Global Market Insights, 2017). Following this trend, pharmaceutical and food industries have made efforts to develop and explore functional oligosaccharides such as fructooligosaccharides (FOS) and inulin.

It has been reported for a long time that prebiotics boost the selective growth of mainly lactobacilli and bifidobacteria. These microorganisms produce short-chain fatty acids (SCFAs), including propionate, acetate and butyrate. These SCFAs turn the intestinal lumen alkaline and, therefore, inhibit the proliferation of bacterial pathogens, such as *Salmonella* and *Helicobacter* (Subin et al., 2017). Also, SCFAs induce the proliferation of enterocytes by the production of ATP. As a result, the cells produce more mucin and make the epithelial barrier less permeable to invasion of pathogens. As additional consequence of oligosaccharides fermentation, the immune system is strengthened by the production of cytokines modulators (Krumbeck et al., 2016).

**Table 1** Molecular structure of most known non-digestible oligosaccharides

Oligosaccharide	Molecular structure <sup>a</sup>	Glycosidic bond
Fructooligosaccharides	(Fr) <sub>n</sub> – Gu	β (2–1)
Galactooligosaccharides	(Ga) <sub>n</sub> – Gu	β (1–3) and β (1–4)
Xylooligosaccharides	(Xy) <sub>n</sub>	β (1–4)
Maltooligosaccharides	(Gu) <sub>n</sub>	α (1–4)
Isomaltooligosaccharides	(Gu) <sub>n</sub>	α (1–6)
Chitooligosaccharides	(GlcNAc) <sub>n</sub> or (GlcN) <sub>n</sub>	β (1–4)
Gentiooligosaccharides	(Gu) <sub>n</sub>	β (1–6)
Pectic oligosaccharides	(GalA) <sub>n</sub>	α (1–4)

<sup>a</sup>Ga: galactose; Gu: glucose; Fr: fructose; Xy: xylose; GlcNAc: N-acetyl-D-glucosamine; GlcN: glucosamine; Gal: galacturonic acid.

Modified from Singh et al. (2017).

Prebiotics are still associated with a vast range of beneficial effects, including improvement of the mineral absorption, prevention of cardiovascular diseases, diabetes, gastrointestinal infections and even some types of cancers (Rastall, 2010). Besides, due to their functional properties, prebiotics can be used as fat replacer and sugar in food industry. In addition, functional oligosaccharides are used in beverages, milk products, meat products, confectionary, breakfast cereals, bakery products, food for infants and other applications (Patel and Goyal, 2011).

## Carbohydrate Active Enzymes

Prebiotics can be produced by extraction from natural sources and by chemical, physical or biotechnological processes using enzymes. The enzymatic approach is normally the most reliable choice due to its high reproducibility and yield, focusing mainly on large scale oligosaccharide production (Moreno et al., 2017). In addition, enzymes normally act on mild reaction conditions. Besides the possibility of obtaining enzymes from different sources, their microbial production has shown to be more interesting for industrial production of prebiotics (Díez-Munício et al., 2014). The main advantages of using microbial enzymes include easier handling, higher production yield, economic feasibility and absence of seasonal fluctuation (Filice and Marciello, 2013).

The enzymes used in the production of different oligosaccharides are called carbohydrate-active enzymes (CAZymes) which are categorized in different classes in the CAZy database (<http://www.cazy.org>). The classes comprise glycoside hydrolases (GHs), glycosyltransferases (GTs), carbohydrate esterases (CEs), polysaccharide lyases (PLs) and auxiliary activities (AAs) (Lombard et al., 2014). These classes are subcategorized into families based on genomic, biochemical and structural information of the enzymes (André et al., 2014) (Fig. 1).

The glycoside hydrolase (GH) and glycosyltransferase (GT) are the most represented CAZymes. GHs normally act on O- and S-glycosyl compounds, hydrolyzing and/or rearranging glycosidic bonds. On the other hand, GTs are able to transfer glycosyl groups (donor to acceptor), catalyzing oligosaccharide synthesis (Díez-Munício et al., 2014). Several of these enzymes are used after cloning and expressing their respective genes in many hosts, including *Saccharomyces cerevisiae*, *Bacillus* sp., *Kluyveromyces* sp., *Aspergillus* sp., *Trichoderma* sp. and others (Patel and Goyal, 2011).

## Oligosaccharides: Enzymatic Production, Biological Activities and Applications

### Fructooligosaccharides

Fructooligosaccharides (FOSs) are oligosaccharides composed of 2–10 fructosyl residues linked by  $\beta$ -(2–1) glycosidic bonds (Rastall, 2010). FOSs are present in trace amounts in honey and several fruits and vegetables. These compounds show moderate sweetness (one-third of sucrose), low glycemic index and low calorimetric value. They can also be manufactured by three different approaches: (i) extraction from plant materials, (ii) enzymatic degradation of inulin, and (iii) enzymatic synthesis from sucrose (Dominguez et al., 2014). However, most of FOSs marketed have been produced either from sucrose or by degradation of inulin using enzymes (Singh et al., 2017).

Inulin is composed of fructosyl units linked by  $\beta$ -(2–1) bonds, with one terminal  $\alpha$ -(1–2) glucosyl residue. FOSs production from inulin is possible by controlled hydrolysis using endoinulinases (enzymes from family GH32) produced by filamentous fungi (*Aspergillus* sp. and *Penicillium* sp.), yeasts (*Kluyveromyces* sp.) and bacteria (*Bacillus* sp., *Pseudomonas* sp. and *Streptomyces* sp.) (Ganaie et al., 2014; Sarup et al., 2016). The action of endoinulinases on inulin randomly breaks down  $\beta$ -(2–1) glycosidic linkages resulting in a mixture of FOSs with DP from 2 to 7 molecules of fructose (Rastall, 2010; Sarup et al., 2016).

On the other hand, FOSs production from sucrose is carried out by enzymes with fructosyltransferase activity. These enzymes are found in family GH32 and possess both transfructosylation and hydrolytic activities, depending on the concentration of sucrose in the reaction medium. At low sucrose concentration, fructosyltransferases have mainly hydrolytic activity. However, the transfructosylating activity is more pronounced at high substrate concentration (Kovács et al., 2013). In the last case, the enzyme

**Figure 1** Diversity of CAZymes according to the CAZy database (<http://www.cazy.org>) (Accessed December 2017).

acts on sucrose by cleaving  $\beta$ -(1–2) linkages and transferring the fructosyl group to an acceptor molecule, such as FOSs and sucrose, with glucose release as a byproduct. The FOSs produced from sucrose contain 2–4 fructofuranosyl residues linked by  $\beta$ -(2–1) bonds, featuring a terminal glucose joined by  $\alpha$ -(1–2) linkage. These are mainly composed of 1-kestose (GuFr<sub>2</sub>), nystose (GuFr<sub>3</sub>) and 1- $\beta$ -fructofuranosyl nystose (GuFr<sub>4</sub>) (Rastall, 2010; Singh et al., 2017). Fucosyltransferase from *Aspergillus* sp. and *Aureobasidium pullulans* have been widely investigated to produce FOSs from sucrose (Ganaie et al., 2014). Sucrose-based FOSs can also be produced from sucrose present in different sources, such as agro-wastes and other low-cost byproducts (Dominguez et al., 2014).

FOS can inhibit the growth of harmful bacteria, improve mineral absorption in the gut, enhance immunity, reduce cholesterol level, prevent the development of colon cancer, promote the synthesis of complex B vitamins, control diabetes mellitus and obesity, and act on intestinal traffic control (Bali et al., 2015).

### Galactooligosaccharides

Galactooligosaccharides (GOSs) are oligosaccharides composed of different galactosyl residues (from 2 to 9 units) and a terminal glucose linked by  $\beta$ -glycosidic bonds, such as  $\beta$ -(1–2),  $\beta$ -(1–3),  $\beta$ -(1–4), and  $\beta$ -(1–6) (Illanes et al., 2016). They naturally occur at low concentrations in the milk of many animals, including humans and cows, but they also can be produced by chemical glycosylation or biocatalysis (Ackerman et al., 2017).

The enzymatic GOSs production can be performed by using galactosyltransferases as well as  $\beta$ -galactosidases. Galactosyltransferases exhibit high catalysis selectivity and produce higher GOSs yield, however they are not used commercially because of the requirement of specific sugar nucleotides as substrates and the extremely expensive costs (Contesini et al., 2013; Osman, 2015). On the other hand,  $\beta$ -galactosidases are robust GHs found in families GH1, GH2, GH35 and GH42 that can catalyze, when the acceptor is water, the hydrolysis of lactose into galactose and glucose. Alternatively, when the acceptor is a sugar such as lactose,  $\beta$ -galactosidases can catalyze transgalactosylation reactions giving rise to oligosaccharides (Hernández-Hernández et al., 2011). Thus, GOSs have been typically synthesized by the action of microbial  $\beta$ -galactosidases, produced by *Kluyveromyces lactis*, *Bacillus circulans*, *Bifidobacterium bifidum*, *Aspergillus oryzae* or *Streptococcus thermophiles*, by transgalactosylation of pure lactose solutions and low-value whey lactose from dairy (Kovács et al., 2013; Illanes et al., 2016; Ackerman et al., 2017).

Some conditions, such as elevated temperatures, high lactose concentrations and low water activity, are required in the reaction medium for GOSs production by  $\beta$ -galactosidases (Gosling et al., 2010; Illanes et al., 2016). Some studies have demonstrated that the concentration of GOSs, yields, and types of GOS formed during their enzymatic synthesis depend on the reaction conditions (e.g. time of reaction, pH, inhibitors) and on the source of enzyme (Gosling et al., 2010; Osman, 2015). For example, it was observed that the  $\beta$ -galactosidase from *B. subtilis* shows the highest GOSs yield (41% after 5 h using 49% lactose), which were mainly tri- and tetrasaccharide linked by  $\beta$ -(1–4) glycosidic linkages (Frenzel et al., 2015).

Currently, different possible human health benefits have been associated with GOSs consumption. Examples are mineral absorption, stool improvement, weight management, carcinogenesis, reduction of the cholesterol level and allergy alleviation (Illanes et al., 2016).

### Xylooligosaccharides

Xylooligosaccharides (XOSs) are sugar oligomers composed of xylose units linked by  $\beta$ -(1,4) bonds, with DP ranging from 2 to 10. They are named according to the number of xylose residues in their composition, i.e.: xylobiose, xylotriose, xylotetraose and so on. XOSs are known to be produced by *Aspergillus*, *Streptomyces*, *Trichoderma*, *Penicillium* and *Bacillus* from xylan rich materials (Belorkar and Gupta, 2016), although they are naturally found in fruits, vegetables, honey, bamboo and milk (Vázquez et al., 2000; Mandelli et al., 2014).

Production of XOSs usually includes chemical and enzymatic methods, as well as a combination of both approaches. The major drawback of chemical methods is the formation of toxic components that include acetic acid, furfural, protein-derived products and soluble inorganic compounds. This approach requires previous purification to obtain food grade XOSs. On the other hand, enzymatic process can be of great interest as it overcomes the limitations of chemical process. However, the direct enzymatic treatment is only suitable for susceptible materials such as citrus peels (Wang and Lu, 2013).

XOSs production from xylan through enzymatic methods is generally obtained after alkaline extraction (KOH or NaOH) from lignocellulosic materials, which are then converted to XOSs by xylanases from GH families 5, 7, 8, 10, 11 and 43. In XOSs production, xylanases having endoxylanase activity are preferred rather than exoxylanase activity since it can minimize xylose production and subsequently increase the XOSs production (Samanta et al., 2015).

Among the biological activities of XOSs it can be included antioxidant, immuno-modulatory, anti-inflammatory, anti-cancer and anti-microbial activities, antiallergy properties, active against diabetes, treatment of arteriosclerosis, among others (Belorkar and Gupta, 2016).

In addition to their biological properties, XOSs stand out for their potential to be used as ingredients in functional foods. They are competitively priced prebiotic ingredients which can be used at low doses comparing to other oligosaccharides. XOSs are safe and effective ingredients, presenting excellent stability over a wide range of pH (2.3–8) and temperatures (up to 120 °C). Moreover, they are suitable for use in a broad range of foods and formulations, are slightly sweet, being 40% as sweet as sucrose, but low in calories, what makes them suitable for low-calorie products. Finally, XOSs can be used with protein powders, overcoming constipation and other digestion problems associated with high protein diets (Kumar et al., 2013).

## Other Relevant Functional Oligosaccharides

Maltooligosaccharides (MOSs) are usually composed of 2 to 10 D-glucopyranosyl residues linked by  $\alpha$ -1,4 glycosidic linkages, while isomaltooligosaccharides (IMOSs) are generally linked by  $\alpha$  (1–6)-, and sometimes by  $\alpha$  (1–2),  $\alpha$  (1–3) or  $\alpha$  (1–4)-linkages (Singh et al., 2017). Both, MOS and IMOS, can be obtained from starch by the action of debranching enzymes. The difference between them is that MOSs are produced by the action of amylases and pullulanases, while IMOSs are obtained after starch liquefaction by amylases, demanding a second stage which involves transglucosylation by  $\alpha$ -transglucosidase (Mussatto and Mancilha, 2007). MOSs and IMOSs are also associated with a lower risk of diarrhea and infections, increase in short-chain fatty acid production, antidiabetic effects, obesity management and improvement of lipid metabolism (Meyer et al., 2015).

Gentiooligosaccharides (GeOSs) consist of glucose units linked by  $\beta$ -(1–6) glycosidic bonds, and can be obtained from pustulan (lichen polysaccharide) hydrolysis. The enzymatic production of GeOS is performed in two steps, starting with the conversion of gentiobiose in gentotriose by the action of  $\beta$ -glucosidase, followed by the conversion of gentotriose into gentiooligosaccharides by the action of  $\beta$ -(1–6)-glucanase (Jung and Park, 2014). In addition to the prebiotic activity, GeOSs can be used as a low-glycemic sweetener and as a taste improver in certain beverages due the bitter taste (Côté, 2009; Singh et al., 2017). Moreover, GeOSs were shown to be an anti-cancer agent against human colon carcinoma (Kothari and Goyal, 2015).

Pectic oligosaccharides (POSs) are a class of emerging prebiotics resulting from partial hydrolysis of the complex heteropolysaccharide, pectin. POSs are composed of D-galacturonic acid units, both in its acetylated or methylated forms, linked by  $\alpha$  (1–4) bonds. POSs production from purified pectins or agro-industrial byproducts can be achieved by hydrothermal processing, physical degradation, and by acid or enzymatic hydrolysis (Gullón et al., 2013). Because of the structural complexity of pectin, different enzymes, such as esterases, pectin lyases and hydrolases are necessary to achieve its degradation (Bonnin et al., 2014). Apart from promoting the bifidiogenic flora, some studies showed others benefits from POSs, such as lowering serum levels of total cholesterol, inhibition in the accumulation of body fat, protection against cardiovascular diseases (Li et al., 2010), reduction of damage by heavy metals, stimulation of apoptosis in human colonic adenocarcinoma cells, antioxidant, antiinfection, and antibacterial properties (Míguez et al., 2016).

## Conclusions

As discussed in this chapter, several oligosaccharides present remarkable functional properties, based mainly on the stimulation of benefic bacteria growth in human gut. Thus, several preventive effects for health can be achieved, including anticarcinogenic properties. Enzymatic synthesis of oligosaccharides is considered a promising alternative to the industrial production of this functional products, since it does not have the common drawbacks found in chemical routes or in the case of extraction from natural products. Many studies have focused on the optimization of CAZymes production and oligosaccharide production through enzymatic routes. However, efforts still must be made in protein engineering to obtain tailor-made functional oligosaccharides. Furthermore, genetic engineering of industrial strains is another bottleneck that must be focused. Finally, the precise identification of oligosaccharides, including branched ones, is still an obstacle to be overcome in order to maximize oligosaccharide market.

# Chemically Reducing Properties of Maillard Reaction Intermediates

George P Rizzi, Miami University, Middletown, OH, United States

© 2019 Elsevier Inc. All rights reserved.

## Introduction

The designation Maillard reaction is in fact somewhat of a misnomer in that the so-called “reaction” represents a large number of discrete, but closely related separate reactions. The MR is initiated by the fundamental interaction of carbonyl and amine-containing reactants. In foods and biological systems the MR begins with a reducing sugar (a carbonyl derivative) and amino acids and/or proteins representing the amine component. Early studies on the MR dealt mainly with reaction end products consisting of colored polymeric materials today commonly known as melanoidins or browning products. Historically, the MR was first investigated by the French/Algerian scientist **L. C. Maillard (1912)** during his researches on peptide syntheses. Many intermediates in the MR have since proven to have potent chemically reducing properties some of which comprise the subject of this chapter.

MR intermediates are typically highly reactive, often present in low concentration and were therefore seldom isolated in early studies. In the decades following the work of Maillard MR chemistry has been thoroughly investigated internationally and results are represented by numerous comprehensive books (**Pigman et al., 1980; Nursten, 2005; Ikan, 1996**) and reviews (**Ledl and Schleicher, 1990**). In the USA pioneering research by J. H. Hodge et al. in the 1950s led to the first mechanistic understanding of the MR and to a sequence of reactions still valid today (**Hodge, 1953**) [vide infra].

## Origin of MR Reducing Properties

Reduction in the chemical sense takes place when a species adds one or more electrons to its structure. Thus substances which can provide these electrons are referred to as reducing agents. In the MR key intermediates with reducing properties are structures containing acyloin ( $\alpha$ -hydroxycarbonyl) or related tautomeric 1,2-enediol elements. Structures containing the predominantly 1,2-enediol tautomeric forms are known collectively as REDUCTONES (**Schank, 1972**). 1,2-Enediols act as reducing agents by their conversion to 1,2-diketones via elimination of two electrons and two hydrogen ions. The equilibrium between acyloins and 1,2-enediols normally favors the acyloin form which is lower in energy. Acyloins such as reducing sugars and Amadori compounds (discussed below) exhibit moderate reducing power and will be described in a later paragraph, however the similarity in their oxidative mechanism is shown in **Fig. 1**.

The presence of strongly acidifying groups e.g. like a carbonyl group on one or both oxygen-bearing acyloin carbon atoms tends to stabilize the enediol form as an  $\alpha$ -oxo-enediol as for example in ascorbic acid. The enhanced acidity of the  $\alpha$ -oxo-enediol hydroxyls readily leads to relatively stable anionic enediolates. And, once formed, these anionic species can act as relatively more powerful reducing agents than simple acyloins by more facile donation of one or two electrons to accepting species. Compounds containing the  $\alpha$ -oxo-enediol moiety, including ascorbic acid, are known collectively as aci-reductones. In addition, compounds in which one or both hydroxyl groups have been replaced by SH, NH<sub>2</sub> or –NHR also belong to the reductone class. Nitrogen-containing reductones were first recognized in disaccharide/amino acid reactions (**Ledl, 1984**) and an aminoreductone, 1-alkylamino-1,2-dehydro-4-deoxy-3-hexulose has been prepared in a reaction of lactose and n-butylamine (**Pischetsrieder et al., 1998**).

## Formation of Reducing Compounds in the Maillard Reaction

The early stages of a typical MR are illustrated in **Fig. 2**. Amino acids and/or proteins react with reducing sugars (aldoses or ketoses) with loss of water to form glycosyl imines (shown in open chain form). In **Fig. 2** an aldose-derived imine undergoes prototropic rearrangement to form a relatively stable isomeric aminoketone known as an Amadori compound (**Yaylayan and Huyghues-Despointes, 1994**). Under similar conditions ketoses yield aminocarbonyls known as Heyns compounds. In the MR thermal or acid catalyzed fragmentation of relatively stable Amadori or Heyns intermediates leads directly to more highly reactive 1,2-dicarbonyl structures most commonly called 1-deoxyosones (1-DEOs) and 3-deoxyosones (3-DEOs). Elimination of the amine function takes place from the two enolic forms of the Amadori compound. The 1,2-enol yields 3-DEOs whereas the 2,3-enol affords 1-DEOs. Both types of DEOs are highly reactive in subsequent reactions by virtue of their 1,2-dicarbonyl functionality. But, 1-DEOs

**Fig. 1** Oxidative mechanisms for tautomers of acyloins and Amadori compounds.

**Fig. 2** Early stage of Maillard reaction.

being  $\alpha$ -oxo-enediols as well are therefore by definition aci-reductones and show characteristic enhanced reducing capability. To date 1-DEOs have escaped detection in the MR although their presence has been proven by chemical derivatization. 1-DEOs share highly reducing properties with similar substances like ascorbic acid and reductic acid.

### Unique Reducing Chemistry of 1-Deoxyosones

The special reactivity of acyclic  $\alpha$ -oxo-enediols (i.e. 1-DEOs) is explained by their ability to form a double 5-membered ring protonic chelate (Fig. 3) which has a central hydroxyl group. The chelate structure provides enhanced protic activity thus allowing enhanced ionization and subsequent ease of electron abstraction. As also shown in Fig. 2 the resulting two electron oxidation products of 1-DEOs are initially 1,2,3-tricarbonyl compounds commonly called dehydroreductones. Carbohydrate derived dehydroreductones are highly reactive and probably undergo facile redox disproportionation with concomitant loss of carbon dioxide (Schank, 1972), a putative scheme for this is shown in Fig. 3. Typical products predicted from such degradation of a 5-carbon tricarbonyl compound are, besides  $\text{CO}_2$ , a 4-carbon diketone and a regenerated 5-carbon dihydroxyoneone.

In practice carbohydrate derived triketoones have not been observed, but their presence has been rationalized in terms of isolated fragmentation products (Voight et al., 2010). Interestingly, the well known bicyclic tricarbonyl ninhydrin is completely stable in the form of its monohydrated central carbonyl carbon. Whereas the reducing power of reductones is well known and can be demonstrated readily in terms of analytical reagents (vide infra) the question of what substances are actually being reduced during the MR remain unanswered. Molecular oxygen has been suggested as a possible electron recipient leading eventually to fragmentation of 1-DEOs without the formation of a dehydroreductone intermediate with formation of acetic acid (Robert et al., 2005), but MR conducted under anoxic conditions suggest alternate possibilities. For example, ample evidence exists for the presence of free radical species during the MR and it's possible that reductones may contribute to their formation in situ (Hayashi and Namiki, 1981). The single electron donating capability of 1-DEOs is also evident in the molecule's antioxidant behavior (Kanzler et al., 2014). Using EPR (electron paramagnetic resonance) measurements, for example special radical scavenging activity was reported for 1-deoxy-D-erythro-hexo-2,3-diulose, a typical 1-DEO.

In contrast to the highly reactive 1-DEOs the 3-DEOs are not reductones and do not exhibit the reductive reactivity associated with enediols. However, 3-DEOs do participate in important subsequent reactions like the Strecker degradation, a well documented source of volatile flavor compounds (Rizzi, 2008).

### Detection and Measurement of MR Reductones

#### Chemical Reagents for Reductone Analysis

Early studies on the MR indicated intermediate compounds were present capable of reducing common reagents such as: methylene blue, ferricyanide, dichlorophenolindophenol, Fehling solution ( $\text{Cu}^{+2}$ ) and Tollens reagent ( $\text{Ag}^{+1}$ ) (Hodge, 1953). Further detailed studies characterized reducing bodies as Amadori compounds and recognized the formation of what were then simply called reductones and dehydroreductones.

Reductones decolorize weakly acidic solutions of iodine by forming carbonyl oxidation products. The oxidation products can be determined gravimetrically using 2,4-dinitrophenylhydrazine (Schank, 1972). A more recent and convenient colorimetric method uses the commercially available reagent 3'-[1-(phenylamino)carbonyl-3,4-tetrazolium]bis (4-methoxy-6-nitro)benzenesulfonic acid hydrate (XTT). Tetrazolium reagents like XTT are readily reduced by reductones to form highly colored formazan derivatives with a UV/VIS max at 470 nm easily quantified spectrophotometrically. The method is practical and has been used to quantify the reductones present in UHT-treated milk and in a model MR of lactose (Shimamura et al., 2000). Using post-column detection

**Fig. 3** Chelate structure and related oxidation and decomposition of 1-deoxyosones.

**Fig. 4** Redox behavior of 2,6-dichloroindophenol.

with alkaline triphenyltetrazolium chloride 16 Amadori compounds were quantified in dried vegetable products (Reutter and Eichner, 1989).

A popular laboratory method for reductone analysis is the use of Tillman's reagent based on the commercially available indophenol dye, 2,6-dichloroindophenol (DCIP). The dye in its normal oxidized state is deep blue, but when used to titrate reductones in solution a sharp colorless endpoint is obtained. The redox chemistry of DCIP with a generalized enediol substrate is shown in Fig. 4.

Results showing DCIP analysis of reductone formation during the phosphate ion catalyzed degradation of reducing sugars (Rizzi et al., 2010) are shown in Fig. 5.

The ordinate (AAE) ascorbic acid equivalents represents the amount of ascorbic acid standardized Tillman's reagent used in the titrations. Under standardized conditions DCIP will respond to aci-reductones like 1-DEOs and Amadori compounds, but is unreactive to less reactive acyloins like reducing sugars.

## Electrical Properties of MR Intermediates

The inherent redox nature of reductones implies electrochemical behavior with both theoretical and practical value (Rizzi, 2003a). In some cases Galvanic activity has been observed in which redox pairs constitute a source of EMF (electromotive force) whose presence can serve to detect the presence of reductones in MR systems and to follow their rates of formation and decay. The magnitude of Galvanic EMF can also serve to estimate the relative propensity of reducing sugars for producing reductones in the MR.

The reversible character of redox pairs also permits the use of electrolytic action in which application of external potentials are used to alter redox equilibria. Typical applications of electrolysis in MR systems are: electrochemical detectors for GC or HPLC analysis; polarography; cyclic voltammetry; amperometry and more recently pulsed amperometry (Blank et al., 2002). With suitable voltage ranges many types of latent enediol systems e.g. acyloins like reducing sugars, Amadori compounds, polyphenolic compounds and late phase MR heterocyclic materials like pyranones may be detected and quantified.

**Fig. 5** Use of Tillman's reagent to titrate reductones in reducing sugar degradation reactions. Reprinted with permission from Ref. Rizzi et al. (2010), Copyright 2010 American Chemical Society.

### Galvanic Activity in the MR

Open circuit EMFs have been measured between platinum and Ag/AgCl electrodes in a model MR systems consisting of reducing sugars,  $\beta$ -alanine in bis/tris buffer at 100 °C (Rizzi, 2003a). Increasing negative voltages were observed with time indicative of reductone production. The existence of a measurable EMF is evidence for the spontaneous ability of a reducing substance (most probably an aci-reductone) present to convert silver ion into metallic silver. In these experiments independent chemical derivatization verified the presence of an aci-reductone and other reductones. Data obtained after 1.0 h (Table 1) indicated greatest reductone activity for pentoses, ribose, arabinose and xylose compared with less reactive glucose. Negative controls i.e. negligible EMF was observed by 2-deoxy-D-glucose, sorbitol and xylitol, compounds incapable of undergoing MR.

### Electrolytic Behavior in MR

Electrolytic aspects of the MR and Galvanic activity have been reviewed recently (Rizzi, 2013). Little published information is available on polarography of the MR. Hayashi and Namiki (1981) observed anodic waves in model MR systems indicative of oxidation and consistent with the presence of enediol moieties. Concurrent DCIP titration data was in agreement with their polarographic results. Cyclic voltammetry (CV) is a type of polarography combining both oxidation and reduction. A CV route was envisioned for electrical conversion of an Amadori compound (eneaminol tautomer) to an otherwise elusive dehydroreductone (Rizzi et al., 2010). A model Amadori compound, N-(1-deoxyfructos-1-yl)piperidine (Fig. 6) was CV analyzed at pH 7.14) Two oxidation waves were observed: + 0.7 V (oxidation of the eneaminol) and + 0.9 V (oxidation of the piperidinium osone, leading ultimately to a piperidinium reductone and presumably by hydrolysis to a triketonic dehydroreductone. However, total lack of

**Fig. 6** Putative oxidation scheme for N-(1-deoxyfructos-1-yl)piperidine.

corresponding reduction waves suggested that initially formed oxidation products had rapidly decomposed to electroinactive products.

The observation of two oxidation (anodic) waves was indicative of a stepwise transfer of electrons possibly involving free radical intermediates in the reduction process. Free radical behavior is known in the chemical reduction reaction of Amadori compounds with nitroblue tetrazolium (NBT) to form the tetrazinoly radical (NBT<sup>•</sup>) (Baker et al., 1994) and during autooxidation induced by copper I ion (Kawakishi et al., 1991). The subject of free radicals in the MR has been recently reviewed (Rizzi, 2003b).

CV results reported by Chaung and Chou (2008) on the Amadori compound, N-(1-deoxy-β-D-fructopyranos-1-yl)-L-valine, revealed a single anodic wave at ca. + 1.0 V with no compounds detected in a cathodic scan. A practical application of voltammetry for determination of reducing substances in beer has been described (Sobiech et al., 1998).

## Electrochemical Detectors (ECD)

Whereas many acyloins (including reducing sugars), Amadori compounds and various reductones exist in the MR electrochemical methods have only occasionally been employed for their unique detection or measurement. Acyloins and Amadori compounds because of their greater stability are generally separated or isolated from MR mixtures by chromatography and detected by optical (diode array detection) or mass spectrometric techniques (Davidek et al., 2005; Yuan et al., 2017). In ECD the emerging analyte is oxidized in a fixed potential electrolytic cell [amperometric analysis (EC/AA)] and resulting current flow provides detection.

An early example of EC/AA was the detection and quantification of the MR product 2,3-dihydro-3,5-dihydroxy-6-methyl-4-H-pyran-4-one, a.k.a. 2,3-dihydro-3-hydroxymaltol (Schnee and Eichner, 1987). This late stage MR product is formed during cacao roasting and is isolated among other volatile flavor compounds during steam distillation. HPLC analysis coupled with UV detection verified its MR origin and complete absence in unroasted cocoa. The pyranone derivative was electroactive by virtue of its inherent enediol structure and was readily detected (oxidized) in an ECD cell maintained at + 0.8 V. Using ECD detection the pyranone was readily quantitated and showed a linear correlation with respect to roasting degree thus providing a practical guide to follow the extent of cocoa bean roasting.

A modification of (EC/AA) called pulsed amperometric detection (EC/PAD) optimizes electrode function and has proven useful for analysis of MR mixtures. Using EC/PAD Amadori compounds were detected and quantified in model MRs of glucose/morpholine and glucose/tryptophan at 100 °C during 3.5 h (Huyghues-Despointes and Yaylayan, 1994). Later, by using synthesized Amadori compounds glu/morpholine and glu/proline their decomposition was studied using EC/PAD in aqueous solution at 100 °C, several electroactive products were observed but none were identified. More recently, refinements in the AA/EC and EC/PAD methodology led to, for example, analysis of the labile pentose-derived compound xyl/gly i.e. N-(1-deoxy-D-xylulos-1-yl) glycine and the analysis of Amadori compounds xyl/ala and xyl/ile synthesized in a mixture MR containing alanine and isoleucine in methanol at 70 °C (Davidek et al., 2005).

## Conclusions

Recent studies continue to confirm the presence of highly reactive, chemically reducing substances in Maillard reactions. Study on the redox behavior of these compounds is helping to elucidate the as yet complex detailed mechanism of this reaction. Modern analytical techniques like cyclic voltammetry and pulsed amperometric detection are providing access to hitherto inaccessible highly reactive intermediates.

### Introduction

Protein oxidation is a complex phenomenon occurring quite often in protein-rich foods like meat, fish, milk, and eggs. Oxidation of proteins has been defined as a covalent modification induced by reactive species or a reaction with secondary products of oxidative stress. This process results in a wide variety of chemical modifications depending on the pathway and nature of the generated oxidation products, which involves the formation of carbonyl derivatives, amino acid side chain modifications, cleavage of protein backbone and protein cross-linking, among others. These modifications have been reported to imply negative effects on human health due to its participation in the pathogenesis of several diseases, as well as negative effects on foods from the sensory, nutritional and technological points of view.

### Chemical Mechanisms and Factors Promoting Protein Oxidation

Protein oxidation can be induced directly by reactive oxygen species (ROS) and reactive nitrogen species (RNS), or indirectly through reactions with secondary products of oxidative stress. Protein oxidation is initiated by many species including i) free radical species such as hydroxyl ( $\text{OH}^\bullet$ ), superoxide ( $\text{O}_2^{\bullet-}$ ), nitric oxide ( $\text{NO}^\bullet$ ), and peroxy ( $\text{PO}^\bullet$ ), ii) non-free radicals such as hydrogen peroxide ( $\text{H}_2\text{O}_2$ ), singlet oxygen ( $^1\text{O}_2$ ), ozone ( $\text{O}_3$ ), and hypochlorous acid ( $\text{HOCl}$ ), and iii) reactive aldehydes and ketones. These reactive species are typically produced through the action of external agents such as ultraviolet light, irradiation (X-rays,  $\gamma$ -rays), metal ions ( $\text{Fe}^{2+}$ ,  $\text{Cu}^+$ ), ozone, air pollution, drugs, nanoparticles, and xenobiotics, or are derived from endogenous muscle sources including metal-catalyzed systems, oxidative enzymes, oxidizing lipids, reducing sugars, and pro-oxidative heme proteins such as myoglobin and hemoglobin.

The free radical-mediated pathway of protein oxidation can be initiated when a ROS abstracts a hydrogen atom from the protein molecule and generates a protein carbon-centered radical ( $\text{P}^\bullet$ ), which is readily converted in the presence of oxygen to an alkyl peroxy radical ( $\text{POO}^\bullet$ ). Afterwards, the abstraction of a hydrogen atom from another molecule, reaction with the reduced form of iron ( $\text{Fe}^{2+}$ ) or with the protonated form of superoxide radical can lead to the generation of alkyl peroxide ( $\text{POOH}$ ). Further reactions with free peroxy radicals ( $\text{HO}_2^\bullet$ ) or  $\text{Fe}^{2+}$  can yield alkoxy radical ( $\text{PO}^\bullet$ ) and its hydroxyl derivative ( $\text{POH}$ ). Additionally, alkyl peroxide and alkoxy radicals can lead to protein fragmentation by the  $\alpha$ -amidation or diamide pathways, generating amine derivative and N-carbonyl derivative, or diamide derivative and isocyanate derivative, respectively.

The nature of oxidation products depends on the target and oxidizing agents, intensity of oxidation conditions as well as the amino acids involved. Sulfur-containing amino acids such as methionine and cysteine are the amino acids more susceptible to ROS and oxidizing lipids, whereas tryptophan residues are quickly oxidized in the presence of metal ions. Other residues such as tyrosine, phenylalanine, proline, histidine, lysine, threonine, arginine, leucine and valine need more severe conditions to be oxidized. The position of these amino acids within the structure of the protein greatly affects their exposure to oxidant factors and thus, their modification. Oxidation of amino acids can imply the modification of essential amino acids such as arginine, lysine, proline and threonine through carbonylation, the hydroxylation of aliphatic amino acids, sulfoxidation of methionine residues, nitrosylation of sulfhydryl groups or hydroxylation and nitration of aromatic amino acids. As a result, a wide variety of oxidation products are generated, which are shown in [Table 1](#).

The formation of protein carbonyls (aldehydes and ketones) is the most common modification resulting from protein oxidation. The side chains of proline, lysine, arginine and threonine residues can be oxidized by metal ion-catalyzed reactions into carbonyl compounds. The reaction between transition-metal ions and hydrogen peroxide ( $\text{H}_2\text{O}_2$ ), namely Fenton reaction, is a source of highly reactive hydroxyl radicals ( $\text{OH}^\bullet$ ). So, the presence of ferric iron ( $\text{Fe}^{3+}$ ) can initiate the oxidative deamination from the intermediate radical molecule, converting lysine into  $\alpha$ -aminoadipic semialdehyde (AAS), arginine and proline into  $\gamma$ -glutamic semialdehyde (GGS) and threonine into  $\alpha$ -amino-3-keto butyric acid. The resulting  $\text{Fe}^{2+}$  can further oxidize other amino acids through reaction with  $\text{H}_2\text{O}_2$  and form hydroxyl radicals. Other metal ions and heme proteins, both activated by  $\text{H}_2\text{O}_2$ , are also able to promote the formation of AAS and GGS. Carbonyls can be formed to a lesser extent by other pathways including oxidative cleavage of peptide backbone, non-enzymatic glycation in the presence of reducing sugars, or covalent binding to non-protein carbonyl compounds from lipid oxidation. Thus, protein oxidation is related with other biochemical reactions occurring in food systems like lipid oxidation and Maillard reaction, as their products can further increase oxidation in a reciprocal manner. Finally, protein carbonyls can participate in advanced reactions, resulting in further oxidative degradation (such as AAS into  $\alpha$ -aminoadipic acid (AAA)) or formation of an aldol condensation product, Schiff-bases or Strecker aldehydes.

Oxidation can also lead to protein backbone cleavage, which is mainly induced by free radical oxidants. Radicals can react with a specific site of the polypeptide backbone resulting in its fragmentation and thus leading to conformational changes in the secondary and tertiary structures of the protein. The oxidation of proline, aspartyl and glutamyl residues of protein can lead to peptide bond cleavage generating derivatives of the oxidation process.

**Table 1** Oxidation products of the most susceptible amino acid residues

<i>Amino acids</i>	<i>Oxidation products</i>
Arginine	$\gamma$ -Glutamic semialdehyde
Cysteine	Cysteic acid, sulfenic acid, sulfinic acid, sulfonic acid, cystine
Glutamic acid	Oxalic acid, pyruvate adducts
Histidine	Aspartate, asparagines, aspartic acid, 2-oxohistidine, 3,4,5-hydroxyleucine, 4-hydroxyl glutamate
Leucine	3,4,5-Hydroxyleucine
Lysine	$\alpha$ -Aminoadipic semialdehyde
Methionine	Methionine sulfoxide, methionine sulfone
Phenylalanine	2-, 3-, 4-Hydroxyphenylalanine, 2,3-dihydroxyphenylalanine, nitrophenylalanine, <i>p</i> -, <i>m</i> - and <i>o</i> -tyrosine
Proline	$\gamma$ -Glutamic semialdehyde, 4,5-hydroxyproline, pyroglutamic acid, 2-pyrrolidone
Threonine	$\alpha$ -Amino-3-keto butyric acid
Tryptophan	2-, 4-, 5-, 6-, 7-Hydroxytryptophan, formylkynurenine, kynurenine, 3-hydroxykynurenine, nitrotryptophan
Tyrosine	3,4-Dihydroxyphenylalanine, 3-nitrotyrosine, dityrosine, Tyr- <i>O</i> -Tyr, 3-chlorotyrosine, 3,5-dichlorotyrosine
Valine	3-Hydroxyvaline

The formation of intra- and inter-molecular cross-links is another manifestation of protein oxidation, and results in the generation of different oxidation products as well as aggregation and polymerization of proteins. Metal ions and heme proteins can act as initiator factors of this modification, as well as two carbon-centered radicals that can react with each other and generate cross-linked derivatives in the absence of oxygen. In the presence of H<sub>2</sub>O<sub>2</sub>, proteins and peptides containing cysteine are highly susceptible to loss of sulfhydryl groups through several and complex reactions of oxidation, generating sulfenic acid, sulfinic acid, and cysteine (disulfide bonds) as oxidation products. On the other hand, tyrosine can be oxidized to tyrosyl radicals that can combine to form dityrosine. Both disulfide and dityrosine bonds result in the formation of cross-linked proteins.

### Effect of Processing on the Oxidation of Proteins

Protein oxidation is well recognized to have an impact on loss of quality during processing and storage of protein foods. Main oxidative modifications of proteins take place at the side chains of amino acids, including thiol oxidation, aromatic hydroxylation, and formation of carbonyl groups. **Table 1** shows the most usual products from amino acids oxidation, which can be formed during processing and storage and have impaired consequences in food. For instance, protein oxidation occurring during the aging and cold storage of meat has been linked to loss of functionality, giving poorer juiciness and increased toughness. The loss of functionality also affects the suitability of such meat to be further processed when functional properties (emulsifying, water-holding capacity, gelling, etc.) play a major role. Additionally, exudation and drip loss, upon thawing of frozen meat, may be due to changes in the water-holding capacity, in some extent related with the oxidation of proteins as frozen storage increases the susceptibility of meat proteins to undergo further oxidation during processing.

Methods to stabilize foods without the use of heat treatments may affect the oxidation of food proteins and further their final quality. So, high pressure treatment of fresh meat results in discoloration attributed in a large degree due to the oxidation of oxymyoglobin and denaturation of myoglobin protein. Different studies have also evaluated the effect of different pressure intensities, between 200 and 800 MPa, on functionality (solubility and water holding capacity) of myofibrillar proteins from pork meat.

The effect of sterilization using different irradiation technologies also induces oxidation in those proteins containing aromatic and sulfur amino acids, which are the most susceptible to be oxidized. Aromatic amino acids react with hydroxyl radicals formed during the radiolysis of water with the generation of three tyrosine isomers (*p*-, *m*- and *o*-tyrosine) from phenylalanine oxidation or  $\alpha,\alpha'$ -diamino acids after ionizing radiation. So, UV irradiation of milk can produce the breakdown of proteins while the application of  $\gamma$ -rays or low dose of <sup>60</sup>Co to chicken, fish or shrimps sample can generate *o*- and/or *m*-tyrosine products that are used as markers of irradiation dosimetry.

Curing process in meat products using a mixture of salts composed of nitrate, nitrite and sodium chloride, constitutes a very used preservation procedure. The curing agent nitrite is a preservative and color enhancer in meat products. This additive behaves as strong antioxidant but, at low pH and high temperature has a pro-oxidant effect through the formation of nitric oxide and peroxynitrite. These RNS are responsible of the nitration of certain amino acids such as tyrosine, which is converted into 3-nitrotyrosine that is considered as protein oxidation biomarker. Sodium chloride may exert a pro-oxidative effect by modifying the conformation, functionality and solubility of proteins, making them more susceptible to be oxidized.

Thermal methods are usual in the sterilization/pasteurization of milk and milk products. During thermal treatment of milk, proteins are oxidized as demonstrated by the increase in the number of carbonylation sites in pasteurized and UHT compared to fresh milk. This fact may reduce the nutritional value of milk and abolish protein functions supporting human health that is especially important for newborns. Oxidative degradation may be increased by other types of processing. For example, mechanical actions during meat grinding would lead to cell disruption and oxygen inclusion, thereby increasing the contact with ROS. Processing technologies involving high temperatures, either for the preparation of "ready to it" products or during cooking at home,

promote the occurrence of protein oxidation. The type of technology used (grilling, roasting, frying, boiling, traditional or microwave oven) has been described to have also an impact on protein oxidation, although at different degrees.

Finally, the exposure to oxygen and light during chilled display at points of sale can further increase oxidation processes. Different packaging systems such as the application of vacuum or the use of modified atmosphere have widely used to minimize oxidation effects in food during storage and later cooking.

### Effect of Protein Oxidation on Health

Chemical modifications produced in proteins by the oxidation of specific amino acids may have implications on human health and safety when consumed. Recent studies have related protein oxidation with many diseases. The investigation of the mechanisms of protein oxidation has been intensified in the last 20 years due to the growing evidence that aging and various human pathologies are correlated with the increase of protein oxidation. Moreover, the presence of abnormal amounts of oxidized amino acids has been observed in many degenerative and chronic diseases.

Most research has been focused on the possible implication of protein oxidation in muscle foods and its contribution to several human diseases. However, it is still pending to demonstrate the effect of extrinsic oxidized amino acids coming through the diet on health.

Given the proved relationship between the presence of lipid oxidation products, consumed or generated in the gastrointestinal tract, and health risks by oxidative stress, the effect of protein oxidation products on the overall oxidative stress and the onset of certain health disorders is under suspicion, especially in view of the association that has recently been made between the consumption of cured and red meat and colorectal cancer.

As described in a previous section, oxidized amino acids can be accumulated in foods during processing and storage, but also can be generated in the organism during gastrointestinal digestion. This last has been studied in the colonic phase during a simulated digestion of red meat, cured meat and cooked meat, where the presence of other food components like heme-iron and fats, can promote the extent of protein oxidation and the complexity in the different oxidative reactions. The biological significance of such reactions and their effects on health is still controversial. Changes in proteins may cause a reduced protein digestion and these non-hydrolyzed proteins can be fermented by colonic flora into mutagenic products. There are also numerous studies showing some kind of disturbance in the intestinal flora, changes in the redox state of intestinal tissues, all contributing to inflammatory bowel diseases that can give place to the onset of carcinogenic processes.

Since protein oxidation markers have been found in blood and organs, the systemic effect of such compounds should be studied for the added risk of incorporating these anomalous amino acids to the *de novo* synthesis of proteins that will not have the expected functionality or even could be toxic. One of the clearest cases is the neurotoxicity of tryptophan oxidation products such as kynurenine, which have been found in processed and stored milk and is absorbed upon digestion; but also oxidized forms of methionine, specially methionine sulfoxide, found in large amounts in dairy products; dityrosine, the main oxidized form of tyrosine, which has been reported to cause hepatotoxicity and fibrotic degeneration of liver and kidney in mice; and aminoadipic acid, the last oxidation product from lysine, which has been associated to diabetes constituting a marker of diabetes risk.

All studies that link the intake of oxidized proteins through diet with age-related diseases require a long time of observation with prolonged exposure in order to obtain conclusive results. In the meantime, a moderate protein-restricted diet is recommended to increase the protection against aging and cancer.

### Effect of Protein Oxidation on Nutritional Sensory and Technological Quality of Foods

Oxidation of proteins can affect nutritive, sensory and technological properties of protein foods. Protein oxidation produces a decrease in the nutritive value of food products due to a reduced digestibility and loss of bioavailability of the modified amino acids. This problem becomes more important because the amino acids most susceptible to oxidation are just the essential amino acids. Protein oxidation before digestion results in impaired proteolysis during digestion. Moreover, free radicals are responsible for the formation of dityrosine bonds during meat cooking or under photo-oxidative conditions, which may result in protein aggregates with reduced digestibility and nutritional quality.

The alteration of the protein structure by oxidative damage can alter its binding ability with volatile compounds affecting aroma. Nevertheless, the overall impact of protein oxidation on sensory attributes still needs to be elucidated.

Other changes due to oxidation lead to changes in hydrophobicity that alter protein aggregation and decrease protein solubility thereby affecting technological properties like gel forming ability, emulsification properties and water binding capacity. The presence of modified amino acids in a protein can prevent the activity of endoproteases in fresh meat and thus might negatively impact tenderness. Also these modifications might affect the activity of peptidases by altering its recognition of substrates, and thus modifying the final quality of processed foods.

## Antioxidant Strategies

The human body possesses an antioxidant defense system that includes enzymes such as superoxide dismutase, catalase and glutathione peroxidase; metal-binding proteins such as ferritin, transferrin and ceruloplasmin; systems to repair protein and DNA damages; and metabolites and cofactors such as glutathione, uric acid and bilirubin. Additionally, dietary antioxidants such as vitamins, minerals, phenolic acids, flavonoids, carotenoids and peptides present in fruits, vegetables, meat, fish, legumes and dairy products also participate in antioxidant mechanisms. However, oxidative stress is inevitable despite this protective system, so the addition of antioxidant compounds, either through dietary or technological strategies, would help to reduce or even prevent oxidation and its negative effects on human health and food quality. Most of the commonly used antioxidant strategies have been focused on preventing lipid oxidation in foods, whereas its use against protein oxidation is a recent trend. Nevertheless, many of these procedures have been shown to be also effective against protein oxidation, due to the relationship between both processes.

The addition of antioxidant compounds to the formulation of products is a common strategy to inhibit protein oxidation. Antioxidants can donate electrons to break and terminate the oxidation cycle at the propagation step and thus prevent the formation of radicals, or they can act as metal chelators to inactive radical initiators. Synthetic antioxidants such as butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), tertiary butylhydroquinone (TBHQ) and propyl gallate have been long used to inhibit oxidation, but their possible adverse effects on health have led to a recent interest in the use of safer and natural antioxidant compounds. Plant extracts including spices, seeds, herbs and essential oils as well as fruit extracts have been traditionally used in foods for organoleptic purposes, but they are also good sources of antioxidants such as tocopherols and phenolic compounds. These substances can act as radical scavengers and metal ion chelators through linkages with food proteins, although these interactions depend on the chemical structure and amount of the antioxidant as well as the characteristics of the protein and intensity of oxidative reactions. On the other hand, plant and fruits extracts also contain vitamins and minerals, which are considered as natural antioxidants due to their function as co-factors of antioxidant enzymes. So, vitamins A ( $\beta$ -carotene as precursor), C (ascorbic acid) and E ( $\alpha$ -tocopherol), as well as minerals such as selenium and zinc, have been described to exert highly effective radical scavenging properties.

Peptides and amino acids derived from the hydrolysis of proteins can also act as antioxidant agents in food systems. Antioxidant peptides generally contain 4–16 amino acid residues and their properties are related to their structure, hydrophobicity as well as composition and location of amino acids. So, methionine, tyrosine, tryptophan, cysteine, lysine, phenylalanine and histidine are well-known amino acids with antioxidant potential, showing radical-scavenging activity, metal ion chelation, inhibition of lipid peroxidation and enhancement of the antioxidant defense system of the human body. Antioxidant peptides can be generated through i) hydrolysis of food proteins by endogenous/microbial enzymes during aging, processing or ripening, and storage, ii) controlled hydrolysis with commercial proteolytic enzymes or iii) release during gastrointestinal digestion after food ingestion. Numerous peptides derived from enzymatic hydrolysis of proteins from soy, corn, potato, and animal-derived proteins such as casein, whey, egg, muscle proteins, and collagen, have been described to exert antioxidant activity and could be used as food additives. Furthermore, the multifunctional nature of antioxidant peptides, being able to exert other bioactivities such as antihypertensive, antimicrobial, cholesterol-lowering effect, opioid, and anticancer, among others, makes them to be considered as novel and potential ingredients of functional foods and nutraceuticals.

The feeding regime of animals raised for food production has a major influence on the oxidative stability of the final food product. So, dietary strategies against muscle food oxidation usually imply reduction of polyunsaturated fatty acids in animal tissues and feed supplementation with tocopherols or carotenoids from plant extracts, which also improve organoleptic properties of foods. In this regard,  $\alpha$ -tocopherol is the most common feed additive because it not only exerts antioxidant effects but it can also maintain the color of meat products due to delay of oxidation of oxymyoglobin and inhibition of PUFA oxidation. Organic minerals, aromatic herbs and essential oils are also being used in animal feed to protect against oxidative damage and improve flavor and palatability of meat.

Other technological strategies used in food systems imply decreasing oxygen content in packaging or its replacement with nitrogen or carbon dioxide in modified atmosphere packaging to attenuate protein oxidation during storage. Furthermore, films and hydrogels would be a suitable food packaging material for preventing oxidation due to their barrier properties. In this regard, protein-based edible films such as those derived from gelatin, soy or casein proteins, can additionally reduce oxidation by their own antioxidant activity, as well as function as matrix carriers for other antioxidant agents such as phenolic compounds. Additionally, the encapsulation of antioxidants by nano-emulsions could be a suitable novel technique to improve the antioxidant capacity of natural ingredients. On the other hand, recent studies have suggested that the inhibition of several endogenous proteolytic enzymes such as calpain, cathepsins or caspase-3 during food storage could have a significant inhibitory effect on protein oxidation. Some examples of these dietary and technological strategies and their respective effects on protein oxidation are shown in [Table 2](#).

## Analytical Procedures

The detection of protein oxidation can be performed by different methodologies including chromatographic, electrophoretic, spectroscopic and spectrometric techniques, or through a combination of them, depending on the oxidative product to be measured.

**Table 2** Examples of dietary and technological strategies against protein oxidation in foods

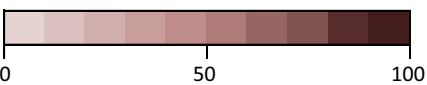

Strategy	Main active compound	Product	Oxidative process	Effects on oxidation compared to control samples	Reference
Addition of rosemary and sage essential oils	Phenolic diterpenes	Pork liver pâté	Refrigerated storage	Lower carbonyl content	Estévez et al. (2006)
Addition of black currant extract	Anthocyanins	Pork patties	Chilled storage	Lower carbonyl content and loss in sulfhydryl content	Jia et al. (2012)
Addition of gelatin hydrolyzates	Antioxidant peptides	Unwashed fish mince	Freeze-thawing process	Retarded carbonyl formation, lower loss in sulfhydryl content	Nikoo et al. (2015)
Supplementation of pig diet with avocado	Tocopherols	Pork loins	Cooking process	Lower carbonyl content and protein cross-linking	Hernández-López et al. (2016)
Use of modified atmosphere packaging	Mix of gases	Tilapia fish muscle	Iced storage	Lower carbonyl content, higher protein solubility	He et al. (2018)
Inhibition of endogenous proteolytic enzymes	Inhibitory compounds	Tilapia fish muscle	Iced storage	Lower carbonyl content, higher protein solubility	He et al. (2018)

Carbonylation is the most remarkable modification resulting from protein oxidation and thus, many analytical procedures are based on the quantification of these compounds. The 2,4-dinitrophenylhydrazine (DNPH)-method allows the quantification of protein carbonyls through their derivatization with DNPH to generate hydrazones, and subsequent spectrophotometric measurements at 370 nm. Carbonyls are also involved in protein cross-linking via Schiff base formation, and these structures are conjugated fluorophores with spectral properties that can be detected by fluorescence using excitation and emission wavelengths of 350 and 450 nm, respectively. These procedures measure the total amount of a variety of oxidation derivatives formed through unspecific pathways, limiting the evaluation of protein oxidation. In this regard, specific methods to determine particular protein carbonyls were developed, enabling a better understanding of the chemical structure and formation pathways of these compounds. High performance liquid chromatography with fluorescence detection (HPLC-FLD) allows the quantification of typical oxidation markers such as AAS and GGS after their derivatization with *p*-amino benzoic acid (ABA). Also compounds resulting from advanced oxidative reactions such as AAA can be identified by HPLC-FLD after a previous derivatization step. The introduction of mass spectrometry (MS) methodologies has allowed a fast, sensitive and accurate determination of these oxidation products. So, AAS and GGS can be detected by gas chromatography-mass spectrometry (GC-MS) in the form of their hydroxyl derivatives, or by liquid chromatography-electrospray ionization-mass spectrometry (LC-ESI-MS) after their derivatization with ABA.

Protein cross-linking is assessed using electrophoresis techniques and the analysis of these cross-linked bonds like disulfide or dityrosine bonds can be performed by RP-HPLC, LC-MS-MS, capillary electrophoresis, and spectroscopic methods including electron spin resonance (ESR) or nuclear magnetic resonance (NMR).

The loss or modification of amino acid residues due to oxidation processes can be assessed by using different chromatographic techniques. In HPLC methods, amino acids are derivatized before reversed-phase HPLC or after cation exchange HPLC separation to be better detected. When analyzed by GC-MS, amino acids are derivatized with *N*-methyl-*N*-(trimethylsilyl)-trifluoroacetamide (MSTFA) or similar, to make them heat-stable and volatile. The loss of tryptophan residues due to oxidative processes can be determined due to its natural fluorescence recording the emission spectra from 300 to 400 after excitation wavelength of 283 nm. On the other hand, oxidized cysteines can be analyzed using the Ellman's reagent. So, protein thiol groups are derivatized with 5,5-dithiobis-(2-nitrobenzoic acid) (DTNB) and release a thiolate ion, which has a maximal absorbance at 412 nm and it is used to evaluate the concentration of thiols. Additionally, the analysis of the wide variety of oxidized residues derived from cysteine and methionine (see **Table 1**) can be performed by LC-MS despite the difficulty in the analysis due to the high reactivity of their thiol groups.

MS, usually combined with LC, are valuable proteomic tools to determine the specific site and nature of oxidative post-translational modifications in proteins such as oxidation of peptides and amino acids. These methodologies allow the identification and quantification of oxidized peptides due to modified amino acids are mass-shifted and thus identifiable in the fragmentation pattern. An example of peptides showing methionine oxidation identified and quantified by LC-MS/MS during the processing of Spanish dry-cured hams is shown in **Table 3**. The development of targeted MS methods that search for peptides containing ions markers of an oxidative modification such as methionine sulfoxide or chlorotyrosine, or the use of chemical reagents that react with oxidative modifications and are used as tags to label oxidized peptides or proteins, would facilitate the analysis of oxidative modifications compared to untargeted approaches. Nevertheless, the analysis of protein oxidation continues to be highly challenging due to the complexity of the oxidative mechanisms, the difficulty in detecting the wide variety of oxidation products as well as the low abundance and lability of some of them under the conditions of sample preparation and/or analysis.

### Glossary

**Maillard reaction** Maillard reaction is a nonenzymatic browning reaction that is taking place between amino acids and reducing sugars.

**Strecker degradation** The deamination and decarboxylation of amino acids to imines and then to aldehydes or ketones, in the presence of a carbonyl compound.

**The degree of roasting** The intensity of the roasting of coffee, which is controlled by the roasting temperature and time. The degree of roasting could be classified as light, medium, or dark.

### Introduction

Coffee is the most traded commodity in the world just next to petroleum with annual production of more than 8.6 million tons (Getachew and Chun, 2017). The popularity of coffee as a beverage is as a result of its refreshing flavor and stimulating effect. The coffee flavor is a result of several stages and processes that involve from the raw bean to the cup. The flavor formation and profile of coffee is influenced by the species or variety of bean, the geographical origin of the bean, the type of raw coffee bean processing (dry or wet processing), the degree of roasting (light, medium, or dark), and the coffee brewing techniques, among others. The roasting process is thought to be the most important factor for the formation of coffee flavor. In this chapter, short and precise recent development on formation, detection, and quantification of coffee flavor compounds has been discussed.

### Formation of Coffee Flavor Compounds

As roasting is the most important factor affecting flavor formation, the focus of this section is on the formation of coffee flavor as result of the roasting process. Raw coffee bean has the pealike, green smell, and only after roasting, the smell of coffee can be converted into pleasant smell characteristic of roasted coffee because of the drastic formation of various flavor impact compounds (Czerny et al., 1999; Czerny and Grosch, 2000). Thus roasting has been the focus of much research in the coffee industries and in the academia (Baggenstoss et al., 2008; Poisson et al., 2009; Esquivel and Jiménez, 2012). The roasting time and temperature have a substantial influence on flavor formation. Roasting temperatures and time can vary between 180 °C and 240 °C and 8 to 15 min, respectively. During roasting, the heat transferred to the bean induces several thermal reactions in the coffee bean. Some of the heat-induced reaction produced during roasting includes Strecker degradation, Maillard reactions, degradation of trigonelline, amino acids, phenolic acids, lipids, and interaction between intermediate products (Sunarharum et al., 2014).

Although the formation pathways of most flavor compounds during the roasting of coffee are still not well understood (Akiyama et al., 2007), the initial chemical composition of raw coffee bean, its moisture content, roasting temperature, and the pressure developed inside the individual coffee beans are thought to be important factors for the formation of coffee flavor (Gloess et al., 2014). Nevertheless, Maillard reaction is believed to play the most significant role in the formation of major coffee flavor compounds.

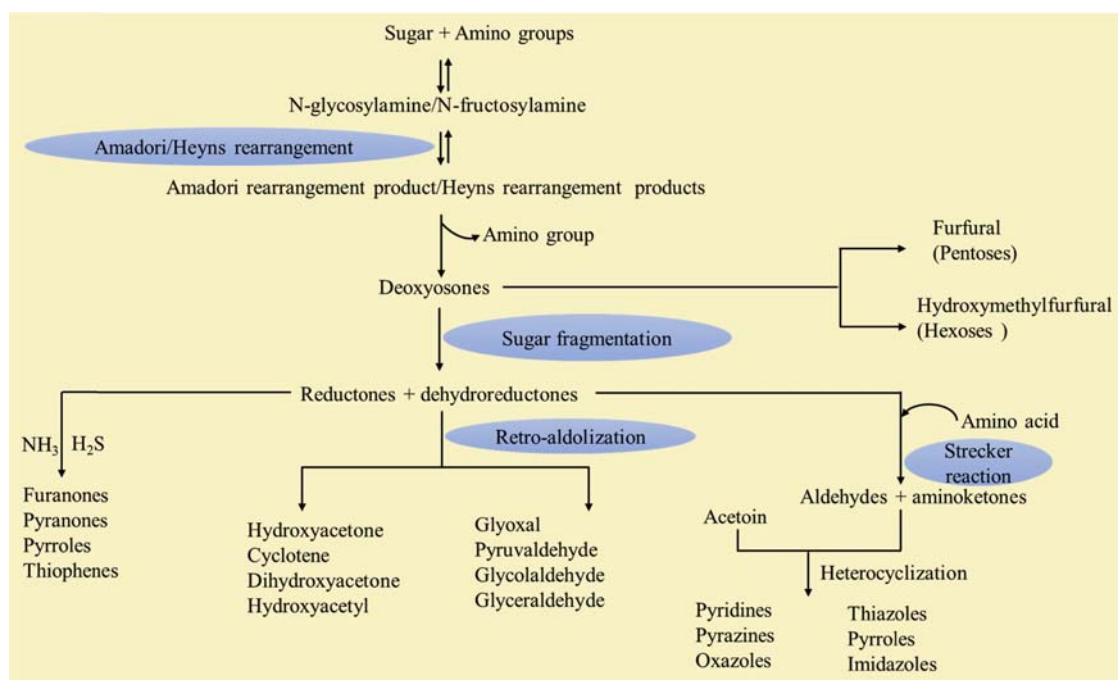

### The Role of Maillard Reaction for Flavor Formation

Most of the coffee flavor impact compounds are produced at a high temperature of roasting above 200 °C. The chemicals present in raw coffee beans such as carbohydrates, proteins, phenolic acids, and trigonelline participate as a precursor in flavor formation. Most importantly, during roasting process, Maillard-type reactions and other chemical transformations play a central role in the formation of coffee flavor. Some of the Maillard-derived aroma compounds produced during coffee roasting include thiols, diketones, pyrazines, furanones, thiazoles, pyrroles, and pyridines. Several researchers have studied the formation of these compounds in model systems under dry heating conditions (Grosch, 1999; Yaylayan and Keyhani, 1999; Poisson et al., 2009). Fig. 1 shows the details of the formation of flavor compounds during Maillard reaction.

### Coffee Flavor Impact Compounds

Since the first identification of few coffee volatile compounds by a German chemist Bernheimer in 1880, around 1000 different volatile compounds have been identified and reported in roasted coffee (Nijssen et al., 1996). Among these numerous volatile

**Figure 1** Flavor formation during Maillard reaction. Adapted from Van Boekel, M.A.J.S., 2006. Formation of flavour compounds in the Maillard reaction. *Biotechnol. Adv* 24, 230–233, as originally reported by Ho, C.-T., 1996. Thermal generation of Maillard aromas. John Wiley & Sons, Chichester, United Kingdom. Van Boekel, M.A.J.S., 2006 & Ho, C.T., 1996.

compounds, only a few of them have been considered as aroma impact compounds. The composition and concentration of the flavor impact compounds vary with the level of roasting, the coffee species, varieties, and the geographic origin (Baggenstoss et al., 2008). Some of the most potent classes of flavor impact compounds are discussed below.

### Furans

Furans are degradation products of sugars, unsaturated fatty acids, and ascorbic acids during the roasting of coffee (Crews and Castle, 2007; Ribeiro et al., 2009). They represent one of the most abundant groups of volatile compounds found in high concentration in both roasted powder and brewed coffee (Sunarharum et al., 2014). Furans have sweet and malty roasted aromas. As compared with other groups of volatile compounds in roasted coffee, they have higher sensory thresholds. However, because of their relatively high concentration, they are still important in coffee flavor (Sunarharum et al., 2014).

### Furanones

Furanones are produced through Maillard reaction following aldol condensation (Grosch, 2001). Furanones are a large group of compounds in coffee with regard to both abundance and potency. The sweet caramel aroma of roasted coffee is a result of different classes of volatile compounds (Sunarharum et al., 2014). The most important furanones in coffee are listed in Table 1.

### Phenolic Compounds

The roasting process generates some phenolic compounds that are part of the most important flavor compounds in coffee (Ribeiro et al., 2009). Among them, guaiacol, 4-ethylguaiacol, and 4-vinylguaiacol contribute for a spicy phenolic aroma (Akiyama et al., 2008; Mayer et al., 2000) and vanillin (Sunarharum et al., 2014). They are produced as a result of heat degradation of phenolic acids (such as quinic, ferulic, and caffeic acids). The concentration of these compounds greatly depends on their respective concentration in the original raw coffee. As the level of chlorogenic acids is high in Robusta coffee in relative to Arabica, consequently, the level of phenolic aroma compounds is higher in the earlier coffee variety (Sunarharum et al., 2014).

### Sulfur-Containing Compounds

Sulfur-containing compounds are among the most important classes of volatile compounds that are responsible for the coffee flavor (Caprioli et al., 2012; López-Galilea et al., 2006; Sunarharum et al., 2014). Despite their low concentration in coffee, volatile thiols

2-Methoxy-4-vinylphenol	Spicy, peanut, winelike, or clove and curry	Thermal degradation of ferulic acid	Buffo and Cardelli-Freire (2004)
4-Ethylguaiacol	Spicy		Blank et al. (1992)
Vanillin	Vanilla-like		Blank et al. (1992)

**Figure 2** Thiols in coffee flavor impact compounds.

are considered to be the most influential sulfur-containing compounds in sensory profile of coffee having very low sensory thresholds (Sunarharum et al., 2014). Fig. 2 shows some of the key aroma impact sulfur-containing volatile compounds in roasted coffee, which are usually associated with roasty, sulfurous coffee flavor (Kumazawa and Masuda, 2003b; Mayer et al., 2000; Sunarharum et al., 2014). As it has been confirmed by different model systems, formation pathways of thiols such as 2-furfurylthiol (FFT) are the reaction of pentose and hexose sugars and cysteine under roasting conditions (Cerny and Davidek, 2003). Other model system comprising arabinogalactan/cysteine showed that arabinogalactan is a key precursor for the formation of FFT (Poisson et al., 2009).

### Pyrazines

Pyrazines are formed during the Maillard reaction, preferably at temperatures above 100 °C. They are frequently found in foodstuffs prepared by a heating process (Amrani-Hemaimi et al., 1995). They contribute to the earthy-roasty character of roasted coffee. Different studies in model systems demonstrated that alkylpyrazines are formed from Strecker degradation of C<sub>6</sub> and C<sub>5</sub> sugar compounds and  $\alpha$ -amino acids through condensation reaction and oxidation of the resulting condensation product (Amrani-Hemaimi et al., 1995).

Table 1 summarizes some of the most important flavor impact classes of compounds, their flavor notes, and formation pathways.

### Influence of Degree of Roasting on Flavor Formation

As discussed in section **Formation of Coffee Flavor Compounds**, roasting is the key factor for the formation of coffee flavor. The degree of roasting also plays an important role for the formation of the flavor profile that better suits the type of coffee, its final use, and the personal preference of the consumers (Bhumiratana et al., 2011). Different roasting level produces different flavor profile. For instance, light roasting produces cocoa, nutty, and sweet aroma and dark roasting produces sour, ashy, and pungent aroma, whereas medium roasting is responsible for the formation of complex aroma profile (Bhumiratana et al., 2011). Furfural derivatives and furanones are yielded in relatively high concentrations under mild roasting conditions and then reduced at higher roasting intensities. More pyridines and pyrroles are formed by high roasting degree than by mild roasting intensities. Chlorogenic acid degradation products, phenols, and lactones are produced more by high roasting degree than by low roasting degree (Moon and Shibamoto, 2009).

### Detection and Quantification of Coffee Compounds

As it is mentioned in section **Coffee Flavor Impact Compounds**, to date, more than 1000 coffee volatile compounds have been identified. The nature of the compounds and their interaction has always created difficulty in detection and quantification. Since the first attempt to isolate and quantify the compounds responsible for coffee aroma by Bernheimer in 1880, there have been several advancements in extraction, isolation, and quantification. This is a result of understanding the nature of the formation of coffee

flavor compounds and the development of advanced analytical instruments. Some of the recent developments in coffee flavor detection and quantification are discussed below.

### Recent Development in Detection and Quantification of Coffee Flavor

The advancement of chromatographic techniques, more specifically gas chromatography coupled with mass spectroscopy, in recent decades has dramatically changed the quantification speed and the accuracy of flavor detection. The recent development of technology is also used to differentiate the geographic source and authenticity of roasted coffee beans based on their signature flavor profiles.

Recently, Quintanilla-Casas et al. (2015) developed a fast analysis method for volatile thiols in brewed coffee. Their developed method involves a simultaneous derivatization/extraction procedure followed by liquid chromatography–electrospray high-resolution mass spectrometry. They identified and quantified seven targeted and nine nontargeted thiols in the coffee brew, and most of them are reported for the first time in brewed coffee. In another study, Yener et al. (2015) used proton transfer reaction–time-of-flight mass spectrometry (PTR/TOF-MS) for the first time to trace the origin of both roasted and brewed coffee using their volatile flavor compounds. In their study, they reported that the switching reagent ion system in PTR-MS instrumentation was applied for the first time to coffee not only with commonly used  $\text{HO}_3^+$  but also with  $\text{NO}^+$  and  $\text{O}_2^+$  as precursor ions to minimize the classification errors of the volatile compounds. For authentication of specialty coffees based on their volatile compounds profile, Özdeştan et al. (2013) used high-sensitivity proton transfer reaction mass spectrometry (HS PTR-MS). They showed that the different coffee samples could be distinguished by their volatile compounds profile obtained from PTR-MS with the help of chemometrics. The basic principles and in-depth discussion of the PTR-MS can be found in Cappellin et al. (2013) and Blake et al. (2009).

### Conclusion

The cup of coffee that millions of people enjoying every day around the world has a complex array of flavors, which is completely different from its original raw material, the raw coffee bean. To get its refreshing flavor, the coffee bean must pass through the roasting process. The roasting process is the most important factor for the formation of coffee flavor along with the chemical composition of the original raw coffee bean. During roasting, several heat-induced reactions take place in the so-called “tiny reactors,” the individual coffee beans. The chemical reactions include Maillard reaction, Strecker degradation, decomposition, and degradation of phenolic acids such as chlorogenic acid and ferulic acids, degradation of trigonelline, and sugars. Thus the formation pathways of the compounds are significantly affected by the composition of the raw coffee bean (which is also affected by its geographic origin), the degree of roasting, the roasting temperature, and time. These heat-induced reactions produce several classes of compounds such as thiols, pyridines, pyrazines, and furans with sensory thresholds ranging from few parts per billion to several hundreds of parts per billion. The advancement of modern analytical instruments and techniques significantly improved the quality and accuracy of flavor analysis.

### Glossary

**Acidolysis** It is an acyl-transfer chemical reaction involving an ester and a free fatty acid.

**Alcoholysis** It refers to an acyl-transfer chemical reaction involving an ester and a free fatty alcohol.

**Amphiphilic** A term that describes molecules that possess both hydrophilic and lipophilic moieties within their chemical structures.

**Antioxidants** These are compounds with the ability to inhibit oxidation when present in food or biological systems.

**Carry-through** It refers to the ability of antioxidants to survive frying conditions and get transferred into the fried foods.

**Fractionation** It is the controlled separation of oil/fat into different fractions by either low temperature (dry fractionation) or solvents (solvent fractionation). Palm oil, for example, is fractionated into palm olein and palm stearin.

**Hydrogenation** A process of adding hydrogen atoms across the double bonds of unsaturated triacylglycerols, usually in the presence of catalysts such as nickel and under controlled temperatures. The process decreases the degree of unsaturation of the vegetable oil but may generate *trans* fats.

**Hydrolysis** The reaction between triacylglycerol and water molecule resulting in the release of free fatty acid from the glycerol backbone, resulting in diacylglycerol, monoacylglycerol and eventually, free glycerol.

**Hydrophilic** A term that describes chemical species (polar molecules) that positively interact with water and are dissolved by it.

**Interesterification** A process whereby the fatty acids on the glycerol backbone of triglycerols are by rearrangement. This could be affected by chemical means or by the introduction of enzymes.

**Isomerization** Heat-enhanced reaction whereby the natural *cis*-configured fatty acid is transformed into the *trans* isomer.

**Lipophilic** A term that describes chemical species (nonpolar molecules) that positively interact with and are soluble in fats and oils.

**Lipophilization** A chemical or enzymatic process for transforming a hydrophilic molecule into a lipophilic species.

**(Poly)phenolic (also polyphenols)** A class of chemical compounds consisting of a hydroxyl group bonded directly to an aromatic hydrocarbon group. They are classified as simple phenols or polyphenols based on the number of phenol units in the molecule.

**Polymerization** This is a heat-driven aggregation of triacylglycerol monomers that can be connected by carbon–carbon, carbon–oxygen–carbon, or carbon–oxygen–oxygen–carbon linkages.

**Prooxidants** These are components or compounds, which encourage oxidative deterioration of edible oils.

**Regiospecific** This refers to the habitual tendency of some enzymes to direct reaction to a particular site on a molecule.

**Thermooxidation** A heat-enhanced reaction between atmospheric oxygen and unsaturated lipids.

**Triacylglycerols** Also known as triglycerides, triacylglycerides, abbreviated TAG or TG are esters obtained from glycerol and three fatty acids.

**Unsaponifiables** These are nontriglycerol minor components of oils, which are not saponified by alkali hydroxides and are extractable into ether.

**Unsaturated** An organic compound (e.g., fatty acids, triacylglycerols) is referred to as “unsaturated” if it possesses one or more carbon–carbon double bond within its chain. It is monounsaturated if it contains one and polyunsaturated if it has more than one carbon–carbon double bond.

### Introduction

Frying is a food preparation technique where the foods are immersed in edible oil at a temperature above the boiling point of water, usually between 150 and 200 °C. It is one of the oldest food preparation methods known to man, and although popularly and routinely used by an average household, the art of frying is hardly simple, and the science is simply hard. The complexity of frying, as a food preparation method, stems from the need to delicately balance many interrelated factors, such as frying time, temperature, fryer types/dimensions, and surface-to-volume ratio, known to modulate the frying process and also sufficiently control the self-sustained physicochemical reactions occurring during the process.

Compositionally, the frying oil is essentially a mixture of triacylglycerols (c. 96%), and the changes observed during frying are primarily related to the chemical structures of the constituent triacylglycerols (Fig. 1). The predominant triacylglycerols of frying oils are unsaturated; and while this may offer some advantages with regards to fluidity, mouthfeel, heat transfer, and health benefits,

**Figure 1** Triacylglycerol composing of three molecules of fatty acid esterified to a glycerol backbone.

unsaturated fatty acids are predisposed to thermal and oxidative degradative reactions prevailing during frying (Choe and Min, 2009).

The high operating temperature (in excess of 170°C) utilized for frying processes inevitably instigates and accelerates a series of complex chemical reactions, involving dissolved oxygen (from air), moisture (from the food and air), the frying oil, and components of the fried foods, resultantly altering the structural composition and sensory qualities of the frying oil and the food prepared in it. Thus, the frying oil is transformed from an almost pure triacylglycerol to a mixture of hundreds of chemical compounds (Blumenthal, 1987). Currently, over 500 chemical compounds have been identified in degraded frying oils with a number of them potentially toxic above certain thresholds (Gertz, 2001). It must be mentioned that at reasonable levels, these chemical compounds are directly and indirectly responsible for the unique golden color and delightful deep-fried flavor of fried foods.

Thermal oxidation (thermooxidation), thermal hydrolysis, polymerization, and isomerization are the most noteworthy reactions occurring during frying, with thermooxidation being the most prevalent and most destructive. The stability of a frying oil is a measure of its ability to offer resistance against any of these degradative reactions, and it is related to the inherent composition of the frying oils (internal factors) and the applied frying conditions/managements (external factors). With regards to the fatty acid composition (triacylglycerol compositions), generally, the higher the level of carbon–carbon unsaturation, the more susceptible the oil is to thermooxidative degradations, and the methods for enhancing the stability along this line have been toward reducing the fatty acids unsaturation through methods such as fractionation, hydrogenation, interesterification (chemical and enzymatic), conventional seed breeding, and genetic engineering (Holm and Cowan, 2008; Clemente and Cahoon, 2009; Dijkstra, 2009; Jhala et al., 2009; Martin et al., 2010; Hayes and Pronczuka, 2010; Kontkanen et al., 2011). Enhancing the stability of frying oils by altering the saturation level is not without controversies and challenges as previously discussed (Lichtenstein et al., 2006; Wang et al., 2010; Turan et al., 2007; Maduko et al., 2008; Jennings and Akoh, 2009; Matthäus, 2007), and the use of antioxidants is often more favored.

As mentioned earlier, the frying oil is almost a pure mixture of triacylglycerols, representing an average of 96% of the oil's composition. Nevertheless, the minor components of frying oils (<5%), also referred to as "unsaponifiables," can and do exert significant influence on the performance of frying oils with respect to their thermooxidative stability. Components of the unsaponifiables, depending on the relative amounts and structural identities, can either enhance the frying stability by limiting lipid oxidation and subsequent polymerization (antioxidant) or destabilize the oil during frying (prooxidant). Generally, for a typical commercially processed frying oil, the influence of the antioxidative compounds (primarily, tocopherols, phytosterols, lignans, phenolics, and to a lesser extent, carotenoids) significantly outweighs the effects of prooxidative compounds (mainly, free fatty acids, hydroperoxides, and metals) in the unsaponifiables, tending the oil's minor components cumulatively toward antioxidative activities.

Although antioxidative minor components such as tocopherols (tocopherols and tocotrienols) offered marked protection to oil during storage and other ambient temperature applications, they offer relatively little protection during frying, since they are quickly decomposed, volatilized, or inactivated, due to the extreme processing conditions utilized for frying operations. Hence, to improve the stability of the frying oils, external antioxidative compounds are generally added (Aladedunye, 2014; Aladedunye et al., 2017). Unlike the complicated, time-consuming, and highly technical procedures required for the modification of fatty acid compositions of frying oils, the addition of external antioxidants is rather simple, economical, and often requires relatively smaller amounts (<0.5%) of the applied antioxidants.

Potentially, naturally occurring (poly)phenolic compounds are excellent antioxidants (Fig. 2), inherently possessing the ability to easily donate hydrogen radicals to hydroperoxy radicals, thereby inhibiting the propagation stage of radical-mediated lipid oxidation (Fig. 3) that is a prominent mechanism for frying oil's deterioration. However, the same structural moiety (phenolic OH functional groups), which confers this antioxidative advantage on polyphenolic compounds, is also the limiting factor to their applications in frying oil. In general, the presence of phenolic OH in a compound decreases its lipophilicity (solubility in oils/fats), and there is an inverse relationship between the number of the phenolic OH and the compound's solubility in oils/fats. Consequently, polyphenolic compounds are poorly soluble in edible oils. While the poor lipophilic nature may be advantageous under storage conditions where lipid oxidative deterioration is localized at the oil–air interface (Porter, 1993; Frankel et al., 1994; Frankel, 2005), it does limit its effectiveness during frying where active agitation (arising from bubbling at the introduction of fresh

**Figure 2** Selected structural diversities in polyphenols ranging from simple phenolic acids (caffeic and gallic), flavonoids (catechin, quercetin, catechin gallate), lignin (sesamin), and Stilbene (resveratrol).

**Figure 3** Typical radical scavenging mechanism of a phenolic compound ( $\text{ROO}^\bullet$  is a lipid hydroperoxy radical).

food and convective stirring as the frying oil bounces back to the preset frying temperature) continually “delocalizes” thermooxidative reactions, requiring a good degree of mixability between the oil and the applied antioxidative compound. In other words, for an antioxidant to be practically effective, it must be located or easily deployable to the site of thermooxidative deterioration. To overcome the challenge of high hydrophilicity in polyphenolics and thereby broadening their applicability as frying oil antioxidants, a restructuring or modification of the moiety is required. Interesterification, a process commonly employed for this purpose, is hereby discussed in relation to the frying process.

## Interesterification—Lipophilization of (Poly)phenolics

Basically, esterification is a reaction between an alcohol and an acid to form an ester as the reaction product. Depending on the functional group of interest in the phenolic compound, a fatty acid moiety can be added by reacting with a fatty alcohol (for phenolic acids) or a fatty acid (for polyphenols), resulting in an amphiphilic molecule with relatively unchanged functional properties such as antioxidant, antimicrobial, UV filter, etc. (Figuerola-Espinoza and Villeneuve, 2005). The reaction can also be an ester exchange between the alkyl ester of the phenolic acid and (1) a fatty acid ester, including triacylglycerols (interesterification, transesterification), (2) a fatty acid (acidolysis), or (3) a fatty alcohol (alcoholysis). This process is technically referred to as lipophilization, since it essentially transforms the hydrophilic polar phenolic compounds to lipophilic (lipid soluble) molecules.

The addition of alkyl chain to the relatively compact hydrophilic phenolic compounds can be achieved by (1) chemical, (2) enzymatic, and (3) chemoenzymatic processes. In chemical lipophilization, the esterification reaction is effected by chemical catalysts; however, chemical modification is not selective and, unless controlled, the entire active phenolic OH sites on the polyphenol can be “blocked” rendering the polyphenolic compound antioxidatively inactive (Danihelova et al., 2012). Furthermore, chemical restructuring of polyphenols often requires relatively severe reaction conditions, including toxic solvents and high temperature, resulting in poor yields, unwanted side products, and unwarranted decomposition of the thermally labile phenolic compounds and the acyl or alkyl donor substrates that often contain unsaturated C—C bonds (Figuerola-Espinoza and Villeneuve, 2005; Chebil et al., 2006). In cases where the phenolic compounds are esterified to the glycerol backbone of a natural edible oil, it has been reported that the acidolysis chemical reaction often results in depleted natural tocopherol contents of the edible oil due to the side reaction between tocopherols and the free fatty acid present in the medium, under the reaction conditions (Hamam and Shahidi, 2006). Consequently, chemical modification of phenolic compounds is not viewed as a practical, economical, sustainable, and viable modification protocol for the lipophilization of phenolic compounds.

Unlike chemical modifications, enzymatic restructuring of polyphenolics, although requiring relatively longer reaction time, is carried out under relatively mild conditions, thereby protecting the structural integrity of both the reactants and products. The yields are generally high, and the side products are minimal, especially since enzymatic restructuring of polyphenolics can be regiospecific, depending on the choice of enzymes (Figuerola-Espinoza and Villeneuve, 2005; Chebil et al., 2006). For wholesome edible oils, enzymatic modification does not result in flavor reversion and the oxidative stability of the oil is not compromised. These advantages and opportunities presented by enzymatic restructuring of polyphenols have resulted in renewed interests in the subject in the last decade.

The effectiveness of enzymatic modification of polyphenol is governed by several parameters, principally, type of solvents, choice of enzymes, operational temperature, and water activity of the system. Consequently, these parameters must be optimized for improved yields and economics (Chebil et al., 2006). Excellent reviews on the enzymatic lipophilization of phenolics up till 2017 are available (Figuerola-Espinoza and Villeneuve, 2005; Chebil et al., 2006; Viskupicova et al., 2009; Gonzalez-Sabin et al., 2011; Laguerre et al., 2013; Crauste et al., 2016; de Araujo et al., 2017; Aladedunye et al., 2017). Several solvents such as acetonitrile, acetone, tetrahydrofurane, *tert*-amyl alcohol, hexane, *tert*-butanol, dioxane, DMF, 3-pentanone, THF, chloromethane, and their binary mixtures have been evaluated for enzymatic lipophilization of phenolic compounds. Solvent-free systems have also been used, and recently, deep eutectic solvent–water binary mixture and ionic solvent have been evaluated and optimized (Lopez-Giraldo et al., 2007; Yang et al., 2012; Durand et al., 2013). Various types of enzymes, notably, lipases, proteases, cellulases, and transferases are being used to effect restructuring reactions with lipases, principally those from *Candida* sp., *Pseudomonas* sp., and *Mucor* sp. or *Rhizopus* sp., being the most widely used. The lipases can be free or immobilized on a support, with immobilized enzymes being the most preferred. Indeed, not only does immobilization makes for easier product recovery/clean up and easier substrate’s access to catalytic sites of enzymes, but it has also been reported that it enhances enzyme’s resistance to inactivation, resulting in extended usage (Chebil et al., 2006).
