Once the thermal-induced protein aggregates form, the cross-linking among them can be done by addition of coagulant. Different types of coagulant and coagulation conditions give rise to various microstructure and textural properties of tofu. Relatively slow cross-linking among the aggregated proteins takes place to form the divalent cation-bridging three-dimensional network structure with fine, homogenous, and smooth texture when sulfate salts are used. However, when chloride salts are used, relatively fast cross-linking among the aggregated proteins takes place to form the divalent cation-bridging three-dimensional network structure with rough and porous texture (Prabhakaran et al., 2006). In addition, different cross-linking sites in the denatured soybean protein molecules exist between calcium and magnesium ions because a loose network structure is observed in  $\text{MgCl}_2$ -induced tofu. Consequently, the hardness and breaking stress of  $\text{MgCl}_2$ -induced tofu are significantly higher than those of  $\text{CaSO}_4$ -induced tofu. Thus,  $\text{MgCl}_2$  is usually used in the form of modified nigari, including  $\text{MgCl}_2$  and  $\text{CaCl}_2$ , and others or by the sustained release of  $\text{MgCl}_2$ -embedding water/oil emulsions (Zhu et al., 2016). By contrast, a smoother and softer structure and greater hardness and firmness are usually observed in the GDL-induced tofu than those in the  $\text{CaSO}_4$ -induced tofu (Shen et al., 1991). The textural properties of tofu can be also modified using MTGase and other polysaccharides (such as chitosan, guar gum, and carrageenan) as a coagulant or additives (Li et al., 2015; Tang et al., 2006). Furthermore, the textural properties are also changed when different coagulation temperature, time, coagulant concentration, and stirring speed during coagulation are used (Hou et al., 1997; Kao et al., 2003).

### Sensory Properties

Because of the unique sensory properties of the white cream surface color, subtle flavor, and bland taste, tofu is commonly used to prepare various types of cuisines with different flavors.

As a type of opaque gel, tofu has a shiny appearance. The color of tofu is usually white to cream but can also be pale yellow because of the variety or quality of soybean seeds used and processing conditions. Different soybean varieties give rise to the seed coat with different shades of color, which affects the resulting color of tofu (Min et al., 2005). Tofu made from soybean seeds with a dark yellow seed coat, black hilum, or black soybean seeds produces a gray or yellow-green surface, which is less attractive to consumers (Khatib et al., 2002). Changes in color of tofu from creamy white to creamy yellow and further slightly brownish are observed when soybean seeds are stored for different storage durations (Kong et al., 2008). The heating of soy milk with high temperature and excessive time might brown the soy milk and finally, making tofu with light brown owing to the possible occurred nonenzymatic browning reaction and lipid oxidation. The coagulant concentration can also influence the tofu appearance. For

example, a whiter gel appearance was observed when high concentration of calcium salts was added to the heated soy milk with high protein content because of the formation of a more aggregated gel with denser network structure, which caused greater light dispersion (Maltais et al., 2005).

The flavor of tofu is often beany, which is an important factor contributing to its flavor. Similar to the color characteristic, the extent of the beany flavor is also related to the variety of soybean seeds and processing conditions (Kobayashi et al., 2000). The Maillard reaction between proteins and reducing sugars and oxidation of unsaturated TAGs taken place during the heating of soy milk are the major reactions for endowing tofu with a roasted nutty, fruity, light beany, and aromatic flavor. For most tofu made from the common variety of soybean seeds, the beany flavor favored by Asians originates from the oxidative decomposition products of unsaturated TAGs enzymatically oxidized by lipoxygenases, such as hexanal and (*E,E*)-2,4-decadienal (Torres-Penaranda et al., 1998). However, this beany flavor is an undesirable off-flavor for Western people, which has led to the breeding of soybean variety without lipoxygenases (Yang et al., 2015). This off-flavor can also be eliminated to a certain degree during tofu production, for instance, to select hot grinding of the soaked soybean seeds and appropriate heating temperature and time of soy milk. Tofu coagulated by most types of coagulant in its OCCs has a similar flavor.

Fresh tofu possesses a smooth, delicate, and bland taste. However, its mouthfeel is unique, and different taste properties are found in tofu induced by different coagulants (Zhang et al., 2016). For example, bitter and astringent tastes are usually shown in  $\text{CaSO}_4$ -induced tofu. Relative strong beany flavor is the characteristics of  $\text{MgCl}_2$ -induced tofu. The GDL-induced tofu has a plain taste. Moreover, according to the various different types of tofu with different textural properties, the type of coagulant has the most influence on the taste properties of tofu. Tofu with better compact structure causes a more full taste. Tofu coagulated by  $\text{MgCl}_2$  fast is prone to have a porous structure, resulting in a rough taste. Sour taste is easily perceived in acidic whey-induced tofu because of the improper fermentation of tofu whey. The water content influenced by the WHC and pressing operation also influences the final taste of tofu. Lower water content of tofu (such as dried tofu or extra firm tofu) might give a residue-like taste compared with those with high content of water (such as silken tofu and soft tofu).

### Syneresis and Cooking Loss

Generally, tofu is sold in fresh form and is eaten after certain thermal treatment, such as boiling, frying, and stewing. Thus, the ability to maintain the taste and textural properties after a fixed selling or storage duration and the thermal treatment is a very important quality of tofu, which is usually expressed as syneresis and cooking loss, respectively.

Syneresis usually reflects the liquid loss of tofu after storage at 4 °C for 24 h (Armstrong et al., 1994). The ability to retain water in the network structure of tofu is closely related to the cross-linking degree of network structure and the content of polar nonprotein compounds. The salt-induced tofu often has lower syneresis compared with that of acid-induced tofu (Murekatete et al., 2014). More water is released when the hardness of tofu is enhanced due to the subsequent bonding among the proteins and coagulants via various interactions during the storage, resulting in the tofu with more dense and compacted texture and increased syneresis (Karim et al., 1999; Murekatete et al., 2014). Consequently, reduced weight and textural properties of tofu are present since the tofu is made. Thus, the way to enhance the water retention or reduce the syneresis of tofu before the reprocessing for eating is very important for the quality maintaining of tofu. For example, the GDL-induced tofu made from soy milk treated by two-step heating showed lower syneresis compared with the GDL-induced tofu made from soy milk treated by one-step heating (Liu et al., 2004; Wang et al., 2007), and the addition of carrageenan or  $\gamma$ -polyglutamate in appropriate concentrations during the coagulation of GDL-induced tofu significantly reduced its syneresis (Lee and Kuo, 2011; Karim et al., 1999).

Cooking loss is the weight loss of tofu after boiling for certain time (Chang et al., 2011). Water and aqueous soluble compounds are released from the tofu matrix under the function of heat and concentration gradients during cooking in water, reflecting the cooking loss of tofu. Cooking loss is also closely related to the type of tofu induced by different types of coagulants. Along with the exudation of water and aqueous soluble compounds during the boiling of tofu in water, the microstructure of tofu changes to impact on its textural properties under severe heating condition. Decreased weight and more tough texture of GDL-induced tofu are usually observed after certain retort cooking treatment (Nonaka et al., 1996). Therefore, MTGase or glucose in appropriate concentrations was tentatively added to the coagulation of GDL-induced packed tofu to reduce the weight loss and retain the textural properties of tofu after retort cooking (Kwan and Easa, 2003). This treatment can be used to modify the physicochemical properties of tofu dishes and retain the quality attributes of tofu under the thermal sterilization conditions.

### Nutritional Value

As one of the best food for supplying vegetable protein with higher amino acid score, tofu also contains considerable unsaturated lipids, phospholipids, polysaccharides, minerals, and phytochemicals (e.g., soybean isoflavones). Apart from the network structure constructed by soybean proteins, other nutrients, especially the water-soluble nutrients, are also entrapped in this network structure. Therefore, the nutritional value of tofu is also related to its structure. Tofu with higher protein content was obtained by the soy milk with higher solids content (Shih et al., 1997). Coagulant used in higher concentration made tofu with decreased protein content (Sun and Breene, 1991). More content of mineral elements is observed in the salt-induced tofu compared with tofu induced by acidic coagulants and enzymatic coagulants (Obatolu, 2008). Therefore, the formation of network structure of tofu influences the nutrient composition of tofu products.

## Conclusions

Based on the influence of various factors on the structure formation of tofu, three-dimensional network structure formed by the coagulation of aggregated proteins is the fundamental skeleton of tofu; other nonprotein components, including water, carbohydrates, and phospholipids, are randomly retained in the spaces among this network structure. Furthermore, other aqueous soluble components (i.e., water-soluble vitamins and metals) and lipid-soluble components (i.e., TAGs and carotenoids) are interacted with water and phospholipids, respectively, to be indirectly contained in this network structure. Consequently, a compact, uniform, and orderly microstructure of tofu is formed. Therefore, even though the factors influencing on formation of tofu texture are various and interaction effect among these factors exists, the expression of tofu texture is based on the three-dimensional network structure of soybean proteins. In other words, the three-dimensional network structure of soybean proteins is the basis for formation of tofu textural and sensory properties, and the nonprotein components spread over the network structure make these textural and sensory properties be more abundant, such as juiciness, smooth, soft, and refreshing. Understanding the close relationship between the structure of tofu and its physicochemical properties promotes the production of tofu products with more edible and nutritional qualities.

### Introduction

Meat is considered as a complete protein source as it contains all 9 of the essential amino acids that cannot be synthesized *de novo* by human beings and are thus must come from the diet alone. Furthermore, the functional attributes of proteins in meat such as gelation, emulsification and water holding capacity are unmatched to any other protein source (Xiong, 2005). In developing countries, consumption of meat per capita has rapidly increased in recent years, primarily due to rapid industrialization, urbanization, increasing population size and rise in income (Kumar et al., 2017). However, there are many issues associated with meat production in its present form and these are leading the search for suitable and sustainable alternatives.

Rearing of animals for meat production involves converting vegetable protein into animal protein, which is highly intensive process. Production of vegetable crops requires comparatively less water, land and energy per unit as compared to per unit production of meat and thus the transition of proteins can be considered inefficient (Steinfeld et al., 2006; Bruinsma, 2009).

Meat production is often associated with environmental strain due to emission of greenhouse gases and water pollution (streams and rivers) as well as rampant deforestation for the expansion of livestock farms that has all put additional pressure on natural resources (Steinfeld et al., 2006; Aiking, 2011).

From a dietary point of view, the consumption of meat delivers essential nutrients and energy but a direct relationship with the overconsumption of meat and the incidence of certain diseases has been established (Mehta et al., 2015). Larsson and Wolk (2006) suggested that the consumption of 120 g red meat/day or 30 g processed meat/day would significantly raise the risk of colorectal cancer in human beings. Certain people avoid the overconsumption (or consumption altogether) of specific types of meat due to high saturated fat and cholesterol content as well as various unrelated reasons such as religious views or animal welfare concerns. All these concerns have combined together to spur the debate on the sustainability of meat as a diet for humans. For years, the fabrication of protein rich foods using plant sources has been a research interest amongst food scientists; the major challenge being the simulation of texture, taste, colour, flavor and nutritive value equitable to meat. Commonly known as meat analogs, meat substitutes, meat alternatives or faux meat, these products have had a surge in popularity in recent years, though presently still only account for a marginal share of the total meat market (De Bakker and Dagevos, 2010).

### Defining Meat Analogs

A product that can closely approximate the characteristics and quality of meat can be termed a meat analog. They are primarily vegetable protein based products developed from pulses, fungi or cereal proteins. Though the term meat analog is frequently used for products based on spun protein filaments, it may also include various other products such as textured vegetable proteins. These can be seen as a good medium through which vegetable and unconventional proteins can be integrated into the diet (Kumar et al., 2017). The key drivers for establishment and growth of this sector is food safety concerns amongst consumers regarding animal products, increasing promotion of the vegetarian or vegan diet, demand for variety by consumers, health concerns surrounding the overconsumption of meat and the increased use of convenience foods (Sadler, 2004).

Some traditional foods are already meat analogues in their own right as they are used as a meat substitute in meals, especially in countries where meat may have been scarce or expensive in the past. Some examples of these types of meat analogues are Tofu and Tempeh, both produced from soy beans. Tofu is already extensively covered in this section (cross reference to tofu article).

Tempeh or tempe is a traditional fermented soybean food widely popular in South-east Asia. It is prepared by using *Rhizopus* strains and known to have superior nutritive qualities and regulation of body metabolism. It is commercially available in strip and cake form with denser texture and can be used in many of the culinary contexts as tofu. During fermentation process, various volatile compounds such as free amino acids, fatty acids, are generated by enzymatic digestion of substrates chiefly lipids and proteins, leading to development of characteristic flavor (Jeleń et al., 2013). Tempeh is less prone to lipid oxidation and has higher amount of isoflavones than other soy products. Dehulled soy seeds are cooked and cooled at room temperature and inoculated with spore suspension and kept for fermentation for 5 days at 37 °C. The fermented soy beans containing overgrowth of *Rhizopus* strains are appear similar to cake which is consumed by roasting, frying, etc.

## Key Ingredients in Meat Analogs

A variety of ingredients can be utilized for the formulation of meat analogs, though plant based derivatives are dominant. At present, the bulk of production is based on soybeans as they provide the cheapest and most common source of alternative proteins. However, algae and fungi have also been used for development of analogs and insect proteins are becoming increasingly likely in future applications. Typical meat analog ingredients and their functions can be found in [Table 1](#).

Soy proteins are known to have various functional and health benefits. Soy protein isolate is the most common soy derivative used in meat analogs along with textured soy protein and tofu ([Sadler, 2004](#); [Kumar et al., 2017](#)). Soy protein isolate consists of approximately 90% protein and is separated from the carbohydrate and fat fraction. Textured soy protein is produced by the extrusion of defatted soy flour, whereas tofu is manufactured from pressing soy curd. As far as the nutritional value is concerned, [Hoffman and Falvo \(2004\)](#) reported that on the PDCAAS (Protein Digestibility Corrected Amino Acid Score) scale, soy protein was comparable to animal protein with a score of 1.0, the highest possible rating. Soybeans are also a good source of calcium and linoleic acid. As soy protein is seen as a viable alternative to animal protein, much research has been conducted. [Ishizuka et al. \(1986\)](#) patented the development of meat analog through decreasing the pH of soy milk to 5.6–6.2, forming tofu; coagulating and dehydrating it to obtain a solid content of 35%–50% and shaping to simulate ground meat. [Lin et al. \(2000\)](#) developed a soy protein meat analog, which was extruded at high temperature and varying moisture content (60%–70%) and concluded that it was moisture that acted as an important factor in determining texture. Low moisture content resulted in higher die pressure for extrusion, a firmer texture and consequent lower protein solubility.

The use of fungi, particularly mushroom varieties for development of meat analogs has been proven popular due to their characteristic chewability ([Naylor et al., 2001](#)). The cell walls of the hyphae are a rich source of dietary fiber whereas; cell membranes are a source of polyunsaturated fat, which can in reducing reduce LDLs (low density lipoproteins) and increase beneficial HDLs (high density lipoproteins) in the body ([Rodger, 2001](#)). While developing analogs from fungi and to attain meat-like textures, the fungal biomass is generally mixed with flavoring agents and protein binders such as egg albumin (although this makes the product no longer solely plant based) which on heating form a gel and bind the product ([Denny et al., 2008](#)). The addition of egg white also increases the total protein content of the product. [Kumar et al. \(2010\)](#) reported a significant improvement in the physico-chemical properties and sensory attributes of meat analogs upon incorporation of egg white.

Flavor is improved by the incorporation of fungi, for e.g. *Fusarium graminearum* was employed for first time in 1984 the commercial development of meat analogs and it provides a meaty flavor due to the presence of sulfur containing amino acids ([Trinci, 1994](#); [Angold et al., 1989](#)). This is an advantage of using fungi compared to textured soy protein as the latter gives a beany flavor rather than a flavor associated with meat. [Kim et al. \(2011\)](#) used *Agaricus bisporus* mycelium to produce a meat analog with distinct umami flavor characteristics and greater textural scores for hardness, springiness and chewiness compared with soy based meat analogs.

A variety of texture modifiers such as carbohydrates and gums are frequently used to develop meat analogs. They can equally be used as fat substitutes for the development of low-fat products as on hydration, starches and maltodextrins form gels that can mimic the fat-like texture in meat analog products.

The use of gluten as a meat analog ingredient has been long established owing to its multi-functional properties of solubility, viscosity, swelling, nutritional qualities, etc. A meat analog resembling chicken breast was developed using wheat gluten in the 1980's by [Nguyen \(1988\)](#) and the formula and processing method were patented. The product included a dry powder blend consisting of 80% wheat gluten, 11% wheat flour and 9% vegetable oil that was mixed and sprayed with water. The prepared dough was

**Table 1** Typical meat analog ingredients and their purpose

Ingredient	Purpose	Usage level (%)
I. Water	Ingredient distribution, Emulsification, juiciness, low cost	50 to 80
II. Textured vegetable proteins: textured soy flour, textured soy concentrate, textured wheat gluten, textured protein combinations such as soy and wheat	Water binding, Texture and mouthfeel, Appearance, protein fortification/nutrition	10 to 25
III. Non-textured proteins: isolated soy proteins, functional soy concentrate, wheat gluten, egg whites, whey proteins	Source of insoluble fiber Water binding, emulsification Texture/mouthfeel Protein fortification/nutrition	4 to 20
IV. Flavors/spices	Flavor, savory, meaty, roasted, fatty Flavor enhancement (for example, salt) Mask cereal notes	3 to 10
V. Fat/oil	Texture/mouthfeel, Succulence	10 to 15
VI. Binding agents: wheat gluten, egg whites, gums and hydrocolloids, enzymes, starches	Texture/"bite," water binding, may contribute to fiber content, can determine production processing conditions	1–5
VII. Coloring agents: caramel colors, malt extracts, beet powder, Food drug and cosmetics (FD and C) colors	Appearance/eye appeal, Natural or artificial	0 to 0.5

Adopted from [Malav et al. \(2015\)](#).

heated by conventional or microwave means. The major advantage was that resultant product lacked the unpleasant flavor of soy based meat analogs. Further, Kumar et al. (2012) reported that the incorporation of wheat gluten in analog meat nuggets improved almost all sensory traits.

### Analogs Versus Real Meat: A Key Comparison

The aim of a meat analog is to make the consumer think that they are consuming meat in all sense of the meaning including mimicking structure, composition and organoleptic properties. However, meat has a complex structure, which is difficult to reproduce. Redman (2008) filed a patent for a meat analog containing 5%–40% protein with a characteristic cross sectional contraction resembling the skin of meat and imparting appearance of cooked meat. Similarly, Kumar et al. (2011) compared chicken nuggets with meat analog nuggets prepared by incorporating texturized soy protein, mushroom, wheat gluten, etc., for their various physico-chemical and sensory attributes. They reported higher sensory scores in chicken nuggets as compared to analogs however, the lipid profile was comparatively better in the latter due to less saturated fats. The scores for the textural properties of real meat were significantly higher than the meat analog in terms of hardness, chewiness and cohesiveness. From a food safety point of view, the microbiological profile of analogs is found to be comparatively better than meat products in many studies (Talabi et al., 1986). However, this is largely determined by the initial load as well as processing conditions adopted. Though, meat analogs are seen as a promising candidate for the replacement of meat in the future, for now a comparative assessment almost always gives better scores to real meat.

### Health Considerations of Meat Analogs

Havlik et al. (2010) determined total purine content in 39 commercially available meat analogs and analyzed them for their protein content. They reported that mycoprotein and soy protein based meat alternatives had significantly higher ( $p < 0.05$ ) purine content than wheat and egg white based products. Therefore, the latter has potential for use in meat analogs for people who need to follow low-purine diets. The high purine diet is associated with high uric acid in the blood and can cause causing crystal formation and accumulation around the joints leading to gout, a problem in populations with high meat consumption. Lousuebsakul-Matthews et al. (2014) conducted a prospective cohort study on meat analogs and legume intake in relation to incidence of hip fractures amongst Caucasian men and women and concluded that hip fracture incidence was inversely proportional to high intake of meat analogs due to high protein content containing lysine which promoted greater absorption of calcium through the intestine and increased bone mineral density. van Nielen et al. (2014) studied the effect of the replacement of meat proteins with soy on insulin resistance and blood lipid profile in post-menopausal women with abdominal obesity and found that replacement lead to the prevention of metabolic syndrome and had clear advantages regarding insulin sensitivity and total and LDL cholesterol.

### Consumer Acceptability of Meat Analogs

Any product can be a success but only if it is widely accepted by a range of consumers. Despite many positive features, the overall acceptability of most of meat analogs is lower than traditional meat products. As a remedial measure, the main emphasis lies on increasing the acceptance and recognition of these products as a partial or total replacement of meat and ensuring, acceptable sensory properties such as appearance, taste, juiciness, texture and even the ability to be cooked in a variety of methods. Common meat analogs available on the market have been listed in Table 2. Currently there is a Dutch research programme, Protein Foods, Environment, Technology and Society (PROFETAS) that is dedicated to pursuing options to increase the sustainability of food production and consumption worldwide ([www.profetas.nl](http://www.profetas.nl)). For what concerns protein, they are examining the difference between animal and vegetable protein production, “pigs v peas” and reporting on a range of issues from the prospect of pro-environmental protein consumption to the habits and motivation of young vegetarians, and groups who consume different quantities of meat in their diet in order to understand the most effective ways to move towards a future of reduced meat consumption (de Boer et al., 2017). As part of this research programme, Elzerman et al. (2011) examined the acceptance and appropriateness of meat substitutes in a meal context and concluded that appropriateness was majorly influenced by the appearance of the meat substitute-meal combination rather than flavor and texture. This provided a major insight into gaining wider acceptability of meat analogs by designing meal combinations for these products rather than serving them alone. Long-term acceptance of environmentally sustainable meat alternatives was studied by Hoek et al. (2013) and they found that initial positivity towards meat substitutes was significantly less than meat and boredom to eat the substitutes occurred more frequently. However, on repeated exposure, the likability tends to increase over time. Furthermore, they also concluded that meal context needs to be considered for such consumer studies. Hartmann and Siegrist (2017) revealed that the general consumer has low awareness about the detrimental effect on the environment as a result of protein production from animal sources. Also, they are least willing to shift dietary preference from meat to a sustainable alternative. Thus, more studies exploring the motivational aspects of food choices need to be conducted to give even more insight into what is required to enhance the acceptability of meat alternatives.

**Table 2** Common meat analogs available in market

Name of product	Introduction/first reported	Main ingredients/origin	Characteristics/remarks	References
Tofu	Japan	Pressed soy curd prepared from coagulated soy	Most widely recognized meat alternatives, bland taste, can impart flavor by smoking/marinating	Sadler, 2004
Tempeh	1851 in Indonesia	Fermented soy based cake	Controlled fermentation of soy	Malav et al., 2015
Tivall	1997	Soy based fibrous vegetable protein	Simulate meat muscle and provide a different eating texture to other soy formats	Sadler, 2004
Wheat Pro™	1992	Wheat protein	Texture resembling meat manufactured by Kerry Ingredients	Sadler, 2004
Arrum™	1995	Wheat and pea protein (1:1)	Resembles chunks of meat	Sadler, 2004

Adopted from Kumar et al. (2017).

## Conclusions

Ease of availability and sustainability of quality protein is a target for achieving nutritional security worldwide. Over reliance on animal based foods has resulted in un-sustainable farming practices and environmental problems. Thus, the search for suitable alternatives has zeroed in on meat analogs. They can provide a choice for health conscious, food source conscious and also economically poor consumers. In recent years, the development and popularization of meat alternatives has resulted in a greater choice of products on the market, which use a variety of different ingredients to mimic and/or replace meat altogether. Time will tell if meat analogs can truly compete with the popularity of meat and earn a substantial share of the food market.

# Nanomaterials in Food: An Overview

Stéphane Dubascoux and Yves Wyser, Nestlé Research Center, Lausanne, Switzerland

© 2019 Elsevier Inc. All rights reserved.

## Introduction

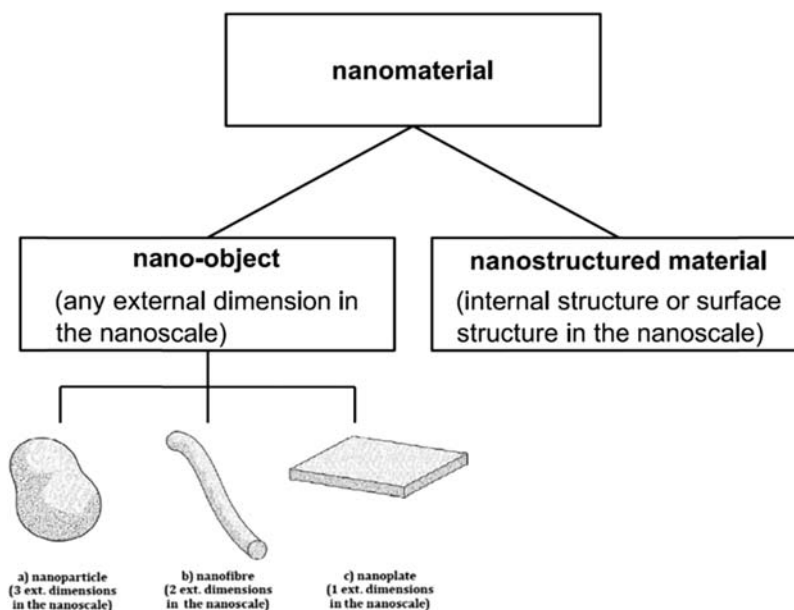

Nanomaterials (NM) utilization gain more and more importance in industrial applications, including food sector, as a route to provide new consumer benefits and added functionality. These applications are often linked to improved properties as bioavailability or active substance release (He and Hwang, 2016). As a prerequisite for the use of such technology, and above all philosophical and consumer acceptance considerations (that are linked to country considered, to socio-demographic factors and knowledge about this field (NanOpinion, 2014; Giles et al., 2015; Yue et al., 2015)), all aspects related to safety and risk linked to usage of any nanomaterials have to be specifically addressed (Cockburn et al., 2012; EFSA Scientific Committee, 2011).

Discussions about nanoparticles and nanomaterials in food and food packaging are continuously increasing in the public and is often associated with a perceived risk to health (as shown in recent reports Illuminato, 2014; Behar et al., 2013), risk that is not always substantiated by scientific evidence and often in contradiction with risk assessments performed by authorities (EFSA, 2016a; EFSA, 2018; EFSA Scientific Committee, 2011). For this reason, Szakal et al. recently highlighted that: “As food products using new nanotechnologies reach commercialization, there is a need to anticipate, to understand, and to manage both potentially positive and negative effects that might result from nanomaterial consumption.” (Szakal et al., 2014).

In order to increase clarity and alignment between all stakeholders, a clear definition about what is a NM has to be accepted.

The International Organization for Standardization (ISO) defines nanomaterials as materials with any external dimension in the nanoscale (approximately from 1 nm to 100 nm) or having internal structure or surface structure in the nanoscale, which includes nano-objects (discrete piece of material with one, two or three external dimensions in the nanoscale, see Fig. 1) and nanostructured materials (material having internal nanostructure (composition of inter-related constituent parts in which one or more of those parts is a nanoscale region) or surface nanostructure) (ISO, 2015).

Strictly speaking, this definition would include most materials, natural and manmade. A classification of these materials is therefore generally made, by defining the origin of the material, either natural, engineered, manufactured or incidental. Regarding these classes, ISO defines engineered nanomaterial as being designed for specific purpose or function, manufactured nanomaterial

**Figure 1** Nanomaterial Framework. Adapted from ISO 2015. ISO/TS. ISO/TS 80004-1:2015, Nanotechnologies – Vocabulary – Part 1: Core terms. 3. 2015. <https://www.iso.org/obp/ui/#iso:std:iso:ts:80004:-1:ed-2:v1:en>; ISO 2015. ISO/TS. ISO/TS 80004-2:2015, Nanotechnologies – Vocabulary – Part 2: Nano-objects. 10. 2015. <https://www.iso.org/obp/ui/#iso:std:iso:ts:80004:-2:ed-1:v1:en>.

as being intentionally produced to have selected properties or composition and incidental nanomaterial as those generated as an unintentional by-product of a process.

While engineered nanomaterials are currently mainly used in food contact material applications, the other classes can be found in food. Examples of the different classes and their origin and use are given further in this paper. Nanomaterials generally used in food, feed and packaging sector can be roughly divided in three main categories: inorganic NM (e.g. metals, metals oxides), organic NM (e.g. micelles, liposomes, emulsions, nano-encapsulates ...) and combined inorganic/organic NM (e.g. modified clays) (Peters et al., 2016).

In addition to the ISO definition, some regulatory bodies refer to specific definitions, often with a limited scope. In the European Union, several definitions coexist in different legislative texts. There is however a desire to harmonize these definitions by aligning them on the European commission recommendation on the definition of nanomaterials which is currently under revision (European Commission, 2011a, 2013). In summary, this definition currently states that nanomaterial means a material containing particles, in an unbound state or as an aggregate or as an agglomerate and where, for 50% or more of the particles in the number size distribution, one or more external dimensions is in the size range 1 nm-100 nm. The scope of the definition is therefore limited to materials composed of a majority of nano-objects, either in isolation, or attached together, whatever the strength of the link between these particles. Contrarily to the ISO definition, this approach limits the definition only to solid particles, i.e. minute piece of matter with defined physical boundaries (European Commission, 2011a). The limitation of the current definition to solid particles is underlined in a working document of the European Commission (European Commission, 2012).

While natural and incidental nanomaterials are present in foodstuffs and packaging as a consequence of the natural structure of certain ingredients and components or as by-products of certain processes, manufactured and engineered nanomaterials are added to the food for their specific properties (obtained either through the design of the materials or as a consequence of the production process used) or to impart specific properties to the food or packaging material.

This chapter gives an overview of such applications and occurrences and presents the analytical challenges and opportunities to assess the properties of nanomaterials, their presence in food and their potential migration from food contact materials.

## Nanomaterials in Food

Consumers' food can potentially contain NM from various sources:

1. Ingredients or components naturally contain nanomaterials as self-assembling nano-fibers and micelles (Rogers, 2016) or NM formed during cooking process which is mostly the case for carbon dots nanomaterials (Li et al., 2017; Mandani et al., 2017; Palashudin et al., 2012).
2. Ingredients or a fraction of ingredients in the nanoform used in the finished product.

This case is the most common case. A distinction is to be made between materials engineered to be under the "nano" form (engineered nanomaterials) and the ones that are "nano" due to the formation process (manufactured nanomaterials).

When NM are voluntary engineered as such, it is generally to benefit from specific attributes: better physico-chemical properties of material (agglomeration state, surface functionality, surface charge ...), better absorption of active ingredients for consumers, enhanced color or flavor, better preservation properties. This is for example the case of novel ingredients that are developed under the nanoform to deliver specific active ingredients thanks to nano-encapsulation (He and Hwang, 2016).

At the opposite, some well-known ingredients are under the nano form due to the production process (manufactured nanomaterials). As an example the approved additive E551 (silicon dioxide, SiO<sub>2</sub>) which has been extensively used in a variety of products for many decades is nanostructured and composed of nano-sized primary particles. In a similar way ultrafine titanium dioxide, TiO<sub>2</sub>, is generated by a precipitation process that generates particles in the nanorange. The size of these particles induce a specific interaction with light which make ultrafine TiO<sub>2</sub> a good barrier to UV light, while maintaining a high level of transparency in the visible range. These optical properties make ultrafine TiO<sub>2</sub> a perfect ingredient to block harmful sunlight wavelength in the UV range and is therefore used in cosmetics such as sunscreens as a physical light filter. In parallel, TiO<sub>2</sub> is also authorized in food as a white coloring agent (E171), application for which ultrafine TiO<sub>2</sub> is not suited. E171 production process forms primary particles in the range 200–400 nm where the coloring property is optimal. Even though the average particle size increases, a small fraction of nanoparticles remains in the final product. In this context, E171 is not a nanomaterial according to European commission recommendation on the definition of nanomaterials as confirmed by EFSA evaluation (EFSA, 2016a) but contains nanoparticles according to ISO definition. For this reason this additive is included in studies on the usage of NM in food as shown in Fig. 2.

As all ingredients, nanomaterials can be present in the food to fulfil a specific function, e.g. anticaking or coloring but also be carried over by some components without having a function in the final product. An example of this is the use of SiO<sub>2</sub> as carrier for some flavors to which it imparts anticaking and free flow properties during their fabrication but has no function in the final product.

**Figure 2** Most frequently used types of NMs in agriculture, feed and food sector. From Peters, R.J.B., Bouwmeester, H., Gottardo, S. et al., 2016. Nanomaterials for products and application in agriculture, feed and food. *Trends Food Sci. Technol.* 54, 155–164.

3. Finally, NM can be present as a result of a contamination, at any step of the value chain, from agriculture where the use of nanomaterial is increasing to improve the efficiency of phytosanitary products (Fraceto et al., 2016), as micro- or nano-sized plastic residues, generated by the slow degradation of littered plastic (EFSA, 2016b), or as migration from packaging and other Food Contact Material (FCM) (Wyser et al., 2016). The specific point of nanomaterials in packaging is developed in next chapter.

Fig. 2, extracted from a review on Nanoparticles for products and applications in agriculture, feed and food from Peters et al., presents the most frequently used types of NMs in agriculture, feed and food sector (Peters et al., 2016):

## Nanomaterials in Packaging

Compared to food industry, the packaging industry has been an early adopter of nanotechnology and nanomaterials, as potential routes to:

- improved properties related to food preservation such as barrier to gasses and vapor, light, improved mechanical properties, active packaging,
- new consumer functionality, such as intelligent and connected packaging.

While some applications of nano-enabled properties are already on the market, some of which since decades, the development of solutions for new functionalities is still ongoing.

An example of nano-enabled packaging are materials coated with thin layer of metals (mainly aluminum) or metal oxides, deposited under vacuum to decrease gas and vapor uptake into the packaging.

To achieve the same goal, engineered nanomaterials, such as exfoliated clay particles or more recently graphene or graphene oxide flakes are added into polymer matrices. Both of these materials are in the form of nanoplates, which are, due to their nature, efficient barrier to the diffusion of dissolved compounds such as oxygen or water molecules. By achieving a good distribution and orientation of the platelets, a tortuous path is created for the migrating species, increasing drastically the diffusing distance, and hence reducing the permeability (see Fig. 3).

**Figure 3** Addition of nanoplates increases tortuosity and decreases permeability. From Wyser, Y., Adams, M., Avella, M., Carlander, D., Garcia, L., Pieper, G., Rennen, M., Schuermans, J., Weiss, J., 2016. Outlook and challenges of nanotechnologies for food packaging. *Pack. Technol. Sci.*, 29, 615–648.

These developments allow the extended use of light weight materials in rigid and flexible packaging, e.g. removing 99% of the aluminum in high barrier metallized packaging materials compared to classical alufoil or replace glass bottles in the range of 300–500 g per liter by coated plastic bottles at least 10 times lighter.

With the recent developments in active and intelligent packaging, the use of nanomaterials in packaging applications will definitely rise (Wyser et al., 2016). A common example for this is the use of silver nanoparticles which are known to impart antimicrobial properties to packaging materials (Mihaly Cozmata et al., 2015). Printed electronics, which will probably be an enabler of intelligent and connected packages, will most probably be based on nanomaterials. However, as mentioned in the next section, their use will depend on their authorization by regulatory bodies, which, together with the low level of public acceptance mentioned previously, might be the main barrier to their implementation in real life applications.

In order to be authorized, the use of nanomaterials in FCM has to go through a risk assessment, i.e. the evaluation of the hazard of an exposure to a specific nanomaterial combined with the expected exposure of the consumer to this material. In this sense, most authorization of nanomaterials in food contact materials have been based on the conclusion that the exposure to them would be negligible. There is indeed increasing evidence that nanomaterials embedded in polymer matrices are not released to the food as nanomaterials (Störmer et al., 2017; Wyser et al., 2016). In some cases, migration through dissolution of the material can be observed. In such cases however, the safety of the substance itself is considered for risk analysis, and not that of the nanoparticles. One exception to the absence of particulate migration, are those active applications where the release of the particles is desired in order to create the functionality, as in the case of nanosilver in anti-microbial materials (Echegoyen and Nerin, 2013).

## Legislation and Analytics

The most advanced part of the world regarding legislation about nanomaterials in food is Europe.

EU regulation 2011/1169 (European Parliament and Council, 2011) on food information to consumers and EU regulation 2015/2283 (European Parliament and Council, 2015) on Novel Food both refer to nanomaterials regarding their labelling and classification as novel foods, respectively. The definition contained therein is due for revision which is expected to be based on the European commission's recommendation on the definition of nanomaterial (European Commission, 2011a).

Although the definition recommended by the European Commission is mainly based on the size of the material, it also mentions that: "material should be considered as falling under the definition where the specific surface area by volume of the material is greater than  $60 \text{ m}^2/\text{cm}^3$ ."

Several other countries (Turkey, Morocco, Switzerland, Ukraine) are aligning their regulation with the EU approach.

For packaging, only nanomaterials (according to European recommendation) authorized and specifically mentioned in Annex I of Regulation 10/2011 can be used in plastic packaging (European Commission, 2011b). In its first release, the later contained three authorized nanomaterials, namely  $\text{SiO}_2$ , carbon black and titanium nitride. These were included in the list of authorized substances as their initial authorization was based on a risk assessment, which evaluated material that were already specified as nanomaterials. In terms of functionality,  $\text{SiO}_2$  is mainly used in flexible packaging as anti-blocking agent (upon unwinding), carbon black as a pigment and titanium nitride as a heat absorption enhancer in PET, to improve the re-heating of preforms prior to the blowing process. The annex has been amended numerous times, including with the addition of additional nanomaterials such as montmorillonite clays and zinc oxide.

European regulation 10/2011, as well as regulation 450/2009 on active and intelligent packaging both specify that the concept of functional barrier (which allows the use of some substances that are separated from the food by a material layer that would theoretically not allow its migration to the food) cannot be applied to nanomaterials (European Commission, 2009, 2011b).

Regulatory definitions imply that analytical methodologies applied to identify or detect nanomaterials must be deployed and able to give information about the size (or specific surface area by volume) but also about the number of particles for each size class (number based distribution).

In the last years, most analytical efforts were put on solid nanomaterials (generally inorganic, if we exclude carbon based NMs).

This topic was reviewed in an important report dealing with “Requirements on measurements for the implementation of the European Commission definition of the term nanomaterial” that has been published by the European Joint Research Center (JRC) in 2012 (Linsinger et al., 2012).

Among all existing analytical methodologies adapted for Nanomaterials analysis, some techniques appear more adapted, mature and promising:

- Microscopy and imaging techniques are considered as the “gold standards” for identification and characterization of nanomaterials. Among them, the most pertinent are Electron Microscopy (EM) based techniques (Scanning Electron Microscopy - SEM and Transmission Electron Microscopy – TEM). Nanoprobes technics as Atomic Force Microscopy (AFM) can also be used. Electron microscopy imaging technics are based on the interaction, in vacuum, of a high energy and accelerated electron beam with the sample. The magnified image is obtained by classical optical physic principles. In the TEM, the image is obtained by the transmission, or not, on the beam through the sample. In the SEM, the focused electron beam is scanning the sample surface and the scattered signal is recorded to create the image. The size range of the imaged sample lies between few hundred micrometers to subnanometric depending on the microscope performances. EM is today the only technique able to cover the full range (1–100 nm) and to give visual aspects of nanomaterials as shown in Fig. 4.

EM will also easily provide a visual evaluation of the aggregation/agglomeration status of nanomaterials (see Fig. 5).

As the imaging is done under high vacuum conditions, samples have to be dried, dehydrated or cryoprepared. It has to be noted that some samples are beam sensitive and therefore can be damaged during the imaging (organic particles or organic-coated particles).

Finally, Energy-dispersive X-ray spectroscopy (EDX) can be associated to either SEM or TEM in order to give information about elemental composition and thus to distinguish between particles of different chemical composition.

**Figure 4** Nanomaterials images obtained from EM. From Wyser, Y., Adams, M., Avella, M., Carlander, D., Garcia, L., Pieper, G., Rennen, M., Schuermans, J., Weiss, J., 2016. Outlook and challenges of nanotechnologies for food packaging. Pack. Technol. Sci. 29, 615–648.

**Figure 5** Example of aggregated nanoparticles.

- **Light Scattering:** among light scattering techniques (including Static or Multi-Angle Laser Light Scattering - MALLS - and dynamic light scattering), only Dynamic Light Scattering (DLS) also known as Photon Correlation Spectroscopy (PCS) or Quasi-Elastic Light Scattering (QELS) has a sufficient dynamic range to cover almost the full size spectrum of nanomaterials definition. In ideal conditions, MALLS can reach tens of nanometers whereas DLS's resolution is nanometric ([Brar and Verma, 2011](#)).

The principle of DLS is based on the evaluation of the short timescales intensity fluctuation of scattered light of particles, nanomaterials or molecules in solution when illuminated with a laser. This fluctuation is due to the Brownian motion of particles caused by thermally induced collision between suspended particles and solvent molecules. These fluctuations are dependent of the size of the particles.

DLS measures particles in suspension in a liquid and gives a light scattering intensity weighted average value which means that results can be strongly affected by the presence of aggregates/agglomerates or by poly-modal distributions and does not give information about primary particles.

For these reasons, DLS can be a powerful tool used for known relatively monodisperse raw materials but can also be associated to nanomaterial separation/fractionation techniques such as Field Flow Fractionation (FFF) for difficult samples in order to introduce a first fractionation step before DLS measurement.

- **Brunauer-Emmet-Teller (BET):** BET method is based on the measurement of gas adsorption (usually  $N_2$  is used as adsorbate) on material surfaces at defined temperature and pressure. The number of adsorbed molecules or atoms on the surface of the particles provides the information of the absolute surface area of the material. Moreover, the knowledge of the particle density allows the determination of the Volume-Specific Surface Area (VSSA) which is used in the recommendation for definition with a threshold at  $60 \text{ m}^2/\text{cm}^3$  ([Wohlleben et al., 2017](#)).

BET measures particles as dry powders and this measurement is affected by the global available surface of the particles meaning that an open porosity in the material will affect the measurement. Some methods (called t-plot methods) appear to be able to separate the surface contributions of the outer particle surface and of the open porosity surface ([Wohlleben et al., 2017](#)).

- **ICP-MS based methods**
  - **Single-particle ICP-MS (sp ICP-MS):** ICP-MS is an elemental detector which allows to quantify elements with very low detection limits. When liquid samples containing a low concentration of nanomaterials/nanoparticles in suspension are introduced at a low flow rate, the assumption that each ICP-MS pulse represents a single particle can be made. Thus, each pulse can be linked to the size and mass fraction of the single nanoparticle. The frequency can thus be linked to the number concentration. This methodology is so called single-particle ICP-MS ([Sannac et al., 2013](#); [Laborda et al., 2014](#)). The size range accessible is 10 nm to micrometers (depending on nanomaterial nature) but even if this technique allows to distinguish polymodal distributions, it is currently limited to nanomaterials with known elemental composition and geometry and to

elements not suffering from current classical ICP-MS limitations and interferences (Laborda et al., 2014; Pace et al., 2011; Loeschner et al., 2018).

- Hyphenation of fractionation techniques with ICP-MS and other detectors: very often, ICP-MS is only used as elemental detector and is coupled with fractionation techniques such as Field Flow Fractionation (FFF) based technologies and other detectors such as Static Light Scattering (SLS) and/or DLS (Pornwilard and Siripinyanond, 2014; Dubascoux et al., 2010). FFF based techniques are separation techniques allowing the fractionation of nanomaterial according to their sizes. The main developed FFF technique is nowadays Asymmetrical Flow Field Flow Fractionation (AF4). The association of AF4 with SLS/DLS and ICP-MS allows to introduce a first fractionation step before DLS measurement and thus to decrease polydispersity while ICP-MS gives information about the chemical composition of fractionated nanomaterials. This kind of coupling is increasingly used due to the sensitivity of ICP-MS and the combination of information given by associated detectors (size, composition). Such coupling and off line sp-ICP-MS analysis of FFF fractions have been notably tested by Loeschner et al. on food samples for the analysis of Ag nanoparticles in chicken meat (Loeschner et al., 2013). In this study, where enzymatic digestion was used as sample preparation, the development of preparation/extraction step appears critical.

Numerous European initiative have been launched in order to address analytical challenges (e.g. European NANOLYSE project from 2010 to 2012 [www.nanolyse.eu](http://www.nanolyse.eu), European NANODEFINE project from 2013 to 2017 [www.nanodefine.eu](http://www.nanodefine.eu)) and have evaluated main techniques and development/optimization for the implementation of the EC Recommendation.

Even if, for pure powdered substances, some methods such as EM, DLS and BET seem to be well fitted and could be applied without too much obstacles, numerous studies highlight the difficulty to evaluate nanomaterials in complex matrices such as food products, due to the difficulty residing in the sample preparation:

- Stamm et al. underline the fact that: “nanomaterials are likely to form part of complex mixtures which may naturally contain particles at the nanoscale (e.g. liposomes, micelles, colloids, etc.), thus making it much more difficult to discriminate intentionally added nanoparticles from natural nanoscale structures (which may also include large organic molecules). Therefore the development of analytical methods, which can be applied routinely by enforcement bodies, is particularly challenging.” (Stamm et al., 2012).
- A review from Calzolari et al. on measurement of nanoparticles size distribution in food and consumer products (Calzolari et al., 2012) explains that: “One recurring theme in the available literature is the need for extensive, carefully executed and documented sample preparation” and “At the moment there is no single technique that can by itself provide a robust analytical method, especially considering the need to measure the number size distribution of nanoparticles introduced by the definition of nanomaterials. The most likely solution to this problem will be to use combinations of instruments, each with a different physical principle of operation, and in this way complement the weaknesses of each instrument with the strengths of another”

It's worth stressing out that, in finished products, since 5–10 years, strong efforts of the analytical community have been put to develop knowledge and to go beyond analytical issues. Some validated work (notably in the frame of European NANOLYSE project) on food matrices have already been conducted for specific combination of nanomaterial/matrix (e.g. SiO<sub>2</sub> in tomato soup (Wagner et al., 2015), Ag nanoparticles in chicken meat (Loeschner et al., 2013), silica nanoparticles in coffee creamer (Heroult et al., 2014) or silicon dioxide (SiO<sub>2</sub>) and titanium dioxide (TiO<sub>2</sub>) nanostructures in commercial dietary supplements (Lim et al., 2015)) but here again sample preparation have to be adapted for each combination.

## Conclusion

While nanotechnology and nanomaterials are generally recognized to be a route to added consumer benefits and functionality for foods and food packaging, their implementation is currently limited by remaining uncertainties on the consequences of their use in such applications.

While nanomaterials manufactured since decades and declared as safe by food safety authorities can be found in current food products, engineered nanomaterial have for now mainly found their way in food packaging applications, in cases where the absence of exposure has been demonstrated.

Further work on all aspects of the technology, i.e. safety assessment, legislative framework, analytical evaluation and a clear identification of consumer benefits, will be needed for a wider introduction of engineered nanomaterials in food related applications.

## Glossary

**Complexation** The combination of individual atom groups, ions or molecules to create one large ion or molecule such as the formation of complexes of proteins and small molecules (ligands).

**Fluorophore** A chemical compound with the ability to absorb light at a particular wavelength (excitation wavelength) and then emit it at a longer wavelength (emission wavelength).

**Fluorescence quenching** A process that decreases the intensity of the fluorescence emission of a given light-emitting substance. A variety of processes can result in quenching, such as excited-state reactions, molecular rearrangements, energy transfer, ground-state complex formation, and collisional quenching.

**Molecular docking** A computational method for bioinformatic modelling to predict the predominant binding mode(s) of a ligand with a protein of known three-dimensional structure, including investigations on ligand conformation, position and orientation within binding sites, and assessment of binding affinity.

**Non-covalent interactions** Different from covalent bonds with pairs of electrons shared by atoms, involve more dispersed variations of electromagnetic interactions between molecules or within a molecule, such as electrostatic interactions, van der Waals forces, hydrophobic interactions and hydrogen bonds.

## Nomenclature

$\text{kJ mol}^{-1}$  Binding energy

$K_a$  Binding constant

$K_{sv}$  Stern–Volmer quenching constant

$n$  Number of binding sites

$fa$  Fraction of fluorophore accessible to solvent

$K_Q$  Quenching constant

## Introduction

Dietary polyphenols exert many health promoting activities. However, their bioactive role in the organism is limited by their poor bioavailability. Epigallocatechin-3-gallate (EGCG) is the well-known representative of the bioactive diet polyphenols of poor bioavailability.

Food macromolecule-based nanoparticles have been fabricated using reassembled proteins, crosslinked polysaccharides, protein–polysaccharide conjugates (complexes), as well as emulsified lipids via safe procedures that could be applied to food processing (Hu et al., 2017; Shpigelman et al., 2012).

Milk proteins are natural vehicles for bioactives. Many of their structural and physicochemical properties facilitate their functionality in delivery systems. These properties include binding to ions and small molecules, excellent surface and self-assembly properties; superb gelation properties; pH-responsive gel swelling behavior (useful for programmable release); interactions with other macromolecules to form complexes and conjugates with synergistic combinations of properties; various shielding capabilities, essential for protecting sensitive payload; biocompatibility and biodegradability, enabling the control of bioactive bioaccessibility and promotion of its bioavailability (Livney, 2010).

## $\alpha$ -Lactalbumin

$\alpha$ -Lactalbumin (ALA) is one of the most important milk proteins, making up 20%–25% of the whey proteins and about 3.4% of total milk proteins. It has important biological functions in mammary secretory cells. ALA is a single chain protein with molecular mass of 14.2 kDa and structure homologous to the lysozyme family. It is a two-domain protein, with a larger  $\alpha$ -domain comprising three major  $\alpha$ -helices (residues 5–11, 23–24 and 86–98) and two short  $3_{10}$  helices (residues 18–20 and 115–118), and a smaller  $\beta$ -domain with a three-stranded antiparallel  $\beta$ -sheet (residues 41–44, 47–50 and 55–56), one short  $3_{10}$  helix (residues 77–80) and loops (Chrysina et al., 2000). There is a high-affinity  $\text{Ca}^{2+}$ -binding site in the loop connecting the two domains (Fig. 1).

ALA in its apo-form has the ability to interact with hydrophobic substances such as retinol (Livney, 2010), vitamin D3 (Delavari et al., 2015), hydrophobic peptides, model lipid membranes, and fatty acids (Barbana et al., 2006; Kehoe and Brodtkorb, 2014). The bioactive complex between ALA and oleic acid is known as BAMLET/HAMLET (Bovine/Human ALA made lethal to tumors) and has been shown to be cytotoxic to a range of cancer cell lines (Mok et al., 2007). Binding of the anthocyanins in the extract from grapes by whey protein isolate presumably involves ALA as a tight binder to malvidin 3-glucoside (Stănciuc et al., 2017). ALA based nanoparticles or nanotubes could find applications in foods and pharmaceuticals for delivery of bioactive substances (Kamau et al., 2010).

## $\beta$ -lactoglobulin

Bovine  $\beta$ -lactoglobulin (BLG), the major whey protein of cow's milk, comprises about 50% of total whey proteins and 10% of whole cow's milk proteins (Le Maux et al., 2014). BLG belongs to lipocalin protein family, which members have a widely diverse series of functions, including ligand binding function. It is assumed that BLG's ability to bind and transport lipophilic compounds is a physiological reason for its high abundance in milk (Kontopidis et al., 2004). BLG has at least two ligand binding sites, which in previous studies have been shown to simultaneously bind different ligands, such as retinol, fatty acids, cholesterol and phenol compounds, such as catechins and phenolic acids (Teng et al., 2015; Kanakis et al., 2011; Jia et al., 2017). Because of its compact structure, BLG is resistant to proteolysis, especially by pepsin. Therefore, ALA is more digestible than BLG in the gastric phase of protein digestion (Fu et al., 2002).

## EGCG

Epigallocatechin-3-gallate is the major and the most biologically active catechin in green tea (Kim et al., 2014), and many of the biological properties of the tea have been attributed to this compound. EGCG can be easily oxidized in aqueous environments, especially at neutral and basic pH (Shpigelman et al., 2012), and EGCG bioavailability and stability can be improved by complexation with food proteins, i.e. heat-treated BLG nanoparticles (Li et al., 2012). Among tea catechins, EGCG has the highest binding affinity to BLG due to galloyl functional group with multiple peptide binding sites, able to form hydrophobic interactions and hydrogen bonds with the proteins (Kanakis et al., 2011). EGCG had stronger binding affinity toward BLG than chlorogenic acid and ferulic acid (Jia et al., 2017).

## Bioavailability

The human gastrointestinal digestive tract is the major place where the food grade macromolecule nanoparticles exert their effects on improving the bioavailability of dietary polyphenols, via enhancing their solubility, preventing their degradation in the intestinal environment, elevating the permeation in the small intestine, and even increasing their contents in the bloodstream.

The stability, structural features and behaviors of nanocarriers in the gastrointestinal tract environment and the effects of nanoencapsulation on the metabolism of polyphenols warrant more focused attention (Hu et al., 2017; Shpigelman et al., 2012).

**Figure 1** Model of native ALA (PDB ID 1F6S) and recombinant ALA (PDB ID 1HFZ) with denoted position of  $\text{Ca}^{2+}$  ions (orange).

Polyphenols are classified into three categories based on their solubility: (1) high solubility but poor cell membrane permeability; (2) low solubility and poor cell membrane permeability; and (3) low solubility but high cell membrane permeability. EGCG belongs to category 1. Therefore, in order to improve bioavailability of EGCG, an attempt should be made to improve membrane permeability (Hu et al., 2017).

Polyphenols from foods and in combinations may have very different bioaccessibilities. Addition of bovine milk, soy milk, rice milk, ascorbic acid, or citrus juice(s) could increase the bioaccessibility of green tea catechins, partially due to the stabilization and protection of polyphenols from auto-oxidation at an alkaline pH (Green et al., 2007). EGCG quickly degrades in the intestinal juice (neutral or alkaline environment), which is mainly attributed to the auto-oxidation of EGCG, forming derived homodimers (Yoshino et al., 1999). Moreover, polyphenols bound with proteins can also be available for the absorption in the small intestine.

Food proteins are abundant and renewable raw materials for developing nanocarriers to deliver drug or nutraceuticals, which is mainly attributed to their exceptional binding capacity of various drugs or nutraceuticals. In addition, food proteins are biodegradable and nonantigenic and have high nutritional value. Protein nanoparticles can be easily prepared and such a production can be scaled up for commercial manufacturing.

### Binding Characteristics of ALA as a Delivery Vehicle for EGCG and Other Polyphenols

Milk proteins can act as delivery vehicles for bioactive compounds, including polyphenols, through noncovalent protein-polyphenol interactions. There are numerous reports dealing with interactions of phenolic compounds with whole milk proteins, whey proteins, as well as individual milk proteins (caseins, bovine serum albumin and BLG) (Ozdal et al., 2013), whilst only several studies described the interactions of phenolics with ALA.

Interactions of ALA with phenolics were investigated including phenolic acids commonly found in food (Zhang et al., 2014), procyanidins (Prigent et al., 2009), genistein and kaempferol (Mohammadi and Moeeni, 2015a), resveratrol and curcumin (Hemar et al., 2011; Mohammadi and Moeeni, 2015b). EGCG binds covalently to ALA (Wang et al., 2014b) and also forms stable noncovalent complexes (Al-Hanish et al., 2016).

Table 1 compares the binding parameters obtained for ALA-EGCG binding and the parameters obtained for binding of other polyphenols to ALA using the method of fluorophore quenching. Mathematical modelling is often applied to estimate binding affinity, and a recent study on the non-covalent interactions of EGCG and ALA estimated the binding affinity using four mathematical models (Stern–Volmer, Lehrer, Double logarithm, Langmoir Isotherm) (Al-Hanish et al., 2016).

Two different ALA crystal structures, native and recombinant, were used to probe the binding site for EGCG. Results of the docking analyses, based on the predicted binding energies and the nature of the putative interactions, indicated the existence of one high-affinity EGCG binding site situated in the cleft between  $\alpha$ -helical and  $\beta$ -sheet-rich domains (Fig. 2) (Al-Hanish et al., 2016). For both studied ALA crystal structures, docking of EGCG to this binding pocket produced a structure with the highest binding energy (Fig. 2A and B). Binding energies estimated by molecular docking simulation were 28.4 kJ mol<sup>-1</sup> for native ALA and 30.1 kJ mol<sup>-1</sup> for recombinant ALA. Bonding of EGCG to this high-affinity binding site is dominated mainly by hydrogen bonding and hydrophobic interactions (Al-Hanish et al., 2016).

Only two molecular docking studies on the binding of polyphenol compounds to ALA are reported, and both (Mohammadi and Moeeni, 2015a) have demonstrated that resveratrol, curcumin, genistein and kaempferol would bind to different regions of ALA. EGCG-binding site is close to, but not the same as, the resveratrol-binding site. This implies that there is no specific polyphenol-binding site in ALA.

When comparing the EGCG binding site on ALA with the EGCG binding site on structurally similar protein, lysozyme (Ghosh et al., 2008), one may find that these binding sites are in the same region. Aligned structures of ALA (PDB 1F6S) with EGCG bound to high-affinity binding site and lysozyme (6LYZ) are presented in Fig. 3. It can be seen that EGCG binds to ALA in the same region as to the lysozyme, e.g. at the entrance of cleft between  $\alpha$ -helical and  $\beta$ -sheet-rich domains in the hydrophobic pocket (Fig. 3), where EGCG interacts with tyrosine and tryptophane residues of lysosyme (Ghosh et al., 2008).

*In silico* analysis suggests that ALA contains at least one putative high-affinity EGCG-binding site, which is positioned in close vicinity to, and interacts with, the dominant fluorophore Trp104 in protein. The high-affinity site is situated at the entrance of the cleft between two ALA domains in the hydrophobic pocket and includes aromatic cluster II residues. It seems that EGCG is spatially too voluminous to penetrate deeper in the cleft of ALA molecule, resulting in a lower affinity in comparison to other less voluminous phenolics (i.e. phenolic acids).

ALA is a good vehicle for delivering EGCG owing to its binding characteristics for other dietary proteins (as summarized in Table 2). The affinity of ALA-EGCG binding is comparable to the binding affinity of EGCG to BLG, Ara h 2 (2S albumin of peanut), trypsin, lysozyme, human serum albumin (HSA), lipase, ovalbumin, alpha- and beta-caseins, catalase, lipase, or alpha-chymotrypsin (Table 2). Interestingly, ALA is more digestible than BLG in the gastric phase of protein digestion (Fu et al., 2002). Therefore, for an EGCG-ALA and EGCG-BLG system, EGCG may be gradually released predominantly from ALA during the gastric digestion, and then progressively released from BLG during the intestinal phase.

It is known that EGCG can influence the fluidity of cell membrane (Kim et al., 2014). Among the important biological activities of EGCG, the inhibition of protein uptake by antigen-presenting cells, such as peripheral blood monocytes (Ognjenovic et al., 2014) and immature dendritic cells (Yoneyama et al., 2008) deserves particular attention. Hagiwara and Matsushita (2014)

reported that the mechanism of endocytosis inhibition could be due to the interference of EGCG with the interaction between small GTPase Rab5 and caveolin-1. To exert such a function, EGCG should be delivered to Rab5 in a biologically active form.

In atherosclerosis, damaged endothelial cells generate more reactive oxygen species (ROS), such as hydrogen peroxide, and inflammatory mediators, which recruit monocytes to endothelium. Antioxidant-loaded monocytes target endothelial cells, and the antioxidants scavenge more than 90% of intracellular ROS generated by cytokines or exogenous ROS (Lee, 2014). Thus, monocytes could contribute to retardation of early-stage atherosclerosis via target-specific delivery of protein-bound natural antioxidants, such as EGCG, to endothelium. Two previous studies examined the uptake of EGCG by monocytes in a complex with dietary proteins, and in both cases, the impact of endocytosis inhibition by EGCG was observed. Therefore, both ALA and ovalbumin complexed with EGCG can efficiently deliver the biologically active polyphenol to monocytes (Ognjenovic et al., 2014; Al-Hanish et al., 2016).

## Conclusions

ALA can serve as a suitable delivery system of biologically active EGCG and possibly other nutraceuticals, due to the low cost and availability of ALA. Further studies are needed to develop EGCG-encapsulating ALA-based or BLG/ALA-based nanoparticles or nanotubes, in order to improve EGCG stability and protect its activity during a prolonged storage. Not only the affinity binding of EGCG to ALA and BLG, but also to other whey proteins, can be utilized for efficient food fortification with EGCG. As a result, in such fortified foods, whey proteins can continuously release EGCG during the digestion process resulting in improved uptake and conveyed health benefits of this powerful polyphenol. As ALA is more digestible than BLG by pepsin, during gastric digestion EGCG will be gradually released predominantly from ALA, and then during intestinal phase, progressively released from BLG.

## Introduction – Food Structure

Food structure is the organization of food constituents at multiple spatial scales and their interactions. In simple terms, different types of food structures are formed when food ingredients are mixed together to make a food product. Many food properties relevant to process engineering and product quality are related to structure. Insights into food structure and how it changes during processing operations are essential for producing high-quality food.

Structures that are relevant to food properties can be considered at different length scales (**Figure 1**):

1. At the smallest scale is the molecular structure: chemical structures that make up the constituents such as water, minerals, vitamins, flavor components, fatty acids, lipids and protein monomers, etc.
2. The next level up is the microscopic level: aggregation of molecules and their assembly into components, colloids and networks which are typically measured between nanometers and micrometers. A range of classic supermolecular structures in food are casein micelles, milk fat globules, starch granules, biopolymer network/gels such as the gluten structure in dough, pectin gel, etc.

**Figure 1** The length scale of structures and examples of representative molecules, food components, networks, and food structures. Microscopic images are kindly provided by Drs S.K. Øiseth, T.H. McCann and A. Leis, CSIRO (Werribee and Geelong, Australia).

3. The macroscopic level of structure considers those features that are perceived by human senses, such as texture and taste. They are often associated with specific types of foods by consumers, for example, tomato paste or fruit purees, recombined meat such as burgers and sausages, porous structures such as cakes and biscuits, and different types of grains, etc.

The processability, texture, flavor, and shelf-life qualities of food are controlled not just by chemical composition, but also by how the various ingredients are distributed and interact at the nano and microscopic length scales. Food structures vary enormously from relatively homogenous liquids to complex, multiphase colloidal systems containing fats, proteins, polysaccharides, salts, and water in the form of fibers, droplets, crystals, networks or even air bubbles. The size, shape and distribution of these structures greatly influence product stability as well as sensory properties and bioavailability of nutrients for absorption when food is consumed and digested (Turgeon and Rioux, 2011).

The important role of food structures in the area of nutrition is more and more recognized: how digestion of food macronutrients such as starch, fat and protein occurs depending on the matrices of food structure and thus accessibility of digestive enzymes in the gut. The same is true of micronutrient accessibility – both the chemical and physical states affect whether the body is able to derive the potential benefit of minerals, phytochemicals and vitamins, etc. (Parada and Aguilera, 2007).

## Food Colloids

Colloids are a widely encountered structural component present in many different food systems. A colloid can be classified as a dispersion of one material state in another, in which the dispersed component typically has dimensions across the micron length scale. The material states that comprise colloids are usually called the dispersed phase and the continuous phase, and each of these can be comprised of solid, liquid, or gas. Usually, the two phases are immiscible with each other, and thus colloidal systems are thermodynamically unstable. Instead, colloids can be kinetically stabilized, either through manipulation of the dispersed phase (such as reducing particle size) or through the continuous phase (increasing viscosity, or imparting a yield stress). In this way, the physical stability (or structural lifetime) of a colloid can be controlled and that for foods can range from a few seconds to in excess of a year, depending on the product in question (Dickinson, 2015).

## Emulsions

Oil and water, when combined, are well known for their immiscibility, yet both materials are frequently encountered together in many food systems. The particular colloidal state used to achieve metastability of mixture of oil and water is the emulsion, in which one phase is dispersed in the other in the form of small droplets. For food products, particularly soft solid foods, the oil-in-water state is more commonly encountered, providing a structural, material, and sensory contribution to products such as homogenized milk, yogurt, mayonnaise, ice cream, and cheese (with butter and margarine as examples of water-in-oil type emulsions). Emulsion stabilization is usually achieved through a combination of processing, in the form of homogenization, and surface stabilization of droplets through formulation design. High-pressure homogenizers and colloid mills are most frequently used in food manufacturing to produce emulsions. Both processes exert high shear forces on mixtures of oil and water, and the resulting flow properties under these shear conditions are sufficient to disperse the oil phase into small oil droplets (typically ranging from  $\sim 0.2$  to  $20\ \mu\text{m}$  in foods). Ingredient stabilization, in which surface active components in the formulation (such as proteins – notably dairy proteins, and polar lipids such as monoglycerides and lecithins) are able to adsorb at the newly formed interface, can be used to not only provide stabilization against coalescence and phase separation, but also to promote specific interactions between droplets. Emulsion structuring through controlled flocculation or partial coalescence contributes to the stability and material properties and sensory properties of many foods, such as cream cheese, which comprise a network structure consisting of protein and fat droplets, and whipped cream for which the foam structure is stabilized by a scaffold of agglomerated fat droplets.

## Foams

Foams are another example of a colloidal state commonly found in foods, such as cakes, breads, whipped cream, confectionary and beverages. Foams are dispersion of air in a liquid continuous phase (which is usually water). Formation and stabilization of foams is similar to that of emulsions, requiring the generation of air bubbles as the dispersed phase (through incorporation of air under high shear, but also potentially through sparging or pressure drop) and their stabilization through adsorption of an appropriate surface active material at the air–water interface (again, proteins and polar lipids can be effective in this respect). Loss of stability occurs through phase separation (drainage), coalescence and disproportionation (in which air diffuses from small bubbles into large bubbles).

Bubble size is typically larger than that observed for emulsions (ranging from  $\sim 50\ \mu\text{m}$  to several millimeters depending on product), and due to the large density difference between air and water, long-term stabilization can be challenging. For some products, such as beer foam, bubble lifetime only needs to be maintained over a matter of few minutes (although even during this short time, the foam provides both a sensory contribution and visual cue to the product). However, for other products such as ice cream and bread, where the foam phase also provides an essential contribution to the sensory properties of the food, foam stability needs

to be maintained for considerably longer. Generally, to avoid separation and destabilization, immobilization of bubbles can be achieved through modification of the continuous phase rheological properties (e.g., increasing viscosity, creating a yield stress or completely solidifying the continuous phase).

## Gels

The formation of a gel state usually occurs as a consequence of the formation of bonds between interacting molecules or colloidal particles within a solvent medium. This can lead to the establishment of a percolating structure that is essentially able to immobilize the solvent phase, transitioning a material from a sol state to a gel state. Gels are often considered elastic materials, and while this is certainly true for a number of examples (such as boiled egg white), it is important to note that depending on the type and extent of interactions, significant diversity in gel material/textural properties can be generated. Accordingly, structures can be produced with material properties varying from soft, readily yielding materials (such as yogurt), through to firm, elastic materials (jelly) and hard, fracturable materials (such as aged cheddar cheese). Gels can also be formed from a variety of food ingredients, based on the broad premise that these materials are able to form bonds, either with each other, or with other ingredients. Specific gelling materials are considered as follows.

**Protein gels** – Proteins with globular molecular structures (such as whey and soy proteins) can form gels as a consequence of protein denaturation (through a variety of mechanisms, such as temperature, pressure, and solvent conditions) usually followed by formation of covalent bonds between neighboring molecules via disulfide exchange. Gel strength can be influenced by protein concentration, ionic and pH conditions and the interactions with other food ingredients.

Proteins can also form noncovalent gels as a consequence of other forms of interactions. Two common examples include casein micelles in milk (which can form particle gels as a consequence of either acidification or rennet treatment) and gelatine, which can form thermoreversible gels as a consequence of hydrogen bond formation.

**Polysaccharide gels** – A number of polysaccharides are able to undergo gelation. This can be achieved through varying mechanisms of interaction including hydrogen bonding (such as for agar), electrostatic cross-linking (low methoxylated pectin, sodium alginate in combination with calcium ions), and hydrophobic interactions (hydroxymethyl cellulose). Gel properties can be influenced as a consequence of polysaccharide concentration, the number and availability of junction sites, and by solvent conditions. Combinations of polysaccharides can generate some interesting synergistic behaviors, allowing expansion of the range of material/textural properties achievable, and similarly interactions with other ingredients (e.g., the interaction between k-carrageenan and milk) can also create specific pathways for gelation.

**Emulsion-based gels** – The interfacial layer of emulsion droplets can allow droplet–droplet or droplet–continuous phase interactions to take place. Where droplets are able to stick together (again, a number of mechanisms may allow interaction to occur), network structures can be formed that percolate the system, causing gelation to take place. Gel material properties are dependent on the type and strength of interaction, the amount of fat present, and the influence of the continuous solvent phase (and any other materials present within it). Cream cheese provides an example of such a structure.

## Suspensions

A suspension is a colloidal state in which a solid phase is dispersed in a liquid. This particular state can be found in a number of food products such as cake batters, molten chocolate, salad dressings, and chocolate milks. For suspensions, the dispersed phase is generally of higher density than the surrounding continuous phase and (where the continuous phase remains liquid) will tend to sediment over time. To ensure that a solid dispersed phase remains uniformly distributed within a food often requires some form of kinetic trapping, usually as a consequence of altering continuous phase rheology such that the solid particles become locked into the structure.

In this way, sugar particles dispersed in the molten fat phase of chocolate are fixed in place on solidification of the chocolate on cooling. For a product such as chocolate milk, solidification of the continuous phase to immobilize cocoa particles would not be appropriate for the product. However, the implementation of a very weak yield stress (through the addition of the polysaccharide carrageenan) can be sufficient to inhibit sedimentation (while still allowing the liquid to properly flow during pouring and consumption). A similar approach is taken with some salad dressings, where xanthan (another polysaccharide) can be used to impart a weak yield stress to arrest the sedimentation of added herbs.

## Food Rheology

Food rheology is the study of the consistency and flow of food under specified applied forces, to understand the underlying physicochemical principles of ‘structuring’ by food materials and their interaction.

The degree of fluidity, consistency and other mechanical properties are important in determining how food ingredients can be mixed and processed during food manufacturing, what kind of product texture can be achieved, and how stable it will remain. The application of rheology to study food is primarily for the following three purposes (Fischer and Windhab, 2011). First, food engineers, who try to develop rheology–process relationships of the food, use rheological data for process or product optimization. Typical flow processes in food processing include mixing/stirring, dispersing, extrusion, coating, injection molding, and spraying.

Rheological measurements are also used in analytical to semiempirical modeling as well as in numerical flow process simulations. Second, material scientists or physicists focus on rheology–structure relationships of soft materials. Model food systems are often used to establish the material properties and develop science for new formulations and food properties. Last, food technologists aim at comparative characterization of food products to establish rheology–property relationships. Typical ‘properties’ of interest correlated with rheology are (1) sensory/perception characteristics (e.g., texture), (2) stability, (3) convenience aspects (e.g., portioning, scooping, dosing, filling), and (4) nutritive characteristics (e.g., release kinetics, satiety).

Rheological characterization involves quantification of the functional relationships between deformation, stresses, and the resulting rheological properties such as viscosity, elasticity or viscoelasticity, flow behavior, and recovery (Fischer et al., 2009). In principle, the experiments are usually carried out by either imposing a small force (*stress*) and measuring the deformation of the sample (*strain*), or a fixed amount of movement (*strain*) and measuring the *stress* developed in the sample. The small deformation measurements enable materials to be probed over supermolecular distances (e.g., nanometer to micrometer range) to establish the relationships between levels of structures and structural organization. On the other hand, measurements made under conditions of large deformation can provide information complementary to that obtained in the small deformation range, particularly time-dependent and nonlinear viscoelastic behavior at large strains and stresses. Measurements obtained at a large deformation regime are more relevant to the use of food materials in practice and the eating experience such as cutting, spreading, or chewing.

## Food Texture

Food texture plays an important role in whether the consumers like the food product or not (Foegeding et al., 2011). Texture is one of the attributes used by consumers to assess the food quality. Food texture is part of our sense when we feel the food in our mouth. It is can be described in the terms such as ‘hard,’ ‘soft,’ ‘liquid,’ ‘solid,’ ‘rough,’ ‘smooth,’ ‘creamy,’ ‘crumbly,’ ‘crispy,’ ‘lumpy,’ ‘gritty,’ etc. Such textural terms are directly related to the density, viscosity, surface tension, and other physical properties of a particular food product (Pascua et al., 2013).

Ultimately, the textural characteristics of a food are measured by sensory assessment tests. Since texture is inextricably linked to food structures at micro- and macrolevels and are strongly influenced by the interactions of food biopolymers such as proteins, polysaccharides, and lipids, instrumental methods designed to measure rheological and/or mechanical properties may be used to establish parameters that relate to relevant sensory textural characteristics (Chen and Opara, 2013).

In addition to the direct contribution to consumer acceptance, texture also has a vital secondary role on modulating flavor release and perception. If flavor components in a food are to be sensed, they must be released from the food matrix to reach the appropriate taste receptors. This release of flavor is closely associated with the way in which the food structure breaks down in the mouth relating to both the initial texture of the food and the change in texture throughout mastication (Stieger and Van de Velde, 2013).

## Food Breakdown

The structure of any given food product is essentially a template of the properties of that food system, representing its material behavior, physical stability, appearance, sensory performance, and other attributes related to the overall quality of that particular food. For manufactured foods, this is primarily considered for product structures essentially in the final processed and packaged form; in other words, a snapshot of the structure as it sits on the supermarket shelf. However, if one wishes to develop correlations between food structure and aspects such as technical functionality (e.g., the spreadability of butter), sensory, and even behavior during digestion, then it becomes essential to determine the structural changes taking place for any given food in response to the environmental conditions that are applied to that food during use, consumption, or digestion.

Thus, the sensory properties of any food can be established as a consequence of the in-mouth failure of that material in response to the conditions of shear generated by the teeth and movement within the oral cavity, by the interaction and dilution with saliva (including the presence of salivary enzymes), by the temperature in mouth, and of course the residence time needed to render the food into an altered structural state appropriate for swallowing (Chen, 2015). The investigation of structural dynamics in the mouth is termed oral processing and is a rapidly growing branch of the Food Structure discipline. This is facilitated by the development of increasingly sophisticated models able to replicate the oral cavity, particularly regarding the shear forces present during mastication, and which allow the changes in food structure during mechanical simulation of the eating process. Additionally, *in situ* analysis of structure changes during eating can be achieved through techniques such as articulography, which allows the breakdown of foods during eating to be directly related to the temporal development of sensory attributes. This approach can be applied to virtually any food type.

Similarly, the study of food material breakdown during gastrointestinal transit is increasingly being used to demonstrate the role of food structure in the digestion and uptake of micro- and macronutrients (Norton et al., 2014). This has been a rapidly developing field of research, aided by the development of sophisticated static and dynamic *in vitro* models that can increasingly be considered representative of digestive physiology (particularly with regard to pH, biochemical, and mechanical conditions) within the stomach and small intestine. Such models are able to determine how the digestion key nutrients, such as proteins and lipids, are influenced by the response of food materials to the digestive environment. An understanding of this relationship can allow food structures to

be developed with the ability to impart specific digestive properties, providing appropriate validation using human studies has been carried out (Bornhorst and Singh, 2014).

## Conclusion

The quality of a food product, in terms of sensory, shelf life, appearance, or nutritional value, is governed by the structure of that food. An understanding of how ingredients are assembled through processing, and how structural elements are across diverse length scales, impacts the material and technical properties of foods and can provide a considerably more iterative means of manipulating product properties. Thus, the intrinsic functionality of raw materials, ingredients, and additives can be tailored to specifically deliver a requisite structural contribution to any given food product.

More recently this approach has been extended to relate the structural disassembly of foods. Knowledge of how foods break down in the mouth through to the human digestive system provides new insights as to how the dynamics of product microstructure influence both food perception, digestion and nutrient absorption. Such knowledge will ultimately allow for the design and development of products able to meet specific requirements in terms of their properties, thus enhancing product value, whether it is in terms of cost, quality, or nutritional benefit.

## The Deformation & Flow of Food

Rheology is the study of how materials flow and deform in response to mechanical stress (Barnes, 1994). It is an important tool for food scientists for two reasons (Fischer and Windhab, 2011). Firstly, flow properties define food structure during preparation. Most processed foods are edible structures that form when ingredients like proteins, polysaccharides, and lipids respond to mechanical and thermal stress (Mezzenga and Fischer, 2013; Van der Sman, 2012). Secondly, how a food is perceived and digested is affected by its flow behaviour (Witt and Stokes, 2015; Scholten, 2017). The focus of this review is the rheology techniques being developed to probe flow behaviour on the multifarious length- and time-scales that are relevant to food on its journey from production to end-use.

Traditional rheometers were developed to study materials that have a well-defined response to stress. A homogeneous liquid like brine, for example, flows steadily when poured out of a container. The flow is characterised by measuring the liquid viscosity on the macroscopic scale. Soft foods like mayonnaise, peanut butter and yoghurt on the other hand flow only once a critical stress had been applied. Otherwise they deform in a finite way, like elastic solids. Small angle oscillatory rheology (SAOS) characterises this behaviour on the macroscopic scale by quantifying the elastic storage modulus ( $G'$ ), which is a measure of the energy stored during a strain cycle, and the viscous loss modulus ( $G''$ ), which is a measure of the energy dissipated when the material flows during a strain cycle. Typically the stress (or strain) is applied sinusoidally and studies are carried out as a function of frequency in order to arrive at a viscoelastic spectra. Changes in the  $G'$  and  $G''$  of materials as a function of the frequency at which they are strained reflects the contribution of different relaxation mechanisms over different time windows, and as such informs on internal dynamics. Recent advances in rheology have been motivated by the complex flow behaviour of many soft materials which can depend on time, the size of the sample being probed, and the history of applied stresses (Chen et al., 2010; Liu et al., 2016).

Many foods are inhomogeneous solutions that drip and splatter when poured, rather than flowing steadily and indeed show complex, time-dependent responses to mechanical stress down to the micrometre scale. Their flow behaviour is complicated by the presence of nanometre and micrometre-sized structures formed by proteins, polysaccharides, and lipids. The microstructures are often meta-stable, which means that how the food responds to stress changes as it ages. The challenge then is to understand how local variations in microstructure and dynamics contribute to the complex interplay between food structure, function and rheology.

## Microrheology

Microrheology is the collective name for a relatively new set of techniques that seek to probe the mechanical properties of soft materials over increasing ranges of time and distance, spanning the molecular to the macroscopic. They have steadily become more visible in food science literature (Fig. 1).

In essence microrheology seeks to replace the traditional, rather invasive, application of stress to the entirety of bulk samples, and the concomitant *sample-averaged* measurements of induced deformation or flow, with what might be thought of as a rheological microscopy. Stresses are imposed locally through microscopic probe particles that are internalised within the samples (such tracer particles can be added at a low phase volume during the preparation of samples if no appropriate native constituents can be identified), and the resultant movement of the probes obtained for example by microscopy in multiple particle tracking (MPT) captures the strain response, potentially allowing a localised measurement of the viscoelastic properties to be performed. The first advantages of microrheology are thus clear: i) applied stresses are considerably less likely to cause measurement-induced modifications to the structure being interrogated, ii) only small sample volumes are required, and iii) there exists the potential to obtain local mechanical properties. Even qualitatively visualising the movement of such micron-sized probe particles in a sample simply with a light microscope conveys the feeling of how 'gloopy' or 'jelly-like' different regions of samples are, holding clues to understanding creep, fracture and transport in food matrices. Fig. 2 shows the trajectories of the centre of mass of three different tracer particles, each one taken from a different concentration of a model food gel, an ionotropic pectin system formed with calcium. The progression from relatively free diffusion in the more viscous, low concentration system, through interesting "cage-jumping" behaviour at 0.5%, to firmly constrained motion as the concentration is increased further seems immediately intuitive.

As described, the stresses in microrheological experiments are not imposed onto the bulk of the sample through the surface of a rheometer plate or other geometry, they are applied by the probe particles being moved within their local environment. The application of these forces can be carried out either by using the modulation of external fields with which the particles interact, such as optical tweezers (OT) or magnetic tweezers, or simply by harnessing the thermal fluctuations of the particle. The former techniques

**Figure 1** (a) The number of publications since 2000 with “food” and microrheology” listed as keywords and (b) the number of times these publications have been cited. Data from Web of Science, December 2017.

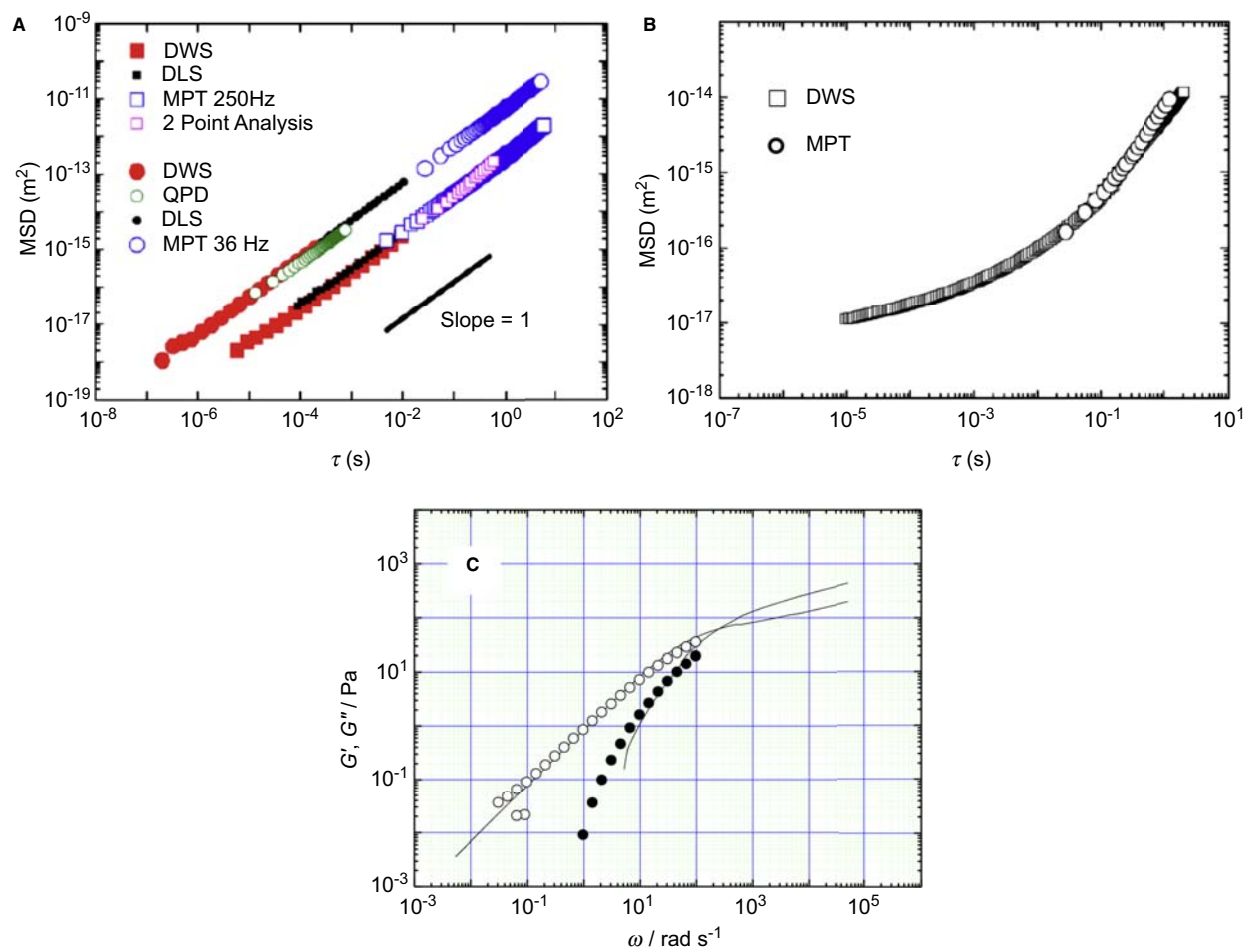

**Figure 2** The centre-of-mass movement of 500 nm latex particles undergoing thermal motion in pectin gels of three different concentrations as shown.

are called “active microrheology” while the latter bear the name “passive”. Passive microrheology then essentially studies the Brownian motion of internalised tracer particles (Fig. 2), and discerns the local mechanical properties from the fluctuation-dissipation theorem of Einstein, in exactly the same way as particle sizing is carried out in techniques such as dynamic light scattering in solutions of known viscosity: here rather than the viscosity being known and the diffusion coefficient of particles revealing their size, their size is known and their diffusion behavior reveals the mechanical behaviour of the surroundings. Indeed, Einstein had eloquently mooted the idea of microrheology himself during his work on the interpretation of Brownian motion, describing microscopic particles as moving like “a buoy in a pudding”.

The main task of quantitative microrheology then is to quantify small movements of tracer particles. In passive microrheology how the mean squared displacement (MSD) of the particles changes with time is the central focus of the measurement. For purely viscous solutions such measurements reveal a linear relationship that can be used to extract a single diffusion coefficient and thus a viscosity (Fig. 3a). While for viscoelastic media how the MSD of the probe particles scales with time is more complex (Fig. 3b), with some extra work the data can be mapped to a traditional quantitative viscoelastic spectrum such as would be measured with SAOS (Fig. 3c) (Cicuta and Donald, 2007).

In active microrheology a materials response function is measured by either driving probe particles with external fields or driving the sample (with a piezo-electric stage for example) and observing the probe response. The response ( $G'$  and  $G''$ ) can be measured as a function of frequency in a similar fashion to SAOS simply by manipulating the different driving frequency (Furst, 2005). While this is somewhat more labour intensive than the passive measurements that essentially measure the response to the entire spectrum of thermal fluctuations, active microrheology does potentially allow one to probe larger forces and even non-linear behaviour.

**Figure 3** (a) The mean-squared displacement (the central measurement) of tracer particles measured in viscous fluids with two different viscosities, measured by several techniques as described in the text; (b) the mean-squared displacement of tracer particles measured in a viscoelastic fluid (PEO) and (c) a viscoelastic spectra obtained from processing the data in (b) (Solid Lines) compared with results obtained by conventional rheological measurement.  $G'$  (Solid Circles) and  $G''$  (Open Circles).

In passive microrheology where no external field is required, simply looking at the thermal fluctuations over smaller and smaller timescales corresponds to measuring the mechanical properties at higher and higher frequencies. Another potential advantage of microrheology is thus revealed, iv) the viscoelastic spectrum of a material can be measured at frequencies several orders of magnitude higher than in a conventional rheometer, as long as the small displacements of the particles undertaken over very small times can be measured. While camera technology continues to improve and using a camera to film many particles at once in principle allows you to obtain information on heterogeneity, frame-rates of 100s of Hz are typically hard to surpass. However, the desire to observe probe particle motion over smaller and smaller time intervals is led, in-part, by the development of alternative methods for measuring the displacement of microscopic particles.

In one approach the position fluctuations of a single particle can be measured by illuminating it with a low power laser, capturing the light scattered onto a quadrant photodiode (QPD) and observing how the intensity of the light in each quadrant fluctuates. As the bead moves the amount of light captured by each quadrant of the photodetector varies, and these measurements can be calibrated to reveal quantitative displacements. However, freely diffusing beads will quickly leave the region of the probe laser so that obtaining a sufficiently averaged displacement is typically only possible by corraling the particle of interest using an optical trap (a focussed laser beam that interacts with the high refractive index particle and restricts it from moving away from the centre of the beam).

In another approach light scattering techniques such as diffusing wave spectroscopy (DWS), in which the ensemble-averaged motion of a set of tracer particles can be measured in steps smaller than a micron, correspond to rheological measurements at a MHz. In this case while sacrificing spatial resolution by monitoring fluctuations in the light scattered by the *ensemble* of particles, rather than observing the particles directly, temporal resolution is gained by using photomultiplier tubes rather than CCD (or faster CMOS) cameras to poll the intensity of scattered light.

**Figure 4** Timescales over which typical microrheology techniques (DLS, DWS, OT and MPT) operate compared with conventional rheology, revealing that a host of new information is available from these new experiments. This corresponds (left to right) to a frequency range from around 10 MHz to 0.05 Hz, and measurable storage moduli from around 10 kPa to 0.1 mPa.

Practically these timescales have an impact on the apparent frequency of the mechanical measurement and thereby on the sort of modulus values one can measure with a particular technique (Fig. 4). Techniques that can measure probe particle displacement at higher frequencies are capable of obtaining smaller displacements and thereby can typically probe materials of higher elasticity.

In summary, microrheology provides a set of new tools for food scientists to address the mechanical properties of food matrices, allowing deformation and flow to be studied over some eight orders of magnitude, from microseconds to hours. As the techniques continue to develop the hope is that more understanding of real structure-function relationships between desired properties such as processibility and breakdown, and different measurable mechanical properties, will be revealed.

## Glossary

**Structure-to-function paradigm** an expression used to define the mutually inclusive relation between molecular function and structure.

**Ingredients compartmentalization** internalization of one or more ingredients in food products, usually in a separated compartment embedded in the formulation or as a separated physical state (phase).

**Binding isotherm** a plot showing the fractional saturation of a quantity (e.g. complex formation between two molecules) as a function of ligand concentration. In order to be meaningful, the measurement has to be taken in conditions of constant temperature (isotherm) and pressure.

**Low-complexity protein sequence** a region of protein sequence space that is characterized by a small variety of amino acids. Low-complexity regions are particularly abundant in disordered proteins, in which particular residues are underrepresented (i.e. aromatic residues).

**Coacervation** process leading to the phase separation of molecular components within a solution, according to changes in concentration or micro-environmental conditions (pH, ionic strength, etc.).

**Cation- $\pi$  interactions** molecular interactions formed between an electron rich  $\pi$ -system and a cation. In proteins, the aromatic ring of phenylalanine or tyrosine residues and the sidechain of arginine usually compose the moieties taking part in cation- $\pi$  interactions.

**Molecular scaffolds** molecular components that are essential for the integrity of a particular cellular body and that provide interaction moieties for other molecular components within the cellular body (clients).

**Molecular clients** molecular components of cellular bodies that are not indispensable for the integrity of the body but that rely on molecular scaffolds (see previous definition) within the body for establishing interactions.

**Hydrotrope** molecule that can solubilize hydrophobic compounds into aqueous solutions and does not have the ability to self-aggregate.

## Introduction

### Intrinsic Disorder in Proteins and the Discovery That Function Can be Mediated by the Lack of Molecular Structure

One of the long-standing paradigms of biology states that the function of biomolecules is rigorously related to the three-dimensional structure that they adopt. DNA can be intended as a paradigmatic example of this: its double-helical structure ensures recognition of DNA-binding proteins as well as the preservation and propagation of genetic material from one generation to another. Proteins were thought not to be an exception to the structure-to-function paradigm.

In the early 1900's, Linus Pauling and Alfred Mirsky observed that protein denaturation generates functional loss (Mirsky and Pauling, 1936). Accordingly, renaturation (or refolding), which was accompanied by the restoration of function, undoubtedly indicated that structure and function would be mutually inclusive. Around that time, the denaturation-driven loss of function had been documented for a consistent number of molecules and the idea that structure and function would be intertwined was almost perceived to be as important as the genetic code (Kolata, 1986).

Considering such findings, the length of time that the community took to realize that some molecules effectively lack well-established secondary structure elements within their explored conformational ensembles, comes with no surprise. The past few years, however, have been characterized by an increased awareness that proteins without structure, now commonly referred to as *intrinsically disordered proteins* (IDPs), are very common and their recognition has ultimately expanded the universe of protein function as we know it. Interestingly, IDPs seem to have increased concomitantly with organismal complexity, for instance from prokaryotes to eukaryotes (Pancsa and Tompa, 2012; Schad et al., 2011), indicating that lack of structure could coincide with an expansion of function (Babu, 2016).

The increasing number of studies on IDPs has revealed exceptional properties of these molecules (Dyson, 2016; Wright and Dyson, 2015). Nevertheless, the uniqueness of such properties goes beyond the brilliance of their function inside cells and crosses disciplinary borders ranging from structural and cellular biology to food science and engineering.

To the question: "*what do intrinsically disordered proteins have to do with food science?*" the most appropriate answer would be *everything*. As food science constantly searches for new solutions to expand the repertoire of formulations for the creation of new products, IDPs provide the means for such solutions because of their chemical versatility that ultimately leads to a variety of behaviors which can be finely tuned by changing micro-environmental conditions.

In order to reply to the question above it is necessary to take a step back and consider the core interests of food science and the demands of the food industry. Based on the necessity to continuously create new products, to move towards the creation of super foods and functionalized ingredients, key methodological needs can be identified. Of these, three will be highlighted here as they are all of great importance: (i) the need to compartmentalize ingredients ultimately obtaining control over their timely release in desired quantities, (ii) the need to increase food security, especially in parts of the world severely affected by desertification due to climatic changes and (iii) the importance of designing and tuning the specificity and affinity of receptors for the development of more sensitive biosensors used for the detection of food pathogens.

### The Tendency of Intrinsically Disordered Proteins to Compartmentalize Makes Them Particularly Interesting for Food Science

One of the most fascinating discoveries of the last decade is that IDPs are majorly responsible, in cells, for the formation of molecular conglomerates composed of intracellular proteins and/or nucleic acids, which are generally referred to as membraneless organelles (MLOs) (Darling et al., 2017; Meng et al., 2015; Shorter, 2016). MLOs are functional entities formed upon the change in micro-environmental factors such as temperature, chemical modifications of their composing molecular components, pH and/or ionic strength (Banani et al., 2017; Molliex et al., 2015; Riback et al., 2017). Although the exact nature of the interactions and the conformational dynamics of the components forming MLOs is unknown, these bodies exhibit the physico-chemical properties of liquid–liquid mixtures, as they are able to drip, fuse and deform (Darling et al., 2017). Altogether, these characteristics are of great potential for both the pharmaceutical and the food industries, a more detailed understanding of the features that allow such behavior in cells needs to be elucidated: hence more research needs to be devoted to these interesting molecules.

Interestingly, the quantity and diversity of MLOs suggests that there is not a single mechanism behind the ability of these components to phase separate or disassemble in a micro-environmentally controlled manner. This ability is strongly related to the presence of low-complexity, intrinsically disordered regions (IDRs). Most IDRs tend to interact via coacervation, a process which is widely explored in the food industry (Yan and Zhang, 2014). The key to control coacervation is an extensive knowledge of the chemical moieties that, upon interaction, favor or disfavor the occurrence of molecular contacts. Due to their sequence variability, IDRs dispose of a large range of interacting moieties leading to phase separation and this can provide numerous possibilities for the industry to control coacervation with increased tunability. For example, IDPs containing hydrophobic residues tend to self-assemble, establishing homotypic interactions leading to simple coacervation (Reichheld et al., 2017). The lowest complexity peptides that have shown the ability to phase separate and at the same time have numerous traits of tunability are perhaps poly glutamine-containing stretches, which, even though glutamine has an extremely high solubility in its monomeric state, quickly modulate their phase behaviour according to their length (hence the overall concentration of glutamine), pH and/or ionic strength (Toretsky and Wright, 2014).

Highly polar random stretches interspaced with repeats containing hydrophobic residues such as phenylalanine, have also shown to phase separate and form hydrogels (Fu et al., 2007, 2010; Sun et al., 2013). An example of those is given by nucleoporins (Lemke, 2016; Peters, 2009; Rexach and Blobel, 1995), which in the nuclear pore complex of eukaryotic cells form hydrogels acting as a selective barrier regulating molecular transport between nucleus and cytoplasm (Rout et al., 2000; Schwartz, 2005). For those proteins it has been shown that the simple mutation of phenylalanine residues to tyrosine leads to the dissolution of the hydrogel (Frey et al., 2006). The phenylalanine residues are also responsible for specific interactions with nuclear transport receptors and mediate an ultrafast association between intrinsically disordered and structured partners, which is at the centre of nuclear transport (Milles et al., 2015).

On the other hand, proteins containing charged residues tend to assemble via complex coacervation in which oppositely charged groups interact in order to ultimately lower their net charge (Pak et al., 2016).

For these cases, it has been observed that charge–charge interactions coupled to cation- $\pi$  interactions between aromatic and positively charged residues, are of major importance for driving phase separation. One example of proteins that undergo phase separation through the formation of complex coacervates are Ddx4 proteins, which phase separate to form nuage organelles in mammals (Pak et al., 2016). In the case of Ddx4 proteins, interactions between FG- and RG-repeats numerously represented along the amino acidic sequence of several Ddx4 proteins, occur. Purely electrostatic interactions are also majorly responsible for the phase separating behavior of these proteins, which are a perfect example of how phase transition is, in this case, extremely sensitive to changes in ionic strength.

From a general and simplistic standpoint, the process of phase separating has been referred to as the interplay of two different components called scaffolds or clients (Salman et al., 2016; Harmon et al., 2017). While scaffolds are moieties that drive the process to exclude solvent and thus phase separate and are also called drivers of phase transition (Brangwynne et al., 2015), client molecules just show passive partitioning behaviour which leads to condensates. With respect to this, the maximum tunability of coacervation that has potential in food science would be driven by a scenario in which a coacervate and its responsiveness to the micro-environment is modulated by the activity of both the scaffolds and the clients composing it.

Recent studies show how the interplay between the conformational properties of scaffolds and clients can switch the equilibrium of assemblages. A classic example of this is given by the process of gelation that can be sometimes coupled with phase transition. Gels are prevalent in the food and pharmaceutical industries from the production of laxatives, gelling agents intended as gelatin substitutes (Armisen et al., 2000; Stanley, 2006), yogurts or desserts (Philips and Williams, 2009; Roopa and Bhattacharya, 2008) to the creation of immobilizing agents for enzymes (Philips and Williams, 2009). Chemically, gelation is considered as the formation of molecular networks that start interacting above a critical concentration defined as the percolation threshold (Broadbent and Hammersley, 1957). Nevertheless, gel formation can also follow phase separation if the gel point (the concentration at which the formation of molecular networks occurs) lies below the critical concentration

required to achieve phase separation. In an extremely interesting computational study, Harmon et al. pinned down the physical principle behind the ability of protein sequences to phase separate with or without the formation of a gel (Harmon et al., 2017). The study reported that the critical property of intrinsically disordered linkers in favoring phase transition followed by gelation is the effective solvation volume of the linkers spacing interacting structured SH3 domains. In the case linkers have effective solvation volume of approximately zero, gelation follows phase separation as the conformational dynamics of linkers is such that interacting moieties composing the polymeric network lie very close. In contrast, linkers with positive effective solvation volume will have a negative impact on phase separation or gelation. Very importantly, effective solvation models are directly related to sequence compositions and mostly due to the presence of charged residues along the linkers. This provides ground rules for the exploration of intrinsically disordered regions that, coupled with scaffolds having diverse binding valences, can modulate the concentration ranges at which polymer mixing shows either gelating, phase separating properties or both.

Another particularly interesting ability of organisms is to control the formation and dissolution of liquid-like super concentrated droplets using out of equilibrium processes. These processes are mainly mediated enzymatically by a series of chaperones or disaggregases to dynamically modulate composition and formation of protein coacervates (Hubstenberger et al., 2013; Kroschwald et al., 2015; Sweeny et al., 2015). A recently presented and very suggestive hypothesis, backed up by experimental evidence concerning the dissolution of FUS granules (Ratti and Buratti, 2016), suggested that the high concentrations of ATP normally present in cells (and falling in the mM concentration range) would be functional not only to promote enzymatic processes requiring energy (which would require concentrations of ATP estimated in the low  $\mu\text{M}$  range) but also for the dissolution of MLOs. Thus proposing ATP as an effective hydrotrope of protein coacervates (Patel et al., 2017). Controlling the formation and the dissolution of coacervates using small, biocompatible molecules by designing formulations featuring ingredients release upon the mixing of hydrotropes to coacervates, is of extreme interest for the food industry, especially in the need to compartmentalize and release functional ingredients in a timely manner.

An additional, extremely important level of regulation for potential food formulations using protein components is represented by the set of chemical modifications that amino acids can experience. *In vivo*, proteins continuously undergo post-translational modifications that *de facto* mutate the sequence composition of proteins through the addition or removal of chemical groups on the residues' side chains (Bürkle, 2001). IDPs, due to the lack of structure and to their extreme functional promiscuity, are particularly prone to post-translational modifications (Bah and Forman-Kay, 2016; Xie et al., 2007).

Overall, the possibility to translationally modify mixture components represents a great opportunity for tunability and therefore for the design and control of coacervates. All these examples demonstrate the great potential of IDPs in applied Science, and considering the fact that we are just beginning to understand the behavior of these fascinating molecules, more research exploring the potential of IDPs in food science will be key to go beyond their functional behavior in cells and support their utilization in different fields of applied research.

### **The Role of Intrinsically Disordered Proteins in Anhydrobiosis Provides Strategies to Enhance Food Security**

The rapid increase in the human population over the last few decades, combined with progressive environmental deterioration due to climate changes are posing questions on how to confront the subsequent lack of food security for large segments of the population (Misra, 2014). The consequences of climate change can also be imagined as an extensive increase in the desertification of several territories followed by extreme migrations (Campbell et al., 2016; Misra, 2014). One of the major aims of food science is to increase food security, especially in areas where desiccation threatens survival.

Importantly, the role of IDPs in anhydrobiosis (Wharton, 2015), which literally translates as "life without water", is becoming progressively evident. The knowledge that some organisms, adapt to extreme conditions and can survive desiccation isn't novel. Many creatures, spanning different phyla from plants to bacteria and fungi, rotifers, micro-animals and even nematodes, demonstrate the ability to "come back to life" after long periods (sometimes lasting several decades) of desiccation (McGill et al., 2015). Scientists have consistently tried to understand the molecular mediators and the mechanisms of such an ability. While in the past, the theory by which desiccation tolerance would be mediated by sugars (trehalose or sucrose) was dominant (Watanabe et al., 2002), further evidence posing IDPs as active mediators of desiccation tolerance is emerging (Boothby and Pielak, 2017; Liu et al., 2017): mostly after the realization that not all the organisms showing anhydrobiotic behavior possess the genes to synthesize or produce great enough quantities of trehalose or other sugars to prevent death upon desiccation.

It has been recently shown that tardigrades can over-express, in conditions of severe drought, a set of proteins actively involved in protecting cellular components from lack of water (Boothby, Tapia, Brozena, et al., 2017). These proteins, subdivided into three classes and defined as secreted abundant heat soluble (SAHS), cytosolic abundant heat soluble (CAHS) and membrane abundant heat soluble proteins (MAHS), share a major single feature: a large amount of structural disorder.

Besides abundant heat soluble proteins, a similar class of cellular components majorly responsible for desiccation tolerance is represented by the better characterized late embryogenesis abundant (LEA) proteins found mostly in plants (Dang et al., 2014; Gao and Lan, 2016; Rodriguez-Salazar et al., 2017; Villar et al., 2011) but also discovered across phyla (Hand et al., 2011). LEA proteins are small, mostly disordered, polypeptide chains showing a high content of hydrophilic residues (Hong-Bo et al., 2005).

Although the mediators of tolerance to dehydration have been identified, the mechanism by which these proteins arbitrate this activity is still unknown. It has been suggested that several mechanisms, which don't necessarily exclude one another, may take place and protect cellular components from the lack of surrounding water.

Firstly, it has been suggested that the ability of these molecules to form glass-like structures, a process called vitrification (Chavali et al., 2017; Uversky, 2015, 2016), may be related to their capacity to protect molecular components in the cell. The formation of glass-like structures has been observed for CAHS proteins and it has been directly related to the survival rate of organisms like yeast, which heterologously expresses CAHS; interestingly, the vitrification of CAHS proteins also leads to an increase in heat tolerance of approximately 10 °C (Boothby et al., 2017). Besides vitrification, a water replacement mechanism, in which IDPs would actively mediate a hydrogen-bonding network with cellular components has also been suggested (Boothby and Pielak, 2017).

Particularly fascinating is the mechanism suggesting that IDPs involved in desiccation tolerance may act as molecular shields. Molecular shields can protect cellular components by crowding their surroundings via non-specific interactions. This mechanism, if proven true, is particularly interesting to food science as it is transposable to other molecules, such as polysaccharides, that already have many applications in food preparations. With respect to this, an interesting study by Chakrabortee et al. investigated the ability of LEA proteins to act as molecular shields and protect crucial components of organismal metabolism. The study proved a divergent functional role of IDPs from molecular chaperones and suggested points of contact with neutral polysaccharides functioning as anti-aggregating molecules to ultimately preserve cellular components from desiccation (Chakrabortee et al., 2012).

Nevertheless, even though research has enhanced our understanding of IDPs in anhydrobiosis, the exact mechanism by which these proteins protect the structure of cellular components is still unknown. While the collected data points towards the fact that IDPs fully preserve function, the consequences of IDPs activity on the structure of the protected components are not always clear. Some evidence suggests that molecular shielding can indeed yield conformational changes leading to apparent functional loss and a suggestive hypothesis re-conciliating such conformational changes and preservation of function is the one from Tompa and Csermely (2004). According to this hypothesis the interaction between chaperone IDPs and targets would generate an initial partial unfolding of the target, which would then re-join the folding pathway and regain structure and function.

It is in the end plausible that the activity of disordered proteins in promoting tolerance to extreme lack of water would be mediated by a combination of the proposed mechanisms or by new mechanisms not yet identified. Nevertheless, just by looking at the collected evidence it is clear how food science can benefit from the study of these components for the creation of new foods (or even food crops, overlapping into plant biology) that would show an increased tolerance to harsh environments. This includes both the possibility to increase the resistance of crops to arid landscapes and the opportunity to reduce the need to refrigerate products in countries where refrigerating is problematic. This line of research would have a direct influence on how food science would impact food security in a scenario where desertification and food shortage will affect increasing portions of the planet's population.

### Using Intrinsic Structural Disorder to Design More Sensitive Biosensors to Increase Food Safety

A high priority of food science research is to enhance global food safety, especially considering the staggering numbers of foodborne diseases, which are estimated to be in the millions with thousands of deaths per year (World Health Organisation, 2017). Technology coupled with basic research therefore needs to step up and find ever more accurate ways to detect foodborne pathogens before they would cause harm. An enormous advancement in the field has been represented by the creation of biosensors that are able to detect elements of pathogens in food samples. The founding elements of biosensors are essentially two: a recognition element and a target analyte which is most commonly a molecule from the pathogen to be detected in the sample. Essentially, the analyte interacts with the recognition element (normally a receptor) and triggers the transduction of a signal which is electronically detected. It is of course necessary to have an interaction between the two molecules (the receptor and the analyte), but it is highly advantageous that the sensitivity of the receptor for the target would be such that the analyte could be detected in the smallest possible concentration. The concentration at which a receptor binds its ligand is a hardwired characteristic of the receptor linked to its structural and dynamical features. Nevertheless, decreasing the concentration threshold required for the detection of foodborne analytes would be a great advantage to enhance food safety further. From a molecular perspective, doing this means increasing the affinity of the receptor for the target, which in other words signifies reducing the binding constant that characterizes the interaction between the two molecules. Attempts to engineer molecules to rationally tune the binding properties of molecular receptors have been characterized by diverse strategies such as allowing a conformational switch of the receptor and pushing the binding-prone population to be maximized (Ricci et al., 2012), combining multiple receptors in tandem (Vallée-Bélisle et al., 2012) using a compound (depletant) that would sequester the ligand without producing an output until ligand concentration would rise enough to stimulate a second, low affinity, receptor that produces a sharp response (Kang et al., 2012; Ricci et al., 2011), or mutating parts of the receptor's structure that would not be directly involved in binding (distal mutations) but that would somehow increase the affinity between the two molecules (Porchetta et al., 2012).

In contrast, part of the research has been devoted to favor cooperative allosteric receptor activation, which means increasing the receptor's affinity by transducing a signal across its structure (Dueber et al., 2007; Liu and Lu, 2006). Usually such a signal is generated by the binding of an analyte that allows the coupling of a second analyte. The two analytes binding the receptor can, at the same time, have a regulatory role and be a substrate of the enzyme (in this case giving rise to homotropic allostery, which mostly occurs when the regulatory element and the substrate are the same molecule) or act either as a regulatory element or enzyme substrate (heterotropic allostery).

Since the point of this review is not to describe allostery in detail, but to show how intrinsic disorder can contribute to food safety through the development of more sensitive biosensors, I will herein limit the explanation of receptor binding to the minimum necessary, to then focus on the use of IDPs in serving the purpose of increasing receptor's affinity.

Receptor occupancy can be described by the fraction of receptor bound as a function of target concentration:

$$\text{Receptor occupancy} = \frac{[\text{target}]}{[\text{target}] + K_D} \quad (1)$$

where  $K_D$  corresponds to the concentration of ligand at which the target is half occupied.

The concentration of analyte required to increase the occupancy of a receptor from 10% to 90% is defined as *dynamic range* of a receptor and essentially provides a measure of the receptor's sensitivity.

$$\text{Dynamic range} = \frac{\text{Receptor occupancy}_{90\%}}{\text{Receptor occupancy}_{10\%}} \quad (2)$$

It would therefore be ideal to decrease the minimum concentration of analyte required to generate an increase in receptor occupancy from 10% to 90%.

While in heterotropic allostery the binding of the second analyte (different from the first) generates a shift in the analyte binding isotherm but it doesn't affect its shape, in homotropic allostery binding of the second analyte can be favored or disfavored by the binding of the first analyte, giving rise to negative or positive cooperativity, respectively (Simon et al., 2014). In this case, the isotherm is described by the Hill equation (Hill, 1910) as follows:

$$\text{Receptor occupancy} = \frac{[\text{target}]^{n_H}}{[\text{target}]^{n_H} + K_{1/2}^{n_H}} \quad (3)$$

and the dynamic range is dominated by the Hill coefficient  $n_H$ . To reduce the concentration at which the receptor's occupancy increases to 90%, strategies to increment the Hill coefficient need to be designed. A Hill coefficient of 1 suggests lack of cooperativity, whereas higher values would indicate cooperative binding and the narrowing of the concentration window required to detect a signal and identify foodborne pathogens.

Intriguingly, intrinsic disorder has been indicated as a strategy to increase cooperativity or to transform non-cooperative into cooperative receptors (Simon et al., 2014). The creation of chimeric proteins composed of two non-cooperative DNA beacons, alternated by non-pairing (disordered) DNA stretches has shown to increase the Hill coefficient and the affinity for the second binding event. The first binding is indeed disfavored by the entropic cost of folding the intrinsically disordered stretch engineered on the receptor. Once the first analyte is bound to the receptor, the gain in structure (due to the disorder-to-order transition) favours the binding of the second analyte through the formation of a binding pocket, thus increasing cooperativity (or transforming a non-cooperative receptor into a cooperative one (Simon et al., 2014)) and ultimately improving the dynamic range.

Interestingly, the enhancement of dynamic range has been partially related to conformational properties of the disordered linker such as its persistence length. Although this approach has successfully been proven only on DNA constructs, the possibility to expand its applications and potential using intrinsically disordered peptides rather than nucleotides can be of enormous advantage. The intrinsic advantage of using DNA is given by its predictive base-pairing which can yield wanted behavior due to limited conformational freedom. Proteins don't carry this advantage as their conformational flexibility is much greater than that of DNA, but at the same time they would come with a much greater potential for applications of this kind. The examples of IDPs folding upon binding, which can be a mechanism useful to favor the occurrence of cooperativity, are numerous and IDPs offer a wide range of post-translational modifications that can play a regulatory role in the attempt to engineer and control cooperative behavior. In the future, it is certain that further investigations of intrinsic disorder used to improve the dynamic range of receptors useful for biosensing will certainly lead to an improvement in the quality of tools available to detect food pathogens.

## Conclusions

In the past decade intrinsic disorder has emerged as an evolutionary advantage for organisms, especially in the framework of increased system complexity. Nowadays, it is documented that the key and lock mechanism describing molecular interactions (Fischer, 1894), their specificity and affinity, is only part of the story and the need to obtain further information about the biophysics of molecules without a well-defined structure is a must to utilize these entities in the numerous fields of applied Science (Csermely et al., 2010). The extreme functional versatility of disordered molecules is of particular appeal to food science, with many areas that can benefit: from ingredient encapsulation to enhancement of food security and safety. Nevertheless, the paradigm shift that intrinsic disorder has brought to the world of Biology is such that new approaches, dealing with the greater molecular flexibility need to be explored. A key aspect of such need is interdisciplinarity (Uversky, 2002, 2013). As intrinsically disordered molecules fall into a new category of functionally viable entities, biology has had to combine the expertise from multiple disciplines to study how intrinsic disorder impacts cellular processes (Uversky and Dunker, 2013). Similarly, the embracement of interdisciplinarity, leading to the combination of multiple and diverse sets of expertise from a wide range of disciplines will empower the food science community with the additional tools necessary to improve human nutrition and drive to market the next generation of food products.

### Introduction

Due to the over consumption of fats, obesity has become the major cardiovascular risk factor according to epidemiologic studies (Nakamura et al., 1994), resulting in an increased risk of diabetes, atherosclerosis, hyperlipidemia, hypertension and cardiovascular disease. Oils and fats in their natural form are usually not desirable due to their physical properties, nutritional value and chemical composition however, lipids can be modified to obtain desired attributes and specific function. Structured lipids (SL) are lipids that are modified chemically or enzymatically to change the fatty acid composition and/or their positional distribution in glycerol molecules (Lee and Akoh, 1998). It involves modifying the chemical structure of the lipid by addition or rearrangement of fatty acids on the glycerol backbone (Iwasaki and Yamane, 2000). SL consist of the most common types of food lipid triacylglycerols (TAG) and others including monoacylglycerols (MAG), diacylglycerols and phospholipids. SL provide specific fatty acids to improve functionality and nutritional properties that could be used to target specific diseases and metabolic conditions (Kim and Akoh, 2015). Therefore, it is important to modify lipids by introducing beneficial fats such as long-chain polyunsaturated fatty acids (LC-PUFAs), fatty acids with 18–20 carbons or more, to replace saturated fatty acids.

Other ways of lipid modification include hydrogenation that converts lipids from liquid or semi-solid forms into solid by partial or full saturation of double bonds to produce fat with high oxidative stability. During the process, hydrogen atoms are added onto double bonds of unsaturated fatty acids in order to obtain physical attributes and functionality to provide cooking stability, creaming ability, steep melting properties and desired appearances (Kadhun and Shamma, 2017; O'Brien, 2008). Due to the production of *trans* fatty acids from partial hydrogenation, industries are replacing hydrogenation with interesterification that produces zero *trans* fat. *Trans* fats have been reported to be associated with increased risk of coronary heart disease hence, regulation on *trans* fats have been implemented and industries are finding alternative methods to avoid their production. Research has observed that consumption of *trans* fats raises the level of low-density lipoprotein cholesterol levels, reduces the level of high-density lipoprotein cholesterol, and increases the ratio of total cholesterol to high-density lipoprotein cholesterol (Katan et al., 1995; Mensink and Katan, 1990; Mozaffarian et al., 2006). *Trans* fat also increases the levels of triglycerides in the blood as compared with the intake of other fats, which further increases the risk of cardiovascular heart disease (Mensink et al., 2003).

### Interesterification

Interesterification is a process which acyl groups exchange positions either within the same glycerol backbone or with other glyceride molecules among triglycerides and phospholipids. A simple description of the reaction would be a random or direct attack on the fatty acids attached to the glycerol backbone resulting in the breakage of the bond between the fatty acids and glycerol backbone. After which, the fatty acid released is mixed with the free fatty acids (FFA) and the empty glycerol position is replaced randomly by another FFA (O'Brien, 2008). The desired properties of lipid can be manipulated by modifying the chemical composition of fats and oils through interesterification. Thus, interesterification has found a wide range of applications in the edible oils industry in order to obtain the desired nutritional properties, plasticity, melting profile of fats and the compatibility of TAGs.

#### Chemical Interesterification

In the process of random chemical interesterification, fat is heated to approximately 100–140 °C for a short period of time, in the presence of an inorganic catalyst such as sodium methoxide. The fatty acids are released from the glycerol backbone and re-esterified by randomization or directed fatty acid interchange within and among the TAGs. The process continues until it reaches thermodynamic equilibrium and this depends on the temperature, time and other conditions of the reaction (Gunstone, 2006). This method is the most common industrially implemented method as it is cheaper and requires a shorter reaction time than enzymatic interesterification. However, the reaction lacks specificity and offers limited positional distribution of fatty acids (Kadhun and Shamma, 2017). Side products that are hard to eliminate may be produced and oxidation of lipids can increase due to the application of high heat.

#### Enzymatic Interesterification

This process utilizes an enzyme such as lipase to catalyse the rearrangement of fatty acids and one of its most important features is the positional specificity that results in higher efficiency and mild conditions with few or no by-product. Specific lipases can hydrolyse sn-1 and sn-3 position, incorporating fatty acids without affecting the fatty acid in sn-2 position allowing improved nutritional

properties in SL. Enzymatic interesterification occurs under mild conditions that reduces the loss of temperature sensitive LC-PUFAs that are susceptible to oxidation, reduces the use of energy and solvents allowing easier recovery of the final product. Lipases are used for enzymatic synthesis of SL that are used as biocatalysts in the hydrolysis and esterification of TAG. Enzymes are used to increase the control over the nature of the product due to the specificity of many different lipases (Farfán et al., 2015). However, industrial application has been slow due to the high cost of enzymes (Kim and Akoh, 2015).

### Acidolysis

The acidolysis reaction consists of the exchange of acyl groups between an acid and an ester. The benefits of utilizing acidolysis is the simpler prediction of reaction product composition, however, it requires thermostable lipases in a solvent-free system, lower fatty acid incorporation, purification and recovery of end products, and requires oil saponification (Şahin-Yeşilçubuk and Akoh, 2017). Acidolysis is usually utilized to enrich oils by increasing the content of fatty acids such as LC-PUFAs in SL.

### Functionality of Structured Lipid

The synthesis of SL utilises a variety of fatty acids to increase melting points of lipid such as medium-chain fatty acids (MCFAs), a fatty acid with 6–12 carbon atoms, which possesses beneficial nutritional and metabolic attributes for nutraceutical and pharmaceutical application. The physical and chemical properties of lipids that can be modified include the solid fat content, slip melting point, melting and crystallization profiles and oxidative stability. Therefore, SL are referred to as nutraceuticals and functional foods that could be modified to satisfy consumer demand (Kim and Akoh, 2015). The nutritional functionality of SL can also be manipulated by utilizing a wide variety of fatty acids that could be used to provide health benefits. Short and MCFAs are used as substrates for SL due to their benefits of increased absorption, digestibility and metabolism (Huang and Akoh, 1994).

Studies have shown the positional distribution of fatty acids on the glycerol backbone influences physical behaviour and metabolism of lipids (Hu et al., 2017). SL with essential LC-PUFAs located at the sn-2 position and MCFAs located at sn-1, 3 positions of the glycerol backbone otherwise called medium-long-, medium -(MLM) chain TAG have increasing interest due to their nutritional properties as SL are able to provide essential LC-PUFAs in a form that provides the hydrolysis and absorption advantages of MCFAs (Jandacek et al., 1987). TAG in the sn-1, 3 position is preferentially hydrolysed by lingual, gastric and mainly pancreatic lipases resulting in FFA, thus producing sn-2 MAGs that can be absorbed efficiently (Bradley, 1998; Derya et al., 2015; Karupaiah and Sundram, 2007). MCFAs act as fast energy via oxidation of the more hydrophilic MCFAs and have lower tendencies to be deposited in the adipose tissue because they are not readily re-esterified into TAGs and also due to their direct transport via the portal vein to the liver rather than through the lymphatic system (Kim and Akoh, 2015). Hence, digestion of incorporated MCFAs at the sn-1, 3 positions are hydrolysed and rapidly absorbed as FFA while LC-PUFAs esterified at the sn-2 position provide increased protection against oxidation of fatty acids and increase absorption (Derya et al., 2015; Kim and Akoh, 2015). LC-PUFAs are the main forms of edible oils and provide essential fatty acids. However, they are metabolised slowly and tend to deposit in human adipose tissue compared to MCFAs which are more easily and readily digested as they isomerise rapidly and target FFA and glycerol (Christophe, 1998; Kim and Akoh, 2015). Beermann et al. (2003) studied the effects of dietary intake of fat containing 72% MCFAs and 22% n-3 LC-PUFAs on the metabolism of fat in healthy people. It was found that a significant reduction of total plasma TAG was possibly caused by increased  $\beta$ -oxidation with a synergistic effect from MCFAs and LC-PUFAs. Therefore, essential LC-FAs at the sn-2 position with MCFAs at the sn-1, 3 position is utilized most efficiently as they are hydrolysed readily with pancreatic lipase and readily absorbed into mucosal cells and through the intestinal wall (Karupaiah and Sundram, 2007; Kim and Akoh, 2015; Xu, 2000).

### Application of Structured Lipid

Cocoa butter is the main component of chocolate but has a natural limited availability resulting in a high cost. Therefore, alternative replacements for cocoa butter are being explored by modifying lipids. Cocoa butter equivalent is an example of a SL, which has a similar TAG composition to cocoa butter but is produced from low-cost vegetable oil instead.

Human milk fat substitutes are SL with a nutritional application. Resembling human milk fat in terms of the fatty acid composition and distribution, they are produced for use as infant formulas, enteral and parenteral nutrition. Human milk is the main source of nutrients and energy for infants and due to the limited availability of human milk, infant formulas are produced to mimic human milk fatty acid composition where high proportions of palmitic acid are esterified at the sn-2 position to provide fat with improved absorption capability in infants (Kim and Akoh, 2015). Current research on human milk fat substitutes have shifted its focus towards the enrichment of LC-PUFAs such as arachidonic acid, stearidonic acid, eicosapentaenoic acid (EPA) or docosahexaenoic acid (DHA) as they are converted more efficiently into EPA as compared to the conversion of  $\alpha$ -linolenic acid to EPA in the human body (Bryś et al., 2014; Li et al., 2014; Nagachinta and Akoh, 2012; Pande, Sabir, Baeshen and Akoh, 2013a, 2013b; Simões et al., 2014; Tecelão et al., 2010; Teichert and Akoh, 2011; Turan et al., 2012; Vázquez and Akoh, 2012; Yüksel and Şahin Yeşilçubuk, 2012; Zou et al., 2014).

Shortening and margarine are produced by lipase-catalysed interesterification to produce SL with low-trans or trans-free plastic fats. This method is used to replace the partial hydrogenation process of producing margarine and shortening that results in the

production of *trans*-fats. Low-calorie fats and oils are SL produced through the synthesis of short-chain fatty acids as their caloric values are significantly lower than typical longer chain fatty acid however, to-date there has been no enzymatic production of low-calorie SL commercially. There have been a wide variety of fatty acids used as substrate to produce SL containing health-beneficial fatty acid to obtain a particular functional or nutritional purpose. Interest surrounding conjugated linoleic acid has increased due to its anti-carcinogenic activities, reduced atherosclerosis risk and reduction of in the level of body fat (Brown et al., 2001; Degen et al., 2012; Kritchevsky et al., 2004). Another important substrate with potential health benefits is omega-3 LC-PUFA especially DHA and EPA that could reduce risk of cardiovascular disease, inflammation, cancer, hypertension, immune response, diabetes and renal disorders (Mori and Beilin, 2004). DHA has potential health benefits for brain health and the development of the brain in infants, thus it is used in infant formula (Lien et al., 2018).

## Conclusion

Currently, most research has been undertaken on MLM TAG and other areas including human milk fat substitutes, cocoa butter equivalents and low-*trans* or *trans*-free plastic fats. Studies on structured phospholipids are limited but have shown potential as an efficient carrier of beneficial fatty acids due to the increased absorption of phospholipids in the body (Küllenberg et al., 2012). Research is on-going on various substrates to produce SL but fatty acid composition is not the only factor that contributes to the nutrition properties of fats. The distribution of fatty acids on the glycerol backbone is important as well. Research into nutraceutical applications of SL has been thorough with the introduction of functional MCFA and essential LC-PUFA from different oils and fats. However, the main issue in developing industrial scale production of SL is the high cost of enzymes thus, development of low cost and robust enzymes via genetic modification and directed evolution could open up more opportunities in the application of SL (Song et al., 2005).

## Introduction

Consumer awareness surrounding the relation between food and health has enhanced the interest to research functional foods, which can exert positive health effects beyond the basic nutrition requirements (Menrad, 2003; Sensory, 2014; Siro et al., 2008). However, the development of functional foods can be challenging, as the bioactive compounds, which are responsible for the beneficial health effects, can be susceptible to degradation during storage. Additionally, the low bioavailability of some of these bioactive compounds has been of concern, posing additional obstacles in the research and development of functional food (Aceituno-Nedina et al., 2013; McClements, 2015; Zhao and Tang, 2016). Consequently, finding a proper delivery system that can improve both the stability and bioavailability of bioactive compounds is a major concern in the field of functional foods. Various bioactive delivery methods, such as coacervation (Calderon-Oliver et al., 2017), spray-drying microencapsulation (Zhao and Tang, 2016), liposome entrapment (Istemic et al., 2016) and many others have recently been studied. Most of these methods involves exposure to heat and/or usage of organic solvents in the processing steps, which might lead to the loss of some bioactives and also raise a toxicity concern associated with presence of residual organic solvents and toxic waste disposal (Ghorani and Tucker, 2015; Lopez-Rubio and Lagaron, 2012). Henceforth, extensive research has been conducted on various novel methods that do not utilize high temperature and possibly less or no organic solvents, including electrospinning, which is the main focus of this paper.

## Fundamentals of Electrospinning

Electrospinning has recently gained significant interest in the fields of bioactive encapsulation and functional food development as it is relatively simple, versatile, low cost, non-thermal, and does not use organic solvents (Ghorani and Tucker, 2015; Kayaci and Uyar, 2012; Lopez-Rubio et al., 2012; Neo et al., 2013; Nguyen et al., 2011). Fig. 1 shows an illustration of the electrospinning system consisting of four major components: a metallic needle or capillary, a high voltage power supply (1–30 kV), a grounded conductive collector and a syringe pump that contains the electrospun solution (Zhang and You, 2014; Bhushani and Anandharamakrishnan, 2014).

At the beginning of the electrospinning process, the polymer is extruded by the syringe pump into a droplet at the needle tip. Two major electrostatic forces, including the Coulombic force of the external electric field, which is applied between the needle tip and the collector, and the internal electrostatic repulsion of similar charges, distort the droplet's hemispherical surface at the needle tip into a conical shape called the Taylor cone. With the increase of electric field, more electric charge accumulates on the suspended droplet until a critical point is reached, where the electrostatic force of the polymer droplets counteracts the surface tension. A charged polymer jet is then ejected from the tip of the Taylor cone. This polymer jet is driven toward the grounded collector, it is whipped or bent by unevenly distributed charges. As a consequence, the jet is elongated and the solvent rapidly evaporates. Then, the thin and solid fiber with random orientation is deposited on the collector as a non-woven mat which has high surface area to volume ratio (Aytac et al., 2014; Neo et al., 2013; Nieuwland et al., 2013; Bhushani and Anandharamakrishnan, 2014). The formation of the Taylor cone is essential in the electrospinning process because if the cone formation does not occur optimally, nano-droplets might be produced instead of nanofibers or worse, the solution might drip without being converted into nanoparticles (Nieuwland et al., 2013). The diameter of electrospun nanofibers can range from 10 to 1000 nm (Kriegel et al., 2008) with the average diameter ranging from 50 to 500 nm (Nurwaha et al., 2013). Despite the simple installation, the electrospinning process is affected by many factors such as flow rate, viscosity of solution, concentration of polymer, applied voltage, humidity and temperature (Drosou et al., 2017).

Nieuwland et al. (2013) stated that both the formation of the Taylor cone and the efficiency of the overall electrospinning process are highly dependent on the characteristics of the solution and polymer used. The solution to be electrospun should have the optimum conductivity, viscosity, and surface tension as all three parameters directly affect the fiber formation and the overall process (Aceituno-Nedina et al., 2013; Doshi and Reneker, 1995; Zeng et al., 2003; Nieuwland et al., 2013). In addition, the polymer used should be highly soluble and able to entangle and overlap with each other. Therefore, since the types of polymer used highly affect the efficiency of the electrospinning process, the following section will discuss food-grade polymers that have been successfully used for the delivery of bioactive compounds in recent years.

## Food-Grade Polymers Used in Electrospinning

Proteins and polysaccharides are common polymers for electrospun nanofibers (Schiffman and Schauer, 2008). As the carriers of bioactive compounds, the selected polymers should be edible, natural and soluble in non-toxic solvents (Ghorani and Tucker, 2015). Over recent years, many food-grade polymers have been used for electrospinning, namely amaranth protein (Aceituno-Nedina et al.,

**Figure 1** Illustration of the electrospinning system.

2013), cellulose acetate (Wongsasulak et al., 2010), gelatin (Nieuwland et al., 2013), egg albumen (Wongsasulak et al., 2010), whey protein (Aceituno-Nedina et al., 2013; Lopez-Rubio et al., 2012; Nieuwland et al., 2013), and pullulan (Lopez-Rubio et al., 2012; Stijnman et al., 2011). Yet, very limited amounts of them have been used to encapsulate bioactives. On the contrary, some bioactives have also been encapsulated with non-food grade polymers like poly(vinyl alcohol) (PVA) (Kayaci et al., 2014) and poly(lactic acid) (PLA) (Vega-Lugo and Lim, 2009).

### Proteins

Proteins are suitable materials for electrospinning because they are bio-compatible and can enhance the nutritional value of food. However, their complex tertiary and secondary structures cause difficulties in electrospinning, therefore, they need to be present in random coil conformations to be spinnable. For instance, soy proteins must be denatured to unfold their globular structures in order to be successfully electrospun (Shanker et al., 2013). Common proteins applied in electrospinning are zein, whey protein, soy protein isolate, collagen and gelatin (Ghorani and Tucker, 2015).

Zein is the most common material used for electrospinning and has been successfully used to encapsulate compounds including fish oil (Moomand and Lim, 2014), beta-carotene (Fernandez et al., 2009) and gallic acid (Neo et al., 2013). Zein is a hydrophobic corn-based storage protein (prolamin) with high thermal stability and oxygen-barrier properties (Neo et al., 2013). Their nanofibers are lustrous and flexible but have poor mechanical properties, however, this can be significantly improved by crosslinking (Yao et al., 2007). Whey protein is another commonly used polymer for electrospinning. The electrospun nanofibers of whey proteins can be treated with heat to improve thermal stability and decrease water solubility due to crosslinking (Sullivan et al., 2014). The nanofibers formed from Collagen are characterized by high porosity with a wide range of pore size distribution, a high surface area to volume ratio and outstanding mechanical strength (Rho et al., 2006). Gelatin gives similar properties, since it is a collagen derivative (Shanker et al., 2013).

### Polysaccharides

Polysaccharides are often considered as a suitable wall material for encapsulation due to their versatility (ability to react with other substances via various functional groups), temperature stability and large particle size (Fathi et al., 2014). The following polysaccharides have been applied for electrospinning: alginate, cellulose, chitin (and chitosan), hyaluronic acid, inulin, pullulan, dextrans and guar-gum (Lee et al., 2009; Ghorani and Tucker, 2015). Additional treatments or a co-solvent are frequently required before polysaccharides can be successfully electrospun. For instance, glycerol is required as a co-solvent to facilitate the formation of electrospun nanofibers from aqueous alginate (Nie et al., 2008), derivatization of cellulose is required to increase solubility (thus electrospinnability) (Wang et al., 2007; Frenot et al., 2007; Zhao et al., 2004), and solubilisation of pure chitosan using 90% acetic acid is required before electrospinning (De Vrieze et al., 2007; Geng et al., 2005).

Cellulose is the most abundant natural biodegradable polysaccharide and is low cost. The nanofibers produced from cellulose have great thermal stability and mechanical properties, as well as having good stability in the human GI tract and are insoluble in most solvents (Rezaei et al., 2015). Another polysaccharide, chitosan has good bio-functionality (e.g. antibacterial, antioxidant and anti-hyperlipidemic properties) and is biocompatibility with living tissue (Arkoun et al., 2017; Goncalves et al., 2017). Electrospun chitosan nanofibers have high porosity and surface area-to-mass ratio (Arkoun et al., 2017). Sodium alginate is a polysaccharide

from algae with low toxicity, good biocompatibility with living tissue, low cost and non-immunogenicity (Wangkaya et al., 2017). However, sodium alginate will need to be combined with other polymers such as poly(ethylene oxide) or PVA to be electrospun. Electrospinning of food carbohydrate-based systems involving complexes with cyclodextrin (CD) have also been studied. This included electrospinning of vanillin and geradinol/CD inclusion complex in PVA to prolong shelf-life and temperature stability (Kayaci and Uyar, 2012a; Kayaci et al., 2014) as well as incorporated CD into zein nanofibres via electrospinning (Kayaci and Uyar, 2012b).

## Encapsulation of Bioactive Compounds via Electrospinning

Electrospinning has been applied to produce nanofibers capable of entrapping bioactive molecules in foods, such as antioxidants, vitamins, essential fatty acids, and living cells such as probiotics (Table 1).

### Technological Aspect

The main advantage of electrospinning may be related to its ability to produce small sized particles in a one-step process, thus it is relatively cheap compared with other methods (Bhushani and Anandharamakrishnan, 2014). The advantage of the small sized particles is that they may have better controlled release at specific body sites. It is also a non-thermal process (Bhushani and Anandharamakrishnan, 2014) that may be suitable for encapsulating heat-labile ingredients, including probiotic bacteria (Lopez-Rubio et al., 2012). This also demonstrates the versatility of electrospinning as an encapsulation method. In enzyme mobilization, the nanofibers produced via electrospinning have large surface area-to-volume ratio and high porosity to allow mass transfer with less limitation (Wang et al., 2009). Moreover, it is possible to obtain sheet or tubular fibril constructs from the same set up simply by using different collectors (Sill and von Recum, 2008). This latter feature demonstrates its adaptability to different processing requirements and ease of use.

However, electrospinning is a slow process and thus multi-jet systems are required to produce nanofibres on the industrial scale (Varesano et al., 2009). Varesano et al. (2009) further explained that increasing the number of jets may lead to technical difficulties

**Table 1** Bioactive components and the polymers applied in electrospinning

Bioactive component	Wall material/Polymer	Finding	References
Epigallocatechin gallate (EGCG)	Zein	Release of EGCG from fibre is dependent on relative humidity	Li et al., 2009
$\beta$ -carotene	Zein	Higher oxidative stability against UV irradiation	Fernandez et al., 2009
$\beta$ -carotene	Whey protein concentrate 10% and 20% glycerol solution	Higher oxidative stability against UV irradiation	Lopez-Rubio and Lagaron, 2012
Gallic acid	Zein	Thermal stability and retention of antioxidant activity	Neo et al., 2013
Anthocyanin-rich raspberry extract	Whey protein isolate	Enhanced antimicrobial activity and anthocyanin content	Wang et al., 2013.
Chitosan	Zein	Enhanced antimicrobial properties for active packaging and biomedical applications	Torres-Giner et al., 2009
Fish oil rich in omega-3 fatty acid	Zein	Enhanced oxidative stability of fish oil	Torres-Giner et al., 2010
Bifidobacterium	PVA	Increased cell viability at room temperature (20°C) and cold storage (4°C)	Lopez-Rubio et al., 2009
Bifidobacterium	Whey protein concentrate/pullulan	Both polymers could be used to encapsulate the cell; pullulan produced fibre with smaller diameter but WPI enhanced the cell viability at 75% humidity, better than pullulan.	Lopez-Rubio et al., 2012
Lactobacillus acidophilus	Soybean solid waste + 8% PVA	Survival of 78.6% to 90% after 21 storage at 4°C.	Fung et al., 2011
Curcumin	Zein	Improved sustained release, free radical scavenging ability	Drosou et al., 2017
Quercetin and ferulic acid	Amaranth protein isolate and pullulan	Enhanced thermal stability, studied release characteristics and antioxidant protection ability during <i>in vitro</i> digestion	Drosou et al., 2017
R-(+)-limonene	Pullulan/ $\beta$ -CD	Increased storage stability, controlled release	Drosou et al., 2017

and less efficiency. Moreover, some materials may not be readily electrospun due to strong inter- and intra-molecular forces in conjunction with the complex three-dimensional structure of macromolecules and therefore, may require toxic solvents, which are undesirable in the food industry (Aceituno-Nedina et al., 2013; Mascheroni et al., 2013). These two areas require further research. A review by Persano et al. (2013) provides some insights into industrial scaling-up of electrospinning.

## Conclusion

Overall, electrospinning is suitable for a wide range of food systems (carbohydrate, protein and lipid) and is a useful method for encapsulation of food functional ingredients including flavour, antioxidants, enzymes and probiotic bacteria. Moreover, it is easy to use and adaptable to different process requirements, for example it is possible to obtain different fibril orientations from the same electrospinning set up simply by changing the collectors. However, some improvements are required concerning its application on the industrial scale. Further research on more food grade materials is required to optimize its use in the food industry, especially to determine suitable food-grade materials for use with different food functional ingredients.

## Acknowledgement

The authors wish to thank Master Tai Wei Loh for his contribution in preparing Fig. 1.

# Food Texture, Oral Processing and Satiation: Examining Their Relationship

Danaé S Larsen, Food Science Consultant, Zurich, Switzerland

## The Texture of Food

The decisions a person makes regarding their food choice, food intake and behaviour are governed by a foods sensory properties (Sorensen et al., 2003), be it the aroma or colour of fruit to check for ripeness, potential toxicity or the a combination of sensorial properties to guide the perceived palatability and enjoyment.

Texture in particular, has a great influence on the acceptability of foods and also in determining quality (Çakör et al., 2012a). However, texture can be a challenging concept purely because it has different meanings to different people, often with different vocabularies used to describe similar sensations. Texture has been defined as “the sensory manifestation of the structure of the food and the manner in which this structure reacts to applied forces; the specific senses involved being vision, kinaesthetic and hearing” (Szczesniak, 2002). Kinaesthetics are described as “those factors of quality that the consumer evaluates with his sense of feel, especially mouthfeel” (Kramer and Twigg, 1959).

The analysis of a foods texture has traditionally meant the instrumental analysis of a foods microstructure and mesostructure or the sensory analysis of texture using a sensory panel. However, a combination of the material properties, oral processing and sensory evaluation of food are required to obtain a complete picture (Wilkinson et al., 2000). Material properties such as rheology and adhesion are commonly analysed in two groups comprising of ‘rheological properties’, which are prior to fracture and ‘fracture properties’, which are at the point of fracture, although these terms are not standard throughout the literature as often the term ‘rheological properties’ is used as a general phrase (Foegeding, 2007).

## Oral Processing and Perceived Texture

In recent decades, it has been acknowledged that oral processing is a crucial component that must not be overlooked when analysing a food’s texture and can give real insight. Oral processing is generally broken down into three different phases: *preparation*, *chewing* and *pre-swallowing* (Guinard and Mazzucchelli, 1996; Wilkinson et al., 2000).

During the *preparation phase* the food is moved from the front of the mouth to prepare for chewing before the teeth close. The aim of the *chewing phase* is to reduce food into particles that are of a size suitable for swallowing. While in the *pre-swallowing phase*, tongue-palate movement moves the food to the back of the tongue without specific jaw movement and forms the bolus. The bolus is eventually swallowed and the process is repeated.

Structural properties, perceived as texture and changes to the food are sensed constantly from the initial bite to the final swallow and modification of the chewing pattern occurs frequently while reducing the food (Mioche, 2004).

Çakör et al. (2012b) described changes in texture as a result of the different stages of oral processing as:

- 1) *First chew*: fracturing of the food between the molars gives the sensation of firmness, fracturability and moisture release.
- 2) *Repetitive chewing*: food is broken down into smaller pieces and chewdown properties are dominant. Chewdown properties include; breakdown rate, particle size, particle distribution, adhesiveness and moisture release.
- 3) *Bolus formation and swallow*: bolus is formed, residual particles are swallowed and moisture is assessed and more lubrication in the form of saliva may be required for an effective swallow.

Considering the chewing variation between individuals during oral processing, many studies focusing on the chewing stage (or mastication cycle) observe masticatory performance (van der Bilt, 2002), which involves evaluation of chewing and particle size reduction and distribution (van der Bilt et al., 2006). During masticatory evaluation the human mouth is little more than a mechanical testing device with a feedback system to prevent damage to the teeth (Foegeding, 2007). The rhythmical sequence of mastication can be measured using methods such as electromyography (EMG) and jaw tracking, which monitor muscular activity and modifications of mandibular forces and movements as a response to the structure of the ingested food.

## Oral Processing, Satiation and Satiety

The amount of food consumed at a meal is controlled by a positive feedback system and negative feedback system. Generally, the orosensory effects in the mouth stimulate the positive feedback system while food entering the stomach and intestines promotes the negative feedback system of satiation signals (Smith et al., 1990; Yeomans, 1996, 2008). Satiation results in the termination of eating while satiety results in the halt of further eating, the decline in hunger and increased fullness post meal (Blundell et al.,

2010). Appetite control by increasing satiation onset or prolonging satiety is of great interest as the overconsumption of food during a meal is a factor in weight gain and obesity (Ebbeling et al., 2004; Louis-Sylvestre et al., 2003). The 'satiety cascade' (Fig. 1), which was initially proposed by Blundell et al. (1987) and modified by Mela (2006) shows how the composition of macronutrients, energy density, sensory attributes and food structure all add to satiation and satiety modulation (Blundell et al., 2010).

The nutritional components of food can have a bearing on satiation and satiety but will only briefly be covered here. General consensus is that consuming foods that are high in fibre promotes satiation and prolonged satiety because stomach distension is increased, which causes a delay in gastric emptying (Howarth et al., 2001). There is also evidence that protein promotes satiation and increases satiety (Lejeune et al., 2006), but as with fibre the background food matrix has an influence on these effects (Slavin, 2005). There has been a considerable amount of research also undertaken concerning peptides from the gastrointestinal tract, which are released as a result of food intake and have various physiological roles in food management (Blundell et al., 2010). It is believed that the intermediate postprandial state is typified by hormonal variations such as a decrease in the orexigenic peptide ghrelin and a simultaneous increase in anorexigenic peptides such as glucagon-like peptide (GLP)-1, cholecystokinin (CCK) and Peptide YY (PYY) (Chaudhri et al., 2006). These peptides have key roles in mediation of satiety, hunger and energy intake by acting on the brain and vagus nerve (Cummings and Overduin, 2007) and thus are often used as satiation biomarkers (de Graaf et al., 2004).

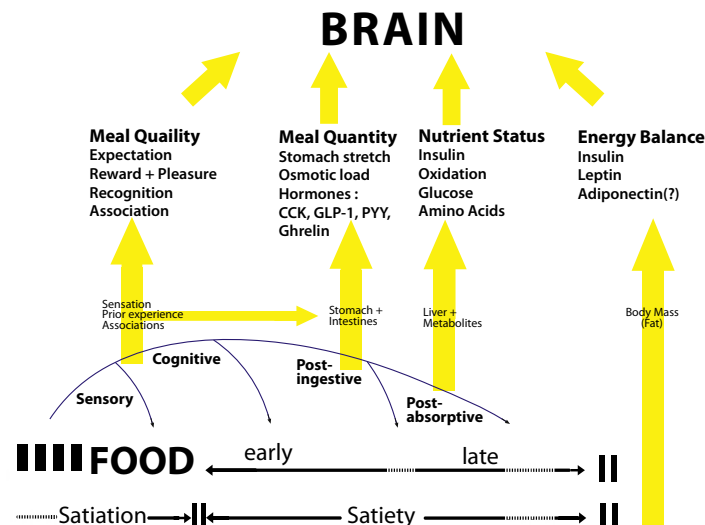

Current thought is that oral processing time (or oral transit time), the time that food has in contact with the oral cavity has some bearing on the relationship between food structure, sensory perception (texture) and satiation and satiety but how this arises is unclear (Campbell et al., 2017; James, 2018). During oral processing, a complex mechanism of interactions occur and being able to prove a link between any number of these is extremely difficult.

An increasing body of literature has shown that the bite-size, eating rate and food phase; liquid versus solid, can influence satiation and satiety and indeed all exhibit an impact on orosensory processing time (de Graaf, 2012). Studies have shown increased satiation and/or satiety by manipulating viscosities of dairy-based drinks (de Wijk et al., 2008; Zijlstra et al., 2008, 2009) with increased oral processing time decreasing the amount of viscous or semi-solid foods consumed. This has repeatedly been shown in the literature in a number of different foods (Bolhuis et al., 2011, 2014).

The difference in satiation response between a liquid, semi-solid or solid form of the same food could be attributed to effort required to bite, chew or swallow the food, with general consensus being the latter requires the most oral processing effort. This hypothesis has not been studied in great depth, although one such study showed that with bite effort eliminated there is no difference in the amount of the food consumed regardless of it being in a liquid or semi-solid state, in this case using chocolate dairy-based beverages of different viscosities (de Wijk et al., 2008). Contrary evidence has been found though, where solid foods with more work required during oral processing having a less satiating effect (Pentikäinen et al., 2017), highlighting the need for more research in the area.

There is also a school of thought that the longer the oral processing time, the greater the Cephalic Phase Response (CPR) (Smeets et al., 2010) such as the production of CCK and GLP-1 hormones as a part of the satiety cascade (Fig. 1).

Although there seems to be some compelling evidence on oral processing time and its effect on satiation and satiety, is it as simple as the effort required to chew a food or the time that it takes to swallow a food all that is required to be manipulated in order to trigger this response and limit food intake? There are many fundamental factors that dictate the oral processing pathway of a food and thus its oral processing time. Going back to the basis of this poses the question, does the structure and texture of a food have more of a role than currently thought and not just as a means of increasing oral processing time but in terms of activating the

**Figure 1** Satiety cascade modified from Blundell, et al. (2010) originally modified by Mela (2006).

perceived sensations one feels while eating and how these may affect the satiation or satiety response. Thus, the complexity of the texture of a food is becoming increasingly significant to this field of research.

### Textural Complexity and Satiation: Is There a Link?

The idea behind textural complexity is that most foods give the person eating them a range of different sensory sensations at once and thus the texture of a food can be difficult to describe using just one or two descriptors. Using sensory evaluation tools such as Temporal Dominance of Sensation (TDS) has allowed the understanding of the whole experience of oral processing by mapping changes in dominant sensation over time. It has also let us further understand the differences that individuals experience between one another when eating the same food. As often there is only consensus of the dominant textures at the beginning and end of oral processing amongst people, with the middle part quite different (Blundell et al., 1987).

The proposed definition of “textural complexity” in its simplest form is “a succession of perceived textures from first bite to the point of swallow” (Larsen et al., 2016a). When studying textural complexity, it is important that oral processing time is not examined as the driving factor of satiation or satiety, rather it is the textural make up of the test food, be it a “real” whole food or a model food designed to create a specific texture profile.

A series of recent studies on textural complexity were undertaken using model gels with varying levels of textural complexity built into them by way of embedded inclusions (Larsen et al., 2016a, 2016b, 2016c; Tang et al. 2016, 2017) (Fig. 2).

These were made by a careful selection of ingredients to give varied and noticeable textures. A low complexity gel and high complexity gel were produced and tested via sensory panels and using TDS for observable texture attributes and for confirmation that the two samples were indeed of a low textural complexity and a high textural complexity. Throughout the R&D phase, chewing rate, chewing time and the number of chews required to swallow were equilibrated so that oral processing time was not a variable. Satiation was measured using a 2-course *ad libitum* meal after the consumption of the low or high complexity model gels as a preload in a single-blind randomized cross over study. Over two separate trials, the panelists who had consumed the high-complexity preload went on to consume significantly less of the *ad libitum* meal overall.

### Textural Complexity as a Future Tool in the Food Industry

Research on the effect of textural complexity on satiation and satiety is still in its infancy and there are clearly other factors that need to be researched to provide a better picture of the mechanism behind this potential link. However, if substantiated, textural complexity may be a promising tool to be used by food manufacturers to create new products with purpose built texture profiles in a bid to cut down food intake by triggering faster satiation responses. This is highly topical due to the escalating obesity epidemic. The World Health Organisation estimates that in 2016 more than 1.9 billion adults were overweight and 650 million adults in this group were obese, with a tripling of obesity prevalence between 1975 and 2016 (World-Health-Organisation, 2018). Even more concerning, is the rates of overweight and obesity in children under 5, estimated at 41 million (World-Health-Organisation, 2018). Overweight and obesity are caused by a number variables, sometimes due to medical reasons but often poor food choices in terms of nutritional quality or the quantity of food being consumed are driving factors along with sedentary lifestyles. Reducing food intake is one realistic way of combating the epidemic from the ground up and this is where a greater understanding of the satiation and satiety response could be used in a bid to improve overweight and obesity outcomes by manipulating peoples responses through the types of foods they eat.

**Figure 2** Gel-based model foods of low and high complexity (James, 2018).

# Food Sensory Perception Influenced by Structure and/or Food–Saliva Interactions

**Xinmiao Wang and Jianshe Chen**, School of Food Science and Biotechnology, Zhejiang Gongshang University, Hangzhou, Zhejiang, China

© 2019 Elsevier Inc. All rights reserved.

## Introduction

It has been long considered that the study of food, Food Science, ranges from raw material production and processing through to digestion and absorption inside the human body. For oral consumption of any type of food, ingestion is the very first step. The sensory experience and/or perception is one of the most important factors influencing consumers' preference of a food product and their intention of purchase. There is no record of when the earliest study of food texture took place, however, it is generally accepted that systematic study of food texture began in the second half of the last century and became an important discipline in the study of food science. Attributes related to food texture, including the elasticity, viscosity, adhesion and many others, for solid, semi-solid and liquid foods were objectively studied using empirical and fundamental techniques and instrumental measurements, then correlated with consumers' sensory perception (Sherman, 1969; Shama et al., 1973; Shama and Sherman, 1973; Christensen, 1979; Cutler et al., 1983). With the technological advances and the integrations of oral physiological studies, other aspects of food oral consumption such as food comminution and swallowing, food structural breakdown and mastication, etc., have become hot topics of food texture research in recent years (Agrawal et al., 1997; Dobraszczyk and Vincent, 1999; van Vliet, 2002; Lucas et al., 2004).

## The Complexity of Saliva

Sensory perception of consumed food does not only depend on the properties of the food, but also on how food is deformed and the distinct structural changes that happen in the mouth (Janssen et al., 2007). The incorporation of saliva drastically alters the physical, biochemical, rheological and tribological properties of food during oral processing, due to not only the diluting effect but more often the enzymatic breakdown of food components. The formation of a food bolus facilitates easy swallowing, but also changes flavor and aroma release (Engelen et al., 2003a,b; de Wijk et al., 2004).

Saliva is a bio-fluid secreted mainly from parotid glands, sublingual glands, submandibular glands and other major glands, which makes up to 90% of the total secretion, along with other small salivary glands. Saliva is generally described as 'tasteless and colorless', consisting of about 99% water, with the rest being electrolytes, proteins, enzymes, carbohydrates etc. 'Colorless' is an objective description; 'tasteless' on the other hand, is not. As a matter of fact, saliva must have a taste otherwise one won't be able to taste or detect real tasteless substances such as water. The reason that saliva is perceived as tasteless is because that saliva is continuously tasted by oneself all the time and functions as the base or the reference for one's sensory perception of any food. Saliva secretion is affected by factors such as medications, neurobiological activities, environmental changes including weather, temperature, humidity etc. Age, mood and diet also influence saliva secretion. Saliva secretion and composition is also affected by if and how secretion is stimulated (stimulated vs. non-stimulated; different stimulation methods). It is now generally accepted that when stimulation is triggered, either physical stimulations (mastication) or chemical/biological stimulations (smell or eat lemon for example), saliva secretion increases in total amount, as compared to resting saliva secretion.

Mejean et al. (2015) analyzed sensory perceptions of lipid, salt and sweet taste among French populations in relation to their saliva compositions and observed a close relationship between sensory perception and one's saliva flow rate and food composition, especially the concentration and variety of salivary enzymes. When using a basic stimulating tastant, Neyraud et al. (2009) demonstrated that, with citric acid stimulation, the saliva secretion was affected to the greatest extent, compared to other stimulations such as using sucrose solutions (sweet taste), NaCl solutions (salty taste), monosodium glutamate (umami taste), or MgSO<sub>4</sub> (bitter taste). When using real food as stimulation, Engelen et al. (2003a) had shown that, despite the stimulation approach, subjects' sensory evaluations for semi-solid foods were not affected by one's saliva flow rates. More interestingly, they designed a follow-up study (Engelen et al., 2003b) in which they added saliva or saliva-like fluid ( $\alpha$ -amylase solution and water) on the spoon below custard and then evaluated subjects' sensory perceptions of odor, flavor and after-feel sensations. They found that a number of textural attributes such as thickness, creaminess and fattiness after-feel were affected by the liquid addition. However, the distinctive attributes of the custard such as almond odor and vanilla flavor were not effected, this also might be attributed to the small volumes of liquid added (0.25 and 0.5 mL, respectively).

The physical properties of saliva have also attracted a lot of research interest. It is now well accepted that saliva secreted from different glands has distinct rheological properties; parotid saliva contains very little mucins and behaves like Newtonian fluid, while sublingual and submandibular saliva have a shear thinning non-Newtonian behavior (van der Reijden et al., 1993). When stimulated differently (chewing gum or citric acid mouth wash for instance), the rheological properties of acquired saliva varied (Stokes and Davies, 2007), let alone the differences in other biochemical and physiological properties (Engelen et al., 2006). The friction occurrence during food oral processing is an additional complexity (Mosca and Chen, 2017). The binding of alkaline proline-rich salivary proteins to polyphenols in food caused protein precipitation and thus increased friction,

a phenomenon commonly seen in consuming unripe fruit or high quality red wines (Brossard et al., 2016). Similar to fat sensation, de Wijk and Prinz (2005) observed that the fat content, which directly correlates with the roughness, creaminess and friction, affected the lubrication status in the mouth, hence a variation in the fat oral texture appreciation.

### Impact of Food Structure on Sensory Perception and Oral Processing

The structure and microstructure of food is clearly a crucial parameter affecting the sensory perception. Kim et al. (2015) found that when ingesting a mix of smaller particles with larger ones, the smaller particles have significantly fewer chances to be selected for mastication. During oral processing they observed gelatin-based gel particles of smaller sizes remained intact and had a relatively shorter oral processing duration. In addition to the food size influence, the structural complexity of the food also alters sensory perception. By using either emulsion-filled gels made of different mechanical properties (de Lavergne et al., 2016) or complex gels with 'built-in' layers (Larsen et al., 2016), researchers all found distinct sensory responses compared to normal and simply-structured food. With higher complexity (adding extra seeds into the food layers for instance), greater food sensory intensity ratings were obtained for common sensory attributes and an even a greater perception of a foods' textural complexity was attained. Interestingly, based on researchers' observations, the foods' complexity seemed to induce a different pathway of food oral breakdown thus a continuously changing bolus during mastication.

The structural change of food during oral processing is also effected by the saliva in mouth. Food gets instantly wetted and coated with saliva once ingested into the mouth (Mosca and Chen, 2017). During oral breakdown by mastication, food particles are either dissolved in saliva or wetted by saliva. During this process, saliva facilitates the diffusion of taste and aroma compounds and serves as an effective media for taste and aroma release. Simultaneously, with the help of tongue manipulation, saliva facilitates the clustering and aggregation of food particles to form a bolus suitable for swallowing. If less saliva is present in the mouth, or the food products are dry and/or porous in structure, longer oral processing time (with more saliva incorporation) is typically needed (Mioche et al., 2003; Gaviao et al., 2004; Drago et al., 2011; Tarrega et al., 2011).

### Impact of Oral Physiology on Sensory Perception and Food Oral Processing

There is no doubt that the sensory perception and eating experience of a food product has an indivisible relationship with saliva secretion, which is largely dominated by our neural system. Lucas et al. (2004) made it very clear that, despite the progresses made by food scientists and oral physiologists, more common ground could be discovered and achieved to further elevate our understanding of the mechanisms of food oral sensation and perception. A convenient example would be a study conducted by Keesman et al. (2016). Their carefully designed experiments showed that the antiquated jokes of quenching one's thirst by looking at plums or to fulfill hunger by drawing a pie in the sky have indeed scientific grounds. By simply imaging in the brain consuming an attractive or sour-taste food, a significant increase in the saliva secretion could be observed.

The physiological aspects of food oral consumption also include how food is manipulated in the mouth by the actions of the tongue and other jaw and oral muscles (Prinz, 1999; Prinz and Lucas, 2001; Schimmel et al., 2007; van der Bilt et al., 2010). When comparing the degree of oral movement complexity during food consumption, one study has shown that the normal oral behavior has the highest degree of oral movement complexity. Once tongue movement is restricted (such as forcing it to hold food still then swallow, or hold the food up against the hard palate then swallow, etc.), the intensity of one's sensory perception decreases (de Wijk et al., 2003). A recent investigation of the oral muscle and jaw activities demonstrated different food breakdown pathways for various types of food (Le Reverend et al., 2016). The difference in initial food properties, largely attributed to differences in the manufacturing process (baking or extrusion for example), would partially contribute to how a food is manipulated during mastication in the mouth. With this in mind, a possible 'family of certain foods' with different textural properties (during manufacture) might be of more interest to predict subjects' chewing behavior and the corresponding sensory perception.

The large oral variations of physiological and habitual behavior amongst individuals, together with the difficulties to obtain objective data from panelists during sensory evaluation, have inspired engineers to work on developing artificial or simulated mouth models with controlled parameters and conditions to mimic an eating process. From the mechanical mastication process (focusing on the clenching and grinding of the jaw during oral processing) (Takanobu et al., 1998) to the saliva-containing *in-vitro* simulation of food oral processing (Prinz et al., 2007), more features were included to reveal how different foods behave differently during oral processing. The devices can be either derived from a fermenter-like chemostat (with temperature and pressure control) equipped with an appropriate rotational apparatus and a set of pressing model teeth (Arvisenet et al., 2008; Poinot et al., 2009), or a made-from-scratch 'steel block' equipped with a simulated dental arch, with controlled shear and compression stress, regulated food comminution and bolus formation functions (Woda et al., 2010). The functionalities and reliability of these devices have been validated recently by Mishellany-Dutour et al. (2011), who compared properties of the bolus collected from these simulated devices with those prepared *in vivo*.

## Concluding Remarks

There is indeed much more research to be done to reveal the underpinning mechanisms of food oral processing and sensory perception. Saliva, as a complex and individual-dependent bio-fluid needs to be further studied from different perspectives, including its cross-interactions with solid, semi-solid and liquid foods and the corresponding sensory and aromatic perceptions (Ployon et al., 2017). It is of necessity to consider the multi-functions of saliva, such as its dilution effect, protein and enzymatic reactions with food. How the tongue behaves during oral processing, especially with different types of food still needs extensive investigation. It is now generally accepted that friction occurrence during food oral processing has a great significance on sensory perception, but the magnitude variation of the stress and friction between the tongue and the palate, teeth and other oral surfaces generated during food breakdown are still largely unclear. Furthermore, the triggering criteria and mechanisms of bolus swallowing remain largely a mystery. Research into this requires joint efforts from food scientists, oral physiologists, neural scientists and clinical doctors. With an elderly population in many countries around the world, research into their health concerns from a food science perspective has become a hot research topic. A recently developed concept of ‘oral comfort’ by Vandenberghe-Descamps et al. (2017) emphasizes the importance of appropriate chewing and easy/safe to swallow to the well-being of elderly individuals. Saliva-induced food moistening, softened texture and others are among the elements of their validated questionnaire for oral comfort assessment. All are aspects to keep in mind when looking into the future of research on food oral processing.

# How Food Structure and Processing Affect the Bioavailability of Nutrients and Antioxidants

**Sui Kiat Chang**, Department of Nutrition and Dietetics, School of Health Sciences, International Medical University, Bukit Jalil, Kuala Lumpur, Malaysia

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Anti-nutritional factors** Natural or synthetic compounds that interfere with the absorption of various nutrients (such as vitamins or minerals) in human body. For example, phytate and oxalate that can interfere with the absorption of minerals, such as calcium, iron, magnesium and zinc.

**Bioaccessibility** Fraction that is released from food matrix and is available for intestinal absorption

**Bioavailability** The fraction of ingested nutrient that is available for utilization in normal physiological functions and for storage.

**Bioactivity** The effect of a given agent, such as food, drugs or vaccine, in a living organism or on living tissue.

**Carotenoids** A family of lipid-soluble plant pigments providing red, yellow, green and orange colors to fruits and vegetables. The main carotenoids studied are lycopene,  $\beta$ -carotene, lutein, zeaxanthin and  $\alpha$ -carotene.

**Encapsulation** A process to entrap bioactive compounds within a carrier material as a useful tool to improve delivery of bioactive compounds or living cells into food. It is a technology where the bioactive components are completely enveloped, covered and protected by a physical barrier.

**Excipient foods** A food specifically designed to increase the bioavailability of bioactive compounds

**Nutraceuticals** Any product derived from natural food sources with extra health benefits in addition to the basic nutritional value in foods. They can be considered non-specific biological therapies used to promote general well-being. The term "nutraceutical" combines two words – "nutrient" (a nourishing food component) and "pharmaceutical" (a medical drug).

**Phytochemicals** Non-nutrient plant chemicals that have protective or disease preventive properties in human. There are more than thousand known phytochemicals.

## Introduction

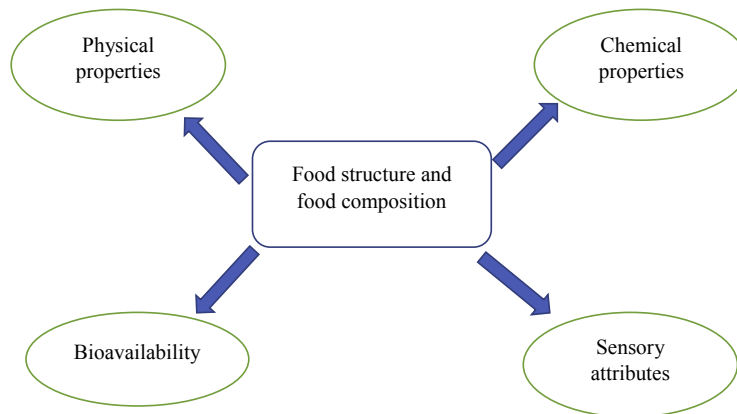

Nutrition is thought to play a major role in the primary and secondary prevention of non-communicable diseases (NCDs). Aside from pleasure, we eat to obtain nutrients to sustain our daily activity. Various epidemiological studies have suggested a relationship between the incidence of NCDs, such as diabetes, obesity and cardiovascular disease with the daily consumption of certain foods (Micha et al., 2017; Mueller and Appel, 2017). Modern consumers have become increasingly health conscious about the relationship between diet and health. Hence, the food industry has invested a great amount of time and money to develop foods with enhanced nutritional and health properties to keep up with the evolving preferences of consumers. Many new designed food products with attractive health properties, such as low sugar and fat, and greater bioavailability of phytochemicals are now available in the market (Sun-Waterhouse, 2011).

The natural food matrices (chemical structures) and man-made microstructures of manufactured foods have been shown to influence how nutrients from the ingested food becomes available for absorption in the human body. This happens because food matrices have significant effects on the nutritional quality (Jacobs and Tapsell, 2007; Parada and Aguilera, 2007). Moreover, the bioavailability of nutrients also depends on various factors, such as chemical state of the nutrient, interaction with other food components, presence of anti-nutritional factors, and their release from the food matrix. Although the nutrient content of natural and fortified foods can be obtained easily from international food composition databases, the understanding of the effects of processing and food structure on nutrients and phytochemicals, and hence, their bioavailability to exert physiological actions in the human body is limited (Cilla et al. (2017); Bohn et al. (2015); McClements and Xiao, 2014; Parada and Aguilera, 2007). In this chapter the effect of different food structures in relation to their physicochemical properties on nutrient bioavailability in the human body, is discussed. Examples of specifically developed food matrices to improve nutrition are also covered based on work from the last 10 years.

## Relationship Between Food Structure and Nutrition

The bioavailability of nutrients and phytochemicals are important determinants for the physiological health of the human body. The microstructure of food is a major factor governing the bioavailability of various nutrients and phytochemicals (Jacobs and Tapsell, 2007; Parada and Aguilera, 2007) (Fig. 1) Foods can consist of macromolecules, such as proteins and polysaccharides, plus

**Figure 1** The effect of different food structure and composition on human nutrition.

lipids, sugars, micronutrients, phytochemicals, and water. These components are arranged in different food matrices naturally or due to processing. Food processing, including fermentation, cooking, and grinding has been shown to improve bioavailability of nutrients and phytochemicals from plant foods since these processes disrupt the plant cell walls, releasing the nutrients stored within the plant organelles (Chang et al., 2013). The bioavailability of bioactive compounds is affected by digestion in the gastrointestinal tract, which includes transformation, transport and absorption at different sites (stomach, small intestine and large intestine) (Fig. 2). The following section discusses the molecular structure of some macronutrients in foods and their impact on the bioavailability of nutrients and phytochemicals.

## Proteins

Proteins exist as different molecular structures with differing chemical and physical properties (Phillips and Williams, 2011). Protein molecules are extremely sensitive to heat, pH and mechanical processes. Heating has been shown to affect the structure of milk  $\beta$ -lactoglobulin, increasing the rate of digestion by the enzymes, trypsin and chymotrypsin at 37 °C. However, the digestion rate was reduced after heating at 78 °C. While, high pressure treatment at 400–800 MPa enhanced the digestion of  $\beta$ -lactoglobulin by pepsin (Chicón et al., 2008; Zeece et al., 2008). It has been observed that protein from milk, which has undergone sterilization has greater resistance to GI digestion compared to unheated milk due to heat induced protein aggregation in milk with the formation of soluble and micelle-bound aggregates (Almaas et al., 2006; Dupont et al., 2010). Specifically, milk proteins, such as casein are susceptible to hydrolysis with or without heating, while  $\beta$ -lactoglobulin is susceptible to hydrolysis after heat treatment (Barbé et al., 2014). Heating at 100 °C can modify the primary structure of proteins by isomerization and destruction of amino acids (arginine, cysteine, isoleucine, lysine, threonine) (Bax et al., 2013).

**Figure 2** Influence of different specific conditions in the digestive tract which influences the digestibility of food and hence, the bioavailability of nutrients and bioactive compounds.

## Carotenoids

Carotenoids are important lipid-soluble antioxidants with numerous health-promoting activities. [Lemmens et al. \(2014\)](#) have published a comprehensive review on the bioaccessibility of carotenoids from fruits and vegetables influenced by food structure and processing in the presence of lipids. Generally, the bioavailability of carotenoids from cooked vegetables (50%) are much higher than raw vegetables (10%) ([Saini et al., 2015](#)). Similarly, processing may enhance the bioavailability of lycopene from the plant cells matrix. [Omoni and Aluko \(2005\)](#) demonstrated that the bioavailability of lycopene in humans is significantly higher in tomato paste compared to raw tomatoes. In contrast, ultrasound treatment reduced the bioaccessibility of lycopene from tomato pulp ([Anese et al., 2013](#)).

A study conducted by [Netzel et al. \(2011\)](#) demonstrated that the bioavailability of  $\beta$ -carotene in cooked and pureed carrots is significantly higher compared to uncooked carrot. Similarly, high pressure homogenization enhanced the bioaccessibility of  $\beta$ -carotene from carrot puree ([Knockaert et al., 2012](#)). However, high-pressure homogenization reduced the bioaccessibility of carotenoids (lycopene and  $\xi$ -carotene) in tomato pulp while the bioaccessibility of the xanthophylls (lutein, zeaxanthin) have increased ([Panozzo et al., 2013](#)). In another scenario, bioaccessibility of various carotenoids from orange juice increased significantly after industrial processing compared to hand-squeezed orange juice ([Stinco et al., 2012](#)). The bioaccessibility of free and esterified carotenoids from green and red pungent peppers was reduced after grilling and boiling. However, xanthophylls have higher bioaccessibility after grilling and boiling ([Victoria-Campos et al., 2013](#)).

## Phenolic Compounds

The daily routine of peeling fruits and vegetables resulted in significant loss of phenolic compounds because a large amount of these compounds are found in the skin rather than the pulp ([Parada and Aguilera, 2007](#)). It has been reported that flavonol contents of canned or frozen foods from onion, kale, apple and beans are significantly lower than the amounts found in fresh food ([Aherne and O'Brien, 2002](#)). However, processing of tomatoes contributed to higher flavonol bioavailability in tomatoes ([Stewart et al., 2000](#)). It was demonstrated that rutin from tomato puree had higher bioavailability even when the portion size was smaller ([Simonetti et al., 2005](#)). This shows that purees could be a good source of phenolic compounds, compared to natural foods.

[Sanz and Luyten \(2006\)](#) studied the matrix effect by determining the release of isoflavones from custard desserts made from starch or carboxymethylcellulose. They found higher amount of isoflavones were released from custards made from starch compared to custards made from carboxymethylcellulose. Presumably, because custards made from carboxymethylcellulose were more resistant to enzymatic digestion. [Nagah and Seal \(2005\)](#) demonstrated that cooking affected the antioxidant capacity of wholegrain foods by destroying the water-soluble antioxidant compounds, while the antioxidant compounds bound within the food matrix are not affected.

Cocoa is rich in phenolic compounds, as is its main product, chocolate. Processing, such as fermentation and drying reduced the total amount of flavanols in cocoa beans ([Parada and Aguilera, 2007](#)). [Serafini et al. \(2003\)](#) reported that the bioavailability of chocolate flavonoids was significantly lower in milk chocolate as compared to dark chocolate, suggesting that lipids and proteins from milk chocolate interacted with flavonoids when they are metabolized in the GI tract ([Serafini et al., 2003](#)). However, others suggested that the differences in the bioavailability of flavonoids from dark and milk chocolate was because of the food matrix interfering with the absorption kinetics instead of flavonoids-milk protein and lipid interactions ([Roura et al., 2007](#)). [Roura et al. \(2007\)](#) studied the possible interaction of milk on the bioavailability of (–)-epicatechin from cocoa powder in healthy humans. They found the presence of milk does not reduce the bioavailability of polyphenols and presumably their health effect in preventing various diseases ([Roura et al., 2007](#)). [Roura et al. \(2008\)](#) extended their studies to determine the effect of milk on the excretion of cocoa metabolites in urine. Results indicated that milk consumption does not significantly affect the total amount of metabolites excreted in urine. [Mullen et al. \(2009\)](#) demonstrated that milk didn't affect the plasma pharmacokinetics of an (epi)catechin-O-sulfate and had no effect on O-methyl-(epi)catechin-O-sulfate. However, the presence of milk significantly lowered the excretion of urinary flavan-3-ol metabolites. Similarly, [Urpi-Sarda et al. \(2010\)](#) discovered that milk partially affects the amount of urinary phenolic acids (protocatechuic, 4-hydroxybenzoic, 4-hydroxyhippuric, hippuric, caffeic and ferulic acids) derived from the colonic degradation of procyanidins and other compounds present in cocoa powder.

## Other Nutrients

Human studies conducted by [Verwei et al. \(2003\)](#) and [Verwei et al. \(2005\)](#) demonstrated that the bioavailability of folate (vitamin B<sub>9</sub>) was lowered with the presence of folate binding proteins [such as, pteroylmonoglutamic acid (PGA)] in fortified milk products. This shows that the food matrix can have significant effect on the bioavailability of folate after GI digestion. [Höller et al. \(2006\)](#) demonstrated that the type of food matrix influences the amount of biotin in food, capsules and premixes. Vitamin E is an important lipid-soluble vitamin with strong antioxidant capacity. It has been shown that the absorption of vitamin E is influenced by the amount of fat and the food matrix ([Reboul, 2017](#)). Recently, [Kim et al. \(2016\)](#) determined the effect of adding cooked whole egg to a raw mixed-vegetable salad on the absorption of vitamin E isomers,  $\alpha$ -tocopherol and  $\gamma$ -tocopherol using a randomized cross-over

trial. Results demonstrated that the consumption of cooked whole eggs helped to enhance the absorption of  $\alpha$ -tocopherol and  $\gamma$ -tocopherol from raw mixed-vegetable salad by healthy young men.

### Phytochemicals and Their Corresponding Antioxidant Activities

Phytochemicals, especially the phenolic compounds are non-nutrient bioactives, being the products of secondary metabolism in plants that have essential functions in plant physiology (Halliwell, 2012; Shahidi and Ambigaipalan, 2015). Polyphenols are the most well-known phytochemicals for their antioxidant capacities (Shahidi and Ambigaipalan, 2015). Nowadays, data from evidenced-based reviews supporting the notion that phenolic compounds from sources, such as fruits and vegetables have the potential to alter the risks of various diseases in humans (Chang et al., 2016a,b, 2018; Slavin and Lloyd, 2012). However, the findings from most of the studies on bioavailability of dietary polyphenols demonstrated that most of the polyphenols have low bioavailability (Halliwell, 2012, 2013; Quideau et al., 2011). Manach et al. (2005) demonstrated that absorption of phenolic compounds by the GI tract is between 1% and 5% of the amount taken from normal diet. The antioxidant polyphenols are poorly absorbed and extensively metabolized to non-antioxidant metabolites (Tomás-Barberán and Andrés-Lacueva, 2012). Even though some of the dietary polyphenols are poorly absorbed and rapidly metabolized, they are still the valuable bioactives in prevention of NCDs (Halliwell, 2013, 2013; Quideau et al., 2011). The low bioavailability of phenolic phytochemicals may be due in part to their low aqueous solubility and poor stability in the GI tract. In view of this, various ways have been developed to enhance the absorption, bioavailability and bioactivity of phytochemicals.

### Phytochemicals in Designed Food Matrices for Delivery

Macronutrients, such as lipids, carbohydrates and proteins have been used to enhance the bioavailability of bioactive compounds. McClements et al. (2015) have reviewed representative studies on the influence of excipient foods (carbohydrates, proteins, lipids, minerals and food additives) on the bioavailability of phytochemicals from various sources (Table 1). Martínez-Huélamo et al. (2015) demonstrated that the bioavailability of carotenoids from tomatoes increased when they were consumed with digestible lipids. The bioavailability of procyanidins from cocoa have also increased significantly when they are consumed with digestible lipids (Ortega et al., 2009). It has been reported that lipid-soluble bioactive compounds have lower bioaccessibility when they are consumed with non-digestible lipids, because the bioactive compounds were trapped in the non-digestible lipid droplets (Qian et al., 2012; Rao et al., 2013). The bioaccessibility of lipid-soluble bioactive compounds has been shown to be higher with small lipid droplet sizes, to be higher for liquid oils compared to solid fats, and to be higher for emulsifiers which enhances digestion in the GI tract (McClements et al., 2015). For example, curcumin can degrade in both neutral and alkaline pH environments in the GI tract (Heeger et al., 2014). Hence, the stability of curcumin could be enhanced by entrapping within the inner surface of large lipid droplets which will be digested slowly in the GI tract.

Carbohydrates, whether they are simple sugars or polysaccharides can affect the bioavailability of bioactive compounds through numerous mechanisms. For example, polysaccharides have been shown to affect the digestion and absorption process of lipids throughout the GI tract, by preventing the interaction of enzymes, such as lipase. Hence, the rate of lipid digestion would be affected (Espinal-Ruiz et al., 2014; Zhang et al., 2015). Mun et al. (2015a) found that lipids incorporated in starch-based hydrogels had higher bioavailability of  $\beta$ -carotene with higher lipid digestion rate. Possibly this happens because starch is able to prevent lipid molecules forming aggregates in the GI tract, increasing the accessibility of lipase.

Zhu (2017) has reviewed various methods of starch-based encapsulation systems to enhance the delivery of food ingredients. Vitaglione et al. (2013) encapsulated cocoa polyphenols in high amylose maize starch and tested the bioavailability of these encapsulated polyphenols in a randomized crossover trial. Encapsulation reduced the bioavailability of cocoa polyphenols as compared with that of polyphenols in a cocoa-nut cream. However, the encapsulated ingredient increased the delivery of flavanols into the gut of the human subjects (Vitaglione et al., 2013). In another study, Cohen et al. (2011) evaluated the bioavailability of genistein encapsulated in amylose inclusion complexes using simulated intestinal conditions in rats. Results showed that the genistein concentration was significantly higher in the plasma and urine of rats and was lower in the feces from the inclusion complexes compared to the control. This suggests that the amylose inclusion complexes increased the genistein bioavailability significantly (Cohen et al., 2011). This enhanced bioavailability of genistein could be due to the increased surface area of the polyphenols in the inclusion complex form as compared with the crystalline genistein (Cohen et al., 2011).

Proteins and peptides have been shown to demonstrate antioxidant capacity, and this may prevent the degradation of phytochemicals in the GI tract. Ribnicky et al. (2014) reported that blueberry anthocyanins bound to proteins had a better absorption rate. In contrast, the bioavailability of  $\beta$ -carotene was reduced in the presence of the milk protein lactoferrin. (Tokle et al., 2013). Some phytochemicals have been shown to enhance the bioavailability of other bioactive compounds. Bioactive compounds, such as quercetin, curcumin, piperine and some catechins interact with the transporters in the epithelium cell membranes, which could potentially affect the bioavailability of bioactive compounds (Martel et al., 2010). For example, the bioavailability of curcumin has been increased with the presence of piperine, where piperine inhibited the actions of digestive enzymes in the GI tract

**Table 1** Summary of various studies studying the effect of excipient foods on the bioavailability of various nutrients and bioactive compounds

<i>Excipient food component</i>	<i>Nutraceutical in co-ingested food source</i>	<i>Effects of excipient food</i>	<i>References</i>
<b>Lipids</b>			
Olive oil	$\beta$ -carotene and $\alpha$ -carotene in carrots	Adding olive oil to carrot during cooking enhanced the solubilization and the amounts of carotenoids	<a href="#">Hornero-Méndez and Mínguez-Mosquera (2007)</a>
Salad oil	Carotenoids in vegetables	Adding oil to vegetables enhanced solubilization and the amounts of carotenoids	<a href="#">Nagao et al. (2013)</a>
Phospholipids	$\beta$ -carotene in emulsions	Adding phosphatidylcholines to emulsions enhanced the bioaccessibility of carotenoids	<a href="#">Verrijssen et al. (2015a)</a>
<b>Carbohydrates</b>			
Sugars	Epigallocatechin-3-gallate in solution	Adding sugars to aqueous solutions prevented destruction of epigallocatechin-3-gallate	<a href="#">Shpigelman et al. (2013)</a>
Starch	$\beta$ -carotene in emulsions	Combining lipid droplets in starch-based hydrogels enhanced lipid digestibility and bioavailability of carotenoids	<a href="#">Mun et al. (2015b)</a>
Pectin	$\beta$ -carotene in emulsions	Adding pectin to emulsions affected lipid digestion and bioaccessibility of carotenoids	<a href="#">Verrijssen et al. (2015b)</a>
Indigestible polysaccharides	Phenolic compounds in chokeberry juice	Multicomponent food matrix reduced the phenolics content and antioxidant capacity of chokeberry juice	<a href="#">Stanisavljević et al. (2015)</a>
<b>Minerals</b>			
Milk minerals	Flavan-3-ols in green tea	The presence of milk minerals enhanced the bioaccessibility of flavan-3-ols significantly	<a href="#">Moser et al. (2014)</a>
<b>Food additives</b>			
EDTA	Iron in corn-masa tortillas	Adding EDTA enhanced the bioavailability of iron in corn-masa tortillas	<a href="#">Walter et al. (2003)</a>
Ethanol	Quercetin, resveratrol and anthocyanins	Ethanol increased cellular uptake of phenolic compounds and anthocyanins using GLUT2	<a href="#">Faria et al. (2009)</a>
Xylitol/citric acid and xylitol/vitamin C	Catechins in green tea	Xylitol/citric acid and xylitol/vitamin C enhanced the intestinal absorption of catechins	<a href="#">Shim et al. (2012)</a>

([Dudhatra et al., 2012](#)). Moreover, the high antioxidant capacity of quercetin has shown to inhibit the oxidative degradation of polyunsaturated compounds in the GI tract ([Lesser and Wolffram, 2006](#)).

Calcium plays an important role in the digestion of milk fat. In the digestive system, calcium enhances lipolysis, the release of fatty acids from triacylglycerols, but also limits the absorption of saturated fatty acids. Previous studies on *in vitro* digestion of cheese have shown that different structures of cheese lead to different behavior during digestion, demonstrating the potential role of the cheese matrix as a lipid-release modulator ([Ayala-Bribiesca et al., 2016](#); [Lamothe et al., 2012](#)). Additionally, Cheddar-type cheeses with different levels of calcium and different types of milk fats (with different contents of long-chain fatty acids) showed different lipid bioaccessibility profiles during an *in vitro* simulated GI digestion model ([Ayala-Bribiesca et al., 2017](#)).

## Microencapsulation

Various matrices can be used to enhance the stability of bioactive compounds during GI digestion in humans. Encapsulation or microencapsulation has been widely used in the pharmaceutical and food industries. The techniques used for microencapsulation include spray drying, spray chilling, extrusion, coacervation, liposomes, co-crystallization and freeze-drying. These techniques have shown to affect the survival of probiotics bacteria negatively, reducing their ability to exert health benefits *in vivo* ([Rajam et al., 2012](#)). Various alginate-based matrices have shown to be highly effective for microencapsulation of probiotics. For example, alginate-chitosan, alginate-gelatin, and alginate-pectin ([Chávarri et al., 2010](#); [Sandoval-Castilla et al., 2010](#)). Microencapsulation with alginate shown to enhance the viability of probiotic bacteria in freeze-dried yogurt stored for 6 months at 4 and 21 °C ([Capela et al., 2006](#)). Similarly, the survival of encapsulated probiotic bacteria in chitosan-coated alginate beads was found to be higher than

that of free cells after storing for a duration of 4 weeks at 4 °C (Krasaekoopt et al., 2006). Protein hydrogels have also been shown to be a useful carrier for the controlled release of bioactive compounds. Remondetto et al. (2004) observed different iron release profiles depending on the microstructure of the gels in which iron was trapped. This result was further supported by another study conducted by Moretti et al. (2006) where extrusion encapsulation of micronized dispersible ferric pyrophosphate in rice meal have resulted in low bioavailability of iron.

The use of dairy foods, such as yogurt, fermented milk drinks and cheeses have been used as carriers for probiotics is well established in the market (Tripathi and Giri, 2014). Dairy foods, specifically, the milk proteins are popular among consumers as they have useful physicochemical properties (Ranadheera et al., 2016). Recently, Prasanna and Charalampopoulos (2018) studied the survival of free and encapsulated bacterial cells *Bifidobacterium longum* subsp. *Infantis* CCUG 52486 in a variety of matrices, such as, sodium alginate, sodium alginate-cow milk, sodium alginate-goat milk and sodium alginate-casein hydrolysate. The bacterial cells encapsulated in sodium alginate-goat milk demonstrated the highest survival rate in cow milk and goat milk after storing for 28 days. The cells encapsulated in sodium alginate and sodium alginate-casein hydrolysate and the free cells had low survival rate under the simulated GI digestion and in all different storage conditions. Similarly, Chen et al. (2017) studied the effectiveness of xanthan-chitosan-xanthan encapsulation on the survival of *Bifidobacterium* BB01 in yogurt stored for 21 days at 4 °C and 25 °C, respectively. Results demonstrated that this encapsulation system improved the viability of the probiotics, which showed higher bioaccessibility in the GI tract. All these results demonstrated that probiotics encapsulated in modified matrices show improved survival during GI digestion.

## Nanoparticle Encapsulation

Nanoparticle delivery system has been widely used in the recent years in the field of pharmaceuticals and nutraceuticals. Nanoparticles have shown to enhance solubility of phenolic phytochemicals with low water solubility through hydrogen bonding and hydrophobic interactions (Li et al., 2015 and McClements (2015)). A study by Zou et al. (2012) demonstrated that the solubility of procyanidin in aqueous solution was increased by encapsulation with zein nanoparticles. Similarly, the water solubility of curcumin was enhanced by encapsulation with chitosan and protein nanoparticles (Kim et al., 2011). In addition, nanoparticles lower the risk of oxidative degradation of phenolic phytochemicals in the GI tract (Ishii et al., 2011). Moreover, nanoparticles have been demonstrated to be able to penetrate across the epithelial cells of the small intestine using paracellular or transcellular pathway. These pathways enhance the absorption of phenolic phytochemicals encapsulated in the GI tract (Li, 2015). However, the stability of nanoparticles in the GI tract are affected by various factors, such as pH, ions, digestive enzymes and mucus layer (Li and Gu, 2011). Hence, future studies are needed to formulate phytochemical encapsulated nanoparticles with higher stability in the GI tract.

## Conclusion

Food matrix (food microstructure) can play an important part in health and disease prevention by influencing the bioavailability of various nutrients and phytochemicals. Various food processing techniques can negatively or positively affect the nutrient contents and their bioavailability. The food matrix can be modified to protect a variety of nutrients and phytochemicals from being degraded during food processing, storage and during GI digestion. However, there is contradictory information on the effects of food matrix on the bioavailability of some nutrients. Hence, more sophisticated studies are needed to establish methods to determine the bioavailability of the genuine metabolites after extensive GI digestion. Additionally well-controlled analytical methods should be developed to determine the location and complexing of nutrients in a specific food matrix. More studies are also needed to determine the interactions between bioactive compounds and various macromolecules in the gut microbiome since the gut microbiota play an important role to influence the bioavailability of nutrients. Hence, the scientific community is expecting more interesting results from researchers in this field of study.

## Glossary

**Entomophagy** Consumption of edible insects

**Food Neophobia** Reluctance to eat new or novel foods

## Entomophagy

Entomophagy is the consumption of edible insects. Over 3000 ethnic groups in mainly African, Asian, and Latin American countries eat insects as part of their normal diet (van Huis et al., 2013). They can be eaten at various life stages including eggs, nymphs, and adults, depending on the species and processing method (Ramos-Elorduy, 2009). Even though over two billion people eat insects, it is still met with great resistance by many Western consumers. Most have grown up viewing all insects as 'bugs', initiating feelings of disgust or fear (Looy et al., 2014; Tan et al., 2015; Yen, 2009). However, there has been an increasing interest in edible insects' due to the nutritional and sustainable benefits. In 2013, United Nations' Agriculture and Food Organisation released a detailed report (van Huis et al., 2013) on the potential of insects as food and feed. The commercial production and distribution of insects and insect products such as cricket flours, protein bars, and chips has increased over recent years in Western societies. Schösler et al. (2012) indicated a trend towards more modern and gourmet insect products sold at specialist stores. Countries such as Canada, Netherlands, Belgium, and others are at the forefront of insect consumption, with a few insect products already on the market (Balzan et al., 2016; Schösler et al., 2012; Verbeke, 2015).

## Benefits

Edible insects have great potential to become a viable protein, fat, or meat alternative due to the numerous sustainability and nutritional benefits. With increases in population estimated to reach 9.7 billion by 2050, food demand will also increase by around 70%, compared to what it is today (FAO, 2009; van Huis et al., 2013). Within this statistic is the increase in meat consumption in both developed and undeveloped countries (Verbeke, 2015; Yen, 2009). Production of locust and other insect species is a very sustainable practice compared to livestock farming, as they require significantly less feed, land, and water. They can be reared vertically, utilising a fraction of the land space conventional meat sources do. As they are cold blooded, they can obtain water through the moisture in their food. When using crickets as an example, they only require 1.5 L of water to make one kg of protein, whereas beef requires an astonishing 3400 L (van Huis et al., 2013). Greenhouse gas emission is also a large concern for the agricultural sector. Insect's emissions are very low, as only cockroaches, termites, and scarab beetles emit methane gas (Oonincx et al., 2011). Insects such as locusts are commonly viewed as pests that ruin crops. In Australia, they are controlled by spraying harsh chemicals to reduce adult numbers (Yen, 2008). There is a potential to not only reduce pesticides into the environment, but to utilise these large outbreaks. Furthermore, insects are beneficial in terms of nutrition with large interest and research investigating the high protein content. They are also rich in unsaturated fatty acids and certain vitamins and minerals such as iron, zinc, calcium, copper, magnesium, manganese, and selenium (Rumpold and Schluter, 2013; Zielińska et al., 2015). With the rising number of health and environmentally conscious consumers worldwide, there is a great opportunity for production of insect products.

## Composition

Insects can be grouped into orders including: coleoptera (beetles), orthoptera (locusts, crickets, grasshoppers), lepidoptera (caterpillars), hymenoptera (wasps, bees, ants), hemiptera (bugs) and so on (Rumpold and Schluter, 2013; Zielińska et al., 2015). Due to the large number of edible species, many studies have presented broad array of results for species within these groups (Bukkens, 1997; Ramos-Elorduy et al., 1997; Rumpold and Schluter, 2013). Conversely, other studies have only investigated a small number of popular insects including, the yellow mealworm (*Tenebrio molitor*), black soldier fly (*Hermetia illucens*), and cricket (*Acheta domesticus*) (Shelomi, 2015). Literature on the composition of the locust species *Locusta migratoria* are limited. Furthermore, each of the 1900-edible species have a unique proximate composition, which differs largely due to their habitat, diet, metamorphic stage and extraction method. This creates variation within the literature for locusts and other insects (Kourimská and Adámková, 2016; Yi et al., 2013).

## Protein

When focusing on the orthopteran class (locusts, crickets, grasshoppers) in particular, protein contents can range from 48.69% to 77.01% (Ndiritu et al., 2017; Raksakantong et al., 2010; Ramos-Elorduy et al., 1997; Rumpold and Schluter, 2013). They also contain satisfactory levels of essential amino acids (Kouřimská and Adámková, 2016; Zhao et al., 2016). The high protein content of edible insects has been outlined in many studies, indicating their potential as a nutrient rich and sustainable protein alternative. However, the use of the nitrogen conversion factor 6.25 has been linked to overestimation of the protein in edible insects. The high amount of non-protein nitrogen (NPN), such as the polysaccharide chitin (found in the exoskeleton), produces a falsely high protein content. Overestimation of protein content in various insect species can be around 8.5% to 22%, with recommendations to subtract NPN from the total nitrogen content, or use a 4.76 conversion factor (Janssen et al., 2017; Jonas-Levi and Martinez, 2017; Zhao et al., 2016). Nonetheless, the high protein content in insects is comparable to other meat sources such as beef, chicken, or fish (Yi et al., 2013), indicating significant potential as a meat and protein alternative.

## Fat

Fat is the second most abundant nutrient in locusts and other edible insects. The average fat content (based on dry weight) for orthopteran species is around 13%, however can range between 3.24% and 53.05% (Kouřimská and Adámková, 2016; Rumpold and Schluter, 2013). Fat is an energy rich nutrient leading to similar insect energy values compared with other meat options (Paul et al., 2016). The fat content and composition of insects vary largely due to differences in species, diet, metamorphic stage, habitat, and extraction method (Dreassi et al., 2017; Ramos-Bueno et al., 2016; Zhao et al., 2016). Paul et al. (2017) found the larvae of the yellow mealworm (*T. molitor*) had a much higher fat content (32%) compared to orthopteran insects that were at the adult stage (10%–15%). The majority of the insect lipids are in the triglyceride form (80%–90%). However, phospholipids (20%), diglycerides, monoglycerides, and steryl esters are also present. Specific concentrations of each lipid class vary, depending on life stage, species, and location in the insect body (Grapes et al., 1989; Kouřimská and Adámková, 2016; Tzompa-Sosa et al., 2014).

## Carbohydrate and Ash

Generally, orthopteran species have reasonably low carbohydrate (CHO) and higher fibre contents. This has been linked to the presence of a hard exoskeleton and life stage of the insect (Mohamed, 2015a). The high amount of indigestible fibre called chitin, can lead to fibre contents of locusts ranging from 15.65% to 27% (Kouřimská and Adámková, 2016; Mohamed, 2015a). Lastly, mineral contents of insect species are diverse. Orthopteran species ash contents range from 0.34% to 9.10%, with an average 3.85% (Rumpold and Schluter, 2013). Some studies have identified high amounts of iron in locust species (Kouřimská and Adámková, 2016; Zielińska et al., 2015) whereas, one study only identified phosphorous in high amounts (Mohamed, 2015a). However, the bioavailability of these minerals still needs to be investigated further. Folic acid, riboflavin (B2) and B12 are also reasonably abundant, especially in cricket species (Rumpold and Schluter, 2013). Although the studies are diverse, the composition of edible insects including the high protein, fat, and energy contents are comparable to meat options. Consequently, insects have the potential to be a sustainable and nutrient rich protein, oil, or meat alternative in the future (Yi et al., 2016; Zielińska et al., 2015).

## Protein Extraction and Functionality

Extracting the protein from insects has been suggested in literature. It would not only improve the protein percentage of the extracted fractions, but also overcome consumer acceptance barriers (van Huis et al., 2013). Many studies have identified consumers are more willing to consume insects when they cannot visually see them in the food (Balzan et al., 2016; Schöslér et al., 2012; Tan et al., 2016). Adding extracted protein fractions means the whole insect can not be seen, and also provides added nutritional and potential functional benefits to food products. Limited research has investigated protein extraction and functionality from insects. Generally, three fractions are extracted following aqueous or alkaline extraction methods. The proteins are solubilised in certain pH conditions (usually pH 10–11) then removed after centrifugation, creating a pellet or insoluble fraction. The remaining soluble proteins are precipitated at their isoelectric point (pH 4–6) and removed again after centrifugation, leading to a residue (soluble) fraction, and the upper liquid layer called the supernatant (Bußler et al., 2016). After extraction, the protein contents of the three fractions (soluble, insoluble and supernatant) are higher than the initial protein content of the whole insect. This has been researched on insects such as *Acheta domestica* (cricket), black soldier flies, yellow mealworms and the Mexican soldier fly (Bußler et al., 2016; Del Valle et al., 1982; Ndiritu et al., 2017; Yi et al., 2013; Zhao et al., 2016). Studies have also investigated the difference in protein content and yields of each fraction, using different extraction parameters or methods. They found experimental parameters can significantly affect results such as extraction method, temperature, and pH (Tirgar et al., 2017; Yi et al., 2013; Zhao et al., 2016). The extracted protein could be used as a functional food in various food products. The foaming ability of such protein has been found to be insufficient (Bußler et al., 2016; Yi et al., 2013). However, sufficient gelling, water and oil holding capacity has been identified for soluble and insoluble cricket protein (Bußler et al., 2016; Ndiritu et al., 2017; Yi et al., 2013). The ability to hold water against gravity is an important application in certain food areas. Moreover, protein fractions are generally yellow and brown colored due to melanoïdins, enzymatic, or non-enzymatic browning (Purschke et al., 2017; Yi et al., 2013).

### Fatty Acid Composition

Fatty acid (FA) composition of insect oils is limited, especially for locust species. The most abundant FA's in most insects are polyunsaturated FA (PUFA), followed by saturated FA (SFA) and monounsaturated FA (MUFA) (Raksakantong et al., 2010; Rumpold and Schluter, 2013). However, again the exact FA composition varies depending on many factors. When investigating the FA composition of *L. migratoria* species in particular, Mohamed (2015b) and Ramos-Bueno et al. (2016) found higher amounts of SFA and MUFA compared to PUFA. The most common SFA were stearic and palmitic acid. Oleic acid was the most abundant MUFA, and the essential FA's linoleic and  $\alpha$ -linolenic (ALA), contribute to a reasonably high PUFA content of 17.8% and 32.3%, respectively. Overall, The PUFA/SFA ratio is higher in cricket species when compared to yellow mealworm's, with ratios of 1–3 and 0.68 respectively (Paul et al., 2017). The PUFA content in orthopteran species has been linked to the diet and enzymatic activity (Yang et al., 2006). Insects that consume grass or plants containing high PUFA also contain high  $\alpha$ -linolenic (omega 3) contents found in their FA composition (Raksakantong et al., 2010). Although commonly known for their high protein content, orthopteran species have huge potential as a sustainable and nutritionally rich lipid source. Omega 3 is an essential FA that humans cannot synthesis in their own bodies. It has known positive effects for heart disease and cholesterol levels (Kris-Etherton, 1999). Additionally, there has been a growing concern over the high amount of omega 6 consumed in human diets. The higher amount of omega 3 in certain insect species produces a desirably low omega 6/omega 3 ratio, indicating opportunities as a healthy oil option.

### Safety and Regulation

Locusts and edible insects are generally found to be safe to consume, with no additional hazards such as contamination and chemical concentrations, when compared to other animal products (Poma et al., 2017). Microbial counts of raw edible insects are reasonably high, with recommendations for processing steps to decrease risks (Stoops et al., 2016; Vandeweyer et al., 2017). Dried then powdered insects, such as cricket flour are popular in the insect market today. However, when the microbial counts of such products were investigated by Grabowski and Klein (2017), they did not pass Belgium and Netherland hygiene regulations. Even though no classical food pathogens were identified after processing, high numbers of microbes were still present. There is large variation in microbial counts, not only due to intrinsic properties of the products, but between species, due to difference in diet and habitat. Therefore, the safety of an insect product should be thoroughly investigated before production and distribution. People with crustacean allergies may also have reactions to insect's due to the high amount of chitin in the exoskeleton (van Huis et al., 2013).

Edible insects are classified as a novel food in European countries, with no specific regulations on breeding or marketing, except for Belgium and the Netherlands (Grabowski and Klein, 2017; Poma et al., 2017). The insects, *Zophobas morio* (super mealworm), *Achaeta domestica* (house crickets), and *T. molitor* (mealworm beetle) were reviewed by the Food Standard Australia New Zealand (FSANZ) Advisory Committee on Novel Foods (ACNF). Although they are not traditionally consumed, they are able to follow normal food regulations (non-novel), due to the lack of safety concerns. Labelling of the true nature of food is required for products containing these insects however. *L. migratoria* would have to be reviewed by the ACNF before classification (novel or non-novel food) and consequent regulations of locust products in New Zealand or Australia.

### Consumer Acceptance Barriers

There is great potential for insects, insect oils, and extracted protein fractions to be used as a food ingredient. With the health and sustainability benefits, consumers may be motivated to purchase insect products. However, in order to successfully introduce such a controversial and innovative product, consumers must first adopt it. Although entomophagy is not uncommon in some Asian, African, and Latin American countries, it is widely unaccepted in others. Most attitudes towards the idea are ones of disgust, fear, or curiosity (Yen, 2009). Over half of the Belgium participants in a study conducted by Caparros Megido et al. (2014) had negative feelings towards insects however, were willing to try due to the curiosity and novelty, as found in many other consumer studies (Tan et al., 2015; Yen, 2009). Culture is a significant barrier towards the actual adoption of entomophagy in many Western societies. With no innate aversion found, these cultures have developed behavioural norms of eating animals as a source of protein, and viewing insects as pests or disease transmitters (Tan et al., 2015; van Huis et al., 2013). This enculturation has created deep-seated ideas about what is and isn't acceptable to eat, consequently generating food neophobia towards edible insects (Caparros Megido et al., 2014).

Food neophobia is the avoidance of new or unknown foods. Rozin and Fallon (1980) claimed that foods are often rejected because they have unknown tastes, origins, or expected harmful consequences from consumption. This has been linked to what is known as the 'omnivores dilemma,' a survival mechanism in which we should be cautious of potentially new and harmful foods, but also need to explore novel options (Hartmann et al., 2015; Rozin and Fallon, 1980). Consumers are more willing to trial products that they have tried before, as they already possess known sensory expectations. If the food and its origin are unknown, they make inferences about the experience, which are often negative in terms of insects decreasing the willingness to trial them (Tan et al., 2015). Both Balzan et al. (2016) and Verbeke (2015) found that food neophobia was the biggest factor affecting willingness to eat or purchase insects. Even though around 60% to 70% of the participants knew about entomophagy, the unknown sensory expectations and consequences of consumption prevented most consumers' acceptance. Some research have found younger males are less neophobic than females (Schösler et al., 2012; Verbeke, 2015), whereas others have found no significant difference in age or gender

(Looy and Wood, 2006). Furthermore, some consumers are motivated by rational reasons such as the health and sustainability benefits, whereas others are motivated by the novel experience gained from eating insects (Hartmann et al., 2015; Tan et al., 2015). Although growing in interest, research on the barriers and motivating factors towards insect consumption is reasonably limited and often limited to European participants. With so many consumer acceptance barriers, just informing consumers of the nutritional and sustainability benefits of insects is not enough (Hartmann et al., 2015; Hartmann and Siegrist, 2016; Shelomi, 2015; Verbeke, 2015). Combined efforts to overcome the initial negative disgust emotions, promote the positive and decrease the negative taste expectations, and increasing the knowledge about preparation and the benefits of insects is hoped to encourage people to adopt or at least try insect products in the future. However, greater investigation into consumer acceptance, potential markets, and promotional strategies is needed for successful integration into Westerners' diets.

### Diffusion of Innovation

Literature commonly investigates consumer willingness to try insects, however actual adoption into their diet is a different thing. The novel vs normal issue is on-going. Even though consumers may be disgusted and fearful of insects, their curiosity and thrill-seeking nature may motivate them to taste an insect (Caparros Megido et al., 2014; Tan et al., 2015). However, actually incorporating insects into the normalised diet of Western consumers is a complex and still reasonably unknown issue. The diffusion of innovation theory described by Rogers (1987) outlines how new products such as insects are taken up by the population. Initially innovators and early adopter categories will be the first on board with the innovative product, and will communicate the benefits to the larger populations (early majority and late majority). Lastly, consumers called laggards who are categorised as traditionalists, will be the last to adopt the idea. The rate of insect adoption can be increased through improving the perceived advantages of insects, producing products consistent with the values of the target market, improving knowledge on how to prepare and source insects, and increasing taste experiences of insect products (Verneau et al., 2016). For example, association between edible insects and similar animals such as crustaceans, and also the dissociation with general "bugs," could help overcome some of the acceptance barriers (Caparros Megido et al., 2016). Changes in consumer behaviour can be difficult but has happened before. Crustaceans such as lobster used to be considered 'poor man's food', but are a delicacy in many parts of the world today. Moreover, in the past thirty years eating raw fish has become a normalised behaviour in Western culture with the introduction of sushi (van Huis et al., 2013). However, in order for insects to follow similar trends, further investigation into possible insect products, food production systems, and also changes in the legislative law need to occur.

### Insect Products

Limited research has investigated consumer expectation and preference of insect products. Some studies have found how insect preparation and presentation affects willingness to eat them. Incorporating insects into products so they can't be seen, and also using them in familiar food formats can increase acceptability (Balzan et al., 2016; Caparros Megido et al., 2014; Gmuer et al., 2016; Hartmann et al., 2015; Tan et al., 2016). Caparros Megido et al. (2014) found most of the Belgian consumers were more willing to try the products where the insects couldn't be seen, and were paired with familiar flavours such as chocolate. By adding insects to familiar foods and taking away their "disgusting" appearance, food neophobia to novel insect products can be decreased. Knowing this, effectively incorporating insects into attractive and familiar insect products is crucial for the adoption of insects in Western societies. However, even with the greater acceptance of insects when incorporated into food, there are still large discrepancies found between insect and non-insect containing snacks (Gmuer et al., 2016). Some have looked at insects as a meat substitute (Caparros Megido et al., 2016; Schösler et al., 2012) or researched acceptance of whole insects. Investigating consumer expectations and preferences for insect products could provide valuable information about potential product development ventures in the future.

### Glossary

**Brushing** Application of a coating with a brush on the food product surface.

**Coating** Solution that when applied directly on the surface of the food leads to the formation of a thin layer that covers the food surface.

**Dipping** Application of a coating by immersing a food product into a coating solution.

**Film** Thin layer that is prepared in a mold separately from the food product and is later applied to it.

**Hydrophilic–lipophilic balance** The balance of size and strength of the hydrophilic and lipophilic moieties of a molecule.

**Glass transition** Exhibited by amorphous polymers or the amorphous regions of partially crystalline polymers when a hard, brittle, glass-like state is transformed into a viscous or rubbery fluid with the increase of temperature.

**Melting** Characteristic of crystalline polymers and corresponds to the transition from the solid to the liquid state at a given pressure.

**Spraying** Application of a coating by spray to cover the food surface.

**Wrapping** Application of a film to cover a food product.

## Introduction

Packaging, in general, helps the delivery of goods to the consumers, being used to protect goods and inform the consumer. In the case of foods, this functionality is augmented once they are able to ensure preservation of perishable products, provide information to the consumers, and ensure convenience (Zepf, 2010). In the food industry, can, glass, paper, and plastic are the most-used packaging materials. In recent years, due to environmental concerns, the use of biomaterials has increased, in which due to their source and biodegradability, they decrease the use of petroleum-based materials and waste disposal, respectively.

Another type of packaging that is increasing in the food industry is edible packaging. Edible packaging is packaging based on food-grade materials that is applied to foods as coating or film and can be eaten. This packaging (film or coating) must maintain their edibility after processing and application, and thus ensure their edible status. Edible packaging is able to protect foods and bring convenience to the consumer, and thus is within the traditional packaging definition. To be considered edible, the used materials must be approved as food ingredients or additives, or be in the group of compounds that can be added and eaten with food products. Nowadays, the legislation is clear regarding to the ingredients and additives that can be eaten with foods. In the case of edible packaging, this legislation must be followed and studied case by case according to the food on which the edible packaging is intended to be used.

The performance of edible packaging depends on the materials used and their main characteristics, pertaining to the main properties of coatings and films, such as barrier, mechanical, and optical properties. The materials shall be selected according to the type of food (i.e., dairy, fruits, soluble coffee, and vegetables) and storage conditions [e.g., temperature and relative humidity (RH)].

Nowadays, several approaches have been evaluated aiming to reduce and control the poor properties of edible packaging materials. Moreover, the reinforcement of the matrix using nanomaterials and the addition of bioactive compounds with edible status has been used to increase the materials' functionality. This functionality could be related to the antimicrobial and antioxidant capacities of those compounds, for example, that help edible packaging increase the quality and safety of food products.

Thus, edible packaging should not be seen as a type of packaging that will replace conventional packaging materials, but as one that can improve the properties of conventional packaging, acting as an additional protection for foods.

## Materials

The materials used to produce edible packaging, both coatings and films, must meet two requirements; one is to be considered edible, and the other is the ability to form a continuous coating or film. In this group of materials are generally polysaccharides, proteins, and waxes that are able to form a continuous coating or film. They can be divided into different categories according to their production method and origin. These include: (1) materials from direct biomass or natural sources (e.g., marine, agricultural, and animal sources), typified by proteins, polysaccharides, waxes, and lipids; (2) materials produced by wild or genetically modified microorganisms, such as polysaccharides and some active compounds; (3) materials produced by classical chemical synthesis, including surfactants, plasticizers, and other active compounds that are normally used in edible packaging.

Among these materials, polysaccharides and proteins are the most used materials as edible packaging. They are widely applied in the food industry according to their source and intrinsic and external factors, which have the capacity to form coatings and/or films. In the food industry, they are also used as emulsifying, foaming, and gelling agents, which are added to foods to attribute new functionalities.

The final properties and behavior of films and coatings will depend on several intrinsic factors, which in the case of polysaccharides are: molecular structure and the presence of functional groups, molecular weight (MW), and charge. In proteins, the type, number, and sequence of amino acids determine their MW, conformation, electrical charge, hydrophobicity, and functionalities. **Table 1** presents the most used polysaccharides in the production of edible packaging, their source, and some of their main characteristics.

Waxes and lipids are materials also used for the production of edible packaging. Waxes have been applied for many years as a coating on fruits, mostly citrus fruits, but in recent years, they have also been tested in combination with other materials, such as polysaccharides and proteins, aiming at the formation of coatings or films with improved properties (i.e., hydrophobic nature). They can be divided into natural waxes and resins, acetoglycerides, fatty acids, and vegetable oils. Their constitution will dictate whether they are liquid or solid at room temperature and is its state at room temperature (related to the melting temperature) that will influence the way they will be used. Due to their hydrophobic nature, they are used to reduce the moisture sensitivity of other materials, such as polysaccharides and proteins, but can also be used directly in foods as a coating, and to decrease the moisture loss from food.

In most of the cases, the formation of films and coatings require the presence of a plasticizer. Normally, polysaccharide- and protein-based films without plasticizers present a brittle and stiff structure due to the extensive interactions between polymer molecules. The type of plasticizer used will depend on the main materials used for the production of films and coatings. In the case of hydrophilic materials, such as most polysaccharides and proteins, water is one of the most effective plasticizers and its presence in the matrix will influence the films' properties. Other plasticizers of low MW, such as polyols, can be incorporated into the matrix, interfering with molecular interactions and leading to increased film flexibility and processability. Others of the materials that can be added are surfactants. Surfactants are amphoteric substances that present simultaneous hydrophilicity and hydrophobicity behavior. They are normally classified according to the hydrophilic-lipophilic balance and are conventionally added to enhance the stability of films and coating produced by mixtures of polysaccharides or proteins and lipids or waxes. The use of surfactants allows the formation of an emulsion, oil in water or water in oil, increasing the stability of film or coating. Surfactants can also be incorporated to reduce the surface tension of the coatings and improve wettability.

## Production Methods

Edible packaging can be applied to foods as edible films or coatings, as commented previously. This choice will depend on the application and the main functionality that is sought. The coating is a solution that is applied directly to the food surface (by dipping, spraying, or brushing) and that after drying forms a thin film, which will perform the desired function. The films are a self-standing material applied on the food product (e.g., wrap). To be considered a film, the thickness must be less than 254  $\mu\text{m}$  (Robertson, 2012).

In the case of coatings, they are applied directly on the food surface and dried. The application method depends on the food product, but the most used methods are immersion and spraying.

The drying process can be performed at different temperatures, i.e., refrigerated and room temperature when they are left to dry for a few hours, and high temperature (40–70 °C), thus increasing the drying rate.

Films can be produced by two different processes, "wet" and "dry". The chosen process will depend on the material used and its application. The most common is the "wet process," in which the materials are solubilized or dispersed in a solvent forming a homogeneous mixture, which is then placed in a mold and, after solvent evaporation, the film is formed. Normally, an aqueous solution is used, but in some cases, a solvent such as ethanol and a change of pH are needed to improve solubilization. In this case, the solvents need to be approved for food applications (food grade); once past the evaporation, some residues can remain in the film matrix and be consumed in foods. The other process used is the "dry process," in which the thermal behavior of the materials is used to fluidize the materials (melting or glass-transition temperatures) without the use of solvents.

**Table 1** Examples of polysaccharides used for the production of edible packaging, source, and main characteristics.

<i>Polysaccharides</i>	<i>Source</i>	<i>Main characteristics</i>
Carboxymethyl cellulose	Cellulose from plant or produced by microorganism	<ul style="list-style-type: none"> <li>• Water soluble</li> <li>• Film- and coating-forming capacity in concentrations ranging from 0.5 to 3% (w/v), depending on the degree of substitution and MW</li> <li>• Negatively charged</li> </ul>
(Hydroxypropyl)methyl cellulose	Cellulose from plant or produced by microorganism	<ul style="list-style-type: none"> <li>• Water soluble</li> <li>• Film- and coating-forming capacity in concentrations ranging from 0.5 to 5% (w/v), depending on the degree of substitution and MW</li> <li>• Neutral</li> </ul>
Ethylcellulose	Cellulose from plant or produced by microorganism	<ul style="list-style-type: none"> <li>• Soluble in organic solvents</li> <li>• Film- and coating-forming capacity in concentrations ranging from 0.5 to 5% (w/v), depending on the degree of substitution and MW</li> <li>• Neutral</li> </ul>
Pectin	Plant	<ul style="list-style-type: none"> <li>• Water soluble (high temperature may be required for total solubilization)</li> <li>• Film- and coating-forming capacity in concentrations ranging from 0.5 to 2% (w/v), depending on the degree of esterification and MW</li> <li>• Negatively charged at pH &gt; 3.5 and sensitive to variations of pH</li> </ul>
Chitosan	Animal and microorganism	<ul style="list-style-type: none"> <li>• Soluble in acidic medium (normally soluble at pH &lt; 4.5)</li> <li>• Film- and coating-forming capacity in concentrations ranging from 0.5 to 3% (w/v), depending on the deacetylation degree and MW</li> <li>• Presents antimicrobial activity</li> <li>• Positively charged</li> </ul>
Galactomannans	Plant	<ul style="list-style-type: none"> <li>• Water soluble (high temperature may be required for total solubilization)</li> <li>• Film- and coating-forming capacity in concentrations ranging from 0.5 to 3% (w/v). This will depend on the mannose/galactose ratio and MW</li> <li>• Neutral</li> </ul>
Alginate	Algae or produced by microorganism	<ul style="list-style-type: none"> <li>• Water soluble</li> <li>• Film- and coating-forming capacity in concentrations ranging from 0.25 to 2% (w/v). This will depend on the mannuronic and guluronic acids ratio and MW</li> <li>• Ability to cross-link in the presence of multivalent counter ions</li> <li>• Negatively charged</li> </ul>
Carrageenan	Algae or produced by microorganism	<ul style="list-style-type: none"> <li>• Water soluble (high temperatures are normally required for total solubilization)</li> <li>• Film- and coating-forming capacity in concentrations ranging between 0.5 and 5% (w/v). This will depend on carrageenan types (e.g., lambda, kappa, and iota) and MW</li> <li>• Negatively charged</li> </ul>

## Characterization

Edible packaging can be characterized through different techniques, depending whether a coating or a film is considered. In the case of a coating, it should be guaranteed that it will spread on the food surface and form a film after drying, with adequate adhesion and durability. In this case, wettability is one of the most important properties. Wettability is determined by the balance between adhesive forces of the liquid on the solid and cohesive forces of the liquid, in which adhesive forces cause the liquid to spread over the solid surface, whereas cohesive forces cause it to shrink. The adhesive forces are determined by the measurement of the contact angle between the coating and the food surface, and the cohesive forces are determined by the liquid–vapor tension of the coating. In practical terms, the closer the wettability values are to zero, the better the surface will be coated.

Another characteristic that influences the coating performance is the surface properties of the food. Therefore, the surface properties of the food (e.g., surface tension) should also be determined. The surface tension of a surface is determined by the measurement of the contact angles between several standard liquids and the material's surface. Thus, it is possible to correlate the surface tension of the liquids with the obtained contact angle values and determine the so-called critical surface tension of the surface. In the case of coatings, another of the important aspects that should be determined is the viscosity, which will greatly influence the method chosen (i.e., dipping or spraying) for the coating application.

In films, barrier and mechanical properties are the most important properties. Barrier properties, the ease or difficulty of permeation through barrier materials by such environmental substances as water vapor, oxygen, and carbon dioxide, give information about the film's capacity to provide a barrier to gases and other volatile compounds between food and the external environment. A film with good barrier properties protects foods against moisture and aroma losses as well as oxygen and carbon dioxide permeation, thus increasing the shelf life and quality of foods. The mechanical properties also give useful information about film

performance, because films with low mechanical strength values will have limited applications. Normally, the mechanical properties of films are evaluated through the determination of tensile strength, elongation at break, and elastic modulus.

Because most materials are soluble in water, it is important to measure the film's resistance to water. This can be determined by measuring the solubility of the films in water, i.e., their integrity in aqueous environments. In some cases, a nonsoluble or low-solubility film is required if the stored foods need to be protected against water in an aqueous medium. However, in some applications, high solubility is required, such as bags or packets that need to be dissolved in water during use. Other of the properties studied in films are the optical properties. They are studied through the evaluation of opacity, transparency, and color, but also the gloss and the haze can be determined. The opacity and transparency indicate the amount of light passing through the film, being the high opacity and low transparency values related to a lower amount of light passing through the film. The color of the films can be determined by the International Commission on Illumination color system (CIE  $L^*a^*b^*$ ) using a colorimeter.

The chemical structure of films can be evaluated for a better understanding of their properties. Techniques such as Fourier transform infrared spectroscopy and X-ray diffraction can be used to evaluate the chemical structure and crystallinity of the materials. The surface morphology of films or cross section can be accessed by microscopy. Scanning electron microscopy and atomic force microscopy are good techniques for the observation of micro- and nanostructure of films whereas optical microscopy can be used as a direct imaging technique in transparent films, and polarized microscopy can be used on crystalline materials to observe how the crystals are dispersed. In addition, thermal analysis can give useful information about a film's chemical structure and thermal stability. Besides the determination of glass-transition temperature and/or melting temperature and enthalpy, it is also possible to evaluate the degradation of materials components that is followed by weight loss of the materials with increase of temperature.

One of the main issues of edible packaging is their sensitivity to external factors, such as temperature and RH. Most of the polysaccharides and proteins used are hydrophilic and the RH greatly influences the properties of the films. Consequently, during the determination of films' properties the RH and temperature should be controlled.

## Introduction

Food packaging is a crucial element in consumption. It is potentially one of the most important forms of packaging in the consumer-packaged goods market, as it maintains product quality, prevents product loss, aids in transportation, allows safe storage and is a form of product advertising (Steenis et al., 2017).

## Traditional Packaging Systems

Traditional food packaging is an inert system, providing physical support and protection for a food product against external environments and stimuli (Robertson, 2012). This packaging must simply protect a product in the process of distribution, transport and storage.

In order to successfully incase and protect a product the packaging system will address the following key functions; containment, protection, convenience and communication (Robertson, 2012). The most basic function is containment, simply avoiding product loss and prevention of pollution during transport.

The primary function for food packaging is protection of the food product. Efficient packaging protection will often aid in the preservation and extension of shelf life, providing a physical barrier to microbial, physiochemical and physical damage.

The convenience of a packaging system simply refers to the ability for consumers to conveniently store and open packaging units.

Ease of use must be considered in design and construction. Effective communication within a packaging design will aid in brand identity while still providing all required information.

In addition to meeting the four key functions, food packaging is required to function in the physical, ambient and human environment (Robertson, 2012). This means that a food package must have the ability to withstand shocks, compression, gases, light, temperature, micro-organisms and dust, and still be usable by consumers with decreased dexterity, vision, strength or cognitive ability.

A poor design, that cannot perform in these environments will result in complaints and p rejection by consumers (Robertson, 2012).

## Smart Packaging

Smart food packaging is an extension of traditional packaging design. It fulfils the basic packaging functions (protection, communication, convenience and containment) and is functional in the physical, ambient and human environments.

Experts have forecasted that smart packaging is the future in food packaging solutions (Aday and Yener, 2015; Realini and Marcos, 2014; Vanderroost et al., 2014). It aims to reduce the safety hazards associated with traditional packaging through deliberate interaction with the environment and the food product (Restuccia et al., 2010). The new form of packaging offers properties and attributes that aid in product differentiation, emphasising unique qualities and ensuring product authenticity (Barska and Joanna, 2016). Smart packaging is understood to consist of two types of food packaging technologies; active and intelligent packaging.

## Active Packaging

Active packaging involves the desirable interaction of the product, packaging and environment through the addition of active agents to maintain product quality and extend product shelf life (Ahvenainen and Hurme, 1997; Barska and Joanna, 2016; Bastarrachea et al., 2011; Rooney, 2005). Active agents can be introduced to the food system either through a sachet containing active materials or

through the addition of active materials directly into the packaging film/material. Numerous active packaging technologies have been developed, with applications for specific food systems, allowing a substantial increase in shelf-life (Restuccia et al., 2010).

### Scavenging

A key limiting factor in a product's shelf life is high concentrations of oxygen ( $O_2$ ). Oxidation can cause off-flavours, unwanted odours, colour changes, nutrient destruction and facilitation of aerobic bacterium, moulds and insects (Ozdemir and Floros, 2004; Suppakul et al., 2003). The elimination of oxygen from packaging, especially the package headspace, has been a leading focus for packaging scientists (Suppakul et al., 2003).

Oxygen sensitive food products often utilise modified atmosphere packaging (MAP) or vacuum packaging, however permeation or complete exclusion of  $O_2$  from the package cannot be guaranteed by these techniques (Vermeiren et al., 1999). The implementation of an  $O_2$  scavenger to a package design will minimise the development of undesirable qualities in  $O_2$  sensitive products (Suppakul et al., 2003; Vermeiren et al., 1999). Current oxygen scavenging systems involve the oxidation of one or more of the following substances: iron powder, ascorbic acid, enzymes (glucose oxidase, ethanol oxidase), unsaturated fatty acids (oleic, linoleic, linolenic), rice extract and immobilized yeast on a solid substrate (Suppakul et al., 2003). These systems are often contained in a sachet.

Oxidation via iron powder is a very common method of oxygen scavenging:

The use of iron powder is common as it has the ability to scavenge oxygen in many food systems, including high intermediate or low moisture foods, and in food systems containing lipids (Vermeiren et al., 1999). Furthermore, they are effective in refrigerated, frozen or microwaveable items (Ozdemir and Floros, 2004).

Ethylene ( $C_2H_4$ ) is a growth-stimulating hormone that often has detrimental effects on the quality and shelf life of fruits and vegetables. It is often responsible for postharvest disorders (Ozdemir and Floros, 2004). This occurs due to the acceleration of respiration rates in climacteric fruits and vegetables, leading to maturity, senescence, softening and ripening (Vermeiren et al., 1999). A commonly used ethylene scavenging system utilises potassium permanganate imbedded in silica. Potassium permanganate cannot be integrated into the food packaging contact surface due to its toxicity, therefore the silica is kept in a sachet, with high permeability to ethylene. This inexpensive system will allow absorption of the ethylene by the silica, which will then be oxidised by the potassium permanganate into ethylene glycol (Ozdemir and Floros, 2004).

Product durability is often compromised by trapped (or product generated) moisture within packaging. Excess moisture can be generated by respiration of horticultural products, melting ice, temperature fluctuations with high equilibrium relative humidity (ERH) or drip of tissue fluid from cut meat and produce (Rooney, 1995). The trapped moisture can result in condensate or foggy film formation, microbial growth, decreased product durability and low consumer appeal (Barska and Joanna, 2016; Ozdemir and Floros, 2004). Excess moisture can be reduced either through liquid water absorption or humidity buffering.

The primary aim in liquid water control is to reduce the water activity ( $a_w$ ) thereby reducing the incidence of mould, yeast and spoilage bacterium growth (Vermeiren et al., 1999). Temperature cycling of high  $a_w$  foods has led to the use of plastics with an anti-fog additive, with the capability of lowering the interfacial tension between the condensate and the film. This contributes to the transparency of the film and allows customers to clearly view the packaged food items, while not affecting the level of liquid present within the packaging (Rooney, 1995).

Drip absorbent sheets are often used in food packaging to remove excess moisture, especially in packaging where ice is expected to melt or under cut or whole meats. The liquid absorbing sheets consist of super-absorbent polymers located between 2 layers of micro-porous or nonwoven polymers, with polyacrylate salts and graft copolymers of starch usually the preferred polymer used (Rooney, 1995).

Humidity buffering involves the interception of moisture in the vapour phase by reducing the in-pack relative humidity and thereby the surface-water content of the food. It is achieved via one or more humectants between two layers of plastic film that is highly permeable to water vapour or by a moisture-absorbing sachet. It has been used commercially to wrap fish and chicken, reducing the ERH in the vicinity of the product.

Pouches containing Sodium Chloride (NaCl) have also been used in the US tomato market (Rooney, 1995). Desiccants have been successfully used in moisture control in a wide range of food items, silica gel, molecular sieves, calcium oxide (CaO) and natural clays (montmorillonite) are often provided in sachets (Rooney, 1995). Silica gel is the most widely used desiccant due to its non-toxic and non-corrosive nature (Ozdemir and Floros, 2004).

Carbon dioxide ( $CO_2$ ) formed after the roasting of coffee may cause coffee packaged in a can or aluminium foil pouch to burst. The  $CO_2$  released from freshly roasted coffee can be scavenged through an absorbing sachet composed of a porous envelope containing calcium oxide and a hydrating agent (silica gel), on which water is absorbed. The water will react with the calcium oxide,

producing calcium hydroxide, which will then react with the CO<sub>2</sub> to form calcium carbonate, as shown below (Ozdemir and Floros, 2004; Vermeiren et al., 1999).

Interactions between the product, product packaging and environment can result in undesirable smells. This degradation is due to volatile compounds, such as aldehydes, amines and sulfides accumulating inside the product packaging. These compounds can be selectively scavenged (Day, 2008). Odour proof packaging consisting of an odour impermeable plastic such as polyethylene terephthalate (PET) together with a port to allow for the passage of respiratory gases and a sachet consisting of charcoal and nickel to absorb odour has been used on Durian fruit (Biji et al., 2015). Further scavenging can be achieved via incorporation of acidic compounds such as citric acid in polymers, or the addition of films containing ferrous salt and organic acid (citric or ascorbic acid) capable of oxidizing volatile amines (Rooney, 1995).

### Emitters

Carbon dioxide (CO<sub>2</sub>) has been shown to suppress microbial activity. At high levels (60%–80%) it is shown to inhibit microbial growth on surfaces, aiding the increase in product shelf life (Suppakul et al., 2003; Vermeiren et al., 1999). In addition, increased CO<sub>2</sub> has been shown to delay the respiration rate of fruit and vegetables but may cause undesirable anaerobic glycolysis in fruits (Ozdemir and Floros, 2004). CO<sub>2</sub> permeability is 3 to 5 times higher than that of O<sub>2</sub> in most packaging films, resulting in the need for continuous CO<sub>2</sub> production to maintain the desired level within a packaging system (Ozdemir and Floros, 2004; Suppakul et al., 2003). Utilization of a dual function system, consisting of an oxygen scavenger and a carbon dioxide emitter is common place in increasing shelf life in fresh meat, poultry, fish and cheese (Suppakul et al., 2003; Vermeiren et al., 1999).

Spraying ethanol on food product surfaces, such as bread, cookies and other bakery products has been shown to be an effective method of extending the shelf life of these commodities through the suppression of mould growth (Ozdemir and Floros, 2004). A food grade ethanol absorbed or encapsulated in carrier material, such as an emitting sachet or film, can be used as a microbial growth inhibitor in food systems. The release of ethanol to the packaging headspace is regulated by the sachet material's permeability to water vapour. The ethanol in the carrier material is exchanged with the water absorbed by the carrier material.

In addition to ethanol, some sachets will contain trace levels of flavouring substances, such as vanilla, to mask the odour of alcohol within the packaging. It is costly to include ethanol embedded films into packaging; however, this is a more effective manner to ensure controlled release of the ethanol.

This cost can be worthwhile, as it eliminates the need for preservatives, such as sorbates and benzoates, for mould inhibition (Ozdemir and Floros, 2004).

### Antimicrobial Packaging

An antimicrobial (AM) packaging system aims to protect packaged food items against different microorganisms through chemical and physical factors (Barska and Joanna, 2016; Suppakul et al., 2003). Muscle based products provide an ideal growth media for a variety of micro-organisms, development of microorganisms will change the aroma, colour and texture of the food item, resulting in shelf life reduction and increased foodborne illness (Kerry, 2014; Kerry et al., 2006). The primary goal for AM packaging is to extend the lag phase and reduce the growth rate of microorganisms, extending shelf life and maintaining product safety and quality (Han, 2005). AM packaging can be classified into two types; migrating AM agents and non-migrating AM agents.

Due to the potential harm AM agents can pose, tight controls are placed on the method of AM release (Vermeiren et al., 1999). Significant research has been done in AM packaging. The most common AM packaging solutions utilise silver based materials, natamycin-based antifungal coating and allyl isothiocyanate a natural antibacterial and antifungal substance (Realini and Marcos, 2014). The primary implementation of AM packaging can be found in meat, bread, cheese, fruit and vegetable sectors (Vermeiren et al., 1999).

### Intelligent Packaging

Intelligent packaging provides information about the food item, environment within the packaging or the external product environment to the consumer. The information is provided via external product indicators (Aday and Yener, 2015; Robertson, 2012). Intelligent packaging can aid and contribute to improving "Hazard Analysis and Critical Control Points (HACCP) and "Quality Analysis and Critical Control Points" (QACCP) systems (Vanderroost et al., 2014). The primary areas targeted by intelligent packaging are; sensors, indicators and traceability technology.

### Sensors

Sensors are devices used to detect matter, then signalling for the detection of the particular matter sought (Kerry et al., 2006). Sensors will contain two main functional parts, a receptor and a transducer (Biji et al., 2015).

Chemical sensors utilise surface adsorption allowing the detection of the presence, activity, composition and concentration of particular chemicals or gases. The observed information is then converted into signals by a transducer, which can be active or passive depending on the external power requirement (Vanderroost et al., 2014). Nano based sensors can be used to detect pathogens,

chemical contaminants, spoilage, product tampering, trace ingredients and track the product through the processing chain (Liu et al., 2007). Sensors can make use of optical transducers such as a silicon based transducer, which do not require electrical power, allowing readings to be made from a distance using VU, visible and IR light (Yebo et al., 2012).

A biosensor can detect, record and transmit information regarding biological reactions (Yam et al., 2005). A bio-receptor will recognise the targeted analyte, such as an enzyme, microbe or nucleic acid. The transducer will convert the biochemical signals into a quantifiable response (Biji et al., 2015). An example of commercial application is the attachment of a pathogen-specific antibody to the membrane forming part of the barcode. Presence of contaminating bacteria will cause formation of localized dark bar on the barcode, rendering the barcode unreadable at the checkout (Yam et al., 2005).

Gas sensors can detect gaseous analytes within a package. There numerous forms of sensors including oxygen, carbon dioxide water vapour and ethanol sensors as well as metal oxide semiconductor field effect transistors, organic conducting polymers and piezoelectric crystal sensors (Kerry et al., 2006). Each sensor has a specific mechanism of action within a food packaging system.

Printed electronics are flexible printed sensors containing a receptor printed in top of a printed transducer. This technology allows the sensors to be light, bendable and more portable. It will also allow printing onto various substrates, allowing a tailored and unique sensor for the food package (Biji et al., 2015; Vanderroost et al., 2014).

An electronic nose consists of chemical or biosensors with specificity and statistical methods allowing recognition of simple and complex flavour or odour compounds (Vanderroost et al., 2014). The electronic nose mimics the mammalian olfactory system, allowing repeatable measurements that successfully identify and classify aromas. It can clearly distinguish volatile compounds produced during deterioration or ripening (Biji et al., 2015).

### **Indicators**

Indicators are substances that indicate the presence, absence or concentration of another substance, or the reaction between two or more substances through irreversible colour changes, by diffusion of dye along a straight path (Biji et al., 2015). Indicators are the most common type of intelligent packaging solution on the market today (Vanderroost et al., 2014).

Time-temperature indicators (TTI) display the measurable time-temperature-dependent changes related to the food to which they are attached. Commercially available TTI's include enzymatic, polymer based, solid state reaction and microbiological systems (Pennanen et al., 2015). TTI's monitor the complete time-temperature history of the food product, and can provide accurate predictions of the remaining shelf life (Pennanen et al., 2015).

Freshness indicators provide information regarding product quality and microbial growth or chemical changes within a food product. A reaction will occur between microbial growth metabolites and integrated indicators on the packaging. Each freshness indicator will be unique to the product, for example, an indicator created for seafood storage will react to volatile amines produced (Biji et al., 2015; Kerry et al., 2006).

Thermochromic ink is a dynamic ink that changes colour with exposure to different temperatures. The activation temperatures of the inks range from refrigerated temperatures up to high heating temperatures. The technology can be used to inform consumers of previous storage temperature as well as providing in home information regarding the product temperature (Vanderroost et al., 2014).

### **Traceability Technology**

The increased number of food safety incidents have resulted in a demand for traceability. Radiofrequency identification (RFID), an automatic identification technology, uses wireless sensors to allow tracking, recording and continued product information along the product lifecycle (Chrysochou et al., 2009). An RFID system can be classified as passive, not requiring a battery source, or active, requiring battery to power the system (Yam et al., 2005).

## **Consumer Perception Towards Smart Packaging**

Consumers are continuously demanding more from their food products. These demands drive innovation in the packaging industry, forcing manufacturers to develop novel solutions in order to remain competitive. However, the success of new packaging technologies relies on consumers' behavioural responses to the innovation (Chen et al., 2013). The success of these developments depends on the perceptions, responses and acceptance of consumers, rather than the effectiveness of the new technology (Siegrist, 2008).

The consumer trends that have a direct influence on consumer choice relating to packaging include; consumer lifestyle, changing retail practices, demand for convenience, purchase of high quality goods, preference for mild preservation, concerns regarding food safety, need for longer shelf life, environmental awareness and the desire for transparency and product traceability (Ahvenainen and Hurme, 1997; Grunert, 2005; Ozdemir and Floros, 2004; Realini and Marcos, 2014; Restuccia et al., 2010; Robertson, 2012; Yam, 2012; Zink, 1997). These consumer trends make it increasingly complex to define and understand consumer demand (Jensen, 2006; Yam, 2012). However, the complexity of these shifts result in increased market awareness, greater spatial and social mobility and innovation in seeking information related to goods and services (Barska and Joanna, 2016).

Food is a basic product, a necessary, often habitual purchase for consumers. Many consumers will not take a great deal of time in choosing the products they purchase, while others will ensure that their personal values are expressed through their purchasing decisions.

While some consumers are well informed about the technology utilised in packaging, the limited knowledge will not withhold consumers from forming opinions and making purchase decisions based on simple inferential cue utilization processes (Steenis et al., 2017).

Research has shown that risk perceptions and food safety concerns are the primary determinants of consumer resistance to novel food technology (Chen et al., 2013).

Providing consumers with information is of vital importance to the implementation of smart packaging. Without a basic knowledge into the technologies employed in smart packaging, consumers may begin to fear the science used to improve food packaging.

## Conclusion

Food packaging is a vital component in the success of emerging food products. Packaging is usually the first point of contact consumers have with a product.

Exciting developments are being made in the packaging industry. It is expected that continued technological advances will occur within the packaging industry, ensuring that food can remain safer for longer, without compromise on the quality.

With continued development, smart packaging will become more economically viable. Understanding consumer perceptions is key. Ensuring that consumers do not fear emerging technologies will be the central factor in whether smart packaging technologies are truly successful.

## Overview

NASA's food system is a unique case study for many of the preservation methods and chemistry principles that extend the shelf life of foods. Currently, foods must be safe, nutritious, and acceptable for a minimum of two years in room temperature storage for International Space Station (ISS) missions (Douglas et al., 2016). Since the food system is constrained by the limitations of microgravity and resources (no cooking, limited food transfer, no high-crumb producing foods, mass, volume, water, and crew time), the current food system is made up of fully processed, individually packaged portions in lightweight flexible laminates. The food system relies on processing and water reduction strategies to inactivate or control microorganisms and enzyme function. In addition to the unique NASA-produced food items, the current ISS food system uses several commercially available shelf stable foods. They are vacuum packed in individual serving sizes to reduce the introduction of oxygen and moisture. The result is a food system that ensures safety, stability, and ease of use in a microgravity environment (Table 1) (Douglas et al., 2016).

Although preservation strategies such as retort thermostabilization, freeze-drying, and irradiation have been adequate for all NASA missions to date, future Mars missions will require a five year shelf life (Douglas et al., 2016). The processing and storage of foods exposes them to light, heat, oxygen, and ingredients that may impact the chemical stability of the vitamins, volatiles, and macromolecules in the foods, ultimately impacting the nutritional and quality shelf life (Fennema, 1996). In this chapter, we will focus on the preservation methods currently used for spaceflight foods and potential alternatives that could be used for Mars missions. Since food quality will change during storage after it is preserved, it is also necessary to consider packaging, environment, and formulation. For example, high barrier packaging will reduce the introduction of oxygen and water into the food after processing, minimizing chemical reactions such as oxidation. Specifics about the packaging and storage is included in each of the subsections.

## Current Preservation Methods

### Freeze-Drying

Foods are freeze-dried by first freezing them and then holding them under vacuum at a pressure below the triple point, which enhances the removal of water by sublimation (Rahman and Perera, 1999). The resulting food structure is porous and more easily rehydrates than traditional air dried foods (Ratti, 2001; Rahman and Perera, 1999). Most water on the ISS is recycled (Carter et al., 2013), so freeze-dried foods reduce launch mass in addition to preserving the food for extended periods at room temperature.

**Table 1** The NASA food system currently being used on the International Space Station (ISS) uses several different preservation methods to ensure a safe, nutritious, and acceptable food system (Douglas et al., 2016)

Food/process	Preservation mechanism	Packaging	Food examples	Shelf life
Freeze-dried	Reduced water activity/inability of microorganisms to grow	Flexible laminate with needle interface for rehydration; overwrapped in foil laminate pouch	Asparagus, shrimp cocktail, mashed potatoes, strawberries	1.5–2.5 years
Retort thermostabilized	High temperature process results in commercial sterility, product is free of pathogens, spoilage microorganisms, and enzyme activity	Foil laminate pouch	Beef stew, candied yams, brown rice, peaches	2–3 years
Irradiated	Gamma ray treatment at 44 kGy results in commercial sterility, product is free of pathogens, spoilage microorganisms, and enzyme activity	Foil laminate pouch	Beef steak, Turkey	2–3 years
Low moisture or dried	Reduced water activity/Inability of microorganisms to grow	Flexible laminate, overwrapped in foil laminate pouch. Beverages in foil laminate pouch with needle interface for rehydration	Brownies, extended shelf life bread products, dried fruit, beverage powders	1.5–2.5 years
Fresh	No preservation mechanism, limited supply on resupply vehicles	Sealed in bags	Fruits, vegetables	1–2 weeks

The quality of a freeze-dried product and its porosity is related to the glass transition temperature ( $T_g$ ). The  $T_g$  is the temperature above which an amorphous solid changes from the glassy to the rubbery state (Bhandari and Howes, 1999). Above the  $T_g$ , some components may crystallize and the porous structure may collapse resulting in shrinkage (Ponginebbi et al., 2000; To and Flink, 1978). Crystallization and collapse expels moisture and volatiles, which results in inadequate rehydration, and loss of aroma (To and Flink, 1978; Ponginebbi et al., 2000). The collapse temperature is dependent on the molecular weight of the food components. For example, foods high in small molecular weight ingredients, such as simple sugars, will have a lower collapse temperature, which can be increased by the addition of higher molecular weight ingredients (Bhandari and Howes, 1999; Roos and Karel, 1991).

Freeze-drying enables daily access in spaceflight to fruits and vegetables that would not retain adequate quality if subjected to other production methods. Strawberries, for example, have a high water content and delicate structure that is more compatible with freeze-drying, as standard air-drying methods cause damage to the structure resulting in poor rehydration (Alvarez et al., 1995). The minimal loss in red color during freeze drying suggests that this process also preserves the nutraceutical content such as anthocyanins (Ratti, 2001).

Unfortunately, freeze-drying does not prevent degradation of labile vitamins. A third of the vitamin C degraded over three years of room temperature storage in freeze-dried strawberries packaged for spaceflight (Cooper et al., 2017). Instability of some vitamins or aspects of quality could be a factor of residual oxygen and moisture in the food package, oxygen and moisture ingress over time, or cooking prior to freeze-drying in some foods. Freeze-dried foods are very hygroscopic, and increases in moisture can reduce the collapse temperature (To and Flink, 1978). Spaceflight freeze-dried foods are gas flushed and vacuum packed in high barrier packaging that contains an aluminum foil layer to prevent moisture ingress. In the absence of cold storage on current missions, foods are stored at room temperature, which enables crystallization and collapse to occur in some foods over time. Several products become difficult to rehydrate or noticeably lose color and aroma within two years, which is a limitation for these foods on long duration missions.

### Retort Thermostabilization

This process, also known as the retort process, inactivates pathogens, spoilage microorganisms and enzyme activity in foods by exposure to steam or water overpressure that achieves elevated temperatures (Barbosa-Cánovas et al., 2014). Temperature and time exposures are calculated based on the product characteristics and the target pathogen lethality (Potter and Hotchkiss, 1998). Increases in the processing temperature and time may also increase the rate of the chemical reactions within the food. The final products are commercially sterile but the heat process does reduce the quality and nutritional content of the food (Chia et al., 1983; Branagan and Pruskin, 1993; Olivas et al., 2002; Rodriguez et al., 2003).

Spaceflight foods are packaged and processed in flexible laminate pouches that contain an aluminum foil layer, which provides an advantage over cans. The shape of the retort pouches decreases the distance to the cold point, allowing for shorter heating times that reduces nutrient losses and maintains quality better than the standard processing of cans (Potter and Hotchkiss, 1998). Thermostabilized spaceflight foods generally retain acceptable quality for at least two years and provide necessary variety to the spaceflight food system. The flexible pouches are also lower in mass and stowage volume, two very important resources in space travel (Perchonok and Bourland, 2002). However, several nutrients and quality factors degrade substantially in the foods, and current processing and storage parameters will not meet the requirements of future long duration space exploration missions (Catauro and Perchonok, 2012; Cooper et al., 2017).

Many foods are compatible with the retort process, but some items require alternative strategies. Spaceflight foods formulated with substantial egg content (63% w/w in Vegetable Omelet and 22.5% w/w in Broccoli Soufflé) are too rubbery and firm to be acceptable. At this time, NASA egg-based food items are freeze-dried (Catauro and Perchonok, 2012).

### Irradiation

Some products, such as larger slices of chicken or beef, become dry and texturally unacceptable if processed with the time and temperatures required in retort processing and will not produce an acceptable freeze-dried product. Irradiation is not typically used to process foods to commercial sterility, but NASA has special dispensation from the United States Food and Drug Administration (FDA) to prepare nine commercially sterile irradiated meat items that are considered to be more acceptable than comparable retorted items (FDA, 2011; WHO, 1999). The impact of irradiation on foods has been extensively reviewed and found to result in products with comparable safety, chemical, and nutritional properties to thermostabilized foods (WHO, 1999). Irradiation involves the use of gamma rays, x rays, or electrons, which at adequate energy levels inactivate spoilage and pathogenic microorganisms (Stewart, 2001). Oxidation products and chemical reactions can be minimized by irradiating foods at freezing temperatures or by packaging products in inert atmospheres (WHO, 1999) so space flight foods are deep frozen in metallized pouches for processing.

NASA has evaluated the nutritional content of some of the meat products following gamma irradiation and compared the results to database values. The results suggested that there may have been some degradation of vitamins A, B<sub>6</sub>, and B<sub>3</sub>, with the exception of B<sub>3</sub> in poultry (Douglas et al., 2016). Vitamin loss is comparable to retort processing (WHO, 1999).

Irradiation has been considered as a method to ensure microbial safety of bulk commodities that may potentially be launched from Earth for use on future long duration missions. Wilson (2005) found that surface irradiation of whole dry soybeans using

electron beam or gamma rays at 10 or 30 kGy provides microbial safety of the bulk commodity. However, oxidative quality changes to the beans resulted from the exposure, rendering them unacceptable for producing adequate soymilk and tofu. Some of the functional qualities altered by the radiation exposure included the soybean color, aroma, solid content, and the germinating capacity of the individual seeds (Wilson, 2005).

## Exploration NASA Food Systems

The nutritional and quality shelf life requirements for food increase from two to five years to support a mission to Mars. Evaluating the potential of strategies to extend the shelf life of the various types of spaceflight foods to five years is a lengthy process that would benefit from kinetic modeling advances. Kinetic data is dependent on formulation, packaging, processing, and storage conditions, so available kinetic data cannot be used to accurately predict losses under other conditions (Evans et al., 1981; Kamman et al., 1981; Lathrop and Leung, 1980; Rao et al., 1981). Ongoing research in modeling may eventually enable more accurate predictions to be made from limited data (Peleg and Normand, 2015; Peleg et al., 2016, 2017), which may expedite evaluations to identify strategies that extend shelf life.

Emerging processing technologies that may provide a higher quality commercially sterile product immediately post-production are some of the strategies that may be investigated (Park et al., 2014). High pressure processing (HPP) and microwave sterilization are expected to have the most potential (Jermann et al., 2015), and therefore are the focus of the rest of this chapter.

## Pressure Assisted Thermal Sterilization (PATs)

High Pressure Processing (HPP) is a pasteurization process that evenly applies up to 1000 MPa of pressure to inactivate vegetative cells and enzymes in foods, with associated temperature increases of only 2–3 °C/100 MPa (Patterson, 2005; Considine et al., 2008; Chefel, 1995). The high pressure can also influence the functionality and gelation of protein and starch ingredients, which has the potential to introduce novel attributes and textural variety to space foods (Knorr et al., 2006). Commercial sterility can be achieved through a variation on the HPP process called pressure assisted thermal sterilization (PATs), where high pressure is combined with a reduced sterilization temperature to inactivate spores (Wimalaratne and Farid, 2008).

Previous studies indicate that covalent bonds are not impacted by pressure, and that vitamins, flavors, and textures are less impacted in high-pressure processed products compared to thermal processes (Nguyen et al., 2010; Oey et al., 2006). Evaluations of PATs processed fruit at NASA indicated color and internal cellular structure were better maintained compared to retorted fruits (Cooper et al., 2015). However, temperature increases in combination with high pressure have been noted to result in degradation of natural pigments such as chlorophyll (Van Loey et al., 1998; Oey et al., 2008).

In 2015, the FDA approved a pressure enhanced sterilization process for low acid multiple components in an effort supported by several food industry partners, the U.S. Army Natick Soldier Research, Development and Engineering Center, and NASA (IFSH, 2015). Although this milestone indicates the potential of this technology to extend the shelf life of the space food system and provide higher quality products, the commercial application of PATs lags behind HPP and the technology is not yet available on a scale that will enable sufficient evaluation for shelf life or production of spaceflight foods (Tao et al., 2015).

## Microwave Assisted Thermal Sterilization (MATS)

Microwave sterilization is a high-temperature, short-time process that uses a frequency of 915 MHz, rather than the 2450 MHz used in conventional home microwaves (Tang, 2015; Barbosa-Cánovas et al., 2014). This shortened heating time, as opposed to the retort process, has the potential to preserve the nutrients, colors, texture and flavor of foods that are sterilized both within a package, and in a continuous flow liquid system with aseptic packaging (Steed et al., 2008; Tang, 2015). In a NASA study, MATS processing did provide better color and texture initially as compared to retort processing in two products (Sweet and Sour Pork and Carrot Coins) (Douglas et al., 2016). However, due to an inadequate oxygen barrier in the MATS package, there was significant loss in carotene pigmentation, chlorophyll stability, several vitamins, and fat stability in sauces, resulting in degradation that was similar or even more extensive than the retorted products (Douglas et al., 2016). Advancements in MATS-compatible packaging is promising (Zhang et al., 2015), but no packaging has yet been validated to sustain improved quality and nutrition over multiple years in complex, multicomponent foods like those in the space food system. Additionally, products do not respond similarly or evenly to MATS processing, and the FDA requires a complex data set, including the dielectric properties, cold spot determination, and microbiological validation for individual products prior to approval for production and consumption (Barbosa-Cánovas et al., 2014). However, if methods can be determined to sustain the initial quality improvements achieved with MATS packaging for multiple years of storage, this technology may yet have the potential to extend the shelf life of spaceflight foods.

## Conclusion

On a Mars mission, a large variety of foods will be required to deliver the required nutritional content, and provide acceptable variation in colors, textures, aromas and flavors to support crew health and well-being. The lack of a food system with a five year shelf life is an ongoing concern that must be resolved for a Mars mission, and will likely require the use of several preservation methods. Food chemistry and engineering advances that extend quality, nutrition, and acceptability while maintaining food safety and minimizing resource use will be a significant contribution to successful future space exploration. These same advances may also have terrestrial benefits. The pouch packaging is now commonly used for some commercial products due to higher quality and improved consumer convenience. Emerging preservation technologies have the potential to deliver higher quality shelf stable foods to consumers.

MRE Meals Ready-to-Eat individual field ration for the United States military

CRP Combat ration packs

### Purpose of Military Foods

Defence forces face unique logistical challenges in supplying food to maintain the health and performance of personnel on deployment. Military food may be the only source of nutrition while engaged in operations on land, in the air, or on-board vessels and meal times are also often the focus for social engagement and activities that promote cohesive teams. Military foods have to maintain the physical and cognitive performance of personnel by providing adequate levels of total energy, macronutrients (protein, fat, and carbohydrate), micronutrients (vitamins, minerals, trace elements) and fiber. Military forces must often operate far from supply bases and must be prepared to function in many different and potentially extreme environments. These can range from ultra-cold locations, to low pressure and cold at high altitude to hot dry desert or humid jungle conditions. Food supplies have to be adapted to remain usable in these conditions. The food format and the nutritional composition must also be varied to meet the specific needs of the personnel and their activities in those environments. Additionally the requirements for advanced preparedness and logistical flexibility for unscheduled or long range deployment means that military foods must also satisfy extreme shelf life requirements for preservation of eating and nutritional quality. Thus military food specifications can greatly exceed those of standard commercial food practice and often require purpose-developed products. Specific solutions in nutrition formulation, packaging and logistics have been designed to deliver the requirements of military foods and their related applications in emergency and remote station or recreational use.

### History of Military Foods

Military food technology arose from the necessity to adequately provision armies and navies as a prerequisite to successful field operations. Early combat feeding by requisitioning or plundering from local food resources had to be supplemented by portable food and water supplies, even in Roman times. Until the industrial revolution stimulated development of large scale food processing, armies and navies relied on traditional long-lasting foods such as dried or salted meats, preserved vegetables, grains that could be converted into bread products, oil, cheeses and wines to provide the nutritional and energy needs for sustenance of the forces. The first major advance in modern food technology was the invention of food sterilization in support of Napoleon Bonaparte's quest to conquer Europe. The original development was of preservation by boiling food in glass vessels. This was rapidly superseded from the 1820s by "canning" using tin-plated cylindrical steel canisters. Further refinements of canning and of dehydration techniques provided improved forms of stabilized foods by the time of the US "Civil War" in the second half of the Nineteenth Century. This was enabled by progression of a more basic understanding of food spoilage, microbiology and preservation science. Subsequently World War I drove the development of modern forms of combat feeding with long-shelf-life food items packaged and preserved in large hermetically-sealed metal containers. During World War II the first combat ration packs, comprised of purpose designed complete nutritional food supplies, came into existence to bridge the gap between the beginning of actual combat and the restoration of field kitchen based food supply (Forbes-Ewan et al., 2016). Post World War II developments in plastic technologies allowed production of flexible barrier packaging based on multi-laminates. These use layers of plastic polymers, aluminum foil, nylon, or paper bonded together where each layer either contributes to strength or provides a barrier to moisture or oxygen to achieve the necessary shelf life and ruggedness for military applications. Further military packaging innovation since the 1990's has resulted in the wide adoption of heat-resistant flexible retort pouches and shelf-stable ready-to-eat meals. These meals provide lighter versions of traditional canned foods reducing the bulk, weight of soldiers loads and waste volumes. Military needs for improved lightweight long shelf life meals also drove the large-scale implementation of freeze-drying technology from the 1960s. Both raw and cooked foods can be dried from the frozen state by low-pressure sublimation of the water directly to gas while retaining the shape, physical structure and nutrients of the food. The resulting ultra-lightweight freeze-dried meal, combined with packaging that excludes oxygen and water, results in food that can be maintained in good edible format for over 10 years under good storage conditions.

## Logistic Demands of Military Food

The military need for long-shelf-life and nutritionally complete foods has been a key driver of technological innovation in food technology. Armed forces have specifications for where food supplies may have to be stored for long periods in hot climates without refrigeration or periodic frozen exposure. For example, USA Ready-Meals (MRE's) have a minimum shelf life of 3 years at 27 °C (80°F) which is 2–3 times standard commercial practice of up to one year. The food must not only remain nutritionally complete but also be of adequate organoleptic standard. These specifications also make military foods, and the technologies behind them, useful in other applications such as lightweight rations for recreational hiking or long-stored reserve food supplies for emergency or catastrophic event planning. The developments in military food rations to meet specific use requirements of high-altitude pilots and for aircraft life raft survival supplies has also extended to providing the technologies for provisioning astronauts. In this context light-weight, long-shelf needs are also complicated by zero gravity feeding issues to avoid dispersion of crumbs and droplets through spacecraft and to facilitate storage and waste disposal. Ultimately, space colonization and planetary exploration will need new solutions beyond food preservation to introduce recycling of nutrients by growing food *in-situ* in constrained space and energy environments.

## Preservation Challenges of Military Food

The increased shelf-life specifications of up to three years at 27 °C (80°F) for military foods is in contrast with normal commercial shelf life purposes where food only has to meet “best-before” specification dates of typically no more than 12 months at ambient temperature. The additional costs of extra protection for standard commercial foods is not warranted and therefore foods for the military often have to be especially prepared and packaged.

Food storage solutions primarily rely on prevention of microbial and enzymatic degradation by applying heat sterilization or ultra-low water activity in combination with exclusion of oxygen and light. For wet foods such as meat-based casseroles, the specifications are easily met by retorting the food in sealed containers at 121 °C for up to 20 minutes to kill all bacterial cells and spores. The high barrier properties of metal containers also effectively prevent light, moisture or oxygen migration into the food. The major determinants of shelf life are therefore the degradation of flavor, texture and nutrients during the thermal processing step added to the slow progression of chemical reactions leading to off-flavours, degradation of texture and nutrient breakdown during storage. Thermally processed foods can have nutritive losses in excess of 40% for naturally occurring vitamin C, folic acid and pantothenic acid (Vit B5) (Cooper et al., 2011).

For dried foods, preservation relies on low water activity ( $a_w$ ). The water activity of a food is defined as the ratio of the vapor pressure of water in the food divided by the vapor pressure of pure water at the same temperature. While most fresh foods have a high  $a_w$  (i.e. > 0.98) the growth of microorganisms ceases below  $a_w$  0.7 and foods with  $a_w$  below 0.6 are stable and classified as a dehydrated foods (Labuza, 1980).

Dried military foods can also be made as intermediate moisture foods with generally less than 25% moisture. The water activity is modified using solutes such as salts or humectants such as glycerol or natural sugars and acids to maintain stability without becoming too hard or brittle to chew. Hurdle technologies, using a combination of preservation mechanisms such as acid pH, preservatives and antioxidants are sometimes used to ensure longer-term stability to meet military needs. Traditional examples are dried fruits ( $a_w$  0.72–0.8), jams ( $a_w$  0.82–0.94), honey ( $a_w$  0.75) and dried meats such as jerky ( $a_w$  0.85) that can be processed and packaged for achieving a long shelf life. Non-traditional items such as shelf stable ready-to-eat sandwiches and pizza were specially developed to diversify military MRE menus and are also used in the US Military First Strike Rations. Other shelf stable intermediate moisture foods produced for the military include pop-tarts, cereal bars, fruit roll-ups, brownies and filled wraps (Richardson, 2012).

As an alternative to standard drying approaches using hot or warm air foods can be freeze dried to extremely low moisture contents using combinations of vacuum and heat. Freeze-drying of food, also known as cryodesiccation, was developed initially primarily for military applications. Food pieces can be individually frozen to be dried as separate free-flow items such as dried peas or carrot pieces. Fully prepared meals can also be frozen as a block or in a tray and processed to dried form retaining the shape, color and nutritional content of the meals. During freeze-drying the free water content is sublimated off under vacuum to leave 1%–4% water remaining. The dried product is then packaged under vacuum or modified atmosphere containing only nitrogen to eliminate reactive oxygen. Commercially measured shelf life outcomes of up to 25 years have been achieved for meats and fruits preserved by this method.

Preservation by gamma radiation sterilization, although technically possible, is only used as a fail-safe additional mechanism for critical operations such as meat products for space flight.

## **Packaging and Oxidation Protection for Long Stored Foods**

Normal commercial applications of food packaging minimize the cost by using thinner walled, lower barrier packaging materials and therefore often do not meet military specifications for shelf life where extra protection is needed. Initial versions of flexible packaging technologies for preservation of military foods usually used aluminum foil based oxygen and moisture barrier films. These metallic barriers could achieve the levels of robustness and low permeability rates necessary for the extended shelf life. Increasingly more advanced polymers and multi-layer films are being developed that can achieve the performance needed for military foods while still using thinner and cheaper films. Ethylene vinyl-alcohol copolymers (EVOH) are an example of an oxygen barrier polymer used in multi-laminate films. EVOH can achieve oxygen permeabilities of less than  $1 \text{ cm}^3/\text{m}^2/\text{day}$  for a  $20 \text{ }\mu\text{m}$  thick film at 1 atm gas pressure. This is a similar level of exclusion to thin metallic foil laminates with the advantage that such plastic is also clear or semi-translucent for product visibility and is microwave permeable for heat processing or reheating of foods (Froio et al., 2012).

In practice, no films or containers are perfect barriers for oxygen and water. Oxidation is the predominant mechanism for nutritional spoilage and flavor defects of long stored foods. Even low levels of oxygen 100 times lower than air can still catalyze food changes. Vacuum packaging is used for densely packed products where the air can be almost completely removed without crushing the food materials to unacceptably compact or broken forms. Some foods such as rice or noodles, however, can contain sharp edges that may cause pinhole damage to the barrier integrity of the packages. In such cases, liners are needed to ensure the integrity of the barrier during packaging and subsequent shock or vibration along the logistics supply chain. In other food types where the packing density is low, the remaining spaces hold residual oxygen. In these instances, modified atmosphere packaging technologies can be used to flush from the food packages replacing it with nitrogen gas.

Remaining oxygen or oxygen slowly leaking through barrier films can be scavenged from foods to achieve the extended shelf life required for military applications. The oxygen can be chemically reacted using a sacrificial food grade reducing agent such as ascorbate although many food types such as meats and fruits contain high natural levels of reducing agents that help preserve product integrity. Oxygen absorbers sachets based on finely divided iron are commonly used to remove any residual oxygen to less than 100ppm through reaction to form iron oxide (Cichello, 2015).

## **Flavor Changes in Long Stored Foods**

Slow oxidation and rancidity changes creating unpalatable tastes are a frequent problem in meeting military food storage specifications. This is exacerbated by the need for military foods to contain a balance of unsaturated fatty acids and increasingly to provide sources of omega 3 essential fatty acids as well as lipid soluble vitamins such as Vitamin E that are easily oxidized. The development of new foods therefore has to consider, not only the exclusion of oxygen to the greatest extent possible but also the elimination of oxidation catalysts like iron that can cause the slow onset of rancidity in otherwise stable dried or intermediate moisture foods. Additionally synthetic lipid phase antioxidants or natural extracts such rosmarinic acid esters are being used to achieve the necessary extended shelf stability.

## **Food Satisfaction Issues With Shelf Stable Military Foods**

Military rations are usually formulated to meet national taste preferences to ensure high levels of acceptability and consumption. Variety and choice, however, are also key considerations for modern military foods, in addition to the conventional standards of palatability and nutritional completeness. While this is not critical for short-term ration consumption, it does apply to extended missions. In addition, changes in dietary preferences or necessities such as food allergies/intolerances and in the future long duration space travel create challenges for maintaining the acceptability of rations as desirable meals. New technologies are being developed to improve the preservation of fresh food characteristics such as textures and flavors that are altered by thermal or drying processing. High-pressure sterilization (HPS) of food uses molecular changes induced by pressures in the range of 400–600 MPa to completely inactivate microorganisms and enzymes at lower temperatures than possible with conventional thermal processing. This results in better retention of colors, textures and flavors to increase eating satisfaction. Similarly microwave assisted thermal sterilization technologies use the volumetric heating ability of microwaves to more rapidly achieve internal sterilization conditions for solid or semisolid food types that otherwise rely on slow thermal conductivity to achieve the required heat penetration. The more rapid processing correspondingly results in improved retention of food properties and nutritional content.

## **Meeting the Complete Nutrition Requirements of Military Foods**

As military foods can be the sole source of nutrition, they need to be formulated to deliver the complete nutritional needs and organoleptic preferences of personnel. Military specifications are different from national medical and health recommendations

to account for the anticipated special needs of members of the armed forces. The recommended nutrient composition of Combat Ration Packs (CRP) for use during combat operations is given in [Table 1](#). According to [NATO \(2010\)](#), combat operations missions involving sustained, dismounted light-infantry or Special Forces operations require approximately 60% more energy than needed by comparable civilians. The dietary macronutrient distribution favors high carbohydrate levels to meet the high-energy needs with dietary carbohydrate contributing 45%–65% of total dietary energy intake, dietary protein contributing 15%–25% and, the balance of the energy being derived from dietary fat intake.

For longer-term sustenance, military foods must also meet critical levels of micronutrient and vitamin content where body stores can be depleted over time. The most well known example was the development of citrus juice supplements, during the 18th Century to prevent scurvy on navy vessels undertaking extended voyages of more than 30 days. Roses Lime Juice was patented in 1867 as a formula to preserve the juice and its anti-scurvy properties with sugar. Ascorbic acid (Vitamin C) was only identified as the active ingredient in 1932 [Wikipedia, Scurvy](#).

The recommended maximum period of continuous use of military foods varies from 10 to 30+ days.

**Table 1** Recommended nutrient composition of individual combat rations for use during combat operations

<i>Nutrient</i>	<i>Unit</i>	<i>Value</i>
Energy	kcal	4900
	kJ	20,515
Carbohydrate	g	550–800
Protein	g	158–185
Total fat	g	110–190
Total Fiber	g	30
Vitamin A	μg	900
Thiamin	mg	1.2
Riboflavin	mg	2.5
Niacin	mg	16
Vitamin B <sub>6</sub>	mg	2.6
Vitamin B <sub>12</sub>	μg	2.4
Folate	μg	400
Pantothenic acid	mg	6
Biotin	μg	30
Vitamin C	mg	45
Vitamin D	μg	5
Vitamin E	mg	10
Vitamin K	μg	70
Choline	mg	550
Calcium	mg	1000
Phosphorus	mg	1000
Zinc	mg	15
Iron	mg	14
Magnesium	mg	410
Iodine	μg	150
Selenium	μg	70
Molybdenum	μg	45
Copper	mg	1.8
Chromium	μg	35
Manganese	mg	5.5
Fluoride	mg	4.
Sodium	mg	2300–12,000 <sup>a</sup>
Potassium	mg	3800

<sup>a</sup>Recommend that lower limit of sodium content be achieved by the main course of the ration primary with the additional sodium (up to 9000 mg) provided in supplemental snack items and seasoning packets to be consumed on individual basis.

[NATO \(2010\)](#).

## Military Foods for Specific Operational Needs

Individual ration packs (CRP) are designed to feed personnel for a 24-hr period. They typically contain two main meals, a number of light meals and snack (consumed either alone or in combination with other items), meal accompaniments, beverages and sundry items. Main meals are typically a casserole style with a fish, lamb, chicken, pork, beef and/or vegetable based in a flavored gravy/sauce. Light meals and snacks can include pouched tuna, noodles, soup, cereal bars, cheese, confectionery, dried fruit, bread, mashed potato and biscuits. Accompaniments include spreads, sweetened condensed milk, sauces and seasonings. Beverages include instant tea and coffee, protein-based and isotonic drink powders. Lightweight variants of ration packs are designed for easy of carriage and typically contain two dehydrated main meals with additional snacks to keep the weight to a minimum. Group rations are designed for feeding detachments such as three to five personnel. The ration is self-contained and does not require supplementation. They typically contain main meals, a number of light meals and snacks but may be supplemented with freshly prepared bread, rice, pasta or noodles.

The composition of rations are also formulated for special needs. Military food specifications differentiate between normal v combat operations (different energy expenditure levels from activity), hot v cold environments and high altitude environments. Soldiers also rarely consume all the food components issued in combat ration packs (CRP) and discarded foods increases the risk of depleted physical and cognitive performance. The development of 'modular' or personalized rations is being advanced to have the ability to tailor rations to meet preferences in foods as well as variations and changes in nutritional needs.

## Conclusions

Military foods require specialized technologies to enable them to meet the complete nutritional needs of personnel and logistics requirements for extended storage. The thermal degradation of nutrients, flavors and texture during sterilization and the slow oxidation promoting rancidity and maillard reactions during prolonged storage are countered by specialized technologies to deliver fit-for-purpose military foods. Further research on meeting new challenges such as making functional foods to deliver health and cognitive performance benefits or satisfying the needs of space exploration are ongoing.

## Examples of Ration Packs and Products

# Crop Plant Adaption to Climate Change and Extreme Environments

David J Burritt, Department of Botany, The University of Otago, Dunedin, New Zealand

© 2019 Elsevier Inc. All rights reserved.

## Introduction

There is now strong evidence that the world has moved into a phase of rapid global climatic change (Norris et al., 2016). This combined with an ever-increasing global population means that the need for sustainable food production and global food security will push current agriculture practices to their limits in the near future (Abdelrahman et al., 2017). To meet these challenges, we not only need to make more efficient use of diminishing fresh water reserves and other natural resources, but we also need to rapidly develop new crops and crop varieties to ensure future agricultural sustainability in a more resource limited and changeable environment.

Plant development is a highly coordinated process that involves complex plant-environment interactions that require the integration of external environmental factors and signaling networks internal to the plant. These signaling networks function together to control a genetic program that when expressed correctly results in a functional plant able to complete its lifecycle. As well as helping to regulate plant development, the environment in which a plant grows also provides the necessary resources to enable that plant to sustain itself. Environmental factors that can influence plant growth and development are generally divided into two groups, biotic and abiotic. Biotic factors are living organisms, including other plants, animals (e.g. insects) and microorganisms (e.g. bacteria, fungi and viruses) that can potentially positively or negatively interact with plants. Abiotic factors include temperature, carbon dioxide (CO<sub>2</sub>), water supply, nutrients and pollutants etc., all of which potentially can directly influence plant growth and development.

Both biotic and abiotic factors can be influenced by climate and it is by altering these factors that climate change will have impacts on plants. This means that crop plant productivity in the future and hence crop yields are highly dependent upon future climatic conditions. As a consequence, the production of most of the food produced for human consumption is also highly dependent upon the future climate.

There is some evidence to suggest that rising CO<sub>2</sub> levels could improve crop yields, by enhancing photosynthesis and reducing crop water use (Kimball, 2011) and that higher temperatures may lengthen growing seasons, in some parts of the world (Myneni et al., 1997), enabling more crop harvests. However, most of the evidence to date suggests that it is more likely that if climate change is not brought under control in the near future, many of our staple crops will be more difficult to grow where we have grown them in the past and that even in developed countries climate change could have impacts on food security (Lobell et al., 2011; Lake et al., 2012).

An important question is how do plants adapt to these changes and what can we do ensure global food security in the face of climate change?

## What Are the Main Climatic Factors Associated With Climate Change and How Can Plants Adapt to Them?

The three main climate related factors that are gaining the greatest attention with respect to crop plant productivity are: elevated CO<sub>2</sub> levels, temperature increases (both mean and the temperature range) and water availability. While it is the above three factors that will be addressed below, it is important to note that other climatic factors, such as wind and relative humidity could also directly influence crop plant productivity and that climate change could influence biotic factors, such as the incidence of plant disease and the availability of pollinators. By influencing these biotic factors climate change could have indirect impacts on crop plant productivity. Another very important point to note is that many of the atmospheric pollutants, which have increased as a result of global industrialization, also have the potential to negatively impact plant growth and development directly, and hence crop productivity. These include, sulfur dioxide and trioxide (SO<sub>2</sub> and SO<sub>3</sub>), nitrogen oxides, soot particles and many organic chemicals and heavy metals.

## A Future With Higher CO<sub>2</sub> Concentrations and Temperatures, and Reduced Water Availability

The composition of the air we breathe is not fixed and can vary in response to both natural e.g. volcanic activity and anthropogenic factors e.g. emissions and deforestation. Over the past decades there has been increasing concern regarding the release of greenhouse gases such as methane and nitrous oxide, and especially CO<sub>2</sub> into the atmosphere. Atmospheric CO<sub>2</sub> concentrations increased from a preindustrial level of approximately 280 ppm to 379 by 2005 and concentrations are predicted to rise to above well 400 ppm by 2050, even with the most conservative emissions pathways (IPCC, 2007).

This increase in CO<sub>2</sub> and other greenhouse gases is resulting in global warming. From the data gathered over several decades it is now clear that in many parts of the world increases in mean temperatures and the frequency of extreme temperature events, such as heat-waves, are already occurring as a result of climate change (IPCC, 2013). It is predicted that global temperatures will continue to increase, with a rise in mean temperatures of 2–3 °C by 2050 and as much as 4.5 °C by AD 2100, depending on the predictive model and mitigation scenario (Allen et al., 2009). Temperature increases are expected to be greatest at high-latitudes; with increases being more pronounced during winter than in summer, and ground-level air temperatures likely to warm more quickly over land

than over the oceans (IPCC, 2013). As temperature is one of the main factors influencing the rate of plant growth and development, these increases could negatively impact the productivity of many crop plants especially in the tropics and subtropics.

As temperatures rise and global weather patterns change, including the frequency and distribution of rainfall, water availability will become an increasingly important factor limiting crop productivity. Depletion and salinization of ground water reserves is already a major problem in many important crop production areas of the world and reduced rainfall and the potential for increased salinization of fresh water due to the depletion of major aquifers and increased sea levels will become an issue for agriculture in the future. Already there is extensive evidence that variations in the amount and regularity of rainfall affect the dominance of plants in natural communities, and growth and yields of crop plants (Jones et al., 2016). According to the FAO (2011), crop plant yields are doubled by efficient irrigation, compared to farming that relies on rainfall (rain-fed agriculture). Climate change induced disruption of rainfall patterns combined with a reduced ability to irrigate crop plants, due to the depletion of ground water reserves, could mean that in the future water availability will be the most critical driver of whether a crop harvest is successful, crops fail completely, or yields are greatly reduced.

### Adaptation of Plants to Elevated CO<sub>2</sub>

For plants, and many other living organisms, it is the oxygen and carbon dioxide levels in the atmosphere that are especially important. As with most other organisms oxygen is essential for the processes associated with normal growth and development of plants, as it is needed for aerobic respiration. While light energy is required to power photosynthesis in plants, CO<sub>2</sub> is the raw material used for the production of sugars and this can be thought of as the first link in the human food chain and in fact that of the whole earth. Hence changes in atmospheric CO<sub>2</sub> levels can have a direct impact on crop plants.

The impact of increased atmospheric CO<sub>2</sub> concentrations on plants is quite well understood as studies of plant specimens collected over the past 200 years, that have been maintained in herbaria, clearly show that a major response of plants to increasing atmospheric CO<sub>2</sub> concentrations is a decrease in the number of stomata (Woodward, 1987). This change in stomatal number is under genetic control (Franks et al., 2015) and varies widely within a species (Miskin and Rasmusson, 1970), suggesting that the ability to adapt to increased atmospheric CO<sub>2</sub> concentrations exists for many crop plants and that the potential exists for the stomatal number of crop plants to be genetically manipulated. This decrease in stomatal number in response to increased atmospheric CO<sub>2</sub> concentrations has the added bonus of reducing water losses, but does have potential consequences for crop productivity as reduced stomatal number can limit gas exchange and hence the uptake of CO<sub>2</sub> for photosynthesis.

With respect to productivity and potential yields increased CO<sub>2</sub> concentrations could have both direct and indirect effects on some of our major crop species. However, the influence of increased CO<sub>2</sub> concentrations on a particular crop will depend on the photosynthetic mechanism used by the crop in question. Terrestrial green plants can be divided into C<sub>3</sub>, C<sub>4</sub>, and crassulacean acid metabolism (CAM) plants, depending on the photosynthetic mechanism used. In C<sub>3</sub> plants their photosynthetic pathway involves a cyclic series of reactions, called the Calvin–Benson cycle, which involves the use and regeneration of ribulose 1,5-biophosphate (RuBP) as a means to fix CO<sub>2</sub>. As the first product of CO<sub>2</sub> photoassimilation is the three-carbon sugar 3-phosphoglyceric acid, the term C<sub>3</sub> is used for plants that use this photosynthetic pathway. The first step of carbon fixation in C<sub>3</sub> plants involves the enzyme ribulose-1,5-bisphosphate carboxylase/oxygenase (rubisco), which catalyzes the carboxylation of RuBP. In C<sub>3</sub> plants, rubisco is contained in mesophyll cells, which are in direct contact with the intercellular air spaces that are in turn connected to the atmosphere via stomata present in the epidermis. As the name suggests, in addition to carboxylase activity rubisco also has oxygenase activity and this oxygenase activity becomes more dominant under low CO<sub>2</sub> and high O<sub>2</sub> concentrations, and at high temperatures (Sage and Kubien, 2007). Under these conditions rubisco's oxygenase activity impairs photosynthetic efficiency as rubisco sometimes fixes O<sub>2</sub> to RuBP instead of CO<sub>2</sub>, resulting in the oxidation of RuBP and the production of 2-phosphoglycolate. This 2-carbon compound is toxic and undergoes a series of reactions in the peroxisomes and mitochondria that result in the release of CO<sub>2</sub> (photorespiration) and a loss of organic carbon and energy. C<sub>3</sub> plants represent approximately 95% of terrestrial plant biomass and generally grow well where water is plentiful and temperatures and light intensities are moderate (Still et al., 2003). Some important C<sub>3</sub> crop plants include, barley (*Hordeum vulgare*), oats (*Avena sativa*), rice (*Oryza sativa*), soybean (*Glycine max*), potato (*Solanum tuberosum*) and wheat (*Triticum* spp.).

In contrast to C<sub>3</sub> plants, C<sub>4</sub> plants use the C<sub>4</sub> carbon fixation pathway, also called the Hatch-Slack pathway, which first involves fixing CO<sub>2</sub> into the three-carbon molecule phosphoenolpyruvate (PEP) to produce the four-carbon molecule oxaloacetate. The enzyme involved in this process, phosphoenolpyruvate (PEP) carboxylase, has no oxygenase activity and has a higher affinity for CO<sub>2</sub> than Rubisco. In C<sub>4</sub> plants the mesophyll cells near the stomata at the surface of the leaf contain PEP carboxylase, but no rubisco. In C<sub>4</sub> plants, rubisco is found in the bundle sheath cells in the interior of the leaf and so the oxaloacetate, which is concentrated in the mesophyll cells of the leaf, is converted into aspartic acid or malic acid and is then transported to the bundle sheath cells, where CO<sub>2</sub> is released and re-fixed by the C<sub>3</sub> pathway. The extra steps involved in the C<sub>4</sub> pathway require more energy (adenosine triphosphate, ATP) and as C<sub>3</sub> plants do not require this extra energy, are more efficient than C<sub>4</sub> plants when they are grown under optimal environmental conditions. However, when grown under high temperatures, low nitrogen levels and/or low CO<sub>2</sub> concentrations, or especially when water is limited, C<sub>4</sub> plants are able to fix CO<sub>2</sub> more efficiently than C<sub>3</sub> plants (Wang et al., 2013). Some important C<sub>3</sub> crop plants include, maize (*Zea mays*), sorghum (*Sorghum bicolor*) and sugarcane (*Saccharum officinarum*).

CAM photosynthesis is a mechanism whereby plants take up and store CO<sub>2</sub> at night and then use the stored CO<sub>2</sub> for photosynthetic carbon fixation during the day, when light is available. As few agricultural crops use CAM photosynthesis, pineapple is an exception, they are not considered important for food security under conditions of climate change.

For C3 crop plants grown under present day conditions, ambient CO<sub>2</sub> levels are sub-optimal and rubisco is not CO<sub>2</sub>-saturated because CO<sub>2</sub> levels are not high enough. Hence the competing oxygenation reaction is not completely inhibited and so photorespiration occurs, which leads to the loss of some organic carbon and energy. However, in the future increased atmospheric CO<sub>2</sub> concentrations could directly affect photosynthesis in C3 plants via a process known as the CO<sub>2</sub>-fertilization effect (CFE) [Wang et al. \(2013\)](#). In C3 crops, increased atmospheric CO<sub>2</sub> concentrations should lead to enhanced carboxylation and reduced oxygenation, so photorespiratory losses would be less and carbon uptake would be enhanced. Therefore C3 crop plants should show an increase in net primary productivity (NPP) and hence increased yields. In addition, if the efficiency of carbon fixation is increased, a plant's carbon demands could be met earlier and so plants growing under increased atmospheric CO<sub>2</sub> concentrations may reduce their stomatal apertures reducing stomatal conductance. This would result in lower water losses due to transpiration and improved water-use efficiency (WUE). Hence soil moisture could be retained and likelihood of crop plants being placed under water stress would be reduced.

In contrast to C3 plants, in C4 plants the C4 mechanism already results in 3 to 6 times higher than atmospheric CO<sub>2</sub> concentrations in the bundle sheath cells where rubisco is localized, which is sufficient to saturate rubisco and largely inhibit photorespiration. Hence, in theory, there would be no CFE for C4 crop plants. However, in C4 plants a reduction in stomatal conductance caused by the increase in atmospheric CO<sub>2</sub> concentrations may still occur, which would increase WUE and potentially this could increase crop yields ([Long et al., 2006](#)).

However, the potential benefit of CFE brought about by CO<sub>2</sub> enrichment is a very controversial topic. While recent studies ([Wang et al., 2013](#); [Degener, 2015](#)) have suggested that CFE will increase under drier and warmer climatic conditions, other studies on C3 plants have suggested that any benefits of future CFE could be reduced or lost completely due to the indirect effects of more extreme weather conditions. For example, [Parry et al. \(2004\)](#) predicted that any CFE yield gains could be cancelled out due to adverse climate-driven yield decreases. In a more recent study using data from temperate grassland plants grown for 16 years under "free-air CO<sub>2</sub> enrichment" conditions, [Obermeier et al. \(2016\)](#) showed that CFE was reduced or lost when conditions varied from "local average environmental conditions", e.g. were wetter, drier and/or hotter. As in the future the demand for fresh water supplies may limit the amount of water available for crop production and the prediction that the frequency and severity of extreme weather conditions is likely to increase under future climate scenarios ([IPCC, 2013](#)), the ability of CFE to improve crop productivity should be viewed with some caution.

### Adaptation of Plants to Increased Temperatures

While most crop plants can survive over a reasonably wide temperature range the optimal day and night temperatures for plant growth and maximal productivity vary greatly between crop species ([Poincelot, 1980](#)). Most cultivars of our main crop plants are adapted to temperate regions and have been bred to yield well when supplied with optimum levels of water and nutrients. Therefore, they do not perform well under the more stressful conditions associated with higher temperatures. The yields obtained from crop plants are heavily dependent on photosynthesis and the chloroplast thylakoid membrane, electron transport systems, light harvesting complexes and the activation status of rubisco are all especially sensitive to heat stress ([Sharkey, 2005](#)). With respect to photosynthetic and respiratory rates, optimum temperature ranges for photosynthesis for C3 crop plants are lower than those of C4 crop plants ([Sharkey, 2005](#)). So C4 photosynthesis would be beneficial for C4 crop plants cultivated under predicted future climates. However, in general the respiratory response of crop plants to temperature is logarithmic, so the potential does exist for a large decrease in net carbon fixation with increasing temperatures, as respiration rates could increase ([Sharkey, 2005](#)).

Data gathered over the past thirty years have already provided strong evidence that significant reductions in the yields of many important crops has occurred due to global warming and it has been predicted that further increases in global temperatures and more frequent heat-waves are likely to result in even greater yield losses in the future ([Long and Ort, 2010](#)). In a recent predictive study [Zhao et al. \(2017\)](#) used data from the published literature and a robust multi-method analysis, comprising four independent methods, to predict the vulnerability of four major crops, wheat, rice, maize, and soybean, to climate change. Globally these four crops provide more than two-thirds of the caloric intake in the human diet. The study predicted that without CFE and the development of cultivars adapted to effectively cope with increasing temperatures, for each 1 °C increase in the mean global temperature the global yields of wheat, rice, maize, and soybean would, on average, reduce by 6%, 3.2%, 7.4% and 3.1% respectively. Importantly they did also point out that their results were "highly heterogeneous across crops and geographical areas, with some positive impact estimates" ([Zhao et al., 2017](#)).

So how will increased temperatures influence plants and what general mechanisms do plants have to cope with temperature increases? From a physiological perspective, an increase in mean temperature could increase the rate of key biochemical processes in plants, but in all likelihood this effect would be reduced by increased transpirational cooling and acclimation responses. Leaving aside the increased likelihood of water deficit, the main danger for crop plants would be a greater frequency of hot days and/or higher temperature extremes. This could result in extended periods of heat stress and result in the induction of typical heat-shock responses. With respect to adaption to temperature extremes, plants possess a wide variety of mechanisms that enable them to grow at elevated temperatures. At the molecular level, plants possess a class of proteins called Heat-shock proteins (HSPs). These proteins are termed "molecular chaperones" as they are known to play an important role in preventing protein

misfolding and in stabilizing proteins under high-temperature induced stress (Jacob et al., 2017). In plants under heat-stress, protein misfolding is common and the genes encoding many HSPs are relatively rapidly upregulated at high temperatures. In addition to their roles under high temperature stress, HSPs/chaperones have been found to play multiple roles in protecting plants from other forms of stress including cold, drought, osmotic, salt, high-light, ultraviolet radiation, pathogen infection and oxidative stress (Swindell et al., 2007). For an in-depth review of plant HSPs readers are referred to Jacob et al. (2017).

In addition to high temperatures causing general stress responses in crop plants, another important factor that should also be considered is the acceleration of a crops development/life-cycle. For example, wheat is a temperate C3 grass species that produces its highest grain yields at temperatures below 26 °C. It is also very sensitive to heat stress and the impact on yields can be severe. Increasing temperatures have already been reported in most of the main wheat producing regions of the world (Asseng et al., 2011). Increasing mean temperatures have been shown to reduce grain yields, even for well-watered wheat crops, with plants most vulnerable to high-temperature induced yield losses at flowering and grain filling (Asseng et al., 2011). For wheat, high temperatures are known to accelerate plant development and hence reduce the growing season. This can limit the plants ability to produce and accumulate the carbohydrates needed for grain set and filling. In addition, heat stress just before flowering can result in floret sterility, which reduces the number of grains produced per plant and hence potential yields. How serious could higher global temperatures be for food production? In a review of the impact of temperature variability on wheat yields, Asseng et al. (2011) stated "With average temperatures and the frequency of heat events projected to increase world-wide with global warming, yield reductions due to higher temperatures during the important grain-filling stage alone could substantially undermine future global food security".

On a positive note, an increase in mean temperature and a reduction in the frequency of cold weather events, would reduce the need for chilling and freezing responses in crop plants, and could increase crop plant growth rates and extend the growing seasons in some parts of the world. However, for this to be of value a global re-evaluation of where we grow our staple food plants is required.

### Adaptation of Plants to Reduced Water Availability

Reduced soil water availability resulting in "drought stress" is becoming an increasingly common problem, due to a combination of climate change and depletion of ground water reserves, often due to excessive agricultural use. A lack of available water is, and is likely to remain so in the future, the main environmental factor that limits crop productivity and yields (Bray, 1997; Dai, 2012).

Depending on the duration and severity of the drought, crop plants can adapt to reduced water availability at the molecular, biochemical, physiological, and morphological levels. However, our main crop plants are not desiccation tolerant and so cannot survive once soil water levels drop below a critical threshold. In addition, adapting to lower soil water availability is costly to plants and so even drought tolerant plants will show reduced yields under drought conditions compared to yields when grown under conditions of optimum soil moisture. The timing of the drought event with respect to the developmental stage of a plant can also be critical, as plants are often more sensitive to drought stress when the drought event occurs during the plants reproductive phase, i.e. prior to or at flowering or seed production (Farooq et al., 2009).

With respect to adaptation to drought, plants have evolved a range of morphological, physiological, and biochemical mechanisms, which are often used together, to cope with reduced soil water levels. However, these mechanisms can result in lower leaf area indexes, lower vegetative biomass and hence reduced yields, compared to plants grown under conditions of optimal soil moisture. While a detailed coverage of the mechanisms associated with adaptation to drought is beyond the scope of this commentary (for brief reviews of how plants cope with drought please see Farooq et al., 2009; Osakabe et al., 2014) the key mechanisms include; smaller leaves, and slower growth rates (that result in a smaller plants), reduced stomatal densities and stomatal closure, osmotic adjustment and the production of compatible solutes, increased scavenging of reactive oxygen species (ROS), and the synthesis of proteins (e.g. dehydrins) that help plants reduce cellular damage due to water loss. The induction of these processes requires that plants are able to sense water loss and then via signaling pathways, which involve crosstalk between the pathways involved in plant responses to other stressors, regulate the expression of drought-responsive genes. Some of the signaling mechanisms that function in plants in response to water deficit include; Absciscic acid (ABA), strigolactones, ROS, sugar mediated pathways, and others. The development of cultivars, by manipulating the above mechanisms in our main crop species, that are both high-yielding under optimal conditions and are able to maintain good yields under drought stress conditions is essential for future food security.

### Can We Produce Enough Food to Feed a Growing Global Population in the Face of Climate Change?

At no time in history have plant scientists and plant breeders had available to them the range of tools with the potential to be applied to crop plant improvement that we have today. Using both conventional breeding tools and molecular marker-assisted breeding (MAB) the natural sources of genetic variation in many important crop plants and their wild relatives can still provide plant breeders with opportunities to identify novel alleles that can be used to produce abiotic stress tolerant cultivars of our main crops (Tester and Langridge, 2010; Huang and Han, 2014; Nunes-Nesi et al., 2016). While in the past this process would have required that numerous breeding lines be grown under a diverse range of environmental conditions, advances in rapid, low-cost sequencing and genotyping technologies and advances in DNA marker assays mean that cultivar development has the

potential to be more rapid than at any time in the past. In addition, although the contribution to agriculture to date has been very limited, the development of genetic engineering tools and the increasing use of gene editing have the potential to produce cultivars with tolerance to the environmental stressors associated with climate change (Barrangou and Doudna, 2016; Schiml and Puchta, 2016; Paul et al., 2017). High-throughput automated phenotyping technologies also have great potential to assist the development of cultivars more tolerant of these stressors (Cobb et al., 2013; Fiorani and Schurr, 2013).

In addition to breeding stress tolerant crop plants, other approaches should also be considering to improve future food security. For example, Davis et al. (2017) compared current and optimized crop distributions, for 14 major food crops, in terms of production and water use. They found that the current distribution of crops around the world was not optimal and identified alternative global crop distributions that they estimated could feed an additional 825 million people and reduce rainwater and irrigation water use by 14% and 12%, respectively.

However, food is not all about calories and Muller et al. (2014) expressed concern that current research on the potential impacts of climate change on food security, largely focuses on yields and calories, and not on nutritional quality. They state that, "Atmospheric CO<sub>2</sub> fertilization may go some way to compensating the negative impact of climatic changes on crop yields, but it comes at the expense of a deterioration of the current nutritional value of food". This is a very important and often overlooked point, as nutritional deficiencies are already a global problem. Future breeding efforts to produce crop plants that are more tolerant to climate change should pay careful attention not only to food quantity, but also to food (nutritional) quality.

## Conclusions

Above, each of the three main climatic factors that could limit crop plant productive have been briefly discussed individually and all have been shown to potentially influence either positively or negatively crop yields. However, as can be seen from the above sections, under natural conditions, these three climatic factors almost always occur together and interact with each other. As future crop growing conditions will likely expose plants to multiple climate change related factors simultaneously, with a sum negative influence on global agriculture, a critical area of future research is how can crop plants be adapted to produce high yields under multiple stressor scenarios? This is a very important, but under researched area. It is also very important to note that many factors other than climate change can influence food security e.g. customer demand, agricultural practices and especially local and global political shifts. However, what is clear is that an understanding of how climate change will influence our stable food plants is critical if plant breeders, farmers, and policymakers, are to work together to ensure future global food security.

# Advancements in the Understanding of Pectin Methyltransferase Enzymes and Their Inhibitors for Use in Food Science Applications

**Davide Mercadante**, Department of Biochemistry, University of Zürich, Zürich, Switzerland

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Enzymatic processivity** ability of enzymes to catalyze several reaction cycles before dissociating from a substrate.

**Glycosidic bond** covalent bond linking two monosaccharides.

**$\beta$ -Helix fold** protein fold characterized by the arrangement of multiple  $\beta$ -strands in a helical configuration.

**Carbohydrate-binding enzymes** class of enzymes that specifically bind carbohydrates, mostly polysaccharides. This ability is ascribable to a particular part of the fold called carbohydrate-binding module and often characterized by a binding groove able to allocate a polysaccharide linear chain.

**De-methyl esterification** chemical reaction having as a substrate a methyl ester and leading to the removal of the methyl group and the creation of a carboxylic acid and methanol.

**Phytopathogen** a pathogenic organism attacking plant hosts.

**Hamiltonian** a function describing the total energy of a system.

**Monte Carlo simulations** simulation technique based on a class of algorithms that obtains numerical solutions through a repeated random sampling of specific observables.

**Multiple sequence alignments** alignment of more than two protein, DNA or RNA sequences.

**Co-evolutionary analysis** method to assess the degree of inter-dependence between molecules by mainly looking at their sequence and scoring the observed recurrence of particular residues along the aligned sequences.

## Introduction

### Pectin Methyltransferase Enzymes, Their Role in Plant Physiopathology and Their Applications in Food Production

Pectin is the most abundant component of the plant cell wall and its modifications are a crucial factor in many life stages of plants. For this reason, the plant cell wall can be considered as a dynamic organelle rather than a simple barrier between the interior of cells and the outside world. From a structural perspective, pectin is a heteropolysaccharide composed by linear chains of homogalacturonan (HG) stretches constituted of  $\alpha$ -(1,4)-linked D-galacturonic acid monomers, branched by xylogalacturan or apiogalacturonan polysaccharides of various length. Besides HG, rhamnogalacturonan (RG) I or II are also present in variable quantities and are composed of a polymer of galacturonic acid-rhamnose disaccharides, which can be branched by neutral sugars such as D-galactose, L-arabinose and D-xylose (Darley, Forrester & McQueen-Mason, 2001; Fasoli et al., 2016; Gorshkova et al., 2013; Mohnen, 2008; Pauly and Keegstra, 2016; Ridley, O'Neill & Mohnen, 2001; Willats, McCartney, Mackie & Knox, 2001; Wilson et al., 2000; Zabackis et al., 1995; Zabolina, 2016).

The metabolism of pectin is extremely important as it regulates a variety of processes linked to both plant development and plant defense and is therefore tightly controlled via a cascade of enzymes (Cosgrove, 1993, 2005; Fry, 1995). Modifications occurring on the HG chains are particularly important as they regulate the assembly and disassembly of pectin and, in this way, the remodeling of the plant cell wall in physiological contexts and during plant infection, in which pathogens aim to create a breach into the cell wall by disrupting HG networks via pectin hydrolysis (Kubicek et al., 2014). Hydrolysis of pectin, however, can only occur after a step-wise modification of the monomeric units composing HG.  $\alpha$ -(1,4)-Linked D-galacturonic acid can exist as a methyl esterified monomer which can then be de-methyl esterified by pectin methyl transferase (PMEs) enzymes. The removal of methyl groups by PMEs transforms neutral HG chains into highly negatively charged polymers, which have different physico-chemical properties with respect to highly methylated pectin and serve different physiological purposes in the plant cell wall (Cosgrove, 2005). Pectin hydrolysis is initiated with the de-methyl esterification of HG chains, as pectinolytic enzymes called polygalacturonases (PGs) can only efficiently recognize de-methylated substrates (Arancibia and Motsenbocker, 2006; Babu and Bayer, 2014; Chen and Mort, 1996; Daas et al., 2001) (Fig. 1).

The activity of PMEs is of such critical importance to the physiopathology of plants that it is tightly controlled in the cell wall and inhibited in a timely manner by the expression of proteinaceous inhibitors called pectin methyl transferase inhibitors (PMEIs) (Giovane et al., 2004; Juge, 2006; S  n  chal et al., 2015). To give an idea of how important the activity of PMEs and PMEIs in plants is, it could be enough to mention that in *Arabidopsis thaliana* 66 different PME-PMEI pairs have been identified, with specificities and expression patterns still mostly unknown (Louv  t et al., 2006).

Importantly, PMEs are of extreme interest for the food industry in various manufacturing processes: for the production of pectin with desired characteristics, the fabrication of low sugar jams and jellies, the clarification of juices or the enhancement of fruit and vegetable firmness (Kohli et al., 2015; Kumar, 2016; Sharma et al., 2017).

**Figure 1** Schematic representation of pectin chemical modifications and breakdown. The modification of pectin is initiated by Pectin methyl transferase enzymes (PMEs) that remove methyl groups (yellow circles) from homogalacturonan chains: the linear polysaccharide of pectin. The exposed negative charges can be recognized by polygalacturonase enzymes (PGs) along the enzymatic cascade. PGs hydrolyze the glycosidic bond between sugar monomers and disassembly pectin. In the presence of divalent (mostly calcium) ions, HG chains modified by PMEs, can assemble by forming gels. Hydrolysis or gelification of pectin is crucially important for the development and, in some cases, infection of plants and is extremely useful to the food industry for several industrial processes, from juice clarification to the enhancement of fruit and vegetable firmness (see text for details).

Pectin is majorly responsible for the cloudiness of juices, which impacts both viscosity and sensory properties of a product. A strategy used to eliminate pectin during the treatment of juice is to favor its precipitation through the addition of PMEs.  $\text{CaCl}_2$ , which forms complexes with the negatively charged pectin (modified by PMEs), is subsequently added to the juice. Ultimately, upon binding  $\text{Ca}^{2+}$ , the pectin precipitates facilitating its removal.

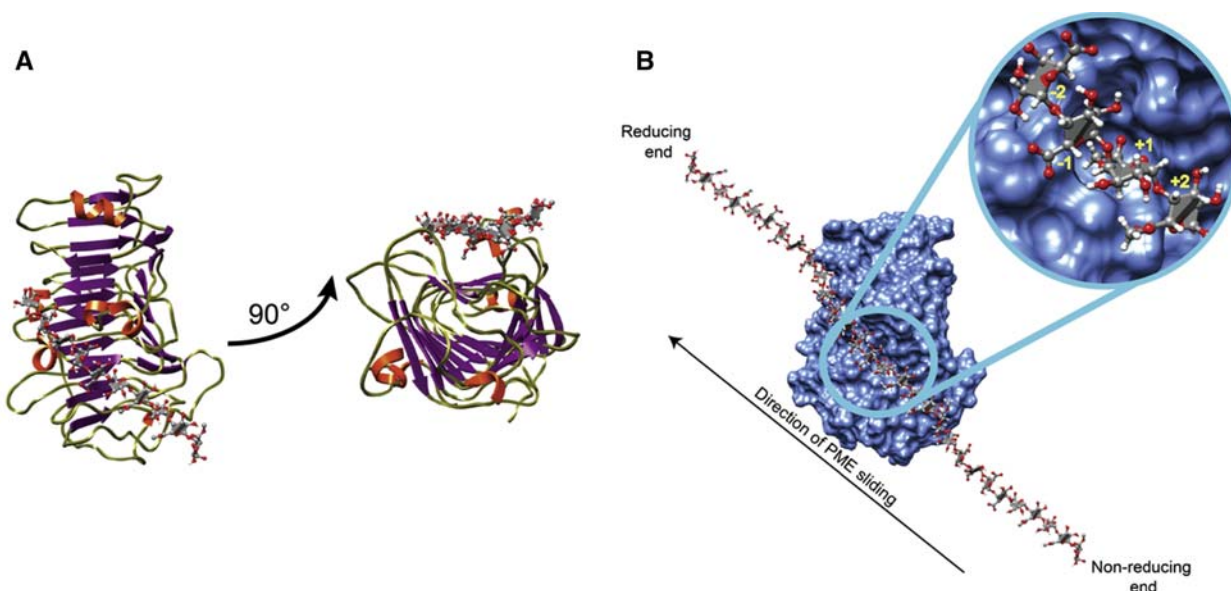

Alternatively, the combination of PMEs and PGs can also improve juice clarification through the hydrolysis of pectin polymers, thus creating shorter polymeric stretches. On the contrary, in order to preserve the firmness of the product by mimicking the polysaccharide networks that maintain the integrity of the plant cell walls, a similar treatment for fruit and vegetables is carried out. During post-harvest treatments of fruit and vegetables, which may include freezing, dehydrating or pasteurizing, the disruption of the cell wall leads to loss of cellular components and fluids and to the deterioration of product firmness. The use of PMEs and  $\text{CaCl}_2$  as previously described for the process of juice clarification is advantageous to avoid loss in firmness. Upon the removal of methyl groups from HG chains,  $\text{Ca}^{2+}$  ions bridge the negatively charged carboxylate groups of de-methylated HG chains favoring the formation of polymeric networks that, in this case, have the effect to preserve the firmness of the processed fruit or vegetable (Fig. 1). Isolated pectin, on the other hand, can be used as a thickening or gelling agent according to the degree of negative charge that it carries (Moreira et al., 2014; Urias-Orona et al., 2010).

Overall, the numerous uses of PMEs in the food industry make these enzymes particularly significant beyond their physiological role. However, a fine control of industrial processes that can be regulated by the use of PMEs can only occur once the biological principles regulating the activity of these enzymes and their inhibitors have been elucidated. Moreover, the rational design of new PMEs needs to be devoted to either enhance or inhibit their activity as a function of pressure or temperature, which may wildly oscillate during product manufacturing. Here I will illustrate the recent advancements made in our understanding of PMEs and will describe how the acquisition of knowledge about these enzymes can lead to the creation of engineered PMEs with desired functional and regulatory properties.

### The Structural and Dynamical Properties of PMEs Reveal Useful Strategies to Enhance Enzymatic Efficiency

The structure of all PME isoforms, so far characterized by means of X-ray crystallography or molecular modelling (Boraston and Abbott, 2012; Camardella et al., 2000; Ciardiello et al., 2008; D'Avino et al., 2003; Jimenez-Lopez et al., 2012; Jolie et al., 2010; Kent et al., 2016; Markovic et al., 2002; Teller et al., 2014), has revealed a triple  $\beta$ -helix as their characteristic three-dimensional fold. Triple  $\beta$ -helices are not rare in carbohydrate-binding enzymes as they allow the formation of a groove able to allocate linear polysaccharides. The binding groove can be then subdivided into a series of subsites, each one able to accommodate the single monomeric units composing the polysaccharide (Fig. 2).

Although the triple  $\beta$ -helical fold is common to all the PME structures known and to numerous other pectinases (Ciccarelli et al., 2002), a quick surf among the published structures reveals profound differences. A paradigmatic example of this is the structure of pmeA expressed in the bacterium *Erwinia chrysanthemum* in which the binding groove is flanked by two long flaps (Jenkins et al., 2001). The exact role of these flaps is still unknown but a plausible explanation for their presence is the bacterial need to avoid the inhibition of this enzyme by plant PMEIs, which act by sterically hindering the binding groove.

**Figure 2** Fold and substrate binding of Pectin Methyltransferase enzymes. (A) Structure of a pectin methyltransferase binding a HG decamer. The  $\beta$ -helix is composed, at each pitch, by the turn of three  $\beta$ -strands (purple) and is alternated with unstructured segments (loops).  $\alpha$ -helical segments are shown in orange, whereas loops are shown in ochre. The HG decamer binding the enzyme is shown using a “balls and sticks” representation and colored by atom type (carbon grey, oxygen red and hydrogen white). (B) Surface representation of a PME enzyme bound to a HG polymer. The arrow shows the directionality of processive PMEs, which slide along the substrate from the non-reducing to the reducing end of the polymer. The binding groove of PMEs is subdivided in smaller subunits called subsites and labelled as -2, -1, +1 and +2 (yellow labels in the inset). The catalytic triad responsible for the enzymatic modification of the substrate is located in the +1 subsite.

Overall, at least three main features of PMEs’ activity are interesting for the food industry. These are enzymatic efficiency, specificity and stability. I will therefore focus on these three features explaining the basis of PME action on pectin substrates and how the acquired knowledge can already be useful to further study and rationally modify these enzymes to meet the needs of industry.

Recently, combined experimental and computational efforts have revealed the basis of PMEs and PMEIs activity (Hocq et al., 2017; Kent et al., 2016; Mercadante et al., 2014; Mercadante et al., 2013; Senechal et al., 2017).

From a biophysical perspective, PMEs are extremely interesting machines. Many proteins, especially those involved in the duplication or translation of genetic material, bind linear polymers (for example, DNA, RNA or polysaccharides) and move along them to perform their action, effectively acting as molecular motors (Maga et al., 2000; Morales and Kool, 1999; Tsurimoto and Stillman, 1991). In order to do this, they mostly require an energetic co-factor, which commonly consists of adenosine triphosphate (ATP): they are ATP-dependent. The energetic co-factor acts as an adjuvant to perform useful work as these molecules need to bias thermal fluctuations that in the nanoscale are not negligible. To explain this concept I will refer to the so called Brownian ratchet, which is a thought experiment first proposed by Marian Smoluchowsky in 1912 (Smoluchowsky, 1912).

A Brownian ratchet is an imaginary device consisting of two chambers that contain gas particles heated at temperatures  $T_1$  and  $T_2$ , with  $T_1 = T_2$  as the boxes are in thermal equilibrium. In one of the chambers there is a paddle, small enough to be hit by the gas atoms and rotate. The paddle is then connected, through an axle, to a second chamber in which a dented wheel, blocked by a pawl, would rotate in a single direction as a consequence of the rotating paddle hit by the gas particles in the first chamber and the pawl impeding backwards movements in the second chamber (Fig. 3).

At first appearance, since the pawl would block the wheel from rotating back and forth, such a device would generate useful work at thermal equilibrium, thus clearly violating the second principle of thermodynamics. Years later Richard Feynman demonstrated that this is not possible, as the thermal fluctuations affecting the gas molecules would also similarly affect the pawl, which, subject to thermal motions of the same magnitude due to the thermal equilibrium, would fail to block the wheel from rotating backwards (Feynman, 1963). As a result, rather than continuously rotating in a single direction, the wheel would rotate back and forth.

*But what does a Brownian ratchet have to do with enzymes sliding on linear substrates?*

Since enzymes work in the nano-scale, their sliding along mono-dimensional chains is similarly affected by non-negligible thermal fluctuations that would therefore randomly produce sliding in both directions. Nevertheless, protein function can only be successfully performed when sliding is unidirectional. Therefore, the energy provided by the hydrolysis of ATP into ADP is commonly used to bias thermal fluctuations so that the sliding along a substrate occurs in only one direction and the molecule doesn’t slide backwards.

The evidence that PMEs can move along linear HG chains catalyzing several de-methyl esterification events before dissociating from the polymeric substrate is given by the observation that some PMEs produce blocks of de-methyl esterified substrates (Cameron et al., 2008; Grasdalen et al., 1996; Guillotin et al., 2007; Willats, 2001) (Fig. 2b). The ability to catalyze several reactions on a linear chain before dissociating from it, is called *processivity* (Berg et al., 2002).

**Figure 3** Schematic illustration of a Brownian ratchet. A Brownian ratchet is composed of two chambers in which gas particles (red circles) diffuse randomly according to Brownian motions. The two chambers are at thermal equilibrium (temperature in the two chambers is identical). By hitting the paddle in the first chamber, gas particles allow the rotation of the wheel in the second chamber. The pawl (green) insures that the wheel moves in a single direction as it blocks backwards movements. Ultimately, this generates useful work that in the example is represented by lifting a weight of a defined mass ( $m$ ). This thought experiment was formulated by Marian Smoluchowsky in 1912 to prove that work can be done in conditions of equilibrium and has been proven wrong by Richard Feynman, who noticed that the pawl in the second chamber will fail in impeding backward movements of the wheel as it will be affected by the same thermal fluctuations of the gas particles in chamber one, ultimately making impossible the achievement of fruitful work at equilibrium.

Processivity of PME is of great relevance to the food industry as blocky or randomly esterified pectins have different physico-chemical properties and can therefore be used for different purposes. In order to control the degree of methyl esterification in pectin, it is thus crucial to understand the basis of the processivity of PMEs. Even of more interest, PMEs do not require energetic co-factors to perform processive catalysis on HG chains, which brings the question of how these enzymes could perform useful work without an external energy source.

An interesting perspective on processivity, analyzed from a purely structural standpoint, has been provided by Breyer and Matthews, who analyzed the structure of numerous enzymes including those of many carbohydrate-binding proteins and featuring either open or closed substrate binding grooves (Breyer and Matthews, 2001). They concluded that structural asymmetry is key to achieve processivity, as it insures topological restraints along the binding interface and these restraints act like the pawl described in the Brownian ratchet formulated by Smoluchowsky (Smoluchowsky, 1912). For proteins featuring an open binding groove rather than a closed toroidal structure, an explanation for processivity is less straightforward and must occur through the binding of substrate moieties with different affinities along the groove: hence generating binding asymmetry (Breyer and Matthews, 2001). Structural or binding asymmetries can therefore be related to the thermal dis-equilibrium that a Brownian ratchet needs in order to work.

The triple  $\beta$ -helix fold of PMEs allows for the formation of an open groove in which HG substrates are allocated. Recent studies characterizing the binding of *E. chrysanthemum* PME to a variety of differently methylated HG oligomers have revealed binding preferences for either methylated or negatively charged sugar units in different subsites of the binding groove (Fries et al., 2007).

Within the binding groove, the subsites can be identified and labelled starting from the position of the catalytic site, which is conventionally placed in subsite +1. Consequently, the subsites flanking the catalytic triad towards the reducing end of the polysaccharide are numbered using the minus sign ( $-1$ ,  $-2$ ,  $-3$ , etc.) while those towards the non-reducing end of the polysaccharide are numbered using the plus sign ( $+2$ ,  $+3$ , etc.) (Fig. 2b). An analysis of the oligosaccharide conformations bound to the enzyme revealed that subsequent monomeric units along the groove point the carboxymethyl ester groups in opposite directions, suggesting that a simple sliding of the enzyme would not be sufficient to assure multiple catalytic events along the chain (Mercadante et al., 2013). Indeed, upon the de-methyl esterification of the first residue in subsite +1, the monomeric unit in subsite +2 would not face the catalytic triad, making catalysis impossible. Therefore, either the rotation along the glycosidic bond of adjacent monomeric HG units or the rotation of the enzyme around the bound chain needs to occur.

Although a structural analysis of PMEs can promote speculation regarding the mechanism adopted by these molecules to achieve processivity, only the analysis of their dynamics could shed direct light on it. Molecular dynamics (MD) simulations of *E. chrysanthemum* PME bound to differently methylated substrates have shown that the catalysis of a D-methyl galacturonate in the active site releases the potential energy necessary to achieve the rotation of the substrate in order to promote a second catalytic event. The de-methyl esterification reveals a negatively charged moiety, which is docked into a negatively charged pocket containing the catalytic triad. Upon catalysis, the repulsion between the two similarly charged moieties (the active site and the freshly generated carboxylate group) increases the potential energy of the system generating a flipping of the monosaccharides along the glycosidic bond linking them (Mercadante et al., 2013). As a consequence, the residue pointing to the methyl ester opposite to the catalytic triad in subsite +2 now points towards it (Video 1). Thus, the sliding of the substrate along the group would position the second methyl ester

in the right position and orientation for catalysis (Video 2). *What then drives the sliding?* The analysis of the electrostatic potential along the binding groove, observed in MD simulations once de-methyl esterification of the monomer docked in the +1 subsite has occurred, suggested that charges along the binding groove are asymmetrically distributed and that such asymmetry drives the sliding of the substrate. A positive patch in the -1 subsite “drags” the freshly de-methylated monomer docked in subsite +1 along the binding groove, ultimately promoting slithering (Mercadante et al., 2014). The processive activity of the enzyme is therefore promoted by an asymmetric chemical potential along the binding groove that allows first rotation and then sliding of the HG chain, finally achieving useful work meant as the unidirectional motion of the enzyme and the subsequent generation of blocky de-methyl esterified pectin. Using this knowledge, the rational engineering of PME by mutating critical residues favoring or disfavoring the above-described mechanism will be crucial to tune processivity and meet the needs of the food industry. Further research comparing the activity of PMEs that show different degrees of processivity will be invaluable.

### **The Molecular Basis of PME Specificity and the Possibility to Design PME Small-Molecule Inhibitors Starting From the Acquired Knowledge Regarding Enzymatic Processivity**

The discovered mechanism of processivity has laid the foundation to understand the specificity of processive PMEs for different substrates. Highly methylated substrates are not good substrates for processive PMEs, because, as evidenced by both structural and dynamical studies, the basis for processivity lies in the ability to bind partially de-methyl esterified substrates. This assures a differential affinity of binding for monomeric units in different subsites of the groove (Breyer and Matthews, 2001; Fries et al., 2007; Mercadante et al., 2014; Mercadante et al., 2013) and this asymmetry is crucial for enzymatic processivity. The mechanism describing processivity therefore explains why processive PMEs may act slower when incubated with highly methylated pectin while becoming progressively more efficient once the de-methyl esterification of the HG chains starts occurring. The mechanism by which a polymeric substrate bound by PMEs slides along the groove is of great importance for the design of small-molecule PME inhibitors, especially considering that the food industry has searched for these to finely control the activity of PMEs. Additionally, an efficient inhibition of PMEs by small-molecule compounds will be useful to investigate the role of specifically expressed PMEs in plants. Interestingly, the search for small-molecule PME inhibitors has focused towards green tea catechins, which have shown the ability to inhibit both isolated PMEs and PME extracts (Lewis et al., 2008), with these investigations having an empirical rather than a rational basis. Nevertheless, the knowledge about the mechanism adopted by the enzyme to achieve processivity, can be used to design substrate analogs that reduce the asymmetry required for the processive action of the enzyme and, in doing so, modulate catalytic efficiency. The design of efficient inhibitors can also be directed towards compounds that are hindered in their ability to rotate around the glycosidic bond, possibly modifying the linkage between D-galacturonate monomers. Overall, although more research is significantly needed, the studies that have elucidated the structural and dynamical basis of a few pectin methyl transferase enzymes from plants, bacteria and fungi, have paved the way for the design of new strategies to be used for the modulation of PME activity.

### **Enhancing the Thermal Stability of PMEs and Their Proteinaceous Inhibitors, for Their Use in the Food Industry**

In plants, the activity of PMEs is tightly regulated through the expression of PMEIs because of their importance in modifying the plant cell wall and consequently affect cellular development. A consequence of this is their redundancy within the proteome of plants. The exact role of all the expressed PME-PMEI pairs is unknown, however it has been described that the activity of different PME-PMEI pairs is dependent from micro-environmental conditions such as pH or ionic strength. The ability of PME-PMEI pairs to be sensitive to the micro-environment is extremely appealing to the food industry as the differential activity of PMEs through the use of their natural proteinaceous inhibitors can be explored according to the conditions in which a single industrial procedure is carried out.

The combined efforts of experiments and molecular simulations have recently explained the structural basis of this micro-environmentally controlled activity. The pH-dependent interaction of several PME-PMEI pairs has been assessed by means of MD simulations to pinpoint the structural and dynamical features of complex stability at different pH values. Simulations revealed that the sensitivity to changes of pH is mediated by the activity of a few protonatable residues at the binding interface (Hocq et al., 2017). The mutation of these residues decreased the stability of a PMEI from *A. thaliana* at pH5 (PMEI7). Mutated forms of the inhibitor were indeed unable to efficiently inhibit their target PME (PME3), transforming a pH-dependent PMEI into a pH-independent protein.

Besides the pH-controlled activity of PMEIs, one of the main interests of the food industry is inhibiting PMEs in industrial processes that undergo high temperatures and at which PMEIs are usually inactive. It is well known that few PMEs in crude fruit extracts are thermo-resistant and that the possibility to have thermally stable inhibitory counterparts (PMEIs) is a crucial advantage. Therefore, strategies for the design of thermally stable proteins can be particularly useful. In addition to the enormous, possibly unsurmountable difficulties in designing protein sequences *de novo*, the biggest limitation for the use of structure-based algorithms for the creation of more stable PMEIs is the lack of structural information. To date, only a few PME/PMEI structures have been resolved and the knowledge about their relative thermal stabilities is limited. On the other hand, the sequence space of these variants, due to the numerous molecular biology and proteomics studies on plant proteomes, has expanded the amount of sequences of expressed PMEs and PMEIs. It is therefore logical to start exploring the possibility to design more thermally stable PMEIs by looking into the sequence space and their co-evolution across many proteins of the same class (Tian and Best, 2017).

Recently, it has been suggested that the design of more stable proteins can be achieved by combining sequence information via multiple sequence alignments (MSA) to design co-evolutionary fit sequences. This approach has proven successful for some folds, such as those found in the GA, GB and SH3 domains (Tian et al., 2018).

Briefly, the design of a co-evolutionary fit sequence is based on extracting information regarding the preferential positions of each residue and its relative position with respect to every other residue, considering a multiple sequence alignment calculated from as many possible relevant sequences. This information is used to estimate the likelihood of a designed sequence using a likelihood estimator. The sequence design proceeds via the shuffling of residues through a Monte Carlo (MC) simulation, where the substitution of each residue is tested using the Metropolis criterion and guides the creation of an artificial sequence, to which an evolutionary Hamiltonian energy is assigned. The Hamiltonian energy has shown to negatively correlate with the designed proteins' ability to fold and with its thermal stability. Overall, the method has proven useful to design new, more stable proteins, and more importantly proteins still retaining their function (Tian et al., 2018). The stability of the newly designed proteins can then be tested using MD simulations run at different temperatures. Since short MD runs performed at high temperatures can be enough to assess stability and finally select a few candidates for experimental validation, a large number of designed sequences can be tested and this increases the probability to find designs with enhanced thermal stability.

Therefore, the application of this method can be extremely useful for the rational control of industrial processes mediated by pectin methyl esterase and other pectinases.

## Conclusions

Pectin methyl esterase enzymes are of enormous interest to both plant biology and food science for their role in the physiopathology of plants and their uses in various industrial applications. Thus, the control of their activity as a function of the micro-environment is particularly important. Recent advancements in the understanding of these enzymes, their mechanism of action and their inhibition by proteinaceous binding partners can fuel innovative research to enhance industrial applications of these enzymes and understand basic processes interesting to food science. Nevertheless, considering that the most recent advancements in understanding these molecular entities have come from single-molecules experimental and computational studies, a multidisciplinary approach that combines more traditional food science branches of research (analytical, textural or sensorial) with new biophysical strategies is needed and will prove beneficial for the improvement of tunability in industrial processes and the expansion of knowledge about food, with positive effects on the global economy.

## Glossary

**Cellular agriculture** a biotechnological process by which agricultural products (including meat, gelatin, leather, egg white, and others) are produced through techniques of cell culture instead of raising and slaughtering livestock

**Clean meat** genuine meat that is grown through culturing animal cells (cellular agriculture) rather than in a living animal

**Essential amino acid** an amino acid that is required for human growth and survival, but must be consumed as part of the diet because it cannot be synthesized by the body

**Extrusion** a physical process by which food ingredients are forced through an opening in a plate or die to shape the plant-based meat end product

**Green Revolution** the period of tremendous advancement in agricultural production realized between the 1930s and 1960s due to developments in agricultural science including fertilizers, pesticides, and crop engineering and selection

**Microcarriers** small spheres or beads used in bioreactor-based cell culture to support the growth of cells that require a surface on which to adhere

**Nucleotide** the base unit of DNA and RNA that is composed of a nitrogenous base, a five-carbon sugar, and one or more phosphate groups

**Plant-based meat** structured protein-based products created from non-animal ingredients designed to directly replace animal meat, including poultry and seafood, that are marketed as meat substitutes; also called meat analogues or meat alternatives

**Protein-energy malnutrition (PEM)** a type of malnutrition resulting from insufficient dietary consumption of protein and/or energy that predominantly affects children, due to their lower protein intake, and individuals in low-income countries who lack sufficient resources to consume a complete diet

**Recommended dietary allowance (RDA)** the average daily dietary intake level of a nutrient considered sufficient by the Food and Nutrition Board of the US Institute of Medicine to meet the requirements of 97.5% of healthy individuals

**Shear cell technology** a type of manufacturing method used to create structured plant-based meat that relies on two concentric cylinders moving tangentially to create laminar flow

**Tolerable upper intake level (UL)** the maximum daily intake for a nutrient that is unlikely to cause adverse health effects in most healthy people

## Dietary Protein

Despite Earth's tremendous biodiversity, the molecular composition of life is relatively simple. Only a handful of chemical elements make up the vast majority of all living matter: carbon, nitrogen, oxygen, and hydrogen are the most biologically abundant elements. These elements combine in unique and varied ways to form the nucleotides, amino acids, carbohydrates, and lipids that comprise cellular structure and perform all functions central to the maintenance and propagation of life (Voet et al., 1999).

Humans require a steady input of the above four elements — along with others such as calcium, phosphorus, and potassium, and trace elements such as iron, copper, and zinc — in order to survive and grow. We acquire these essential nutrients from our food, where they exist in more complex macromolecular structures such as proteins, carbohydrates, and fats which must then be processed by our bodies into smaller bioactive components. Proteins, which are the most abundant component of cells other than water, are our body's primary nitrogen source. Unlike carbohydrates and fats, ingested proteins are not stored by the human body but are immediately broken down into amino acids that can be incorporated into newly synthesized proteins, used for the production of other cellular components, or lost through excretion, oxidation, or conversion to metabolic waste products. Approximately 43% of the protein in the human body is present in skeletal muscle, and about half of the body's protein content is comprised of only four proteins: myosin, actin, collagen, and hemoglobin (Otten et al., 2006).

Protein is clearly essential, but how much do humans require on a daily basis? The answer varies based on an individual's metabolic demand and efficiency of utilization of dietary protein. Physiological characteristics that influence these properties include age, lifestyle factors such as physical activity level, special conditions such as pregnancy and lactation, and certain diseases and metabolic conditions that may impact the body's ability to properly metabolize specific amino acids (World Health Organization, 2007). In the US, the Institute of Medicine's Food and Nutrition Board, which is part of the National Academies of Sciences, Engineering, and Medicine, serves as the authoritative body for establishing dietary intake recommendations that guide health professionals in assessing both individuals' and populations' nutrient needs. The Acceptable Macronutrient Distribution Range (AMDR) for protein is

5%–20% of total calories for children 1–3 years of age, 10%–30% of total calories for children 4–18 years of age, and 10%–35% of total calories for adults older than 18 years of age (Otten et al., 2006). The recommended dietary allowance (RDA) for both adult males and females is 0.8 g of protein per kilogram of body weight per day (Otten et al., 2006). This translates to an RDA of 56 g of protein per day for a 70 kg (154 lb) adult male and an RDA of 46 g of protein per day for a 57 kg (126 lb) adult female. The dietary reference intake recommendations for total protein do not include a tolerable upper intake level (UL) because insufficient evidence exists to determine whether excess total protein (amino acid) intake poses a risk of adverse effects for most healthy people (Otten et al., 2006; World Health Organization, 2007).

Data from the National Health and Nutrition Examination Survey (NHANES), a survey conducted by the Centers for Disease Control and Prevention (CDC) among a nationally representative sample of about 5000 persons each year, demonstrate that dietary protein consumption among US adults (15.9% of calories from protein for males and 15.5% for females) is well within the stated AMDR (Wright and Wang, 2010). However, these daily average protein consumption levels translate to about 99 g for males and 68 g for females, suggesting a high likelihood of higher-than-recommended levels of protein intake. On a global level, data from the UN Food and Agriculture Organization suggest that over the past several decades, the world has experienced a steady increase in protein supply and intake among both developed and developing countries.

So why does this matter? If protein is an essential macronutrient and there is no UL, shouldn't this increase in protein consumption be viewed as a beneficial trend? Are there implications to rising global protein demand that extend beyond human health impacts? From a global perspective, are there any negative consequences stemming from our hunger for protein? Certainly in developing countries that disproportionately experience the burden of deaths attributable to protein-energy malnutrition (PEM) (Grover and Ee, 2009), one would expect that increased protein consumption is desirable. But is it leading to better health outcomes? We explore these questions next.

### Not All Proteins Are Created Equally

Protein quantity is not the only consideration when analyzing dietary protein intake. Protein quality must also be taken into account. The primary intrinsic determinant of protein quality is amino acid composition. Humans cannot synthesize all of the amino acids our cells use to synthesize proteins and thus we must obtain the non-synthesizable (essential) amino acids from dietary sources. Additional determinants of protein quality include factors within foods that impact digestibility and bioavailability of the protein's amino acids (Wu, 2013).

Protein quality varies by source and according to subsequent processing and cooking methods. While certain foods may contain low amounts of one or more of the essential amino acids — for example, many cereal grains naturally contain lower amounts of lysine, methionine, histidine, and tryptophan (Koehler and Wieser, 2013) — eating a variety of foods ensures that adequate amounts of each amino acid are consumed. One reason why PEM is still a major concern for developing countries despite the increase in overall protein consumption is because there is a lack of diversity in the diet. There is a common belief that diets reliant on proteins from plant sources are inferior for human health compared to diets rich in animal-based protein sources. However, scientific evidence supports the nutritional adequacy of well-balanced plant-based diets (Sanders, 1999), and a growing body of work points to the health benefits of reducing consumption of animal-based foods in favor of plant-based foods (Richter et al., 2015; Song et al., 2016; Kahleova et al., 2018).

Fig. 1 depicts daily per capita protein consumption across the world's regions dichotomized by whether the protein comes from plant sources or animal sources. On average, people worldwide are consuming more protein than physiologically needed. Not surprisingly, developed countries usually over-consume to a much larger extent than developing countries. Globally almost 60% of protein intake comes from plant sources. What is particularly striking, however, is the percentage of daily protein intake that comes from animal sources versus plant sources when comparing developed regions to developing regions. While India and Sub-Saharan Africa rely on plant-based protein for over 80% of their daily intake, the US and Canada consume approximately two-thirds of their daily protein intake from animal sources, which is the equivalent of almost 60 g of animal protein per capita per day on average.

As developing regions gain wealth, they experience a nutrition transition defined by a shift to a more Westernized diet reliant on animal products and higher in saturated fat, sugar, and refined foods and lower in fiber (Popkin et al., 2012). Thus, demand for animal-based protein is likely to increase substantially as developing countries continue to move through these demographic transitions and their associated epidemiology.

This is concerning for multiple reasons. From a public health perspective, though humans have consumed meat for millennia, overconsumption of animal products is linked to obesity, cardiovascular disease, Alzheimer's disease, and several other chronic conditions currently plaguing developed countries (Grant, 2014; Levine et al., 2014; Wolk, 2017). From an environmental viewpoint, the production of animal protein through industrialized animal agriculture is an inefficient, resource-intensive process. Growing evidence suggests that our current methods of animal protein production are not sustainable, especially as we experience population growth and increasing demand for protein, particularly animal protein (Walker et al., 2005; Gerber et al., 2013; Harwatt et al., 2017). The ultimate question we must answer, then, is how can we feed the world's growing population with safe, nutritious, and accessible protein-rich foods produced through systems that do not negatively impact global health, the climate, and scarce natural resources?

## People Are Eating More Protein than They Need—Especially in Wealthy Regions

**Figure 1** Per capita daily protein consumption by world region and protein source (plant-based vs. animal-based). Figure created by and reprinted with permission from the World Resources Institute.

### Food for Thought: Protein Product Innovation

In the study, “Shifting Diets for a Sustainable Food Future,” the World Resources Institute estimates we will need 70% more food to meet global demand in 2050, compared to 2006. It is unlikely that improvements in agricultural productivity alone will be able to close this gap, given yields would have to increase 33% faster than they did during the Green Revolution. The authors suggest that closing this 70% food gap will require both productivity increases and dietary shifts away from consumption of animal-based proteins, due to the fact that the production of animal-based foods involves substantially more resources and generates more environmental stress than the production of plant-based foods (Ranganathan et al., 2016).

Nevertheless, decades of work by scientists, public health authorities, environmentalists, and others to persuade people to consume more plants and less meat have not put a dent in meat consumption. Despite rising awareness of the global impacts of our dietary choices, consumers continue to base their purchasing decisions primarily on price, taste, and convenience (Glanz et al., 1998). Quite simply, reducing meat consumption is intractable for most people due to a lack of appetizing and affordable products that could serve as alternatives to conventional meat products. The challenge, then, is to innovate and bring to market diverse protein alternatives that are as delicious, price-competitive, and convenient as the animal-based food products currently on the market. Doing so would make the healthy and sustainable choice the default choice.

The remainder of this chapter focuses on two types of products that exhibit tremendous potential for becoming the protein foundation of a sustainable global food system. We refer to these products as plant-based meat and clean meat. After defining these terms, we discuss the current challenges and research gaps that must be addressed in order to bring appetizing, affordable, and accessible plant-based and clean meat products to market.

### What Is Plant-Based Meat?

Plant-based meats are structured plant-derived products designed to directly replace animal meat — including poultry and seafood — and that are marketed as meat substitutes. These meat substitutes can also be called meat analogues or meat alternatives. The name plant-based meat is sometimes used to refer to fungus-derived products, though this is not the most accurate terminology given that fungi are not technically plants. Products such as seitan – a mixture of water and the wheat protein gluten that when

cooked has a meat-like look and texture – are traditional foods in some cultures and are also included as plant-based meat because they are a central component of many meat analogues and are marketed as such. Similarly, veggie burgers — even those that do not simulate meat (e.g., black bean burgers) — are included in this definition because they serve as a direct replacement for a beef, chicken, or fish patty.

While plant protein isolates, concentrates, and textured vegetable protein (TVP) are typically used to make plant-based meat, such ingredients should not be confused with plant-based meat itself, which is the final consumer product designed to replace meat directly. TVP is extruded (or otherwise textured by kneading or mixing) protein in the form of small chunks or shreds and is not typically seasoned or prepared for direct consumption. Although protein is the primary ingredient consideration during the creation of plant-based meat, the final products are typically a mix of multiple types of plant-based ingredients, including other nutrients such as fats, carbohydrates, and fiber. Converting these mixtures of plant protein ingredients into plant-based meat usually requires processing in an extruder or forming machine, with additional formulation and flavoring to create an appetizing plant-based meat product. Optimal proteins for plant-based meat applications are those that can be structured such that the final product recaptures the texture and mouthfeel of meat. These attributes can be quantitatively described using food science functional metrics like gelling and crosslinking capacity for structuring and water-holding and fat-holding capacity for juiciness.

To effectively compete with animal-based meat products, the plant-based meat industry must expand and innovate to develop a variety of replacements that are as appetizing and affordable as conventionally produced animal meat. Fortunately, opportunities for innovation in the plant-based meat industry are even vaster than for the conventional meat industry. Relatively few species comprise the vast majority of all animals that are bred, raised, and killed for meat. Each species produces many different types of meat, some of which is sold relatively unprocessed while a significant amount of meat is ground, minced, or processed in other ways. But ultimately, the conventional meat industry is inherently constrained by limitations in the diversity, anatomy, and physiology of the animals it uses, whereas plant-based meat companies can innovate beyond mere replication of the limited types of animal meat currently manufactured. In [Fig. 2](#), we visualize categories of meat replacements that represent areas for plant-based meat product innovation that align with this premise.

## What Is Clean Meat?

Unlike plant-based meat, clean meat is genuine animal meat that can replicate the exact sensory and nutritional profile of conventionally produced meat. Clean meat is comprised of the same cells — and even the same myosin and actin proteins responsible for muscle cell contractility — that comprise the overall three-dimensional structure of muscle tissue in living animals, but clean meat is produced without the need to raise and slaughter whole animals. The process is inherently much more efficient than conventional production methods because resources and inputs are not being expended to grow parts of the animal that are not consumed. Furthermore, clean meat eliminates the need for massive amounts of crops to be grown and fed to livestock, only a small fraction of which are converted to meat as the vast majority are expended through the animal's metabolic processes.

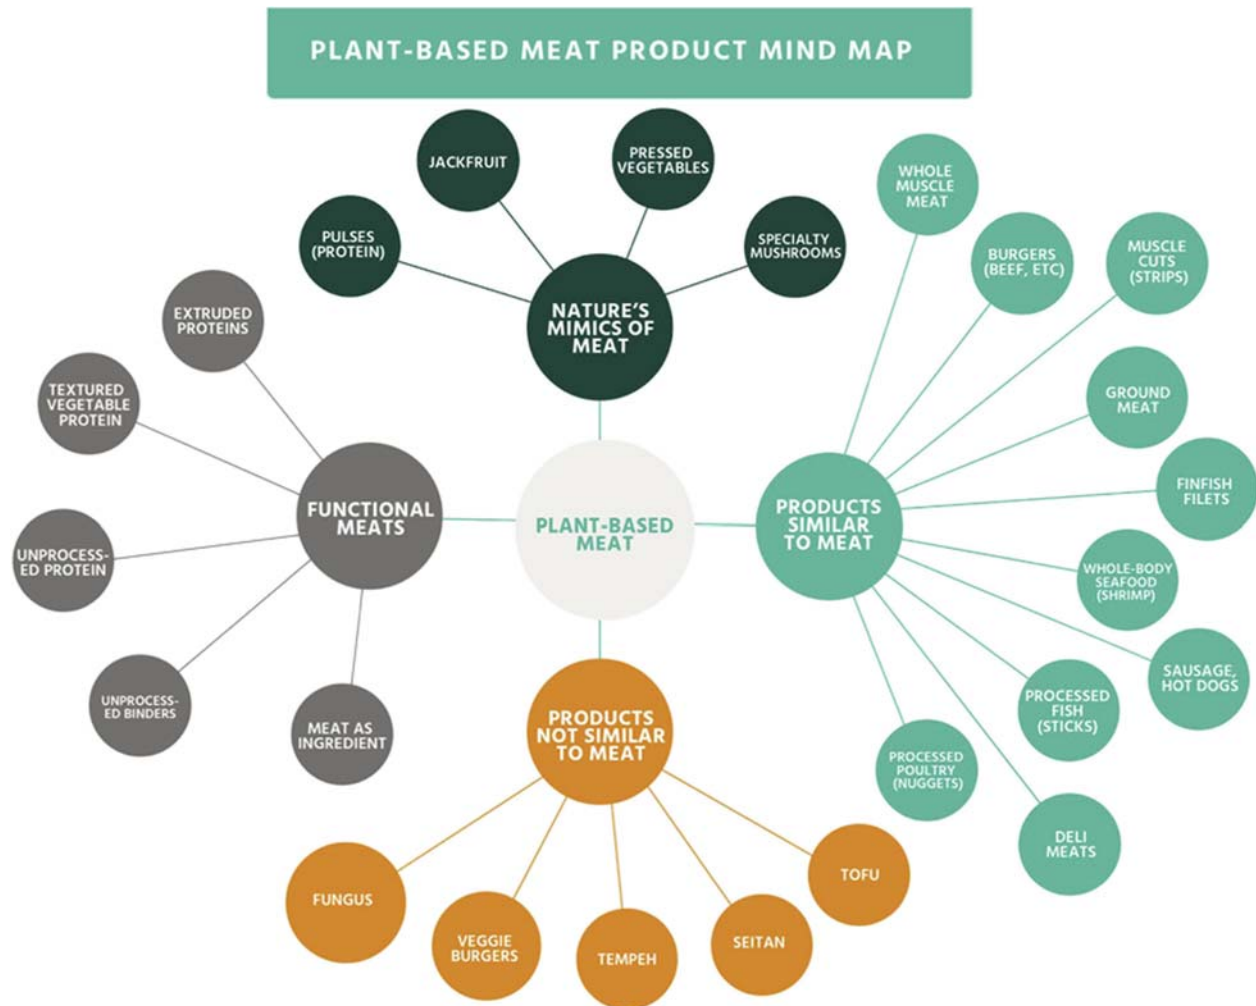

So how is clean meat actually produced? Clean meat relies on advances in cell culture and tissue engineering — many of which were developed for biomedical applications like cell therapy and organ implants — to directly grow the types of cells that comprise meat. Meat is essentially just a collection of muscle cells, fat cells, and connective tissue cells, all of which can be grown outside the body of an animal in controlled, enclosed environments. In general the process involves collecting a small number of animal cells from an agriculturally relevant species (cow, pig, chicken, turkey, fish, etc.) and proliferating them in a bioreactor where they are fed a nutrient broth media to supply them with the ingredients they need to survive. The cells then undergo a differentiation process during which they mature into the muscle cells, fat cells, and connective tissue cells that comprise meat. These two stages (proliferation and differentiation) may or may not be spatially separated, but they will almost certainly be temporally distinct as the signals and environments that encourage cellular proliferation differ from those that induce differentiation ([Specht, 2018](#)). [Fig. 3](#) provides a graphical representation of this process.

At first glance, plant-based and clean meat may seem like two distinct solutions to sustainable protein production. However, they are better represented as two ends of a continuous spectrum ([Fig. 4](#)) exhibiting overlap among the raw materials and ingredients used, and products are developed that incorporate both plant-based and clean meat ingredients. Clean meat and other cellular agriculture products will likely find an early market entry point as a high-value ingredient in foods that are predominantly plant-based. Because the taste profile of meat is highly complex and the texture and mouthfeel are specific to each type and cut of meat, incorporating clean meat into plant-based products may make it easier to create products that meet the sensory expectations of consumers without sacrificing health and environmental impact profiles.

## Current Research and Development Needs for Plant-Based Meat

The concept of plant-based meat is not a modern development. Various forms of plant-based meat have been made for centuries, with early forms predating modern food processing techniques like extrusion by nearly a millennium. The prevalence and variety of plant-based meat has steadily increased over time, culminating in an explosion of innovation throughout the sector during the last decade. Despite this long history and exciting present development, the future success of plant-based meat depends heavily on

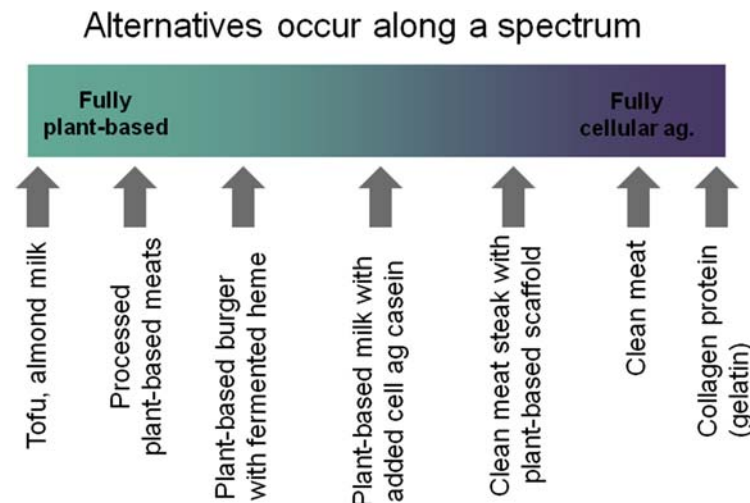

**Figure 2** Plant-based meat product mind map.

**Figure 3** Schematic of clean meat production.

**Figure 4** Spectrum showing progression of foods from fully plant-based to fully cellular agriculture.

continued research and technological development in ingredient sourcing, raw material isolation and functionalization, product formulation, and manufacturing technologies.

### Ingredient Sourcing

The vast majority of commercially available plant-based protein ingredients come from only 2% of the 150 plant species on which today's global food supply depends (Vernooij, 2003). A significant pool of potential plant protein sources is thus available for exploration, and this does not even take into account the nearly 250,000 additional plant species not currently used in large-scale agriculture. Innovation opportunities in this area include expanding and diversifying our use of plant protein sources, determining which sources are best suited for particular plant-based meat products, and ensuring that the proteins from these novel sources are optimized specifically for plant-based meat rather than for other plant-based foods that do not require proteins with the specific structural properties needed for meat analogues. While protein is often the primary ingredient consideration for meat analogues, it is also important to consider plant-based sources of fats and other ingredients that contribute to the sensory and nutritional profiles of plant-based meat products. Finally, all decisions related to plant sources for plant-based meat applications must be made within the context of agronomy so that the desirability of the plant's end-use characteristics is balanced with its suitability for production in particular geographic regions and climates.

### Raw Material Isolation and Functionalization

Some meat analogues, such as those made from jackfruit or certain types of mushroom, require minimal post-harvest processing of the source plant or fungus. However, many other plant-based meat products currently on the market rely upon plant protein concentrates or isolates as raw materials. To obtain refined ingredients such as proteins, fats, and starches from plants, the source plant is typically milled and processed to acquire more purified and concentrated ingredient fractions. The inherent characteristics of the proteins, such as molecular weight and amino acid composition, determine how well each protein concentrate or isolate will perform in the final product. The quality and performance of plant-based meat would be greatly advanced by implementing environmentally friendly methods for protein conditioning, which increase the desirable functional traits of a protein, such as gelation capacity, solubility, and fat adsorption. Moreover, the idea of processing plants into functional fractions instead of highly purified fractionates of single types of macromolecules may be beneficial not only in making the production of plant-based meat products more efficient, economical, and sustainable, but also for the sensory profiles of the products themselves (van der Goot et al., 2016).

### Product Formulation

Product formulation is a complex process that includes the culinary art of flavor selection, consideration of nutrition and ingredient interactions, and testing for desired texture and sensory attributes. Plant-based proteins—especially hydrolyzed proteins, which are more soluble and thus exhibit greater functionality—are often prone to bitter or “beany” off-flavors. This could be addressed by creating new bitter-blocking agents as part of a larger opportunity for developing new flavoring components, particularly those derived from natural sources and specifically designed to address the challenges of working with plant-based proteins. The selection

and incorporation of flavoring in the production process is vital for creating plant-based meat that replicates the sensory palette of animal meat.

Formulation must also consider the desired nutritional qualities of the plant-based meat product. In some cases, the goal is to replicate as precisely as possible the nutritional composition of animal-based meat. In other cases, product developers may intentionally alter the nutritional profile of the plant-based meat product in beneficial ways. For example, while animal-based meat contains no fiber, enhancing natural plant fiber incorporation into plant-based meat products without sacrificing taste and texture would provide a nutritive advantage to these products compared to animal-based meat. Given the complexity of product formulation, this process should include both culinary experts and food scientists.

### Manufacturing Technologies

After successful formulation, the mixture of ingredients that will become the final plant-based meat product must be structured and shaped into an appropriate form. Methods for transforming plant-based ingredient mixtures into meat analogues include a variety of manufacturing processes, such as stretching, kneading, shear-cell processing, press forming, folding, layering, and extrusion. Each of these processes can produce unique forms and textures of plant-based meat and affect the nutritional quality of the final product. Furthermore, different plant proteins perform differently in each of these manufacturing processes due to their unique compositions and functional properties. Therefore, it is essential to understand how particular plant proteins and combinations of plant proteins from various sources react to specific production techniques. Additionally, another manufacturing (and formulation) challenge involves identifying the optimal methods and timelines for combining proteins with other ingredients to ensure that the process is scalable and does not compromise the nutritional quality or sensory aspects of the end product. For example, how and when should fats, vitamins, and carbohydrates be mixed with the protein(s) to ensure that the end product cooks properly, possesses the desired nutritional profile, taste, and texture, and does not fall apart while eating? Critical needs exist for optimizing current technologies and developing novel manufacturing techniques for making plant-based meat, with particular emphasis on technologies that require minimal resource use, produce minimal waste, and could be easily adapted for use in rural areas and developing countries.

### Current Research and Development Needs for Clean Meat

Although plant-based meat analogues have been produced, sold, and consumed for millennia, clean meat has yet to be commercialized. In fact, the first clean meat prototypes have been produced only in the past five years. Despite the recent emergence of this industry, it is advancing rapidly due in large part to its ability to adapt underlying technologies from the fields of tissue engineering, stem cell biology, and cell-based therapeutics (Specht et al., 2018). Leveraging decades of research and billions of dollars of public investment into these relevant fields effectively provides the clean meat industry with an accelerated path to commercialization. The primary technological challenges currently facing the clean meat industry include further development and refinement of agriculturally relevant cell lines, cell culture media, scaffolding, and bioreactors. We briefly discuss these below. Because no clean meat products yet exist on the market, regulatory approval and consumer acceptance also need to be addressed as the technology develops (Specht, 2018).

#### Cell Lines

Clean meat production begins with obtaining primary cells and, in some cases, developing cell lines for the desired agriculturally relevant animal species. Generating a cell line means isolating a population of cells that is stable and capable of long-term proliferation in culture. In other words, the cell line must behave in a consistent and predictable way through many generations, while ideally maintaining an unlimited capacity to divide and efficiently differentiate. Creating cell lines for agriculturally relevant species that can be banked and then shared with researchers and companies around the world will limit duplication of effort from each individual researcher creating his or her own cell lines, and it will also enable more informative comparisons across different labs and food companies as there will be consistency in the starting cell line material.

#### Cell Culture Media

Just like cells inside an organism, cells in culture require nutrients to grow. Cell culture media is a nutrient solution containing salts, pH buffers, and the building blocks of cellular structures like proteins and fats. Animal cell culture media typically contains molecules called growth factors, which are signalling molecules that direct the cells to behave in certain ways. The cell culture media is likely to be a driving factor of clean meat cost at scale; as such, innovation in media ingredients and media recycling processes is a crucial need for commercialization of clean meat products that are cost-competitive with meat products currently on the market.

## Scaffolding

Scaffolds provide a support structure for cellular adherence. In the simplest case, microcarriers within a stirred bioreactor may act as scaffolds during cell proliferation. For more complex, structured products, the scaffold requirements are much more demanding and must be integrated within the final product. The material must be edible and/or biodegradable, inexpensive, derived from abundant sources, and amenable to large-scale fabrication. While the first clean meat products that come to market may not require significant scaffolding if they are primarily ground meat products or simply designed to be used as ingredients in other products, scaffolding supporting sophisticated, highly structured products incorporating multiple cell types — such as chicken breasts, pork chops, and steaks — will ultimately be required by the industry.

## Bioreactors

Bioreactors are the machines in which every other element in clean meat production is contained: where cells proliferate, and where the maturation from cells to meat occurs. As with media, clean meat bioreactors will have unique design requirements depending on the stage of production. Proliferation bioreactors are already widely used in industries ranging from pharmaceuticals to food ingredients so it is likely that more of the innovation in clean meat bioreactor technology will be needed for the maturation or differentiation step of the clean meat production process as opposed to the proliferation stage. Creating bioreactors or alternative technologies that enable easy harvest of the final meat product and require minimal inputs to function will help advance the clean meat industry. Simultaneous and coordinated advancement of all four of the above primary technology areas for clean meat (cell lines, cell culture media, scaffolding, and bioreactors) will be the most efficient way to move this industry forward, as these components all interact in complex ways. For example, cell culture media will need to be optimized for different cell lines; bioreactors must produce fluid dynamics that are tolerable by the cells; and parameters of the media like pH and density may affect the stability of the scaffold.

## Conclusion

Meat has long been synonymous with protein in Western culture and animal protein provides the vast majority of dietary protein intake in the US as the world population expands and developing countries gain greater wealth, the global demand for animal protein continues to increase. To meet this growing demand for animal protein, our food system has shifted to large-scale, industrialized methods of raising farm animals for food. The small-scale, regenerative farming of our grandparents' generation now exists for only a tiny fraction of animal protein production and typically commands premium prices, rendering it inaccessible to a large fraction of the population.

Yet there is growing recognition that our current methods of industrialized animal agriculture are not sustainable. Emerging innovation in two specific areas — plant-based meat and clean meat — show promise for revolutionizing our food system. These areas represent both tremendously profitable market opportunities and substantial promise for addressing the urgent challenges facing our global food supply. For this to happen expeditiously, there is an urgent need for additional technical talent and expertise from around the world to enter these industries; the next generation of scientists and entrepreneurs will play a critical role in advancing the quality, cost, and availability of plant-based and clean meat products, positioning them as economically viable and sustainable sources of protein. If successfully implemented on a global scale, a food system with a much greater reliance on plant-based and clean meat has the potential to sustainably feed 9.7 billion people by 2050, mitigate climate change and other pressing environmental problems, reduce animal suffering, and decrease global public health issues such as antibiotic resistance, zoonotic threats, and diet-related chronic disease.

# Anthocyanidins and Anthocyanins

Giovana B Celli, Chen Tan, and Michael J Selig, Cornell University, Ithaca, NY, United States

© 2019 Elsevier Inc. All rights reserved.

## Overview

Anthocyanidins (or glycosidic forms, anthocyanins) are members of the flavonoid class of secondary metabolites and highly important water-soluble pigments in plants. They are polyhydroxy or polymethoxy derivatives of the flavylium cation (2-phenylbenzopyrylium ion), containing a C-15 backbone structure arranged in two C-6 benzyl rings (A and B) and a heterocyclic C-3 ring (C) (Zaffino et al., 2015). More than 700 compounds have been described in the literature (Andersen and Jordheim, 2013) and mainly derive from six anthocyanidins: cyanidin, delphinidin, pelargonidin, peonidin, petunidin, and malvidin (Kahkonen and Heinonen, 2003). Their structure is shown in Fig. 1.

In plants, anthocyanins accumulate in vacuoles of certain cells in vegetative and reproductive organs (Mushtaq et al., 2016) and are responsible for functions involved in the preservation and protection against biotic and abiotic stress. For instance, they act as sunblock that protects the plant against photo-oxidation (Feild et al., 2001) and exhibit antioxidant activity by scavenging reactive oxygen species generated during normal plant metabolism (Nakabayashi et al., 2014). Human consumption of anthocyanins has been associated with reduced risk of degenerative diseases (Cassidy et al., 2013), although a considerable gap still exists between *in vitro* study results and those confirmed *in vivo* (Celli et al., 2016).

## Chemistry of Anthocyanins

Owing to their physicochemical properties (e.g., poor stability and low solubility), anthocyanidins (aglycone) are most often found in nature as salts of their glycosidic forms, known as anthocyanins (ACNs). Glycosylation results in the formation of an intramolecular H-bonding network that helps stabilize the ACN molecule, in addition to improve its water solubility (Borkowski et al., 2005). These ACNs can differ in relation to the type, number, and position of the sugar moieties attached to the main backbone. Glucose, galactose, rhamnose, arabinose, xylose, and rutinose are the sugar groups frequently attached to anthocyanidins by substitutions of the hydroxyl groups in positions 3 (i.e., 3-glycosides) and 5 (i.e., 3,5-diglycosides). Other structures identified include 3-diglycosides, 3-diglycoside-5-monoglycosides, and 7-glycosides. In certain cases, these sugar groups can be esterified (acylated) with organic aliphatic or aromatic acids (e.g., caffeic, ferulic, cinnamic, malonic, acetic, and malic acids). Acylation with organic acids can also improve ACN stability; however, unlike glycosylation, acylation reduces their water solubility (He and Giusti, 2010).

In addition to their chemical structure, the stability of ACNs is also affected by variations in pH, temperature (Sui et al., 2014), oxygen (Weber et al., 2017), light (Mahdavi et al., 2016), water activity (Tonon et al., 2010), and the presence of other compounds (e.g., ascorbic acid) (Guldiken et al., 2017). Overall, ACNs are unique flavonoids as they can rearrange and form resonant structures with changes in the pH, which affects their color and stability. The different forms observed for ACNs are the flavylium cation ( $AH^+$ , orange/red), quinoidal base (A, blue/violet), carbinol pseudobase (B, colorless), and chalcone (C, yellow), shown in Fig. 2.  $AH^+$  predominates at very acidic conditions (generally below pH 2) and it is the most stable form. At mild acidic conditions, this cation is converted into bases by deprotonation of one of the three most acidic phenolic OH groups (in C7, C4', or C5, in this order). When the pH is close to neutrality, A can lose another proton and form its ionized form,  $A^-$ . It is also possible that, above pH 2,  $AH^+$  becomes hydrated at C2 forming B that rapidly equilibrates with  $C_{cis}$ , which is itself in a slow equilibrium with  $C_{trans}$  (Trouillas et al., 2016). In general, the ACN stability is significantly compromised at pH values close to neutrality. It is also interesting to note that these forms can coexist in equilibrium, as shown in Fig. 3.

Modifications of the main ACN structure can also modify the color exhibited. For instance, an increase on the number of hydroxyl and methoxyl substitutions has been associated with blue and red hues, respectively (Delgado-Vargas et al., 2000), whereas purplish shades were observed with substitution on position 5 or acylated with cinnamic acids (Stintzing et al., 2002). However, variations in pH and structural transformations alone are not sufficient to explain the diversity of ACN-based hues found

**Figure 1** Basic structure of the anthocyanidins (left) and substituents of the six major types of molecules found in nature (right). The numbering systems presented is the most commonly accepted for these compounds.

**Figure 2** Resonant structures of ACNs as a function of the pH.  $K_a$ ,  $K_h$ ,  $K_t$ , and  $K_i$  refer to the acidity, hydration, hemiketal-chalcone tautomerization, and *cis-trans* chalcone isomerization thermodynamic constants. Reproduced with permission from Trouillas et al. (2016), © 2016, American Chemical Society.

in nature. In fact, these compounds can be associated with other polyphenols (Wigand et al., 1992) and/or metals (Buchweitz et al., 2013) to produce a variety of hues and improve their stability *in vivo*. A unique feature of ACNs is the copigmentation phenomenon that serves to protect the flavylium cation from nucleophilic attack and, consequently, stabilize color by weak association with polyphenols (Teixeira et al., 2013), carbohydrates (Fernandes et al., 2016), among others. Additionally, ACNs can donate protons to free radicals, thus preventing their propagation, or chelate metal ions that can lead to the formation of these radicals, which are the underlying mechanisms of their antioxidant activity.

## Extractions From Food Sources

ACN-rich extracts can be prepared from fresh, frozen, or dried plant materials. Examples of plant materials rich in ACNs include blueberry (Skrede et al., 2000), elderberry (Veberic et al., 2009), purple corn (Pedreschi and Cisneros-Zevallos, 2007), among others. The particle size of source materials is an important factor during extraction; they are often milled or ground to increase available surface area and, consequently, the amount of compound extracted. Liquid nitrogen can be used during the grinding step to reduce ACN degradation. Since these compounds are susceptible to degradation by various factors, considerable care should be taken when designing and carrying out the extraction procedure.

**Figure 3** Graphic representation of the mole fractions of catechin-(4,8)-malvidin-3-*O*-glucoside structures (from red wine), with variations of pH. Abbreviations: flavylium cation,  $AH^+$ ; quinoidal base and its ionized form, A and  $A^-$ , respectively; hemiketal or carbinol pseudobase and its ionized form, B and  $B^-$ , respectively; *cis*-chalcone,  $C_{cis}$ ; *trans*-chalcone,  $C_{trans}$ . Reproduced with permission from Nave et al. (2010), © 2010, American Chemical Society.

Extraction procedures are commonly classified as solid or liquid extraction. Solid extraction is applied to liquid matrices, although typically only during purification rather than extraction due to saturation of the absorbents. Liquid extraction yields good recovery of ACNs and is the most-used technique to extract from fruit samples. In general, ACNs are commonly extracted with acidified water and polar organic solvents (methanol, ethanol, and acetonitrile) due to their hydrophilic nature. More recently, the use of deep eutectic solvents (e.g., lactic acid-glucose and choline chloride-malic acid mixtures) has been proposed as a green alternative to extract ACNs in favor over conventional (and often toxic) organic solvents (Dai et al., 2016). The extraction system can also interfere with subsequent analytical procedures, which is an important consideration when designing a study. For example, Myjavcova et al. (2010) noticed that less polar solvents (ethanol and acetone) used for the extraction of ACNs from haskap berries compressed the Sephadex LH-20 gel used for extract purification. This resulted in longer retention times when the fractions were analyzed by high-performance liquid chromatography and, additionally, the co-extraction of impurities. This study also noted that acetone had a low extraction efficiency and formed ACN-derived complexes (5-methyl-pyranoanthocyanin) which were not found in fresh fruits (Myjavcova et al., 2010).

In relation to the techniques, various methods have been developed to increase the efficiency of liquid extractions, decrease the processing time, and minimize the use and exposure to organic solvents. Examples are supercritical fluid extraction (Maran et al., 2014), pressurized liquid extraction (Feuereisen et al., 2017), microwave-assisted extraction (Pap et al., 2012), and ultrasound-assisted extraction (Celli et al., 2015).

### Proposed Mechanisms of Action

Several studies have found a positive link between ACNs and health-promoting properties, mostly in *in vitro* and animal studies. A potential cause for the gap that exists between the results obtained *in vitro* and the clinical practice would be the short residence time of the parent ACNs in their absorption window and in sites in the body where their stability is favored (Celli et al., 2016). Although the stomach is not often considered an absorption site of exogenous molecules, there is a considerable amount of evidence supporting the role of this organ in ACN absorption (Talavera et al., 2003) via bilitranslocase carrier (Passamonti et al., 2003), in addition to the small intestine (Mueller et al., 2017). The compounds that are not absorbed are extensively degraded by changes in pH and metabolized by host enzymes or intestinal microbiota, and eliminated mainly through feces and urine.

As with other flavonoids, ACNs are most known for their antioxidant activity, by scavenging free radicals or metals that could generate such radicals. Structure-antioxidant activity relationships have been strongly demonstrated by earlier researchers (Azuma et al., 2008; Rice-Evans et al., 1996). More specifically, the antioxidant activity of anthocyanidins greatly depends on the functional groups present on the B-ring and as well as different glycosylation patterns. Generally, the antioxidant activity increases with an increasing number of hydroxyl substituents present on the B-ring. Wang et al. (1997) reported that glycosylation of cyanidin to cyanidin 3-glucoside improved the antioxidant activity, whereas glycosylation of malvidin and pelargonidin to the corresponding

3-glucosides decreased the activity. On the other hand, antioxidant action resulting from differences in glycosylation can be closely related to the assay used. [Kahkonen and Heinonen \(2003\)](#) studied six common anthocyanidins and their glycosidic forms in three lipid-containing models and found that most ACNs and their aglycones exerted strong antioxidant activity in emulsions and human low-density lipoprotein (LDL), but weak activity or even pro-oxidation in bulk oil.

ACNs have additionally been associated with antidiabetic by activation of AMP-activated protein kinase (AMPK) ([Takikawa et al., 2010](#)), anti-inflammatory by downregulation of cyclooxygenase (COX)-2 ([Pereira et al., 2017](#)), and neuroprotective properties by improving the glutamatergic neurotransmission ([Shah et al., 2015](#)), as well as the prevention and improvement of cardiovascular diseases by increasing the superoxide dismutase antioxidant activity ([Wang et al., 2017](#)). A summary of health beneficial properties and some of the proposed mechanisms of action based on *in vitro* and *in vivo* studies is provided in [Table 1](#). In one example, ACN-rich extracts from maqui berry were shown to ameliorate diabetic conditions *in vitro* by reducing glucose production and increasing its uptake ([Rojo et al., 2012](#)). Compared to insulin, ACNs were shown to have a mild effect on the downregulation of the gene for glucose-6-phosphatase (G6Pase), an enzyme that catalyzes glucose-6-phosphate hydrolysis to liberate free glucose into circulation. However, significant increases in glucose uptake were observed in cells treated with ACNs alone or in combination with insulin and it has been suggested that ACNs may sensitize the cells to insulin ([Martineau et al., 2006](#); [Rojo et al., 2012](#)).

On the prevention and amelioration of cardiovascular disease, it has been shown that ACNs can inhibit 15-lipoxygenase and xanthine oxidase that produce reactive oxygen species in vascular cells ([Bräunlich et al., 2013](#)). Furthermore, one *in vitro* study ([Edirisinghe et al., 2011](#)) demonstrated that ACNs from black currant enhance the activation of endothelial nitric oxide synthase (eNOS), which also has positive effects on the cardiovascular system through increased nitric oxide production. In a study using rats, [Liu et al. \(2015\)](#) showed that animals treated with blueberry ACNs presented an attenuation of mean arterial blood pressure (by approximately 15 mmHg) and heart rate (around 100 bpm) after cyclophosphamide-induced cardiac injury. The beneficial effect of ACNs on blood pressure was observed in a cross-sectional study with 1898 women, where high intake of these compounds was associated with a significantly lower blood pressure ([Jennings et al., 2012](#)).

**Table 1** Health-related properties of anthocyanins and proposed mechanisms of actions

(2014)</a> <a href="#">Badshah et al. (2015)</a>
<i>In vivo</i>	Antidiabetic	Activation of AMPK and expression of glucose membrane transporters. Downregulation of G6Pase Activation of insulin receptor phosphorylation, increasing glucose uptake, and prevented apoptosis of pancreatic cells	<a href="#">Takikawa et al. (2010)</a> <a href="#">Nizamutdinova et al. (2009)</a>
	Anti-inflammatory	Reduction of pro-inflammatory molecules (interleukin-6, monocyte chemoattractant protein-1, and tumor necrosis factor- $\alpha$ ) Downregulation of inducible nitric oxide synthase (iNOS) and COX-2	<a href="#">Sogo et al. (2015)</a> <a href="#">Pereira et al. (2017)</a>
	Prevention and amelioration of cardiovascular diseases	Attenuation of mean arterial blood pressure (by ~5–15 mmHg) and heart rate (by ~100 bpm) after cyclophosphamide-induced cardiac injury. Improvement of cardiac dysfunction and left ventricular hypertrophy Reduction of cytokine levels (by almost 100 pg/mL) and increase of superoxide dismutase antioxidant activity (by ~3 U/mL) after exposure to fine particulate matter	<a href="#">Liu et al. (2015)</a> <a href="#">Wang et al. (2017)</a>
	Neuroprotection	Reduction of glutamate-induced neurotoxicity and increased the content of glutathione and other endogenous antioxidants Improved glutamatergic neurotransmission, synaptic dysfunction, and neural apoptosis by stimulating specific pathways in the hippocampus	<a href="#">Shah et al. (2016)</a> <a href="#">Shah et al. (2015)</a>

Additionally, ACNs have been demonstrated to have neuroprotective effects. In one pig-based study (Kalt et al., 2008), blueberry ACNs (1.3–8.5 to 6.6–42.3  $\mu\text{mol/kg}$  of body weight) were shown to be distributed to various organs and tissues following prolonged consumption, including the eyes (average 1.58 pmol/g of tissue, in a fresh weight basis), liver (1.30 pmol/g), brain cortex (0.878 pmol/g), and cerebellum (0.664 pmol/g); even when consumed for just a short period of time (four weeks). In the brain, ACNs can suppress the dopaminergic cell death via modulation of mitochondrial dysfunction and the release of pro-inflammatory nitrite from microglial cells, both of which are important factors in the development and progression of Parkinson's disease (Strathearn et al., 2014). In this and other health beneficial contexts, it should be noted that most of the benefits identified in *in vitro* or animal studies have not been confirmed in clinical trials.

## Conclusion

Continuing public concern over the healthfulness and nutritional quality of foods and other products intended for human consumption will inevitably continue to drive growing demand for the utilization and study of anthocyanins. The structural diversity of these flavonoids already makes them suitable in a range of applications. Still, this diversity leaves significant room for research and product-specific developments aimed at improving the stability and functionality of the many specific variations available. Furthermore, increasing reports highlighting new health benefits anthocyanins have to offer consumers will certainly lead to growth in the importance in a range of industries.

### Diet and Diseases

The increasing embrace of preventive, dietary and alternative approaches to cancer therapy stem from the failure of conventional methods to stem the tide of the disease or provide reliable and effective treatment outcomes. Worldwide, cancer remains a leading cause of mortality with developing countries where the disease was hitherto not common now witnessing very high incidence and prevalence. One of the reasons adduced for this trend is the increasing shift from traditional to western diets. This partly makes cancer a diet-related disease, and the focus on anticancer functional foods and nutraceuticals is, therefore, plausible.

The notion that foods may possess the ability to prevent disease and or be used as treatment of ailments dates back a couple millennia. Hippocrates proclaimed some 2500 years ago, "Let food be thy medicine and medicine be thy food" (Wildman, 2000). Recent experimental, epidemiological and clinical evidences have established negative correlations between the quality of diet and incidence, mortality and morbidity from chronic and non-infectious diseases (Bontempo et al., 2015; Reedy et al., 2014; Thorburn et al., 2015; Siri-Tarino and Krauss, 2016; Lange et al., 2017; Yeh et al., 2016; Taylor et al., 2017; Mahady and George, 2016; Imperatore et al., n.d.). Moreover, the choice of diet after cancer diagnosis may improve survival (Playdon et al., 2017).

### Dietary Phytochemicals and Cancer

Dietary phytochemicals have been shown to be the major components in diets conferring these observed health benefits and their chemopreventive, carcinopreventive and anti-cancer properties have been demonstrated in several studies. A large number of dietary phytochemicals have been demonstrated to have anti-proliferative, anti-metastatic, antioxidant, reactive oxygen species (ROS)-inducing, anti-angiogenic and pro-apoptotic effects including efficacy in targeting cellular molecules and pathways implicated in malignancy. Combinational therapy of phytochemicals with standard therapeutic drugs has also been proposed (Banudevi et al., 2015; González-Vallinas et al., 2013; Ma and Adjei, 2009). In addition, observational studies have revealed an inverse relationship between consumption of polyphenol-rich diets and the incidence of cancer (Rosato et al., 2016; Filomeno et al., 2015).

### Flavonoids

#### Biological Activities of Flavonoids

Polyphenolic compounds, or polyphenols, are polyhydroxylated phytochemicals, of which the two main classes comprise flavonoids and phenolic acids (Lotito and Frei, 2006). Flavonoids are a large family of polyphenolic compounds that have a common chemical structure. With their broad spectrum of pharmacological activities and ubiquity in the plant kingdom, they are arguably the class of phytochemicals eliciting the most interest as well as the most promising in cancer chemoprevention through dietary and herbal interventions.

Flavonoids are a broad and biologically active class of polyphenolic compounds. They are one of the largest and most widespread groups of plant secondary metabolites, with marked antioxidant properties (Corradini et al., 2011). The number of individual molecules in this class of phytochemicals has been estimated to be over 10,000 (Amawi et al., 2017; George et al., 2017). Other pharmacological effects ascribed to flavonoids include antimicrobial (Thongnest et al., 2013; Bahrin et al., 2014; Iranshahi et al., 2015), hepatoprotective (Farombi et al., 2009; Olaleye et al., 2014a; Vázquez-Flores et al., 2017), renoprotective (Cai et al., 2017; Athira et al., 2016), antidiabetic (Keshari et al., 2016; Unnikrishnan et al., 2014; Wang et al., 2017), protection against reproductive dysfunctions, cardioprotective (Olaleye et al., 2014b; Testai, 2015; Lv et al., 2017), anti-arthritis (Somasundaram et al., 2013; Li et al., 2015; Liu et al., 2017), neuroprotective and anti-neurodegenerative (Choudhary et al., 2011; Nabavi et al., 2015; Ayuso et al., 2017; Falode et al., n.d.; Preethi Pallavi et al., 2018), gastroprotective (Mota et al., 2009; Antonisamy et al., 2016; Hari Babu et al., 2010; Olaleye and Akinmoladun, 2013), antigenotoxic and antimutagenic (Nwankwo et al., 2000; Snijman et al., 2007; Zarev et al., 2017; Serpeloni et al., 2015; de Carvalho-Silva et al., 2014); and antiproliferative, antimetastatic and carcinoprotective (George et al., 2017; Yang et al., 2008; Rengarajan and Yaacob, 2016; Klimaszewska-Wiśniewska et al., 2017) properties. Epidemiological studies have established inverse relations between flavonoid intake and the incidence of cancer (Zamora-Ros et al., 2014; Petrick et al., 2015).

## Flavonoid-Rich Foods

Flavonoids are ubiquitously present in fruits and vegetables and are the most abundant species of phytochemicals in human diets with their mean daily intake in the diet estimated to be up to approximately 500 mg (Havsteen, 2002; Burkard et al., 2017; Dai and Mumper, 2010). Being phytochemicals, they cannot be synthesized by humans or animals and can only come from plant sources (Kumar and Pandey, 2013). Flavonoids occur either as the aglycones or glycosides in nature. Generally, the aglycones show better activity as glycosylation renders the flavonoid more polar and less reactive (Corradini et al., 2011). Table 1 shows some exceptionally rich dietary sources of flavonoids.

## Chemistry

Flavonoids are synthesized via the phenylpropanoid pathway and are localized inside vacuoles in virtually every part of a plant (Catarino et al., 2016). As depicted in Fig. 1, the basic structure is a 15-carbon benzopyranone or benzopyran in which the three-carbon bridge between the phenyl groups is commonly cyclised with oxygen forming a C<sub>6</sub>–C<sub>3</sub>–C<sub>6</sub> flavan nucleus. Simply put, the flavonoid backbone consists of two benzene rings (A and B) linked via a heterocyclic pyrene ring (C) (Corradini et al., 2011; Kumar and Pandey, 2013; Beltz et al., 2006).

The main subclasses of flavonoids are flavones, isoflavones, flavanones, flavonols, flavanols (also called catechins), and anthocyanidins (Fig. 2). As shown in Fig. 3, the various classes of flavonoids differ in the level of oxidation and pattern of substitution of the C ring, while individual compounds within a class differ in the pattern of substitution of the A and B rings (Kumar and Pandey, 2013). Although most flavonoids have their Ring B attached to the C<sub>2</sub> position of Ring C, some flavonoids such as isoflavones and neoflavonoids, whose Ring B is connected at the C<sub>3</sub> and C<sub>4</sub> position of Ring C, respectively, also occur

**Table 1** Selected flavonoid-rich foods

<i>Food</i>	<i>Main flavonoids</i>	<i>Flavonoid subclass</i>	<i>References</i>
<b>Fruits</b>			
Apple	Quercetin, Myricetin, Kaempferol, Epicatechin, Catechin, Epigallocatechin gallate	Flavanols	Lotito and Frei, 2006; Hooper et al., 2008; Macready et al., 2014; Bertoia et al., 2016
Pears	Quercetin, Myricetin, Kaempferol, Epicatechin, Catechin, Epigallocatechin gallate	Flavanols	Lotito and Frei, 2006; Bertoia et al., 2016

**Figure 2** Major categories of flavonoids. Source: Catarino, M.D., Talhi, O., Rabahi, A., Silva, A.M.S., Cardoso, S.M., 2016. The antiinflammatory potential of flavonoids. Stud. Nat. Prod. Chem. 48, 65–99.

plants. Chalcones (flavan-opened chain compounds) though lacking the heterocyclic Ring C, or 5-membered C-ring derivatives aurones and auronols are still categorized as members of the flavonoid family (Beltz et al., 2006; Cheng et al., 2016). These basic structures of flavonoids are aglycones; however, in plants, most of these compounds exist as glycosides. Biological activities of these compounds, including antioxidant activity, depend on both the structural difference and the glycosylation patterns.

Flavones, flavonols, flavanones and flavanols flavonoid subgroups are the most common, and almost ubiquitous, throughout the plant kingdom. Flavones and their 3-hydroxy derivatives flavonols, including their glycosides, methoxides and other acylated products on all three rings, make this the largest subgroup among all polyphenols. The most common flavonol aglycones, quercetin and kaempferol, alone have at least 279 and 347 different glycosidic combinations, respectively. Isoflavones are mostly found in the leguminous family of plants and have great impact on human health since beans are a major part of the diet in many cultures. Neoflavonoids are not often found in food plants while the open-ring chalcones are found in fruits such as apples (Cheng et al., 2016).

### Anticancer Property of Flavonoids

Flavonoids can exhibit anticarcinogenic effects due to their antioxidant property, ability to regulate signaling pathways involved in carcinogenesis, interaction with proteins that control cell cycle progression and effective modulation of the wingless-related integration site (Wnt) signaling pathways in which most conventional therapeutics are ineffective (Ramos, 2008). Flavonoids can interfere with all three stages of cancer: initiation, development and progression by modulating cellular proliferation, differentiation, apoptosis, angiogenesis as well as metastasis (Kris-Etherton et al., 2002). Moreover, the chemopreventive effect of dietary flavonoids is quite specific as cancerous cells have been shown to be more sensitive to polyphenol actions than normal cells (Brglez Mojzer et al., 2016).

Polyphenols, including flavonoids have some distinct properties that contribute to their efficacy as anticancer agents. They are reported to differentially show cytoprotective effects toward normal cells and cytotoxic effects toward cancerous cells and to regulate

**Figure 3** Main classes of flavonoids and examples. Source: Catarino, M.D., Talhi, O., Rabahi, A., Silva, A.M.S., Cardoso, S.M., 2016. The anti-inflammatory potential of flavonoids. *Stud. Nat. Prod. Chem.* 48, 65–99.

growth factor-receptor interactions and cell signaling cascades that can induce cell cycle arrest and have impact on cell survival and apoptosis of cancerous cells (Ramos, 2008; Tabrez et al., 2013). Depending on their concentration, target molecules, cell type and other conditions, they can induce apoptosis through pro-oxidative action that is exerted instead of their anti-oxidative action (Brglez Mojzer et al., 2016; Beltz et al., 2006). In addition, polyphenols help to establish the body's immune system by inhibiting

angiogenesis necessary for tumor growth and act also as anti-inflammatory agents (Tabrez et al., 2013). In the final stages of cancer, polyphenols attenuate the adhesiveness and invasiveness of cells therefore reducing their metastatic potential (Brglez Mojzer et al., 2016).

### Anticancer Mechanisms of Flavonoids

A large amount of data exists on the biochemical and molecular mechanisms of the carcinoprotective property of flavonoids. Some general properties of flavonoids which underlie their biological activities are also applicable to their anticancer effect but other unique mechanistic aspects are also involved. The tumour microenvironment is dynamic and complex and phytochemicals, including flavonoids have been widely documented to directly or indirectly target multiple signaling pathways and networks in cancer cells (Cheng et al., 2016).

### Modulation of Redox Balance

Flavonoids are potent antioxidants *in vitro*, mainly due to their low redox potential and ability to donate electrons or hydrogen atoms. For example, catechins have a redox potential of +0.53–0.57 V, which from a thermodynamic standpoint enables them to protect urate (+0.59 V), but not ascorbate (+0.28 V), from oxidation by peroxy radicals (+1.06 V). The redox potentials of quercetin and (–)-epigallocatechin gallate (EGCG) are even lower (+0.33 and 0.43 V, respectively), which places them close to ascorbate in the biological antioxidant network (Lotito and Frei, 2006; Bors et al., 2001; Jovanovic and Simic, 2000).

Cancer is characterized by increased aerobic glycolysis and oxidative stress. The link between ROS and cellular transformation was first identified in 1981, when it was found that insulin elevated intracellular  $H_2O_2$  levels and increased tumour cell proliferation suggesting the potential efficacy of antioxidant therapy. In addition, commonly used radio- and chemotherapeutic drugs can influence tumor outcome through ROS modulation. However, it is now apparent that the link between oxidative stress and cancer is far from simplistic (Roleira et al., 2015). ROS could promote or act as barrier to tumorigenesis depending on their levels. The redox status of cancer cells usually differs from that of normal cells with cancer cells exhibiting elevated ROS levels because of metabolic and signalling aberrations. This is said to influence development of powerful antioxidant mechanisms and alternative pathways by which pre-neoplastic cells evade the deleterious consequences of large amounts of ROS accumulation without compromising the energy demand required by cancer cells. At low to moderate levels, ROS may contribute to tumour formation either by acting as signalling molecules or by promoting the mutation of genomic DNA. For instance, ROS can stimulate the phosphorylation of mitogen-activated protein kinase (MAPK) and extracellular signal-regulated kinase (ERK), cyclin D1 expression and JUN N-terminal kinase (JNK) activation (Gorrini et al., 2013; Sosa et al., 2013). Based on the foregoing, it has been opined that targeting enhanced antioxidant defence mechanisms may represent a strategy that can specifically kill cancer cells, including tumour initiating cells TICs, while sparing normal cells (Gorrini et al., 2013). Supplemental antioxidants have become an important strategy in ROS-scavenging, and therefore cancer chemoprevention. Some antioxidants can also act as potent pro-oxidants, sensitizing cancer cells to chemotherapy (El Bairi et al., 2017). Flavonoids also act by inhibiting prooxidant enzymes. Downregulation of superoxide-producing NADPH oxidase 1 (NOX 1) reversed tumor growth while its overexpression is associated with tumor progression (Fukuyama et al., 2005; Arnold et al., 2007). In addition, lipoxygenases (LOX), cyclooxygenases (COXs), and xanthine oxidase (XO) are metalloenzymes whose catalytic cycle involves ROS such as lipid peroxy radicals, superoxide, and hydrogen peroxide. Flavonoids may exert part of their anti-oxidant and anti-inflammatory activities via direct inhibition of these prooxidant enzymes (LOXs, COXs, and XO), which are also important inflammatory cascades (Batra and Sharma, 2013). ROS function as secondary messengers in several pathways that contribute to increase in cell proliferation, resistance to apoptosis, in addition to activation of proto-oncogenes such as cFOS, cJUN and cMyc. In human hepatoma cells, ROS modulated the expression of cFOS and cJUN through PKB pathway (Liu et al., 2002). The inhibitory property of flavonoids against prooxidant enzymes can, therefore be intertwined with other distinct inhibition mechanisms such as the anti-inflammatory mechanism.

### Induction/Inhibition of Drug Metabolizing Enzymes

Flavonoids are good substrates and inducers of phase II enzymes. The capacity of flavonoids to induce detoxifying enzymes is regarded as a major mechanism by which flavonoids protect against mutagens and carcinogens. Flavonoids can interact with phase I xenobiotic metabolizing enzymes (such as various isoforms of the heme-containing cytochrome P450 (CYP) monooxygenases), which has been associated with the generation of oxidative stress in the liver and involved in the activation of procarcinogens (Lotito and Frei, 2006; Martín and Ramos, 2016; Hodek et al., 2009). Flavonoids also modulate the detoxification of carcinogens through induction of phase II enzymes such as UDP-glucuronyl transferase, quinone reductase and glutathione S-transferase (Cederbaum and Muriel, 2017). Flavonoids can affect CYP activity in several ways including regulation of gene expression and direct binding to the enzyme. For example, quercetin binds to aryl hydrocarbon receptor (AhR) as an agonist and stimulates gene expression for CYP 1A1 with a parallel increase in CYP 1A1-mediated O-deethylation of 7-ethoxyresorufin in human breast cancer cells. Flavones and flavonols, also directly bind to several CYP isoforms (1A1, 1A2, 1B1, 3A4) involved in xenobiotics metabolism and inhibit enzyme activity. Flavonoids can positively influence cellular level of UDPglucuronosyltransferases (UGT), sulfotransferases (SULT), glutathione transferases (GST), N-acetyltransferases, which are all phase II enzymes. For example, increased mRNA levels, protein

expression and enzyme activity of UGT isoform 1A1 by chrysin, apigenin, baicalein, diosmetin, quercetin and kaempferol has been reported in human Hep G2 cells and human colon carcinoma cells (Batra and Sharma, 2013; Sugatani et al., 2004).

### Genome Stabilization

Carcinogenesis involves genetic and epigenetic changes that lead to the initiation, promotion, and progression of cancer. DNA damage, which could be caused by exposure to ultraviolet radiation (UVR), ionizing radiations (IR), mutagenic chemicals, environmental agents, therapeutic agents or diagnostic imaging instruments can lead to carcinogenesis. Maintaining genomic integrity is, therefore highly important for the organism (George et al., 2017; Weitzman et al., 2010). Several studies have shown that dietary flavonoids prevent DNA damage thereby contributing to genomic stability and cancer prevention. For instance, quercetin, quercitrin, isoquercitrin and rutin isolated from the leaves of *Scutia buxifolia* L. were found to protect against chromosome damage in cultured human lymphocytes by retaining mitotic index (at a concentration of 50 µg/mL) and genomic stability (at the concentration range of 1–100 µg/mL) against H<sub>2</sub>O<sub>2</sub>-induced toxicity (Boligon et al., 2012).

### Inhibition of Multidrug Resistance

Typically, in cancer cells, there is overexpression of P-glycoprotein (Pgp) or multidrug resistance associated protein (MRP) which is a group of ATP-dependent transmembrane transporters capable of expelling a wide variety of chemically unrelated drugs used in cancer therapy at the expense of ATP hydrolysis. This phenomenon is known as multidrug resistance (MDR) and its inhibition to prevent drug efflux has potential clinical applications during cancer therapy. Quercetin (10, 30 or 100 µM) and Kaempferol (10 or 30 µM) in different *in vitro* experimental set-ups, were shown to inhibit P-Glycoprotein function and expression (Batra and Sharma, 2013; Chen et al., 2010; Kioka et al., 1992; Limtrakul et al., 2005).

### Anti-angiogenesis

Flavonoids inhibit angiogenesis and this activity can cause non-diffusion of nutrients and oxygen to rapidly growing cancerous cells due to anti-angiogenic properties and hence lead to cell death. Inhibition of angiogenesis could be through the inhibition of PKs. Luteolin was found to inhibit VEGF-induced angiogenesis and endothelial cell survival and proliferation by targeting phosphatidylinositol-3-kinase action (Tosetti et al., 2002; Bagli et al., 2004). He et al. (2011) indicated that hispidulin targets the VEGF receptor 2-mediated PI3K/Akt/mTOR signaling pathway in endothelial cells, leading to the suppression of pancreatic tumor growth and angiogenesis.

### Induction Apoptosis and Cell Cycle Arrest

Poly (adenosine diphosphate-ribose) polymerase (PARP) is involved in DNA repair, genomic stability and apoptosis. Flavonoids induce the cleavage of PARP which contributes to cell cycle arrest. Also, the tumour suppressor gene, p53 plays a pivotal role in controlling the cell cycle, apoptosis, genomic integrity, and DNA repair (Caltagirone et al., 2000) by acting as transactivator or as transrepressor (Ho et al., 2005). After activation, p53 can bind to regulatory DNA sequences and activate the expression of genes involved in cell cycle inhibition (p21, reprimin, cyclin G1, GADD45), apoptosis (PERP, NOXA, PUMA, p53AIP1, ASPP1/2, Fas, BAX, PIDD) and genetic stability (p21, DDB2, MSH2, XPC). Epigallocatechin 3-gallate (EGCG) activated p53 and BAX in breast carcinoma cells. Using MDA-MB-468 human breast cancer cell line as an *in vitro* model of ER-negative breast cancers, it was found that treatment with EGCG resulted in dose-dependent (5–80 µg/mL) and time-dependent (24–72 h) inhibition of cellular proliferation and cell viability in MDA-MB-468 cells with decrease in cell viability associated with the induction of apoptosis (Roy et al., 2005). Genistein (100 µM) induced G2/M arrest and apoptosis in human malignant glioma cell lines by activating p53 and p21 (Schmidt et al., 2008). Flavonoids may block one or more steps in the NF-κB signaling pathway. The NF-κB target genes influenced by the flavonoids include inhibition of Bcl-2 and Bclx(L), cyclin D1, matrix metalloproteinases (MMP), and VEGF. Flavonoids have been found to suppress activator protein-1 (AP-1) activation and modulate AP-1 target genes (Batra and Sharma, 2013; Schmidt et al., 2008; Li et al., 2006).

Summarily, flavonoids act on specific tumor and stromal targets which could be grouped as membrane-bound receptor kinases (HGF/c-Met, human epidermal growth factor receptor and insulin growth factor receptor pathways), intracellular signalling kinases (Src, PI3k/Akt/mTOR, and mitogen-activated protein kinase pathways), epigenetic abnormalities (DNA methyltransferase and histone deacetylase), protein dynamics (heat shock protein 90, ubiquitin-proteasome system), and tumor vasculature and micro-environment (angiogenesis, HIF, endothelium, integrins) (Ma and Adjei, 2009) (Fig. 4).

### An Overview of the Interaction of Some Dietary Flavonoids With Enzymatic and Molecular Targets

Many studies have reported the anticancer property of flavonoids and flavonoid containing food and the list continues to grow almost on a daily basis. An exhaustive or detailed treatment is not possible within the scope of this article.

**Figure 4** Scheme showing regulatory processes, proteins, factors and signalling pathways inhibited (↓) or activated (↑) by flavonoids leading to anti-cancer effects. Flavonoids interact with multiple cellular and molecular targets thereby regulating a wide variety of cell function. Key: **IKK**, I kappa B kinase; **NF-κB**, nuclear factor kappa-light-chain-enhancer of activated B cells; **TNF-α**, tumor necrotic factor alpha; **IL-1,6**, interleukin 1,6; **MPO**, myeloperoxidase; **COX**, cyclooxygenase; **PGE**, postaglandin E; **PARP**, poly (ADP ribose) polymerase; **G1/2 and G2/M**-gap 1-synthesis stage and gap 2-mitosis stage of cell cycle; **mTOR**, mechanistic target of rapamycin; **CDK**, cyclin-dependent kinase; **CDKI**, CDK inhibitor; **YB1**- Y box binding protein 1; **Bcl-2**, B-cell lymphoma-2; **Bcl-xL**, B-cell lymphoma-extra-large; **Bak**, Bcl-2 homologous antagonist/killer; **BIM**, Bcl-2-like protein 11; **MMP 2,7 and 9**, Matrix metalloproteinases 2,7 and 9; **MTA**, metastasis-associated protein; **EMT**, epithelial-to-mesenchymal transition; **p53**, protein 53 gene.

### Cocoa Flavonols

A lot of studies have reported the anticancer property of flavonoids and flavonoid containing food. [Martín and Ramos \(2016\)](#) reported that cocoa and its flavanols modulate the first steps of carcinogenesis by protecting against cell damage via direct free radical scavenging and metal-chelation, alteration of pro-carcinogenic metabolism by inhibiting phase-I drug-metabolising enzymes (cytochrome P450, CYP) and/or activating phase II conjugating-enzymes, and induction of pro-oxidation.

### Chrysin

Cotreatment with 20 and 40 mg/kg (p.o.) of the flavonoid, chrysin for 16 weeks suppressed N-nitrosodiethylamine-induced and ferric nitrilotriacetate-promoted renal carcinogenesis in male Wistar rats. Chrysin treatment resulted in marked decline in renal hyperplasia, renal ornithine decarboxylase activity and protein expression of proliferating cell nuclear antigen, iNOS, COX-2 and secretion of proinflammatory cytokines, all of which are traditional markers of inflammation and tumor promotion. Chrysin treatment maintained antioxidant armory and suppressed activation of redox active transcription factor NF-κB ([Srivastava et al., 2016](#)). Chrysin was also found to induce aryl hydrocarbon receptor-dependent apoptotic cell death in human colorectal cancer cells involving up-regulation and activation of the tumor necrosis factor-mediated transcriptional pathway ([Ronnekleiv-Kelly et al., 2016](#)).

### Curcumin

[Srinivasan \(2017\)](#) elaborated on the antimutagenic and carcinoprotective properties of culinary spices like turmeric, garlic, ginger, and black cumin. These spices showed chemopreventive effects against cancers of the skin, forestomach, pancreas, liver, colon, and oral cancer in experimental models by impeding cell division and promoting apoptosis in cancerous cells as well as regulating inflammation and immunocompetence. Curcumin of turmeric, in particular, was noted to impede carcinogenesis at all three stages and mediate its anticarcinogenic effect partly through its inhibition of the transcription factor NFκB and inhibition of pro-inflammatory pathways as well as by inducing apoptosis and suppressing proliferation and angiogenesis. Anti-metastatic action of curcumin includes inhibition of transcription factors and their signalling pathways (e.g., NFκB, ApP-1 and STAT3), inflammatory cytokines (CXCL1, CXCL2, IL-6, IL- 8), proteases (uPA, MMPs), protein kinases (MAPKs, FAK), regulation of miRNAs (miR21, miR181b) and heat shock proteins (H1J1). The author suggested that use of spices as food adjuncts could, therefore be a promising approach to reduce the risk of cancer and these spices deserve to be considered as nutraceuticals for deriving anticancer influences. In a rat bladder carcinogenesis model, curcumin (0.2 mL, 240 μM) administered intravesically every other day for a total of seven doses, inhibited N-methyl-N-nitrosamine-induced urothelial tumor development via suppression of IGF2 and IGF2-mediated PI3K/AKT/mTOR signalling pathway ([Tian et al., 2017](#)).

### Fenugreek

Similarly, both *in vitro* and *in vivo* studies have alluded to the anticancer property of Fenugreek [*Trigonella foenum-graecum* Linn (Fabaceae)], a seed spice which is also employed for medicinal purposes in many traditional systems. Fenugreek flavonoids such as quercetin, luteolin, vitexin cinnamate, vicenin and isovitexin are believed to support the anticancer activity of the herb. Fenugreek alcohol seed extract (100 and 200 mg/kg) administered for five days inhibited experimental Ehrlich ascites carcinoma in mice. In another experiment, 400 mg/kg methanol extract of Fenugreek ameliorated skin papillomas in Swiss albino mice (El Bairi et al., 2017). Naringenin was reported as one of two main constituents in Fenugreek seed extract with anticancer activity through p53, Bax, and PCNA upregulation in a caspase-3 dependent manner (Khalil et al., 2015).

### Hesperidin

Siddiqi et al. (2015) provided evidence suggesting that hesperidin was a potent chemopreventive agent against renal carcinogenesis possibly by virtue of its antioxidant properties and by modulation of multiple molecular pathways. They found that hesperidin (100 and 200 mg/kg, administered by oral gavage to male Wistar rats for 16 weeks protected against DEN-initiated and Fe-NTA-promoted renal carcinogenesis in a dose dependent manner. Hesperidin was found to induce caspase-3, caspase-9, and bax expression and downregulate bcl-2, NFκB, iNOS, TNF-α, and PCNA expression. Histopathological findings further revealed hesperidin's chemopreventive efficacy shown by the complete restoration of renal morphology at the dose of 200 mg/kg.

### Kaempferol

Kaempferol, initially discovered in *Camellia sinensis* (tea tree) and abundant in different genera of plants such as *Capparis spinosa* (Capers) and *Crocus sativus* (Saffron) has been described as a valuable functional food ingredient with a broad range of therapeutic applications (Kashyap et al., 2017). Anticancer mechanisms of kaempferol have been demonstrated to include cell cycle arrest and apoptosis, anti-angiogenesis effect through alteration of the VEGF expression and possible down-regulation of ERK-NFκB-cMyc-p21-VEGF signalling pathway, antimetastasis effect through mechanisms including suppression of STAT3 and downregulation of MMP-2 & 9, ERK ½ and p38. In an *in vivo* study, 28 days post-treatment with kaempferol (100 mg/kg p.o.) showed ameliorative effects in AFB<sub>1</sub>-induced experimental hepatocarcinogenesis in male Wistar rats (Kulanthaivel et al., 2012).

### Apigenin

Many fruits and vegetables such as parsley, celeriac, celery and chamomile tea are rich in apigenin. Apigenin demonstrated ability to halt cancer growth in a wide range of cancers including liver, pancreatic, colorectal, blood, prostate, breast, lung, thyroid, skin, neck and head, and bone cancers by a variety of mechanisms. Examples include reduction of Snai1 and NF-κB expression, leading to reversal of increased epithelial-mesenchymal transition (EMT) marker levels, improved cellular adhesion, controlled actin polymerization and cell migration, and inhibited invasion and migration in experimental liver cancer. Others include inhibition of STAT3 signalling evident from up-regulated levels of cleaved caspase-8 and caspase-3, and provoked cleavage of PARP. Another mechanism involved induction of extrinsic apoptosis, blockage of the phosphorylation of JAK2 and STAT3 in addition to inhibition of CoCl<sub>2</sub>-induced VEGF secretion and decreased nuclear staining of STAT3 in breast cancer cells. Apigenin also acted as an anti-cancer agent through binding with IKKα, attenuation of IKKα kinase activity and suppression of NF-κB/p65 activation leading to inhibition of cell proliferation, invasiveness and decrease in tumor growth in experimental prostate cancer. Lastly, apigenin stimulated the mitochondrial pathway of apoptosis, modified expression of apoptotic proteins, as well as significantly up-regulated the expression of cytokine genes IL17F, LTA, IL17C, IL17A, and IFNβ1 in experimental pancreatic cancer (Salmani et al., 2017). Apigenin and quercetin (25 and 50 mg/kg) were equipotent in dose-dependent inhibition of melanoma growth following their intraperitoneal administration at the time of i.m. injection of B16-BL6 cells into female C57BL/6N syngeneic mice. EGCG at 50 mg/kg was found to be more effective than apigenin and quercetin (Caltagirone et al., 2000). Also, 50 mg/kg apigenin administered i.p. to female Sprague Dawley rats for 21 days prevented the development of medroxyprogesterone acetate accelerated 7,12-dimethylbenz(a)anthracene-induced mammary tumors in Sprague Dawley rats (Mafuvadze et al., 2011) while 20 mg/kg apigenin administered i.p. to C57BL/6 mice showed anti-tumoral effect in malignant mesothelioma induced by transplanting mice with MM# 40a cells forming ascites (Masuelli et al., 2017). In another study, inclusion of 0.1% apigenin and 0.02% naringenin in diet of male Sprague-Dawley rats for 10 weeks suppressed colon carcinogenesis in azoxymethane-treated rats (Leonardi et al., 2010).

### Quercetin

Quercetin is a prominent member of the flavonoid family and a medically important dietary antioxidant. Quercetin is found in various medicinal plants and commonly consumed vegetable and fruits such as onions, apples and berries. The anticancer property of quercetin is due to binding to cellular receptors and proteins, which modulates various cell signalling mechanisms. It also involves inhibition of enzymes responsible for the activation of carcinogens. Treatment with 25 μM Quercetin inhibited the phosphatidylinositol 3-kinase (PI3K)-Akt/PKB (protein kinase B) pathway in cancer cells which suggests that this compound may have therapeutic benefit against tumorigenesis and cancer progression. In an *in vivo* experiment, Swiss albino mice with Ehrlich Ascites Carcinoma (EAC) cells-induced tumor showed a remarkable reduction in tumor volume when orally administered with 6 doses of quercetin (1 mg/kg) on every third day, after the 10th day of treatment. Xenograft NOD/SCID female mice post-treated with quercetin (30 mg/kg p.o.) for two weeks following implantation of human gastric carcinoma SNU791 cells for 2 weeks as well, showed inhibition of the human gastric carcinoma as from day 5 of treatment with the flavonoid. In a model of pancreatic cancer, quercetin (1%) administered orally in the diet, inhibited orthotopic tumor growth and induced tumor cell apoptosis in mice. Quercetin

extensively downregulated the potential oncogenic MAPK signalling *in vivo*. Both Raf and MAPK/extracellular signal-regulated kinase (ERK) kinase (MEK) act as direct targets for quercetin, leading to the potential to decrease MEK1 activity. Quercetin binds with SAPK/ERK kinase 1 (SEK1), c-Jun N-terminal kinase 1/2 (JNK1/2), MEK1 and ERK1/2 thereby modulating reprogramming events related to gene expression, potentiation of cellular growth, and antiapoptotic properties. Other mechanisms adduced for the anticancer property of quercetin include induction of senescence, inhibition of telomerase, induction of apoptosis even in cells which are resistant to TNF-related apoptosis-inducing ligand (TRAIL), and inhibition of the aryl hydrocarbon receptor (AhR), which is a ligand-gated transcription factor that is activated by the interaction with synthetic and natural chemicals (Culati et al., 2006; Srivastava et al., 2016; Lee et al., 2016; Angst et al., 2013; Kumamoto et al., 2009; Ashida et al., 2000; Khan et al., 2016; Murray et al., 2014).

#### **Garcinia kola Biflavonoid Complex (Kolaviron)**

Kolaviron is a biflavonoid complex, extracted from *Garcinia kola* seeds, containing GB1, GB2 and kolaflavanone. The anticancer potential of kolaviron, especially its protective potential in hepatic cancer has been highlighted in several studies. Kolaviron showed chemopreventive effect on aflatoxin B1 (AFB1) - induced toxicity. AFB1 is a potent hepatocarcinogen in experimental animals and is also a human carcinogen (Eaton and Gallagher, 1994; International Agency for Research on Cancer, 1993). Studies of the chemopreventive effects of kolaviron on AFB1-induced genotoxicity in rats showed that co-treatment of rats with 500 mg/kg kolaviron 30 min before and then after AFB1 administration inhibited the induction of micronucleated polychromatic erythrocytes. In addition, kolaviron inhibited AFB1 induction of markers of hepatic oxidative damage (Farombi et al., 2005). Rats administered kolaviron alone showed significant elevation in the activities of phase 2 enzymes—glutathione S-transferase, uridyl glucuronosyl transferase and NADH:quinone oxidoreductase. Also, *Garcinia* biflavonoid inhibited aflatoxin B1-induced genotoxicity in HepG2 cell. Kolaviron specifically induced CYP 3A4 activation. In addition, GST isozymes  $\alpha$ -1 and  $\alpha$ -2.2 were also induced, which signified molecular mechanisms of action of antigenotoxic properties of kolaviron via induction of phase 2 detoxifying enzymes. Studies have shown that kolaviron suppressed the expression of COX-2 and iNOS and the DNA binding activity of NF- $\kappa$ B and AP-1 induced by dimethyl nitrosamine (DMN) (Gonzales et al., 2016). Kolaviron demonstrated antiproliferative effect by suppressing the growth and survival of both colon adenoma (LT97) and carcinoma cells (HT29) (Farombi and Owoeye, 2011).

#### **Myricetin**

Myricetin is a flavonol with powerful antioxidant activity. It has been shown to have a therapeutic effect in different cancers both *in vitro* and *in vivo*. It exerts apoptotic effects in combination with TRAIL or by other mitochondrial-dependent pathways, as well as inducing G2/M cell cycle arrest (Siegelin et al., 2009; Zhang et al., 2008). Several myricetin-derived, synthetic flavonoids with improved antioxidant properties, specific mitochondrial targeting and optimised physicochemical properties and drug-like attributes have been developed. They showed more potency and enhanced potential as antitumour agents than myricetin. Among them, Oncamex was the most potent compound. Oncamex was capable of specific mitochondrial delivery and redox modulation. It specifically targeted the mitochondrial compartment, with rapid delivery and stable accumulation. *In vivo* study in mice implanted with the MDA-MB-231 breast cancer xenograft showed that treatment with Oncamex (25 mg/kg/day, i.p.) over 14 days inhibited tumour growth, reducing tissue viability and Ki-67 proliferation, with no signs of untoward effects on the animals. Oncamex exerted its antitumour effect through induction of cytotoxicity and apoptosis, induced gene expression changes related to cell cycle and apoptosis regulation and inhibited tumour proliferation and viability (Martínez-Pérez et al., 2016).

#### **Tea Catechins**

Tea, made from the dried leaves of the plant *C. sinensis*, is the most popular beverage worldwide after water. The major catechins in green tea are (–)-epigallocatechin-3-gallate (EGCG) (–)-epigallocatechin (EGC) (–)-epicatechin-3-gallate (ECG) and (–)-epicatechin. Among tea catechins, EGCG is the most effective in reacting with the majority of ROS. EGCG has been shown to bind directly to several receptors and signalling molecules, and to inhibit the functions of key receptors, kinases, proteinases and other enzymes thereby affording protection against cancer. Inclusion of <0.5% tea polyphenols or EGCG in drinking water of experimental animals for multiple weeks have been reported to inhibit various types of experimental carcinogenesis (Yang et al., 2009). Cancer treatment using a combination of EGCG and anticancer drugs have been reported to produce remarkable results (Suganuma et al., 2011).

#### **Fisetin**

Fisetin (10–80  $\mu$ M) was reported to bind to tubulin and stabilize microtubules with binding characteristics far superior than paclitaxel. It enhanced tubulin polymerization and increased  $\alpha$ -tubulin acetylation and MAP-2 and MAP-4 expression. Fisetin arrested cells in the G2/M phase of cell cycle, inhibited cell proliferation, invasion and migration. In addition, this polyphenol was found to inhibit the viability, colony formation and decrease the expression of P-gp in multidrug-resistant cancer cell line NCI/ADR-RES (Mukhtar et al., 2015). Results of experiments by Meng et al. (2016) provided insight into antitumor, anti-proliferative and the induction of apoptosis efficacy of fisetin against ovarian cancer *in vitro* and *in vivo*. Data obtained suggested a safe promising therapeutic potential of fisetin in ovarian cancer treatment. In their athymic nude rat model, under the influence of fisetin, tumor volume and tumor mass were significantly decreased. Treatment with fisetin resulted in a significant decrease of Bcl-2 and a significant increase of Bax.

### Multiple Dietary Flavonoids

Kuo et al. (2016) proposed dietary flavonoid supplements to be the key to improving the efficacy of chemotherapy and reducing cancer recurrence rate as well as side effects from chemotherapy. They reported that dietary flavonols (kaempferol, fisetin, quercetin), anthocyanidin (cyanidin), flavanol ((-)-catechin, EGCG), isoflavone (genistein), and flavanone (naringenin) which are common flavonoids in the diet could inhibit Chk1 phosphorylation and decrease clonogenic cell growth once breast cancer cells receive ultraviolet irradiation, cisplatin, or etoposide treatment. They also proposed that since the ATR-Chk1 pathway mainly involves response to DNA replication stress, flavonoid derivatives can reduce the side effect of chemotherapy by improving the sensitivity of cycling cells.

### Concluding Remarks and Outlook

Overwhelming evidences from epidemiological, *in vitro* and *in vivo* studies reveal the anticancer potential of dietary flavonoids and the mechanistic routes of their chemopreventive property. Therefore, consumption of flavonoid-rich foods is recommended as it will go a long way in reducing the scourge of the various cancers plaguing the world today. It is apparent that some mechanistic aspects of the action of flavonoids still need to be clearly delineated and properly elucidated so that health benefits inherent in this unique class of bioactives can be fully unlocked. However, the enormous volume of research works that are on-going and the impressive outputs and important discoveries being made as a result of these investigations present a positive outlook in the fight against the disease. There should be focus on discovery/formulation of carcinoprotective flavonoid-based nutraceuticals and functional foods. Efficient and effective synergy of flavonoid-based interventions with orthodox cancer therapeutics for optimum results in the battle against the disease should be further explored.

## Antihypertensive Foods: Protein Hydrolysates and Peptides

**Rotimi E Aluko**, Department of Food and Human Nutritional Sciences, University of Manitoba, Winnipeg, MB, Canada

© 2019 Elsevier Inc. All rights reserved.

### Glossary

**Antihypertensive** The ability of an agent to reduce high blood pressure below the pathological level

**Bioactive** Compounds that induce physiological changes when present within the body

**Diastolic blood pressure** The pressure exerted on vascular walls when the heart muscles relax in-between beats

**Membrane ultrafiltration** The use of membranes with specific molecular weight cut-offs to separate protein hydrolysates into peptide fractions with defined sizes

**Oral gavage** A method that involves inserting a hollowed plastic or metal tube in the throat of a rat (or mouse) for direct deposition of a liquid sample into the oesophagus

**Peptides** Protein fragments released during proteolysis

**Protein hydrolysates** A mixture of peptides obtained after protein hydrolysis; the peptides differ according to chain length, amino acid sequence, amino acid composition and bioactive properties

**Proteolysis** Breakdown of food proteins into smaller fragments and free amino acids using enzymes, acids or bases

**Renin-angiotensin-aldosterone system** A cascade of enzyme-catalyzed reactions that regulates mammalian blood pressure through vascular contractions and control of blood sodium ion level

**Systolic blood pressure** The pressure exerted on vascular walls when the heart muscles contract to pump blood

### Nomenclature

**ACE** Angiotensin-I converting enzyme

**DBP** Diastolic blood pressure

**GIT** Gastrointestinal tract

**HPH** Hemp seed protein hydrolysate

**RAAS** Renin-angiotensin-aldosterone system

**RBPH** Rice bran protein hydrolysate

**RP-HPLC** Reverse-phase high-pressure liquid chromatography

**SBP** Systolic blood pressure

**SHR** Spontaneously hypertensive rats

**UF** Ultrafiltration

### Introduction

High blood pressure is a precursor of the pathological condition called hypertension, which can become fatal if left untreated or improperly managed with appropriate therapeutic interventions (WHO, 2013). Hypertension exists when the systolic blood pressure (SBP) exceeds 140 mmHg and the diastolic blood pressure (DBP) is  $\geq 90$  mmHg (Pickering et al., 2005). The mammalian blood pressure is controlled principally by the renin-angiotensin-aldosterone system (RAAS), which consists of a cascade of reactions that eventually lead to production of angiotensin II, the main vasopressor agent (Acharya et al., 2003). Activities of the RAAS begin with conversion of angiotensinogen (a 55 kDa protein secreted by the liver) into an inactive angiotensin I, which is the rate-determining reaction catalyzed by renin (EC 3.4.23.15). Angiotensin I-converting enzyme (ACE; EC 3.4.15.1) then removes the C-terminal dipeptide (His-Leu) of angiotensin I to form angiotensin II, which binds to receptors on blood vessels to cause contractions that maintain blood flow and normal blood pressure (Acharya et al., 2003). However, under disease conditions or as a result of aging, genetic disposition, diet or environment, the rate of RAAS reactions become very high with excessive angiotensin II production (Allen et al., 2012; MacMachon et al., 1990; Pickering et al., 2005). Additionally, ACE also hydrolyzes and inactivates bradykinin (a protein that enhances blood vessel dilation), which leads to reduced vasodilation (Acharya et al., 2003). Therefore, excessive activities of renin and ACE lead to higher-than-normal levels of angiotensin II, which cause high rate of vasoconstriction but reduced vasodilation and consequently high blood pressure. Angiotensin II also enhances aldosterone activity to cause excessive reabsorption of sodium that leads to enhanced water retention, increased blood volume and ultimately contributes to the development of high blood pressure (Acharya et al., 2003). Hence, clinical blood pressure management involves the use of compounds that reduce activities of RAAS enzymes, mainly renin and ACE to produce and maintain homeostatic levels of angiotensin I,

angiotensin II or aldosterone. These blood pressure control agents are mainly pharmaceutical agents (drugs) that are based on synthetic compounds with inhibitory effects against renin and ACE activities (Acharya et al., 2003). However, the use of antihypertensive drugs is accompanied by negative side effects such as persistent dry cough (Yesil et al., 1994), angioedema (Gunkel et al., 1996; Vleeming et al., 1998), teratogenicity (Cooper et al., 2006; Pryde et al., 1993), and erectile dysfunction (Blumentals et al., 2003; Fogari and Zoppi, 2002). These undesirable effects are believed to be the main reasons for lack of compliance with physician-prescribed medication doses by patients, which then leads to increased intensity of hypertension and associated deteriorations in health quality (Bangalore et al., 2007; Flack et al., 1997). Therefore, recent trends have involved the search for and development of natural antihypertensive compounds that are less likely to cause severe negative side effects while maintaining therapeutic efficiency. One of the likely alternatives to drugs is food protein digests that contain short-chain peptides with affinity for renin and ACE. The short-chain peptides are preferred because of the increased potential for high rate of absorption from the gastrointestinal tract into blood circulation (Grimble et al., 1987; Roberts et al., 1999). Previous reports have also confirmed the absorption of food protein-derived di- and tripeptides from the gastrointestinal tract into human blood circulatory system following oral consumption (Foltz et al., 2007; Matsui et al., 2002). In addition, *in vivo* suppression of renin and ACE activities as well as angiotensin II concentration has also been demonstrated as a mechanistic explanation for observed blood pressure reducing effects (Brasil et al., 2018; Fernández-Musoles et al., 2013; Girgih et al., 2014a,b; Onuh et al., 2016). Therefore, peptides could function effectively as antihypertensive agents as a result of proven absorption properties. However, rather than depend on *in vivo* gastrointestinal enzyme digestion through feeding of whole proteins, these peptides are created mostly by custom *in vitro* digestion of food proteins (Chen et al., 2013, 2017; Guo et al., 2017; Garcia-Tejedor et al., 2015; Pattarayangsakul et al., 2017; Udenigwe et al., 2017). *In vitro* food protein digestion avails researchers the opportunity to produce specific range of peptides using a variety of highly efficient microbial enzymes that are not present within the gastrointestinal tract (GIT) such as alcalase (Chen et al., 2013), neutrase and flavourzyme (Uluko et al., 2013), or protamex, savinase and corolase (Garcia-Mora et al., 2015). This approach has enabled the creation of a wide variety of antihypertensive food protein hydrolysates.

### Production and Efficacy Evaluation of Antihypertensive Food Protein Hydrolysates

Within the primary structure of food proteins are encrypted specific amino acid sequences that have bioactive properties because of their ability to influence various physiological conditions. These sequences, which are called cryptides (encrypted peptides) or bioactive peptides will be inactive when presented as part of the protein primary structure but become active when released through enzyme or acid-based hydrolysis (Mora and Hayes, 2015; Udenigwe, 2013). Enzyme hydrolysis is usually preferred because of the high specificity and reproducibility of the reaction when compared to the non-specific nature of acid hydrolysis. However, a recent work has shown that acid hydrolysis of hemp seed proteins yielded specific bioactive peptides that can be produced with a high degree of reproducibility (Orio et al., 2017). The hemp seed protein (5 g) was mixed with 25 mL of 6 M HCl, stirred at 110 °C for 6 h, cooled, and followed by additions of 4 M NaOH and then 1 M Na<sub>2</sub>CO<sub>3</sub> under stirring to reach pH 5.8; the digested mixture was freeze-dried as the protein hydrolysate. *In vitro* evaluation showed that the acid-digested hemp seed protein hydrolysate (aHPH) inhibited ACE activity up to ~45% at 1.1 mg/mL. Further separation and purification of aHPH led to identification of the following four peptide sequences that also inhibited *in vitro* activity of ACE: GVLY, IEE, LGV, and RVR. At 1 mg/mL or less, GVLY, IEE, LGV, and RVR had ACE inhibitory values of 95, 21, 95, and 93%, respectively.

However, the most popular means of food protein hydrolysate production involves the use of proteases to reduce protein size and lead to a peptide-enriched product. Table 1 shows the antihypertensive activities of various food protein hydrolysates obtained from enzymatic hydrolysis of proteins. To measure antihypertensive effects, the protein hydrolysates are usually administered to spontaneously hypertensive rats (SHR) by oral gavage followed by blood pressure measurements using the tail-cuff or telemetry method. It is evident from the results that the effective dose differs, which is a reflection of the differences in the types and levels of bioactive peptides present within each hydrolysate. The differences in antihypertensive efficacy could also be due to the nature of starting materials, since primary structure will vary between proteins. But the low doses ( $\leq 1000$  mg/kg SHR body wt) indicate feasibility for commercial exploitation as alternatives to antihypertensive drugs. Based on the animal-to-human dose translation (Reagan-Shaw et al., 2007) these protein hydrolysate doses are equivalent to 1–10 g/day for a typical 70 kg human being, which can be readily achieved. In addition to the effect on SBP, food protein hydrolysates also can reduce DBP, mean arterial blood pressure and heart rate (Li et al., 2011; Lin et al., 2017; Neves et al., 2017; O’Keeffe et al., 2017).

The wide variation in blood pressure-reducing effects as evident in Table 1 also suggests that conditions during protein hydrolysis are very vital for producing strong antihypertensive protein hydrolysates. During *in vitro* enzymatic protein hydrolysis, the protease is added to a protein substrate that can range from seed flours (<30% protein content) to defatted oilseed meals (30%–50% protein) or concentrates (50%–90% protein) and isolates (>90% protein) as well as animal protein preparations (Chen et al., 2017; Eckert et al., 2018; Girgih et al., 2014a,b; Garcia-Mora et al., 2015; Guo et al., 2017; Udenigwe et al., 2017; Uluko et al., 2013). Protein content of the raw material is important to the quality of the protein hydrolysate because it determines the level of soluble non-peptide contaminants that can reduce efficacy as antihypertensive agents. Therefore, in general, higher purity protein materials (concentrates and isolates) are more frequently used than seed flours for protein hydrolysate production. There is now a wide choice of enzymes available for protein hydrolysis, ranging from microbial to gastrointestinal enzymes. The purity of the enzyme is not as important as that of the protein raw material because of the low enzyme to substrate ratios normally used (1:10 to 1:200). However, the protease preparation must be standardized for activity in order to ensure consistency in quality of

the protein hydrolysates from batch to batch. Some of the mostly commonly-used proteases include alcalase, flavourzyme, neutrase, papain, pepsin, trypsin, chymotrypsin, thermolysin (thermoase), and pancreatin (Aluko, 2015). The enzyme choice is important because each has a unique proteolytic activity, which can determine the type and efficacy of peptides liberated from the protein substrate. Therefore, the degree of hydrolysis (DH) will vary according to enzyme type, hence the activity of resultant protein hydrolysates will differ. DH is determined as the ratio of number of peptide bonds broken by the enzyme (measured as quantity of free amino groups) to the total number of peptide bonds present in the original protein using the pH-Stat (Gong et al., 2017) or colorimetric (Adler-Nissen, 1979; Guan et al., 2018; Nielsen et al., 2001) methods. Thus, in most cases, ACE inhibition will increase as the DH becomes higher until a maximum inhibition level is reached (Hall et al., 2018), beyond which the inhibition could actually decrease (Garcia-Mora et al., 2014; Huang et al., 2014). The decrease in ACE inhibition after maximum inhibitory level has been reached could be due to excessive structural degradation of active peptides when protein hydrolysis (hence DH) proceeds beyond the optimum point. DH will also increase but eventually reach a plateau or even start to decrease with increases in hydrolysis time, substrate concentration and enzyme-to-substrate ratio (Huang et al., 2014; Rutella et al., 2016). However, the DH due to hydrolysis time had better correlation to ACE-inhibitory activity of the hydrolysate when compared to the relationships of ACE inhibition with DH calculated from variations in substrate concentration or enzyme-to-substrate ratio (Huang et al., 2014). Production of small size peptides also increases with length of digestion time (You et al., 2010), which enables formation of low molecular weight peptides that have bioactive properties and are suitable for absorption from the GIT.

One of the most used enzymes for protein hydrolysate production is alcalase because it is a non-specific protease that cleaves at random points with high degree of efficiency and produces smaller-sized peptides than most other proteases. Another commonly used enzyme is flavourzyme, which contains endo- and exoproteinases that are suitable for trimming of peptides to reduce peptide size but the product will have a higher content of free amino acids when compared to other protease preparations. Others include trypsin, which is highly specific for peptide bonds formed by arginine and lysine and will produce longer peptide sequences than alcalase or flavourzyme. In contrast, pepsin and chymotrypsin have high specificity for peptide bonds formed by aromatic amino acids or those with bulky side groups. Thermolysin is fairly unique because of the ability to release peptides that contain branched-chain amino acids. Irrespective of the enzyme choice, protein hydrolysis can be performed using one or more enzymes, depending on the type of target product. Each enzyme reaction must be performed at the optimum temperature and pH in order to realize the full potential of the proteolytic activity. The significance of enzyme choice was evident in the work of Huang et al. (2014), which compared the ACE-inhibitory activity of wheat germ protein hydrolysates produced from six different enzymes (trypsin, neutrase, chymotrypsin, pepsin, alcalase, and papain). The alcalase hydrolysate had the highest ACE inhibition followed by chymotrypsin, neutrase, papain, trypsin and pepsin in decreasing order.

### Single Enzyme Digestion

The simplest hydrolysis protocol involves addition of a single enzyme to the protein substrate, which is usually dispersed in water, heated to the desired temperature and then adjusted to the optimum pH for the enzyme reaction (Ruiz-Ruiz et al., 2013; Senaphan et al., 2018). Some investigators use protein substrates that have been dispersed in buffers instead of water (Aiello et al., 2017; del Castillo et al., 2007; Guan et al., 2018; Hall et al., 2018; Vasquez-Villanueva et al., 2018). The use of buffer has the advantage of resisting pH change during proteolysis and therefore, will require minimal pH adjustment. However, the buffer also introduces

a high level of salt in the final protein hydrolysate, which may not be desirable for taste and could introduce impurities that are originally present in the buffer salts. After the protein has been dispersed in water or buffer with adjusted temp and pH, the enzyme is added at a predetermined level or a range may also be used. Digestion is then allowed to proceed for a predetermined period that could range from 1–24 h. During digestion, peptide release is accompanied by  $H^+$  production, which causes pH to fluctuate from the original set value. In order to maintain the original set pH, dilute acid or alkali is usually added at intervals; this is more frequent during the first 30 min of digestion when proteolysis rate is very high and copious amounts of  $H^+$  are released within a short period of time. However, as digestion proceeds, less amounts of  $H^+$  are released and the pH fluctuation becomes less frequent, hence longer intervals will be required for pH adjustment. It is also important to use a thermostated hot plate to maintain the temperature throughout the digestion period. At the end of the enzyme hydrolysis period, the digest can be cooled to room temperature and freeze-dried as a protein hydrolysate. Using this method, a rice bran protein hydrolysate (RBPH) was produced and tested for cardiovascular benefits in Sprague Dawley rats that developed hypertension after feeding on a high-carbohydrate and high-fat diet. Daily oral administration of 500 mg RBPH/kg rat body weight led to significantly lower systolic and diastolic blood pressure values, which were better than the 250 mg dose (Senaphan et al., 2018). However, rats that consumed the 250 mg dose had significantly lower blood pressure values than those that were not given the RBPH treatment. Oral administration of the RBPH also led to reductions in pulse pressure and heart rate of the rats, which suggest ability of this product to ameliorate hypertension progression.

But post-digestion processing protocols might be used to enhance bioactive quality of protein hydrolysates. First, after cooling to room temperature, the digest is adjusted to a pH value that is close to the isoelectric point (pI) of the protein substrate. At the pI, the protein is mostly insoluble and this causes the undigested proteins to precipitate out of solution and leave behind in solution, the desired short-chain peptides. After adjusting to the pI, the digest is then centrifuged and the supernatant (contains the antihypertensive peptides) is freeze-dried for further testing while the precipitate (contains undigested proteins) is discarded. Second, the digest is heated to  $>90^\circ C$  before cooling to room temperature and freeze-dried or adjusted to the pI, centrifuged and supernatant freeze-dried. Advantage of post-digestion heating is the ability to inactivate the proteolytic enzymes and prevent further protein/peptide degradation that could inactivate already-formed antihypertensive peptides. Heating also enhances coagulation and insolubility of the undigested proteins, which increases efficiency of the subsequent centrifugation step to separate peptides from undigested proteins.

### Multiple Enzyme Digestion

Protein digestion can also be accomplished with the addition of more than one protease either simultaneously or consecutively (Aluko, 2018). For simultaneous hydrolysis, the enzymes must have similar optimum operating conditions, which ensures that each protease will work to the maximum potential as part of the enzyme cocktail. In contrast, if the enzymes have different optimum operating conditions such as pepsin (pH 2.0–3.0) and pancreatin (pH 7.0–8.0), protease addition is done one at a time in a pre-determined sequence. For example, pepsin will first be added and digestion conducted for a given period, then the mixture is adjusted to pH 7.0–8.0 and pancreatin added to continue the digestion. The consecutive use of pepsin and pancreatin (or trypsin) is sometimes used to simulate GIT digestion with or without addition of bile salts; pepsin addition simulates stomach digestion while pancreatin or trypsin is used to simulate intestinal digestion (Aiello et al., 2017; Girgih et al., 2011; Jakubczyk et al., 2017; Pattarayingsakul et al., 2017; You et al., 2010). Using this consecutive digestion method, antihypertensive protein hydrolysates were prepared from hemp seed proteins and shown to reduce SBP of SHR by up to 30 mmHg after 8 h of oral administration (Girgih et al., 2011). The hemp seed protein hydrolysate (HPH) had inhibitory activities against RAAS enzymes with  $IC_{50}$  values of 1.89 and 0.67 mg/mL against renin and ACE, respectively. Mechanism of *in vitro* inhibition was mixed-type, which indicates that the hemp seed peptides were bound to the active and non-active sites of ACE and renin enzyme molecules. During an 8 week feeding trial, the HPH prevented hypertension development in SHR (Girgih et al., 2014a). This long-term feeding trial confirmed that blood pressure reductions were due to reductions in the plasma levels of ACE and renin, which indicate that the HPH peptides were absorbed from the GIT. Canary seed protein was also subjected to pepsin + pancreatin consecutive hydrolysis to yield a hydrolysate with comparable ACE-inhibitory activity as the product made with single enzyme (trypsin) hydrolysis (Estrada-Salas et al., 2014). However, the advantage of pepsin + pancreatin digestion is that the peptides may not undergo further structural degradation within the GIT when ingested. Therefore, preservation of structural properties may enhance the antihypertensive properties of protein hydrolysates produced from pepsin + pancreatin digestion. In a variation of the simulated GIT digestion, pepsin hydrolysis was followed by trypsin hydrolysis to produce ACE-inhibitory peptides that reduced blood pressure of SHR (Guo et al., 2017). Simulated GIT digestion of foxtail millet also produced protein hydrolysates that reduced the systolic blood pressure of SHR (up to 29 mmHg) in addition to significant reductions in plasma ACE activity and angiotensin II level (Chen et al., 2017). The beneficial effect of double enzyme digestion has also been shown with spent hen meat where consecutive treatment with pepsin and pancreatin produced a protein hydrolysate with ACE-inhibitory  $IC_{50}$  value of 0.42 mg/mL when compared to the 0.65 mg/mL for the pepsin-only digest (Udenigwe et al., 2017). More importantly, the protein hydrolysate from pepsin + pancreatin hydrolysis reduced systolic blood pressure of SHR by  $\sim 36$  mmHg, which is significantly better than the  $\sim 27$  mmHg for the pepsin hydrolysate. Casein hydrolysis with thermolysin + alcalase, thermolysin + proteinase K, alcalase + proteinase K and papain + proteinase K all produced protein hydrolysates with stronger ACE-inhibitory activity than when individual enzymes were used (Lin et al., 2018). However, even though consecutive hydrolysis with two enzymes may produce higher DH (Jakubczyk et al., 2017) it does not always lead to the production of stronger ACE-inhibitory peptides as evident in the digestion of egg yolk proteins where an  $IC_{50}$  value of 1.1  $\mu g$  was obtained for single enzyme in comparison to

5.3 µg for 2 enzymes (Eckert et al., 2018). Similarly, casein hydrolysis with thermolysin + papain, alcalase + trypsin and papain + trypsin produced protein hydrolysates with similar or weaker ACE-inhibitory activity when compared to hydrolysates from individual enzymes (Lin et al., 2018). Therefore, the ACE-inhibitory beneficial effect of using 2 enzymes for protein hydrolysis is dependent on the type of enzyme combination.

If a third or more enzyme use is desirable for protein hydrolysis, appropriate pH and temperature adjustments can be made prior to further proteolysis. Irrespective of whether simultaneous or consecutive hydrolysis is conducted with multiple enzymes, the digest is processed using similar protocols as already described for the single enzyme digestion.

### Other Proteolysis Methods

The original discovery of food protein-derived ACE-inhibitory peptides was made during milk fermentation (Nakamura et al., 1995). When administered to SHR, the so called 'sour milk' was found to reduce blood pressure (Nakamura et al., 1995; Sipola et al., 2002). Investigation of the active components led to the discovery of two main peptides, IPP and VPP that were liberated from milk proteins by proteases produced by fermenting microorganisms. A recent work has also shown that milk fermentation with yeast (*Kluyveromyces marxianus*) can produce peptides with ACE-inhibitory activity (Li et al., 2015). VLSRYP and LRFF were the two main peptides identified from the yeast-fermented milk; both peptides inhibited ACE activity in a competitive manner. Camel milk fermentation with lactic acid bacteria led to increased ACE-inhibitory activity of the peptides, which was directly related to higher proteolytic activity as incubation period increased (Solanki et al., 2017). Kefir, another type of fermented milk has been shown to contain ACE-inhibitory peptides (Quiros et al., 2005). Oral administration of the soluble portion of kefir to SHR produced significant reductions in mean arterial pressure and heart rate in addition to a lower plasma ACE concentration (Brasil et al., 2018). Fermentation of pea seed proteins was performed with *Lactobacillus plantarum*, which led to production of ACE-inhibitory peptides (Jakubczyk et al., 2015). Fermentation for 7 days led to the production of pea peptides with an ACE-inhibitory IC<sub>50</sub> value of 0.19 mg/mL. Buckwheat sprout was also fermented with *L. plantarum* and after 2 weeks, the soluble product had antihypertensive effects in SHR at a very low dose of 0.010 mg/kg body weight (Nakamura et al., 2013). The fermented buckwheat sprout caused reductions in ACE activity within several SHR organs, including heart, kidneys, lungs, and the liver. The active compounds in the buckwheat sprout were identified as six main peptides: FQ, VAE, VVG, WIFR, DVWY, and FDART all of which reduced ACE levels in the SHR heart and liver (Koyama et al., 2014). Oral administration of fermented soybean-derived peptides to human subjects produced significant reductions (mean = 9.69 mmHg) when compared to 2.91 mmHg for the control group after 8 weeks (Kwak et al., 2013). However, even though the soybean peptides had *in vitro* ACE inhibition (Shin et al., 1995, 2001), there were no significant changes in the plasma level of this enzyme after the 8 weeks of human intervention trial. Therefore, the antihypertensive mechanism of action of the soybean peptides was attributed to reduction in oxidative stress as evident in the significant increase in superoxide dismutase and decrease in lipid peroxides as represented by malondialdehyde concentration.

Post-mortem muscle hydrolysis can be used to generate peptides with potential antihypertensive properties. For example, cow muscles (*longissimus thoracis* and *semitendinosus*) were aged for 1, 10 and 20 days followed by extraction of generated renin and ACE-inhibitory peptides (Fu et al., 2017). Extracts from raw and cooked muscles were also compared for enzyme inhibition capacity. The results showed significant increases in potency of the muscle-generated peptides against renin and ACE activities as aging progressed from 1 to 20 days. Moreover, cooking also enhanced potency of the peptides, which suggests higher extraction efficiency as a result of temperature treatment. Microbial-fermented sausages also contained peptides with capacity to inhibit ACE activity and could potentially be used as an antihypertensive food (Mejri et al., 2017). Generally, the ACE-inhibitory activity of aqueous extracts of the fermented sausages increased with length of ripening, which suggest time-dependent microbial breakdown of the meat proteins.

### Post-hydrolysis Processing

A crude protein hydrolysate produced from single or multiple enzyme digestion contains several protein fragments, which could be dominated by active or non-active peptides. Therefore, in order to enhance antihypertensive activity, the crude protein hydrolysate can be subjected to post-hydrolysis refining such as membrane ultrafiltration or column chromatography to produce fractions with superior properties. Post-hydrolysis processing is also required for peptide purification that enables isolation of homogenous preparations and identification of amino acid sequence. In all the separation protocols, activity of the fractions are then compared with that of the crude protein hydrolysate in order to determine fractionation efficiency.

### Membrane Ultrafiltration (UF) Processing

Protein hydrolysate separation using UF membranes has become an integral part of the production of antihypertensive peptides. This is because the process is size-based and enables separation of protein hydrolysates into fractions with distinct but broad range of peptide sizes, usually from <1 kDa up to 10 kDa. The process is based on evidence indicating small peptides are more rapidly absorbed than big peptides. Therefore, membrane UF offers the opportunity to collect high amounts of small size peptides and test the effect of peptide size on antihypertensive activity. For example, walnut protein hydrolysate was separated using a 3 kDa membrane into a permeate (<3 kDa), which led to a higher protein recovery (82%) when compared to 18% for the >3 kDa retentate (Liu et al., 2013a). A <3 kDa peptide fraction of pea protein hydrolysate had significant blood pressure-reducing effects during

short-term (24 h) and long-term (8 weeks) oral administration to rats (Li et al., 2011). The <3 kDa pea peptides had *in vitro* inhibitions of ACE and renin but only renin expression was ameliorated during the long-term *in vivo* rat study, which suggest that this product may target renin to lower blood pressure. The ACE-inhibitory activity of egg yolk peptides was improved after ultrafiltration where the >5 kDa fraction had a significantly lower IC<sub>50</sub> value of 0.84 µg in comparison to 1.1 µg for the protein hydrolysate (Eckert et al., 2018). Similarly, a <3 kDa rice peptide fraction had a significantly lower ACE-inhibitory IC<sub>50</sub> value of 0.28 mg/mL when compared to 0.84 mg/mL and 1.57 mg/mL for 3–10 and >10 kDa fractions, respectively (Chen et al., 2013). The <3 kDa peptide fraction of fermented sausage peptides also had stronger ACE inhibition than the >3 kDa peptides (Mejri et al., 2017). Using a papain-digested bovine blood proteins, UF produced a low molecular fraction (<1 kDa) that exhibited stronger ACE and renin inhibitions than high molecular weight (>1 kDa) peptides (Lafarga et al., 2015, 2016). In contrast, the ACE and renin-inhibitory activities of lima bean peptides was not dependent on small size as the >3 kDa fraction was a stronger inhibitor than the <3 kDa fractions (Ciau-Solis et al., 2018).

Since UF is compatible with large-scale production, the process can be used to obtain refined antihypertensive peptide fractions that can be readily commercialized. UF can be conducted using a single membrane, which produces a permeate (flow-through peptides) and a retentate (peptides bigger than the membrane pore size). The permeate and retentate are then tested for antihypertensive effects in comparison to the crude protein hydrolysate. However, narrower peptide size fractions can be obtained by the use of multiple membranes to collect only permeates or retentates (Aluko, 2018). For permeate collection, the process begins with the smallest membrane size, e.g. 1 kDa, which produces a permeate that consists essentially of <1 kDa peptides. The retentate is then passed through a membrane of bigger pore size, e.g. 3 kDa, which will enable collection of permeate peptides with 1–3 kDa sizes. The 3 kDa membrane retentate can then be passed through a 5 kDa to obtain a permeate containing 3–5 kDa peptides; the process can be continued using the 5 kDa retentate with a bigger pore size membrane whose retentate can be processed with an even bigger size membrane and so on until the maximum desirable size membrane has been used. To perform retentate only collection, the process is reversed such that the biggest size membrane is used first (Aluko, 2018). For example, the crude protein hydrolysate will be passed through a 10 kDa membrane and the retentate collected as >10 kDa peptides. The 10 kDa permeate is then passed through a 5 kDa membrane to obtain a retentate that contains 5–10 kDa peptides. The permeate from 5 kDa membrane can be passed through a 3 kDa membrane and the retentate collected as the 3–5 kDa peptides. Passing the 3 kDa membrane permeate through a 1 kDa membrane will then yield 1–3 kDa peptides in the retentate while the final permeate will contain <1 kDa peptides. Irrespective of the membrane process used, the permeates or retentates are analyzed for antihypertensive activities in comparison with the crude protein hydrolysate. Overall, the permeate collection route is more convenient and avoids contamination since the retentate is never collected but simply passed over another membrane. In contrast, if the retentate method is to be used, the ultrafiltration container needs to be washed and cleaned after each collection and prior to setting up the next membrane.

### Column Chromatography Processing

In general, column chromatography is used as a tool for peptide purification rather than to collect peptide fractions that represent the final antihypertensive product. The most commonly used chromatographic methods include reverse-phase HPLC (RP-HPLC), size-exclusion (SEC) and ion-exchange (IEC). In RP-HPLC, the peptides are separated according to net hydrophobicity whereby less hydrophobic peptides are eluted first while strongly hydrophobic peptides come out last. Therefore, the use of RP-HPLC produces peptide fractions with a wide variation in hydrophobicity, which offers the potential of different ability to inhibit ACE activity in comparison to the crude hydrolysate. This was demonstrated by the work of Eckert et al. (2018) who showed that RP-HPLC fractions of egg yolk peptides had significantly lower ACE-inhibitory IC<sub>50</sub> value (~0.024 µg) when compared to 1.1 µg and 0.84 µg for the crude hydrolysate and membrane fraction, respectively. A RP-HPLC fraction of rice peptides had an ACE-inhibitory IC<sub>50</sub> value of 0.02 mg/mL, which was significantly lower than the 0.28 and 0.46 mg/mL for the <3 kDa fraction and protein hydrolysate, respectively (Chen et al., 2013). Hydrophobicity was shown to contribute to renin-inhibitory property of seaweed peptides as the most hydrophobic fraction (last fraction to elute from the reverse-phase column) had the strongest activity (Fitzgerald et al., 2012). The ACE-inhibitory activity of RP-HPLC-fractionated olive seed peptides was also positively related with hydrophobicity because the IC<sub>50</sub> value decreased as retention time increased (Vasquez-Villanueva et al., 2018).

In contrast, SEC separates the peptides according to size with bigger peptides eluting first followed by smaller-size peptides. SEC separation of egg yolk protein hydrolysate produced 5 fractions with the smallest size peptides (fraction #5) having significantly higher ACE-inhibitory activity (Eckert et al., 2018). A similar result showing higher ACE inhibition by smaller-size peptides from SEC separation has been reported for walnut protein hydrolysate (Wang et al., 2014) and bamboo shoot peptides (Liu et al., 2013b). In contrast, the bigger-size peptides from an insect protein hydrolysate (Pattarayingsakul et al., 2017), rapeseed (He et al., 2013b) and fermented bean (Jakubczyk et al., 2017) exhibited higher ACE-inhibitory activity after SEC separation. The results suggest that peptide size alone does not dictate ACE inhibition but the influence of amino acid composition and sequence arrangement is also important. IEC can utilize a positively-charged column resin (anion exchanger) or a negatively-charged resin (cation exchanger). Negatively charged or positively-charged peptides will bind to the anion-exchange or cation-exchange column and be eluted according to their binding strength. Using either RP-HPLC, SEC or IEC methods, fractions are collected at pre-determined intervals based on elution volume or time. The fractions are usually concentrated in a vacuum rotary evaporator, then freeze-dried and assayed for antihypertensive activities using *in vitro* or *in vivo* methods. The most active fraction or

fractions will normally be subjected to further column separations until pure peptides are obtained, which can then be subjected to amino acid sequence analysis, usually involving mass spectrometry protocols.

## Structure and Function of Antihypertensive Peptides

Protein hydrolysates contain a complex mixture of peptides, which can be inactive or active as antihypertensive agents. Therefore, identification of active peptide sequences involves series of separation and isolation protocols that involve one or more of the post-hydrolysis protocols discussed in the preceding section. For example, in order to identify the active peptide sequences responsible for the antihypertensive activities of an alcalase rapeseed protein hydrolysate, samples were subjected to 3 rounds of consecutive RP-HPLC separation (He et al., 2013a). Three main ACE- and renin-inhibitory peptides (LY, TF and RALP) were identified from the rapeseed protein hydrolysate by tandem mass spectrometry. RALP ( $IC_{50}$ , 0.97 mM) was the most active against renin while LY ( $IC_{50}$ , 0.11 mM) had the strongest ACE inhibition. Oral administration of the peptides to SHR reduced SBP by 26, 16 and 12 mmHg for LY, RALP and TF, respectively. Therefore, the results show correlation of *in vitro* inhibition of the RAAS enzymes with actual *in vivo* effects since LY and RALP had the highest inhibitions and renin when compared to TF. In a separate approach, the pepsin + pancreatin hydrolysate of rapeseed protein was first separated by SEC followed by two rounds of RP-HPLC purification of the most active fraction (He et al., 2013b). GHS, a novel tripeptide was subsequently identified by tandem mass spectrometry with  $IC_{50}$  values of 0.52 and 0.32 mg/mL against ACE and renin activities, respectively. GHS also produced antihypertensive effects with a maximum SBP reduction of 17 mmHg reached 6 h after oral administration to SHR. Table 2 shows a list of food protein-derived peptides that have been reported to produce antihypertensive effects through oral consumption. It is evident from the data that there is a wide variation in the efficacy of peptides with those having same chain length differing in blood pressure-lowering effects. Therefore, the structural characteristics, especially arrangement of amino acids seem to be important determinants of ACE inhibition potency and antihypertensive efficacy.

Previous works have used statistical modeling tools to investigate the structural requirements of ACE-inhibitory peptides. Based on partial least square regression modeling, Wu et al. (2006a,b) determined the positional arrangements of peptides containing 2–10 amino acids with respect to potency as ACE inhibitors. Major findings suggest that dipeptides require amino acids with hydrophobic or bulky side groups while tripeptides require an aromatic amino acid in the C-terminal, a positively-charged residue in the middle and a hydrophobic residue in the N-terminal (Wu et al., 2006a). For longer peptides, the C-terminal tetrapeptide residue was determined to be the major determinant of ACE-inhibitory potency but type and arrangement of the four amino acids depend on peptide length (Wu et al., 2006b). This was supported by a subsequent report that found tetrapeptides contain enough structural features to bind to ACE and inhibit enzyme activity because presence of additional amino acid residues did not confer significant inhibition advantage (Zhou et al., 2013). A recent work suggested that hydrophobicity, steric and electronic properties of amino acids of dipeptides are important for ACE inhibition (Deng et al., 2017). Likewise, the C-terminal amino acids contribute more than the N-terminal residues to the inhibition of ACE activity by peptides. The work of Sun et al. (2017) also suggests that the C-terminal residues are important for ACE inhibition, especially when the peptides contain amino acids with hydrogen bond acceptor groups, which facilitates bond formation the enzyme. But as shown in Table 2, the peptide chain length may not be relevant to blood pressure-reducing efficacy. For example, increasing chain length was reported to produce better antihypertensive effects (Tavares et al., 2012). Girgih et al. (2014b) also showed that tetra and pentapeptides had stronger antihypertensive effects than a tripeptide. Meanwhile, DPYKLRP produced almost twice the SBP-reduction of RPYL when orally administered to SHR at the same dose (Garcia-Tejedor et al., 2015). It is possible that the long-chain peptides are broken down into smaller peptides within the GIT or blood such that the resultants fragments are also active, which potentiates antihypertensive activity through synergistic effects. This is illustrated by HLPLP, which was shown to be fragmented into HLPL, LPLP and HLP by rat plasma peptidases, all of which had SBP-lowering effect when orally administered to SHR (Sanchez-Rivera et al., 2016). In contrast, PLP and LPL produced SBP reductions that were similar to HLPLP (Sanchez-Rivera et al., 2016), which suggest that longer chains are not necessarily always more antihypertensive. Apart from peptide chain length, the type of amino acid may also be important for peptides of the same chain length as evident in the higher SBP-reducing ability of VWP when compared to VNP (Chen et al., 2013).

A major issue with bioactive peptides is whether absorption actually occurs as part of the antihypertensive mechanism (Matsui, 2018). However, several works have demonstrated the presence of peptides in the blood of animals (Matsui et al., 2004; Sontakke et al., 2016) and humans (Foltz et al., 2007; Iwai et al., 2005; Ohara et al., 2007; Matsui et al., 2002; Shigemura et al., 2011, 2018) after oral consumption. These findings are not surprising because the presence of peptide transporters within intestinal cells have been confirmed (Ding et al., 2015; Hanh et al., 2017; Meredith and Price, 2006; Xu et al., 2018). Moreover, peptides may also cross the intestinal barrier into blood by diffusion through the paracellular route. Therefore, the ability of an orally ingested peptide to cross into blood circulation is dependent mainly on resistance to gastrointestinal enzymes and not transportability (Matsui, 2018). While detection in the plasma has not been proven for most peptides, there is strong evidence of antihypertensive effects after oral administration to SHR (Table 2). Moreover, various works have also shown that food protein-derived peptides lower activity of RAAS enzyme in the blood. For example, oral administration of HPH to SHR led to >50% reduction in ACE and renin activities in the blood, which were positively correlated to blood pressure reductions (Girgih et al., 2014a). Similarly, the soluble portion of kefir (contains peptides) reduced the serum ACE activity of SHR down to the normal level present in non-hypertensive rats (Brasil et al., 2018). Meanwhile, blood ACE and angiotensin II levels were significantly reduced after oral ingestion of lactoferrin hydrolysate by SHR (Fernández-Musoles et al., 2013). Overall, the presence of peptides within the blood coupled with measured

decreases in ACE, renin and angiotensin II levels confirm that most orally-fed peptides are absorbed into the blood circulatory system from where they exert antihypertensive effects.

## Conclusions

Food proteins remain a veritable source of bioactive peptides that could make significant contributions to human health care management and delivery. This is especially the case in developing countries where access to life-saving antihypertensive drugs are limited. Since protein hydrolysis is a fairly straightforward and well-established procedure, bioactive peptides can be readily produced and marketed as antihypertensive peptides. Moreover, the wide choice of protein materials coupled with availability of cost-effective microbial proteases provide the necessary impetus for continued investigation and development of potent antihypertensive peptides. While potency level remains below that of antihypertensive drugs, bioactive peptides can be used at high doses to prevent or suppress hypertension. In this regard, peptides that modulate activities of the RAAS have been proven to be potentially powerful antihypertensive tools. Protein hydrolysates remain the cheapest products that meet commercialization needs but purified peptides offer the potential to develop strong antihypertensive peptidomimetics for the nutraceutical industry. However, there are still several regulatory hurdles that limit widespread marketing and utilization of antihypertensive peptides. To overcome these hurdles, more extensive human intervention trials are required that will confirm utility of bioactive peptides as efficient antihypertensive agents. Moreover, further knowledge of the structural requirements that potentiate peptide-dependent inhibition of RAAS enzyme activities (especially renin and ACE) are required to develop the next generation of antihypertensive food protein hydrolysates and peptides.

### Glossary

**Acidosis** A condition when the body fluids or tissues become highly acidic

**Dietary fibers** The indigestible part of plants which is fermented by gut bacteria

**Functional food** Food with health-promoting or disease preventing properties

**Inflammation** A condition when parts of the body become red, swollen, painful, and hot, resulting from injury, infection, or allergen contact

**Metabolic syndrome** A group of health conditions: high blood pressure, high blood sugar, excess body fat around the waist, and abnormal cholesterol or triglyceride levels

**Microbiota** Microorganisms inhabiting a particular niche

**Paleo diet** The diet that is composed of fruits, vegetables, nuts, roots, and meat

### Introduction

Metabolic syndrome (MetS), which has surged in the past decades, encompasses a large repertoire of disorders, including obesity and diabetes. Due to the reliance on processed foods, adoption of sluggish lifestyle, the onslaught of pollutants, chemicals exposure, and drug abuse, these MetS health conditions have evolved as major morbidity and mortality factors. It is paradoxical that, while healthcare facilities have risen to unprecedented heights, human quality of life is not necessarily optimal. It is horrifying that the instances of terminal illnesses and premature deaths are soaring. The current situation calls for a scrutiny of lifestyle habits, which might be leading to the dismal picture of public health.

Among the conditions of MetS, obesity and diabetes are most common and often co-occurring, which has led to the terminology diabetes. Obesity is the metabolic disorder of high body mass index (BMI above 30), triggered by rapid adipocyte differentiation. It is a result of imbalance in energy and hormone homeostasis, and other important signaling components such as neurotransmitters. Diabetes is a metabolic, inflammatory, and autoimmune disease. In type 1 diabetes, ionic imbalance occurs due to the malfunction of hormone vasopressin. Perturbation of the renin-angiotensin-aldosterone system (RAAS) affects blood pressure, setting off type 1 diabetes. In type 2 diabetes, the malfunction of insulin raises fasting blood glucose concentration, which causes plasma hyper-osmolality. This hypertonic plasma is responsible for cell shrinkage, mitochondrial depolarization, loss of DNA integrity, cell cycle arrest, apoptosis, protein carbonylation, etc. The RAAS metabolite angiotensin II is a vasoactive peptide that promotes obesity by mediating hypertension, dyslipidemia, and insulin resistance. The adipose tissues secrete adipokines such as leptin (a 16-kDa peptide), and adiponectin, which fuel obesity. Once MetS starts to manifest, the vicious cycle continues, causing cancer, neuropathies, cardiovascular complications, and other inflammatory conditions. As the pathological mechanisms of diseases are being studied with advanced tools, their common origin is emerging. The links between obesity, diabetes, bipolar disorder, asthma, autism, endometriosis, polycystic ovarian syndrome (PCOS), and viral infections have emerged. All of them originate from the route of 'stressor-inflammation- acidosis – aberrant enzyme activation – disturbed immune-neuro-endocrine axis-pathologies'.

Drugs from different classes target different components of the human body, and evoke undesirable side effects as well. There are several anorectic anti-obesity drugs in the pharmaceutical market. Orlistat, an agonist at 5-HT<sub>2C</sub> (5-hydroxytryptamine or serotonin) receptors can also inhibit intestinal lipase to prevent fat absorption. The glucagon-like peptide-1 (GLP-1) analog liraglutide is another drug marketed for the management of obesity. However, liraglutide shows adverse effects like nausea, headache, and diarrhea. Other anti-obesity drugs like sibutramine (a serotonin and norepinephrine reuptake inhibitor) and rimonabant (a selective CB1 endocannabinoid receptor antagonist) cause cardiovascular, neuropsychiatric and congenital issues. The diabetes drug metformin has adverse effects like lactic acidosis, nausea, arrhythmia, etc. With the easy accessibility of drugs, multiple drugs are being taken by a patient, so adverse reactions are emerging. As public awareness towards the limitations and deleterious effects of drugs is rising, the interest towards alternative solutions is increasing. Western diet is replete with high glucose, saturated fats, and chemical additives. With the evidences of its association to multiple metabolic diseases, the deficiencies with Western diet are being recognized. Acidogenic attribute of dairy products, meat-based, and processed foods are coming forth. The acidosis caused by the high carbohydrate, high fat, highly-processed diet leads to aberrant posttranslational modifications of proteins and dysregulated enzyme activity (Patel, 2017). Epigenetic changes such as glycosylation, methylation, acetylation, phosphorylation, and sulfation of proteases such as serine proteases, metalloproteinases (MMP), and cysteine proteases (cathepsins) have been linked to diabetes, pancreatitis, cancer, neurodegenerative diseases, cardiac, and renal complications. The additives such as preservatives (e.g. potassium metabisulfite, benzoic acid, sorbic acid) in processed foods are known to

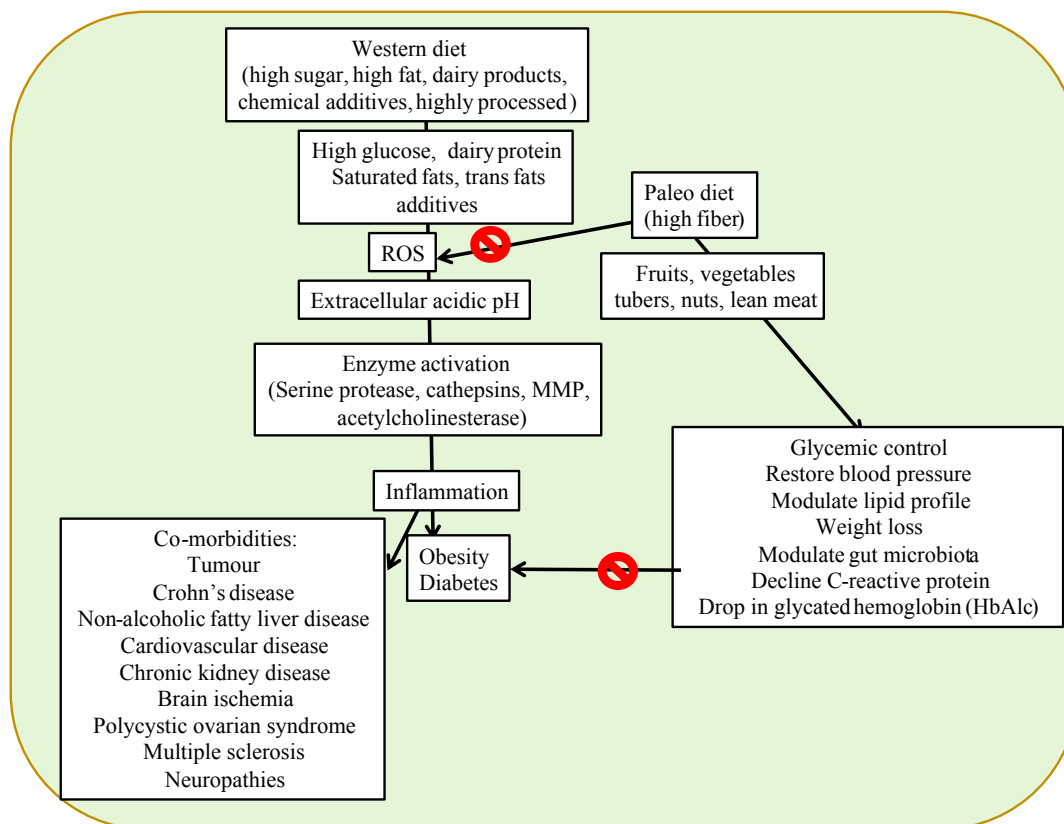

manipulate acetylcholinesterase. Some chemicals act as estrogen mimics, rendering the body susceptible to carcinogenesis. Cyclooxygenase-2 (COX-2), aromatase, kinases (MAPK, etc.), glycosidases, urease, and phospholipases are other crucial enzymes that are affected by the acidic milieu in the body. Acidic pH prevents the polymerization/depolymerization of actins, which are the ubiquitous proteins in the cytoskeletons, thus affecting vesicular trafficking, angiogenesis, autophagy, innate immunity, among a number of other crucial aspects. The hypoxic, acidic condition also favors the expression of efflux proteins such as p-glycoprotein (P-gp), and the cancer-associated G-protein-coupled receptor (GPCR) proteins such as OGR1 (ovarian cancer G-protein-coupled receptor 1), GPR4 (G-protein-coupled receptor 1), and TDAG8 (T-cell death-associated gene 8). P-gp, encoded by the ABCB1 gene, is overexpressed in cancers and infectious diseases, and it can eject drugs such as anticancer agents, antibiotics, antidepressants, reducing their efficacies. Due to the modified pH, sodium, potassium and calcium channels, which maintain ionic homeostasis, are manipulated, leading to pain, edema, and a range of other issues. Acidic pH is sensed as a stressful condition, and in retaliation, immune activation, neutrophil infiltration, platelet reactivity, platelet aggregation on collagen, etc. take place.

## Dietary Fibers

Incorporating functional ingredients in the diet to alleviate obesity and diabetes has spurred research in nutraceuticals. Dietary fiber encompasses polysaccharides (cellulose and hemicellulose), oligosaccharides, lignin, pectin, gum, wax, and mucilages and assorted phytochemicals. Fiber-rich foods are mostly from plant origin, though algae and fungi-based foods are fiber-rich as well. Seaweed polysaccharides (Patel, 2018) and mushroom beta glucan (Pillai and Uma Devi, 2013) have earned reputation as bioactive components. The inclusion of dietary fiber in food has been verified to ameliorate obesity and diabetes (Anderson et al., 2009). The total dietary fiber can be soluble or insoluble type. Soluble dietary fiber which encompasses oatmeal, beans, apples, nuts, and blueberries, can lower cholesterol level and blood pressure, can enhance mineral absorption, and can prevent gastrointestinal inflammations. Insoluble dietary fiber occur in cereal brans, whole grains, fruit peels etc. and on ingestion they prevent constipation, and hemorrhoids. The mucilage and oligosaccharides are substrates for gut bacteria that metabolize them into short-chain fatty acids (SCFA). Cereal brans that are rich in dietary fibers have been convincingly proven to confer satiety (Patel, 2015). Nutritional value of rice bran oil with tocotrienols, oat  $\beta$ -glucan fiber, anthocyanin in pigmented barley, the bran of wheat, sorghum, corn, barley etc. have been reported. Arabinoxylan, pectin, inulin, and resistant starch are other active components of dietary fibers with proven biological functions. Mediterranean diets dominated by olive oil, fruit, vegetables, and whole grain cereals are deemed beneficial for the patients with type 2 diabetes and high cholesterol. Fermented foods are well-regarded for their health attributes (Patel and Shukla, 2016). Kimchi, the fermented cabbage, was found to be low in calories, high in vitamins, minerals and phytochemicals, apart from dietary fiber. Red yeast rice, the mold *Monascus purpureus*-fermented product, owing to its polyketide monacolin K, apart from fiber content, has been shown to lower blood glucose level, by promoting insulin secretion (Patel, 2016). Fiber-rich oligosaccharides are important components of prebiotics, administered to promote the proliferation of probiotics in human gut (Patel and Goyal, 2010; Kothari et al., 2014). Paleo diet, the food habit of the human ancestors in the Paleolithic Era, which was dominated by plant products, has garnered much attention for their claimed and proven health benefits (Patel and Suleria, 2017). Several studies have confirmed their beneficial effects. The polyphenolic phytochemicals in the paleo diet lower acidity, maintain electrolyte balance and restore homeostasis. This diet improved glycemic control (glucose tolerance, insulin level) and cardiovascular risk factors (glucose tolerance, insulin level) in type 2 diabetes patients (Klonoff, 2009). Inflammation markers such as C-reactive protein (CRP) and glycated haemoglobin (HbA1c) were measured to be low in the paleo diet group. Paleo diet increased incretin (the hormone stimulating insulin secretion), anorectic gut hormone (glucagon-like peptide-1 (GLP-1) and peptide YY (PYY), which confer satiety feeling. The levels of interleukin-6 (IL-6), IL-1 $\beta$ , tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and inducible nitric oxide synthase (iNOS), known to be inflammation mediators, were reduced following paleo diet consumption. Fiber-rich foods attenuate inflammation and thus protect the insulin-secreting islets of Langerhans from oxidative stress. This diet also manipulates HMG-CoA reductase and sterol response element binding protein-2 (SREBP-2), reducing adiposity and tumor risks. Dietary fibers are fermented by gut bacteria, which generate SCFA such as acetate, and butyrate. The fibers improve microbiota composition, prevent constipation, reduce toxin generation (relieves the load on the liver and kidneys), and enhance vitamin B absorption from the gut. Also, they play role in modulating intestinal viscosity, passage frequency, and the production of gut hormones. Fig. 1 illustrates the variations in physiological effects of fiber-deficient Western diet and fiber-rich paleo diet.

The incorporation of dietary fibers of diverse sources such as algae, fungi, mushrooms, and underutilized plants have been endorsed by recent research findings. Fig. prunes, blueberry, barley, chicory root extract, flax seed, oat fiber, acacia fiber, apple pectin, and psyllium husks are increasingly used in diverse food products. *Amaranthus* flour has dietary fiber in a high amount (53.81 g/100 g), 79% of which is insoluble. The healthy property of cruciferous vegetables is attributed to the high content of fiber and phytochemicals such as glucosinolate. Phytochemicals are often associated with dietary fibers. Some of the phytochemicals such as berberine, catechins, curcumin have been consistently verified to be health promoters.

In recognition of the multiple health benefits of fiber-high diet, novel sources of dietary fibers are being investigated. Such research efforts has unveiled the potential of bamboo shoot, sugarcane, defatted strawberry seeds, soybean residue (okra), grape

**Figure 1** An illustration of the physiological effects of fiber-deficient Western diet and fiber-rich paleo diet. Western diet is acidogenic and inflammatory, which favors obesity and diabetes.

pomace, mango peel, date palm fruits, cassava root, agave bagasse, pumpkin seeds, coffee silverskin, grains (triticale), and pseudo grains (quinoa) to be included in food. The inclusion of phytochemicals such as quercetin with dietary fiber in nano-formulations has also been evaluated.

### Health Promotion Mechanisms of Dietary Fibers

Multiple studies have proven the mechanisms by which dietary fiber-rich plant diet lowers obesity and diabetes risk. Some prominent pathways have been mentioned below. Ghrelin hormone secreted by empty stomach induces hunger. Bulking agents quench hunger and provide satiety. Dietary fiber is difficult to digest, so its transit through the gut is slow, which gives a sensation of fullness. Satiety prevents further food intake, which helps in weight control. In studies, rice bran improved insulin resistance and wheat bran lowered glycemic index. Oat  $\beta$ -glucan fiber-based breakfast attenuated insulin secretion and improved the peptide hormone cholecystokinin. The metabolism of fiber-rich diet is likely to be generating metabolites, which favorably influence the anorexigenic pro-opiomelanocortin (POMC) neurons and the orexigenic neuropeptide Y (NPY)/agouti-related peptide (AgRP) neurons of hypothalamus. Studies have shown that the blockade of CB1 cannabinoid receptor induced weight loss and improved metabolic parameters. The fiber metabolites might be able to block the above receptors. SCFA generated by dietary fiber metabolism by gut bacteria ameliorated inflammation in animal model of gout, by augmenting the production of anti-inflammatory mediators such as IL-10, TGF- $\beta$ , and annexin A1. The roles of dietary fibers in alleviating gastroesophageal reflux disease, ulcer, colon cancer, and hemorrhoids have also been observed. Therefore, the health effects of fibers have been proven to be multifarious.

### Food Processing and Its Impact on Dietary Fibers

Now that the health benefits of dietary fibers have been validated through different experimental models, they are aggressively marketed as panacea. A wide range of food products such as chocolate, dairy milk shakes, pastries, ice cream, pasta, pizza, yogurt, and cereals are now fortified with dietary fiber. Consumers are enticed by this labelling, but, there lies a lacuna, which gets underreported. Dietary fibers have no taste; therefore food manufacturers make them appetizing by adding sugar and other ingredients

like cheese, dairy products, egg, monosodium glutamate (MSG), etc. For aesthetic appeal and texture, leavening (sodium aluminium phosphate), vinegar, artificial color, and carrageenan etc. are added to the fibre-enriched products. For longer shelf-life of the products, preservatives are added. If a product has high amounts of dietary fiber but has sodium benzoate and antibiotics, the product is still proinflammatory. With these combinations, do the benefits of dietary fiber remain intact? Also, the effects of processing techniques on the dietary fiber are not well-investigated. Techniques like canning, grinding, frying, drying, freezing, microwave treatment, extrusion-cooking, and boiling, modify the physico-chemical properties of dietary fiber. If vegetable chips marketed as fiber-rich are fried in oil and are heavily salted, the benefits of fiber are questionable. Similarly, trading canned vegetables as fiber-rich is lost in its preservatives, and the use of catchy names is not going to make the product healthy. Modern consumers should be able to see through these gimmicks and ought to make appropriate dietary decisions.

### Adverse Effects of Dietary Fibers

Also, the anti-nutrient aspect of dietary fibers has not been investigated well. Oxalic acid associated with fibers might interfere with iron absorption. Also, other components such as phytic acid, nitrate, lectins, hemagglutinin, trypsin inhibitor,  $\alpha$ -amylase inhibitor, alkaloids, and saponin contents ought to be determined. Glucosinolates in cruciferous plants are goitrogenic glycosides, which meddle with thyroid function. So, high fiber diet and minimal processing entail these negative aspects. Though the relevance of dietary fiber in constipation is proven, depending on the fiber type, and the host metabolic status, fibers can promote constipation and related symptoms (bloating and abdominal discomfort). The causes have been explained to be due to the fermentation of dietary fiber by colonic bacteria, resulting in the production of carbon dioxide, hydrogen, methane, and other gases.

Food crops like the legumes have antinutrient oligosaccharides such as stachyose and raffinose, which are fermented by colon microflora to release gas and cause abdominal distension. Other plant products such as pumpkin and watermelon seed flours that are known to be high in dietary fiber can also cause bloating. Excess consumption of dietary fiber can obstruct the intestinal tract and cause bezoar, a gastrointestinal mass of hardened undigested materials. Pomegranate seeds, sunflowers seed, pumpkin seed hull, persimmon peel etc. have been frequently associated with bezoar formation. Phytobezoar formation is more likely in older individuals and patients with weak digestive system. So, in these groups, high-fiber diets might not be too beneficial. Depending on the severity, bezoar removal can require surgical intervention. In the existing science literature, often the negative attributes are overlooked and the positive effects are overemphasized. So, it is very important that the consumer is aware of the complete picture.

### Discussion

Drugs are not the solution for all diseases, not especially for chronic metabolic diseases. Every drug furnishes its therapeutic effects via enzymes such as cytochrome P450, which also synthesize steroids. So, any therapeutic intervention manipulates hormone as well, which is not risk-free. So, expecting medications to shed weight, or restore glucose or ionic balance, is naïve. General public should be aware that drugs are synthetic compounds, which save lives in serious health conditions, but they must not be used in a routine manner. Radical lifestyle modifications and ingestion of fiber-based food may be used to address the rising epidemic of obesity and diabetes, both of which are tied to the common cause of inflammations, originating due to different stressors, including acidogenic food. The inclusion of fruits, vegetables and whole grains in diet, while cutting down on acidogenic, and inflammatory agents is a recommendable antidote against chronic conditions like obesity and diabetes. The exploration of edible dietary fiber from underutilized sources, and developing technologies to incorporate them in diets can be an effective way to keep MetS away. The type of fiber, dosage ingested, and host genotype are the factors, which determine the safety and efficacy of the fibers in diet. Furthermore, in a pragmatic vision, it can be stated that the importance of fiber for alleviating metabolic diseases is only one approach, which can go null if lifestyle abuse in other forms continues. Adherence to a chemical-free lifestyle can improve the beneficial prospects of high-fiber diet.

## Introduction

Protease inhibitors (PIs) are natural or synthetic compounds that inhibit the activity of proteases. Most natural protease inhibitors are small proteins (Liener, 1989). They are ubiquitous in living organisms and play a significant role in many biological processes by regulating proteolytic functions of their target enzymes (Liener, 1980). PIs occur abundantly in many food plants such as legumes, cereals, tubers and oil seeds (Ryan, 1990; Liener, 1994). Plant PIs were investigated as early as 1938, when Read and Haas recognized the presence of an inhibitor in soybean (Liener, 1980). The fraction of the functional protein was then partially purified by Bowman, as well as Ham and Sandstedt, followed by its subsequent isolation in crystalline form by Kunitz (Kunitz, 1947; Liener, 1980). Because of their ability to inhibit proteases including those in the human digestive system and reduce protein bioavailability, PIs are long regarded as anti-nutrients in foods such as soybean. On the other hand, it is increasingly recognized that PIs may have a positive contribution to human nutrition and health. Studies show that plant PIs, especially Bowman-Birk type inhibitors (BBI), may have the capacity to prevent and mitigate a number of diseases such as cancer, multiple sclerosis, inflammation and Duchenne muscular dystrophy (Losso, 2008; Clemente et al., 2011; Kobayashi, 2013; Hernández-Ledesma and Hsieh, 2017).

## Classification of Protease Inhibitors

In the most recent release of the MEROPS database (Release 12.0, September 2017), 134011 PI sequences were identified (Rawlings et al., 2018). This is an increase of 59353 sequences over the July 2015 release (Release 9.13), which is a testimony to both the vast number of PIs in nature and rapid increase in their identification (Rawlings et al., 2016, 2018). These sequences are grouped into 82 families based on their sequence homology, which are further clustered into 39 clans based on similarity in their tertiary structure. Only about 725 of the PIs, a fraction of the total number, were experimentally characterized (Rawlings et al., 2018). These PI families are found to be specific in their inhibitory action against the five major mechanistic classes of proteolytic enzymes and are classified accordingly as serine, cysteine, aspartic, metalloprotease and threonine protease inhibitors (Lehninger et al., 1993; Whitaker, 1997; Shewry, 2000; Laskowski and Qasim, 2000; Lawrence and Koundal, 2002). Serine and cysteine PIs are the largest groups and also the most extensively studied, partly because of their reputation as major antinutritional factors in plant storage tissues such as seeds and tubers. In some legumes, such as soybean, PIs may account as much as 10% of the soluble proteins (Whitaker, 1997; Mandal et al., 2002).

Serine PIs are the most extensively studied protease inhibitors. They are strictly competitive inhibitors forming 1:1 complexes with the enzymes they inhibit (Batista et al., 1996; Mello et al., 2001; Bhattacharyya et al., 2006, 2007; Macedo et al., 2007). The major common elements in the structures of serine PIs are their reactive site peptides, which generally comprise 10 – 15 amino acid residues. Their specific nature strongly affects both the strength and the specificity of enzyme–inhibitor interaction (Bode and Huber, 1992; Laskowski and Qasim, 2000). These reactive site peptides adopt a conformation that is complementary to the surface of the target enzymes and resemble the conformation of a substrate bound to the active site. Therefore, a range of conformations are found in different inhibitor families. Plant serine protease inhibitors have been identified from various leguminous seeds (Batista et al., 1996; Mello et al., 2001; Garcia et al., 2004; Bhattacharyya et al., 2006, 2007; Macedo et al., 2007), which are able to inhibit serine proteases *in vitro* with the optimum inhibitory activity at pH 9 – 11 range (Lawrence and Koundal, 2002).

The Kunitz-type soybean trypsin inhibitor (SBTI) is a typical serine PI. It consists of a single polypeptide chain with molecular weight in the range of 18–24 kDa. The protein structure is cross linked by two disulfide bonds which are located at Cys 136–145 and Cys 39–86, and its reactive site is located at Arg 63 and Ile 64 (Liener, 1980, 1989; Norton, 1991; Liu, 1997). The isoelectric point (pH 4.5) and the dissociation constant ( $K_i = 3.2\text{--}6.2 \times 10^{-9}$ ) of SBTI at pH 8.0 were reported (Deshimaru et al., 2002). They are quite resistant to denaturing reagents such as urea and guanidinium chloride; however, the rupture of both disulfide bonds leads to inactivation (Liener, 1980). Apart from legumes, Kunitz-type PIs have been widely found in cereals and solanaceous species (Magdalena, 1996; Habib and Fazili, 2007).

BBIs are another major family of serine PIs that have a molecular weight of 8–10 kDa with high cysteine but lack glycine and tryptophan contents and consist of two homologous domains each bearing a separate reactive site. They are widely distributed in monocot and dicot species (Richardson, 1991). BBIs from monocotyledonous plants are of two types. One group (8 kDa) consists of a single polypeptide chain with a single reactive site and another group (16 kDa) has two reactive sites (Habib and Fazili, 2007). In soybean, BBI is a relatively small molecule with a single polypeptide chain of 71 amino acids with seven disulfide bonds (Liener, 1989). It exhibits marked stability toward heat, acid and alkali; even after the disulfide bonds are broken by heating it still has stable conformation (Liener, 1989; Liu, 1997). BBI binds to trypsin and chymotrypsin at independent sites – a trypsin-reactive site (Lys 16–Ser 17) and a chymotrypsin-reactive site (Leu 44–Ser 45) with reported dissociation constant ( $K_i$ ) of  $2.8 \times 10^{-10}$  and  $2.9 \times 10^{-8}$ , respectively (Liener, 1980; Liener and Seidl, 1972).

Cysteine proteases catalyze the hydrolysis of peptides through a thioester intermediate. Common proteases in this group include papain, calpain and lysosomal cathepsin. These proteases are widespread in nature and so are their inhibitors. Their optimum

inhibitory activity usually occurs in the pH 5 – 7 range (Lawrence and Koundal, 2002). Egg white cystatin and rice cystatin are classic examples of cysteine PI (Gomes et al., 1997; Lawrence and Koundal, 2002; Oliveira et al., 2007). Aspartic proteases include human immunodeficiency virus (HIV) proteases, angiotensin converting enzyme, carboxypeptidases, pepsin and renin. Aspartic PIs have been isolated from sunflower, barley, cardoon (*Cyanara cardunculus*) flowers and potato tubers (Lawrence and Koundal, 2002) as well as animal tissues. There are two families of metallo-protease inhibitors, namely metallo-carboxypeptidase inhibitor family in potato and tomato plants, and a cathepsin D inhibitor (27 kDa) family in potato tubers (Lawrence and Koundal, 2002). Compared with other proteases, threonine proteases are studied not as extensively and their inhibitors have not been widely reported in foods.

## Inhibition Mechanisms

An enzyme inhibitor is a molecule that decreases the measured rate of enzyme-catalyzed hydrolysis of a given substrate. Protease inhibition usually applies to the competition between two substrates in a reaction with an enzyme (protease) where one can decrease the apparent rate of hydrolysis of the other (Nagase and Salvesen, 2001). The mechanism of enzymatic inhibition can be considered both kinetically as how it affects the efficiency of enzyme–substrate interactions and molecularly to examine how the inhibitor protein, especially its active site, interacts with the substrate at molecular level. From the kinetic standpoint, there are two types of inhibition – reversible and irreversible. Reversible inhibitors fall into three categories – competitive, uncompetitive and non-competitive. Non-competitive inhibitors can be further divided into two additional categories which are pure and mixed inhibitors (Lehninger et al., 1993).

### Competitive Inhibition

In competitive inhibition, the substrate (S) and the inhibitor (I) compete for the same active site of the enzyme (E), but only the substrate molecule completes the catalytic reaction. The inhibitor binds to E to form E–I complex and thus blocks the active site, but no catalytic reaction will occur. Since the inhibitor and substrate compete for the same site, raising the substrate concentration can fully dislodge the inhibitor from the active site (Lehninger et al., 1993). All serine inhibitor families from plants are competitive inhibitors (Lawrence and Koundal, 2002) and most of the PIs interfere with their respective proteases through a similar mechanism, known as the conical (standard) mechanism (Rolka et al., 2013). These inhibitors are characterized by a number of common features: small molecular weight (1.5–2.1 kDa) with compact structures that are stabilized by several disulfide bridges and rather resistant to thermal and chemical denaturation. Also, they all have an exposed short primary binding segment of less than 10 amino acid residues, also known as the “binding loop”, which is responsible for direct interaction with the target enzyme (Bode and Huber, 2000). While most inhibitors have a single binding loop, some contain multiple such motifs, which allow them to interact with and inhibit more than one protease simultaneously. As studied extensively by Laskowski and co-workers (Laskowski and Kato, 1980; Laskowski and Qasim, 2000; Rolka et al., 2013), the PIs act by forming a stable complex with the target protease through a classic “lock and key” mechanism where the inhibitor binding loop inserts into the active site of the enzyme. Unlike the S–E interaction, however, the I–E complex dissociates very slowly, thus blocking access of the substrate to the site (Silverman et al., 2001). The enzyme cleaves the inhibitor in a similar fashion to that of the substrate, but at a much reduced speed, and leads to a modification of the inhibitor. As the incubation progresses, the amount of the modified inhibitor will continually accumulate until equilibrium is reached with the intact inhibitor (Rolka et al., 2013). Soybean Kunitz-type trypsin inhibitor (SBTI) is a classic example of competitive inhibitors.

### Other Types of Inhibition

**Uncompetitive inhibition:** Uncompetitive inhibitors do not compete for the active site with the substrate; they only bind to the E–S complex and form an enzyme-substrate-inhibitor complex (E–S–I). This can occur as a result of conformational changes in enzyme structure that accompanies substrate binding, opening up a previously occluded site. The binding of an inhibitor to the E–S complex leads to a decrease in the concentration of the E–S complex, thus accelerating the affinity of the enzyme for the substrate to form E–S complex. By Le Chatelier’s principle, the equilibrium of the enzyme and substrate will shift to form more E–S complex in the presence of an uncompetitive inhibitor (Lehninger et al., 1993). This type of inhibition is rarely found in single-substrate reactions, and usually occurs in two-substrate reactions (Belitz and Weder, 1990). It has not been reported for any leguminous protease inhibitors.

**Non-competitive inhibition:** Non-competitive inhibitors bind at the site distinct from the substrate active site and leave the active site unblocked. Therefore, the inhibitor can react equally with free enzyme or with the E–S complex. However, the E–S–I complex cannot convert the substrate into product. Furthermore, non-competitive inhibitors can be divided into two additional categories which are pure and mixed inhibitors. In pure non-competitive inhibition, the substrate has an identical affinity for both the free enzyme and the E–I complex. However, with mixed non-competitive inhibition, the affinity of the E–I complex for the substrate is not the same as the free enzyme (Lehninger et al., 1993). Therefore, non-competitive inhibition cannot be overcome by high concentrations of substrate (Belitz and Weder, 1990).

**Irreversible inhibition:** Irreversible inhibitors usually covalently modify an enzyme and, therefore, the inhibition cannot be reversed. Electrophilic groups of the inhibitor, such as aldehydes, haloalkanes or alkenes, react with the enzyme’s side chains

containing nucleophiles, such as hydroxyl or sulfhydryl groups, including serine, cysteine, threonine or tyrosine (Lehninger et al., 1993). The irreversible inhibitors form a reversible non-covalent complex as E-I or E-S-I complex and then produce a “dead-end complex”. The reaction cannot be reversed by diluting the reaction medium.

## Biological and Health Functions of Protease Inhibitors

Plant PIs can both positively and negatively impact human nutrition and health. Plant PIs are well documented antinutritional factors. They exhibit strong inhibitory activity against trypsin and chymotrypsin, by forming stable complexes in the digestive tract, thus causing a decrease in the ability of body to utilize proteins in foods (Liener, 1980, 1989; Norton, 1991; Vagadia et al., 2017). Prolonged consumption of food with high levels of active PIs may lead to protein deficiency, which can be especially serious in populations with insufficient supply of high protein foods. However, plant PIs are relatively heat labile (although they are usually more stable than most other proteins) and can be easily inactivated by either dry or moist heat treatment such as roasting, steaming and many of other methods of cooking (Deshpande, 1992; Liener, 1994; Vagadia et al., 2017). In most societies where legumes are consumed as a traditional staple, people have developed methods such as soaking and boiling of soy beans, usually by trial and error, to inactivate the PIs (Vagadia et al., 2017).

On the other hand, PIs can also play a number of significant positive roles in agriculture and human health. One of the early recognized beneficial functions of plant PIs is their effect on plant pathogens. As early as in 1947, Mickel and Standish observed that the larvae of certain insects were unable to develop normally on soybean products (Lawrence and Koundal, 2002). Since then, plant PIs have been investigated extensively for their potential use as bioinsecticides and fungicides (Macedo et al., 2003; Haq et al., 2004; Abdeen et al., 2005; Park et al., 2005; Habib and Fazili, 2007). Numerous PIs purified from legumes, cereal seeds and tubercles, especially those belonging to the Kunitz and Bowman-Birk families, have been found to play a significant role in plant defense against insect and phytopathogen attacks by interfering with the digestive enzymes of the pests (Richardson, 1991; Bode and Huber, 2000; Macedo et al., 2004; Bhattacharyya et al., 2007; Oliveira et al., 2007). Studies on the insecticidal activity of PIs from black-eye pea (Oliveira et al., 2002) and *Pithecellobium dumosum* seeds (Oliveira et al., 2007) suggest that the digestive system of Lepidopterans and Dipterans is mainly based on serine proteases whereas cysteine proteases are predominant in Coleopterans of the Bruchidae family. It has also been reported that cowpea vicilins (7S globulins) provide resistance to a range of invertebrate pests and the germination of fungal spores (Gomes et al., 1997).

Proteolysis is one of the most prevalent mechanisms of biological regulation and it is involved in many fundamental physiological processes. Aberrant functioning of certain proteases is well recognized as an underline cause of many pathological disorders such as cancer, angiogenesis, inflammation, neurodegenerative and cardiovascular diseases (Heutink et al., 2010; Clemente and Arques, 2014). As one of the regulating mechanisms of proteolysis, it not surprising that PIs may play a role in mitigating these disorders. Interest in the health functions of plants PIs gained special momentum following the discovery that certain PIs from legumes are effective in preventing or suppressing carcinogenic processes in a wide variety of *in vitro* and *in vivo* model systems and they might be used as chemopreventive agents for certain cancers (Kennedy, 1998a, 1998b). Of all the PIs, the health effects of BBI are the most intensely studied and the subject has been extensively reviewed (Kennedy, 1993a, 1993b, 1993c, 1994, 1995, 1998c, 2007, 2009, 2013; Kennedy and Wan, 2002; Morris et al., 2005). Numerous pharmacological effects and health functions have been reported for BBI, including antitumor and cancer preventive effects, anti-inflammatory activities, prevention of multiple sclerosis and Duchenne muscular dystrophy (DMD), as well as a number of other benefits such as protection against radiation-induced birth defect, hair and weight loss in cancer patients, improved efficacy of certain chemotherapeutic drugs and life-span extension (Armstrong et al., 2000, 2003; Morris et al., 2005, 2010; Gran et al., 2006; Arbogast et al., 2007; Touil et al., 2008; Dai et al., 2011; Leung et al., 2013; Clemente and Arques, 2014). Recent *in vivo* studies using animal models indicate that daily administration of BBI concentrate (BBIC) at 200 mg rat<sup>-1</sup> for 16 days can effectively inhibit and ameliorate clinical and pathological symptoms of experimental autoimmune neuritis (EAN) - an animal model of Guillain-Barré syndrome (GBS), suggesting that BBIC may have therapeutic effects in human GBS (Jin et al., 2016).

With regard to the antitumor properties, BBI has been reported to exhibit therapeutic effects against colorectal cancer, oral leukoplakia, prostate and breast cancers in a number of *in vitro* as well as *in vivo* studies using cancer cell lines and animal models (Kennedy, 1993a, 1993b, 1993c, 1994, 1995, 1998c, 2007, 2009, 2013; Kennedy and Wan, 2002; Morris et al., 2005; Chan et al., 2013). At the present the therapeutic targets of BBI have not been identified and the action mechanism is yet to be elucidated. Most of the exciting evidence suggests that BBIs exert their preventive effect through protease inhibition in carcinogenesis (Clemente and Arques, 2014). In one of the studies (St Clair et al., 1990), colon carcinogenesis in DMH-treated mice was suppressed when purified and semi purified soybean BBIC was administrated at 0.5% of the diet or less for 20 weeks. When the protease inhibitory activity of the BBIC was inactivated by high temperature treatment, such suppression on DMH-induced colon carcinogenesis was not observed, suggesting that the chemopreventive effect of BBI is associated with its ability to inhibit serine proteases. In another study, soybean BBI in the concentration range of 0–125 µM was found to cause a significant, dose- and time-dependent decrease in the proliferation of human colorectal adenocarcinoma cells, whereas BBI inactivated by alkaline and reducing agents was unable to exert such an effect (Clemente et al., 2010). Studies using BBI from mutant pea seeds that do not possess trypsin and chymotrypsin inhibitory activity, and BBI whose activity have been destroyed by chemical scission also demonstrate the linkage between the anti-proliferation activity of plant BBI and its protease inhibitory activity. These works suggest that trypsin- and chymotrypsin-

like proteases involved in the early stages of carcinogenesis are likely the targets of BBI for the therapeutic effects (Yavelow et al., 1985; Clemente et al., 2012).

A number of the studies have progressed to clinical trials. However, while the results of tissue culture and animal model studies have been generally promising, results of clinical trials are mixed. For example, in a Phase IIa clinical trial on the effect of BBIC on oral leukoplakia, it was found that about one-third of the subjects receiving BBIC at 200–1066 chymotrypsin inhibitor units (CIU) for one month showed a dose–response relationship in decreased lesion size (Armstrong et al., 2000). However, in the subsequent randomized, placebo controlled phase IIb trial, such effect was not observed (Armstrong et al., 2013).

Soybean BBI also exhibits potent anti-inflammatory effects. Both soybean BBI and BBIC were able to significantly suppress colon and anal gland inflammation of carcinogen-treated rodents (Billings et al., 1990; Armstrong et al., 2000). Soybean BBIC also reduced the severity of inflammatory conditions in mice with dextran sulfate sodium-induced ulcerative colitis (Ware et al., 1999). The mechanisms of BBI's anti-inflammatory action is not fully understood but could be related to their capacity to decrease the production and release of superoxide anion radicals and hydrogen peroxide, which are mediators of acute and chronic inflammation. The decrease in these highly oxidative species might reduce levels of oxidative damage to DNA, lipid peroxidation of cellular membranes and incidence of malignant transformation (Clemente and Arques, 2014).

A recent exciting development is the potential therapeutic role of soybean BBI in the prevention and treatment of HIV. It was shown that BBI could inhibit HIV reverse transcriptase (Ye et al., 2001; Ye and Ng, 2009; Prasad et al., 2010), inhibit HIV replication in macrophages through induction of the intracellular antiviral factors and block HIV entry into macrophages (Ma et al., 2016, 2018). Furthermore, BBI is also important in protecting lunasin from proteolysis in the gastrointestinal tract (GIT). Lunasin is a short peptide found in soybeans and cereals, which has been reported to confer a number of health benefits including anticancer effects (Jeong et al., 2002, 2003, 2007, 2009; Hernandez-Ledesma et al., 2013; Nakurte et al., 2013; Dinelli et al., 2014). Inhibition of gastric pepsin and pancreatic trypsin by BBI is crucial for the intact passage of lunasin through the GIT for absorption into the blood system of the body (Hsieh et al., 2010; Hernandez-Ledesma et al., 2013).

While most of the studies have focused on BBI of soybean, studies are beginning to explore BBI from other sources. Ng and co-workers isolated a BBI from brown kidney beans and trypsin inhibitor from the Faba beans (Fang et al., 2010a,b,c, 2011; Chan et al., 2013). The BBI, which has a MW of about 17 kDa, exhibited similar biochemical characteristics to soy BBI such as strong thermal and pH stability, and it inhibited the proliferation of human breast cancer MCF7 cells with an  $IC_{50}$  of 71.52  $\mu$ M (Chan et al., 2013). As BBIs are found widely in legumes and cereal seeds, their bioactivities remain a worthy subject for exploration. Other than BBI, Kunitz-type protease inhibitors (KTIs) have also been shown to exert anticancer effects. KTIs isolated from both Korean and Chinese mini-black soybean displayed potent anti-tumour effects by suppressing the proliferation of breast cancer MCF-7 cells, hepatoma HepG2 cells, nasopharyngeal carcinoma cells CNE-2 and HNE-2 cells (Fang et al., 2010a,b,c; Ye and Ng, 2011). They also showed strong inhibitory activities against HIV-1 reverse transcriptase, an important enzyme in the virus's replication in the host and entrance to host genome. Kunitz-type protease inhibitors isolated from other sources such as Bauhinia tree species also displayed antiproliferation activity against a number of cancer cell lines including human nasopharyngeal carcinoma cell CNE-1 and Hep G2 (Fang et al., 2010a,b,c, 2012). Moreover, a recent study has shown that legume seeds also contain matrix metalloproteinases (MMP) inhibitors which inhibited MMP-9 (an enzyme that is closely involved in colorectal cancer metastatic progression) and reduced colon cancer cell migration (Lima et al., 2016).

## Extraction of Protease Inhibitors

Extraction and purification of PIs from biological matrices involve a complex process, which usually involves multiple steps and requires careful consideration to select the most appropriate methods. Cell disruption is usually the first step to release the protein in a soluble form from its intracellular compartment. Several disruption techniques, both mechanical and chemical, are available for different materials. For plant seeds, grinding is found to be more efficient than alternatives such as enzymatic digestion, homogenization, pressing and sonication (Ahmed, 2005).

Many plant storage organs, such as seeds and tubers contain >10% of their soluble proteins as PIs (Mandal et al., 2002). Seed proteins are normally classified based on their solubility in a sequential series of solvents (Tanford, 1961). These are water soluble albumins, dilute salt solution soluble globulins, alcohol soluble prolamins and dilute acid or alkali soluble glutelins. However, proteins are extremely heterogeneous biological macromolecules. Their properties can be affected by small changes in hydrogen ion concentration, and thus a stable pH of the environment is necessary (Ahmed, 2005). Thus, appropriate buffer solution is usually used in the extraction of soluble proteins including PIs.

The purification of protein is an essential step for the study of its molecular and biological properties. On the basis of the properties of proteins, such as molecular weight, charge, hydrophobicity, binding affinity and isoelectric point (pI), several chromatographic and non-chromatographic (precipitation, electrophoretic and membrane filtration) separation techniques are available. These fractionation procedures need to be accompanied by bioactivity assays and possibly other characterization analyses. The purpose of these characterizations is to determine whether the specific activity of the PIs increases after fractionation. A failure to increase the specific activity suggests that the initial apparent inhibition might be due to endogenous substrates competing with the test substrate, rather than the presence of PIs (Nagase and Salvesen, 2001).

PIs may be purified by a single step using affinity chromatography, or by a combination of several steps, such as ammonium sulfate precipitation (salting out), organic solvent precipitation, ion-exchange and gel filtration chromatography (Bollag et al.,

1996). Among the commonly used salts, sulfites ( $\text{SO}_3^{2-}$ ) have the strongest effects in reducing solubility (Liu, 1997). Salting out process works best with divalent anions like sulfate, according to the Hofmeister series (Zhang and Cremer, 2006), especially ammonium sulfate  $((\text{NH}_4)_2\text{SO}_4)$ , which is highly soluble even at icy temperatures. It is useful for fractionating a mixture of proteins and purifying target PIs. Since large proteins tend to precipitate first, smaller ones will stay in solution (Tanford, 1961). The initial decrease in solubility is due to decreased electrostatic repulsion and enhanced hydrophobic interaction between protein molecules as a result of electrostatic shielding of charge groups in proteins by ions (Liu, 1997; Zhang and Cremer, 2006).

Column chromatography is a powerful method for fractionating proteins and the success of the technique is often determined by the selection of appropriate packing material for the column. In general, anion-exchange chromatography is employed for the purification of an acidic protein. Similarly, cation-exchange chromatography is suitable for the purification of a basic protein. Reverse-phase chromatography is suitable for a family of active proteins of similar charge (Ahmed, 2005).

Combination of anion-exchange chromatography, membrane ultrafiltration and reversed-phase or gel-filtration chromatography has been used successfully to obtain gram quantity of lunasin from a kilogram of defatted soy flour (Dia et al., 2009; Seber et al., 2012). However, these procedures are cumbersome, time-consuming and can be cost prohibitive. As a result, some innovative methods have been developed recently. For example, Krishnan and Wang (2015) developed a simple procedure to isolate and purify lunasin from soy flour by extraction with 30% ethanol followed by preferential precipitation of lunasin and protease inhibitors by calcium salt. The procedure was able to obtain 3.2 g of active lunasin concentrate from 100 g soy flour.

## Concluding Remarks

Protease inhibitors are a large and important group of molecules that are ubiquitously distributed in nature. They play a crucial role in many biological processes by regulating proteolytic functions of their target enzymes in living organisms. PIs are widely found in food plants with particular abundance in legumes but also in cereals and tubers, where they form part of the plant's defense against pest attack. Although PIs are traditionally regarded as anti-nutrients as they interfere with the digestion of protein in foods, studies over the last three decades have increasingly revealed their positive contribution to human health. There is a substantial and growing body of evidence demonstrating that plant PIs, especially soybean Bowman-Birk inhibitors, have preventive and therapeutic effects against several common cancers, as well as multiple sclerosis, inflammation and a number of other diseases. However, more research activities are needed to confirm these effects through clinical trials and to elucidate their mechanisms of action. Future research could also direct at exploring the health-benefitting properties of PIs from other legumes as well as cereals and other seeds.

## Introduction

Carotenoids are lipophilic natural pigments responsible for the yellow, orange, or red color of many plant foods. They are known for their structural diversity and multiple functions and actions.

Plants are able to synthesize carotenoids *de novo*, thus carotenoids are widely distributed in plant-derived foods and the composition is variable and usually complex. Along with the principal carotenoids, low or trace levels of their biosynthetic precursors and derivatives are found (Rodriguez-Amaya, 1999a). The carotenoids are located in subcellular organelles (plastids), mainly associated with proteins in the chloroplasts and deposited in crystalline forms or as oily droplets in chromoplasts (Bartley and Scolnik, 1995).

Maturation/ripening of carotenogenic fruits, roots, and seeds is characterized by heightened carotenoid biosynthesis and oxidative cleavage of a part of these carotenoids to volatile compounds that contribute to the typical aroma/flavor (Rodriguez-Amaya, 2015).

Carotenoids have limited occurrence in foods of animal origin. Incapable of carrying out carotenogenesis, animals are limited to selectively or unselectively absorbing dietary carotenoids, which are accumulated unchanged or slightly altered into carotenoids typical of animal species.

## Chemical Structures and Physicochemical Properties

Food carotenoids are generally C<sub>40</sub> tetraterpenoids, having a centrally located conjugated double bond system (Fig. 1). The basic linear and symmetrical skeleton has lateral methyl groups separated by six C-atoms at the center and the others by five C-atoms. Modifications by cyclization, hydrogenation, dehydrogenation, introduction of oxygen-containing groups, migration of the double bonds, rearrangement, chain shortening or extension, or combinations thereof result in an impressive array of structures.

Carotenoids may be acyclic (e.g. lycopene) or may have a six-membered ring at one (e.g.  $\gamma$ -carotene) or both extremities (e.g.  $\beta$ -carotene,  $\alpha$ -carotene) of the molecule. Exceptionally, capsanthin and capsorubin have five-membered rings.

Hydrocarbon carotenoids are known as carotenes, and the oxygenated derivatives are called xanthophylls. Typical oxygen-containing substituents are hydroxyl (as in  $\beta$ -cryptoxanthin), epoxy (as in violaxanthin), and aldehyde (as in  $\beta$ -citaurin) groups.

Carotenols in ripe fruits are esterified with fatty acids (Breithaupt and Bamedi, 2001; Delgado-Pelayo and Hornero-Méndez, 2012; Etzbach et al., 2018; Inbaraj et al., 2008; Weller and Breithaupt, 2003), except in a few fruits, particularly those that remain green when ripe (e.g. kiwi) (Gross, 1987), in which limited or no esterification occurs. In green leaves (Kobori and Rodriguez-Amaya, 2008), hydroxycarotenoids are unesterified; those of corn (Rodriguez-Amaya and Kimura, 2004; De Oliveira and Rodriguez-Amaya, 2007) are mostly unesterified. Lutein, the principal carotenoid, occurs free or esterified in one (monoester) or both hydroxyl groups (diester) in nasturtium (Niizu and Rodriguez-Amaya, 2005) and marigold (Breithaupt et al., 2002) flowers, with the esters predominating. Esterification occurs progressively during maturation, increasing the lipophilic character of xanthophylls and facilitating their accumulation in the chromoplasts (Gross, 1987). Esterification was recently shown to facilitate accumulation of carotenoids and their deposition throughout tritordeum grains (Mellado-Ortega and Hornero-Méndez, 2018). Moreover, esterified carotenoids appear to have greater stability, as observed in red and hot chili peppers during processing (Schweiggert et al., 2007).

Carotenoids in which the carbon skeleton has been shortened by removal of fragments from one or both ends of the usual C<sub>40</sub> structure are called apocarotenoids. Natural examples are bixin and crocetin, the main coloring component of annatto and saffron, respectively.

The conjugated double bond system constitutes the light-absorbing chromophore that confers the carotenoid's attractive color and is mainly responsible for their special properties and many functions (Rodriguez-Amaya, 1999a). As the pale yellow  $\zeta$ -carotene, a carotenoid should have at least 7 conjugated double bonds in order to have perceptible color. Lycopene, with 11 conjugated double bonds in an acyclic structure, is red. Cyclization takes the  $\pi$  electrons of the ring double bond out of plane with those of the chain, thus the monocyclic  $\gamma$ -carotene and the dicyclic  $\beta$ -carotene, although possessing 11 conjugated double bonds, are red-orange and yellow-orange, respectively. The hydroxyl groups do not affect the chromophore, thus both  $\alpha$ -carotene and lutein are pale yellow, while  $\beta$ -cryptoxanthin and zeaxanthin, have the same color as  $\beta$ -carotene.

## Food Sources and Composition

The carotenoids most commonly encountered in foods are  $\beta$ -carotene,  $\alpha$ -carotene, lycopene,  $\beta$ -cryptoxanthin, lutein, and zeaxanthin (Fig. 1). Rich sources of  $\beta$ -carotene are some palm fruits, some squash cultivars, green vegetables, carrot, orange-fleshed sweet potato, cantaloupe, mango, and apricot.  $\alpha$ -carotene sometimes accompanies  $\beta$ -carotene, as in carrot and some varieties of squashes,

**Figure 1** Carotenoids commonly found in foods.

pumpkins, and palm fruits.  $\beta$ -Cryptoxanthin is the main pigment of many orange-fleshed fruits, such as peach, nectarine, orange-fleshed papaya, tangerine, persimmon, and tree tomato. Lycopene-rich foods are tomato, pitanga, pink-fleshed guava, red-fleshed papaya, and watermelon. The richest sources of lycopene, however, are the Asian gac fruit (Ishida et al., 2004; Vuong et al., 2006) and the Spanish sarsaparilla (Delgado-Pelayo and Hornero-Méndez, 2012). Corn and corn products are major dietary sources of zeaxanthin/lutein. Leafy and other green vegetables are the main sources of lutein.

The carotenoids of green vegetables have a defined pattern, with lutein,  $\beta$ -carotene, violaxanthin, and neoxanthin as the main carotenoids (Frazie et al., 2017; Kimura and Rodriguez-Amaya, 2002; Kobori and Rodriguez-Amaya, 2008). Lettuce, exceptionally, also has lactucaxanthin as a major carotenoid. Fruits, including those used as vegetables, have variable and often complex carotenoid compositions (Rodriguez-Amaya et al., 2008a; Rodriguez-Amaya, 2015).

The different factors affecting the carotenoid composition of plant foods have been extensively investigated, such as cultivar/variety, maturity, climate or season, geographic site of production, agronomic practices, part of the plant utilized, harvesting and post-harvest handling (Gross, 1987, 1991; Maiani et al., 2009; Rodriguez-Amaya, 1999a, 2015; Rodriguez-Amaya et al., 2008b).

## Stability and Alterations During Processing and Storage of Food

Carotenoid stability is influenced by the nature of the carotenoid (carotene or xanthophyll, *trans* (*E*-) or *cis* (*Z*-), esterified or unesterified) and the food matrix (fruit, root, leaf, juice, peeled, sliced, shredded), oxygen, light, water activity, atmosphere, oxidizing enzymes, antioxidants, metal catalysts, pro-oxidants, processing and storage conditions and duration.

Degradation increases with destruction of the food cellular structure, greater surface area or porosity, duration and severity of processing conditions, duration and inadequate conditions of storage, permeability of packaging material to O<sub>2</sub>, and exposure to light (Hager and Howard, 2006; Maiani et al., 2009; Pénicaud et al., 2011; Rodríguez-Amaya, 1999b, 2015; Shi and le Maguer, 2000; Xianquan et al., 2005).

Alteration or loss of carotenoids during processing and storage of foods takes place through physical removal, geometric isomerization, and enzymatic or nonenzymatic oxidation (Rodríguez-Amaya, 1999b, 2015). Carotenoids are more concentrated in the peel than in the pulp, thus peeling and juicing result in substantial losses of carotenoids. Enzymatic oxidation of carotenoids can occur to a greater extent than thermal decomposition in many foods. Blanching may provoke some losses of carotenoids, but the inactivation of oxidative enzymes will prevent further and greater losses during processing and storage.

In nature, carotenoids occur primarily in the all-*E*-configuration. *E-Z* isomerization is promoted by acids, heat, and light. The release of organic acids during slicing, pulping or juicing of fruits can provoke this isomerization, but it occurs to a greater extent during thermal processing (Cervantes-Paz et al., 2014; Imsic et al., 2010; Knockaert et al., 2012; Lessin et al., 1997; Marx et al., 2003; Mayer-Miebach et al., 2005; Nguyen and Schwartz, 1998; Seybold et al., 2004; Shi et al., 2003; Updike and Schwartz, 2003; Vásquez-Cañedo et al., 2007).

Some double bonds are prevented from isomerizing because the *Z*-configuration is sterically hindered. Thus, the *Z*-isomers of symmetrical  $\beta$ -carotene commonly found in foods are 9-*Z*-, 13-*Z*-, and 15-*Z*-  $\beta$ -carotene (Fig. 2). The acyclic lycopene is isomerized to 5-*Z*-lycopene, along with the 9-*Z*-, 13-*Z*-, and 15-*Z*-isomers (Li et al., 2012; Schierle et al., 1997; Stinco et al., 2013; Tiziani et al.,

**Figure 2** Geometric isomers of  $\beta$ -carotene, lycopene, and lutein. Taken from Rodríguez-Amaya (2015).

**Figure 3** General scheme for the oxidative degradation of carotenoids. Taken from [Rodríguez-Amaya \(2015\)](#).

2006). The unsymmetrical  $\alpha$ -carotene,  $\beta$ -cryptoxanthin, and lutein ([Achir et al., 2010](#); [Aman et al., 2005](#); [Dachtler et al., 2001](#); [Humphries and Khachick, 2003](#); [Lessin et al., 1997](#); [Updike and Schwartz, 2003](#)) give rise to 13'-Z- and 9'-Z-isomers in addition to 13-Z-, 9-Z-, 15-Z-isomers.

E-Z isomerization decreases color intensity and the ability to quench singlet oxygen ([Conn et al., 1991](#); [Stahl and Sies, 1993](#)). It also results in loss of provitamin A activity and alteration of bioavailability and metabolism.

Enzyme-catalyzed oxidation takes place prior to heat treatment, during peeling, slicing, and pulping, but can also occur in minimally processed foods and in unblanched frozen foods during thawing ([Rodríguez-Amaya, 1999a, 2015](#)).

Nonenzymatic oxidation (also called autooxidation) is accompanied by isomerization, and both the Z- and E-isomers are oxidized ([Fig. 3](#)) ([Rodríguez and Rodríguez-Amaya, 2007, 2009](#)). Oxidation initially involves epoxidation, cleavage to apocarotenals, and hydroxylation ([Marty and Berset, 1988, 1990](#); [Rodríguez and Rodríguez-Amaya, 2007, 2009](#); [Zepka and Mercadante, 2009](#)). Subsequent fragmentations result in a series of compounds of low molecular masses (volatiles).

Epoxidation of  $\beta$ -carotene begins with oxygen attack at the terminal double bond of the conjugated double bond system on one side of the molecule, and then on the other side, forming  $\beta$ -carotene-5,6-epoxide and  $\beta$ -carotene-5,6,5',6'-diepoxide, respectively. Rearrangement of the 5,6- to the 5,8-epoxide yields  $\beta$ -carotene-5,8-epoxide and  $\beta$ -carotene-5,8,5',8'-diepoxide ([Henry et al., 2000](#); [Kanasawud and Crouzet, 1990](#); [Marty and Berset, 1986, 1988, 1990](#); [Rodríguez and Rodríguez-Amaya, 2007](#)).

Epoxidation of lycopene occurs at both the terminal conjugated double bonds and the isolated double bonds with the formation of lycopene-1,2-epoxide and lycopene-1,2,1',2'-diepoxide, along with lycopene-5,6-epoxide and lycopene-5,6,5',6'-diepoxide ([Khachik et al., 1998a,b](#); [Rodríguez and Rodríguez-Amaya, 2009](#)). Combinations of these epoxides and cyclization result in a greater number of products and a more complicated epoxidation scheme.

Cleavage of  $\beta$ -carotene results in  $\beta$ -apo-carotenals ( $\beta$ -apo-15-carotenal,  $\beta$ -apo-14'-carotenal,  $\beta$ -apo-12'-carotenal,  $\beta$ -apo-10'-carotenal, and  $\beta$ -apo-8'-carotenal). Similarly, lycopene is cleaved to apo-15-lycopenal, apo-14'-lycopenal, apo-12'-lycopenal, apo-10'-lycopenal, apo-8'-lycopenal, and apo-6'-lycopenal ([Kopeck et al., 2010](#); [Rodríguez and Rodríguez-Amaya, 2009](#)).

Volatile compounds are generated from carotenoids by direct cleavage of the polyene chain, sequential cleavage, and transformation of the initial volatiles ([Rodríguez-Amaya, 2015](#)). These are mostly aldehydes, ketones, alcohols, hydrocarbons, furans, and pyrans ([Caris-Veyrat et al., 2003](#); [Kanasawud and Crouzet, 1990](#); [Kobori et al., 2014](#); [Rios et al., 2008](#)). Now devoid of the color and the biological activities of carotenoids, they contribute to the desirable flavor of foods and beverages, as in wine and tea, or to off-flavor, as in dehydrated carrot.

## Carotenoids as Food Colorants

Carotenoids are produced commercially as food and feed color additives and supplements. Commercial carotenoids (e.g.,  $\beta$ -carotene, astaxanthin, and canthaxanthin) are mostly products of chemical synthesis, but they are also produced by extraction from

a small number of rich natural sources (annatto, paprika, saffron, tomato lycopene extract or concentrate, marigold lutein) and by microbial fermentation ( $\beta$ -carotene by the microalga *Dunaliella* sp., astaxanthin by the microalga *Haematococcus pluvialis*, and  $\beta$ -carotene by the fungus *Blakeslea trispora*).

Stimulated by consumers' concern about the safety of artificial food dyes and the possible health-promoting effects of natural colorants, the replacement of the former by the latter is a current trend. Natural colorants, however, are usually less stable, more costly, not as easily utilized as synthetic dyes, besides having weaker tinctoral strength, interaction with food components, and limited range of hues (Sigurdson et al., 2017; Wrolstad and Culver, 2012). The utilization of carotenoids in particular is hampered by their insolubility in water, instability, and low bioavailability. The first two problems have been addressed by the formulation of water-dispersible market products, as colloidal suspensions, emulsions, or dispersions in suitable colloids. In recent years, attention has centered on encapsulation and nanoencapsulation (Rodriguez-Amaya, 2015).

## Health Effects

The long established function of carotenoids in terms of human health is the provitamin A activity. To serve as a precursor of vitamin A, a carotenoid should have an unsubstituted  $\beta$ -ring with an 11-carbon polyene chain.  $\beta$ -carotene can potentially yield two molecules of vitamin A.  $\alpha$ -Carotene and  $\beta$ -cryptoxanthin would have about half the bioactivity of  $\beta$ -carotene. The acyclic carotenoids (i.e., lycopene) and xanthophylls, in which both  $\beta$ -rings have substituents (i.e., lutein and zeaxanthin), are not provitamins A.

In more recent years, other health benefits have been attributed to carotenoids, provitamins A or not, such as immunoenhancement and reduction of the risk of developing chronic diseases such as cancer, cardiovascular diseases, cataract, and macular degeneration (Krinsky and Johnson, 2005; Rao and Rao, 2007; Tapiero et al., 2004).

The action of carotenoids against diseases has been widely attributed to their antioxidant activity (Müller et al., 2016; Kiokias and Gordon, 2004; Krinsky, 2001; Rodriguez-Amaya, 2015; Stahl and Sies, 2003). However, non-antioxidant mechanisms are increasingly cited, such as retinoid-dependent signaling, modulation of carcinogen metabolism, regulation of cell growth, inhibition of cell proliferation, enhancement of cell differentiation, stimulation of intercellular gap junction communication, gene regulation, modulation of DNA repair mechanisms, induction of detoxifying enzymes, hormonal and immune system modulation, and filtering of blue light (Krinsky and Johnson, 2005; Rao and Rao, 2007; Stahl et al., 2002; Tapiero et al., 2004).

Lycopene's possible role in human health has drawn considerable attention, especially in relation to prostate cancer (Hadley et al., 2002; Miller et al., 2002; Stacewicz-Sapuntzakis and Bowen, 2005; Wertz et al., 2004). Lutein and zeaxanthin selectively accumulate in the macula of the human retina (Bone et al., 2001; Landrum and Bone, 2001) and are associated with reduced risk of age-related macular degeneration, the major cause of irreversible blindness in the elderly (Bone et al., 2001; Carpentier et al., 2009; Gale et al., 2003; Moeller et al., 2000), and cataract (Delcourt et al., 2006; Gale et al., 2001; Moeller et al., 2000).

The literature on carotenoids and human health is now voluminous, but inconsistent results persist, the carotenoid intake having significant or no association/effect on disease incidence. These discrepancies have been mainly attributed to differences in the experimental protocols applied in the different studies (Costa-Rodrigues et al., 2018). Mordente et al. (2011), for example, in his review of 54 clinical trials of lycopene supplementation and cardiovascular diseases, noted that the number of subjects varied from 12 to 100, the dose from 4 to 80 mg/day and the duration from 1 to 60 days. There are, however, at least three major findings that make studies on this topic especially challenging, raising the possibility that consistent results may not be achieved even when the protocols are optimized and standardized (Rodriguez-Amaya, 2015). First, the effect of bioactive compounds on the human body may be very small over relatively short periods (months or a few years), but can contribute significantly throughout life as part of the daily diet. The health effect may not be observed during the study period, perhaps explaining studies reporting no significant effect. Doses above the physiological levels have been used in an attempt to observe the outcome better, but the results cannot be extrapolated to actual human situations. Second, it is now known that reduction of the risk of chronic diseases is not due to a single constituent or a single class of compounds but to the mixture of bioactive compounds contained in foods. Thus, while the evidence for the beneficial effects of plant foods is compelling, that for individual phytochemicals is often inconclusive. On the other hand, when food is used, attributing the effects to specific bioactive compound is presumptive. Third, there is considerable variation in inter-individual responses to the administered bioactive compound, further masking the health effects and making it difficult to draw conclusions. Genetic variation appears to be a key factor in this huge inter-individual variability.

The consensus is that there is ample evidence to support and recommend increased consumption of carotenoid-rich foods, but caution and more investigations are needed to evaluate the benefits and risks of supplements. High-dose  $\beta$ -carotene supplement was shown to be harmful to smokers and asbestos-exposed workers, increasing rather than lowering lung cancer incidence (ATBC, 1994; Omenn et al., 1996). The applied doses of  $\beta$ -carotene in the intervention studies were 20 mg per day in the ATBC study and 30 mg per day plus 25,000 IU vitamin A in the CARET study. In the epidemiological studies in which dietary  $\beta$ -carotene was inversely associated with decreased risk of lung cancer, the daily intake of  $\beta$ -carotene was about 4 mg (CARIG, 1996).

## Bioactive Gums

**NA Michael Eskin**, Department of Food and Human Nutritional Sciences Faculty of Agricultural and Food Sciences, University of Manitoba, Winnipeg, MB, Canada

### Introduction

Gums and mucilages are widely distributed in plants, animals, seaweeds, fungi as well as in microorganisms. They play an important role in structure and metabolism. Since plants are the major sources of gums and mucilages, this section will focus on seed polysaccharide gums including gum Arabic, guar gum, locust bean gum, flaxseed gum, psyllium and fenugreek. These gums, composed mainly of polysaccharides, are used by the food industry to enhance viscosity, improve texture, stabilize foams and emulsions, and for film formation and coating purposes (Dabestani et al., 2018). Over the years, however, increasing evidence has accrued regarding the bioactive properties of many of these natural gums. Besides being economical, they are readily available and generally non-toxic (Prajapati et al., 2013).

### Gum Arabic

Gum Arabic (GA), also known as Acacia gum, is an edible gummy exudate obtained from the stems and branches of *Acacia senegal* and *Acacia seyal* trees growing in abundance in central Sudan, central Africa and in West Africa (Dauqan and Abdullah, 2013; Sander et al., 2018). GA is very rich in low viscosity soluble fibers and provides the trees with a protective layer that prevents invasion by insects and molds when wounded. It is the oldest and probably the best known of the plant natural gums (Verbenken et al., 2003). Guar gum is composed of a complex polysaccharide varying in composition, depending on the tree, and occurring as either neutral or slightly acidic. The major backbone consists of 1,3-linked  $\beta$ -D galactopyranosyl units joined with linked branches of arabinose and rhamnose by  $\alpha$  1,6 linkages found in nature as a magnesium, potassium and calcium salt. The gum is used extensively in the food industry as a stabilizer, emulsifier, flavoring agent or thickener in confectionery, baking, dairy and beverages as well as a microencapsulating agent (Mariana et al., 2012).

GA has been used in folk medicine internally to treat inflammation of the intestinal mucosa and externally to cover inflamed surfaces (Gamal el-din et al., 2003). Animal studies demonstrated the protective antioxidant properties of GA against experimental gentamicin and cisplatin nephrotoxicity (Al-Majed et al., 2002, 2003) and dioxorubin cardiotoxicity (Abd-Allah et al., 2002) in rats and against acetaminophen-induced hepatotoxicity (Gamal el-din et al., 2003) in mice. Ali et al. (2004), however, were unable to confirm the work by Al-Majed et al. (2003) as they observed only a slight palliation of gentamicin in fed GA. Using eight different polysaccharides including GA, Trommer and Neubert (2005) showed GA protected against lipid peroxidation. However, Cindoruk et al. (2007) found GA ineffective in reducing hepatocellular damage in cholestasis induced by fenofibrate in rats. Subsequent work by Ali et al. (2004) further suggested that GA did not exhibit strong antioxidant properties.

### Guar Gum

Guar gum (GG) is a galactomannan gum found in the large endosperm of guar beans (*Cyamopsis tetragonoloba*). It is used extensively as a food additive in the food industry because of its thickening and binding properties (Butt et al., 2007). It is composed of high molecular weight polysaccharides with a molecular weight ranging from 50000–8000000 Da (Kawamura, 2008). Structurally it is a galactomannan composed of a linear chain of  $\beta$  1  $\rightarrow$  4 D-mannose residues with D-galactose linked 1,6 at every second mannose and the ratio of galactose to mannose being approximately 1:2.

The beneficial effects of GG were demonstrated by Hartesmink et al. (1999) who showed that it is completely degraded by *Chloridium butyricum*. While a high concentration of GG above 1% interferes with the nutritional, physicochemical and sensory properties of food, partial hydrolysis lowers reduced chain length and molecular weight and reduces the viscosity. Under these conditions, the hydrolyzed guar gum increases dietary fiber ability, which reduces diarrhea and symptoms of irritable bowel syndrome (Greenberg and Sellman, 1998; Slavin and Greenberg, 2003). The water-solubility and non-gelling properties of partially hydrolyzed guar gum proved ideal for treating both constipation and/or diarrhea predominant in either forms of irritable bowel syndrome (Gianni et al., 2006).

The beneficial effects of the gel forming properties of GG include its ability to lower cholesterol and glucose. The hypocholesterolemic effect of GG is attributed to the increase in bile acids in feces and decrease in enterohepatic bile acid. This may enhance bile acid production thereby reducing the amount of hepatic free cholesterol (Rideout et al., 2012). With respect to GG's ability to lower glucose, it acts as a barrier between starch and the starch-digesting enzymes (Dartois et al., 2010). The gel-forming properties of GG also increases satiation due to slow gastric emptying thereby increasing weight loss and preventing obesity by decreasing appetite, hunger and the desire to eat (Butt et al., 2007).

## Locust Bean Gum

Locus bean gum is obtained from the seeds of the carob tree (*Ceratonia siliqua*) grown in abundance in the Mediterranean region, particularly Spain, Italy and Cyprus. The gum is a high molecular weight polysaccharide composed of galactose and mannose units referred to as a galactomannan. It is a linear chain of 1→4-linked β-D-mannopyranosyl units with (1→6)-linked α-D-galactopyranosyl residues as side chains (Barak and Mudgil, 2014). Using gel-permeation chromatography, the average molecular weight of locust bean gum ranged from 0.3–2.0 million, depending on seed source, plant growing conditions and manufacturing conditions. It has an extended ribbon-like structure at the solid state and a semi flexible coil-like conformation in solution. The galactose-mannose ratio in locust bean gum ranges from 1:3.1 to 1:3.9 (Gaisford et al., 1985; Kok, 2007; McCleary et al., 1985).

Locust bean gum is considered a dietary fiber suitable as a supplement for weight control and for the treatment of diabetes and hyperlipidemia. As a viscous soluble fiber, it slows down the degradation of carbohydrates during digestion to regulate postprandial blood glucose and insulin levels. The latter are important events in the prevention and treatment of obesity and diabetes (Ferguson and Harris, 2005). The hypocholesterolemic effects of locust bean gum were reported by Zavoral et al. (1987) in familial hypercholesterolemic adults and children and shown to be a safe and effective approach to controlling hyperlipidemia.

## Flaxseed

Flaxseed is obtained from the flax plant (*Linum usitatissimum*). The seed coat or testa is rich in a thick mucilage (epidermis) layer that is soluble in cold water (Cui et al., 2007). The mucilage is composed of high-molecular weight water soluble heteropolysaccharides which represent 3%–9% of the total seed (Kaur et al., 2018). Depending on the different varieties and growing conditions, flaxseed gum contains 50%–80% carbohydrates, 4% to 20% protein and 3%–9% ash. Two major polysaccharide fractions are found in flaxseed gum, a neutral polysaccharide (composed of xylose, arabinose, and galactose), and an acidic polysaccharide (composed of D-galactose, L-rhamnose, and D-galacturonic acid). In the neutral polysaccharide, arabinoxylan forms a (1→4)-β-D-xylosyl backbone with arabinose and galactose residues on the 2 and 3 positions. The backbone in the acidic polysaccharide is a (1→2)-linked α-L-rhamnopyranosyl (1→4) linked D-galactopyranosyluronic acid with fucose and galactose side chains.

*In vitro* studies strongly suggested that flaxseed gum was capable of lowering cholesterol (Fodje et al., 2009; Denis et al., 2007; Theuvsissen and Mensink, 2008). This was attributed to its high bile acid-binding capacity with the generation of acetate and propionate. The prebiotic nature of flaxseed gum was also demonstrated by its stimulation of *Lactobacilli* growth in vivo (Alzueta et al., 2003). A recent study by Lou et al. (2018) reported that flaxseed gum reduced body weight by regulating the gut microbiota. Using male Sprague Dawley rats, flaxseed gum decreased Firmicutes/Bacteroidetes ratio and altered specific bacteria.

## Psyllium

The seed coats, including both the husk and hull, from the plants of the *Plantago* genus are rich in mucilage (dietary fibre). Commercially it is produced in European countries, Pakistan and India from the husks of *Plantago ovato* and *Plantago psyllium*. The largest importer of psyllium husks remains the United States where the pharmaceutical industry uses it for the production of fiber-based laxative products (Cui et al., 2007). Psyllium mucilage is a heteroxylan composed of (1→3) and (1→4) linked β-D-xylopyranosyl backbone chains with 1,4-linked β-D-xylopyranosyl residues attached at the 2- and 3-positions in the chain. The side chains consist of β-D-xylopyranosyl and α-D-arabinofuranosyl residues. Pectic acid is also found containing 1→4 linked α-D-GalpA residues with small amounts of 1,2,4-linked Rha and 1,3-, 1,6- and 1,3,6-linked Galp (Samuelson et al., 1999).

Psyllium has a long history of medicinal use. Using rats, many studies showed psyllium was far more effective in lowering lipids compared to other dietary fibers. A meta-analysis of 12 studies involving 404 adults, suffering from mild to moderate hypercholesterolemia, found a respective reduction in total and LDL cholesterol of 5% and 9%, respectively when fed a psyllium-enhanced cereal product (Olson et al., 1997). An earlier study by Davidson et al. (1996) reported a 7% reduction in LDL cholesterol in hypercholesterolemic children on a low-fat diet were fed psyllium-enriched cereal. Similar results were reported by Anderson et al. (2000) who reported 4.7% and 6.7% reductions in serum total and LDL cholesterol, respectively in hypercholesterolemic subjects given 5.1 g psyllium twice a day over 26 days. The overall evidence from these and other studies clearly confirmed the ability of psyllium to lower serum cholesterol, particularly LDL-cholesterol levels.

The ability of water-soluble fibers, such as psyllium, to lower postprandial glucose and insulin levels in non-insulin dependent diabetic patients when taken with meals, was confirmed in several studies (Hannary et al., 2006; Pastoro et al., 1991). Overall studies suggest that including psyllium with a conventional diet provides a safe approach for improving the glycemic index (Anderson et al., 1999; Ziai et al., 2005).

Other health benefits associated with psyllium is its extensive use as a laxative (Marlett et al., 2000) and its ability to prevent colon and breast cancers (Morita et al., 1999; Nakamura et al., 2004, 2005). Brum et al. (2018) recently studied the satiety effects of psyllium supplementation on the diets of healthy male and female volunteers prior to breakfast and lunch over a 3 day period. In addition to being well tolerated, psyllium supplementation significantly affected satiety by decreasing hunger, increasing fullness, and reducing the desire for eating between meals.

## Fenugreek

Fenugreek (*Trigonella foenum graecum*) is an annual leguminous plant grown in northern Africa, the Mediterranean, western Asia and northern India. It produces a pod containing 10–20 seeds that are rich in mucilage or gum (Cui et al., 2007). Fenugreek gum, a galactomannan, was shown by Brummer et al. (2003) to be highly substituted with the ratio of galactose to mannose ratio being from 1.00:1.02 to 1.00:1.14. While the gum had a higher molecular weight than locust bean gum and guar gum, it exhibited a reduced intrinsic viscosity and rheological behavior. It possessed substantial surface activity, which is normally associated with the presence of small amounts of protein. However, the gum was still shown to possess substantial surface activity even after separation of protein residues (Garti et al., 1997).

Seed powders from fenugreek were reported to exert antidiabetic and hypocholesterolemic effects in humans (Al-Habori and Raman, 1998). The main components of fenugreek gum, galactomannans, are associated with reduced cholesterolemia (Roberts, 2011). Rats treated with fenugreek extract were shown by Xue et al. (2007) to have lower triglycerides, total cholesterol and higher HDL cholesterol in a dose dependent manner. These researchers also reported an increase in body weight and decrease in kidney/body ratio weight in rats treated with fenugreek extract compared to the corresponding diabetic group. It was apparent that rats treated with fenugreek extract had lower blood glucose and glycated hemoglobin than in the diabetic group.

## Introduction

With the emergence of enhanced technologies to assess and quantitate their therapeutic and practical applications, functional foods are receiving increased recognition. Among these are dietary fibers, which in recent decades, have been attributed with properties promoting cardiovascular, gastrointestinal, and overall health (Brown, 2004; Marshall, 2008; Roberfroid, 2007; Walker and Painter, 2015). However, frequent modifications to dietary guidelines and nutritional recommendations have instilled public skepticism. Currently, a highly controversial topic is the potential of prebiotic dietary fibers in modulating and mitigating disease risks and outcomes. Owing to advances in this field of research, governmental public health agencies are increasingly recommending a suitable intake of prebiotics with the aim of maintaining and improving health and well-being (Slavin, 2013). Historically, prebiotics have been an integral component of the human diet; however, it is only recently that their therapeutic properties and key mechanistic actions have been elucidated, allowing for the identification of limitations to the current commercial generation, as well as the development of innovative strategies to produce well-defined prebiotics with targeted health benefits (Marshall, 2008).

The term 'prebiotic' was first coined in the mid-1990s by Roberfroid (2007), which subsequently led to its success as a therapeutic approach that specifically targets indigenous colonic bacteria that are regarded as beneficial (Marshall, 2008; Roberfroid, 2007) for promoting gastrointestinal health (Brown, 2004; Kaczmarczyk et al., 2012; Slavin, 2013). As a class of dietary fiber, prebiotics also confer a variety of systemic health benefits (e.g., protection against atherosclerosis and cardiovascular diseases, anti-tumor/cancer activity, antioxidant properties, etc.) (Guinane and Cotter, 2013; Huebner et al., 2007; Kaczmarczyk et al., 2012) and are hence finding increasing applications in functional foods, owing to their high stability and resistance to heat (Marshall, 2008; Padma Ishwarya and Prabhasankar, 2013). Certain prebiotics can also improve food quality characteristics such as mouthfeel by serving as low-calorie fat mimetics (Laguna et al., 2014; O'Brien et al., 2003), while others are exploited for their use as sweetening agents (Gallagher et al., 2003; Padma Ishwarya and Prabhasankar, 2013). Within the context of food and health, our review of prebiotics examines: the criteria required to fulfill their designation; sources in a standard human diet; the range of physiological benefits they confer; functional deficits of commercial preparations; enzymatic approaches for synthesizing novel, well-defined compounds with enhanced prebiotic potential; and their application as multi-functional food ingredients.

## Modulation of Health and Well-Being by the Intestinal Microbiota

The human alimentary tract is becoming more prominently recognized as a hidden metabolic 'organ' owing to its integral impacts on overall health (including metabolism, physiology, nutrition and immune function) that are the result of the colonization and metabolic activities of diverse microbial communities occurring along its entire length (Guinane and Cotter, 2013; Marshall, 2008; Vrieze et al., 2010). This environment promotes bacterial growth due to its slow transit time, readily available nutrients, and favorable pH (Slavin, 2013). On a quantitative basis, 10–20 genera dominantly reside in the colon, including *Bacteroides*, *Lactobacillus*, *Clostridium*, *Fusobacterium*, *Bifidobacterium*, *Eubacterium*, *Peptococcus*, *Peptostreptococcus*, *Escherichia* and *Veillonella* (He and Shi, 2017; Kolida and Gibson, 2007). The large intestine can harbor pathogens either belonging to the resident flora, or existing as transient members (Marshall, 2008; Roberfroid, 2007). Attachment and subsequent overgrowth of these undesirable microorganisms generally results in acute diarrheal infections, or can be manifested in the form of chronic intestinal diseases, including inflammatory bowel diseases (ulcerative colitis and Crohn's disease) and colon cancer (Campieri and Gionchetti, 2001; Guinane and Cotter, 2013; Rastall and Gibson, 2015). To varying extents, microflora composition and metabolic activity, and thereby the structure of the human diet since it provides the nutrients for their growth, have been implicated in the incidence of these disorders (Kaczmarczyk et al., 2012; Rastall and Gibson, 2015; Walker and Painter, 2015). In fact, it has been established for several decades that numerous disease states associated with modern Western civilization are related to the transit time of digesta and to the bulk and consistency of stools, which are factors heavily influenced by dietary fiber consumption (Walker and Painter, 2015). Further, an increasing body of evidence suggests that the stimulated growth of beneficial bacteria within the intestinal microbiome can reduce the risk of disease through pathogen inhibition and the production of benign and favorable metabolites (Kolida and Gibson, 2007; Roberfroid, 2007).

According to Gibson and Collins (1999), the diverse availability of fermentation substrates is arguably the most crucial determinant of the dynamics and stability of species existing in the human colon (Marshall, 2008). Human colonic bacteria consume primarily complex carbohydrates (i.e., food fibre, resistant starch, oligosaccharides, etc.) that are resistant to degradation by gastric acid and the host's digestive enzymes (Mardo et al., 2017; Sonnenburg et al., 2010). This distinct group of anaerobic beneficial bacteria include *Lactobacillus*, *Bifidobacterium*, *Bacteroides*, *Roseburia*, *Faecalibacterium*, *Anaerostipes*, and *Coproccoccus* (Fernández

et al., 2016; Guinane and Cotter, 2013a). Fermentation in the colon primarily occurs by saccharolytic and proteolytic activity of resident bacteria (Marshall, 2008; Slavin, 2013). The proximal colon is a saccharolytic environment in which the majority of non-digestible carbohydrates are fermented by *Bacteroides*, *Bifidobacterium*, *Ruminococcus*, *Eubacterium*, *Lactobacillus* and *Clostridium* (the main saccharolytic species among colonic microflora) (Guinane and Cotter, 2013; Marshall, 2008). Saccharolytic fermentation is more advantageous to the host due to the range of metabolic end-products generated (Kolida and Gibson, 2007). These include short-chain fatty acids (predominantly butyrate, acetate, and propionate) and other metabolites of microbial origin that confer an array of beneficial functions for the host, including the production of vitamins, modulation of the immune system, enhanced digestion and absorption, inhibition of harmful species, as well as the removal of carcinogens and other toxins (Adhikari and Kim, 2017; Kolida and Gibson, 2007; Nyman, 2002; Phillips, 2013). SCFAs are rapidly absorbed by the colonic mucosa and contribute towards the energy requirements of the host (Fernández et al., 2016; Roberfroid, 2007; Slavin, 2013). Furthermore, propionate is a gluconeogenesis factor that has been implicated in the suppression of cholesterol synthesis, and is recognized by several authors as an anti-tumor agent, owing to its ability to down-regulate cell multiplication pathways and promote pro-apoptotic routes (Fernández et al., 2016; Nyman, 2002). Butyrate is preferentially metabolized by colonocytes that are simultaneously regulated in terms of cell growth and differentiation, and serves as the primary energy source for beneficial bacteria residing in the colon (i.e., bifidobacteria) (Cummings et al., 2001; Fernández et al., 2016; Valcheva and Dieleman, 2016). Certain oligosaccharides, particularly fructooligosaccharides, galactooligosaccharides and lactulose, may be preferentially fermented by bifidobacteria, an effect that initially gave rise to the concept of prebiotics. Mechanisms regarding unfavorable alterations in gastrointestinal behavior have previously been postulated in explaining the occurrence of common disorders such as ischemic heart disease, diverticular disease, as well as appendicitis, and varicose veins (Walker and Painter, 2015). To varying extents, each has been linked to microflora composition and activities, thus underlining the instrumental role of diet in gastrointestinal health, since it is the major source of their growth.

### Approaches for Managing Colonic Microflora: Prebiotics, Probiotics, and Synbiotics

Generally, there are two concepts involved in the modulation of colonic microflora for beneficial health outcomes: 1) prebiotics; and 2) probiotics (Marshall, 2008; Rastall and Maitin, 2002; Roberfroid, 2007; Slavin, 2013). According to the scientific consensus, a prebiotic is defined as a 'non-digestible food ingredient that beneficially affects the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the colon and thus improves host health' (Fernández et al., 2016; Marshall, 2008; Roberfroid, 2007). A crucial mechanism of action for prebiotics is fermentation in the colon, the products of which confer numerous local and systemic health benefits (Marshall, 2008; Rastall and Gibson, 2015; Slavin, 2013). In this context, the stimulated bacteria should mainly constitute bifidobacteria and lactobacilli, considered to be probiotic strains (Fernández et al., 2016; Guinane and Cotter, 2013; Sonnenburg et al., 2010). According to Marshall (2008), human breast milk can be considered the original prebiotic with specific roles in gut microflora management due to its potent bifidogenic effects. The majority of prebiotics, however, are of plant origin, demonstrating chemical stability across wide temperature and pH ranges (Rastall and Gibson, 2015; Singh et al., 2017). Table 1 summarizes the range of natural prebiotic sources in a standard human diet, with the most frequently occurring ones being inulin, FOSs, and galactooligosaccharides (Marshall, 2008; Singh et al., 2017; Valcheva and Dieleman, 2016). The concept of probiotics was introduced to select for beneficial colonic taxa (Adhikari and Kim, 2017; Chow, 2002).

While the definition for probiotics is continuously evolving, this class of microorganisms is officially designated as 'non-pathogenic, live microbial, mono- or mixed-culture preparations, which, when administered in sufficient doses, beneficially affect the host by improving the intestinal microbial balance and its properties' (Adhikari and Kim, 2017; Marshall, 2008; Rastall and Maitin, 2002). The presence of prebiotic carbohydrates can be instrumental to the sustained survival of these populations, especially if they have been evidenced in the selection for useful species of *Bifidobacterium* and *Lactobacillus* (Chow, 2002; Kailasapathy and Chin, 2000; Reid, 2008). Among probiotic species, different genetic mechanisms are employed for the metabolism of

**Table 1** Natural sources of dietary prebiotics

Prebiotic compound	Sources	Type of glycosidic linkage	References
Inulin (fructan)	Jerusalem artichoke, chicory root	$\beta$ -(2,1)	Adhikari and Kim, 2017; Marshall, 2008; Reid, 2008; Roberfroid, 2007; Singh et al., 2017; Slavin, 2013; Subin et al., 2017; Valcheva and Dieleman, 2016
Fructooligosaccharides	Asparagus, sugar beet, garlic, chicory, wheat, rye, honey, banana, barley, tomato	$\beta$ -(2,1) and/or $\beta$ -(2,6)	
Galactooligosaccharides	Milk	$\beta$ -(1,3) and $\beta$ -(1,4)	
Maltooligosaccharides <sup>1</sup> , Isomaltooligosaccharides <sup>2</sup>	Honey, sugarcane juice, food-grade molasses	<sup>1</sup> $\alpha$ -(1,4) <sup>2</sup> $\alpha$ -(1,6) and $\alpha$ -(1,2) or $\alpha$ -(1,3) or $\alpha$ -(1,4)	
Lactulose <sup>1</sup> , lactosucrose <sup>2</sup> , lactulosucrose <sup>3</sup>	Milk (whey)	<sup>1</sup> $\beta$ -(1,4) <sup>2,3</sup> $\beta$ -(1,4) and $\alpha$ -(1,2)	
Raffinose, stachyose	Soybean and other pulses	$\alpha$ -(1,6)	

non-digestible oligosaccharides, hence the physiological benefits conferred by a given prebiotic are markedly determined by their structure (Rastall, 2010).

Mixtures of probiotics and prebiotics that function synergistically to improve the survival and implantation rate of viable microbial supplements in the gastrointestinal tract, referred to as synbiotics, have the capacity to improve therapeutic potential in the gastrointestinal tract (Roberfroid, 2007; Marshall, 2008). This may occur by multiple mechanisms: 1) increased survival of probiotic bacteria owing to the supplementation of prebiotics in consumer products, resulting in increased shelf-life and thereby ingestion of viable cells (Shin et al., 2000); 2) a higher count of probiotics reaching the colon due to simultaneous consumption of a prebiotic, which can competitively serve as an energy substrate and promote survival (Holzapfel and Schillinger, 2002); and 3) stimulated growth and/or activity of not only the supplemented probiotic strain(s), but also that of beneficial indigenous bacteria (Roberfroid et al., 2010).

### Criteria for Prebiotic Classification and Evaluation of Their Efficacy

Since it was first introduced by Roberfroid in 2007, the term 'prebiotic' has been mis-used on frequent accounts. While all prebiotics can be classified as dietary fibers, not all types of dietary fiber fulfill the criteria necessary to demonstrate the full spectrum of characteristics exhibited by prebiotics (Marshall, 2008; Roberfroid et al., 2010). Officially, prebiotics must: 1) resist gastric acidity, hydrolysis by mammalian digestive enzymes, and absorption in the upper gastrointestinal tract; 2) remain intact as it reaches the distal colon, where it is fermented by indigenous intestinal microflora; and 3) selectively stimulate the growth and/or activity of intestinal bacteria, which are associated with health and well-being (i.e., bifidobacteria and lactobacilli) (Marshall, 2008; Roberfroid, 2007; Slavin, 2013). Considering these criteria, non-digestible oligosaccharides (highlighted in Table 1) have demonstrated the highest efficacy, through their ability to confer selectivity to the target bacterial species (Marshall, 2008). In particular, fructooligosaccharides (FOSs) have been one of the most frequently explored sub-classes in this context. These comprise a glucose moiety followed by fructose moieties ranging from 2 to 60 linked by  $\beta$ -(2,1) or  $\beta$ -(2,6) glycosidic bonds (Singh et al., 2017). FOSs remain relatively intact during transit through the alimentary tract until they reach the colon, where the products of their fermentation constitute primarily SCFAs, and other bioactive molecules beneficial to human health (Hutkins et al., 2016). On the basis of chemical structure, FOSs are categorized as being either of the inulin or the levan type, the distinguishing coordinate being the nature of the glycosidic bond joining the fructose monomers (Rastall, 2010). In inulin and oligosaccharides derived from such, fructose units are linked in a linear fashion by  $\beta$ -(2,1) bonds, while in levan and associated derivatives,  $\beta$ -(2,6) bonds join the fructose moieties in the fructan main chain, and  $\beta$ -(2,1) bonds occur at branching points (Slavin, 2013). These crucial structural features will be discussed later in comparing the functional capacities of various FOSs.

The majority of early studies on prebiotics were performed on pure cultures, which typically involves the selection of a representative range of *Bifidobacterium* and *Lactobacillus* strains, as well as other bacteria (i.e., *Bacteroides* spp., *Clostridium* spp. and *Escherichia coli*) (Eckburg et al., 2005; Marshall, 2008). In these cases, a carbohydrate was classified as a prebiotic if bifidobacteria metabolized oligosaccharides more efficiently than other bacteria (Bouhnik et al., 2004; Gopal et al., 2001; Kilian et al., 2002; Marshall, 2008). The paramount limitation of this methodology; however, is that the selected strains cannot truly simulate human colonic microbiota and thus should solely be used for initial screening purposes (Goodman et al., 2011). Alternatively, *in vitro* methods, entailing the use of fecal inocula (mixed cultures), for investigating prebiotic oligosaccharides have also been explored. In these cases, changes observed in populations of selected genera or species can establish whether fermentation is selective (Guinane and Cotter, 2013; Marshall, 2008). However, while the use of fecal inocula may be representative of events in the distal colon, it is in the proximal regions that saccharolytic activity is more likely to occur, and both the composition and metabolic behavior of the microbiota indigenous to the colon are variable depending on the region sampled (Marshall, 2008; Rastall and Gibson, 2015; Slavin, 2013). In addition, identification of the genera and species present in fecal inocula is highly challenging, making this approach insufficient for accurately simulating changes in the demographics of the intestinal microbiome. Emerging molecular-based methods of identifying bacteria are significantly more reliable, as evidenced by the recently implemented rapid, cost-effective DNA sequencing methods. In this context, the 16S rRNA gene has been most frequently targeted for compositional analysis of changes in colonic microflora, owing to its ubiquity in all prokaryotic cells, and the presence of variable sequence domains that allow for different taxa to be distinguished (Guinane and Cotter, 2013). While this approach provides data regarding the demographics of the intestinal microbiome, it lacks the ability to detect microbial viability or the functional potential of the populations present, a deficit that has recently been overcome by the application of shot-gun sequencing in metagenomic studies (Kurokawa et al., 2007; Qin et al., 2010).

### Emerging Prebiotic Candidates

Recently, numerous non-digestible carbohydrates exhibiting prebiotic potential have been identified; however, further human/animal trial data need to be acquired in order to determine whether these compounds fulfill the designation criteria proposed by Gibson and Roberfroid. Current scientific efforts are towards the implication of the compounds in minimizing health risks, such as those associated with diabetes, cardiovascular disorders, cancer, acute infection, inflammation, and obesity (Marshall, 2008; Singh et al., 2017; Slavin, 2013; Subin et al., 2017). Emerging prebiotic candidates include gentiooligosaccharides, a derivative of lichen, which has not only exhibited anti-cancer properties, but also stimulatory effects on *Bifidobacterium infantis* and *Lactobacillus*

*acidophilus* (Kothari and Goyal, 2015). Similarly, chitosan oligosaccharides have demonstrated stimulatory effects on *Bifidobacterium bifidum* and *Lactobacillus* sp., and are currently the subject of study for anti-tumor, anti-inflammatory, antioxidant, and immune-modulatory properties (Liu et al., 2008; Subin et al., 2017). Other prebiotic candidates include the complex heteropolysaccharide, pectin, as well as oligosaccharides derived from such (e.g., rhamnogalacturonooligosaccharides, arabinooligosaccharides, oligogalacturonides, etc.), as they have been observed to exert potent bifidogenic effects (Sulek et al., 2014). In addition to possessing prebiotic potential, these compounds have previously been found to confer anti-ulcer, anti-cancer, anti-obesity, and anti-inflammatory properties (Gomez et al., 2016). Xylooligosaccharides, constituting xylose monomeric units, also possess prebiotic potential, and are emerging in the agricultural, nutraceutical, and pharmaceutical industries as functional ingredients (Nabarlatz et al., 2007). Most recently, fucoidans (sulfated polysaccharides) naturally occurring in the cell wall of brown algae are being investigated to confirm their anti-tumor, immuno-modulatory, and anti-inflammatory bioactivities (Ale et al., 2011; Fitton et al., 2015). As the use of more refined and reliable technologies are applied to prebiotics research, the range of candidates is likely to expand. In designating non-digestible carbohydrates as prebiotics, it is necessary to take into consideration that these compounds are metabolized differently among probiotic bacteria, and that therefore, the extent of therapeutic efficacy is highly dependent on the type of prebiotic biomolecule consumed.

### Physiological Health Benefits of Consuming Prebiotics

Prebiotics are frequently studied for their roles in promoting overall consumer well-being, as they have been widely reported to have positive effects on gastrointestinal physiology (i.e., improved colonization resistance, reduced toxigenic microbial metabolism, increased mineral absorption, fecal bulking), lipid metabolism, glucose homeostasis, and general health (Adamberg et al., 2015; Dahech et al., 2013; Marshall, 2008), as evidenced in Table 2. Physiological effects of prebiotics (specifically non-digestible oligosaccharides) are primarily determined by their chemical structure, in particular the nature of the glycosidic bonds, level of solubility, viscosity, fermentability, and degree of polymerization (Marshall, 2008; Rastall and Gibson, 2015; Singh et al., 2017). However, the degree of efficacy also strongly hinges upon the composition of products from their utilization by colonic bacteria. For instance, it has been reported that high proportions of propionate to acetate from the fermentation of non-digestible oligosaccharides has

**Table 2** Health benefits of prebiotic consumption and/or supplementation

Scope of physiological effect	Prebiotic activity	Functional compounds	Models	References
Gastrointestinal	Bifidogenic	GOSs, FOSs, inulin, soybean oligosaccharides, neokestose	Human studies: infants and adults; animal studies: rodents; <i>in vitro</i> fermentation	Bouhnik et al., 2004; Kaczmarczyk et al., 2012; Kilian et al., 2002; Marshall, 2008
	Fecal bulking, contributing to constipation relief and protection against colorectal cancer	Inulin, oligofructose	Human studies: healthy adults; animal studies: rats	Nyman, 2002
	Inhibition of enteropathogens	Inulin, FOSs, GOSs, lactulose, raffinose	<i>In vitro</i> fermentation	Shoaf et al., 2006
	Prevention and treatment of acute diarrheal infections		Human studies: infants	Tuohy et al., 2003
Systemic	Modulation of lipid metabolism resulting in decreased serum TAGs and phospholipids	Inulin, oligofructose	Animal studies: male Wistar rats	Delzenne et al., 2002
	Reduced risk factors for cardiovascular disease and atherosclerosis; hypolipidemic effects; antioxidant activity	Levan polysaccharide	Animal studies: male rats	Belghith et al., 2012; Dahech et al., 2013
	Anti-inflammation (by decrease of inflammation-associated biomarkers)	GOSs, FOSs	Human studies: infants and adults; animal studies: rodents	Kaczmarczyk et al., 2012; McLoughlin et al., 2017
	Enhanced immune function in GALT resulting from increased antibody levels	FOSs, MOSs, inulin	Animal studies: chickens	Adhikari and Kim, 2017

FOS: fructooligosaccharide; MOS: maltooligosaccharides; GOS: galactooligosaccharide; TAG: triacylglycerol; GALT: gut-associated lymphoid tissue.

pronounced benefits on glucose and lipid metabolism (Nyman, 2002). Additionally, production of SCFAs contributes to a lower luminal pH, which has been implicated in the enhanced bioavailability and absorption of essential mineral nutrients (e.g., iron, magnesium, and calcium), as well as increased colonic mobility (Chen et al., 2016; Fernández et al., 2016).

Table 2 highlights the bifidogenic properties of most types of prebiotics characterized to date. Stimulation of bifidobacteria is beneficial for the host as these species operate several mechanisms, which inhibit the growth of common pathogens and infectious agents in the alimentary tract (Marshall, 2008; Rastall and Gibson, 2015; Roberfroid, 2007; Slavin, 2013; Sonnenburg et al., 2010). For instance, the intestinal microbiome of breast-fed infants, high in bifidobacteria, has demonstrated preventative effects against gastrointestinal conditions in comparison to those who were bottle-fed (Marshall, 2008). As research methodologies advance and human clinical trials and meta-analyses continue to reach scientifically-substantiated conclusions regarding the health benefits of consuming prebiotics (whether in the form of dietary supplements or from natural sources) their implications in overall consumer well-being are likely to expand beyond those summarized in Table 2.

## Enzymatic Approaches for Prebiotic Synthesis

Until recently, methods of obtaining prebiotic compounds primarily relied on extraction from natural sources and chemical synthesis/hydrolysis. These techniques are progressively receiving less scientific effort as, in general, extraction yields are low to exceptionally low, making them impractical for industrial applications (Itaya et al., 2007; Sangeetha et al., 2005), and chemical synthesis is an inefficient, laborious, multi-step endeavor due to the use of toxic polluting reagents and the challenge of manipulating the stereospecificity of glycosidic bonds (Michaud and Clermont-ferra, 2005; Palcic, 1999). In addition, due to the inevitable formation of brown contaminants from conventional thermal processes, chemical hydrolysis of polysaccharides to defined-size oligosaccharides is difficult to manipulate (Warrand and Janssen, 2007).

In comparison to the aforementioned methods, enzymatic approaches to the production of FOSs confer regiospecificity and stereospecificity to glycosidic linkages present in the end-products, and hence are more promising for the synthesis of commercial oligosaccharides with enhanced prebiotic potential (Plou et al., 2007). FOSs can be synthesized by  $\beta$ -fructofuranosidases (EC 3.2.1.26) or fructosyltransferases (EC 2.4.1), also referred to as fructansucrases (Antosova and Polakovic, 2002 (Miasnikov, 1997), which have been reported in plants, bacteria, and fungi. Fructansucrases comprise inulosucrase (EC 2.4.1.9) and levansucrase (EC 2.4.1.10), and are fructosyl-transferring enzymes that employ sucrose for the synthesis of inulin (Tungland, 2003) and levan (Li et al., 2016), respectively. Previous studies have mainly focused on levansucrases rather than on inulosucrases due to the broader range of acceptors, and hence wider range of expected end-products (Cote and Tao, 1990; Li et al., 2015; Seibel et al., 2006). It has been observed that certain fructosyltransferases exclusively catalyze the synthesis of FOSs, and not polymers (Antosova and Polakovic, 2002; Linde et al., 2012; Trujillo et al., 2001). Levan-degrading enzymes, referred to as levanses (2,6- $\beta$ -D-fructanohydrolase, EC 3.2.1.65), characteristically hydrolyze  $\beta$ -(2,6)-linked fructans consisting of more than 3 fructose units to fructose or various levanoligosaccharides (Lim et al., 1998; Mardo et al., 2017). They can further be classified according to two types: 1) exo-levanase (EC 3.2.1.64), and 2) endo-levanase (EC 3.2.1.65). Fructose is essentially the only product of levan hydrolysis by exo-levanases, while endo-levanases degrade levan into various fructooligosaccharides as the final hydrolysis products (Miasnikov, 1997). Typically, in addition to levan, these enzymes are also capable of hydrolyzing sucrose and inulin (Lim et al., 1998; Mardo et al., 2017; Miasnikov, 1997); however there are exceptions with regards to substrate specificity, as evidenced by the *Bacillus subtilis* 168 endolevanase characterized by Jensen et al. (2016), which does not possess the ability to hydrolyze inulin. Increased interest in levanses is primarily attributed with the prebiotic properties demonstrated by the products of their biocatalysis. Table 3 summarizes sources of the aforementioned prebiotic-synthesizing enzymes according to their functional classification, as well as their corresponding end-products.

**Table 3** Prebiotic-synthesizing microbial enzymes and their corresponding end-products

Enzyme	Sources	Prebiotic products	References
$\beta$ -fructofuranosidases (EC 3.2.1.26)	<i>Aureobasidium pullulans</i> , <i>Aspergillus niger</i> and <i>A. oryzae</i>	Short-chain FOSs	Fernandez-Arroyo et al., 2007; Shin et al., 2004; Sangeetha et al., 2005

Endolevanase (EC 3.2.1.65)	<i>Arthrobacter</i> spp., <i>Bacillus</i> spp., <i>Gluconobacter diazotrophicus</i> SRT4	Levan-type FOSs	Avigad and Bauer, 1966; Jensen et al., 2016; Mendez-Lorenzo et al., 2015; Miasnikov, 1997; Porras-Domínguez et al., 2014

To date, there has been limited investigation of the combined use of complementary/synergistic biocatalysts for the production of prebiotics. High concentration/yield of FOSs (i.e., up to 90%) have previously been obtained from the combined use of *Aureobasidium pullulans* KFCC 10524 fructosyltransferase and *Aspergillus niger* glucose oxidase (Yun and Song, 1993). A subsequent study on FOS production employing *Aspergillus japonicus* CCRC 93007  $\beta$ -fructofuranosidase and a commercial glucose oxidase achieved more than 90% (w/w) yield (Sheu et al., 2001). With the emergence of levan-type prebiotics, Tian et al. (2014) investigated and optimized the combined use of *B. amyloliquefaciens* levansucrase and a commercial endo-inulinase in one-step and two-step bi-enzymatic systems, achieving maximal FOS yields of 65% (w/w). Most recently, Porras-Domínguez et al. (2017) reported the production of levan-type FOSs (6-kestose, levanbiose, and blastose) up to 40% (w/w) from a fusion enzyme constituting *B. subtilis* levansucrase and *Bacillus licheniformis* endolevanase.

### Limitations of Commercial Prebiotic FOSs and the Shift Towards Levan-Type FOSs

Currently, the prebiotics industry is dominated by galactooligosaccharides and inulin-type FOSs: 1-kestose, nystose and fructofuranosylnystose (Rastall, 2010; Subin et al., 2017), which are hampered by major deficits, namely the lack of targeted functions, and most importantly selective fermentation by beneficial colonic bacteria at the species level (Manning and Gibson, 2004). This can be attributed to their relatively low molecular weights, which prevent them from reaching the distal colon, and limit their physiological effects exclusively to the proximal region (Rastall and Maitin, 2002; Van de Wiele et al., 2007). During digestion, as nutrients are transited to the distal colon, carbohydrate availability decreases, and proteins and amino acids become the dominant metabolic energy sources (Marshall, 2008). In this context, the primary products of fermentation are phenolic compounds, amines and ammonium (Manning and Gibson, 2004). These metabolites, which can be detrimental to host well-being, underline the health significance of tailored prebiotic preparations that can be competitively and selectively fermented by beneficial bacteria in the distal colon. In this regard, the functional properties of commercial prebiotic FOSs may be improved by employing sucrose analogues (Seibel et al., 2006), for instance, galactose (Baciu et al., 2005) as acceptors. This promotes the synthesis of FOSs with different terminal residues (i.e., galactose), which may possess anti-adhesive properties similar to those of galactooligosaccharides (Shoaf et al., 2006). The production of levan-type FOSs is becoming an increasingly attractive method of enhancing commercial prebiotic preparations. Recently, neokestose, a  $\beta$ -(2,6)-linked FOS, revealed higher bifidogenic effects than commercial FOSs (Marx et al., 2000; Kilian et al., 2002; Omori et al., 2010). Furthermore, Adamberg et al. (2015) observed increased growth of levan-degrading (e.g., *Bacteroides*) and butyrate-producing (e.g., *Faecalibacterium*) taxa following levan supplementation. These authors not only reported modulation of colonic microbiota in the presence of levan, but also that the principal products of its fermentation were acetate, lactate, butyrate, propionate, and succinate, which confer numerous targeted physiological benefits as previously discussed. Long-chain, levan-type FOSs have also been demonstrated to resist digestive degradation to a greater extent than their short-chain counterparts (de Paula et al., 2008; Marx et al., 2000; Rastall and Maitin, 2002). The production of longer-chain FOSs would facilitate prebiotic activity in the distal colon, which is more susceptible to colon cancer (Guinane and Cotter, 2013; Rastall and Maitin, 2002). Furthermore, highly polymerized FOSs are less likely to provoke intestinal discomfort (Fanaro et al., 2005). In general, current efforts in the development of prebiotic preparations are towards those which are structurally well-defined and demonstrate higher selectivity and colonic persistence than their first-generation, inulin-type predecessors (Rastall and Maitin, 2002).

### Applications of Prebiotic FOSs: Past, Present, and Future

Since the introduction of the prebiotic approach, one of the first and most prevalently available applications is fortified infant formulas (Marshall, 2008). Currently regarded as a class of GRAS (Generally Recognized As Safe) additives, prebiotic FOSs are being increasingly exploited in the food, nutraceutical, and pharmaceutical industries (Adhikari and Kim, 2017; Huebner et al., 2007; Reid, 2008; Singh et al., 2017). Research advances within this scope have allowed for the identification of key functional attributes, namely the low glycemic load and caloric density of prebiotic FOSs, which make them highly attractive for the food industry as functional ingredients in reduced-calorie products (Fernández et al., 2016; Roberfroid and Slavin, 2000). Furthermore, inulin and other FOSs possess the ability to extend shelf-life and aid in moisture retention (e.g., of bakery products) (Franck, 2002; Karimi et al., 2015; Padma Ishwarya and Prabhasankar, 2013). Generally, FOSs are more soluble than inulin and also impart a higher degree of sweetness, making them more desirable as sweetening agents and sugar substitutes (Fernández et al., 2016). Other food applications of prebiotics, either already commercially available or which are under formulation trials include: fortified dairy products; beverages and health drinks; confectionery products (e.g., chocolate); savory products (e.g., soups); sauces and dressings; meat products; non-perishable foods (e.g., canned and dried instant products); and dietary supplements (Celligoi et al., 2015; Fernández et al., 2016; Marshall, 2008; Slavin, 2013). Regarding the future use of prebiotics as therapeutic agents, additional applications will likely be elucidated as clinical trials and meta-analyses continue to reach concrete findings. For instance, several authors have conducted preliminary trials to determine the ability of prebiotics to prevent allergies in infants (Cuello-Garcia et al., 2017), and (Notay et al., 2017) recently reported the successful administration of prebiotics in the prevention of adult dermatological diseases, with promise for the combined probiotic and prebiotic treatments they will continue to investigate.

## Concluding Remarks

As the scope of knowledge regarding prebiotics continues to expand, methodologies for investigating their functionality, particularly in colonic microflora management, are becoming increasingly advanced and stringent. Clinical trials to determine the value of prebiotics in the mitigation of gastrointestinal and systemic health disorders are ongoing, as is the development of a quantifiable index to evaluate and compare therapeutic efficacy. The numerous drawbacks of natural extraction and chemical methods for producing commercial inulin-type prebiotics underline the demand for novel technologies, namely enzymatic synthesis of structurally-defined, controlled-size levan-type compounds. However, knowledge regarding the structural and functional attributes of enzymes exploitable for prebiotic synthesis remains limited to date, as are studies divulging the structure-function relationships of different prebiotics. These are undoubtedly the most commercially relevant barriers to the production of ideal prebiotic preparations, and will need to be overcome in order to characterize their complete range of physiological benefits and functional properties for industrial applications.

## Introduction

Interest in full utilization of marine resources and processing by-products, especially their bioactive components, has increased considerably in recent years. According to Food and Agricultural Organization (FAO, 2016), the total global capture fishery production reached 93.4 million tonnes in 2014 including those from both marine (81.5 million tonnes) and inland (11.9 million tonnes) waters. It is predicted that fisheries could contribute to food security and adequate nutrition for world population. China is the major contributor of marine fisheries followed by Indonesia, United States and the Russian Federation (FAO, 2016). Fish is a rich source of proteins that contain essential amino acids, long chain omega-3 polyunsaturated fatty acids (PUFAs), vitamins (A, B and D) and minerals (calcium, iodine, zinc, iron, potassium, phosphorus and selenium). Average edible portion of fish is approximately 49%, on a dry weight basis, while by-products contributes up to 51%: these include head (18%), backbone/frames (10%), off-cut (10%), viscera (7%) and skin (6%) (Rustad, 2007). The utilization of world fisheries catch for human consumption has significantly increased, reaching 146 million tonnes in 2014 and the remaining 21 million tonnes were utilized for non-food applications such as fish meal and fish oil for use in different applications including aquaculture feed (FAO, 2016). Hence utilization of seafood processing by-products is most important for reducing waste in a safe and hygienic manner. For example, by-products such as heads, frames and fillet cut-offs are directly used as food or processed into fish sausage, fish cake, gelatin, snack and sauce. Moreover, other by-products could be used to produce biodiesel/biogas, enzymes (proteolytic enzymes, lipase), dietetic products (chitosan, glucosamine), pharmaceuticals (oils), natural pigments (astaxanthin and other carotenoids), minerals, cosmetics (collagen), silage and fertilizers, handicrafts, and leather (FAO, 2016). Several research reports have appeared on bioactives from seafood processing by-products (Shahidi and Synowiecki, 1991; Shahidi et al., 1994a, b, c, 1995, 1996, 2002; Shahidi, 1997, 2007a, b; Shahidi and Kim, 2002; Shahidi and Kamil, 2001; Rustad, 2003; Shahidi and Zhong, 2007; Ferraro et al., 2010; Roslan et al., 2014; Sila and Bougatef, 2016; Ambigaipalan and Shahidi, 2017).

## Proteins From By-Products

Generally, fish is a good source of protein. The amount of crude protein in fish flesh varies between 17% and 22% (w/w), while it is present at 8%–35% in fish by-products (Roslan et al., 2014; Sila and Bougatef, 2016). Fish proteins are a rich source of essential amino acids such as lysine and leucine as well as non-essential ones like aspartic and glutamic acids (Nunes et al., 2011). Protein-rich by-products include cut-offs, backbone, head, skin, milt, stomach, viscera and blood that could be used to produce collagen/gelatin and proteoglycan, protein hydrolysate, bioactive peptides, surimi, protein concentrate and fish silage, among others.

## Protein Hydrolysate and Bioactive Peptides

Protein hydrolysates are produced chemically or biologically by breaking down the proteins to peptides of varying sizes with bioactive peptides so produced generally containing 2–20 amino acid units but this range may vary in certain cases. Fish protein hydrolysates have desirable functional properties such as good solubility, foaming and gelling ability, emulsifying property and water holding capacity, hence contribute to the texture of food (Skanderby, 1994; Kristinsson, 2007). Bioactive peptides have been shown to exert antihypertensive, antagonists, immunomodulatory, anti-thrombotic, antioxidant, anti-cancer and anti-microbial activities (Clare and Swaisgood, 2000; Elias et al., 2008; Shahidi and Zhong, 2008). In addition, di- and tripeptides are absorbed more rapidly than free amino acids and even more rapidly than intact protein (Di Pasquale, 1997). Several studies have shown the utilization of marine by-products to produce protein hydrolysates and bioactive peptides (Table 1).

## Collagen and Gelatin

Seafood processing by-products are valuable sources of biomolecules such as collagen and gelatin. Utilization of fish collagen and gelatin in fish processing could produce value-added products and reduce any adverse impact on the environment (Kittiphattanabawon et al., 2005, 2013; Wang et al., 2014). Several marine by-products have been used as a source of collagen and gelatin such as fish skin, scales, bones and fins, mantle of scallops, the muscle layer of ascidians and the adductor of pearl oysters (Nomura et al., 1995; Mizuta et al., 2002; Kim and Mendis, 2006; Shen et al., 2007; Hernández-Briones et al., 2009). Fish collagen and gelatin have been widely used in food, pharmaceutical and cosmetic industries. A summary of marine by-products used for the production of collagen and gelatin is shown in Table 2.

**Table 1** Marine by-products used to produce protein hydrolysates/bioactive peptides

Marine by-products	Product	Activity	References
Shrimp shell	Protein hydrolysate		Synowiecki and Al-Khateeb, 2000
Alaska pollack skin	Gelatin hydrolysate	Antioxidant	Kim et al. (2001)
Yellowfin sole frame	Protein hydrolysate/ bioactive peptides	Antioxidant	Jun et al. (2004)
Alaska pollack frame	Protein hydrolysate/ bioactive peptides	Antioxidant	Je et al. (2005b)
Jumbo squid skin	Gelatin peptides	Antioxidant	Mendis et al. (2005)
Hoki frame	Protein hydrolysate/ bioactive peptides	Antioxidant, decreased t-butylhydroperoxide-induced cytotoxicity on human embryonic lung fibroblasts and protected free-radical-induced DNA damage	Je et al. (2005a), Kim et al. (2007)
Tuna backbone	Protein hydrolysate/ bioactive peptides	Antioxidant	Je et al. (2007)
Cod backbone	Protein hydrolysate	Antioxidant	Šližytė et al. (2009)
Sardinelle by-products (heads and viscera)	Protein hydrolysate/ bioactive peptides	Antioxidant	Bougatef et al. (2010)
Salmon skin	Collagen peptide	Improved glucose and lipid metabolism in diabetic and hypertensive patients	Cui-Feng et al. (2010)
Tuna frame	Bioactive peptide	Antihypertensive	Lee et al. (2010)
Chum salmon skin	Collagen peptide	reduced oxidative damage in the brain in mice	Pei et al. (2010)
Salmon by-product (pectoral fin)	Protein hydrolysate/ bioactive peptides	Antihypertensive	Ahn et al. (2012)
Atlantic salmon skin	Collagen hydrolysates/ Peptides	Antihypertensive	Gu et al. (2011)
Skate skin	Protein hydrolysate/ bioactive peptides	Antihypertensive	Lee et al. (2011)
Black pomfret viscera	Protein hydrolysate/ bioactive peptides	Antioxidant	Nazeer and Kumar (2011)
Bluefin tuna head	Protein hydrolysate	Antioxidant	Bougatef et al. (2012)
Pacific cod skin	Bioactive peptide	Antihypertensive and protected the cellular macromolecules from oxidative damage	Himaya et al. (2012)
Horse mackerel ( <i>Magalaspis cordyla</i> ) and croaker ( <i>Otolithes ruber</i> ) skin	Protein hydrolysate/ bioactive peptides	Antioxidant	Kumar et al. (2012)
Blacktop shark skin	Gelatin hydrolysate	Antioxidant	Kittiphattanabawon et al. (2012, 2013)
Cuttlefish skin	Gelatin hydrolysate	Antioxidant	Jridi et al. (2014)
Salmon pectoral fin	Protein hydrolysate/ bioactive peptides	Anti-inflammatory	Ahn et al. (2015)
Bluefin leatherjacket skin	Protein hydrolysate/ bioactive peptides	Antioxidant	Chi et al. (2015)
Seabass skin	Gelatin hydrolysate	Antioxidant, immunomodulatory, antiproliferative	Sae-leaw et al. (2016)
Shrimp shell discards	Protein hydrolysate/ bioactive peptides	Antioxidant, Antihypertensive	Ambigaipalan and Shahidi (2017)

## Proteoglycan

Proteoglycans are cartilaginous tissues produced from marine by-products that include glycosaminoglycans, namely chondroitin-4-sulphate and chondroitin-6-sulphate (Garnjanagoonchorn et al., 2007; Iozzo and Schaefer, 2015). Kato (2016) identified a method for extracting proteoglycans from fish cartilage using water to heat small particles of frozen fish. This method that uses only water for extraction was found to be efficient, and safe compared with using organic solvents, alkali or acid for extraction. Proteoglycan was extracted from salmon nasal cartilage using magnesium chloride and then isolated using anion-exchange chromatography. When prepared, it was found that the protein core was intact (Tatara et al., 2015). A new proteoglycan material was also made from shrimp waste and different binders. Testing showed that this method can be used to produce proteoglycans as feed supplement for monogastrics (Widjastuti and Haetami, 2015). Salmon nasal cartilage was examined and found to contain 14 types of proteoglycans, one of which, epiphykan (EPY) is a type of leucine-rich proteoglycan (Tatara et al., 2013).

**Table 2** Marine by-products used to produce collagen/gelatin

Marine source	By-product	References
Cod ( <i>Gadus morhua</i> )	Backbone	Gildberg et al. (2002)
Flounder ( <i>Platichthys flesus</i> )	Skin	Fernández-Díaz et al. (2003)
Black drum ( <i>Pogonia cromis</i> ) and sheepshead seabream ( <i>Archosargus probatocephalus</i> )	Bones and scales	Ogawa et al. (2004)
Baltic cod ( <i>Gadus morhua</i> ), salmon ( <i>Salmo salar</i> ), herrings ( <i>Clupea harengus</i> )	Skin	Kołodziejaska et al. (2008)
Channel catfish ( <i>Ictalurus punctatus</i> )	Skin	Liu et al. (2008)
Deep-sea redfish ( <i>Sebastes mentella</i> )	Skin, bone and scale	Wang et al. (2008)
Usky spinefoot ( <i>Siganus fuscescens</i> ), sea chub ( <i>Kyphosus bigibbus</i> ), eagle ray ( <i>Myliobatis tobijei</i> ), red stingray ( <i>Dasyatis akajei</i> ) and yantai stingray ( <i>Dasyatis laevis</i> )	Skin	Bae et al. (2008)
<i>Catla catla</i> and <i>Cirrhinus mrigala</i>	Skin, scales and fins	Mahboob (2015)

Proteoglycans have been shown to exert therapeutic benefits such as anti-angiogenic and anti-metalloproteinase effects as well as improving joint function and help in pain reduction in osteoarthritis patients (Morreale and Manopulo, 1996; Ronca and Palmieri, 1998; Iozzo and Schaefer, 2015).

## Marine Lipids

Marine lipids include marine fish oil and mammal oil as well as squalene, mainly from shark liver oil.

### Marine Fish and Mammal Oils

Marine by-products have been utilized for the production of fish oils which contain omega-3 PUFAs that provide a myriad of health benefits in humans (Shahidi and Miraliakbari, 2004, 2005; Shahidi and Ambigaipalan, 2015, 2018). Fish by-products from tuna (heads), herring, salmon (head and viscera) and walleye pollock (head, skin, frame and viscera) have been utilized for production of fish oil (Shahidi, 1994a,b; Chantachum et al., 2000; Aidos et al., 2002; Wu and Bechtel, 2008, 2009; Shahidi, 2007a,b,c). Rubio-Rodríguez et al. (2012) extracted fish oil using supercritical fluid extraction from cut offs of hake orange roughly and salmon as well as livers of jumbo squid. Chantachum et al. (2000) reported that tuna by-products obtained during canning process serve as a good source of docosahexaenoic acid (DHA)-rich oil.

On the other hand, marine mammals are a unique source of omega-3 PUFAs, where the lipids are mainly stored subcutaneously, known as blubber (Shahidi, 1998; Shahidi, 2007a,b,c). Wanasundara et al. (1998) reported that seal blubber oil is the only significant source of docosapentaenoic acid (DPA) in addition to eicosapentaenoic acid (EPA) and DHA. Shahidi (1998) reported that the distribution pattern of fatty acids in triacylglycerols (TAG) differs in fish and marine mammal oils, which greatly influence the metabolism, deposition, and potential health benefits. Long-chain  $\omega$ 3 PUFAs are mainly located in the sn-2 position of TAG in fish oils, whereas in marine mammal lipids they are predominantly in the sn-1 and sn-3 positions.

### Squalene

Squalene ( $C_{30}H_{50}$ ) is a highly unsaturated triterpenoid, an aliphatic hydrocarbon with six unconjugated double bonds. It is a thermally unstable and light-sensitive molecule (Fig. 1). Livers of deep sea sharks provide an excellent source of squalene (~89%) (Summers, 1987; Spanova and Daum, 2011).

Squalene is a metabolic precursor of cholesterol and other sterols. Squalene has been shown to exert antioxidant activity and prevent oxidation of lipids (Boskou, 1999; Warleta et al., 2010). It also acts as a moisturizer, wrinkle remover, protect skin from sun and UV damage and wound healer (Kaiya, 1990), chemopreventive and improves the immune system (Rao et al., 1998; Kim and Karadeniz, 2012).

## Chitin, Chitosan and Their Oligomers and Monomers

### Chitin, Chitosan and Chitosan Oligomers

Chitin and chitosan polymers are natural amino-polysaccharides (Fig. 2). Chitin is made up of *N*-acetyl- $\beta$ -D-glucosamine units, while chitosan is derived from varying degrees of deacetylation of chitin (Shahidi, 2007a,b,c). Chitosan is a copolymer of chitin consisting of  $\beta$ -(1 $\rightarrow$ 4)-2-acetamido-D-glucose and  $\beta$ -(1 $\rightarrow$ 4)-2-amino-D-glucose units as the deacetylation of chitin is usually incomplete (Shahidi et al., 1999, Shahidi, 2007a,b,c).

**Figure 1** Chemical Structure of squalene.

**Figure 2** Chemical structure of chitin and chitosan.

Chitosan has been widely used in medicine and pharmacology, agriculture, food, biotechnology, nutraceuticals, bioremediation, gene therapy and cosmetics due to their biodegradability, non-toxicity, biocompatibility, physiological inertness and hydrophilicity (Shahidi et al., 1999; Jeon et al., 2000; Shahidi, 2007a,b,c; Hayes and McKeon, 2014).

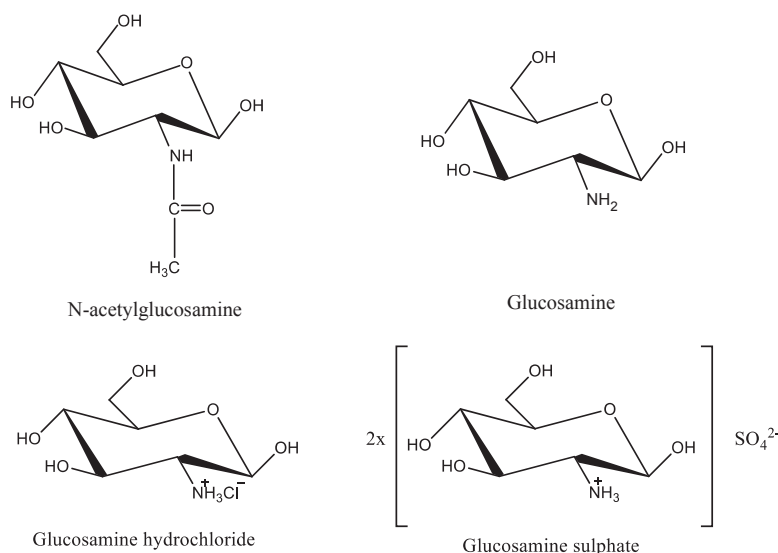

Chitosan oligosaccharides (COS) and low-molecular-weight chitosan (LMC) are partially depolymerized products of chitosan or chitin, using enzyme or acid hydrolysis. Kim et al. (2008) reported that the degree of polymerization (DP) and degree of acetylation influence the biological activities of COS and LMC. By-products from shrimp and different parts of crab have been shown to contain 17%–32% of chitin on a dry weight basis (Shahidi and Synowiecki, 1991). Recently, Hamed et al. (2016) reported that crustacean by-products are excellent sources of chitin, and chitosan, which is well known, but also of chitoooligosaccharides which may improve their industrial application.

### Glucosamine and N-Acetylglucosamine

Glucosamine (GlcN) and N-acetylglucosamine (GlcNAc) are the monomers of chitosan and chitin, respectively (Fig. 3). Glucosamine is most widely used to treat osteoarthritis due to its anti-inflammatory properties (Shikhman et al., 2001). Glucosamine used as pharmaceutical products is generally available in the form of hydrochloride salt or glucosamine sulphate (Fig. 3) (Shikhman et al., 2001). Chitin, chitosan, their oligomers and monomers are used as orthopedic/periodontal and wound-dressing materials, as well as for tissue engineering or controlled drug/gene delivery (Patrulea et al., 2015).

### Fish Bone Minerals (Calcium and Phosphorus)

Fish bone is a potential source for minerals, especially calcium and phosphorus (Kim and Mendis, 2006; Shahidi, 2007a,b,c). Few studies in the literature have shown the use of fish bone as a functional material and a source of minerals (Larsen et al., 2000; Kim

**Figure 3** Chemical structures of glucosamine and its derivatives.

and Jung, 2007). Jung et al. (2005) reported that fish meal prevents Ca deficiency in rat models due to the increased Ca bioavailability by the intake of fishbone phosphopeptides.

## Carotenoids

Crustacean processing discards are the major potential sources of carotenoids, mainly astaxanthin and its esters that occur as carotenoprotein and could be economically and feasibly recovered and used (Shahidi et al., 1998). Carotenoids are red, yellow, and orange pigments that include highly unsaturated hydrocarbon carotenes (C<sub>40</sub>H<sub>56</sub>; lycopene,  $\alpha$ -carotene,  $\beta$ -carotene, and  $\epsilon$ -carotene) and xanthophylls (cryptoxanthin, lutein, zeaxanthin, rhodovibrin, capsanthin, rhodoxanthin, violaxanthin, flavoxanthin, luteochrome, bixin and crocetin) (Fig. 4). Xanthophylls are oxygenated while carotenes are devoid of oxygen and are usually orange and red in colour and generally soluble in petroleum ether. Shahidi and Synowiecki (1991) reported that 3.4–14.7 mg/100 g of carotenoid pigments, mostly astaxanthin and its esters, were recovered from by-products of shrimp and different parts of snow crab. Charest et al. (2001) extracted astaxanthin from crawfish shells using supercritical CO<sub>2</sub>.

## Seafood Flavour

Seafood flavours may be extracted from finfish and shellfish processing by-products using aqueous extraction, fermentation and enzymatic hydrolysis (Lee, 2007). Free amino acids and peptides act as precursors of the volatile compounds, which are often formed through Maillard reaction (Izzo and Ho, 1992). Hayashi et al. (1981) reported that glycine and glutamic acid are the most important taste-active components of lobster and prawn. Seafood flavours are widely used in seafood sauces, chowders, soups, bisques, instant noodles, snacks and surimi products (Lee, 2007). It was shown that shrimp by-products (heads, shells, and tails) could serve as a potential source of flavorants in shrimp sauce (Kim et al., 2003). Several other studies have also shown the utilization of fish by-products for the development of seafood flavours (Peinado et al., 2016).

## Enzymes

Marine processing by-products, especially the glands and digestive organs such as stomach, pyloric cecum, pancreas, and intestines are major sources of enzymes (Nayak et al., 2003; Kurtovic et al., 2009). Several enzymes have been isolated from fish and shellfish processing discards such as alkaline phosphatase, hyluronidase, acetylglucosaminidase, chitinase and protease (Table 3, Venugopal, 1995a). Raa (1990) prepared and commercialized production of alkaline phosphatase from thaw water of shrimp.

## Marine Carbohydrates

Marine algae contain a large number of polysaccharides such as carrageenan, alginate, fucoidan and agar-agar that have been of industrial importance, especially in the food industry (Senanayake et al., 2011). Fucoidan, a sulphated polysaccharide derived

**Table 3** Marine derived enzymes

Marine source	Enzyme	References
Lobster and shrimp processing by-products	Polyphenolase	Ferrer et al. (1989); Gallas-Galvan et al. (1999); Simpson et al. (1988)
Fish liver	Urease	Kinsella et al. (1985)
Atlantic cod viscera	Pepsin, trypsin, chymotrypsin, elastase, collagenase and alkaline phosphatase	Simpson and Haard (1984a, 1984b) Gildberg et al. (1990)
Carp and harp seal stomach	Chymosin	Cohen and Gertler (1981); Han and Shahidi (1995)
Hake stomach	Gastricsin	Sanchez-Chiang and Ponce (1981)
Fish intestinal viscera	Collagenases, elastases and carboxypeptidases	Shahidi and Kamil (2001)
Pyloric ceca/pancreas of Atlantic cod	carboxyl ester lipase	Gjellesvik et al. (1992)
Viscera (pyloric ceca, intestines, and associated mesenteries) of Grey Mullet	Lipase	Aryee et al. (2007)
Squid liver, shrimp waste silage and shrimp by-products	Chitinase	Matsumoto et al. (2004); Olsen et al. (1991)
Spleen of skipjack tuna, yellowfin tuna and tongol tuna	Trypsin-like serine proteinases	Klomklao et al. (2006)
Tilapia intestine	Aminopeptidase and carboxypeptidase	Taniguchi and Takano (2004)
Walley Pollock liver	Transglutaminase	Kumazawa et al. (1996)

from marine algae are effective coagulation modulators and have the potential to be used as alternatives to heparin, a conventional anticoagulant drug (Collic et al., 1994).

## Summary

Seafood by-products (cut-offs, backbones, heads, skin, milt, stomachs and viscera blood) are potential sources of bioactives (protein hydrolysates, bioactive peptides, collagen and gelatin, marine mammal and fish oils, squalene, chitin, chitosan and chitosan oligomers, glucosamine, fish bone minerals, carotenoids and various enzymes). These bioactives have been shown to possess a myriad of health benefits. More work is needed to explore high-value products for food, medicinal and cosmoceutical applications.

## Glossary

**Hypercholesterolemia** a condition in which a patient's blood cholesterol levels are elevated, as indicated by a lipid blood panel.

**Coronary heart disease (CHD)** a disease where plaque accumulates in the arteries responsible for supplying oxygen-rich blood to the tissues of the heart.

**Hypocholesterolemic effects** effects which lower the amount of cholesterol in the blood.

**Thermally labile** susceptible to destruction/degradation by heat treatment.

**Atherogenesis** a dysfunction that occurs in artery walls characterized by a multi-step process whereby atherosclerotic plaques are formed.

**Atherosclerosis** a disease of the arteries characterized by the deposition of plaques on the inner walls.

**Micelles** aggregates of molecules in a colloidal solution, formed by differences in the polarities and charges of the substances in the solution.

**Micellar solubilization** the process of incorporating a substance into a micelle. This process facilitates the absorption of sterols and cholesterol.

**Myocardial ischemia** reduced blood flow to the tissues of the heart via a coronary heart disease. A consequence of CHD.

**Microencapsulation** the process of creating very small droplets or capsules with a coating around them, meant to protect the inner contents. Frequently used in food applications to protect capsule contents from degradation due to heat, oxidation, etc.

**Lyophilic colloids** a type of colloid which is "solvent-loving." Adding these to a solution will result in a stable solution due to the affinity of the colloid for the solvent.

**Colloidal/jet milling** a process that results in the reduction of the particle size of either a solid or a liquid of a suspension or emulsion. This process works on the rotor-shear force.

**Micronization** the process of reducing the average diameter of solid particles to obtain very fine micro-sized particles via mechanical means such as grinding or milling.

## Introduction

The term phytosterols (plant sterols) encompasses both phytosterols and phytostanols. These compounds are the most-studied group of nutraceuticals, with health benefits that have been recognized for more than seven decades. The earliest studies on phytosterols were conducted in the twenties and thirties, on various animal species including rabbits, mice, rats, cats and dogs (Pollak, 1952). These studies showed that simultaneous feeding animals with cholesterol and phytosterols resulted in inhibition of hypercholesterolemia induced by consumption of cholesterol. Consequently, researchers focused on phytosterols due their health benefit potential related to the risk reduction of coronary heart disease (CHD). Between 1950 and 1980, a pharmaceutical company, Eli Lilly, marketed phytosterols under the drug name Cytelin™. This product contained phytosterols derived from tall oil, and was supported by one of the first human clinical studies, where subjects consumed 9 to 50 g/day of Cytelin™ (Pollak and Kritchevsky, 1981). Over the years, phytosterols have been proven to be very effective in attenuating the risk of coronary heart disease, via their hypocholesterolemic effects, which are a function of their chemical structure. Furthermore, phytosterols have antioxidant and anti-inflammatory capabilities, which may also contribute to the risk reduction of CHD, albeit in the lesser extent (Jenkins et al., 2005; Van Rensburg et al., 2000). Over 200 clinical studies conducted globally support the health benefits of phytosterols and this has led to worldwide regulatory approval of these compounds for use in foods, dietary supplements and natural health products (Table 1). Furthermore, foods containing phytosterols are eligible to bear health claims in many regulatory jurisdictions (Zawistowski and Jones, 2015). There are many functional food categories enriched with phytosterols available in global markets. This chapter will provide an overview of phytosterols including their sources, chemical structure and properties, and the health benefits of consuming sterols. Additionally, the practical challenges encountered when formulating sterol-enriched food products are discussed in addition to the regulatory aspects of marketing phytosterol-containing foods in different countries.

## Occurrence and Manufacturing of Phytosterols

As the name suggests, phytosterols can be derived from many plant sources including fruits and vegetables, nuts, seeds, cereals, vegetable oils and coniferous trees. They occur in relatively small amounts – vegetable oils such as olive, and sesame oils contain between 2 and 10 mg/kg (Moreau et al., 1999). Other oils such as soybean, rapeseed and corn may contain 2 to 8 g/kg (Phillips

**Table 1** Examples of regulatory venues in various countries for food products enriched with phytosterols and/or phytostanols<sup>a</sup>

<i>Country</i>	<i>Regulatory venue</i>	<i>Type of health claim</i>	<i>Examples of health claim wording</i>	<i>Foods enriched with phytosterols that may bear the CHD health claim</i>
USA	GRAS Notification Dietary Supplement Health and Education Act (DSHA)	Disease risk reduction (the Nutrition Labelling and Education Act - Sterol/stanols and coronary heart disease claim)	“Foods containing at least 0.5 g per serving of plant sterols/stanols eaten with meals or snacks for a daily total intake of 2 g as a part of a diet low in saturated fat and cholesterol, may reduce the risk of heart disease. A serving of [name of the food] supplies X g of plant sterols/stanols.”	Conventional foods, which complied with requirements of the disqualifying nutrient levels (CFR 21.101.14 a 4), low saturated fat (21CFR 101.62 c 2), and low cholesterol (21CFR 101.62 d 2) rules and, the minimum nutrient contribution requirement (CFR 21.101.14 e 6) Dietary Supplements
European Union	Novel Food Regulations	Disease risk reduction (Regulation EC, 1924/2006) on Nutrition and Health Claims Made on Foods, Article 14)	“Plant sterols (stanols) have been shown to lower/reduce blood cholesterol. High cholesterol is a risk factor in the development of coronary disease”.	Yellow fat spreads; milk-type products with the addition of fruits or cereals or vegetable fat or protein; yogurt-type products; and other fermented milk-type drinks, soy and rice drinks, fat spreads, salad dressings, spicy sauces, and cheese-type products with fat $\leq$ 12% fat; rye bread ( $\geq$ 50% rye flour, $\leq$ 4% sugar, no added fat); edible oils, mayonnaise Unstandardized spreads, margarine, calorie-reduced margarine, mayonnaise, salad dressing and unstandardized salad dressings, yogurt, yogurt drinks, vegetable and fruit juices
Canada	Novel Foods Regulations (Food and Drug Regulations, Part B, Division 28	Therapeutic Claim	“Plant sterols help reduce/lower cholesterol. High cholesterol is a risk factor for heart disease”.	Edible oil spreads, breakfast cereals (excluding breakfast cereal bars), milk, and yogurt. Cheese and processes cheese (tall oil phytosterols only)
Australia and New Zealand	Novel Food Standard, Standard 1.5.1	Standard 1.2.7., Schedule 2 – High level health claims. Requires pre-approval by FSANZ	“With natural plant sterols which reduce cholesterol uptake”	Edible oil spreads, breakfast cereals (excluding breakfast cereal bars), milk, and yogurt. Cheese and processes cheese (tall oil phytosterols only)
Japan	Food of Specified Health Uses (FOSHU)	Function Claim	“Good for those concerned about serum cholesterol”, “Good for those having relatively high serum cholesterol and triglycerides with mild obesity” “Assisting blood lipids reductions”	Edible Oils, fat spreads, other food products and dietary supplements as long as approved under standardized FOSHU
China	Decree of State Food and Drug Administration No. 19 (Health Foods)	General Biological Function	“Assisting blood lipids reductions”	Milk drink, other food products as long as approved under the Resource Food Regulations
South Korea	Health Functional Food Act	Disease risk reduction, Structure function claim	“Phytosterols may reduce risk of coronary heart disease”	Green tea, coffee and milk drinks, cooking oils, dietary supplements
Taiwan	Health Food Control Act	Maintenance Claims	“Consumption of the product may help lower blood total cholesterol”	Milk enriched with tall oil phytosterols

Malaysia	Food Act and Regulation, Food Supplement	Nutrient Function Claims	“Plant sterol or stanol helps lower or reduce cholesterol”	Milk, and soy drinks
Indonesia	Drug and Food Control Regulations	Disease Risk Reduction	“May reduce risk of coronary heart disease”	Milk, smoothies, fat spreads, and foods with phytosterols approved in the US
Singapore	Food Regulation Act, Approval on case-by-case bases by Food Control Department of Singapore	Disease Risk Reduction	“Plant sterols/stanols have been shown to lower/reduce blood cholesterol. High blood cholesterol is a risk factor in the development of coronary heart disease.”	Fat spreads, salad dressing, mayonnaise, and low fat dairy products
Thailand	The notification for foods for special dietary uses	Nutrient Function Claims	“Plant sterol may help lower cholesterol”	Yogurt drink
Philippines	Food Fortification Act	Structure/function claim	“This product contains natural plant sterols that help lower cholesterol”	Milk, milk and yogurt drinks
Brazil	Technical regulation on procedures for registration of foods and or new ingredients	Structure/function claims	“Phytosterols help in reducing the absorption of cholesterol.” “helps to maintain healthy level of cholesterol when associated with a healthy diet and life style”	Fat spreads, yogurt, and milk

Note: the term of phytosterols/phytostanols includes free sterols and stanols, as well as sterol and stanols esters.

<sup>a</sup>Adapted from Phillips et al. (2002).<sup>b</sup>Author's unpublished data.<sup>c</sup>Adapted from Piironen and Lampi (2004).

et al., 2002). Some specialized oils such as those extracted from corn fiber may contain up to 10 g of sterols per 100g of oil (Moreau, 2005). Cereals, nuts, vegetables, berries and other fruits contain sterols in the range of 0.05–0.22 g/100 g (Piironen et al., 2000). Table 2 shows a list of common phytosterol sources and their respective phytosterol contents. Approximately 200 plant sterols exist but the most predominant are:  $\beta$ -sitosterol, campesterol, stigmasterol, and in a lower degree, their saturated counterparts - stanols (Piironen et al., 2000).

The most common sources of plant sterols for commercial production are tall, soybean and rapeseed oils. Sterols from these sources occur as by-products of the manufacturing of other products. Tall oil is produced from the processing of coniferous trees; sterols from soybeans and other oilseeds are obtained from the production of vitamin E (Quilez et al., 2003). Phytosterols may also be obtained during the production of biodiesel fuel, which in turn, uses a variety of vegetable oils. Since the sterols are produced as a by-product of these processes, they are not produced in very large quantities; 2500 tonnes of vegetable oil or the same volume of coniferous trees are required to yield just one tonne of phytosterols. The exception to this is when sterols are manufactured directly from the deacidification of rapeseed oil, or from deodoriser distillates that are created during fatty acid methyl ester (FAME) production (Verhe et al., 2007). In these cases, about 54 kg can be produced from only one tonne of distillate (Verhe et al., 2007). Despite these small yields, manufacturers who already process these materials can profit from extracting the sterols from their post-production materials. For example, breweries and distilleries can derive 100 tonnes of sterols from 18 000 to 65 000 tonnes of grain residues (Wong, 2008).

## Chemistry and Properties of Phytosterols

Phytosterols are triterpenes, which are lipid-like compounds that are closely related to cholesterol, except sterols are more hydrophobic. A comparison of the structures of various phytosterols and cholesterol can be found in Fig. 1. This is attributable to the presence of a side chain substitution of a methyl or an ethyl group on carbon 24. The methyl-substituted variation is campesterol, and the ethyl-substituted configuration is called sitosterol. Stigmasterol has an additional double bond at position 22 on a side chain. The similar chemical structures of cholesterol and sterols are reflected in their closely-related functions in the organisms from which they originate; cholesterol stabilizes and regulates the cell membranes of animals and phytosterols perform a similar function in plants. In nature, phytosterols exist as free alcohols; steryl esters with the fatty acid moiety located at C12–C18, steryl glucosides and acetylated steryl glucosides (Moreau et al., 2002; Ferrer et al., 2017). In terms of manufacturing functional foods, sterols and steryl esters are the most important.

Stanols are a type of phytosterol formed from the hydrogenation of plant sterols. Thus, campestanol is the saturated counterpart of campesterol while sitostanol is the saturated counterpart of sitosterol, and both are formed through hydrogenation of the 5 $\alpha$ -position double-bond. Moreover, hydrogenation of stigmasterol yields stigmastanol, which is the same as sitostanol, since both double bonds at the 5 and 22 positions are saturated.

## Solubility

Due to their lipophilic nature, phytosterols exhibit minimal solubility in aqueous solutions. Their solubility in fats and oils will depend on the properties of the fat/oil as well as the temperature. Generally, phytosterols are better solubilized in more polar oils such as diacetyl glyceride oil and this can be attributed to the partially polar nature of phytosterols, which is imparted by the hydroxyl group. It is possible to incorporate 10%–20% of phytosterols into vegetable oil at 50–80 °C but upon cooling, the

**Figure 1** Chemical structure of the main phytosterols and cholesterol. a – cholesterol, b–campesterol, c –  $\beta$ -sitosterol, d –  $\beta$ -sitostanol, e – stigmasterol, f –  $\beta$ -sitosteryl ester.

phytosterols will crystallize (Engel and Schubert, 2005). Below 50 °C, the solubility of phytosterols decreases even further; at these temperatures in corn oil, solubility is limited to 2%–6%. However, it has been shown that sterols and mixtures of sterols and stanols exhibit improved solubility when compared to stanols alone. Different stanols have varying levels of solubility; wood stanols tend to solubilize better than those from soybeans (Vaikousi et al., 2007). When water is added to oil/lipids, this decreases the solubility of phytosterols by two-fold due to the formation of monohydrate molecules (Christiansen, 2002).

Another factor which contributes to the generally poor solubility of phytosterols is their melting point, which is in the range of 138–145 °C (Vaikousi et al., 2007). There is an inverse relationship between the log solubility and melting points for many aromatic compounds (Yalkowsky, 1981).

In order to improve fat solubility, esterification of phytosterols with long-chain polyunsaturated fatty acids was introduced in the late 1980's (Mattson et al., 1977). Ester is formed via the hydroxyl group at the position 3 (Fig. 1). This technique increased the solubility of phytosterols in fat by ten-fold and enabled the incorporation of sterols into fat-based food products such as vegetable fat spreads (Ostlund, 2002). Among phytosterol esters, those with a larger number of double bonds and a longer fatty acid chain length are more soluble (Noakes et al., 2005). These features are also associated with a decrease in the melting point, which makes these phytosterols easier to incorporate into the food matrix. Commercial sterol esters with long chain polyunsaturated fatty acids have melting points in the range of 25–45 °C (ADM, 2007; Cognis, 2007). Even esterification with medium-chain fatty acids can reduce the melting point of phytosterol: the esterification of stanols with C8–C12 fatty acids was able to reduce the melting point of the stanols by about 40 °C (Vaikousi et al., 2007).

Some phytosterols, including avenasterol and fucosterol, feature an ethylidene side chain on their structures (Boskou, 1998; Guillen and Manzanos, 1998). This is significant because it gives the sterols antioxidant capabilities and they may inhibit the thermal oxidation of various oils; for example, avenasterol is able to prevent the deterioration of soybean oil when heated to 180 °C (White and Armstrong, 1986). This is most likely because free lipid radicals react with phytosterols at allylic carbon atoms, forming stable isomers and slowing down further oxidation by interrupting the chain of auto-oxidation. Not all sterols have the same antioxidant capacity, however; in the example above, avenasterol is able to exert antioxidant effects, but  $\beta$ -sitosterol is not because it lacks a double bond on a side chain. It is also possible that some phytosterols actually have pro-oxidant effects, such as stigmasterol (Yoshida and Niki, 2003).

### Thermostability

Phytosterols, as antioxidants, undergo oxidation to spare more thermally labile compounds such as polyunsaturated fatty acids. However, heating may cause reduction of phytosterol content, and lower or even eliminate their efficacy. In addition, oxidized phytosterols may be harmful to health in the same way as oxidized cholesterol (Dutta, 2002).

Sterols are relatively thermoresistant as has been demonstrated by several studies. Continuous frying in various oils for 9 h caused phytosterol losses in the range of 4%–6% (Winkler et al., 2007). Similarly, commercial frying for two days only reduced phytosterol content slightly, in the range of 6%–8% (Dutta and Appelqvist, 1996). When subjected to extreme heat treatment, changes in phytosterol content depend on the type of oil. For example, when various oils were continuously fried for 35 h, phytosterol content in corn, soybean, and expeller-pressed soybean oils decreased by 15%, 9.4% and 4%, respectively (Winkler et al., 2007). This is likely due to the differences in saturation of the fatty acids that these oils are composed of. Unsaturated fatty

acids are oxidized faster, providing some thermal protection to phytosterols (Ghavami and Morton, 1984; Soupas et al., 2004). For this reason, stanols, the saturated counterparts of sterols, are more thermoresistant and losses of stanols upon thermal treatment were significantly lower than those of sterols.

## Health Benefits of Phytosterols

The blood lipid profile is a screening tool which is used to assess a patient's risk of developing cardiovascular disease. This profile examines the amount of triacylglycerides (TAGs) as well as the amounts of various lipoproteins in circulation (NHLBI, 2018). A high level of TAGs in the blood is a risk factor for cardiovascular disease because they promote atherogenesis. Lipoproteins are significant because the levels of cholesterol in the blood depend on their cholesterol-transporting activity. Since cells are not able to destroy excess cholesterol, they must transport it instead (NHLBI, 2018). Low-density lipoprotein (LDL) is a lipoprotein, which is known to be harmful because it transports cholesterol from the liver to the bloodstream and then to peripheral tissues. Furthermore, it is susceptible to oxidation which also promotes atherogenesis. Meanwhile, high-density lipoprotein (HDL) transports excess cholesterol in the opposite direction to reduce the amount of cholesterol in the blood, and bring it to the liver, where it is converted to bile salts (NHLBI, 2018). Therefore, it is desirable to have lower levels of TAGs and LDL and a higher level of HDL in the blood.

Cholesterol in the intestine originates from three sources: diet (200–400 mg/day), bile (up to 1 g/day) and exfoliated enterocytes (300–400 mg/day) (Northfield and Hoffman, 1975; Vuoristo and Miettinen, 1985). An estimated 50% of this amount is absorbed into the intestinal lumen, re-esterified by intestinal cells, formed into chylomicrons and secreted into the bloodstream (Turley and Dietschy, 2003). This amount may be modified by genotype or by diet (Sehayek, 2004). The consequence of a high level of cholesterol in the blood, or hypercholesterolemia, is increased susceptibility to atherosclerosis (Law et al., 1994). Data from epidemiological studies suggest that lowering LDL (LDL-C) cholesterol by 10% to 19% reduces the risk of CHD by about 41% (WSCP, 1998). It has been estimated that lowering blood cholesterol by only 10% may prevent approximately 100,000 deaths annually (Havel and Rapaport, 1995). This can be achieved by a dietary intervention using phytosterols. In fact, phytosterols are recommended as a part of adjunctive lipid-lowering therapy by the US National Cholesterol Education Program (NCEP, 2001).

## Hypocholesterolemic Effects

### Effect on LDL-Cholesterol

The most notable health benefit of consuming phytosterols is the reduction in risk of CHD achieved through decreased blood cholesterol. This effect has been studied and recognized since the early 1950's. The optimal efficacious dose is 2 g of phytosterols consumed daily over three to four weeks. Initial research on the efficacy of stanols when compared to sterols revealed that stanols are more potent, and practically unabsorbable, which make them better hypocholesterolemic nutraceutical than stanols (Heinemann et al., 1986). However, later research showed that sterols were equally as effective as stanols, if they were a component of a food (Hallikainen et al., 2000; Heinemann et al., 1986; Judd et al., 2002; Vanhanen and Miettinen, 1992; Vuorio et al., 2000).

As mentioned earlier, the amounts of sterols, which naturally occur in plant-based foods such as vegetables, vegetable oils, nuts and seeds, are negligible in comparison to the 2 g/day required to observe an optimal hypercholesteremic effect. A wide variety of products have been formulated to be a better phytosterol delivery system and these are a more effective way to take advantage of the hypocholesterolemic effects of these bioactives. Functional food products have been studied extensively as the subjects of clinical trials, which often examine the effects of phytosterols on total and LDL cholesterol. Dairy drinks such as single-shot yogurt and milk have shown the highest efficacy among clinically-tested sterol-containing beverages. The cholesterol-lowering effect of sterol-containing foods depends on the matrix. For example, milk enriched with phytosterols is about three times more efficacious than bread or cereals containing the same amount of sterols (Clifton et al., 2004). Other factors which may impact the efficacy of phytosterols include the dose of sterols, the genotype of the clinical subject and if the drink is consumed with food. Generally, consuming the enriched food product with meals will result in a greater reduction in LDL-C than when consumed alone (Seppo et al., 2007). It has been conjectured that this is due to the increased bile flow that occurs with the energy and fat intake from meals, which increases the efficacy of sterols (Seppo et al., 2007). It had previously been believed that for sterol-enriched foods to be effective, they needed to have a high level of fat but this was disproven by more recent studies, and it is now known that low-fat products such as low-fat fermented milk can be just as effective as other, high-fat matrices (Clifton et al., 2004; Hansel et al., 2007; Plana et al., 2008). Frequency of consumption of sterol-containing dairy drinks has not been shown to make a significant difference in hypocholesterolemic effects (Niittynen et al., 2008). It has been shown, however, that the method of incorporating sterols into no- or low-fat foods and beverages can affect efficacy; when emulsifiers were used, the efficacy of the sterols was improved compared to sterols incorporated into foods without emulsifiers (Noakes et al., 2005). Commonly used for this purpose is lecithin, which prevents the crystallization of sterols and makes them more soluble in the mixed micelles, thereby improving efficacy (Engel and Schubert, 2005).

### Effect on Other Blood Lipids

It was previously thought that the consumption of functional foods with phytosterols did not impact the levels of TAGs and HDL in blood and rather, that the sterols exert their effect only through the modulation of LDL-C. However, recent clinical studies have shown that sterols consumed in low-fat yogurt drinks and fermented milk (1.6 g of free sterol equivalents) may reduce the levels

of circulating TAG by 14% as compared to control (Plana et al., 2008). It does appear that the magnitude of this effect depends on the initial baseline concentration of TAG, with normolipidemic subjects exhibiting almost no change in their circulating TAGs when treated with sterol-containing beverages. Significant reduction of plasma TAG was shown in patients with dyslipidemic metabolic syndrome. It was suggested that this was associated with lowering of hepatic large TAG-rich very low-density lipoprotein particles, which are present in blood of metabolic syndrome patients (Plat and Mensink, 2009). Meta-analysis of twelve clinical studies by Demonty and co-workers (2013) revealed that consumption of phytosterols by subjects with normal to borderline high TAG levels modestly lowered plasma TAG by 6%.

Recently, a few studies have also shown that phytosterols can cause modest increases in HDL-C, potentially via an increase in a specific sub-fraction of HDL, the HDL3-C (Ruiu et al., 2009). The plasma level of HDL-C is also increased by 7.5% when consumption of sterol-containing margarine (1.8 g of free sterol equivalents) is combined with physical activity in previously sedentary hypercholesterolaemic patients (Varady et al., 2004). The effects of phytosterols on HDL-C and TAG are not as extensively studied as their effects on LDL-C and thus, the factors that modulate their efficacy are not clear. These may include food matrix, baseline blood lipid profile of the clinical subjects, among others, and these should be further studied to optimize the health benefits of sterols.

### **Mechanism for Hypocholesterolemic Action**

As mentioned before, phytosterols have similar chemical structures to cholesterol and this is the basis for the hypercholesteremic effects of sterols. They are similar enough that they both must undergo the same process of micellar solubilization in order to be absorbed, which allows phytosterols to compete with cholesterol for these micelles (Gylling and Miettinen, 1999; Hendriks et al., 1999). However, a key difference between the structures of phytosterols and cholesterol afford plant sterols an advantage whereby they are preferentially incorporated into micelles (Gylling and Miettinen, 1999; Hendriks et al., 1999). Sterols have a higher affinity for micelles than cholesterol due to a bulkier hydrophobic side chain (Fig. 1). This results in the displacement of cholesterol from micelles, reducing its absorption and promoting its excretion from the body (Gylling and Miettinen, 1999; Hendriks et al., 1999). It should be noted that this mechanism applies to both free sterols and sterol esters because the latter are hydrolyzed by pancreatic cholesterol esterase in the intestine.

Furthermore, phytosterols are minimally soluble in the intestinal chyme, which interferes with the micellar solubility of cholesterol. This results in the co-precipitation of cholesterol and phytosterols in the intestinal lumen, which reduces the bioavailability of cholesterol.

Similar to how sterols compete with cholesterol for micelles, they also compete with cholesterol for esterification in enterocytes which is a prerequisite for absorption into the bloodstream (Moghadasian, 2000). They also compete for various transporters, present in the apical surface of enterocytes: Niemann-Pick C1-like 1 protein (NPC1L1), and ATP cassette protein binding transporters (ABCG5/G8), which regulate the influx and efflux of cholesterol and sterols between the intestinal lumen and the intestinal mucosa (Calpe-Berdiel et al., 2006). These mechanisms are less significant than the previously mentioned ones but they do contribute to the reduction of cholesterol absorption into the blood stream.

The decrease in cholesterol absorption caused by these mechanisms induces compensatory cholesterol synthesis in the liver but this is not sufficient to offset the decrease in cholesterol caused by sterols. The overall effect will still be a decrease in circulating cholesterol levels.

### **Antioxidant and Anti-inflammatory Effects**

Sterols also produce antioxidant and anti-inflammatory effects, which help to decelerate the processes of atherosclerosis and CHD.

#### **Antioxidant**

Oxidative stress is caused by free radicals generated by molecules with unpaired electrons. Free radicals may lead to membrane structural damage and dysfunction as well as increasing the risk of myocardial ischemia due to decreased membrane fluidity and permeability. Free radical scavengers are those compounds, which can accept electrons and act as free radical scavengers that demonstrate antioxidant properties. Sterols such as  $\beta$ -sitosterol have been reported to have protective effects against free radical damage due to its ring structure that includes an acetyl group and the presence of oxygen that accepts electrons (Van Rensburg et al., 2000). The antioxidant effect of  $\beta$ -sitosterol is even more pronounced in  $\beta$ -sitosterol glycoside due to the presence of glucose (Van Rensburg et al., 2000). Other studies have noted that  $\beta$ -sitosterol also inhibits the oxidation of LDL-C in vitro.  $\Delta^5$ -avenasterol, a substantial sterol in oats; and fucosterol, from algae, also have antioxidant properties due to the presence of an ethylidene group (Boskou, 1998; Moreau et al., 2002). In a study done on mice, a mixture of phytosterols was able to increase the activity of various antioxidant enzymes (Moghadasian et al., 1999). The same study found that sterols were more effective at preventing atherosclerotic lesions than probucol (Moghadasian et al., 1999). The authors postulated that the increased antioxidant enzyme activity caused by the sterols may have contributed to the athero-protective effect observed (Moghadasian et al., 1999). The antioxidant properties of phytosterols do not only positively contribute to health, but also prevent oxidative damage in various food matrices. Sterols inhibited the thermal oxidation of olive oil, soybean oil and medium-chain triglyceride oils, which were heated at 180 °C (Du and Zawistowski, 2002; Gordon and Magos, 1983; White and Armstrong, 1986; Winkler et al., 2007). Finally, the antioxidant properties of sterols may contribute to antimicrobial activities, as is the case with other antioxidants. This was demonstrated in milk, as the incorporation of a mixture of coniferous sterols was found to extend the shelf life (Monu et al., 2008). There also exists

preliminary evidence to suggest that  $\beta$ -sitosterol obtained from several plants possesses antimicrobial activity against *Bacillus subtilis* and *Candida albicans* (Beltrame et al., 2002; Moshi et al., 2004).

### Anti-Inflammatory

Inflammation is believed to contribute to atherogenic plaque formation and consequently, the risk of heart disease and stroke. Therefore, current clinical studies of sterols, in addition to investigating their hypocholesterolemic efficacy, are also focused on their anti-inflammatory properties. The anti-inflammatory effect is studied by monitoring the levels of C-reactive protein (CRP), a recognized inflammation bio-marker (Devaraj et al., 2006). It appears that the consumption of foods containing phytosterols alone is not sufficient to cause a reduction in CRP but sterols as part of the portfolio diet were found to reduce CRP levels (Jenkins et al., 2005; Jenkins et al., 2008). Clinical studies have found that the anti-inflammatory effect is even more pronounced when the phytosterols are consumed with omega-3 fatty acids and aside from the reduction in CRP, other markers of inflammation such as interleukin-6, tumor necrosis factor- $\alpha$  and leukotriene B4 were also reduced (Micallef and Garg, 2009).

## Challenges in Food Product Formulation With Phytosterols

Free phytosterols are available commercially in crystalline form. These can present several challenges for food product formulation. The main challenge is the insolubility of sterols in water and their sub-optimal solubility in lipids. In addition, sterols may negatively impact the sensory attributes of products because of their waxiness, grittiness and powder-like qualities.

The poor solubility of phytosterols can be overcome by using phytosterol esters, which are in the form of a semi-liquid paste. The process of stanol esterification was patented by Finnish food manufacturer, Raisio Oy., in 1989 and this led to the development of the very first stanol ester-containing functional foods. The first products to be marketed which contained phytosterols were margarines and vegetable fat spreads. In 1995, Raisio Oy. developed a margarine called Benecol for the EU market and this initiated the widespread marketing and popularity of functional foods in the EU and subsequently, the US. Sterol esters are more soluble in fat and have a lower melting point so they are more easily incorporated into foods. However, sterol esters present unique challenges not encountered with free phytosterols. They are more thermally labile when compared to free phytosterols. Sterol esters are also more likely to produce oxidative products when subject to extreme thermal treatments (Zawistowski, 2010). In terms of the nutritional quality of the final product, sterol esters may pose a problem because they contain added fat, so more fat must be added to a product to achieve the same levels of sterols. This is a challenge in low-fat products especially, where the formulator must keep the fat content below a certain threshold such as in a low-fat vegetable oil spread.

## Challenges and Solutions Pertaining to Beverage Formulation

Beverages are increasing in popularity as they are a more convenient source of phytosterols and are more easily incorporated into the daily diet when compared to more traditional sources such as fat spreads. Due to their liquid form, they are also associated with unique formulation challenges, which are discussed in this section.

Uniform distribution of the sterols throughout the liquid product requires a stabilization system because without one, the free sterols will sediment or float within the matrix. They may also aggregate and form non-dispersible clusters. For this reason, it is necessary to use sterols with the smallest particle size possible to improve solubility and stability, preferably between 15–20  $\mu\text{m}$ . Smaller particles are advantageous because they have more surface area per unit of volume and therefore, they are more likely to stay in solution. They also contribute to improved mouthfeel, as larger particles are perceived as having a gritty texture.

As most issues surrounding the formulation of sterol-enriched beverages are related to the particle size of the sterols, most solutions present various methods of minimizing particle size. This can be achieved by mechanical grinding (including dry milling and micronisation) as well as wet milling (including colloidal/jet milling and microfluidization). Microfluidization, also known as particle collision technology, is a method in which phytosterols are processed in high concentration slurries to create uniform dispersions comprising particles of less than 10  $\mu\text{m}$  (Zawistowski, 2003). Nanotechnology is a novel approach to provide solutions for creating sterol-fortified beverages and can make phytosterols dispersible even in clear beverages (Yoon et al., 2003). In this method, sterol micelles of a small size (preferable below 300 nm) are formed (Yoon et al., 2003). Phytosterol nanoparticles are not currently available on the market due to safety concerns regarding the enhanced absorbability of sterols in this form. Some authors suggest that absorbed phytosterols can actually increase the risk of CHD (Weingartner et al., 2009) and while these findings are not conclusive, increased sterol absorption should be avoided, especially as this does not increase their efficacy.

Most other methods for formulating beverages with phytosterols involve the addition of lyophilic colloids to stabilize the suspension. These may include carrageenan, alginate, guar gum, and xanthan gum. Other stabilizers include microcrystalline cellulose and emulsifiers such as polysorbates, sucrose-fatty acid esters, lecithin and protein (Zawistowski, 2003; Moreau, 2004). One technique was developed where lecithin micelles were used to formulate stanol-enriched fat-free beverages (Ostlund et al., 1999). The presence of lecithin allowed for the use of only 300 mg of stanols to achieve comparable efficacy to the optimal 2 g/day (Ostlund et al., 1999). However, lecithin is expensive, which limits its commercial applications. Another novel approach used to increase the aqueous solubility and stability of sterols was recently developed, and it involved the use of a sterol-egg yolk lipoprotein complex (PSY) (Matsuoka et al., 2008). Due to the emulsifying capacity of egg phospholipids, the PSY is readily dispersible in water (Matsuoka et al., 2008). Other techniques for the formulation of dispersible phytosterols for beverage

formulation include the use of various emulsifiers, and subjecting the mixture to homogenization. A characteristic of emulsifiers called the hydrophobicity-lipophilicity balance (HLB) may be helpful when choosing an emulsifier (Auriou and Ferreres, 2002). An emulsifier with a HLB than that of the sterol is desired to promote solubility (Auriou and Ferreres, 2002). Microencapsulation followed by spray-drying is also a feasible approach to sterol-fortified beverage formulation.

## Regulatory Aspects

Review of the global regulatory frameworks for functional foods containing phytosterols and phytostanols was recently published (Zawistowski and Jones, 2015). Table 1 contains a summary of the regulatory framework and health claims on foods with phytosterols in various jurisdictions. This is important when designing a sterol-enriched product for the market because it will have a significant impact on the choice of food product, the serving size, the ingredient list and nutritional composition. It will also be important when marketing products to ensure that all advertisements are truthful, well-substantiated and do not mislead consumers.

## Conclusion

There are many clinical studies which support the health benefits of consuming phytosterols and thus, regulatory agencies have acknowledged their benefits by approving these compounds for use in foods. Phytosterol-containing food products and beverages are already quite popular and as consumers continue to demand health benefits from their food beyond just nutrition, the demand for these products is growing. It is therefore important to find ways of overcoming the challenges associated with adding phytosterols to food products.

# Caseinophosphopeptides

Alice B Nongonierma and Richard J FitzGerald, University of Limerick, Limerick, Ireland

© 2019 Elsevier Inc. All rights reserved.

## Nomenclature

ACP amorphous calcium phosphate

ACFP amorphous calcium fluorophosphate

CPPs caseinophosphopeptides

DF diafiltration

DH degree of hydrolysis

E:S enzyme to substrate ratio

EtOH ethanol

FOS fructo-oligosaccharides

ITF inulin-type fructans

nd not determined

o/n overnight

RCT randomized controlled trial

RO reverse osmosis

UF ultrafiltration

## Introduction

The basic nutritional role of milk proteins is in the provision of nitrogen and essential amino acids. Additionally, milk proteins have the potential to beneficially modulate a range of different physiological systems within the human body. Intact milk proteins possess many bioactive properties such as antimicrobial, antidiabetic, antihypertensive, anticancer and anti-inflammatory activities (Nongonierma and FitzGerald, 2015a). Milk proteins, in addition, contain an extensive range of bioactive peptide sequences which are encrypted within their primary structures (FitzGerald and Meisel, 2003; Korhonen and Pihlanto, 2006; Miralles et al., 2018; Nongonierma, O'Keeffe and FitzGerald, 2016). Milk protein-derived bioactive peptides, with a diverse range of physiological targets in the immune, nervous, skeletal, endocrine and vascular systems, have been identified following different *in vitro* and *in vivo* studies (Korhonen, 2009; Miralles et al., 2018; Nongonierma and FitzGerald, 2015b; Nongonierma et al., 2016; Sultan et al., 2018). Therefore, milk protein-derived bioactive peptides have been proposed as health promoting and disease risk reducing agents.

Casein-derived phosphorylated peptides are known as caseinophosphopeptides (CPPs). Numerous CPP sequences have been identified within heat-processed, hydrolyzed and fermented bovine milk products (Pinto et al., 2012b). Additionally, milks from other mammals, i.e., human, equine, goat, donkey and buffalo have also been shown to be a source of CPPs (Caira et al., 2016; Cunsolo et al., 2009; Ferranti et al., 1998; Matéos et al., 2010; Smialowska et al., 2017). Due to their high content of carboxylate (Glu and Asp residues) and phosphate groups esterified to Ser and Thr residues, CPPs are negatively charged and therefore have the ability to bind and solubilize bivalent cations such as calcium, iron, copper and zinc (Bouhallab and Bouglé, 2004; FitzGerald, 1998; Mekmene and Gaucheron, 2011). These properties have been explored with the aim of developing CPPs as natural ingredients having the ability to enhance mineral bioavailability. The interest in increasing calcium and iron solubility and bioavailability is relevant due to the increasing prevalence of public health issues related to conditions such as osteoporosis, iron deficiency anemia and dental caries (Bonjour et al., 2009; Nongonierma and FitzGerald, 2012). Therefore, the main aim of this chapter is to review current scientific information with respect to CPPs as remineralizing agents. The structure of CPPs will be outlined followed by details of the production and enrichment techniques applied to the preparation of CPPs. The scientific data on the biofunctional properties of CPPs will be discussed with a specific focus on human studies. Finally, the applications of CPPs as ingredients in food products will be outlined.

## Structure of CPPs

CPPs are casein-derived peptides rich in clusters of phosphorylated Ser and occasionally Thr residues. Caseins are phosphorylated during milk biosynthesis via the activity of specific kinases in the mammary gland (FitzGerald, 1998). As shown in Table 1, different

levels of phosphorylation have been observed in the individual caseins depending on the mammalian species. In addition, the extent of phosphorylation may depend on the number of Ser/Thr phosphate groups present in individual protein molecules, which is influenced by genetic polymorphism in the caseins (Caroli et al., 2009; Selvaggi et al., 2014; Uniacke-Lowe et al., 2010).

A number of different phosphorylated sequences occur in  $\alpha_{s1}$ -,  $\alpha_{s2}$ - and  $\beta$ -casein. This is linked with the higher level of phosphorylation observed in these three individual caseins in comparison to  $\kappa$ -casein, which generally contains a lower number or, in some instances, no CPP sequences (Table 1). A specific sequence consisting of 3 serine phosphate groups followed by two glutamic acid residues (i.e., Ser(P)-Ser(P)-Ser(P)-Glu-Glu, with Ser(P) a phosphorylated Ser residue), also known as the “acidic motif”, has been identified in several CPPs (Bouhallab and Bouglé, 2004). The “acidic motif” is found in the sequence of  $\alpha_{s1}$ -casein (f66–70),  $\alpha_{s2}$ -casein (f8–12) and (f56–60) and  $\beta$ -casein (f17–21) (Cruz-Huerta et al., 2015). The “acidic motif” plays a central role in the binding of bivalent minerals to CPPs (Fig. 1).

## Production and Enrichment of CPPs From Milk Proteins

CPPs are encrypted within the primary sequence of caseins. Therefore, they need to be released in order to display their bioactive properties. CPPs have been reported as naturally occurring at low levels in bovine milk as a result of milk protein hydrolysis by plasmin and somatic cell proteinases (Pinto et al., 2012a). CPPs are also released during other processes such as microbial fermentation (in cheese and yoghurt) (Ardö et al., 2007; Ferranti et al., 1997; Ferrazzano et al., 2008; Kawahara et al., 2005; Roudot-Algaron et al., 1994). Additionally, CPPs have been produced using *in vitro* enzymatic hydrolysis of milk proteins (McDonagh and FitzGerald, 1998; Reynolds et al., 1994). Finally, CPPs have been identified within digestates of human subjects following milk ingestion, indicating their *in vivo* release in the digestive tract (Boutrou et al., 2013; Chabance et al., 1998; Meisel et al., 2003).

The main method employed to produce CPPs at laboratory and industrial scale is through enzymatic hydrolysis of milk proteins. A summary of the different processes used during the generation of CPPs is outlined in Fig. 2. The milk protein substrates used during hydrolysis generally consist of commercially available casein-rich preparations (e.g., sodium caseinate) which possess protein contents as high as 90% (w/w). Several commercial enzyme preparations have been described during the generation of CPPs (Table 2). Porcine trypsin and the *Bacillus licheniformis*-derived preparation, Alcalase™ (Novozymes, Bagsvaerd, Denmark),

**Figure 2** Outline of the procedures used during the generation of caseinophosphopeptide (CPP) preparations. Adapted from [Adt et al. \(2011\)](#), [Ferrazzano et al. \(2011\)](#), and [Reynolds et al. \(1994\)](#). EtOH: ethanol; UF: ultrafiltration.

appear to be the most frequently used enzyme activities for the generation of CPPs ([FitzGerald, 1998](#); [Nongonierma and FitzGerald, 2012](#); [Vegarud et al., 2000](#)). However, [McDonagh and FitzGerald \(1998\)](#) demonstrated that a broad range of mammalian, bacterial and plant-derived enzyme preparations (27 different enzyme preparations were evaluated) could be employed to prepare CPPs.

Differences in the composition of CPP products prepared under various conditions have been highlighted. Trypsin and Alcalase™ were employed under the same conditions to generate CPP preparations. The CPP sequences obtained from the Alcalase™ hydrolyzate were generally shorter (6–15 amino acid residues) when compared to those obtained in the trypsin hydrolyzate (11–37 amino acid residues), which was attributed to the broader specificity of Alcalase™ ([Adamson and Reynolds, 1996](#); [Reynolds et al., 1994](#)). Enzymatic hydrolysis has conventionally been conducted with free enzymes, however, encapsulated enzyme preparations have also been described during the generation of CPPs ([Rocha-Martin et al., 2018](#)). The advantages of encapsulation lie in the possibility of recycling the enzyme and carrying out repeated hydrolysis reactions. This may help to reduce costs associated with the generation of CPP preparations and possibly lead to the application of less severe heat treatments during enzyme inactivation steps.

Following enzymatic hydrolysis of caseins, enrichment steps are generally applied ([Fig. 2](#)) to remove unhydrolyzed caseins from the hydrolyzate and subsequently to separate non-phosphorylated peptides from CPPs. The selective precipitation of caseins at their isoelectric point ( $pI = 4.6$ ) renders them insoluble and allows their subsequent removal from the hydrolyzate by centrifugation or decantation. The soluble fraction contains non-phosphorylated peptides and CPPs. In a second step, mineral-bound CPPs are prepared using mineral salts (e.g.,  $CaCl_2$ ,  $BaCl_2$  and  $FeCl_2$ ) and the complexes formed may be precipitated by pH adjustment (generally to pH 7.0) and the addition of ethanol. The CPP complexes are recovered by decantation, centrifugation or ultrafiltration (UF). The hydrodynamic radius of Ca-CPP ( $\alpha_{s1}$ -casein (f59–79)5P and  $\beta$ -casein (f1–25)4P) aggregates was determined to be of 60 nm ([Gravaghi et al., 2007](#)). The relatively large size of CPP aggregates aids in their subsequent recovery by UF separation. Chromatographic separation involving anion-exchange resins (e.g. hydroxyapatite) has also been used to isolate CPPs from milk protein hydrolyzates ([Fig. 2](#)). The advantage of chromatographic separation is the ability to isolate individual CPP sequences. CPPs may also be extracted from fermented dairy products (cheese and yoghurt), generally by preparing a water-soluble extract of cheese or from yoghurt supernatants. CPP preparations are generally dried using either spray- or freeze-drying processes ([Fig. 2](#) and [Table 2](#)).

The recovery obtained during CPP manufacture is typically reported for all phosphorylated peptides obtained during the extraction process regardless of whether they contain the “acidic motif” or not. The yield obtained during CPP generation is calculated using the following formula ([Zhao et al., 2007](#)):

**Table 2** Examples of the different conditions used at laboratory- and pilot-scale to generate caseinophosphopeptide (CPP)-enriched preparations

$$\text{Yield} = \frac{\text{Amount of N in the CPPs}}{\text{Amount of N in the protein substrate}} \times 100 \quad (1)$$

Different extraction yields have been reported following CPP generation. Yields vary and depend on the hydrolysis conditions employed as well as the parameters (i.e., pH, mineral concentration, ethanol content, etc.) used during the aggregation steps (Table 2). They also depend on the peptide sequences released as these dictate overall mass of the phosphorylated peptides generated. The susceptibility to precipitation under certain conditions also depends on the CPP sequence. Therefore, conditions such as mineral concentration and pH value should be appropriately chosen to selectively precipitate the CPPs present within specific casein hydrolyzates (Adamson and Reynolds, 1996). In addition, the duration of the hydrolysis reaction and the pH value employed during CPP precipitation have been shown to affect the recovery of individual CPPs (Cruz-Huerta et al., 2015). These parameters, therefore, need to be optimized to maximize the yield of specific CPPs. When comparing 27 commercial enzyme preparations, the highest yield of CPPs (i.e., 16.0%) was obtained from a Bioprotease N100L (a *Bacillus subtilis*-derived preparation, Quest International, Carrigaline, co. Cork, Ireland) sodium caseinate hydrolyzate (McDonagh and FitzGerald, 1998). CPP yields as high as 28.7% (w/w) have been reported with an Alcalase™ hydrolyzate of sodium caseinate (Prakash and Lakshmi, 2015).

Interestingly, the calcium binding ability of the CPP preparations did not appear to be related to the yield as the highest binding value (i.e., 24 mg  $\text{Ca}^{2+}$  mg<sup>-1</sup> CPP) was obtained with Pancreatin™ (McDonagh and FitzGerald, 1998). The binding affinity of  $\text{Ca}^{2+}$  was shown to depend on the CPP sequence. For example, a higher  $\text{Ca}^{2+}$ :peptide ratio was reported for  $\beta$ -casein (f1-25)4P than for  $\alpha_{s1}$ -casein (f59–79)5P, i.e., 4 and 1  $\text{Ca}^{2+}$ :peptide, respectively. Similarly, the  $\text{Ca}^{2+}$  binding constant was higher for  $\beta$ -casein (f1-25)

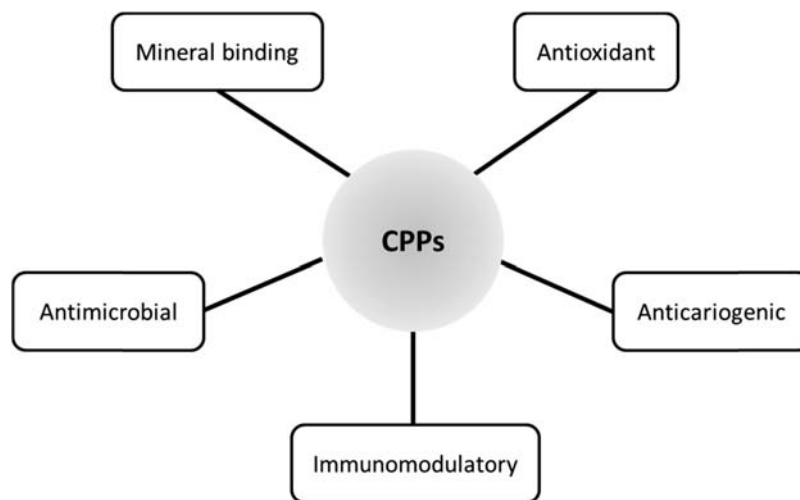

4P than for  $\alpha_{s1}$ -casein (f59–79)5P, i.e., 0.63 and 0.85 mM<sup>-1</sup>, respectively (Meisel and Olieman, 1998). Optimization experiments have been performed to maximize the amount of mineral bound by CPPs. In this context, optimization of binding of Fe<sup>2+</sup> to a commercial CPP preparation (VIVID Casein Phospho Peptide-H, Zhengzhou Friend Biological Engineering Co., Zhengzhou, Henan, China) has recently been investigated using a central composite design combining pH, Fe:CPP ratio and holding time (Delshadian et al., 2018). Optimization of these three parameters was achieved using response surface methodology (RSM). The most important parameter for Fe<sup>2+</sup> binding was the pH value. The optimum conditions (pH 6.5, 0.14 Fe:CPP ratio and a holding time of 72 min) yielded a product containing  $67.62 \pm 0.95$  mg Fe<sup>2+</sup> g<sup>-1</sup> CPP preparation.

The CPP format generally used in dentistry and oral hygiene products consists of CPP-amorphous calcium phosphate (ACP). CPP-ACP has been used since in the presence of water, it converts into hydroxyapatite, the precipitated form of calcium and phosphate at the surface of dental enamel (Boskey and Posner, 1973; Skrtic et al., 2003). In several instances, fluoride has been included with the ACP to obtain amorphous calcium fluorophosphate (ACFP). CPP-ACFP complexes are claimed to have a greater remineralizing effect than CPP-ACP. This is linked to the fact that tooth enamel, where fluoroapatite is deposited, is claimed to be particularly resistant to demineralization. This has been explained by the poor aqueous solubility of fluoroapatite (Ostrom et al., 1984). The manufacture of CPP-ACP and CPP-ACFP complexes has also been described in the patent literature (Reynolds, 2008b, 2011). The starting point for the release of CPPs still involves enzymatic hydrolysis of caseins followed by isoelectric precipitation of unhydrolyzed caseins at pH 4.6 as outlined in Fig. 2. However, differences are found during the aggregation step of the CPPs. The addition of CaCl<sub>2</sub> to CPPs is performed slowly while NaOH is added to set the pH value within 5.0 and 9.0 (Walsh, 2009). An aqueous solution of Na<sub>2</sub>HPO<sub>4</sub> is then mixed with the CPP-Ca sample, leading to the formation of CPP-ACP complexes. CPP-ACFP complexes are prepared by adding NaF to CPP-ACP. Membrane separation, such as microfiltration or dialysis through a 1 kDa UF membrane, allows separation of the CPP-ACP or CPP-ACFP complexes from the other peptides (Cross et al., 2004). The CPP-ACP complexes formed consist of [ $\alpha_{s1}$ -casein (f59–79) (ACP)<sub>7</sub>]<sub>6</sub> and [ $\beta$ -CN(f1–25) (ACP)<sub>8</sub>]<sub>6</sub>. The [ $\alpha_{s1}$ -casein (f59–79) (ACP)<sub>7</sub>]<sub>6</sub> complexes have an average hydrodynamic radius of 2.12 nm (Cross et al., 2004). The average hydrodynamic radius of [ $\beta$ -CN(f1–25) (ACP)<sub>8</sub>]<sub>6</sub> is between  $1.526 \pm 0.44$  and  $1.923 \pm 0.082$  nm (Cross et al., 2007; Cross et al., 2016). CPP-ACFP complexes are reported to have an average diameter of 41 nm (Sun and Chow, 2008). Recently, Cross et al. (2016) demonstrated that ACP interacts with the entire CPP sequence and not only with the “acidic motif” to form CPP-ACP complexes.

## Bioactive Properties of CPPs

### Mechanisms of Action of CPPs

Using *in vitro* protocols and small animal studies, a number of bioactive properties have been identified with CPPs (Fig. 3). These comprise mineral binding, anticariogenic, antimicrobial, antioxidant and immunomodulatory properties (Bouhallab and Bouglé, 2004, 2011; FitzGerald, 1998; Kitts, 2005, 2006; Nongonierma and FitzGerald, 2012; Vegarud et al., 2000). Most of the reported bioactive properties of CPPs have systemic targets (i.e., associated with bone, the circulatory system and various internal organs). Therefore, CPP bioavailability is necessary in order for their bioactive properties to be observed. Numerous *in vitro* studies have evaluated the effect of CPPs on intracellular mineral uptake (for reviews, see: Bouhallab and Bouglé, 2011; Sun et al., 2016). A range of cell models including intestinal (Caco-2 and HT29 cells) (Cao et al., 2017; Cosentino et al., 2010a; Cosentino et al., 2010b; Ferrarretto et al., 2003; Gravaghi et al., 2007; Kibangou et al., 2005; Perego et al., 2012; Perego et al., 2015), human hepatoma cells

**Figure 3** Main bioactive properties of caseinophosphopeptides (CPPs). Adapted from Bouhallab and Bouglé (2004), FitzGerald (1998), Kitts (2005), (2006), Nongonierma and FitzGerald (2012), and Vegarud et al. (2000).

(HuH7) (García-Nebot et al., 2015) and osteoblasts (SaOS-2M and C3T3-E1) (Donida et al., 2009; Tulipano et al., 2010) have been used to demonstrate the role of CPPs as enhancers of mineral uptake at cellular levels.

Bovine  $\alpha_{s1}$ -casein (f59–79)5P and  $\beta$ -casein (f1–25)4P are the most studied CPPs in the scientific literature. Both peptides contain the “acidic motif”. This “acidic motif” is rich in negatively charged groups at alkaline pH (Rose, 2000). The negative charges arise from the phosphate groups and Glu residues (Fig. 1) (Kitts, 2006; Mekmene and Gaucheron, 2011). These negative charges confer the ability of CPPs to bind bivalent minerals ( $\text{Ca}^{2+}$ ,  $\text{Zn}^{2+}$ ,  $\text{Fe}^{2+}$  and  $\text{Mn}^{2+}$ .) and a range of trace elements (barium, selenium, nickel, cobalt and chromium) (Bouhallab and Bouglé, 2004; FitzGerald, 1998; Kitts, 2006). The central role of the “acidic motif” in mineral binding has been demonstrated by Ferrarretto et al. (2003) during a study on truncated and/or dephosphorylated peptides originating from bovine  $\beta$ -casein (f1–25)4P. Inorganic mineral salts such as calcium phosphate and ferrous sulfate have low solubility in water (Skibsted, 2016). Binding of minerals to CPPs causes an increase in their water solubility. Their mineral solubilizing properties have, therefore made CPPs attractive for the development of mineral supplements with enhanced bioavailability. The presence of negative charges within CPPs and their complexation with minerals have also been linked to their purported resistance to gastrointestinal digestion (Boutrou et al., 2010; Kitts, 2005; Meisel and Frister, 1988; Vegarud et al., 2000).

The anticariogenic properties of CPP-ACP and CPP-ACFP have been reviewed in several publications (Bijle et al., 2018; Li et al., 2014; Lopatiene et al., 2016; Nongonierma and FitzGerald, 2012; Peters, 2010; Wang et al., 2017). Due to its low solubility, calcium phosphate is inefficient at remineralizing tooth surfaces (Reynolds, 2008a). CPPs have been shown to increase calcium and phosphate solubility and stabilize these compounds at the tooth surface, thereby promoting enamel remineralization (Peters, 2010; Reynolds, 1997). In the oral cavity, CPP-bound calcium allows the maintenance of a supersaturation of  $\text{Ca}^{2+}$  at the tooth surface. This in turn leads to remineralization of tooth enamel and repair of enamel lesions (Adamson and Reynolds, 1996). The anticariogenic properties of CPP-ACP and CPP-ACFP involve various modes of action including (a) reduction in the rate of tooth demineralization, (b) remineralization of dental enamel and (c) anti-plaque activity through their buffering capacity and antimicrobial effects (El Mehdi et al., 2016; Nongonierma and FitzGerald, 2012; Pinto et al., 2012a; Reynolds, 1998). Some contradictory reports in the literature have, however, raised several questions in terms of the efficiency of CPPs as tooth remineralization agents in humans (Azarpazhooh and Limeback, 2008; Bijle et al., 2018; Sonesson et al., 2016).

The antimicrobial activity of CPPs has been mostly shown against strains found in the dental plaque (i.e., aciduric bacteria and *Streptococcus mutans*) (Beerens et al., 2010; Rose, 2000). The mechanism of action involves binding of CPPs to the dental plaque. The negative charges of the bound CPPs induce repulsive forces, preventing the binding of microorganisms to the enamel surface (Rahiotis et al., 2008). Recent studies have shown that CPPs display an antiviral activity *in vitro* against human norovirus, which is involved in gastroenteritis (Lebetwa et al., 2017). In this study, the presence of phosphate groups in CPPs was shown to be a requirement to observe the antiviral activity.

CPPs also display immunomodulatory properties such as in the stimulation of immunoglobulin production and lymphocyte proliferation (for review, see: Meisel and FitzGerald, 2003). CPPs generated during tryptic hydrolysis of bovine milk proteins (i.e.,  $\alpha_{s1}$ -casein (f59–79)5P and  $\beta$ -casein (f1–25)4P) demonstrated a mitogenic activity and a stimulatory effect on immunoglobulin production in mouse spleen and rabbit Peyer's patch cells (Hata et al., 1998). Immunoglobulin release may be influenced by the increase in  $\text{Ca}^{2+}$  uptake, which has a mitogen-induced proliferative action for lymphocytes (Hata et al., 1998; Hosono et al., 2002).

The antioxidant properties of CPPs have also been shown *in vitro* (Kitts, 2005). CPPs can act both as primary (scavenging of antioxidants) and secondary (sequestering of potential metal pro-oxidants) “site-specific” antioxidants. The antioxidant properties of CPPs have been linked with phosphoserine residues, and their proximity, within CPP sequences. The arrangement of phosphoserine residues within CPP sequences results in anionic and polar domains, which have the ability to sequester cationic metal ions (Kitts, 2005). CPPs also protect cells (Caco-2) against  $\text{H}_2\text{O}_2$  oxidation (García-Nebot et al., 2011; Laparra et al., 2008). The CPPs are reported to act at different levels, i.e., having a cytoprotective effect (increase in cell viability) and a regulatory effect on cellular redox systems (e.g., glutathione production, stimulation of catalase activity and reduction of lipid peroxidation).

### Bioavailability of CPPs

In the context of dietary mineral deficiencies (e.g., osteoporosis and anemia), it appears that an increased bioavailability for  $\text{Ca}^{2+}$  and  $\text{Fe}^{2+}$  is a requirement to enhance their uptake in the body. The increased bioavailability of minerals bound to CPPs has been linked with the enhanced solubility of minerals in the ileum (Kitts and Yuan, 1992; Zidane et al., 2012). Consequently, CPPs must be able to arrive intact at, or be released in the small intestine. The theoretical maximum luminal yield of  $\alpha_{s1}$ -casein (f43–58), (f59–79) and  $\beta$ -casein (f1–25) has been determined to be 3.24, 4.58% and 4.81% (w/w protein), respectively (Meisel, 1998). CPP sequences have been found in *in vitro* simulated gastrointestinal digests of milk and cheese (Cattaneo et al., 2017; Picariello et al., 2010, 2013; Sánchez-Rivera et al., 2014; Sanchón et al., 2018) and CPPs (Ait-Oukhatar et al., 2000; Bouhallab et al., 1999; García-Nebot et al., 2010; Miquel et al., 2006). In addition, CPPs have been identified in the gastrointestinal tract of mammals following casein or CPP ingestion (for reviews, see: Boutrou et al., 2015; FitzGerald, 1998; Nongonierma and FitzGerald, 2017).

The phosphorylated region of CPPs is reported to confer resistance to gastrointestinal enzyme-mediated degradation (Cattaneo et al., 2017; Picariello et al., 2010; Sánchez-Rivera et al., 2014; Vegarud et al., 2000). The bioavailability of CPPs has been reported in

several *in vivo* studies (Ait-Oukhatar et al., 2002; Bennett et al., 2000). CPPs were detected in the feces of rats fed with diets containing 50–500 mg kg<sup>-1</sup> casein or commercial CPP preparations (CPP I and CPP III, Meiji Seika, Tokyo, Japan) (Kasai et al., 1995). Detection of CPPs has also been reported in the gastrointestinal contents of pigs fed with a diet containing 145 g skimmed milk powder (Barbé et al., 2014) and rats fed with 17.2 µg of CPP III (Hirayama et al., 1992). Detection of CPPs in feces of animals following the consumption of milk proteins or CPPs indicates their relative stability in the gastrointestinal tract (Barbé et al., 2014; Hirayama et al., 1992; Meisel and Frister, 1988). However, contradictory studies have been shown in other animal studies, reporting no improvement in the bioavailability of minerals. This was the case when a diet containing 120 µg CPP-Zn was administered to rats (Matsui et al., 2002).

A limited number of human intervention studies have been conducted with CPPs *per se* or dairy products as a source of CPPs. The format and outcomes of the human intervention studies carried out to date are summarized in Table 3. Early studies (before 2010) have mainly focused on the role of CPPs on mineral (Ca<sup>2+</sup>, Fe<sup>2+</sup> and Zn<sup>2+</sup>) absorption and uptake (principally in bone) following dietary intervention. The results obtained are contradictory as some studies have reported beneficial effects of CPPs on mineral absorption following intake of 175 mg CE90CPP (DMV International, Veghel, the Netherlands) (Adolphi et al., 2009). However, other studies reported no differences compared to a control diet when amounts between 250 and 2000 mg CPPs were administered (Ait-Oukhatar et al., 2002; Hansen, Sandström, Jensen and Sørensen, 1997a; Hansen, Sandström, Jensen and Sørensen, 1997b; López-Huertas et al., 2006; Narva et al., 2003). One study reported a reduction in fractional Ca<sup>2+</sup> absorption following ingestion of ~100 mg CPP-Ca (Teucher et al., 2006). Other human studies have reported enhancement effects by CPPs (amounts ingested between 87.5 and 2000 mg) on Ca<sup>2+</sup> absorption, the effects being population- (Heaney et al., 1994) or diet-dependent (Hansen et al., 1997a).

The reported lack of an observed beneficial effect of CPP intake in certain studies may arise from different factors, including the CPP format (free CPPs vs. intact or partially hydrolyzed milk proteins), the population tested (healthy vs. mineral deficient subjects), the diet (low vs. phytate-rich), food format (liquid vs. solid), timing of ingestion, CPP dose and CPP:mineral ratio (Nongonierma et al., 2016). Antinutritional components such as phytates can bind bivalent minerals and, therefore reduce their overall bioavailability. This may be the reason in the case of a rice-based meal, which is low in phytates, why CPPs (1000 and 2000 mg) were observed to increase Ca<sup>2+</sup> and Zn<sup>2+</sup> absorption by ~30% in human subjects in contrast with the whole grain meal, which contained phytates (Hansen et al., 1997a). Furthermore, no effect on Ca<sup>2+</sup> and Zn<sup>2+</sup> absorption were found on the ingestion of CPPs (250 and 1000 mg) with white bread, which is also a phytate-rich food (Hansen et al., 1997b). Another factor which may modify the effect of CPPs is the stability of CPPs in the gastrointestinal tract. It has been shown that milk proteins appear to have a protective effect on CPP integrity, which translates to the prevention of CPP degradation during gastrointestinal transit. This was demonstrated following the consumption of CPP preparations or milk. Higher levels of CPPs were detected in the ileostomy fluid of humans fed with cow's milk (250 g) than with CPP preparations (1520 mg), i.e., 7.10 and 0.2 nmol mL<sup>-1</sup>, respectively (Meisel et al., 2003). The timing of CPP intake may also play a role on their effects on mineral absorption. Nocturnal intake of inulin-type fructans (ITF) and CPPs (175 mg) had a positive effect on Ca<sup>2+</sup> absorption in post-menopausal women, compared to fermented milk with or without a Ca<sup>2+</sup> supplement (Adolphi et al., 2009). The dietary status of the subjects is also another important factor, which needs to be taken into account. Heaney et al. (1994) identified differences in Ca<sup>2+</sup> absorption in post-menopausal women depending on their Ca<sup>2+</sup> status. Women having low basal Ca<sup>2+</sup> absorption could absorb more Ca<sup>2+</sup> in the presence of CPPs (87.5 mg) as opposed to women with high basal Ca<sup>2+</sup> absorption (Heaney et al., 1994).

The other human studies outlined in Table 3 are linked to the detection of CPP sequences in humans. Most of these studies have reported on the detection of CPPs in the small intestine (duodenum, jejunum and ileum) following the ingestion of bovine milk proteins (Boutrou et al., 2013; Chabance et al., 1998; Meisel et al., 2003). Recently, Caira et al. (2016) reported the identification of CPPs in the plasma of human subjects who ingested 100 g Parmigiano Reggiano cheese daily for 7 days. Significant interindividual differences were found regarding the detection of CPPs in the plasma. This was the case for α<sub>s1</sub>-casein (f43–50)2P, α<sub>s2</sub>-casein (f7–12)2P and (f8–12)3P, which were only detected in the plasma of one out of four subjects (Caira et al., 2016). It is also interesting to note that the detection of CPPs in humans has been carried out post ingestion of intact or partially hydrolyzed milk proteins (i.e., cheese and yoghurt). As previously stated, the stability of CPPs in the gastrointestinal tract may be low (Meisel et al., 2003). Therefore, CPPs appear to survive digestion when they are ingested in their encrypted format, i.e., within intact or partially digested milk proteins. This may be part of the reason why most human intervention studies which have evaluated the effect of CPP intake in the precursor substrates for CPP release (intact or partially hydrolyzed milk proteins), as opposed to ingesting CPPs *per se*, have reported a positive effect on mineral absorption (Table 3).

In summary, major differences are reported in the relative stability of CPPs during *in vivo* and *in vitro* digestion (García-Nebot et al., 2010; Meisel et al., 2003; Perego et al., 2015). These findings highlight the need to assess/validate both the stability and the bioactivity of biofunctional peptides within specific food delivery matrices. Therefore, there may be a need for the application of specific reformulation and/or protective methodologies (e.g., encapsulation) if the biofunctional peptide is not stable during gastrointestinal transit in a given food matrix.

## Functional Properties in Foods

CPPs are manufactured commercially and the process for their production has been extensively patented over the years (for review, see: Nongonierma and FitzGerald, 2012). A range of CPP preparations are sold as food-grade ingredients both for food and oral

hygiene applications (Table 4). To date, CPPs appear to have been mainly used in oral hygiene products such as toothpaste, mouthwash and chewing-gums. However, foods formulated with CPPs have also been developed, especially in beverage format (Nongonierma and FitzGerald, 2012; Pinto et al., 2012b).

Different studies have shown that components within the food matrix may play a significant role in the bioavailability of dietary minerals. As already discussed, foods which are rich in antinutritional compounds such as phytates can reduce the bioavailability of minerals. Similarly, the bioavailability of  $\text{Ca}^{2+}$  from CPP-Ca is lowered in the presence of inorganic phosphate (Erba et al., 2001). The food matrix may have a protective effect on CPP stability to digestive enzymes. This has been demonstrated when CPPs were ingested in their precursor in the format of milk proteins or fermented products. Other matrices such as a fruit beverage have also been shown to protect CPPs against degradation during simulated gastrointestinal digestion (García-Nebot et al., 2010).

The antioxidant properties of CPPs have been exploited to bind  $\text{Fe}^{2+}$  and therefore inhibit lipid peroxidation in oil-in-water emulsion systems and in meat (Díaz and Decker, 2004; Díaz et al., 2003). The antioxidant activity of CPPs was, however, not linked to their phosphorylated fragments, it was suggested that Glu and Asp residues were responsible for the  $\text{Fe}^{2+}$  chelation (Díaz et al., 2003).

Studies have linked casein phosphorylation with an enhancement in certain technofunctional properties such as foaming, emulsifying and solubility (for review, see: Broyard and Gaucheron, 2015). Alterations in these properties have been explained by the increased charges associated with the phosphate groups. This in turn is linked to a reduction in the isoelectric point of the caseins and in their surface hydrophobicity. Due to their high charge contents, CPPs *per se* may present similar tensioactive properties. However, studies on the foaming and emulsifying properties of CPPs do not currently appear to exist in the published literature.

## Conclusions

Several *in vitro* and small animal studies have demonstrated that CPPs are effective as mineral carriers. Therefore, CPPs may have the ability to be exploited as food-grade ingredients with mineral-binding and possibly delivery properties. To date, most human intervention studies, which have been conducted with CPPs have failed to demonstrate a real effect as bone remineralizing agents. However, the format in which the CPP is ingested appears to play a major role in their bioavailability. Human intervention studies reporting beneficial mineralization effects of CPPs have employed CPPs, which were encrypted within intact caseins or in partially hydrolyzed caseins. In these formats, it seems that CPPs are less likely to be degraded in the gastrointestinal tract. The detection of CPPs in the small intestine and in the circulation of humans following ingestion of intact or partially hydrolyzed milk proteins is well documented. However, different research approaches may need to be taken to demonstrate the biological activity of CPPs. These include the development of processes for the manufacture of CPP precursors (partially hydrolyzed milk-protein derived peptides containing the “acidic motif”) yielding more stable and thus ultimately bioavailable CPPs. The encapsulation of CPPs is another approach, which may be explored in the delivery of CPP ingredients that remain stable until they reach the small intestine where maximal absorption of dietary minerals takes place in humans.

## Introduction

### Eye Health and Its Related Diseases

The eye is a unique sensory organ which needs more attention to ensure a productive and healthy lifestyle (Abdel-Aal et al., 2013). However, less attention was given to eye health as several eye diseases during the early stage did not show any signs or symptoms (pain or change in vision) until it transformed to an advanced stage. Hence, the ophthalmologist always recommends regular eye examinations (at least once in a year) to cross check eye health status (Ono et al., 2010; Sloan et al., 2005). Therefore, the importance and the awareness of eye health help everyone to preserve vision and thus can lead to better quality of life (Scott et al., 2016). A global action plan was adopted by the World Health Organization (WHO) to decrease global vision impairment (blindness) as well as to increase the rehabilitation for already visually impaired people (Bourne et al., 2017). Copious number of studies have concluded that the prevalence of age-related visual impairments and blindness are considerably increased in developed or high-income countries as the life expectancy has increased significantly (Chan et al., 2017; Finger et al., 2011). WHO, in their 2010 survey concluded that about 253 million people are experiencing various degrees of visual impairment. Nonetheless, only 39 million people are completely blind based on best-correction visual acuity (BCVA) score. It has been estimated that by 2050 the number of visually impaired would be tripled (WHO, 2012; Bourne et al., 2017).

Moreover, the economic burden of visually impaired or blind people was substantially increased in recent times in developing and developed countries. It is predicted that in the year 2050 the economic burden for visual impairment would cross \$70 billion in developed countries especially in US, UK, Germany and Canada (Rein et al., 2009; Koberlein et al., 2013). Most of the age-related eye diseases including Age-related macular degeneration (AMD), cataract, and glaucoma have a negative impact on the quality of life as they need utmost care (basic needs) as well as expensive treatments (Eckert et al., 2015; Kundtson et al., 2005). Currently, many researchers are more focused on eye diseases that include age-related macular degeneration (AMD) and cataract as they contribute to almost 50%–60% of total blindness or visual impairment globally in the elderly population (Flaxman et al., 2017; Resnikoff et al., 2004). Therefore, for the current study, we included only age-related eye diseases like AMD and cataract and its correlation with carotenoids and  $\omega$ -3 fatty acid supplementation as the oxidative stress (light induced) is the common contributor for both types of vision impairment.

### Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is characterized by the progressive loss of macular pigment (in macula) or photoreceptors, which subsequently results in blindness (Vujosevic et al., 2017; Van Lookeren Campagne et al., 2014). AMD is one of the major causes of vision impairment or blindness globally in the elderly population (over 65 years) next to cataract and glaucoma (WHO, 2012; Abdel-Aal et al., 2013). Two main types of AMD are dry (atrophic) and wet (neovascular or exudative). Dry type AMD is quite common, which affects about 80%–90% individuals. The exact reason is still unknown, but drusen deposition (white or yellowish deposits) beneath the macula could be responsible for the macular deterioration/degeneration with large choroidal vessels (Van Lookeren Campagne et al., 2014). Whereas, wet type (neovascular) AMD only affects 10%–15% of individuals, but very dangerous as it contributes to 90% of blindness in AMD patients (Abdel-Aal et al., 2013). Wet type AMD is mainly caused by an abnormality in a retinal blood vessel (bleed, leak fluid) growth, which leads to damaging the macula and eventually lowers the macular density and thus results in blindness.

There are 3 stages of AMD including early, intermediate and late or advance AMD. In the early stage of AMD, the patient might not experience any vision loss, without any symptoms. Early-stage AMD is diagnosed by the presence of smaller or medium-sized (<125  $\mu$ m in diameter) drusen (white or yellowish deposits) beneath the macula of the retina (Coleman et al., 2008). In contrast, at the intermediate stage of AMD, patients may experience slight vision loss or blurred vision (central vision loss) without any noticeable symptoms, but the density of macular pigment might have decreased as compared with the normal eye. Intermediate stage AMD is diagnosed by the presence of medium or large sized (>125  $\mu$ m in diameter) drusen (Vujosevic et al., 2017). During advanced or late stage of AMD, the patient could experience vision loss due to large-sized drusen with thin macular pigment density/bruch membrane and the chances of reverting to normal level is very low (Vujosevic et al., 2017; Ach et al., 2015).

AMD affects approximately 30–35 million worldwide and the numbers are increasing lately in developed and developing countries owing to modified lifestyle (Kawasaki et al., 2010; Friedman et al., 2004). AMD patients encounter various difficulties in their day to day life as they depend on others for all basic needs and thus the quality of life is significantly hampered (Choudhury et al., 2016). AMD is strongly correlated with environmental, behavioral and genetical factors. Some causative factors include smoking, obesity, gender (females are highly prone to AMD), colour of eye (especially lighter eye colour), race (Caucasians are more likely to develop AMD) and genetical factors (complement H and B) (Lim et al., 2012; Kawasaki et al., 2010; Friedman et al., 1999). The

prevalence of AMD in black and Hispanic are lesser than in the white population (Klein et al., 2006). Nevertheless, the exact pathophysiology of AMD is still unexplored, but few researchers have demonstrated that oxidative stress and inflammation might contribute to the onset of AMD (Klein et al., 2014; Van Lookeren Campagne et al., 2014). Especially, photoreceptors and retinal pigment epithelium (RPE) of the retina are highly exposed to UV and blue light, which trigger excessive production of A2E (lipofuscin fluorophore) during the aging process and subsequently results in drusen formation. Hence, supplementation of antioxidants and anti-inflammatory agents may considerably lower the onset of early AMD (Chang et al., 2017; Peng et al., 2016; Buschini et al., 2015).

Currently, no known cure or medication are available for AMD, but the risk of AMD and its progression rate can be reduced by altering lifestyle modification (regular exercise and smoking cessation), less exposure to blue or UV light, intravitreal injection of anti-VEGF (ranibizumab and bevacizumab) or laser treatment as well as increased intake of carotenoids (antioxidant or micronutrients) to maintain macular density (Jager et al., 2008). *In vitro* studies have shown that presence of lutein and zeaxanthin might lower the A2E (lipofuscin) production in RPE cell model (Bhosale et al., 2009; Sundelin and Nilsson, 2001). Ample amount of preclinical and clinical studies (meta-analysis) have concluded that consumption of carotenoids (lutein, zeaxanthin or meso-zeaxanthin) alone or combined with antioxidants (Vit C, E or  $\omega$ -3-Fatty acids) can significantly lower the incidence of AMD and revert the late onset AMD to early stage AMD (Ma et al., 2012; Chong et al., 2008).

## Cataract

Cataract (clouding of the lens) is another common age-related (degenerative) eye disease in which eye lens gradually become opaque (impaired protein fibers leads to the crystalline lens), and thus contributes to blindness than any other eye diseases (WHO, 2012; Gupta et al., 2003). The three main types of age-related cataracts are nuclear, cortical and subcapsular. Nonetheless, nuclear cataract is a common one, which profoundly affects women than men (Congdon et al., 2004). Approximately, 80 million people with cataract are known with impaired vision (reduced vision) and is a causative factor for blindness in about 18 million people. The number of cataract patients is increasing day by day, which is attributable to modified lifestyle (lack of carotenoids) and increased life expectancy (Weikel, 2014; Manayi et al., 2016). Surgery is an effective procedure to treat cataract, but it's too expensive (for an ordinary man) and thus contributes to economic burden in most of the countries (Hodge et al., 2005).

It has been identified that aging, smoking, hypertension, diabetes mellitus, malnutrition and UV/sunlight are the major risk factors for the development of cataract (Roberts et al., 2011). Nuclear cataract is a multifactorial disease, but oxidative stress is the main culprit that alters the protein fibres and subsequently triggers the onset of cataract (Bai et al., 2016; Karppi et al., 2012). Therefore, natural antioxidants like carotenoids (lutein, zeaxanthin,  $\beta$ -carotene, lycopene) are extensively used for attenuating the nuclear cataract development (Ma et al., 2014; Karppi et al., 2012; Christen et al., 2004; Olmedilla et al., 2003). Moeller et al. (2008) concluded that intake of diets rich in lutein and zeaxanthin are associated with decreased incidence of nuclear cataract. In addition, Vu et al. (2006) enrolled 3271 nuclear cataract patients in his trial and treated them with an increased concentration of lutein and zeaxanthin, which led to 36% reduction in nuclear cataract formation. A study conducted by Chang et al. (2011) reported that AREDS (age-related eye disease study) patients after consumption with AREDS formula showed a slight decrease in the risk of nuclear cataract. The correlation between lens clarity with macular pigment implies the importance of lutein and zeaxanthin to treat cataract, which has been confirmed by the clinical trial conducted by Chew et al. (2013a), using AREDS2 supplements (rich in lutein and zeaxanthin) and demonstrated that supplementation of lutein/zeaxanthin could lower the risk of cataract, but no significant changes were noted.

## Carotenoids

Carotenoids are the plant pigments (polyphenol) responsible for different colours (orange, yellow or red) in many vegetables and fruits with various beneficial properties like antioxidant (quenching of free radicals) as well as light harvesting (quenching of excessive light) and photosynthesis (Gong and Bassi, 2016; Demmig-Adams and Adams, 2002). Carotenoids are highly hydrophobic with C40 backbone structure of isoprene units (tetraterpenoid) and usually binds to the membrane with specific membrane proteins. Carotenoids are not synthesized by our body and hence should be supplied with food or supplement (Roberts et al., 2009). Six major carotenoids found in human plasma or tissue are lutein (meso-zeaxanthin)/zeaxanthin,  $\beta$ -cryptoxanthin, astaxanthin, lycopene,  $\alpha$ -carotene,  $\beta$ -carotene (Landrier et al., 2012). The structures of all major carotenoids are shown in Fig. 1. The conventional sources of carotenoids are fruits and vegetables including carrots, papaya, pumpkin, watermelon, sweet potato, yam, tomato, bell peppers, capsicum, paprika, kale, mango, kiwi, spinach, broccoli, cantaloupe, avocado, and orange (Saini et al., 2015; Fernandez-Garcia et al., 2012; Thurnham, 2007). Other sources include algae like *Dunaliella*, *Chlorella*, *Haematococcus*, *Muriellopsis*, *Chlamydomonas*, *Spirulina* spp., (Gong and Bassi, 2016; Guedes et al., 2011), fungi/yeast including *Phytophthora blakesleanus*, *Blakeslea trispora*, *Neurospora crassa* (Mata-Gomez et al., 2014; Pegklidou et al., 2008) and bacteria such as *Halophilic*, *Myco/myxobacterium*, *Paracoccus*, and *Streptomyces* spp. (Schweiggert and Carle, 2016).

Carotenoids are broadly used in food industry as a colorant, additives, feeds (aquaculture) and in the cosmetic industry for treating sunburns or skin related disorders (Schweiggert and Carle, 2016). Moreover, recent studies have indicated that carotenoids display

**Figure 1** Chemical structure of all major carotenoids.

a broad spectrum of biological activities including antioxidant, anti-inflammation, anti-cancer, anti-aging, immunomodulatory as well as vision improvement, cardioprotective, neuroprotective, hepatoprotective functions (Chuyen and Eun, 2017; Zhang et al., 2014; Fiedor and Burda, 2014). Moreover, few carotenoids ( $\beta$ -carotene and  $\beta$ -cryptoxanthin) act as precursors for vitamin A (provitamin A activity). Therefore, many pharmaceutical industries have commercialized carotenoids as health or nutritive supplements. Currently,  $\beta$ -carotene, astaxanthin, and lutein (with zeaxanthin) are the well-recognized carotenoids in the nutraceutical market (Gong and Bassi, 2016). Carotenoids exist in free or esterified form (with fatty acids), and both forms are well absorbed in the intestine and transported (free form) by lipoprotein (high-density lipoprotein-cholesterol, HDL-c or low-density lipoprotein-cholesterol, LDL-c) in blood. Hence, commercialized carotenoids (supplements) are available in free or esterified form (Nolan et al., 2016; Norkus et al., 2010). Carotenoids are classified into two types as xanthophyll's and carotenes (Yaroshevich et al., 2015).

### Xanthophylls (With $O_2$ Has Hydrocarbon- Yellow)

Xanthophylls are an oxygenated derivative of carotenes, which are relatively hydrophilic in nature owing to many hydroxyl group (OH) and keto group ( $=O$ ) as compared with carotenes. The major xanthophylls are lutein, zeaxanthin,  $\beta$ -cryptoxanthin, astaxanthin (Rao and Rao, 2007). Of which lutein, zeaxanthin,  $\beta$ -cryptoxanthin are classified as primary xanthophylls as they produced directly, whereas astaxanthin and canthaxanthin are classified as secondary xanthophylls as they are synthesized from primary xanthophylls.

### Lutein (Meso-zeaxanthin) and Zeaxanthin (Macular Xanthophylls)

Lutein and its stereoisomer zeaxanthin (different OH position) cannot be synthesized by our body and must be supplied through foods (fruits and vegetables) or commercial supplements (Calvo, 2005). Lutein alone or with zeaxanthin have been reported to show potent antioxidant, anti-cancer, anti-inflammatory activities as well as neuroprotective, and cardioprotective properties (Vijayapadma et al., 2014; Abdel-Aal et al., 2013). Nevertheless, lutein and zeaxanthin have a central role in maintaining eye health (Liu et al., 2015; Huang et al., 2008). Lutein or meso-zeaxanthin (produced from macular lutein) and zeaxanthin are the macular carotenoids found in retina (macular lutea-yellow spot) at a ratio of 1:1:1 and contribute to macular pigment (MP) composition, thereby preserving central vision through protecting retina (RPE) from blue light by efficiently scavenging excessive free radicals (Manayi et al., 2016; Ahmed et al., 2005).

However, lutein (also called eye vitamin) is mainly focused as it is prevalent in the diet (especially in spinach, carrot, kale, marigold) with higher bioavailability (with a fatty meal) and better blue light filtering property than zeaxanthin (Sindhu et al., 2010). Lutein is reported to protect the retina from blue light via inhibiting lipid peroxidation, neuronal nitric oxide synthase (inflammation) and c-fos expression (Sasaki et al., 2012). Meanwhile, for macular deposition (centre) the levels of meso-zeaxanthin are considerably higher, but lutein dominates the peripheral macula (Bone et al., 2007). Both lutein and zeaxanthin could quench most of the free radicals including superoxide, peroxyxynitrite, singlet oxygen, hydroxyl radical (Li et al., 2010) as well as upregulate various antioxidant enzyme systems via Nrf2 signaling pathway in the retina (Wu et al., 2015; Zou et al., 2014). Furthermore, zeaxanthin and meso-zeaxanthin are attached to glutathione-S- transferase isoform (GSTp1) and thus maintain the glutathione levels in the macula (Bhosale and Bernstein, 2005).

Meso-zeaxanthin is supplemented to improve macular health (increase the macular pigment density) especially in AMD patients because the machinery for conversion of lutein to Meso-zeaxanthin is impaired (Bernstein et al., 2016). Epidemiological studies have indicated that supplementation of lutein and zeaxanthin would considerably elevate plasma lutein and zeaxanthin level, which in turn significantly abolish the risk of AMD and cataract (Delcourt et al., 2006; Mares, 2004). Several experimental and conservative studies have demonstrated that intervention with lutein and zeaxanthin could considerably increase the macular pigment density (levels) in the retina and thus enhance eye function (Bone et al., 2007; Ma et al., 2012; Liu et al., 2015). Furthermore, lutein and zeaxanthin with omega-3 fatty acids were added to AREDS2 (age-related eye disease study 2) formula with the original AREDS formula including vitamin C and E with zinc, copper, and  $\beta$ -carotene (Chew et al., 2013a).

### $\beta$ -Cryptoxanthin

$\beta$ -Cryptoxanthin is a type of natural xanthophyll carotenoid pigment and hence used as a coloring agent. The primary sources for  $\beta$ -cryptoxanthin are oranges, tangerines, persimmons, papaya, red peppers, apples, and peaches. It structurally resembles  $\beta$ -carotene, lutein and zeaxanthin with high bioavailability (Burri et al., 2016; Burri, 2015). It possesses antioxidant, anti-inflammation and anti-cancer activities (Lorenzo et al., 2008; Lian et al., 2006). Moreover, it improves ocular health owing to its pro-vitamin A, antioxidant properties as well as structural similarity with lutein and zeaxanthin. Recent studies showed that  $\beta$ -cryptoxanthin could efficiently form retinol using the enzyme system involved in  $\beta$ -carotene to retinol conversion (Burri et al., 2016; Burri, 2015).

A clinical trial conducted by Turner et al. (2013) concluded that  $\beta$ -cryptoxanthin-rich tangerines were better absorbed than  $\beta$ -carotene-rich sweet potatoes. A cross-section study conducted in India revealed that low antioxidant ( $\beta$ -cryptoxanthin) concentration was associated with increased risk of cataract formation (Dherani et al., 2008). Lyle et al. (1999) showed a marginal inverse association of lutein and  $\beta$ -cryptoxanthin intake with nuclear cataract, however few other studies indicated no correlation exists between intake of  $\beta$ -cryptoxanthin and the risk of cataract or AMD (Zhou et al., 2011; Delcourt et al., 2006). Hence, more research (preclinical and clinical studies) is required to confirm the direct involvement of  $\beta$ -cryptoxanthin in ocular health.

### Astaxanthin

Astaxanthin is a yellow or orange xanthophyll (terpenes) mostly present in the aquatic environment. It is commonly present in salmon, microalgae, shrimp, and trout (Olaizola et al., 2007). It is also used as a coloring agent as well as feed additives (aquaculture) and thus extensively used in the food industry (Avalos and Limon, 2015). Astaxanthin is one of the best antioxidant carotenoids and hence preferred by the pharmaceutical industry for marketing (Dhankhar et al., 2012; Hussein et al., 2006). It also displays anti-inflammatory, anti-cancer, anti-diabetic, anti-aging activities as well as cardio, neuro and derma protective (Park et al., 2010; Fassett and Coombes, 2009; Pashkow et al., 2008). Astaxanthin is recommended for treating AMD, cataract and other ocular diseases along with lutein and zeaxanthin attributing to its antioxidant, anti-inflammatory and UV filtering activities (Lennikov et al., 2012; Parisi et al., 2008; Olaizola et al., 2007).

Pre-treatment of human lens epithelial cells with xanthophylls (Astaxanthin) led to a significant reduction in the UVB-induced lipid peroxidation and stress signaling and thus showcase that astaxanthin possess strong UV-filtering activity (Chitchumroonchokchai et al., 2004). Astaxanthin is reported to reduce ocular inflammation (uveitis) by suppressing the expression of various pro-inflammatory markers via inhibiting NF- $\kappa$ B signaling pathway in rat endotoxin-induced inflammatory model (Suzuki et al., 2006). Astaxanthin also helped in the prevention of ocular hypertension, cataract and eye strain or fatigue (asthenopia) in various models (Cort et al., 2010; Liao et al., 2009; Nagaki et al., 2006; Shiratori et al., 2005). Moreover, a double-blind clinical trial conducted by Nagaki et al. (2002), demonstrated that astaxanthin considerably improved the accommodation amplitude (adjustment of the lens) in visual display terminal workers.

### Carotenes (With O<sub>2</sub>- Orange)

Carotenes ( $\alpha$  and  $\beta$ -carotene) are terpenoids without oxygen and mainly responsible for orange/red color, with 40 carbon molecules. Both  $\alpha$  and  $\beta$ -carotene are the critical carotenes, which act as a provitamin A (retinal/retinol/retinoic acid) and thus directly involved in improving ocular health as deficiency of vitamin A could lead to night blindness (Strobel et al., 2007; Christen et al., 2000). However,  $\beta$ -carotene (trans form) has higher potential to produce vitamin A than  $\alpha$  carotene or  $\beta$ -cryptoxanthin and thus has been extensively studied (Fernandez-Garcia et al., 2012; Grune et al., 2010).  $\beta$ -carotene is the most abundant carotenoids in nature, which is used as a food colouring agent/additives; it also exhibits numerous pharmaceutical properties including antioxidant, anti-obesity, anti-cancer, anti-aging, anti-atherosclerotic and anti-sunburn properties as well as hepatoprotective, neuroprotective and improved vision and night blindness prevention (Virtamo et al., 2014; Dufosse et al., 2005).

$\beta$ -carotenes are highly absorbed in duodenal region (small intestine) and transported via VLDL, CM and LDL and subsequently stored in the liver and other peripheral tissues; finally, the stored form is converted to active vitamin A using various retinoid metabolizing enzymes (retinal/retinol/retinoic acid/retinyl esters) as required (Li et al., 2014; Fernandez-Garcia et al., 2012). Studies have

shown that vitamin A (retinol) can effectively protect the surface of the eye (cornea) from various pathogenic infections like bacteria, virus, and fungi and is thus recommended for treating dry eyes. In addition, vitamin A is also prescribed for lowering ocular inflammatory conditions like superior limbic keratoconjunctivitis/retinitis (Toshida et al., 2017; Strobel et al., 2007; Smith and Steinemann, 2000). Hence,  $\beta$ -carotenes were included in the AREDS trial sponsored by the National Eye Institute, to improve ocular health. Chronic supplementation of  $\beta$ -carotene could increase the prevalence of lung cancer in smoking population owing to excessive oxidation of  $\beta$ -carotene (Tanvetyano and Bepler, 2008). Few randomized clinical trials (RCTs) have indicated that no significant association exists with the risk of cataract (Cui et al., 2013; Christen et al., 2003); however when combined with vitamins or antioxidants,  $\beta$ -carotenes showed a significant reduction in the risk of cataract (Wang et al., 2014a; Ravindran et al., 2011).

## Lycopene

Lycopene is one of the pivotal carotenoids, which is responsible for bright red color in various fruits and vegetables including tomatoes, watermelon, apricots, and papaya (Chan and Hung, 2014). Tomatoes are the best sources of lycopene (*cis*-isoform), which are highly absorbed after cooking. Lycopene has antioxidant, anti-inflammatory, anti-cancer (prostrate), osteoprotective, and neuroprotective activities as well as vision performance improvement particularly against cataract and AMD (Yang et al., 2016; Wei and Giovannucci, 2012). Moreover, lycopene has higher bioavailability than  $\beta$ -carotene with better free radical scavenging property, which makes lycopene a potent candidate to preserve visual function by attenuating macular degeneration (Gupta et al., 2003).

Lycopene is present in human RPE-choroid and ciliary body (Chan and Hung, 2014). The effect of lycopene on ocular health (owing to its antioxidant, anti-inflammatory and anti-angiogenic activities) is ambiguous because few reports have showed positive results (Yang et al., 2016; Abdulazeez et al., 2012; Cardinault et al., 2005) against various eye diseases, whereas others showed negative results (Cui et al., 2013; Brown et al., 1999). An *in vitro* study conducted by Yang et al. (2016) concluded that lycopene treatment could considerably abolish oxidative stress and inflammation and thereby protect retinal pigment epithelium in ARPE-19 cell model and might be recommended for treating AMD in combination with other standard drugs. A study conducted among the Indian population indicated an inverse correlation between the blood antioxidant (lutein, lycopene,  $\beta$ -cryptoxanthin) concentration and the risk of cataract formation (Dherani et al., 2008).

## Omega-3-Fatty Acids

Omega( $\omega$ )-3-fatty acids belong to polyunsaturated fatty acids (PUFA) and are also classified as essential fatty acids. Since these  $\omega$ -3 fatty acids cannot be synthesized by our body, humans rely on dietary sources (Chong et al., 2008). The major omega-3-fatty acids are  $\alpha$ -linolenic acid (ALA), docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) (Fig. 2). ALA is a precursor of DHA and EPA, but its synthesis in our body is very limited (SanGiovanni and Chew, 2005). Omega fatty acids are reported to show several beneficial effects including antioxidant, anti-inflammatory, immunomodulatory, hypolipidemic, anti-cancer as well as cardioprotective, neuroprotective and hepatoprotective activities (Swanson et al., 2012; Hooper et al., 2006). Studies have shown that intake of diets rich in  $\omega$ -3 fatty acids and fish is inversely proportional to the risk for AMD development (Querques and Souied, 2014; Seddon et al., 2003). Especially, DHA (structural lipid) deficiency is reported to initiate the onset of AMD as it is present in outer segments of retina, especially photoreceptor membranes (Chong et al., 2008). Moreover, DHA plays a vital role in altering the G-protein coupled signaling pathway and thus contributes to rhodopsin regeneration and thereby healthy vision maintenance (Litman et al., 2001).

Few studies have confirmed that EPA might play a vital role in retinal function by acting as a precursor for many signaling molecules (Chow et al., 2013b; Augood et al., 2008). Furthermore,  $\omega$ -3 fatty acids play a key role in maintaining optical function by protecting macular region from oxidative stress (lipid peroxidation), inflammation, as well as regulate retinal blood vessel growth

**Figure 2** Chemical Structure of Omega Fatty Acids.

(new choroidal vessel formation) and thus suppress the risk of both early and advanced AMD (Christen et al., 2011; SanGiovanni et al., 2008). A meta-analysis conducted by Chong et al. (2008) with 3202 AMD subjects that consumed diets rich in  $\omega$ -3 fatty acids (at least twice a week) showed a reduced risk of late/advanced AMD. Likewise, a cross-section study also showed that eating oily fish (at least once a week) could protect against neovascular AMD (Augood et al., 2008). In addition, omega-3-fatty acids can lower the risk of cataract and computer vision dry eye syndrome via regulating tear production and evaporation rate (Bhargava et al., 2015; He and Bazan, 2010; Lu et al., 2005).

### Holistic Activity of Lutein/Zeaxanthin and $\omega$ -3 Fatty Acid

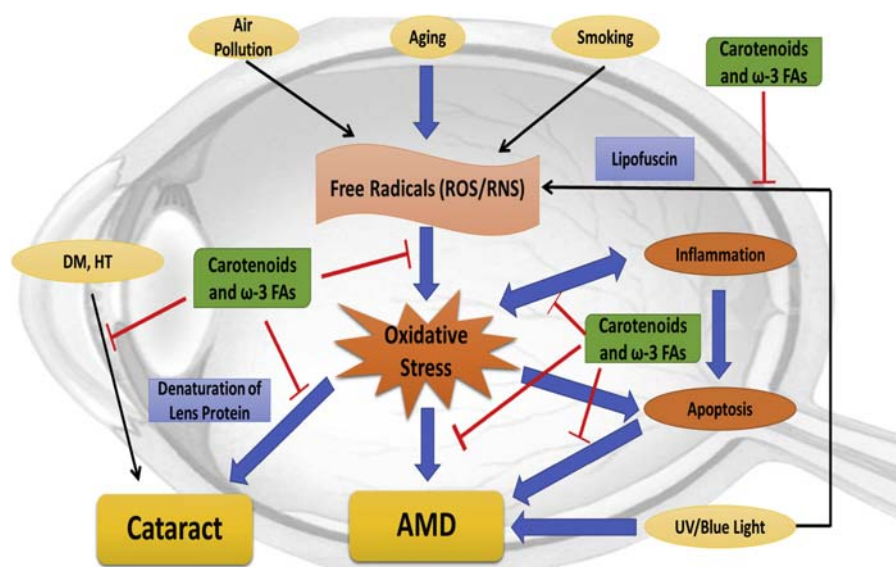

Epidemiological studies have shown that increased intake of carotenoids like lutein/zeaxanthin and  $\omega$ -3 fatty acids (FA) was found to be associated with decreased risk of cataract and AMD (Wang et al., 2014b; Huang et al., 2008; Delcourt et al., 2006; Moeller et al., 2000). Many clinical trials have proved that consumption of a diet rich in carotenoids (lutein/zeaxanthin) and  $\omega$ -3 fatty acid (DHA/EPA) can considerably reduce the risk of neovascular AMD and nuclear cataract (Ho et al., 2011; Olmedilla et al., 2003). Another study conducted by Johnson et al. (2008) demonstrated that DHA might facilitate the macular deposition of lutein (especially central part of fovea), which synergistically combats AMD or cataract. The AREDS research group (2001a) concluded that daily oral supplementation with AREDS formula (Vit C, E,  $\beta$ -carotene, copper, and Zinc) could considerably lower the risk of developing advanced AMD by 25%. Likewise, AREDS research group (2001b), demonstrated that daily oral supplementation with AREDS formula did not show any statistical significance on age-related lens opacities (cataract) or visual acuity. Based on experimental and observatory studies, it has been hypothesized that addition of macular carotenoids (lutein, zeaxanthin) and  $\omega$ -3-fatty acids with AREDS formula might further reduce the risk of developing advanced AMD.

Chew et al. (2013b) conducted an AREDS2 study between 2006–12 with 4203 participants (aged 50–85) at risk of progression to advanced AMD and found that supplementation with AREDS2 formula (Vit C, E, lutein, zeaxanthin,  $\omega$ -3-fatty acids and Zinc) did not show any further decrease in the risk of progression to advanced AMD or visual acuity in comparison with AREDS. Nevertheless, lutein and zeaxanthin replacement with  $\beta$ -carotene in AREDS2 formulation could potentially decrease the incidence of lung cancer in former smokers, which has been noted in the AREDS study. Similarly, AREDS2 formula was used to evaluate the beneficial effect of age-related cataract, but no marked changes were observed on age-related cataract (Chew et al., 2013a).

Overall, AREDS2 formula is highly preferred for abolishing the risk of developing advanced AMD, but not for cataract. Dawczynski et al. (2013) concluded that long-term supplementation with lutein, zeaxanthin,  $\omega$ -3 PUFA (LUTEGA) would significantly increase the MP, which in turn improves and stabilize the vision (BCVA) in AMD patients. Rotterdam study conducted by Ho et al. (2011), demonstrated that high dietary intake of carotenoids (antioxidants) and  $\omega$ -3-fatty acids suppressed the prevalence of early AMD. The schematic representation of current review is illustrated in Fig. 3.

### Conclusion

This contribution summarized that supplementation of micronutrients or antioxidants with modified lifestyle (regular exercise, quit smoking) could considerably improve ocular health. Carotenoids (lutein, zeaxanthin) can act as a protective shield (improving

**Figure 3** The schematic representation of current review: DM, Diabetes Mellitus; HT, Hypertension; ROS, Reactive oxygen species; RNS, Reactive nitrogen species; AMD, age-related macular degeneration;  $\omega$ -3 FAs, omega-3 fatty acids.

macular pigment density as well as scavenging excessive free radicals) and thus prevent the formation of AMD (neovascular AMD) and cataract (nuclear cataract). Whereas  $\omega$ -3 fatty acids did not effectively protect retina/macula (insufficient evidence), and therefore, it might be preferred with other antioxidants (carotenoids) or micronutrients for better protective action against AMD or cataract. This is because DHA might enhance the macular deposition of lutein in the macula (synergic effect). However, large-scale studies are needed in future to evaluate the effective dose of these carotenoids, alone or in combination with  $\omega$ -3 fatty acids against AMD or cataract as well as the exact mechanisms of action need to be explored.

# Cholesterol-Reducing Foods: Proteins and Peptides

Anna Arnoldi, Lammi Carmen, and Gilda Aiello, University of Milan, Milan, Italy

© 2019 Elsevier Inc. All rights reserved.

## Glossary

**Bioabsorption** The process whereby substances are absorbed by the tissues and organs of organisms.

**Bioactive peptides** Bioactive peptides are a key category of molecules useful for functional food application. Most known bioactive peptides are fragments that are encrypted in the primary sequences of proteins and provide physiological functions beyond basic nutritional benefits.

**Mass spectrometry** An analytical technique that ionizes chemical species and sorts the ions based on their mass-to-charge ratio.

**Modulation of metabolic pathway** Modulation of the activity of one and/or more targets involved in the same intracellular metabolic pathway.

**Peptidomics** The branch of molecular biology that studies the set of peptides of an organism or a biological sample.

## Nomenclature

**HMGCoAR** 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase

**AMPK** Adenosine monophosphate-activated protein kinase

**AP** Apical

**BL** Basolateral

**CE** Capillary electrophoresis

**CID** Collision induced dissociation

**ECD** Electron capture dissociation

**ETD** Electron transfer dissociation

**ESI** Electrospray ionization

**ER** Endoplasmic reticulum

**(GSK)-3 $\beta$**  Glycogen synthase kinase 3 $\beta$

**HPLC** High Pressure Liquid Chromatography

**IEX** Ion-exchange

**LDLR** LDL receptor

**LDL** Low-density lipoprotein

**MALDI** Matrix-assisted laser desorption/ionization

**MRM** Multiple reaction monitoring

**PI3K** Phosphatidylinositol-3-kinase

**PCSK9** Proprotein convertase (PC) subtilisin/kexintype 9

**Akt** Protein kinase B

**RO** Reverse osmosis

**RPC** Reverse-phase

**SEC** Size exclusion

**SCAP** SREBP cleavage-activating protein

**SREBPs** Sterol-responsive element binding protein

**UF** Ultrafiltration

## Introduction

The edible seeds of numerous plants are major staple foods in most countries. Their importance is currently increasing owing to the growing awareness of their lower environmental impact when compared to animal foods. Moreover, the interest of consumers is attracted by the numerous health benefits they provide, particularly in the area of hypercholesterolemia and hypertension prevention. The first published papers refer to soybean, but other seeds are also promising in these areas, although available literature is still scarce. The seed components responsible for the observed activities are probably numerous: in particular, different papers have underlined the importance of protein, soluble and insoluble fiber, polyunsaturated lipids, phytosterols, tocopherols, and other

phytochemicals, such as polyphenols. The final observed effects derive probably from a combination of the specific activities of all these components probably also with a synergistic behavior.

The importance of plant proteins has been underlined by numerous clinical studies performed on soybean protein. A recent meta-analysis (Harland and Haffner, 2008) has shown that the consumption of 25 g per day of soybean protein leads to a reduction of mean total cholesterol by 0.22 mmol/L (95% CI -0.142 to -0.291,  $p < 0.0001$ ), mean LDL-cholesterol by 0.23 mmol/L (95% confidence interval, CI -0.160 to -0.306,  $p < 0.0001$ ), and mean blood triglycerides by 0.08 mmol/L (95% CI -0.004 to -0.158,  $p = 0.04$ ), concluding that a modest amount of soybean protein in the diet of mild hypercholesterolemic patients results in a small but significant 6% reduction of LDL-cholesterol.

Other plants have been investigated, particularly grain legumes. Hypocholesterolemic effects have been observed when suitable animal models have been treated with white lupin, narrow-leaf lupin, pea, and broad bean proteins versus casein. On the contrary, some clinical studies have been performed on the protein of narrow-leaf lupin, that produced only a moderate decrease of total and/or LDL cholesterol in mild hypercholesterolemic subjects who had consumed about 30 g per day of lupin protein included in different model foods for 4–12 weeks.

Since proteins undergo an extensive hydrolysis during gastrointestinal digestion, the actual bioactive species should be specific peptides encrypted in their sequences that are released by digestive enzymes. These peptides are sometimes referred to as cryptides. The experimental approach to sort out these peptides involves a series of steps: 1) release of the bioactive sequences; 2) initial screening for targeted bioactivities, mainly in suitable cell models; 3) purification and separation; 4) further determination of the biological activity of purified peptides; 5) peptide identification by mass spectrometry (MS); 6) final *in vitro* and *in vivo* validation of the biological activity (often performed on synthetic peptides).

As far as cholesterol metabolism is the topic of interest, HepG2 cells are the preferred reference model, which has permitted experimental demonstration that protein hydrolysates from soybean, lupin bean, hempseed, and amaranth are able to modulate cholesterol metabolism. These initial results have stimulated numerous investigations aimed at assessing: a) the actual bioactive species; and b) the mechanism of action.

## Technological Strategies in Peptidomics

### Production and Purification of Peptides From Plant Foods

The most common methods to produce bioactive peptides from plant proteins are by enzymatic hydrolysis or fermentation (Lee and Hur, 2017). Generally, the use of enzymatic hydrolysis is preferred over microbial fermentation due to the short reaction time, easy scalability, and predictability. More than a single proteolytic enzyme (purified or crude) can be used for protein hydrolysis to produce hydrolysates containing short peptide sequences. However, the optimized mode of enzyme addition (whether simultaneously or sequentially) depends on the optimal pH and temperature conditions for each enzyme. The selection of the best enzymes and hydrolytic conditions is a critical aspect for producing bioactive hydrolysates, since peptide sequences and their biological activities may differ depending on the type of enzyme used. Many known bioactive peptides deriving from plant proteins have been produced using a single enzyme, such as pepsin or trypsin or a combination of them in order to simulate the gastrointestinal digestion, as recently reported for the investigation of hemp seed protein hydrolysates (Girgih et al., 2014a).

However, the large number of peptides contained in the hydrolysates, produced either by enzymatic hydrolysis or by fermentation, suggests the need to perform some preliminary separation before identification by MS. In addition, peptides vary in size, hydrophobicity and net charge. In most cases, multi-step procedures are needed, since their natural diversity can make it very difficult to perform a comprehensive isolation of peptides from a complex mixture using a single purification method. Peptide enrichment is primarily conducted using membrane filtration and chromatographic methods. Ultrafiltration (UF), nanofiltration, and reverse osmosis (RO) are frequently used membrane-based technologies employed for bioactive peptide separation. However, membrane filtration can result in incomplete protein removal (Lemes et al., 2016) due to the possible aggregation of some peptides and peptide loss in the precipitate. HPLC has become therefore, the preferred technique for the separation of peptides, because of its versatility, efficiency, and automation capabilities. Reverse-phase (RPC), ion-exchange (IEX), size exclusion (SEC), and affinity chromatography are currently used in peptide fractionation. Specific innovative methods are applied in the area of “phosphopeptidomics” (Leitner et al., 2010) using metal oxide affinity chromatography.

### The Role of Mass Spectrometry in Peptidomics

MS-based peptidomic approaches set a new standard in the discovery and quantification of nutritionally relevant bioactive peptides, becoming the undisputed tool in bioactive peptide analysis, which reduces the use of other identification techniques, such as amino acid analyzers or Edman sequencing. High sensitivity and accurate mass information, likely structure elucidation, and short time analysis are the main benefits of the use of MS in peptide identification.

The electrospray ionization (ESI) source and matrix-assisted laser desorption/ionization (MALDI) are the most important ionization sources used in peptidomics. Despite MALDI ionization is an alternative source used in peptidomic and proteomic investigations, the majority of peptidomic studies are conducted using LC-ESI-MS/MS approach. In fact, about a half of the known bioactive peptides are shorter than 10 amino acids and therefore fall into the low mass range where MALDI matrix interference

is overwhelming (Panchaud et al., 2012). This severely limits the applicability of MALDI MS in peptidomic studies. In addition to LC, capillary electrophoresis (CE) has also been extensively used for peptide separation.

MS experiments can be addressed directly to measure the molecular mass of derived peptides (single-stage MS) or used to generate AA-sequence information from tandem mass spectra (MS/MS or MSn), obtained in the hybrid arrays by collision induced dissociation (CID). Very recent technological improvements further enlarge the capabilities of tandem mass spectrometry strategies. Electron transfer dissociation (ETD) and electron capture dissociation (ECD) have emerged as new tools to sequence peptides in very complex samples. For example, hybrids LC-ESI-Q-IT has been used to identify the major hypocholesterolemic peptides generated by the *in vitro* hydrolysis of *Amaranthus cruentus* protein (Soares et al., 2015). In particular, GGV, IVG, and VGVV have been identified by coupling ultrafiltration steps to MS analysis.

In peptidomics, there are two complementary kinds of strategies for the discovery and/or quantification of potentially bioactive peptides: the hypothesis-free approach and the hypothesis-driven targeted one. The former strategy, referred to as shotgun or data-dependent analysis (DDA), is widely used for obtaining a comprehensive peptide profile of biological systems in a complex peptide mixture. For example, this strategy, including database searching, was adopted to characterize some hemp seed protein hydrolysates produced by using single enzymes or a combination of proteases in order to mimic the gastrointestinal digestion. Specifically, the number of peptides identified ranged from 90 belonging to 33 species-specific parent proteins in the peptic hydrolysate to 9 belonging to 6 proteins in the pancreatin digest. The peptic and tryptic hydrolysates provided the best hypocholesterolemic candidates (Zanoni et al., 2017a).

The latter strategy, referred to as targeted multiple reaction monitoring (MRM), is used to probe a predefined subset of peptides. LC-MRM was used to obtain quantitative information of the degree of transport of some hypocholesterolemic soy peptides, i.e. IAVPGEVA, IAVPTGVA, LPYP, across Caco-2 cell model as well as to elucidate the metabolic degradation due to the action of brush border peptidases, to which they may be subjected when exposed to the microvilli surface. LC-MRM is used for the identification of small peptides, even in the presence of complex mixtures consisting of di-, tri- and tetra-peptides, containing amino acids such as Val, Leu, and Ile (where Leu and Ile are isobaric amino acids), which have similar chromatographic behaviors.

The application of integrated multiple-omics information, such as structural information provided by MS and bioinformatics driven-modeling, to a peptic hydrolysate from lupin protein allowed the identification of LILPKHSDAD and LTFPGSAED, two specific peptide sequences very powerful in the modulation of cholesterol metabolism (Zanoni et al., 2017b).

In conclusion, mass spectrometric measurement with high-energy collision-induced dissociation (CID) tandem MS data (yielding immonium ion and other MRM-relevant data) can provide sufficient information for peptide sequences, when combined with retention times and relevant protein sequence databases and bioinformatics-driven approaches.

## Absorption of Bioactive Peptides

Food-derived bioactive peptides have to cross the gastrointestinal barrier and enter the circulation in order to reach their target sites for exerting their biological activities. Therefore, the transport through intestinal cells is a major factor influencing their bioavailability and is a very critical issue that needs to be addressed. The hypothesis that small peptides may escape complete digestion and be transported from intestinal lumen into blood circulation is gaining acceptance, mainly due to numerous studies describing the *in vitro* trans-epithelial transport of bioactive peptides. In fact, the primary *in vivo* function of the small intestine is to absorb nutrients from the lumen and to transport them to blood circulation. This absorption is mainly performed by enterocytes, which are continuously exposed to food components able to modulate some of their physiological functions, although the mechanism of passage across the intestinal mucosa is still largely unknown.

In light of these observations, the Caco-2 cell model is very often employed in order to study the ability of small peptides (2–20 amino-acidic residues) to permeate the gastro-intestinal barrier. Despite its tumoral origin, this human intestinal cell line (originally isolated by J. Fogh from a human colon adenocarcinoma) has been extensively used over the past 30 years and represents the best available cellular model to investigate intestinal barrier functions, absorption mechanisms, and metabolic activities (Rubas et al., 1996).

When seeded in culture inserts fitted with polycarbonate filters, Caco-2 cells undergo a process of spontaneous differentiation leading, after 21 days, to the formation of a monolayer of polarized cell, coupled by tight junctions and expressing several morphological and functional features of small intestinal enterocytes. Differentiated Caco-2 cells on filters create a two-compartment system, where the apical (AP) side of the cell monolayer (*in vivo* corresponding to the intestinal lumen) is separated from the basolateral (BL) side (*in vivo* facing the intestinal vascular and lymphatic circulation).

Recently, this model has been used for evaluating the bioavailability of antioxidant and hypocholesterolemic peptides from soybean  $\beta$ -conglycinin and lupin protein (Amigo-Benavent et al., 2014). Both studies provided innovative information on the absorption of these peptides, through the analysis of the efflux in the BL compartments from the AP side by using suitable analytical techniques based on mass spectrometry approach.

Briefly, the former study (Amigo-Benavent et al., 2014) evaluated the bioavailability of antioxidant peptides released by gastrointestinal digestion from soybean 7S globulins. In total, 25 different peptides were identified in AP sample, out of which 22 were found also in the BL chamber, indicating that they are absorbed by the Caco-2 cells. Among the 22 identified peptides,

YVNPNDNEN and YVNPNNEN were demonstrated to have the capacity to modulate cholesterol metabolism in hepatic cells (Amigo-Benavent et al., 2014).

A similar study performed on tryptic and peptic hydrolysates from lupin protein has shown that 11 tryptic peptides and 8 peptic ones are bioavailable in the same Caco-2 cell model (Lammi et al., 2016a). Considering the overall features of absorbed peptides, they are very heterogeneous being constituted by 9–23 amino acid residues and mostly belong to  $\beta$ -conglutin, the acidic 7S globulins of lupin. The mechanisms of absorption across intestinal epithelium may vary from passive diffusion of hydrophobic molecules across membranes to active transport, either by membrane transporters or vesicular-mediated transcytosis, and finally to permeation across tight junction complexes. Moreover, the transport of these peptides to the BL compartment takes place with a certain degree of selectivity. Interestingly, the same paper showed that the absorbed peptides maintained the hypocholesterolemic activity previously observed in the parent tryptic and peptic lupin hydrolysates.

## Bioactivity

### Cholesterol Metabolism Pathway

From a physiological point of view, the main cholesterol-lowering organ in our body is the liver. In fact, the majority of plasma cholesterol is transported by the low-density lipoprotein (LDL) fraction, and the cellular uptake of LDL is mediated by the LDL receptor (LDLR) mainly expressed at hepatic levels. The circulating level of LDL cholesterol is determined in large part by its rate of uptake through the LDLR pathway. In general, the LDLR expression is finely tuned by changes in intracellular cholesterol. In fact, since the transcription of the LDLR and the genes required for cholesterol and fatty acid synthesis are controlled by membrane-bound transcription factors called sterol-responsive element binding protein (SREBPs), the intracellular cholesterol acts with a negative feedback inhibition mechanism. In particular, the SREBP-2 isoform is responsible for the LDLR and 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase (HMGCoAR) transcription, and the SREBP-2 maturation is regulated by the intracellular cholesterol homeostasis. Moreover after synthesis, SREBP-2 forms a complex with the SREBP cleavage-activating protein (SCAP) and is localized in the endoplasmic reticulum (ER), as an inactive precursor (pro-SREBP-2). Sterol deficiency results in the release of SREBP-2/SCAP complex from ER and transport to the Golgi, where pro-SREBP-2 is processed further, allowing the N-terminal fragment (mature SREBP-2) to enter the nucleus and up-regulate transcription of LDLR and HMGCoAR (Goldstein et al., 2006; Sato, 2010).

HMGCoAR is the enzyme, which plays a key role in intracellular cholesterol biosynthesis, because it is the rate-controlling enzyme in the mevalonate pathway, and therefore it constitutes the target of numerous investigations aimed at lowering the rate of cholesterol biosynthesis. Emerging evidences suggest that the phosphatidylinositol-3-kinase (PI3K)/Akt/Glycogen synthase kinase (GSK)-3 $\beta$  pathway is implicated in the regulation of lipid metabolism through the activation of SREBP-2 with a positive effect on the LDLR levels at cellular membranes. Moreover, the adenosine monophosphate-activated protein kinase (AMPK) pathway is also involved in the regulation of the cholesterol metabolism through its effect on the phosphorylation of HMGCoAR, which is its main target. In particular, when AMPK is activated through an increase of its phosphorylation on the threonine 172 residue, it is able to inhibit the HMGCoAR activity through increased phosphorylation of serine 872 residue.

Recently, proprotein convertase (PC) subtilisin/kexintype 9 (PCSK9) has been identified as a key player in the regulation of the cholesterol metabolism through a direct effect on the LDLR activity (Horton et al., 2007). Briefly, in the absence of PCSK9, hepatic LDLR is shuttled back to the plasma membrane after cholesterol delivery to the lysosome for degradation. PCSK9 binding, instead, prevents this LDLR shuttling and targets it for degradation. PCSK9 primarily acts on the LDLR as circulating plasma protein and several studies have underlined the positive relationship between circulating PCSK9 and plasma LDL cholesterol levels. On the contrary, PCSK9 inhibition significantly reduce the LDL cholesterol levels reducing the risk of cardiovascular event. For this reason, PCSK9 is considered an attractive target for the management of hypercholesterolemia.

### Lupin Peptides

A study on human hepatic HepG2 cells has provided a detailed elucidation of the molecular mechanism by which lupin peptides exert the hypocholesterolemic activity observed in animal models and in clinical trials. Both the tryptic and peptic hydrolysates from lupin protein are able to interfere with the HMGCoAR activity, up-regulating the LDLR due to the activation of SREBP-2, through the modulation of the Akt/GSK3 $\beta$  pathway (Lammi et al., 2014). In addition, from a functional point of view, both peptic and tryptic peptides increase the LDLR protein levels inducing an increased LDL-uptake by HepG2 cells. The research was subsequently concentrated on P5 (LILPKHSDAD) and P7 (LTFPGSAED), two peptides containing 10 and 9 amino acid residues, respectively, deriving from the hydrolysis of lupin protein with pepsin. Both peptides belong to  $\beta$ -conglycinin and are potentially absorbable at intestinal level since they can be transported through the Caco-2 cell system. Interestingly, an *in silico* approach had suggested that both P5 and P7 might be able to bind the HMGCoAR catalytic site inhibiting the enzyme activity. Indeed, biochemical and cellular studies have confirmed that these peptides are able to modulate in a positive manner cholesterol metabolism leading to an increase of the LDLR protein levels (Zanoni et al., 2017b).

A recent clinical study has shown that the consumption of 30 g/day lupin protein for 3 months led to a 12.7% reduction in plasma PCSK9 level (Lammi et al., 2016b). The molecular mechanism through which lupin peptides modulate PCSK9 was

**Figure 1** Hypocholesterolemic mechanism of action mediated by lupin peptides in human hepatic HepG2 cells. Upon cell penetration, peptic and tryptic lupin peptides act as competitive inhibitors of HMGCoAR, leading to a reduction of intracellular cholesterol synthesis. When intracellular cholesterol level decreases, the transcription factor SREBP2 is activated and LDLR and HMGCoAR genes are transcribed with subsequent increase of LDLR and HMGCoAR protein levels and localization of LDLR in plasma membrane (A). In parallel, in a synergic way, lupin peptides reduce the PCSK9 protein level production and secretion. In particular, through the reduction of HNF1- $\alpha$  protein level, they lead to a decrease of intracellular precursor and mature PCSK9 protein levels. In agreement, the PCSK9 down-regulation is translated in a reduction of HepG2 cell ability to secrete mature PCSK9 in the extracellular medium, with the consequent stabilization of active LDLR on hepatic cellular membrane (B). For this reason, the distinct modulation of the two pathways leads to hypocholesterolemic effects through an improved and synergic activity of LDLR, which can bind and carry the extracellular LDL in HepG2 cells. Reprinted with the permission from Lupin protein exerts cholesterol-lowering effects targeting PCSK9: From clinical evidences to elucidation of the *in vitro* molecular mechanism using HepG2 cells. Lammi, C., Zannoni, C., Calabresi, L., Arnoldi, A., 2016. Journal of Functional Foods 23, 230–240. Copyright 2017, Elsevier.

investigated using HepG2 cells, demonstrating that both peptic and tryptic lupin hydrolysates decrease the mature PCSK9 protein levels and secretion at the extracellular environment (Fig. 1). An investigation on absorbable peptides indicate that P5 is mainly responsible of this mechanism of action. In addition, P5 is also able to inhibit the protein–protein interaction (PPI) between PCSK9 and LDLR with an  $IC_{50}$  equal to 1.6  $\mu$ M. Using bioinformatic tools, it was possible to build an *in silico* docking model of the P5 interaction with the PCSK9 LDLR binding site, which permitted elucidation of how this peptide impair the PPI between these two crucially important proteins (Lammi et al., 2016c).

### Hemp Seed Peptides

Hemp seed contains about 25%–30% proteins and is currently gaining a big interest in human nutrition (Girgih et al., 2014b). A recent paper has shown that a peptic hydrolysate of total hemp seed protein is able to mediate a hypocholesterolemic effects on human hepatic HepG2 cells by inhibiting the HMGCoAR activity and regulation with a statin-like mechanism. Moreover, the same hydrolysate activated the AMPK pathway which led to intracellular inhibition of HMGCoAR activity and induced LDLR protein level augmentation with consequence of an increased ability of HepG2 cells to absorb the LDL from the extracellular environment (Zannoni et al., 2017a). Similarly to statin, the hemp seed protein hydrolysate increased the mature PCSK9 protein levels versus the untreated samples. This is the main divergence of action between hemp seed and lupin peptides.

### Soybean Peptides

Different authors have pointed out that both glycinin and  $\beta$ -conglycinin contain some hypocholesterolemic peptides encrypted in their sequences. Two peptides, LPYP and IAVPGEVA, were isolated and characterized after digesting glycinin with trypsin and

pepsin, respectively. Both peptides were able to inhibit HMGCoAR activity. Moreover, the alignment of IAVPGEVA with the glycinin sequence permitted the identification of another inhibitory peptide, IAVPTGVA. *In vitro* experiments using the catalytic domain of HMGCoAR showed that these peptides acted as competitive inhibitors. Further experiments in HepG2 cells showed that the inhibition led to an increased LDLR protein levels by the activation of the SREBP2 pathway and to an enhanced LDL-uptake in the same cells. Moreover, these peptides were able to increase the phosphorylation level of HMGCoAR on Ser 872 (the inactive form of HMGCoAR) via the activation of the AMPK-pathway (Lammi et al., 2015). Another study has instead reported evidence on the hypocholesterolemic activity of YVNPNDNEN and YVNPNNEN, two peptides that are derived from  $\beta$ -conglycinin. Research in HepG2 cells aimed at investigating their effects on cholesterol metabolism showed that they are able to up-regulate the LDLR protein levels and behave as competitive inhibitors of HMGCoAR activity with a statin-like mechanism. Interestingly, the former is a fragment of LRVPA GTTFYVNPNDNENLRMIA, previously shown to increase the LDL-uptake and degradation in hepatocytes.

### Amaranth Peptides

A recent investigation (Soares et al., 2015) provided evidence underling the ability of peptides derived from amaranth protein hydrolysis to exert hypocholesterolemic effect. In particular, *in vitro* experiments using the catalytic domain of HMGCoAR demonstrated that the peptides GGV, IVG, and VGV are able to inhibit the reductase activity. These findings suggest that these peptides act as HMGCoAR competitive inhibitors, similarly to the soybean (IAVPGEVA, IAVPTGVA, LPYP, YVNPNDNEN and YVNPNNEN) and lupin (P5 and P7) peptides. However, more detailed studies should be performed in order to better characterize the hypocholesterolemic mechanism of action at cellular level and to find out the potential bioavailability of these peptides.

### Conclusion

The search of hypocholesterolemic peptides from food proteins is certainly an intriguing topic, although it has not reached any practical application yet. To achieve this, the open issues to be solved are: a) the selection of the best enzymes, b) the analysis of very short peptides; c) the stability verification and implementation by tools such as microencapsulation; c) the assessment of the bioavailability; d) the validation of the mechanism of action; and e) the confirmation of the activity by clinical trials. Several research groups are actively working on different protein sources to address all these issues all over the world.

### Glossary

**Oligospermia** a condition of low sperm concentrations defined as less than  $15 \times 10^6$  sperm per mL.

**Asthenozoospermia** a condition defined as low sperm motility with less than 32% progressive motility in a semen sample.

**Teratozoospermia** a condition of abnormal sperm morphology defined as less than 4% spermatozoa with normal morphology.

**Normozoospermic** a condition defined having equal to or above lower reference limit set by World Health Organization in total number of spermatozoa, and percentage of progressively motile and morphologically normal spermatozoa

**Oligoasthenozoospermia** a condition defined having low sperm concentrations, combined with low sperm motility moving progressively in a semen sample

PUFA Polyunsaturated fatty acids

WHO World Health Organization

## Introduction

The testis is a central organ responsible for male fertility. Abnormal testis function results in decreased human semen quality, low sperm count, or both, which are associated with more than 90% of male infertility cases. Among the several potential risks of male infertility, such as genetic, chemical, and physical environmental toxins, the quality of food we consume is getting recognized as a major contributing factor. The human testis and sperm are structurally and biochemically enriched with omega-3 (n-3) polyunsaturated fatty acids (PUFA), thus maintenance of optimal concentration of n-3 PUFA may be critical for normal physiological functions of testis and sperm.

## Overview of Testis and Sperm

### Testis

The testis has two major functions: steroidogenesis and spermatogenesis. In adult men, the testis weighs about 20 g with a testicular volume of 15–20 cm<sup>3</sup>. The testicular volume is known to be associated with testicular function. The testicular volume is decided by the thread-like seminiferous tubules occupying about 80% of testis. Cells responsible for steroidogenesis (Leydig cells) and spermatogenesis (germ and Sertoli cells) are located in the interstitial connective tissue, and seminiferous tubules, respectively. Spermatogenesis requires 65–75 days in humans to proceed from the germ cell to spermatozoa. Since the rate of cellular proliferation and differentiation are high during these periods, any external and internal insults could result in negative impacts on testis function. This is why testis is considered to be one of the most vulnerable tissues in our body.

## Sperm

Sperm quality is commonly accessed in the semen analysis, which is a key analysis for the evaluation of testicular function. According to the World Health Organization (WHO), four common terms are used to describe sperm quality in semen analysis (**Table 1**): i) oligozoospermia, a total number of sperm to be less than the lower reference limits of 15 million sperm/mL ejaculate; ii) azoospermia, defined as the absence of spermatozoa in the ejaculate; iii) asthenozoospermia, a semen sample testing motility, where less than 32% of sperm exhibit forward progression; iv) teratozoospermia, a semen condition of abnormal sperm morphology to have less than 4% morphologically normal sperm ([Cooper et al., 2010](#)). In morphology, many different abnormalities can occur, including abnormalities in the head neck or mid-piece, or tail. All of the above sperm characteristics including concentration, motility, and morphology, are reproductive challenges that need to be overcome for fertilization to occur. Sperm is the only cell designed to leave the male body and join with the female ovum for fertility, thus any challenges leading to poor semen quality and abnormal morphology could impact fertility success.

## Lipid Composition in Testis and Sperm

### Testis

The importance of lipids in testis structure and function has been recognized in the early 1930s in a rodent model ([Burr and Burr, 1930](#)). However, the lipids data from the human testis are still scarce. It has been reported that the total lipid in adult male testis are in the range of 25.6–39.0 (mg g<sup>-1</sup> wet tissue) and total phospholipids are 15.6–15.9 (mg g<sup>-1</sup> wet tissues) representing approximately 40%–60% of the total lipids ([Coniglio et al., 1975](#)), which indicates the testis to be a phospholipid enriched tissue. In terms of the fatty acid compositions, the total lipids of adult human testis is composed of 38%–45% saturated fatty acids, 19%–24%, monounsaturated fatty acids, 22%–32% of n-6 fatty acids, and 7%–10% n-3 fatty acids ([Coniglio et al., 1974, 1975](#); [Hoffmann et al., 2005](#); [Bieri and Prival, 1965](#)). Among PUFAs, arachidonic acid (AA, 20:4n-6, 11%–13%, w/w total lipids) and DHA (8%, w/w total lipids) are the predominate fatty acids of n-6 and n-3 PUFA, respectively (**Figure 1**; **Table 2**) ([Coniglio et al., 1974, 1975](#); [Hoffmann et al., 2005](#); [Bieri and Prival, 1965](#)). Interestingly, only DHA, not AA, has been found to decrease in testis during degeneration ([Coniglio et al., 1974](#)), indicating DHA is a significant factor for the development of germinal cells in the human testis.

**Table 1** WHO semen analysis reference with lower limits

Sperm characteristics	Reference value (lower ref limits)	Infertility conditions	
Semen volume (mL)	1.5–5.0 (1.4–1.7)		
Sperm conc (mL)	>15 × 10 <sup>6</sup> (12–16)	<12 × 10 <sup>6</sup>	oligozoospermia
Sperm conc (ejaculate)	>39 × 10 <sup>6</sup> (33–46)	absence	azoospermia
Total motile sperm (%)	>40 (38–42)		
Progressive sperm (%)	>32 (31–34)	<31	asthenozoospermia
Vitality (live spermatozoa, %)	58(55–63)		
Normal morphology (%)	>4 (3.0–4.0)	<3	teratospermia

Numbers in the bracket represents fifth centile and their 95% confidence intervals. Conc., concentration. [Cooper et al. \(2010\)](#)

**Table 2** The overall fatty acid composition in testis and spermatozoa from normal and infertile males

Fatty acid	Testis <sup>a</sup>	Spermatozoa <sup>b</sup>	
		Normozoospermic	Infertile men <sup>c</sup>
Palmitic acid (16:0)	28.4 ± 2.6	30.2 ± 1.1	33.4 ± 5.1
Stearic acid (18:0)	11.2 ± 0.6	9.9 ± 5.0	15.3 ± 1.2
Oleic acid (18:1n-9)	18.0 ± 2.1	9.9 ± 0.5	11.8 ± 0.6
Linoleic acid (18:2n-6)	6.0 ± 1.1	5.8 ± 3.1	4.0 ± 0.5
Arachidonic acid (20:4n-6)	13.3 ± 2.8	4.4 ± 3.8	3.3 ± 1.7
Docosahexaenoic acid (22:6n-3)	7.4 ± 0.9	21.3 ± 7.3	13.4 ± 3.0
Total SAT	40.5 ± 2.8	48.9 ± 4.4	51.0 ± 4.2
Total Mono	21.3 ± 1.6	17.2 ± 2.6	19.1 ± 2.7
Total n-6 FA	25.3 ± 3.8	14.4 ± 6.7	13.9 ± 3.7
Total n-3 FA	8.5 ± 1.3	17.4 ± 2.4	15.8 ± 2.9
Ratio of n-6/n-3 FA	3.1 ± 0.9	0.7 ± 0.4	1.0 ± 0.3

Values are mean ± SD.

<sup>a</sup>An average of 4 studies (% w/w testis total lipids) (Coniglio et al., 1975; Hoffmann et al., 2005; Coniglio et al., 1974; Bieri and Prival, 1965).

<sup>b</sup>An average of 3 studies (mole% of spermatozoa) (Zalata et al., 1998; Martínez-Soto et al., 2013; and Tavilani et al., 2006). Zalata and Tavilani used phospholipids.

<sup>c</sup>Infertile men includes Fatty acids were combined for men with oligospermia, asthenozoospermia and oligoasthenozoospermia.

## Sperm

Like testis, sperm lipids are composed of a heterogeneous mixture of glycolipids, sterols, phospholipids, saturated and PUFA, which are believed to play an important role in the viability, maturation, motility and fertilizing ability of the sperm. Human sperm lipid profiles are generally determined on ejaculated sperm which have undergone epididymal maturation, thus the lipid profile may differ from testicular spermatozoa which have yet to mature. Among the lipids, the fatty acid composition of sperm has received significant attention due to its direct relationship with fertility. Several studies have carried out detailed fatty acid profiling of human spermatozoa (Table 2). The major saturated and monounsaturated fatty acids are palmitic acid (16:0, 30.2%) and stearic acid (18:0, 15.3%), and oleic acid (18:1, 9.9%). The PUFAs are mainly linoleic acid (18:2n-6, 5.8%), arachidonic acid (20:4n-6, 4.4%) and then remarkably high amounts of DHA (21.3%), ranging from 14%–32% of total fatty acid in phospholipids (Zalata et al., 1998; Martínez-Soto et al., 2013; Tavilani et al., 2006). Most studies agree with the distinctively high content of DHA in spermatozoa, which is thus considered as a marker for infertility. Interestingly, DHA is not evenly distributed in sperm. Learning from monkeys, DHA is significantly enriched in the tail of sperm (19.6%, w/w total fatty acids) in comparison to the head (1.1%, w/w total fatty acids) (Connor et al., 1998), suggesting that DHA is involved in sperm movement (Figure 2).

Unlike normozoospermic males who have above the lower reference limits in sperm characteristics described in Table 1, men with oligospermia, asthenozoospermia, and oligoasthenozoospermia had significantly lower concentration of DHA in their spermatozoa (Tavilani et al., 2006; Connor et al., 1998; Safarinejad et al., 2010) (Table 2). Men with these conditions were found to have increased levels of saturated and monounsaturated fatty acids, and lower PUFA levels (Coniglio et al., 1975; Zalata et al., 1998; Aksoy et al., 2006), compared with the normozoospermic men. This indicates that decreased sperm fertility potential is closely associated with alteration of sperm lipid content and composition.

## n-3 Fatty Acid Containing Foods or Supplementation in Healthy and Infertile Population

Emerging evidence to date has shown a possible relationship between diet and semen parameters. It is well known that membrane fatty acids are affected by dietary fat types, which are directly related to the maintenance of cell membrane for its optimal functions. Dietary fat intake thus, can affect the male reproductive function by modulating the fatty acid composition of testis and spermatozoa.

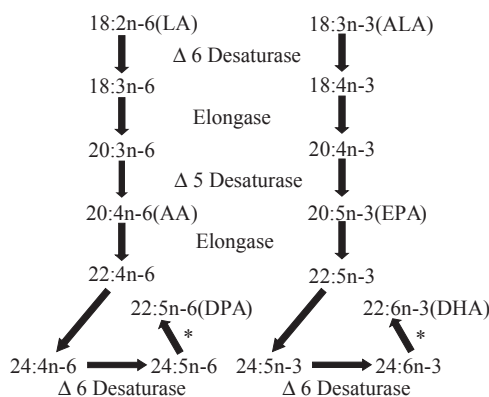

## Observational Studies

### n-3 Fatty Acid Food

Based on a few observational studies, higher intake of saturated fats is associated with lower sperm counts and concentration, whereas higher intake of n-3 PUFA is related to higher normal sperm morphology with lowering the sperm head defect (Attaman et al., 2012) (Table 3). Even in healthy young men, higher intake of fish as a part of a heart healthy diet was positively associated with sperm motility (Gaskins et al., 2012). In sub-fertile and asthenozoospermic men, higher intake of n-3 PUFA, fish and sea foods

**Figure 3** The n-3 and n-6 polyunsaturated fatty acid synthesis from the dietary essential fatty acids. Linoleic acid (LA) and  $\alpha$ -linolenic acid (ALA) from the diet are enzymatically desaturated and elongated to longer-chain, more unsaturated fatty acids via the same desaturases and elongases. Due to the same enzymes involved in desaturation of the ALA and LA, the high n-6 to n-3 fatty acid ratio in the Western diet inhibits the desaturation of ALA, leading to the reduction of DHA synthesis. EPA, eicosapentaenoic acid; DPA, docosapentaenoic acid; DHA, docosahexaenoic acid. \* Presents one-step  $\beta$ -oxidation.

### Intervention Studies

A limited number of studies assessing diets high in n-3 fatty acids for semen quality in both healthy men and men with infertility conditions exist (**Table 4**). For healthy men, 75 g of walnut a day (a source of ALA) for 12 weeks improved sperm morphology, motility and vitality (**Robbins et al., 2012**). However, healthy men receiving 50 mL menhaden fish oil for 4 weeks did not find a significant difference in sperm quality (**Knapp, 1990**).

Limited evidence is available to determine if dietary supplementation with n-3 PUFA, as fish oil or DHA, improves sperm parameters in males with fertility issues (**Table 4**). Evidence from a relatively large study of infertile males ( $n = 238$ ) with idiopathic oligoasthenoteratospermia, a condition including oligospermia, asthenozoospermia and teratozoospermia, showed that 1.84 g supplementation of fish oil (1.84 g: 0.72 g of eicosapentaenoic acid (EPA, 20:5n-3), 0.48 g of DHA) per day for 32 weeks improved sperm concentration, motility and morphology, which suggests fish oil as a cheap and non-aggressive treatment strategy for these patients (**Safarinejad, 2011**). Another study performed with 27 infertile men receiving 1 g DHA in addition to 0.35 g n-6 fatty acids and vitamins for 24 weeks, showed that the sperm concentrations were increased with a concomitant increase in pregnancy in their female partner (**Comhaire et al., 2000**). However, not all studied agreed with these positive effects of n-3 PUFA consumption. Asthenozoospermic men supplemented with 0.4 or 0.8 g DHA per day for 12 weeks did not show any changes in their sperm parameters

**Table 4** Intervention studies showing the effect of n-3 PUFA supplementation on healthy and infertile population

Population	Participant #	n-3 PUFA treatment	Study length	Semen quality
Healthy men <sup>a</sup> Walnut vs. control	$n = 59$ vs $n = 58$	75 g d <sup>-1</sup> Walnut vs usual diet without tree nuts (control)	12 wks	Increased sperm motility, normal morphology and vitality in those receiving walnut than the control group consuming their normal diet
Healthy men <sup>b</sup>	$n = 10$	menhaden oil (50 mL/d)	4 wks	There was no significant effect with or without menhaden fish oil consumption on sperm motility and count
Asthenozoospermic men <sup>c</sup> in three groups	$n = 28$	DHA (0.4 g d <sup>-1</sup> and 0.8 g d <sup>-1</sup> ) vs no DHA (control)	12 wks	No significant effect on sperm parameters between 2 DHA interventions and control
Infertile men <sup>d</sup>	$n = 27$	1 g DHA, 0.25 g LNA and 0.10 g AA	24 wks	Increased sperm concentrations, with improved sperm membrane fluidity and acrosome reaction
Oligoasthenoteratospermia <sup>e</sup> Fish oil vs. controls	$n = 119$ vs $n = 119$	Fish oil (1.12 g d <sup>-1</sup> EPA + 0.72 g d <sup>-1</sup> DHA) vs. corn oil (control)	32 wks	Increased sperm concentration, motility and morphology in fish oil treatment group than controls

DHA, docosahexaenoic acid; LNA, linolenic acid; AA, arachidonic acid; EPA, eicosapentaenoic acid.

<sup>a</sup>Robbins et al. (2012).

<sup>b</sup>Knapp (1990).

<sup>c</sup>Conquer et al. (2000).

<sup>d</sup>Comhaire et al. (2000).

<sup>e</sup>Safarinejad (2011).

(Conquer et al., 2000). Although the level of DHA in serum and seminal plasma increased dose-dependently, dietary DHA was unable to incorporate into spermatozoa phospholipid in asthenozoospermic men. It raises a question of whether the quality of sperm can be improved if the intervention period is longer as other studies in the above.

### n-3 Fatty Acids Dietary Sources and Recommendations

In order to have adequate dietary n-3 fatty acids, especially DHA, knowledge regarding their dietary sources is required. Dietary n-3 fatty acids can be found in three main forms in the diet: ALA, EPA and DHA. In addition to the plant-source of DHA precursor, food-based approach for achieving EPA and DHA is recommended. Seafoods, particularly marine fish and shellfish, are the main sources of DHA. The American Dietetic Association/Dietitians of Canada recommended two servings of 8 oz of fatty fish (herring, salmon, sardine; accounting > 0.5 g DHA/100 mg) per week for health promotion and reduced risk of various chronic diseases (Kris-Etherton and Innis, 2007). DHA also can be found in the liver of some special lean fish (cod). Halibut and Pollock are known as moderate sources of DHA corresponding to 0.3–0.5 g of DHA/100 mg.

Nutritional supplements or fortified food with fish oil or DHA, such as eggs containing 0.15 g and algae supplements, are also needed to meet current recommendations for some individuals with limited or lack of fish intake in their diet. Although vegetable oils are not a good source of EPA and DHA, some are rich sources of ALA, such as flax oil.

The general male population has been encouraged to consume n-3 fatty acids-rich foods to benefit their reproductive tract health. Institute of Medicine of the National Academies issued a Dietary References Intake (DRI) for ALA to be 1.6 g d<sup>-1</sup> providing 0.6%–1.2% of energy, for men 19 to >70 years (Otten et al., 2006). DHA is then synthesized endogenously from ALA in the body, but its dietary intake is also recommended due to the low efficiency in DHA production. There are no DRI for DHA or EPA, but some recommendations have been issued for different population groups based on evidence demonstrating the various health benefits of these n-3 PUFA. The American Dietetic Association/Dietitians of Canada recommended 500 mg day<sup>-1</sup> of EPA + DHA (Kris-Etherton and Innis, 2007). Although this amount is required for normal growth and neural development, as well as preventing nutrient deficiencies, it is questionable if it is enough for males with reproductive health issues. Regardless, to achieve the recommendation for DHA intake, it is required to increase the dietary intake of DHA in a preformed state in addition to its plant-derived precursors.

### Conclusions

DHA is a significant structural and functional component of testis and sperm. Only few studies have measured the effects of n-3 PUFAs and DHA supplementation on male reproductive functions in both healthy and sub-fertile or infertile populations. Although more interventional studies are required to fully elucidate the relationship between n-3 PUFA and male reproductive health, consistent findings of reduced DHA in the sub-fertile or infertile populations provide potential to DHA for being used as an intervention strategy for male reproductive function. To have robust data, future intervention plans should consider the effects of dose, duration, and types of the n-3 PUFA supplementation, as well as the n-6/n-3 fatty acid ratio on these males. This will lead to developing an effective daily dietary recommendation of DHA-rich food or supplementation for optimal male fertility. Based on the epidemiological studies providing evidence of high dietary n-3 PUFA foods improving semen quality, habitual consumption of n-3 PUFA may overall improve the male reproductive health.

## Hydrolysable Tannins

**Ryszard Amarowicz and Michał Janiak**, Institute of Animal Reproduction and Food Research, Polish Academy of Sciences, Olsztyn, Poland

© 2019 Elsevier Inc. All rights reserved.

### Glossary

**Hydrolyzable tannins** Secondary plant metabolites, which are also phenolic compounds.

**Gallic acid** Trihydroxybenzoic acid, a type of phenolic acid. A compound of gallotannins (see Fig. 1).

**Ellagic acid** A compound of ellagitannins. It is an ilactone of hexahydroxydiphenic acid (see Fig. 1).

**Gallotannins** Natural polymers formed by the subsequent esterification of hydroxyl groups of D-glucose and gallic acid.

**Ellagitannins** Esters of hexahydroxydiphenic acid and polyols, like glucose or quinic acid.

**Food antioxidant** Chemical compound that inhibits the oxidation of food constituents (*e.g.*, lipids, proteins).

**Astringency** Dry, puckering mouthfeel caused by tannins.

### Classification of Hydrolysable Tannins

Hydrolyzable tannins are secondary plant metabolites, which are also phenolic compounds. Interest in hydrolyzable tannins has grown over the past decade due to their biological activity. According to their structure, hydrolyzable tannins are classified into three subclasses: simple gallic acid derivatives, gallotannins (GTs), and ellagitannins (ETs). The hydrolysis of GTs yields gallic acid whereas ETs yields ellagic acid. The chemical structures of gallic and ellagic acids are depicted in Fig. 1.

#### Simple Gallic Acid Derivatives

Simple gallic acid derivatives are composed of five or less galloyl groups that are esterified to either glucose or quinic acid. Examples include 1,2,3,4,6-penta-*O*-galloyl- $\beta$ -D-glucose (PGG) (Fig. 2). Fruits of *Galla chinensis*, the kernel and peel of *Mangifera indica* L. (mango), and the seeds of *Sideritis raseri* (a mountain tea) are rich sources of PGG (Tian et al., 2009; Pljevljaković et al., 2011; Luo et al., 2014).

#### Gallotannins

Gallotannins are natural polymers formed by the subsequent esterification of hydroxyl groups of D-glucose and gallic acid in polymeric chains, in which the galloyl moieties are linked by so called “depside” bonds. The term “depside” refers to polyphenols composed of two or more monoaromatic units linked via an ester bond, and include a wide array of compounds. Other types of gallotannins are formed by the esterification of shikimic acid and quinic acid with gallic acid. Gallotannins of these types contain one free carboxylic group in the quinic moiety and, as in glucose-derived gallotannins, a varying number of depside bonds between their galloyl residues, leading to high structural diversity (Karas et al., 2017). In glucitol-core containing gallotannins (GCGs), galloyl groups are bonded to a 1,5-anhydro-D-glucitol center (Fig. 3). GCGs have only been isolated from maple (*Acer*) species, including the red maple (*Acer rubrum*).

**Figure 1** Chemical structure of gallic acid and ellagic acid.

**Figure 2** Chemical structure of PGG.

**Figure 3** Chemical structure of GCG isolated from red maple.

## Ellagitannins

Ellagitannins (ETs) are esters of hexahydroxydiphenic acid and polyols, like glucose or quinic acid. After hydrolysis, the liberated ET molecule from hexahydroxydiphenic acid is spontaneously rearranged into ellagic acid, which is a water-insoluble compound. Methylation, glycosylation, and methoxylation lead to numerous derivatives of ETs in plants.

Chemical structure of ETs of pomegranate and walnut is depicted in [Figs. 4 and 5](#).

## Sources of Hydrolysable Tannins

The content of ETs in several plant products is high. Ellagitannin-containing plant species of economic importance as foodstuffs include cashew nuts, pistachios, mangos, hazelnuts, persimmons, chestnuts, walnuts, guavas, cloves, pimento, pomegranates, plums, apricots, peaches, bird cherries, strawberries, raspberries, blackberries, blackcurrants, gooseberries, teas, grapes, and muscadine grapes ([Clifford and Scalbert, 2000](#)). To illustrate, a glass of pomegranate juice can provide 1 g of ETs; 100 g of raspberries provide ~300 mg ETs; 100 g of strawberries ~70 mg; and four walnuts about ~400 mg of ETs ([Larrosa et al., 2010](#)). Daily consumption of two servings (250 mL each) of a functional beverage, based on a dealcoholized red wine matrix fortified with a pomegranate extract, provides 82 mg of total ellagitannins (ETs), corresponding to the sum of punicalagin A and B as well as ellagic acid ([Tárrega et al., 2014](#)). Juices produced only from the edible portion of pomegranates possess lower quantities of ETs compared to those extracted from the entire fruit ([Fischer et al., 2011](#)). The major contributors of ETs intake in Western diets are red fruits such as strawberries, raspberries, and blackberries. The main dietary source in France is undoubtedly strawberries. On average, the French ingest 1.7 kg of fresh strawberries yearly, and equally as much in the form of processed products ([Landete, 2011](#)).

**Figure 4** Chemical structure of punicalagin (ET of pomegranate).

**Figure 5** Chemical structure of pendunculagin (HT of walnut).

### Biological Activity of Hydrolysable Activity

Gallotannins have been reported to exhibit anti-cancer, anti-angiogenic, antioxidant, anti-inflammatory, and anti-ulcerative activities, as well as to inhibit *P*-glycoproteins (Karas et al., 2017). The tannin fraction isolated from the leaves of bearberry (*Arctostaphylos uva-ursi* L. Sprengel), which contain gallotannins comprising glucose and three, four, and five residues of gallic acid, showed anti-proliferative activities in a concentration-dependent manner against five carcinoma cell lines, namely MCF-7 (estrogen receptor-positive breast carcinoma), DU-145 (androgen receptor-negative prostate carcinoma), HT-29 (colon carcinoma), SK-MEL-5 and MDA-MB-435 (melanoma; skin carcinoma) (Amarowicz and Pegg, 2013).

PGG exhibited anti-cancer, anti-viral, anti-microbial, anti-inflammatory, and anti-diabetic activities (Torres-León et al., 2017). The anti-radical activity of PGG against the DPPH radical was reported by Shaikh et al. (2016): it exhibited an effective concentration that scavenged 50% of the radical ( $EC_{50}$ ) value of 20.5  $\mu$ M. The activity against reactive nitrogen species was also noted and reported: the inhibitory concentration that reduced 50% of the species ( $IC_{50}$ ) values for NO and ONOO<sup>-</sup> were 0.20 and 0.06  $\mu$ M, respectively (Kiss and Naruszewicz, 2012).

The GCGs showed superior activities when compared to the synthetic antiglycating agent, aminoguanidine, at the early, middle, and later stages of glycation (Ma et al., 2016). Furthermore, the GCGs containing 1 to 4 galloyl groups were noncompetitive inhibitors of  $\alpha$ -glucosidase (Ma et al., 2015), and should be further investigated for their antidiabetic potential.

Ellagitannins are not absorbed *in vivo*, but reach the colon and release ellagic acid that is metabolized by the human microflora to urolithins (García-Villalba et al., 2013). These compounds exhibit both estrogenic and antiestrogenic activities (Larrosa et al., 2006a). The results of Larrosa et al. (2006b) suggest that the anticarcinogenic effect of dietary ETs could be mainly due to ellagic acid liberated from ETs, which induces apoptosis via the mitochondrial pathway in colon cancer Caco-2 cells, but not in normal colon cells. In an experiment using Caco-2 cells, punicalagin (the chief ET of pomegranates) was hydrolyzed to yield ellagic acid, which then entered Caco-2 cells. After methylation and conjugation with glucuronic acid, urolithin derivatives (Fig. 6) were detected (Larrosa et al., 2006b).

**Figure 6** Chemical structure of urolithin C-methylether-glucuronide – ellagic acid metabolite found in plasma and urine after ETs intake.

### Hydrolysable Tannins as Natural Antioxidants

Mullen et al. (2002) listed sanguine H-6 (*i.e.*, an ET) as an important contributor to the antioxidant capacity of raspberries compared to that of vitamin C and anthocyanins. The findings of Kähkönen et al. (2012) indicated that cloudberry and red raspberry ETs were highly effective as free-radical scavengers. Berry ETs also showed significant antioxidant activity toward oxidation of both human LDL and methyl linoleate emulsions. Yet, only weak or moderate antioxidant activity was observed by ETs toward oxidation of bulk oils. In the raspberry, the ETs sanguine H-6 and lambertianin C were responsible for 44.7% and 13.6% of the total antioxidant capacity of the berries, respectively (Borges et al., 2010).

Thermal hydrolysis of gallotannins enhanced their antioxidant properties. Furthermore, such prepared gallotannins exhibited a synergistic antioxidant effect with  $\alpha$ -tocopherol, ascorbyl palmitate, and citric acid in an edible oil-based system (Terán-Hilares et al., 2018). In terms of their antioxidant activity, analyses of the gallotannins of *G. chinensis* showed that with higher degrees of galloylation these tannins exhibited stronger antioxidant activities than those with low degrees of galloylation. Moreover, for the first group, the antioxidant activities increased with a greater number of galloyl moieties (Tian et al., 2009). The antioxidant potential of raspberry jam is generated by the presence of ellagic acid, 4-arabinosylellagic acid, 4-acetylxylellagic acid, 4-acetyl arabinosylellagic acid, and two other derivatives of ellagic acid. The antioxidant activities of the aforementioned compounds range from 0.5 to 4.3 mM Trolox equivalent/mM compound (Zafilla et al., 2001).

### Astringency

Hydrolysable tannins just like condensed tannins (*i.e.*, proanthocyanidins) are astringent. The astringency derives from their interaction with salivary proteins that leads to precipitation of the formed complexes in the oral cavity. The more galloylated tannins are in grape seeds, which are then extracted during the process of maceration and fermentation, the stronger their contribution to wine astringency (Aron and Kennedy, 2007). Additionally, the GTs and ETs released from oak barrels can markedly influence wine astringency (Glabasnia and Hofmann, 2006). It is interesting to note that the complexes formed between a representative salivary protein and hydrolysable tannins are more soluble than those of condensed tannins (Lu and Bennick, 1998). The organoleptic properties were significantly impacted by the content of ETs, as the wine with the lowest ET level was described as less astringent, bitter, woody, and smoky/toasty (Michel et al., 2016). The results of Engström et al. (2016) showed that the oxidizability of ETs was directly correlated with the tendency of the tannins to form highly stabilized complexes with bovine serum albumin at an increased pH (7.6). However at a slightly lower pH (6.7), other tannin features, such as the size and flexibility of the tannin, appeared to dictate the formation of highly stabilized tannin–protein complexes.

### Influence of the Technological Process and Storage on Hydrolysable Tannins

The content of ETs in food and beverages can be changed by technological processing and during storage. In experiments with raspberries, on average 68.1% of the ETs were retained in the press cake, especially in its seedless fraction. Moreover, a significant negative correlation was found between the molecular mass of ETs and their transfer to juice. An increase in molecular mass from 1568 to 2805 Da resulted in a more than a 10-fold decrease in ET transfer (Sójka et al., 2016).

The impact of thermal pasteurization on hydrolysable tannins of pomegranate juice has been scarcely studied. With regard to this, Mena et al. (2013) demonstrated that the content of punicalagins increase after thermal treatment, while other compounds such as punicalagin-like and ellagic acid (both free and in glucoside forms), decrease. Overall, other researchers have reported that thermal pasteurization does not modify the content and form of ETs appreciably, apart from punicalagin isomers, pointing to depolymerization of higher-molecular-weight ETs (Hager et al., 2010). During processing of berries into jams, the total ellagic content decreased by 20% in all jam samples (Hakkinen et al., 2000). Thermal processes triggered a significant breakdown of hydrolysable tannins from witch hazel, *Hamamelis virginiana*, with 6 to 10 galloyl units to give pentagalloyl glucose. The release of high concentrations of free gallic acid, especially in long-term thermally processed samples, leads to an increase in the antioxidant capacity of heated *H. virginiana* extracts. Such an increase was evidenced by an increment in the reducing and free-radical scavenging capacities as well as by an improvement in the antioxidant effectiveness for inhibiting lipid oxidation of processed fatty fish muscle (González et al., 2010).

The results of an investigation by Qu et al. (2014) showed that liquid pomegranate peel extracts, containing, punicalagin A, punicalagin B, and ellagic acid, had acceptable thermal stability after sterilization (121 °C for 10 s) and storage up to 180 days.

During typical industrial processing of a blackberry-based beverage using glass bottles, ETs underwent severe losses during blanching and hot-filling of the final blackberry beverage. Indeed, blanching reduced the contents of hydrolyzable tannins (e.g., lambertianin C and sanguin H-6) by almost 20%, as they were hydrolyzed, during heat treatment, partially into insoluble ellagic acid. After hot-filling and holding, additional losses were as high as 59% for lambertianin C and 17% for sanguin H-6. Over the entire process, lambertianin C and sanguin H-6 ETs were reduced by 80% and 50%, respectively (Gancel et al., 2011).

In the research of Truchado et al. (2012), processing increased the quantity of free ellagic acid 2.5-fold in strawberries, but this had no effect on the transformation in urolithins by the gut microbiota or in the excretion of urolithin metabolites in urine (i.e., urolithin glucuronides). These results show that processing does not modify the potential health effects of strawberry polyphenols.

The effect of storage on the ET and ellagic acid contents in strawberries is not unambiguous. The content of free ellagic acid in strawberries during 10 days of post-harvesting at 5 °C increased significantly, although this was delayed at an elevated CO<sub>2</sub> concentration (Gil et al., 1997). Their storage at 6, 16, and 25 °C did not result in any significant change to free ellagic acid under the conditions employed (Cordenussi et al., 2005). The freezing of raspberries and their long term storage at −20 °C for 12 months decreased the total content of ellagic acid from 21% to 14%. The change, however, depends on the raspberry cultivar investigated (De Ancos et al., 2000) and could be related to the release of polyphenoloxidase linked to the cellular wall.

## Hydrolyzable Tannins and the Problem of Sediment and Haze

The use of fruits containing high ET as a fruit juice and for wine is limited by the problem of sediment and haze. Hydrolysis of ETs during processing and storage liberates less water-soluble ellagic acid that precipitates (Bakkalbasi et al., 2009). This problem is especially important when processing of muscadine grapes (*Vitis rotundifolia*) (Le and Talcott, 2002). According to Bakkalbasi et al. (2009), methods to avoid sediment in juice include the application of thermal processing or hydrolysis and filtration of precipitated ellagic acid before bottling; removal of skins and other fruit parts rich in ETs; and the selection of cultivars characterized by lower contents of ETs. Application of centrifugation and filtration can also be an effective method protected against the appearance of sediment in the final product (Siriwoham et al., 2005). Nanofiltration membranes with a molecular weight cut-off around 200 Da were evaluated to concentrate anthocyanins and ellagitannins in a blackberry juice (Acosta et al., 2017).

## Ellagitannins in Wine and Spirits

Ellagic acid and ETs are the most important phenolic compounds of wine and spirits aged in barrels. Their influence is not only on the color, astringency, and bitterness of wines and spirits, but also on the antioxidant capacity of these beverages (Bakkalbasi et al., 2009). During the aging of spirits in barrels, ETs are solubilized by the spirit. A part of the ETs can then be hydrolyzed to ellagic acid or degraded without formation of ellagic acid. Insoluble ETs present in barrel wood can also be hydrolyzed to yield ellagic acid. Then, it can diffuse from the barrel into the spirit (Viriot et al., 1993).

# Food for Skin Health: Collagen Peptides

Kenji Sato, Kyoto University, Kyoto, Japan

© 2019 Elsevier Inc. All rights reserved.

## Background

The skin provides a protective barrier against the external environment. The skin consists of the epidermis, dermis, and subcutaneous tissue. Keratin is the main protein compound found in the epidermis. On the other hand, collagen and elastin are the main protein compounds present in the dermis. When the skin is mechanically damaged, blood clotting occurs and inflammation is subsequently induced, which attracts neutrophils and fibroblasts into the damaged area (Reinke and Sorg, 2012). The fibroblasts synthesize collagen and other extracellular matrix compounds, which replace the necrotic tissue and form granulation tissue. Keratinocytes cover the granulation tissue to regenerate the epidermis. The skin is also damaged by ultraviolet (UV) irradiation, exposure to dryness, aging etc. These factors induce epidermal thickening and barrier dysfunction of the epidermis and cause a decrease in the levels of extracellular matrix compounds, thus resulting in the decline of skin elasticity, roughness and dryness, wrinkle formation, and sagging (Ichihashi et al., 2009).

Collagen, one of the main constituents of the dermis, consists of three subunit chains called the  $\alpha$  chains, which form a triple helical structure. This collagen molecule has a rod-like shape and is derived from a molecular family consisting of more than 46 gene products (UniProtKB/Swiss-Prot - ExPASy). Collagen molecules are designated by 'type', followed by a Roman numeral, as type I to type XXVIII. Subunit chains are designated by Arabic and Roman numerals. For example,  $\alpha 1(I)$  represents the subunit 1 of type I collagen. The type I collagen consists of two  $\alpha 1(I)$  and one  $\alpha 2(I)$  subunits and is designated as  $[\alpha 1(I)]_2\alpha 2(I)$ . Some types of collagen (I, II, III, V, and XI) molecules self-assemble and form fibrils; these are stabilized by covalent cross-links. Collagen fibrils are associated with different types of collagen molecules and other extracellular matrix compounds, resulting in the formation of larger fibers. The collagen fibers provide mechanical strength to the dermis, while the elastin fibers provide elasticity. Type I collagen is the main protein constituent of the skin, bone, tendons and other non-cartilage tissues. In cartilage, type II collagen is the main protein constituent. Other types of collagen also play important roles in regulating the diameter and properties of the collagen fibrils. In addition, some of them form the basal lamina, although their content is relatively lower (van der Rest and Garrone, 1991). Collagen has unique amino acids; hydroxyproline (Hyp) and hydroxylysine (Hyl), which are generated after translation by prolylhydroxylase and lysylhydroxylase. Hyp accounts for approximately 10% of the total amino acids in collagen.

The triple helical structure of collagen collapses after heating with water and is converted to a globular structure, which is referred to as gelatin. Gelatin is soluble in water, while the collagen in tissues is not. Cooling of the gelatin solution induces partial formation of the triple helical structure between adjacent gelatin molecules, resulting in gel formation. Gelatin has been used in food, pharmaceuticals, photographic films, cosmetics, etc., owing to this gel-forming property. Gelatin can be degraded by protease. However, while the triple helical structure of collagen resists most of the protease. The gelatin hydrolysate or collagen peptides are prepared on an industrial scale and are widely used as food ingredients. Collagen peptides are water-soluble but lose their gel-forming ability in water. They do not have a bitter taste, unlike other protein hydrolysates such as soy protein and casein hydrolysates. Thus, relatively large doses (2–10 g) of collagen peptides can be easily consumed by dissolving in water or a similar beverage. Numerous reports suggest that ingestion of collagen peptides might improve skin condition and enhance wound healing. However, it was assumed that orally administered peptides were degraded into amino acids during the digestion and absorption processes. Thus, strong doubts were cast to the suggested beneficial effects of ingestion of collagen peptides. However, the observation of the presence of food-derived collagen peptides in human blood at unexpectedly high levels has dramatically changed this view. Some food-derived collagen peptides in human blood have been identified and demonstrated to exert significant biological activities on fibroblasts and keratinocytes. The structure, contents, and biological activities of the food-derived collagen peptides present in human blood and possible mechanism for the beneficial effects of ingestion of collagen peptides are addressed in the following sections.

## Detection of Collagen Peptides in the Body

In the 1960s, early studies demonstrated the presence of Hyp-containing peptides in human urine after ingestion of gelatin (Prockop and Sjoerdsma, 1961). This indicates the presence of collagen peptides in the blood after the ingestion of gelatin. However, this important finding was almost forgotten. In 2005, the presence of food-derived collagen peptides in human blood was rediscovered (Iwai et al., 2005). Blood was collected from the cubital vein before and after ingestion of collagen peptides (10 g). The contents of peptide form of Hyp in human blood plasma, namely, the collagen peptide content, was estimated by subtracting free Hyp from total Hyp in the HCl hydrolysate of the deproteinized fraction of blood plasma. As shown in Fig. 1, the collagen peptide content increased 30–60 min after the ingestion compared to the levels before the ingestion. Using this method, an increase in the collagen peptide levels in human blood after ingestion of collagen peptides has been demonstrated (Ohara et al., 2007, Shigemura et al., 2014, 2017). Both the maximum level and the area under curve of the collagen peptide content increased in a dose-dependent manner (Shigemura et al., 2014). The maximal levels of collagen peptides in human blood after ingestion of 10–20 g of collagen

**Figure 1** Contents of peptide form of hydroxyproline (Hyp) in human plasma after ingestion of 10 g of collagen peptides. This figure was adapted with permission from Iwai, K., Hasegawa, T., Taguchi, Y., Morimatsu, F., Sato, K., Nakamura, Y., Higashi, A., Kido, Y., Nakabo, Y., Ohtsuki, K., 2005. Identification of food-derived collagen peptides in human blood after oral ingestion of gelatin hydrolysates.

peptides were observed to be 20–100  $\mu\text{M}$ . These values are far higher than those previously reported for the peptides with in vitro angiotensin converting enzyme inhibitory activity (approximately 1 nM) (Matsui et al., 2002; Foltz et al., 2007).

### Structure of the Food-Derived Collagen Peptides in Blood

Blood plasma contains numerous compounds. The direct injection of the deproteinized fraction of plasma into reversed phase-high performance liquid chromatography (RP-HPLC), the most powerful tool for the resolution of peptides, generated numerous unresolved peaks. Thus, it was difficult to isolate food-derived peptides in plasma by direct RP-HPLC analysis. To tackle this problem, pre-fractionation using size exclusion chromatography (SEC) was used. An oligo peptide fraction was prepared by SEC and used for the isolation of collagen peptides by RP-HPLC (Iwai et al., 2005; Ohara et al., 2007). Furthermore, a pre-column derivatization technique using phenyl isothiocyanate (PITC) was used to improve the resolution and detection of short chain peptides in human blood. PITC derivatives, namely phenyl thiocarbonyl (PTC)-peptides can be well resolved by RP-HPLC and the isolated PTC-peptide can be sequenced by the Edman degradation method (Aito-Inoue et al., 2006; Shigemura et al., 2011, 2017). This is possible, as the PTC-peptide is an intermediate of the Edman degradation. Using these techniques, some food-derived di- and tri-peptides, Pro-Hyp, Hyp-Gly, Pro-Gly, Glu-Hyp, Ala-Hyp, Ile-Hyp, Leu-Hyp, Phe-Hyp, Ser-Hyp-Gly, Ala-Hyp-Gly, Gly-Pro-Hyp, and Pro-Hyp-Gly have been identified. Among these, Pro-Hyp accounts for more than 50% of the total collagen peptides in the blood. Some research groups have confirmed the presence of Pro-Hyp and other peptides using liquid chromatography tandem mass spectrometric (LC-MS/MS) analysis (Ichikawa et al., 2010; Taga et al., 2014). An in vitro study using porcine brush-border membrane vesicles demonstrated that Pro-Hyp is transported via the peptide transporter (PepT1) on enterocytes (Aito-Inoue et al., 2007). In addition, peptides longer than tri-peptides have been demonstrated to pass through the Caco-2 cell monolayer by paracellular diffusion. This suggests that larger peptides are potentially absorbed into the blood circulating system (Shimizu et al., 2010). However, collagen peptides longer than tri-peptides have not been detected in the human blood circulating system after ingestion of collagen peptide. This observation is possibly due to their degradation by blood peptidase.

### In Vitro Activity of Pro-Hyp and Other Peptides

The effect of Pro-Hyp, the most abundant collagen peptide present in human blood, on skin fibroblasts has been examined. Generally, the fibroblasts of established cell lines are used for this purpose. However, in our preliminary experiments, the effect of Pro-Hyp on the growth of fibroblasts depended on the passage of the cell line. In order to obtain reproducible results, we opted to use a skin tissue culture system. The number of fibroblasts migrating from the skin into the serum free medium containing Pro-Hyp and constituting amino acids was evaluated (Shigemura et al., 2009). As shown in Fig. 2, Pro-Hyp significantly increased the number of fibroblasts migrating from the mouse skin, while the free Pro and Hyp did not show significant effects. This effect of Pro-Hyp on increase of number of outside fibroblasts was abolished in the presence of 10  $\mu\text{g}/\text{mL}$  of mitomycin C, which arrests the cell cycle and does not affect cell migration. Furthermore, Pro-Hyp enhances the growth of fibroblasts attached to the collagen gel in a dose-dependent manner (Shigemura et al., 2009). These results indicate that Pro-Hyp enhances the growth of fibroblasts in the skin. Hyp-Gly was also observed to enhance the growth of fibroblasts attached to the collagen gel (Shigemura et al., 2011). In addition, Pro-Hyp increases the production of hyaluronic acid from cultured human dermis fibroblasts (Ohara et al., 2010).

An animal study demonstrated that the ingestion of collagen peptides upregulated the keratin-associated proteins in mice, while the direct addition of Pro-Hyp to a keratinocyte culture system did not increase the expression of these proteins. However, upon

**Figure 2** Numbers of fibroblasts migrating from mouse skin in the presence of 200  $\mu$ M of Pro-Hyp, free Pro, or Hyp. This figure was adapted with permission from Shigemura, Y., Iwai, K., Morimatsu, F., Iwamoto, T., Mori, T., Oda, C. Taira, T., Park, E.Y., Nakamura, Y., Sato, K., 2009. Effect of prolyl-hydroxyproline (Pro-Hyp), a food-derived collagen peptide in human blood, on growth of fibroblasts from mouse skin.

addition of Pro-Hyp to a keratinocyte-fibroblast co-culture system, upregulation of the keratin-associated proteins was observed. These results indicate that Pro-Hyp can affect the production of proteins from keratinocytes by affecting the excretion of some biological substances from fibroblasts (Le Vu et al., 2015).

Recently, it has been demonstrated that Pro-Hyp is generated by the degradation of endogenous collagen in the inflammation and wound healing process without the ingestion of collagen peptide (Kusubata et al., 2015; Jimi et al., 2017). These observations indicate that Pro-Hyp and Hyp-Gly are not just inactive degradation products of collagen in food and in the body but are vital collagen derived-bioactive peptides.

### Effects of Collagen Peptide on the Skin

In 2003, a human clinical study demonstrated that ingestion of collagen peptides increases the moisture contents of the epidermis and promotes skin flexibility (Kikuchi and Matahira, 2003). However, these findings were not considered valid and not accepted by peer-reviewed journals, even though the conclusion was based on the results of a randomized double-blind placebo control study. After discovery of the presence of food-derived collagen peptides in human blood, a couple of peer-reviewed papers demonstrating the beneficial effects of collagen peptides on human skin have been published. These human trials have demonstrated that ingestion of collagen peptides increases skin moisture (Ohara et al., 2009; Asserin et al., 2015; Inoue et al., 2016), elasticity (Proksch et al., 2014a; Inoue et al., 2016), and decreases wrinkle volume (Proksh et al., 2014b; Inoue et al., 2016) compared to the placebo control. Furthermore, a study on human volunteers demonstrated that daily ingestion of 2.5 g collagen peptides significantly increased the gene expressions of type I collagen and elastin in the skin compared to that in the placebo control (Proksh et al., 2014b). These results suggest that an increase in the number of fibroblasts and/or enhancement of the production of type I collagen and elastin may be responsible for the reduction of wrinkle volume. Some human trials revealed that older subjects responded better to the ingestion of collagen peptides than younger subjects (Ohara et al., 2009; Proksch et al., 2014a). These findings suggest that the ingestion of collagen peptides could improve age-related deterioration of skin condition. Further, the skin conditions are also dependent on environmental conditions such as temperature and humidity in addition to the subject's age. Thus, the data from different studies should be carefully evaluated by understanding that the conditions of the subject and environment can affect the results. To my knowledge, there has been no animal study confirming the beneficial effects of collagen peptides on skin aging. On the other hand, some animal studies have demonstrated that ingestion of collagen peptides attenuates the UV irradiation-induced pathological changes of the skin, such as inflammation, thickening of the epidermis, dysfunction of the barrier function of the epidermis, water loss, and decrease of collagen (Pyun et al., 2012; Oba et al., 2013). Recently, a human trial using male volunteers demonstrated that ingestion of collagen peptides (5 g) suppressed UV irradiation-induced erythema in the subjects older 30 years (Koyama et al., 2014). These facts suggest that ingestion of collagen peptides has the potential to attenuate UV irradiation-induced skin damage.

Some human studies have also demonstrated that ingestion of collagen peptides enhanced the healing of pressure ulcers compared to the placebo control (Sugihara et al., 2015). Enhancement of the proliferation of fibroblasts by Pro-Hyp, a food-derived collagen peptide, might be associated with wound healing.

## Conclusions

Human and animal studies have demonstrated and suggested that ingestion of collagen peptides can improve subjective and objective skin conditions and attenuate UV irradiation-induced damage to skin. The efficacy of the collagen peptides depends upon background of the subjects and the environmental conditions. Elucidation of effects of the subject's background on the efficacy is necessary. Several *in vitro* studies have demonstrated that Pro-Hyp, a prominent peptide in human blood after ingestion of collagen peptides, exerts significant biological activities on fibroblasts and keratinocytes. These effects could be associated with the beneficial effects caused by the ingestion of collagen peptides. The effects of Pro-Hyp on the fibroblasts migrating from the skin are different from those on the fibroblasts in cell lines. Therefore, the effects of the degree of differentiation and cell division of fibroblasts on their response to Pro-Hyp could be potential subjects for further studies.

### Introduction

Bone health is a lifelong concern because healthy bones form the foundation for a vital and energetic life. Skeleton provides mobility, flexibility, and mechanical support as well as protects various organs, stores minerals, and serves as a calcium reservoir to keep physiological calcium balance ([Office of the Surgeon General, 2004](#)). During childhood and adolescence, bone is continuously deposited until a maximum level is reached in the adult, which is also called peak bone mass, after which losses in bone mass begin ([Weaver, 2017](#)). Peak bone mass is the maximum amount of bony tissue present at the end of the skeletal maturation, which is the most important factor for bone health ([Bonjour et al., 1994](#)). Thus, two strategies to reduce the risk of bone health problem are to maximize peak bone mass within our genetic potential and to slow the rate of bone loss with age ([Weaver, 2017](#)). Meanwhile, other diseases can also damage bone health, such as arthritis, fractures, infections, osteoporosis and tumor; osteoporosis, also called “silent killer”, is one of the most serious health issues. Even though the annual incidence of osteoporotic fracture approaches 2 million in America and 1.5 million in Canada aged 40 years or older ([Weaver, 2017](#); [Osteoporosis Canada, 2017](#)), the public awareness of osteoporosis remains low. This might be because osteoporosis is difficult to realize before people get fracture, as well as its lower risk of mortality. However, hip fracture does increase the risk of dying, especially through pneumonia associated with immobility ([Weaver, 2017](#)). Moreover, the loss in quality of life with associated pain and reduced mobility and growing healthcare cost deserve more attention. The overall yearly cost to Canadian healthcare system of treating osteoporosis and associated fractures was over \$2.3 billion as of 2010 and this was estimated to rise to \$3.9 billion if a proportion of Canadians were assumed to be living in long-term care facilities ([Osteoporosis Canada, 2017](#)). Although genetics and preprogrammed body size is considered responsible for 60%-80% of bone mass ([Weaver, 2017](#)), diet and living style are vital to bone health management since these can be changed and modified. In this chapter, the relation between nutrient and bone health will be reviewed.

### Bone Physiology

The skeleton is initially formed by a series of programmed mesenchymal condensations followed by formation of a cartilaginous template for all major skeletal structures ([Dempster and Raisz, 2015](#)). In general, bone consists of two distinct layers: an outer compact layer called cortical bone and an inner lattice-like layer called trabecular bone ([Kini and Nandeesh, 2012](#)). Although bone is always viewed as settled, it is a dynamic and living tissue and consequently requires all essential nutrients for growth and maintenance. Bone is built mainly of two compounds: the collagen protein framework providing flexibility while the mineralized calcium phosphate (hydroxyapatite) offers strength and rigidity ([Heaney, 2012](#)). This combination of protein and hydroxyapatite allows bone to withstand considerable mechanical stress. Throughout life, bone constantly undergoes a cycle of tear down and repair, named remodeling, to remove old, microdamaged bone and replaces it with new, mechanically sound bone to preserve bone strength ([Kini and Nandeesh, 2012](#)). To mediate the remodeling process, three types of cells are composed in bone, including formation cells called osteoblasts and osteocytes, and resorption cells called osteoclasts ([Dempster and Raisz, 2015](#)). The remodeling may be in balance when the amount of newly-formed bone equals to the amount of resorbed, or maybe be imbalanced when the bone formation is either more or less than the bone resorption. The remodeling process is subject to systemic and local regulations, such as nutritional status, sex hormone status, parathyroid hormone level, and vitamin D status.

### Bone Diseases and Nutrition-Related Disorders

The body systems that control growth and maintenance of the skeleton can be disrupted in different ways that result in a variety of bone diseases and disorders. Since genetic effect plays a fundamental role in bone development, some bone diseases can occur at or before birth, such as genetic abnormalities and developmental defects (US Department of Health and Human Services, 2004). Genetic factors cause skeletal diseases either by affecting other tissues and involve the skeleton indirectly such as neurofibromatosis, Gaucher's disease, alkaptonuria, or directly affect skeleton, which is known as skeletal dysplasia or constitutional disorders of bone ([McCarthy, 2011](#)). The most common skeletal dysplasias are osteogenesis imperfect (OI), achondroplasia, and osteopetrosis ([McCarthy, 2011](#)). Compared to genetic-caused bone diseases, most bone problems occur during later life, which may be due to natural aging, nutrition disorder or improper lifestyle. Osteoporosis is one of the most common bone disorders that can have devastating consequences. Although osteoporosis is always considered as an age-related disease, it could also happen in children, adolescents and adults since osteoporosis could be a by-product of medication use like glucocorticoid-induced osteoporosis (US Department of Health and Human Services, 2004). Environmental abnormalities can also cause bone diseases such as rickets and osteomalacia because of vitamin D or phosphate deficiency (US Department of Health and Human Services, 2004). Moreover, some other diseases may also lead to bone health issues. Patients with chronic renal disease are not only at risk of developing rickets

and osteomalacia, but they are also at risk of a complex bone disease known as renal osteodystrophy (US Department of Health and Human Services, 2004). Genetic factors primarily contribute to the variance of the determinants of bone strength. Environmental factors also play an important role in bone health management, especially nutritional intakes. The prevalence of eating disorders has increased in last few decades which may cause the impairment of bone mass gain (Rizzoli, 2014). Bone mineral density is reduced at several skeletal sites in most of women with anorexia nervosa (AN), which is frequently observed in young women (Kasner et al., 2013).

## Nutrients and Bone Health

### Protein Intake and Bone Health

Bone is a composite tissue, made up of 60% minerals, 30% organic matrix, and 10% water (by weight), respectively. Protein makes up one-third of bone mass, and undergoes continuous formation and resorption (Heaney and Layman, 2008). Type I collagen, the major part of the organic matrix, represents 98% of total bone proteins that offers the basic structure of bone, binds to mineral crystals, and provides resilience. Other main non-collagenous proteins including osteocalcin, osteopontin, sialoprotein, and osteonectin can help to strengthen the collagen matrix, and further regulate its ability to bind minerals (US Department of Health and Human Services, 2004). Thus, dietary protein represents a key nutrient for bone health as the “brick supplier”. Although it is still repeatedly claimed that high dietary proteins may be a risk factor for bone health, a large amount of studies confirmed the positive influence of protein on bone health management, and the potential in preventing osteoporosis.

During growth, protein undernutrition from infancy to childhood and adolescence results in reduced bone mass and strength (Bonjour et al., 2015). Moore et al. (2008) studied the effects of average childhood protein intake on adolescent bone health and reported that high intakes of dairy, meats and other proteins were positively associated with high bone mineral content and bone area (Moore et al., 2008). High protein intake, particularly when associated with physical activity, favors healthy development and peak bone mass acquisition enabling individuals to reach their genetic potential (Bonjour et al., 2015). Meanwhile, resistance exercise and high-protein supplementation have been considered as a preventive therapy for osteoporosis associated with aging (Matsuo et al., 2003). A positive correlation between protein intake and bone mass has also been found in premenopausal women (Feskanich et al., 1996). Since bone health is a multifactorial musculoskeletal issue, muscle mass and strength is also important to the development and maintenance of bone health. Loss of bone mass (osteopenia) and loss of muscle mass (sarcopenia) that occur with age are closely related (Heaney and Layman, 2008). Factors that affect muscle anabolism, especially protein intake, also affect bone mass. Dietary protein is a widely accepted strategy for muscle synthesis for elder population (Paddon-jones et al., 2008). Thus, dietary protein could also protect bone health by benefitting muscle health.

One hypothesis indicated that dietary proteins could induce increase in urinary calcium excretion and thereby enhance bone resorption. However, there is a positive interaction between dietary protein, calcium-phosphate economy, and bone metabolism mediated by the anabolic bone trophic factor insulin-like growth factor 1 (IGF-1) (Bonjour et al., 2015). The changes in circulating IGF-1 have been observed in response to various protein intakes in both animal (Ammann et al., 2010) and human studies (Schurch et al., 1998). IGF-1 could increase the circulating level of 1,25-dihydroxyvitamin D, the active form of vitamin D, and boost the intestinal absorption of both calcium and inorganic phosphate (Bonjour et al., 2015). Ammann et al. (2010) found protein undernutrition-induced bone loss is associated with decreased IGF-1 level and/or estrogen deficiency, and leads to a consequent imbalance in bone remodeling. The effects of protein supplements on patients with recent hip fracture also indicated that the increase of serum IGF-1 induced by protein intake could attenuate bone loss (Schurch et al., 1998). Despite the effects of IGF-1 on mineral absorption, the possible mediating role of IGF-1 on the anabolic effect of subcutaneous administration of parathyroid hormone (PTH) was investigated and confirmed (Tahimic et al., 2013). As one of the most important regulating hormones for bone formation, PTH has already been used as an efficient drug for osteoporosis treatment. Eli et al. (2010) indicated that the higher serum IGF-1 levels could synergize PTH action on the skeleton (Eli et al., 2010). Thus, an adequate intake of protein should be recommended in the prevention and treatment of postmenopausal and age-dependent osteoporosis.

### Minerals and Bone Health

Bone consists of a mineral phase of an imperfect hydroxyapatite  $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$  and other ions. There is no doubt that calcium and phosphate are two of the most important minerals affecting bone health. Dietary requirements for calcium are determined by the needs for bone development and maintenance, which vary throughout the life stage. It has always showed great needs during the periods of rapid growth in childhood and adolescence, pregnancy and lactation, as well as in elderly life (Flynn, 2003). Dietary calcium intake has an important impact on bone metabolism and bone health, especially when bone also serves as a reservoir for calcium. Chronic calcium deficiency resulting from inadequate intake or poor intestinal absorption is one of the several important causes of reduced bone mass and osteoporosis (Cashman, 2002). Currently, it has become a common sense that calcium supplements could benefit bone health and help to prevent osteoporosis. A number of calcium supplements or calcium-rich foods are also recommended in the dietary guidelines (Cashman, 2002). Meanwhile, consumption of functional foods, which contain ingredients such as lactulose (Seki et al., 2007), insulin (Weaver, 2005), or oligofructose (Weaver, 2005), might positively influence calcium absorption and lead to optimized calcium bioavailability from foods (Cashman, 2002). Like the calcium, maintaining physiological phosphate balance is important for bone health. Phosphorus is widely distributed in all natural foods, because of

its incorporation into the structure and machinery of most cellular tissues (Heaney, 2015). Major sources of phosphate are protein-rich foods, including milk, meat, fish, poultry eggs, and cereal grains (Penido and Alon, 2012). Although phosphorus is essential for maintaining bone structure and bone cell activity, serum phosphorus concentrations substantially above the normal range increase the risk of extraskeletal calcification, especially for people who have renal dysfunction or kidney disease (Moe and Chen, 2008). Also, it is sometimes argued that high phosphorus intakes lead to increased PTH secretion, an outcome presumed to be bad for bone health (Katsumata et al., 2014). High phosphorus intakes have even been proposed as contributor to pathogenesis of osteoporosis (Nieves, 2005). The recommended dietary allowance (RDA) in the US for phosphorus is 700 mg/day for adults (Heaney, 2015). Although there is no evidence for prevailing phosphorus deficiency, some studies reveal low intakes of phosphorus in adults (Heaney, 2015). Calcium supplements are widely recommended for osteoporosis prevention and recognized to bind food phosphorus. But, for individuals with already low phosphorus intake, the effect of calcium supplementation will be a reduction in available phosphorus, which could potentially induce hypophosphatemia (Heaney, 2015). Thus, individuals who are taking calcium supplements, and who are receiving anti-osteoporosis therapies should pay attention to their home diets and nutritional statutes to keep the balance of Ca:P ratio.

While predominant attention has been given to calcium (with vitamin D) and phosphorus, other nutrients also affect bone status, although they are less commonly factored or mentioned into dietary recommendations for the prevention of osteoporosis or the support of anti-osteoporosis therapy. Sodium, potassium, and magnesium influence bone status by affecting calcium economy as well as bone cells. Sodium is the best-studied nutrient among these four minerals. High salt intake is a well-recognized risk factor for osteoporosis because it induces calciuria (Teucher et al., 2008). Additionally, high salt intake also appears to increase bone resorption in postmenopausal women (Harrington and Cashman, 2003). However, in most cases when the papers speak of “sodium”, what is meant is “sodium chloride, which is the form about 90% of contemporary sodium intakes are ingested. This is probably a mistake to ignore the accompanying chloride anion (Heaney, 2015). Nevertheless, it remains true that contemporary intake of excess sodium chloride usually leads to hypercalciuria and harm for bone health.

Compared to calcium, only small amounts of potassium will be trapped when calcium phosphate is precipitated (Heaney, 2015). Zhu et al. (2009) found potassium intake shows positive association with bone density in elderly women, suggesting that increasing consumption of potassium-rich foods may play a role in osteoporosis prevention. In addition, potassium also shows effects on maintaining calcium homeostasis, particularly urinary calcium conservation and excretion (Heaney, 2015). Rafferty et al. (2005) asserted that increases in dietary potassium result in decreased urinary calcium, which helped to reduce the loss of calcium.

Magnesium is considered to condition bone mineral crystal solubility. Without enough magnesium, bone will be brittle and fragile (Castiglioni et al., 2013). The RDA for magnesium is 320 mg/day in women and 420 mg/day in men, but more than 70% of the adult population in the US fall below these recommended intakes (Heaney, 2015). It is unclear whether the magnesium deficiency has skeletal consequences, although several direct or indirect mechanisms contribute to the effects of low magnesium on bone density (Castiglioni et al., 2013). Magnesium deficiency leads to hypomagnesemia, which is in part buffered through the mobilization of surface magnesium from the bone (Creedon et al., 1999). Meanwhile, animal study revealed magnesium deficiency decreased bone formation by blocking osteoblastic activity (Rude and Gruber, 2004). Apart from direct effects on the structure and cells of skeleton, magnesium deficiency indirectly impact the homeostasis of parathyroid hormone (PTH) (Pironi et al., 2009) and 1,25(OH)<sub>2</sub> vitamin D (Gray et al., 1972). Hypomagnesemia also promotes inflammation, which could elevate bone resorption (Mazur et al., 2007). Although the evidence of magnesium and bone health is still fragmentary, most studies available now point out the contributor factor of magnesium to bone health.

## Fat and Bone Health

Body weight is one of the major determinants of bone mineral density. Population studies show a positive influence between body fat and bone density, leading to a positive association between adipocytes and bone strength (Kawai, de Paula and Rosen, 2012). Ellis et al. (2003) studied the bone mineral mass in overweight and obese children and concluded obese children do not show lower bone mineral mass compared with leaner children, even after adjustments for height, age, gender, and ethnicity. Goulding et al. (2008) also investigated the relationship of total body mass and bone area in New Zealand five-year-old children, and suggested that increased fat mass is associated with outward expansion of the total-body-less-head skeletal envelope independently of height and lean mass in very young children. However, controversy remains whether fat has a positive or detrimental effect on the bone. Goulding et al. (2000) reported that overweight and obese children have low bone mass and area for their weight, suggesting a negative effect of body fat on bone health. Another aspect to be taken into account in the evaluation of fat's influence on bone strength is adipocyte distribution (de Paula and Rosen, 2015). Lv et al. (2016) studied the fat distribution and bone quality in healthy Chinese men and found body fat mass, especially android fat and visceral fat, have negative effects on bone microstructure. Similar results have also been found in health postmenopausal Chinese women (Shao et al., 2015). Recently, the relation between regional fat mass and bone mineral was studied. Visceral adipose tissue is an independent inverse determinant of bone density in obesity and it was suggested that this association may be mediated by adipokines and a chronic inflammatory state (Russell et al., 2010). Surplus energy leads to fat accumulation not only on subcutaneous and visceral pads, but ectopic deposition of fat in muscle and liver contributes to the degenerative disorders associated with obesity (de Paula and Rosen, 2015). Bone marrow adipose tissues develop around 50%–70% of bone marrow volume in healthy adults (Cawthron and Scheller, 2017). Common conditions associated with osteoporosis including aging, menopause, and glucocorticoid therapy show increased marrow adiposity indicating

the relation between bone marrow fat and osteoporosis (Gallagher et al., 1979; Kohles et al., 1996). However, the nutritional relationship between bone mass, bone marrow fat, and white adipose tissue is much more complex and incompletely understood.

Dietary fats can influence bone health by affecting intestinal calcium absorption, and possibly renal calcium excretion (Corwin, 2003). Several studies have shown the importance of individual fatty acids on enterocyte membrane dynamics, vitamin D activity, and prostaglandin formation, which can have important effects on intestinal calcium absorption as well as urinary calcium excretion. The proper quantities of dietary fat show benefits on calcium absorption, while large amounts can increase intestinal and urinary calcium excretion. Hormones are critical to bone turnover, especially growth hormone, which is involved in the regulation of IGF-1 and bone formation (Corwin, 2003). Studies have found that secretion of growth hormones is inhibited by increases in serum free fatty acids (Lanzi et al., 1999; van Dam et al., 2000). In addition to serum lipids, dietary lipids can also influence growth hormones. Previous reports also showed that calcitonin level increased when high-fat diet was consumed (Defetos et al., 1989), while PTH did not change (Sanderson et al., 1997). Moreover, dietary fat could also affect bone remodeling by exacerbating the uncoupling of bone resorption and formation. Osteoblasts are derived from mesenchymal stem cells, which are also the progenitor of several other different cell types including adipocytes (Dempster and Raisz, 2015). Several studies indicated that when the differentiation process is directed to adipocyte formation, osteoblast formation might be compromised (Nuttall and Gimble, 2000; Nuttall et al., 1998). Fatty acids and their oxidation products serve as natural ligands for peroxisome proliferator-activated receptors (PPARs), the important nuclear transcription factor involved in adipocyte differentiation (Kliwer et al., 1997; Nagy et al., 1998), and an inhibitor of osteoblast differentiation.

Although the influence of dietary fat on bone has been rarely studied, evidence is accumulating that dietary lipids play an important role on bone health. Epidemiological data indicate that high-fat diets, especially those rich in saturated fatty acids, may contribute to reduced bone density and increased fracture risk, in both elder and younger people (Corwin, 2003). Although large amounts of fat may, especially saturated fatty acids (Corwin et al., 2006), have negative effects on bone health, fats composed of other fatty acids may have positive effects. Recent research highlights the role of polyunsaturated fatty acids (PUFAs) in inflammatory regulation of bone remodeling via cellular pathways (Mangano et al., 2013). Treatment with docosahexaenoic acid (DHA, n-3 FA) promotes proliferation of osteoblasts due to its binding affinity for peroxisome proliferator active receptor gamma (PPAR $\gamma$ ), which is a transcription factor with negative effects on bone homeostasis (Maurin et al., 2005; Wan, 2010). PUFA may also affect bone through attenuation of pro-inflammatory cytokines (LeBlanc et al., 2008), increase of nitric oxide production (Rahman et al., 2009), and promotion of osteoblastic differentiation by stimulating production of IGF-1 and PTH (Shen et al., 2006; Watkins et al., 2003). But the role of dietary PUFAs on bone turnover is controversial. Several studies showed protective associations with arachidonic acid and alpha-linolenic acid (Farina et al., 2011, 2012), while others showed no association (Orchard et al., 2010; Virtanen et al., 2010). Thus, more research works need to be conducted to confirm the effects of PUFA on bone health.

### Vitamins and Bone Health

Vitamin D, the sunshine vitamin, is well recognized for its significance in the development and maintenance of bone health throughout life (Holick, 2015). Vitamin D deficiency not only causes rickets in children and osteomalacia in adults, but also exacerbates osteoporosis including risk of bone fracture (Holick, 2012). The major source of vitamin D for children and adults is from sun exposure. Without proper solar ultraviolet B radiation, 1,25-dihydroxyvitamin D [1,25(OH) $_2$ D], the active form of vitamin D, cannot be formed. 1,25(OH) $_2$ D interacts with its vitamin D receptor in the intestine, which helps to maintain both serum calcium and phosphate concentrations (Holick, 2012, 2015). Thus, when dietary calcium is inadequate to satisfy the body's requirement for calcium, vitamin D becomes a catabolic hormone that mobilizes calcium stores from the skeleton and leads to bone loss (Holick, 2012). Meanwhile, vitamin D interacts with the vitamin D receptor in mature osteoblasts and induces the expression of alkaline phosphatase, osteocalcin, and RANKL (Khosla, 2001). There are very few foods that naturally contain vitamin D, including oily fish like mackerel, eel, and salmon, cod liver oil, sun- and UV-exposed mushrooms, and egg yolks (Holick, 2015). Several products have been produced to contain vitamin D, such as fortified dairy, fortified juice, and fortified breakfast cereals (Calvo et al., 2004). However, sensible sun exposure in combination with vitamin D supplementation is encouraged to prevent vitamin D deficiency.

Although calcium and vitamin D have been most widely studied as the essential nutrients in bone physiology, other vitamins appear to play a role in bone health as well. In 1998, Melhus et al. (1998) reported that greater intake of vitamin A is associated with reduced bone density and increased risk of hip fractures. Other studies also showed that excessive level of retinol intake might be associated with compromised bone health, which can lead to different types of bone abnormalities (Ahmadiéh and Arabi, 2011). But experiments also pointed out that insufficient level of retinol intake or vitamin A deficiency decreases bone mineral content and results in bone health problem as well (Ahmadiéh and Arabi, 2011; Baybutt et al., 2011). Thus, until additional evidence is available, it is still important to ensure sufficient vitamin A supplementation, especially in children.

Another potentially modifiable risk factor for osteoporotic fracture is the elevated homocysteine (Hcy) level. Individuals with high Hcy levels exhibit reduced bone mineral density, alteration in microarchitecture, and therefore lead to the increased risk of fracture (Fratoni and Brandi, 2015). The B vitamins serve as cofactors or substrates for the enzymes involved in Hcy metabolism (Dai and Koh, 2015; Fratoni and Brandi, 2015). Animal studies have shown that a deficiency in folic acid and vitamin B $_6$  and B $_{12}$  can lead to increased levels of Hcy and eventually cause osteoporosis (Fratoni and Brandi, 2015).

Ascorbic acid, more commonly known as vitamin C, is an essential vitamin required for the formation of stable collagen, which is important for bone formation (Aghajanian et al., 2015). Moreover, as an important antioxidant, it is not only involved in the regulation of development and function of bone cells (Aghajanian et al., 2015), but can limit bone resorption induced by oxidative

stress (Hart et al., 2015). Human trials also confirmed that high dietary intake and supplementation with vitamin C reduced the risk of hip fractures in postmenopausal women (Pasco et al., 2006). Same as vitamin C, vitamin E has also gained increasing scientific interest recently in bone health because of its high antioxidative activity (Mohamed et al., 2012). Vitamin E supplementation is able to protect bones from oxidative damage and maintain bone matrix (Feresin et al., 2013). In the ovariectomized rat model, vitamin E showed improvement of the bone microarchitecture, and less bone calcium loss (Norazlina et al., 2007). Additionally, recent studies also claimed the importance of vitamin K in age-related bone loss (Shea and Booth, 2015). This is mainly through five vitamin K-dependent proteins: osteocalcin, matrix gla protein, growth-arrest-specific gene 6 protein (Gas6), protein S, and periostin (Vermeer and Knapen, 2012). Many observational studies have demonstrated that poor vitamin K status is associated with low bone mineral density and increased fracture risk in older adults (Koshihara et al., 2003; Shah et al., 2014). But Booth et al. (2008) indicated that vitamin K supplementation did not confer any additional benefit for bone health when taken with recommended amount of calcium and vitamin D, suggesting that vitamin K might need to be accompanied by other nutrients to show positive effects on bone health.

## Lifestyle and Supplements

Understanding the role of nutrients, food components, and diet on bone health is important as a means available to individuals to build and maintain peak bone mass within their genetic potential. Smoking and alcohol consumption are two lifestyle factors that have been recognized as significant contributors to reduced bone mass and increased fracture risk (Sahni and Kiel, 2015). Hermann et al. (2010) studied the bone density of premenopausal smoking women and reported the negative effect of smoke on bone health. Baheiraei et al. (2005) investigated the bone mineral density and cigarette smoking among Iranian women in Australia as well, and confirmed that smoking weakens bone strength. Although the mechanism is still unclear, there are several research works that have investigated the direct and indirect effects of smoking on skeletal health and fracture risk. Smoking directly affects osteogenesis including alteration in the RANK-RANKL-OPG system, collagen metabolism, and bone angiogenesis. Meanwhile, smoking has indirect effects on bone by decreasing intestinal calcium absorption, dysregulation in sex hormone production and metabolism, alterations in metabolism of adrenal cortical and gonadal hormones as well as calciotropic hormones such as 25-hydroxy-vitamin D and PTH. The role of alcohol on skeletal health was not as well studied as smoking, but the direct effects of alcohol on bone and mineral metabolism have been described in both rats and humans (Sahni and Kiel, 2015). Chronic ethanol administration to growing rats was attended by decreased bone density and microarchitecture (Baran et al., 1980). Prabhakaran et al. (2014) studied the bone mineral metabolism and bone mineral density in alcohol related chronic pancreatitis patients and found majority of patients had low bone mineral density.

A wealth of animal and human data provides evidence for the relationship between physical activity and bone health at all ages. Although the goal of physical exercise is not always the same at different life stages, an exercise prescription is important for the prevention and treatment of osteoporosis at all ages. The goal of physical activity in relation to bone health in youth is to maximize peak bone mass, which is attained at various sites by age 16–26 years in most studies (Vuori, 1996), in order to potentially reduce the burden and delay the onset of osteoporotic fracture in adults (Singh, 2015). An initial emphasis on weight-bearing aerobic and high-impact activities in youth, shifting toward resistive loading and balance-enhancing exercise in old age, appears to address optimally the needs and capacities of the musculoskeletal system throughout the lifespan (Singh, 2015). Thus, a lifestyle including nonsmoking, a high physical activity level, and a high body weight reduces bone loss and fracture risk in both sexes, with increasing effect from peak bone mass to old age (Wilsgaard et al., 2009).

The use of dietary supplements or nutraceuticals is common and exceeds 50% of US adults with higher rates in individuals that suffer from chronic diseases (Nieves, 2015). Many adults resort to the use of supplements and nutraceuticals to improve their bone health. Calcium and vitamin D are the most common supplements to maintain bone health while various other nutrients may also provide benefits to the skeleton as discussed in **Nutrients and Bone Health** section. Although there are no clear or consistent results for the relationship between skeletal health and nutritional intake of protein, magnesium, phosphorus, various antioxidants, flavonoids, carotenoids, omega-3 fatty acids, and various vitamins, it is important for adults to consume adequate amounts of these nutrients in order to maintain and promote musculoskeletal health.

## Summary

Bone health is critically important to the overall health, vitality and quality of life; however, public awareness of bone health management remains low. Despite the significance of genetic factor, daily diet and nutrients play more important role in maintain skeletal health because it is a modifiable condition. Calcium and vitamin D play a clear role in bone health; it is important to have a well-balanced diet that is rich in calcium and vitamins. Meanwhile, proper intakes of protein, fat, mineral and various micronutrients are also crucial for bone strength. Although a great amount of supplementation and nutraceuticals are applied, the first choice is still to consume the nutrients from foods.

ARA arachidonic acid  
BSTR batch stirred tank reactor(s)  
C6:0 caproic acid  
C8:0 caprylic acid  
C10:0 capric acid  
C12:0 lauric acid  
C18:0 stearic acid  
CB cocoa butter  
CBE cocoa butter equivalent(s)  
CLA conjugated linoleic acid  
CPL *Carica papaya* lipase  
DAG(s) diacylglycerol(s)  
DHA docosahexaenoic acid  
EPA eicosapentaenoic acid  
FA(s) fatty acid(s)  
FBR fluidized-bed reactor(s)  
FFA(s) free fatty acid(s)  
GLA gamma-linolenic acid  
HMFS human milk fat substitute(s)  
L long-chain fatty acid (C14–C24)  
LCTAG(s) long-chain triacylglycerol(s)  
Lipozyme RM IM commercial immobilized *Rhizomucor miehei* sn-1,3 regioselective lipase from Novozymes<sup>®</sup> A/S, Bagsvaerd, Denmark.  
Lipozyme TL IM commercial immobilized *Thermomyces lanuginosa* sn-1,3 regioselective lipase from Novozymes<sup>®</sup> A/S, Bagsvaerd, Denmark.  
Lyso-PL(s) lysophospholipid(s)  
M medium-chain fatty acid (C6–C12)  
MAG(s) monoacylglycerol(s)  
MCTAG(s) medium-chain triacylglycerol(s)  
MLM triacylglycerol presenting a medium-chain fatty acid at positions sn-1 and sn-3 and a long-chain fatty acid at position sn-2  
Novozym 435 commercial immobilized *Candida antarctica* lipase from Novozymes<sup>®</sup> A/S, Bagsvaerd, Denmark.  
OPO 1,3-dioleoyl-2-palmitoyl-glycerol  
PA palmitic acid  
PBR packed-bed reactor(s)  
PC phosphatidylcholine  
PL(s) phospholipid(s)  
PLip phospholipase(s)  
POP 1,3-dipalmitoyl-2-oleoyl-glycerol  
POS 1-palmitoyl-2-oleoyl-3-stearoyl-rac-glycerol  
PPP tripalmitin  
PUFA polyunsaturated fatty acid(s)  
ROL *Rhizopus oryzae* lipase  
S short-chain fatty acid  
SFA saturated fatty acid(s)  
SL(s) structured lipid(s)

SPhenL(s) structured phenol lipid(s)  
 SPL(s) structured phospholipid(s)  
 StOSt 1,3-distearoyl-2-oleoyl-glycerol  
 TAG(s) triacylglycerol(s)

## Definition of Structured Lipids and Principal Types

Formulating foods for health, i.e. *functional foods*, having physiologically-active components to provide a health benefit beyond nutrition, enhancing both physical and mental health and well-being, is one of the top trends in the food industry (Hasler, 2000). In the field of oils and fats, these novel products are called Structured Lipids (SLs) or “Tailor-made” fats.

The SLs are modified lipids (or fats and oils) that do not exist in nature but present improved technological, functional and/or pharmaceutical properties. The SLs are currently defined as triacylglycerols (TAGs) or phospholipids (PLs) that have been (i) modified by the incorporation of new fatty acids (FAs), (ii) restructured to change the positions of FA or the FA profile, from the natural state, or (iii) synthesized to yield novel TAG (or phospholipids), either chemically or enzymatically (Osborn and Akoh, 2002).

Among the SLs obtained from TAG restructuring, the most important examples are: (i) low-calorie TAGs, (ii) human milk fat substitutes (HMFS), (iii) cocoa butter equivalents (CBE), (iv) TAGs rich in omega-3 polyunsaturated fatty acids (omega-3 PUFA), conjugated linoleic acid (CLA), gamma-linolenic acid (GLA) or in other interesting fatty acids or (v) *trans*-free plastic fats. The structurally modified phospholipids are usually enriched in specific FAs with health benefits (Lemaître-Delaunay et al., 1999).

In the last years, the definition of SLs has been enlarged to other modified lipids with nutritional or pharmaceutical applications, such as partial acylglycerols (monoacylglycerols and diacylglycerols) and structured phenolic lipids (Jala et al., 2012; Kim and Akoh, 2015). The structured phenol lipids (SPhenLs) are esters of a phenol acid or its ester with TAGs with antioxidant, anticarcinogenic, anti-inflammatory, anti-Alzheimer's disease effects and are potential UVA and UVB absorbing ingredients in cosmetics, due to the presence of phenolic acid (Jala et al., 2012).

These different types of SLs and respective properties have been described in several reviews (Willis et al., 1998; Gunstone, 1999; Osborn and Akoh, 2002; Gupta et al., 2003; Sakurai and Pokorný, 2003; Senanayake and Shahidi, 2005; Shahidi, 2006; Ferreira-Dias, 2010; Jala et al., 2012; Ferreira-Dias et al., 2013; Ferreira-Dias and Tecelão, 2014; Kim and Akoh, 2015).

## Biocatalysts Used for Structured Lipids Production

Some types of SLs (e.g. *trans*-free plastic fats) can be obtained using chemical catalysts, under high temperatures (higher than 100 °C). Since chemical catalysts are non-selective, they catalyze competing reactions and they act at random towards the acyl-positions in TAGs. Therefore, the yields are low, and the required products must be purified to remove side-products.

In the Food Industry, the replacement of inorganic catalysts by the enzymatic route has great benefits. SLs can be produced enzymatically using mainly lipases (EC 3.1.1.3., triacylglycerol acyl-hydrolase). Lipases catalyze the hydrolysis of esters at lipid/water interfaces, but when in organic media at low water activity, they can also catalyze esterification and interesterification reactions (Kazlauskas and Bornscheuer, 1998). The use of lipases as biocatalysts for the production of SLs has recognized advantages over the classical chemical catalysts, namely: (i) lipases act under milder conditions (temperature < 70 °C, atmospheric pressure), (ii) they present high selectivity (regio-, stereo-, typo-, and substrate selectivity), leading to a decrease in side products formation and to an easy product recovery and purification, (iii) the number of unit operations is smaller and (iv) the products can be labelled as “natural” since they result from a natural process. Also, (v) lipases are enzymes that do not need co-factors.

Lipases from microbial, plant or animal origin can be used as biocatalysts. Some lipases do not exhibit regioselectivity and they act at random in the acyl residues of TAGs (*sn*-1,2 or *sn*-3) like the chemical catalyst but under softer conditions (near-room temperature and normal pressure). The *sn*-1,3 regioselective lipases can only act at positions *sn*-1,3 of TAGs. Thus, the original fatty acids in the internal position (*sn*-2) of the acylglycerols are preserved, which is nutritionally desirable and not possible to attain by inorganic catalysis (Michalski et al., 2013). The use of this type of lipases is mandatory for the synthesis of SLs where the original FAs at *sn*-2 position must be maintained.

In SLs production, immobilized lipases have been used to lower the costs with the biocatalyst. These immobilized lipases in solid supports must present both high catalytic activity and operational stability, which allows using them in continuous bioreactors or reusing in consecutive batch reactions. However, the commercial immobilized lipases from microbial sources, which have been extensively used for SLs production, are expensive, limiting the economic viability of some processes and products (e.g. commodity fats for margarine manufacture).

Lipases can also be used as a catalyst for the synthesis of structured phospholipids, by acting on acyl ester bonds of the phospholipids, and structured phenol lipids.

Phospholipases A1 (EC 3.1.1.32) and A2 (EC 3.1.1.4) are enzymes, which specifically act on the first and second bond of phospholipids and can also be used as catalysts for the production of structured phospholipids (Kim and Akoh, 2015).

The search for alternative non-commercial enzymes and/or cheap immobilization supports and immobilization techniques, are routes to be explored to reduce production costs related with the biocatalyst. Plant lipases are interesting biocatalysts to explore because they can be obtained at lower cost, they are readily available, and present wide versatility and stability in organic media. Latexes with lipase activity obtained from *Carica papaya* and *Carica pentagona* (both tropical and subtropical plants) and *Euphorbia characias*, a wild plant growing in the Mediterranean area, are examples of plant biocatalysts (Villeneuve, 2003).

The cost of immobilization supports can also be reduced if agro-forestry and inert industrial wastes are used as immobilization supports.

## Reaction Systems for SLs Production

### Reactions

The most used reactions to synthesize SLs are as follows: acidolysis, interesterification (ester interchange), transesterification (alcoholysis) or direct esterification.

**Acidolysis:** is a reaction between an ester (a single TAG, oil or fat or phospholipid) and a free fatty acid (FFA), which can be compared with hydrolysis or alcoholysis, since the acid has a similar role of water or alcohol, respectively. This reaction is currently used to produce SLs modified in their FA composition, catalyzed by a *sn*-1,3-specific lipase, in non-aqueous media (Fig. 1).

**Intesterification (ester interchange):** this reaction consists of a redistribution of the fatty acid moieties present in a TAG over its glycerol moieties. The interesterification of a blend of different TAGs will originate a mixture with novel TAG profile (Fig. 2).

**Transesterification (alcoholysis):** it consists of the reaction of an alcohol and a carboxylic acid ester to form a different carboxylic acid ester, i.e., one ester is transformed into another ester. When methanol, ethanol or glycerol are the alcohols used, this reaction is currently called as methanolysis, ethanolysis and glycerolysis, respectively.

**Esterification:** it is the general name for a chemical reaction in which an alcohol and an acid react to form an ester, as the reaction product, and water.

### Reaction Mechanisms

The mechanisms of lipase-catalyzed acidolysis, alcoholysis and interesterification involve hydrolysis of ester bonds in TAGs followed by re-esterification (Xu, 2000). Thus, the optimization of interesterification reactions results from a balance between the rates of hydrolytic and esterification reactions. Enzymatic interesterification is a reversible reaction and equilibrium will be eventually reached. The product yield under reaction equilibrium is decided by the substrate ratio. Even when *sn*-1,3 regioselective lipases are used, the undesirable and unavoidable side reaction of acyl migration will occur, with the formation of undesirable TAG products (Kim and Akoh, 2005). Thus, acyl migration must be minimized mainly by controlling the following parameters: reaction temperature, biocatalyst load, type of immobilization support, water content and water activity, solvent type and reaction system (Xu, 2003).

**Figure 1** Schematic acidolysis of a long-chain TAG (LLL) with medium-chain (M) fatty acids catalyzed by a *sn*-1,3 regioselective lipase (the L at position *sn*-2 is maintained).

**Figure 2** Schematic interesterification (ester interchange) between TAGs with different fatty acid residues (A, ...F) catalyzed by a *sn*-1,3 regioselective lipase (the FAs at position *sn*-2 are maintained).

### Reaction Medium Composition

Currently, the production of SLs is carried out either in presence of an organic solvent or in solvent-free media. In these media, water must be present only in small amounts needed to maintain the catalytic activity of the biocatalyst but not in higher levels, to avoid lipid hydrolysis.

When fats of high melting point are used, an organic solvent can be used to dissolve them and, therefore, the reaction can take place at near-room temperature (saving-energy). Also, the use of an organic solvent immiscible with water facilitates the extraction and recovery of the final hydrophobic products (SLs) and promotes the balance of the reaction towards the desired direction (synthesis of SLs). However, the use of an organic solvent will increase (i) the complexity of the reaction medium, (ii) the operation costs and (iii) product recovery and purification. Also, the solvent used must be biocompatible (Laane et al., 1985) and food-grade.

As alternative, "solvent-free media" consist only of the substrates involved in the reaction. When these substrates are liquid at room temperature, lipases from mesophilic organisms can be used as catalysts. Conversely, when high melting point fats are used, the reaction must proceed at a temperature higher than that of the melting point of these substrates and thermostable biocatalysts are needed (Paula et al., 2015). Solvent-free media is a green option for SLs production systems, although a higher reaction temperature is required in some situations.

### Bioreactors

The synthesis of SLs by immobilized enzymes in solid carriers can be performed in batch or in continuous bioreactors, either in the presence of an organic solvent or in solvent-free media. At laboratory-scale, batch stirred tank reactors (BSTR) have been currently used. BSTR can be a good option if the support particles are not damaged by shear forces. This configuration is adequate to situations of substrate inhibition.

However, for process implementation in continuous mode, packed (PBR) or fluidized-bed (FBR) tubular bioreactors are preferred to completely-stirred tank reactors. Continuous PBR are the most adequate reactors to repress acyl-migration, due to shorter residence times needed (Xu et al., 1998; Xu, 2003). Fluidized-bed reactors allows for high mass transfer rates and low shear stress for the immobilized biocatalyst particles (Osório et al., 2005, 2006; Paula et al., 2015).

### SLs Modified in Their FA Composition: Characterization, Health Benefits and Production

The synthesis of this type of SLs is usually performed by acidolysis reaction between an ester (a single TAG, oil or fat or phospholipid) and a free fatty acid, catalyzed by a *sn*-1,3-regioselective lipase, in non-aqueous media. These SLs can also be obtained by ester-interchange between a single TAG, oil or fat and fatty acid alkyl esters containing the desired FA to be incorporated in the SLs.

#### Human Milk Fat Substitutes

The TAGs from Human Milk Fat (HMF) have a USU structure, *i.e.*, unsaturated fatty acids, U, at the external positions of the glycerol backbone, namely oleic acid, and saturated FAs (S) at the *sn*-2 position, predominantly palmitic acid. The 1,3-dioleoyl-2-palmitoyl-glycerol (OPO) is the major TAG in human milk fat. This structure is crucial for the efficient absorption of palmitic acid as mono-acylpalmitate. In infant formula, the use of TAGs from vegetable oils and cow's milk, both with a SUS structure, may lead to the formation of insoluble calcium soaps with saturated fatty acids released by the action of the *sn*-1,3 regioselective pancreatic lipase. This results in a deficient absorption of calcium and fatty acids by the infants (López-López et al., 2001). Kennedy et al. (1999) compared bone matrix development in breast-fed infants and in infants fed with standard formula or with a formula containing a SL with 50% of *sn*-2 palmitate (*sn*-2 formula). After 12 weeks, infants receiving the high *sn*-2 formula had a bone matrix development similar to the ones fed with human milk, and significantly higher than the ones fed with the standard formula. Moreover, infants fed with SL formula presented softer stools with a lower concentration of soap fatty acids.

The synthesis of HMF substitutes (HMFS) can be attained by acidolysis or interesterification with ethyl esters using *sn*-1,3 regioselective lipases as catalysts. Both reactions require the use of a TAG source rich in palmitic acid at the *sn*-2 position, namely high purity tripalmitin, palm stearin, palm oil, fractionated palm stearin, butterfat or lard. The use of tripalmitin has been restricted to lab-scale due to its high-cost and high melting point. Also, the use of lard may be limited due to ethical and religious issues. OPO is the target TAG in the synthesis of human milk fat substitutes.

In the acidolysis reaction, wide sources of FFA have been used, either as: (i) single mono- or polyunsaturated FA (namely oleic acid and DHA), (ii) blends from different vegetable oils (e.g. olive oil, rapeseed oil, sunflower oil, hazelnut oil), or (iii) sources of omega-3 PUFA (such as fish oils and, most recently, microalgae oil) (Soumanou et al., 2013; Ferreira-Dias and Tecelão, 2014).

In the interesterification reaction, blends of vegetable oils rich in long chain FA or methyl or ethyl esters, namely of oleic acid, have been used as acyl donor.

Also, multistep processes have been implemented to attain higher yields of TAGs resembling HMF, namely, a two-step process of an alcoholysis reaction followed by esterification (Soumanou et al., 2013).

Both acidolysis and interesterification reactions can be performed batchwise or in continuous mode (usually using packed-bed reactors) either in solvent or in solvent-free media.

The use of solvent-free media for HMFS production is preferred from economical and food safety perspectives. In solvent-free media, the use of thermostable lipases is required due to the high melting point of fats used as palmitic acid source, namely, tripalmitin.

Nowadays, commercial HMFS have been produced for incorporation in infant formula. "Betapol", developed by IOI Loders Croklaan (the Netherlands), is prepared by enzymatic acidolysis of fractionated palm oil with fatty acids from high-oleic sunflower oil. "InFat", sold by Advanced Lipids, is a structured TAG with a total palmitic acid content of at most 38% of the total fatty acid and a *sn*-2 position content of at least 60% of palmitic acid.

**Table 1** presents some examples of recently published studies on lipase-catalyzed HMFS production.

### Low Calorie and Dietetic Triacylglycerols

Low calorie and dietetic TAGs present one of the following structures: (i) SLS (short chain FAs at the external positions of glycerol backbone and long chain fatty acid at the *sn*-2 position), MLM (medium chain FAs at the external positions and long chain fatty acid at the *sn*-2 position) and MMM type SL.

MLM type SLs have been extensively studied as food source for people with fat malabsorption and other metabolism problems. The low caloric value of these TAGs (about 5 kcal/g) is due to the fact that medium chain fatty acids are more rapidly metabolized than long chain fatty acids, due to its higher solubility, being transported directly to the liver, thus providing a rapid source of energy.

One of the first uses of these SLs was in enteral (oral tube feeding) and parenteral (intravenous feeding) nutrition, as an alternative to physical mixtures of long-chain and medium-chain triacylglycerols (LCTAGs and MCTAGs). [Chen et al. \(2013\)](#) evaluated the effect of SLs as part of parenteral nutrition in elderly patients with severe sepsis. SLs emulsions proved to be safe, improving protein synthesis and contributing to a better prognosis. Several studies in mice have proved that SLs and physical mixtures with the same FA composition have different metabolic pathways due to the prevalence of PUFA at

**Table 1** Examples of lipase-catalyzed production of human milk fat substitutes (HMFS)

Product type	Reaction	Substrates	Biocatalyst	System type	Operation mode	Reference
HMFS rich in omega-3 PUFAs	Acidolysis	Microalgae TAG rich in PA at <i>sn</i> -2 position + FFA from microalgae oil rich in <i>n</i> -3 PUFA	Novozym 435, Lipozyme 435, Lipozyme TL-IM and Lipozyme RM IM	Solvent-free	Batch	<a href="#">He et al. (2017)</a>

SLS	Acidolysis	Rapeseed oil + C6:0	Lipozyme RM IM	Solvent-free	Zhou et al. (2001)
LSL	Acidolysis	Triacetin + C18:0	Chirazyme L-2	Solvent-free	Yang et al. (2001)

the *sn*-2 position. Faster absorption rates of the SLs were observed when compared to the other types of SLs (Lee et al., 2008; Straarup and Høy, 2000). Also, an increase in inflammatory response was observed in rats fed with SLs as total parenteral nutrition (Lin et al., 2009).

The anti-obesity effect of these SLs has been investigated. Mice fed with SLs gained less weight, had reduced amounts of adipose tissue and lower liver weight, the amount of fat excreted in the faeces increased, total-cholesterol and LDL-cholesterol levels decreased, while HDL-cholesterol levels in plasma increased (Cao et al., 2013; Moreira et al., 2017).

The production of MLM type SL is currently attained through acidolysis reaction between medium chain fatty acids, such as caprylic (C8:0) or capric (C10:0) acids, and different oils as source of long-chain fatty acids (e.g. olive, soybean, avocado, borago, corn and pine nut oils), catalyzed by *sn*-1,3 regioselective lipases.

The interesterification reactions between vegetable oils with long and medium fatty acids have also been performed to obtain a mixture of TAGs containing both M and L fatty acids, that is, MLM, MML, LML and LLM (Lee et al., 2012).

Several examples of this type of SLs obtained by acidolysis or interesterification reactions are presented in Table 2.

Structured lipids with low-calorie values have been commercialized namely SALATRIM (Nabisco, United States), Caprenin and Olestra (both manufactured by Procter and Gambler, United States).

### Cocoa Butter Equivalents

Cocoa butter (CB) is an important ingredient in chocolate and other confectionery industries. It is valued for its unique physico-chemical properties, which is given by its peculiar fatty acid composition and TAG profile. More than 70% of CB TAGs are symmetrical with oleic acid (O) at the *sn*-2 position. The three most important TAGs are 1,3-dipalmitoyl-2-oleoyl-glycerol (POP), 1-palmitoyl-2-oleoyl-3-stearoyl-rac-glycerol (POS), and 1,3-distearoyl-2-oleoyl-glycerol (StOSt) (Xu, 2000; Naik and Kumar, 2014).

Due to the high cost and fluctuations in supply and demand for cocoa butter, the industry is looking for CB alternatives. Cocoa butter equivalents (CBE) are SLs with TAG composition that is similar to cocoa butter and can be produced by (i) acidolysis using *sn*-1,3 regioselective lipases to incorporate palmitic and stearic acids into vegetable oils rich in oleic acid at the *sn*-2 position or by (ii) interesterification of fat blends containing similar fatty acid composition to CB.

Enzymatic modification of low-cost fats and oils have been successfully developed by Unilever and Fuji Oil to produce cocoa butter substitutes at a large scale via lipase-catalyzed reactions (Coleman and Macrae, 1977; Matsuo et al., 1981).

Several studies have been performed to obtain products similar to cocoa butter by (i) interesterification or (ii) acidolysis using commercial immobilized *sn*-1,3 regioselective lipases, such as Lipozyme RM IM and Lipozyme TL IM (Table 3).

**Table 3** Examples of lipase-catalyzed synthesis of cocoa butter equivalents (CBEs)

Product type	Reaction	Substrates	Biocatalyst	System type	Operation mode	Reference
CBE rich in StOst TAGs.	Acidolysis	High-oleic sunflower oil or high stearic high oleic sunflower oil + FAs (stearic acid, palmitic acid, myristic acid, arachidic acid)	Lipozyme RM IM	Solvent-free	Batch	Kadivar et al. (2016)
CBE	Acidolysis	Refined olive oil + mixture of palmitic-stearic acids	Lipozyme IM	<i>n</i> -hexane	Continuous PBR	Mohamed (2015)
CBE rich in POS TAGs	Interesterification	High-oleic sunflower oil + palmitic acids (ethyl palmitate ester) + stearic acids (ethyl stearate ester)	Lipozyme RM IM	Solvent-free	Continuous PBR	Kim et al. (2014)
CBE	Acidolysis	Refined olive pomace oil + with palmitic acid + stearic acid	Lipozyme IM	Solvent ( <i>n</i> -hexane)	Continuous PBR	Ciftci et al. (2009)
CBE	Transesterification	TAGS from <i>Pentadesma butyracea</i> + ethyl palmitate	Lipozyme TLIM	Solvent-free	Batch	Tchobo et al. (2009)
CBE	interesterification (reaction at high pressure)	Lard + tristearin	Lipozyme IM-20	Solvent-free	Batch	Liu et al. (2007)
CBE	interesterification (reaction at high pressure)	Camel hump fat + tristearin	Lipozyme TL IM	Solvent-free	Batch	Shekarchizadeh et al. (2009)

Currently, Fuji Oil holds the world market in the production of CBE by enzymatic synthesis. Other products on the market include Coberine® Cocoa Butter Equivalents developed by IOI Loders Croklaan (<http://europe.ioiloders.com/products/coberine/>).

### Triacylglycerols Rich in Specific Long-Chain Fatty Acids

SLs rich in specific long-chain fatty acids, some of them essential FA, with recognized health benefits, are synthesized for the purpose of obtaining nutraceutical or functional lipids. The most interesting fatty acids used to incorporate in these SLs are: linoleic acid (C18:2, omega-6), alpha-linolenic acid (C18:3, omega-3), arachidonic acid (C20:4; omega-6), eicosapentaenoic acid (EPA, C20:5 omega-3), docosahexaenoic acid (DHA, C22:6, omega-3), gamma-linolenic acid (GLA), and conjugated linoleic acid (CLA) (Ruiz-Rodriguez et al., 2010). SLs enriched in omega-3 polyunsaturated fatty acids (omega-3 PUFA), especially in EPA and DHA, have a great potential due to their benefits in human health, namely the prevention and treatment of heart diseases by increasing high density lipoprotein cholesterol levels in serum, and the reduction of inflammatory conditions (Simopoulos, 1998; Osborn and Akoh, 2002).

The incorporation of PUFA in food products more readily available for consumption than marine fat fish, such as vegetable oils, dressings and margarines, may be an interesting option to human diet.

The production of TAGs rich in specific long-chain fatty acids has been usually carried out by (i) acidolysis, (ii) interesterification of a single TAG, oil or fat with ethyl or methyl esters, or by (iii) direct interesterification, either in organic or in solvent-free media, as reported in several studies (Table 4). In the majority of these studies, commercial immobilized *sn*-1,3 regioselective lipases were used.

Different sources of oils, commercial or natural, were used to prepare these SLs namely: commercial concentrates of triacylglycerols rich in EPA and DHA, perilla and linseed oils, high-stearidonic soybean and echium oils and tuna or sardine oils or their free FA fractions (Table 4).

An example of commercial DHA-rich SLs manufactured by biocatalytic processes is Marinol D-40 from Stepan Lipid Nutrition. Marinol D-40 is a concentrate of natural fish oil with a high content of docosahexaenoic acid (DHA) in glyceride form. Concentration is done by means of an enzymatic process and molecular distillation ([https://www.stepan.com/uploadedFiles/Literature\\_and\\_Downloads/General\\_Lit/Product\\_Line\\_Information/MarinolBrochure.pdf](https://www.stepan.com/uploadedFiles/Literature_and_Downloads/General_Lit/Product_Line_Information/MarinolBrochure.pdf)).

### Structured Phospholipids

The principal reason for phospholipids (PLs) modification is to adapt PLs for specific applications by providing technical or physiological properties that the natural substance does not possess. PLs incorporated into lipoproteins of the blood stream are more efficient carriers than TAGs for PUFAs to several tissues and organs (i.e., brain, liver, lung, heart, etc.), including blood cells such as platelets and erythrocytes (Lemaître-Delaunay et al., 1999; Burri et al., 2012).

**Table 4**     Examples of lipase-catalyzed synthesis of TAGs rich in specific long-chain fatty acids in batch bioreactors

Product type	Reaction	Substrates	Biocatalyst	System type	Reference
Omega-3 FA-rich oil	Direct esterification	sardine oil FAs + Glycerol	Lipozyme IM	Solvent-free	Bispo et al. (2014)
Omega-3 FA-rich oil	Interesterification	Linseed oil + palm stearin	Lipozyme TL IM	Solvent-free	Farfan et al. (2013)
<i>n</i> -3 FA-rich oil	Interesterification	Grape seed oil + perilla oil	Lipozyme TL IM	Solvent-free	Yang et al. (2013)
Conjugated FA-rich oil	Acidolysis	Soybean oil + conjugated linoleic acid ethyl esters	Lipozyme RM IM	Solvent-free	Yang et al. (2012)
SL rich in omega 3 PUFA for table margarines	Interesterification	Palm stearin + Palm Kernel oil + "EPAX 4510 TG"	Lipase/acyltransferase on Accurel MP1000	Solvent -free	Osório et al. (2009)
LLL rich in C18:0	Acidolysis	Rice bran oil + C18:0	Lipozyme RM IM	Solvent ( <i>n</i> -hexane)	Chopra et al. (2008)
TAG rich in CLA	Acidolysis	Rice bran oil + CLA	Lipozyme TL IM	Solvent-free	Alim et al. (2008)
TAG rich in CLA and C:12	Acidolysis	Modified castor oil + C12:0	Lipozyme TL IM	Solvent-free	Villeneuve et al. (2007)
TAG rich in DHA and GLA	Acidolysis	Borage oil (source of GLA) + DHA	<i>Carica papaya</i> latex Novozym 435	Solvent ( <i>n</i> -hexane)	Senanayake and Shahidi (2002)

The molecular structure of PLs can be changed by either enzymatic or chemical means. The enzymatic processes permit the synthesis of new PL compounds for functional applications and human nutrition such as: *sn*-1 lysophospholipids (*sn*-1 Lyso-PLs); *sn*-2 lysophospholipids (*sn*-2 Lyso-PLs); *sn*-1 modified phosphatidylcholine (PC); *sn*-2 modified PC, which have not been possible to obtain by chemical routes.

Lyso-PLs are obtained by partial hydrolysis of the PL molecule with the removal of one fatty acid. When the hydrolysis of PLs is catalyzed by phospholipases A2, *sn*-2 Lyso-PL is obtained; if phospholipases A1 or *sn*-1,3 regioselective lipases are used, the final product is the *sn*-1 Lyso-PL (Guo et al., 2005; Kim and Akoh, 2015). The Lyso-PLs can also be synthesized by alcoholysis, esterification of glycerophosphorylcholine and thermodynamic transacylation of 2-acyllysophospholipids to 1-acyllysophospholipids (Guo et al., 2005).

Enzyme-catalyzed PLs modification to incorporate SFA, medium-chain fatty acids and/or PUFA to improve the absorption of these FAs by the humans has been carried out (Vikbjerg et al., 2007; Kim and Yoon, 2014; Zhao et al. 2014). These modifications have been currently performed, either in organic or in solvent-free media, by (i) acidolysis with FFA or (ii) interesterification between PLs and fatty acid esters (Table 5).

### Production of SLs Modified in the Original FA Position: Characterization, Health Benefits and Production

The production of TAGs modified in the original position of the fatty acids is usually performed by chemical-catalyzed interesterification, to change and improve certain physical properties of fat blends, namely the melting point, solid fat content and crystallization pattern, to obtain adequate fats for the margarine industry. In these SLs, the original fatty acid composition is maintained, and no *trans*-fatty acids are produced, conversely to what happens when the physical properties of fat blends are modified by hydrogenation (Erickson, 1995). The consumption of *trans* fatty acids has been associated with increased risk of coronary heart disease, due to increased low-density lipoprotein (LDL) cholesterol, and reduction in high density lipoprotein (HDL) cholesterol. Recently, the U.S. Food and Drug Administration (FDA) has banned the use of partially hydrogenated oils in processed foods, so the demand for *trans*-free solutions is increasing (<https://www.fda.gov/Food/IngredientsPackagingLabeling/FoodAdditivesIngredients/ucm449162.htm>).

The enzyme-catalyzed production of *trans* acid-free alternatives for margarines and shortenings, together with the incorporation of specific long-chain fatty acids (e.g. omega-3 PUFA) in these products, is an increasing market trend. The use of regioselective lipases as catalysts for the interesterification has the advantages previously presented. If a non-regioselective lipase is used, the final TAG profile is comparable to the product obtained with chemical catalysts; when a *sn*-1,3 regioselective lipase is used, the TAG profile is completely different because the original FA at *sn*-2 position is maintained, which is nutritionally desirable (Pires et al., 2008).

The margarine industry currently uses blends of high-saturated fats (e.g., palm stearin, palm kernel, palm or coconut fats) with polyunsaturated vegetable oils (e.g., canola, sunflower and soybean oils) to obtain plastic fats with intermediate physicochemical characteristics.

Several studies have been carried out to produce low-*trans* or *trans*-free plastic fats by interesterification, either in the presence of organic solvents or in solvent-free media, using commercial immobilized lipases (e.g. Novozym 435, Lipozyme RM IM, Lipozyme TL IM) or non-commercial lipases (e.g. *Candida parapsilosis* lipase/acyltransferase) (Table 6).

**Table 5** Examples of enzymatic synthesis of structurally modified phospholipids in batch bioreactors

Product type	Reaction	Substrates	Biocatalyst	System type	Reference
SPC	Acidolysis	phosphatidylcholine and free medium -chain FAs	Immobilized PLip A1	Solvent-free	Ochoa-Flores et al. (2017)
DHA-rich PC	Acidolysis	PLs and DHA-enriched FAs extracted from <i>Schizochytrium</i> sp	PLip A1	isooctane	Chen et al. (2017)
DHA/EPA-rich PC	Interesterification	PC and DHA/EPA rich ethyl esters	Immobilized PLip A1	Solvent-free	Li et al. (2016)
DHA/EPA-rich PC	Interesterification	Soy phosphatidylcholine + DHA ethyl ester and EPA ethyl ester	Immobilized PLip A1	Solvent-free	Li et al. (2014)
omega-3 FA-rich PC	Acidolysis	Soy phosphatidylcholine + fish oil FAs	Immobilized PLip A1	Solvent-free	Zhao et al. (2014)
MCFA-rich PC	Acidolysis	Phosphatidylcholine + C8:0	PLip A2 (free); <i>Mucor javanicus</i> lipase (free)	Solvent-free	Kim and Yoon (2014)
Lyso-PC	Hydrolysis	Sunflower lecithin	PLip A2	Solvent-free	Cabezas et al. (2011)

**Table 6** Examples of lipase-catalyzed synthesis of TAGs modified in the original position of the fatty acids

Product type	Reaction	Substrates	Biocatalyst	System type	Operation mode	Reference
<i>trans</i> -free SL for shortening	Interesterification	Coix seed oil, fully hydrogenated palm oil and <i>Cinnamomum camphora</i> seed oil	Lipozyme RM IM	Solvent free	Batch	Xu et al. (2018)
<i>trans</i> -free SL for confectionery and bakery products	Interesterification	high oleic sunflower oil + fully hydrogenated soybean oil	Lipozyme TL IM	Solvent free	Batch	Morselli-Ribeiro et al. (2017)
<i>trans</i> -free SL for margarine fats	Interesterification	camellia seed oil, palm stearin and coconut oil	Lipozyme TL IM	Solvent free	Batch	Ruan et al. (2014)
<i>trans</i> -free SL rich in omega 3 PUFA for table margarines	Interesterification (reaction under high pressure)	Palm stearin + Palm kernel oil + "EPAX 4510 TG"	Lipozyme TL IM	Solvent -free	Batch	Osório et al. (2008)
<i>trans</i> -free SL for margarines and shortenings	Interesterification	Palm stearin + Palm kernel oil + sunflower oil	Lipozyme TL IM	Solvent -free	Continuous PBR	Osório et al. (2006)
<i>trans</i> -free SL for margarines and shortenings	Interesterification	Palm stearin + soybean	Novozym 435	Solvent -free	Continuous FBR	Osório et al. (2005)

Commercial examples of SLs, obtained via enzymatic interesterification, include ADM's NovaLipid™ products (naturally stable oils and fats, trait-enhanced oils and fats, margarines and shortenings, and custom blends) (<https://www.adm.com/products-services/food/oils/novalipid>), and Crokvitol™ line of products (Crokvitol™ Stand, Crokvitol™ Allround, Crokvitol™ Vitality) from Lodders Croklaan. They were designed to provide an alternative to hydrogenated palm oil, low-*trans* or *trans*-free plastic fats for industrial margarine for bakery applications, standard table spreads and margarines and for healthy table spreads (<http://europe.ioiloders/products/>).

## Monoacylglycerols and Diacylglycerols

Traditionally, monoacylglycerols (MAGs) and diacylglycerols (DAGs) have been used as important emulsifiers in the food and pharmaceutical industries. However, MAGs and DAGs can also be considered as SLs with recognized health benefits (Taguchi et al., 2000). Partial acylglycerols have a positive effect in the reduction of obesity and of high TAG plasma levels. Also, *sn*-2-MAGs have beneficial effects for human health because they are most readily absorbed through the intestinal mucosa and are used directly for the resynthesis of new TAGs (Michalski et al., 2013). Furthermore, *sn*-2-MAGs are involved in the synthesis and degradation of endocannabinoids, which can regulate appetite, pain sensation, inflammation and lipid metabolism (Blankman et al., 2007; Panikashvili et al., 2006). In a study performed by Eom et al. (2010), the anti-obesity effect of DAGs was tested in

mice. A diet rich in the synthesized DAGs (20% w/w) reduced both body weight gain and plasma biochemical marks of obesity (total cholesterol, triacylglycerol and glucose levels) in these animals, when compared to a diet rich in triacylglycerols (TAGs) (20% w/w).

The industrial production of MAGs and DAGs has been usually carried out by chemical catalysis which requires the use of expensive and toxic solvents. As green alternative, MAGs and DAGs can be produced by lipase-catalyzed glycerolysis of a TAG, fat or oil in non-aqueous media (Ferreira-Dias et al., 2003; Liao et al., 2003). The use of non-selective or of a *sn*-1,3 regioselective lipase as biocatalysts will determine the yield and type of MAGs or DAGs obtained. With a *sn*-1,3 regioselective lipase, *sn*-2-monoacylglycerols (*sn*-2-MAG) or *sn*-1,3-DAGs are obtained; using a non-regioselective lipase, all types of MAG and DAG can be obtained. Partial acylglycerols can also be obtained by lipase-catalyzed esterification of glycerol with FFAs or by incomplete hydrolysis of TAGs.

With respect to DAG production, in late 1990s, specialty commercial SLs were developed with hypotriglyceridemic and anti-obesity effects. Commercial DAG oils such as Japan Enova oil (sold as Healthy Econa™ Cooking Oil) consists of 80% DAGs, being 70% of these DAGs of the *sn*-1,3 form (<https://pgio.info/project/enova-oil/>). In the human body, *sn*-1,3-DAGs are less efficiently utilized in the resynthesis of TAGs for chylomicron formation and secretion compared with typical TAGs. For the preparation of *sn*-1,3-DAGs, recent studies have used glycerolysis of plant oils as well as direct esterification of glycerol with free FAs catalyzed by commercial immobilized lipases (Dhara and Singhal, 2014; Wang et al., 2014; Mangas-Sánchez et al., 2015).

## Final Remarks

Structured lipids are important novel lipids with recognized technological, functional and health benefits. Some of these novel lipids can be synthesized either by chemical or enzyme-catalyzed reactions. However, some of them can only be obtained by enzyme catalysis, which is a green technology and presents great advantages with respect to the conventional inorganic routes. Also, the SLs obtained by reactions catalyzed by *sn*-1,3 regioselective lipases present superior bioactivity than those obtained by inorganic-catalyzed reactions. However, high prices of commercial immobilized lipases have been a constraint to the industrial implementation of some of these processes, such as the production of low-value commodity fats for the Food Industry. The enzyme preparations used must have both high catalytic activity and operational stability to be reused in batch or used in continuous bioreactors to make the process competitive. In addition, the implementation of low-cost sustainable enzymatic processes for SLs synthesis must address the following main issues: the use of solvent-free reaction media, the search for novel low-cost enzymes and the use of natural cheap oils and fats and/or oils extracted from agro-industry by-products, as raw materials to minimize costs.

### Introduction

The brain is a metabolically active and peculiar organ that coordinates every activity of an organism. The brain is always in use, even in the state of sleep. As a result, brain health is important to the overall well-being of the entire organism. It is now an established scientific fact that nutrition plays a significant role in brain health. Diet has both structural and functional effects on the brain with diet quality and adequacy being directly linked to cognitive processes and emotions (Gómez-Pinilla, 2008; Sarris et al., 2015; Jacka et al., 2015; Zamroziewicz et al., 2016).

Available statistics paint a disturbing picture of the problem of neurologic diseases worldwide. The heavy impact of neurologic disorders and cerebrovascular disease is particularly evident in underdeveloped and developing countries (Chin and Vora, 2014; Silberberg et al., 2015). An estimated 795,000 strokes occur annually in the USA alone, which is the equivalent of one new stroke every 40 seconds. Although stroke mortality and morbidity have been decreasing over the past decade in the USA, stroke remains the second leading cause of death worldwide, with over two-thirds of stroke-related deaths occurring in the developing world (Wallin et al., 2015). The incidence of other neurologic diseases like epilepsy, dementia, Parkinsonism, Alzheimer's disease, brain neoplasms and multiple sclerosis is also a cause of worry as their global burden is on the increase and effective and reliable therapeutic remedies are presently unavailable (Wallin et al., 2015; Gaskin et al., 2016).

With increasing adoption of habits that promote poor mental health by many people and the predicted increase in global burden of neurologic diseases worldwide, it is imperative to unravel and adopt new approaches that can effectively address the menace of brain and nervous system disorders in addition to pharmacological based approaches. Lifestyle changes and nutritional medicine are gaining increasing prominence as veritable channels to achieving this goal (Sarris et al., 2015; Carroll, 2017).

Flavonoids are polyphenolic compounds which are widely distributed in the plant kingdom but particularly abundant in fruits, vegetables and teas, and having a broad spectrum of pharmacological properties such as cardiovascular, cerebrovascular and anti-cancer activities (Hoensch and Oertel, 2015; Varzakas et al., 2016; Watson and Preedy, 2010). Flavonoids are increasingly finding applications, not only in prophylaxis and therapy of diseases, but also as nutraceuticals and functional foods for improved health and well-being (Varzakas et al., 2016; Nasri et al., 2014). Physicochemical and pharmacodynamic properties of flavonoids meet demands imposed by the metabolic peculiarities of the brain enabling them to exert salubrious effects on brain and nervous system function through actions such as protection of neurons against injury induced by neurotoxins, suppression of neuroinflammation and excitotoxicity, and the potential to promote memory, learning and cognitive functions (Spencer, 2009; Muralidhara et al., 2015; Diniz et al., 2015).

### Metabolic Peculiarities and Functions of the Brain

The brain is a complex, heterogeneous organ in which many pathways for its input and output are organized in a somatotopic manner. Brain energy metabolism is dynamic, highly regulated and largely governed by moment-to-moment interactions among brain cells that process information from sensory and cognitive activities and to direct functions of the body. Cellular energy demands, consumption of oxygen and glucose, and blood flow are often described as "coupled" because these processes rise and fall together (Dienel, 2014).

### Brain Energy Metabolism

The energy requirement of the brain is high. Although the brain represents only 2% of the total body mass, about 20% of the oxygen and 25% of the glucose consumed by the human body are dedicated to cerebral functions. Maintenance and restoration of ion gradients dissipated by signaling processes such as postsynaptic and action potentials, as well as uptake and recycling of neurotransmitters, are the main processes contributing to the high brain energy needs (Bélanger et al., 2011; Alle et al., 2009). The overall energy use by human brain is estimated to be 21  $\mu\text{mol ATP/g/min}$ . Even during sleep there is only a relatively small decrease in cerebral metabolic rate which may be increased in rapid eye movement (REM) sleep (Clarke and Sokoloff, 1999).

Glucose and oxygen are the major, obligatory brain fuels and must be continuously supplied by blood to maintain brain functions. Glucose is transported into brain cells by specialized carriers and metabolized in the glycolytic, pentose-phosphate shunt, and TCA cycle pathways to generate ATP, which is primarily used for signaling processes. Oxygen is utilized in the brain almost entirely for the oxidation of carbohydrates (Dienel, 2014; McKenna et al., 2012). Glucose is catabolized by interrelated pathways to generate energy and synthesize neurotransmitters, redox compounds to manage oxidative stress, and essential compounds that cannot cross

the blood–brain barrier. Oxidative metabolism generates most of the ATP, but glycolysis is usually disproportionately up-regulated during activation, with release of lactate (Dienel, 2014).

### Lipid Composition of the Brain

The brain is the second most lipid-rich organ in the body after the adipose tissue (Betsholtz, 2015; Moutinho et al., 2016). Lipids represent up to 50% of its dry weight (Woods and Jackson, 2006; Fantini and Yahi, 2015) and up to 80% of the dry weight of myelin. The lipid composition of the whole brain of adult rats expressed in mmol/g of wet weight was estimated to be 89, 69 and 31 for glycerophospholipids, cholesterol, and sphingolipids, respectively (Fantini and Yahi, 2015; Schnaar et al., 2014). Brain lipids are not used for energy storage but as essential building blocks of cell membranes, which are extremely abundant in the brain, particularly in the vastly arborized neurons and astrocytes and in the myelin sheaths wrapped around axons by oligodendrocytes. How the brain builds and maintains this high lipid content has puzzled researchers because any transport of lipids from the blood to the brain has to pass the blood–brain barrier (BBB) which efficiently blocks the passage of lipoproteins and albumin, the main lipid carriers in the blood. However, emerging discoveries are pointing to the importance of transport proteins in lipid build-up in the brain (Betsholtz, 2015).

### The Blood Brain Barrier

The blood–brain barrier (BBB) is a diffusion barrier, which acts as a strict control point for the influx of compounds into the brain. It is a complex, dynamic system that involves biomechanical and biochemical signaling between the vascular system and the brain. Three cellular elements of the brain microvasculature compose the BBB–endothelial cells, astrocyte end-feet, and pericytes (PCs) (Ballabh et al., 2004; Hawkins et al., 2006; Obermeier et al., 2013; Wong et al., 2013). Every constituent cell type makes an indispensable contribution to the BBB's integrity and BBB disruption can cause or contribute to neurological disease (Obermeier et al., 2013). Although the BBB prevents harmful chemicals and bacteria from reaching the brain, it also blocks roughly 95% of medicine delivered orally or intravenously. As a result, doctors who treat patients with neurodegenerative diseases, such as Parkinson's, often have to inject drugs directly into the brain, an invasive approach that requires drilling into the skull. Minor successes are being recorded in getting intravenous drugs across the BBB with the help of ultrasound, in the form of nanoparticles, or other delivery systems but those methods can target only small areas and there are often other limitations such as toxicity (Brouillette, 2016; Yonehara and Roska, 2017; beeline).

### Brain Redox Homeostasis

The brain is more vulnerable to oxidative stress than any other organ. The brain requires higher amount of oxygen to meet metabolic demands compared to other organs. However, it possesses lower antioxidant capacity. The brain also contains a high content of polyunsaturated fatty acids (PUFAs). These factors, make it is very susceptible to free radical-mediated oxidative stress that affects brain health negatively (Kiple and Ornelas, 2000; Edem, 2002). Oxidative stress (OS), caused by the imbalance between the generation and detoxification of reactive oxygen and nitrogen species (ROS/RNS), plays an important role in brain aging, neurodegenerative diseases, and other related adverse conditions, such as ischemia. While ROS/RNS serve as signaling molecules at physiological levels, an excessive amount of these molecules leads to oxidative modification and, therefore, dysfunction of proteins, nucleic acids, and lipids (Salazar et al., 2009) which contribute to diverse pathologies.

The structural and functional complexity of the brain, its high lipid content, cerebral blood flow and oxygen utilization, coupled with the limitation imposed by the BBB makes it especially susceptible to oxidative stress and various dysfunctions which require that potential efficacious prophylactic and therapeutic agents possess suitable pharmacokinetic and pharmacodynamic characteristics. Flavonoids appear to satisfy many of these requirements.

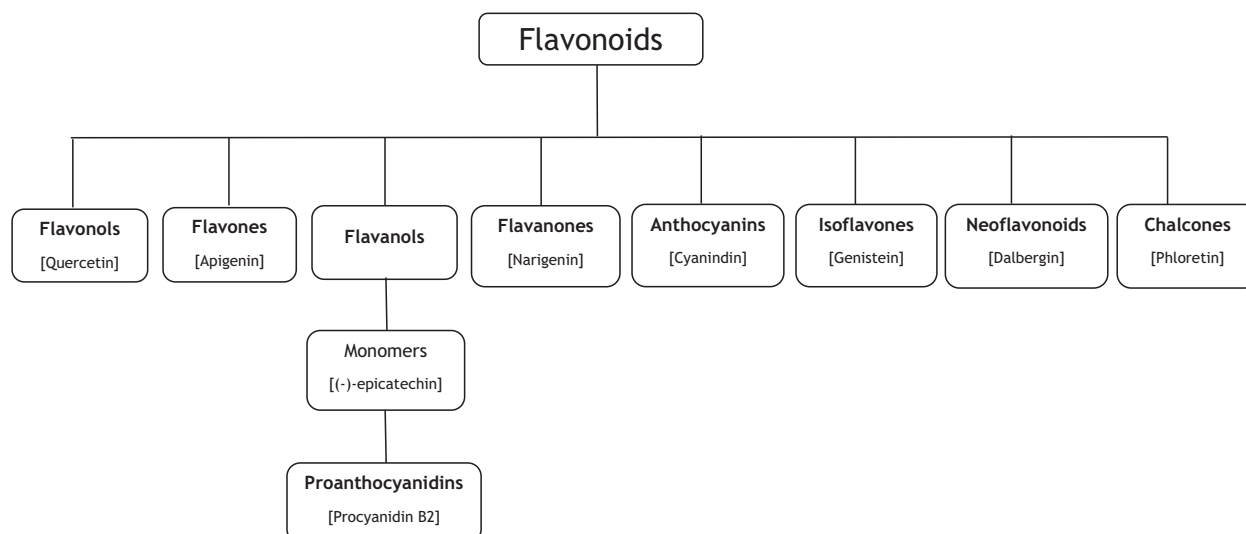

## Flavonoids

### Occurrence, Distribution and Classification

Flavonoids are a diverse group of bioactive phytochemicals with over 10,000 identified individual compounds. However, only very few of them have been investigated in detail (Pollastri and Tattini, 2011; Kozłowska and Szostak-Wegierek, 2014). They are a large group of polyphenolic compounds in plants and constitute one of the largest groups of plant secondary metabolites. Flavonoids are the most common and widely distributed group of plant phenolic compounds, occurring virtually in all plant parts, particularly the photosynthesizing plant cells. They are a major coloring component of flowering plants (Kumar and Pandey, 2013).

Flavonoids are synthesized through the shikimate/phenylpropanoid and acetate/malonate pathways and possess a characteristic C6–C3–C6 skeleton in which two aromatic rings are linked by a three-carbon bridge giving rise to a phenylchromane arrangement (Santos-Buelga and Feliciano, 2017).

Based on the degree of unsaturation, substitution pattern, hydroxylation pattern and variations in the chromane ring (Ring C), different flavonoid classes are distinguished: flavones, flavonols, flavanones, flavan-3-ols, anthocyanins, dihydroflavonols, and iso-flavones, as well as neoflavonoids and the biogenetic intermediate chalconoid forms (Fig. 1). While the vast majority of the

**Figure 1** Flavonoid classes and examples.

flavonoids have their Ring B attached to the C2 position of Ring C, some flavonoids such as isoflavones and neoflavonoids, whose Ring B is connected at the C3 and C4 position of Ring C, respectively, are also found in plants. Chalcones (flavan-opened chain compounds) though lacking the heterocyclic Ring C, or 5-membered C-ring derivatives aurones and auronols, and coumarins are still categorized as members of the flavonoid family (Catarino et al., 2016; Rodriguez-Mateos et al., 2014). In natural sources, flavonoids may occur in free forms (aglycones), as glycosylated or acylated derivatives, and as oligomeric and polymeric structures such as the flavan-3-ol-derived condensed tannins (or proanthocyanidins) (Santos-Buelga and Feliciano, 2017; Tsao, 2010).

Isoflavones are mostly found in the leguminous family of plants. Since beans, particularly soybean, are a major part of the diet in many cultures, isoflavones have a potentially great impact on human health. Genistein and daidzein are the two main isoflavones found in soy along with glycitein, biochanin A and formononetin (Mazur et al., 1998; Wang and Murphy, 1994). Neoflavonoids are not often found in food plants, but dalbergin is the most common and relatively widely distributed neoflavone in the plant kingdom (Garazd et al., 2003). The open-ring chalcones are found in fruits such as apples and hops or beers (Tsao et al., 2003; Zhao et al., 2005).

The position of the benzenoid substituent divides the flavonoid class into flavonoids (2-position), isoflavonoids (3-position) and neoflavonoids (4-position) (Catarino et al., 2016; Rodriguez-Mateos et al., 2014). Flavonols differ from flavanones by hydroxyl group at the 3-position and a C2–C3 double bond. Flavonoids are often hydroxylated in positions 3, 5, 7, 2, 3', 4', and 5'. Methyl ethers and acetyl esters of the alcohol group are known to occur in nature. When glycosides are formed, the glycosidic linkage is normally located in positions 3 or 7 and the carbohydrate can be L-rhamnose, D-glucose, glucorhamnose, galactose, or arabinose (Kumar and Pandey, 2013). Biological activities of these compounds, including antioxidant activity, depend on both the structural difference and the glycosylation patterns (Tsao, 2010).

Flavanols can occur in different states such as monomers, oligomeric or polymeric forms, whereby the latter are referred to proanthocyanidins. Proanthocyanidins represent a unique class of secondary metabolites with high-molecular weight that despite their limited bioavailability, exhibit a wide range of sometimes astonishing antioxidant, vasorelaxant and other bioactivities (Xu et al., 2012; Ebrahimnejad et al., 2014). Generally, proanthocyanidins consist of successive monomeric units linked through carbon–carbon and ether linkages. Proanthocyanidins that comprise only (epi)catechin units, are called procyanidins, and are the most abundant type of proanthocyanidins in plants (Ebrahimnejad et al., 2014).

### Major Dietary Sources of Flavonoid Intake

Flavonoids are an integral part of human and animal diet and constitute the most abundant polyphenols in the human diet (Bawaked et al., 2017). The amounts of antioxidant flavonoids and polyphenols in plant-based foods of the human diet—in particular vegetables, fruits, tea, and wine—are generally much greater than the amounts of other antioxidants in these foods, such as vitamins C and E and carotenoids (Haytowitz et al., 2006; Lotito and Frei, 2006). Fruits and fruit juices are among the best sources of flavonoids in the human diet because of their high content in most fruits and the relatively large serving sizes. Vegetables are also very good sources of flavonoids.

Observational studies have repeatedly suggested a beneficial health effect of flavonoids intake and these class of polyphenolics may contribute more than any other, to the effect of plant-based diets on the risk of chronic diseases and mortality. Knowledge of population-based flavonoid intake pattern is important for the development of dietary recommendations. Additionally, the

identification of dietary patterns related to increased flavonoids consumption is relevant because of the potential impact of these bioactive compounds in disease prevention (Bawaked et al., 2017; Watzl, 2008).

Dietary flavonoid intake and sources vary according to cultural, regional or national diet patterns. Flavonoid sources and intake for different populations and population groups have been documented for some countries in the Americas, Europe, Oceania and Asia but no data currently exists for any African country. In the US, the major dietary sources of flavonoid intake consisted of tea, citrus fruit juices, berries, citrus fruit, wine, and apples (Kim et al., 2016). Among Spanish youth, the major dietary sources of total flavonoids intake were fruits (including fruit juices), vegetables, and chocolate products. Fruits were the major contributors. Vegetables, particularly spinach, onions, artichokes and lettuce as well as Cocoa powder and chocolate were also significant contributors to total flavonoid intake (Bawaked et al., 2017). The American and Spanish studies revealed that flavan-3-ols were the most abundant class of dietary flavonoids in children and adults (Kim et al., 2016). Tea was the major contributor to dietary flavonoid intake among Australians (Johannot and Somerset, 2006). Generally, fruits are the main dietary contributors to flavonoid intake in children, adolescents, and young adults (Bawaked et al., 2017).

In Mediterranean countries, fruits and wine are the principal sources for flavonoid intake in adults (Zamora-Ros et al., 2013). A study found that among Spanish adults, the richest sources of total flavonoid intake were apples (23.0%), red wine (21.0%), unspecified fruit (12.8%), oranges (9.3%), beans (4.9%), pears (4.0%), peaches (3.3%), chocolate (2.6%), and tea (2.2%) (Zamora-Ros et al., 2010). Specific foods that were major contributors (~60%) of flavonoid intake in the UK and Ireland include the following: grapes and oranges (41.6% UK, 34.9% Ireland); beer and wine (8.8% UK, 12.8% Ireland); apples and onions (6.8% UK, 6.5% Ireland); and tea (4.0% UK, 5.3% Ireland) (Beking and Vieira, 2011). In a study among Finnish adults, berries and berry products, including berry-based sweetened drinks, were the main anthocyanidin contributors. Bilberries (*Vaccinium myrtillus*) were the main food source for anthocyanidins. The most important contributors to the intake of flavanols, flavanones, and flavones were fruits (especially apple and citrus fruit) and tea. The main contributors to proanthocyanidins intake were apples, berries, tea, and chocolate (Ovaskainen et al., 2008). Tea was adjudged to be the main contributor to total flavonoid intake among middle aged and elderly Chinese men and women (Zhang et al., 2014). Fruits (35%), non-alcoholic beverages, Cocoa products and alcoholic beverages were estimated to be the main sources of flavonoids in a study on the dietary intake of 337 polyphenols in French adults (Pérez-Jiménez et al., 2011). Legumes were the most important source of dietary flavonoids in a study based on Brazilian National Dietary Survey (Corrêa et al., 2015). In another Brazilian study limited to adults and elderly adults of the state of Sao Paulo, major contributors of intakes of flavonoids were citrus fruits, mainly oranges (17.0%), and beans (14.3%) (Miranda et al., 2016). In a cross-sectional analysis aimed at estimating dietary intakes of all currently known individual polyphenols and total intake per class and subclass in the European Prospective Investigation into Cancer and Nutrition (EPIC) study, the main food sources of flavonoids were fruits in Mediterranean countries (45%), and tea in both non-MED countries (34%) and the UK health-conscious group (64%) (Zamora-Ros et al., 2016).

### Flavonoid-Rich Foods

Knowledge of flavonoid-rich foods is important because such may be unwittingly neglected even where available, in favor of popular ones that may not be as rich in flavonoids. Dietary sources of flavonoid intake in a population may not correlate with consumption of flavonoid-rich foods due to climatic, geographical and cultural factors and this could contribute to reduce scores for total flavonoid intake in such populations. Many commonly consumed foods are excellent sources of flavonoids. Apples, peas, grapes, berries, spinach, broccoli, onions, hot peppers, cherry tomatoes, sweet potato, black tea, coffee, red wine, dark chocolate and cocoa powder are rich sources of the flavanols, quercetin, myricetin and kaempferol. Dark chocolate, red wine, black tea, berries, grapes, pears and apples are additionally rich in epicatechin, catechin and epigallocatechin gallate. The anthocyanidins, cyanidin, malvidin, delphinidin and pelargonidin are relatively abundant in grapes, berries and red wine while the flavanones, naringenin, hesperetin and eriodictyol abound in citrus fruits (Kozłowska and Szostak-Wegierek, 2014; Lotito and Frei, 2006; Maccready et al., 2014; Bertoia et al., 2016; Hooper et al., 2008).

### Flavonoid Biokinetics and the Blood Brain Barrier

The bioavailability of flavonoids is low and this presents a limitation to their applicability as potent bioactive molecules. The limited bioavailability and consequently low plasma concentrations raise questions about the mechanisms by which they attain effective intracellular concentrations in the target tissues. For the brain, an additional impediment is presented by the BBB.

Variation in pathways affecting absorption, distribution, metabolism, and excretion (ADME) of flavonoids possibly influences exposure at the circulatory system, thus modifying disease risk in individuals. These factors include nuclear receptors (NRs), gene transcriptional regulation of drug-metabolizing enzymes (DMEs), and efflux transporters (ETs) (Liu et al., 2017).

All flavonoids are subject to phase I and II metabolism in the small intestine and liver during their absorption. Studies have detected several flavonoids, their aglycone forms and their metabolites such as O-methylated, sulphated, and glucuronidated conjugates in plasma of humans after ingestion of flavonoid-rich foods (Faria et al., 2012). The appearance of flavonoids in plasma provides evidence that these compounds are bioavailable to tissues in the periphery but cannot be used as evidence that they are also present in the brain and CNS (Faria et al., 2012).

The mechanisms of absorption of flavonoids have not been completely elucidated but some highlights could be deduced. Specific trans membrane transporter proteins and diffusion through the lipid portion of the membrane are involved. The

transporters are important in mediating the protective activity of flavonoids (Zibera et al., 2014). An important role has also been proposed for the mucus layer of the small intestine which modified previously held views. According to Gonzalez (Gonzales et al., 2016), hydrophobic flavonoid aglycones that reach the small intestines are unable to penetrate through the mucus layer and are thus pushed to the large intestines via peristalsis to be metabolized (i.e. into smaller phenolic acid derivatives) by intestinal bacteria. However, in the presence of dietary fat and bile, micelles form and serve as carriers of aglycones through the mucus layer. They are then released upon contact with the brush border where passive diffusion is likely to occur through the cells. Soluble flavonoid glycosides on the other hand, are able to penetrate through the mucus layer to reach the epithelium. Upon contact with the brush border,  $\beta$ -glucosidases such as the lactasephlorizin hydrolase (LPH) cleave-off the glucose moiety to release the aglycone, which could then passively diffuse through the cells. Since intestinal cells are unable to produce rhamnosidases, flavonoids that contain rhamnose moieties, such as rutin (quercetin-3-rutinoside) and hesperidin (hesperetin-7-rutinoside), remain intact in the small intestine and are thus pushed to the large intestine, where fermentation by intestinal bacteria occurs or the action of secreted bacterial rhamnosidases releases the aglycone. In the end, the aglycones that were released on the brush borders, or smaller phenolic acid derivatives that were produced after bacterial metabolism both in the small and large intestines, reach the epithelia, where phase I metabolism and phase II metabolism take place. It must be noted however, that while bacteria also exist in the small intestines, the rate of mucosal diffusion and intestinal uptake at that stage occurs rapidly and thus the effect of duodenal bacteria is not as pronounced as in the colon, where the absorption is slower and longer (Gonzales et al., 2016).

With respect to the brain, mounting evidence from several lines or investigations confirm that flavonoids and some of their metabolites are able to traverse the BBB (Faria et al., 2012, 2014; Ishisaka et al., 2011; Jäger and Saaby, 2011; Pogačnik et al., 2016). The major issue regarding the bioavailability of flavonoids to the brain concerns the mechanisms by which flavonoids (conjugated or unconjugated) are transported across the BBB. Lipophilicity-dependent and transporter-mediated uptake are involved but the precise nature and extent of uptake of flavonoids by the CNS are still poorly defined (Faria et al., 2012, 2014).

Several techniques have been employed to increase bioavailability of flavonoids by greatly increasing the aqueous solubility of the flavonoid aglycone. These include incorporation of flavonoids to borneol/methanol eutectic mixtures, micro-emulsions, polyvinylpyrrolidone dispersion, lecithin complexation, cyclodextrin complexation (Thilakarathna and Rupasinghe, 2013) and methylation (Koirala et al., 2016; Wen et al., 2017). Prenylation, while not specifically improving bioavailability, aids flavonoid tissue bioaccumulation by modulating cell uptake/efflux (Terao and Mukai, 2014). The formulation of flavonoid aglycones into nanocrystals has also been reported as an effective way of improving bioavailability (Li et al., 2013). Dietary factors have also been shown to greatly improve the bioavailability of flavonoid aglycones. For instance, it has been shown that dietary fat increases the bioavailability of quercetin aglycones (Azuma et al., 2002; Guo et al., 2013).

In addition, studies have shown that other dietary components may affect the access of flavonoids into the CNS. In a study by Ferri et al.,  $\alpha$ -tocopherol was reported to promote quercetin transport across the BBB (Ferri et al., 2015).

### Extraction Techniques for Flavonoids

Although there are general extraction methods for flavonoids, it is becoming increasingly realized that there is no extraction protocol that suits all types of flavonoids and matrices, and therefore sample preparation and extraction conditions usually need to be optimized depending on the nature of the sample, target analyses, and aim of the study (Santos-Buelga and Feliciano, 2017).

Extensive documentation of conventional and innovative procedures for the extraction of bioactive compounds in general (Houghton and Raman, 2012; Ong, 2004; Sarker et al., 2005; Wang and Weller, 2006; Colegate and Molyneux, 2007; Azmir et al., 2013; Rostagno and Prado, 2013; Mandal et al., 2015; Prado et al., 2015; Brglez Mojzer et al., 2016; Wu et al., 2017) and flavonoids in particular abounds in literature. Only an overview of the extraction techniques for flavonoids is intended in this section. Methods have also been developed for specific subclasses of flavonoids or individual flavonoids some of which are mentioned later on in this chapter. Preparation of samples for extraction may vary depending on the flavonoid-containing matrices involved, i.e. whether samples are solid, liquid, very hard, etc.

Traditionally, extraction of flavonoids from natural products has been carried out through simple direct solvent extraction and this is still the most widely used method. In these solvent-based methods, solvent type is a critical variable that influences the nature and composition of the extracted flavonoids. Due to their possible enzymatic degradation in fresh samples, the use of dry, lyophilized or frozen samples is advisable. To improve extraction efficiency, solid samples are usually pulverized. The choice of solvent is predicated on the type of flavonoid required with less polar flavonoids being extracted with chloroform, dichloromethane, diethyl ether, or ethyl acetate, while flavonoid glycosides and more polar aglycones are extracted with alcohols or alcohol–water mixtures (Marston and Hostettmann, 2005). Acidic, basic or enzymatic hydrolyses are frequently used to remove the sugar moieties from glycosides. The hydrolysis process could be to minimize degradation reactions of glycosides during prolonged extraction and to achieve complete release of aglycones (Stalikas et al., 2010).

Powdered plant material can also be extracted in a Soxhlet apparatus, first with highly non polar solvents, hexane for example, to remove lipids and then with ethyl acetate or ethanol to obtain phenolics. This approach is not suitable for heat-sensitive compounds. A convenient and frequently used procedure is sequential solvent extraction. A first step, with dichloromethane, for example, will extract flavonoid aglycones and less polar material. A subsequent step with an alcohol will extract flavonoid glycosides and polar constituents (Marston and Hostettmann, 2005). Other techniques \*revolve around obtaining a crude extract from samples using aqueous alcohol mixtures (Stobiecki and Kachlicki, 2006) and then fractioning the crude preparation into a series

of solvents which would include one with appropriate polarity to harvest the flavonoids or, the flavonoid fraction could be obtained from the crude extract preparation through procedures including hydrolysis and precipitation. A lot of procedures have been developed to obtain flavonoids and other polyphenols from specific sources (Choudhary et al., 2011; Furer et al., 2015; Kandikattu et al., 2015; Falode et al., n.d; Ajayi et al., 2017; Zhang et al., 2017).

Relatively modern techniques which improve extraction efficiency and yield over the traditional maceration and Soxhlet methods have gained increased prominence in the last couple of decades. These include Pressurized Liquid Extraction, Microwave Assisted Extraction (MAE), Ultrasound Assisted Extraction and Supercritical Fluid Extraction. Additional advantages of these new methods include lower solvent consumption, reduced quantity of starting material, milder conditions of extraction and reduced extraction time.

Other innovative extraction techniques used to extract dietary flavonoids include Pulsed-electric field extraction (PEF) and enzyme assisted extraction (EAE) (Azmir et al., 2013). These methods are often optimized and adapted for targeted extraction of flavonoids from specific sources. In addition, novel extraction methods are commonly developed and have multiplied in recent times.

Following extraction, quantitation, fractionation, purification, separation and detection of the flavonoids are often carried through chromatographic and spectroscopic analyses. In contemporary times, several hyphenated techniques including HPLC-DAD, HPLC/MS/MS, GC-MS, LC-MS, LC-MS/ESI and LC-NMR-MS are used to combine separation and resolution/identification of individual flavonoids from extracts.

## Flavonoids and Brain Health

A basic and prominent characteristic of flavonoids is the possession of strong antioxidant ability shown either directly by scavenging free radicals or, indirectly, by augmenting cellular antioxidant defenses (Ferri et al., 2015). In the face of recurrent failures in the development of clinically effective drugs against neurologic dysfunctions, experimental, clinical and epidemiologic evidences substantiate the cognitive enhancing, neurobehavioral modulating and neuroprotective efficacy of dietary flavonoids. Consumption of flavonoid-rich foods has been linked to reduction in the incidences of neurodegenerative diseases and other neurologic pathologies. It has also been amply shown that even when used as therapeutic interventions, dietary flavonoids still confer neuroprotection against neurologic dysfunctions. These observations support the concept of flavonoids as food for the brain. Flavonoids exert a multiplicity of neuroprotective actions within the brain, including a potential to protect neurons against injury induced by neurotoxins, an ability to suppress neuroinflammation, and the potential to promote memory (Vauzour et al., 2013).

Reports of neuroprotective property of single dietary flavonoid compounds as well as flavonoid-rich/total flavonoid fractions of food and medicinal plants in *in vitro*, *in vivo* and other models of neurologic diseases abound in scientific literature (Vauzour et al., 2008; Hwang et al., 2012; Zeng et al., 2013; Nakayama et al., 2011; Hosseinzadeh et al., 2017; Ren et al., 2016; Choi et al., 2013; Keddy et al., 2012; Dok-Go et al., 2003; Dajas et al., 2003; Jobaliya and Benzeroual, 2011; Farooqui, 2017; Zhu et al., 2007; Nabavi et al., 2016; Sun et al., 2014; Seo et al., 2014; Pu et al., 2007; Spencer and Crozier, 2012; Bei et al., 2009; Solanki et al., 2016; Wang et al., 2017). Variations between pharmacological effects of isolated flavonoids or actions of the same molecules in complex mixtures which may be due to metabolism, bioavailability or final brain concentrations have been observed (Dajas, 2012; Dajas et al., 2015; Zhou et al., 2008). This appears consistent with the notion that the consumption of flavonoid-rich foods throughout life holds the potential to limit neurodegeneration, decrease neuroinflammation, and prevent or reverse age-dependent losses in cognitive performance (Vauzour et al., 2013). It also underpins the fact that while discovering therapeutically efficacious agents is the major goal of neuroprotective drug development, prophylactic approaches based on dietary lifestyle modification should also be emphasized (Akinmoladun et al., 2015a).

In the following paragraphs, some reports revealing the neuroprotective action of individual flavonoids and flavonoid mixtures/extracts are highlighted.

## Neuropharmacology of Some Individual Flavonoid Compounds

Quercetin, a ubiquitous flavonoid present in beverages, food and plants has been shown to have an important role in the prevention of neurodegenerative and cerebrovascular diseases. Quercetin demonstrated neuroprotection in models of cerebral ischemia, Parkinson's disease, Alzheimer's disease, epilepsy and Huntington's disease (Dajas et al., 2015; Chakraborty et al., 2014; Nassiri-Asl et al., 2013a; Sabogal-Guáqueta et al., 2015; Sriraksa et al., 2012; Akinmoladun et al., 2015b; Elumalai and Lakshmi, 2016). Specifically, treatment with 50 mg/kg i. p. quercetin for days showed protective effects in a 3-nitropropionic-induced experimental Huntington's disease in rats (Sriraksa et al., 2012). The same dose, also administered i. p. attenuated pentylentetrazole-induced seizure severity in kindled rats (Akinmoladun et al., 2015b) while 100, 200 and 300 mg/kg of the flavonoid administered orally for 14 days cognitive-enhancing effect in 6-hydroxydopamine-induced PD (Sriraksa et al., 2012), and 20 mg/kg administered i. p. 30 min before ischaemia afforded protection in global ischemia/reperfusion induced brain injury in rats (Nassiri-Asl et al., 2013a). Quercetin, and not caffeine was reported as a major neuroprotective component in coffee (Lee et al., 2016). In neuronal culture, quercetin increases survival against oxidative insults. Antioxidation appears to be a necessary but not sufficient condition for its neuroprotective action. Modulation of intracellular signaling and transcription factors, increasing the expression of antioxidant and pro-survival proteins and modulating inflammation, appear as important for neuronal protection. Quercetin also regulates

the activity of kinases, changing the phosphorylation state of target molecules, resulting in modulation of cellular function and gene expression. Co-treatment with orally administered quercetin at 10 and 20 mg/kg for 45 days ameliorated manganese-induced neurotoxicity through mechanisms associated with restoration of acetyl cholinesterase activity, augmentation of redox status and inhibition of lipid peroxidation in brain of rats (Adedara et al., 2017).

The flavonol, rutin is a vital nutritional component of food stuff that is abundantly found in sources such as passion flower, buckwheat, tea, and apple. It is a common dietary flavonoid that has been much studied by the scientific community. Hundreds of products containing rutin are currently marketed in the USA (Gullón et al., 2017; Ganeshpurkar and Saluja, 2017). Post-treatment of female Sprague-Dawley rats with rutin at 50 and 100 mg/kg, i.p., for three days significantly reduced the levels of reactive oxygen species, malondialdehyde, NLRP3, ASC, caspase-1, IL-1 $\beta$ , IL-18, and tumor necrosis factor- $\alpha$  and improved locomotor recovery in rats with spinal cord injury (Wu et al., 2016). Rutin promoted microglial proliferation and induced microglial polarization to the M2 profile when cells are stimulated with a lipopolysaccharide, which reveals its potential in the treatment or prevention of neurodegenerative disorders (Bispo da Silva et al., 2017). Rutin showed anti-epilepsy potential (Nieoczym et al., 2014; Nassiri-Asl et al., 2013b), protective effect in cerebral ischemia/reperfusion injury, and was able to promote significant recovery of sensor motor loss, which correlated with reduction of neurodegeneration in the periphery of cortical injury (Rodrigues et al., 2013). Post-treatment with rutin at 100 mg/kg, i. p. for 3 weeks also ameliorated the destructive effects of A $\beta$  on memory through increased extracellular signal-regulated protein kinase 1 (ERK1), cAMP response element-binding protein (CREB) and brain-derived neurotrophic factor (BDNF) gene expression in the hippocampus of rats (Moghbelinejad et al., 2014). Rutin (50 mg/kg i. p.) administered 30 min after injury, conferred protection in a rat model of subarachnoid hemorrhage possibly through inhibiting RAGE–NF- $\kappa$ B mediated inflammation signaling pathway (Hao et al., 2016). Supplementation of diets of rats with 0.75% rutin for 20 days was protective against toxicant-induced hippocampal injury (Koda et al., 2009). At 100 mg/kg and 200 mg/kg, rutin afforded protection against acrylamide-induced neurotoxicity (Motamedshariaty et al., 2014). Other neuropharmacological effects attributed to rutin include sedative, anticonvulsant, anti-Alzheimer, analgesic and antidepressant effects (Ganeshpurkar and Saluja, 2017).

Apigenin, found in several dietary plant foods such as parsley, celery, thyme, celeriac, chamomile, onions, lemon balm, and oranges demonstrated potent anti-inflammatory and antioxidant activities in various neurodegenerative diseases and epilepsy. Apigenin at 10 and 20 mg/kg, i.p., post administered to male SD rats was also found to ameliorate oxidative stress and neuronal apoptosis in early brain injury following subarachnoid hemorrhage, which is a serious condition with high rates of mortality and morbidity in the world. In addition, oral pre-treatment with apigenin at 100 mg/kg ameliorated traumatic brain injury in rats (Nabavi et al., 2015a; Kanazawa et al., 2006; van Gijn et al., 2007; Han et al., 2017). Apigenin was potent in increasing the life span, dopamine content, and reducing the oxidative stress as well as apoptosis in transgenic *Drosophila* model of PD (Siddique and Jyoti, 2017). Also, apigenin (10  $\mu$ M) improved neuron formation and strengthened the connections between brain cells, *in vitro*, indicating potential for the treatment of diseases like schizophrenia, depression, Alzheimer's and Parkinson's (Souza et al., 2015a).

The flavone, diosmin is generally utilized as an antioxidant in food supplements and by pharmaceutical companies. It is considered a vascular-protection cure for chronic venous insufficiency and can protect the brain by enhancing the activity of antioxidant enzymes and thus reduce the inflammation induced by cerebral ischemia. Pre-treatment with diosmin showed protective effects against traumatic brain injury-induced memory and long-term potentiation impairment possibly through a decrement in the hippocampal concentration of the pro-inflammatory cytokine, TNF- $\alpha$  (Benavente-García and Castillo, 2008; Silambarasan and Raja, 2012; Liu et al., 2014; Mirshekar et al., 2017). Oral pre-treatment of mice with 50 and 100 mg/kg diosmin for 6 days protected against cerebral ischemia (Liu et al., 2014).

Luteolin (3',4',5,7-tetrahydroxy flavone) is an important flavone, which occurs in several plant species including carrot, broccoli, pepper, thyme, and celery, olive oil, lettuce, chocolate, rooibos tea, pomegranate and cucumber (López-Lázaro, 2009). Luteolin, luteolin containing extracts and combinations of luteolin with other phytochemicals have been reported to have beneficial effects in models of epilepsy, autism spectrum disorders, Alzheimer's disease, Parkinson's disease, traumatic brain injury and multiple sclerosis (Kritas et al., 2013; Tambe et al., 2017; Choi et al., 2014; Nabavi et al., 2015b). A single dose i. p. pre-treatment with 10 and 20 mg/kg luteolin was in an acute model of epilepsy in mice (Liu et al., 2014). Mechanistic insights into the neuropharmacological activities of luteolin were provided in experiments, which showed that luteolin inhibited cytokine expression, nuclear factor kappa B (NF $\kappa$ B) signaling, and TLR4 signalling at micromolar concentrations in immune cells, including mast cells. Luteolin was also shown to attenuate microglial activation and mediate BDNF-like behaviour both *in-vitro* and *in-vivo*. Luteolin also reduced the mRNA expression of numerous genes up regulated in response to exogenous 6-OHDA, including BIM (a pro-apoptotic BH3-only member of the Bcl-2 family, required for initiation of apoptosis induced by endoplasmic reticulum [ER] stress), the p53 target genes, GADD45a and PUMA, and TRB3 (a proapoptotic gene that is upregulated in response to a variety of stresses, including ER stress, nutrient deprivation, and hypoxia). Luteolin can induce unfolded protein response, leading to decreases in phospho-eIF2 $\alpha$ , ATF4, GRP78 and CHOP (which are upregulated in response to ER stress). In addition, luteolin can also inhibit the Keap1-Nrf2-ARE pathway, leading to decreases in the expression of heme oxygenase-1 (HO-1) and glutamate cysteine ligase (GCL) (Nabavi et al., 2015b; Lee et al., 2009; Weng et al., 2015; Patil et al., 2014; Lin et al., 2010; Zhang et al., 2013a). Post-treatment with luteolin (4 mg/kg), injected through the tail vein, reduced infarct area and inhibited neuronal cell death in cerebral ischemia/reperfusion injury in rats (Zhang et al., 2013a).

Chrysin is a hydroxylated flavone derivative mainly found in honey, propolis and many plant species (Nabavi et al., 2015c). Chrysin treatment significantly inhibited the release of nitric oxide (NO) and proinflammatory cytokines such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin-1 $\beta$  (IL-1 $\beta$ ) in lipopolysaccharide (LPS)-stimulated microglia. Additionally, expressions of inducible NO synthase (iNOS) and cyclooxygenase-2 (COX-2) were also significantly inhibited by chrysin. Also,

chrysin was shown to inhibit the activations of c-Jun N-terminal kinase (JNK) and nuclear factor- $\kappa$ B (NF- $\kappa$ B). These observations point to neuroprotective potential in neuropathologies like Alzheimer's and Parkinson's disease, and stroke (Nabavi et al., 2015c; Gresa-Arribas et al., 2010; Ha et al., 2010; Madeira et al., 2015; Yao et al., 2014). Pre-treatment of male mice with 75 mg/kg chrysin administered by oral gavage for 7 days protected against cerebral/ischemia reperfusion injury by ameliorating increase in glial cell numbers and proinflammatory cytokine secretion as well as inhibiting up-regulation of NF- $\kappa$ B, COX-2 and iNOS (Yao et al., 2014). Chrysin or chrysin-rich extracts have demonstrated antioxidant and neurotrophic effects, antidepressant effects, anti parkinsonism, anti-epileptic effect and protective effect in spinal cord injury. These effects are mediated through mechanisms that include modulation of brain-derived neurotrophic factor (BDNF) and nerve growth factor production, increased nuclear factor-erythroid 2-related factor 2 protein expression and transcriptional activity, inhibition of nuclear factor- $\kappa$ B activation and downregulation of inducible nitric oxide synthase expression, and reduced expression of bax, bcl-2 and caspase-3 (Souza et al., 2015b; Filho et al., 2015; Zhang et al., 2015; Singh et al., 2012; Kandhare et al., 2014). Specifically, pre-treatment with chrysin at 1 or 10 mg/kg (p.o.) for 60 days prevented age-related cognitive decline via attenuation of oxidative stress and modulation of BDNF levels in aged mouse brain (Souza et al., 2015b). At 20 mg/kg (p.o.) for 28 days, chrysin showed antidepressant effect in female mice subjected to chronic unpredictable mild stress by up-regulating BDNF and NGF levels and ameliorating oxidative stress (Filho et al., 2015) while at 20 and 40 mg/kg (p.o.) pre-treatment for 28 days, chrysin showed neuroprotection in experimental spinal cord injury in male rats through antioxidant and anti-apoptotic mechanisms (Kandhare et al., 2014).

Hesperidin and its aglycone, hesperetin are two citrus flavonoids with widely reported *in vivo* and *in vitro* neuropharmacological properties. Hesperidin and hesperetin have demonstrated neuroprotective potentials via antioxidant and other mechanisms. The antioxidant activity of Hsd was not limited to radical scavenging activity, but included augmentation of the antioxidant cellular defenses via the ERK/Nrf2 signaling pathway (Elavarasan et al., 2012). Hsd and Hst enhanced learning and memory through elevation of brain-derived neurotrophic factor (BDNF) and other mechanisms. Hesperidin (100 mg/kg, i. p.) administered for 10 days attenuated oxidative stress and neuronal damage caused by global ischemia (Oztanir et al., 2014). Hsd showed antidepressant activities via some mechanisms differing from those of conventional antidepressant drugs. At 0.1, 0.3 and 1 mg/kg (i.p.) for 21 days, hesperidin exerted antidepressant-like effects through decrease in hippocampal NOx and increased BDNF levels in adult male Swiss mice (Donato et al., 2014). Along with other flavanones, they protected PC-12 cells against H<sub>2</sub>O<sub>2</sub>-induced cytotoxicity. They also inhibited amyloid  $\beta$ -induced autophagy and improved glucose utilization in Neuro-2A cells, which suggests potential efficacy against Alzheimer's disease. The two flavonoids also protected neurons from excitotoxic damage in primary cultured rat cortical cells. Rotenone-disrupted mitochondrial membrane potential, increased reactive oxygen species generation, depleted glutathione, enhanced activities of enzymatic antioxidants, up-regulated Bax, cytochrome c, and caspases 3 and 9, and down-regulated Bcl-2 protein expression were attenuated by Hsd indicating its potential application in the treatment of Parkinson's disease. Hsd showed anti-seizure and cognitive-enhancing effects in pentylenetetrazole (PTZ)-induced neurotoxicity, and NO/cGMP pathway and BDNF modulation-dependent anti-depressant effect (Donato et al., 2014; Tamilselvam et al., 2013).

Kaempferol is a natural flavonol, found in fruits vegetables and herbs, including grapes, tomatoes, broccoli, tea, and *Ginkgo biloba* leaves (Shields, 2017). Equimolar kaempferol-3-O-rutinoside (10 mg/kg) and kaempferol 3-O-glucoside (7.5 mg/kg) administered through tail vein injection at the beginning of reperfusion prevented ischemic brain injury and neuroinflammation by inhibition of STAT3 and NF- $\kappa$ B activation. This showed that kaempferol has therapeutic potential in neuroinflammation-related diseases, such as ischemic stroke (Yu et al., 2013). The neuroprotective effect of 50 and 100 mg/kg (p.o.) kaempferol administered to male mice for 14 days in a 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine-induced mouse model of Parkinson's disease has been reported. Kaempferol improved motor coordination, raised striatal dopamine and its metabolite levels, increased SOD and GSH-PX activity, reduced the content of MDA and prevented the loss of TH-positive neurons induced by MPTP (Li and Pu, 2011).

Catechin is present in many dietary products, plants, fruits (such as apples, blueberries, gooseberries, grape seeds, kiwi, strawberries), green tea, red wine, beer, cacao liquor, chocolate, cocoa, etc (Zanwar et al., 2014). Catechins possess pleiotropic neuroprotective actions within the brain and have a potential to protect neurons against injury, an ability to inhibit oxidative stress, and the potential to promote learning, memory, and other cognitive functions. These effects appear to be related to the interactions of catechins with key signaling cascades in the brain, leading to an inhibition of apoptosis and to a promotion of neurogenesis, neuronal survival, and synaptic plasticity. Catechins-elicited increased levels of neurotrophins, namely, the brain-derived neurotrophic factor (BDNF) and antiapoptotic proteins, such as B cell lymphoma-2 (Bcl-2), stimulate synaptic plasticity, neurogenesis, and improved neuronal survival. Pre-treatment of male Wistar rats with 20 mg/kg (p.o.) of catechin hydrate for 21 days protected the brain from damage caused by focal cerebral ischemia by ameliorating redox imbalance and limiting inflammatory response possibly through down regulation of NF- $\kappa$ B expression (Ashafaq et al., 2012). These pleiotropic properties of catechins suggest that green tea can be helpful in delaying the harmful effects of aging in the brain and preventing neurodegenerative diseases (Andrade and Assunção, 2015).

Naringin at 80 mg/kg (p.o.) for two weeks demonstrated neuroprotective effect against 3-Nitropropionic acid (3-NP)-induced neurodegeneration through decreased expressions of pro-apoptotic markers like Bad and Bax and inhibition of 3-NP-induced decrease in Bcl-2 mRNA expression in male Wistar rats (Gopinath et al., 2011). Its aglycone, naringenin at 10, 20 and 50 mg/kg administered by oral gavage to male ICR mice displayed potent antidepressant-like property via the central serotonergic and noradrenergic systems suggesting its therapeutic potential in central nervous system disorders especially depression where monoaminergic systems are involved (Yi et al., 2010).

The citrus flavonoid 3,5,6,7,8,3',4'-heptamethoxyflavone (HMF) showed protective effect on hyperactivity induced by MK-801 in the Y-maze test and open field test suggesting that HMF has the ability to relieve MK-801-induced schizophrenia positive symptom-like behavior (Okuyama et al., 2013).

Fisetin, found in various fruits and vegetables, such as strawberry, apple, persimmon, grape, onion, and cucumber (Khan et al., 2013), is emerging as a potential efficacious agent for Parkinson's and Alzheimer's disease (Nabavi et al., 2016; Patel et al., 2012; Ahmad et al., 2017; Prakash and Sudhandiran, 2015). Fisetin post-administration at 20 mg/kg (i.p.) for two weeks corrected the A $\beta$ 1–42 intracerebroventricular injection-induced cognitive/synaptic dysfunctions, neuroinflammation and neurodegeneration in adult mice. It decreased the accumulation of A $\beta$ , BACE-1 expression, and hyperphosphorylation of tau protein at serine 413. Fisetin also markedly reversed A $\beta$ 1–42-induced synaptic dysfunction by increasing the levels of both presynaptic (SYN and SNAP-25) and postsynaptic proteins (PSD-95), SNAP-23, p-GluR1 (Ser 845), p-CREB (Ser 133) and p-CAMKII (Thr 286). Fisetin significantly activated p-PI3K, p-Akt (Ser 473), and p-GSK3 $\beta$  (Ser 9) expression in A $\beta$ 1–42-treated mice (Yi et al., 2010). Fisetin (15 mg/kg, p. o.) showed potential anti AD activity when co-administered with aluminum chloride for 4 weeks through regulation of neuronal apoptosis (Prakash and Sudhandiran, 2015).

The potential efficacy of rutin, quercetin, apigenin, chrysin, kaempferol, and 3',4'-dihydroxyflavone in the inhibition of tumor growth and migration of central nervous systems tumors has been reported. The flavonoids, exhibited the capacity to induce differentiation and inhibit the migratory and invasive activity in human glioblastoma cell cultures, as well as induce ultrastructural modifications indicative of death by apoptosis suggesting that these flavonoids can be considered positive candidates in aid of treatment of malignant gliomas (Santos et al., 2015).

### Neuroprotective Profile of Flavonoid Extracts From Dietary Sources

There is a copious mention of the neuroprotective property of dietary flavonoid extracts and extracts containing flavonoids in addition to other phytochemicals in scientific literature. Due to the relative ease of preparing these extracts, there are lots of studies investigating their bio-efficacy in neurological diseases with reported beneficial outcomes in majority of cases. The mechanisms involved in the neuroprotective action of these extracts include oxidative stress amelioration, antiexcitotoxicity, anti-inflammatory responses, modulation of the activity of cholinesterases, prevention of dysfunction of mitochondrial enzyme complexes such as complex I, regulation of cell death pathways and cell signaling mechanisms. There are positive and negative sides to the use of extracts. Extracts could show a more potent activity than individual compounds due to synergistic interactions amongst constituent compounds. On the other end, inactive chemical entities could mask the bioactivity of one or more compounds in the extract leading to reduced activity of the extract.

Flavonoid extracts of *Rosa laevigata* Michx fruit, *Radix Ilicis pubescentis*, *Scutellaria baicalensis* Georgi, *Garcinia kola*, and *Cyperus rotundus*, grape seed procyanidin extract, among others demonstrated neuroprotection in brain ischemia/reperfusion injury. This pointed to the potential of the extracts in the management of ischemic stroke (Akinmoladun et al., 2015b; Zhang et al., 2006, 2013b; Yan et al., 2017; Tang et al., 2004; Sunil et al., 2011; Kong et al., 2017). For example, pretreatment of male SD rats with 50, 100 and 200 mg/kg flavonoid-rich extract from *Rosa laevigata* Michx, intragastrically, for 7 days protected against cerebral ischemia–reperfusion injury through suppression of apoptosis and inflammation (Zhang et al., 2013b). In addition, a meta-analysis of prospective cohort studies by Tang and colleagues showed that higher dietary flavonoid intake may moderately lower the risk of stroke (Tang et al., 2016).

The anti-aging and protective effect of flavonoid extracts against neurodegenerative diseases is a research area of current interest. The anti-aging effects of A-type proanthocyanidins (PACs)-rich cranberry concentrate and B-type PACs-rich grape seed extract was reported (Jiao et al., 2017). Both extracts exerted anti-aging effects probably via regulating *in vivo* redox state.

Ethyl acetate extract from persimmon leaves consisting of flavonoids and triterpenoids displayed potent protective effect on cognitive deficits induced by A $\beta$  when administered intragastrically to male SD rats at 200 and 400 mg/kg for 30 days. This effect appears to be associated with the regulation of the antioxidative defense system and the mechanism of mitochondrial-mediated apoptosis (Huang et al., 2016). Black tea extract rich in flavonoids protected against aluminium induced Alzheimer's disease (Mathiyazahan et al., 2015). Also, flavonoid extracts from sausage tree demonstrated protective potential in Alzheimer's disease (Falode et al., n.d.).

Flavonoid extracts from dietary sources have been shown to confer neuroprotection in Parkinson's disease. These extracts are from sources such as green tea, *Ginkobiloba*, Safflower, grapes, cocoa, purple basil, etc (Ren et al., 2016; Hang et al., 2016; Bensalem et al., 2015).

Acetyl cholinesterase inhibitors are used clinically to counteract various pathologies. The use of reversible acetyl cholinesterase inhibitors has attracted attention, in particular for the treatment of Alzheimer-type dementia (Bivar et al., 2012). Individual flavonoid compounds as well as flavonoid extracts have been shown to possess anticholinesterase activity alluding to their neuroprotective properties (Bivar et al., 2012; Hacöbekiroğlu and Kolak, 2015; Sevindik et al., 2015; Dzoyem and Eloff, 2015; Cao et al., 2015; Akkol et al., 2012; Khan et al., 2009).

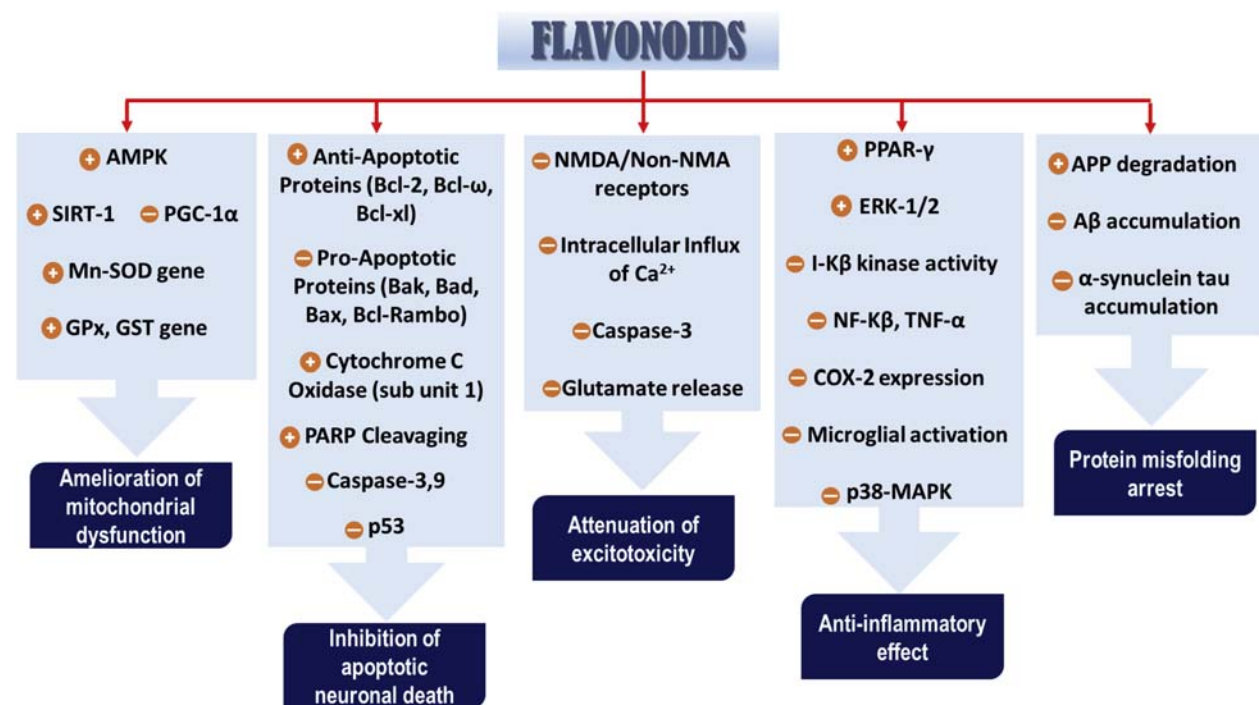

Flavonoid extracts have also shown promising activity in epilepsy (Citraro et al., 2016; Singh et al., 2014; Taiwe et al., 2016; Chindo et al., 2015), cognitive and memory enhancement (Kirisattayakul et al., 2017; Cho et al., 2013; Kandikattu et al., 2017; Smach et al., 2015) and environmental toxicant-induced neurotoxicity (Gupta et al., 2015; Abdou and Wahby, 2016; Igado et al., 2012; Abarikwu et al., 2011).

### Common Mechanistic Routes in Flavonoid Neuroprotection

Flavonoids principally address neuroprotective effects throughout the modulation of signal transduction cascades or effects on gene expression (Ferri et al., 2015). It has been argued that the classical hydrogen-donating antioxidant activity for which flavonoids are historically known, cannot account for the bioactivity of flavonoids in the brain, where they are found at only very low concentrations. It has become apparent that flavonoids are able to exert neuroprotective actions (at low concentration) via their interactions with critical neuronal intracellular signalling pathways pivotal in controlling neuronal survival and differentiation, long-term potentiation (LTP) and memory (Spencer, 2009). As depicted in Fig. 2, these effects appear to be underpinned by their interaction with critical protein and lipid kinase signaling cascades in the brain leading to an inhibition of apoptosis triggered by neurotoxic species and to a promotion of neuronal survival and synaptic plasticity (Vauzour et al., 2013).

Flavonoids affect the synthesis of neurotrophic factors such as brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF). They interact with and modulate signaling pathways involved in neuroprotection such as protein kinase C (PKC) and PI3 kinase. During activation of glial cells in neuroinflammatory states, various transcription factors including NF- $\kappa$ B, activator protein-1 (AP-1), and the signal transducer and activator of transcription-1 (STAT-1) have been shown to be involved in proinflammatory responses in astrocytes and microglia (Sun et al., 2014; Seo et al., 2014; Pu et al., 2007; Spencer and Crozier, 2012; Bei et al., 2009), which can contribute to neuronal death and flavonoids act to suppress this pathway. Flavonoids also act on the ERK pathway. ERK activation often leads to the activation of the cAMP response element-binding protein (CREB), a transcription factor which regulates the expression of a number of important genes, including brain-derived neurotrophic factor (BDNF), which is linked with the control of synaptic plasticity and long-term memory. CREB and BDNF expressions have also been shown to lead to the activation of the PI3 kinase/Akt signaling pathway through binding of BDNF to TrkB receptors. Activation of Akt/PKB, which is under the control of a lipid kinase, PI3K by flavonoids afford neuroprotection by inhibiting proteins associated with cell death such as apoptosis signal-regulating kinase 1 (ASK1), Bad, caspase-9, and caspase-3 (Vauzour et al., 2008, 2013).

**Figure 2** Scheme illustrating several mechanistic routes of neuroprotection by flavonoids. Flavonoids and their physiological metabolites are capable of inducing neuronal and glial signalling pathways crucial in inducing synaptic plasticity, though at nanomolar concentrations. Flavonoids ameliorates mitochondrial dysfunction by activating AMPK which in turns activates SIRT-1 and inhibits PGC-1 $\alpha$  leading to adequate expression of Mn-SOD, GPx and GST genes. By activation and inhibition of anti-apoptotic and pro-apoptotic proteins respectively, flavonoids and their physiological metabolites possesses the ability to inhibit apoptotic neuronal death. Flavonoids attenuates excitotoxicity by greatly inhibiting NMDA receptors, intracellular Ca<sup>2+</sup> influx, caspase-3 expression and glutamate release in the pre-synaptic cleft. Also, flavonoids can act as inflammatory suppressor through a series of cascade that synergistically inhibit NF- $\kappa$ B signaling pathway and microglial activation. Finally, flavonoids can correct protein misfolding by activation of APP degradation which prevents eventual accumulation of misfolded proteins. AMPK => AMP activated protein kinase; SIRT-1 => Sirtuin protein family-1; PGC-1  $\alpha$  => peroxisome proliferator-activated receptor-gamma co-activator 1 alpha; PARP => poly (ADP-ribose) polymerase; NMDA => N-methyl-D-aspartate; PPAR- $\gamma$  => peroxisome proliferator-activated receptor-gamma; Erk-1/2 => extracellular signal related kinase-1,2; IKK => inhibitory kappa-b kinase; TNF- $\alpha$  => Tumor necrotic factor-  $\alpha$ ; COX-2 => cyclooxygenase-2; P38-MAPK => p38 mitogen-activated protein kinase; APP => Amyloid precursor protein; A $\beta$  => Amyloid-  $\beta$ .

## Conclusion and Future Perspectives

The multitarget nature of flavonoids, their ability to cross the BBB and their relative safety in the CNS make them suitable candidates for promotion of brain health. Their wide availability in diets and nutraceuticals are advantageous and will preclude the regimented condition involved in therapeutic interventions with orthodox drugs. The barriers posed by low bioavailability of flavonoids in the CNS due to the BBB are already being addressed by methods including designed synergistic interactions with other natural products and the use of other special delivery systems.

Much is still to be done before optimum benefits of neuroprotection can accrue from dietary consumption of flavonoids. Factors that contribute to individual differences in disposition of flavonoids must be delineated. More controlled pharmacokinetic and pharmacodynamics investigations are needed including studies to evaluate effects of genotypes on flavonoid disposition. Also, a framework for standardized pharmacological and toxicological assessment of flavonoids and flavonoid-based nutraceuticals should be established.

As human lifespan increases due to advances in medical care, cases of neurodegenerative, neurologic and other age-related diseases are also bound to increase. In addition, the unchecked increase in environmental pollution in many countries will contribute to increasing cases of neurotoxicity and poor mental health. Lifestyle adjustment focusing on consumption of dietary flavonoids will do a lot to safeguard human health. How early the consumption of flavonoid should start is another area requiring careful evaluation.

### Glossary

**Anthropometric** Refers to the measurement of the human individual.

**Autoimmune** Condition in which the immune system mistakenly attacks the body.

**Dysbiosis** Condition of having imbalances in the microbial communities either in or on the body.

**Endotoxemia** The presence of toxins in the blood.

**Homeostasis** Tendency towards a relatively stable equilibrium between interdependent physiological processes.

**Metabolism** Chemical processes that occur within a living organism in order to maintain life.

**Microbiota** Ecological community of commensal and pathogenic microorganisms.

**Probiotic** Denoting a substance that stimulates the growth of microorganisms, especially those with beneficial properties.

**Symbiosis** Any type of a close and long-term biological interaction between two different biological organisms.

### Nomenclature

ALT alanine aminotransferase

CFU colony forming unit

GST glutathione S-transferase

HE hepatic encephalopathy

LPS lipopolysaccharide

HVPG hepatic venous pressure gradient

NAFLD non-alcoholic fatty liver disease

NASH nonalcoholic steatohepatitis

RCTs randomized clinical trials

VHB viral hepatitis B

VSL#3 a probiotic cocktail which includes *Streptococcus thermophilus*, *Lactobacillus (acidophilus, delbrueckii, casei and plantarum)* as well as *Bifidobacterium*

## Probiotics Mechanisms of Action

The expression “probiotics” is defined as products containing one or more types of live microorganisms that, when administered in adequate amounts, provide a favorable result to the host by altering the intestinal microbiota (Patel and Denning, 2013; Schrezenmeier and de Vrese, 2001; Sanders et al., 2016). Probiotics may be useful in health-related benefits due to their potential ability to decrease the population of pathogenic bacteria through acidification of the intestinal lumen and by the production of antimicrobial substances that reduce inflammation and activate the host's immune system. Probiotics also regenerate intestinal microbiota equilibrium between host and pathogenic bacteria by competition for nutrients, as well as prevent bacterial translocation to preserve the intestinal barrier integrity and lower toxic products that come from the food or the microbiota itself (Nakamura et al., 2010).

The appropriate dose of probiotic changes depends on the strain; nevertheless, the majority is in a range of 1–10 billion CFU/dose. Even so, it is difficult to determine an accurate treatment, which should be established by well-controlled clinical trials focused on health benefits (Merenstein and Salminen, 2017). *Lactobacilli* and *Bifidobacteria* have been used in either animal or human models as probiotics in the treatment of different liver disorders. The results show that there is an improvement not only in hepatic function tests but also a decrement in endotoxemia and inflammatory responses has been observed (Abdou et al., 2016).

Indeed, some species such as *Bacillus*, *Lactococcus*, *Pediococcus*, *Streptococcus* and *Escherichia coli* are also used together with the yeast *Saccharomyces boulardii* as probiotics (Guarner et al., 2017). Moreover, the benefits provided by probiotics seem to depend on bacterial strains (Isaacs and Herfarth, 2008), which are classified by gender, species, subspecies (if applicable) and an alphanumeric designation. Therefore, it is essential to accurately recognize the strains using new molecular technologies that include:

determining the presence of genetic elements, fermentation of sugars and detection of products obtained from fermentation (Fijan, 2014).

The intestinal microbiota, composed by viruses, fungi, parasites as well as non-pathogenic bacteria, occupy the gastrointestinal tract from the mouth to the colon (Doulberis et al., 2017), partly regulating the host metabolism (Al-Muzafar and Amin, 2017); this symbiosis represents a complex ecosystem that plays a vital role in the body's homeostasis (Tsilingiri et al., 2012).

In humans, *Bacteroidetes* and *Firmicutes* represent the predominant phyla (90%) and to a lesser extent *Proteobacteria*, *Verrucomicrobia*, *Actinobacteria*, *Fusobacteria* and *Cyanobacteria* (Miura and Ohnishi, 2014; Paoletta et al., 2014). Starting with the mouth, which contains approximately more than 500 distinct bacteria (D'Argenio and Salvatore, 2015), the complexity and diversity of the intestinal microbiota increases distally reaching up to  $10^{12}$  per gram in the colon (Berg, 1996). Environmental factors, such as age, body mass index (BMI), health status, the diet, gender, and others may have an impact on the bowel bacteria settlement (Bashiardes et al., 2016; Power et al., 2014). Also, the amount of anaerobic versus aerobic bacteria varies, depending on the mucosa layer, where the anaerobes are closer to the epithelium and aerobic are superficially close to the lumen (Shanahan, 2002). However, there are data implying that human's microbiome singularity can be under the host's genetic influence (Van de Merwe et al., 1983).

Some of the functions carried out by the regular gut microbiota are opposite those of pathogenic species in addition to differences in the substances they produce (bacteriocins), pH modification, and stimulation of mucin secretions, all of which contribute to the maintenance of the host defense (Aguirre Valadez et al., 2016). The regular microbiota also functions as an assistant for internal and external stimuli by producing various nutrients and metabolites that are transported to the liver through the intestine-liver axis by means of the venous portal system, where the liver plays a crucial defense role (Usami et al., 2015). Changes in these factors could modify the number of microorganisms available to maintain the intestinal balance that leads to the storage of energy in the form of lipids, bringing adverse effects on the metabolism and increasing obesity, which would later develop liver diseases (Miura and Ohnishi, 2014).

Different liver diseases such as non-alcoholic fatty liver disease (NAFLD), alcoholic liver disease and viral hepatitis may have diverse intestinal microbiota mechanisms to influence liver fibrosis as well as progression of the disease to cirrhosis and subsequently to hepatocarcinoma (Usami et al., 2015).

## Nonalcoholic Fatty Liver Disease

Obesity and accumulation of liver fat are intimately associated to a modification in the composition of the gut microbiota. Therefore, it is thought that probiotics could play a significant role in the treatment of patients with NAFLD and nonalcoholic steatohepatitis (NASH) by reducing bacterial translocation through the intestine and the balance of pathogenic bacteria (Bashiardes et al., 2016; Qamar, 2015). Therefore, it is suggested that different strains of probiotics can be used as a therapeutic option in humans as it has been observed in various animal models (Ma et al., 2013).

*L. acidophilus* did not improve the steatosis or intestinal permeability, but *B. longum* probiotic attenuated hepatic fat accumulation (Xu et al., 2012a). On the other hand, *Clostridium butyricum*, a butyrate-producing probiotic, decreased hepatic inflammatory indexes, insulin resistance, triglycerides content and endotoxin level.

VSL#3, a probiotic cocktail which includes *Streptococcus thermophilus*, *Lactobacillus (acidophilus, delbrueckii, casei and plantarum)* as well as *Bifidobacterium*, was administered during 4 weeks to mice with NAFLD. The results showed a reduction in liver function tests, hepatic inflammation, serum lipid levels, as well as insulin resistance and reversed hepatic steatosis (Kirpich et al., 2015; Ma et al., 2008). Also, another model of mice that were given VSL#3 and a diet deficient in methionine and choline (promotes NASH development without being associated with obesity or the metabolic syndrome), had less hepatic fibrosis (Velayudham et al., 2009). Another study conducted in rats with a diet deficient in choline found a decrease in the expression of tight junction proteins and an increase in antioxidant enzymes, which enhanced suppression of oxidative stress in the liver (Endo et al., 2013).

In other studies with mice that received a diet rich in fats and sucrose, intestinal microbiota dysbiosis occurred due to changes in oxidant stress, inflammation markers, short chain fatty acids and lipopolysaccharide (LPS); however, the intake of probiotics reduced these adverse effects as well as hepatic steatosis while dysbiosis was improved (Haque, 2016).

So far there are few human studies on the efficiency of probiotics in NAFLD or NASH prevention or treatment. Loguercio et al. studied patients diagnosed with NAFLD, who were treated with VSL # 3 for 3 months and patients with NASH who were administered a mixture of symbiotic *Lactobacillus*, *L. casei*, *L. plantarum*, *L. lactis*, *L. bifidus*, *L. rhamnosus*, *L. salivarius*, *L. bulgaricus*, *L. breve*, *L. bulgaricus*, fructooligosaccharides and antioxidants for 60 days (Loguercio et al., 2002, 2005). Both studies showed the beneficial effects of probiotics, indicating a decrease in oxidative stress as well as liver damage and inflammatory levels. Novel double-blind, randomized clinical trials (RCTs) also evaluated the employment of probiotics in liver disease, which showed a decrease in liver function levels. However, there was no difference in anthropometric and cardiovascular risk factors (Aller et al., 2011).

An RCT with obese children and nonalcoholic fatty liver studied the effect of *Lactobacillus rhamnosus* GG and found a significant decrease in alanine aminotransferase (ALT) values and concentrations of polysaccharides (Vajro et al., 2011). Another study with children with the same characteristics, who were supplemented with VSL#3 for four months, the same benefit in liver function tests and inflammation markers was observed (Alisi et al., 2014). A recent meta-analysis (Ma et al., 2013) demonstrates the improvement in inflammation markers and liver function tests of patients with NAFLD, suggesting that the clinical benefits of probiotics is a real hypothesis for this condition.

Most studies in animal and human models demonstrate that probiotics reduce proinflammatory cytokines and liver enzymes, which confirms the benefits of different probiotics strains in the treatment of NAFLD/NASH. The evidence in animal models is clear, but more studies are needed in humans with larger sample sizes and population diversity to propose the use of probiotics in different patients with liver disease.

## Viral Hepatitis

It is known that hepatitis viruses, particularly B and C, may cause long-term hepatocellular damage. As in other liver diseases, the plasma level of endotoxin increases in these patients due to changes in the intestinal microbiota. High levels of proinflammatory molecules cause cell death and worsen liver disease. Lu et al. (2008) studied patients with severe symptomatic hepatitis, dividing individuals into different research groups, controls and treatments, who then received an unspecified probiotic preparation. Proinflammatory molecules concentrations decreased, while anti-inflammatory molecules increased. Moreover, clinical symptoms improved in 84% of the treated group. On the other hand, it has been seen that immune regulation through the production of interferon could also be modified with probiotics (at least in vitro) (Sugimura et al., 2013; Weiss et al., 2011).

In a research study with three groups: apparently healthy patients, infected with hepatitis B virus and with cirrhosis caused by viral infection, changes in fecal *Bifidobacterium* species were measured. The results showed that patients with cirrhosis had a lower amount of *B. longum*, *B. dentium* and *B. pseudocatenulatum/catenulatum* compared with patients who were only infected with viral hepatitis B (VHB) and in turn with the control patients (Xu et al., 2012b). The effects of probiotics in VHB with vaccines have also been studied. Soh et al. administered probiotics to 0–1 month-old infants vaccinated against VHB and a booster of the VHB plus the combined diphtheria pertussis tetanus vaccine at six months of age. The results showed a better surface antibody response when compared to babies that did not receive the probiotic (Soh et al., 2010). Therefore, this study concluded that probiotics could stimulate the immune responses of babies through specific antibodies, although more studies are required to adequately evaluate the benefits of probiotic therapy.

Moreover when the probiotic VSL#3 was administered during 4 months, 20 patients with chronic hepatitis related to virus C and 16 patients who progressed to cirrhosis due to viral infection type C had reduced levels of liver damage; however, the  $\gamma$ -glutamyl transferase (enzyme that shows liver cell death) only developed in the first group (Loguercio et al., 2005).

All these findings sustain the possible use of probiotics in patients infected with the hepatitis virus who present an altered microbiota, serving as a guide for future interventions.

## Cirrhosis

One RCT of patients with cirrhosis and large esophageal varices without hemorrhage classified the study subjects into three groups. The first were patients treated with propranolol and placebo, the second received propranolol and norfloxacin (400 mg) and the third received propranolol and VSL#3 (900 billion/day) with all treatments administered for two months. Supplementation with the probiotic improved the rate of response to the hepatic venous pressure gradient (HVPG) when compared to adjuvant antibiotics and the placebo group (Gupta et al., 2013).

In cirrhosis, probiotics restore the phagocytic faculty of neutrophils, decreasing the bowel wall permeability, bacterial translocation, and endotoxemia in both animal models and clinical trials, in addition to limiting oxidative stress and inflammatory damage in the liver. In fact, VSL#3 lowered oxidative/nitrosative stress parameters in patients with alcoholic liver cirrhosis (Doulberis et al., 2017; Fukui, 2015).

A systematic review by Barjesh et al. demonstrate that probiotics are employed for the prevention of hepatic encephalopathy (HE), a medical term assigned to describe a neuropsychiatric abnormality caused by brain and nervous system toxicity secondary to liver failure mainly produced when the patient has cirrhosis. A significantly lower plasma ammonia concentration was found in patients treated with three months of probiotics, resulting in a representative health improvement, where the absolute risk reduction was 23.8% (Sharma and Singh, 2016).

In the work by Radha K. et al., the use of VSL#3, a probiotic combination of eight strains of *Lactobacilli*, *Bifidobacteria* and *Streptococcus*, for HE secondary prophylaxis, significantly decreased hospitalization over a 6-month period, with reference to the importance of concomitant encephalopathy and inflammatory markers. On the other hand, there was a progress in the health-related quality of life and the pumped heat electrical storage parameters. Also, hepatic function and biochemical measurements of systemic hemodynamics improved, without significant adverse effects (Dhiman et al., 2014).

## Hepatocellular Carcinoma

In a study in which an in vitro and in vivo model was used, Endo et al. demonstrated the efficacy of *C. butyricum*, showing how the whole spectrum of NAFLD to NASH improves, including some mechanisms involved in hepatocarcinogenesis, such as the reduction in the placental glutathione S-transferase (GST) expression (Endo et al., 2013). As well, *Bifidobacterium* and *Lactobacillus* could modify the pathogenic T Helper 17 cells that are involved in the immunogenic mechanisms of liver cancer (Sung et al., 2012).

Analogous data in a murine model supplemented with *L. rhamnosus* GG, showed a decrease in proteins responsible for cell cycle progression after exposure to aflatoxin (Kumar et al., 2011). Interesting clinical data showed how probiotics (*L. rhamnosus* LC705 and *Propionibacterium freudenreichii* subsp. *Shermanii*) reduced the effective biological dose of aflatoxin exposure (El-Nezami et al., 2006).

There is limited information on epidemiology that suggests the role played by nutrients as a risk factor for hepatocellular carcinoma. However, changes in the microbiota as a result of our eating habits could be responsible pathogenic mechanisms; however, the role of probiotics in this clinical scenario is still limited (Mandair et al., 2014).

## Conclusion

Some probiotics produce several intestinal benefits, such as reduction of inflammation, which in turn influence host immunity, restore the regular gut microbiota, but also prevent bacteria and toxins translocation by maintaining the intestinal barrier integrity. Therefore, since the liver receives a constant flow of toxic molecules, the use of probiotics represents an alternative therapeutic approach. Thus, probiotics could play a fundamental role in the treatment of liver diseases such as NAFLD, NASH and even advanced conditions like fibrosis or hepatocellular carcinoma.

Currently, there are numerous probiotic foods and strains available on the market; however, the question that still arises is how to determine the real potential of microorganisms. Thus, to maintain or improve overall health, safety assessments must be demonstrated to develop a promising probiotic with specific characteristics that offer desirable opportunities for successful commercialization. On the other hand, more RCTs are needed to determine the therapeutic doses and the appropriate probiotic for each liver disease.

In most chronic liver diseases, the main effect of probiotics lies in the resolution of the endotoxemia and the proinflammatory mechanisms. However, evidence of the probiotics effect on cirrhosis and hepatocellular cancer remains weak due to the complexity of their natural history and comorbidities. In summary, modifications of the intestinal microbiota and its metabolites may promote liver damage. But it can be prevented or modified by a healthy diet, the use of probiotics, as well as exercise.

### Introduction

Oxygen is required for a myriad of activities in the body and lack of thereof, appropriate form or imbalance may preclude proper functioning and be lethal to vital processes and organs in the body. However, the oxidizing potential of oxygen has been implicated in free radical production and resulting oxidative stress. Uncontrolled oxidative stress has been associated with carcinogenesis, DNA damage, cardiovascular disease, cancer, inflammation and other disorders and diseases (Cobley et al., 2018; Rogers and Moorthy, 2018). These diseases and disorders account for millions of morbidity and mortality globally annually. As such, several strategies have been devised to mitigate the incidence and prevalence of these major public health burden. Certain compounds, including polyphenols have been shown to be effective against oxidative stress. The protective role of polyphenols has been linked to their antioxidant properties and impact on other regulatory pathways. Food-source polyphenols from fruits, vegetables, spices, and oils such as artichokes, berries, grapes, capers, cilantro, red onions, tea, coffee are rich in anthocyanins, quercetin and other polyphenolic compounds, and are gaining popularity among consumers as alternative to pharmaceutical remedies (Meshkini, 2018; Rogers and Moorthy, 2018). The use of pharmaceutical drugs to attenuate these pathologies are riddled with negative side effects and longterm safety concerns. Polyphenols function against oxidative stress by various mechanisms. In anti-atherosclerosis, polyphenols regulate lipid metabolism, vascular, endothelial and platelet function (Meshkini, 2018; Santhakumar et al., 2018). The anti-inflammatory role of polyphenols in diseases such as diabetes and obesity include inhibitory effect on sources of reactive oxygen species (ROS) as well as antioxidant activity (Rochette et al., 2014). Other mechanisms include metal sequestration, modulating cellular signaling processes, and expression of metabolic and antioxidant genes (Han et al., 2007; Priftis et al., 2018; Rafei et al., 2018; Rogers and Moorthy, 2018).

### Oxidative Stress

A class of important biochemical substances that is necessary for life is free radicals, which play a key role in physiological processes such as signal transduction, cell division, elimination of damaged cells, and defense against infections in living body systems (Valko et al., 2006; Seifried et al., 2007; Winterbourn, 2015). As the name suggests, free radicals are highly reactive species with unpaired electrons and often produced from oxygen (reactive oxygen species/ROS), nitrogen (reactive nitrogen species/RNS), and metal ions (Valko et al., 2006; Phaniendra et al., 2015). The production of free radicals is inevitable, since organisms are constantly exposed to these substances from external sources such as atmospheric pollutants, energy radiations (UV, X-ray, gamma rays, etc.), or via internal generation during normal metabolic processes of organelles such as mitochondria and peroxisomes (Winterbourn, 2015). However, as with most ingested substances in life, it is the dosage that makes the poison. The presence of high levels of free radicals in the body results in negative consequences in a phenomenon called oxidative stress, which could lead to the damage of sensitive cellular macromolecules such as proteins, DNA and lipids (Liochev, 2013). Living organisms counteract the harmful effects of free radicals by producing a cascade of antioxidant defense systems, which keep the concentration of these radicals under control. Failure in the antioxidant system leads to oxidative stress, which has been identified as a risk factor in the pathological development of several age-related illnesses such as cancers, inflammations and neurodegenerative disorders (Jomova and Valko, 2012; Liochev, 2013; Singh et al., 2015). Table 1 gives a list of some common reactive species implicated in oxidative stress.

### Strategies to Control Oxidative Stress

Natural and synthetic antioxidants have been used to control the harmful effects of reactive species. Antioxidants do so by preventing the formation of excess ROS or by inhibiting the reactions of ROS with other biological molecules (Finkel and Holbrook, 2000; Seifried et al., 2007; Maharjan et al., 2016). Antioxidant defense involves a number of enzymatic and non-enzymatic strategies (Giustarini et al., 2009; Halliwell and Gutteridge, 2015). Some examples of antioxidant enzymes are superoxide dismutase (SOD), catalase, thioredoxin reductase, and glutathione peroxidase (GPx). Non-enzymatic antioxidant systems include glutathione (GSH), and phytochemicals such as tocopherols, carotenes, ascorbates, ubiquinol, isoflavones, flavanoids and polyphenols (Giustarini et al., 2009; Halliwell and Gutteridge, 2015).

**Table 1** Types and description of some common reactive species implicated in oxidative stress

Group	Name	Chemical symbol
Reactive oxygen species	Superoxide	$O_2^{\bullet-}$
	Hydroxyl	$OH^{\bullet}$
	Alkoxy radical	$RO^{\bullet}$
	Peroxy radical	$ROO^{\bullet}$
	Hydrogen peroxide	$H_2O_2$
	Singlet oxygen	$^1O_2$
	Ozone	$O_3$
	Organic peroxide	$ROOH$
	Hypochlorous acid	$HOCl$
	Hypobromous acid	$HOBr$
Reactive nitrogen species	Nitric oxide	$NO^{\bullet}$
	Nitrogen dioxide	$NO_2^{\bullet}$
	Peroxynitrite	$ONOO^-$
	Nitrosyl cation	$NO^+$
	Nitrosyl anion	$NO^-$
	Dinitrogen trioxide	$N_2O_3$
	Dinitrogen tetraoxide	$N_2O_4$
	Nitrous acid	$HNO_2$
	Peroxynitrous acid	$ONOOH$
	Nitryl chloride	$NO_2Cl$
Metal ions	Iron	Fe
	Copper	Cu
	Chromium	$Cr^{+5}$ and $Cr^{+6}$
	Cobalt	$Co^{2+}$
	Vanadium	$V^{5+}$
	Peroxo vanadyl radicals	$V(IV)-OO^{\bullet}$
	Vanadyl hydroperoxide	$V(IV)-OH^{\bullet}$
	Cadmium	Cd
	Arsenic	$As_2O_3$
	Dimethylarsinic peroxy radical	$(CH_3)_2AsOO^{\bullet}$
	Dimethylarsinic radical	$(CH_3)_2As^{\bullet}$
	Nickel	Ni

## Role of Polyphenols in Controlling Oxidative Stress

Polyphenols are one of the most abundant groups of plant metabolites recognized for their ability to control oxidative stress (Sabu et al., 2002; Katiyar et al., 2001; Pignatelli et al., 2006; Morillas-Ruiz et al., 2006).

### Types and Sources of Polyphenols

Polyphenols are mainly plant-derived. They comprise a wide variety of molecules that have a polyphenol structure. They also have molecules with one phenol ring, such as phenolic acids and phenolic alcohols (D'Archivio et al., 2007; Holland et al., 2017). The main groups of polyphenols are flavonoids, phenolic acids, phenylethanoid, stilbenes and lignans (D'Archivio et al., 2007).

#### Flavonoids

Flavonoids are divided into six subclasses, including flavonols, flavones, flavanones, isoflavones, anthocyanidins and flavanols (D'Archivio et al., 2007; Holland et al., 2017). Important sources of flavonoids are soybeans, hazelnuts, oranges, celery, oregano, grapefruit, green tea, peaches, vinegar, apples, almonds and blueberries (Tangney and Rasmussen, 2013). The chemical structures of two flavonoids are presented in Fig. 1.

#### Phenolic Acids

Phenolic acids are divided into two classes, namely hydroxybenzoic and hydroxycinnamic acids (Holland et al., 2017). Examples of hydroxybenzoic acid are gallic, vanillic and protocatechuic acids, while those of hydroxycinnamic acid include coumaric, caffeic, ferulic, sinapic and quinic acids (Holland et al., 2017). Dietary sources of phenolic acids include grape, flaxseed, plum, red wine, black tea, rosemary, green olives, chokecherries and tomatoes (Liu, 2013, D'Archivio et al., 2007; Tangney and Rasmussen, 2013). The chemical structures of gallic acid and sinapic acid are shown below (Fig. 2).

**Figure 1** Chemical structures of (A) quercetin and (B) apigenin.

**Figure 2** Chemical structures of (A) gallic acid and (B) sinapic acid.

**Figure 3** Chemical structures of (A) tyrosol and (B) hydroxytyrosol.

### Phenylethanoid

Three prominent types of polyphenols in this group are tyrosol, hydroxytyrosol and oleuropein. They are found mainly in olive leaf and oil (Holland et al., 2017). Tyrosol and hydroxytyrosol (Fig. 3) have also been reported to be present in argan oil (Rueda et al., 2016).

### Lignans

Lignans are a group of fiber-associated polyphenols that are mostly present in nature in the free form or glycosidically linked to different carbohydrates (D'Archivio et al., 2007). Secoisolariciresinol and matairesinol (Fig. 4) are the major types of lignans that have been found in food products such as flaxseed, sesame seed, rye bran and flour, broccoli, garlic, strawberry, black and green tea (Willför et al., 2006).

### Stilbenes

Resveratrol (3,5,4'-trihydroxy-trans-stilbene) is the most widely known stilbene. Polydatin or pieced is another example, but it is a glucoside of resveratrol in which the glucoside group bonded in position C-3 substitutes a hydroxyl group (Lanzilli et al., 2012) (Fig. 5). Plant sources of these stilbenes are grapes, berries and peanuts (D'Archivio et al., 2007).

### Polyphenols as Antioxidants

Since oxidation plays a major role in several disease pathways, the potent antioxidant activity of many polyphenols *in vitro*, can be linked to their ability to prevent some diseases. The abilities of polyphenol to protect against cardiovascular and neurodegenerative diseases are as a consequence of their potent antioxidant and radical scavenging activities (Holland et al., 2017). These properties help them quench ROS and RNS, thus blocking the onset of cardiovascular diseases (Quinones et al., 2013). Polyphenols inhibit

**Figure 4** Chemical structures of (A) secoisolariciresinol and (B) matairesinol.

**Figure 5** Chemical structures of (A) resveratrol and (B) polydatin.

the oxidation of low density lipoprotein (LDL) *in vitro* and *in vivo* (Urquiaga and Leighton, 2000). For instance, procyanidin was found to reduce the levels of oxidized LDLs in diabetic patients (Brito et al., 2009). Also, red wine polyphenols have been reported to reduce the susceptibility of LDL to oxidation (Urquiaga and Leighton, 2000). Polyphenols such as procyanidin B<sub>4</sub>, catechin, and gallic acid were found to prevent oxidative damage of cellular DNA (Fan and Lou, 2004), which has been implicated in age-related development of cancer (Bjelland and Seeberg, 2003; Urquiaga and Leighton, 2000). Polyphenol-rich foods and beverages may also increase plasma antioxidant capacity (Pandey and Rizvi, 2009).

### Methods for the Extraction of Polyphenols

To facilitate the utilization of polyphenols as nutraceuticals or functional food ingredients, an extraction step is often required. The extract may be further processed or formulated with other ingredients to improve their biological properties and storage stability. The extraction of polyphenols is also useful as a strategy for adding value to polyphenol-rich plant material wastes. This is an important value-added strategy because some of these wastes (e.g. olive pomace and waste waters) are produced in very huge quantities (4 million tons and 3 million cubic meters per year, respectively) and contain very high levels of phytochemicals that can negatively impact soil quality as well as plant, microbial and aquatic life when these wastes are deposited into the environment without treatment without treatment (Dermeche et al., 2013; Muktadirul et al., 2013).

To obtain polyphenols from plant waste materials, four key steps are followed, namely: (a) preparation of plant matrix, (b) extraction of polyphenols using solvents and fluids, (c) fractionation of polyphenols with the aid of resins, and (d) conjugation/modification of polyphenols to improve their activity, storage stability, and delivery efficiency.

Preparation of plant matrix involves steps such as milling of matrix to reduce particle size, drying, removal of lipids, and disassociation of polyphenols in complex with other molecules such as carbohydrate and proteins (Khoddami et al., 2013). The purpose is to render the polyphenols in the plant matrix more accessible to extraction agents to be employed in later stages. The extraction of polyphenols is achieved using solvents and fluids at subcritical and supercritical states. The chemical diversity of polyphenols precludes the suitability of a single solvent in removing all polyphenols found in a plant matrix. As such, parameters such as polarities of the solute and solvent are taken into consideration. For food application, the safety or potential toxicity of the solvent is also taken into consideration. Examples of solvents/plant matrix systems that have been used for the extraction of polyphenols include water/sorghum leaves (Agbangnan et al., 2012), aqueous ethanol/wheat bran (Verma et al., 2008), ethanol/olive mill wastewater (Lafka et al., 2011; Azaizeh et al., 2012), or ethyl acetate/olive mill wastewater (El-Abbassi et al., 2012; Kalogerakis et al., 2013). Use of solvents present certain demerits: some are toxic and cannot be used to extract polyphenols for food applications, while others have a negative impact on the structural integrity and therefore, biological properties of the polyphenol extracts. But overall, the use of solvents for the extraction of polyphenols offers several advantages such as, relatively low cost, ease of scalability, ability to recycle solvents, possibility of improving polyphenol yield and purity by using solvent mixtures, feasibility of use on all plant matrixes, and compatibility with energy treatments such as heating or microwave technology to improve extraction efficiency.

Pressurized fluids (e.g. supercritical fluids, subcritical water, and high hydrostatic water) are alternative extractants that offer advantages (excellent food compatibility; low extraction time; high extraction yields, product quality and purity) over organic solvents, although they are usually accompanied with higher processing and investment costs. 'Green' and inert compounds such as water and carbon dioxide are converted into the supercritical states, resulting in a compound with superior properties (e.g. density, diffusivity, dielectric constant, etc.) that make them better extraction agents (da Silva et al., 2016). Supercritical fluid extraction has been used to obtain polyphenol extracts from rocket salad (Solana et al., 2016), peach (Kazan et al., 2014), olive oil mill wastes (Lafka et al., 2011), red dragon fruit (Fathordoobady et al., 2016), etc. Polyphenols from pomegranate seed residues (He et al., 2012), flaxseed meal sticks (Kanmaz, 2014), olive fruit dreg (Yu et al., 2015), citrus peels (Casquete et al., 2014), grape pomace (Kangliang et al., 2017), etc. have also been obtained by using sub-critical water and high hydrostatic water extraction techniques.

After extraction, polyphenols can be subjected to further separation to give pure fractions by harnessing their adsorption behavior to solid phase resins such as activated carbon (Yangui and Abderrabba, 2018), ion exchange resins (Bertin et al., 2011), and molecularly imprinted polymers (Puoci et al., 2012). The purified polyphenol fractions can be further conjugated to other biomolecules such as lipids to modify (and often enhance) their physicochemical and biofunctional properties (Holland et al., 2017; Akanbi and Barrow, 2018).

## Effect of Polyphenols on Oxidative Stress

Several studies have shown the ability of polyphenols to prevent or attenuate the damage caused by oxidative stress *in vivo* and *in vitro*. A comparison of the results within test is complicated by the variability in amount, type, and dose of polyphenolic compounds used as well as the duration of the study. Some of these will be discussed in this section.

### In Vitro and Cell Culture Tests

Several *in vitro* studies have shown the protective effect polyphenols in attenuating oxidative stress. Acetone extracts of almond green hulls prevented the propagation of free radical reactions and exerted an inhibitory effect on platelet aggregation (Meshkini, 2018). Black-sticky rice was shown to have higher antioxidant activity than red rice and also DNA-protective characteristics in human mononuclear leukocytes in hydrogen peroxide-induced environments (Warin et al., 2010). Polyphenols in red and purple rice extracts were demonstrated to inhibit adipocyte differentiation by significantly reducing lipid accumulation and down-regulating expression of peroxisome proliferator-activated receptor gamma (PPAR $\gamma$ ) in C3H10T1/2 adipocyte (Callcott et al., 2018). Foods containing polyphenolic compounds such as resveratrol, quercetin, catechin, cyanidin, and kuroman in protected against palmitate-induced nitroso-oxidative stress, mitochondrial impairment and endoplasmic reticulum stress (Rafiei et al., 2018). These factors have been shown to be involved in the progression of steatosis and apoptosis. Ethanolic extracts of grape pomace and coffee showed different composition and amount of polyphenols and exhibited different antioxidant mechanisms (Priftis et al., 2018). Using C2C12 cells, the grape pomace extract with low concentration of polyphenols scavenged free radicals, whilst coffee extract induced the expression of metabolic and antioxidant genes (Priftis et al., 2018).

### In Vivo Tests

Grape fruit flavonoids have been found to provide protection against oxidative stress *in vivo*. These grape polyphenols protected serum, plasma proteins and LDL against oxidation in healthy adults (O'Byrne et al., 2002). In another study, grape polyphenols helped reduce oxidative stress and lowered plasma lipids in pre- and postmenopausal women (Zern et al., 2005). Authors found that the major polyphenols responsible for these were flavans, anthocyanins, quercetin, myricetin, kaempferol and resveratrol. The 4 week study found a significant reduction in the plasma triglyceride concentrations, plasma LDL cholesterol and apolipoproteins B and E in a total of 42 pre- and postmenopausal women (Zern et al., 2005). Polyphenols in red wine synergistically inhibited oxidative stress in 20 healthy subjects (Pignatelli et al., 2006). After drinking 300 mL of red wine for 15 days, there was a significant decrease in PGF-2 $\alpha$ -III, a marker of oxidative stress in the subjects. Their level of plasma polyphenols also increased significantly (Pignatelli et al., 2006). Green tea epigallocatechin gallate suppressed tumorigenesis in a xenograft mouse model by directly targeting the proliferation of cells expressing peptidyl prolyl *cis/trans* isomerase (Urusova et al., 2011).

## Conclusion

The use of polyphenols as antioxidants in food has received greater acceptance in recent years, because they are natural alternatives to the synthetic commercial antioxidants such as butylated hydroxytoluene (BHT), butylated hydroxy anisole (BHA) and tert-butylhydroquinone (TBHQ). Polyphenols have also been widely reported to be more effective antioxidants than ascorbic acid (vitamin C) and tocopherols (vitamin E) (Rice-Evans et al., 1997; Urquiaga and Leighton, 2000; Akanbi and Barrow, 2018). A number of polyphenols have been used as antioxidants in edible oils rich in omega-3 and omega-6 fatty acids (Akanbi and Barrow, 2018; Zhang et al., 2017; Wang et al., 2018). Hydroxytyrosol, procyanidins, ferulic, caffeic and tannic acids are some of the polyphenolic compounds that have been used to retard lipid oxidation in fish mince and other muscle-based food products (Maqsood et al., 2014; Holland et al., 2017).

# Health-Promoting Fermented Foods

**Gbenga Adedeji Adewumi**, Department of Microbiology, Faculty of Science, University of Lagos, Akoka, Lagos, Nigeria

© 2019 Elsevier Inc. All rights reserved.

## Introduction: Overview of Fermented Foods

Fermentation of food substrates is an ancient practice, often described as a cheap, energy efficient, low-technology, and one of the oldest forms of traditional food processing and preservation techniques, usually carried out to introduce a variety of diets into food preparations (Ferri et al., 2016; Guyot, 2012; Kebede et al., 2007; Simango, 1997). Most food materials are highly perishable in their raw states (e.g. milk, cassava, fruits and vegetables, edible bamboo shoots etc.), which make them prone to spoilage attack, and in some cases, inedible and surplus after harvesting. Hence, they are fermented by natural inoculation and biochemical activities of microorganisms, which help to achieve post-harvest preservation, prevent physiological deterioration and losses, make inedible ones edible, with improved shelf-life, food safety, as well as ensuring availability of foods all year round (Patra et al., 2016; Rolle and Satin, 2002). Generally, these microorganisms are mostly from the raw food materials, fermentation vessels and utensils, processors, contaminants and other environmental microflora, selected to actively dominate and ferment the substrates through competitive adaptation and direct competition for available nutrients (Franz et al., 2014; Tamang, 1998).

A diversity of fermented foods and beverages obtained from food substrates, such as cereal grains, legumes and pulses, roots and tubers, fruits, vegetable leaves and edible bamboo shoots, milk and dairy products, meat and seafoods, miscellaneous food commodities (e.g. tea leaves, cocoa, sugar cane juice, oil palm sap etc.) is abundantly available in different parts of the world (Tamang et al., 2016a). Divergent microbial strains of bacteria (*Bacillus*, lactic acid bacteria, *Acetobacter*, Micrococcaceae), yeasts and mycelia or filamentous moulds have been reported to be principally responsible for the biotransformation of these food materials, resulting in the production of either acidic, alcoholic or alkaline-fermented food products (Steinkraus, 1997; Tamang, 1998). During the process of fermentation, microorganisms become exposed to food substrates, which leads to utilization of the nutrient contents. The nutrients and organic chemical compounds are used as carbon, nitrogen, electron and energy sources, through various enzymatic and biochemical reactions, which bring about desirable functional changes along with the production of metabolites that impart functional benefits. Beneficially, microbial fermentation enhances nutrient enrichment and bioavailability, development of attractive flavour, taste, aroma and texture, in addition to improved digestibility of carbohydrates and proteins, as well as bio-preservative effects (Blandino et al., 2003; Nout, 2009; van Boekel et al., 2010). Apart from the production of pleasant and acceptable quality food substances preferred by consumers (compared to their respective raw food materials), food fermentation also supports prolonged shelf-life of final food products (Caplice and Fitzgerald, 1999; Holzapfel, 1997). Other benefits include detoxification and reduction in undesirable toxic components and anti-nutritional factors, food fortification with essential amino acids and fatty acids, vitamins, minerals and antioxidants, stimulation of health promoting functions, value-added advantage and new products development (Oboh, 2006; Ouoba et al., 2003; Teniola and Odunfa, 2001).

Among these advantages, the consumption of fermented foods and beverages for their health-promoting properties, especially in disease prevention and improvement of human health has long been recognized by consumers. This is in consonant with early comments by the Russian Scientist, Élie Metchnikoff who suggested that the prolonged life span of the Bulgarian peasants resulted from the consumption of fermented dairy foods, such as yoghurt, sour milk and *kefir*, which contain lactic acid bacteria (LAB) (Metchnikoff, 1907). Metchnikoff's observation has since then stirred up consumers' consciousness and awareness in the consumption of foods with health-promoting values, beyond the purpose of nutrition and other basic benefits. Thus, food fermentation has received increasing research interests and attention, especially in food science, human nutrition and applied microbiology (Saarela et al., 2002; Salmerón, 2017). Multiple studies and evidence-based investigations have shown that fermented foods carrying both large populations of live microbial cultures and their metabolites, or either of these, may impart health beneficial functions (Barla et al., 2016; Kim et al., 2016; Singh et al., 2014; Tamang et al., 2016b). Hence, the scope of this chapter provides a comprehensive account and current information on health-promoting fermented foods and beverages around the world. Such benefits include reduction in serum and blood cholesterol, production of exopolysaccharides (EPSs) and bioactive compounds, production of anti-microbial compounds against potential pathogenic microorganisms, anti-mutagenic, anti-carcinogenic, anti-tumour effects and fibrinolytic activities. Other health effects include amelioration of metabolic and physiological disorders, improvement in cognitive brain functioning, enhanced probiotic properties, etc. In addition, highlights of the different types of fermented foods, and the predominant microorganisms associated with them will be discussed.

## Diversity of Fermented Foods and Beverages Around the World

Fermented foods and beverages are classified on the basis of raw food materials used in producing them, whether alkaline, acidic, alcoholic, or both acidic and alcoholic as well as the predominant group of microorganisms (Table 1).

**Table 1** Some selected fermented foods and beverages around the world, based on divergent raw food substrates

Products	Food substrates	Nature	Predominant microorganisms	Country of origin
<i>mawé</i>	maize	acidic dough	<i>Lactobacillus fermentum</i> , <i>Saccharomyces cerevisiae</i>	Benin Republic
<i>tchoukoutou</i>	sorghum	alcoholic opaque beer	<i>Sac. cerevisiae</i> , <i>Candida krusei</i> , <i>Lac. fermentum</i>	Benin Republic
<i>dosa</i>	rice and black gram	acidic and slightly alcoholic batter	<i>Leuconostoc mesenteroides</i> , <i>Lac. fermentum</i> , <i>Bacillus amyloliquefaciens</i> , <i>Sac. cerevisiae</i> , <i>Debaryomyces hansenii</i>	India, Sri Lanka, Malaysia, Singapore
<i>pozol</i>	maize	mildly acidic dough	<i>Lac. fermentum</i> , <i>Lac. plantarum</i> , <i>Lac. casei</i>	Mexico
sourdough	rye, wheat	mildly acidic, leavened bread	<i>Lac. sanfranciscensis</i> , <i>Lac. alimentarius</i> , <i>Lac. buchneri</i>	United States of America, Europe, Australia
<i>iru</i>	African locust bean	alkaline condiment	<i>Bac. subtilis</i> , <i>Bac. amyloliquefaciens</i> , <i>Bac. cereus</i>	Nigeria
<i>kinema</i>	soybean	alkaline condiment	<i>Bac. subtilis</i> , <i>Bac. licheniformis</i> , <i>Bac. cereus</i>	India
<i>natto</i>	soybean	alkaline condiment	<i>Bac. subtilis</i> ( <i>natto</i> )	Japan
<i>fufu</i>	cassava	acidic dough	<i>Lac. plantarum</i> , <i>Lac. cellobiosus</i> , <i>Bacillus</i> species	West Africa
<i>tarubá</i>	cassava	acidic beverage	<i>Lac. plantarum</i> , <i>Lac. brevis</i> , <i>Leu. mesenteroides</i> , <i>Pichia exigua</i> , <i>Can. tropicalis</i>	Brazil
sauerkraut	cabbage	acidic, sour salad	<i>Leu. mesenteroides</i> , <i>Pediococcus pentosaceus</i> , <i>Lac. plantarum</i> , <i>Lac. brevis</i>	Europe, Canada, United States of America, Australia
table olives	olive	acidic, side dish salad	<i>Lac. plantarum</i> , <i>Lac. pentosus</i> , <i>Leu. mesenteroides</i> , <i>Ped. pentosaceus</i> ,	United States of America, Spain, Portugal, Peru, Chile
<i>kimchi</i>	cabbage, green onion, hot pepper	acidic, mildly sour, side dish	<i>Leu. mesenteroides</i> , <i>Leu. citreum</i> , <i>Leu. kimchi</i> , <i>Lac. plantarum</i> , <i>Weissella cibaria</i>	Korea
<i>kefir</i>	milk	acidic, mildly alcoholic fermented milk	<i>Lac. kefiranofaciens</i> , <i>Lac. brevis</i> , <i>Streptococcus thermophilus</i> , <i>Lac. plantarum</i> , <i>Lac. casei</i> , <i>Can. kefir</i> , <i>Sac. cerevisiae</i>	Russia, Europe, Middle East, North Africa
<i>dahi</i>	milk	acidic viscous curd	<i>Lac. alimentarius</i> , <i>Lac. paracasei</i> , <i>Lac. acidophilus</i> , <i>Lac. helveticus</i>	India, Nepal, Sri Lanka, Bangladesh, Pakistan
<i>amasi</i>	milk	acidic, sour, with thick consistency	<i>Lactococcus lactis</i> subsp. <i>lactis</i> , <i>Lac. lactis</i> subsp. <i>cremoris</i> , <i>Leuconostoc</i> spp.	South Africa, Zimbabwe
<i>alheira</i>	pork or beef	dry/semi-dry sausage	<i>Lac. plantarum</i> , <i>Lac. paraplantarum</i> , <i>Lac. brevis</i> , <i>Lac. sakei</i>	Portugal
<i>ngari</i>	fish	mildly acidic fermented fish	<i>Lac. plantarum</i> , <i>Lac. pobuzihii</i> , <i>Lac. coryniformis</i> , <i>Bac. subtilis</i> , <i>Staphylococcus carnosus</i>	India
<i>tej</i>	honey	sweet, effervescent and cloudy alcoholic	<i>Sac. cerevisiae</i> , <i>Deb. phaffii</i> , <i>Kluyveromyces bulgaricus</i>	Ethiopia
<i>kombucha</i>	tea	fermented tea drink	<i>Sac. cerevisiae</i> , <i>Acetobacter aceti</i> , <i>Gluconobacter oxydans</i>	China, India

Adapted and modified from Tamang et al. (2016a).

## Cereal Fermented Foods

Non-alcoholic fermented cereal foods produced from maize (*Zea mays* L.) in Africa include *doklu* (Côte d'Ivoire), *kenkey* (Ghana), *amawewu* (or *mahewu*) and *incwancwa* (South Africa), *mawè* (Benin Republic), *ogi* (Nigeria), *poto-poto* (Congo), *togwa* (Tanzania), *ikii* and *uji* (Kenya), *munkoyo* and *chibwantu* (Zambia), as well as *tobwa*, *mutwiwa* and *ilambazi lokubilisa* (Zimbabwe). *Ben-saalga* and *dégué* (Burkina Faso), *koko* or *akasa*, *koko* sour water and *fura* (Ghana), and *kunun-zaki* (Nigeria) are made from pearl millets [*Penisetum glaucum* (L.) R. Br.], while *mangisi* (Zimbabwe) is from finger millet (*Eleusine coracana* Gaertn.). Fermented sorghum [*Sorghum bicolor* (L.) Moench] foods include *obushera* (or *bushera*) (Uganda), *gowè* (Benin Republic), *hussuwa* and *kisra* (Sudan), *bogobe* (Botswana), *obiolor* and *ogi-baba* (Nigeria) (Assohoun-Djeni et al., 2016; Gadaga et al., 1999; Odunfa and Adeyele, 1985; Owusu-Kwarteng et al., 2012; Schoustra et al., 2013). Major fermented cereal alcoholic beverages are *pito*, *dolo*, *tchapalo*, *burukutu*, *tchoukoutou*, *busaa*, kaffir beer, *muramba*, *pombe*, *impeke*, *malwa*, *merissa*, *amgba*, *bouza*, *umbugug*, *doro/uthwala*, *tella* (Holzapfel, 1997; Jespersen, 2003). Fermented baked snacks and pancakes also produced from cereals include *injera*, *kisra* and *masa*. Common fermented cereal foods in Asia are *dosa* (pancake), *idli* (pudding), *hamei* and *xaj-pitha* (rice wines, India), *congee* and *suanzhou* (acidic gruel, China), *chhang* (barley beer, India), *jalebi*, *koozh* (Indian porridge), *adhirasam* (rice doughnut), *hopper* (steamed baked, Sri Lanka), *puto* (Philippines), *sake* (also *saké*, Japanese rice wine) and *dhokla* (dough) (Jeyaram et al., 2008; Qin et al., 2016). Bread, sourdough bread, *San Francisco* bread, rye bread, beer, *boza* (Turkish sour drink), *bagni* (millet alcoholic drink, Russia), *hulumur* (sorghum beverage drink, Turkey), *kvass* (a non-alcoholic beverage similar to *boza*), *perkarnaya* (Russia), *pumpernickel* (Switzerland), and Mexican *pozol* and *atole agrio* comprise the various cereal fermented foods in Western and Eastern countries. Products such as *champús* and *chicha de jora* (both mild alcoholic beverages), and *masa agria* (maize dough) are found in South America (Chaves-Lopez et al., 2016; Elizaquível et al., 2015; Väkeväinen et al., 2018; Ventimiglia et al., 2015).

## Fermented Legume Protein-Rich Seeds

Traditional fermented protein-rich, legume-based foods are widely consumed in many African and Asian countries. In East and Southeast Asia, soybean [*Glycine max* (L.) Merr.] seeds are fermented by *Bacillus subtilis* to produce varieties of alkaline fermented food condiments, such as Japanese *natto*, Indian *kinema*, *hawaijar*, *bekang*, *tungrymbai*, *peruyaan* and *aakhone*, Thailand *thua nao*, Korean *cheonggukjang*, and Chinese *douchi* and *yandou* (Sanjuka and Rai, 2016). The major biochemical change is protein hydrolysis due to high proteinase activity of *Bac. subtilis*, which results in rapid production of polypeptides, amino acids, ammonia, and polyglutamic acid (PGA) in addition to other volatile compounds that contribute to the product's characteristic pungent smell and ammoniacal flavour (Leejeerajumnean et al., 2001; Odunfa, 1985). A similar food flavouring agent in Africa from soybean is *soy-dad-dawa*, but *iru* (also known as *daddawa*), *soumbala*, *afitin*, *nététou*, *kinda*, *oso*, *kawal*, *cabuk*, *bikalga*, *dawadawa botso*, *datou*, *mbuja*, *furundu*, *maari* and *tayohounta* are produced using non-soybean seeds, while cassava leaves form the raw material for the production of *ntoba mbodi* (Adewumi et al., 2014; Parkouda et al., 2009; Vouidibio Mbozo et al., 2017). Other fermented soybean foods in Asia where filamentous and mycelia moulds like *Aspergillus oryzae*, *Rhizopus oligosporus*, *Rhi. oryzae*, *Rhi. microsporus*, *Mucor sufu*, *Muc. wutungkiao*, *Muc. plumbens*, *Actinomucor taiwanensis*, *Act. elegans* and *Absidia corymbifera* dominate the fermentation process or with the participation of *Bacillus* species, include Indonesian *tempe*, Chinese *sufu* (also *fu-ru* or *tofu*) and *soy sauce*, Korean *meju*, *doenjang*, *ganjang* (a soy sauce), *doenjang-meju* and *gochujang*, Japanese *miso* and *shoyu* (Han et al., 2001; Jung et al., 2014; Nout and Kiers, 2005).

## Fermented Starchy Roots and Tuber Products

Cassava, yam, cocoyam and potatoes constitute starchy root and tuber crops that provide carbohydrate, an energy source in the diets of millions of people, especially in sub-Saharan (Cock, 1982; O'Hair, 1990). In Africa, cassava (*Manihot esculenta* Crantz) is the most abundant and importantly consumed root crop despite the presence of linamarin and lotaustralin, which are toxic cyanogenic glucosides (Aryee et al., 2006; Kimaryo et al., 2000). Processing by fermentation, involving *Lactobacillus plantarum*, *Lac. fermentum*, *Lac. pentosus*, *Lac. brevis*, *Leuconostoc mesenteroides* subsp. *mesenteroides*, *Weissella paramesenteroides*, *Wei. cibaria*, *Wei. confusa* and *Pediococcus pentosaceus*, primarily brings about detoxification and biochemical activities of the cassava tubers. This enhances acidification and imparts organoleptic properties, leading to the production of varieties of edible fermented food products, such as *gari*, *agbelima*, *akyeke*, *attiéké*, *fufu*, *kiwunde*, *lafun* (or *kokonte*), *chikwangue*, *cingwada*, *kocho*, *ikivunde*, *imikembe*, *inyange*, and *ubuswage*, among others (Adesulu-Dahunsi et al., 2017; Amoa-Awua et al., 1997; Kostinek et al., 2007; Obilie et al., 2004). Cassava fermentation for *gari* production is a solid-state natural inoculation, unlike *fufu*, *attiéké*, *lafun* and *agbelima* where submerged fermentation is employed (Coulin et al., 2006; Oyewole, 2001). Other microorganisms, including *Bacillus* species and yeasts have also been reported to partake in cassava fermentation. *Bac. subtilis* was found to produce amylases that were involved in the initial breakdown of cassava starch into simple sugars that are then fermented by LAB (Amoa-Awua and Jakobsen, 1995). *Saccharomyces cerevisiae*, *Pichia scutulata*, *Kluyveromyces marxianus*, *Hanseniaspora guilliermondii*, *Candida tropicalis*, *Can. glabrata* and *Can. krusei* are the yeasts species isolated during traditional *gari* and *lafun* production in West Africa (Oguntoyinbo, 2008; Wilfrid Padonou et al., 2009). Cassava is also processed by solid-state fermentation for the production of *tarubá*, an indigenous beverage by the Amerindian tribes in Brazil (Ramos et al., 2015).

## Fermented Fruits and Vegetables

Lactic acid fermentation of fruit and vegetable foods is traditionally carried out in most parts of Europe, United States of America and Asian sub-continent for the purpose of preservation against spoilage and rotting. Other reasons include prevention of post-harvest

losses, shelf-life extension, improvement in nutrient composition, detoxification and reductions in levels of anti-nutritional components (e.g. glucosinolates in cabbage and oleuropein in olive), in order to make them edible and available during the off season (Gail-Eller and Gierschner, 1984; Ross et al., 2002; Sánchez et al., 2000a). Fermentation processing of heads of white cabbage (*Brassica oleracea* var. *capitata* L.), cucumber (*Cucumis sativus* L.) and olive (*Olea europaea* L.) for the production of sauerkraut ('sour herb' or 'sour cabbage' as known in Germany), pickles and table olives respectively, is commonly practised in Western countries. However, Korean kimchi from Chinese cabbage (*Brassica rapa* subsp. *pekinensis*) is the most popular fermented vegetable side dish food in Asia (Oguntoyinbo et al., 2016a; Patra et al., 2016). Fermented vegetable ethnic foods that are also common in Asia are gundruk, sinki, khalpi, sunki, pak-sian-dong, tursu, suan-tsai, salgam, kanji, jiang-gua, hardaliye, dhamuoi, dakguadong, goyang, phak-gard-dong and gherkins, while the edible fermented bamboo shoots include mesu, soidon, soibum, soijim, ekung, herring, naw-mai-dong, inziangsang, doubanjiang and pao cai (Altay et al., 2013; Anandharaj et al., 2015; Tamang et al., 2008; Tamang and Tamang, 2009). In Africa however, very few vegetable leaves like those from cowpea [*Vigna unguiculata* (L.) Walp.] and African kale [*Brassica carinata* A. Braun] are subjected to fermentation before consumption (Kasangi et al., 2010; Oguntoyinbo et al., 2016b). Spontaneous fermentation of fruits of capper berries (*Capparis spinosa* L.), sweet cherry (*Prunus avium* L.) and 'Almagro' egg plant (*Solanum melongena* var. *esculetum* L.) are equally found in the Mediterranean, where they form part of various cuisines (Perez Pulido et al., 2005; Sánchez et al., 2000b).

### Fermented Milk and Dairy Products

Among other fermented food substrates is milk, which is highly perishable with a very short shelf-life because it contains major classes of nutrients. The high nutrient density makes milk a suitable medium for microbial contamination and colonization by autochthonous, spoilage and pathogenic microorganisms. For preservation and digestibility purposes, milk is naturally fermented at ambient temperature, or with starter cultures in the raw form or after pasteurization (Jans et al., 2017). Yoghurt is a fermented dairy food that is produced commercially from pasteurized milk using strains of *Lac. delbrueckii* subsp. *bulgaricus* and *Streptococcus thermophilus* starter cultures. While *Str. thermophilus* is responsible for the metabolism of lactose sugar to produce lactic acid, which enhances milk acidification, *Lac. delbrueckii* subsp. *bulgaricus* contributes to aroma and flavour production (Innocente et al., 2016). Cheese is another commercial fermented milk food, with different types depending on the origin of production, ripened or unripened, soft or hard. During cheese manufacturing, the acidic environment created by LAB, neutralizes the negative charge ion of the milk casein, for precipitation and coagulation, forming a gel cheese curd at isoelectric point of pH around 4.6. The major cheese microbiota includes *Lactococcus lactis* subsp. *lactis*, *Lac. lactis* subsp. *cremoris*, *Lac. lactis* subsp. *lactis* var. *diacetylactis*, *Leu. mesenteroides* subsp. *cremoris*, *Lac. helveticus*, *Lac. casei*, *Lac. plantarum*, *Lac. salivarius*, *Enterococcus faecium*, *Ent. durans*, *Propionibacterium freudenreichii*, *Debaryomyces hansenii*, *Yarrowia lipolytica*, *Kluveromyces marxianus*, *Geotrichum candidum*, *Penicillium roqueforti*, *Pen. camemberti*, *Pen. glaucum* and *Staphylococcus* species (Quigley et al., 2011).

Naturally fermented milk (NFM) products are likewise available in different parts of the world apart from cheese and yoghurt. Examples include kefir (fermented milk with kefir grain), koumiss (in Russia), sethemi, amasi/wakakora, mukaka, hodzeko, mbanik, kule naoto, mursik, amabere, amaruranu, suusac, raib, zabady (like plain yoghurt), urubu, amateregua, amavuta, jben, leban, rob, gariss, fenè, mabisi, dhanaan, makamo, nunu, nyarmie, kindirmo, maishanu, arera and pendidam (from different parts of Africa), laban (Lebanon), doogh (Iran), aryan (Turkey), and kurut (China) (Akabanda et al., 2013; Franz et al., 2014; Jans et al., 2017). Others are lāngfil, film-jölk, viili, tettemelk, ymer and talouspiimä in the Scandinavian, and dahi (yoghurt-like), chhurpi, somar, chhu, khachu, philu, shrikhand, philu and shyow in India (Duboc and Mollet, 2001; Ghatani and Tamang, 2017). Fermented curds similar to cottage cheese include datsi, warankashi/woagashi, oscypek, batzos, rigouta, ergo, ititu, ayib, while traditional fermented butters are kibe, neterkibe, omashikwa, klila and chhash.

### Fermented Meat and Seafood Products

Meat and fish products are highly nutritious, and perhaps the richest source of protein foods, when compared to plants, because of their amino acid quantity and quality, which may be lacking in other protein sources (Lücke, 2000). Fresh cut meat and fish are susceptible to microbial contamination and spoilage because of their relatively high moisture contents and water activity ( $a_w$ ) (Adams, 2010; Gram and Huss, 1996). They are usually processed by cooking, smoking, drying, canning and grilling before consumption. Fermentation of meat and seafood is also carried out, especially in Southern and Central Europe, United States of America, including Asia and some parts of Africa. Fermented sausage (also called 'salami' in Italy) is the most popular and the microbial ecology indicates the important presence and technological roles of two main groups of bacteria, LAB (*Lac. sakei*, *Lac. curvatus*, *Lac. paracasei*, *Lac. plantarum*, *Lac. pentosus*, *Lac. buchneri*, *Lac. brevis*, *Lac. rhamnosus*, *Lac. alimentarius*, *Lac. farciminis*, *Ped. pentosaceus*, *Ped. acidilactici*, *Leu. mesenteroides*, *Leu. pseudomesenteroides*, *Leu. carnosum*, *Leu. gelidum*), and Gram-positive coagulase-negative cocci (CNS: *Staphylococcus xylosum*, *Sta. carnosus* subsp. *carnosus*, *Sta. pasteurii*, *Sta. warneri*, *Sta. saprophyticus*, *Sta. epidermidis*, *Sta. equorum*, *Sta. simulans*, *Sta. sciuri*, *Sta. succinus*, *Kocuria varians*) (Greppe et al., 2015; Rantsiou et al., 2005; Villani et al., 2007). *Can. famata*, *Deb. hansenii*, *Willopsis saturnus*, *Pen. nalgiovense*, *Pen. chrysogenum* and *Pen. camemberti* have also been found to be present. Other sausage-like fermented meat products are alheira in Portugal, sucuk in Turkey, nham in Thailand, nem chua in Vietnam, Taiwanese ham, wakalim in Ethiopia, jamma, arjia and karyong in India (Albano et al., 2008; Bacha et al., 2010; Kesmen et al., 2012; La Anh, 2015; Oki et al., 2011; Tu et al., 2010).

Fermented fish are numerous and predominantly produced in South and Southeast Asian regions, with a few of them in Africa and some other parts of the world. They include salted fermented fish sauce (e.g. budu, kecap ikan/bakasang, nam-pla, ngan pyaye, nuoc

mam, patis, yu-lu, shottsuru, ishiru, jeotkuk, garos), and fish pastes (bagoong, belacan, hentak, jaadi, kapi, kung chao, mehiawah, ngapi, nar-ezushi, pla ra, trassi, tungtap (Jung et al., 2013; Thapa et al., 2004). Fermented fish foods that are neither sauce nor paste, with or without salt, and sometimes sun-dried include jeotgal, hákarl, surströmming, rakÖrret, fessiekh, ngari, pedah, balao balao, guedj, bonome, shiokara, pekasam, kung som (Devi et al., 2015; Guan et al., 2011; Sanchart et al., 2017).

### Alcoholic Drinks and Other Miscellaneous Fermented Foods

Non-cereal alcoholic beverages and miscellaneous fermented food products are available in various parts of the world, and are produced from different food raw materials. For example, wine made from grape juice/must, is consumed throughout the world, and fermentation occurs through a divergent community species and strains of yeasts, although predominantly by *Sac. cerevisiae* strains (Perrone et al., 2013). LAB, mostly *Oenococcus oeni*, is responsible for secondary or malolactic fermentation (MLF) that involves conversion/decarboxylation of dicarboxylic L-malic acid found in grape juice to monocarboxylic L-lactic acid (Liu, 2002; Osborne and Edwards, 2005). Technologically, *Oen. oeni* population in wines usually cause reductions in pH below 3.5, resulting in a softer-tasting wine; ensures microbial stability, and evolution of various sensory changes, due to production of a number of secondary metabolites (Dicks and Endo, 2009; Swiegers et al., 2005). *Oen. oeni* has been described as the preferred starter culture for MLF, whereas other wine-related LAB are known to cause spoilage in wine. This is because *Oen. oeni* has higher tolerance to wine conditions, such as pH < 3.5 and ethanol concentration > 10% and is less prone to off-flavour production (Versari et al., 1999).

Traditional wines, beers and alcoholic drinks, prepared from carbohydrate-rich substrates and indigenous fruits are particularly popular in Africa, South America and some other parts of the world. These include palm wine from palm sap/juice, *tej* (honey wine in Ethiopia), *mbege*, *urwarwa* and *isongo* (banana beer in Tanzania and Burundi), *marula*, *murara*, *mutandavira*, *masau* and *mudetemwa* fruit wines and beer in Zimbabwe, *basi* and *cachaça* (fermented sugar cane juices), *kanji* and *aloja* (alcoholic beverages from carrot and carob beans respectively), *caxiri*, *pulque* etc (Aloys and Angeline, 2009; Escalante et al., 2008; Gadaga et al., 1999; Mulaw and Tesfaye, 2017; Nyanga et al., 2013; Santos et al., 2012). Apart from black tea that is popularly consumed around the world, traditional fermented tea products such as *miang*, *fuzhuan brick*, *puer* and *kombucha* are also found in Asia. Other miscellaneous fermented products are coffee and cocoa beans in chocolate manufacturing, *nata de coco* and *nata de piña*.

## Health-Promoting Effects of Fermented Foods and Beverages

### Production of Antimicrobial Compounds Against Pathogenic Microorganisms

In starchy food materials, LAB species typically secrete  $\alpha$ -amylase enzyme, which hydrolyzes complex carbohydrates into fermentable sugars such as glucose and maltose. Upon sugar metabolism, LAB produce lactic acid as the principal metabolite but bacteriocins, a group of antimicrobial proteins or peptide compounds that inhibit closely related bacterial genera and other unrelated microbial species are also released. The production of lactic acid causes pH reduction to below 4.2 in acidic fermented foods and beverages, facilitating the inhibition and/or elimination of the onset and growth of food spoilage microorganisms and food-borne pathogens, which are known causative agents of several food-borne diseases and human illnesses (Giraffa, 2004; Holzapfel, 1997). Lactic acid-fermented food products containing viable bacterial cultures and metabolites, and their potential health benefits in diseases control have been previously identified.

Odugbemi et al. (1991) demonstrated the effective control of enteropathogenic *Escherichia coli* (EPEC), *Salmonella typhi* and *Sal. paratyphi* in *ogi*, a lactic acid cereal gruel used for infant feeding in West Africa. Mbugua and Njenga (1992) reported the antimicrobial activities of LAB against diarrhoea-causing bacteria – *Sal. typhi*, EPEC and *Shigella dysenteriae* in *uji*. Other studies on *mahewu*, *kenkey*, *ikii*, *bushera* and *togwa*, revealed the inhibition of the proliferation of food-borne pathogens and disease-causing bacteria such as *Campylobacter jejuni*, *Shi. flexneri*, EPEC and coliforms (Kalui et al., 2009; Kingamkono et al., 1998; Mensah et al., 1988, 1991; Muyanja et al., 2003; Nout et al., 1989; Simango and Rukure, 1991). An optimized *ogi*, 'DogiK', prepared with lactobacilli strain starter cultures, was developed for the control of infantile diarrhoeal disease in Nigeria (Olukoya et al., 1994). In a related study, Adebolu et al. (2007) confirmed the anti-diarrhoeal potential of *ogi* liquor harbouring *Lactobacillus* species, with respect to *Shi. dysenteriae*, *Sal. typhimurium*, *Esc. coli*, *Sta. aureus* and *Enterobacter* spp. Bacteriocinogenic *Lac. plantarum* strains from *ben-saalga* was found to exhibit broad spectra antimicrobial properties against food-borne pathogenic strains of *Bac. cereus*, *Ent. faecalis*, *Listeria innocua*, *Lis. monocytogenes*, *Sta. aureus* and *Sal. enterica* (Omar et al., 2006). In like manner, bacteriocin-producing *Lac. plantarum*, *Ent. faecium* and *Leu. lactis* in *boza* demonstrated bactericidal effects regarding *Esc. coli*, *Klebsiella pneumoniae*, *Listeria* spp. *Pseudomonas aeruginosa* and *Staphylococcus* spp. (Todorov, 2010).

There are various reports on the health-promoting functions of LAB in fermented milk foods, fruits and vegetables. Yoghurt and acidophilus-fermented milk containing *Lac. acidophilus* were effectively used in the treatment of gastrointestinal tract (GIT) disorders, including colitis, diarrhoea and constipation (Sanders, 1993). Olasupo et al. (1999), Ghrairi et al. (2004) and Mitra et al. (2010) isolated a nisin Z *Lac. lactis* strain from *wara* (short form of *warakanshi*), *rigouta* and *dahi* respectively, which possessed anti-listerial characteristics, by inhibiting *Lis. innocua*, *Lis. monocytogenes*, as well as *Clostridium butyricum*, *Clo. perfringens*, *Bac. cereus* and *Sta. aureus*. Another *Lac. lactis* strain from goat cheese whey in Brazil likewise showed anti-listerial properties (Chaves de Lima et al., 2017). LAB present in Iranian, Turkish and Algerian fermented dairy foods produced bacteriocin and bacteriocin-like inhibitory substances (BLIS) against *Lis. monocytogenes*, *Lis. innocua*, *Sal. enteritidis*, *Sta. aureus*, *Ent. faecalis*, *Bac. cereus*, *Sta. epidermidis*, *Esc.*

*coli* and *Yersinia enterocolitica* (Aslim et al., 2005; Iranmanesh et al., 2014; Mezaini and Bouras, 2013). Bacteriocin-producing LAB screened from *kurut*, a Chinese traditional fermented *yak* milk was antagonistic towards *Sta. aureus* and *Esc. aerogenes* (Luo et al., 2011). *Lac. lactis* subsp. *lactis* biovar. *diacetylactis* strain was used alone as starter culture or in combination with *Can. kefir*, to produce traditional fermented milk in Zimbabwe; this retarded the growth and survival of *Esc. coli* and *Sal. enteritidis* strains originating from human clinical samples (Mufandaedza et al., 2006). Similarly, *Lac. lactis* subsp. *lactis* bacteriocin was applied *in situ* for the biological control of *Lis. monocytogenes* in *jben* (Benkerroum et al., 2000). A crude extract containing antimicrobial peptide of milk fermented with *Lac. plantarum* 26, displayed antagonistic characteristic towards food-borne pathogens, particularly *Lis. innocua* (Aguilar-Toalá et al., 2017). Pediocin, a bacteriocin, produced by a strain of *Pediococcus* in *kimchi*, was characterized to have bactericidal effects, and was resistant to *Micrococcus luteus*, *Clo. perfringens*, *Lis. monocytogenes*, *Sta. aureus*, *Esc. coli*, *Shi. flexneri* and *Sal. typhimurium* (Kwon et al., 2002). Lee et al. (2009) investigated the growth inhibitory effects of LAB species from *kimchi* on food-borne pathogens, and found strong antimicrobial activities against *Lis. monocytogenes*, *Sta. aureus*, *Esc. coli* and *Sal. typhimurium*. Fruits and vegetables fermented by lactobacilli strains in India and Romania showed antimicrobial activities against *Lis. monocytogenes*, *Esc. coli* (including ESBL strains), *Sta. aureus* and multi-drug resistant *Sta. aureus* (MRSA) strains (Grosu-Tudor and Zamfir, 2013; Patel et al., 2014).

An intervention programme on hospitalized children suffering from acute diarrhoea was conducted in New Delhi, India. The consumption of *dahi*, containing *Lac. lactis*, *Lac. lactis* subsp. *cremoris* and *Leu. mesenteroides* subsp. *cremoris* starter strains, significantly reduced the mean duration of diarrhoea in a randomized, double-blind study (Agarwal and Bhasin, 2002). *In vitro* screening of enterococci from *dahi* showed antimicrobial inhibition of food-borne pathogens, such as *Lis. monocytogenes*, *Sal. typhi*, *Sta. aureus* and *Shi. dysenteriae* (Gupta and Malik, 2007). Historically, the Maasai nomadic communities in Kenya have been consuming *kule naoto*, for the treatment of diarrhoea and constipation (Mathara et al., 2004).

In addition to the antibacterial activities of LAB in fermented foods, their antifungal properties have also been documented. Mould growth and mycotoxin production in food substances pose serious health risks and concerns to the consumers (Batish et al., 1997). Aflatoxins (AFs) and ochratoxins (OTs) are among the most potent mycotoxins reported so far with carcinogenic, mutagenic, teratogenic, neurotoxic, nephrotoxic, immunosuppressive and estrogenic effects when consumed, even at low concentrations (Bennett and Klich, 2003; IARC, 1993; Nwagu and Ire, 2011). Studies have shown the potentials of LAB as bio-protective cultures, in controlling or preventing mould growth and development, and their mycotoxins production in various fermented food matrices, thereby conferring significant health benefits on them.

Roger et al. (2015) confirmed the inhibition of the growth of *Asp. flavus* and its aflatoxin B<sub>1</sub> (AFB<sub>1</sub>) metabolism by divergent LAB strains in *kutukutu*, a fermented maize dough in northern Cameroon. Carboxylic acids synthesized by *Lac. plantarum* FST1.7 and *Lac. brevis* R2Δ starter strains during wort fermentation were antagonistic against spores of mycotoxin-producing *Fusarium culmorum* (Peyer et al., 2016). Strains of *Lac. brevis* from *katak* (a yoghurt-like drink) in Bulgaria showed broad spectrum antifungal activities, suppressing the growth of carcinogenic *Asp. niger*, *Asp. awamori* and *Pen. claviforme*, and partially inhibiting mycelial growth and conidia germination of *Asp. flavus* (Tropcheva et al., 2014). Hassan and Bullerman (2008) earlier reported the anti-mycotoxigenic potentials of *Lac. paracasei* isolated from sourdough bread culture, against several species of *Aspergillus*, *Penicillium* and *Fusarium*. *Lac. brevis*, *Lac. plantarum* and *Lac. sanfranciscensis* strains used as starter cultures for cocoa fermentation, exhibited antifungal properties in the control of ochratoxinogenous *Asp. ochraceus*, *Asp. niger* and *Asp. carbonarius* (Essia Ngang et al., 2015). LAB present in naturally fermented *amahewu* and other fermented maize meal, potentially reduced AFB<sub>1</sub>, fumonisin B<sub>1</sub> (FB<sub>1</sub>) and zearalenone (ZEA) to undetectable levels (Chelule et al., 2010; Mokoena et al., 2005). The ability of some lactobacilli species, originating from fermented dairy foods, to bind AFB<sub>1</sub> was assessed. Specifically, *Lac. amylovorus* and *Lac. rhamnosus* strains bind more than 50% AFB<sub>1</sub> throughout a 72-h incubation period (Peltonen et al., 2001). Generally, the anti-mycotic compounds of LAB that make them active against mycotoxigenic moulds, include lactic acid, indole lactic acid, phenolic acid, phenyllactic acid, 4-hydroxy-phenyllactic acid, 3-(R)-hydroxydecanoic acid, 3-hydroxy-5-cis-dodecenoic acid, 3-(R)-hydroxydodecanoic acid, 3-(R)-hydroxytetradecanoic acid, cyclo (L-Phe-trans-4-OH-L-Pro), cyclo (L-Phe-L-Pro) and 3-hydroxylated fatty acids (Crowley et al., 2013; Haskard et al., 2001; Lavermicocca et al., 2000; Sjögren et al., 2003).

The production of antimicrobial compounds against pathogenic microorganisms, which cause various human diseases and other health related issues, has also been reported in fermented food products that are not lactic acid fermented. One example is the alkaline pH-fermented protein-rich legume foods that are widely consumed in West Africa sub-region and Southeast Asia. A number of traditional alkaline-fermented food condiments in West Africa like *bikalgá*, *maari*, *okpehe* and *soumbala* have been found to possess health beneficial functions. They contain vegetative cells of *Bac. subtilis*, *Bac. pumilus*, *Bac. amyloliquefaciens* ssp. *plantarum*, *Bac. subtilis* subsp. *subtilis* and *Bac. licheniformis* that are capable of producing inhibitory peptide and antibiotic compounds. These substances such as iturin, fengycin, surfactin, difficidin, macrolactin, bacillaene, bacilysin, subtilisin, subtilosin A, subtilin, sublan-cin and ericin, showed broad spectrum antagonistic properties towards *Mic. luteus*, *Sta. aureus*, *Bac. cereus*, *Ent. faecium*, *Lis. monocytogenes*, *Esc. coli*, *Sal. typhimurium*, *Shi. dysenteriae*, *Yer. enterocolitica*, *Asp. ochraceus* and *Shi. flexneri* (Compaoré et al., 2013a; b; Kaboré et al., 2012; Oguntoyinbo et al., 2007; Ouoba et al., 2007). *Bac. natto* TK-1 and *Bacillus* strains from Japan, Korea and Thai fermented soybean foods, *natto*, *chungkookjang* and *thua-nao* respectively, produced heterogenous and bio-surfactant lipopeptides against *Bac. cereus*, *Lis. monocytogenes* *Ent. faecalis*, *Sal. typhimurium*, *Esc. coli* and *Sta. aureus*, including inhibition of *Asp. flavus* growth and significant detoxification of AFB<sub>1</sub> and ochratoxin A (OTA) by more than 70% (Cao et al., 2009a; Lee et al., 2016; Petchkongkaew et al., 2008). *Bac. subtilis* HJ18–4 isolated from buckwheat *sokseongjang*, a traditional Korean fermented soybean food, produced an antimicrobial peptide against *Bac. cereus*, causing the down-regulation of expression of diarrhoeal and enterotoxin genes (Eom et al., 2014).

Two strains of *Ent. faecium*, LMG 19827 and 19828 identified in Malaysian *tempe* produced enterocins that inhibited *Lis. monocytogenes* growth (Moreno et al., 2002). The antimicrobial potentials of Indonesian *tempe* was earlier demonstrated by its protective effects against diarrhoeal EPEC and enterotoxigenic *E. coli* (ETEC), with health beneficial functions in diarrhoea prevention, control and management among children (Karyadi and Lukito, 2000; Kiers et al., 2003; Kiers et al., 2002). Bacteriocin-producing *Bac. coagulans* was found in *ngari*, which inhibited *Bac. cereus*, *Sta. aureus* and *Mic. luteus* (Abdhal et al., 2015). A peptide antibiotic, polyxin, from *Paenibacillus polymyxa*, isolated from Argentinean fermented sausage, was previously found to be antagonistic to *Esc. coli*, *Sal. newport*, *Serratia marcescens*, *Sta. aureus*, *Kle. pneumoniae*, *Bac. thuringiensis israeliensis* and *Bac. cereus* (Piuri and Ruzal, 1998). Another *Pae. polymyxa* strain isolated from *kimchi*, co-produced a lantibiotic (polymyxin E1) and an antimicrobial peptide (paenibacillin) that were active against *Clo. sporogenes*, *Sta. aureus* and *Listeria* spp. (He et al., 2007).

### Bioactive Compounds Synthesis

Different biologically active compounds, synthesized during food fermentations, either as metabolites of wild-type microbial strains/starter cultures or as substances released from the hydrolysis of organic components of food substrates, are widely associated with various functional health-promoting benefits. These bioactive compounds usually have antimicrobial (already discussed above), antihypertensive, antioxidant, anti-diabetic, anti-mutagenic, anti-cancer, anti-tumour effects and fibrinolytic activities.

#### Antihypertensive

Angiotensin converting enzyme-inhibitory (ACE-I) peptides are among the bioactive peptides formed during food fermentation by the action of proteolytic enzymes (i.e. proteases) on the native proteins present in many protein-based food substrates. They are not digested by the GIT digestive enzymes (e.g. trypsin, pepsin and chymotrypsin), and inhibit the enzyme responsible for converting angiotensin I to angiotensin II, a potent vasoconstrictor that causes re-absorption of water and sodium ions, thereby affecting the electrolyte balance, volume and blood pressure (BP) (Hartmann and Meisel, 2007; Rai et al., 2017). The inhibition of angiotensin converting enzyme (ACE) by ACE-I peptides is suggested to be made possible by the presence of hydrophobic (aromatic or branched side chain: Tyr, Phe, Trp, Ala, Ile, Val and Met) and positively charged amino acids (Arg and Lys), including Pro at the C terminal of ACE-I peptides, which show affinity for ACE protein (Haque and Chand, 2008; He et al., 2012; Rai et al., 2017). In addition to converting angiotensin I to angiotensin II, ACE also inactivates bradykinin and kallidin, two important vasodilators, which leads to increased BP, and risk of hypertension, including other cardiovascular diseases (CVD), strokes, etc (Sanjuka and Rai, 2016). Investigations on ACE-I peptides production are mostly on fermented milk products and legumes, and there are reports of their ACE inhibition, to cause vasodilator effects, which lowers BP. They are thus gaining wide popularity as antihypertensive agents in prophylactic medicine.

An *in vitro* spectrophotometric analysis is most commonly used for the evaluation of ACE-I activities. Hippuryl-His-Leu (HHL) serves as the substrate, which is hydrolysed by ACE to produce hippuric acid and His-Leu. ACE-I peptides in the water-soluble fraction, produced by bacterial cell wall proteinase enzymes system, prevents this reaction from taking place. ACE-I peptide activity is then expressed as the percentage of ACE inhibition or as the minimum concentration of peptide to inhibit 50% of ACE activity, the IC<sub>50</sub> (Hernández-Ledesma et al., 2011). Several LAB strains have been screened for high proteinase and ACE-I activities of dipeptides, tripeptides and oligopeptides liberated from milk proteins,  $\alpha$ <sub>s1</sub>-casein and  $\beta$ -casein, as a strategy for the development of fermented milk foods with antihypertensive properties. Empirical studies on different LAB dairy and non-dairy starter cultures, alone or in combination with yeasts species, including wild-type strains, to ferment milk, for yoghurt, cheese and other traditional fermented milk products, as well as their specific ACE-I peptide sequences, properties and IC<sub>50</sub> values after fermentation and during storage, have been documented (Beltrán-Barrientos et al., 2016; Rai et al., 2017). Li et al. (2017) characterized the ACE-I peptides in milk fermented with *Lac. casei* strains. More than half of the strains produced fermented milks with ACE-I activity of over 60%, and maximum Val-Pro-Pro (VPP) and Ile-Pro-Pro (IPP) concentration of  $6.60 \pm 0.25$   $\mu$ mol/L. Goat and camel milk fermented by *Lac. plantarum* 69 and *Lac. rhamnosus* MTCC 5945 (NS4), respectively had ACE-I activities up to 78.09% and 91.62%, under optimum fermentation conditions (Chen et al., 2018; Solanki and Hati, 2018).

To validate the *in vitro* antihypertensive potential of ACE-I peptides, animal models, using spontaneously hypertensive rats (SHR) and clinical trials of human subjects are conducted, measuring reduction or drop in systolic blood pressure (SBP) or diastolic blood pressure (DBP), after oral or intravenous/intra-peritoneal administration. Earlier works on fermented milk products, like *calpis* sour milk in Japan, fermented with *Lac. helveticus* and *Sac. cerevisiae*, and containing tripeptides VPP and IPP, showed hypotensive effects and decrease in ACE tissue activity of SHR (Nakamura et al., 1995; Nakamura et al., 1996). Milk fermented with *Lac. lactis* strains NRRL B-50571 or NRRL B-50572 had similar reductions in SBP and DBP of SHR, in comparison with captopril administration (Rodríguez-Figueroa et al., 2013). A single oral dose of *Lac. helveticus* H9 in fermented milk significantly lowered the systolic, diastolic and mean blood pressure of SHR (Chen et al., 2014). Increase in frequency unit of Gamalost cheese consumption, rich in ACE-I peptides, among Norwegian population, corresponded to a reduction in SBP of 0.72 mm Hg (Nilsen et al., 2014). Beltrán-Barrientos et al. (2018) examined the BP-lowering effect of milk fermented by *Lac. lactis* NRRL B-50571 in a double blind, randomized controlled, clinical trial of pre-hypertensive patients, administered daily for 5 wk, and observed reductions in SPB and DBP, in addition to triglyceride, total cholesterol and low density lipoprotein in blood serum. Other *in vivo* studies involving SHR and human subjects on both short- and long-term antihypertensive effects of fermented milk peptides are available in Beltrán-Barrientos et al. (2016) and Rai et al. (2017) reviews.

Similarly, protein-rich legume fermented seeds, particularly soybean, containing glycinin and  $\beta$ -conglycinin protein fractions, have also been reported to possess ACE-I peptides. But while information is available on the antihypertensive activities of different fermented soybean foods consumed in Asia, little or none is known about closely related fermented foods in Africa. For instance, an antihypertensive peptide identified in *natto*, fermented with *Bac. subtilis natto* O9516, showed *in vitro* ACE-I activity, and *in vivo* reduction of SBP within 5 h of single dose oral administration in SHR (Ibe et al., 2009). Extracts of *tofu* composed of Ile-Phe-Leu and Trp-Leu peptide sequences were resistant to GIT digestive enzyme treatments and had good ACE-I activity (Kuba et al., 2003). Toshiro et al. (2004) reported *chunggugjang* soy product to possess antihypertensive peptides, which when administered in volunteer human subjects reduced SBP and DBP by 15 mm Hg and 8 mm Hg, respectively after 2 h. ACE-I activity was recorded in *suifu*, fermented with fungal strain, which correlated with peptide content, and increased during fermentation and maturation (Ma et al., 2013). Pigeon pea seeds [*Cajanus cajan* (L.) Millsp.] fermented with a strain of proteolytic *Asp. niger*, produced an ACE-I octapeptide Val-Val-Ser-Leu-Ser-Ile-Pro-Arg, which had competitive inhibition against *in vitro* ACE activity (Nawaz et al., 2017). Fermented soymilk products with strains of *Lac. casei*, *Lac. acidophilus*, *Lac. bulgaricus*, *Ent. faecium* and *Bifidobacterium longum* have been shown to possess ACE-I properties (Martinez-Villaluenga et al., 2012; Tsai et al., 2008). In addition to milk and legume, fermented fish sauce from salmon, sardine, anchovy, blue mussel and oyster in Asia were reported to contain ACE-I peptides. A purified peptide from fermented blue mussel significantly reduced BP in SHR by oral administration (Je et al., 2005).

Gamma-aminobutyric acid (GABA) is another peptide compound with hypotensive activity, in addition to other physiological functions such as relaxation, sleep enhancement (opioid), anti-depression, enhanced immunity, anti-diabetic, anti-cancer and anti-obesity. GABA also possesses anti-inflammatory, pro-neurotransmitter, menopausal syndrome relief, activation of liver and kidney function, amelioration of oxidative stress, as well as treatments of Parkinson's disease, seizures, Alzheimer's disease, stiff-man syndrome and schizophrenia (Wong et al., 2003). It is a non-protein four-carbon free amino acid (FAA), synthesized by the irreversible  $\alpha$ -decarboxylation of L-glutamic acid or its salts, i.e. monosodium glutamate (MSG), catalysed by glutamic acid decarboxylase (an enzyme found in bacteria, moulds and yeasts), in the presence of pyridoxal 5' phosphate cofactor (Shelp et al., 1999). Evidence of GABA hypotensive effect on SHR was established in *Lac. plantarum*-fermented skim milk diet, where SBP and DBP were significantly decreased (Liu et al., 2011). *Lac. plantarum* produced 77.4 mg/kg of GABA in an enriched functional fermented milk food; this increased in concentration to 144.5 mg/kg, in combination with other LAB strains, and was recommended for mild hypertensive condition (Nejati et al., 2013). GABA concentration of 10–12 mg in 100 mL of milk fermented by *Lac. casei* strain Shirota and *Lac. lactis* YIT 2027, significantly decreased BP when fed two or four weeks in a randomized, placebo-controlled trial with mild hypertensive patients as participants (Inoue et al., 2003). *Lac. lactis* ssp. *lactis* improved the GABA content of cheese (16 mg of GABA/50 g cheese), which decreased BP by 3.5 mm Hg in human subjects (Pouliot-Mathieu et al., 2013). GABA and nattokinase in *Bac. subtilis* B060-fermented beans significantly lowered SBP and DBP in SHR and Wistar-Kyoto rats (Suwanmanon and Hsieh, 2014).

### Antioxidant

Free radicals (i.e. atoms or molecules with an unpaired electron) and reactive oxygen species (ROS), such as superoxide anion radicals ( $O_2^{\cdot-}$ ), hydroxyl radicals ( $HO^{\cdot}$ ), hydrogen peroxide ( $H_2O_2$ ) and singlet oxygen ( $^1O_2$ ) are frequently generated in the human body during various metabolic processes and environmental stresses, besides those consumed in oxidized edible fats and oils. These free radicals play significant roles in cell signalling, apoptosis, gene expression and ion transportation (Lü et al., 2010). However, oxidative stress occurs when these molecules are produced in excess and/or there is lack of cellular defences against them, leading to oxidation of proteins and lipids, DNA mutation, cell and tissue disruption, permanent damage, and eventually death, as well as oxidative modification of low density lipoproteins (LDL) (Hu et al., 2004). Consequent upon this is the development of a number of degenerative diseases e.g. CVD (atherosclerosis), cancer, tumour growth, diabetes, arthritis, increase in blood cholesterol level, Alzheimer's and Parkinson's diseases (Afonso et al., 2007). Though not enough, the human system has non-enzymatic, i.e. reduced glutathione (GSH) and enzymatic antioxidants in the form of superoxide dismutase (SOD), glutathione peroxidase (GSHPx) and catalase (CAT), as defence and repair mechanisms against oxidative damages (Miller and Britigan, 1997). To alleviate oxidative stress, hydrolysed antioxidative peptides, FAA, free polyphenols (intermediates of  $\beta$ -glucosidase hydrolysis of polyphenols), genistein and daidzein (isoflavones), malvidin and delphinidin (flavonoids) and aglycones, which are naturally enhanced in fermented foods, can chelate metal ion, scavenge free radicals (by a way of proton or  $H^+$  donation) and quench singlet oxygen (Mathew and Abraham, 2006). For peptides, the radical scavenging activity (RSA) is supported by the side chain groups of the amino acids residues, i.e. imidazole, indole and phenol in His, Trp and Tyr, respectively (Guo et al., 2009). Therefore, these bioactive compounds can serve anti-cancer, anti-tumour, anti-mutagenic and anti-diabetic purposes.

Fermentation of buckwheat, wheat gram, barley and rye with *Lac. rhamnosus* and *Sac. cerevisiae*, compared to their unfermented equivalents, led to increase in total phenolic content (TPC), and antioxidant activities (AOA) as assessed using 2,2-diphenyl-1-picrylhydrazyl (DPPH) scavenging capacity, ferric ion-reducing antioxidant power (FRAP) and thiobarbituric acid (TBA) methods (Đorđević et al., 2010). Ethanolic extract of wheat *koji* prepared with *Asp. oryzae* and *Asp. awamori nakazawa* greatly increased the TPC and free RSA (Bhanja et al., 2009). Fermentation of adlay, chestnut, lotus seed and walnut cereal grains by food-grade *Bac. subtilis* and *Lac. plantarum* increased the phenolic and flavonoid contents of the methanolic extracts, with a stronger DPPH radical scavenging and FRAP activities (Wang et al., 2014). Solid-state fermentation (SSF) of wheat improved the water-soluble TPC and antioxidant property. There was a 14-fold improvement in TPC in *Asp. oryzae*-fermented wheat, as well as 6.6 and 5.0-fold enhancements of DPPH and ABTS radical scavenging, respectively in *Rhi. oryzae*-fermented wheat (Dey and Kuhad, 2014). The

TPC, total flavonoids and AOA were significantly enhanced in ethyl acetate extracts of SSF-fermented wheat using *Asp. oryzae* var. *effuses*, *Asp. oryzae* and *Asp. niger* (Cai et al., 2012).

During milk fermentation in the presence of *Leu. mesenteroides* ssp. *cremoris*, *Lac. jensenii* and *Lac. acidophilus* strains, antioxidative peptides released (4–20 kDa) were responsible for RSA and inhibition of lipid peroxidation (Virtanen et al., 2007). Low molecular weight bioactive peptides and FAA (His, Tyr, Thr and Lys) in commercial yoghurt provided antioxidant activities by inhibiting oxidation in a liposome model, in addition to possession of strong DPPH radical scavenging and high  $\text{Fe}^{2+}$  chelation (Farvin et al., 2010). An antioxidative undecapeptide (Ala-Arg-His-Pro-His-Pro-His-Leu-Ser-Phe-Met) isolated from milk fermented with *Lac. delbrueckii* subsp. *bulgaricus* strain demonstrated scavenging activity against DPPH radical (Kudoh et al., 2001). Soy whey fermented using *Lac. plantarum* B1-6 when compared to unfermented, possessed more TPC and isoflavone aglycone, higher ABTS, hydroxyl and superoxide RSA, ferric reducing antioxidant power, and greater protection against oxidative DNA damage (Xiao et al., 2015). Milk-kefir and soymilk-kefir fermented using kefir grains LAB and yeasts strains showed significant anti-mutagenic property against different mutagens, as a result of scavenging activity against DPPH radicals, inhibition of linoleic acid peroxidation and ferrous ion chelation (Liu et al., 2005).

Fermentation of soybeans to produce *tempe*, *natto*, *kinema* and *douchi* by mould or bacterial strains has also led to antioxidant effects in the methanolic extract or water-soluble fractions of these food products. Enhancement in TPC, DPPH scavenging activity,  $\text{Fe}^{3+}$  reducing power,  $\text{Fe}^{2+}$  chelation, inhibition of lipid peroxidation and oxidation of LDL correlated with increased FAA, peptide content, free isoflavones and phenolic acids, protease and  $\beta$ -glucosidase activities, in most of the investigations, suggesting their potential to mitigate oxidative stresses (Sanjukta and Rai, 2016). Earlier, free soluble phenol in fermented underutilized legume seeds significantly enhanced reducing power, DPPH scavenging ability and inhibition of lipid peroxidation more than the bound phenols (Obboh et al., 2009). The ethanolic extract of *Bac. subtilis* or *Asp. oryzae* fermented red beans decreased MDA as well as increased GSH and SOD in the liver tissue of Sprague–Dawley rats, while only *Bac. subtilis* extract increased the levels of ascorbic acid and  $\alpha$ -tocopherol in the liver tissue; *Asp. oryzae* also increased ascorbic acid in the brain tissue better than the control (Chou et al., 2008). In an attempt to demonstrate the beneficial functions of antioxidant compounds in the management of diabetes mellitus (DM), Lim et al. (2012) assessed the *in vivo* anti-diabetic potential of fermented soybean extract with a *Bac. subtilis* strain, previously isolated from *chungkookjang*. Intra-peritoneal administration of the extract caused significant reduction in the plasma glucose level in addition to significant increases in plasma insulin level and activities of SOD, GSHPx, CAT and malondialdehyde (MDA) in streptozotocin (STZ)-induced diabetic rats, suggesting hyperglycemia inhibition (i.e. hypoglycemic action), due to the protection of pancreatic  $\beta$ -cells from free radical-mediated oxidative stress.

### Anti-diabetic

Both *in vitro* and *in vivo* anti-diabetic effects of *meju* and *chungkookjang* fermented soybean products, rich in isoflavonoid aglycones and small peptides have been investigated. While peptide fractions in *chungkookjang* slightly enhanced glucose-stimulated insulin secretion, daidzein extract in *meju* and *chungkookjang* better improved insulin-stimulated glucose uptake by activating peroxisome proliferator-activated receptor- $\gamma$  (PPAR- $\gamma$ ) in 3T3-L1 adipocytes than unfermented soybeans. Furthermore, mouse insulinoma (Min6) cells treated with genistein and peptides had greater glucose-stimulating insulin secretion capacity, as genistein and daidzein stimulated glucagon-like peptide-1 (GLP-1) secretion in enteroendocrine NCI-H716 cells, generating insulinotropic actions (Kwon et al., 2006, 2011). Experiments with type-2 diabetic male Sprague-Dawley (SD) rats fed *meju* and *chungkookjang*, prepared with microbial starter strains, significantly improved glucose homeostasis and tolerance, by way of glucose-stimulating insulin secretion and increased pancreatic  $\beta$ -cell mass, than the unfermented products (Yang et al., 2013; Yang et al., 2012). Fermented soybean diets, enriched with phenolic compounds, in STZ-induced diabetic rats reduced blood glucose, thiobarbituric acid reactive species (TBARS) contents, pancreatic MDA,  $\alpha$ -amylase, intestinal  $\beta$ -glucosidase and acetylcholinesterase activities, with corresponding increase in pancreatic glutathione peroxidase (GPx) and GSH (Ademiluyi et al., 2014, 2015).

### Anti-cancer

Apart from the lunasin anti-cancer peptide present in soybean, only very few reports are available on the anti-cancer compounds produced during food fermentation. Hydrophobic peptides in Korean traditional soy sauce displayed anti-tumour activity by their cytotoxic effects on different *in vitro* cell lines, including human colon cancer cells (Kim et al., 1998). *Bac. subtilis* natto T-2 and *Bac. natto* TK-1 in *natto* produced cyclic lipopeptide and lipopeptide bio-surfactant respectively, which induced apoptosis in human leukemia cells and inhibited the proliferation of human breast cancer cells (Cao et al., 2009b; Wang et al., 2007). Also, a surfactin-like compound from *Bac. subtilis* CSY 191-fermented *cheonggukjang* resulted in growth suppression of human breast cancer (MCF-7) cells (Lee et al., 2012). In camel milk fermented with *Lac. lactis* and *Lac. acidophilus* strains, the water-soluble extract ( $\leq 3$  kDa) significantly inhibited proliferation of Caco2, MCF-7 and HELA carcinoma cell lines (Ayyash et al., 2018). Fractionated peptides released by *Lac. helveticus* in fermented milk suppressed the growth of fibrosarcoma tumours induced by methylcholanthrene crystals, and increased the number of immunoglobulin A (IgA)-secreting cells in BALB/c mice (LeBlanc et al., 2002).

### Fibrinolytic Enzymes

Developments in the study of fibrinolytic enzyme activities and its potential thrombolytic property started when Sumi et al. (1987) observed that one of the *natto* beans developed a clear zone on a fibrin plate, indicating that insoluble fibrin (i.e. blood clot) around the bean was digested by an unknown enzyme produced by *Bac. subtilis* (*natto*), which was thereafter characterized and named

nattokinase (NK). Subsequently was the report of oral administration of NK in *natto* to healthy adults, which increased fibrinolytic activity two-folds in plasma, together with fibrin/fibrinogen degradation products in serum, and tissue plasminogen activator (tPA) (Sumi et al., 1990). In furtherance to this, Fujita et al. (1995) described the passage of NK through intestinal cells of rats, showing degradation of fibrinogen and appearance of NK in the plasma. Fibrinolytic enzymes from other protein-based fermented foods apart from *natto* include: choggokkinase from *chonggakjang*, myulchikinase from *myul-chi-jeot-gal*, katsuwo kinase from *shiokara*, subtilisin DFE from *douhchi*, subtilisin DJ-4 from *doenjang*, metalloprotease from fish *jeotgal* and TPase from *tempe*. They are specific in their actions toward fibrin clots. Fibrin, the key protein constituent of blood clot, is formed following fibrinogen degradation by thrombin (Wolberg, 2007). Its presence is checked by fibrinolysis, to maintain a balance in homeostasis, by endogenous plasmin, which is activated from the non-active plasminogen by tPA. However, an imbalance situation arises in the human physiology, when there is challenge in hydrolysing fibrin. This results in its excessive accumulation in the blood vessels, which interfere with blood flow, to cause thrombosis, leading to myocardial infarction, ischemic heart disease, CVD, high BP and stroke (Mine et al., 2005).

For treatment purpose, different thrombolytic agents [e.g. urokinase, streptokinase, staphylokinase and tissue-type plasminogen activator (t-PA)] are available for clinical use, and they follow same mechanism for plasmin activation as previously described. They are however expensive, and suffer some drawbacks, such as short half-life in their specificity towards fibrin, gastrointestinal bleeding, allergic reactions, etc (Blann et al., 2002). Fibrinolytic enzymes produced by food-grade, edible microorganisms in traditional fermented foods that have the ability to degrade fibrin and inhibit thrombin, are cheap, highly specific toward fibrin, with safe records of consumption and no side effects. They have been isolated and characterized, and recommended as alternative therapy for the prevention and management of thrombosis (Kim et al., 1997; Montriwong et al., 2012; Singh et al., 2014; Stephani et al., 2017). However, much more than enzyme purification and identification, is the need for sufficient evidence-based and empirical scientific investigations to demonstrate the therapeutic efficacy of these enzymes in animal models and human subjects, involving clinical trials. Unfortunately, only very few studies exist on this aspect of therapeutic effectiveness. For example, subcutaneous administration of NK from *Bac. natto*, preceding intravenous kappa carrageenan to the tail of rats, produced infarcted regions that were significantly shorter in mean length in rats administered NK than those in control rats, signifying the anti-thrombosis prophylactic effects of NK (Kamiya et al., 2010). The fibrinolytic enzyme from *Stenotrophomonas* sp. in Indonesian soybean fermented food dissolved thrombin and reduced blood clot induced by  $\kappa$ -carrageenan injection in the tail of Wistar rats (Nailufar et al., 2016). In human subjects with cardiovascular risk factors, oral intake of NK for 2 months significantly decreased plasma levels of the CVD-associated coagulation factors of fibrinogen, factor VII and factor VIII (Hsia et al., 2009). Bacilopeptidase F preparations, a serine protease secreted by *Bac. subtilis* (*natto*) that was orally administered to human volunteers showed fibrinolytic and amidolytic activities by shortening euglobulin lysis time and positive changes in local blood flow (Omura et al., 2004).

### Production of Exopolysaccharides (EPSs)

Complex polysaccharide metabolites are generally synthesized by wild-type microorganisms, autochthonous or starter cultures that are involved in the fermentation of different food substrates. Though these polysaccharides are secreted outside the microbial cells as extracellular metabolites, they are either adherent, remaining tightly bound to the cell wall surface appendages (e.g. capsule), referred to as capsular polysaccharides (CPSs) or permanently unattached to the cell surface as EPSs. EPSs may have two forms; those loosely attached to the bacterial surface and the ones freely released to the cell's external environment, which forms mucus, ropiness and slimy materials (Badel et al., 2011). Structurally, EPSs are long-chain, high molecular weight carbohydrate polymers, consisting of branched, repeating sugar units (mainly glucose, galactose and rhamnose), substituted sugars or sugar derivatives, including substituents such as phosphate and acetyl group (De Vuyst and Degeest, 1999; Du et al., 2017). They could be homopolysaccharides (HoPSs), composed of only one repeating monosaccharide moiety (D-glucose or D-fructose of two major groups: glucans and fructans), and examples are cellulose, dextran, mutan, alternan, pullulan, levan and curdlan, or heteropolysaccharides (HePSs), comprising different sugar molecules e.g. glucose, galactose, rhamnose, mannose, *N*-acetylglucosamine, *N*-acetylgalactosamine and glucuronic acid, to form gellan and xanthan (Fabera et al., 1998; Laws et al., 2001). Because the biosynthesis of EPSs is a complex one, and the fact that the mechanism of polymerization of the repeating unit is unclear, its discussion remains out of the scope of this review.

Other than the technological properties (i.e. viscosity, texture, rheology and firmness) of EPSs in fermented foods, they have been reportedly found to impart a number of physiological and health beneficial functions on the consumers, which include adhesion and colonization of probiotic microorganisms for competitive exclusion of food-borne pathogens, prebiotic activity, acting as a physical barrier to many pathogenic bacteria. Other health benefits include serum and blood cholesterol reduction, immunomodulation and immunostimulatory effects, antimicrobial, antioxidant, antihypertensive, anti-diabetic, anti-cancer, anti-tumour, anti-proliferative, anti-allergic, anti-ulcer, anti-viral, anti-biofilm formation of pathogens, generation of short chain fatty acids (SCFAs) upon degradation in the gut by the colon microbiota, and protection against the harsh gut environment (Caggianiello et al., 2016; Dilna et al., 2015).

Purified EPS (EPS\_DN1) produced by *Lac. kefirifaciens* in *kefir* completely inhibited *Lis. monocytogenes* and *Sal. Enteritidis* at 1% least concentration, exerting bactericidal effects against them *in vitro* (Jeong et al., 2017). EPSs of *Leu. citreum*, *Leu. mesenteroides*, *Leu. pseudomesenteroides* and *Ped. pentosaceus* obtained from Tunisian fermented foods showed pre- and post anti-biofilm activities at 1 mg/mL against *Esc. coli*, *Ent. faecalis* and *Sta. aureus*, with minimum adhesion inhibition of 86.9% and 53.4% for *in vitro* pre- and post-treatments, respectively (Abid et al., 2018).

*Lac. plantarum* LRCC5310 isolated from *kimchi* produced an EPS that had anti-rotavirus effect against human rotavirus (HRV) Wa strain. At 1.95 mg/mL, it reduced the viral RNA copy numbers significantly, when compared to the control; it also caused cytopathic effects and interference towards the viral cells, due to strong adherence to MA104 cell lines. In the *in vivo* study with the same EPS but rotavirus EDIM (RV-EDIM) strain, neonate mice pre-treated with EPS for 2 d, followed by administration of RV-EDIM together with EPS at 1 mg/mouse for 5 d, significantly lowered the number (50%) that developed RV-EDIM-induced diarrhoea than in control (Kim et al., 2018). For mice with acute diarrhoea and severe dehydration, the mean diarrhoea score and rotavirus shedding with this EPS also decreased significantly at 8 d post-infection in comparison with those in control (Kim et al., 2018). The EPS of *Lac. delbrueckii* ssp. *bulgaricus* 1073R-1 from traditional Bulgarian yoghurt at 20 µg/d orally administrated to BALB/c mice for 21 d, prior to intranasal infection, significantly decreased influenza virus (H1N1) titre, and increased its antibodies (IgA, IgG<sub>1</sub>) at 4 d post-infection, when compared to the control (Nagai et al., 2011). However, the acidic EPS (APS) prolonged the survival rate of influenza virus-infected mice, and not the neutral EPS (NPS).

EPS prepared from *Lac. plantarum* YW11 used to ferment Tibetan *kefir* showed *in vitro* AOA against hydroxyl radicals at 75% of 1.22 mg/mL, superoxide anion at 62.71% of 1.54 mg/mL, DPPH at 35.11% of 0.63 mg/mL, and 41.09% ferrous ion chelation at 1.07 mg/mL concentration. In the oxidant-induced stress experiment by subcutaneous injection of 500 mg/kg per day of 5% D-galactose in an ageing mouse, followed by 2.5 mg/mL EPS of *Lac. plantarum* YW11, there was a significant reduction in serum MDA, which reflects lipid oxidation inhibition as well as increased GSHPx, SOD, CAT and total antioxidant capacity (TAOC) activities (Zhang et al., 2017). Pyrosequencing data analysis of the gut microbiota of the ageing mouse revealed gut modulation and improvement, where *Lac. plantarum* YW11 EPS recovered the microbiome and phylotypes initially decreased or eliminated by D-galactose, with further increase in SCFAs content (Zhang et al., 2017). *Wei. confusa* OF126 strain isolated from *ogi*, having EPS of  $1.1 \times 10^6$  Da exhibited hydroxyl radical and DPPH activities of 86.5% and 67.4%, respectively at 4 mg/mL (Adesulu-Dahunsi et al., 2018). *Ent. faecium* BDU7 cultured from *ngari* was assayed for EPS; its purified form (8 mg/mL) showed significant scavenging of DPPH (63.5%), superoxide anion (77.3%) and hydroxyl (38.4%) radicals (Abdhuil et al., 2015). The antioxidant activity of a purified EPS ( $6.9 \times 10^5$  Da) from *Lac. lactis* subsp. *lactis* in Chinese pickled cabbage, revealed significant decrease in MDA and increased SOD and CAT in mice serum in a concentration-dependent manner (Pan and Mei, 2010). An EPS (LPC-1) extracted from *Lac. plantarum* C88 found in Chinese dairy *tofu*, demonstrated strong RSA of 85.21% hydroxyl radical and 52.23% DPPH at 4 mg/mL. LPC-1 also significantly inhibited the formation of MDA and exerted AOA against H<sub>2</sub>O<sub>2</sub>-induced injury in Caco-2 cells (Zhang et al., 2013).

Wang et al. (2018) characterized a neutral EPS (EPS0142) produced by *Lac. plantarum* JLK0142 from *tofu*. EPS0142 significantly induced macrophage-derived nitric oxide (NO) production in RAW 264.7 cell lines, in a dose-dependent manner, without any cytotoxic effect, as well as improved phagocytic activity. High dose of EPS0142 also administered to previously cyclophosphamide-induced immunosuppressed female BALB/c mice, significantly increased the spleen index and splenic lymphocyte proliferation, including the intestinal immunoglobulin A (sIgA) content and the levels of IL-2 and TNF- $\alpha$  cytokines. EPS extracted from milk fermented with *Lac. lactis* subsp. *cremoris* FC, and orally administered to male BALB/c mice before skin exposure to 2,4,6-trinitro-1-chlorobenzene (TNCB), significantly suppressed skin thickening induced by TNCB and penetration of mast cells in skin lesions (Gotoh et al., 2017). There was also the regulation of IL-4, IFN- $\gamma$ , IL-6 and TNF- $\alpha$  over-expression, as a result of TNCB exposure, and stimulation of bone marrow cell proliferation in dose-dependent EPS-treated Payer's patch cell of C3H/HeJ mice. EPS derived from *Lac. delbrueckii* ssp. *bulgaricus* 1073R-1 as previously described, and the respective yoghurt product, caused immunostimulation of IFN- $\gamma$  and augmentation of NK cells production in female BALB/c mice spleen cells, but not other yoghurts that also contain lactobacilli cultures (Makino et al., 2006, 2016). EPS fraction (B-EPS) from *Bac. subtilis* J92 isolated from *kimchi* increased NO, TNF- $\alpha$ , IL-6 and IL-1 $\beta$ , and their proteins and mRNA expressions in IFN- $\gamma$ -primed RAW 264.7 macrophages cell lines, including cytokine (IL-2 and IFN- $\gamma$ ) production by CD3/CD28-stimulated splenocytes (Jung et al., 2015). In addition, post-orally administered B-EPS significantly lowered the immunosuppression effects of cyclophosphamide in mice thymus and spleen, in a concentration-dependent manner.

EPS-producing *Str. thermophilus* strains in fermented milk, as well as their purified EPS in sterile milk, prevented the development of gastritis ulcer, when previously fed to BALB/c mice for 7 d before acetyl-salicylic acid (ASA)-induced gastritis, based on histological parameters and immune responses (Rodríguez et al., 2009). Two novel homogeneous EPSs synthesized by *Lac. casei* SB27 that was previously isolated from fermented *yak* milk, significantly inhibited the proliferation of HT-29 colorectal cancer cells, as an anti-tumour agent; induced apoptosis by the activation of *caspase-3* and *-8* genes in addition to up-regulation of pro-apoptotic genes *Bad* and *Bax* (Di et al., 2017). EPS of probiotic *Ent. faecium* K1, an isolate from a traditional fermented milk product, *kalarei*, showed significant cholesterol reduction potential, lowering the concentration from 100% to 48.81% *in vitro* (Bhat and Bajaj, 2018). *Lac. delbrueckii* subsp. *bulgaricus* strains from homemade yoghurt that produced high amount of EPS, removed more cholesterol from the medium, compared to those strains with low EPS production (Tok and Aslim, 2010).

### Probiotic Properties of Fermented Foods

Probiotics are defined as preparation of live microorganisms, which when consumed in adequate amounts ( $10^7$ – $10^9$  cfu/g or mL), induce health beneficial effects by qualitatively or quantitatively influencing gut microbiota, modifying immune status and contributing to general well being of the host, beyond basic nutrition (FAO/WHO, 2002; Phippen et al., 2009). Most fermented foods and beverages contain high population of viable microorganisms, and they serve as vehicles for the delivery of probiotics. For a probiotic microorganism to exert health benefits and other positive desirable effects on the host when administered, it is expected to be

resistant to gastric acidity of the stomach and tolerant to bile salts of the small intestine, produce antimicrobial compounds against pathogenic microorganisms, adhere to GIT mucosal and epithelial cell linings, as well as *in vivo* persistence (colonization) for competitive exclusion of pathogens, in addition to a long history of safety and non-pathogenicity (Ouwehand et al., 2002).

Even though the precise mechanisms by which probiotics perform their functions in the host have not been fully elucidated, some manner of probiotic functions has been proposed. These include up-regulation of immune responses (e.g. IgA) towards pathogens or vaccines, down regulation of inflammatory responses, production of bacteriocins and SCFAs, improving gut mucosal barrier function, enhanced stability and recovery of commensal microbiota when disturbed, as well as modulation of host gene expression and delivery of functional proteins (e.g. lactase) (Sanders, 2009). A probiotic *Lac. gasseri* SBT2055 used to prepare fermented milk significantly reduced abdominal visceral and subcutaneous fat, weight and body mass index (BMI) in adults with obese tendencies, in a randomized controlled trial (Kadooka et al., 2010). Fermented milk curd containing probiotic *Lac. acidophilus*, *Lac. casei* and *Lac. lactis* biovar *diacetylactis* had anti-tumour effect in rats, inhibiting 1,2-dimethylhydrazine (DMH) colon genotoxic compound, as a result of significant reduction in DNA damage, in comparison to the control (Kumar et al., 2010). The anti-diabetic effect of *dahi* fermented with probiotic *Lac. acidophilus* and *Lac. casei* was evaluated in high fructose-induced type-2 diabetic male albino Wistar rats. *Dahi*-supplemented diet significantly reduced blood glucose, glycosylated hemoglobin, glucose intolerance, plasma insulin, liver glycogen, plasma total cholesterol, triacylglycerol, low density lipoprotein cholesterol (LDL-C), very low density lipoprotein cholesterol (vLDL-C), and blood free fatty acids that were initially increased after high fructose feeding (Yadav et al., 2007). High cholesterol diet supplemented with cereal-mix fermented food containing probiotic *Pic. kudriavzevii* OG32, significantly lowered serum total cholesterol, triacylglycerol and LDL-C in rats, when compared to the control high cholesterol feed without probiotic supplementation (Ogunremi et al., 2015). Total serum and liver cholesterol, including the atherogenic index of rats fed high cholesterol chow, supplemented with milk fermented by probiotic *Lac. plantarum* HLX37, significantly decreased by 23.33%, 32.37% and 40.23% respectively, when compared to the hyperlipidemia diet (Guan et al., 2017). Probiotic bacteria in fermented milk were able to maintain consistent microbial community shift in the human GIT, where *Bacterioidetes* species increased during the intervention programme (Unno et al., 2015). Chung et al. (2014) investigated the effects of probiotic *Lac. helveticus*-fermented milk on cognitive functions in healthy older adults, in a double-blind, randomized control experiment. Their results showed an improvement in cognitive functioning, in relation to neuropsychological and cognitive fatigue.

## Conclusion

Fermented foods and beverages constitute a significant component of human nutrition, dietary supply and calories intake in different parts of the world. Fermentation of diverse plant and animal substrates by microorganisms and their enzymes provides desirable features, such as post-harvest preservation of perishable food materials, nutritional enrichment, bio-preservative effects and specific health-promoting benefits. Nowadays, fermented foods and beverages are consumed not only for nutritional values, wholesomeness or palatability, but importantly for their health beneficial functions. Live microorganisms and/or their metabolites in fermented foods are responsible for various health-promoting properties. An example is lactic acid, the primary metabolite in non-alcoholic fermented cereal foods (pH < 4.2) that demonstrates potential health benefits, by inhibiting pathogens causing food-borne diseases and human illnesses. Bioactive peptides, free amino acids and polyphenols, flavonoids, isoflavones and enzymes, which are naturally enriched in fermented foods possess antimicrobial, antihypertensive, antioxidant, anti-diabetic, anti-cancer, anti-tumour, anti-mutagenic, anti-proliferative and anti-thrombosis health benefitting properties. In addition, exopolysaccharides (EPSs) consumed in fermented foods can serve as prebiotics; they are also metabolized by colon microbiota to produce short chain fatty acids (SCFAs), which induce apoptosis of cancer cells and stimulate immune responses in the host. Furthermore, fermented foods contain viable probiotic microorganisms that confer health benefits on the host. However, to justify their development as functional foods and nutraceuticals, there is need for further and detailed scientific investigations on the in-depth characterization of the bioactive compounds and mechanism of actions in animal models and human intervention programmes, involving clinical trials.

## Glossary

**Antigen-presenting cells (APCs)** specialized cells that process antigens and display their peptide fragments on the cell surface.

**CD4<sup>+</sup> antigen-specific T helper cells** type of T cell which usually reacts with antigenic peptides associated with class II MHC.

**Cupin** protein family that contains 11S and 7S seed storage proteins, and germins.

**Dendritic cells (DCs)** professional antigen-presenting cells that link the innate and adaptive immune systems by capturing and then presenting antigens to T cells.

**Epitope** binding site for antibodies.

**FcεRI receptor** a receptor on the surface of mast cells and basophils that binds free IgE. When antigen binds this IgE and cross-links FcεRI, it causes mast cell activation.

**Gene silencing** prevention of the expression of a specific gene.

**Lipid Transfer Proteins** class of food allergens with low molecular weight found in plant derived foods and highly resistant to pepsin digestion.

**Major Histocompatibility Complex Class II** molecules made by antigen-presenting cells (macrophages, dendritic cells, and B cells) which help trigger an acquired immune response.

**Prolamin** type of gluten protein found in certain grains. These proteins are insoluble in water but soluble in alcohol/water mixtures.

## Nomenclature

APC antigen-presenting cell

BAT basophil activation test

CD4 cluster difference 4

DBPCFC double blind, placebo controlled food challenge

DC dendritic cell

ELISA enzyme-linked immunosorbent assay

FcεRI high-affinity IgE receptor

GMO genetically modified organism

HPP high pressure processing

IgE immunoglobulin E

IL13 interleukin-13

IL4 interleukin-4

IUIS International Union of Immunological Societies

MHC-II Major Histocompatibility Complex Class II

nsLTP non-specific lipid transfer protein

SPT skin prick test

## Introduction

Food allergy has emerged as a prominent global public health and food safety issue. It is defined as an “adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food” (NIAID, 2010). This definition comprises immunological reactions, which may be mediated either by immunoglobulin-E (IgE) antibodies or other immunological pathways (non IgE-mediated). IgE-mediated food allergy also known as immediate type hypersensitivity (type I reaction) represents the main form of food allergy, which causes the most severe reactions (Johnston et al., 2014; Kimber and Dearman, 2002). In this paper, food allergy is understood to refer to IgE-mediated reactions of the human immune system to food.

The true prevalence of food allergy is difficult to establish because factors such as allergy definitions, study populations, methodologies, geographic variation, age, dietary exposure, and other factors influence the estimates. Taken together, current available data substantiate food allergy prevalence nearing 5% in adults and approaching 8% in children (Longo et al., 2013; Sicherer and Sampson, 2014; De Silva et al., 2014). Although there are methodological limitations, there is a large consensus that prevalence of food allergy has been increasing in recent decades (Sicherer and Sampson, 2014; Rona et al., 2007; Tang and Mullins, 2017). To date, elimination of causative foods remains the principal treatment for food allergies. This can lead to nutritional deficiencies unless a proper nutritional support is given. Given the negative impact of food allergy, on health, psychosocial (Sicherer et al., 2001; De Blok et al., 2007), and socio-economics of food allergic sufferers and their families (Cornelisse-Vermaat et al., 2008; Fernández-Rivas and Miles, 2003; Fox et al., 2009), the prevention and treatment of allergic reactions to foods is a major challenge that must be addressed.

The development of hypoallergenic foods and ingredients is sought as one approach that could potentially contribute to the treatment and prevention of food allergies by avoiding elicitation of allergic reactions and reducing new sensitizations and cross-reactions (Mahler and Goodman, 2017). This is particularly relevant as recommendations about the prevention of food allergy and atopic disease through diet have changed radically in recent years (Du Toit et al., 2016). The paradigm has, indeed, shifted from recommending avoidance of common food allergens to considering early consumption to prevent allergy development. The availability of hypoallergenic foods, would theoretically improve the life quality of food allergy sufferers through increasing dietary variation and reducing restrictions on product selection (van Putten et al., 2010).

This article discusses the current knowledge and approaches being taken to develop hypoallergenic foods, and highlights their usefulness and challenges in the implementation of efficient food allergy management strategies.

## **Food IgE Allergy Mechanism and Definition of Terms**

To facilitate understanding an overview of IgE-mediated food allergy mechanism and term definitions is first provided hereafter.

### **Food IgE Allergy Mechanism**

The initial phase in the development of IgE-mediated allergy is termed sensitization, which occurs when a food allergen comes into contact with the immune system, generally through the epithelial barrier of the gut. Food allergen are internalized by antigen-presenting cells (APCs) such as dendritic cells (DCs), processed and presented to T cells, with Major Histocompatibility Complex Class II (MHC class II) molecules, on the surface of APCs. Upon stimulation by APCs, the naïve CD4<sup>+</sup> antigen-specific T helper (Th0) cells will either develop into Th1, Th2 or Th17 effector cells or regulatory T-cells (Treg). In individuals where signals from the APCs will cause differentiation of Th2 cells, production of IL-4 and IL-13 from these cells will drive B-cell class switch to IgE production and secretion of allergen specific IgE. The secreted allergen-specific IgE will subsequently bind to tissue mast-cells and blood basophils via the high-affinity receptor FcεRI. Upon second encounter with the same allergen, cross-linking of FcεRI-bound IgE occurs leading to mast-cells activation and release of potent inflammatory mediators, such as histamine, proteases and leukotriene (Rindsjö and Scheynius, 2010). Mast-cells and basophils are activated within a few minutes of IgE cross-linking, therefore this process is called an immediate allergic reaction; symptoms occur shortly after allergen contact. The immediate allergic reaction leads to intense inflammation that can become life threatening (Valenta et al., 2015; Berin, 2015).

### **Food Allergens**

Food allergens are defined as those specific components of food or ingredients within food (typically proteins) that are recognized by allergen-specific immune cells and elicit specific immunologic reactions, resulting in characteristic symptoms (NIAID, 2010). There is a global diversity in the foods that cause the majority of allergic reactions and the current regional regulatory lists of allergenic foods requiring labelling reflects to some degree regional patterns and prevalence of food allergies worldwide (Chan et al., 2011). Most of the research is concentrated on those few foods that are responsible for the majority of observed allergic reactions, namely, milk, egg, peanuts, tree-nuts, soy, wheat, fish, shellfish, fruits of the latex group (e.g. kiwi, banana), fruits of the *Rosaceae* family (e.g. apples, pears, prunes), and vegetables of the *Apiaceae* family (e.g. carrot, celery), thereby guiding food hypoallergenization efforts worldwide.

Each allergenic food contains a multitude of different proteins that can cause allergy. Owing to the development of proteomics, spectroscopic methods and gene cloning, numerous allergens have been isolated, purified and well characterised. By convention in the systematic International Union of Immunological Societies (IUIS) nomenclature (King et al., 1994), allergens are designated by the first three letters of the genus, the first letter of the species name according to the Linnaean taxonomic system and an Arabic number reflecting the chronological order in which the allergen was identified and characterised (e.g. Ara h 1 stands for allergen 1 from *Arachis hypogea* (peanut)) (EFSA Panel on Dietetic Products, 2014). Up to date structural information, biochemical characteristics and clinical relevance for each known allergen are compiled in a number of open-access databases. The most important ones are: the IUIS official website; the Allergome database (Mari et al., 2006); the Protein family (Pfam) database, which assigns sequences of clinically proven food allergens to protein families (Jenkins et al., 2005); AllFam,

which merges the Allergome allergens database with data on the Pfam database (Radauer and Breiteneder, 2007); the Structural Database of Allergenic Proteins (SDAP) provides detailed structural data on allergens in the IUIS Nomenclature, including sequence information, Protein Databank files (PDB-files) and computational tools to analyse IgE epitopes (EFSA Panel on Dietetic Products, 2014; Lorenz et al., 2015).

Currently, known food allergens are clustered according to their common structural, biochemical and functional features into a relatively small number of protein families, indicating that conserved structures and biological activities play a role in determining or promoting allergenic properties of proteins (Breiteneder et al., 2007; Breiteneder and Mills, 2009; Scheurer et al., 2015). Thus, around 65% of those from plants belong to just four protein families, the prolamin, cupin, Bet v 1-like, and profilin families (Breiteneder and Mills, 2009; Radauer et al., 2008), with the most comprehensively characterized plant allergenic proteins being profilins, seed storage proteins (2S albumins, 7S/11S globulins), and pathogenesis related proteins such as non-specific lipid transfer proteins (nsLTPs) (Scheurer et al., 2015). Similarly, animal food allergens are grouped into three main families, the tropomyosins, parvalbumin, and caseins (Breiteneder and Mills, 2009; Kuehn and Hilger, 2015). Food allergens are further classified either as class I or class II food allergens. Class I allergens act as the primary sensitizing agents via the gut and elicit an allergic reaction upon ingestion (e.g., storage proteins, such as peanut Ara h 1 and Ara h 2, milk  $\beta$ -lactoglobulin Bos d 5, nsLTPs). They are generally very stable to digestive enzymes and are often associated with severe and anaphylactic reactions. Class II food allergens, instead, are allergens, which IgE-reactivity results from primary sensitization to homologous allergens from different source, particularly inhalant allergens (e.g., Bet v 1 family, profilins, such as hazelnut Cor a 2). They are frequently associated with mild allergic reactions (Lorenz et al., 2015).

The allergenicity of food proteins depends on the reactivity to specific T-cell and B-cell epitopes (Lorenz et al., 2015). T-cell epitopes and B-cell epitopes differ in the way they are recognised by the immune system. T-cell epitopes refer to the regions on the allergen that are recognized after degradation, when presented to T-cells as peptides in (MHC-II) molecules (Bohle, 2006). These epitopes are generally short linear segments, located anywhere along the amino acid sequence and may be buried in its three-dimensional fold (Dall'Antonia et al., 2014). B-cell epitopes also called IgE-binding epitopes refer to the regions on the allergen, which are recognized in their native conformation by free IgE or membrane-bound B-cell receptors (Dall'Antonia et al., 2014; Van Regenmortel, 2009). IgE-binding epitopes can be linear/sequential epitopes comprising continuous amino acids sequences or conformational epitopes, which are formed by spatially adjacent amino acids segments that are distantly separated in the sequence and brought into physical proximity by protein folding. Allergens are typically defined based on their ability to bind specific IgE antibodies and induce IgE-mediated immediate reactions, while the allergen's potential to trigger T-cell reactivity is in many cases not very well studied and is not taken into account when categorizing a protein as an allergen (Schulten et al., 2014). Even though most allergens can be grouped into a small number of structural classes, many allergens do not exhibit any known physicochemical, functional or structural properties that would account for their allergenicity (Scheurer et al., 2015). Only few structural features are currently known to be common for certain allergens. As an example, important plant food allergens of the prolamin superfamily (such as nsLTPs and 2S albumins) contain the conserved pattern of cysteine skeleton that form three or four intramolecular disulfide bonds that gives stability to heating and digestion to these proteins (Breiteneder and Mills, 2005; Radauer and Breiteneder, 2009). However, the available information on allergen structures indicates that allergens are heterogeneous, and IgE-epitope repertoire too large to make specific IgE epitopes a realistic target for allergenicity prediction (Scheurer et al., 2015; Aalberse and Crameri, 2011; Dall'Antonia et al., 2014; Matsuo et al., 2015). Moreover, there is a general consensus that the molecular basis of allergenicity is likely not defined solely by the epitope structure, but is determined by additional factors, including the amount and duration of exposure to the immune system and environmental conditions (Scheurer et al., 2015). Nonetheless, molecular characteristics of allergens, in particular the identification of T-cell and B-cell epitopes, constitute essential information for the design of effective hypoallergenization approaches.

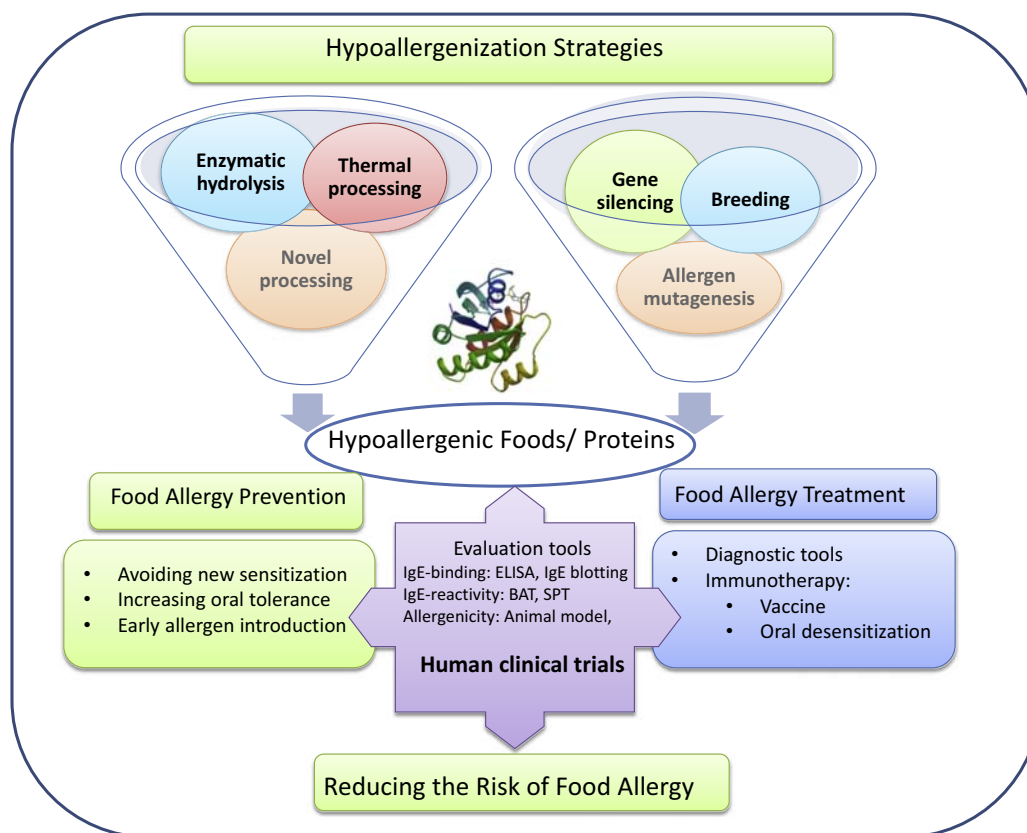

### Hypoallergenic Foods

There is actually no legal definition or standards that govern the utilisation of the term "hypoallergenic food", although it is commonly understood to refer to foods that are having little like hood of causing allergic reactions in humans. Hypoallergenic foods are also defined as being foods that have significantly reduced in vivo capacity to elicit an allergic reaction compared with naturally occurring foods (Mahler and Goodman, 2017; Muraro et al., 2004). Foods that are precisely defined as hypoallergenic to date are primarily restricted to cow's milk formulations treated using food processing techniques (hydrolysis, heat treatment, and/or ultrafiltration), with the aim of destroying or inactivating IgE-binding and T-cell epitopes (Beyer, 2007). For a formula to be considered hypoallergenic, it should be well tolerated in double-blind, placebo-controlled food challenge (DBPCFC) by at least 90% (with 95% confidence) of individuals who are allergic to the parent protein from which that formula has been derived (Muraro et al., 2004; Beyer, 2007; Chung and Reed, 2014).

### Food Hypoallergenization Strategies

The principle of hypoallergenization consists in blocking, reducing or eliminating the capacity of allergens to induce new sensitization or to trigger allergic reactions in already-sensitized individuals. Elimination or reduction of food allergenicity has been attempted for years by various investigators, essentially through the use of a wide range of conventional and novel thermal and

**Figure 1** Strategies behind hypoallergenic foods.

non-thermal food processing techniques (e.g. wet and dry heat, enzyme hydrolysis, glycation, lactic fermentation, irradiation, high pressure processing, etc.) (Verhoeckx et al., 2015; Vanga et al., 2017) or genetic engineering tools (Herman et al., 2003). Current state of the science with regard to food hypoallergization strategies (Fig. 1.) is discussed below. Their potential benefits, limitations, and perspectives are highlighted.

### Food Processing Approaches

Food processing induces several physical and biochemical changes to proteins such as unfolding, aggregation and degradation resulting in different reversible and irreversible changes on the levels of quaternary, tertiary and secondary structures, and cleavage or formation of intra and/or inter-molecular covalent and non-covalent interactions. Interactions with other constituents of the food matrix during processing such as sugars, lipids, and polyphenols can lead to additional modifications (Mills et al., 2009). In this way IgE-epitopes on an allergen can either be destroyed, modified, or masked thereby interfering with its ability to be recognized by IgE (Soler-Rivas and Wichers, 2001). Food processing approaches are undoubtedly the most attempted strategies for the reduction of food allergenicity (EFSA Panel on Dietetic Products, 2014; Verhoeckx et al., 2015; Vanga et al., 2017; Jiménez-Saiz et al., 2015; Rahaman et al., 2016). A majority of published works on the reduction of food allergenicity by processing were essentially based on the evaluation of IgE-binding capacity using in vitro immunological assays (e.g. ELISA, immunoblotting). However, IgE binding of food proteins does not always translate to clinical symptoms (Shi et al., 2013; Panda et al., 2015). Thus, the assessment of cross-linking and degranulation capacity is essential (Panda et al., 2015; Vissers et al., 2011). Clinical reactivity by oral food challenge remains the ultimate tool to be performed before concluding the effect of any processing method on the allergenicity of any food (Høst and Halken, 2004). In the context of this report, we would like to highlight those processing techniques that demonstrated reduction in food and/or protein allergenicity, and which were minimally supported by additional bio potency tests, such as release of allergic mediator (histamine and cytokines) test, animal allergic models, skin prick test (SPT) or human oral challenges.

### Thermal Processing

Heating is the most common technological treatment applied to food preservation and quality improvement. It includes blanching, pasteurization, sterilization, boiling, cooking, baking, roasting, frying, steaming, etc. It is now widely proven that thermal treatments can lead to significant alterations in allergen structure through denaturation, aggregation, fragmentation and Maillard reaction

(Mills et al., 2009; Davis et al., 2001). The nature and extent of such changes are however, dependent on the type (e.g., wet vs dry heat), the temperature and duration of heating treatment as well as on the intrinsic characteristics of the protein and the physico-chemical conditions of its environment, resulting either in an increased, decreased or unaltered IgE binding activity of food allergens (Verhoeckx et al., 2015; Jiménez-Saiz et al., 2015; Rahaman et al., 2016; Wal, 2003; Blanc et al., 2011; Verma et al., 2012).

For example, numerous studies have shown that extended boiling (100 °C, 1–16 h) reduced peanut IgE-binding through a combination of leaching of allergens into cooking water, fragmentation and denaturation of allergens (Blanc et al., 2011; Beyer et al., 2001; Turner et al., 2014). The reduction in allergenicity of 2 to 4 h boiled peanut extracts was demonstrated in vivo on 20 peanut-allergic subjects by a reduction of 55% of the mean SPT diameter when compared to raw extract (Tao et al., 2016). However, boiled peanut extracts maintained their ability to stimulate T-cell activation and proliferation. In two clinical studies, roasting of hazelnut resulted in reduced allergenicity in patients with birch pollinosis allergy by DBPCFC (Hansen et al., 2003; Worm et al., 2009). Still, 5/17 and 17/20 of patients, respectively, developed oral symptoms showing that the allergenicity was not completely abolished. The decrease in allergenicity of hazelnut was attributed to the decreased IgE-binding of the birch pollen related allergens, Cor a 1 and Cor a 2 (Pastorello et al., 2002; Schocker et al., 2000). In contrast, seed storage proteins and nsLTPs in hazelnut, almond, and cashew nuts were reported to be very stable regardless of the heat treatment and conditions (Pastorello et al., 2002; Venkatachalam et al., 2002; Venkatachalam, 2008; Masthoff et al., 2013).

The effect of extensive heating such as baking on the allergenicity of bovine milk and egg proteins has been investigated by few clinical studies. These studies have shown that a majority, 68% and 50%–85%, of milk and egg allergic children, respectively, tolerated baked (180 °C, 20–30 min) milk and egg products in oral challenges (Nowak-Węgrzyn et al., 2008) (Des Roches et al., 2006; Lemon-Mulé et al., 2008; Turner et al., 2013). Moreover, through these studies, it was also observed that incorporation of baked forms of milk and egg foods into the diets of children who are allergic to milk and eggs has generated immunological changes that could lead to the development of oral tolerance to the unheated forms of milk and eggs (Lemon-Mulé et al., 2008; Kim et al., 2011), indicating the potential role of hypoallergenic foods in the induction of oral tolerance. Larger and well-designed randomized clinical studies are, however, still needed to assess the accuracy of this hypothesis (Lambert et al., 2017). In contrast, moderate forms of heat treatments (temperatures <80 °C) still retained to a great extent, the allergenic properties of egg (Des Roches et al., 2006; Lemon-Mulé et al., 2008; Turner et al., 2013; Bartnikas and Phipatanakul, 2013; Cortot et al., 2012), and milk proteins (Bu et al., 2009; Loss et al., 2011; Waser et al., 2007). Partial reduction of allergenicity is achieved, presumably by destroying conformational epitopes (Thomas et al., 2007), while reactivity to linear epitopes is retained (Bu et al., 2013). It is important to appreciate here, that apart from the allergen intrinsic properties and processing conditions (type, temperature and duration), the food matrix composition and structure may also affect the digestibility and release of allergens, thereby modifying the way they are presented to the gut immune system, and subsequently modulating the overall food allergenicity (Wickham et al., 2009; Mackie et al., 2012).

### Enzymatic Hydrolysis

The principle behind enzymatic hydrolysis (proteolysis) as means for reducing food protein allergenicity is to hydrolyse protein peptide bonds into smaller peptides and even amino acids, thereby disrupting the structure of both linear and conformational epitopes present in food allergens. The extent of hydrolysis is highly dependent on the amino acid sequence, secondary structure, protein modification, and enzyme specificity (Thomas et al., 2007). Trypsin, pepsin and chymotrypsin are frequently used for hydrolysis, but other enzymes of plant and microbial origins have been also investigated (e.g., papain, alcalase, pronase, etc.). Currently, the only commercially available food preparations that are considered hypoallergenic are extensively hydrolysed milk formulas or free amino acids based formulas (Bahna, 2008; Baker et al., 2000; Niggemann et al., 2008; Oldæus et al., 1991; Terheggen-Lagro et al., 2002). Their hypoallergenicity for children with confirmed cow milk allergy was demonstrated with oral food challenges in a number of clinical trials (Berni Canani et al., 2013). However, it was reported recently that extensively hydrolysed formulas may still elicit reactions in some children with cow milk allergy (Chauveau et al., 2016). Enzymatic hydrolysis has been also attempted for reducing the allergenicity of other food allergens. For example, hypoallergenic wheat flour was developed using the combined hydrolytic action of cellulase and actinase (Watanabe et al., 2000). In vitro IgE-reactivity to treated wheat was abolished, and only 2/15 of wheat-allergic patients developed an immediate reaction after oral challenge with the hypoallergenic wheat-based products (Tanabe, 2008). Cashew protein also showed a decreased allergenicity in a mice allergic model when hydrolysed to very low molecular weight peptide (Kulis et al., 2012). Similarly, enzymatic hydrolysis of soluble protein extracts of three legumes – kidney bean, black gram, and peanut resulted in an important reduction in the bio potency of hydrolysates by SPT. Only 1/10 kidney bean-sensitive individuals, 2/6 black gram sensitive individuals and 1/7 peanut-sensitive individuals were found positive to their respective hydrolysates (Kasera et al., 2015). In another study, combining the application of heat treatment and enzymatic hydrolysis in egg resulted in low allergenicity and induction of oral tolerance in mouse allergic model (Hacini-Rachinel et al., 2014). From these studies, it appears, that enzymatic hydrolysis has the potential to reduce allergenicity of some food proteins by destroying specific IgE-epitopes, but care should be taken to not uncovering previously masked epitopes or simply leaving protein fragments with retained IgE-binding (Bu et al., 2013). Human oral challenges should be performed for more accurate evaluation of the allergenicity reduction. Moreover, hypoallergenic protein hydrolysates and peptides that have diminished capacity to cross-link IgE on mast-cells and basophils, but maintained capacity to target CD4<sup>+</sup> T-cells, are postulated as useful candidates for immunotherapy (Tao et al., 2016; Kulis et al., 2012).

### **Combined Conventional and Novel Food Processing Approaches**

In a search of more effective food hypoallergenization strategies, researchers have showed keen interest to evaluate the potential of emerging novel food processing techniques in reducing protein allergenicity (e.g., high hydrostatic pressure (HPP) (Lee et al., 2016), microwave (Garino et al., 2012),  $\gamma$ -irradiation (Oh et al., 2009), high-intensity ultrasound (Li et al., 2013), pulsed ultraviolet light (Chung et al., 2008), and so on (Vanga et al., 2017).

As for the conventional techniques, these novel processes can modify protein structure and consequently lead to a partial or complete reduction, or increase in protein immunoreactivity/allergenicity. To date, it remains difficult to draw conclusions because most of these reports are mainly focused on in vitro assays, and none of them produced results of clinical importance (Vanga et al., 2017). Nonetheless, combinations of novel processes with conventional (thermal or enzymatic hydrolysis) that may act synergistically appear to be more effective in achieving reduction in protein allergenicity. In a study combining the effect of high pressure and enzymatic hydrolysis, it was shown that milk  $\beta$ -lactoglobulin's peptic and chymotryptic hydrolysates treated at 400 MPa, had an abrogated allergenicity in a milk allergy mouse model (López-Expósito et al., 2012). Such high pressure induced protein unfolding facilitated enzymatic digestion and resulted in shorter peptide fragments (7–10 residues long, MW < 1.5 KDa) that had lost their ability to cross-link 2 human IgE antibodies to induce mast-cell degranulation. Others studies demonstrated the efficiency of combining high pressure and thermal treatment in the reduction of allergenicity of walnut (Yang et al., 2017), peanut (Long et al., 2016) and shrimp (Long et al., 2015) proteins in mouse allergic models. In another study, the synergistic effect of high pressure (autoclaving at 2.56 atm/30 min) and roasting treatment was also found to be efficient in reducing IgE binding properties of peanut protein extracts and abolishing skin reactivity in 8 peanut allergic patients (Cabanillas et al., 2015) by SPT. These results are promising, but need substantiation by relevant human oral challenges, to further confirm the usefulness of this approach for producing hypoallergenic foods.

### **Genetic Engineering Approaches**

#### **Breeding and Genetic Modification**

Breeding and genetic modification approaches for eliminating allergenic proteins from crop plants has long been explored for the development of hypoallergenic foods and ingredients based on (a) screening of low-allergenic cultivars from the existing biodiversity of a given crop, (b) breeding using characterized genotypes and genetic markers for low allergenicity, and (c) genetic modification to silence native genes encoding allergenic proteins (Gilissen et al., 2006; Riascos et al., 2010; Scheurer and Sonnewald, 2009).

In soybean for example, the three major allergens designated as Gly m Bd 60K, Gly m Bd 30K, and Gly m Bd 28K were eliminated by the development of a mutant line, Tohoku 124. Oral challenge test conducted with soybean-sensitive patients reported that about 80% of the soybean-allergic patients could ingest hypoallergenic products prepared from this mutant line without any adverse reactions (Ogawa et al., 2000). In another example, peanut cultivars missing either an Ara h 2 or Ara h 3 isoform were cross-bred and produced a variety lacking both isoforms (Perkins et al., 2006). Gene silencing by means of RNA interference (RNAi) offers the possibility to inhibit expression of entire gene families (Small, 2007) and it was successfully used for the silencing of Ara h 2; Ara h 1/Ara h 3 (Ananga et al., 2008) and Ara h 6 (Chu et al., 2008) in peanuts, and of PR-10 isoforms in carrots (Peters et al., 2011).

Although genetic engineering technologies have shown great promise to produce crops with a reduced or “null” content of allergenic proteins, these technologies are found to be limited by several big drawbacks (Riascos et al., 2010): (a) the development of allergen-free crop is unrealistic given the multitude of allergenic proteins; (b) hypoallergenization through conventional breeding is time consuming (Schenk et al., 2011); (b) the potential risk of sensitization to newly overexpressed proteins and questions regarding the long-term stability of transgenic suppression of allergenic proteins; (c) the consumer acceptance of transgenic food (GMOs); (d) the requirement for tight control on labeling. All these concerns require further attention from the perspective of food allergy management.

#### **Allergen Site-Directed Mutagenesis**

Site-directed mutagenesis is a molecular biology method that is used to make specific and intentional changes to the DNA sequence of a gene to produce hypoallergenic mutants of specific food allergen that can be used in immunotherapy with few adverse reactions (Mahler and Goodman, 2017; Patel et al., 2017). The approach consists in mutating the sequence of IgE binding epitopes or by targeting the secondary structure of the protein, such as overlapping (offset of one or two amino acid positions), substitution, or disrupting cysteine–cysteine disulphide bridges in protein domain. The produced hypoallergenic variant of the protein is then expressed in *Escherichia coli* (*E. coli*) and tested for reduced IgE immunoreactivity. T-cell reactivity is generally unaffected. Successful results were observed with egg allergens, in particular Gal d 1 (Dhanapala et al., 2017), as well as other major allergens such as shrimp allergen Pen a 1 (Reese et al., 2005), and peanut recombinant of Ara h 1, Ara h 2, and Ara h 3 (EMP-123) (Wood et al., 2013). However, these results remain to be translated into well-designed clinical studies. Thus, while the developed mutated peanut recombinant EMP-123 product did not bind IgE and showed reduced allergic symptoms in mouse allergy models, acute allergic reactions were still found in human clinical trial (Wood, 2016).

## Conclusion and Perspectives

A variety of food processing and genetic engineering technologies have been investigated in a proof-of-concept trials to reduce the allergenicity of food either by reducing their IgE-binding capacity or eliminating certain major allergens (Fig. 1). Based on the findings of these initial trials, producing hypoallergenic foods is technically feasible, but it is clear, that at present, there are a number of challenges and limitations that make absolute certainty regarding the absence of potential for allergic reactions not possible for most hypoallergenic foods. Examples of these challenges are (a) the multiplicity of the allergenic proteins contained in a whole food, (b) the variability of the impact of food processing and the food matrix on the allergenic properties of proteins, (c) the intra- and inter-individually variability of sensitization and thresholds of reactions against allergens, and (d) the presence of unknown allergenic proteins in the food that have not been identified yet. Moreover, in order to ensure the safety of food-allergic individuals, a thorough safety assessment and substantiation by human clinical studies using scientifically appropriate standards are necessary to confirm their presumed hypoallergenicity. Regulatory requirements that define and control the utilisation of the term “hypoallergenic food” will also need to be developed and reinforced throughout the entire food chain. In this regard, in vitro testing of IgE-reactivity remains a valuable tool for food quality control and assurance as well as for labelling.

With the progress being made in the understanding of factors that contribute to the development of sensitization and tolerance to foods, and with the substantial progress being made in clinical and molecular allergy diagnostics, hypoallergenic foods and proteins will certainly find their utility in food allergy treatment and prevention in the future through (a) the setup of efficient well-targeted and personalized management strategies, (b) the development of specific hypoallergenic protein molecules to be used for improved immunotherapeutic strategies tailored to the sensitization pattern of each patient, and (c) by facilitating and rendering more effective the new global approach to allergy prevention, which has recently shifted from recommending avoidance of common food allergens to consideration of early consumption strategy to prevent allergy development.

### Glossary

**Entomophagy** The practice of eating insects

**Larva** Immature form of insects that undergo complete metamorphosis

**Nymph** Immature form of insects that undergo incomplete metamorphosis

**Pupa** Immature form of insects between larva and adult stages

### Overview

Insects are a group of invertebrate animals within the class Insecta, phylum Arthropoda. They are the largest group of animals on the planet with an estimated diversity of 1.4 million to over 5 million species (Capinera, 2008). Incorporation of insects into human diet is not entirely novel. Historically, these six-legged creatures composed an important food source for our ancestors. Evidence of insect consumption by early American Indians dates back to 7000 BC (Van Itterbeeck and Van Huis, 2012). This is not surprising considering that insects are virtually eaten by all primates (McGrew, 2014). Insectivory may even play a role in human evolution as some of the first bone tools (1.7 million year old) were developed for the extraction of termites (Lesnik, 2011) that served as a nutrient-dense dietary supplement for large-brained hominins (Lesnik, 2014). Today, as many as 2 billion people of 3071 ethnic groups in 130 countries practice insect-eating regularly (Costa-Neto and Dunkel, 2016). For unintentional entomophagy (insect-eating), this number is expanded to the entire human population as food infestation by pests are unavoidable. That is why the United States Food and Drug Administration established the Food Defect Action Levels (levels of natural or unavoidable defects in foods that present no health hazards for humans) instead of a zero tolerance for insect contaminants in food. For example, the acceptable maximum of insects in canned citrus fruit juices are five *Drosophila* eggs or one maggot per 250 mL (FDA, 2016). Despite the fact that insects are already in our food, the bugs on the menu concept is still relatively new and somewhat repulsive for the general public in developed countries.

### Entomophagy Around the World

Insects are considered as ordinary food items in certain regions. Fig. 1 illustrates a food cart selling edible insects along with other arthropods in China. In his pioneer works on entomophagy, Professor Gene R. DeFoliart documented a large number of insect species consumed worldwide: 148 in Mexico, 12 in Central America and Caribbean Islands, 65 in South America, 83 in Southern Africa, 163 in Central and Eastern Africa, 25 in North and West Africa, 16 in Southwest Asia, 52 in South-Central Asia, 151 in Southeastern Asia, 66 in Eastern Asia, and 84 in Oceania (Defoliart, 2002). An updated inventory comprises 1544 edible insect species and this number is still just a tiny fraction of the total insect species (Dossey et al., 2016). Although widely practiced around the world, entomophagy is generally absent in Canada, United States, and Europe but this was not always the case. Ancient Greeks and Romans enjoyed insects, particularly grasshoppers and cicadas, as food. Aristotle (3rd century BC) himself described cicada nymphs and egg-bearing females as delicacies (Defoliart, 2002). Up until the famine of 1688, cockchafer grubs were still eaten by peasants and mountain inhabitants in Ireland as an important protein source (Bodenheimer, 1951).

The prejudice against insect-eating was likely developed alongside the agricultural advancement. When food became readily available, insects faded away from our diet because insect-gathering was no longer economical (Bodenheimer, 1951). Over time, these once considered delicacies turned into something alien and disgusting, and entomophagy became a taboo. This prejudice was later brought to North America. In the 1600s, the European colonists classified the New England lobster as an insect and refused to eat it (Kiple and Ornelas, 2000). It is interesting how lobster has been widely accepted as a premium food in the Western world today while insect-eating is still considered repulsive, unusual, or newsworthy at best. Recently, using insects as a “novel” food has become a trending topic in the food science community. So what has changed to make us re-embrace this once abandoned food?

### Sustainability of Insect Farming

The fifth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) underscores that climate change has had detectable negative impacts on crop yields (IPCC, 2014). This comes in the background of growing global population. It is projected

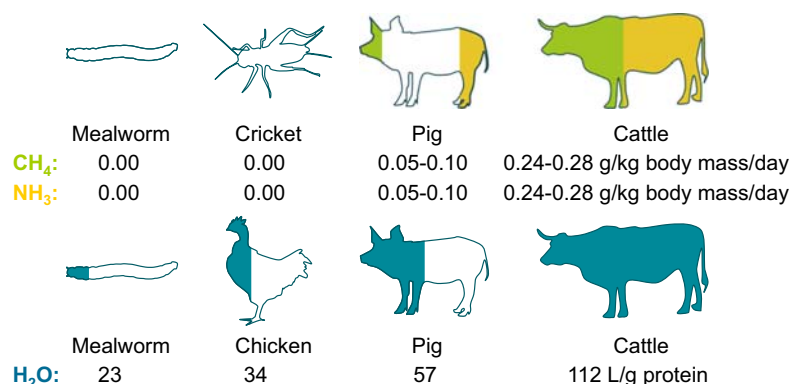

**Figure 1** A food cart selling (left to right, front to back) fried shrimps, crabs, cicadas, cockroaches, grasshoppers, bamboo weevils, silkworm pupae, and scorpions in Sichuan, China.

that by 2050 the global population will reach 9 billion. To feed the planet, current food production has to be doubled in the context of water and farmland shortages (Van Huis et al., 2013). Agriculture consumes approximately 70% of freshwater and livestock production is particularly water intensive. It is estimated that 22,000 L of water are required to produce 1 kg of beef (Van Huis, 2013). In addition, agriculture (e.g., enteric fermentation in livestock, manure management, and rice cultivation) remains a main source of anthropogenic methane emissions worldwide (Kirschke et al., 2013). Increasing agricultural activities may worsen climate change and complete the vicious cycle. Therefore, improving sustainability of food production is imperative to meet the growing demand for food and to address the pressing environmental challenges.

The Food and Agriculture Organization (FAO) of the United Nations has suggested using insects as an alternative food source. Insects have higher feed conversion rate as compared to the conventional livestock. For example, the feed-to-food conversion rate of cricket (*Acheta domesticus*) is twice that of chicken, four times that of pig, and 12 times that of cattle (Van Huis et al., 2013). Moreover, insects have low environmental footprints such as water use and emission of greenhouse gas and ammonia (Fig. 2) (Van Huis, 2013). Species such as yellow mealworms (*Tenebrio molitor*) and buffalo worms (*Alphitobius diaperinus*) are drought resistant and can live on organic side streams (Ramos-Elorduy et al., 2002) while the black soldier fly (*Hermetia illucens*) larvae have great potential to recycle organic waste and to be utilized as nutritious animal feed (Nguyen et al., 2015).

### Nutrient Composition of Insects

The most commonly eaten insect species belong to the orders of Coleoptera (30%), Lepidoptera (19%), Hymenoptera (17%), and Orthoptera (14%) (Dossey et al., 2016). As the most diverse group of animals, insects exhibit considerable variation in nutritional composition among species (Rumpold and Schlüter, 2013) (Fig. 3). Nutrient compositions of 471 edible insects are available in the FAO/INFOODS Food Composition Database for Biodiversity (Charrondière et al., 2013).

**Figure 2** Environmental footprints of the production of select animals. Data from Oonincx et al. (2010) and Miglietta et al. (2015).

**Figure 3** Proximate composition (dry weight basis) of commonly consumed insect orders. Data from Rumpold and Schlüter (2013) and Dossey et al. (2016).

Insects are a good source of proteins with well-balanced amino acid composition. Protein content of 203 edible insects in the FAO/INFOODS Database ranged from 1.8% to 72.7% with an average of 23.3%. Based on the definition of FAO/WHO, the majority of insects (89%) are regarded as “high in protein” (over 10 g proteins/100 g edible portion on fresh weight basis) (FAO/WHO, 2007). It is worth noting that most reported protein content of insects are calculated from the total nitrogen content using a nitrogen-to-protein conversion factor of 6.25, which overestimates the protein content due to the presence of non-protein nitrogen in insects. A conversion factor of 4.76 was obtained for *T. molitor*, *A. diaperinus*, and *H. illucens* larvae based on amino acid analysis (Janssen et al., 2017). With regards to protein digestibility, insect proteins are comparable to other animal proteins and are superior to many plant proteins (Rumpold and Schlüter, 2013). Essential amino acid scores of insect proteins ranged from 46% to 96%, which are above the FAO/WHO recommended score of 40% (Ramos-Elorduy et al., 1997). Essential amino acid composition of different insect orders is illustrated in Fig. 4.

The fat content of edible insects vary considerably from 0.66% to 77.13% (Rumpold and Schlüter, 2013). The fatty acid makeup of insect fat is generally preferable with high levels of polyunsaturated fatty acids (PUFA), particularly in isopteran (36%), orthopteran (37%), and lepidopteran (40%) insects (Fig. 5). Moreover, many insects exhibit a low ratio of omega-6/omega-3 fatty acids, which is desirable in reducing the risk of chronic diseases (Simopoulos, 2002). For example, toasted silkworm pupa (*Bombyx mori*) has a good omega-6/omega-3 ratio of 0.3 (Pereira et al., 2003).

The exoskeletons of insects are mainly composed of the polysaccharide chitin, which can serve as a dietary fiber. Fiber content of edible insects ranged from 0.12% to 29.13%. In addition to dietary fibers, insects are rich in a variety of micronutrients such as the vitamins riboflavin, pantothenic acid, biotin, and in some cases folic acid, and the minerals copper, iron, magnesium, manganese, phosphorous, selenium, and zinc (Rumpold and Schlüter, 2013). The minerals are not only abundant but also readily available. For example, bioavailability of iron from buffalo worm (*A. diaperinus*) is superior to that of sirloin beef (Latunde-Dada et al., 2016). Due to their high iron and zinc content, many edible insects play an important role in alleviating deficiencies in pregnant women’s diet in developing world (Belluco et al., 2013). Apart from the nutritional values, numerous bioactive components in insects with

**Figure 4** Essential amino acids in edible insect proteins. Data from Rumpold and Schlüter (2013).

**Figure 5** Fatty acids composition of edible insect fat (SFA: saturated fatty acids, MUFA: monounsaturated fatty acids, PUFA: polyunsaturated fatty acids). Data from [Rumpold and Schlüter \(2013\)](#).

immunological, analgesic, antibacterial, diuretic, anesthetic, and antirheumatic properties have been used for medicinal purposes ([Costa-Neto, 2005](#)).

Although a substantial amount of nutrient composition data are available for edible insects, they are subject to a large variation. Small sample size, species-specific metabolism, varying accuracy of sampling and/or analytical techniques, and contamination may contribute to the variation ([Ooninx and Dierenfeld, 2012](#)). Meanwhile, most insects analyzed are collected from the wild with highly variable growing environment and food, which may also affect the results. On top of that, many species undergo complete metamorphosis and their nutrient composition may change in different life cycle stages. Thorough nutrient analyses and life cycle assessments of different species reared in controlled conditions are therefore, warranted.

### Insect Processing Technology

Some insects are eaten alive such as certain isopteran and hemipteran species consumed in Africa ([Van Huis, 2003](#)) and the cheese skippers (larvae of *Piophilidae casei*) in the maggoty cheese *casu marzu* ([Overstreet, 2003](#)). However, edible insects are more often subjected to processing methods including appendix removal, degutting, baking, boiling, drying, frying, grilling, pickling, roasting, smoking, steaming, and toasting before consumption ([Rumpold et al., 2014](#)). Such processing methods are important for enhancing flavor, shelf-life, and safety of the products. A wealth of traditional processing methods and recipes around the world are documented in The Food Insects Newsletter ([Defoliart et al., 1988–2000](#)). The historic and cultural accumulation of entomophagy practices lays a foundation for developing edible insect-based products while modern food processing technologies offer innovative approaches. For example, cold plasma treatment and high hydrostatic pressure treatment have been applied as effective decontamination techniques for mealworms (*T. molitor*) ([Rumpold et al., 2014; Bußler et al., 2016a](#)).

Edible insects are also ground or milled into granular or paste form and used as food ingredients. For instance, many insects are prepared as chutneys in India ([Rumpold et al., 2014](#)) and ground giant waterbugs (*Lethocerus indicus*) are an essential ingredient for certain chili pastes in Thailand and the Lao People's Democratic Republic ([Van Huis et al., 2013](#)). In contrast to eating whole insects, using ground insects as ingredients in conventional food products is also preferred by Western consumers ([Gmuer et al., 2016; Tan et al., 2017](#)). Many edible insects, in bits and pieces, have made their way into baked goods, bars, burgers, chips, meat balls, nuggets, pasta, rice, schnitzels, and sausages ([Van Huis, 2016; Kim et al., 2016; Tan et al., 2017; Gmuer et al., 2016](#)). Likewise, extracting and isolating proteins, fats, and carbohydrates from insects as food ingredients is a good strategy for utilizing insects in regions where people cannot readily accept the intact form of insects in their food. Proteins of insects are often isolated by alkaline extraction ([Azagoh et al., 2016](#)) or alkaline extraction followed by isoelectric precipitation ([Bußler et al., 2016b](#)) although protein extraction in water have also been reported ([Yi et al., 2013](#)). [Mariod and Fadul \(2015\)](#) described extraction of gelatin from melon bugs (*Coridius viduatus*) and sorghum bugs (*Agonoscelis versicoloratus*) using distilled water, mild acid, and hot water, with an ascending extraction efficiency in that order. Edible insect oils are isolated by either solvent extraction or supercritical CO<sub>2</sub> extraction with the latter technology demonstrating a high yield of solvent-free oil at low extraction temperature ([Purschke et al., 2017; Mariod et al., 2010](#)). Chitins are prepared by removing minerals, proteins, and pigments from the exoskeleton of insects ([Kaya et al., 2016](#)). The isolated components can be further processed into value-added products such as bioactive peptides. Bioactive peptides with antioxidant ([Zielińska et al., 2017](#)), antihypertensive ([Wu et al., 2015](#)), and antidiabetic ([Zhang et al., 2016](#)) activities have been produced by enzymatic hydrolysis of insect proteins using either mammalian or microbial enzymes ([Nongonierma and FitzGerald, 2017](#)). Chitosan is a polycationic derivative of chitin that can form flexible and durable film with the help of plasticizing agent. Chitosan film is edible and biodegradable. It also possesses antimicrobial activity and good thermal stability, making it an excellent food packaging material ([Martínez-Camacho et al., 2010](#)).

Different processing techniques may affect the nutritional value and functional properties of edible insects in different ways. It is reported that solar drying and toasting resulted in a 7% decrease in protein digestibility and a 11%–68% reduction in vitamin content of grasshoppers (*Ruspolia differens*) (Kinyuru et al., 2010) whereas smoke drying effectively reduced the cholesterol content of palm larvae *Rhynchophorus phoenicis* and *Oryctes monoceros* by 41% and 80%, respectively (Edijala et al., 2009). For the *R. phoenicis* larvae, roasting and grilling respectively resulted in a 35% and 29% reduction in water holding capacity while smoking led to a seven-fold increase in protein solubility and a 50% decrease in oil holding capacity (Womeni et al., 2012). Therefore, it is necessary to optimize the processing methods for each insect species based on the desired attributes of the final products.

## Safety Concerns of Eating Insects

Despite the environmental and nutritional benefits of edible insects, the potential safety issues associated with insect-based foods need to be identified and addressed. Insects may contain physical hazards, toxins, antinutrients, allergens, pathogens, and parasites. Food safety is particularly worrisome for edible insects collected from the wild due to possible exposure to harmful substances. Entomophagy-induced pesticide and lead poisonings have been reported (Defoliart, 1999; Handley et al., 2007). Bioaccumulation of arsenic and cadmium by insects is also known (Van Der Fels-Klerx et al., 2016). Consequently, the United States Food and Drug Administration requires edible insects to be raised specifically for human food in good manufacturing practice facilities and prohibits wildcrafted insects to be sold as food (Ramaswamy, 2015).

Many insects are armed with hairs, spines, and stingers that can cause irritation or choking. One example is spiny elm caterpillar (*Nymphalis antiopa*), an edible insect in Mexico (Ramos-Elorduy et al., 2011), that stings with its setae (Hossler, 2010) (Fig. 6). Another example is the grasshoppers with heavily spined tibiae, which can cause internal hemorrhage, intestinal occlusion, or even death in animals and humans (Defoliart, 2002). Therefore, the heads, legs, and wings of the grasshoppers and the hairs and spines of the caterpillars are often removed before cooking (Defoliart, 2002).

Other insects defend themselves with venoms, toxins, or bad smell. We are well alarmed of the painful stings or bites by ants, bees, wasps, caterpillars, and assassin bugs and the obnoxious smell of certain true bugs, beetles, and caterpillars. A myriad of poisonous substances are present in a variety of insect species including benzoquinone in tenebrionid beetles, cantharidin in meloid beetles, cyanogenic substances in coleopteran and lepidopteran insects, leptinotarsin and Bushman arrow poisons in chrysomelid beetles, metabolic steroids in dytiscid beetles, pederin in staphylinid beetles, pyrrolizidine alkaloids in cinnabar moths, toluene in longhorn beetles, and heart-toxic cardenolides in monarch butterflies and laygaed bugs (Belluco et al., 2013; Schmidt, 2008). Some of the chemical hazards can be removed or inactivated through cooking or digestion while some cannot (Belluco et al., 2013). Careful assessment of the toxicity of different insect species is warranted for developing safe products for human consumption. Although not recommended, consumption of toxic insects are practiced. For example, cantharidin- and pederin-containing beetles are used as anti-fungal agents in folk medicine. These toxic terpenoids can cause severe blistering of the skin (Mitsuhashi, 2008). Cantharidin is also the active component of the well-known ‘aphrodisiac’ Spanish fly (*Lytta vesicatoria*), which is banned due to its lethal toxicity (Karras et al., 1996).

Antinutrients are another entomophagy-related health concern. Consumption of African silkworm (*Anaphe* spp.) pupae is responsible for an acute seasonal ataxic syndrome in Nigeria for over 40 years due to the presence of a highly active and heat-resistant thiaminase (Nishimune et al., 2000). Antinutrients of plant origin such as oxalates, phytates, saponins, and tannins, which are likely accumulated from feed, are also found in edible insects (Omotoso, 2006; Musundire et al., 2014; Chakravorty et al., 2016). In order to utilize insects as a nutritious food source, such antinutritional factors need to be mitigated, eliminated, or inactivated.

For sensitive individuals, insects may cause adverse immune responses. Non-food-mediated allergic reactions such as Hymenoptera venom allergy are excluded from discussion. Food allergies to bee larva and pupa, cicada pupa, *Clanis bilineata*, cochineal insect (*Dactylopius coccus*), field cricket (*Gryllus bimaculatus*), grasshopper, lentil weevil (*Bruchus lentis*), locust, mopane caterpillar (*Imbrasia belina*), and silkworm pupa (*B. mori*) have been documented (Ji et al., 2009; Dicello et al., 1999; Srinroch et al., 2015; Armentia et al., 2006; Kung et al., 2011; Ji et al., 2008). The allergens identified include arginine kinase (*B. mori*, *G. bimaculatus*), hexamerin 1B (*G. bimaculatus*), phospholipase (*D. coccus*), and tropomyosin (*T. molitor*) (Broekman et al., 2015; Srinroch et al., 2015; Liu et al., 2009; Ohgiya et al., 2009). Allergens of insect origin can act either as a primary allergen (i.e., the original sensitizing molecule) or as a cross-reactive allergen with the latter being more common in Western countries. Arginine kinase and tropomyosin are well-known invertebrate pan-allergens responsible for insect-shellfish cross-reactivity (Reese et al., 1999; Binder et al., 2001). Therefore,

**Figure 6** Spiny elm caterpillar (*Nymphalis antiopa*).

individuals with shellfish allergy are recommended to avoid entomophagy. Moreover, patients allergic to inhalant arthropod allergens (e.g., cockroach and house dust mite) may experience oral allergy syndrome when eating insects.

Some insect species are notorious for spreading diseases because they are vectors of pathogenic microorganisms such as bacteria, virus, fungi, and protozoa (Van Huis et al., 2013). Unlike conventional livestock, many insects are consumed with their gut microflora. Practices such as fasting and evisceration may affect the microbial composition of the insect food product (Van Huis et al., 2013). In general, raw insects are high in microbial load. The microbial counts were as high as 8.6 log cfu/g in fresh mealworm larvae (*T. molitor*) and grasshoppers (*Locusta migratoria*) sold for human consumption (Stoops et al., 2016). Microbial contamination is also common in improperly processed or stored insects. Pathogenic bacteria including *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Bacillus cereus* were found in rhinoceros beetle grubs (*Oryctes monocerus*) (Banjo et al., 2006) and mycotoxin producing fungi (e.g., *Aspergillus*, *Penicillium*, and *Fusarium*) were isolated from stored mopane caterpillars (*I. belina*) (Mpuchane et al., 2000). Proper processing and storage are therefore important. For example, boiling for 5 min is effective in eliminating Enterobacteriaceae but not sporeforming bacteria in mealworm larvae (*T. molitor*) and house crickets (*A. domesticus*). Consequently, storage at refrigeration temperature is recommended for these processed insects (Klunder et al., 2012).

Insects may also carry parasites or act as parasites themselves. Consumption of aquatic insects such as dragonflies and damselflies in Southeast Asia is associated with foodborne intestinal flukes (Chai et al., 2009). A case of *Gongylonema* infection due to accidental ingestion of an uncooked insect has been reported in the United States (Wilson et al., 2001). The cheese skippers (*P. casei*) in *casu marzu* are sometimes consumed alive in Italy and are repeatedly reported for causing intestinal myiasis (Peckenschneider et al., 1952). Although thoroughly cooked insects pose no risk of parasite infection, it is recommended to avoid consumption of insects that are known vectors of parasites.

## Consumer Acceptance

Besides the safety concerns, consumer acceptance is another challenge to the utilization of insects as human food. Due to unfamiliarity in Western countries, insects are considered disgusting and often evoke negative emotions in consumers (Lensvelt and Steenbekkers, 2014; Looy et al., 2014; Gmuer et al., 2016). Among the Western consumers who are willing to taste insect-containing foods, insects eating is mostly out of curiosity (Yen, 2009; Verkerk et al., 2007). Consumer acceptance studies have been performed in Netherlands, Belgium, Italy, Hungary, Germany, and China (De Boer et al., 2013; Vanhonacker et al., 2013; Verbeke, 2015; Megido et al., 2016; Cicatiello et al., 2016; Sogari, 2015; Laureati et al., 2016; Gere et al., 2017; Hartmann et al., 2015). According to these investigations, the major barriers of consumer acceptance towards insect-based foods are unfamiliarity/culture prejudice, safety concerns, nutritional value, and flavor (Lensvelt and Steenbekkers, 2014; Tan et al., 2015; Cicatiello et al., 2016). Several studies have shown that if the insect ingredients are incorporated in familiar food products instead of having the insects visible, consumers in Western countries are more likely to accept the product (Gmuer et al., 2016; Schösler et al., 2012; Hartmann et al., 2015; Megido et al., 2016). In fact, studies have shown that the taste of insect-based foods was well accepted by consumers with a preference to known flavors and textures (Caparros Megido et al., 2014; Elzerman et al., 2013).

The fact that most people in Western cultures associate insects with negative emotions and disgusting feelings is probably because they are only familiar with insects that are pests or hazards while not having much exposure to the edible species. Insect tasting helps consumers get acquainted with entomophagy, and therefore, is considered important to decrease food neophobia (Megido et al., 2016). In order to increase the consumer acceptance, activities that expose more consumers to insect-based food products and educate consumers about the sustainability, nutritional values, and safety of edible insects should be promoted. Recently, many insect-based food companies have emerged, introducing new products and recipes to the market (Dossey et al., 2016). Information on edible insects are also advocated through dedicated insect food festivals (e.g., the Annual Montana State University Bug Buffet), conferences (e.g., the Insects to Feed the World International Conference), and organizations such as the North American Coalition for Insect Agriculture.

Apart from consumers' willingness to try insect-based foods, a higher level of consumer acceptance is their willingness to pay for the products. A gap between the intention to eat insects and the actual purchase of insect-based products is likely to exist, even among the consumers who have declared an interest towards entomophagy (Cicatiello et al., 2016). Tan, Verbaan and Stieger (2017) reported that even with high interest and good products, willing consumers still hesitate to consume insect-based foods regularly due to other practical and socio-cultural factors.

## Conclusions

Entomophagy is an old idea that dates back to prehistory and it is regularly practiced in many regions until now. Although eating insect is still adventurous for Western consumers, people are getting acquainted with this novel food. Thanks to their nutritional values and environmental benefits, these little creatures may not only provide a solution for the food security challenge on this planet, but also serve as an animal protein source for astronauts during deep space exploration in the future (Tong et al., 2011). Despite the great potential of edible insects, more studies are warranted for nutrition and safety assessment, mass production and processing, product development, and consumer testing. Collaborative efforts from researchers, insect farmers, food manufacturers, regulatory agencies, and consumers are needed to incorporate edible insects in our daily diet.

GI glycemic index

GIP gastric inhibitory polypeptide

GLP-1 glucagon like peptide 1

Min minutes

PYY peptide tyrosine tyrosine

VAS visual analog scale questionnaire

### Overview

Pulses and pulse ingredients (fractions and flours) have many positive nutritional attributes. Regular consumption of pulses (1/2 cup/day) is related to higher quality diets, including higher intakes of fiber, protein, folate, zinc, iron, and magnesium as well as lower intakes of saturated fat and total fat compared to diets low in pulses (Mitchell et al., 2009). Substantial scientific evidence supports the notion that low glycemic index (GI) foods can positively influence many physiological processes, which are relevant to health such as postprandial glycaemia. Based on their inherent nutritional composition, pulses are a very suitable food for glycemic control. Pulses contain high amounts of protein, which make them unique in comparison to other plant foods. In fact, the protein content of pulses ranges from 17%–30% of dry weight which is typically twice the amount found in cereals (Boye et al., 2010). Pulses are limited in sulphur-containing amino acid content, but are high in lysine (McCrory et al., 2010). Higher intakes of protein in a meal have been shown to decrease the glycemic response (Smith et al., 2012). Pulses also contain high amounts of complex carbohydrates including both soluble and insoluble fiber (Tosh and Yada, 2010), as well as resistant and slowly digestible starch (Tosh and Yada, 2010; Hoover et al., 2010). Pulses contain about 15%–32% total dietary fiber; 33%–75% is insoluble fiber with the remainder being soluble fiber (McCrory et al., 2010). A variety of health benefits are associated with the intake of dietary fiber, including improved glycemia and insulin sensitivity in non-diabetic and diabetic individuals (Anderson et al., 2009). Similar to dietary fiber, demonstrated health effects of resistant and slowly digestible starches are improved glycemic and insulin responses (Nugent, 2005; Anderson et al., 2010; Bodinham et al., 2010).

### The Glycemic Index

The GI is defined as the incremental area under a two-hour blood glucose (BG) response curve (AUC) following a 12h fast and ingestion of a food (Sc et al., 1981; Wolever et al., 1991). For glycemic studies, the test food has a certain quantity of available carbohydrate, usually 50 g, and is compared relative to a control food containing the same amount of available carbohydrate. A lower GI suggests slower rates of digestion and absorption of the carbohydrate in the test food, and usually equates to a lower insulin demand. In vivo testing is considered standard.

Substantial scientific evidence supports the notion that low GI foods can influence many physiological processes which are relevant to health. The ingestion of high GI foods where there is rapid absorption can pose a challenge to beta-cells. It has been suggested that hyperglycemia as a result of consuming a high GI diet may contribute to developing insulin resistance. This can lead to diminished beta cell function as a result of the increased insulin demand (Schofield and Sutherland, 2012), which may increase risk of developing type 2 diabetes (Grill and Bjor, 2000).

### Effects of Whole Pulse Consumption on Post-prandial Glycemia

The effects of whole pulses on short term glycemic control have been assessed in over 80 published human studies including GI and postprandial glycemic response studies. A variety of whole pulses have been studied (Jenkins et al., 1980; Potter et al., 1981; Jenkins et al., 1982; Traianedes and O'Dea, 1986; Dilawari et al., 1981; Mollard et al., 2011; Thompson et al., 2012; Mollard et al., 2012).

The following paragraphs discuss relevant whole pulse research findings. A summary of these findings along with other relevant findings are summarized in [Table 1](#).

The father of the GI, Dr David Jenkins, examined the BG response of 35 carbohydrate rich foods in his early glycemic research. The foods tested included varieties of pulses, potatoes, grains, breads, pasta, cereals, and biscuits. The pulse treatments included butter beans, haricot beans, kidney beans, soya beans, black eye peas, chickpeas, marrowfat peas, and lentils. Blood glucose samples were obtained by fingerpick at baseline and were followed over 2 h following the consumption of the treatment ([Jenkins et al., 1980](#)). Results showed that the mean BG for each pulse treatment was significantly lower than the mean curves of all other foods tested for at least two measurement time points each. The AUC and mean peak in BG were significantly lower for all dried legumes than the other treatments ([Jenkins et al., 1980](#)). This study established that pulses are low glycemic compared to other common carbohydrate foods.

[Potter et al. \(1981\)](#) examined the effect of varying dietary fiber content of foods, including pinto beans, on plasma insulin and BG response. The treatments were a glucose formula control, brown rice, pinto beans, and all bran cereal. The bran and pinto bean treatments resulted in lower BG compared to control at 30, 60, and 180 min. For insulin, the response to bran was lower at 30 and 60 min compared to the control. Consumption of the pinto treatment also had lower insulin concentrations at 30 min compared to control. Bran and pinto bean both resulted in lower insulin concentrations compared to rice at 30 min. The authors concluded that dietary fiber was most likely responsible for the differences in insulin and glucose concentrations. Fiber content was analyzed for each treatment, and the higher the BG and insulin, the lower the non-digestible fibers including lignin, hemicellulose, and cellulose. Pinto beans and all bran were very similar in non-digestible fiber content which corresponds to their similar BG and insulin responses ([Potter et al., 1981](#)). This study demonstrates that the fiber content of pinto beans is comparable to that of bran and possesses acute insulin and BG lowering effects.

[Jenkins et al. \(1982\)](#) also examined the effects of processing on lentils. The treatments were a white bread control, boiled 20 min lentils, boiled 20 min blended lentils, 1 h boiled lentils, and 1 h boiled 12 h oven dried lentils. The BG response to the bread and 12 h dried lentil treatment were very similar. The BG responses to the bread and 12h dried lentil treatment were higher than the 20 min boiled lentil treatment at 15, 30, and 45 min following treatment consumption. There were no differences in BG response between 20 min boiled lentils, 1h boiled lentils, and 20 min blended lentils. Through in vitro digestion testing it was found that carbohydrates were more rapidly digested from the lentils that were dried for 12 h compared to the lentils boiled for 20 min, which explains the higher BG response ([Jenkins et al., 1982](#)). This research indicates that processing can significantly affect the BG effects observed. Lentils that were dried for 12 h compared to boiled for 20 min resulted in an increased BG response due to carbohydrate being more rapidly digested. Blending does not appear to increase BG but prolonged exposure to heat does ([Jenkins et al., 1982](#)). This study established that 12 h of dry heat cooking raises the BG response to lentils. The effects of processing are supported by other research studies that have shown that the digestion of starch is also affected by the duration of pressure cooking, and temperature ([Traianedes and O'Dea, 1986](#)).

Studies examining the glycemic response of pulses when served in a mixed meal have shown that the glycemic effects are retained ([Mollard et al., 2011](#); [Dilawari et al., 1981](#); [Mollard et al., 2012](#); [Thompson et al., 2012](#)). [Mollard et al. \(2012\)](#) investigated the acute effects of BG following a meal with pulses and after a pizza meal 4 h later. The treatments included chickpeas, lentils, navy beans, and yellow peas served with pasta and homemade tomato sauce. The control was the pasta and sauce alone. All treatments resulted in a significantly lower BG compared to the control over the testing period, navy beans also resulted significantly lower compared to chickpeas. Following the pizza meal, BG was not affected by treatment. In response to all pulse treatments, BG before the pizza meal was significantly lower compared to control ([Mollard et al., 2012](#)).

Complementing the previous study, [Thompson et al. \(2012\)](#) examined the effects of three pulse varieties on BG using mixed meal formats. Treatments were long grain rice (control), pinto beans, black beans, and red kidney beans. The bean treatments were served with rice and were matched for 50 g of available carbohydrate. Results demonstrated that the BG response was lower compared to the control for all bean treatments at 90, 120, and 150 min and for pinto beans at 180 min. The black and pinto bean treatments led to a lower overall BG response compared to the red kidney beans though black beans had lower total fiber. The authors expected the bean treatments to result in a more uniform BG response because they were matched for carbohydrate content, however, the difference in fiber content among the beans may have been responsible for the effects observed ([Thompson et al., 2012](#)). Similar to the research by [Mollard et al. \(2012\)](#), some pulse treatments performed more favourably than others. The study concluded that bean and rice meals elicit an attenuated BG response compared to rice served alone, and that the difference in BG between bean types warrants further investigation ([Thompson et al., 2012](#)).

In summary, research of whole pulses consumed alone has demonstrated that compared to common carbohydrate foods that they are low glycemic ([Jenkins et al., 1980](#); [Traianedes and O'Dea, 1986](#)) and possesses acute insulin ([Traianedes and O'Dea, 1986](#); [Potter et al., 1981](#)) and BG lowering effects ([Potter et al., 1981](#); [Jenkins et al., 1982](#); [Traianedes and O'Dea, 1986](#); [Wong et al., 2009](#)). Additionally, the benefits of whole pulses when consumed alone are retained when consumed within a mixed meal ([Mollard et al., 2012](#); [Thompson et al., 2012](#)). While whole pulses have shown to be low glycemic, it appears that some pulses reduce glycemic response to a greater degree than others.

**Table 1** Acute glycemic response to whole pulses

Study	Participants	Treatment	Results
Jenkins et al. (1980)	Groups of 5–10 healthy volunteers of 110% ideal body weight. Age was not specified.	50 g carbohydrate portions of eight dried and boiled legumes (butter beans, haricot beans, kidney beans, soya beans, blackeye peas, chick peas, marrowfat peas, lentils), and 35 other high carbohydrate foods.	- Mean BG for each dried legume was significantly lower than the mean curves of all other foods at least two time points. The AUC and mean spike in BG was significantly lower for dried legumes than the other treatments.
Potter et al. (1981)	Eight healthy sedentary men aged 22–45 y.	1. Glucose formula (control, 102 g) 2. Brown rice (97 g) 3. Pinto beans (118 g) 4. All bran (106 g) Meals were blended and had water added so they were of equal volume. Matched for fat, protein, and carbohydrates.	Blood Glucose: - Bran and pinto bean was significantly lower than the control at 30, 60, and 180. Insulin: - Bran was significantly lower at 30, 60, and 120 compared to the control, and beans was significantly lower at 30. Bran and beans were also significantly lower compared to rice at 30 min. - The insulin response peak of the control was nearly twice that of pinto beans and bran. - There were no significant differences in BG between 20 min lentils compared to blended lentils or 1 h boiled lentils. - 12 hour dried lentils had a significantly higher BG response than 20 min lentils at some time points.
Jenkins et al. (1982)	Eight healthy participants (two men, six women) aged 21–37 y.	1. White bread control 2. Boiled 20 min lentils 3. Boiled 20 min blended lentils 4. One hour boiled lentils 5. One hour boiled, 12h oven dried lentils Meals were served with tomato, 500 mL of water, as well as tea or coffee.	- 12 hour dried lentils had a significantly higher BG response than 20 min lentils at some time points.
Traianedes et al. (1986)	Six normal weight participants (four men, two women) aged 25–40 y.	1. D-glucose (control) 2. Home cooked baked haricot beans 3. Heinz vegetarian baked haricot beans The home cooked beans were served with a sauce made of molasses, mustard and tomato.	- The home cooked beans BG AUC was significantly lower than canned beans.
Wong et al. (2009)	Healthy normal weight men aged 18–35 y. Study I: n = 14 Study II: n = 14 Study III: n = 15	I: Canned navy beans manufactured in Canada, canned navy beans manufactured in the UK, homemade navy beans made following a recipe, glucose drink (control). II: Canned navy beans in tomato sauce, canned navy beans maple style, canned navy beans pork and molasses, homemade navy beans pork and molasses, white bread (control). III: chickpeas, lentils, navy beans, yellow peas, white bread (control), water (control).	I: All beans resulted in a reduced BG with the exception of at 90 and 120 min compared to control. II: Homemade pork and molasses navy beans and canned navy beans in tomato sauce led to a reduced BG net AUC compared to control. III: BG net AUC was significantly reduced compared to white bread control for all beans except navy.

**Table 1** Acute glycemic response to whole pulses—cont'd

<i>Study</i>	<i>Participants</i>	<i>Treatment</i>	<i>Results</i>
Mollard et al. (2011)	25 men aged 20–30 y with a BMI between 20–24.9 kg/m <sup>2</sup> .	<ol style="list-style-type: none"> <li>1.Chickpea</li> <li>2.Lentil</li> <li>3.Yellow pea</li> <li>4.Macaroni &amp; cheese (control)</li> </ol> Pulse treatments were canned and served with macaroni pasta and served with homemade tomato sauce. All pulse treatments contained 40 g available carbohydrate. Overall available carbohydrate was matched between treatments at about 100 g, meals were isocaloric.	<ul style="list-style-type: none"> <li>- No differences in pre-meal pizza AUC.</li> <li>- Chickpea and lentil significantly lowered post-pizza meal BG AUC, yellow pea did not.</li> </ul>
Mollard et al. (2012)	24 healthy males aged 20–30 y of normal weight.	<ol style="list-style-type: none"> <li>1.Chickpeas</li> <li>2.Lentils</li> <li>3.Navy beans</li> <li>4.Yellow peas</li> <li>5.Pasta and tomato sauce (control)</li> </ol> Treatments were served with pasta and homemade tomato sauce. 44% of energy from the meals was from pulses. The meals were isocaloric.	<ul style="list-style-type: none"> <li>- BG effect of treatment was significantly lower compared to control for all treatments to 260 min.</li> <li>- AUC was significantly lower compared to the control for all treatments.</li> </ul>
Mollard et al. (2014)	15 healthy males aged 18–35 y of normal weight.	<ol style="list-style-type: none"> <li>1.White bread (control)</li> <li>2.Chickpeas</li> <li>3.Lentils</li> <li>4.Navy beans</li> <li>5.Yellow peas</li> </ol> The meals were isocaloric. A pizza meal was served at 135 min following treatment consumption	<ul style="list-style-type: none"> <li>- All pulses led to a mean decreased BG response compared to control. Chickpea and lentil were also lower compared to yellow pea</li> <li>- Pre-pizza BG AUC was lower for chickpea, navy bean, and lentil compared to control.</li> <li>- Post-pizza BG AUC was lower for lentil compared to control</li> </ul>

**Table 2** Acute glycemic response to pulse flours

Study	Participants	Treatment	Results
Hall et al. (2005)	11 participants (nine men, two women) aged 25–45 y with a BMI of 20.9–28.6 kg/m <sup>2</sup> .	1. White bread (control) 2. White bread with 7.7 g of Australian sweet lupin flour (ASLF) added Consumed with margarine, apricot jam and decaffeinated tea.	- BG response of the ASLF bread was significantly lower than the control. - Insulin response was significantly higher for the ASLF bread than the control.
Johnson et al. (2005)	11 healthy participants (nine men, two women) aged 25–45 y.	1. White bread (control) 2. Chickpea flour 3. Extruded chickpea flour	- BG of the chickpea bread was significantly lower than the control at 90 min, and the extruded chickpea bread BG was significantly lower than the control at 120 min.
Marinangeli et al. (2009)	20 healthy participants (seven men, 13 women) aged 22–67 y, with a BMI between 21–42 kg/m <sup>2</sup> .	1. Boiled whole yellow pea (control) 2. White bread (control) 3. Banana bread with WYPF 4. Biscotti with WYPF 5. Pasta with WYPF	- Decreased iAUC BG response for WHPF biscotti and banana bread compared to white bread.
Anderson et al. (2014)	Healthy young men Ex. I (n = 17) Ex. II (n = 12) Ex. III (n = 12)	Ex. I/II/III 1. Whole navy bean/lentil/chickpea 2. Pureed navy bean/lentil/chickpea 3. Powdered navy bean/lentil/chickpea	- Overall no significant differences seen between the treatments due to processing. - For lentil and chickpea treatments mean BG was lower over 120 min compared to control, for navy bean only peak BG was lowered compared to control.

### Effects of Pulse Flour Consumption on Post-prandial Glycemia

Limited pulse flour research exists, however, research has demonstrated that despite milling, varying benefits of whole pulses are retained compared to control (Anderson et al., 2014; Marinangeli et al., 2009; Johnson et al., 2005; Hall et al., 2005). The following paragraphs discuss relevant pulse flour research findings. A summary of these findings along with other relevant findings are provided in Table 2. Hall et al. (2005) examined the effects of Australian sweet lupin flour (ASLF) bread on glycemic response. Treatments were a white bread control and ASLF containing bread. The BG peak was seen at 30 min for both treatments and the BG response of the ASLF bread was lower than the control. The peak insulin response was seen at 30 min for both treatments and the insulin response was significantly higher for the ASLF bread than the control (Hall et al., 2005). This study demonstrates that the acute beneficial BG effects of lupins are still observed when milled to a powder and made into bread.

Another aspect of processing was examined by Johnson et al. (2005) by incorporating chickpea flour, and extruded chickpea flour into bread and comparing it to a white bread as control. The treatments all had 50 g of available carbohydrate and were very similar in energy, protein, and fat. The control bread contained 3 g total fiber, chickpea flour bread contained 5 g total fiber, and extruded chickpea flour bread contained 6 g total fiber. The chickpea bread replaced 24.3% of the white bread flour in the chickpea bread treatments, this amount was chosen because it kept the bread palatable. For all treatments, BG peaked at 30 min and returned to and fell beneath baseline between 60–90 min. There were no differences in BG iAUC for any treatments. Consuming chickpea bread resulted in a lower BG compared to the control at 60 min, and at 120 min the extruded chickpea bread resulted in lower BG compared to control. At 60 min both treatment breads had lower insulin compared to the control. The insulin iAUC was also significantly higher for chickpea bread than the control bread. The authors suggested that perhaps the incorporation of chickpea flour was too low or the particle size too small to observe the glycemic and insulin benefits seen by whole chickpeas. They believed that further studies with varying particle size and greater incorporation of chickpea flour are needed (Johnson et al., 2005). It was surprising to see a hyperinsulinemia effect from the chickpea flour, which also warrants further investigation.

Marinangeli et al. (2009) explored the glycemic response of whole yellow pea flours (WYPF) in food products. Treatments were WYPF incorporated into banana bread, biscotti, and pasta. Controls were boiled whole yellow peas, white bread, and whole wheat flour (WWF) (Marinangeli et al., 2009). WYPF biscotti and WYPF banana bread resulted in a significantly lower (61.9% and 55.1%) iAUC BG response compared to WB. The WYPF biscotti resulted in a 29.2% BG reduction compared to the WWF biscotti. However, WYPF pasta resulted in significantly higher BG iAUC than boiled yellow peas. The WYPF pasta did not result in a lower BG response compared to WWF. This difference in BG response suggests that the manner in which the treatments are cooked affects the glycemic effect exhibited. It was not indicated whether WYPF possesses the same beneficial effects as whole yellow peas, but the cooking method utilized appeared to be responsible for the beneficial effects of WYPF. This research supports the use of whole pea flour in novel foods products intended to be low glycemic (Marinangeli et al., 2009).

In another study examining pulse flours, Anderson et al. (2014) found that the beneficial effects of whole pulses are not diminished when ground to a powder. Three experiments were conducted, each with a control of whole-wheat flour. In experiment I, the treatments were whole navy bean, pureed navy bean, and navy bean powder. In experiment II, whole lentil, pureed lentil, and lentil powder were provided. In experiment III, whole chickpea, pureed chickpea, and chickpea powder were provided. There were 38.8 g of available carbohydrate in each treatment and water was added so treatments were of equal weight (Anderson et al., 2014).

Participants consumed a fixed-size pizza meal at 120 min. In experiment I, prior to the pizza meal there was a significant time by treatment interaction. At 15 min the bean powder treatment did not differ from the control in BG response. At 30 min the three bean treatments resulted in a significantly lower BG compared to control. At 45 min the navy bean powder resulted in lower BG compared to the pureed treatment. At 60 min whole wheat resulted in lower BG compared to the whole navy bean treatment. The difference in pre pizza meal BG net AUC was significant for the navy bean powder compared to the control, and was intermediate for the other two treatments. In experiment II there was a significant time by treatment interaction for BG; mean BG was also significantly lower compared to the control for all lentil treatments at all time points preceding the pizza meal. Compared to the control, the BG net AUC was lower for whole and powdered lentils. In experiment III, time points preceding the pizza meal had a time by treatment interaction and BG was significantly lower for powdered, pureed, and whole chickpeas compared to the control. The authors concluded that pureeing and commercial processing does not negate the acute glucose regulation benefits of consuming pulses as there were overall no significant differences seen between the treatments due to processing (Anderson et al., 2014).

The four published studies discussed above are encouraging in that it is evident that the BG lowering effects of consuming whole pulses are retained when pulses are processed to flours (Anderson et al., 2014; Marinangeli et al., 2009; Johnson et al., 2005; Hall et al., 2005). More studies exploring pulse flour incorporation are needed to determine the relative efficacy of specific pulse types across different food matrices, the most effective doses of incorporation, and the effectiveness following different processing methods.

### Pulse Fraction Extraction

Two primary fractionation processes are utilized on pulses; dry and wet fractionation. The dry fractionation process involves several steps: dehulling, pin milling, and air classifying fractions (Doney and Jolene, n.d.). During dehulling, the outer kernel is removed. This process is easier with lentils and peas and more difficult with beans and chickpeas due to differences in characteristics. Dehulling can be done by impact or by stone dehulling processes. Pin milling utilizes rapid pulverization to achieve product that is very fine. Air classification of fractions is then conducted utilizing a fluidized tower system. Particles are separated in a vacuum based upon particle size. Protein fractions range from 2–20  $\mu\text{m}$ , starch fractions range from 20–40  $\mu\text{m}$  (Tulbek, 2010).

The dry process allows for increased concentrations of target pulse components. In the dry fractionation process protein fractions have a 53% protein content compared to 22% in whole peas. The fiber fractions have 87% fiber content, which is the same achieved with the wet process. The carbohydrate fraction reaches 75% of starch/sugar content compared to 48% in whole pulses (Doney and Jolene, n.d.).

With wet fractionation the process has different steps: dehulling, milling, steeping, precipitation, decanting, dewatering, and drying (Doney and Jolene, n.d.). The dehulling process is the same as dry fractionation. Milling is performed using the same process or by hammer mill. The fine product is then solubilized in an NaOH solution for 1 h following which the protein and starch can be removed by ultrafiltration or by decanter. Protein may also be precipitated. Drying of protein and starch is then initiated by fluidized bed drying or by spray drying (Tulbek, 2010). An 86% protein content is achieved in the protein fraction, and the carbohydrate fraction achieves a 99% starch/sugar content (Doney and Jolene, n.d.).

### Effects of Pulse Fractions on Post-prandial Glycemia

The investigation of the effectiveness of the different pulse fractions is important in understanding the compositional aspects of pulses that are responsible for any shift in acute postprandial glycemia. It is also important to determine whether the benefits are retained when whole pulses are fractionated and incorporated into different food matrices. Limited pulse fraction studies exist thus far; however, studies that have been conducted are summarized in the following paragraphs and summarized in Table 3.

Smith et al. (2012) studied the effects of yellow pea protein and fiber on post-prandial glycemia. Two experiments were conducted. In experiment I, participants received an ad libitum pizza meal at 30 min, and in experiment II at 120 min (Smith et al., 2012). Treatments were tomato soup used as a control, and tomato soup with 10 g or 20 g of fiber or protein. In the treatments there were 9.5–10.5 g of available carbohydrate (Smith et al., 2012). In experiment I, BG was significantly lower over the whole treatment period for both protein treatments compared to the control. BG was overall significantly lower with protein 20 g treatment compared to control and fiber 10 g treatment. Both protein treatments had a significantly lower BG immediately following the pizza meal compared to the control and fiber 10 g treatment. The glycemic responses to yellow pea protein pre-meal were independent of dose; however, response to the post-pizza meal was dose dependent. In experiment II, there were no differences in BG response across treatments. The authors attributed the null results in experiment II to be due to pea protein's rapid digestion. The authors suggested that the null results from the fiber treatments, though surprising, may have been because the fiber was taken from the hull only and not from the entire pea. Pea hull contains 45.8% more insoluble fiber and 21% more soluble fiber than dehulled peas that contain fiber derived from the cotyledon of the pulse. There may be different benefits derived from consuming hull fiber vs consuming cotyledon and hull fiber in combination (Smith et al., 2012).

Mollard et al. (2014) conducted a study investigating the effects of pea fractions on glycemia when served with tomato sauce and noodles. Five treatments included yellow peas, pea hull fiber and pea protein, pea hull fiber, pea protein, and the control. An ad libitum pizza meal was given 135 min following treatment consumption (Mollard et al., 2014). The combined pea protein and

**Table 3** Acute glycemic response to pulse fractions

Study	Participants	Treatment	Results
Smith et al. (2012)	Experiment I (pizza meal at 30 min) n = 19 healthy men. Experiment II (pizza meal at 120 min) n = 20 healthy men.	Experiment I and II had the same five treatments: 1. Tomato soup (TS) 2. TS + 10 g yellow pea fiber 3. TS + 20 g yellow pea fiber 4. TS + 10 g yellow pea protein 5. TS + 20 g yellow pea protein	Ex I: BG was overall significantly lower with protein 20 g treatment compared to control and fiber 10 g treatment. Ex II: No BG differences.
Mollard et al. (2014)	15 healthy young men.	1. Tomato sauce and noodles (control) 2. Yellow peas 3. Pea hull fiber and pea protein 4. Pea protein 6. Fiber alone	- Combined pea protein and fiber treatment lowered the glycemic response compared to the control, this was not seen by the fiber or protein treatment alone.

fiber treatments lowered the BG response compared to the control similar to yellow peas. This was, however, not seen by the fiber or protein treatment alone (Mollard et al., 2014). The authors suggested that the dose of protein and fiber alone may have been too low to observe a difference in BG, however, the fiber treatment was observed to have resulted in the highest BG responses. This study establishes that fractions of pea fiber and protein combined retain the effects of whole peas, but suggests that fractions alone do not.

Results of the pulse fraction studies suggest that pea protein and fiber combined are more effective at reducing BG than protein or fiber alone. Smith et al. (2012) found that protein at a dose of 10 g as well as 20 g reduced BG following the consumption of a second meal at 30 min. However, when the second meal was served at 120 min there were no differences (Smith et al., 2012). Mollard et al. (2014) served a pea protein treatment of similar protein content (18 g) with tomato sauce and noodles and found that the protein treatment alone did not reduce BG significantly, but that the combined protein + fiber treatment lowered BG compared to control. A second meal was supplied at 135 min and did not produce significant differences in BG post-meal (Mollard et al., 2014). These results suggest that effects of pea protein alone are transient and that pea protein and fiber combined may have synergistic effects that allow BG lowering effects to last longer than protein alone. So far it remains unclear as to whether a specific fraction is responsible for the BG reduction effects. Further research is needed to investigate whether protein alone lowers BG, and to investigate whether there are synergistic effects when protein and fiber are consumed together. Research with varying amounts of protein and fiber are also needed to determine if there is a specific dose needed to elucidate effects.

### Potential Mechanisms of Action of Pulses

A low glycemic response ensues when pulses are consumed whole. When pulses are milled as served as flours the low glycemic response is mainly retained (Marinangeli et al., 2009; Anderson et al., 2014; Hall et al., 2005; Johnson et al., 2005). It is when pulses are processed into fractions that individual aspects of pulse composition can be investigated for their role in glycemic response.

As previously discussed, research indicates that the protein content of pulses appears to be a stronger modulator of BG response than pea fiber (Smith et al., 2012), however, in other research findings, fiber appears to be a strong contributing component when served in combination with protein (Mollard et al., 2014). One explanation on the effectiveness of pulse protein may be increased secretion of insulin. If pulse protein is insulinotropic, that could explain the beneficial effects seen on post-prandial blood glucose. The viscous properties of pulse fiber may decrease the speed of protein and carbohydrate absorption (Mollard et al., 2014). When served alone pulse protein appears to digest more quickly similar to whey protein (Smith et al., 2012). Pulse protein combined with fiber may also decrease gastric emptying (Mollard et al., 2014). The mechanisms behind the low glycemic response of pulses are still unclear. Further research is needed involving fractions, varying processing conditions, and hormonal response.

The effects of pulses on intestinal satiety should also be considered as a modulator of BG response. Close interaction between nutrients and the intestinal wall causes the release of satiety signal hormones. Increasing the viscosity of digested food as it travels through the small intestine increases its residence time, and time that nutrients are being absorbed. Prolonged residence of digested food in the small intestine also impacts gastric emptying through the release of satiety hormones (Paradis et al., 2011). GLP-1 and GIP are secreted during and after the consumption of a meal containing carbohydrates. They slow gastric emptying and stimulate insulin release (De Silva and Bloom, 2012). PYY increases following a meal, remains elevated for up to 6 h and slows gastric emptying (De Silva and Bloom, 2012). These and other metabolic factors involved with glucose metabolism should be explored to help elucidate the low glycemic effect of pulses.

Apart from differences in composition there are some effects of processing that should be considered. When processing pulses, starch granule damage may occur. Damaged starch granules are digested more quickly than non-damaged starch granules (Sandstedt and Mattern, 1960) and may explain differences in BG response among typically low GI pulses that have been processed. Pulse research has shown that the digestion of starch has been affected by the duration of time of pressure cooking, and temperature (Traianedes and O'Dea, 1986). Lentils that were dried for 12 h compared to boiled for 20 min produced carbohydrates that resulted

in increased BG response due to being more rapidly digested. Blending does not appear to increase BG but prolonged exposure to heat does (Jenkins et al., 1982).

Another aspect to consider is the effects of processing on protein. For example, extrusion improves pulse protein digestibility by causing protein to unfold and denature. Extrusion also increases protein digestion by inhibiting protease inhibitors that hinder protein digestion (Hood-Niefer and Tyler, 2010; Day and Swanson, 2013).

Along with inhibiting protease inhibitors that prevent protein digestion, extrusion also decreases other anti-nutrients. Some anti-nutrients, however, have desirable effects such as  $\alpha$ -glucosidase and  $\alpha$ -amylase inhibition (Sievenpiper et al., 2009).  $\alpha$ -glucosidase and  $\alpha$ -amylase are important glucosidases needed by humans to digest starch (Yilmazer-Musa et al., 2012). These glucosidases are crucial to carbohydrate digestion as all carbohydrates other than monosaccharides require being broken down by enzyme activity prior to absorption. Indeed,  $\alpha$ -glucosidase and  $\alpha$ -amylase inhibition impedes carbohydrate digestion leading to lower postprandial BG concentrations (Kim, 2013; Heacock et al., 2005; Paradis et al., 2011). Heating used during extrusion can decrease or inactivate compounds that contain anti-nutrition factors such as the  $\alpha$ -amylase inhibitor, which affects digestibility (Martín-Cabrejas et al., 1999). The temperature used for pulse cooking impacts the degree at which anti-nutrition factors are inactivated. These anti-nutrients could be more resistant during certain cooking processes in some pulses than in others leading to differences in glycemic response.

## Conclusion

In summary, pulses are well established as low glycemic foods that are high in protein, fiber, and other nutrients. Despite the merits of consuming pulses, they are not consumed as readily as they could be, this could be a result of unfamiliarity of cooking with pulses and lengthier preparation time.

Incorporating pulse fractions into commercial products could not only increase the nutritional content of the products but would also increase the number of individuals consuming pulses by having them available in a ready to consume form that individuals are familiar with, and many consume often. Greater awareness of how to cook with pulses and pulse fractions could also aid in increasing consumption. While it is well established that pulses are low glycemic, the exact mechanisms warrant further investigation.

# Microencapsulated Food Ingredients

Chang Chang, Andrea K Stone, and Michael T Nickerson, University of Saskatchewan, Saskatoon, SK, Canada

© 2019 Elsevier Inc. All rights reserved.

## Introduction

Microencapsulation technology is used in a wide range of pharmaceutical, nutraceutical, and food and beverage industries for the delivery and/or protection of sensitive ingredients. The technology isolates or embeds bioactive ingredients (e.g., flavors, probiotics, omega fatty acids, vitamins, minerals, and enzymes) within a physical barrier of one or more macromolecules (proteins, polysaccharides and lipids), to produce capsules of varying morphologies [microcapsules (well-defined core-shell morphology) and microspheres (bioactive ingredients are disbursed within the matrix)] (Thies, 1996). As such, the capsules consist of two parts: the encapsulated substances, also known as core, internal, or payload phase, and the protective materials, also known as wall, external, or coating phase. Generally, microencapsulation offers protection to sensitive core materials from moisture, oxygen, light, pH, and temperature to prolong shelf-life; converts liquid materials into an easily handled and dispersed solid powder; prevents nutrient loss of the encapsulant; provides controlled release of core ingredients; and masks undesirable flavor, taste and odor (Desai and Park, 2005; Lakkis, 2008; Nedovic et al., 2011).

This chapter provides a brief review of the microencapsulation of food ingredients (flavors, probiotics, omega fatty acids, micronutrients, and enzymes), addressing issues surrounding: the coating materials and techniques for encapsulation, the physicochemical and release properties of the microcapsules themselves, and processing challenges. Table 1 presents examples of the microencapsulation of different core materials using different processing techniques.

## Microencapsulation of Flavors

Flavors determine the overall acceptability and preference of food and beverage products among different consumers. The perception of flavor is triggered by various components, including aromatic compounds (perceived by olfactory epithelium, e.g., burnt, musty, and fresh), gustatory components (perceived by taste receptor cells on the tongue, e.g., sweet, sour, salty, bitter, and umami), chemical heat principals (perceived by filiform taste buds, e.g., spicy and numb), and physical properties of foods (perceived by cells on the tongue and palate, e.g., crispy, hard, and soft) (Delwiche, 2004). However, many flavor compounds are susceptible to environmental changes (e.g., light, pH, humidity, and temperature), which results in ingredient–ingredient interactions altering the flavor profile and in turn decreases consumer acceptance. Therefore, microencapsulation is introduced to maintain a consistent flavor in food products over a period of storage and provide controlled release during processing and consumption.

Depending on the affinity of the flavor components for certain encapsulation operations or materials, different techniques can be used (Table 1). For example, spray drying and chilling are appropriate for both nonpolar and polar flavor systems, whereas co-extrusion is typically used for nonpolar systems. The specific wall material used can determine the controlled release, flavor masking abilities, and level of protection. It is required that wall materials should have generally recognized as safe (GRAS) status, film-forming capacity, good dispersability in the solvents, neutral taste, and chemical inertness to the flavor compounds during processing and storage. Food grade biopolymers such as proteins, lipids, gums, and cellulose, are common encapsulation matrix materials (Shahidi and Han, 1993; Zuidam and Heinrich, 2010). Charve and Reineccius (2009) selected proteins (sodium caseinate, whey and soy protein isolates) and hydrocolloids (gum acacia and modified starch) to encapsulate limonene and aldehydes [(E)-2-hexenal, (E)-cinnamaldehyde, and citral] using spray drying. They found hydrocolloids (especially gum acacia) greatly prevented the flavor loss, whereas proteins effectively limited limonene oxidation during 28 d of storage at 40 °C, with a 1:4 ratio of flavors to wall materials providing the best retention (Charve and Reineccius, 2009; Zuidam and Heinrich, 2010). Therefore, both type and concentration of encapsulation matrix materials are identified as important factors influencing flavor encapsulation.

Spray drying has been the most widely used encapsulation technique in the flavor industry, but many novel techniques (spray chilling, melt extrusion, molecular inclusion complexation, and coacervation) were recently developed to satisfy product development and manufacturing requirements (production efficiency, particle size, storage stability, cost, and production yield) (Gouin, 2004; Sobel et al., 2014). Due to simple operation procedures and low temperature, spray chilling (also known as spray cooling) is an attractive method to entrap flavor compounds and form solids via crystallization. Therefore, it is critical for the selected wall materials (stearin, waxes, polyols, and mono- or diacylglycerols) to undergo solidification at low temperature (Sillick and Gregson, 2012). Oriani et al. (2016) used three different lipids (palmitic acid, oleic acid and palm fat) to convert ginger oleoresin into a powder that remained solid at room temperature using spray chilling; they reported that the best retention of pungent (>95%) and volatile (>80%) compounds occurred when using palmitic acid alone.

Molecular inclusion complexation is another novel technique to utilize the porous structure of materials (cyclodextrin and hydrophobic modified starches) to entrap flavor molecules, and is typically used to maintain flavor stability and mask undesirable taste (Yu and Huang, 2010; Sobel et al., 2014). Saldanha do Carmo et al. (2017) formed cyclodextrin inclusion complexes with limonene for enhanced flavor retention in non-alcoholic beverages. Additionally complex coacervation has been utilized as an

<b>Probiotics</b>				
<i>Lactobacillus</i> spp.	Sodium alginate (double coating)	Freeze drying	Increased survivability under simulated digestive conditions and increased heat tolerance	Rather et al., 2017
<i>Lactobacillus acidophilus</i> and <i>Bifidobacterium</i> spp.	Hydrogenated vegetable oil, ethylcellulose E100, maltodextrin, sodium alginate, microcrystalline cellulose, and calcium alginate	Fluidized bed drying	Improved heat resistance, and ability to withstand relative high humidity and shear force	Penhasi et al., 2010
<i>Lactobacillus</i> spp.	Sorbitol and trehalose	Vacuum drying	High stability of bacteria at non-refrigerated temperatures for three months	Foerst et al., 2012
<b>Omega fatty acids</b>				
Canola oil	Lentil protein isolate, maltodextrin, sodium alginate, and lecithin	Spray drying	Better oxidative stability, and higher entrapment efficiency	Chang et al., 2016
Olive oil	Gelatin and sodium alginate	Complex coacervation	Improved thermal stability, controlled release properties, no interaction between core and wall materials, and free flowing spherical structure	Devi et al., 2012
Fish oil	Soybean soluble polysaccharide, maltodextrin, and octenyl succinic anhydride starch	Fluidized-bed coating	Very high entrapment efficiency (96%–99%), great protection against oxidation	Anwar and Kunz, 2011
<b>Enzymes</b>				
Lactase	Shellac, gum acacia, and hydroxypropylmethyl cellulose	Spray coating	Protected lactase activity under acidic conditions, and effectively reduced lactose in the dairy products	Soloman, 2013
Lipase	Sodium chloride and hydroxypropylmethyl cellulose	Fluidized-bed coating	Decreased oil rancidity, maintained lipase activity and extended the shelf-life	Plijter and Meesters, 2000
Proteinase (Flavourzyme)	Lecithin and cholesterol	Liposome	Entrapment efficiency of 25%, accelerated ripening of Iranian white cheese	Jahadi et al., 2016

encapsulation method, for example, [Yang et al. \(2014\)](#) encapsulated vanilla oil with hydrocolloid materials (chitosan, gum Arabic, and genipin) using complex coacervation to improve the thermostability and flavor retention of the vanilla oil.

### Microencapsulation of Probiotics

Probiotic microorganisms have garnered much attention for their health benefits and disease prevention effects. They are defined as non-pathogenic and non-toxicogenic living microorganisms (e.g. *Lactobacillus*, *Bifidobacterium*, and *Streptococcus*) that provide nutritional and therapeutic benefits to the host such as modulating immune response, increasing resistance to infectious intestinal diseases, and preventing colon cancer ([Schrezenmeir and de Vrese, 2001](#); [Kotzampassi and Giamarellos-Bourboulis, 2012](#)). However, considering the fragility of probiotic microorganisms to a variety of adverse environmental conditions and manufacturing processes, encapsulation can be used to extend shelf-life, protect the probiotics, and control their release in the intestinal tract ([Table 1](#)).

Polymeric materials (e.g., high amylose starch, pectins, and carrageenans) are most frequently used for probiotic encapsulation to immobilize the bacteria to prevent cell death in the stomach and release them across the intestinal tract. For example, high amylose starch is able to form a strong gel matrix through the hydration of starch granules in boiling water under stirring, which is non-digestible in the stomach but readily degradable by gut microflora in the intestine ([Cook et al., 2012](#)). Due to the simple preparation and crosslinking conditions, alginate has been extensively studied for its use in microencapsulation. However, those polymeric matrices tend to form a porous structure that decreases microcapsule stability; an extra coating of biopolymers is often a means to help circumvent this issue. [Rather et al. \(2017\)](#) double coated probiotics (composed of *Lactobacillus* spp.) in alginate to produce freeze dried microcapsules that survived treatment under simulated digestive conditions and had increased heat tolerance as compared to free cells. Co-encapsulation has also been utilized to protect probiotics during digestion and increase their viability upon release. [Eratte et al. \(2015\)](#) co-encapsulated a probiotic bacteria with tuna oil in complex coacervates consisting of whey protein isolate and gum Arabic; the oil increased bacteria survival through *in-vitro* digestion as well as the cell surface hydrophobicity, which is used as a measure of the ability of the bacteria to adhere to the lining of the intestine.

Comparing with other methods (spray drying and fluidized bed drying), freeze drying and vacuum dehydration are most favorable for use in probiotic microencapsulation, due to low temperature, better encapsulation efficiency, and less contamination concerns ([Roser, 1991](#)). During the freeze drying, lyophilization under vacuum is applied after freezing the liquid containing the probiotics, therefore, the formation of ice crystals may result in loss and damage of living microorganisms. [Harel and Tang \(2014\)](#) stated that appropriate amounts (typically >50%) of food grade cryoprotectants (glycols, sugars, and salts) can be added to the liquid as antifreeze agents, to minimize the generation of ice crystals through depressing the freezing point of the probiotic liquid. In addition, controlled low-temperature vacuum dehydration, which involves the dehydration of non-frozen liquids containing probiotics at low temperature under vacuum, was also developed to avoid the damage from ice crystals associated with freeze drying. This is a faster drying technique due to the increased surface area and the vacuum condition, which can be easily controlled by the adjustment of the applied vacuum ([Harel and Tang, 2014](#)). [Foerst et al. \(2012\)](#) used sorbitol and trehalose for encapsulation of *Lactobacillus paracasei* F19 by vacuum drying and reported that while trehalose encapsulation produced the highest survival rate after drying, sorbitol provided the best bacteria protection during long-term storage of the probiotics at 20 and 37 °C. In addition the authors reported that vacuum drying produced cells with much higher stabilities than freeze dried cells. The applications of probiotics in nutraceuticals, functional foods, and supplements have been rapidly expanding through various delivery forms (e.g., tablets, soft gel capsules, and dry powders) and numerous probiotic products are commercially available in the market place.

### Microencapsulation of Oils Rich in Omega Fatty Acids

Omega fatty acids (omega-3, -6, and -9) play an essential role in the prevention and treatment of cardiovascular diseases and immune response disorders, development of the central nervous systems for infant growth, and maintenance of mental health ([Shibasaki et al., 1999](#)). However, because of their unsaturated structure, they are susceptible to oxidative deterioration and readily produce free radicals, which are deemed to negatively affect the shelf-life, sensory properties, and overall acceptability of food products ([Velasco et al., 2003](#)). As such, microencapsulation offers a means to protect the sensitive omega fatty acids, decrease nutrient loss, increase shelf-life, mask unpleasant taste, and transform oils into an easily handled and dispersed solid powder in the marketplace ([Desai and Park, 2005](#)) ([Table 1](#)). The number of commercial food products (e.g., dairy products, baked goods, snacks, and beverages) fortified with encapsulated omega fatty acids (especially omega-3) is dramatically increasing as advances in storage stability and desirable sensory properties of the products are made.

The use of just one wall material can create challenges in providing high entrapment efficiencies and protection to the core material; however, this can be overcome by using a combination of polysaccharides and proteins. Typically the wall material involves the use of proteins (e.g., whey proteins, gelatin, and soy protein isolate) because of their emulsifying and film-forming properties, and polysaccharides (e.g., maltodextrins, starches, and chitosan) because of their matrix forming properties, and specifically the use of maltodextrin as a drying agent ([Young et al., 1993](#); [Gharsallaoui et al., 2010](#); [Nesterenko et al., 2013](#)). [Chang et al. \(2016\)](#) investigated the microencapsulation of canola oil (rich in oleic acid, linoleic acid, and  $\alpha$ -linolenic acid) using different wall materials [lentil protein isolate (LPI), maltodextrin, sodium alginate and lecithin], and found that the combination of LPI,

maltodextrin, and sodium alginate produced microcapsules with better entrapment efficiency (~88%) and protection against oxidation in comparison with the mixture of LPI and maltodextrin.

Among the various encapsulation techniques (spray drying, freeze drying, coacervation, extrusion, and fluidized-bed coating), spray drying is the most commonly applied, due to its low cost and wide availability of equipment (Desai and Park, 2005). For example, Sanguansri et al. (2013) and Can Karaca et al. (2013) encapsulated omega fatty acid-rich oils, within a polysaccharide (glucose and maltodextrin, respectively) and protein (sodium caseinate and chickpea protein isolate, respectively) mixture using spray drying to generate capsules with relatively high entrapment efficiencies (>85%). However, using extremely high temperatures (160–180 °C) for spray drying may result in damage of the microcapsule wall structure (pores, shrinkages, and invaginations), adversely affecting the oxidative stability of the omega fatty acids (Bakry et al., 2016). Limited oil payload (5%–50%) is also a drawback for spray drying encapsulation applications in the food industry (Desai and Park, 2005). Therefore, research activities surrounding encapsulation by complex coacervation have increased as coacervation provides a number of potential advantages over spray drying, such as higher oil payload (up to 99%), lower surface oil, better storage stability and controlled release properties (Xiao et al., 2011). Olive oil was encapsulated within a gelatin and sodium alginate matrix using complex coacervation at pH 3.5–3.8, in which the entrapment efficiency and release characteristics of oil from the microcapsules were greatly dependent on the polymer concentration and oil concentration (Devi et al., 2012). Yan and Jin (2011) invented single- and multi-core (fish oil) capsules with multiple layers using a mixture of polysaccharides (pectin, gum Aracia, and carboxymethyl guar gum) and proteins (gelatin and whey protein) by complex coacervation, which delivered 140–180 mg of omega-3 fatty acids (per g powder) and greatly increased the shelf-life of the oil to 18 months when stored at 4 °C.

## Microencapsulation of Enzymes

Enzymes (e.g., amylase, cellulase, isomerase, lactase, lipase, and pectinase) extracted from plants, animals, or microbial fermentations have been widely used in food applications (e.g., baking, brewing, sweeteners, dairy, oil, and juice productions) (Schwimmer, 1981; Dale, 2014) as they can catalyze specific biochemical reactions to alter or strengthen the texture, flavor, and storage stability of food products (Schwimmer, 1981). However, these enzymes are susceptible to degradation in response to changes in temperature, moisture, pH, shear stress, and air, through oxidation, deamidation, and glycation, which adversely affects their performance in various applications (Dale, 2014). Encapsulation is an effective way to mitigate enzyme exposure to detrimental environmental conditions, but is dependent on the specific application and associated challenges (Table 1).

As mentioned previously, spray drying has been universally used to produce microcapsules, and this includes entrapping enzymes for use in food applications. Horn (2003) described how  $\alpha$ -amylase was substantially coated with an oil using spray drying and then incorporated into dough before baking, in which the enzyme was released at an acceptable rate to retard staling of the baked product. Many other approaches (e.g., wet granulation, fluidized-bed coating, and liposome) have been studied to efficiently encapsulate enzymes. Plijter and Meesters (2000) utilized fluidized-bed coating to entrap lipase onto sodium chloride particles, which was then further covered by a hydroxypropylmethyl cellulose layer and utilized in baking applications to decrease oil rancidity during storage. Moreover, using liposomes to entrap enzymes is a technique used for accelerating ripening in cheese production. Jahadi et al. (2016) entrapped proteinase within liposomes using a heating method, which does not need organic solvents and allows for scale-up of the liposome production, for use in Iranian white brined cheese.

Enzyme encapsulation has provided unique benefits in food applications, such as improving production processes, optimizing product quality, and delivering the enzyme at the correct time and place (Panesar et al., 2010; Dale, 2014). It can be homogeneously distributed in the baking products to booster the dough characteristics by amylases, improve dough quality by proteases, and extend the shelf-life by lipases. It can also be used in dairy products to modify the texture, promote flavor formation, and reduce the aging process (Dale, 2014). The production of syrups and sweeteners is another area that uses enzyme encapsulation, in which glucose isomerase is immobilized to have better stability under high temperature for promoting the conversion of glucose to fructose, so, the reaction is continuously run and enzymes can be reused to decrease production cost (Dale, 2014).

## Conclusion

Microencapsulation of flavors, probiotics, omega fatty acids, and enzymes, in addition to other core materials, has been extensively investigated. Selection of the appropriate wall materials and encapsulation techniques are crucial as they primarily determine the success of the encapsulation through measures of entrapment efficiency, stability of capsules and protection of the core material. Effective targeted release properties and efficient delivery of the health benefits of the core materials are becoming drivers of the utilization of microencapsulation and as such new innovations in encapsulation as well as the use of microencapsulated ingredients in the food industry continues to grow.

# Multifunctional Foods

Koji Yamada, Sojo University, Kumamoto, Japan

© 2019 Elsevier Inc. All rights reserved.

## Overview

Foods contain biologically active substances that exert various activities, including plural functions (Yamada, 2017). Thus, foods are basically multifunctional in nature. However, contents and composition of these functional factors are fairly different with foods. Therefore, we have to take various foods to maintain our health. On the other hand, unbalanced diet may lead to the occurrence of various food style dependent diseases. To avoid such diseases, it is important to produce and afford nutritionally balanced foods.

In addition, excess intake of energy and some food components induce such diseases. Among food components, excess intake of lipids, especially unsaturated fatty acids, induces various diseases. To avoid induction of such diseases, it is necessary to produce and afford multi-functional foods which prevent various diseases simultaneously. Fortunately, we can utilize multifunctional factors to produce multifunctional foods. Dietary fiber (DF) is a typical multifunctional factor present in various plant foods and used for production of healthy foods in various countries. Though oxidized products of unsaturated fatty acids induce various diseases, they can also inhibit the occurrence of other diseases. Thus, the addition of antioxidants is important to utilize the abilities of unsaturated fatty acids.

Since antioxidants suppress the oxidation of unsaturated fatty acids, they can suppress the expression of their many inconvenient effects. In addition, antioxidants exert multifunctional effects independent with their anti-oxidative activity. Effective use of these multifunctional factors may greatly enhance the ability of multifunctional foods.

In designing multifunctional foods, maintenance of safety is very important. Highly effective functional factors often induce side effects when they are taken excessively. To enhance the safety of multifunctional foods, simultaneous uses of biologically active factors may be effective. Some multifunctional factors are reported to have synergic effects. For example, simultaneous use of  $\alpha$ -tocopherol (Toc) and sesamin exert their biological effects at lower doses. Such decreases in dosage are attributes that contribute to the maintenance of safety of multifunctional foods, as well as reduction of production cost.

## Biologically Active Food Components

As summarized in Table 1, foods contain various biologically active substances. Digestive polysaccharides and sugars are important energy sources for animals. However, persistent elevation of serum glucose level leads to the occurrence of diabetes. On the other hand, hardly digestible polysaccharides suppress the degradation of digestible polysaccharides and incorporation of glucose. This leads to the prevention of diabetes. In addition, hardly digestible polysaccharides can bind lipid-soluble components such as carcinogenic components and lipids. This leads to the expression of anti-cancer and lipid-metabolism improving activities. Thus, hardly digestible polysaccharides are called DF and are widely used for the production of health-oriented foods. Some oligosaccharides are also hardly digestible. In addition, such oligosaccharides enhance the growth of *Lactobacillus* and *Bifidus* bacteria which improve the circumstance of gut. Thus, these saccharides are widely used as low-calorie biologically active components.

Proteins are polymers composed of about 20 amino acids. Since humans cannot synthesis some amino acids in sufficient quantities, they are called essential amino acids (EAA), which should be taken from various foods. Balanced intake of EAA is important to keep health, because they are necessary for *in vivo* synthesis of various regulatory proteins. Food proteins are digested to peptides or amino acids in the digestive track and incorporated into our body. Some peptides have been reported to exert biological effects such as enhancement of Ca absorption and inhibition of angiotensin-inducing enzyme activity. The former is useful for the prevention of osteoporosis and the latter for the inhibition of blood pressure elevation.

Lipids are hydrophobic, water-insoluble components present in foods. Major component is neutral lipid (triacylglyceride) in which glycerol is bound to three fatty acids. The function of neutral lipid is highly dependent on fatty acid composition. Animal fats are rich in saturated fatty acids and oleic acid (OA, C18:1n-9) while most plant oils are rich in polyunsaturated fatty acids (PUFA) that belong to the n-6 series. On the other hand, fish oils are rich in PUFAs that belong to the n-3 series. PUFAs with 20 carbons are oxidized by lipoxygenase or cyclooxygenase to give various eicosanoids, which have diverse biological effects. Leucotrienes (LT) produced from arachidonic acid (AA, C20:4n-6) are one of food allergy inducers, but the activity of LT produced from eicosapentaenoic acid (EPA, C20:5n-3) is very low. In addition, EPA-derived LT suppresses the expression of allergic effect of AA-derived LT, through a competition with AA-derived LT. Thus, the composition of PUFAs in diets is highly important in the prevention of food allergy.

PUFAs are easily oxidized *in vivo* and the oxidized products induce various diseases. To prevent the *in vivo* oxidation of PUFAs, intake of antioxidants is important. Vitamins are low molecular regulatory factors present in various foods, and balanced intake of vitamins is important to maintain healthy condition. Among them, vitamin E is a lipid-soluble antioxidant which efficiently suppresses the oxidation of unsaturated fatty acids in lipophilic environments such as in cell membranes. On the other hand, vitamin C is a water-soluble antioxidant, which is effective in the prevention of oxidation in foods or in body fluids. In addition, various types of antioxidants are present in foods. These antioxidants prevent the occurrence of food style-dependent diseases via

**Table 1** Biologically active food components

<i>Food components</i>		<i>Functions</i>
Saccharides	Monosaccharides	Glucose is a major energy source of body, especially of brain. Fructose and galactose are also available for energy source. Sugar alcohols are hardly absorbable, and used as low-calorie sweetener.
	Oligosaccharides	Digestible ones such as sucrose are utilized as an energy source. Hardly digestible ones are used as low-calorie sweetener. Some of them enhance the growth of lactic acid bacteria.
	Polysaccharides	Digestible ones such as starch are utilized for energy source. Hardly digestible ones called dietary fibers exert various biological effects.
Proteins	Amino acids	Essential amino acids should be taken from foods. Nonessential amino acids can be synthesized via TCA cycle. These amino acids can be converted to various biologically substances such as nucleic acid bases via TCA cycle
	Peptides	Degraded products of proteins. Some of them exert biological activities such as enhancement of mineral absorption, inhibition of blood pressure elevation, anti-oxidative activity etc.
	Proteins	Digestible ones afford essential and nonessential amino acids. Some that are hardly digestive can act as dietary fibers. Most functional proteins lose their activities through digestion. Those that exert their activities in the digestive track such as digestive enzymes are useful for our health.
Lipids	Fatty acids	They are composed of saturated and unsaturated fatty acids. The former is divided into 3 groups, such as short-chain, medium-chain, and long-chain fatty acids. Short-chain fatty acids enhance excretion of feces and middle-chain fatty acids are effective energy source of digestive tract disease patients. Long chain fatty acids are classified into n-3, n-6, and n-9 groups depending on the position of the first double bond counted from methyl end. They exert various biological effects, varying with groups.
	Neutral lipids	The glycerol molecule is bound to 3 fatty acids. Their functions differ based on fatty acid composition.
	Phospholipids	The glycerol molecule is bound to 2 fatty acids and one basic component. Main component of cell membrane. Their functions are different with fatty acid composition.
	Lipid soluble components	Cholesterol is important as a component of cell membrane and a starting material of bile acid synthesis. Increase of serum cholesterol level leads to the occurrence of circulatory disease.
Vitamins	Water-soluble	Vitamin Bs and C. The former is important for the regulation of metabolism. The latter is essential for collagen synthesis and exerts anti-oxidative activity.
	Lipid-soluble	Vitamins A, E, D and K. Vitamin E effectively suppress oxidation of unsaturated fatty acids especially in lipophilic circumstances such as within the cell membrane
Others	Minerals	Ca is important for maintenance of bones and teeth. Fe is essential for the transport of oxygen. K is useful for the decrease of blood pressure. Some of minerals regulate the metabolism as co-factors of various enzymes.
	Antioxidants	The components with anti-oxidative activity.

suppression of unsaturated fatty acids oxidation. In addition, some antioxidants induce various biological effects independent of their anti-oxidative activity. This means that antioxidants are important multi-functional factors just like DF and PUFAs.

### Multifunctional Activity of Dietary Fats

**Table 2** shows typical multifunctional factors in foodstuffs. Among them, most popular multifunctional factor is dietary fibre (DF). DF is a group of polysaccharides which are not digestible or hardly digestible by human digestive enzymes. Some of them are water-insoluble and the others are water-soluble. Typical water-insoluble DF is cellulose. Because of its hydrophobic surface, it adsorbs lipophilic food components, such as dietary fats or carcinogenic compounds. Since DF cannot be absorbed in our body, it inhibits the absorption of these lipophilic components. This leads to the expression of its lipid metabolism regulating and anti-cancer activities.

On the other hand, water-soluble DF (WSDF) are partially digested by intestinal bacteria to give short-chain fatty acids (SCFA), such as acetic, propionic and butyric acids. Since acetic acid is absorbed at intestinal wall and used as an energy source, WSDF afford some amounts of energy. On the contrary other SCFA exert some physiological activities. For example, butyric acid arrests the cell cycle of diploid mammalian cells at both G1 and G2 phases, and the cells arrested at the G2 phase are rapidly converted to tetraploid G1 cells (Yamada and Kimura, 1985). This leads to the production of polyploid cells with a high efficiency (Yamada et al., 1985). On the other hand, the cells transformed with oncogenes are hardly arrested to the G2 phase by butyric acid and the cells that passed the G2 phase lose viability quickly. This leads to the expression of its anti-cancer effects (Yamada et al., 1992).

In addition, WSDF can express lipid metabolism regulating and anti-cancer activities simultaneously, since they have lipophilic part on their surface as well as water-insoluble DF. A previous work tried to clarify the difference in physiological activities between two types of DF and found that WSDF exert much stronger immuno-regulatory activity than cellulose (Lim et al., 1997). Among WSDF, the rats fed glucomannan (GM) or pectin (P) gave higher serum IgA and IgG levels and a lower serum IgE level than those fed cellulose.

In the feeding experiments, lipid metabolism regulating activity of food components can be assayed simultaneously with immuno-regulatory activity. The rats fed WSDF such as guar gum (GG), GM or P gave lower serum cholesterol and triglyceride levels than those fed cellulose, when aged eight-month-old Sprague-Dawley (SD) rats were fed the diets containing the above DFs for

**Table 2** Typical multifunctional factors in foodstuffs

Food components	Characteristics
Dietary fibers	Water-insoluble ones are non-digestible. Cellulose, hemicellulose and lignin are plant cell wall components. Chitin is a polymer of N-acetyl glucosamine isolated from shells of crustacean. Deacetylated chitin (chitosan) is acid-soluble. Intestinal regulation, anti-cancer, anti-lipidemia, and anti-diabetes. Water-soluble ones are partially digestible and give smaller calories than digestible polysaccharides. Glucomannan and fructomannan are present in vegetables, and pectin in fruits. Gums isolated from various plants (Arabia gum, karaya gum, tragacanth gum, locust bean gum, guar gum), seaweed polysaccharides (agarose, arginic acid, carageenan) and bacterial products (xanthan gum and pullulan) are also used in food industries. In addition to the effects of water-insoluble DF, they exert strong immune-regulatory effects.
Fatty acids	Oleic acid (OA, C18:1 <i>n</i> -9) is a representative monoenoic fatty acid, which enhances growth of mammalian cells. Since it can be produced from a saturated fatty acid rich in animal tissue, it is not essential. Animal cells cannot introduce second double bond in monoenoic fatty acids. Thus, polyunsaturated fatty acids (PUFAs) should be taken from plant foods. Linoleic acid (LA, C18:2 <i>n</i> -6) is a starting material of n-6 series PUFAs synthesis and metabolized to $\gamma$ -linolenic (GLA, C18:3 <i>n</i> -6), dihomo- $\gamma$ -linolenic (DGLA, C20:3 <i>n</i> -6), arachidonic (AA, C20:4 <i>n</i> -6) acids. DGLA and AA are further metabolized to eicosanoids which exert various biological effects. PUFAs that belong to n-3 series such as eicosapentaenoic (EPA, C20:5 <i>n</i> -3) and docosahexaenoic (DHA, C22:6 <i>n</i> -3) are metabolized from $\alpha$ -linolenic acid (ALA, C18:3 <i>n</i> -3). EPA is further metabolized to eicosanoids which exert various biological effects.
Antioxidants	It is composed of various compounds with anti-oxidative activity. Some polyphenols with more than two OH groups in benzene ring exert strong anti-oxidative activities. Catechins are antioxidants rich in green tea and exert diverse biological effects such as anti-cancer, anti-allergic and anti-obesity effects. Flavonoids (flavone, flavonol, anthocyanin) are antioxidants present in vegetables and fruits. In addition, various foods contain various non-polyphenolic antioxidants.

3 weeks (Yamada et al., 1999a). On the other hand, these results were not obtained in 8-month old aged SD rats (Yamada et al., 2003). The results suggest that the dietary effects of WSDF are age-dependent. Similarly, the young SD rats fed GG, GM or P gave significantly higher serum IgA levels than those fed cellulose, but the effect was not observed in aged rats.

In the feeding experiments, lymphocytes were isolated from spleen and mesenteric lymph node (MLN), and cultured for 24 hr in the absence of DF to determine the effect on Ig productivity of these lymphocytes. In this experiment, lymphocytes isolated from MLN of young SD rats fed WSDF gave higher IgA, IgG, and IgM productivities than those isolated from the rats fed cellulose.

In the case of splenocytes, the stimulating effects were weaker than those observed in MLN. In aged rats, the stimulating effect was observed only in MLN lymphocytes, but not in splenocytes. These results suggest that the feeding effect of WSDF is dependent on immune tissue, as well as age of rats.

As shown above, feeding experiments using experimental animals afford an excellent system to study multifunctional activity of food components. When some biological effects were observed in animal experiments, cultured cells are often used to clarify the regulatory mechanism of food components. However, the *in vitro* system was not effective in WSDF. When established cells or lymphocytes with Ig-producing activity were cultured in the presence of WSDF or SCFA, such changes in Ig productivity were not induced. This suggests that the effect of WSDF was not induced through the direct interaction of WSDF with immune cells.

### Multi-functional Activity of Polyunsaturated Fatty Acids

Biological activities of unsaturated fatty acids are dependent on their structures. Linoleic acid (LA, C18:2*n*-6) has a double bond at the sixth position from its methyl terminal and metabolized to dihomo- $\gamma$ -linolenic acid (C20:3*n*-6) and finally to arachidonic acid (AA, C20:4*n*-6) via  $\gamma$ -linolenic acid (GLA, C18:3*n*-6) and dihomo- $\gamma$ -linoleic acid (DGLA, C20:3*n*-6). The AA in membrane phospholipids (PL) is cut out by phospholipase and then oxidized with lipoxygenase to 4-series LT, which induce type I allergy. On the other hand,  $\alpha$ -linolenic acid (ALA, C18:3*n*-3) has a double bond at the third position from its methyl terminal and metabolized to EPA (C20:5*n*-3) and docosahexaenoic acid (DHA, C22:6*n*-3). EPA is also oxidized with lipoxygenase to 5-series LT, which suppress type I allergy. Since n-3 PUFAs can be substituted with AA in membrane PL, they can suppress allergic reaction through the reduction of membrane AA level.

In addition, dietary n-3 PUFAs decreased serum triglyceride and cholesterol levels (Huglund et al., 1991). The lipid metabolism-regulating activity can be observed in the rats fed fish oils rich in EPA or DHA, as well as the above immuno-regulatory effects (Hung et al., 1999). The fish oils with different EPA and DHA contents can be prepared by mixing some fish oils, but it is impossible to prepare the fish oil containing solely EPA or DHA, because all fish oils contain both components. To clarify the difference of biological activity between EPA and DHA, purified EPA and DHA esters were used in the feeding experiment and it was found that EPA ester exerted stronger anti-allergic effect than DHA esters, as expected (Hung et al., 2000).

In addition, conjugated linoleic acid (CLA) exerts multifunctional effects, such as anti-cancer (Yamasaki et al., 2002), lipid metabolism-regulating (Yamasaki et al., 2003), and immune-regulatory activities (Yamasaki et al., 2004). CLA is a generic term for the positional and geometric isomer of LA. LA is converted to CLA by intestinal bacteria and small amount of CLA is detected in dairy products. The naturally produced CLA has 9-cis, 11-trans (9c, 11t) conformation. On the other hand, 10-trans, 12-cis (10t, 12c) CLA is produced at the similar level with 9c, 11t CLA, when LA is heated in alkaline solution. Among them, 10t, 12c CLA exerts much stronger biological effects than 9c, 11t CLA. This means that the artificially produced CLA is more excellent effector than naturally produced CLA. To use the artificial product for human health improvement, confirmation of safety is essential.

## Multi-functional Activity of Antioxidants

There are various types of natural and synthesized antioxidants which are used for the inhibition of oxidation of food component *in vitro* or *in vivo*. They exert various physiological activities in addition to the anti-oxidative activity. Among them, biological effects of polyphenolic compounds were widely studied. Diphenol compounds with two OH groups on a benzene ring at ortho or para position exert strong anti-oxidative activity, as well as anti-allergic effects (Yamada et al., 1999b, 1999c). These polyphenols may exert the activities through the binding to cell surface or through the interaction with intracellular components after their incorporation into cells. In general, triphenol compounds exert stronger activity than diphenol compounds on cell surface (Yamada et al., 1999b, 1999c), probably due to stronger interaction with cell surface (Yano et al., 2007).

Among tea polyphenols, epigallocatechin gallate (EGCG) with 2 triphenol groups exerts strong biological activities. For example, it exerts much stronger toxicity against rat 3Y1 diploid fibroblasts transformed by E1A than other tea polyphenols, but their toxicities against normal 3Y1 cells are unchanged (Yamada et al., 1993). This means that EGCG is more effective anti-cancer compound with low toxicity against normal cells than other catechins. Since it strongly suppresses both histamine and LTB<sub>4</sub> release from rat peritoneal exudates cells stimulated with a calcium ionophore A23187 (Yamada et al., 1999c), EGCG may also be useful for prevention of type I allergy.

In the case of vitamin E derivatives, clarification of their tissue distribution is important (Okabe et al., 2002). Tocopherol (Toc) derivatives are distributed to various tissues, but the presence of tocotrienol (T3) derivatives is limited in several tissues. When a mixture of Toc and T3 is administered into the stomach of SD rats and their tissue contents are determined after around 16-hr fasting, T3 can be detected only in small number of tissues. On the other hand, T3 derivatives are detected in various tissues, when their tissue levels are determined without fasting. Though  $\alpha$ -Toc is detected in various tissues and the levels are fairly stable, the levels of  $\alpha$ -T3 and  $\gamma$ -T3 are usually much lower than that of  $\alpha$ -Toc. In the adipose tissues, small amounts of  $\alpha$ - and  $\gamma$ -T3 are detected at 0 hr and the levels are increased with the elongation of ingestion time.

Detection of T3 derivatives without T3 administration and the increase of T3 levels after T3 administration suggest that T3 derivatives are accumulative in the adipose tissues. In other tissues, T3 derivatives are not detectable at 0 hr and accumulated with the elongation of ingestion time in some tissues. In the liver and MLN, the levels of T3 derivatives were highest at 8 hr after ingestion and decreased at 24 hr. In these tissues, T3 may be incorporated quickly and then released or metabolized thereafter. The quickness of disappearance in some tissues may be the reason why T3s are detectable only in limited tissues. T3 derivatives often exert stronger biological effects than Toc derivative in cell culture assays (Sakai et al., 2006). However, such biological effects cannot be expressed in the tissues where T3 are not present. Thus, clarification of tissue distribution is essential for the determination of target tissue of biologically active substances.

## Design of Multi-Functional Foods

Some biologically active substances interact with other substances. For example, two anti-oxidative components, such as  $\alpha$ -Toc and sesamin, exert a synergic effect (Gu et al., 1994). When rats were fed these compounds simultaneously, these components exert anti-allergic effects at the doses where each component exerts no activity. In addition, tea polyphenol administration enhances the anti-allergic effect of n-3 PUFA. Though LTB<sub>4</sub> productivity of peritoneal exudates cells isolated from the rats fed perilla oil rich in n-3 PUFA was significantly lower than that from the rats fed safflower oil rich in n-6 PUFA, administration of tea polyphenols further decreased LTB<sub>4</sub> of the cells (Matsuo et al., 2000). In the case of EGCG, coexistence of phosphodiesterase inhibitor strongly enhanced the expression of its biological activity (Kumazoe et al., 2013). Such combinational use of biologically active components allows us to decrease the dose of these components. This leads to the improvement of safety and reductions in production costs. Thus, the studies on the interaction of biologically active substances are also important to produce multifunctional foods with a high safety.

## Glossary

**Amphiphilic** A compound possessing both hydrophilic (water soluble) and lipophilic (fat soluble) properties

**Anticoagulant** The effect of hindering or preventing the process of blood forming a clot (a solid mass)

**Antidiabetic** Tending to alleviate or prevent diabetes by control of glucose (sugar) in the blood

**Antigenic** Substance that stimulates antibody production when introduced to the immune system. Future interactions with the antibody and similar substances can induce allergy symptoms

**Antihypertensive** The ability to lower high blood pressure

**Antimicrobial** Killing or preventing the growth of microorganisms, particularly pathogenic microorganisms

**Endoprotease** Proteolytic enzymes that catalyzes the cleavage peptide bonds within the molecule (nonterminal amino acids)

**Exoprotease** Proteolytic enzymes that catalyzes the cleavage of peptides bonds from the end of a polypeptide chain (terminal amino acids)

**Hydrophobic interaction chromatography** A technique to separate molecules based on hydrophobic properties

**Ionizable** Molecules capable of dissociating into electrically charged atoms or radicals

**Isoelectric precipitation** Precipitation of materials at its isoelectric point (pI), at which the net charge is zero and is least soluble

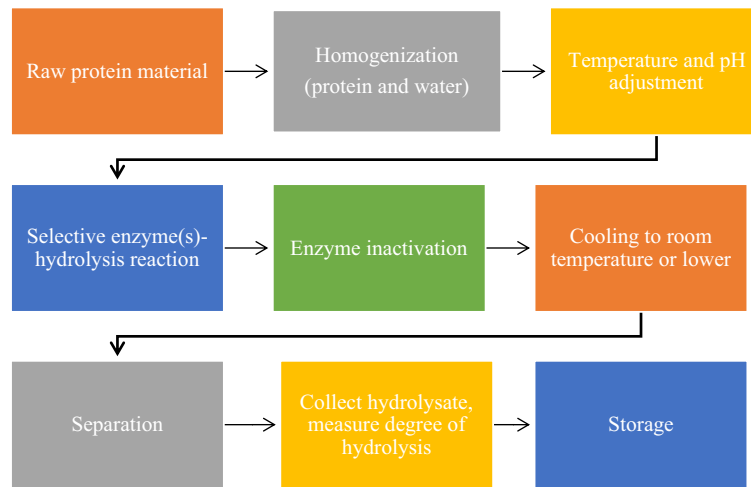

**Physicochemical** Relating to both physical and chemical properties.

## Protein Hydrolysates Definition

Protein hydrolysates are defined as the products derived from hydrolysis of the protein's peptide bonds, producing peptides with different sizes and free amino acids. This type of protein structure modification has an effect on its physicochemical and functional properties (Severin and Xia, 2006). The most notable modifications that affect functionality include a decrease in molecular weight of the peptide chain, an increase in polar groups ( $-\text{NH}_4^+$ ,  $-\text{CO}_2^-$ ) which increase hydrophilicity, and a change in molecular configuration. Acids, alkalis or enzymes can be used to cleave the peptide bonds. While acid/alkali hydrolysis are less expensive procedures, they are difficult to control and yield products with lower nutritional quality and functionality (Lahl and Windstaff, 1989; Sinha et al., 2007). Nevertheless, acid hydrolysis is used in the production of flavor enhancers (Pasupuleti and Braun, 2010). Although more expensive than chemical hydrolysis, enzymatic hydrolysis using proteases derived from plants and microorganisms that cleave peptide bonds at specific sites is the preferred method (Haard, 2001). Research on the degree of hydrolysis and enzyme specificity has allowed for decrease in cost associated with enzymatic hydrolysis (Pacheco-Aguilar et al., 2008).

## Procedure for Enzymatic Hydrolysis

The process for enzymatic hydrolysis varies in literature. A general overview of the process is given in Fig. 1. The process begins with homogenization of the starting material as either the whole food (i.e. whole milk or meat slurry) or protein that has been extracted, isolated, or concentrated prior to hydrolysis. An appropriate protein to water ratio (e.g. 1:2, w/v) is required to ensure sufficient water for enzyme mobility. Pasteurization of the solution may follow depending on the protein's autolytic activity. Temperature (between 40–60 °C) and pH (6–8) are adjusted to create optimal conditions for enzyme activity. Commercial protease(s) is added to the slurry in various concentrations and the enzymatic reaction varies from minutes to hours depending on the extent of hydrolysis required (Kristinsson and Rasco, 2000). During the enzymatic reaction an initial rapid phase occurs where large peptide bonds are hydrolyzed at specific sites; later the rate of enzymatic hydrolysis decreases as it reaches a stationary phase (Shahidi et al., 1995; Haard, 2001). The choice of enzyme specificity is an important factor influencing amino acid sequence of peptides or amino acid residues that lead to different nutritional, functional and bioactive properties in the hydrolysates. Each class of protease contains specialized catalytic sites that provide substrate specificity and guide their cellular localization to cleave distinct peptide bonds (Lopez and Bond, 2008). Enzymes can be endoproteases, exoproteases or a combination of both. Commercial enzymes such as alcalase, flavourzyme, neutrase, pepsin, and papain are some examples of proteases typically used. These proteases contain catalytic sites that provide substrate specificity to cleave distinct peptide bonds. Exo-proteases (e.g. flavourzyme) selectively cleave peptides at either the N- or C- terminus of the protein, whereas, endo-proteases (e.g. alcalase, neutrase, and pepsin) catalyze hydrolysis of non-terminal amino acids (Kristinsson and Rasco, 2000). Some proteases such as papain, display a broad range of

**Figure 1** General procedure for enzymatic protein hydrolysis.

functions with both exo- and endo-peptidase activity. **Table 1** gives a summary of the most commonly used commercial proteases reported in literature for preparation of hydrolysates from different protein sources.

The extent of hydrolysis also depends on various factors applied during the enzymatic reaction such as temperature, pH, enzyme to substrate ratio and substrate concentration (Alder-Nissen, 1986). After hydrolysis, the enzyme is inactivated by pasteurization and/or pH adjustment. The hydrolysate slurry is cooled down, separated (i.e. centrifugation, ultrafiltration) and stored (i.e. freezing, spray drying). Aliquots of the hydrolysate are used to determine the extent of hydrolysis or degree of hydrolysis, measuring the amount of peptide bonds broken compared to the total amount of peptides in the un-hydrolyzed proteins (Alder-Nissen, 1986). Therefore, a higher degree of hydrolysis is indicative of more peptide bonds cleaved resulting in lower molecular weight peptides.

### Nutritional Quality of Protein Hydrolysates

It is established knowledge that the human body requires a regular supply of protein and amino acids to maintain a normal adult nutritive state. Inadequate amounts of dietary protein causes catabolism in which the body uses its own tissue protein as a nitrogen source (Wu, 2016). In addition to quantity, protein quality is a determinant factor. Protein quality is determined by its digestibility, release of amino acids, di- and tri-peptides that can be absorbed in the small intestine, and its amino acid pattern. Hence, the presumption that amino acids from hydrolysates are more easily and quickly absorbed compared with intact protein, which has proven to give hydrolysates a nutritional advantage over intact dietary proteins (Bilsborough and Mann, 2006; Koopman et al., 2009). For example, Koopman et al. (2009) have illustrated this phenomena; they observed that enzymatically hydrolyzed casein increased protein digestion and absorption rate from the gut and postprandial amino acid availability which results in an increased rate of amino acids into skeletal muscle protein.

The protein digestibility-corrected amino acid score (PDCAAS) is considered the best method to evaluate dietary protein quality and is used as the standard by the Food and Drug Administration (FDA) to determine the percentage daily value for protein. It is estimated based on the mg of the limiting amino acid in 1 g of test protein divided by the mg of the same amino acid in 1 g of reference protein, and multiplied by the fecal true digestibility percentage (Schaafsma, 2000).

For decades, protein hydrolysates have been used in medical and clinical diets for people with food allergies or patients with digestive ailments that affect nutrient absorption. Clemente (2000) provides a detailed overview of some of the most common clinical applications of protein hydrolysates. Other common applications include protein supplementation in sports nutrition products. Athletes frequently consume protein hydrolysate products to increase plasma amino acid levels with the hopes of maximizing muscle protein anabolism and post-exercise recovery (Manninen, 2009).

Animal feeding studies have corroborated the nutritional advantages of protein hydrolysates. For example, rice bran protein hydrolysates improved insulin resistance in rats, compared with rats fed a carbohydrate-fat diet for twelve weeks (Boonloht et al., 2015). In another study, rats were fed a protein-free diet to induce muscle loss and then administered daily a whey protein diet (intact protein, amino acids, or whey protein hydrolysates). It was observed that feeding whey protein hydrolysates protected muscle mass loss better than the free amino acids and intact whey protein diets (Kobayashi et al., 2016). Martínez-Alvarez et al. (2015) provided a compilation of works that illustrate the benefit of protein hydrolysates in animal feeding. Based on the positive effects protein hydrolysates have on animals, it is expected that they will have a positive effect on humans as well. Several human clinical trials have shown that ingesting protein hydrolysates versus intact protein accelerates protein digestion and absorption which can augment amino acid availability and thus increase the rate of amino acids to skeletal muscle proteins (Morifuji et al., 2010; Deglaire et al., 2009).

**Table 1** Summary of Functional and Bioactive properties of protein hydrolysates derived from different protein sources and commercial enzymes reported in literature

<i>Protein source</i>	<i>Enzyme</i>	<i>Functional properties</i>	<i>Bioactive properties</i>	<i>References</i>

Algae	Pepsin, Amyloglucosidase	–	Anticancer, Antioxidant, Antiproliferate	Athukorala et al. (2006b), Sheih et al. (2009a,b)

## Functional Properties of Protein Hydrolysates

Apart from the nutritional quality, the functionality of the protein in a food system during processing, storage and consumption are very important factors. Proteins are highly functional molecules used in the chemical, pharmaceutical and food industries for processes such as emulsification, foaming, viscosity enhancement, encapsulation and gelation. Protein functionality refers to the properties that contribute to the flavor, texture, stability, and appearance of the final food (Kristinsson and Rasco, 2000). In many instances, intact proteins are molecularly heavy and have intramolecular bonds that prevent them from producing stable emulsions, foams and solutions (Foegeding, 2015). Minimally hydrolyzing food proteins has proven beneficial to their food industry applicability. Research shows that protein hydrolysates derived from enzymatic hydrolysis can have improved functionality. Functional properties of proteins hydrolyzed with various types of proteases and under varying hydrolysis conditions have been compared and described in literature (Hoyle and Merritt, 1994; Liceaga-Gesualdo and Li-Chan, 1999; Nilsang et al., 2005; King et al., 2007; Humiski and Aluko, 2008; Pacheco-Aguilar et al., 2008; Cheung et al., 2009; Nchienzia et al., 2010; Ktaria et al., 2012; Zhao et al., 2013; Hall et al., 2017; Nguyen et al., 2017).

Protein solubility is the most the important functional property because it will influence other properties such as emulsification and foaming, making it a good indicator of overall functionality (McCarthy et al., 2013). A protein's solubility is dependent upon its affinity to water or other polar solvents, which is dictated by non-covalent forces such as hydrogen bonding and hydrophobic and ionic interactions (Damodaran et al., 2007). Hydrophobic interaction decreases protein solubility as it promotes protein-protein interactions while ionic forces increase solubility by promoting protein-water interactions and repulsion between protein molecules (Wilding et al., 1984). Enzymatic hydrolysis results in a major structural change where enzyme cleavage of the protein results in smaller peptides and exposed ionizable amino and carboxyl groups of the amino acids, which increases the solubility of the protein (Kristinsson and Rasco, 2000).

In literature, solubility of wheat protein hydrolysate was reported as strongly influenced by pH with the highest level of solubility observed at pH 4.0 and lowest at pH 6.0 (Claver and Zhou, 2005). Soy protein hydrolysates were found to also be pH-dependent and almost completely soluble in the pH 2.0–9.0 range (McCarthy et al., 2013). Solubility of whey protein hydrolysates was influenced by hydrolysis time, with solubility increasing with increasing hydrolysis. This was attributed to the degradation of the protein into smaller peptide units which have more binding sites as hydrolysis continues (Sinha et al., 2007). Pacific hake (*Merluccius productus*) protein hydrolysates also showed improved solubility when compared to un-hydrolyzed fish protein (Pacheco-Aguilar et al., 2008). Generally, most native food proteins have hydrophobic amino acids in the interior of their tertiary structure. Hydrophobic interactions decrease protein solubility by promoting protein-protein interactions (Wilding et al., 1984). Enzymatic hydrolysis decreases protein molecular size which affects hydrophobicity, as well as polar and ionizable groups. The resulting hydrophilic interactions increase solubility by promoting protein-water interactions and repulsion between protein molecules (Wilding et al., 1984). Similarly, protein hydrolysates may also have increased water-holding capacity, which influences texture and integrity of food products like frozen fish fillets or meat (Cheung et al., 2009).

The amphiphilic nature of proteins allows them to act as emulsifying and foaming agents by lowering the surface tension between the phases. This requires favorable intermolecular interactions between the protein and the phases in the colloidal system (e.g. lipid, gas, aqueous, etc.). Limited enzymatic hydrolysis of proteins can release peptides containing hydrophobic groups as well as increase hydrophilic carboxylic and amino groups to contribute to its amphiphilic nature. Thus, a balance of hydrophilic and hydrophobic groups, that will support protein suspension in solution, are obligatory for good emulsifying and foaming properties (Hettiarachchy and Ziegler, 1994).

Since protein size influences functionality, hydrolysis time and protease specificity play a key role during preparation of functional protein ingredients. While the protein's size and structure are modified by hydrolysis, other characteristics of the native protein such as amino acid sequence, conformation, and hydrophilic-hydrophobic balance have a strong influence on functionality. For example, soy protein hydrolysates with larger molecular weight peptide fractions showed higher emulsification (Barca et al., 2000). Other hydrolysates from various protein sources, fish (Pacheco-Aguilar et al., 2008; Nguyen et al., 2017), wheat gluten (King et al., 2007), hemp (Yin et al., 2007), egg white (23), and chickpea (del Mar Yust et al., 2010) have shown improved emulsifying and foaming activity compared to unhydrolysed protein. Moreover, limited enzyme hydrolysis can partially denature proteins to aggregate and forms gels (Ni et al., 2015). For instance, partially hydrolyzed oat protein formed stronger gels compared to oat protein isolate under the same conditions (Nieto-Nieto et al., 2014). Similarly, soy protein hydrolysates formed a gel with better network structure than that of the intact soy protein isolate (Tsumura et al., 2005).

Since functionality depends on different protein characteristics, that may not be achievable simultaneously, enzymatic hydrolysis can be controlled in such a way that specific protein modifications may be attainable. It is important to note that depending on the type of protein, hydrolysis exceeding a certain level can result in peptides that are too small (higher degree of hydrolysis) to interact with multiple components in a food matrix. This has been proven by the consistent decline in foaming and emulsion stability of extensively hydrolyzed proteins (van der Ven et al., 2001; Guan et al., 2007). Other authors have also shown the color and aroma of protein hydrolysates to be mostly conserved and somewhat neutralized, respectively, when incorporated into a food matrix, though the flavor may be adversely affected (Mackie, 1982; Hoyle and Merritt, 1994). Hydrolysis reactions, coupled with the conditions to inactivate the enzyme and inactivation of spoilage and pathogenic organisms, can release oligopeptides with high nonpolar amino acid contents (Adler-Nissen, 1984; Gildberg et al., 2002). In an aqueous system, this is perceived as bitter-metallic flavorings, and it is dependent on factors that are intrinsic and extrinsic to the enzyme and source protein which are often collectively difficult to control (Kristinsson and Rasco, 2000). Thus, attaining the desired functionality of the

resulting hydrolysate may generate unpalatable characteristics, which can interfere with successful marketability as a value-added ingredient.

### Bioactive Properties of Protein Hydrolysates

Based on structural properties, amino acid composition and peptide sequence, protein hydrolysates have also been studied for their biological activity in human health (Hartmann and Meisel, 2007; Möller et al., 2008; Chalamaiah et al., 2012; Udenigwe and Aluko, 2012). Peptides from various sources of hydrolysates have also been indicated to have other bioactive potential such as anticancer (Yi et al., 2003; Picot et al., 2006; Kannan et al., 2009; Sheih et al., 2009b; Alemán et al., 2011; Suarez-Jimenez et al., 2012), antimicrobial (Liu et al., 2008; Di Bernardini, Harnedy et al., 2011; Chalamaiah et al., 2012; Najafian and Babji, 2012), and anticoagulant (Koyama et al., 1998; Jung et al., 2002; Rajapakse et al., 2005; Athukorala et al., 2006a; Jung and Kim, 2009) activity. **Table 1** summarizes some of the literature available on biological activities of protein hydrolysates, while a brief overview of some of the most commonly studied biological activities of protein hydrolysates is given below.

Cardiovascular disease (CVD) is the leading problem in developed countries and high blood pressure is one of the risk factors for CVD onset. Angiotensin-I converting enzyme (ACE) plays a key role in regulating blood pressure by converting inactive angiotensin-I into its active form angiotensin-II, a vasoconstrictor, resulting in high blood pressure. Several food proteins and peptides have shown potent ACE inhibitory activity, which is a major target in regulating hypertension. Milk proteins have been the most studied source of antihypertensive peptides (Udenigwe and Aluko, 2012). Casein and whey hydrolysates have been identified to have strong antihypertensive activity, by way of ACE inhibition (Miguel et al., 2009; Tavares et al., 2011; Nongonierma et al., 2016). Other potent antihypertensive peptides have been identified from protein hydrolysates of plants, nuts, seeds (Li et al., 2007; Jamdar et al., 2010; Li and Aluko, 2010; Fritz et al., 2011), egg (Miguel and Aleixandre, 2006; Majumder and Wu, 2010), fish (Lee et al., 2010; Chalamaiah et al., 2012), insects (Vercruysse et al., 2005; Vercruysse et al., 2009), and other meat proteins (Ahhmed and Muguruma, 2010).

Type II diabetes is a long term metabolic disorder which is also recognized as a major risk factor for (CVD) as there is a link between insulin resistance and high blood pressure (Mannino et al., 2008). Similarly, protein hydrolysates provide a natural therapeutic strategy for the management of type-2 diabetes. Dipeptidyl peptidase-IV (DPP-IV) protease activity degrades incretin hormone involved in blood glucose regulation (Barnett, 2006). Other modes of a diabetic regulation may include  $\alpha$ -glucosidase and  $\alpha$ -amylase inhibition. Peptides derived from protein hydrolysates contain structural characteristics that allow them to exert these antidiabetic properties (Yu et al., 2011; Lacroix and Li-Chan, 2012; Li-Chan et al., 2012; Nongonierma and FitzGerald, 2013; Zhang et al., 2016; Vilcacundo et al., 2017).

Antioxidant activity is among the most researched bioactive functions of protein hydrolysates. Numerous reports and publications have confirmed that enzymatically-derived protein hydrolysates, can serve as a natural source of antioxidants (Sarmadi and Ismail, 2010). Antioxidant peptides from protein hydrolysates contain certain amino acid residues that aid in hindering lipid-oxidation, as well as chelating oxidant metal ions. Antioxidant hydrolysates have been studied from a plethora of protein sources including fish (Dong et al., 2008; Chalamaiah et al., 2012; Malaypally et al., 2015), fish by-products (Bougatef et al., 2010; Di Bernardini et al., 2011; Ketnawa and Liceaga, 2017), corn (Kong and Xiong, 2006; Li et al., 2008a; Zhou et al., 2012), nuts/seeds/legumes (Li et al., 2008b; Jamdar et al., 2010; Girgih et al., 2011a,b; He et al., 2013a; Ambigaipalan et al., 2015; Karamać et al., 2016), egg (Park et al., 2001; Davalos et al., 2004; Sakanaka and Tachibana, 2006; You and Wu, 2011; Chen and Chi, 2012; Chen et al., 2012a,b; Shi et al., 2014), milk (Hernández-Ledesma et al., 2005; Pihlanto, 2006; Nongonierma et al., 2016), insects (Nongonierma and FitzGerald, 2017), and algae (Athukorala et al., 2006b; Sheih et al., 2009b; Samarakoon and Jeon, 2012).

### Conclusion

Protein hydrolysates have been widely used for their nutritional, functional and bioactive activities. Although hydrolysates can be obtained from chemical hydrolysis, a controlled enzymatic hydrolysis, targeting specific peptide bonds, is the preferred method. Research over the years has allowed for the study of the impact that different proteases have on the quality, functionality and bioactivity of protein hydrolysates. The superior protein quality of many hydrolysates has allowed for their application in food formulation destined for individuals with diet restrictions or those seeking a higher protein intake (e.g. athletes). The improved functionality in protein hydrolysates is dependent on the hydrolysis conditions used and the extent of hydrolysis. Protein hydrolysates have an important role in the food industry applications as emulsifying, foaming and gelling ingredients. More recently, the interest in protein hydrolysates has shifted towards their biological activities with benefits to human health.

There are, however some challenges that need to be further investigating with regards to the application of protein hydrolysates. The primary drawback for using protein hydrolysates in the food industry is the possibility of producing a bitter taste due to release of bitter hydrophobic peptides. Industry efforts have led to bitter taste masking using other flavors or using a de-bittering process such as treatment with activated carbon, extraction with alcohol isoelectric precipitation, chromatography on silica gel and hydrophobic interaction chromatography (Saha and Hayashi, 2001). In addition, although protein hydrolysates tend to have lower antigenic activity, studies have shown that in some situations, allergenicity can still be present. The use of more extensive hydrolysis or pre-hydrolysis treatment of the protein (e.g. heat, microwave and ultrasonication) as a mean for lowering the antigenicity continues to be explored.

## Omega-3 Fatty Acids

**Fereidoon Shahidi and Priyatharini Ambigaipalan**, Department of Biochemistry, Memorial University of Newfoundland, St. John's, NL, Canada

© 2019 Elsevier Inc. All rights reserved.

### Introduction

The omega-3 fatty acids (n-3) are a group of polyunsaturated fatty acids (PUFAs) with the first double bond at the third carbon from the methyl end group. Human body lacks the ability to produce PUFAs, including n-3 fatty acids, hence it is necessary to obtain adequate n-3 fatty acids from various food sources such as plants, fish and fish oils. Omega-3 fatty acids are derived from alpha-linolenic acid (ALA; 18:3 n-3), an essential fatty acid, and include stearidonic acid (SDA; 18:4 n-3), eicosapentaenoic acid (EPA; 20:5 n-3), docosapentaenoic acid (DPA; 22:5 n-3) and docosahexaenoic acid (DHA; 22:6 n-3). Several researchers have shown the beneficial effect of n-3 fatty acids on cardiovascular function, fetal development and age-related diseases (Alzheimer disease and dementia) (Finley and Shahidi, 2001; Lopez et al., 2011; Shahidi and Ambigaipalan, 2018). This contribution provides a cursory account of their chemistry, sources and health effects.

### Structure and Synthesis of Omega-3 Fatty Acids

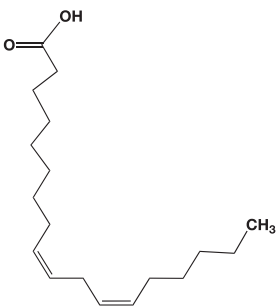

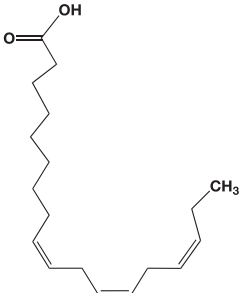

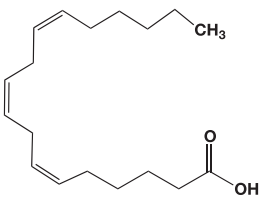

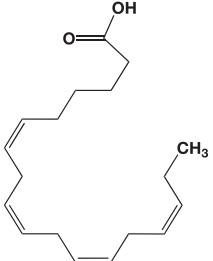

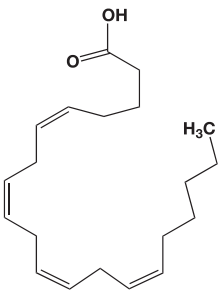

Omega-3 fatty acids are the long chain polyunsaturated fatty acids (PUFAs) with 18 to 22 carbon atoms in their chain. The term omega-3 refers that the first methylene interrupted double bond being located at the third carbon atom from the methyl end of the fatty acid chain, which include alpha-linolenic acid (ALA; *cis*-9, *cis*-12, *cis*-15-octadecatrienoic acid, 18:3<sup>Δ<sup>9,12,15</sup></sup>), stearidonic acid (SDA; *cis*-6, *cis*-9, *cis*-12, *cis*-15-octadecatetraenoic acid, 18:4<sup>Δ<sup>6,9,12,15</sup></sup>), eicosapentaenoic acid (EPA; *cis*-5, *cis*-8, *cis*-11, *cis*-14, *cis*-17-eicosapentaenoic acid, 20:5<sup>Δ<sup>5,8,11,14,17</sup></sup>), docosapentaenoic acid (DPA; *cis*-7, *cis*-10, *cis*-13, *cis*-16, *cis*-19-docosapentaenoic acid, 22:5<sup>Δ<sup>7,10,13,16,19</sup></sup>) and docosahexaenoic acid (DHA; *cis*-4, *cis*-7, *cis*-10, *cis*-13, *cis*-16, *cis*-19-docosahexaenoic acid, 22:6<sup>Δ<sup>4,7,10,13,16,19</sup></sup>). However, linoleic acid (LA; *cis*-9, *cis*-12-octadecadienoic acid, 18:2<sup>Δ<sup>9,12</sup></sup>), gamma-linolenic acid (GLA; *cis*-6, *cis*-9, *cis*-12-octadecatrienoic acid, 18:3<sup>Δ<sup>6,9,12</sup></sup>), and arachidonic acid (AA; *cis*-5, *cis*-8, *cis*-11, *cis*-14-eicosatetraenoic acid, 20:4<sup>Δ<sup>5,8,11,14</sup></sup>) are omega-6 PUFAs, where the first methylene interrupted double bond starts at the sixth carbon atom from the methyl end of the fatty acid chain. The structures of omega-3 and omega-6 polyunsaturated fatty acids are shown in Table 1. Omega-3 fatty acids generally exist in a curved form (Table 1) due to the presence of *cis* configured double bonds that result in a low melting point hence being liquid at room temperature.

The metabolic pathway of synthesis of omega-3 and omega-6 PUFAs from dietary LA and ALA is shown in Fig. 1. Dietary ALA, which is the precursor of omega 3 series could be converted into SDA, EPA, DPA and DHA using series of microsomal enzymes from endoplasmic reticulum (ER) mainly in the liver of mammals. These enzymes are desaturase and elongase, which introduces new double bonds or lengthen acyl chains, respectively. DHA synthesis involves peroxisomal β-oxidation of tetracosahexaenoic acid (24:6<sup>Δ<sup>6,9,12,15,18,21</sup></sup>) that removes 2-carbonyl acetyl-CoA. Similarly, omega 6 fatty acids, especially arachidonic acid are synthesized from dietary LA (precursor of omega-6 series) in human body. Arachidonic acid and EPA could be either metabolized to a fatty acid via elongase or produce eicosanoids that are key mediators and regulators of inflammatory responses such as prostaglandins, thromboxanes, leukotrienes, resolvins and lipoxines via cyclooxygenase (COX) and lipoxygenase (LOX). There is a competition between the omega-3 and omega-6 fatty acids for the same set of enzymes for their metabolism. Thus, the ratio of omega-6 to omega-3 plays a vital role in the human body. Wall et al. (2010) reported that the optimum ratio of omega-6 to omega-3 as being 4:1. However, the intake of omega-6 is generally 15- to 16-fold higher than that of omega-3 in the Western countries due to the higher intake of vegetable oils, hence omega-3 supplementation is required (Simopoulos, 2003). Arachidonic acid is the major substrate for eicosanoid synthesis due to its higher concentration in inflammatory cells in comparison to EPA (Calder, 2001). Omega-6 fatty acids serve as precursors for the synthesis of series-2 prostaglandins (E<sub>2</sub>) that are potent mediator of inflammation and cell proliferation while omega-3 fatty acids produce series-3 prostaglandins (E<sub>3</sub>), which are generally anti-inflammatory (Bagga et al., 2003). Tilley et al. (2001) reported that prostaglandins-E<sub>2</sub> cause pain and vasodilation via promoting the production of the pro-inflammatory cytokine interleukin-6 in macrophages, while prostaglandin-E<sub>3</sub> is less potent in producing cytokine interleukin-6. Thus, the increased ratio of omega-6 to omega-3 plays a vital role in the development of chronic diseases.

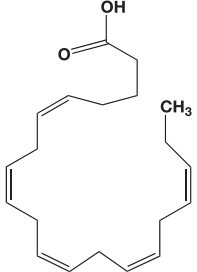

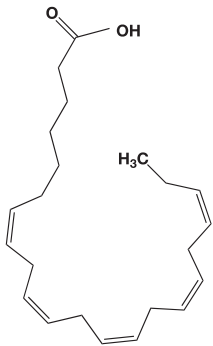

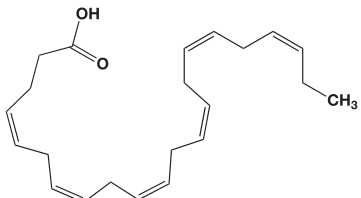

### Sources of Omega-3 Fatty Acids

Aquatic species are the major source of omega-3 fatty acids. Omega-3 fatty acids are primarily synthesized in algae and phytoplankton and transferred to fish and marine mammals via the food web. Flesh of fatty fish (mackerel, tuna, herring, sardines, menhaden and salmon), liver of lean fish (cod and halibut) and blubber of marine mammals (seals and whales) are the main sources of omega-3s, especially EPA and DHA (Shahidi, 1998). Crustaceans, bivalves and cephalopods are also good sources of omega-3s. In addition, plant seeds such as flax, chia, echium and canola as well as walnuts are good sources of ALA, which is the precursor of omega-3s in the human body (Shahidi and Ambigaipalan, 2015). Furthermore, microalgae, namely *Cryptocodinium cohnii* and

**Table 1** Structures of omega-3 and omega-6 polyunsaturated fatty acids

<i>Omega-3 fatty acid</i>	<i>Structure</i>	<i>IUPAC name</i>
Linoleic acid (LA; 18:2 <sup>Δ9,12</sup> )		<i>cis</i> -9, <i>cis</i> -12-Octadecadienoic acid
Alpha-linolenic acid (ALA, 18:3 <sup>Δ9,12,15</sup> )		<i>cis</i> -9, <i>cis</i> -12, <i>cis</i> -15-Octadecatrienoic acid
Gamma-linolenic acid (GLA, 18:3 <sup>Δ6,9,12</sup> )		<i>cis</i> -6, <i>cis</i> -9, <i>cis</i> -12-Octadecatrienoic acid
Stearidonic acid (SDA; 18:4 <sup>Δ6,9,12,15</sup> )		<i>cis</i> -6, <i>cis</i> -9, <i>cis</i> -12, <i>cis</i> -15-Octadecatetraenoic acid
Arachidonic acid (AA; 20:4 <sup>Δ5,8,11,14</sup> )		<i>cis</i> -5, <i>cis</i> -8, <i>cis</i> -11, <i>cis</i> -14-Eicosatetraenoic acid

**Table 1** Structures of omega-3 and omega-6 polyunsaturated fatty acids—cont'd

<i>Omega-3 fatty acid</i>	<i>Structure</i>	<i>IUPAC name</i>
Eicosapentaenoic acid (EPA; 20:5 $\Delta^{5,8,11,14,17}$ )		<i>cis-5, cis-8, cis-11, cis-14, cis-17-eicosapentaenoic acid</i>
Docosapentaenoic acid (DPA; 22:5 $\Delta^{7,10,13,16,19}$ )		<i>cis-7, cis-10, cis-13, cis-16, cis-19-Docosapentaenoic acid</i>
Docosahexaenoic acid (DHA; 22:6 $\Delta^{4,7,10,13,16,19}$ )		<i>cis-4, cis-7, cis-10, cis-13, cis-16, cis-19-Docosahexaenoic acid</i>

*Schizochytrium* spp. are the two major algal sources of DHA at levels of 55% and 40%, respectively (Senanayake and Fichtali, 2006). Another omega-3 fatty acid SDA, has been found in seeds from *Boraginaceae* family, such as borage, *Echium* (Viper's bugloss), and *Buglossoides* (Corn gromwell), and hemp oil. Guil-Guerrero (2007) reported that dietary supplementation of SDA could increase the EPA level to a higher degree than ALA supplementation, hence its recent attraction to researchers. Some novel approaches such as genetic modification (soy modified with omega-3) and synthesis of structured lipids (incorporation of borage oil and evening primrose oil) have also been used to enhance the level of omega-3s in various plant sources (Senanayake and Shahidi, 2002; Hamam and Shahidi, 2006; Shahidi and Zhong, 2015). Safflower, sunflower, corn and soybean oil are the primary sources of omega-6 fatty acids, especially linoleic acid (Shahidi and Miraliakbari, 2004; 2005). Evening primrose is a good source of gamma-linolenic acid. Dietary sources of omega-3 and omega-6 PUFAs are shown in Table 2.

## Health Benefits

Bang et al. (1980) reported that traditional Greenlandic diet (rich in marine mammals and fish) significantly retarded the incidence of cardiovascular disease in the Inuit population and Danish settlers based on the earliest reports and epidemiological studies that is known as "Eskimo Paradox". Omega-3 PUFAs, especially EPA and DHA, play a beneficial role against cardiovascular disease and inflammation. A recent review suggests that the death rate was perhaps higher for Eskimos from myocardial infarction than the Danes based on book keeping (Fodor et al., 2014). However, this short-sighted approach and misconception that ignored different genetic background and lifestyle was criticized by Shahidi (2015). American Heart Association recommends intake of 1 g of omega-3 per day to lower the triacylglycerol levels and to prevent arrhythmias and atherosclerosis. Many clinical studies have shown that the omega-3 PUFAs could be beneficial to cardiovascular disease by preventing sudden cardiac death as well as heart failure outcomes (Burr et al., 1989; Hu et al., 2002; Harris et al., 2007; Tavazzi et al., 2008; Mozaffarian and Wu, 2011; Mozaffarian et al., 2013; Macchia et al., 2013; O'Connell et al., 2016; Siscovick et al., 2017; Shahidi and Ambigaipalan, 2018).

Oil	5.899	—	—	—	5.899	15.330

Modified from Canadian Nutrient File (2016).

The cardiovascular effects of omega-3 PUFAs are attributed to their ability to compete with arachidonic acid for cyclooxygenase enzyme that generates prostaglandins and thromboxane (Shahidi and Miraliakbari, 2006). DeFilippis et al. (2010) suggested serving of fish oil (900 mg of EPA + DHA/day) and ALA rich diet for cardiovascular and congestive heart failure patients because of their beneficial health effect. A review summarizing all epidemiological and clinical studies from the period of 1957 to 2013 established a clear link among diet, atherosclerosis, and cardiovascular events (Dalen and Devries, 2014). These authors suggested that the Mediterranean-style diet consisting of vegetables, fruit, fish, whole grains, and olive oil, reduces cardiovascular events to a greater extent than that of low-fat diets (Dalen and Devries, 2014).

High consumption of omega-3 PUFA rich diet for 8 weeks has been shown to increase insulin sensitivity and decrease serum C-reactive protein in older individuals (Tsitouras et al., 2008). However, there is limited clinical evidence available for the effect of omega-3s on type 2 diabetes mellitus. Anti-carcinogenic effect of omega-3s has also been studied; however, omega-6 and saturated fatty acids have been shown to promote cancer development. Prener et al. (1996) reported that the rate of prostate cancer incidents among Inuit population was less (70%–80%) than that of non-Inuit population due to their intake of omega-3 rich seafood diet. It has been suggested that omega-3 PUFAs could inhibit the growth of tumour cells by decreasing cyclooxygenase COX-2 and prostaglandins PGE<sub>2</sub> levels, thus could serve as a natural cyclooxygenase (COX) inhibitor (Kobayashi et al., 2006). Increased consumption of omega-6 fatty acids has been shown to be associated with breast, prostate and colon cancers due to the lipid peroxidation, generation of carcinogen after 17-beta-estradiol (E2) epoxidation and acting as co-carcinogen by enhancing the genotoxic effect of other compounds (chromatin) (Yu et al., 2004; Sakai et al., 2012).

DHA is a known primary element of membrane phospholipids in the brain (cerebral cortex, mitochondria, synaptosomes and synaptic vesicles) (Connor, 2000). Hence, consumption of omega-3 PUFAs is associated with decreased risk of cognitive decline or dementia, especially for Alzheimer disease and depression (Cole et al., 2009). Dijk-Brouwer et al. (2005) reported that lower fetal DHA, AA and essential fatty acid levels negatively influence neurological condition of early postnatal. Mathai et al. (2004) suggested that early neonatal deficiency in omega-3s is associated with the risk of developing Huntington's disease, Schizophrenia, high blood pressure and increased appetite signaling during adult life. In addition, Newberry et al. (2016) reported that intake of omega-3 PUFAs is associated with the length of gestation, preterm birth, birth weight, peripartum depression, gestational hypertension/preeclampsia, postnatal growth patterns, visual acuity, neurological development, cognitive development, autism spectrum disorder (ASD), attention deficit hyperactivity disorder (ADHD), learning disorders, atopic dermatitis (AD), allergies and respiratory disorders. However, there is still insufficient evidence for several potential health effects of omega-3's, hence more clinical trials are required to shed light on these aspects.

## Summary

The intake of omega-3 PUFAs is associated with various health benefits such as cardiovascular health, cancer, cognitive and neurological function. However, there are insufficient clinical trials to allow making solid statements in some cases. Thus, more studies, including clinical trials are needed in the future on certain aspects that have not yet been fully explored.

### Glossary

**Bioactive compounds** Bioactive compounds are chemical compounds found in small amounts in foods such as fruits, vegetables, nuts, whole grains, oils etc, that have an impact on physiological functions in the human body. In the nutrition field, bioactive compounds are separately studied from the macro and micro nutrients.

**Agricultural waste** Waste material produced due to various agricultural and farming operations. These wastes can be generated at any step of the agricultural operations.

**By-products** An incidental or intentional secondary product generated in the production or processing of a primary product of interest.

**Dietary fibre** Dietary fibre is a type of carbohydrate that the human body can not digest through gastrointestinal enzymes. It can be classified into soluble, insoluble or resistant starch depending on their physicochemical properties.

**Bioactive peptides** Bioactive peptides are the specific protein fragments with several amino acids resulting from physical, chemical or enzymatic protein hydrolysis that have a positive impact on physiological functions or conditions leading to improved health.

**Phytochemicals** Phytochemicals are biologically active chemical compounds found in plants, mainly their secondary plant metabolites used by the plants to compete and thrive within their environment.

### Overview

Agriculture and food processing industries generate several billions of metric tons of by-product biomass worldwide (Santana-Méridas et al., 2012; Kumar et al., 2017a). These by-products and waste streams can be generated in every phase of their lifecycle including agricultural production, industrial manufacturing, processing and distribution at different levels (Kumar et al., 2017a). According to the physicochemical and biochemical nature of the agricultural processing waste and by-products, it can be broadly classified into animal-derived materials and plant-derived materials (Ravindran and Jaiswal, 2016). Agricultural processing waste and by-products are considered to be one of the cheapest and abundantly available sources of biomass (Singh nee Nigam, 2009). However, proper techniques are essential in managing agricultural wastes and by-products to avoid potential environmental pollution (Liang et al., 2011). Therefore, it is essential to develop improved methods to enhance the use of agricultural residues. Several value-added applications have been explored recently ranging from animal feeding, fertilizers, platform chemicals and extraction of bioactive compounds, etc (Schieber et al., 2001; Kumar et al., 2017a).

Bioactive compounds have gained tremendous research and industrial interest in the recent past due to their ability in prevention and management of human chronic diseases (Joana Gil-Chávez et al., 2013). The growing trend in developing novel functional food and nutraceutical products have reinvigorated the search of alternative sources for extracting bioactive compounds, rather than relying on traditional food materials. In this context, academia and industry are looking into the possibility of using agricultural and food industry by-products as a source of bioactive compounds, mainly due to the abundant availability, low price and the absence of competing interest with food production (Joana Gil-Chávez et al., 2013; Ravindran and Jaiswal, 2016). Several agricultural by-product sources including meat processing, marine food processing, fruit processing wastes such as grape, apple pomace, citrus fruits, and vegetable and potato processing wastes such as tomato, carrot, olives and onions have been extensively studied for extracting different forms of bioactive compounds, among others (Schieber et al., 2001; Naumovski et al., 2017).

### Bioactive Compounds From Animal Derived By-products

Livestock processing industries generally produce byproduct streams such as skin, hide, blood, horns, wools, hoofs, offal, mechanically separated meat residue and feathers (Lafarga and Hayes, 2014; Suleria et al., 2016). In addition to the regular livestock processing by-products, marine processing industry by-products have gained increased attention, mainly due to the presence of broad spectrum bioactive compounds in abundant levels (Suleria et al., 2016). Researchers and industry have made continuous efforts to develop value-added applications for these by-products, where major efforts were made on identifying, extracting and purifying bioactive compounds with specific benefits (Mullen et al., 2017).

## Meat Processing By-products

The increased global demand for high quality, high value meat and poultry products has increased the production of low value, non-edible meat products such as offal, blood, skins, horns, and feathers, almost up to 54%–56% on total animal weight for bovine meat and up to 48% for porcine (Marti et al., 2012; Mullen et al., 2017). These by-products are rich in nutrients such as proteins, lipids, minerals and certain bioactive molecules; however, the food value has been limited due to the flavour, texture, and socio-logical barriers (Mora et al., 2014; Toldrá et al., 2016). Therefore, extraction of individual components for specific uses can become a useful methodology for value-added applications in meat industry by-products. The major research focus on extracting bioactives from meat industry by-products were targeted towards extraction of protein hydrolysate, collagen, and developing bioactive peptides with different functionalities (Ravindran and Jaiswal, 2016; Hong et al., 2018).

### Collagen/Gelatin

Collagen and collagen peptides are one of the primary bioactive compounds of focus from meat industry by-products (Fu et al., 2018). Collagen is a triple helical fibrous structural protein present in most parts of the animal body. However, extraction and purification process of collagen will hydrolyse the triple helical structure and produce gelatin (Mullen et al., 2017; Fu et al., 2018). Even though skins and bones have been used as primary source of collagen/gelatin extraction in the past (Mullen et al., 2017), recent studies focus on using other underutilized by-products such as meat & poultry processing waste (Khiari et al., 2014), spent hen (Hong et al., 2017, 2018) and mechanically separated meat residue (Du et al., 2014). Moreover, the recent research on collagen/gelatin has been mainly focused on extracting functional bioactive peptides using novel processing and purification methods (Khiari et al., 2014; Hong et al., 2017, 2018).

### Bioactive Peptides and Protein Hydrolysate

Bioactive peptides are short fragments of proteins with 2 to 30 amino acid residues and display several health promoting bioactivities in addition to their nutritional value (Ryan et al., 2011; Mullen et al., 2017). All meat by-products are rich in protein; therefore, traditionally proteins were extracted from the by-products and then subsequently hydrolysed to release small peptide fragments with different bioactivities (Lemes et al., 2016). Compared to the other protein rich by-products, research on meat by-product based bioactive peptides are limited to few specific types of by-products; however, peptides with different bioactivities such as antioxidant, antimicrobial, antihypertensive, anti-diabetic, anti-hypercholesterolaemic or mineral binding have been reported with different meat products (Sharma et al., 2011). Meat trimmings and cuttings are one of the meat by-products explored for bioactive preparation. Angiotensin converting enzyme (ACE)-inhibitory peptides MNPPK and ITNP from porcine skeletal muscle hydrolysate (Arihara et al., 2001), antioxidant peptide DAQEKLE from pork myofibrillar protein (Saiga et al., 2003), and anti-fatigue peptides DLYA, SLYA and VW (Arihara, 2006) are some of the bioactive peptides extracted from meat trimming and cuttings. Animal bones, horns, and hooves resulting from meat processing are mainly used in animal feeding; however, recent studies have extracted antioxidant peptides QYDQGV, YEDCTDCGN, AADNNELFPPN from these by-products (Liu et al., 2010). Animal blood and their hydrolysates were also used in preparing bioactive peptides such as GFPTTKTYFPHF, KLLSHSL, and LVVYPWT etc, with ACE-inhibitory, antioxidant and opioid activity (Yu et al., 2006; Adje et al., 2011). Most recent studies have focused on using non-conventional livestock industry by-products such as spent hen in bioactive peptide preparation (Hong et al., 2017, 2018; Yu et al., 2018), specifically with immunomodulatory, antihypertensive (Udenigwe et al., 2017) and anti-inflammatory activities (Chalamaiah et al., 2018; Yu et al., 2018).

## Marine Processing Waste/By-products

Marine capture fisheries account for more than 50% of total world fish production. Marine fish processing industry generates a great quantity of by-products as waste every year. These by-products include head, skin, blood, trimmings, fins, frames, roes and viscera (Rustad et al., 2011; Chalamaiah et al., 2012; Sila and Bougatef, 2016). Additionally, crustaceans and shellfish processing also produce considerable quantity of shells as by-products. About 20 million tons of marine processing by-products are discarded as waste every year, which accounts for 25% of the total annual marine capture (Hou et al., 2016). Currently, marine processing by-products are majorly utilized for the production of fishmeal, marine oil, pet food, fertilizer, and fish silage, which have low market value (Rustad et al., 2011). Recently, several bioactive compounds have been identified and isolated from marine processing by-products for human use. Proteins, lipids, chitin and minerals are the major sources of bioactive compounds from marine processing by-products (Kim and Mendis, 2006).

### Fish Oil

Marine processing by-products are an excellent source of high quality fish oil that can be used for human consumption (Rustad et al., 2011). Fish oil is the major product produced from leftovers of fatty fish processing. Fish contains fat in the range of 2%–30%, which depends on the species, age and seasonal changes. Several methods are currently used to extract the fish oil from fish processing by-products. Fish oil is conventionally produced by cooking and pressing followed by centrifugation. Recently, proteolytic hydrolysis of fish by-products has been applied to extract the fish oil with high yield and better quality (Liaset et al., 2003; Rustad et al., 2011). The major fatty acids of fish oil are omega-3 fatty acids such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Omega-3 fatty acids are essential nutrients for good health and several studies have showed that

consumption of fish oil (EPA and DHA) twice a week is linked with a lowered risk of developing cardiovascular disorders. Fish oil has been proved to lower blood pressure, reduce triglycerides, decrease chance of abnormal heart rhythm, reduce the progress of plaque in the arteries and lower the chances of heart attack and stroke (Kromhout et al., 2012).

### **Fish Collagen and Gelatine**

Fish skins, scales and bones contribute to ~30% of total by-products from fish-processing industry. Fish skins, scales and bones are good sources to separate collagen and gelatin. Collagen is a most abundant and fibrous structural protein composed of three chains forming a tight triple helix (Shoulders and Raines, 2009). Gelatin is produced by partial hydrolysis of collagen. Heat treatment or treatment with dilute solutions of acid or alkali transforms collagen into gelatin. Marine collagen from fish skin, scales and bones is widely used in biomedical and pharmaceutical industries as a scaffold and a drug carrier due to its bioactive properties such as non-antigenic, biodegradable, bioreabsorbable, non-toxic and biocompatible, compatible with synthetic polymers, synergic with bioactive components, and cell growth potential (Lee et al., 2001; Jeevithan et al., 2013; Subhan et al., 2015). Several clinical studies reported that consumption of collagen hydrolysate reduces the pain in osteoarthritis patients (Bello and Oesser, 2006). Peptides prepared from gelatin have been shown to contain antioxidant, ACE-inhibitory, immunomodulatory and antiproliferative effects (Kim and Mendis, 2006; Chalamaiah et al., 2012; Chalamaiah et al., 2018).

### **Bioactive Peptides**

Marine processing industry generates large quantities of proteins as by-products. Recently, several attempts have been made to produce bioactive peptides from marine wastes. Marine processing by-products such as viscera, heads, skin, bones, dark muscle, scales, frames, cephalothorax, cut offs, and shells from various species successfully used to produce peptides with variety of bioactivities (Sila and Bougatef, 2016). Bioactive peptides are generally obtained from marine processing wastes by using proteolytic hydrolysis or fermentation. Pepsin, chymotrypsin, trypsin, Alcalase, Flavozyme, Protamex and papain are routinely employed enzymes for the generation of bioactive peptides from marine waste proteins. Marine by-product derived peptides showed various bioactivities such as antioxidant, anticancer, ACE-inhibitory, antimicrobial, immunomodulatory, hypocholesteremi, anti-diabetic and mineral binding activities (Harnedy and FitzGerald, 2012). Bioactive peptides from marine processing by-products can be used in food and pharmaceutical applications.

### **Chitin and Chitosan**

Crustacean shells and shellfish wastes are an important group of by-products from marine processing industry. The main component of these wastes is chitin, a bioactive and abundant polysaccharide, after cellulose. By-products from shrimp, lobster, krill and crab processing plants contain large quantities of chitin. The amount of chitin in exoskeleton wastes varies from 20%–30% depending on the species and seasons. The chitin by-product from shellfish waste accounts for about 10,000 tons per year (Hamed et al., 2016). Chitin is a linear polymer of N-acetyl-D glucosamine units. Removal of some acetyl groups from chitin results in the formation of its derivative, chitosan (water soluble form). Demineralization and deproteinization are commonly used processes to obtain chitin from exoskeletons of crustaceans. Chitin and chitosan have been widely used in biomedical and pharmaceutical industries for drug release and wound dressing due to its biocompatible and biodegradable properties in the body (Younes and Rinaudo, 2015). In food industry, they are used as edible films for food preservation. Chitin and chitosan showed various bioactivities such as antioxidant, anti-microbial, anti-cancer, and anti-coagulant activities (Vongchan et al., 2003; Yen et al., 2008; Goy et al., 2009; Salah et al., 2013; Hamed et al., 2016).

### **Minerals**

Bone by-products from marine processing industry are important source of minerals. Calcium is major mineral in the fish bones and accounts for about 60% of the total minerals of the fish bones (Rustad et al., 2011). Calcium from bone by-products of Atlantic salmon and Atlantic cod was reported to be well absorbed in healthy men and can be used as natural Ca source for preparation of functional foods or as supplements (Malde et al., 2010). Calcium from fish bones should be modified into an edible form by using hot water and hot acetic acid treatments before its application in food fortification (Kim and Mendis, 2006). In addition to calcium, fish bone by-products are also considerable sources of the inorganic constituent, hydroxyapatite ( $\text{Ca}_5(\text{PO}_4)_3\text{OH}$ ). Hydrothermal alkaline hydrolysis and high temperature (~1300 °C) treatments are commonly used methods to isolate hydroxyapatite from fish bones (Ferraro et al., 2010). Hydroxyapatite from fish bones is most suitable for bone reconstruction or substitution due to its biocompatibility with human bones.

## **Bioactives From Plant-Derived By-products**

Plant-based agricultural by-products have been considered as one of the major source for extracting different bioactive compounds over the past few decades. In reality, fruits and vegetables can be considered as the most simple forms of functional food due to their composition enriched with different bioactive compounds (Kumar et al., 2017a). Therefore, the by-products generated from fruit and vegetable processing industries provide a great potential for extracting and developing different bioactive molecules. Different groups of phenolic compounds, carotenoid & other vitamins, bioactive polysaccharides, lignin, tannin and dietary fibres are some of the examples of potential bioactive compounds (Kumar et al., 2017a). In addition to the traditional fruit and vegetable

processing industries, the wine and brewing industries generate by-products such as grape pomace and brewers spent grains respectively, that are enriched with a wide array of bioactive compounds (Barba et al., 2016). Cereal and oilseed processing is another important agricultural operation that produces a variety of by-products such as protein meals, bran, and husk which can potentially use in extracting bioactive compounds (Ravindran and Jaiswal, 2016). Table 1 summarizes some of the key plant based agricultural by-products and their major bioactive compounds.

### Fruit, Vegetable and Wine Processing By-products

Most of the recent research works on fruit, vegetable and wine industry by-products were focused at extracting valuable phytochemicals (e.g. sterols, tocopherols, carotenes, terpenes, & other polyphenolic compounds), bioactive polysaccharide & dietary fibre, industrial enzymes and bioactive proteins and peptides (Schieber et al., 2001; Ravindran and Jaiswal, 2016; Kumar et al., 2017a). Table 1 shows some of the major phenolic compounds present in the fruit and vegetable by-products.

#### Phenolic Compounds

Phenolic compounds and other secondary plant metabolites are the major class of bioactive compounds studied and used in research or commercial level applications. Phenolic compounds extracted from plant-based by-products have been studied for their capacity to scavenge free radicals in both food systems and *in-vivo* models (Deng et al., 2012; Banerjee et al., 2017). Therefore, majority of the plant-based phenolic compound research were focused on finding their antioxidant activity in *in-vitro*, *in-vivo* and in animal models (Banerjee et al., 2017). Anticancer and anti-proliferative activities of phenolic compounds are another area of research interest. Terpenoids isolated from apple peel (He and Liu, 2007) and sea buckthorn (sea berry) fruit phenolics (Olas et al., 2018) have shown both antiproliferative and anticancer activity in *in-vivo* studies. Antihypertensive activity of plant based phenolic compounds is another promising area of research in food and nutritional science. Several plant phenolics extracted from fruits such as blueberries (Ahrén et al., 2015) and guava fruit (Ademiluyi et al., 2016) have shown antihypertensive activity *in-vivo*. Some of the bioactive phenolics extracted from plant based agricultural by-products have reached up to the commercialization stage. Resveratrol extracted from wine industry by-product grape pomace and olive oil processing waste is a prime example of commercialized phenolics from agricultural processing by-products in recent history (Banerjee et al., 2017).

#### Bioactive Polysaccharides

The recent research interest on fruit & vegetable processing by-products as a lignocellulosic biomass has directed the efforts to extract bioactive polysaccharides (Liu et al., 2015; Banerjee et al., 2017). Cellulose extracted from fruit & vegetable industry by-products and their derivatives showed potential uses in diagnostic, pharmaceutical and nutraceuticals applications such as sugar lowering effect, antibody immobilization, hydrogel forming ability, and water retention (Credou and Berthelot, 2014; Liu et al., 2015). Hemicellulose extracted from fruits and vegetable by-products have been used to extract xylans and their derivatives such as xylooligosaccharides with dietary fibre applications (Aachary and Prapulla, 2011). In addition, mango kernels and banana peels have been used in producing resistant starches (Banerjee et al., 2017).

#### Bioactive Proteins and Peptides

Fruit and vegetable seeds are rich in protein; therefore, they can be used in preparing protein hydrolysates with functional and bioactive applications. Several fruit and vegetable seeds such as date (*Phoenix dactylifera*), chilli pepper (*Capsicum annum*), and passion fruit (*Passiflora edulis*) have been explored in preparing peptides and or protein hydrolysate with antioxidant, antimicrobial, anti-fungal, and ACE-inhibitory activities (Pelegri et al., 2006; Ribeiro et al., 2007; Ambigaipalan and Al-Khalifa, 2015; Ambigaipalan and Shahidi, 2015). The presence of aromatic amino acids and histidine also contribute towards some of the bioactivities such as quenching metal ions and reactive oxygen species (Deng et al., 2012). Extraction of vicilin-like protein from watermelon seeds (Wani et al., 2008), and leptin from jackfruit seeds (Devalaraja et al., 2011) are some of the other examples of potential bioactives that can originate from fruit and vegetable seeds.

#### Bioactive Lipids

Both fruit and vegetable processing wastes are rich sources of lipids and their derivatives, mainly in the form of free fatty acids, waxes, isoprenoid hydrocarbons, acylglycerols, sterols and vitamins exhibiting different bioactivities (Banerjee et al., 2017). Citrus fruit peels, mango kernels, apricot seeds, pomegranate seeds, and tomato seeds are some of the plant-based by-products that are rich in lipids and their derivatives (Lisichkov et al., 2011; Banerjee et al., 2017). Especially, pomegranate seed oil has shown antioxidant, anti-obesity, anti-asthmatic and inhibition of breast cancer cell proliferation due to the presence of a conjugated omega-5-fatty acid "punicic acid" (Grossmann et al., 2010; Goula and Adamopoulos, 2012; Patterson et al., 2012; Goula, 2013). Lipids extracted from mango kernels (mango butter) has shown emollient and anti-aging properties; thus can be used in skin healing cosmetic applications (Mandawgade and Patravale, 2008).

**Table 1** Bioactive components present in different plant-based agricultural and food industry by-products

Source	Residue	Bioactive components	References
<b>Fruits</b>			
Apple	Peel and pomace	Epicatechins, catechins, anthocyanins, quercetin glycoside, chlorogenic acid, hydroxycinnamates, procyanidins	Lu and Foo, 1997; Yeap Foo and Lu, 1999; Wolfe and Liu, 2003
Avocado	Peel and seed	Epicatechins, catechins, gallic acid, chlorogenic acid, cyanidin 3-glucoside, homogentisic acid	Deng et al., 2012
Banana	Peel	Gallocatechin, anthocyanins, delphinidin, cyaniding, catecholamine	Kanazawa and Sakakibara, 2000; Someya et al., 2002; González-Montelongo et al., 2010
Citrus fruits	Peel	Hesperidin, naringin, eriocitrin, narirutin	Coll et al., 1998
Grapes & grape pomace	Seed and skin	Coumaric acid, caffeic acid, ferulic acid, chlorogenic acid, cinnamic acid, neochlorogenic acid, <i>p</i> -hydroxy-benzoic acid, vanillic acid, gallic acid, proanthocyanidins, quercetin, resveratrol	Shrikhande, 2000; Negro et al., 2003
Guava	Skin and seeds	Catechins, gallic acid, cyanidin 3-glucoside, galangin, homogentisic acid, kaempferol	Deng et al., 2012
Litchi	Pericarp, seeds	Cyanidin 3-glucoside, cyanidin 3-rutinoside, malvidin-3-glucoside, gallic acid, epicatechin-3-gallate	Lee and Wicker, 1991; Duan et al., 2007
Mango	Kernel	Gallic acid, ellagic acid, gallates, gallotannins, condensed tannins	Arogba, 2000; Puravankara et al., 2000
Palm	By-product of palm milling	Tocopherols, tocotrienols, sterols, phenolic antioxidants	Choo et al., 1996; Tan et al., 2007
Pomegranate	Peel and pericarp	Gallic acid, cyanidin-3,5-diglucoside, cyanidin-3-diglucoside, delphinidin-3,5-diglucoside	Gil et al., 2000; Noda et al., 2002
<b>Vegetables</b>			
Carrot	Peel	Phenolic compounds, beta-carotene	Chantaro et al., 2008
Cucumber	Peel	Chlorophyll, pheophytin, phellandrene, caryophyllene	Zeyada et al., 2008
Potato	Peel	Gallic acid, caffeic acid, vanillic acid	Zeyada et al., 2008
Tomato	Skin and pomace	Carotenoids	Strati and Oreopoulou, 2011
<b>Cereals &amp; Oilseeds</b>			
Barley	Bran & brewers spent grain	$\beta$ -glucan	Sainvitu et al., 2012
Rice	Bran	$\gamma$ -oryzanol, rice bran oil	Oliveira et al., 2012; Perretti et al., 2003
Wheat	Bran and germs	Phenolic acid, antioxidants	Wang et al., 2008
Canola	Canola meal	Bioactive proteins and peptides, phenolic compounds	Yoshie-Stark et al., 2006; Chandrasekara et al., 2016
Soybean	Soy meal	Bioactive proteins and peptides, flavonoids, phenolics	Singh et al., 2014

## Cereal, Oilseed Processing and Brewing Industry By-products

The cereal and oilseed industry generates great deal of by-products, mainly in the form of oilseed meal (soy meal, canola meal, sunflower meal etc.), bran and germ, and brewers spent grain resulting from brewing industries (Naumovski et al., 2017; Vanamala et al., 2017). Cereal grains and oilseeds in general are rich in phenolics, protein and lipids with different biological activities. Especially, processing operations can enrich the composition of these bioactive compounds due to removal of one or more high value components; thus, making them a valuable source for bioactive compounds extraction.

### Bioactive Proteins and Peptides

Cereal and oilseed industry by-products have become one of the primary sources of bioactive proteins and peptides in the past few decades (Maestri et al., 2016). Soy protein is one of the key substrates for developing hydrolysate and peptides with a wide array of bioactivities including antioxidant, ACE inhibition, hypocholesterolemic, anti-cancer, anti-obesity, and immunomodulatory activities (Singh et al., 2014; Maestri et al., 2016). Canola protein is the major by-product generated from canola oil processing and gained increased attention recently in value-added utilization (Aider and Barbana, 2011). ACE-inhibitory activity, antioxidant activity, anti-thrombotic activity, and bile acid binding are some of the bioactivities reported for peptides extracted from canola proteins (Aider and Barbana, 2011). Hemp seed meal (Girgih et al., 2014), sunflower seed meal (Zhao et al., 2017), and camelina meal (Kumar et al., 2017b) are the emerging minor oil seed meals with high protein contents that can be used in extracting bioactive peptides. The extraction of bioactive peptides from cereal proteins are mainly done with the extracted protein from cereal grains rather than their by-products, except in the case of brewers spent grain (BSG). BSG resulting from brewing industry are rich in fibre and protein (70% and 20% respectively) (Guido and Moreira, 2017), and has been used for developing ACE-inhibitory peptides (Connolly et al., 2015), glycaemic response modulating peptides (Connolly et al., 2017), immunomodulatory peptides (Crowley et al., 2015), antioxidant peptides (Vieira et al., 2016), etc.

### Bioactive Lipids

Bioactive lipids are another class of active compounds present in the cereal and oilseed industry by-products. Rice bran oil is a prime example of bioactive lipid generated in the rice processing industry with a wide array of bioactivities (Khoei and Chekin, 2016). Rice bran oil especially contain  $\gamma$ -oryzanol which has shown biological activities in serum cholesterol lowering, anti-oxidation, anti-carcinogenic and attenuating allergic inflammations (Nagasaka et al., 2011; Khoei and Chekin, 2016).

### Dietary Fibre

Cereal processing by-products such as bran and BSG are rich in fibre content, that can be used for extraction of biologically active materials such as dietary fibre (Gangopadhyay et al., 2015).  $\beta$ -glucan is one of the key form of dietary fibre extracted from both oat and barley bran and BSG due to their superior bioactivities in reducing serum cholesterol level, reducing blood glucose level and potential antihypertensive effect (Gnai et al., 2012; Gangopadhyay et al., 2015). In addition,  $\beta$ -glucan has shown positive effects on body weight management (Koh-Banerjee et al., 2004).

## Conclusions

There is a growing demand and interest on bioactive compounds for human health applications due to their potential effects on reducing and managing chronic disease conditions. In this context, exploring new sources for extraction of bioactives hold a special interest among the scientific community. Agricultural by-products and waste materials are a valuable biomass that contains a wide array of biologically active materials at different concentrations. Extraction of these bioactives from by-product biomass can provide benefits to both agricultural and nutraceutical industries. However, the bioactive materials present in by-product biomass may possess their own challenges due to structural and functional changes that can occur during various steps of processing. Therefore, further research should be carried out to explore non-traditional agricultural by-products for bioactive extraction, developing new extraction techniques for customized applications in by-product biomass. In addition, a detailed comparative study on the biological activity of bioactives extracted from agricultural by-products Vs bioactives extracted from traditional (native materials) feedstock should be carried out to assess the value of agricultural by-product based bioactives.

# Bioactives From Land-Based Animal Processing By-Products

Yu Fu and René Lametsch, University of Copenhagen, Frederiksberg, Denmark

© 2019 Elsevier Inc. All rights reserved.

## Introduction

The slaughter of livestock animals generates considerable amounts of by-products each year. According to Regulation EC 1069/2009, animal by-products are defined as materials of animal origin that people do not consume in a direct way (Lafarga and Hayes, 2014; Toldrá et al., 2012). In the European Union, it is estimated that over 20 million tons of animal by-products are produced annually (Henchion et al., 2016). These by-products are mainly composed of blood, meat trimmings, offal and bone/skin (Toldrá et al., 2016); however, they are normally used for production of low-value products, such as animal feed, fertilizers and pet food (Alao et al., 2017). Animal by-products are abundant in proteins, essential amino acids, minerals and vitamins, which can provide a great valorization opportunity for meat processing industry (Toldrá et al., 2016). Therefore, utilization of animal by-products for production of high value-added ingredients not only diminishes environmental impact but also provides new food ingredients and improves the potential revenue for food industry (Henchion et al., 2016). For instance, animal by-products rich in high-quality protein can serve as starting materials for generation of protein hydrolysates/peptides with relevant functional properties or bioactivities (Mora et al., 2014; Toldrá et al., 2016). Bioactives cover a wide range of compounds, including peptides, oligosaccharides, fatty acids and enzymes (Lafarga and Hayes, 2014; Mora et al., 2014). Bioactive peptides are defined as short peptides with approximately 2–20 amino acids that can exert health-promoting effects on humans. They are inactive when present within the primary sequence of the parent protein but exert beneficial effects on body systems once they are released (Udenigwe and Aluko, 2012). In recent years, there is an increasing interest in exploration of bioactive peptides/hydrolysates from animal by-products (Mora et al., 2014; Toldrá et al., 2012, 2016). Therefore, this chapter aims at providing some updated information on the composition and nutritional characteristics of animal by-products and bioactive peptides/hydrolysates recovered from these by-products.

## Composition and Nutritional Characteristics of Animal Processing By-Products

Blood is a major by-product representing approximately 4% of live animal weight (Bah et al., 2013). Currently, blood generated in slaughterhouses are under-utilized because they are processed mainly for use as animal feed and fertilizer (Bah et al., 2016; Mora et al., 2014). Blood is normally separated into two fractions during the slaughter process, namely blood cells and plasma (Lynch et al., 2017). The blood cell fraction contains red and white blood cells and platelets, while plasma includes several proteins such as albumins, globulins and fibrinogen (Bah et al., 2013; Lynch et al., 2017). Red blood cells represent the most abundant cells, containing hemoglobin, an iron-containing protein that can facilitate binding of oxygen to increase solubility and transportation (Bah et al., 2016; Lafarga and Hayes, 2014). Heme iron is more easily absorbed from meat into the body, compared with non-heme iron (Buzala et al., 2016). In addition, heme has been applied as a natural color enhancer for meat products in the food industry (Ofori and Hsieh, 2012). Plasma, on the other hand, mainly contains serum albumins, globulins and fibrinogen, among which albumins are the most abundant proteins responsible for regulation of fluid distribution, osmotic pressure and transport of small metabolites in animals (Lafarga and Hayes, 2014; Ofori and Hsieh, 2012).

Trimming is defined as the remaining portions of meat after chopping of primal cuts from the animal carcass and contain meat, fat, cartilages and mechanically recovered meat (Mora et al., 2014). However, portions of head meat, internal organs, major tendons, or ligaments are not considered trimmings (Mora et al., 2014; Toldrá et al., 2016). The protein content in meat trimmings may vary from 14% to 17% in pork and from 7% to 12% in beef (Mora et al., 2014).

Slaughtering offal is described as the entrails and internal organs of the slaughtered animal excluding muscle and bone (Pereira and Vicente, 2013). Offal can be further divided into two categories, namely red and white offal. Red offal (e.g. heart, liver and lung) are normally employed in many processed meat products or serve as food ingredients in sausages, while edible white offal, such as intestines and stomach, requires further processing (Florek et al., 2012). The average protein content in offal ranges from 15% to 18%, which is a good source of essential and non-essential amino acids (Pereira and Vicente, 2013). In contrast, the contents of protein and fat in offal tend to be lower than that of meat cuts (Florek et al., 2012).

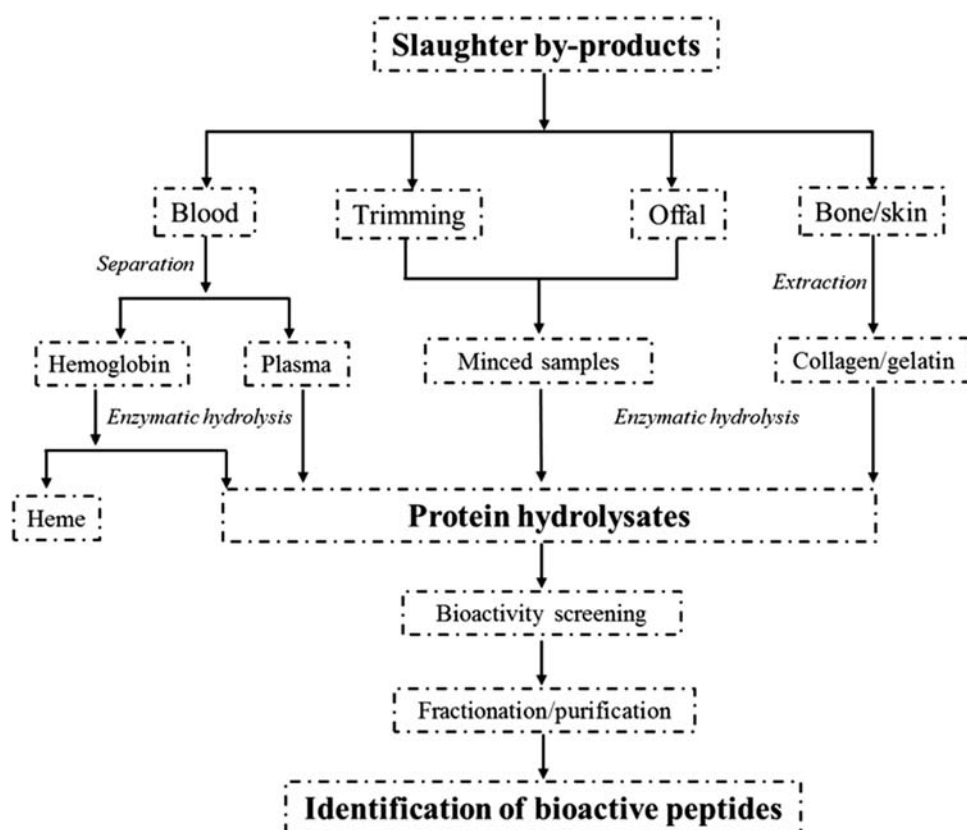

Bones and hides act as the major meat by-products during meat processing, which are typically used for feeding purposes or production of collagen/gelatin (Mora et al., 2014; Toldrá et al., 2016). Collagen constitutes approximately 30% of all vertebrate body proteins. Collagen molecule is composed of three almost identical  $\alpha$ -chains, namely collagen triple helix. This triple helix consists of a repetitive motif, Gly-X-Y, where X is proline and Y is hydroxyproline, which can contribute to stability of the helical structure. Collagen can be extracted from meat by-products through chemical or biochemical treatment, followed by extraction process using water (Fu et al., 2018). This process can cleave covalent and hydrogen bonds, leading to breakdown of triple helix and transformation to soluble collagen (Fu et al., 2018).

## Production of Bioactive Peptides Derived From Animal Processing By-Products

Animal processing by-products rich in proteins constitute a good substrate for proteolysis (Mora et al., 2014). Enzymatic hydrolysis of by-products by commercial proteases is an effective approach to recover protein-containing part from by-products (Lafarga and Hayes, 2014). Prior to enzymatic hydrolysis, the pre-treatment procedures are imperative for certain raw materials. For example, collagen is normally subjected to pre-treatment at high temperature or pressure so that the structure is partially or completely destroyed, making it easier for enzyme access (Zhang et al., 2013). Schematic diagram for production of bioactive peptides from animal processing by-products is illustrated in Fig. 1. Following optimal pH and temperature adjustments, animal by-products are usually minced and diluted with water. Hydrolysis reaction usually lasts for a few hours either in batch reactors or in continuous reactors. Once the desired degree of hydrolysis is achieved, the reaction is terminated by heat treatment to inactivate the enzymes. Afterwards, the digests are subjected to centrifugation to recover supernatant after removal of fat and pellet. The resultant hydrolysates (supernatants) can be submitted to bioactivity screening, followed by fractionation and purification with the aid of chromatographic techniques to identify potent bioactive peptides (Fig. 1). In terms of blood or hemoglobin samples, after heat treatment, the pH of hydrolysate is lowered to precipitate heme (Vatsyayan and Goswami, 2011). Subsequently, the hydrolysate mixture is centrifuged to separate insoluble heme from the aqueous solution.

Although bioactive peptides can be naturally released by endogenous enzymes in meat during postmortem aging (Fu et al., 2017), the activities of endogenous enzymes are limited so that the resultant peptides may be inactive or have low bioactive potencies. In this regard, the most common approach to release bioactive peptides is use of exogenous proteases (Udenigwe and Aluko, 2012). An array of commercial food-grade proteases have been used for generation of bioactive peptides from animal by-products, including Alcalase, Neutrase, Flavourzyme, Bromelain, Papain, Pepsin, Trypsin and Protamex (Lafarga and Hayes, 2014). After enzymatic hydrolysis, thousands of peptides can be released, but a limited number of them possess promising bioactivity. Therefore, a follow-up purification procedure needs to be implemented, including a series of chromatography, membrane filtration or electrodialysis technologies (Udenigwe and Aluko, 2012). However, fractionation and purification are time-consuming and the yield is relatively low. In order to optimize screening process, *in silico* approaches have been recently employed to search for certain bioactive peptides from animal by-products (Fu et al., 2016a,b; Lafarga et al., 2014), which involves screening of the optimal protein/enzyme combination, followed by virtual prediction of the potential bioactivity of peptides (Fu et al., 2016a,b).

**Fig. 1** Schematic diagram for production of bioactive peptides from animal processing by-products.

## Health Beneficial Potentials of Bioactive Peptides From Animal By-Products

As the major component of animal by-products is protein, they are excellent precursors for production of protein hydrolysates that can be extracted, purified and commercialized as high value-added ingredients (Mullen et al., 2017). Bioactive peptides recovered from animal by-products were reported to possess antihypertensive, antioxidant, antidiabetic and antimicrobial activities (Lafarga and Hayes, 2014). A number of examples of bioactive peptides/hydrolysates from animal processing by-products are summarized in Tables 1–3.

### Antihypertensive Activity

Hypertension is a major risk factor responsible for most cardiovascular diseases (Padwal et al., 2001). Angiotensin-I converting enzyme (ACE) and renin, two main elements in the renin-angiotensin-aldosterone system, play a pivotal role in regulation of blood pressure and fluid homeostasis (Manrique et al., 2009). Simultaneous inhibition of these two enzymes has been shown to exert a synergistic effect on treatment of hypertension. However, long-term administration of synthesized drugs may provoke several side effects on human health (Manrique et al., 2009). Therefore, there is an increasing interest in development of natural ACE- and renin-inhibitory peptides with fewer side effects. In recent years, several ACE- and renin-inhibitory peptides have been identified from animal processing by-products, such as collagen, heart, viscera, hemoglobin, plasma and whole blood (Table 1).

Although a considerable number of *in vitro* experiments have confirmed ACE- or renin-inhibitory activity of peptides/hydrolysates from animal by-products, their *in vivo* efficacy has not been adequately documented. Chicken skin protein hydrolysates with ACE- and renin-inhibitory activities have been reported to exhibit antihypertensive effects *in vivo* based on metabolomics data and animal models (Onuh et al., 2013, 2014; Onuh et al., 2015; Onuh et al., 2016). Fu et al. (2015) produced collagen hydrolysates with potent ACE-inhibitory activities and confirmed their stability towards temperature, pH and digestive enzymes. The most active ACE-inhibitory peptides were identified to be VGPV and GPRGF that can be transported across the monolayer of human intestinal epithelial Caco-2 cells through paracellular pathway and retained their ACE-inhibitory activities (Fu et al., 2016a, 2016b). Recently, the *in vivo* antihypertensive effect of papain hydrolysates from bovine globulins and bovine serum albumin (BSA) were verified (Lafarga et al., 2016a). A decrease in systolic blood pressure of 14.3–36.2 mm Hg was observed at the oral dosage of 200 mg kg<sup>−1</sup> (Lafarga et al., 2016a, 2016b).

**Table 1** ACE- or renin-inhibitory peptides/hydrolysates identified from animal processing by-products

ACE-inhibitory activity	Hydrolysate/Sequence	Source	Enzyme	IC <sub>50</sub>	In vivo bioactivity	References
Renin-inhibitory activity	TY, FL	Bovine hemoglobin	Pepsin, Trypsin	96.43 and 290.66 μM	N/A	Wang et al. (2017)
	VGPV, GPRGF	Bovine collagen	Alcalase, Papain	405.1 and 200.9 μM	Transported across monolayers of human intestinal epithelial Caco-2 cells through paracellular pathway	Fu et al. (2016a,b)
	Whole hydrolysates	Bovine connective tissue	Pepsin, Pancreatin	N/A	N/A	Ryder et al. (2016)
	YY	Bovine serum albumin	Papain	180 μM	Antihypertensive effect on SHR over 24 h at the dosage of 200 mg/kg of body weight	Lafarga et al. (2016a,b,c)
	SLR	Bovine serum albumin	Papain	171.9 μM	Antihypertensive effect on SHR over 24 h at the dosage of 200 mg/kg of body weight	Lafarga et al. (2016a)
	HF, KR	Bovine hemoglobin	Papain	221.2 and 383.7 μM	N/A	Lafarga et al. (2016c)
	YF	Bovine fibrinogen	Papain	94.6 μM	N/A	Lafarga et al. (2015)
	HR, YR, HLP	Bovine hemoglobin	Papain	7.0, 8.7 and 6.4 mM	N/A	Lafarga et al. (2016c)
	SLR	Bovine fibrinogen	Papain	7.2 mM	N/A	Lafarga et al. (2015)

**Table 2** Antioxidant hydrolysates from animal processing by-products

Samples	Source	Enzyme	Assays	References
Whole hydrolysate	Porcine tissues (colon, appendix, rectum, pancreas, heart, liver and lung)	Protamex, Alcalase	DPPH, ABTS, inhibition of oxidation, iron chelation capacity	Damgaard et al. (2014, 2015)
Whole hydrolysate	Bovine fibrinogen and $\gamma$ -globulins	Papain	FRAP and ORAC assays	O'Sullivan et al. (2017)
Whole hydrolysate	Bovine connective tissue proteins	Pepsin and Pancreatin	ORAC	Ryder et al. (2016)
Whole hydrolysate	Bovine plasma proteins	Papain, bromelain, FP400 and FPII	DPPH, FRAP	Bah et al. (2016)
Whole hydrolysate	Bovine plasma proteins	Alcalase	Reduced TBARS and peroxide values	Seo et al. (2016)

**Table 3** Antidiabetic peptides/hydrolysates from animal processing by-products

Hydrolysate/Sequence	Source	Enzyme	IC <sub>50</sub>	References
PPL	Bovine serum albumin	Pepsin or ficain	0.3 mM	Lafarga et al. (2014)
ER	Bovine serum albumin	Papain	4.4 mM	Lafarga et al. (2016a)
PPG	Bovine collagen	Papain, ficain, bromelain	2.2 mM	Lafarga et al. (2014)
Whole hydrolysate	Bovine hemoglobin	Pepsin and pancreatin	1.62 mg mL <sup>-1</sup>	Caron et al. (2017)

### Antioxidant Activity

Oxidative stress is an imbalance between production of reactive oxygen species (ROS) and antioxidant defenses, which is implicated in a series of chronic diseases, such as cardiovascular disease, neurodegenerative disorders, inflammation, gastric ulcers, diabetes mellitus and cancer (Samaranayaka and Li-Chan, 2011). Therefore, a substantial attention has been paid to search natural antioxidants to protect against ROS and other free radicals present in the food system (Samaranayaka and Li-Chan, 2011). In the past years, protein hydrolysates with antioxidant activities are of great interest, as it is more cost- and time-saving to prepare, compared with purified antioxidant peptides (Lafarga and Hayes, 2014). In this respect, several recent studies have focused mainly on antioxidant activities of the whole hydrolysates from animal by-products (Damgaard et al., 2015; Damgaard et al., 2014). Antioxidant hydrolysates have been produced from porcine tissues through enzymatic hydrolysis from colon, appendix, rectum, pancreas, heart, liver, and lung (Damgaard et al., 2015). The relevant information on antioxidant hydrolysates and peptides derived from animal by-products are listed in Table 2.

Antioxidant activity can be monitored by a variety of assays with different mechanisms, including hydrogen atom transfer (HAT), single electron transfer (ET), reducing power and metal chelation (Shahidi and Zhong, 2015). The commonly used antioxidant assay include DPPH (2,2-Diphenyl-1-picrylhydrazyl), FRAP (ferric reducing antioxidant power), ORAC (oxygen radical absorbance capacity) and metal ion chelating ability assays (Shahidi and Zhong, 2015). In addition, some cell models have been applied to assess antioxidant activities *in vitro* against inducers of oxidative stress (e.g. H<sub>2</sub>O<sub>2</sub>). The main assays include measurement of cell proliferation, cycle arrest and apoptosis and cellular antioxidant enzymes, such as superoxide dismutase, catalase, and glutathione peroxidase (Shahidi and Zhong, 2015).

### DPP-IV Inhibitory Activity

Type 2 diabetes (T2D) is a chronic metabolic disorder characterized by hyperglycemia, insulin resistance and pancreatic beta-cell dysfunction (Patil et al., 2015). Inhibition of dipeptidyl peptidase-IV (DPP-IV) activity is one of the latest strategies for prevention and treatment of T2D (Nongonierma and FitzGerald, 2016). DPP-IV inhibitors can play a key role in regulation of glucose level through retarding degradation of glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) (Power et al., 2014). Enzymatic hydrolysis of animal by-product proteins can release DPP-IV inhibitory peptides (Table 3), such as ER and PPL from hemoglobin (Lafarga et al., 2016c) and PPG from bovine collagen (Lafarga et al., 2014). Furthermore, *in vivo* animal studies demonstrated that hydrolysates from porcine skin gelatin with DPP-IV inhibitory activities exhibited antidiabetic effects (Nongonierma and FitzGerald, 2016). For instance, ingestion of gelatin hydrolysates (300 mg per day) from porcine skin can improve glucose tolerance in streptozotocin-induced diabetic rats after 21 and 42 days (Huang et al., 2014).

### Antimicrobial Activity

Antimicrobial peptides (AMPs) are oligopeptides with the ability to inhibit growth of certain pathogen bacteria (Pellegrini, 2003). Compared with conventional antibiotics, AMPs can exhibit antimicrobial activity against a broad-spectrum of microorganisms, including gram-positive and gram-negative bacteria and fungi (Pellegrini, 2003). Overall, the antimicrobial mechanisms can be

categorized into the barrel-stave mechanism, the toroid pore or wormhole mechanism and the carpet mechanism (Guilhelmelli et al., 2013).

To date, antimicrobial peptides have been isolated and characterized from animal blood proteins. Daoud et al. (2005) isolated antimicrobial peptides from bovine hemoglobin through hydrolysis and the most active peptide sequences were characterized to be VTLSHLPSTFT PAVHASLDKFLANVSTVL. A recent study by Przybylski et al. (2016) revealed that an antimicrobial peptide (TSKYA) can serve as meat preservative (0.5%, w/w) to reduce the lipid oxidation and inhibit bacterial growth during 14-day refrigeration storage.

### The Other Bioactivities

Apart from bioactivities mentioned previously, hydrolysates/peptides from animal by-products have been reported to exhibit some other physiological functions. An iron-binding peptide derived from porcine plasma protein hydrolyzed by Flavourzyme was characterized to be DLGEQYFKG (Lee and Song, 2009). Recently, O'Sullivan et al. (2017) produced hydrolysates from  $\alpha/\beta$  globulin, serum albumin,  $\gamma$ -globulin and fibrinogen and confirmed their anti-cancer potentials against several cancer cell lines, such as lymphoma cells, breast cancer cells and epithelial colorectal adenocarcinoma cells. The high safe profiles combined with the bioactive potentials of hydrolysates/peptides from animal by-products makes it interesting to explore new bioactive potentials in future research activities.

### Future Perspectives

Currently, tons of land-based animal processing by-products are generated annually. From the perspectives of economic benefits, by-product management and sustainability, these protein-rich by-products are, undoubtedly, ideal precursors of hydrolysates/peptides with an enormous variety of bioactivities. In this regard, transforming by-products into valuable bio-functional ingredients, which improves individual health by alleviating the burden of metabolic diseases, will be achievable. In spite of their great potentials, there are scarce studies on *in vitro* and *in vivo* studies aiming to fully unlock and confirm bioactive potencies of animal protein-derived peptides.

## Pancreas-Stimulating Foods: Cholecystokinin Enhancers

Chibuike C Udenigwe, Elisa Di Stefano, Flagot (Fila) Tsige, and Aynur Gunenc, School of Nutrition Sciences, University of Ottawa, Ottawa, ON, Canada

© 2019 Elsevier Inc. All rights reserved.

### Glossary

**Anorexigenic** the ability of a compound to suppress appetite leading to reduced food intake.

**Cholecystokinin** a gastrointestinal hormone that stimulates the secretion of pancreatic enzymes and emptying of the gallbladder.

**Cholecystokinin receptors** a group of receptors on which cholecystokinin binds to activate signalling processes leading to appetite suppression.

**Cholecystokinetic** to cause the contraction and emptying of the gallbladder in order to release bile into the intestine.

**Gut hormones** a group of peptides secreted by the enteroendocrine cells of the gastrointestinal tract that regulate appetite and the digestion process.

**Orexigenic** the ability of a compound to stimulate appetite leading to increased food intake.

**Pancreozymic** to cause the release of pancreatic enzymes for food digestion.

### Gastrointestinal Processing of Food

Consumption of energy-dense food, digestion and energy metabolism are important contributors to the development of obesity. The mouth, stomach, small intestine and large intestine are major locations for food digestion, in addition to other contributors such as the salivary glands, liver, gallbladder, and pancreas. Bacteria present in the gastrointestinal tract, also known as the gut microbiota, also play an important role in this process. Digestion typically involves the interaction of ingested food components with digestive enzymes, bile salts, bacteria, and hormones (Wallace, 2013). In general, food intake is regulated through processes that are coordinated *via* the gut–brain axis. The gut hormones play significant roles in this process by activating different signalling pathways that control appetite (Cummings and Overduin, 2007; Morton et al., 2006; Sternini et al., 2008; Wren and Bloom, 2007). In fact, pharmacological approach for body weight and obesity management includes the alteration of the gut hormones, namely orexigenic (appetite-suppressing) ghrelin and anorexigenic (appetite-suppressing) cholecystokinin (CCK), glucagon-like peptide-1, pancreatic polypeptide, peptide YY, and oxyntomodulin (Hameed et al., 2009; Wren and Bloom, 2007). This article discusses the structure and roles of CCK, as well as the effects of foods and food-derived compounds in stimulating CCK secretion in the gastrointestinal tract and in controlling appetite.

### Cholecystokinin, a Gut Peptide Hormone

Cholecystokinin is a gut hormone that controls the secretion of pancreatic enzymes (pancreozymic action) for food digestion, and emptying of the gallbladder (cholecystokinetic action); the latter was discovered first, thus, the hormone was named on the basis of its gallbladder function (Liddle et al., 1985; Rehfeld, 2004). CCK is a part of the gut hormone triad, with secretin and gastrin, and functions as an endogenous anorectic, i.e. appetite-suppressing, factor (Rehfeld, 2004). The identification of the gut peptide depends on the number of amino acid residues that it contains. For instance, CCK-58 contains 58 amino acid residues in its structure (Reeve et al., 1996). The various structural forms, including bioactive CCK-5, CCK-8, CCK-22, CCK-33, CCK-39, CCK-58 and CCK-83, are derived from posttranslational modifications of preprocholecystokinin, a 115-amino acid residue CCK precursor, mostly by prohormone convertase activity (Chaudhri et al., 2006; Rehfeld, 2004). All CCK forms have the sequence -Tyr-Met-Gly-Trp-Met-Asp-Phe at their C-terminal, with  $\alpha$ -amidation at Phe and O-sulfation at Tyr residues. The latter modification is introduced by the activity of tyrosylprotein sulfotransferase and is important in determining the affinity of CCK for its cell surface receptors in the body (Rehfeld, 2004; Rehfeld et al., 2007).

The physiological activity of CCK starts when it binds its G-protein-coupled receptors, CCK1R and CCK2R, formally known as CCK-A and CCK-B receptors, respectively. CCK1R selectively binds sulphated CCK with high affinity and is responsible for pancreatic enzyme secretion and gastric emptying, whereas CCK2R is predominant in the brain and binds both sulphated and non-sulphated CCK (Rehfeld, 2004). Although produced by several gastrointestinal and neuronal cells, CCK is mainly secreted from enteroendocrine I cells located in the proximal regions of the duodenum and jejunum. In the small intestine, CCK dose-dependently stimulates physiological effects that lead to appetite suppression, which can lead to food intake reduction in humans (Larsson and Rehfeld, 1978; Tripathi et al., 2015; Zhang et al., 2015). Therefore, CCK and its receptors and signalling pathways have

become important physiological targets for exogenous factors intended for use in controlling body weight and obesity (Witkamp, 2011).

### Models for Studying the Effects of Food on CCK Secretion

Several studies have investigated the effects of food and its components on CCK secretion in healthy, overweight and obese human subjects (Bourdon et al., 2001; Feltrin, 2004; Pasman et al., 2008; Schwartz et al., 1994). Such studies typically measure plasma CCK levels in different subjects before and after treatments with single or multiple doses of the food component by direct ingestion, intake with meals, or by intra-duodenal infusion. In the studies, postprandial plasma CCK level serves as an indication of appetite status. However, a study involving humans that consumed high fat or high carbohydrate meals could not associate the increased postprandial CCK-8/-33(S) levels with satiety and satiation (Gibbons et al., 2016). This suggests that CCK may not be working independent of the other gut hormones in controlling appetite and food intake. Similarly, rodents have been used as models for studying the effects of food compounds on CCK secretion (Nishi et al., 2003, 2001; Sharara et al., 1993). Although evidence from *in vivo* studies is important for practical applications, it is challenging to determine which components of the food are bioactive and to elucidate effects on molecular signalling processes *in vivo*. In this instance, cultures of murine enteroendocrine cell lines and primary intestinal mucosal cells have been used to study the effects of food compounds on CCK-activated signalling pathways (Nishi et al., 2001; Choi et al., 2007; Pasman et al., 2008; Nakajima et al., 2010, 2011; Kim et al., 2013; Park et al., 2014; Al Shukor et al., 2016). Particularly, murine intestinal secretin tumour cell line (STC-1) has emerged as an ideal model for this type of study. STC-1 cell expresses similar features as regular enteroendocrine cells, including the expression of genes and proteins involved in CCK production, secretion of CCK, and CCK receptor-mediated signalling processes; for a detailed discussion, see McCarthy et al. (2015). The cellular model is important for studying molecular events that may have occurred *in vivo*, but would be insufficient if used as the sole means of establishing bioactivity of the food compounds.

### Effects of Food Compounds on CCK Secretion

Foods contain compounds that affect many physiological processes in the body, including biochemical pathways involved in energy metabolism. Therefore, some food-derived compounds can play a role in obesity management, for instance, *via* regulation of gut hormone secretion. In this case, food products can be strategically formulated to contain well-defined components that are capable of modulating appetite signalling processes (Prinz and Stengel, 2017; Serrano et al., 2017). CCK is secreted when dietary components reach the duodenum (Gribble, 2012). A number of foods and their components activate CCK secretion, and this is relevant for controlling appetite and body weight. For instance, consumption of spinach thylakoid, with high fat or high carbohydrate meals, dose-dependently elevated plasma CCK level in healthy and obese humans compared to control groups that did not consume the thylakoid (Roberts and Moreau, 2016). This activity was attributed to the thylakoid membrane content, which has multiple components, and was proposed to be responsible for the anti-obesity property of spinach. As discussed below, fatty acids, proteins, peptides, dietary fibres and phenolic compounds present in foods have particularly demonstrated CCK-secreting effects in humans, animals and cell cultures (Tables 1–3).

#### Free Fatty Acids

In humans, the ingestion of lipids, and subsequent presence of intraluminal lipids, stimulates the secretion of CCK. Although the mechanism of the interaction has yet to be clarified, the length and degree of unsaturation of the fatty acid chain affect the magnitude of the CCK response. Several studies demonstrated that only fatty acids with 12-carbon chain length or higher are able to trigger a significant increase in plasma CCK level (Barbera et al., 2000; Feltrin, 2004; Hopman et al., 1984; McLaughlin et al., 1999). Maher and Clegg (2018) suggested that the differential response could be because the digestion of medium-chain and short-chain fatty acids does not require emulsification with bile acids, which are secreted by CCK activity. Degree of unsaturation of fatty acids is also an important factor in triggering CCK release. Unsaturated fats, especially polyunsaturated fatty acids, significantly increase plasma CCK levels compared to saturated fatty acids (Shall et al., 1989; French et al., 2000; Pasman et al., 2008). Moreover, administering polyunsaturated fatty acids in the free fatty acid (FFA) form, rather than as a part of triglycerides (TG), led to a more pronounced effect on CCK secretion (Pasman et al., 2008). This could be because of the release of only two FFA during TG digestion, thus the administration of FFA would contribute to a higher amount of FFA in the gastrointestinal tract when compared to TG intake.

#### Proteins, Protein Hydrolysates and Peptides

There is ample evidence that intake of dietary proteins or their hydrolysates affects CCK secretion in cultured cells, animal models and humans. Plant-derived and synthetic trypsin-inhibitors have also shown stimulatory effects on CCK release. The compounds act indirectly by competitively inhibiting trypsin activity thereby preserving trypsin-sensitive CCK-releasing peptides in the lumen (Herzig, 1998). Studies with potato proteins, which have a high content of protease inhibitors, reported significant increases in CCK

**Table 1** Some examples of food-derived free fatty acids and their CCK-stimulating effects

Sample	Model	Dose	Treatment	Duration	Outcome	References
Long Chain Fatty Acids (LCFA)	Human (upper intestinal infusion in 7 healthy male volunteers, aged 18–35, with body mass index of 20–25)	One dose	5 duodenal infusions: (i) 0.9% saline (control), (ii) 20% Intralipid (mixture of linoleic (C18:2) and linolenic (C18:3) acid), (iii–V) 20% emulsions of oils enriched with stearic (C18:0), oleic (C18:1), linoleic (C18:2) acids	Rate of 1 mL/min over a 100 minutes period	All lipid infusion conditions significantly triggered CCK response; no differences between the modified FAs composition of the oils.	<a href="#">French et al., 2000</a>
Long Chain (LCT) vs. Medium Chain (MCT) Triglycerides	Human (ingestion in 6 healthy male volunteers, aged 22–38)	60 mM	Ingestion of 60 mM LCT (corn oil: 7% palmitic acid (C16:0), 3% stearic acid (C18:0), 44% oleic acid (C18:1), 39% linoleic acid (C18:2)) or MCT (Ceres-MTC-dietary oil: 58% octanoic acid (C8:0), 39% decanoic acid (C10:0)).	Single intake	Ingestion of LCT triggered significant increase in plasma CCK; ingestion of MCT did not trigger any significant increase in CCK.	<a href="#">Hopman et al., 1984</a>
Unsaturated vs. Saturated Fatty Acids	Human (6 healthy volunteers, aged 20–41, 1 woman and 5 men)	Five meals with at least one week between meals	Ingestion of five meals with different fat contents (2 meals containing 3.5 g pure FAs, 3 meals containing 30 g triglycerides)	Single intake	Unsaturated fats triggered a significantly higher CCK release than saturated fats; diunsaturated fatty acids showed higher CCK release than monounsaturated fatty acids.	<a href="#">Shall et al., 1989</a>
Medium (MCT) vs. Long (LCT) Chain Fatty Acids	Human (9 healthy subjects, aged 20–56, 3 women and 6 men)	Two doses on two different days	Duodenal infusion of saline followed by LCTs (26% oleic acid, 52% linoleic acid) and MCTs (56% octanoic acid, 40% decanoic acid) in a randomised order on two different days.	Rate of 1 mL/min	Significant increase in plasma levels of CCK after LCT infusion; no significant increase in plasma levels of CCK after MCT infusion.	<a href="#">Barbera et al., 2000</a>

**Table 1** Some examples of food-derived free fatty acids and their CCK-stimulating effects—cont'd

<i>Sample</i>	<i>Model</i>	<i>Dose</i>	<i>Treatment</i>	<i>Duration</i>	<i>Outcome</i>	<i>References</i>
C12 vs. C10 Fatty Acids	Human model (12 healthy male subjects, aged 19–47, normal body weight). 4 subjects studied in a nonrandomised study, 8 subjects in the randomised study.	Three doses separated by 3–10 days	Intraduodenal infusion of fatty acid solutions containing 5.3 g of FAs (lauric acid (C:12) or decanoic acid (C10:00)).	Rate of 2 mL/min for 90 min	Both C:12 and C:10 triggered increase in plasma CCK levels; C:12 increased CCK to a greater extent than C:10.	<a href="#">Feltrin, 2004</a>
C12 vs. C10 Fatty Acids	Human (9 healthy male subjects, aged 18–35)	Single dose	Infusion in the upper gut of the three test solutions (0.10 mol/L C10 or C12 emulsions, or vehicle solution)	2 minutes infusion	C12 significantly increased plasma CCK level; C10 did not have an effect on CCK.	<a href="#">McLaughlin et al., 1999</a>
Korean pine nut FAs, Italian stone pine nut FAs, oleic acid, linoleic acid, $\alpha$ -linolenic acid, capric acid	STC-1 cell culture model	Single dose	50 $\mu$ M FAs added to STC-cells, then media harvested after 60 min.	60 min incubation	Korean pine nut FAs triggered the highest CCK release (8 folds more potent than the others FAs tested).	<a href="#">Pasman et al., 2008</a>
Korean pine nut FFA, Korean pine nut TG	Human (18 female subjects, aged 54–56, post-menopausal, overweight, BMI 27).	Single dose	Gel capsules containing 3 g Korean pine nut FFA (15.2% pinolenic acid, 45.1% linoleic acid, 26.8% oleic acid, 7.2% saturated FAs), or 3 g Korean pine nut TG (15.3% pinolenic acid, 45.6% linoleic acid, 26.4% oleic acid, 6.9% saturated FAs), or 3 g live oil (0.7% linolenic acid, 5.6% linoleic acid, 77.4% oleic acid, 11.7% saturated FAs). Randomised, placebo-controlled, double-blind cross-over trial	Single intake	Pine nut FFA had a stronger effect than pine nut TG on CCK-8 release.	

**Table 2** Some examples of food proteins, protein hydrolysates and peptides, and their CCK-stimulating effects

Sample	Model	Dose	Treatment	Duration	Outcome	References
Protein POTII	Human (6 type II diabetic subjects, aged 34–62, five men and one woman)	Single administration	Oral ingestion of a glucose/protein solution (control) or glucose/protein solution with addition of 1.5 g POTII.		Significant increase in plasma CCK by POTII.	<a href="#">Schwartz et al., 1994</a>
Potato extract containing trypsin inhibitor proteins	STC-1 cells		Potato extract (Potein) and digested form were incubated with STC-cells for 60 minutes	60 minutes	Dose-dependent increase in CCK secretion in STC-cells supernatant; CCK releasing ability comparable to effect of positive control; digested sample triggered higher CCK response than the untreated.	<a href="#">Nakajima et al., 2011</a>
Proteins, protein hydrolysates, amino acids	Rat model	Single administration	5 mL of liquid containing the different formulations was fed to rats <i>via</i> orogastric tube		Intact proteins had strong stimulatory effect on CCK secretion; carbohydrates and amino acids did not trigger any CCK response.	<a href="#">Sharara et al., 1993</a>
Casein, soybean protein isolate (SPI), egg white, wheat gluten hydrolysates, SPI-like amino acid mixture	Rat intestinal mucosal cells	Single exposure	15 mL of hydrolysates containing solution was incubated 5 minutes with the mucosa	5 minutes	All hydrolysates stimulated CCK release in cells; SPI hydrolysates triggered the highest CCK response; SPI-like amino acids mixture did not trigger any CCK response.	<a href="#">Nishi et al., 2001</a>
Peptone and lysophosphatidic acid (LPA)	STC-1 cells		6.25–50 mg/mL peptones exposure for 6 hours	6 hours	Peptone activated GPR93, which in turn induced CCK release; peptone induced higher cAMP level (from GPR93 overexpression) than LPA.	<a href="#">Choi et al., 2007</a>
$\beta$ -51–63 peptide (from soybean $\beta$ -conglycinin)	Rat model	Single exposure	Intraduodenal infusion of 3 $\mu$ M hydrolysates (flow rate 0.5 mL/min for 5 minutes) followed by 1 hour of basal diet (15 g)	5 minutes	Intraduodenum infusion of $\beta$ -51–63 peptide significantly increased plasma CCK concentration.	<a href="#">Nishi et al., 2003</a>
$\beta$ -51–63 peptide (from soybean $\beta$ -conglycinin)	STC-1 cells	Single exposure	60 minutes exposure of STC-1 cells with 1.2 mM $\beta$ -51–63 peptide	60 minutes	Exposure to $\beta$ -51–63 peptide caused dose-dependent CCK secretion in STC-1 cells.	<a href="#">Nakajima et al., 2010</a>
0.5%–1% w/v Protein hydrolysates (meat, casein, soybean, ovalbumin)	STC-1 cells	Single exposure	STC-1 cells exposed to peptones for 2 hours	120 minutes	Protein hydrolysates caused dose-dependent increase in CCK release; peptone-induced CCK release was lost by the addition of extracellular and intracellular $\text{Ca}^{2+}$ chelating agents.	<a href="#">Némoz-Gaillard et al., 1998</a>

**Table 3** Some examples of dietary fibres and phenolic compounds, and their CCK-stimulating effects

<i>Sample</i>	<i>Model</i>	<i>Duration</i>	<i>Treatment</i>	<i>Dose</i>	<i>Outcome</i>	<i>References</i>
<b>Fibres</b>						
Guar Gum	Human, lean health men (n = 12)	1 week	Liquid Formula diet	27 g/L of fibre per day	Fasting plasma CCK level increased	<a href="#">Meier et al., 1993</a>
	Human, postmenopausal, obese women (n = 15)	5 weeks	800 kCal meal	20 g fibre per day	Postprandial plasma CCK level increased	<a href="#">Heini et al., 1998</a>
White Bean Flakes	Human, healthy men (n = 10)	Single administration	Meal containing 60 g white bean flakes	11.8 g	Postprandial plasma CCK level increased	<a href="#">Bourdon et al., 2001</a>
<b>Phenolic compounds</b>						
Hesperetin and hesperidin	Cell culture, STC-1 cell	1 hour	Cells were washed with HEPES buffer and incubated with hespetin and hespeidin at 37 °C for 60 min. CCK concentrations measured using commercial EIA kit.	0.1 mM, 0.5 mM, 1 mM	Hesperetin significantly and dose-dependently increased CCK secretion; hesperidin (glycoside) showed no effect on CCK release.	<a href="#">Kim et al., 2013</a>
Naringenin and naringin	Cell culture, STC-1 cells	1 hour	Cells incubated with naringenin and naringin at 37 °C for 60 min. CCK concentrations measured using commercial EIA kit.	0.1 mM, 0.5 mM, 1 mM	Naringenin significantly increased CCK secretion; naringin (glycoside) did not show any significant effect on CCK secretion.	<a href="#">Park et al., 2014</a>
Quercetin, kaempferol, apigenin, rutin and baicalein	Cell culture, STC 1-cells	2 hours	Incubation of cells with flavonoid samples at 37 °C. CCK measured by RIA.	20 µM	Significant increase in CCK secretion by quercetin, kaempferol and apigenin; rutin showed a lower activity compared to its aglycone, quercetin.	<a href="#">Al Shukor et al., 2016</a>

release in humans and cellular model as a result of the treatments (Nakajima et al., 2011; Schwartz et al., 1994). Gastrointestinal digestion is regarded as a major step in the CCK stimulatory effect of dietary proteins. This was confirmed by the observation that only intact or moderately hydrolysed proteins triggered a notable CCK response, while extensively ( $\geq 60\%$ ) hydrolysed proteins, or the corresponding amino acid mixtures, did not cause any effect on CCK level (Sharara et al., 1993; Nishi et al., 1999, 2001). The digestion process determines the release of bioactive peptides in the lumen, where they can interact with the brush border barrier and stimulate gut hormone release. A number of peptide-cell membrane interactions can lead to increase in CCK secretion, as shown in Fig. 1. Dietary peptides could trigger the release of CCK directly (Nakajima et al., 2010), or through intermediate elements such as luminal CCK-releasing factor (LCRF), calcium-sensing receptor (CaSR) or G-protein coupled (GPCR) receptors, and calcium ion channels (Caron et al., 2017; Némóz-Gaillard et al., 1998). Moreover, peptides are also capable of influencing CCK gene transcription, by stimulating membrane elements such as GPR93, which in turn induces increase in cAMP level and activation of pathways involved in CCK expression and secretion, including the extracellular signal-regulated protein kinases 1 and 2, phosphokinase A, and calmodulin-dependent protein-kinase signalling pathways (Caron et al., 2017; Choi et al., 2007). Although the mechanism is not clear yet, dietary arginine-containing peptides are also important stimulators of CCK secretion (Nishi et al., 2003, 2001). Furthermore, proteolysis occurs during food processing, e.g. fermentation, meat ripening and exogenous protease treatments (Udenigwe and Aluko, 2012), and it is possible to produce appetite-suppressing peptides as a result. There is also an opportunity in exploring if some food-derived peptides are structurally similar to CCK1R binding motif of CCK, and if these peptides can act as agonists for appetite stimulation.

### Dietary Fibres

Several studies have established the effects of dietary fibres on appetite, satiety and gastrointestinal functions (Anderson, 2009; Haber et al., 1977; Poppitt et al., 2002). Although the mechanism of action is not well established yet, the intake of some dietary fibres can elevate and sustain postprandial plasma CCK levels. In a study by Meier et al. (1993), the addition of 27 g/L guar gum to a liquid formula diet consumed by healthy men led to an increase in fasting plasma CCK level and a decrease in colonic transit time.

**Figure 1** An overview of intestinal signalling pathways activated by food peptides for cholecystokinin (CCK) secretion. The activation of calcium-sensing receptor or G protein-coupled receptor (GPR93) by protein hydrolysates results in an increase of intracellular calcium level, initiation of calcium-mediated signalling and CCK gene transcription, leading to CCK synthesis and secretion. Figure reprinted from Caron, et al., 2017. Protein digestion-derived peptides and the peripheral regulation of food intake. *Front. Endocrinol.* 8, 85. <https://doi.org/10.3389/fendo.2017.00085>, © 2017 Caron, Domenger, Dhulster, Ravallec and Cudennec.

A study with obese women supported this observation, as the consumption of high-fibre, low-calorie diet resulted in an elevated postprandial plasma CCK level (Heini et al., 1998). Moreover, a study on the effect of low vs. high fibre meals reported a significant increase in postprandial CCK after ingestion of meals containing 11.8 g of bean flakes (Bourdon et al., 2001). It was also found that plasma CCK remained above the baseline level for a longer duration (4 h) after the intake of the bean flake meal in comparison to 180 min recorded after low fibre meal intake (Bourdon et al., 2001). According to the authors, the physiological responses associated with dietary fibres, such as slower colonic transit time and lower absorption efficiency in the small intestine, are possibly responsible for the prolonged CCK secretion. There is also the potential activity of other components of the flakes, including phytochemicals, as discussed below.

### Phenolic Compounds

Foods rich in phenolic compounds have demonstrated anti-obesity effects in animal and human studies (Chan et al., 1999; Lai et al., 2015; Mohamed et al., 2014). For this reason, several studies have investigated the interaction of plant-derived phenolic compounds with appetite-regulating intestinal hormones, including CCK. For example, the release of CCK from cultured STC-1 cells was elevated in the presence of flavonoids, hesperetin or 3',5,7-trihydroxy-4'-methoxyflavanone (Kim et al., 2013), naringenin or 4',5,7-trihydroxyflavanone (Park et al., 2014), and quercetin or 5,7,3',4'-flavon-3-ol (Al Shukor et al., 2016). In contrast, their respective glycosides, hesperidin, naringin and rutin, did not stimulate CCK secretion in the cells. Although the flavonoids are mainly found in their glycoside forms, they are enzymatically converted into their aglycone forms (hesperetin, naringenin and quercetin) in the gastrointestinal lumen (Li et al., 2010), prior to their transport to the enteroendocrine cells. Other flavonoids, kaempferol and apigenin, increased CCK release in STC-1 cells, but no activity was observed for baicalein (Al Shukor et al., 2016). Interestingly, baicalein is the only aglycone without a B-ring hydroxyl group, of all the flavonoids studied. This underscores the relevance of B ring substituents in determining the CCK releasing activity of phenolic compounds. Detailed mechanisms of bioactivity is still scanty. A proposed mechanism involves the activation of transient receptor potential (TRP) ankyrin 1 channels (TRPA1), which are non-selective cation channels, leading to an influx of extracellular calcium ions into the enteroendocrine cells and subsequent dose-dependent increase of CCK release (Kim et al., 2013; Park et al., 2014). Activation of TRP and TRPA1 channels increases intracellular calcium level, which mediates the release of CCK (Purhonen et al., 2008). This mechanism was confirmed in the studies by removing calcium ions from the media, and in the presence of TRP and TRPA1 antagonists, which resulted in inhibition of the hesperetin- and naringenin-induced CCK releasing effects (Kim et al., 2013; Park et al., 2014).

In addition to direct effect on CCK secretion, there is interest in investigating compounds that can mimic CCK in binding their receptors and activating the appetite-suppressing signalling processes. On the basis of this approach, eight food-derived phenolic compounds, including tannic acid, gallic acid, benzoic acid, hydroxybenzoic acid, protocatechuic acid, quercetin, kaempferol and resveratrol, were found to have no effect in activating the CCK1R signalling pathway in cultured CHO epithelial cells (Al Shukor et al., 2014). In fact, the compounds had anti-CCK1R activities. In the study, CCK sequestration occurred due to its interaction with one of the compounds, tannic acid, and this could be responsible for the antagonistic effect. If translated *in vivo*, the anti-CCK1R effect of the compounds can lead to a loss of the appetite-suppressing capability of CCK. Considering the lack of effect on CCK1R pathway activation, it is possible that the aforementioned mechanisms, and the other satiety hormones, receptors and pathways play a role in mediating the satiety-inducing effects of polyphenol-rich foods.

### Concluding Remarks

CCK plays a major role in appetite and food intake control, and an increase in its secretion from enteroendocrine cells is an important factor in energy metabolism. This article highlights some examples of the effects of food components on CCK release based on cellular, animal and human studies. Proteins and fatty acids are the most potent dietary CCK stimulants, and their structures are the major determinants of bioactivity. The processes triggered by polyphenols leading to CCK secretion in cells could explain, at least in part, the anti-obesity activity of polyphenol-rich foods. There is however limited information on the molecular mechanisms of action and structure-function relationships, especially for dietary fibres. Future studies need to investigate the CCK-stimulating effects of the various food components when consumed as food products, as the beneficial compounds can become more or less bioaccessible in the food matrix thereby influencing their bioactivity.

# Bioactives From Spices and Herbs

Milda E Embuscado, McCormick & Company, Inc., Hunt Valley, MD, United States

© 2019 Elsevier Inc. All rights reserved.

## Introduction

For centuries, spices and herbs are not only excellent sources of flavors and food colors but are also excellent sources of bioactive compounds. The term bioactive came from the phrase biologically active, meaning the compound has a positive effect on living organisms, tissues or cells. Bioactive molecules are food substances that play an important role in human health and growth, biochemical reactions, mechanisms and development and have proven health benefits. They also amend disease risks by alleviating these conditions. The National Institutes of Health (NIH) defines bioactive food components as “constituents in foods or dietary supplements, other than those needed to meet basic human nutritional needs, which are responsible for changes in health status”. Bioactives are present in foods in small quantities and they occur naturally in both plants and animals in low concentrations. The major sources of bioactive food components are plants and many come from spices and herbs. Some examples of bioactive substances are phytosterols, lutein, lycopene, fatty acids and peptides. Bioactives also include antioxidants such as polyphenols. Antioxidants protect the human body from oxidation brought about by free radicals, superoxide, oxygen radicals and other substances that trigger oxidation. Some bioactive compounds such as piperine can enhance bioavailability of other bioactives or nutritional substances. Black pepper is a good source of piperine. Piperine and capsaicin belong to the vanilloid family of compounds, which provides the pungent taste in foods. Piperine also has putative anti-inflammatory activity and may be active at promoting digestive processes. This chapter will provide the recent advances in bioactives derived from spices and herbs, their chemistry and mechanisms of action. It will also include the current and emerging extraction technologies employed for the extraction of bioactives from spices and herbs.

## Spices and Herbs

Spices and herbs are plant materials that have been used for thousands of years as food flavorings and as sources of substances for medicinal purposes. In fact, spices established and enriched empires centuries ago due to their functional properties. Spices were an important part of the ancient commercial trade before the 15<sup>th</sup>-century. The spice trade was monopolized by the middlemen from the Middle East and North Africa for more than 5000 years and at the time, they protected and secured their valuable Asian sources of spices. These middlemen became very rich from the spice trade, which was used for flavoring food, as preservatives for meat, in making perfume and as sources of substances for traditional medicine. For this reason, European countries tried ways of finding new routes to the sources of spices, Spain being one of them, which set forth voyages to find new paths for sources of spices. During that time, the spices were very expensive. In Europe, a pound of nutmeg was believed to be more valuable than gold. Spices were among the most valuable commodities in the ancient as well as medieval times. The search for spices from the East by European explorers such as Ferdinand Magellan, Vasco da Gama, Bartholomeu Dias, and Christopher Columbus led to the great Age of Exploration and the discovery of the New World. One of the successful voyages was led by Da Gama who found the route to India through the tip of Africa and returned from his voyage with nutmegs, cinnamon, ginger and peppercorns for the king of Portugal, King Manuel. During this period, the dominance of European countries came about and the monopolies of the Portuguese, Dutch, French, Spanish and English were established in various parts of the spice trades. This started and enriched the European empires.

Spices and herbs are harvested from different parts of the plant. Herbs are the leafy materials while spices are the seeds, bark, fruit/berries, pods and flowers of the plant. [Table 1](#) summarizes what parts of the plant the spices come from. Saffron, vanilla and cardamom are the most expensive spices in the world. [Table 2](#) shows the global primary and secondary producers of spices. India is the main source of spices followed by Indonesia then China. For the herbs, [Table 3](#) summarizes the sources of herbs in the world.

## Chemistry of Bioactives From Spices and Herbs

Bioactives are secondary metabolites that perform important functions in plants. Bioactives are produced in the plants to function as protectants, attractants or signaling compounds. The flavonoids are examples of bioactives that protect the plant from free radicals generated during photosynthesis. Alkaloids on the other hand fend off insect attacks while terpenoids attract pollinators. Plants produce these substances to defend themselves against various agents in the environment for their survival and for adaption. The roles of phenolic compounds and flavonoids include structural functions in different supporting or protective tissues, involvement in defense strategies, as attractants for pollinators and seed-dispersing animals, as allelopathic agents, ultra violet (UV) protectants and signal molecules in the interactions between plants and their environment ([Jaganath and Crozier, 2010](#)). There are other functions of bioactives in plants, which have yet to be discovered or explained.

**Table 1** Sources of spices and herbs

<i>Part of the plant</i>	<i>Spice/Herb</i>
Leaves	Basil, oregano, bay leaf, thyme, tarragon
Bark	Cinnamon, cassia
Seed	Fennel, fenugreek, dill mustard
Flower/bud, pistil	Clove, saffron
Fruits/berries	Clove, chilli, black pepper, allspice
Bulbs	Onion, garlic, leek
Root	Ginger, turmeric
Aril	Mace

**Table 2** Main production areas of spices in the world

<i>Spice</i>	<i>Largest producer</i>	<i>Second largest producer</i>
Cardamom	Guatemala	India
Ginger	India	China
Turmeric	India	Pakistan
Chili pepper	India	China
Cumin	India	Turkey
Vanilla	Indonesia	Madagascar
Nutmeg	Indonesia	Grenada
Cinnamon	Indonesia	China
Cloves	Indonesia	Madagascar
Saffron	Iran	Spain
Pepper	Vietnam	India

The main groups of plant bioactive compounds are classified based on their functions, molecular structures or sources. One classification includes the following:

*Glycosides* - secondary metabolites bound to a carbohydrate, mono- or oligosaccharide or to uronic acid) – cardiac glycosides, cyanogenic glycosides, glucosinolates, saponins and anthraquinone glycosides;

*Flavonoids and proanthocyanidins* – pigment containing substances with phenol groups;

*Tannins* – large polymers of flavonoids and hydrolysable tannins;

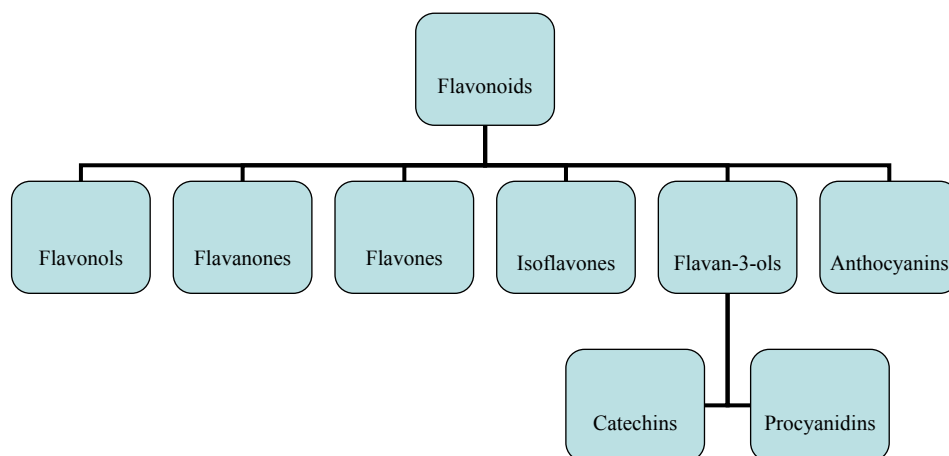

*Mono- and sesqui-terpenoids and phenylpropanoids* – synthesized from 5-carbon building blocks isoprene;

*Diterpenoids* – composed of 4 isoprene units and are hydrophobic in nature;

*Resins* – complex lipid-soluble mixtures that may consist of both diterpenoid and triterpenoids and mono- and sesquiterpenoids;

*Lignans* – lipophilic phenylpropanoids that form an 18-carbon skeleton, which have special functions in the plant cell membranes;

*Alkaloids* – heterocyclic compounds which contain nitrogen

**Figure 1** Different classes of flavonoids.

Fig. 1 shows the categories of flavonoids while Fig. 2 illustrates their basic structures. The chemical structures of bioactives of commonly used spices are shown in Fig. 3, illustrating the complexity and common features of the different structures that can be correlated to their functions. There are more than 6000 different flavonoids that have been described in literature and this list of bioactives continues to grow (Harborne and Williams, 2000) as new ones are discovered from different plant materials. Table 4 summarizes the different groupings that are important in spices and herbs, examples of bioactive compound from each group and spices/herbs sources. Tables 5 and 6 show a summary of the diverse health benefits derived from spices and herbs bioactives that includes blocking low-density lipoproteins and cholesterol, antioxidant activity, anticancer, improving cardiovascular functions, joint and digestive health as well as strengthening the immunity system. It is of great benefit to include bioactives particularly from spices and herbs as an essential part of our daily diet due to the immeasurable and considerable health benefits they provide.

## Bioactives From Spices and Herbs for Health and Wellness - Mechanism of Action

The bioactives from spices and herbs have been studied for their efficacy in ameliorating health and wellness in man by modulating human metabolism in a manner favorable for the prevention or reduction in the risk of degenerative diseases such as cardiovascular diseases, diabetes, obesity and cancer (Anderson et al., 1999). The impact of bioactives on health from selected spices and herbs are discussed below.

### Black Pepper

Black pepper (*Piper nigrum* L.) contains a bioactive phytochemical, piperine (Fig. 4), that exhibits many physiological and pharmacological properties including antioxidant, anti-inflammatory, antimutagenic, antitumor, antiapoptotic, antigenotoxic, antiarthritic, antifungal, antidepressant, anti-HVB (hepatitis B) and gastro-protective activities. Piperine also enhances the bioavailability of phytochemicals (e.g., curcumin) and drugs. Piperine inhibits free radicals and reactive oxygen species and lipid peroxidation due to their flavonoids and phenolic contents. The antioxidant activity of black pepper was evaluated through the determination of glutathione peroxidase, catalase, superoxide dismutase including measurement of reduced glutathione content and the amount of malondialdehyde, and protein carbonyl levels in the hippocampus.

Table 7 summarizes the bioactivities and pharmacological effects of piperine from black pepper including the researchers who conducted these studies. Black pepper (*P. nigrum* L.) is a very widely used spice and is known for its pungent taste and aroma. It is also widely known that black pepper has important bioactive and preservative properties. Piperine has been shown to affect enzymes that bring about various effects such as chemoprevention, detoxification, and enhancement of the absorption and bioavailability of nutrients and drugs. It has also been shown based on modern cell, animal, and human studies that piperine has immunomodulatory, antioxidant, anticarcinogenic, and anti-inflammatory properties (Bang et al., 2009). The chemical structure of piperine has the formula of C<sub>17</sub>H<sub>19</sub>NO<sub>3</sub> and the IUPAC name 1-(5-[1,3-benzodioxol-5-yl]-1-oxo-2,4-pentadienyl). It is also known as piperoylpiperidine. It is a very weak base that hydrolyzes to piperidine and piperic acid (Pruthi, 1999; Agarwal, 2010). 1-Piperoylpiperidine (piperine) exists as 4 isomeric structures: piperine (trans-trans isomer), isopiperine (cis-trans isomer), chavicine (cis-cis isomer), and isochavicine (trans-cis isomer) as shown in Fig. 5. The 3 geometric isomers of piperine have almost no pungency (Ravindran, 2003). Since piperine constitutes about 98% of the total alkaloids in black pepper (Hirasa and Takemasa, 1998), it is considered as the main contributor of pungency. Thus piperine content is used as a measure of total pungency of black pepper (Parthasarathy et al., 2008).

**Figure 2** Basic structures of flavonoids.

## Cinnamon

There are four main species of cinnamon that are used for food. These are *Cinnamomum cassia* (cassia or Chinese cinnamon), *Curcuma burmanni* (Korintje, Padang cassia or Indonesian cinnamon), *Curcuma loureiroi* (Saigon cinnamon, Vietnam cassia or Vietnamese cinnamon) and *Curcuma verum* also known as *Curcuma zeylanicum* (Sri Lanka cinnamon or Ceylon cinnamon). The differences between species of cinnamon are shown in [Table 8](#). The composition, antioxidant properties and essential oil components of cinnamon are presented in [Tables 9](#) and [10](#).

Cinnamon has shown potent antioxidant activity ([Table 9](#)), can lower blood sugar, and inhibit inflammation and lower cholesterol and triglycerides in the blood. The antioxidant activity of cinnamon is due to their bioactive components namely the polyphenols such as flavonoids, phenolic acids, lignans, essential oils and alkaloids ([Fig. 6](#)). Eugenol, limonene, terpineol, catechins, proanthocyanidins, tannins, linalool, saffrole, pinene, methyl eugenol and benzaldehyde are some of the bioactive compounds from cinnamon.

The effect of cinnamon bioactive compounds to mitigate diabetes through various mechanisms has been under investigation for more than 15 years. [Peng et al. \(2010\)](#) investigated the inhibitory effects of proanthocyanidins, catechin, epicatechin and procyanidin B2 from cinnamon bark on the formation of specific advanced glycation end products (AGEs). The cinnamon polyphenols displayed inhibitory effects on these AGEs which were attributed to their antioxidant activities and carbonyl scavenging properties ([Peng et al., 2010](#)). AGEs accumulation has been implicated as a major pathogenic process in diabetic complications and other disorders such as atherosclerosis and Alzheimer's disease ([Peng et al., 2010](#)). According to [Peng et al. \(2010\)](#) the cinnamon polymers were composed of monomeric units with a molecular mass of 288. They isolated two trimers with a molecular mass of 864 and a tetramer with a mass of 1152.

[Anderson et al. \(2004\)](#) isolated and characterized the insulin-enhancing complexes from cinnamon. They found that polyphenolic polymers are A type doubly linked procyanidin oligomers of catechins and/or epicatechins that may function as antioxidants and potentiate insulin action ([Anderson et al., 2004](#)). The cinnamon polyphenolic polymer may be beneficial in the control of glucose intolerance and diabetes ([Anderson et al., 2004](#)).

Research works have agreed that dietary factors are involved in the regulation and prevention of type 2 diabetes. A number of publications came to similar conclusions that cinnamon and its bioactive components act as antioxidants and potentiate insulin action. A summary of recent research works on cinnamon illustrating their bioactive roles in mitigating diseases is shown in [Table 11](#).

## Turmeric

Turmeric (*Curcuma longa*) belongs to the ginger family and is widely grown and used in various parts of the world particularly India, Bangladesh, China, Thailand, Cambodia, Malaysia, Indonesia and the Philippines. It has been used for centuries in India and China for treatments of infection, skin ailments, stress and depression. The main bioactive in turmeric is curcumin, the orange-yellow colored lipophilic polyphenol that is responsible for its antioxidant, anti-inflammatory and anticancer effects. It has been determined that diet will alleviate certain diseases and food is considered as a major potential source of cancer chemopreventive agents, curcumin being one of them (Fig. 7) through the modulation of inflammatory pathways. It has also been shown that at the molecular level, this multi-targeted agent exhibited anti-inflammatory activity through the suppression of numerous cell signaling pathways including NF- $\kappa$ B, STAT3, Nrf2, ROS and COX-2 (Kunnumakkara et al., 2017). The anti-inflammatory and antioxidant effects have been attributed to the hydroxyl and methoxy groups of curcumin (Deogade and Ghate, 2015; Rahman and Biswas, 2009), which includes down-regulating enzymes of inducible synthase (iNOS), cyclo-oxygenase-2 (COX-2), lipoxygenase and xanthine oxidase activity. Furthermore, curcumin has shown its effectiveness by inhibiting inflammatory cell proliferation, metastasis and angiogenesis through various molecular targets (Shehzad et al., 2013). Curcumin has been found

**Table 4** Classification of bioactive compounds

Structural classes	Examples	Spices and herbs sources
<b>Flavonoids</b>		
Flavanols	Quercetin, quercetin-3-O-rutinoside, myricetin, kaempferol, isorhamnetin, gingerol, myricetin, quercetin, kaempferol, nobiletin, scutellarein, sinensetin, tangeretin, isoorientin, orientin	Onion, ginger, Celery, parsley, lemon grass, onion leaves, bird chili, bell pepper, fenugreek seed, peppermint, oregano, rosemary, sage
Flavones	Apigenin, luteolin, chrysin, luteolin, diosmetin	Parsley, thyme
Flavanones	Eriodictyol, hesperetin, naringenin	Cumin, peppermint
Flavan-3-ols	Catechin, epicatechin, procyanidins, gallic acid esters of catechins, epicatechins and gallic acid esters of epicatechins, theaflavins and gallic acid esters of theaflavins, thearubigins	Mint, basil, rosemary, sage, dill
Anthocyanidins and anthocyanins	Cyanidin, delphinidin, petunidin, peonidin, malvidin,	Red onions
<b>Nonflavonoid phenolic compounds</b>	Gallic acid, <i>p</i> -hydroxybenzoic acid, procatechuic acid, vanillic acid, syringic acid, ellagic acid, rosmarinic acid, tannic acid, gallic acid	Cinnamon, clove, anise, dill, fennel, caraway, parsley
Phenolic acids	<i>p</i> -coumaric, caffeic, ferulic, chlorogenic acid, curcuminoids, curcumin	Ginger, cardamon, turmeric
Hydroxycinnammates		
Carotenoids	$\beta$ -Carotene, lycopene, lutein, zeaxanthin	Cayenne pepper, chili pepper
Organosulfides, indoles, glucosinolates/sulfur compounds	Sulphoraphane, allyl methyl trisulfide, diallyl sulfide, indol-3-carbinol, sulforaphane, sinigrin, allicin, alliin, allyl isothiocyanate, piperine	Garlic, onions, leeks, chives, shallots, horseradish, mustard, wasabi, black pepper, mustard green
Terpenes	Pinene, myrcene, linalool, caryophyllene	Parsley, basil, rosemary, thyme, lemon grass, lavender, clove, rosemary, black pepper

**Table 5** Classification of bioactives from spices and herbs and their associated health benefits

Class	Examples	Food source	Health benefit	References
Carotenoids	Pro-vitamin A carotenoids: $\alpha$ -carotene, $\beta$ -carotene, $\beta$ -cryptoxanthin Non-provitamin A carotenoids: lycopene, lutein, zeaxanthin, astaxanthin	Yellow and red peppers	Antioxidant, antioxidants trapping free radicals, source of Vitamin A, enhance functioning of immune system, help reproductive system properly function, antiproliferative, anticancer, prevention of cardiovascular disease, maintains healthy eyes, prevention of colon cancer, prevention of macular degeneration	Rao and Agarwal (2000) Seo et al. (2005) Burri (2000) Delgado-Vargas et al. (2000) Handelman (2001) Krinsky (2001) Wang and Bohn (2012) Ottaway (2008) Scheerens (2001) Watson and Preedy (2012) Young and Lowe (2001)
Polyphenols	Phenolic acids, anthocyanins, flavonols, flavones, flavonoids, flavanones, isoflavones, flavonones, catechin, epicatechin	Spices and herbs	Antioxidant and cardiovascular benefits, lipid-lowering, immunomodulator, anticancer antiestrogen, anti-osteoporotic, antiproliferative, lower risk of heart attack and stroke, anticarcinogenic activity, inhibit atherosclerosis, anti-inflammatory	Scheerens (2001) Manach et al. (2004) Liu (2003) Pan et al. (2009)
Organosuplhur compounds	Allicin., diallyl sulphide, diallyl disulphide, diallyl trisulphide	Garlic, onion, leek, chive, scallion, shallot	Cholesterol lowering, anti-inflammatory, improved liver function, improved immunity, antimicrobial effect	Tapsell et al. (2006) Block et al. (1992) Block et al. (1993a) Block et al. (1993b) Block and Thiruvazhi (1993) Block (1994) Scheerens (2001)

to have positive effect against many diseases such as cancer as it has been determined to suppress transformation, beginning, development and invasion of tumor, angiogenesis and metastasis (Kocaadam and Sanlier, 2017). It has been shown by extensive evaluation and preclinical tests that curcumin is a strong antioxidant and it suppresses activation of NF $\kappa$ B and other molecules that are involved in carcinogenesis (Kocaadam and Sanlier, 2017). Curcumin also prevents cancer cell proliferation and exhibits anticancer potential (Prasad et al., 2017).

**Table 6** Bioactive functions of selected spices and herbs

Spice/Herb	Effect/function
Cayenne pepper	Capsaicin in cayenne pepper has been shown to reduce appetite and increase fat burning (weight management) Help combat lung, liver and prostate cancer
Cinnamon	Potent antioxidant activity Help fight inflammation Lower cholesterol and triglycerides in the blood
Fenugreek	Improve function of insulin Lower blood sugar levels
Garlic	Help combat sickness and cold Reduce cholesterol and LDL Help improve heart health
Ginger	Reduce blood pressure in people who are hypertensive Treat nausea caused by morning and sea sickness, and chemotherapy Strong anti-inflammatory Help pain management
Rosemary	Prevent allergies and nasal congestion Strong antioxidant
Sage	Improve brain function and memory Inhibits breakdown of acetylcholine, a chemical messenger in the brain
Turmeric	Powerful antioxidant and help fight antioxidant damage in the body Strong anti-inflammatory Fight Alzheimer's
Vanilla	Reduce the risk of heart disease and cancer Antioxidant activity Anti-inflammation Potential for lowering blood cholesterol

Curcumin has been found to work synergistically with other bioactives such as resveratrol, piperine, catechins, quercetin and genistein. According to Kunnumakkara et al. (2017), there has been over 100 different completed clinical trials with curcumin, which clearly show its safety, tolerability and its effectiveness against various chronic diseases in humans. Various studies conducted using in vitro, in vivo, and in human intervention trials have indicated that curcumin may be effective in the prevention and

treatment of many diseases through molecular targets, which further elaborate the safety of this natural product (Kocaadam and Sanlier, 2017). Table 12 summarizes the most recent studies on turmeric and curcumin. Goozee et al. (2016) elegantly described the potential clinical value of curcumin and its mechanisms of action in Fig. 8.

## Vanilla

Vanilla is extracted from cured vanilla beans. The vanilla beans come from a climbing, tropical orchid plant that is native to Mexico. There are four main commercial cultivars of vanilla. These are the Bourbon vanilla or Bourbon-Madagascar vanilla that is produced from *Vanilla planifolia* plants in Madagascar, Coromos and Réunion but is also grown in India. Mexican vanilla is extracted from *V. planifolia* in Mexico where vanilla plant originally came from. Tahitian vanilla produced from *Vanilla tahitiensis* comes from French Polynesia and was hypothesized to be a hybrid of *V. planifolia* and *Vanilla odorata* through genetic testing. On the other hand, West Indian vanilla is made from *Vanilla pompona*, which is grown in the Caribbean and Central and South America.

**Table 11** Functions of cinnamon

Function	References
Insulin mimetic properties – bioactives enhance glucose uptake by activating insulin receptor kinase activity, autophosphorylation of the insulin receptor and glycogen synthase activity	Baker et al., 2008 Crawford, 2009 Solomon and Blannin, 2009 Safdar et al., 2004
Methyl hydroxyl chalcone polymer from cinnamon – increased insulin-dependent glucose metabolism by 20-fold in vitro	
Cinnamon polyphenols - decreased oxidative stress and improved fasting glucose	Lu et al., 2012 Hlebowicz et al., 2009 Davis and Yokoyama, 2011 Ziegenfuss et al., 2006 Qin et al., 2010 Akilen et al., 2010 Roussel et al., 2009 Wang et al., 2007 Ziegenfuss et al., 2006 Allen et al., 2013
Aqueous extract significantly improved metabolic syndromes – fasting blood sugar, systolic blood pressure and body composition	
Cinnamon is associated with a statistically significant decrease in levels of fasting plasma glucose, total cholesterol, LDL-C, and triglyceride levels, and an increase in HDL-C levels	
Leaf essential oil from cinnamon (40.24% linalool) – tested in diabetics significantly lowered fasting blood glucose and fructosamine and are concomitant with elevated plasma and pancreatic insulin levels under a fasting condition; appropriate doses linalool chemotype exhibited therapeutic potential in glycemic control in diabetics	Lee et al., 2013
Cinnamaldehyde (CAL), cinnamic acid (CA), and cinnamyl alcohol (CALC) (bioactives of Cinnamomum), aqueous cinnamon extract (ACE) - Pharmacoinformatics studies implicated that ACE and its Bioactives (CAL, CA, and CALC) exhibited comparable activity with that of Trichostatin A (TSA), a well-known anti-cancer agent and histone deacetylase (HDAC) inhibitor; based on both the experimental and computational data that cinnamon bioactives exhibited significant HDAC8 inhibitory activity, thereby suggesting their potential therapeutic implications against cancer. The altered expression of histone deacetylase family member 8 (HDAC8) has been found to be linked with various cancers making its selective inhibition a potential strategy in cancer therapy.	Patil et al., 2017

Bourbon-Madagascar vanilla is the most popular because of its desirable aroma and flavor profile. Vanilla is the one of the most expensive spices, second to saffron, the most expensive spice in the world which is retailing from \$5000 to 10,000 per pound.

Vanilla extracts are rich in polyphenols (Fig. 9), which are also responsible for their pleasing aroma and flavor. In addition to these compounds, vanilla extracts contain more than 200 volatile constituents. Vanilla also contains complex tannins, polyphenol resins, free amino acids and waxes. It is not surprising that vanilla and its components can provide health benefits. Studies show that vanillin, one of the main polyphenols in vanilla extract, is able to inhibit early and advanced glycation modification and amyloid-like aggregation of albumin and thus exhibits protective effect toward its native conformation (Awasthi and Saraswathi, 2016). In another study, Iannuzzi et al. (2017) employed biophysical, biochemical and cell based assays, which showed that vanillin and curcumin similarly affect insulin amyloid aggregation by promoting formation of harmless fibrils and that vanillin restrains AGE formation and protects from AGE-induced cytotoxicity. Iannuzzi et al. (2017) added that their novel findings suggest that the curcumin degradation products (vanillin is one) can also provide health benefits. Vanillin was found to suppress metastasis in a mouse model as well as divanillin, apocynin and diapocynin based on the Transwell invasion assay as reported by Jantaree et al. (2017). In this study the dimeric forms exhibited potency higher than those of vanillin and apocynin in inhibiting invasion. Both monomeric and dimeric forms target regulation of the invasion process by inhibiting phosphorylation of FAK and Akt and the molecular docking studies suggested that the dimers should bind more tightly than vanillin and apocynin to the Y397 pocket of the FAK FERM domain (Jantaree et al., 2017). In another study by Lirdprapamongkol et al. (2009), they examined the antimetastatic potential of vanillin and its structurally related compounds, vanillic acid, vanillyl alcohol, and apocynin on hepatocyte growth factor (HGF)-induced migration of human lung cancer cells by the Transwell assay. They found that vanillin and apocynin could inhibit cell migration, and both compounds selectively inhibited Akt phosphorylation of HGF signaling, without affecting phosphorylation of Met and Erk. In addition, vanillin and apocynin could inhibit the enzymatic activity of phosphoinositide 3-kinase (PI3K), as revealed by an in vitro lipid kinase assay, suggesting that inhibition of PI3K activity was a mechanism underlying the inhibitory effect on cancer cell migration. They also concluded that the presence of an aldehyde or ketone group in the vanillin structure was important for this inhibition and that vanillin and apocynin also inhibited angiogenesis as determined by the chick chorioallantoic membrane assay. Furthermore, Taner et al. (2017) found that vanillic acid exhibited antioxidant activity using the

**Table 12** Functions of turmeric/curcumin

Function	References
Curcumin-free turmeric (CFT) exhibits activity against human HCT-116 color tumor xenograft and has similar in vivo activity to turmeric and curcumin in inhibiting growth promoting proteins and induces apoptosis.	Prasad et al., 2017
The anti-inflammatory activity of curcumin, demethoxycurcumin, bisdemethoxycurcumin was found to be greater than that of eugenol in relation to the COX-2 receptor obtained from silico studies. The findings therefore suggest that the combination of zinc oxide with turmeric liquid extract has a higher anti-inflammatory effect than eugenol as demonstrated by both in vivo and in silico studies.	Meizarini et al., 2018
The tumor volume within the CMG group (curcumin $\beta$ -D-glucuronide or curcumin monoglucuronide) was significantly less than that of the control group and there was no significant loss of body weight which suggest that CMG could be used as an anticancer agent without the serious side effects that most anticancer agents have.	Ozawa H et al. (2017)
Dalton's lymphoma ascites (DLA) cell viability was inhibited by the Curc-Alb conjugate (Conjugation of curcumin, Curc) to albumin, lb) in a dose dependent manner in vitro, as evidenced by the MTT assay. Significant tumor reduction was observed when the Curc-Alb conjugate was administered intraperitoneally in DLA-induced mice after 1 day (prevention therapy) and 7 days (reduction therapy) of tumor induction. There was significant reduction in both tumor volume and tumor cell numbers in the treated animals as well as a marked increase in their mean survival time and percent increase in life span. The effect was greater when the conjugate was administered soon after inducing the tumor as compared to when treatment was started after allowing tumor to grow for 7 days. Results demonstrate that curcumin albumin conjugate has immunomodulatory and tumor growth inhibition properties and has the potential to be used as an anticancer agent in affected human subjects.	Aravind SR and Krishnan LK (2016)
Evaluation of a liquid extract of turmeric roots (TEx) formulated for its in vitro, anticancer activity against several human, colorectal cancer cell lines. TEx had potently inhibited the growth of all human colon cancer cell lines tested in a dose- and time-dependent manner. TEx inhibited the formation of HCT116 spheroids when the cells were incubated with the extract. The extract also disrupted the formation of tubules formed by MDA-MB231 cells grown on Matrigel at concentrations that did not affect the overall viability of the cells, indicating a potent anti-invasive activity.	Dimas et al. (2015)

trolox equivalent antioxidant capacity (TEAC) assay, did not have cytotoxic and genotoxic affects and seemed to decreased DNA damage induced by  $H_2O_2$  in human lymphocytes.

### Extraction of Bioactives From Spices and Herbs

Bioactives can be extracted from spices and herbs in a variety of ways. The extraction methods can be classified in to two: conventional extraction and nonconventional extraction methods. Under the conventional extraction methods are Soxhlet extraction, maceration and hydrodistillation. The Soxhlet method was named after the German chemist Franz Ritter Von Soxhlet who proposed the said extraction technique. This method was originally designed for extraction of lipids but it is being used for a variety of products including in the extraction of bioactives. A small amount of sample is placed in a thimble which is then placed in the extraction chamber and distillation of the solvent is contained in a distillation flask then heating of the solvent starts. As the solvent distills into the thimble, the amount of solvent in direct contact with the plant material increases until it reaches the overflow level and the solvent is aspirated by a siphon action into the distillation flask. This method of extraction ensures intimate contact of the sample matrix with the extraction solvent. The extraction cycle is repeated several times to ensure complete extraction of the bioactives. The rate of cycling of solvent aspiration can be controlled by the solvent heating temperature. After the extraction is completed, the bioactives in the solvent can be used as is or can be concentrated in a rotary evaporator or by using a freeze dryer depending on the type of solvent used in the extraction process. The Soxhlet method is applicable to the extraction of nonvolatile and semivolatile organic compounds with extraction time of 2–18 h.

For the maceration extraction, the plant material is milled or ground into small particles and mixed with the solvent and sealed. At the end of the extraction process, the extract is filtered and the solid residue is pressed to remove all the extract being held by the solid. The extract is sometimes filtered again to completely remove the particulates that will tend to sediment at the bottom of the extract during storage. It is typical for the maceration technique to last from 2 to 5 days.

Hydrodistillation is another traditional method of extraction. There are three types of hydrodistillation: water distillation, water and steam distillation and direct steam distillation. For water distillation, the plant material is packed in a steel container then a measured amount of water is added and this is heated to boiling temperature. In direct steam distillation, steam is used to extract the bioactives by injecting steam directly into the plant material while in water and steam distillation a combination of boiling water and steam are used. Hydrodistillation method cannot be used if the bioactives are heat labile. For these three methods of extraction, the efficiency of the process will depend on the solvent selection. The efficiency of the extraction process is affected by the solvent polarity, affinity of the bioactives to the solvent, mass transfer/diffusion and extraction temperature.

Under the nonconventional extraction methods are: ultrasound-assisted extraction (UAE), microwave assisted extraction (MAE), pulsed-electric field extraction (PEF), enzyme-assisted extraction (EAE), pressurized liquid extraction (PLE), and supercritical fluid extraction (SFE). Ultrasound-assisted extraction uses ultrasound to facilitate extraction by disrupting the cellular material of the plant thereby freeing the bioactives from the cell walls and for the solvent to diffuse easier through the cellular material. The typical

**Table 13** The advantages and disadvantages of greener extraction methods

Method	Advantages	Disadvantages
Microwave-assisted extraction (MAE) (used with traditional methods)	Rapid extraction; small amount of solvent; relatively low additional costs	Use of high pressure and temperature; limited amount of sample; non-selective (large number of compounds extracted)
Supercritical fluid extraction (SFE) methods	Rapid extraction; small amount of organic solvent or no solvent; no solvent residue; preserves thermally labile compounds; tunable solvent (SCF) density; selective extraction (small number of compounds extracted); inexpensive to operate/run	High setup cost; technical knowledge of SCF properties required (e.g., phase behavior, cross-over region)
Mechanical extraction	Mainly for extraction of oil and juice; does not require external heat and solvent	Limited application and non-selective
Ultrasound-assisted extraction (UAE) (used with traditional methods)	Rapid extraction; small amount of solvent; relatively low additional cost	Non-selective

Source: Khaw, et al., 2017. Solvent supercritical fluid technologies to extract bioactive compounds from natural sources: a review. *Molecules* 22, 1186 (Open access article).

sound waves used are from 20 kHz to 100 mHz. The sound waves create compression and expansion that causes the disruption of the cellular components of the plant, in a process called cavitation. Bubbles produced during this process collapse at high level of energy and pressure. The factors that affect the efficiency of the process are particle size of the plant material, nature of the solvent, temperature, pressure, and frequency of sound waves used and the time of extraction.

Microwave energy has been used in several processes including sterilization, pasteurization, thawing and extraction. Microwave-assisted extraction (MAE) has been in use for several years due to the refinement of laboratory, pilot plant and commercial scale equipment. The principle is based on generation of heat through the conversion of electromagnetic energy due to ionic conduction and dipole rotation. From the change in directions of molecules, collision occurs between molecules and these collisions generate heat. The heat created facilitates diffusion of the solvent into the plant matrix and also increases the efficiency of the solvent to dissolve the bioactives. MAE offers several advantages in extraction of bioactives, including quick heating (results in quick extraction) and better yield compared to traditional extraction techniques. In addition, using MAE reduces the amount of solvent employed in the extraction process.

Pulsed-electric field extraction (PEF) uses an electric field to facilitate extraction. When an electric potential passes through the cellular membrane, there is segregation of molecules based on their charge and this brings about repulsion between charged molecules thereby creating pores and weakening of certain locations in the membrane. This increases permeability of the cellular structure that results in more efficient diffusion of the solvent through the cellular material. The efficiency of PEF depends on the field strength employed, specific energy input, pulse number, temperature and the properties of the plant material and solvent used.

Use of enzymes to breakdown the cellular materials of the plant is another novel method of extraction. Plant cellular materials are composed of structural biomolecules such as cellulose, hemicellulose, lignin and pectin which form the structure, bind and strengthen the plant cell wall. In some instances, location of the bioactives is not readily accessible to the solvent. In addition, some of these bioactives are bound to the structural polysaccharides. Employment of enzymes can facilitate the release of the bioactive by breaking down the cell walls through hydrolysis of the polysaccharides and the lipid material. Cellulases,  $\alpha$ -amylase, hemicellulases and pectinase are some of the enzymes used to hydrolyze the cell wall. Various factors affect the efficiency of the process for EAE. These factors are the type of enzyme used, concentration of enzyme, time and temperature employed, pH of the medium, particle size of the plant material and ratio of solid to solvent.

Pressurized liquid extraction (PLE) is another novel technique for the extraction of bioactives in plant materials. The principle is the application of high pressure so that the solvent will remain liquid above its boiling point during the extraction process. Several terminologies are used to describe this extraction technology in addition to PLE: accelerated fluid extraction (ASE), high pressure solvent extraction (HSPE) and enhanced solvent extraction (ESE). Employment of high pressure increases the efficiency of the extraction process. In addition, high temperatures increase the solvency of the analytes, reduces the viscosity of the solvent and increases diffusion and mass transfer.

Supercritical fluid extraction (SFE) is a technique of extraction when the supercritical state of a solvent is employed. Supercritical state is attained when a substance is subjected to temperature and pressure beyond its critical point. At this point, the fluid has different properties and acts like a gas in terms of diffusion, viscosity, surface tension, density and solvation power. Due to these properties, the supercritical fluid is more efficient in extracting substances and in a shorter time. SFE has been successfully employed in commercial extraction of volatile flavor compounds. Carbon dioxide is the ideal solvent for SFE due to its critical temperature of 31 °C and has been used in a variety of supercritical CO<sub>2</sub> extractions. Carbon dioxide is an ideal solvent for hydrophobic substances like lipids and fats but is not as effective for hydrophilic compounds. A modifier is often used to alter the low polarity of carbon dioxide thereby making it a good solvent for specific polar substances. To efficiently extract bioactives using supercritical CO<sub>2</sub> extraction, the following parameters are controlled: temperature, pressure, particle size of the plant material, time of extraction,

**Table 14** Extraction of bioactives from spices and herbs

Spice or herb	Extraction method used	Findings	References
Fresh lemon balm and peppermint leaves	Conventional and ultrasound-assisted extraction (UAE)	A significant increase in bioactives when UAE was used	<a href="#">Sic Zlabur et al. (2016)</a>
Wild garlic ( <i>Allium ursinum</i> )	UAE using response surface methodology	Successfully optimized the extraction process	<a href="#">Tomsik et al. (2016)</a>
Ginger	Conventional extraction, UAE, high pressure homogenization-assisted extraction	UAE gave the highest polyphenol content and antioxidant activities at lower extraction temperature	<a href="#">Gunathilake and Vasantha Ripasinghe (2015)</a>
Coriander	Subcritical water extraction (SWE), hydrodistillation	Extraction efficiency of SWE was higher than hydrodistillation with reduced extraction time	<a href="#">Saim et al. (2008)</a>
Chili pepper compared with tomato by-products	SFE	Extraction process from chili was faster from tomato under identical operating conditions	<a href="#">Venturi et al. (2017)</a>
Clove bud	SFE, steam distillation and MAE	The oil yield was higher in steam distillation and microwave oven extraction but oil extracted by using SFE contained higher amount of eugenol and eugenyl acetate.	<a href="#">Yasdani et al. (2014)</a>
Rosemary	SFE	SFE extracts have higher antioxidant activities than commercial and Soxhlet extracts and dibutyl hydroxytoluene (BHT)	<a href="#">Caldera et al. (2012)</a>
Lavender	Microwave-assisted hydrodistillation and enzyme pretreatment	An increase of 25% in yield in comparison with the classic extraction conditions of conventional hydrodistillation	<a href="#">Calinescu et al. (2014)</a>
Licorice and skullcap	Bifunctional enzyme	The extraction yield of liquiritigenin and isoliquiritigenin aglycones increased 6.51- and 3.55-fold increases, respectively.	<a href="#">Xu et al. (2013)</a>

flow rate of CO<sub>2</sub> and solid to solvent ratio. [Khaw et al. \(2017\)](#) outlined the advantages and disadvantages of some of the extraction methods discussed above in [Table 13](#).

[Table 14](#) summarizes recent techniques applied in the extraction of bioactives from spices and herbs. The nonconventional extraction methods have been successfully applied in bioactive extraction and surpass the traditional extraction methods in terms of quantity and quality of yield. These examples in [Table 14](#) also show that combination processes work well in specific bioactive extraction applications. This strategy is good to explore especially for hard-to-extract bioactive compounds.

### Introduction

“Let food be thy medicine and medicine be thy food” is quoted from Hippocrates (Smith, 2004). Plants and animals of marine and terrestrial origins are considered to be main food resources for humans, of which the marine environment is considered to be one of the best and huge reservoirs. It has been repeatedly reported that marine sources consist of animals and plants, which can be potentially used as foods in our daily life (Kim, 2012; Kim and Taylor, 2011). Macroalgae is one of the class of marine plants that has gained much attention in the recent years for health food supplements used as food ingredients and animal feeds in East Asia. These macroalgae are rich sources of soluble dietary fibers, proteins, peptides, carotenoids, polysaccharides, minerals, and potential metabolites (Yang et al., 2016; Sánchez-Camargo et al., 2016). It has also been suggested elsewhere that metabolites derived from macroalgae have potential biological activities such as antibacterial, antioxidant, anti-inflammatory, antiadipogenic, antidiabetic, anti-HIV, and anti-cancer activities (Yang et al., 2016). Owing to ample of these medicinal properties, the marine macroalgae can be considered as a potential health benefitting medicinal food.

### Phlorotannins

“Phlorotannin” (1,3,5-trihydroxy benzene), is a group of polyphenolic compounds which are commonly present in the brown algae accounting for about 5–12% of the dry mass (Sathya et al., 2017). The development of phlorotannin can occur through polymerization of phloroglucinol oligomers via acetate-malonate (polyketide) pathway (Li et al., 2011a; Sathya et al., 2017). *Eisenia bicyclis*, *Ecklonia cava* and *Ecklonia kurome* are commonly found in Japanese and Korean coastal areas. Phlorotannin content in *Eisenia bicyclis* accounts for 3% of total dry mass of algae. HPLC results suggest that *E. bicyclis* consists of phloroglucinol (0.9%), phloroglucinol tetramer (4.4%), eckol (7.5%), phlorofucofuroeckol A (21.9%), dieckol (23.4%), and 8,8'-bieckol (24.6%), plus some 17.3% of other unknown phenolic compounds (Shibata et al., 2004). However, phlorotannin content in seaweeds can also vary through the individual species, geographic region and extraction techniques (Jégou et al., 2015). Fucodiphlorethol G was isolated from *E. cava* for the first time and acetylated to make different derivatives of the compound (Young et al., 2007).

### Extraction Procedure

Phlorotannins (Fig. 1) are commonly isolated from the seaweeds, particularly brown algae, through conventional organic solvent isolation followed by chromatographic techniques to purify the compounds (Kim et al., 2016; Koivikko et al., 2007; Venkatesan, Kim, & Shim, 2016). Furthermore, nuclear magnetic resonance spectroscopy is widely used to characterize the structure of compounds. Supercritical carbon dioxide has also been used at times to extract the phlorotannins (Saravana et al., 2017; Sánchez-Camargo et al., 2016).

HPLC-HRMS (high resolution mass spectrometer) is the most commonly used method to characterize phlorotannins (Melanson and Mackinnon, 2015). Folin–Ciocalteu assay is a commonly used technique to quantify the phlorotannin content in a given species. Recently, <sup>1</sup>H qNMR was also used to quantify the phlorotannin content in brown algae (Jégou et al., 2015; Parys et al., 2007). Furthermore, Ultra High Performance Liquid Chromatography (UHPLC) has also been employed to study the isomeric complexity between the phlorotannins (Heffernan et al., 2015). Water-Organic solvent mixtures were also used to extract the phlorotannins. The details of step by step extraction procedure and purification were given by Gall et al. (2015). Balboa et al. (2015) developed a biorefinery process for the isolation of phlorotannin in a single method. In this method, conventional solvent extraction with 96% ethanol, supercritical CO<sub>2</sub> extraction method, and membrane microfiltration were used. Tierney et al. (2013, 2014) developed pressurized a liquid extraction method, which was used to extract the polyphenol compounds from Irish macroalgae *Ascomphylum nodosum*, *Pelvetia canaliculata*, *Fucus spiralis* and *Ulva intestinalis* and compared with the traditional solid–liquid extraction techniques in terms of their antioxidant properties. The results suggest that pressurized liquid extraction produces higher phenolic compounds when compared to traditional extraction methods (Tierney et al., 2013, 2014). Two-dimensional liquid chromatography was used to isolate phlorotannin from seaweed (Montero et al., 2014). Centrifugal partition chromatography (CPC) was used to separate the phlorotannins, which were isolated from the ethyl acetate fraction using the solvent system n-hexane:EtOAc:methanol:water (2:7:3:7, v/v). Dieckol (fraction I, 40.2 mg), phlorofucofuroeckol-A (fraction III, 31.1 mg), and

fraction II (34.1 mg) with 2,7-phloroglucinol-6,6-bieckol and pyrogallol-phloroglucinol-6,6-bieckol were isolated from the crude extract (500 mg) by a one-step CPC system (Lee et al., 2014). In another study, a macroporous adsorption resin was used for chromatographic purification of seaweed phlorotannins (Figs. 2 and 3). Four different resins (HP-20, SP-850, XAD-7HP, and XAD-2) were tested, and HP-20 resin showed the highest adsorption and desorption capacities (Kim et al., 2014). Compared to organic solvent extract, the recovery yield of dieckol from the boiling water of *E. cava*, *Ecklonia stolonifera*, *Ecklonia bicyclis* was found to be 86%, 93%, and 98%, respectively (Chowdhury et al., 2014).

Hydrophilic interaction chromatography techniques were used to extract and determine the phlorotannin content in *Eisenia bicyclis*. The yields of the phlorotannins increased 2–4 times in summer (June–October) and then were decreased to normal levels in winter (November–March). In the extraction of *E. bicyclis*, ethanol percentage in water, extraction time and washing time significantly affected the yield of the extract and the phlorotannins, whereas the temperature and the sample/solvent ratio impacted the extraction to a lesser degree (Kim et al., 2013b).

The use of a microwave-assisted extraction (MAE) method for the extraction of phlorotannins from *Saccharina japonica* Aresch has been evaluated with particular emphasis on the influential parameters, including the ethanol concentration, solid/liquid ratio, extraction time, extraction temperature, and microwave power (He et al., 2013). Biosynthesis of phlorotannins has also been explored (Bertoni, 2013). The UHPLC-HRMS method described was successful in rapid profiling of phlorotannins in brown seaweeds based on their degree of polymerisation. HILIC (Hydrophilic interaction chromatography) was demonstrated to be an effective separation mode, particularly for low molecular weight phlorotannins (Steevensz et al., 2012). Mature thalli contained

**Figure 1** Chemical structures of: (1) phloroglucinol; (2) eckol; (3) fucodiphlorethol G; (4) phlorofucofuroeckol A; (5) 7-phloroeckol; (6) dieckol; (7) 6,6'-bieckol; (8) triphlorethol-A; and (9) 2,7'-phloroglucinol-6,6'-bieckol (Venkatesan, Kim, & Shim, 2016).

1.5-fold more dieckol (1.82 mg/g-dry tissue) than young thalli. In the tissues of *E. cava*, blade tissue contained more phlorotannins than the stipe or holdfast. Among differently dried thalli, approximately 90% or more dieckol and phlorofucofuroeckol-A were extracted from shadow-dried tissue as compared with lyophilized tissue (Chowdhury et al., 2011). The 2,4-dimethoxybenzaldehyde (DMBA) assay was developed whereby the chemical specifically reacts with phlorotannins to form a coloured product (Stern et al., 1996). Phlorotannins from different regions and species of North American and Australasian marine herbivores vary significantly in terms of structure and function (Van Altena and Steinberg, 1992). Important and chemically characterised phlorotannins with HPLC and NMR techniques are shown in Figs. 1–3.

### Biological Activities of Phlorotannins

Phlorotannins show promising biological activities such as antioxidant, anti-HIV, antiproliferative, radio protective, antidiabetic, skin protection, and antiallergic activities (Wijesekara et al., 2010) due to their structural properties. Few of them will be discussed here.

**Figure 2** Important structures of phlorotannins isolated from seaweeds, (10) heptaphlorethol, (11) heptafucol, (12) Octaphlorethol A, (13) fucotetraphlorethol A, (14) fucotetraphlorethol J, (15) trifucodiphlorethol A, (16) hexafucol B, and (17) fucotetraphlorethol D (Tierney et al. 2014); (Sánchez-Camargo et al. 2016); (Lee et al. 2016).

**Figure 3** Important structures of phlorotannins from seaweed, (18) Tetrafulcol A, (19) Tetraphlorethol B, (20) Eckol, (21) Fucodiphlorethol, (22) Tetrafulhalol A, (23) Diphoethohydroxycarmalol (24) Tetraisofulhalol, (25) Tetrafulcol A, (26) dioxinodehydroeckol (27) Phlorofucofuroeckol, (28) Phlorofucofuroeckol B (29) Tetrafulcol B (30) 6,8-bieckol, (31) phlorofucofuroeckol A, and (32) 8,8'-bieckol (Lopes *et al.* 2012) (Sugiura *et al.* 2007) (Parys *et al.* 2007) (Lee *et al.* 2012).

### Antimicrobial Activity

The antibacterial activities of phlorotannins have been reported in the literature by several research groups (Shannon and Abu-Ghannam, 2016), and phlorotannins have the ability to bind to the bacterial protein and cause cell lysis. The phenolic group of phlorotannins can bind with the amino group of bacterial proteins (Wang *et al.*, 2009). Eom *et al.* (2012, 2013, 2014) reported the effective ways to overcome methicillin-resistant *Staphylococcus aureus* growth by phlorofucofuroeckol-A, which is derived from *E. bicyclis* marine algae. The phlorotannins suppressed *mecl*, *mecR1*, and *mecA* gene expression in a dose-dependent manner (Eom *et al.*, 2012, 2013, 2014). Lopes *et al.* (2013) reported the antifungal activity of phlorotannins against dermatophytes and

**Figure 4** Effect of purified phlorotannins extracts from *F. spiralis* in the dimorphic transition of *C. albicans* ATCC 10231 (Untreated control cells - A1; cells treated with extract at MIC/32 - B1), in the adherence of the yeast to the epithelial cells (Untreated control cells - A2; cells treated with extract at MIC/32 - B2) and in the germ tube formation (C). The figure was adapted with permission from Lopes et al. (2013).

yeasts. Antimicrobial activity of phlorotannins against Gram positive and Gram negative bacteria was checked and the phlorotannin extracts were found to have excellent antimicrobial inhibition activity (Lopes et al., 2012) as shown in Fig. 4. Recently, marine-derived compounds have shown potential biological activity in terms of antibacterial effects as well (Lee et al., 2016).

### Antioxidant Activity

Food industry often searches for antioxidant molecules to prevent the food from spoilage. Natural derived antioxidants are considered to be safe for human health. Phlorotannins have ability to scavenge the reactive oxygen species (ROS) such as hydroxyl, peroxyl, superoxide radicals (Kirke et al., 2017). In addition to this, phlorotannins can act as total antioxidant with high reducing power activity. DPPH free radical scavenging of *Sargassum aquifolium* species were the highest, corresponding to  $6.770 \pm 0.001$  mg phlorotannin  $\text{g}^{-1}$  dry weight (DW),  $6.1290 \pm 0.0200$  mg ascorbic acid  $\text{g}^{-1}$  DW,  $19.7210 \pm 0.0300$  mg  $\text{FeSO}_4$   $\text{g}^{-1}$  DW and  $76.28 \pm 0.20\%$  of 25  $\mu\text{g}$  DPPH  $\text{mL}^{-1}$  extract (Cuong et al., 2016). It is obvious to say that higher amounts of phlorotannin content show higher antioxidant activity (Charoensiddhi et al., 2014; Wang et al., 2012). The general method to check the antioxidant activity of compound were as follows with the small modifications (Yotsu-Yamashita et al., 2013). First, 5  $\mu\text{L}$  of sample solution were mixed with 95  $\mu\text{L}$  of 1:1 volume of 0.4 M ethanolic solution of DPPH and 100 mM aqueous MES (sodium 2-(N-morpholino)ethanesulfonate) buffer (pH 6.0) for 1 min. Further, the plates were incubated for 30 min at 37 °C and read at 517 nm. The radical scavenging activity of the sample was calculated using the following formula:

$$A_{\text{sample}}/A_{\text{control}} \times 100$$

$A_{\text{sample}}$  is the absorbance of DPPH incubated with test compound;  $A_{\text{control}}$  is the absorbance of DPPH incubated without compound.

The following experiments are the most commonly used assays to measure the radical scavenging activities of the bioactive compounds.

- Ferric reducing/antioxidant power (FRAP) assay (Quéguineur et al., 2013) (Quéguineur et al., 2012)
- DCFH-DA (Dichloro-dihydro-fluorescein diacetate) assay (Yotsu-Yamashita et al., 2013)
- Trolox equivalent antioxidant capacity (TEAC) assay (Audibert et al., 2010)
- Electron spin resonance spectroscopy (Ahn et al., 2007)

The most important antioxidant activities of phenolic compounds and phlorotannins from the brown seaweed have been discussed in a previous review (Balboa et al., 2013). These reviews are also useful to get more information on antioxidant activities of other polysaccharides, proteins, peptides, lipids, terpenoids and steroids (Balboa et al., 2013; Li and Kim, 2011). Trifucodiphlorethol A, trifucotriphlorethol A as well as fucotriphlorethol A can significantly scavenge the ROS with  $\text{IC}_{50}$  range around 10.0–14.4  $\mu\text{g}/\text{mL}$

(Parys et al., 2010). Fig. 1 shows the important phlorotannins, which were isolated from *E. cava*. All the isolated compounds showed promising biological activity in terms of their antioxidant properties (Li et al., 2009).

The phlorotannins from *E. cava*, *E. kurome*, and *E. bicyclis* had significant radical scavenging activities against the superoxide anion (IC<sub>50</sub>: 6.5–8.4 µM) and DPPH (IC<sub>50</sub>: 12–26 µM), which were more effective as compared with ascorbic acid and α-tocopherol (Shibata et al., 2008). In another study, diphlorethohydroxycarmalol was isolated from brown algae, *Ishige okamurae* and antioxidant activity was evaluated as IC<sub>50</sub> value of DPPH to be 3.41 µM and 4.92 µM (Heo et al., 2008). The scavenging activity of the fraction against superoxide anion radicals was estimated to be 1.0 mg/mL (IC<sub>50</sub>), which was approximately five times stronger than that of catechin (Nakai et al., 2006). The IC<sub>50</sub> values of 974-A, 974-B, phlorofucofuroeckol-A, and dieckol were significantly smaller than those of phlorofucofuroeckol-B, phloroglucinol, α-tocopherol, and ascorbic acid (Yotsu-Yamashita et al., 2013).

### Anti-inflammatory Activity

Chronic inflammation is one of the main reasons behind majority of diseases. Several kind of anti-inflammatory drugs are available in the market to treat the inflammatory diseases, but those drugs are often associated with some side effects. Therefore, much attention has been paid to natural marine-based anti-inflammatory compounds (Cheung et al., 2016; Balboa et al., 2012; Shin et al., 2006). Marine-based compounds are unique and have proven to be potentially useful to treat inflammatory diseases. Yang et al. (2016) proposed that the phlorotannin-rich *E. cava* can be used to treat sepsis. Eom et al. (2017) investigated anti-inflammatory effects of eckol on *Propionibacterium acnes* induced human skin keratinocytes (HaCaT) cells. The functions of eckol in production of nitric oxide, matrix metalloproteinase 2 and 9, NO synthase, cyclooxygenase-2 and necrosis factor-α were also studied. Eckol significantly inhibited the expression or formation of proinflammatory mediators and cytokines in HaCaT cells (Eom et al., 2017). In most of the studies, LPS (lipopolysaccharide) was used to induce the inflammation in RAW 264.7 cells. Kang et al. (2015) reported that diphlorethohydroxycarmalol reduced interleukin 6 (IL-6), DPHC (12.5 and 100 µM) and suppressed the phosphorylation and nuclear translocation of NF-kappa (NF κB). In another study, Wijesinghe et al. (2013) reported that phlorotannin-rich fermented *E. cava* by-product extract dose-dependently inhibited nitric oxide production, prostaglandin-E2 production and suppressed inducible nitric oxide synthase and cyclooxygenase-2 expressions in LPS stimulated RAW 264.7 cells. Sugiura et al. (2013) reported the inhibitory effect of histamine release from rat basophile leukaemia (RBL) 2H3 cells. The anti-inflammatory activity potential of the methanolic extract and its fractions from *Eisenia bicyclis* was in the order of dichloromethane > methanol > ethyl acetate > n-butanol (Jung et al., 2013). 6,6'-Bieckol, and phlorofucofuroeckol A also suppressed LPS-induced iNOS, COX2 and PEG2 production and inflammatory cytokine expression in macrophages (Yang et al., 2012; Kim et al., 2009, 2011a).

### Antiproliferative Activity

Phlorotannin derived from *Sargassum muticum* showed antiproliferative effect against HT-29 cells (Montero et al., 2016). Compounds from *E. cava* have shown cytotoxic action against HeLa, HT1080, A549, and HT-29 cells (Li et al., 2011b). In another study, the antiproliferative effect of phlorotannins derived from *Laminaria japonica* was evaluated against hepatocellular carcinoma cells (BEL-7402) and murine P388 leukemic cells (Yang et al., 2010).

### Antitumor Activity

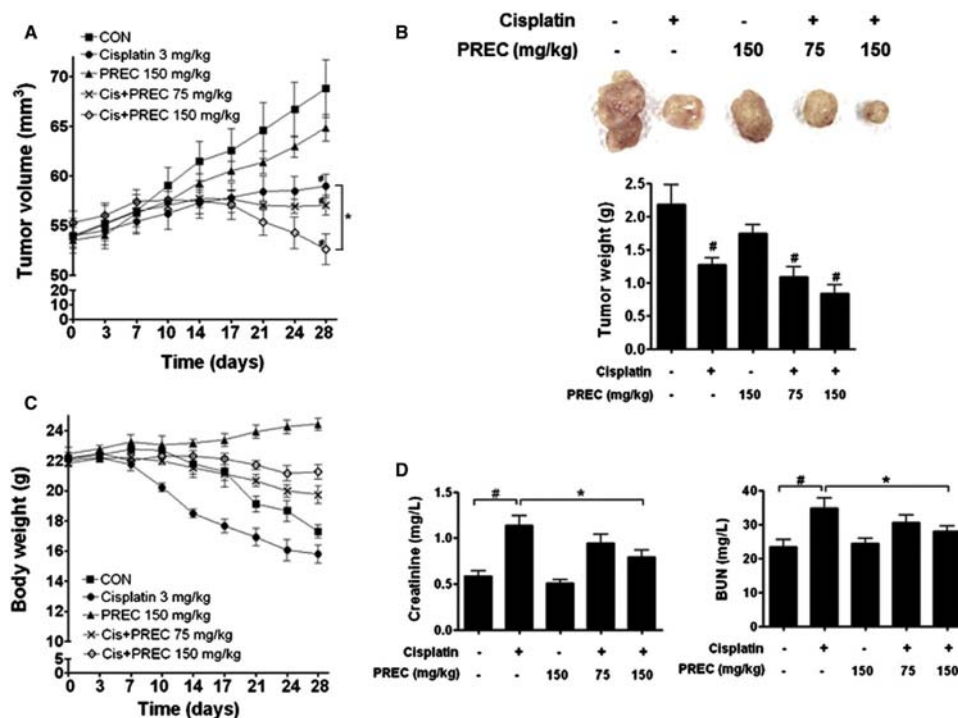

Antitumor effect of phlorotannin-rich extract with cisplatin were checked and results (Fig. 5) suggest that the combination improved the properties of cisplatin due to the synergetic effect (Yang et al., 2015).

Dieckol was isolated from *E. stolonifera* and its anticancer activity was checked against human Hep3B hepatocellular carcinoma cells. The compound has excellent ability to control cancer cell proliferation in a dose-dependent manner. In addition to this, important genes were expressed such as caspases-3, 7, 8 and 9 (Yoon et al., 2013). In another study, phlorotannin eckol suppressed stemness and malignancies in glioma stem-like cells (Hyun et al., 2011).

### Antidiabetics Activity

Diabetes mellitus is a chronic disease and mainly classified as type 1 and type 2. Type 2 diabetes incidence in people has increased considerably throughout the world due to the consumption of high-fat and carbohydrate foods. Even though, several chemically-derived antidiabetic drugs are available to treat diabetes, the problem persists with adverse side effects. Ultimately, there is a need to find effective molecules with less or none side effects. Polyphenol-rich molecules from marine seaweeds show promising effects in treating diabetes mellitus in terms of digestive enzymes, hepatic glucose metabolizing enzymes, lipid peroxidation and lowering the glucose plasma levels (Murugan et al., 2015).

Lee and Jeon (2015) conducted a study on intake of dieckol-rich extract and measured the glycemic parameters, serum biochemistry and hematology. About 80 pre-diabetic male and female adults were randomized and separated into two groups, namely, placebo control and dieckol-rich extract (1500 mg/day). The results showed that dieckol rich extract group decreased in insulin and C-peptide levels in 12 weeks, however there is no significant difference between the groups (Lee and Jeon, 2015). Antidiabetic

**Figure 5** Phlorotannins improve the antitumor activity of cisplatin. SKOV3 xenograft treated three times per week for 4 weeks (A), tumor weight after the experiment has been conducted (B), mouse body weight changes (C), Plasma creatinine and BUN levels were measured using a calorimeter testing kit. The figure was adapted with permission from (Yang et al., 2015).

effect of phlorotannins can follow diverse mechanisms, such as to improve insulin resistance or inhibition of hepatic glucose by stimulating GK (Hepatic glucokinase) activity (Lee and Jeon, 2013). Dieckol isolated from brown seaweed significantly attenuated type II diabetes which was investigated in C57BL/KsJ-db/db mouse model. Dieckol was administered through intraperitoneal route at 10 mg/kg and 20 mg/kg dose for 14 days. The results show that reduced thiobarbituric acid reactive substances (TBARS), as well as increased activities of antioxidant enzymes including SOD, catalase (CAT) and GSH-px in liver tissues were observed in the dieckol administered group (Kang et al., 2013d). Even though the phlorotannins from *E. kurome* showed some amount of toxicity, their consumption might be useful in ameliorating diabetes-related complications (Xu et al., 2012).

Extracts from *Palmaria*, *Ascophyllum* and *Alaria* inhibited  $\alpha$ -amylase activity to some extent, but *Ascophyllum* extracts were very effective with an  $IC_{50}$  of approximately 0.1  $\mu$ g/mL gallic acid equivalent (GAE). The *Ascophyllum* extracts inhibited  $\alpha$ -glucosidase, another key enzyme involved in starch digestion and blood glucose regulation, at low levels, e.g.  $IC_{50}$  of approximately 20  $\mu$ g/mL GAE (Nwosu et al., 2011). It is evidenced that diphlorethohydroxycarmalol (DPHC) has the ability to reduce the effects of  $\alpha$ -glucosidase and  $\alpha$ -amylase. The  $IC_{50}$  values of DPHC against  $\alpha$ -glucosidase and  $\alpha$ -amylase were 0.16 and 0.53 mM, respectively. In addition to this, increased postprandial blood glucose levels were significantly suppressed in the DPHC-administered group than those in the streptozotocin-induced diabetic or normal mice. Moreover, the area under curve (AUC) was significantly reduced via DPHC administration (2022 versus 2210 mmol min/L) in the diabetic mice as well as it delayed the absorption of dietary carbohydrates (Toume et al., 2004; Lee et al., 2012). High glucose (30 mM) treatment induced the death of rat insulinoma cells, but treatment with 10 or 50  $\mu$ g/mL 6,6'-bieckol significantly inhibited the high glucose-induced glucotoxicity. In addition to this, usage of 6,6'-bieckol significantly reduced the level of TBARS, generation of intracellular ROS and NO level, all of which were increased at high glucose concentrations (Park et al., 2015).

### Radio-Protective Effects

Drug-induced toxicity such as ototoxicity from platinum-based compounds and aminoglycosides, often leads to hearing loss and hair loss. This may be caused because of the extensive formation of reactive species. Several small molecules have been used to suppress the reactive oxygen species to prevent further damages (Shin et al., 2014). Some of the compounds from marine resources have also been used such as dieckol and dioxinodehydroeckol (DHE) from *E. cava*. Chang et al. (2016) investigated drug-induced ototoxicity with dieckol in mice model; mice pre-treated with gentamicin were later exposed to dieckol for 48 h. Partial protection of gentamicin induced hair loss was observed after the treatment of dieckol (Chang et al., 2016). DHE has been explored for protective effect against UVB-induced damages in HaCaT cells. The cells were exposed to 20 mJ cm<sup>-2</sup> of UVB irradiation which is the minimal

erythema dose (MED) for individuals to be able to tan. Furthermore, the expression levels of Bax/Bcl-2 and caspase-3, -8, -9, which are the genes associated with apoptosis were investigated when cells were either treated with DHE doses after UVB irradiation or exposed to UVB only. Clear UVB-protective effects were observed in DHE-treated cells (Ryu et al., 2015). In another study, DPHC was used to protect from UVB-induced DNA damages in HaCaT cells (Piao et al., 2015).

Doxorubicin-induced hepatotoxicity was protected with several brown seaweed extracts (Jung et al., 2014b). In another study, Kang et al. (2013c) used zebrafish model to check the protective effect against ethanol-induced damages. Phloroglucinol, eckol and dieckol were used, and dieckol showed highest protective effect against ethanol-induced cell apoptosis. Furthermore, the dieckol-treated group scavenged intracellular ROS and prevented lipid peroxidation and ethanol-induced cell death in the zebrafish embryo (Kang et al., 2013c). From the same group, reports suggest that most of the phlorotannins possess noticeable free radical scavenging activity, which can be potentially useful in diseases concerned with oxidative stress (Kang et al., 2013b). Eckstolonol from *E. cava* showed the protective effective against UVB-induced ROS in human keratinocytes (HaCaTs). Cell viability was decreased by UVB radiation and restored by the treatment with different eckstolonol concentrations (0, 5, 50, 100, and 200  $\mu$ M). Furthermore, eckstolonol reduced UVB-induced ROS, lipid peroxidation, damaged DNA levels, and cell death (Jang et al., 2012). In another study, Heo et al. (2010) showed the UVB-protective effect of DPHC via damaged DNA tail length and morphological changes in fibroblast. Dieckol also showed protective effect from the UVB-induced damages (Heo et al., 2009), and phloroglucinol and eckol showed strong protective effects against gamma irradiated damages (Moon et al., 2008; Kang et al., 2010).

### Antiadipogenic Activity

Obesity is one of the most common health problems, which leads to several diseases such as type 2 diabetics, cardiovascular diseases, and hypertension. Increase in the number of mature adipocytes is the main cause of obesity (Kim et al., 2013a). Some of the phlorotannins have shown inhibitory activity towards adipogenesis and obesity. Kang et al. (2015) investigated the phlorotannin from *E. cava* for inhibitory effect of adipogenesis. The researchers also examined the adipogenic activities by measuring glycerol release level and adipogenic-related gene expression in differentiating 3T3-L1 preadipocytes. The phlorotannin increased glycerol secretion and reduced glucose consumption level in cells. In addition, effects on PPAR $\gamma$ , C/EBP $\alpha$  and differentiation-dependent factor 1/sterol regulatory element-binding protein 1c, as well as downstream genes such as fatty acid binding protein-4, fatty acid transport protein-1, fatty acid synthase, leptin and acyl-CoA synthetase 1 were also studied (Kong et al., 2015). In another study by Karadeniz et al. (2015), it was reported that phlorotannin suppressed adipogenesis in preadipocytes. Triphlorethol-A, eckol and dieckol were checked against the antiadipogenesis activity. Phlorotannin (20  $\mu$ M) reduced lipid accumulation and suppressed the adipogenic differentiation markers (Karadeniz et al., 2015). In another study, dieckol from *E. cava* suppressed lipid accumulation in animal model. Mice were used in the study with normal diet, high-fat diet and dieckol-treated groups. Dieckol-supplemented groups showed significant decreases in body weight gain (36%) when compared with the high-fat diet group. In addition, dieckol downregulated the adipogenic factors and decreased the triacylglycerol content in MT3-L1 cells (Choi et al., 2015).

Phloroglucinol, eckol, dieckol, dioxinodehydroeckol, and phlorofucofuroeckol A from *E. stolonifera* were isolated and checked for their abilities to inhibit adipogenesis over a range of concentrations (12.5–100.0  $\mu$ M). Phloroglucinol, eckol, and phlorofucofuroeckol A significantly and concentration-dependently inhibited lipid accumulation in 3T3-L1 cells without affecting cell viability. All the five compounds reduced the expression levels of several adipocyte marker genes, including PPAR $\gamma$  and CCAAT/enhancer-binding protein  $\alpha$  (C/EBP $\alpha$ ) (Jung et al., 2014a). In another study, dieckol showed adipogenesis inhibition and down-regulated the expression of PPAR $\gamma$ , CCAAT/enhancer-binding proteins (C/EBP $\alpha$ ), sterol regulatory element-binding protein 1 (SREBP1) and fatty acid binding protein 4 (FABP4) in a dose-dependent manner. The specific mechanism mediating the effects of dieckol was confirmed by AMP-activated protein kinase (AMPK) activation (Ko et al., 2013).

### Other Activities

Several other biological activities of phlorotannins have been reported earlier in the literature. These include sleep induction (Cho et al., 2012, 2014b), arousal inhibitory effect (Cho et al., 2014a), SARS-CoV 3CL inhibition (viral replication) (Park et al., 2013), antiviral activity (Kwon et al., 2013), anti-Alzheimer disease (Kang et al., 2013a), inhibitory effect against melanin synthesis (Kang et al., 2012c), neuroprotection (Kang et al., 2012b), hepatoprotection (Kang et al., 2012a; Kim et al., 2011b), osteogenesis (Ali and Hasan, 2012), neuraminidase inhibitory activity (Ryu et al., 2011), and inhibition of high glucose-induced oxidative stress (Lee et al., 2010). Other reported effects include antioxidant (Kim et al., 2010), anti-arthritis (Ryu et al., 2009), hepatocellular carcinoma inhibition (Yoon et al., 2008), inhibition of glycosidase (Shibata et al., 2002, 2003), antiplasma inhibitor (Fukuyama et al., 1989a, 1989b, 1990; Nakayama et al., 1989), carbolytic enzyme inhibition activity (Kellogg et al., 2014), antiallergic activity (Ahn et al., 2015; Sugiura et al., 2006, 2007; Le et al., 2009) and anti-HIV activity (Karadeniz et al., 2014; Ahn et al., 2004; Artan et al., 2008; Vo and Kim, 2010).

## Conclusion

To conclude, the information provided in this chapter point to phlorotannins as excellent materials to treat various diseases at a lower concentration due to their exceptional biological activity. Recently, considerable attention has been paid on natural materials for the development of cosmeceuticals, pharmaceuticals and nutraceuticals. Currently, few companies around the world have been utilizing the extract of phlorotannin for the development of cosmeceutical and nutraceutical products. However, the utilization of seaweed in many countries is not yet well-explored.

## Acknowledgements

The authors thank the Yenepoya Research Centre, and Yenepoya University, Mangalore, Karnataka, India for their support to write this book chapter. IB is thankful to CSIR-CCMB for providing access to intellectual resource materials for compilation of this work.

## Introduction

Gamma-aminobutyric acid (GABA) is a non-proteinogenic amino acid composed of four carbon atoms, which is widely present in bacteria, plants and vertebrates (Diana et al., 2014). GABA has multiple health-promoting properties including acceleration of the synthesis of proteins in the brain, increase of the secretion of growth hormones (Takahara et al., 1977; Tujioka et al., 2007, 2009; Powers et al., 2008; Suwanmanon and Hsieh, 2014), as well as anti-hypertensive, diuretic, anti-diabetic, anticancer, antihypercholesterolemic, and tranquilizer effects (Adeghate and Ponery, 2002; Huang et al., 2013; Roohinejad et al., 2009, 2010; Shimada et al., 2009; Suwanmanon and Hsieh, 2014). Some other studies have revealed the role of GABA as stress and anxiety reducer (Enna and McCarson, 2006; Lydiard, 2003). GABA is biosynthesized from glutamic acid by the irreversible decarboxylation of L-glutamic acid or its salts (Fig. 1). It is involved in the Krebs cycle metabolism when synthesized in plants and bacteria, and as neural signal transmitter in mammalian cells. Some physiological and metabolic processes of GABA were previously reviewed (Shelp et al., 1999). Due to its biological functions, GABA is largely employed in certain countries as a food additive or supplement (e.g. GABA is a GABA-rich chocolate product that has been exclusively commercialized in Japan by Glico Company).

The enzyme catalyzing the biosynthesis of GABA is glutamic acid decarboxylase (GAD; EC 4.1.1.15) (Fig. 1), which has been biochemically characterized (Nomura et al., 1999) and identified in numerous organisms including bacteria (e.g. lactic acid bacteria (LAB) (Bertoldi et al., 1999), *Aspergillus* (Kato et al., 2002), etc.), plants (e.g. tea (Zhao et al., 2011), cowpea (Johnson et al., 1997), etc.), mammalian animal brain (Nathan et al., 1994), and insects (Anthony et al., 1993). In this chapter, the main production processes of GABA will be discussed.

## GABA Production

Multiple GABA synthetic pathways have been proposed during the last decade. Most of them involve lactic acid bacteria (LAB)-producing strains. However, the synthetic pathways of GABA by other microorganisms (e.g., yeasts, other bacterial strains) as well as its production by plants have also been described (Diana et al., 2014). Current development of novel culturing techniques and genetic tools has led to optimize GABA production using microorganisms. These techniques include cell immobilization and co-culturing technologies as well as enhancement of growth conditions by the formulation of modified culture media (Kim et al., 2009a; Li and Cao, 2010; Seok et al., 2008).

## Chemical Synthesis of GABA

Recent efforts have been made for amplifying GABA production using various chemical processes from different bio-based or non-chemical precursors. Pure GABA is isolated as a white microcrystalline powder that melts at about 203.7 °C. Usually, about three or four chemical steps are required to obtain the target amino acid in good yields and sufficient purity. To date, many attempts have been concentrated to reduce the number of steps. Unfortunately, in the literature no real improvement of the process has been reported using organometallic complexes-catalyzed reactions. For example, a Pd/Cu methoxy carbonylation of *N*-propargylphthalimide derivative or a ruthenium complex catalyzed cross-metathesis between 2-propen-1-amine and acrylic acid can afford an unsaturated GABA precursor that needs further noble metal catalyzed reduction of their unsaturated bond in pressurized hydrogen atmosphere to lead to the target amino butyric acid (Ego et al., 1986; Robinson et al., 2014).

Typical chemical synthesis pathway involves the condensation of a 4-halobutyric acid ester on a source of nitrogen such as potassium phthalimide or ammonia aqueous solution. Besides, some results in a recent Chinese patent described the total GABA synthesis after 3 steps using the  $\gamma$ -butyrolactone (GBL) as the starting material (Fig. 2) (Zhiyong et al., 2013).

To access the GABA, GBL is first exposed to thionyl chloride (SOCl<sub>2</sub>) in methanol, amination of the resulted alkyl halide 3 then leads to the amino ester 2, which is generally saponified in presence of sodium hydroxide at room temperature. However, a pH adjustment is necessary to obtain the desired GABA under its dipolar ion, also called zwitterionic form. Interestingly, Talbot et al. (1958) have already reported a shorter pathway leading to GABA synthesis. They claimed that direct condensation of potassium phthalimide on GBL was possible without using a catalyst and gave the carboxylic acid derivative of compound 3. Thus, simple acidic treatment in hot hydrochloric acid of the *N*-protected amino acid afforded water-soluble GABA hydrochloride in solution after removal by filtration of the hydrophobic phthalates.

Instead of the 4-chlorobutyrate derivatives,  $\gamma$ -halobutyronitrile (compound 4 in Fig. 3) could react by the same manner with potassium phthalimide to produce a cyano derivative (compound 6) (Dewitt, 1943). When this compound is stirred in dilute sulfuric acid solution, simultaneously, the phthalimide protecting group is cleaved releasing the free primary amino group, and the cyano function is hydrolyzed into carboxylic acid group. Thus, GABA could be rapidly produced in good yields (Fig. 3).

On the above synthetic scheme, Nordcliffe et al. (2011) developed a strategy to produce GABA in mixture with traces of pyrrolidone, a five-member nitrogen rich heterocycle, starting this time from an alkyl azide derivative (compound 5 in Fig. 3).

**Figure 1** Metabolism and role of GABA. GS/GOGAT, glutamine-synthetase/glutamate-synthase cycle; GDH, glutamate dehydrogenase; GAD, glutamate decarboxylase (GAD); CaM, Ca<sup>2+</sup>-calmodulin complex; GABA-TK,  $\alpha$ -ketoglutarate-dependent GABA transaminase; GABA-TP, pyruvate-dependent GABA transaminase; SSADH, succinic semialdehyde dehydrogenase; TCA, tricarboxylic acid cycle;  $\alpha$ -KGDH,  $\alpha$ -ketoglutarate dehydrogenase; GHB,  $\gamma$ -hydroxybutyric acid; SSR, semialdehyde reductase. Reprinted with permission from Poojary, M.M., Dellarosa, N., Roohinejad, S., Koubaa, M., Tylewicz, T., Gómez-Galindo, F., Saraiva, J.A., Dalla Rosa, M., Barba, F.J., 2017. Influence of innovative processing on  $\gamma$ -aminobutyric acid (GABA) contents in plant food materials. *Compr. Rev. Food Sci. Food Saf.* 16, 895–905.

**Figure 2** Chemical synthesis of GABA from  $\gamma$ -butyrolactone (GBL).

The compound **5** is transformed into its 4-aminobutyronitrile counterparts through a reaction using sodium thiophosphate after 3 h reaction at 90 °C. GABA could then be obtained by further hydrolysis of the nitrile function.

Using shorter molecule; 2-bromopropanoic acid (compound **7** in Fig. 4), the halogen needs to be replaced by cyanide in order to extend the carbon chain (He et al., 2014; Nudelman et al., 2008). Obviously, the hazardous character of the cyanide could limit the industrial exploitation of this process. Only two steps are required and the second one is the reduction of the cyano moiety into primary amine group on platinum oxide in H<sub>2</sub> pressurized atmosphere.

On the other hand, another patent reported direct oxidation of 4-aminobutanol into GABA in presence of sodium periodate (NaIO<sub>4</sub>) and sodium dichromate (Na<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>). Both are strong oxidative agents active in sulfuric acid aqueous solution (Alsters et al., 2001).

As another starting material, ornithine or 2,5-diaminopentanoic acid could be oxidized by osmium (VIII) in association with diperiodatocuprate (III) or diperiodato argentate (III) in alkaline aqueous solution (Abbar et al., 2010; Malode et al., 2010). In this case, the amino acid is subjected to successive oxidative deamination and decarboxylation leading to the production of GABA. Apparently, it seems to be difficult to transfer this reaction on an industrial scale due to the formation of by-products. On the other hand, some other works reported the ring opening reaction of a lactam or other types of heterocycles to get the desired GABA. Bon et al. (1994) started from a *N*-protected butyrolactame or more exactly the *N*-tosylpyrrolidone attacked by amino group of tertibutylamine in presence of 1.3 equivalents of aluminium chloride (AlCl<sub>3</sub>), a Lewis acid. Then, the ring was opened from its amide function and a disubstituted  $\gamma$ -aminobutylamide was formed prior to its protecting groups cleavage in hydrobromic acid phenolic aqueous solution. Compared to recent Chinese articles and patents (Wang et al., 2010; Zhan, 2005; Zhang et al., 2015), the method appeared to be less economical than the direct opening of pyrrolidone ring in refluxing water in alkaline condition (e.g., KOH, Ca(OH)<sub>2</sub>, NaOH, etc) or catalyzed by potassium fluoride (KF) supported on alumina (Al<sub>2</sub>O<sub>3</sub>). Here the cost of GABA production should be strongly correlated to the price of the lactam on the market.

Starting from the commercial 4-hydroxyproline, Hausler (1987) reported the GABA synthesis, but, using a too long synthetic route that need to be improved to become industrially exploitable. Another nitrogen containing heterocycle called glutanamide (compound **10** in Fig. 5) could be used as a promoter to synthesize GABA. According to a patent proposed by Hua and Cai (1995), glutaric anhydride (compound **9** in Fig. 5) is allowed to stir in ammonia aqueous solution forming its useful corresponding imide (compound **10**) derivative, which is oxidized in presence of sodium hypochlorite (NaOCl) in sodium hydroxide aqueous solution. Unfortunately, from a carbon economy point of view, this process is not the greener reaction because of loss of one atom of carbon for each molecule of GABA formed during the opening of the ring.

### Microbial Production of GABA

For the GABA production, chemical synthesis is more and more rejected due to the corrosive reactants used and the health-related issues caused by the presence of toxic chemicals. Therefore, more “greener” methods are currently employed. Nevertheless, recovering GABA from naturally producing microorganisms remains difficult due to the low amounts of GABA accumulated in biological tissues.

**Figure 3** Chemical synthesis of GABA from  $\gamma$ -halobutyronitrile.

**Figure 4** Chemical synthesis of GABA from 2-bromopropanoic acid.

**Figure 5** Chemical synthesis of GABA from glutaric anhydride.

Numerous works have reported the presence of GAD enzyme in LAB cells and their ability to produce high concentrations of GABA. For instance, concentrations from 15 to 63 mg/kg have been reported when culturing LAB (e.g., *Lactobacillus brevis* PM17, *Lactobacillus plantarum* C48, *Lactobacillus paracasei* PF6, *Lactobacillus delbrueckii* sbsp. bulgaricus PR1 and *Lactococcus lactis* PU1) in different media (Siragusa et al., 2007). *L. brevis* strains have been widely investigated for the production of GABA. Park and Oh (2005) and Park and Oh (2007) investigated the production of GABA from the *L. brevis* strains OPY-1 and OPK-3, and found respectively 0.825 g/L and 2.023 g/L. Other strains of *L. brevis*; NCL912 and GABA057 produced respectively 35.66 g/L and 23.40 g/L (Li et al., 2010). In addition, fermentation of black raspberry juice (Kim et al., 2009b) and sea tangle solution (Baejin et al., 2010) using *L. brevis* strains has been reported to produce 27.6 mg/mL and 2.465 mg/L, respectively. Higher concentrations were obtained using other strains of *L. brevis* such as that reported by Yokoyama et al. (2002) producing 1.049 g/L, while, the highest one reported was 76.36 g/L (Huang et al., 2007a, 2007b), which shows the interesting production way of GABA that could be scaled-up. These bacteria were isolated from different sources including kimchi (Cho et al., 2007; Lu et al., 2008; Seok et al., 2008), koumiss (Sun et al., 2009), cheese starter (Nomura et al., 1998), and red seaweed beverage (Ratanaburee et al., 2011). Obviously, obtaining high concentrations of GABA in fermented food is highly correlated to the concentration of glutamic acid and the activity of GAD enzyme.

In addition to LAB, other microorganisms such as filamentous fungi (e.g., *Aspergillus nidulans*, *Aspergillus niger* and *Neurospora crassa*, etc.) have been also reported as producers of GABA (Kubicek et al., 1979; Schmit and Brody, 1975). More recently, production of GABA using *Monascus purpureus* by fermenting rice and nutrient media (Jannoey et al., 2010; Su et al., 2003), as well as using *Rhizopus microsporus* strains by fermenting soybeans (Aoki et al., 2003) has been demonstrated. Some other authors have investigated the isolation of GABA producer microorganisms from marine environment, such as *Pichia* (Guo et al., 2009), *Saccharomyces* (Masuda et al., 2008), and some pseudomonas species (Mountfort and Pybus, 1992).

### Production of GABA by Plants

Producing GABA by plants remains less interesting than that of microorganisms due to the low concentrations accumulated and the unclear mechanisms of production. Many research works have reported that GABA could be accumulated after exposure to stress factors or infection by some fungal species (Solomon and Oliver, 2001). For instance, GABA level was reported to increase 20 to 40 times within 5 min following either a cold shock or mechanical manipulation (Wallace et al., 1984).

Accumulation of GABA was also observed during the developmental stages of plants, their differentiation, and their reproduction (Gallego et al., 1995; Molina-Rueda et al., 2015; Yang, 2003; Roohinejad et al., 2009; Nikmaram et al., 2017). Also, it plays a crucial role in the regulation of pH, where increased levels of  $\text{H}^+$  and  $\text{Ca}^{2+}$  have been reported as GAD enzyme activators (Poojary et al., 2017). Another factor influencing GABA accumulation in plants is culture conditions, which was previously observed during germination of fava beans (Li et al., 2010) and brown rice (Roohinejad et al., 2011; Banchuen et al., 2010; Oh, 2003).

### GABA Extraction and Purification

GABA was mainly extracted and purified from fermented broth cultures, which allows the recovery of higher quantities than that naturally accumulated. For instance, high concentration of GABA ( $997 \pm 51$  mM) was first obtained by fermentation using *L. brevis* NCL912. Sequential recovery steps of GABA including centrifugation, filtration, decoloration, desalination, ion-exchange chromatography (IEC), and crystallization were performed. Using this methodology, the authors were successful to reach approx. 50% recovery yield. The purity of the extract was  $98.66 \pm 2.36\%$ , determined using thin-layer chromatography (TLC) and high-pressure liquid chromatography (HPLC) (Li et al., 2011).

In another work, GABA was produced by fermentation of defatted rice bran extract using *L. brevis* VTTC-B-454 (Tuan et al., 2017). Rice bran, used as substrate in this study, contains high concentrations of nutrient compounds, including glutamic acid that could be converted into GABA using LAB. After fermentation, GABA was purified using cation exchange resin. Results showed that a GABA recovery yield of 84.2% with a purity of 44% was obtained using an eluent with a pH of 6.5 and a concentration of 0.8 M NaCl. The authors concluded about the feasibility of using cation exchange resin for GABA purification from fermentation broth.

In another recent work, GABA was produced by fermentation using *Enterococcus raffinosus* TCCC11660 strain, and then separated and purified by flocculation and chromatographic methodologies (Gao et al., 2013). GABA concentration in the fermentation broth was 31.2 g/L. A flocculation step was first performed using chitosan and sodium alginate in order to remove the impurities. Following this pre-treatment, ultrafiltration followed by two discontinuous diafiltration steps was used in order to remove macromolecules. The resulting permeate was then loaded into DA201-CII resin for further decoloration. GABA was finally purified

using ion exchange chromatography with Amberlite 200C resin. GABA crystals with high purity (99.1%) were then obtained by precipitation using ethanol. The authors concluded that their approach is promising for possible scaling-up of GABA extraction and purification from fermentation broth.

When GABA content is relatively low in human diet, its intake via GABA-enriched foods is required (Oh et al., 2003). Numerous GABA-enriched products are currently commercialized including fermented dairy products (Hayakawa et al., 2004), soy sauces (Yamakoshi et al., 2007), cheeses (Siragusa et al., 2007), and many others, which were very well reviewed recently (Diana et al., 2014). Some of the health-related benefits of GABA-enriched foods have been reported in the literature, which were either tested on human or animals. For instance, antihypertensive effects and other benefits have been demonstrated either on animals or humans following the administration of GABA enriched foods such as fermented milk, soymilk drink, soy sauce, green tea, purple sweet potato fermented milk, cheese, fermented vinegar, etc (Hayakawa et al., 2004; Inoue et al., 2003; Joye et al., 2011; Liu et al., 2011; Shizuka et al., 2004).

## Conclusion

Several GABA synthetic pathways have been reported during the last decade. GABA has been synthesized from different materials such as  $\gamma$ -butyrolactone (GBL),  $\gamma$ -halobutyronitrile, 2-bromopropanoic acid, and glutaric anhydride. However, chemical synthesis of GABA has been rejected due to the corrosive reactants used and the health-related issues caused by the presence of toxic chemicals. Thus, more “greener” methods such as GABA production using microorganisms or in plants have been suggested. GABA produced by these methods needs to be extracted and purified to allow recovery of higher quantities than that naturally accumulated. However, numerous health-promoting GABA-enriched foods have been produced and commercialized, especially fermented products, which are used to supplement the low GABA content in human diets. Although these achievements in GABA production and food use have been demonstrated, further research works need to be conducted to better understand the mechanisms involved in enhancing the accumulation of GABA in plants or its production by microorganisms.

### Introduction

Phenolic acids belong to a highly diversified group of phytochemicals, phenolics which are found in all foods of plant origin in the human diet. Phenolics are secondary metabolites composed of an aromatic ring bearing one or more hydroxyl substituents together with a number of other side groups (Shahidi and Yeo, 2016; Shahidi and Nazck, 2004). Phenolic compounds most widely occurring in plants include phenolic acids, flavonoids, coumarins, stilbenes, tannins, lignans and lignins (Nazck and Shahidi, 2006).

Phenolics are synthesized as first line of defense chemical compounds against biotic (infections, wounding) and abiotic (nutrient deficiencies or excess, cold and visible light) stresses of plants (Beckman, 2000; Beggs et al., 1987; Christie et al., 1991; Graham, 1991; Hahlbrock and Scheel, 1989). In addition, phenolics contribute to different attributes of foods such as bitterness, astringency, color, flavor, odour and stability against lipid oxidation (Shahidi and Nazck, 2004). Phenolic acids possess a myriad of health benefits such as anti-inflammatory, antibacterial, antiproliferative, anticarcinogenic and antioxidative activities (Ambriz-Pérez et al., 2016; Cheng et al., 2007). *In vivo* and epidemiological studies suggest that phenolic compounds through their antioxidant properties may exert health benefits thus ameliorating chronic diseases associated with oxidative damage (Arts and Hollman, 2005; Kennedy, 2014; Kris-Etherton et al., 2002; Slavin, 2003). Dietary phenolics exert their health benefits by various biological activities such as free radical scavenging, metal chelation, reducing potential, chain breaking, and modulation of enzymatic activity as well as alteration of signal transduction pathways (Cheng et al., 2007; Rice-Evans et al., 1996; Reiners et al., 1999).

In general, the phenolic profile of a plant food is species specific (Mekeehen et al., 1999). However, the level of individual phenolic compounds available in a given species of plant material depends on a number of factors such as cultivar, environmental conditions, cultural, and postharvest practices, as well as processing and storage conditions (Abdel-Aal and Hucl, 1999; Chethan and Malleshi, 2007; Chandrasekara and Shahidi, 2011a; Kumari et al., 2017; Levakova and Lacko-bartošová, 2017; Li and Zhang, 2001; Rao and Muralikrishna, 2002; Siebenhandl et al., 2007; Yang et al., 2001; Yu et al., 2002; Zhou et al., 2004).

This review discusses phenolic acids and their derivatives for potential *in vitro* and *in vivo* bioactivities. Food sources of phenolic acids are reviewed first, followed by discussion of the extraction methods of different forms of phenolic acids from food materials. *In vitro* antioxidant activities and structural significance of compounds of interest are discussed. Finally, *in vivo* studies on the bioactivities of phenolic acids are presented.

### Chemistry and Overview of Phenolic Acids

Two classes of phenolic acids based on C1–C6 and C3–C6 backbones are hydroxybenzoic acids and hydroxycinnamic acids, which are ubiquitously found in plant materials at varying levels (Shahidi and Nazck, 2004). Hydroxybenzoic acids include gallic, *p*-hydroxybenzoic, vanillic, syringic, and protocatechuic acids (Fig. 1). The hydroxycinnamic acids commonly found in foods and beverages are *p*-coumaric, caffeic, ferulic, sinapic and cinnamic acids (Fig. 2).

Phenolic compounds are derived from a limited pool of biosynthetic precursors such as pyruvate, acetate, a few amino acids, acetyl CoA and malonyl CoA via the action of pentose phosphate, shikimate, and phenylpropanoid metabolism pathways (Robards et al., 1999; Randhir et al., 2004). Two main amino acids involved in the synthesis of phenolics in plants include phenylalanine and to a lesser extent tyrosine (Shahidi, 2002; Herrmann, 1989).

Phenolics which are extractable into aqueous or aqueous - organic solvent mixtures are generally referred to as soluble phenolics and these includes phenolic compounds existing in the free, non-conjugated form as well as phenolic compounds conjugated to soluble carbohydrates by ester (esterified) and ether (etherified) bonds (Fig. 3; Shahidi and Yeo, 2016; Shahidi and Nazck, 2004). Furthermore, the left over residue after extraction of the soluble phenolics can be used to obtain insoluble bound phenolic compounds, especially hydroxycinnamic acids which are mainly esterified to the sugar residues of polysaccharides providing cross-linking between cell wall polymers (Ishii and Hiroi, 1990). They also form ether bonds and C–C linkages with lignins (Grabber et al., 2000). Some studies have shown that conjugated and insoluble bound phenolics may be released at the variable alkaline and acidic gastro-intestinal conditions and under colonic fermentation and may impart health benefits even at the local sites such as intestinal epithelium and beyond after absorption (Andreassen et al., 2001a; Chandrasekara and Shahidi, 2012).

Cereals contain mainly free and conjugated forms of phenolic acids, which include derivatives of hydroxybenzoic and hydroxycinnamic acids (Chandrasekara and Shahidi, 2011a). The occurrence of phenolic acids in different food groups is presented in Table 1.

### Extraction and Analysis of Phenolic Acids

The identification of phenolic acids depends on the ability to isolate them from plant tissues. In general, the structural diversity of the phenolic compounds makes the analysis difficult and complicated. Several phenolic compounds are easily hydrolyzed, oxidized

Food source	Phenolic acids and derivatives	References
<b>Cereals</b>		
Barley	ferulic, <i>p</i> -coumaric, caffeic, chlorogenic acids, 8- <i>O</i> -4 diFA, 5-5 diFA, 8-5 diFA (benzofuran) 8-5 diFA	Yan et al. (2001); Hernanz et al. (2001)
Corn	ferulic, <i>p</i> -coumaric, 8-5 diFA, 8-8 diFA (cyclic), 8- <i>O</i> -4 diFA,	Bunzel et al. (2008)
Rice	ferulic, <i>p</i> -coumaric, caffeic acids, 5-5 diFA, 5-8 diFA (benzofuran form), 8-5 diFA, 8-8 diFA, 8- <i>O</i> -4 diFA, 4- <i>O</i> -5 diFA, 6'- <i>O</i> -( <i>E</i> )-feruloylsucrose,	Bunzel et al. (2000, 2002); Zhou et al. (2004); Tian et al. (2004)
Rye	ferulic, caffeic, <i>p</i> -coumaric, sinapic acids, 8- <i>O</i> -4 diFA	Weidner et al. (1999); Zielinski et al. (2001); Andreassen et al. (2001a); Amarowicz and Weidner (2001)
Wheat	ferulic, caffeic, <i>p</i> -coumaric, sinapic acids, campestanil, sitostanyl (steryl ferulates), 8-8 diFA (cyclic), 5-8 diFA, 5-5 diFA, 8- <i>O</i> -4 diFA, 8-5 diFA (benzofuran)	Sosulski et al. (1982); Hakala et al. (2002); Parker et al. (2005); Liyana-Pathirana and Shahidi (2005, 2006); Liyana-Pathirana et al. (2006)
Millet	ferulic, caffeic, <i>p</i> -coumaric, sinapic Gallic, <i>p</i> -hydroxybenzoic, protocatechuic, syringic, gentisic, vanillic acids	Rao and Muralikrishna, 2001, 2002, 2004; Chethan and Malleshi, 2007; Shobana et al., 2009; Vishwanath et al., 2009; Chandrasekara and Shahidi, 2011b
<b>Vegetables</b>		
Celery	caffeic, <i>p</i> -coumaric, ferulic, chlorogenic acids	Viña and Chaves (2007)
Lettuce	caffeoyl tartaric, chlorogenic, dicaffeoyl tartaric, isochlorogenic acids	Cantos et al. (2001)
Tomato	chlorogenic, caffeic, <i>p</i> -coumaric, ferulic acids	Martinez-Valverde et al. (2002)
<b>Oilseeds</b>		
Flax	<i>p</i> -coumaric, ferulic, caffeic acids	Kazimierz et al. (1984)
Mustard	<i>p</i> -coumaric, ferulic, caffeic, sinapic ( <i>trans</i> and <i>cis</i> ) acids	Kazimierz et al. (1984)
Rapeseed	ferulic, sinapic ( <i>trans</i> and <i>cis</i> ) acids, sinapine	Nazck and Shahidi (2006), Kazimierz et al. (1984), Larsen et al. (1983)
Safflower	<i>p</i> -coumaric, ferulic, caffeic acids	Kazimierz et al. (1984)
Sunflower	<i>p</i> -coumaric, ferulic, caffeic, chlorogenic acids	Kazimierz et al. (1984)
<b>Legumes</b>		
Beans (including soybeans)	ferulic, <i>p</i> -coumaric, sinapic, caffeic, chlorogenic; gallic, protocatechuic, vanillic, syringic, acids	Xu and Chang (2008); Garcia et al. (1998); Dabrowski and Sosulski (1984); Espinosa-Alonso et al. (2006); Diaz-Batalla et al. (2006); Luthria and Pastor-Corrales (2006); Ranilla et al. (2007)
Peas	caffeic, <i>p</i> -coumaric ( <i>trans</i> and <i>cis</i> ), ferulic, cinnamic, <i>trans p</i> -coumaroylmalic, <i>trans</i> feruloyl-malic acids	Cai et al. (2003); Duenas et al. (2004)
<b>Fruits</b>		
Apple	chlorogenic acids	Duda-Chodak et al., 2011; McGhie et al. (2005); Guyot et al. (1998)
Mangoes	Chlorogenic, gallic, vanillic, protocatechuic acids	Palafox-Carlos et al. (2012)
Grapes	<i>trans</i> -caftaric acid, <i>p</i> -coumaric ( <i>trans</i> and <i>cis</i> ) acids, gallic, protocatechuic, vanillic and syringic	Baderschneider and Winterhalter, 2001; Lu and Foo (1999)
Blackberries	gallic, caffeic, ferulic, <i>p</i> -coumaric, and ellagic	Hager et al. (2008)
Pears	chlorogenic, <i>p</i> -coumaroylquinic, <i>p</i> -coumaroylmalic, and dicaffeoylquinic acids	Simirgiotis et al. (2016); Schieber et al. (2001)

and subjected to isomerization (Jeandet et al., 1997), thus precautionary steps should be taken during sample handling to assure the integrity of the analyte (Montedoro et al., 1992a,b).

Sample preparation vary from a simple to a very complicated process depending on the nature and particle size of the food material, chemical nature of phenolic compounds, storage time and conditions and presence of substances that interfere with the isolation process (Nazck and Shahidi, 2006). Cereals, legumes, oilseeds, nuts, dried fruits and vegetables are ground to generate a powder of a defined particle size followed by defatting with an organic solvent such as hexane (Chandrasekara et al., 2016; Chandrasekara and Shahidi, 2011a,c; Liyana-Pathirana, and Shahidi, 2006; Madhujith and Shahidi, 2006a,b). Phenolic extracts obtained from the plant materials are a mixture of different classes of compounds, which are soluble in the solvent used (Nazck and Shahidi, 2006). Methods of extraction vary depending on the location of phenolic compounds as well as their occurrence as free, conjugated or bound compounds.

Solid-liquid extraction of free and soluble esters of phenolic acids is done with water as well as absolute and aqueous organic solvents. Different solvents are used such as hot water, methanol, ethanol, acetone, methanol-ammonia-water and ethyl acetate (Table 2). Reported extraction times vary with the technique, which include soxhlet extraction (Sun et al., 2001), vortexing followed by centrifugation (Montedoro et al., 1992a,b), ultrasound-assisted extraction (Chandrasekara and Shahidi, 2010), mechanical

stirring by homogenization (Chandrasekara et al., 2016; Krygier et al., 1982a,b), continuous rotary extraction (Guillen et al., 1996a,b), pressurized liquid extraction (Bonoli et al., 2004) and microwave-assisted extraction (Beejmohun et al., 2007; Pomponio et al., 2002) (Table 2). Ultrasound extraction is considered as an alternative method to classical extraction methods of phenolic compounds due to its high efficiency, low energy and water consumption (Wang et al., 2008). Ultrasound waves contribute to the disruption of the cell walls and reduction of the particle size. Furthermore, they enhance the mass transfer of the cell contents into the solvent through collapse of the bubbles produced by cavitation (Paniwnyk et al., 2001). Phenolic compounds released could vary with the extraction techniques used (Chandrasekara et al., 2016) (Table 3).

Insoluble residue left is separated by centrifugation or filtration. The extraction of phenolic compounds is influenced by ratio of solvent-to-sample (Nazck and Shahidi, 2006). Bound phenolic compounds are released by alkali, acid or enzymatic treatment (Table 4). Many studies have reported the use of alkaline hydrolysis which can be a rapid hydrolysis (from 1 to 4–6 h) or long hydrolysis, when the digestion time is more than 16 h (de Camargo et al., 2016; Sosulski et al., 1982; Maillard and Berset, 1995; Sun et al., 2001; Hernanz et al., 2001; Bonoli et al., 2004). A number of investigators have allowed alkaline hydrolysis reactions to occur at room temperature (Tian et al., 2004). Some studies were carried out in the dark and under inert atmosphere such as argon or nitrogen to minimize the isomerization of compounds such phenolic acids and other compounds (Kazimierz et al., 1984). Few studies have used acid hydrolysis for the recovery of bound phenolics (Bonoli et al., 2004).

Enzymatic reactions have been used to release bound phenolic acids. Enzymes such as amylases, pectinases and cellulases have been employed for the degradation of carbohydrate linkages (Yan et al., 2001; Zhou et al., 2004). Upon enzymatic hydrolysis, the phenolic acids are released by cleavage of an acetal or hemiacetal bond between carbohydrate moieties and the hydroxyl groups on the aromatic rings (Robbins, 2003).

Food	Method	Description	References
Barley	Acid hydrolysis	With 0.2 N H <sub>2</sub> SO <sub>4</sub> heated for 1 h in a boiling water bath. Reaction terminated by cooling in an ice-water bath for 10 min	Yan et al., 2001
Barley, rice	$\alpha$ -amylase hydrolysis	Samples were first acid hydrolyzed and then added 2% (w/v) $\alpha$ -amylase prepared in 2.5 M aqueous sodium acetate. Incubated for 1 h at 30 °C.	Zhou et al., 2004; Yan et al., 2001
Barley	Cellulase hydrolysis	First samples were hydrolyzed with acids and then with $\alpha$ -amylase. Then samples were added 2% (w/v) cellulase prepared in 0.1 M aqueous sodium acetate. Incubated for 10 h at 30 °C.	Yan et al., 2001
Oat, wheat, rye, barley, buckwheat, corn	Alkaline hydrolysis and acid hydrolysis	10 M NaOH stirred 16 h at 20 °C then conc. HCl 85° C for 30 min.	Mattila and Kumpulainen, 2002
Finger millet	Alkaline hydrolysis	Fat and free phenolics free dried samples were added 1 M NaOH containing 0.5% sodium borohydride under N gas	Rao and Muralikrishna, 2002
Barley	Alkaline hydrolysis	2 M NaOH at RT, shaken under N gas for two periods at 4th h and 20th h	Bonoli et al., 2004
Barley	Soft –acid hydrolysis	96% EtOH and 25% HCl at 65 °C for 30 min	Bonoli et al., 2004
Lentils	Acid hydrolysis	1 N HCl heated for 10 min in a steam bath	Sosulski and Dabrowski, 1984; Duenas et al., 2004

RT, room temperature; EtOH, ethanol.

After the extraction of phenolic compounds, the determination of their content may be carried out by spectrophotometric analysis (SA), high performance liquid chromatography (HPLC), or gas chromatography (GC). GC and HPLC techniques are widely used for both separation and quantification of phenolic compounds (Nazck and Shahidi, 2006).

HPLC is frequently used for the analysis of phenolic compounds. Examples for different procedures and detectors used for the analysis of food materials are given in Table 4. HPLC coupled with mass spectrometry, <sup>1</sup>H and <sup>13</sup>C nuclear magnetic resonance spectrometry or infrared spectroscopy are used to identify structural characters of phenolic compounds (Beninger and Hosfield, 2003; Gujer et al., 1986; Kruger et al., 2003; Wu and Prior, 2005).

### Mechanism of Action *In Vitro* and *In Vivo*

Protective activities of phenolic compounds are due to three main different mechanisms, namely hydrogen atom transfer (HAT), electro transfer-proton transfer (ETPT) and sequential proton loss-electron transfer (SPLET) (Ajitha et al., 2012; Wright et al., 2001; Fiorucci et al., 2007; Litwinienko and Ingold, 2007; Tishchenko et al., 2008; Leopoldini et al., 2011). In the process of free radical scavenging, phenolic acids produce phenolic radicals and they can be stabilized by establishing intra-molecular hydrogen bonds and extending delocalization and conjugation of the electrons enhanced by resonance stabilization (Chen et al., 2015). Phenolic acids are absorbed when they are in free form and bound phenolic acids can be released in the body. Ferulic acid can be absorbed from rat stomach in its free form and is likely to be metabolized into conjugated ferulic acid in the liver (Zhao

**Table 4** Examples of HPLC procedures for determination of phenolic acids in cereals and legumes

TFA, Trifluoroacetic acid; EtOH, ethanol; MeOH, methanol.

et al., 2004). In addition, excretion of ferulic acid in its sulphate and glucuronide forms in human subjects has been observed, thus suggesting its absorption and metabolism in the body (Virgili et al., 2000). Bound phenolic acids, especially hydroxycinnamates such as ferulic and *p*-coumaric acids in cereal grains are linked via an ester bond to the arabinoxylans in the plant cell wall (Boz, 2015). It has been reported that gastrointestinal esterase from intestinal mucosa and microflora (both human and rat) can release ferulic and diferulic acids from cereal bran (Andreasen et al., 2001b).

### ***In Vitro* Antioxidant Activities of Hydroxycinnamates**

Ferulic acid has been shown to be an effective antioxidant in several *in vitro* assays. It is also approved in some countries as an additive to prevent oxidation in foods (Graf, 1992; Itagaki et al., 2009). Ferulic acid has demonstrated *in vitro* free radical scavenging properties against hydroxyl radical, peroxynitrite and LDL oxidation (Yu et al., 1999; Kanski et al., 2002; Kikuzaki et al., 2002; Ogiwara et al., 2002). Kampa et al. (2004) showed time and dose-dependent inhibitory effects of caffeic acid, syringic acid, sinapic acid, protocatechuic acid, ferulic acid and 3,4-dihydroxy-phenylacetic acid (PAA) on growth of T47D human breast cancer cells. However, the antioxidative activity of these phenolic acids in T47D cells does not coincide with their inhibitory effect on tumoral proliferation suggesting a direct effect on anti-proliferation.

Caffeic acid and some of its derivatives, namely caffeic acid phenethyl ester (CAPE), rosmarinic acid, chlorogenic acid, and caffeic acid have shown potent antioxidant properties (Sudina et al., 1993; Kikuzaki et al., 2002; Gulcin, 2006). Caffeic acid has the ability of scavenging several reactive species, such as DPPH (Silva et al., 2000; Kikuzaki et al., 2002; Gulcin, 2006), peroxyl (Castelluccio et al., 1995), hydroxyl (Kono et al., 1997), superoxide radical anion (Sudina et al., 1993; Gulcin, 2006), peroxynitrite (Pannala et al., 1998), and singlet oxygen (Foley et al., 1999). Furthermore, caffeic acid demonstrated antimutagenic activity against nitrosamines (Kono et al., 1997; Nardini et al., 2001; Tapiero et al., 2002) and anti-inflammatory activity against 5- and 12-lipoxygenase (Koshihara et al., 1984; Sudina et al., 1993). Among several hydroxycinnamates, chlorogenic, and caffeic acids reported higher antioxidant activity than ferulic and *p*-coumaric acids in peroxidation of lipid systems mediated by metmyoglobin (Castelluccio et al., 1995).

A higher radical scavenging activity of chlorogenic and caffeic acids compared to *p*-coumaric can be explained by the arrangement of substituents in the molecule to favour the reactions with free radicals. In ferulic acid, the hydroxyl group at the third position of the benzene ring is methoxylated, which decreases the scavenging activity, compared to caffeic acid in which hydroxylation occurs in place of methoxylation. However, ferulic acid is more effective than *p*-coumaric acid due to its electron-donating methoxy group, which facilitates increased stabilization of the resulting phenoxyl radical following hydrogen donation by the hydroxyl group (Castelluccio et al., 1995).

Hydroxyl groups contribute to the antioxidant activity of phenolic acids and the number available for activity determines their potency as an effective antioxidant. Caffeic acid contains two hydroxyl groups whereas rosmarinic acid contains four hydroxyl groups and show high antioxidative efficiency (Chen and Ho, 1997). However, esterification of caffeic acid by a sugar moiety decreases its antioxidant activity (Cuvelier et al., 1992). This has been demonstrated using DPPH radical scavenging activity, and oxidation inhibition in an oil-in-water emulsion system (Chen and Ho, 1997).

Caffeic acid inhibit LDL oxidation (Nardini et al., 1995; Meyer et al., 1998; Wang and Goodman, 1999; Cartron et al., 2001). At a concentration of 7.5  $\mu$ M, caffeic acid showed 97.5% inhibition of copper-catalyzed human LDL oxidation (Meyer et al., 1998). Cheng et al. (2007) showed that caffeic acid and chlorogenic acid showed equally high antioxidant activities by inhibiting AAPH and copper-catalyzed human LDL peroxidation. Furthermore, they found that each molecule of caffeic and chlorogenic acid may trap about two peroxyl radicals, thus more active as antioxidants than other hydroxycinnamates such as sinapic, ferulic and *p*-coumaric acids.

Chlorogenic acid and caffeic acid have been shown to scavenge nitrogen sesquioxide (Kono et al., 1995a), organic free radicals, hypochlorous (Kono et al., 1995b), superoxide, hydroxyl radicals and peroxynitrite (Kono et al., 1997) as well as peroxyl radicals (Laranjinha et al., 1994; Kono et al., 1997) effectively *in vitro*; DNA is sensitive to peroxynitrite-mediated oxidative damage. Grace et al. (1998) showed that chlorogenic acid inhibited the formation of single strand breaks in supercoiled pBR322 DNA by acting as a peroxynitrite scavenger.

Caffeic acid had showed greater activity than ferulic acid in inhibiting the formation of N-nitroso compounds in simulated gastric fluid (Kuenzig et al., 1984). Bakalbassis et al. (2001) showed that the calculated heat of formation value in radical formation could be used to describe antioxidant activity of caffeic, ferulic, *p*-coumaric and sinapic acids. In accordance with experimental data, caffeic acid showed lower difference in the heat of formation of its phenoxyl radical, which could be raised from the less energy demanding hydrogen atom abstraction (Bakalbassis et al., 2001). This explained the high antioxidant activity of caffeic acid in DPPH radical scavenging system among other tested hydroxycinnamates such as sinapic, ferulic and *p*-coumaric acids (Bakalbassis et al., 2001).

### ***In Vivo* Bioactivities of Phenolic Acids and Derivatives**

Oxidative stress is known to involve in a number of non-communicable chronic diseases and neurodegenerative disorders. Antioxidants scavenge free radicals and reduce the incidence of oxidative stress-provoked damage, in addition to maintain cellular redox

balance (Chauhan and Chauhan, 2006; Di et al., 2012). Itagaki et al. (2009) demonstrated protective effects of ferulic acid on ischaemia-reperfusion (IR) associated intestinal injury using a rat model. The amount of lipid peroxide after IR was significantly reduced by treatment with ferulic acid (Itagaki et al., 2009). Elevated vascular permeability is one of the indicators of IR injury (Pompermayer et al., 2007) and ferulic acid prevented the elevation of vascular permeability following IR injury in the intestine. This could be due to the possible chain breaking activity ferulic acid that plays a protective role in oxidative injury.

Neuroprotective efficacy of vanillic acid against  $\beta$ -amyloid<sub>1-42</sub> peptide-induced oxidative stress, neuroinflammation and cognitive impairment was demonstrated using an *in vivo* Alzheimer's disease mouse model (Amin et al., 2017).  $\beta$ -amyloid peptide is known as a major component of senile plaques formed during the pathogenesis of Alzheimer's disease (Behl, 1999). The results showed that vanillic acid treatment (30 mg/kg intraperitoneally for 3 weeks) reversed cognitive deficits in A $\beta$ <sub>1-42</sub> treated mice. The investigators further showed that the antioxidant activity of vanillic acid treatment was associated with an increased expression of HO-1, which is mediated by the activation of Akt/GSK-3 $\beta$ /Nrf2 signaling pathway. In a previous study Yan et al. (2001) demonstrated chemopreventive activity of ferulic acid *in vivo* against Alzheimer's disease by resisting  $\beta$ -amyloid peptide-induced oxidative stress in a rat model. Results of this study further demonstrated that long-term administration of ferulic acid induces resistance to  $\beta$ -amyloid peptide toxicity in the brain, suggesting potency of ferulic acid as a protective agent against Alzheimer's disease.

Ferulic acid treatment has shown beneficial effects by attenuating oxidative stress in diabetic subjects (Balasubashini et al., 2004). A significant decrease in the levels of thiobarbituric acid reactive substances (TBARS), hydroperoxides and free fatty acids was demonstrated in the liver along with an increase in glutathione and antioxidant enzymes. The antioxidant enzymes include glutathione peroxidase, superoxide dismutase and catalase. Furthermore, Jung et al. (2007) reported the hypoglycemic effects of ferulic acid in a type 2 diabetic mice model. Ferulic acid oral administration for 17 days decreased blood glucose levels and increased plasma insulin levels. In addition, ferulic acid had significantly elevated hepatic glycogen synthesis and glucokinase activity of mice compared to those in the control group. Plasma total cholesterol and LDL cholesterol concentrations were significantly decreased by ferulic acid administration, suggesting the overall beneficial effects of ferulic acid for treatment of type 2 diabetes (Jung et al., 2007).

The topical application of caffeic and ferulic acids exerted a significant protection to the human skin against ultraviolet radiation-induced erythema (Saija et al., 2000). Ferulic acid showed a better protection to the skin than caffeic acid and these results are in line with the findings of an *in vitro* assay, which demonstrated better percutaneous absorption of ferulic acid than that of caffeic acid (Saija et al., 2000).

The effect of ferulic acid on blood pressure was investigated in spontaneously hypertensive rats (Suzuki et al., 2002). The oral administration of ferulic acid (1 to 100 mg/kg) significantly decreased systolic blood pressure in a dose-dependent manner. A 60 days treatment with syringic acid prevented diabetic cataract of rat lenses by inhibiting aldose reductase activity (AR) and gene expression (Wei et al., 2012). Syringic acid forms a complex with AR that may reduce the occurrence and progression of diabetic cataracts caused by glycometabolism dysfunction. Furthermore, investigation of the mechanism of syringic acid action showed that it downregulated mRNA expression of AR and inhibited AR activity in a noncompetitive and dose dependent manner (Wei et al., 2012).

Sinapic acid demonstrated anti-inflammatory potential using serotonin- and carrageenan-induced paw edema of mice (Yun et al., 2008). Suppression of the expressions of iNOS, cyclooxygenase-2, tumor necrosis factor-R and interleukin-1 $\beta$  via nuclear transcription factor kappa-B inactivation were responsible for the anti-inflammatory effects of sinapic acid. Nuclear transcription factor kappa-B plays an important role in the pathogenesis of inflammation.

Oral administration of *p*-coumaric acid (317 mg/day) to adult rats for 30 days significantly inhibited LDL oxidation and reduced LDL cholesterol levels by 33% in serum (Zang et al., 2000). The levels of high-density lipoprotein (HDL) cholesterol were not affected by the respective treatment of *p*-coumaric acid. Further, it was showed that *p*-coumaric acid significantly reduced the levels of 8-epiprostaglandin F<sub>2 $\alpha$</sub>  (8-EPI), by 60% in the serum. The 8-EPI, is a product of lipoprotein peroxidation and is reported to be a potent vasoconstrictor in rats and rabbits. This lipoprotein by-product can be used as a marker of oxidative stress in atherosclerosis and carcinogenesis (Morrow et al., 1990a,b). Chiang et al. (2014) showed that caffeic acid derivatives inhibit the growth of colon cancer through the involvement of phosphatidylinositol 3-kinases (PI3-K)/Akt, and AMP-activated protein kinase (AMPK) signaling pathways.

## Conclusions

Major plant food groups, in addition to the basic macro and micro nutrients provide phenolic compounds, among other bioactive phytochemicals that may provide beneficial health effects. Ferulic acid is the predominant phenolic acid reported continuously in all cereals. Generally, the major phenolic acids detected in legumes include ferulic acid, protocatechuic acid and *p*-coumaric acid. Phenolic acids in oilseeds include hydroxylated derivatives of benzoic and cinnamic acids. Sample preparation and extraction of phenolic compounds of food matrices have been done using different methodologies though a standardized procedure is not reported. Chromatographic and spectrometric methods are employed for the determination and quantification of phenolic acids in foods and beverages. Phenolic acids are effective antioxidant compounds that can attenuate chronic diseases associated with oxidative stress.

## Structure and Occurrence

Phospholipids (PLs) are important components for human body, especially in cell membrane formation. They are amphiphilic lipids consisting of a glycerol backbone (glycerophospholipids, GPLs) or an amino-alcohol sphingosine backbone (sphingophospholipids, SPM), which is esterified with one or two fatty acids (FAs), a phosphate group and a hydrophilic residue such as choline, ethanolamine, inositol, etc (Fig. 1). The normal dietary intake of PLs is 2–8 g per day, which just represents a small part of PLs in the intestinal lumen while the rest is derived mostly from bile (Cohn et al., 2010; Iqbal and Hussain, 2009). Foods with a high PLs content are soybeans, egg yolk, milk, or marine organisms like fish, roe or krill. Lately, the PLs from marine organisms have captured increasing interest due to being abundant in health-beneficial omega-3 polyunsaturated fatty acids (n3-PUFAs) (Burri et al., 2012). PLs are supposed to be highly effective in delivering their FA residues for incorporation into the membranes and altering the FA composition of membrane PLs within a certain cell type (Küllenberg et al., 2012). Therefore, dietary supplementation of PLs carrying n-3 PUFAs is believed to contribute to a higher health benefit.

## Extraction

Extraction of PLs from food materials is the first step for their further analysis and utilization. For analysis purposes, the modified extraction procedures based on a mixture of chloroform/MeOH introduced by Folch et al. (1957) and Bligh and Dyer (1959) are most commonly used. In recent years, a low toxic extraction procedure employing methyl *tert*-butyl ether (MTBE) instead of chloroform, which was introduced by Matyash et al. (2008) is widely applied. Meanwhile, the direct extraction of lipids from food materials using single and mixed solvents is also used in some cases (Cajka and Fiehn, 2014). However, the aforementioned extraction methods are not applicable for food industrial use due to the high toxicity of chloroform and methanol. Thus, low or non-toxic organic solvents of relatively high polarity such as ethanol, acetone and ethyl acetate are more often used for edible PLs extraction. For example, a two-step solvent extraction using acetone and ethyl acetate as well as a supercritical CO<sub>2</sub> in combination with approximately 20% ethanol were used to extract PLs enriched oils from Antarctic krill (Sampalis, 2012; Bruheim et al., 2015). Single SC–CO<sub>2</sub> can not efficiently extract PLs from food materials, but can be used to remove neutral lipids from materials for extracting PLs with high purity by a subsequent extraction (Ali-Nehari and Chun, 2012).

**Figure 1** Structure of glycerophospholipids.

## Analysis

Recently, high performance liquid chromatography-mass spectrometry (HPLC–MS) has been used extensively for the quantification of phospholipids (PLs) according to both class and molecular species due to its greater specificity, selectivity, and, in many cases, better sensitivity than HPLC-ultraviolet detector (UV), HPLC-evaporative light scattering detector (ELSD), HPLC-charged aerosol detector (CAD) and  $^{31}\text{P}$  nuclear magnetic resonance (NMR) (Fong et al., 2013). Hydrophilic interaction chromatography-triple quadrupole tandem mass spectrometry (HILIC-QqQ-MS/MS) method is usually used to quantify PLs by class (Peterson and Cummings, 2006). This is because that HILIC can separate PLs by class, while QqQ-MS/MS can specifically detect a class of PLs by precursor-ion scanning (PIS) or neutral loss scanning (NLS) due to the loss of the head group (Peterson and Cummings, 2006; Nováková and Vlčková, 2009). However, there are no special requirements for the types of chromatographic column and MS for the quantification of PLs according to molecular species (lipidomics analysis). Reversed-phase HPLC, normal-phase HPLC, HILIC, and even direct-infusion without HPLC coupled to QqQ-MS/MS, quadrupole time-of-flight (Q-TOF)-MS/MS and Orbitrap MS are now widely used for lipidomics study. It is not feasible to get reference standards for each target PLs molecular species in food materials due to their unavailability or prohibitive price. Therefore, it is acceptable to quantify the individual molecular species using one corresponding standard for each lipid class through single-point internal standard method or standard curve method (Wang and Zhou, 2017).

In the intestinal lumen, dietary PLs are cleaved into 1-lysophospholipid and free fatty acids (FFAs) by activated pancreatic phospholipase  $A_2$  (Iqbal and Hussain, 2009). The resulting FFA is mainly re-synthesized into triacylglyceride (TAG) whereas 1-lysophospholipid is mainly re-synthesized into PLs before they are transferred into the lymph and the blood (Cohn et al., 2008). This means the fate of FAs at the *sn*-1/*sn*-2 position of oral PLs *in vivo* is different, which suggests that analysis of FA distribution in PLs is necessary for further revealing the health-beneficial effects of PLs-containing FFAs. Initially, an empirical rule that the *sn*-2 of GPL is the preferred position for the more unsaturated FFAs was used to determine the distribution of the two FFAs in the glycerol backbone of PLs (Napolitano et al., 1992). Then a phospholipase  $A_2$  hydrolysis and gas chromatography (GC) analysis procedure was used to determine the stereospecific distribution of the FFAs in the glycerol backbone of GPLs (Wang et al., 1997). However, this method still can not reveal the distribution of the two FFAs in the glycerol backbone of each individual PL.

## Health Benefits

PLs are essential in living organisms since they are the major component of double-layer cell membranes, containing hydrophobic fatty acyl chains on the inside and hydrophilic phosphate head groups on the membrane surface. In addition to their structural function, PLs are degraded by phospholipases to release FFAs, which are a source of cellular energy.  $\beta$ -oxidation of FFAs produces acetyl-CoA, nicotinamide adenine dinucleotide (NADH), and flavin adenine dinucleotide ( $\text{FADH}_2$ ), that are further metabolized via tricarboxylic acid (TCA) cycle and oxidative phosphorylation, to obtain energy molecule known as adenosine triphosphate (ATP). Another function of PLs is to regulate cell metabolism. PLs constitute a source of signaling molecules such as diacylglycerol (DAG), inositol phosphate, etc (Espinosa-Salinas et al., 2011). The detail of some major PLs is included.

Phosphatidylcholine (PC), the most abundant PL in mammalian cells, is de novo biosynthesized majorly via cytidine diphosphate (CDP)-choline pathway by a rate-limiting step, CTP:phosphocholine cytidyltransferase, and two other enzymes using choline and cytidine triphosphate (CTP) substrates. Only in the liver that PC is alternatively synthesized from the conversion of phosphatidylethanolamine (PE) via PE N-methyltransferase. PC plays a role in lipoprotein secretion. It is required for assembly and secretion of not only chylomicron and very low-density lipoprotein (VLDL) from the intestinal cells and the liver, respectively to the circulation (Van Der Veen et al., 2017), but also high-density lipoprotein (HDL) and low-density lipoprotein (LDL) via reverse PC transport to supply PC to the liver (Vance, 2008). PC also influences lipid droplet formation in the cells. Inhibition of PC biosynthesis during conditions that promote TAG storage increases the size of the lipid droplets presumably due to the ratio of the surface area (or the amount of phospholipid) to the volume (TAG) of the droplets. In addition, PC controls de novo lipogenesis via regulation of sterol regulatory element-binding proteins (SREBPs). Experimental studies have demonstrated SREBP-1 accumulation and increased lipogenic gene expression when PC synthesis was attenuated (Van Der Veen et al., 2017). In response to cell stimulation, PC also generates signaling molecules including diacylglycerol (DAG) via hydrolysis of phosphatidylinositol 4,5-bisphosphate, leading to an activation of protein kinase C (PKC) isoforms that have been implicated in the regulation of cell division (Cui and Houweling, 2002).

PE, the second most abundant phospholipid in mammalian cells, is synthesized via two major pathways: 1) CDP-ethanolamine pathway from ethanolamine and CTP substrates in endoplasmic reticulum, and 2) phosphatidylserine decarboxylase reaction via the conversion of phosphatidylserine (PS) in mitochondria (Patel and Witt, 2017). Based on charge-carrying structure of PE, it can bind to membrane proteins and assist their folding, introducing not only the change in physical structure, but also their functions. PE, which is normally enriched in the inner leaflet of the cell membrane, transiently accumulates on the external leaflet as an important factor regulating a late-stage cell division. The fusion of Golgi membranes that occurs after cell division also requires PE to increase the head group spacing between lipids on the membrane, allowing conformational changes during membrane fusion (Calzada et al., 2016). Regarding lipoprotein secretion, in addition to PC, PE also affects VLDL metabolism by stimulating VLDL removal from the circulation. In mitochondria, an increase in PE content, as well as a decrease in the PC/PE ratio, stimulates

mitochondrial respiration and activities of proteins of the electron transport chain to increase energy production (Van Der Veen et al., 2017).

PS is a minor membrane PL. In mammalian cells, it is synthesized by PS synthase-1 and PS synthase-2 from PC, and PE substrates, respectively. Since PC, PE, and PS are synthesized using one molecule or another as a substrate, perturbation of one PL contributes to cellular homeostasis of the others. PS synthase-1 mRNA is distributed through most murine tissues with highest expression in the liver, heart, brain, kidney and testis, while PS synthase-2 is only highly expressed in the testis. PS is mostly enriched in the inner leaflet of the plasma membrane and acts as an enzyme cofactor. One of the best-known roles of PS is as a specific activator of the classical PKC isoforms. PS induces the insertion of one of the protein domains to cell membrane, allowing the kinase to bind to DAG, thereby stimulating the enzyme activity. Another example is on the selective binding of heat-shock proteins (Hsps) on the target cell surface, which induces the formation of an ion conductance channel in the membrane and decreases cell viability. Exposure of PS on the cell surface also increases during the early-stage apoptosis. It makes apoptotic cells recognizable and subsequently removed by phagocytes (Vance and Steenbergen, 2005).

Phosphatidylinositol (PI) is also a minor constituent of plasma membrane. It is synthesized in the endoplasmic reticulum from CDP-DAG and myo-inositol substrates by a PI synthase (Balla, 2013). PI is a precursor of important signaling molecules, phosphoinositides, which are the products of PI phosphorylation at D3-, D4- or D5-positions of the inositol ring. The most abundant phosphoinositides are phosphatidylinositol 4,5-bisphosphate and its main precursor, phosphatidylinositol 4-phosphate. Phosphatidylinositol 4,5-bisphosphate is known as a substrate of phospholipase C, and class I phosphatidylinositol 3-kinases, which are enzymes producing major secondary messengers. In canonical mammalian pathway, phospholipase C produces two secondary messengers: 1) DAG and 2) inositol 3,4,5-trisphosphate, which contribute to the regulation of a wide-range of cellular functions such as cell homeostasis, fertilization, motility, sensory transduction, as well as the switch between proliferation and differentiation. In metazoan cells, phosphatidylinositol 4,5-bisphosphate is metabolized to phosphatidylinositol 3,4,5-trisphosphate by class I phosphatidylinositol 3-kinases. This major signaling pathway also involves regulation of various biological processes including cell directional movements, embryogenesis, immune response, neuronal patterning, and wound healing (Delage et al., 2013).

Although de novo synthesis of PLs occurs in the cells, experimental studies have demonstrated positive impacts of dietary PLs in different illnesses and symptoms, such as inflammation, cancer and coronary heart disease. This raises the possibility of using synthetic or naturally occurring PL isolates as nutraceuticals or functional foods. Beneficial effects of PLs can be partially explained by the effectiveness of PL in delivering their fatty acid residues and incorporating them into cell membranes that is involved in different diseases such as immune or cancer cells. Alteration of membrane composition is assumed to influence characteristics of cellular membrane including activity of membrane proteins, and biosynthesis of lipid secondary messengers (Küllenberg et al., 2012). The following examples demonstrate biological activities of dietary PLs. A PC-rich krill oil and soybean PC were shown to be effective in reducing inflammatory arthritis in patients and in chronic murine model, respectively (Deutsch, 2007; Erős et al., 2009). In addition, PLs improved anti-inflammatory and analgesic activity of nonsteroidal anti-inflammatory drugs in acute and chronic arthritis models by enhancing transport and bioavailability of the medicine (Lichtenberger et al., 2001, 2009). In a murine cancer model, PC showed a significant reduction of cancer cells by promoting apoptosis, and synergistically acted with menaquinone-4 (vitamin K2) to suppress nodule formation (precursors of hepatic cancer) and preneoplastic liver lesions (Sakakima et al., 2007). In case of patients with coronary artery disease, supplementation with krill oil changed blood lipid profile by reducing total cholesterol, LDL and TAG levels, while increasing HDL. The significant increase of blood HDL after PL supplementation could be attributed to the fact that PLs can be partially absorbed by the intestine and are preferentially incorporated into HDL (Küllenberg et al., 2012).

## **Oxidative/Antioxidative Properties**

In addition to health benefits, PLs, especially lecithins, are widely used as natural emulsifiers with gaining interest as they are natural antioxidants to control lipid oxidation. For example, sunflower lecithin was shown to possess better oxidative stability in oil-in-water emulsions than the system stabilized by synthetic food-grade surfactants, such as Tween 20 (Liang et al., 2017). In soybean oil, PC and other phospholipids components in the oil enhanced synergistic effect in inhibiting oxidation (Jiang et al., 2016). The antioxidant activity of the PLs has been attributed to their properties in free radical scavenging, metal ion chelation, the formation of specific structures that can prevent pro-oxidants interacting with lipids, as well as synergism between PL and other compositions in the food system (McClements and Decker, 2017). However, the presence of unsaturated fatty acids in dietary PLs, such as meats and dried milk products, makes them susceptible to lipid oxidation. Bulk oil, a heterogeneous system containing not only TAG, but also 200–800 ppm water and a variety of amphiphilic minor components such as monoacylglycerols (MAGs), DAGs, free FAs, PLs, phytosterols and oxidation products, is an example in which PLs act either as antioxidants or prooxidants depending on critical micelle concentration (Cui and Decker, 2016).

### Phytochemicals: A Brief Review

Naturally occurring chemical compounds in plants are called Phytochemicals. Several studies have shown the therapeutic potentials (Raul et al., 2016). They are widely distributed in fruits, vegetables, legumes, whole grains, nuts, seeds, fungi, herbs and spices and in plant-based beverages such as wine and tea.

### Classifications

Phytochemicals can be classified into groups based on their chemical structure: alkaloids, terpenoids, sulfur-containing phytochemicals, carotenoids and polyphenols.

### Polyphenols

Polyphenols form a large part of the phytochemicals. They can be classified as flavonoids and non-flavonoids considering their chemical structures. Flavonoids are a large group of compounds found in many fruits, vegetables and legumes.

Flavonoids can be further divided into six subfamilies on the basis of differences in their molecular backbone structure: flavonols, flavones, flavanols, flavanones, anthocyanidins and isoflavonoids. Examples of flavonols, are quercetin (Lee et al., 2010; Hossion et al., 2011; Liu et al., 2010; Al-Saif et al., 2014), galangin (Cushnie and Lamb, 2006; Eumkeb et al., 2010; Pepeljnjak and Kosalec, 2004), kaempferol and myricetin (Ansari et al., 2015). Flavones are only found in citrus varieties as un-conjugated polymethyl-flavone (Hollman and Arts, 2000). Anthocyanins are a large group of compounds that are responsible for the colors of many flowers, vegetables, fruits and berries (Pazmiño-Durán et al., 2001). Flavanols are a large group of flavonoids, which include catechin, epicatechin, epigallocatechin, epicatechin gallate and epigallocatechin gallate. These polyphenols are the most important constituents of tea leaves and appear to have great health benefits in humans (Daglia et al., 2014). Flavanones are mostly found in citrus fruits such as oranges, grapefruit and lemons. Isoflavones are mainly found in leguminous plants, especially soybean.

The non-flavonoid polyphenol groups include: phenolic acids, stilbenes, coumarins and tannins. Phenolic acids are plant metabolites widely spread throughout the plant kingdom. They are mainly contained in chokeberry, blueberry, dark plum and cherry among fruits, while among beverages the best sources of phenolic acids are coffee as well as green and black teas. Gallic acid is found in almost every plant part: bark, wood, leaf, fruit, root and seed, and in many common foodstuffs such as blueberry, blackberry, strawberry, plums, grapes, wine and tea among others (Daglia et al., 2014). Ferulic acid occurs in the seeds and leaves both in free form and covalently linked to lignin and other biopolymers. It is found in wheat and some vegetables and sweet corn (Balasubashini et al., 2003).

### Sources of Phytochemicals

There are various sources where phytochemicals can be obtained, including plant foods, medicinal plants and nutraceuticals.

### Plant Foods

Examples of phytochemicals derived from plant foods are; Ellagic acid conjugates are the major components of raspberry fruits, with other phenols, such as flavonoids and phenolic acids, occurring at significantly lower concentrations (Mazur et al., 2014). Epigallocatechin gallate is the ester of gallic acid and epigallocatechin. This polyphenolic compound is mostly present in green tea (Khan et al., 2006; Wang et al., 2012a,b). Quercetin, a compound present in many plants including apple, apricot, broccoli, spices, brussels sprout, cauliflower, grape, honey, kale, lettuce, lemon juice, citrus peel, onion, strawberry, wine, juice, wolfberry, black tea infusions, and tomato (Le et al., 2007; Hertog et al., 1992; Lin et al., 2007; Pellegrini et al., 2010; Petrus et al., 2011; Adefegha and Oboh, 2012; Ademosun et al., 2015a).

Genistein, an isoflavonoid compound, is found in some dietary plants such as alfalfa, soybean, fava bean, kudzu, psoralea, cowpea, yellow pea, green lentil, and lupine (Kaufman et al., 1997). Pterostilbene is a phenolic phytoalexin found in almond, rabbit, eye blueberry, and deerberry (Rimando et al., 2004; Xie and Bolling, 2014). Resveratrol is a stilbenoid and a type of natural phenolic compound, which is abundant in many fruits including blueberry, bilberry, cranberry, deerberry, lingonberry, partridge

berry, cocoa, grape, peanut, plum, red wine, and tomato (Sanders et al., 2000; Burns et al., 2000; Rimando et al., 2004; Ragab et al., 2006; Hurst et al., 2008; Sebastia et al., 2012). Ellagic acid, a natural phenol antioxidant, occurs in some fruits such as blackberry, green leafy vegetables, cloudberry, cranberry, strawberry, raspberry, wolfberry, grape seed, grape pulp, grape skin, pecan, and walnut (Daniel et al., 1989; Koponen et al., 2007; Bobinaite et al., 2012; Lee et al., 2012; Oboh et al., 2015a; Pantelic et al., 2016; Donno et al., 2016; Nwanna et al., 2016). Lycopene, a noncyclic carotenoid found in tomatoes (*Solanum lycopersicum*, Solanaceae), has received considerable scientific interest in recent years (Rao et al., 2006; Ademoseun et al., 2013).

## Medicinal Plants

Medicinal plants include various types of plants used as herbs and some of these plants have medicinal properties. These plants are considered as rich sources of phytochemicals, which can be used in drug development. Examples include; Gallic acid, which is found in almost every plant parts including: bark, wood, leaf, fruit, root and seed, and in many common food such as blueberry, blackberry, strawberry, plums, grapes, wine and tea among others (Oboh et al., 2016a; Daglia et al., 2014). Curcumin is a combination of three molecules: diferuloylmethane (1,7-bis-(4-hydroxy-3-methoxyphenyl)-hepta-1,6-diene-3,5-dione), p-dihydroxycinnamoylmethane (1,7-bis-(4-hydroxyphenyl)-hepta-1,6-diene-3,5-dione), and phydroxycinnamoylferuloylmethane (1-(4-hydroxyphenyl)-7-(4-hydroxy-3-methoxyphenyl)-hepta-1,6-diene-3,5-dione). This polyphenol is present in turmeric rhizomes (Ademiluyi et al., 2012; Kim et al., 2013; Akinyemi et al., 2017a).

Benzyl isothiocyanate is the myrosinase-induced hydrolysis product of benzyl glucosinolate (glucotropaeolin), which occurs in some cruciferous plants (for example, cabbage, horseradish root, and garden cress) and papaya seed (Bennett et al., 2004; Agneta et al., 2014; Nakamura et al., 2007; Williams et al., 2009). Phenethyl isothiocyanate, an isothiocyanate compound, is widely distributed as gluconasturtiin in some cruciferous plants, including broccoli, cabbage, cauliflower, kale, horseradish, kohlrabi, black radish, and watercress (Bennett et al., 2004; Gupta et al., 2014; Ares et al., 2014; Loebers et al., 2014; Ediage et al., 2011; Yi et al., 2015). Sulforaphane is an isothiocyanate compound found as glucoraphanin in cruciferous plants including broccoli sprout, mature broccoli, brussels sprouts, cabbage, cauliflower, kohlrabi, kale, radish, arugula, black radish, turnip, and rucola (Zhang et al., 1992; Bennett et al., 2004; West et al., 2004; Nakagawa et al., 2006; Higdon et al., 2007; Sivakumar et al., 2007; Ediage et al., 2011; Sasaki et al., 2012; Aires et al., 2013; Yi et al., 2015; Ku et al., 2016; Oboh et al., 2017). Indole-3-carbinol, a natural indole carbinol compound, is produced by the breakdown of glucobrassicin. It is present in cruciferous vegetables like broccoli, brussels sprouts, cauliflower, cabbage, horseradish, kale, and watercress (McNaughton and Marks, 2003; Higdon et al., 2007; Pellegrini et al., 2010; Loebers et al., 2014). 3,3'-Diindolylmethane, a dimer of I3C, is widely distributed as glucobrassicin in cruciferous vegetables such as broccoli, brussels sprouts, cauliflower, cabbage, horseradish, kale, and watercress (Kushad et al., 1999; Suzuki et al., 2006). Diallyl disulphide is a sulphur containing organic phytochemical. It is mostly found in garlic (Lee et al., 2003; Wang et al., 2015). Oleoanolic acid is a member of triterpenoids found in apple, grape, olive fruit and leaf, rosemary, sage, and virgin olive oil (Pensec et al., 2014).

## Nutraceuticals

Nutraceuticals are isolated food bioactive constituents that provides medical or health benefits, including the prevention and/or treatment of a disease. In other words, it provides medical or health benefits and helps in the prevention and treatment of diseases (Zeisel, 1999). The major active nutraceutical ingredients in plants are flavonoids. As is typical for phenolic compounds, they can act as potent antioxidants and metal chelators. Flavonoids such as quercetin have been reported to possess anti-inflammatory, antiallergic, hepatoprotective, antithrombotic, antiviral, and anticarcinogenic properties (Pal et al., 2009; Oboh et al., 2016b).

## Metabolism and Bioavailability of Phytochemicals

Phytochemicals have preventive and therapeutic potential for diseases. Most of these compounds have low levels of solubility, stability, and bioavailability in the body. For instance, resveratrol found in grapes, epigallocatechin gallate found in green tea, quercetin found in red onions and curcumin found in turmeric, Ferulic acid found in wheat, which are known for the prevention and treatment of many pathologies.

## Resveratrol

Resveratrol (*trans*-3,4',5-trihydroxystilbene) is a polyphenol abundant in the skin of red grapes and other fruits such as berries. Resveratrol possess two structural isomers: *cis*- and *trans*-resveratrol. Under UV exposure, *trans*-resveratrol is converted into *cis*-resveratrol (Orallo, 2006). Nanoencapsulation protects *trans*-resveratrol against light-exposure degradation and hence increases its stability (Sanna et al., 2012).

## Curcumin

A study reported that curcumin has a poor aqueous solubility, has low bioavailability and is quickly metabolized by hepatic enzymes in humans and research animals (Akinyemi et al., 2015; Bansal et al., 2011). The bioavailability of curcumin is low. After oral administration of 1 and 2 g/kg body weight of curcumin to rats, the peak blood concentrations detected after 48min were 1.4 and 3.7  $\mu$ M, respectively (Wahlstrom and Blennow, 1978). Nanoencapsulation increases curcumin bioactivities (Mohanty and Sahoo, 2010; Yallapu et al., 2010; Anand et al., 2010; Yekollu et al., 2011; Kim et al., 2011; Doggui et al., 2012; Wang et al., 2012a,b). Nanocurcumin significantly enhanced the inhibitory effect of curcumin on cancer cell viability, which is accompanied by an increase in curcumin uptake by cancer cells (Mohanty and Sahoo, 2010; Yallapu et al., 2010; Kim et al., 2011; Nair et al., 2012).

## Quercetin

Quercetin is a hydrophobic compound, and its solubility in an aqueous solution varies from 0.00215 g/L at 25 °C to 0.665 g/L at 140 °C (Srinivas et al., 2010). It was reported that quercetin has low aqueous solubility and bioavailability and is quickly metabolized in the body, which may reduce its efficacy as an application in preventing or treating diseases (Kumari et al., 2012; Oboh et al., 2016b). Quercetin has a high solubility in organic solvents such as ethanol, dimethyl sulfoxide (DMSO) and dimethyl formamide. The solubility of quercetin is approximately 2 g/L in ethanol and 30 g/L in DMSO at 25 °C (Srinivas et al., 2010). Quercetin in human bodies is rapidly metabolized by enzymes in the liver as well as the other organs or tissues (Hong and Mitchell, 2004), found that at least 21 metabolites of quercetin are detected in human urine after ingestion of quercetin glycosides from onions.

## Therapeutic Potentials of Phytochemicals

Phytochemicals are considered as potential agents against a wide range of diseases, such as neurodegenerative diseases, diabetes, cancer and cardiovascular disorders (Soobrattee et al., 2005; Oboh et al., 2016b). These phytochemicals are widely distributed in the plant kingdom and they are an integral part of the diets, with significant amount present in vegetables, fruits and beverages (Luximon-Ramma et al., 2005).

### Anticancer Effect

Free radicals are considered as important factors in the origin of cancer. Phytochemicals can exert anticancer activity, partially based on their ability to quench ROS and thereby protecting insulin (Roy et al., 2003). Phytochemicals may also interfere with intracellular signaling pathways, such as those, which regulate proliferation, induction of apoptosis and response to oxidative stress (Loo, 2003). Curcumin (Plummer, 1999), Gingerol (Bode et al., 2001) and citrus peel phenolic rich-extracts (Ademosun et al., 2015a,b) have been shown to possess anticancer effects.

### Antidiabetic Effect

Diabetes is the most common endocrine disorder characterized by the hyperglycemia, which causes overproduction of free radicals, thereby result in oxidative stress (Arango et al., 2000). This stress is an imbalance between the levels of prooxidants and antioxidants in the biological systems, leading to cellular injury (Villa-Caballero et al., 2000). Studies have shown that phenolics such as ferulic acid reduced blood glucose level (Villa-Caballero et al., 2000; Balasubashini et al., 2004; Noumura et al., 2003; Ohnishi et al., 2004). Quercetin and its derivative-rutin have also been reported to inhibit key enzymes linked to type-II diabetes in vitro (Oboh et al., 2015b).

### Neuroprotective Effect

An example of neurodegenerative disease is Alzheimer's disease (AD). This disease is an age associated dementing disorder, and many other neurodegenerative disorders, are characterized by free radical-mediated oxidative stress in the brain (Butterfield et al., 2002). Studies have shown that phytochemicals has been reported to act as a potent scavenger of ROS and RNS, thereby reducing the chance of free radical attack on proteins and hence preventing their oxidative modifications (Joshi et al., 2006; Oboh et al., 2016c). Curcumin has been reported to offer neuroprotective effect and was recently reported to synergize the anticholinesterase activity of donepezil-a major drug for AD (Akinyemi et al., 2017a). Proposed mechanism behind the neuroprotective properties of curcumin includes anticholinesterase, anti-inflammatory and antioxidant properties (Akinyemi et al., 2017a,b), as well as suppression of the acetylcholinesterase gene expression (Akinyemi et al., 2017b). Furthermore, caffeine and caffeic acid

(predominant phytochemicals in coffee and other beverages) have been reported extensively to offer neuroprotective properties in various experimental models essential via anticholinesterase, antioxidant and cytoprotective properties (Obboh et al., 2016a,b,c; Deshmukh et al., 2016; Akomolafe et al., 2017a, b; Winerdal et al., 2017).

## Sexual and Reproductive Hormones

Over the years, the use of plant-derived chemicals otherwise known as phytochemicals have been shown to influence human health most especially hormonal related diseases (Slavin et al., 1997; Manson et al., 2003). This is owing to the fact that hormonal imbalances i.e. too high or too low, or inability of the body to respond to hormones in the appropriate ways, which could be an indication of endocrine system disorder, is a hallmark of many human diseases such as infertility, diabetes, depression, among others (Verthelyi, 2001). In simple term, a hormone is a substance that affect physiological activity when get to the target site/cell differentiation from the producer cell via the bloodstream (Nelson et al., 2008). Basically, all animals/human hormones can be categorized into three: lipid-derived, amino acid-derived, and peptide hormones. Lipid-derived hormones differ from others in that is that they can diffuse across plasma membranes, whereas the amino acid-derived and peptide hormones cannot. Primarily, lipid hormones in humans belongs to the class of steroid hormones such as sex hormones e.g., estradiol (Adlercreutz, 1990; Behl, 2002). Sex hormones otherwise known as gonadocorticoids and gonadal steroid hormones establish their effects by interacting with vertebrate androgen or estrogen receptors, thereby mediating most of their biological activities via both genomic and nongenomic mechanisms (Handa et al., 1994). Earlier report has suggested that sex hormones also act via the thymus gland, and influence immune system (Ahmed et al., 1985). Sex hormones are of three types; androgens, oestrogen and progesterones.

## Sex Hormones

Androgen: a sex/steroid hormone that controls the growth and development of male characteristics, including the activity of the primary male sex organs (Lindzey et al., 1994; Debes and Tindall, 2004). Although, androgens are regarded as dominant male sex hormones, its presence has also been found in female vertebrates in varying degrees, and increase during puberty (Carlson, 2012). Example of androgens includes progesterone, dehydroepiandrosterone, androstenedione (A4), androstenediol (A5), androsterone, dihydrotestosterone (DHT). Androgens have been reported to be used in hormone replacement therapy to treat hypogonadism, while androgen deprivation therapy is used to treat prostate cancer (Kaufman and Graydon, 2004; Rhoden and Morgentaler, 2004; Sharifi et al., 2005).

Estrogen or oestrogen is the primary female sex hormone that is responsible for the development and regulation of the female reproductive system and sex characteristics. It is synthesized in all vertebrates and some insects, therefore, suggesting their ancient evolutionary history. The three major naturally occurring forms of estrogen in women are estrone (E1), estradiol (E2), and estriol (E3), estetrol (E4) is produced only during pregnancy (Burger, 2002). While estrogen is known as female hormones, it has also been found significantly amount in male vertebrates, carrying out important physiological roles (Lombardi et al., 2001). Among these, estriol is the most abundant, but also the weakest, while estradiol is the strongest with a potency of approximately 80 times that of estriol. However, all of them are synthesized from androgens, specifically testosterone and androstenedione, by the activity of the enzyme aromatase (Nelson and Bulun, 2001). Their medical uses in the past include the management of prostate cancer in men (Oh, 2002), breast cancer in women (Miller et al., 2002; Lumachi et al., 2011), induction of growth attenuation in tall girls (Gunther and Diekema, 2006). It has also been used in the treatments of the cognitive behavioral disorder and also women suffering from bulimia nervosa: an eating disorder characterized by binge eating followed by purging, which has been linked to a hormonal imbalance in the brain (Slade, 1982).

## Reproductive Hormones

Reproductive hormones play pivotal roles in the reproductive systems of both male and female puberty development, as well as their growth and sexual character. Although the synthesis of both hormones is stimulated by the hypothalamic gonadotropin releasing hormone (GnRH) and they are produced in the same cells, the expression and circulating levels of each hormone are distinct, in accordance with their different roles in reproductive function. In the female ovulatory cycle, FSH is responsible for inducing follicular growth, while also increasing estrogen production, while LH, apart from enhancing cholesterol availability for steroidogenesis, also signals ovulation following its peak mid-cycle. The reproductive hormones, including testosterone (T), and free testosterone (free T), follicle-stimulating hormone (FSH), luteinizing hormone (LH), sex hormone-binding globulin (SHBG), oestrogen (E2) are present in the broad range of tissues (Kjeldsen and Bonefeld-Jørgensen, 2013).

## Progesterone and Its Actions

Progesterone belongs to the class of steroid hormone, and is essential for reproductive functions in males and females of several species (Spark and Willis, 2012). Though, it is synthesized by the placenta and ovaries in the females, adrenal glands and testes in males, but it is involved in the regulation of other tissues, including the brain, breast, and bone (Singh and Su, 2013). Progesterone causes its effects by ligand binding to nuclear progesterone receptors (PRs), which subsequently binds to gene regulatory regions, including progesterone response elements (PREs) to initiate transcription of progesterone-responsive genes, and also through non-classical signaling pathways. Studies have shown that progesterone has other biological effects other than being a reproductive hormone. For example, it has been reported to possess neuroprotective potentials (Singh and Su, 2013), reduce the formation of lipid peroxidation, thus possess antioxidant activity (Roof et al., 1997), and reduced the expression of pro-inflammatory genes (Pettus et al., 2005), cardiovascular and venous systems and breast cancer in the climacteric and postmenopausal women (Schindler et al., 2003).

Follicle-stimulating hormone (FSH) is a glycoprotein hormone that plays a major role in the development and maturation of ovarian follicles before the release of an egg from one follicle at ovulation, increases oestradiol production, and the secretion of gonadal hormones (Kim et al., 2013). In men, FSH acts on the testes' Sertoli cells to stimulate production of sperm otherwise known as spermatogenesis (De Kretser et al., 1998). Although, it plays a major sex-related role, but it's usually not regarded as sex hormone. FSH is synthesized and secreted by the gonadotropic cells of the anterior pituitary gland (Nett et al., 2002) and regulates the development, growth, pubertal maturation, and reproductive processes of the body (Lincoln, 1998). FSH and luteinizing hormone (LH) are structurally related, and also work together in the reproductive system (Smitz et al., 2016).

Luteinizing hormone (LH) is another gonadotropic hormone, produced by gonadotropic cells of the anterior pituitary gland (Soldani et al., 1995). LH triggers ovulation and development of the corpus luteum, and also involved in the stimulation of Leydig cell production of testosterone (Lin et al., 2001; Acosta and Miyamoto, 2004). LH acts synergistically with FSH, which is frequently used in assisted reproductive technology (ART), in the stimulation of follicular growth and ovulation (Raju et al., 2013).

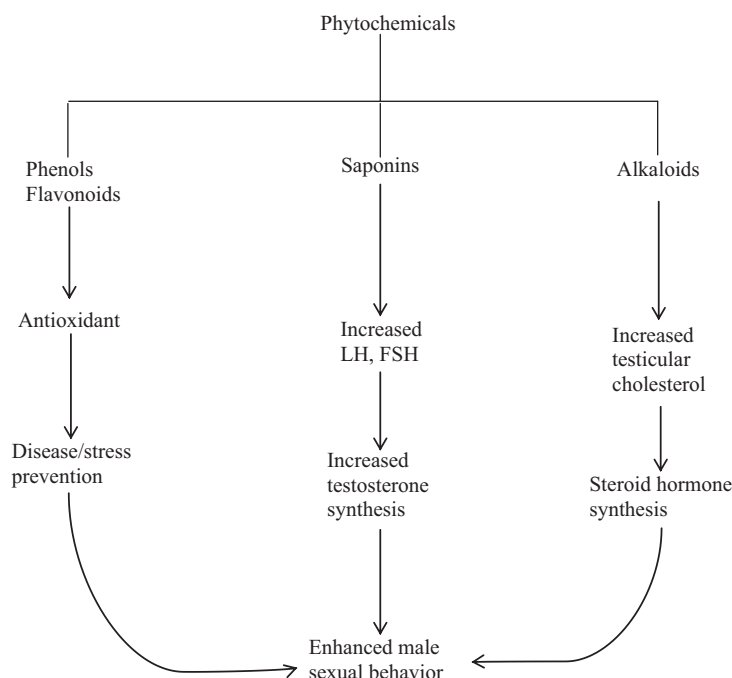

## Enhancement of Reproductive Hormones by Phytochemicals

Men develop and experience premature coronary artery disease earlier than women, increasing the risk of cardiovascular mortality by more than twofold. This led to the belief that testosterone exerts a detrimental influence upon the cardiovascular system; however, evidence has emerged over recent years to suggest that a number of the cellular mechanisms associated with the atherosclerotic process are beneficially modulated by testosterone. Indeed, it is well established that total and biologically available testosterone in men decreases with age and the age-associated decline may be related to the increased prevalence of cardiovascular disease (CVD) and comorbidities. Lack or reduced level of testosterone has been reported in population studies to be associated with an increase in mortality, and this has been shown to be accounted for mainly by CVD (Khaw et al., 2007; Vikan et al., 2009; Araujo et al., 2011). Moreover, accumulating evidence suggests that testosterone deficiency is an independent cardiovascular risk factor and many recent reviews have focused on the link between hypogonadism, erectile dysfunction, type-2 diabetes mellitus and CVD (Makhrida et al., 2005; Shabsigh et al., 2008; Yassin et al., 2008; Corona et al., 2009). Testosterone is converted to 17 $\beta$  oestradiol (E2) by the enzymatic activity of aromatase in adipose tissue. Thus, higher expression of aromatase in adipocyte reduces bioavailability of testosterone. Falling testosterone promotes increasing adipocyte number and fat deposition, which gradually leads to a further lowering effect on testosterone levels.

The relevance of androgen in the normal functioning of the entire male reproductive system and male sexual activity has been documented (Aversa and Fabbri, 2001; Yakubu et al., 2005). Neurons in the hypothalamus secrete gonadotropin-releasing hormone into the median eminence. This in turn stimulates the release of luteinizing hormone (LH) and follicle stimulating hormone (FSH) into the general circulation. The LH binds to receptors in the Leydig cells of the testes to synthesize pregnenolone, and via a two-step reaction produce dehydroepiandrosterone before finally synthesizing and releasing testosterone. Testosterone then acts on androgen receptors to stimulate the components of sexual behavior (Yakubu et al., 2005; Aversa and Fabbri, 2001; Subramoniam et al., 2007). Testosterone is the main synchronizer of sexual activity, acting both centrally and peripherally to regulate libido, the synthesis and release of enzymes like nitric oxide synthase (NOS) and phosphodiesterase-5 (PDE5), which are crucial for the erectile process (Vignozzi et al., 2005). It can enhance erection by attenuating the alpha-adrenergic vasoconstrictor activity in vascular smooth muscles of the corpus carvenosum (Heaton and Varrin, 1994). Furthermore, testosterone and FSH can act on the receptors in the Sertoli cells to stimulate spermatogenesis in the seminiferous tubule.

Invariably, most of the plants with acclaimed aphrodisiac activities act centrally by altering the concentrations of specific neurotransmitters or elevating testosterone concentration as reported in previous studies (Vignozzi et al., 2005; Yakubu et al., 2005; Aversa and Fabbri, 2001; Yakubu and Jimoh, 2015). Hence, the enhanced sexual stimulating activities of several plant extracts/phytochemicals has been considered as an important factor that contributed to the entire restoration of sexual activity in sexually impaired male rats (see Fig. 1) (Chauhan et al., 2013). Experimentally induced male infertility with ethanol reported a significant decrease in the androgenic hormones (testosterone, LH, FSH and inhibin B) (Akomolafe et al., 2017b) however, in ethanol-induced rats pretreated with aqueous extract of African Walnut leaf (*Tetracarpidium conophorum* (Mull.Arg.) Hutch & Dalziel) showed a significant reversal in the decreased bioavailability of these androgenic hormones. These decreased androgenic hormones induced by ethanol in this study was equally accompanied by reduced testicular weight, sperm count viability and abnormalities (Akomolafe

**Figure 1** Proposed mechanism of action of plant phytochemicals on sexual hormones.

et al., 2017b). Quercitrin, luteolin and quercetin have previously been reported by same author to be the predominant phenolic phytochemicals present in African Walnut leaf and was associated with its androgenic properties including modulation of the androgenic hormones (Akomolafe et al., 2015, 2017b,c). In another study, Akomolafe et al. (2017d) examined the effect of co-administration of caffeine and caffeic acid on androgenic properties in normal rats. They observed that there was significant increase in reproductive hormones (testosterone, FSH and LH) and decreased oxidative stress in the testes and epididymides of the treated rats as typified by elevation in antioxidant molecules. In addition, photomicrographic examination of sperm cells revealed no significant alterations. The authors hypothesized that these combination exhibited additive/synergistic effects on the reported biochemical markers and thus, suggested that the combination of these phytochemicals could improve male reproductive function.

Interestingly, studies has shown that the enhanced stimulation of testosterone has been reported to be accompanied by corresponding elevations of gonadotropins which involve a possible impact of plant phytochemicals on the pituitary gland resulting in the release of both LH and FSH. Findings from previous studies revealed elevations in both levels of testosterone and gonadotropins following the administration of some plants extract to sexually compromise male rats (Akomolafe et al., 2017d).

## Conclusion

Phytochemicals are non-nutritive components of plants that studies have shown to exhibit various therapeutic properties, especially in the management of several diseases including cancer, diabetes, cardiovascular disease and erectile dysfunction. The therapeutic properties of phytochemicals are often as a result of interaction with the various biological systems including the endocrine and hormonal systems. However, the complex interactions between sex hormones have made comprehensive studies on pathophysiology roles hormones and interactions of therapeutic phytochemicals challenging. Nevertheless, with the few available studies, more in-depth studies are still encouraged.

## Introduction

Tocopherols and tocotrienols, collectively known as tocopherols, are lipid-soluble phenolic compounds. Tocopherols (Fig. 1) exist as four homologues (alpha, beta, gamma, and delta) and they differ from each other according to the location and number of methyl groups in their chemical structures, while the side chain in tocotrienols is saturated, there are three double bonds at positions 3', 7', and 11' in the side chain of tocotrienols. Tocopherols have three chiral centres, thus explaining the existence of eight stereoisomers for each of them. In contrast, the absence of chiral centres in the side chain of tocotrienols explains the existence of only two stereoisomers for each one. In addition to the difference between each homologue, different isomers may also have distinct activity and/stability (Shahidi and de Camargo, 2016). Tocopherols and tocotrienols are monophenols, therefore, like other phenolic compounds, they act as antioxidants in the human body and in animal tissues. Their antioxidant properties in food systems have also been well substantiated. Fat depots, lipoproteins (e.g. low-density lipoprotein cholesterol) and lipid-rich regions of cells such as mitochondrial membranes may contain tocopherols. Besides the antioxidant activity, which protects both lipid and protein fractions from oxidation (Estévez, 2011; Nagy et al., 2016), tocopherols may also act through regulation of gene expression, signal transduction and modulation of cell functions (Zingg, 2007). As for the health benefits, a myriad of evidences on the potential protective effects of tocopherols and tocotrienols against cardiovascular diseases, certain types of cancer, and metabolic disorders, neurodegeneration, and oxidative stress has been reported. Additionally, immune regulation and anti-inflammatory properties have also been highlighted (Meganathan and Fu, 2016; Nesaretnam and Meganathan, 2011; Reiter et al., 2007; Shahidi and de Camargo, 2016). Plant foods containing high concentrations of unsaturated fatty acids are good sources of tocopherols and fewer sources of tocotrienols are currently known. The concentration of tocopherols in animal food products is influenced by their dietary intake (Mercier et al., 1998; Ventanas et al., 2007). Oilseeds (Syväoja et al., 1986), nuts (Kornsteiner et al., 2006) and other common edible oils (e.g. olive, palm, rice bran, wheat, and corn) are among the major sources of tocopherols, whereas their contribution in most fruits and vegetables is negligible, possibly due to their low lipid contents (Shahidi and de Camargo, 2016). Furthermore, seeds and other plant processing by-products are emerging as novel sources of these bioactives (da Silva and Jorge, 2014). In terms of food chemistry, the presence and/or concentration of tocopherols may be influenced by different feedstocks (Kornsteiner et al., 2006; Syväoja et al., 1986), cultivars, crop year (Lavedrine et al., 1997; Shin et al., 2009), climate and stress conditions, life cycle (Holländer-Czytko et al., 2005; Munné-Bosch, 2005), soil quality (Egesel et al., 2008), storage and processing conditions (Raiola et al., 2015).

## Natural Sources of Tocopherols and Tocotrienols

Among all homologues, alpha-tocopherol is for sure the most studied form. As can be noted in Table 1, wheat germ oil presents a high concentration of alpha-tocopherol, which is also the major homologue in common edible oils (e.g. barley, cottonseed, olive, palm, safflower, and sunflower) and emerging specialty seed oils (e.g. grape, lemon, orange, papaya, and tangerine) (Table 2). Cashew nut oil is the only feedstock presenting beta-tocopherol as the predominant form (Gómez-Caravaca et al., 2010). Likewise, among the examples given in the latter contribution, only one feedstock (passion fruit seed oil) showed delta-tocopherol as the main one. Beta-tocopherol in linseed and rapeseed was detected only in trace amounts (Schwartz et al., 2008), whereas the same has been reported for the presence of delta-tocopherol in cottonseed (Schwartz et al., 2008). Nuts are well recognized sources of tocopherols (Alasalvar and Pelvan, 2011). Several tree nut oils have been examined (Miraliakbari and Shahidi, 2008), including almonds, Brazil nuts, hazelnuts, pecans, pine nuts, pistachios and walnuts. According to the above-mentioned study, alpha- and gamma-tocopherols were the predominant homologues present in these samples. The same trend has been found for peanuts (de Camargo et al., 2012; Shin et al., 2009). However, among the reported nuts, macadamia seems to be an exception, for which the contribution of tocopherols has been found to be minor or non-existent (Elisia et al., 2013; Kornsteiner et al., 2006; Wall, 2010). It has been reported that alpha-tocopherol is found mostly in the chloroplasts of plant cells, whereas beta-, gamma-, and delta-tocopherols are commonly found outside these organelles. Tocotrienols are usually absent in the green parts of the plants, but may be found in the bran and germ fractions of certain seeds and cereals (Shahidi and Ambigaipalan, 2015). Data about the presence and contribution of tocotrienols is still scarce in emerging dietary sources. However, all forms of tocotrienols have been detected in barley, palm, rice bran, and wheat germ (Shahidi and de Camargo, 2016). The presence of alpha-tocotrienol in almond has been reported (Piironen et al., 1986; Zhu et al., 2015). According to Zhu et al. (2015), some samples presented similar or higher concentrations compared to that of gamma- and beta-tocopherols, thus suggesting that the presence of alpha-tocotrienols should be monitored in this oilseed. Additionally, as mentioned earlier, macadamia also appears to be an exception amongst other nuts. Kaijser et al. (2000) evaluated several macadamia samples from different cultivars and locations. Their study

**Figure 1** Chemical structures of tocopherols and tocotrienols (Shahidi and de Camargo, 2016).

demonstrated that the content of alpha-tocotrienols may be up to 44 and 11 times higher than that of alpha- and delta-tocopherols, respectively. The presence of both alpha- and gamma-tocotrienols in grapeseeds was reported by Choi and Lee (2009). Regardless of the fraction (hexane-soluble fraction versus methanol-soluble fraction), tocotrienols were the most prominent homologues compared with that of alpha- and gamma-tocopherols. In fact, the methanol-soluble fraction showed about 54-fold higher recovery of gamma-tocotrienol compared to the recovery of gamma-tocopherol. Furthermore, gamma-tocopherol was not detected in the hexane-soluble fraction. In the nineties, the presence of tocotrienols in tocotrienol-free vegetable oils was proposed as a means to indicate their authenticity (Dionisi et al., 1995). The advance in the breeding technology has, however, brought new challenges for such assumption. In contrast to common sunflower cultivars, at which alpha-tocopherol is the dominant tocol, the development of a new cultivar with higher contents of gamma-tocopherol has been reported (García-Moreno et al., 2012). Therefore, the use of the dominant tocol to indicate oil adulteration requires reevaluation (Shahidi and de Camargo, 2016).

### Identification and Quantification of Tocopherols and Tocotrienols

Tocols are lipophilic phenolic compounds, therefore, the American Oil Chemists' Society (AOCS) has published an official method (AOCS, 2003) for determination of tocopherols and tocotrienols in vegetable oils and fats by high-performance liquid chromatography (HPLC). Extraction of tocopherols is influenced by the solvent system employed (Table 3). Hexane is the most commonly used solvent system, but ethanol (Bueno-Borges et al., 2017; Ng et al., 2004) and solvent mixtures such as heptane–diethyl ether (Schwartz et al., 2008), and ethyl acetate–hexane (Shin et al., 2009) have also been used for their recovery. Furthermore, the lipid fraction extracted with chloroform–methanol rendered higher contents of tocopherols than that of hexane (Miraliakbari and Shahidi, 2008). The contribution of each tocopherol has been found to be quite different in ethanolic oil-rich miscella (71% gamma-

25% delta-, 3% alpha-, and 1% beta-tocopherol) compared to the oil procured by hexane extraction (82% gamma-, 11% alpha-, 6% delta-, 1% beta-tocopherol) (Bueno-Borges et al., 2017). Tocotrienols are also recovered in hexane, but the literature has demonstrated that methanol may be a better option in recovering tocotrienol-rich fractions (Choi and Lee, 2009). The AOCS (2003) official methods recommends the use of normal-phase liquid chromatography, but the use of reverse phase chromatography has also been reported (Choi and Lee, 2009). The literature (Moreau et al., 2007; Ryyänen et al., 2004) has demonstrated that tocopherols elute before tocotrienols during chromatographic separation. The technique seems to be very simple, but requires the use of authentic standards for identification and quantification of all tocol homologues. Furthermore, due to co-elution, gamma- and

beta-tocopherols have often been reported (Delgado-Zamarreño et al., 2016; Kornsteiner et al., 2006) as their sum, which jeopardizes the prediction of their actual benefits in food and/or biological systems. Co-elution of gamma- and beta-tocopherols may be explained by the presence of three methyl groups in their chromanol ring structures. The influence of the number of methyl groups in the chromanol rings of tocopherols is higher than that of the steric effects of methyl groups. Although some research groups (Moreau et al., 2007; Schwartz et al., 2008; Tang et al., 2015) have used hyphenated techniques such as LC-MS<sup>n</sup>, data procured using such a technique is still scarce. Both atmospheric pressure chemical ionization (APCI) (Moreau et al., 2007; Schwartz et al., 2008) and electrospray ionization (ESI) have been used (Bustamante-Rangel et al., 2007). Likewise, both positive (Moreau et al., 2007) and negative ionization modes (Bustamante-Rangel et al., 2007) have been employed. Ionization of non-polar substances may be hindered because of the lack of protonation and/or deprotonation sites (Bustamante-Rangel et al., 2007; Rentel et al., 1998). Therefore, the use of metal salts in the mobile phase has been practiced to overcome such a problem. Silver–tocopherol adducts have been found to enhance the ionization of tocopherols (Rentel et al., 1998), but addition of acid to the mobile phase, which is more common, has also been found to be a good option (Mottier et al., 2002). Finally, due to different reporting methods, comparing literature results might be challenging. Due to the lipophilic nature of such compounds, it is recommended to publish the final results on the basis of their fat and/or oil fraction (e.g. mg/100 g of oil).

## Properties and Stability of Tocopherols and Tocotrienols in Food Systems

The antioxidant properties of tocopherols and tocotrienols are well substantiated. This property stems in part from their ability to donate their phenolic hydrogen to free radicals (Kamal-Eldin and Appelqvist, 1996). Both the number and position of methyl groups of tocols affect their capacity to donate a hydrogen atom and, in turn, their antioxidant effectiveness (Kamal-Eldin and Budiarto, 2015). Tocols may protect lipids from oxidation by either physically quenching or by reacting with ROS (Kamal-Eldin and Appelqvist, 1996; Shahidi and Ambigaipalan, 2015), but prooxidant effects of tocopherols at high concentrations have also been reported (Kamal-Eldin and Appelqvist, 1996). However, the contents of tocopherols in natural systems seem to be close to their optimal values. In food manufacturing, the recommended levels of total alpha-tocopherol (naturally occurring or added) should be between 50 and 500 ppm (Kiokias et al., 2008). The prooxidant effect of alpha-tocopherol is inversely proportional to the temperature of the system. Under low-to-mild temperatures, and at optimum concentrations to achieve their antioxidant potency, the order of activity of tocopherols is alpha- > beta- > gamma- > delta-tocopherol. However, at higher temperatures their potency follows a different trend. Additionally, under different conditions (60 °C or 160 °C), gamma- and delta-tocotrienols were more active in preventing coconut fat oxidation than their corresponding tocopherols (Wagner et al., 2001). Furthermore, gamma-tocotrienol was also a better antioxidant than alpha- and delta-tocopherol in stripped corn oil (Dolde and Wang, 2011). Regardless of the chemical nature (tocopherols or tocotrienols), their activity is influenced by light exposure, presence of trace metal ions, substrate, medium pH, presence of synergists, and/or regenerating substances such as ascorbic acid, chitosan, glutathione, dehydrozingerone, flavonoids, carotenoids, melanoidins, and phospholipids (Georgantelis et al., 2007; Hudson and Mahgoub, 1981; Kamal-Eldin and Appelqvist, 1996; Kancheva et al., 2014; Pekkarinen et al., 1999; Shahidi and Ambigaipalan, 2015; Zou and Akoh, 2015b). In addition, the efficacy of tocols may differ according to the parameter evaluated (e.g. hydroperoxides, aldehydes, etc) (Huang et al., 1994). Because of its amphiphilic nature, the synergistic effect of phospholipids has been attributed to their ability to form microemulsions in organic solvent systems. Tocopherols are then solubilized in these microemulsions and their polar hydroxyl groups are located near the membrane surface where they can easily scavenge aqueous peroxy radicals. Furthermore, the hydrocarbon chain length in the phospholipid has been found to be positively correlated to its ability to enhance the antioxidant activity of alpha-tocopherol (Koga and Terao, 1995). The loss of tocopherols during the refining of vegetable oils may exceed 30% (Gogolewski et al., 2000). During the industrial processing and production of refined-bleached-deodorized soybean oil, delta- and beta-tocopherols were the most affected homologues (Bueno-Borges et al., 2017). Tocopherols and tocotrienols are procured by distillation of the residue generated and collected in the deodorizer-distillate during the refining of several vegetable oils. These tocols, recovered in such a process, may be used to enhance the oxidative stability of sensitive oils such as those from the marine origin (Shahidi and de Camargo, 2016). Despite their wide range of health benefits, marine oils contain a high percentage of polyunsaturated fatty acids, which makes them very sensitive to oxidative reactions, thus potentially jeopardizing their quality and biological function. As an alternative to the use of tocopherols and tocotrienol as food additives, the literature (Wang and Shahidi, 2017) has demonstrated that vegetable oils such as wheat germ oil, which contain high concentrations of tocols, are also able to improve the oxidative stability of marine oils (Wang and Shahidi, 2017). The application and proven efficiency of tocols in food emulsions (e.g. salad dressings, infant formulas, and meat) are also numerous (Georgantelis et al., 2007; Let et al., 2007; Zou and Akoh, 2015a) and, as mentioned for fats and bulk oils, the literature (Zou and Akoh, 2015a) supports the higher potency of tocotrienols compared to that of tocopherols. Furthermore, tocopherols and tocotrienols (alpha and gamma) were found to be more effective in inhibiting fatty acid oxidation than anthocyanins. Nitrosating agents react with primary and secondary amines producing potentially carcinogenic *N*-nitrosamines (NAs) (Tricker and Preussmann, 1991). Malondialdehyde, a well-accepted biomarker for lipid oxidation in muscle food, influences the generation of *N*-nitrosamines (NAs) (Kurechi et al., 1980) and the degree of unsaturation of the feedstock plays a crucial role in the level of NAs formation in cured meats (Gray et al., 1984). Several studies support the use of alpha-tocopherol to prevent/decrease the formation of NAs in cured meat products (Fiddler et al., 1978; Gray et al., 1984; Wang et al., 2015). During the storage of meat products, oxymyoglobin is oxidized to metmyoglobin, which is easily noted by a brownish colour development of the product (Pegg and Shahidi, 1997). Furthermore, metmyoglobin is also able to initiate lipid oxidation (Melo et al., 2016). Endogenous (from the diet) or added alpha-tocopherol has been used to reduce myoglobin oxidation (Djenane et al., 2002; Morrissey et al., 1998). The higher the degree of unsaturation of the lipid fraction, the lower the stability of tocols (Corsini et al., 2009). Finally, tocopherols incorporated in active packaging may be released to the surface of different food products, thus acting as antioxidants (Chen et al., 2012).

## Tocols as Antioxidants and Anti-inflammatory Compounds

Several studies have supported the potential benefits of tocopherols and tocotrienols under physiological conditions. Regardless of the chronic ailment, different homologues may have a different bioavailability (Saito et al., 2010). Gene mutations, health status (e.g. metabolic syndrome, inflammation, and oxidative stress) also affect the uptake of tocopherols and tocotrienols, in turn, their concentration in plasma and other tissues. In addition, the presence and action of tocols also differs among several tissues (Jansen et al., 2016). Fenton reaction is often used to generate hydroxyl radical, a highly reactive oxygen species. In this system, Fe(II) and H<sub>2</sub>O<sub>2</sub> are present, therefore, it has been hypothesized that the protective effects of several plant food phenolics may include both the chelation of iron and/or the scavenging of hydroxyl radicals. The scavenging activity of alpha-tocopherol towards hydroxyl radicals generated via Fenton reaction has been reported by Inami et al. (2012). Phenolic extracts from different plant sources are known to

exhibit chelating capacity (Ayoub et al., 2016). Likewise, both alpha-tocopherol and tocotrienol-rich fractions showed chelating effect towards ferrous ion, with the latter one presenting the highest efficiency. The oxidation of low-density lipoprotein cholesterol (LDL-c) has long been used as a biomarker to predict potential development of cardiovascular diseases. Pearce et al. (1994) have ranked antioxidant effect of tocopherols using the copper-induced LDL-c oxidation model *in vitro*. The protective effect was found to be in the order of gamma-tocotrienol > gamma-tocopherol > alpha-tocotrienol > gamma-tocopherol. Additionally, gamma-tocotrienol ( $IC_{50} = 1.8 \mu M$ ) showed around twice as much oxidative prevention than gamma-tocopherol ( $IC_{50} = 3.9 \mu M$ ). Likewise, peroxy and hydroxyl radical-induced DNA damage has also been accepted as an early stage indicator of cancer development. Besides that, toxins and NAs are found to induce DNA fragmentation (strand breaks, oxidized pyrimidines and oxidized purines) (Delgado et al., 2008; Shahidi and de Camargo, 2016). Both alpha-tocopherol and gamma-tocotrienol have been reported to inhibit DNA damage (Abid-Essefi et al., 2003; Pathak et al., 2016). Other factors involved in antitumour action of tocopherols (e.g. cell cycle arrest, antiangiogenesis, anti-metastasis, nuclear factor- $\kappa B$  suppression, and telomerase inhibition) have also been reported (Eitsuka et al., 2016). Furthermore, tocopherols and tocotrienols are known to perform apoptotic and antiproliferative functions in cancer cell lines (Campbell et al., 2006; Wada et al., 2005; Yu et al., 1999), with the advantage of being safe towards normal cells (Shahidi and de Camargo, 2016). Nonetheless, in human breast cancer cells, tocopherols and tocotrienols also play a synergistic effect in combination with tamoxifen (Guthrie et al., 1997). Tocopherols and tocotrienols exhibit significant anti-inflammatory activity *in vitro* and *in vivo*, and their molecular mechanisms of action include, at least in part, modulation of inflammatory mediators responsible for orchestrating several stages of inflammation (Ahsan et al., 2014; Jiang, 2014; Jiang et al., 2001; Mathur et al., 2015; Reiter et al., 2007; Singh and Jialal, 2004; Yang et al., 2010). According to the literature (Jiang et al., 2000), gamma-tocopherol treated RAW 264.7 macrophages and human epithelial cells show reduction in prostaglandin E2 (PGE2) synthesis. The same study further reported that 2,7,8-trimethyl-2-(b-carboxyethyl)-6-hydroxychroman, the main metabolite of gamma-tocopherol, also showed anti-inflammatory effect in the same cell lines. According to these authors, the mechanism of action was related to inhibition of cyclooxygenase-2 (COX-2) enzymatic activity. In another study (Jiang and Ames, 2003), the treatment with gamma-tocopherol (at 33 or 100 mg/kg) or with its main metabolite (2 mg/pouch) *in vivo* was likewise effective in reducing the synthesis of PGE2 at carrageenan-induced inflammation sites in rats. In addition, gamma-tocopherol showed inhibitory activity on leukotriene B4 (LTB4) and tumour necrosis factor-alpha (TNF- $\alpha$ ) synthesis. Yam et al. (2009) examined the *in vitro* anti-inflammatory activity of tocotrienols and found that tocotrienols (gamma-, alpha- and delta-tocotrienol) or a tocotrienol-enriched fraction had a significant anti-inflammatory effect on lipopolysaccharides (LPS)-stimulated macrophages. Among their findings, delta-tocotrienol was found to be most effective in inhibiting the production of interleukin 6 (IL-6), nitric oxide and PGE2 as well as gene expression of COX-2. The synthesis and release of inflammatory mediators by activated cells is controlled by different intracellular signaling pathways, which involves the participation of protein kinases, such as mitogen-activated protein kinases (MAPK) as well as transcription factors (Arthur and Ley, 2013; Li and Verma, 2002). Several studies on tocopherols and tocotrienols have demonstrated that the anti-inflammatory activity of these compounds stems from their ability in inhibiting inflammatory intracellular pathways (Azzzi et al., 2004; Cook-Mills and McCarty, 2010; Rimbach et al., 2002). Ekstrand-Hammarström et al. (2007) have shown that treatment with alpha-tocopherol reduced interleukin 8 (IL-8) production in human alveolar type II and bronchial epithelial cells stimulated with TNF- $\alpha$ . The intracellular mechanism of action of alpha-tocopherol was found to be related to decreased phosphorylation of p38 MAPK and extracellular signal-regulated kinases (ERK) 1/2 as well as of nuclear factor kappa B (NF- $\kappa B$ ). A study by Shibata et al. (2010) suggested that gamma-tocotrienol displays anti-inflammatory activity by suppressing the expression of COX-2, interleukin 1 beta (IL-1 $\beta$ ), IL-6 and monocyte chemoattractant protein-1 (MCP-1) genes in HaCaT cell cultures exposed to UVB irradiation. Furthermore, treatment with gamma-tocotrienol decreased phosphorylation of c-Jun amino-terminal kinases (JNK), p38 and ERK. A tocotrienol-rich fraction (15.4% alpha-tocotrienol, 28.2% gamma-tocotrienol, 6.4% delta-tocotrienol, 15.3% alpha-tocopherol, 12.8% plant squalene and 5.1% phytosterol), led to increased anti-inflammatory activity as compared to those of alpha-tocopherol and alpha-tocopheryl acetate in a mouse peritoneal macrophage culture. Inhibition of the activation of the transcription NF- $\kappa B$  was found to be the main intracellular modulatory mechanism of the enriched fraction (Ng and Ko, 2012). Besides activating the synthesis and release of inflammatory mediators, the transcription factor NF- $\kappa B$  also regulates the expression of adhesion molecules on endothelial cells (Tak and Firestein, 2001). Adhesion molecules play a crucial role in leukocyte migration into the inflammatory focus. Therefore, modulation of cell adhesion during inflammatory processes constitute a promising pharmacological approach for development of novel anti-inflammatory compounds (Griffith and Luster, 2013; Mackay, 2008; Peres et al., 2016). Muid et al. (2016) investigated the activity of all four homologues of tocotrienols in activating endothelial cells. These authors demonstrated that delta-tocotrienol was the most potent inhibitor of intercellular adhesion molecule type 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1) as well as the transcription factor NF- $\kappa B$ . Zapolska-Downar et al. (2000) investigated the effects of alpha-tocopherol on the expression of adhesion molecules in human vascular endothelial cells and found a significant down regulation of VCAM-1. Such pharmacological activity was therefore associated with the antiatherogenic activity of alpha-tocopherol. In another study (Yoshikawa et al., 1998), cocubation of neutrophils with alpha-tocopherol and pretreatment of human umbilical vein endothelial cells reduced platelet-activating factor (PAF)-induced CD11b/CD18 expression and IL-1 $\beta$ -induced positive regulation of ICAM-1 and VCAM-1, respectively. Preclinical and clinical studies have confirmed the efficiency of tocopherols and tocotrienols, alone or by using tocopherol-enriched fractions, in preventing the development of inflammatory diseases (Reiter et al., 2007; Jiang, 2014). A tocotrienol-rich fraction from palm oil (23.5% alpha-tocotrienol, 43.2% gamma-tocotrienol, 9.8% delta-tocotrienol, and 23.5% alpha-tocopherol) attenuated the progression of atherosclerosis in mice by modulating the action of peroxisome proliferator-activated receptors (Li et al., 2010). The therapeutic effect of delta-tocotrienol by attenuating the development of collagen-induced arthritis in rats by reducing edema, joint damage, and T-cell proliferation

has also been demonstrated (Haleagrahara et al., 2014). According to Kim et al. (2016), gamma-tocotrienol was able to attenuate the activation of NACHT, LRR and PYD domains-containing protein 3 (NLRP3) inflammasome and delayed the progression of type 2 diabetes. A preclinical trial with gamma-tocopherol demonstrated that its administration was effective in attenuating moderate colitis in mice (Jiang et al., 2013). In addition, Wagner et al. (2008) showed that acute administration of gamma-tocopherol over a 4-day period led to extensive protection of ovalbumin-sensitized Brown Norway rats challenged with allergen via the airways. Among the parameters analyzed, a reduction in the recruitment of inflammatory cells and in the production of inflammatory mediators (e. g. PGE2 and leukotrienes) was reported. Later on, the same research team (Hernandez et al., 2013) conducted pre-clinical and clinical trials and demonstrated that gamma-tocopherol-enriched supplementation was effective in reducing airway neutrophil recruitment following challenge with inhaled LPS. Furthermore, Devaraj et al. (2008) carried out a clinical study in patients with metabolic syndrome and showed that alpha-tocopherol supplementation, alone or in combination with gamma-tocopherol, not only reduced biomarkers related to oxidative stress (e.g. lipid peroxidation), but also reduced inflammation markers, such as TNF- $\alpha$ . Therefore, supplementation with the combination of alpha- and gamma-tocopherol seemed to have a greater protective effect compared to the use of isolated homologues. As mentioned before, a wealth of evidences have demonstrated the antioxidant properties of tocopherols and tocotrienols. However, in several chronic ailments the oxidative stress comes along with inflammatory responses. Therefore, this contribution demonstrates that tocols may counteract both oxidative and inflammatory responses.

## Conclusions

In this contribution, sources, analytical methods, and effects of tocols in food and biological systems were discussed. While alpha-tocopherol is the most studied form, fewer sources of tocotrienols, especially for emerging dietary sources (e.g. specialty oils), are currently known. The dominant tocol as an indicator of product adulteration has been proposed by some authors, however, advances in the breeding technology has brought new challenges which require reevaluation. In terms of analytical methods, co-elution of gamma- and beta-tocopherols may be a challenge in some cases, therefore, special attention should be paid to this potential problem. In addition, regardless of the application, some studies have supported the superior activity of tocotrienols compared to tocopherols. Therefore, production of high-tocotrienol cultivars and prospection of already available sources of tocotrienols and further application as functional food ingredients and nutraceuticals are promising areas of interest.

## Resistant Starch

**Zeynep Tacer-Caba<sup>a</sup> and Dilara Nilufer-Erdil<sup>b</sup>**, <sup>a</sup> University of Helsinki, Helsinki, Finland; and <sup>b</sup> Istanbul Technical University, Istanbul, Turkey

© 2019 Elsevier Inc. All rights reserved.

### Glossary

**Gastrointestinal** Part of digestion system comprising stomach and intestines.

**Glycemic index** The potential of food product to raise postprandial blood glucose level.

**In vitro** A biological process made to occur in an artificial environment such as laboratory vessel or other controlled experimental environment instead of within a living organism or natural setting.

**In vivo** A biological process made to occur in the living body of a plant or animal.

**Resistant starch** Part of starch that is not digested in the upper gastrointestinal tract and reaching the colon either unchanged or slightly changed.

**Retrogradation** Loss of the crystalline structure of amylose and amylopectin molecules when native starch is heated and dissolved in water.

### Introduction

Starch is the main storage carbohydrate in plants and mainly functions as a reserve for supplying about 50% of the nutrient and energy requirements in the human diet. Moreover, starch quantity and quality is a major concern in terms of blood glucose level and homeostasis in human body (Ahuja et al., 2013). Structurally starch has two major constituents of amylose and amylopectin. Amylose is a linear glucan polymer formed through  $\alpha$ -1,4 glycosidic bonds, whereas amylopectin is a highly-branched glucan polymer consisting of  $\alpha$ -1,6 glycosidic linkages. Native starch involves 15%–30% amylose, depending on its botanical origin, maturity level, growing condition and the method of analysis while the remaining part is amylopectin (Hasjim et al., 2009). The amylose/amylopectin ratio may be considered as one of the most significant factors that affect starch properties.

Starch digestion is a multi-step process and it is initiated by the oral salivary  $\alpha$ -amylases, then pancreatic  $\alpha$ -amylase and finally intestinal brush border glucoamylases, maltase-glucoamylase, and sucrase-isomaltase that convert the resultant products into molecules suitable for absorption into the vascular system (Nichols et al., 2003; Ahuja et al., 2013). Starches are classified according to their rates of digestion such as; rapidly digestible starch (RDS); slowly digestible starch (SDS) and resistant starch (RS). RDS is digested in the small intestine and results in a high glycemic response while SDS is digested at a slower rate, having a relatively lower glycemic response in blood. Glycemic response or glycemic index is defined as the potential of food product to raise postprandial blood glucose level. It is expressed as a percentage of area under the blood glucose response curve of a test food, divided by the area under the curve after eating a similar amount of control/reference food (usually white bread) (Ludwig and Eckel, 2002). RS, on the other hand, is not digested in the upper gastrointestinal tract. RS is resistant to enzymatic hydrolysis within 120 min of consumption; therefore, it does not contribute to postprandial hyperglycemia. Instead microorganisms available in the large intestine ferment the RS into short chain fatty acids (mainly butyrate, propionate and acetate) and gases ( $\text{CO}_2$ ,  $\text{CH}_4$  and  $\text{H}_2$ ) (Englyst et al., 1992). Short chain fatty acids in the large intestine are significant in terms of colonic health in addition to their reducing role on certain diseases such as irritable bowel syndrome, inflammatory bowel disease, cardiovascular diseases and cancer (Roe-diger, 1980; Wong et al., 2006). Current interest in RS is not only related to its health effects, but also its formation mechanisms and functional properties in cereal products such as heat or processing stability.

### Structure and Types of RS

The part of starch which is not digested in the small intestine and reaches the large intestine in the intact form is called RS. Therefore, RS is the part of starch that acts like a dietary fiber within the gastrointestinal tract. The resistance against enzymatic digestion in the small intestine (Englyst et al., 1992) has been recently linked to numerous positive physiological benefits on the health such as; prebiotic effect on colon microflora, improvement of cholesterol metabolism and reducing the risks of ulcerative colitis and colon cancer (Shi et al., 2013; Ozturk et al., 2009). RS is defined under 5 sub-classes: (1) physically inaccessible (RS1), (2) native B- and C-type polymorphic starch granules or ungelatinized starch (RS2), (3) retrograded or crystalline starch (RS3), (4) starch chemically modified (RS4) and (5) amylose-lipid complexes (RS5) (Shi et al., 2013; Hasjim et al., 2013). All different sub-classes of RS are generally assumed to have similar metabolic fate by being fermented in the large intestine. However, differences in site, magnitude and diversity of biochemical and physiological actions through the large intestine might be possible.

RS1 is not accessible to digestive enzymes physically because it is bound within the fibrous cell walls, in other words, it is captured in the food matrix such as whole or coarsely ground grains or seeds (Sajilata et al., 2006; Champ et al., 2003). The thick cell walls and the protein matrix in cereal and in particularly legumes, such as beans or lentils grains, prevent water penetration into the starch. Because water cannot penetrate the starch granule, there is lack of necessary moisture that is required to gelatinize and swell; therefore, it is not readily susceptible to enzymatic hydrolysis. RS2 is defined as the characteristic of B-type starches such as those present in uncooked potato starch, green banana starch and high-amylose maize starch that are very resistant to enzymatic hydrolysis. In the native (raw) form, RS2 is digested at very low levels in the small intestine but becomes totally digested when freshly cooked due to the gelatinization of starch and loss of the B- and C-type crystalline structures. The compact structure of RS2 is a limiting factor to accessibility by digestive enzymes, including some of the amylases. Since cooking is highly effective, raw banana starch is known as the most significant example of RS2 (Sajilata et al., 2006). RS3 is also slowly and partially digested but has reversible characteristics, and digestibility may be enhanced by reheating. Amylose retrogradation is a causative factor of RS3 generation. Amylose molecules tend to form double helices around refrigeration temperatures (4 °C) because of their linear structures. In addition, retrograded amylose has higher gelatinization temperatures, and they cannot be dissociated by cooking. Among all RS types, RS3 has been the most commonly studied particularly because of its advantages such as thermal stability, high gelatinization temperature, very low water holding properties, as well as improved texture, appearance and organoleptic properties (Sajilata et al., 2006). Some previous works had aimed to increase the amount of RS3 in food samples using different methods (such as heat treatment, partial acid hydrolysis, enzymatic modifications together with acidic modification and heat treatment, extrusion or chemical methods) (Shi et al., 2013; Ozturk et al., 2009; Dundar and Gocmen, 2013; Van Hung et al., 2016; Liao and Hung, 2015; Reddy et al., 2013; Demirkesen-Bicak et al., 2018; Faraj et al., 2004; Hasjim and Jane, 2009). Although the formation of RS is generally related to retrogradation of amylose, retrograded amylopectin has also been stated as a contributor to RS content (Thompson, 2000). Amylopectin retrogrades slower than amylose and crystalline amylose is more resistant to heat in comparison to similar amylopectin structures. Therefore, temperature and branched structure of amylopectin may be considered as limiting factors for RS formation in these amylopectin moieties. The preventive effect of amylopectin structure has been overcome using enzymatic treatment with pullulanase or isoamylase enzymes. They are able to cleave  $\alpha$ -1,6 glycosidic bonds in amylopectin molecule to increase the number of linear glucans so that re-association to form RS3 becomes easier (Thompson, 2000). Some of very recent studies on enzymatic treatment with pullulanase (Shi et al., 2013; Reddy et al., 2013; Demirkesen-Bicak et al., 2018) focused not only on the different conditions for enzymatic treatment of starch with pullulanase but also the use of different starch sources.

RS4 is basically the chemically modified starch and consists of starches in which chemicals have been used to etherize, esterify or crossly-bond the molecules in order to decrease their digestibility. They can also be classified into four sub-categories according to their solubility characteristics in water or methods used for analysis (Nugent, 2005). Chemical modification methods that include conversion, substitution or cross-linking may be used to block the enzyme access and form different linkages such as  $\alpha$ (1  $\rightarrow$  4) and  $\alpha$ (1  $\rightarrow$  6) linkages to prevent starch digestion (Kim et al., 2008; Sajilata et al., 2006). Cross-linking raises the gelatinization temperature and it permits the starch granule to stay intact at high temperatures. RS4 type can also be formed by dextrinization during which new linkages that cannot be degraded by mammalian digestive enzymes are formed between starch molecules. RS5 has been quite recently introduced as high-amylose starch that are preheated, debranched with isoamylase and complexed with palmitic acid to form an amylose-lipid complex that is resistant to enzymatic digestion (Hasjim et al., 2010). According to this finding, lipids form complexes with the hydrocarbon portions found in the helical cavity of amylose, dominated by unbranched (linear molecule with  $\alpha$ -1,4 linked D-glucose units) glucan chains (Tang and Copeland, 2007). Mechanism behind the enzyme susceptibility of amylose-lipid complex was proposed to be two-fold: 1) The starch-lipid complex decreases the extent of granule swelling and therefore, the enzyme may not easily reach inside of the starch granule or 2) The amylose-lipid complex is more resistant to enzymatic digestion in comparison to free amylose (Zhang et al., 2012; Okumus et al., 2018).

## Factors Effecting RS Formation

### Effect of Starch Composition on RS Formation

Granule structure, amylose-amylopectin ratio, starch source, etc. were previously reported to affect starch resistance to digestion (Finocchiaro et al., 2009). Total amount of amylose substitution was the main factor to determine the variations in resistant starch measurements. Since higher amylose content is expected to lower starch digestibility, positive correlation between amylose content and resistant starch exist and has been reported in many different studies (Leeman et al., 2006; Sang et al., 2008). This correlation may be associated with the digestion kinetics that defines two distinct limiting factors: 1) binding of enzyme to starch prevented by the barriers and 2) decrease in amylase activity because of starch structural features (Zhang et al., 2015). Therefore, depending on the structural differences in the amylose and amylopectin, small intestinal  $\beta$ -amylase access is limited by the straight chains of amylose (forms tightly-bound complexes) and the two terminal glucose units on the amylose chain. However, the highly-branched (porous) structure of amylopectin enabled  $\beta$ -amylases access (Ahuja et al., 2013).

## Effect of Processing on RS

Resistance to digestion derives from modifications in the specific physical state of starch such as the effects of heat treatments, amylose/amylopectin ratio, chain length of molecules, presence of amylose–lipid complex, etc (Demirkesen-Bicak et al., 2018). Sources of cereal grains, roots, tubers and legumes produce RS through the process of cyclic heating, autoclaving and extrusion methods. Different RS types are not specific to food samples. For example, RS1, RS2 and RS3 can be present in the same food. Both RS1 and RS3 can exist in beans, while RS1 and RS2 are usually found in bananas. Food processing, in most cases, decreases natural types of RS1 and RS2, but may lead to formation of RS3. Among all RS types, RS3 has been the most commonly studied particularly because its formation is dependent on various processes such as thermal treatment, gelatinization, extrusion etc. Generally, severity of the conditions such as moisture, temperature, number of heating/cooling cycles, autoclaving, storage, and drying will determine the amount of RS formed during processing (Fuentes-Zaragoza et al., 2010).

Starch has been reported to display more resistance to  $\alpha$ -amylase at higher temperatures (Zabar et al., 2008). This phenomenon has been related to starch gelatinization. During gelatinization, amylose molecules are leaching out of the swollen starch granules in coiled polymer structures while through cooling, they associate as double helices and form hexagonal networks, which resist digestion (Ahuja et al., 2013). Moreover, the method used for drying has also been reported to affect the RS content in green bananas (Tribess et al., 2009). Although the use of repeated heating–cooling cycles in the presence of moisture has attracted interest as an effective approach to increase the RS3 levels (Masatcioglu et al., 2017), heat-moisture treatments gave some contradictory results such as increases in corn, lentil and pea starches (Chung et al., 2009) but a decrease in corn starch (Brumovsky et al., 2009). Moisture or heat-moisture treatments followed by storage have been reported as a positive approach for increasing the RS content (Kim et al., 2006). Autoclave cycles followed by cooling were also promising (Hickman et al., 2009). Gelatinization alone has been considered as a negative factor for total RS formation (Chung et al., 2006), although gelatinization followed by cooling processes which are generally referred to as annealing procedures, are the common methods used to enhance the RS formation, in particular RS3 (Thompson, 2000; Chung et al., 2006). Among a number of different foods that were cooked, cooled and stored, the highest amount of total RS was obtained for the retrograded gelatinized starch (Rosin et al., 2002).

Acidic treatments applied as a pre-treatment before gelatinization using HCl at 40 °C (Koksel et al., 2008) and as a post-retrogradation treatment with citric acid (Zhao and Lin, 2009) was found to have increased the levels of RS. Gamma irradiation was also promising to increase the RS content of corn starch because the effect of gamma irradiation has commonly been related to increases in the degree of polymerization and/or branching of glucan polymers (Chung and Liu, 2009). Enzymes have roles in changing the amylopectin chain length distributions by means of increasing  $\alpha$ -1,6 linkages and decreasing  $\alpha$ -1,4 linkages. This structure aids in retrogradation which produces more resistant starch (mostly RS3). Starch becomes more resistant to digestion with an increase in the proportion of longer chains (Ahuja et al., 2013). Results revealed that the enzymatic hydrolysis by pullulanase followed by thermal processes and retrogradation increases the amylose contents and the formation of resistant starch (Reddy et al., 2014; Demirkesen-Bicak et al., 2018).

## Measurement of RS

Growing interest in resistant starch research (more than 200 SCI-indexed articles in the period of 2015–7) focusing on different perspectives, and underlines the significance of resistance starch measurements. However, resistance to digestion derives from specific physical states; therefore, different RS studies are not truly directly comparable at all times. In particular, the temperature of a RS assay may tremendously affect the measured value (Haralampu, 2008). Moreover, another significant point is that the measurement of RS compromises the sum of “added” and “naturally occurring” RS, as different types of RS may exist in the same food, although their susceptibility to various conditions are different. Digestion resistance might be affected from subjective physiological differences during the process of digestion, such as efficiency of chewing, time of gastrointestinal transit and the quantity of enzyme secretion. In addition, differences during preparation of ingredients, food processing and cooking conditions, food storage etc. might also affect the measured content of total RS (Brown et al., 2008). In particular, the method used for isolation of starch from food commodities and/or the extent of its purity might be significant. Calculation of RS is commonly made by subtracting the total amount of RDS and SDS generated from non-homogenized food samples by enzyme digestion, from the total starch obtained from homogenized and chemically treated sample.

Because of the difficulties during measurement, approaches such as comparison with both *in vitro* and *in vivo* RS measurement methods, use of a wide range of population and validation with large number of RS sources have been proposed (Champ et al., 2003). *In vitro* methods mimic the digestion process, which has been approved by AOAC as an Official Method 2002.02 or AACC Recommended method 32–40.01. In addition, several *in vivo* methods such as the hydrogen breath test, and direct collection of ileal effluent from healthy subjects or patients of ileostomy who had their colon removed have been reported (Champ et al., 2003). Besides, differential scanning calorimetry (DSC) is a common instrument used to identify mostly the RS3 produced from retrograded amylose, and has been proposed as a vehicle to display the time–temperature history between the glass transition temperature and the melting temperature of the starch micro crystallites (Haralampu, 2008).

## Conclusion

RS with its different sub-groups has gained increased importance recently. Increase in its broader use in food industry will probably direct future research more towards changes and responses during food processing. The relationship between food processing and RS may be considered as two-sided; both to determine its limits of susceptibility and to discover new potential mechanisms that encourage its formation. Therefore, the true determination and chemistry of RS will likely gain more interest in future studies.

## Introduction

Increasing human population and the demand for safe and nutritious food impose food security challenges worldwide (Bajagai et al., 2016). It has been reported that an estimated 600 million, which means almost 1 in 10 people in the world, fall ill after eating contaminated food that can cause notably severe diarrhea and 420000 die every year (WHO, 2017). To face this threat it is critical to ensure food safety throughout the entire food chain from the production to the consumption of the end-products (WHO, 2014).

Foodborne illnesses are usually caused by bacteria, viruses, and parasites entering the body through microorganisms-contaminated foodstuffs (Pisoschi et al., 2018). Bacteria can account for both food spoilage and toxicity (Gram et al., 2002). Indeed, major foodborne illnesses are caused by *Salmonella* sp, *Campylobacter* sp, *Escherichia coli*, *Listeria* sp and *Vibrio cholera* (WHO, 2017). Administration of antibiotics is still the main practical strategy to treat these infections (Hassan et al., 2012). However, their overuse and misuse in veterinary and human medicine has been linked to the emergence of resistant foodborne pathogens, rendering the treatment of infectious diseases ineffective in animals and humans (Dong et al., 2007).

Microbial resistance development is one of the main fears to modern medicine and it has driven the search for new antimicrobial agents to replace conventional antibiotics (Hassan et al., 2012). Hence, both pharmaceutical and food industries are looking for safe new types of antimicrobials from natural sources (Boisvert et al., 2015). Besides, there is a growing consumer demand for natural alternatives to replace synthetic food preservatives such as nitrates, benzoates, sulfites, sorbates, and formaldehyde, which are known for their life-threatening side effects (Sultana et al., 2014). The search for an alternative to chemical preservations has led to defined novel methods like biopreservation that ensure food safety (Pisoschi et al., 2018). Plant and animal-derived antimicrobials, natural or controlled microflora, such as lactic acid bacteria (LAB) and their antibacterial metabolites such as lactic acid, bacteriocins demonstrated ability to prevent lipid oxidation, inhibited colour loss, prolonged shelf life and ensured food security (Pisoschi et al., 2018). Antimicrobial peptides (AMPs) such as bacteriocins have attracted particular attention as their producer organisms could obtain GRAS (generally recognized as safe) status and are naturally present in many food products (Tahiri et al., 2009). Either low toxicity, thermostability or high specificity make these molecules of clear interest to the food industries (de Castro and Sato, 2015).

Moreover, there is an urgent need for innocuous antimicrobials in food preservation, which has led numerous research activities towards AMPs (Boisvert et al., 2015; Beaulieu et al., 2015; Ennaas et al., 2015a, 2015b, 2016). AMPs are components of the innate immune defenses and exhibit high structural diversity (Reddy et al., 2018; Shabir et al., 2018). They generally have amphipathic structure facilitating their attachment and the formation of pores in the cytoplasmic membrane of microorganisms (Mor, 2000). This characteristic, unlikely to lead to the development of the microorganism's resistance, has stimulated their studies for alternative antimicrobial agents (Mor, 2000). Furthermore, the newly identified AMPs should be specifically active against foodborne pathogens, and they are expected not to influence negatively the consumer's own microbiome (Pisoschi et al., 2018). In addition, AMP-containing formulations have to exhibit the expected antimicrobial effects, with least chemical or biological degradation of peptides (Nordström and Malmsten, 2017).

This chapter will focus on the potential of AMPs as one of the key novel food preservatives for the future.

## Origins of Natural Antimicrobial Peptides (AMPs) and Their Different Functions

### Plant

Plant AMPs are small cysteine-rich peptides that have been isolated from roots, seeds, flowers, stems, and leaves of a wide variety of species (Terras et al., 1995). They are grouped into several families and many share general features, such as an overall positive charge, the presence of disulfide bonds, which stabilize the structure and a mechanism of action targeting outer membrane structures, such as ion channels. Based on amino acid sequence homology, AMPs were classified mostly as  $\alpha$ -defensins, thionins, lipid transfer proteins, cyclotides, snakins and hevein-like (Broekaert et al., 1997). In addition to their role in host defense and their appeal as simple models for studying the molecular mechanism of antimicrobial peptide action, AMPs have the potential to inhibit pathogens, including those showing increased resistance to conventional antimicrobial compounds. These peptides usually have a broad-spectrum of antimicrobial activity and therefore, representing promising candidates for plants applications (Nawrot et al., 2014). PhytAMP is a database that provides a very useful interactive platform that enables easy access to systematized information about all families of plant antimicrobial peptides. PhytAMP also provides useful tools that facilitate analysis of these peptides and search for new members of the plant AMP classes (<http://phytamp.hammamilab.org/>).

## Bacteria

Most families of bacteria are able to produce AMPs namely bacteriocins. Bacteriocins of gram-positive bacteria are more abundant and more diverse than those produced by gram-negative bacteria. Archaea are also able to produce their own bacteriocin-like-antimicrobials known as archaeocins (Riley and Wertz, 2002). Bacteriocins are ribosomally synthesized molecules and have bacteriostatic or bactericidal effects. Bacteriocins have narrow or broad spectra of activity that inhibit the growth of bacteria of the same species or other genera including pathogenic and antibiotic-resistant strains (Cotter et al., 2012). Bacteriocins represent a heterogeneous family of small, heat-stable peptides in terms of size, microbial spectrum of activity, modes of action and release and mechanism of bacterial immunity (Gordon et al., 2007). All this information has been assembled in a database named Bactibase, which is a web-accessible database that contains calculated or predicted physicochemical properties of several bacteriocins produced by both Gram-positive and Gram-negative bacteria. The information in this database is very easy to extract and allows rapid prediction of structure/function relationships and target organisms of these peptides and therefore, better exploitation of their biological activity in both the medical and food sectors (<https://www.ncbi.nlm.nih.gov/pubmed/17941971>).

## Fish and Marine Products

Many marine organisms such as crustaceans, crab, mollusks and fish are potential sources of bioactive peptides such as antimicrobial peptides (Kang et al., 2015; Cheung et al., 2015). Marine AMPs belong to a particular group of peptides. They have high cysteine content and are positively charged in their active forms. They play a crucial role as a first line of defence protecting the hosts against a broad range of pathogenic infections (da Costa et al., 2015). Marine AMPs differ in length, isoelectric point, secondary structure, hydrophobicity, and amphipathicity, and in their antimicrobial activities. Marine AMPs may be classified into four main categories, namely: (a) linear-helical peptides; (b) linear or helical peptides with abundance of one amino acid (proline, tryptophan, histidine or glycine rich peptides); (c) peptides forming hairpin-like-sheet or -helical/-sheet mixed structures stabilized by intramolecular disulfide bonding; and (d) cyclic peptides (Falanga et al., 2016). Most of the marine AMPs are described in APD (<http://aps.unmc.edu/AP/>), a database that contains information for 116 antimicrobial peptides identified from fish.

## Milk and Milk Products

Milk and milk products are shown to be good sources of a variety of bioactive compounds such as AMPs (Mohanty et al., 2016). AMPs have already been isolated and characterized from major milk proteins such as caseins, lactoferrin,  $\alpha$ -lactalbumin and  $\beta$ -lactoglobulin (Meisel, 1998). They were shown to have a broad spectrum of activity against pathogenic organisms like bacteria, yeast, fungi, and some parasites (Mohanty et al., 2016). Milk-derived AMPs may be found in inactive form within the sequence of the precursor protein but may also be produced by enzymatic digestion especially during the gastrointestinal digestion (Gobbetti et al., 2007). Recently, a database, MilkAMP (<http://milkampdb.org/>), has been created to assembly all information about natural and artificial (synthetic or modified) antimicrobial peptides derived from amino acid sequences of dairy proteins of different origins and provides. This database contains most complete information on peptide structure/function relationships, inhibitory activity, spectrum of action and minimal inhibitory concentration (MIC) determined for each tested microbial strain. It also allows rapid prediction of structure/function relationships and target organisms and hence should lead to better use of the biological activities of peptides in both the pharmaceutical and food sectors.

## Algae and Mushrooms

Only a few studies concerning the inhibitory activities of macroalgal AMPs have been carried out. The lectin is an example of antibacterial algal protein reported in the literature (Liao et al., 2003; Holanda et al., 2005). In addition, a cyclic depsipeptide obtained from green seaweed *Bryopsis* sp. has demonstrated activity against *Mycobacterium tuberculosis* (Hamann and Scheuer, 1993; Hamann et al., 1996), while a dipeptide derivative originated from red delesseriacean macroalgae has displayed antibacterial effect against *Serratia marcescens* and *Salmonella typhi* XLD (N'Diaye et al., 1996). More recently, AMPs have been extracted from the brown macroalga *Saccharina longicuris* in order to recover antibacterial peptides by enzymatic hydrolysis with trypsin. The protein hydrolysate fraction exhibited activity against the bacterium *Staphylococcus aureus* (Beaulieu et al., 2015).

Mushrooms reported as producers of a large number of proteins and peptides with interesting biological activities, such as lectins, fungal immunomodulatory proteins (FIP), ribosome-inactivating proteins (RIP), antimicrobial proteins, ribonucleases, and laccases. These bioactive components have become popular sources of natural antimicrobial, antiviral, antioxidative, antitumor and immunomodulatory agents (Xu et al., 2013; Jose Alves et al., 2013; Lavanya and Subhashini, 2013). Some mushrooms-derived AMPs are described in APD (<http://aps.unmc.edu/AP/>), a database that contains information for 2 antimicrobial peptides identified from mushrooms.

## Mechanisms of Action

AMPs have diverse structures and functions and interact with cell membranes of invader cells by disturbing the membrane integrity. As shown in Fig. 1, adapted from Brogden (2005), AMPs may be divided into different groups based on their mechanisms of action. Some of them have the cell membrane as target and may act by inhibition of cell membrane synthesis, alteration of the cytoplasmic membrane and inhibition of cell septum formation or activation of the cell autolysis. Other peptides seem to act on intracytoplasmic targets. For example, arginine-rich peptides have been shown to act either by inhibiting the synthesis of the cell membrane, DNA, RNA or proteins. Other peptides such as histatins act rather by inhibiting enzymatic activity.

AMPs mechanisms of action could be classified in two main groups, AMPs targeting external processes or internal processes of microorganisms.

### Extracellular-Targeting AMPs

#### Outer Surface Lipids

AMPs must first be attracted to bacterial surfaces, and one obvious mechanism is electrostatic bonding between anionic or cationic peptides and structures on the bacterial surface such as lipids that constitute the outer membrane (de Leeuw et al., 2010). Defensins, nisin and other lantibiotics were able to interact with lipids constituting bacterial cells, and notably the lipid II that is a central component of the bacterial cell wall synthesis (de Leeuw et al., 2010; Sass et al., 2010; Hsu et al., 2004). The interaction of cationic AMPs is well understood and be explained by their initial electrostatic attraction with the outer leaflet of Gram-negative bacteria initiating the passage of AMPs across the outer membrane through a self-promoted uptake mechanism (Hale and Hancock, 2007). Such as the Cecropin P1, this attachment to the bacterial membrane could induce in many cases its disruption and membrane permeabilization, leading to cell-killing (Strauss et al., 2010).

#### Outer Membrane Proteins

Inside the outer membrane of bacteria, it is known that several proteins play an important role as a receptor for AMPs. As describe by Lin et al. (2010), outer membrane protein I (OprI) plays a critical role in maintaining the integrity of the outer membrane of *Pseudomonas aeruginosa* and this protein serves as the receptor for the cationic-helical AMPs, SMAP-29 and CAP-18. In consequence, the bacterial membrane became permeable to metabolites. Other AMPs showed a non-membrane-lytic mechanism of action such as analogs of proteogrin I that are able to target the  $\beta$ -barrel protein LptD, a protein implicated in the outer-membrane biogenesis (Srinivas et al., 2010).

### Intracellular-Targeting AMPs

#### Inner Membrane

Membrane interactions remain important even for intracellular-targeting peptides because they must have a means of translocation (Nguyen et al., 2011). AMPs could create pores in the cell membrane, through different transmembrane pore-forming mechanisms such as toroidal pores, carpet or barrel stave (Hale and Hancock, 2007; Nguyen et al., 2011). All these mechanisms of action were directly correlated to the peptide structure and were the most common and studied among all the mechanisms of action known and

**Figure 1** Modes of action for cellular antimicrobial peptide activity. adapted from Brogden (2005).

identified from AMPs. Once in the cytoplasm, translocated peptides can alter the cytoplasmic membrane septum formation, and inhibit synthesis of the cell wall, nucleic acids, proteins or enzymatic activity.

### Nucleic Acids

While many AMPs kill bacteria through membrane permeabilization, a smaller subset of AMPs is believed to inhibit bacterial growth by interfering with essential intracellular functions (Hale and Hancock, 2007). For example, Buforin II and DesHDAP1 (histone-derived AMPs) are both able to target DNA of bacterial cells (Uyterhoeven et al., 2008; Sim et al., 2017) by electrostatic attraction to negatively charged phosphodiester bonds in the nucleic acid backbone (Sim et al., 2017). The AMP indolicidin interacted with DNA by covalent links with a basic site of single or double DNAs of the HIV-1 viral cDNA (Marchand et al., 2006). As they are able to bind DNA, AMPs such as the fish peptide pleurocidin, interact with RNA and thus inhibit macromolecular synthesis and all protein synthesis (Patrzykat et al., 2002).

### Intracellular Proteins

All the interactions with nucleic acids of bacterial cells lead indirectly to disruption of macromolecular process mechanisms, but AMPs also directly target macromolecules and proteins. The most detailed information on inhibition of protein synthesis derived from the studies of proline-rich AMPs, a group of AMPs with high content of proline and arginine (Scocchi et al., 2016). These AMPs exhibited in some cases, a polyproline helix II structure, which permits it to bind ribosome subunits and inhibit protein synthesis (Scocchi et al., 2011). Daptomycin is known as altering bacterial envelope architecture before killing but this lysis occurs as a secondary event, so it may be the late consequence of a general cell dysfunction and not the main action of this lipopeptide (Pogliano et al., 2012). However, in most other cases, the intracellular targets of AMPs are either unknown or need to be confirmed. All the mechanisms of action underline the complexity of interactions occurring at the most molecular level between AMPs and microbial structures.

## Applications of Natural AMPs as Food Additives

AMPs are gaining much attention as potential active components of food products. However, some limited application could be related to their selective intestinal uptake and physiological instability when consumed orally (Udenigwe and Fogliano, 2017). AMPs are subject to structural changes and to interact with the food matrix during product development and as a result possibly reducing their bioaccessibility, bioavailability as well as biological activities (Udenigwe and Fogliano, 2017). The selection of friendly processing methods and less reactive matrices is imperative to preserve AMPs integrity and stability.

Many approaches exist for preparation of AMP-containing formulations such as inoculating food products with LAB producing strains and using their antimicrobial metabolites to inhibit the growth of undesirable microorganisms (Tahiri et al., 2009), delivery systems by controlling AMP release rate (Nordström and Malmsten, 2017) or active packaging material incorporating AMPs to extend storage life (Meira et al., 2017).

### Lactic Acid Bacteria Producing Strains

The use of LAB with known antimicrobial activity as biopreservatives has been largely studied and reviewed in O'Bryan et al. (2015). Nisin was the first bacteriocin approved for use in food (FDA, 1998) and a commercial crude fermentation product of LAB containing pediocin has also been manufactured by Quest International (Alta 2341). LAB may be present as natural flora of the food, or be intentionally incorporated as starter cultures in an industrial fermentation process. Several applications of LAB in foods such as poultry and meat (Woraprayote et al., 2016), seafood (Calo-Mata et al., 2008), fruits and vegetables (Hanning et al., 2009) have been studied to increase safety or maintain quality in foods. For instance, the potential of bacteriocin-producing LAB of traditional Thai fermented meat has been studied in order to decrease risks due to *Salmonella* spp., *S. aureus*, and *Listeria monocytogenes* (Swetwiwathana and Visessanguan, 2015). In addition, it has been clearly demonstrated that *Carnobacterium divergens* M35 culture as well as divergicin M35 bio-ingredient could be applied to the inactivation of *L. monocytogenes* in ready-to-eat seafood (Tahiri et al., 2009), which have been enabled by Health Canada's Food Directorate as food additives. Recently, the effects of a starter culture for controlling kimchi fermentation, a traditional Korean lactic acid-fermented vegetable, have been determined to prolong shelf life (Moon et al., 2018).

### Active Packaging Material Encapsulating AMPs

Another strategy to control the microbial contamination in foods that have received much attention in recent years is the development of innovative films enriched with bacteriocins (Woraprayote et al., 2018). The important role of packaging system is maintaining the concentration of bacteriocins above the active concentration and constantly releasing bacteriocins to kill target contaminant microorganisms (Appendini and Hotchkiss, 2002). For instance, an antimicrobial biodegradable film containing bacteriocin to control the growth of *Aeromonas*, *Escherichia*, *Pseudomonas*, *Staphylococcus*, *Listeria* and *Salmonella* in pangasius fish fillets have been successfully developed (Woraprayote et al., 2018). Additionally, the inhibition of *L. monocytogenes* by liposomal

nanovesicles containing bacteriocins produced by *Lactobacillus sakei* has been shown to efficiently retard bacterial growth in UHT goat milk (Malheiros et al., 2016).

### Food Matrix Interaction and Bioavailability of AMPs

For evidencing the technological applicability of AMPs, tests on toxicity, functionality and consequences to sensorial properties when added to different food matrices are necessary. Compared to other antimicrobial compounds such as oil and phenolics, AMPs tend to introduce less negative influence on the sensory qualities of food (Gould, 1996). As peptides, AMPs could be easily digested in the stomach, avoiding residue build-up and some of them may even contribute benefits to health (Wang et al., 2015). In the food matrix, the stability of AMPs has to be recognized through evaluation of different parameters such as insensitivity to salt, adaptation of a wide range of pH, thermal resistance and low cytotoxicity or hemolytic activity (Wang et al., 2015).

### Food Additive Regulation and Approval of AMPs

In the food sector, each AMP must be subjected to a very rigorous evaluation by regulatory agencies, such as the Food and drug administration (<http://www.fda.gov/FoodGuidances>) or Health Canada (<https://www.canada.ca/fr/sante-canada/services/aliments-nutrition/legislation-lignes-directrices/documents-reference.html#add>) before being recognized as safe (GRAS status) and approved as a food additive. The applicant must provide the following information during the evaluation and the approval process:

1. Scientific name
2. Proposed name
3. Composition and distinctive characteristics
4. Method of manufacture
5. Quantity used, proposed uses and purposes thereof, detailed directions for use, and recommendations
6. Data on the effectiveness of the antimicrobial bio-preservative
7. Detailed report on product safety under recommended conditions of use including gastrointestinal stability, allergenic potential, effect of a long-term exposure
8. Data on the quantity of residue that might remain on or in the food product
9. Proposed limit for residue on or in the food product method of detecting and monitoring the bio-preservative in the food product
10. Example of a proposed label for the additive

### Conclusion

Identification of AMPs has attracted a lot of attention in recent years. Their biological activity as well as their GRAS status makes them very attractive and offers a very promising alternative for use in food, animal and human sectors. As described in this book chapter, AMPs are widely distributed in nature and are relatively well documented in the literature. However, very few AMP-based products are currently authorized by regulatory agencies for food, medical or veterinary use despite the increasingly urgent demand for this type of compound. Research on both fundamental and applied aspects to characterize AMPs, to understand their mechanisms of action, to study their behavior and biological activity in complex matrices, is still necessary to reach their true potential.

Future work should focus on the following priority targets:

- Evaluation of the extent of the spectrum of action of AMPs not only against bacteria but also fungi and viruses;
- Characterization of the nature of antimicrobial compounds and their complete physicochemical property. At present, only few AMPs have been relatively well studied;
- Study of the behavior and the biological activity of AMPs under the real conditions of use. Moreover, the interactions of these compounds with the endogenous microbial ecosystem (animal or food) must be well studied;
- Study of their safety and their potential undesirable effects for the animal and the human;
- The development of technological processes enabling large scale, efficient and cost-effective production and stabilizing of AMPs.

These studies will generate essential knowledge for a more efficient and better targeted use of AMPs in different sectors. This knowledge is crucial in the present context where the use of chemical additives is increasingly challenged in foods and that the problem of resistance to antibiotics as well as the emergence of new pathogens are increasing continuously in the veterinary and medical sectors.

# INDEX

---

## Notes

Cross-reference terms in *italics> are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space).*

The index is arranged in set-out style with a maximum of three levels of subheading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by t, f, and b refer to Tables, Figures, and Boxes respectively. *vs.* indicates a comparison.

The index entries are presented in word-by-word alphabetical sequence in which a group of letters followed by a space is filed before the same group of letters followed by a letter. For example, entries beginning 'air density' are alphabetized before 'aircraft.' Prefixes and terms in parentheses are excluded from the initial alphabetization.
